ADSORPTION OF BENZENE AND ETHANOL UP TO HIGH RELATIVE PRESSURES ON FINELY DIVIDED SODIUM CHLORIDE

PART I. PARTICLE SIZE EFFECTS AND THE ADSORPTION OF BENZENE
PART II. THE LOWERING OF SURFACE FREE ENERGY BY ETHANOL[1]

R. R. WEILER,[2] J. BEECKMANS,[3] AND R. MCINTOSH

ABSTRACT

Adsorption of benzene has been studied using four samples of fine sodium chloride. The range of relative pressures employed extended to 0.99. The data were employed to show that a correction to the relative pressure should be applied because of the curvature of the surface. The correction was made in the form of a reduction of the apparent relative pressure by application of the Kelvin equation, since the relative pressure over a convex surface would be less than over a plane surface. The adsorption data at high relative pressures for several samples of salt could then be represented by a common curve. It was further concluded that the thick-layer theory of adsorption due to Frenkel, Halsey, and Hill was applicable to adsorption on salt. Adsorption data for ethanol were then obtained and the reduction of surface free energy of the salt by the saturated vapor was evaluated. This figure was then combined with van Zeggeren's and Benson's value of the solid–liquid interfacial free energy for salt and ethanol to provide a provisional value of the surface free energy of sodium chloride of 227 ergs cm^{-2}.

INTRODUCTION

Theoretical estimates of the total surface energy of ionic crystals at the absolute zero of temperature have been made many times, and the values are quite sensitive to the assumed model and to the interaction terms employed (1, 2, 3). The values may even change importantly with the values of the van der Waal's coefficients which are chosen (4). At $T = 0$, $E_s = \sigma_{so}$, where σ_{so} is the surface free energy of the solid. E_s at all temperatures closely approximates the value of the total surface enthalpy H_s, which can be measured by the method of Lipsett, Johnson, and Maass (5). Experimental values of H_s have been much greater than the computed values of E_s, and other procedures to measure either E_s or σ_{so} have been sought. One such possible procedure involves the determination of the enhanced solubility of small particles and the use of the Kelvin equation for an assumed spherical interface between particles and the solution saturated with respect to the particles. This measurement leads to a value of σ_{sl}. The additional relation

$$\sigma_{sv}^* - \sigma_{sl} = \sigma_{lv} \cos \phi$$

is available, and with many systems the wetting angle is small so that $\cos \phi \simeq 1.0$. σ_{sv}^* is the free energy of the solid-saturated vapor interface. Although the value of this quantity cannot be determined, the lowering of surface free energy from that of the clean solid surface may be determined from the Gibbs relation

$$\sigma_{so} - \sigma_{sv}^* = RT \int_0^{p^\circ} \Gamma \, d \ln p \qquad [1]$$

where Γ is the surface excess of adsorbed vapor in moles cm^{-2} and p° is the saturated vapor pressure. Thus a value of σ_{so} may be obtained. To summarize the state of knowledge of the total surface energy of sodium chloride one may note that the value of $E_s = \sigma_{so}$ (at $T = 0$) from the work of Benson, Schreiber, and Patterson (2), which takes into account surface distortion in conjunction with Shuttleworth's result in which

dipole–dipole and dipole–quadrupole interactions were considered, leads to 113 ergs cm^{-2}. A more recent treatment by Benson, Balk, and White leads to the value 124 ergs cm^{-2} for the {100} face (3). Van Zeggeren and Benson's (6) quantum mechanical calculation leads to 187 ergs cm^{-2}. Experimental values of H_s for room temperature have been 386 ergs cm^{-2} by Lipsett, Johnson, and Maass (5), 395 ergs cm^{-2} by Boyd and Harkins (7), and 366 ergs cm^{-2} by Hutchison and Manchester (8). Benson and Benson (9) found a value of 305 ergs cm^{-2}, and with purer salt, Benson, Schreiber, and van Zeggeren (10) obtained a value of 276 ergs cm^{-2}. The surface specific heat C_{p_s} is not sufficient to account for the difference in values of 276 ergs cm^{-2} and 124 ergs cm^{-2}, which are the best experimental and theoretical values available.

Van Zeggeren and Benson (11) investigated the enhanced solubility of fine sodium chloride in ethanol and obtained 171 ergs cm^{-2} for σ_{s1}, which was considered to approximate σ_{so}. Since σ_{so} at room temperature must be less than E_s at $T = 0$, this result is inconsistent with the theoretical value of 124 ergs cm^{-2} but it is consistent with the experimental value of $E_s = 276$ ergs cm^{-2}. However, it is advantageous to obtain σ_{so} rather than σ_{s1}, and to this end an attempt has been made to evaluate $\sigma_{so} - \sigma_{sv^*}$. The attempt is described in Part II of this paper. As experimental observations cannot be made for relative pressures of 1.0, it is important to know something of the shape of the adsorption isotherm at relative pressures as close to 1.0 as feasible. Since sintering in the presence of water vapor is known to occur (12), and since Benson obtained some evidence of the sintering of salt in the presence of large pressures of ethanol (13), it was decided to study the adsorption of benzene at these high relative pressures. The study using benzene supports the contention of theory due to Frenkel (14), Halsey (15), and Hill (16) that adsorption approaches infinity as p/p° approaches 1.0 according to the expression $-a/\Gamma^3 = \ln (p/p^\circ)$, so that $-a/\Gamma^3$ is zero at $p/p^\circ = 1.0$. The study also reveals that the larger the specific surface of the powder sample, the less is the adsorption (in relative terms) at high relative pressures. The importance of the curvature of the surface of the particles has been recognized and discussed by Hill (17). Although discrepant results between two sets of samples remain to be clarified, the correction for surface curvature can apparently be made by application of the Kelvin equation and the assumption of spherical particles for which the surface free energy is taken to be that of bulk liquid. The details of this study are described in Part I.

PART I. PARTICLE SIZE EFFECTS AND THE ADSORPTION OF BENZENE

Experimental

The apparatus for measuring adsorption is shown schematically in Fig. 1. One part consisted of a McBain-type balance. The extension of the quartz spiral was observed by its movement relative to a pointer on a long quartz rod attached to the same support. Thus temperature effects and settling of the column were eliminated from the observations. Changes of weight of about 1 μg could be detected when extension of the spiral was small, and 6 μg was the limit of detection at large extension because the pointers moved out of the focal plane of the lens system. The weight of adsorbent varied between 0.05 and 0.13 g.

The temperature of the column was maintained at $92 \pm 1^\circ$ C by a control unit described by Benedict (18). The chamber holding the quartz bucket and sample was kept at a temperature of approximately 35° C with a variation of $\pm 0.1^\circ$ C as measured in the surrounding air bath.

The adsorbates benzene and ethanol were obtained purified and dried from the

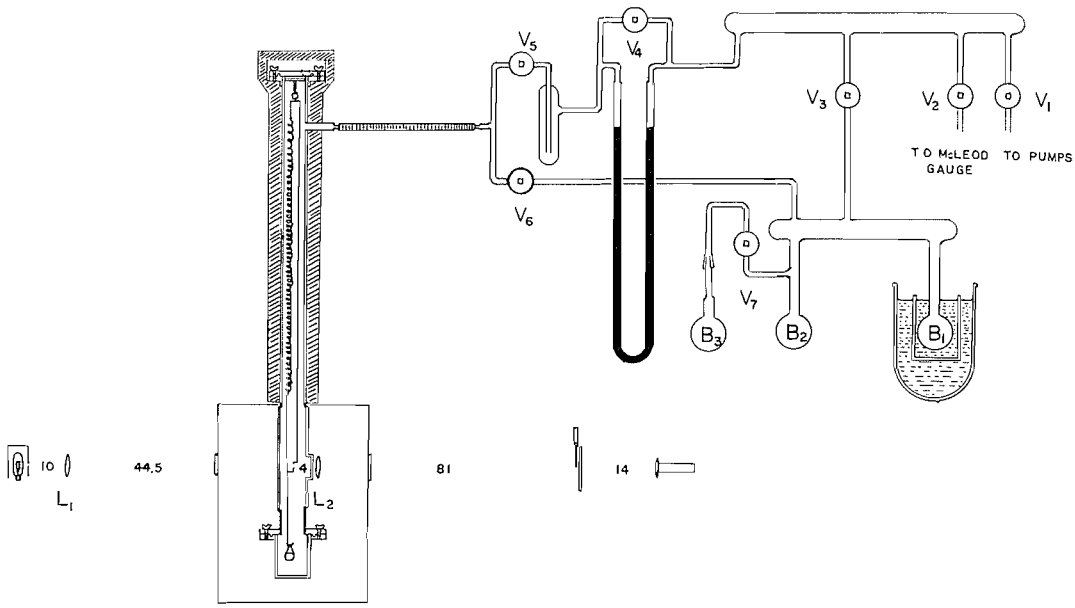

FIG. 1. Schematic representation of adsorption apparatus.

Organic Chemistry Section. After storage over Drierite they were distilled into the adsorption assembly under vacuum, and were repeatedly frozen and melted under vacuum to eliminate permanent gases. The desired adsorbate pressures were generated by fixing the temperature of the surrounding thermostat at the appropriate values. Temperature variations did not exceed $\pm 0.05°$ C. All glass tubing and Hoke 413 metal valves connecting the vapor reservoirs with the adsorption assembly were kept above 35° C to prevent condensation. The vapor pressures of the adsorbates were computed from the equations

$$\log_{10} p_{\text{mm}} = -\frac{1882.0}{244.0+t}+9.0963 \qquad \text{for } t < 4.5° \text{ C}$$

$$\log_{10} p_{\text{mm}} = -\frac{1206.35}{220.237+t} \qquad \text{for } t > 5.5° \text{ C}$$

for benzene (19) and from

$$\log_{10} p_{\text{mm}} = -\frac{2310.43}{273.2+t}+9.5171$$

based upon data in the *Handbook of Physics and Chemistry* (20) for ethanol.

Corrections for buoyancy, etc. in the extension of the spiral system were made by observing the extension without adsorbent in the sample bucket.

The salt samples were prepared in the apparatus described by Moffat and McIntosh (12) which had been modified so that the carrier stream was recycled nitrogen. One sample was obtained from Dr. J. A. Morrison and was an aliquot of the sample B studied by Morrison and Patterson (21). Analyses for nitrate were performed for all samples (22) and the percentage P of surface molecules that are sodium nitrate may be estimated from the approximate relation $P = 1200\,X/A$ where X is the weight% of sodium nitrate and A is the area (23). Obviously, this equation cannot apply to sample 45 and the detection of lines due to sodium nitrate in similar samples by X-ray examination certainly suggests that the impurities are not completely in the surface layers (12). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

surface area of the samples was usually obtained by the adsorption of carbon dioxide, and in the case of the sample received from Dr. Morrison, an area measured by nitrogen adsorption was available. The areas obtained using the different adsorbates differ and lead to a variety of estimates of particle size of which the effects are discussed later. In an adsorption experiment using benzene or ethanol the time to equilibrium was about 45 minutes. Both adsorption and desorption points were obtained and no hysteresis in the isotherms was discovered. The salt samples were not heated during the pumping for fear of sintering, so that evacuation was carried out in the main at about 30° C.

Results

Experiments using four samples will be discussed. These samples were labelled No. 7, No. 25, No. 45, and NRC. Relevant data concerning them are given in Table I. Areas

TABLE I

Sample No.	% nitrate	Area by benzene, $m^2 g^{-1}$	Area by N_2, $m^2 g^{-1}$	Area by CO_2, $m^2 g^{-1}$
7	0.5	8.97	39.9	30.0
25	0.5	4.90	21.8	21.6
45	5.0	14.9	66.5	70.0
NRC	0.05–0.10	11.7	52.0	—

determined using benzene were, of course, available for all the samples and were calculated using the familiar B.E.T. multilayer theory (24) and an area for the benzene molecule of 35.0 Å^2 (25). Nitrogen areas were obtained from the ratio of the nitrogen area to the benzene area for sample NRC. Areas using carbon dioxide were employed by us merely to select the samples, although it is interesting to note a reasonable measure of agreement between these values and the values computed for nitrogen. For the purposes to be discussed below, none of these values of area satisfactorily accounted for the effect of particle size. The nature of the problem and the attempts made to resolve it will now be outlined.

If various samples of an adsorbent differ only in specific surface area, and if the surface of each sample may be considered as planar, the adsorption isotherms should be identical except for a proportionality factor. This factor might be estimated by means of a reliable theory of adsorption, or determined empirically without reference to any adsorption theory. When such attempts to correlate the adsorptive properties of one sample with another have been attempted in this laboratory, it has been found that a proportionality factor would usually suffice to superimpose one curve upon another in the region of low relative pressures, but not in the high. Moreover, those samples with the large specific surfaces always showed less adsorption at high relative pressures when the scale factor obtained from the low relative pressure region was employed. This phenomenon was attributed to a particle-size effect, which for the higher relative pressure range, may be thought of as producing an enhanced vapor pressure over the curved surface of the liquidlike adsorbed layers. Hill has discussed the effect of curvature on the adsorption of thick layers (17). In dealing with the same problem we have found the use of the Kelvin equation satisfactory provided that a reasonable assessment of area and hence particle size can be achieved.

In the case of the adsorption of benzene, a mean particle size was calculated on the basis of the area determined by the use of the B.E.T. equation and the assumption that the particles were spherical. The value of the mean radius was then employed with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Kelvin equation $RT \ln p/p^\circ = 2\sigma\bar{V}/r$, taking the value of the surface free energy of the curved interface to be 27.0 dynes cm^{-1} at 35.0° C. This provided a value of the pressure p over the curved surface which is greater than the value p° over a plane surface of the liquid adsorbate. On this basis the equilibrium pressure is a lower relative pressure, by the ratio p°/p, than the experimenter would expect to obtain if the particles were considered to have planar surfaces. A proportionality factor was also calculated on the basis of adsorption in the low relative pressure range. The proportionality factors for the four samples, in conjunction with the corrections to the relative pressures (which become important in the higher relative pressure range) should suffice to yield a common adsorption curve for the four samples. A comparison is given in Fig. 2. Clearly, samples 7 and 25 may be paired, and also samples 45 and NRC. Agreement is satisfactory in

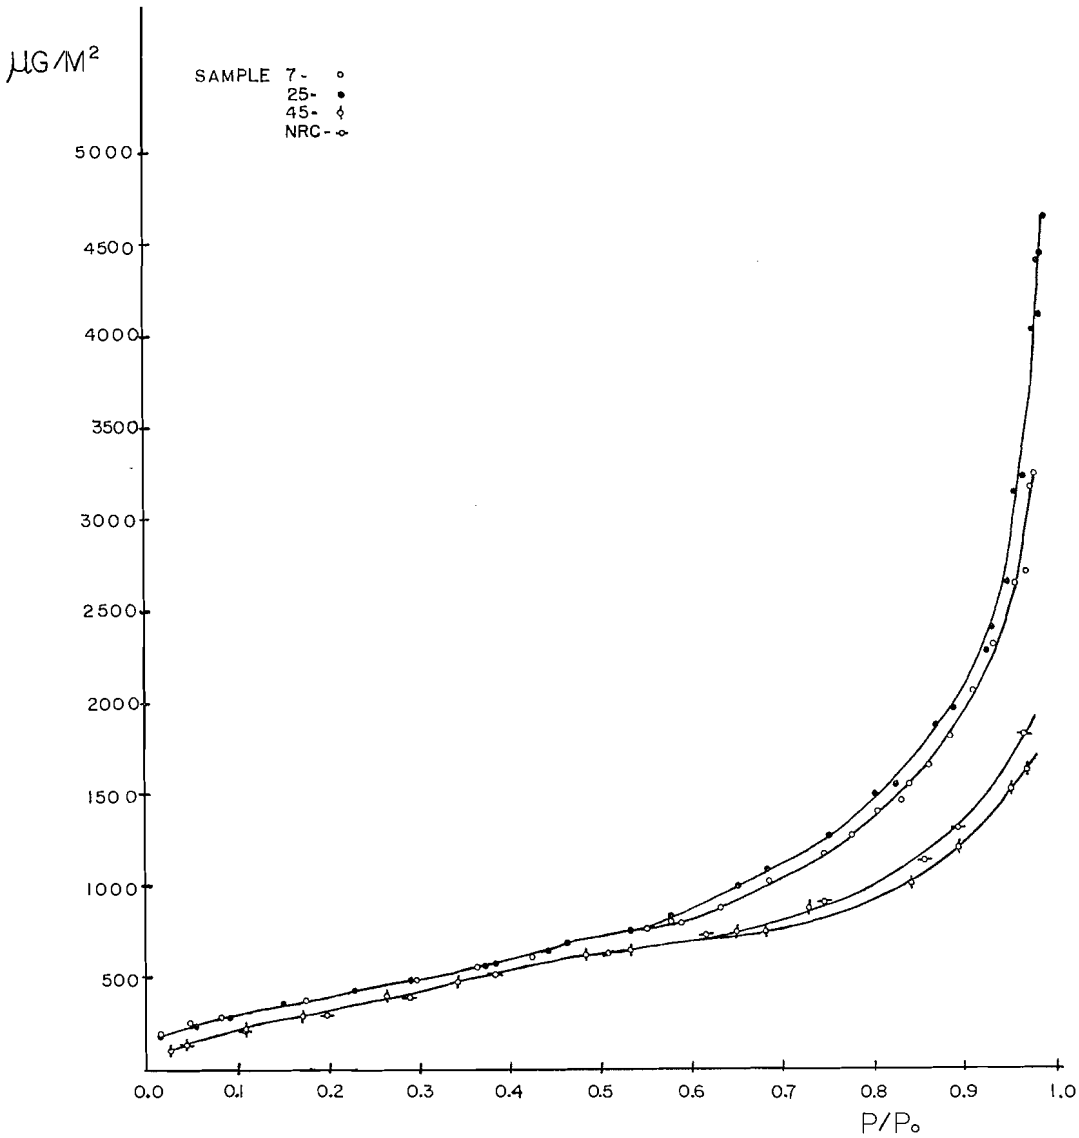

FIG. 2. Adsorption isotherms for benzene at 35° C represented after application of a scale factor and correction of p/p° based upon the area to benzene.

the low-adsorption range, which shows that the appropriate proportionality factor has been achieved for each pair of samples, although it has not been for all four samples. Leaving aside for the moment the fact that all four samples have not been made to show a common adsorption curve even in this range, it is also clear that success has not been achieved in the high-pressure range for either pair of samples.

The areas by nitrogen were next employed to obtain the mean particle radius, and as before, the value of the saturation pressure for particles of such curvature predicted by the use of the Kelvin equation. When this was done samples 7 and 25 showed a common adsorption curve and similar results were found for samples 45 and NRC. In spite of this partial success in correlating adsorption data for the samples, it was considered that the correction factor applied on the basis of nitrogen areas was somewhat too great, for the reason outlined below. Since the thick-layer theory of adsorption due to Frenkel (14), Halsey (15), and Hill (16), should be applicable in this range, a plot of $1/\Gamma^3$ vs. $\ln p/p^\circ$ should yield a straight line, and should pass through zero (Γ infinite) for a corrected relative pressure of 1.0. For samples 7 and 25, for which the data were more extensive, intercepts were found at a value of 0.966 when relative pressures corrected for the particle-size effect were employed. The saturation pressures estimated for particles of the size indicated by the nitrogen areas were 1.057 and 1.031 times that for a plane surface in the case of samples 7 and 25, respectively. It was therefore found that the predicted saturation pressures should have been 1.057×0.966 and 1.031×0.966, that is 1.022 and 0.996 times the usual saturation pressure for these two samples. The latter figure is well within experimental error of 1.0. Thus it was shown that the experimental equilibrium pressures over sample 7 were, on a relative pressure scale, 1/1.022 times those thought to have been generated. Using relative pressures corrected in this manner and a proportionality factor of 1.83, the data for samples 7 and 25 could be represented by a common curve, as shown in Fig. 3 and Table II. Although the data

were much less extensive for samples 45 and NRC, the correction factors were established as $1/1.05_6$ and $1/1.03_5$, respectively, for these two samples. The adsorption data for them are depicted in Fig. 4 and given in Table III. It is to be noted that in estimating these correction factors no account was taken of the thickness of the adsorbed layer, because that thickness was only a few per cent of the particle radius.

Several matters remain to be discussed. The two pairs of salt samples cannot be made to yield a common adsorption curve by means of a proportionality factor along with corrections to the relative pressure. However, as is illustrated in Fig. 5, samples 7 and 45 may be made to correspond from a relative pressure (corrected) of about 0.37 to the highest relative pressures, by addition of 3.0×10^3 μg per g to the data for sample 7 (see Table II). This means that adsorption data of all four samples may be made to fit a single curve above a relative pressure of 0.37. Chemical composition, as measured by nitrate content, does not appear to be the cause of the difference between pairs of samples. Similarly, surface area does not permit a grouping into pairs. From the experimental standpoint, the benzene, employed to generate the equilibrium pressures, was changed between the accumulation of the two sets of data. There is no independent reason, however, to believe that this is the cause. Possibly the structure of the particles

in samples of widely differing areas is involved. Agreement in the high-pressure range could still be expected because the influence of the surface is small, apart from the effect of curvature.

Secondly, it should be noted that a value of particle size is employed which is not based upon the area obtained using nitrogen. Presumably this arises because there is a distribution of particle sizes and a variation of the curvature effect with particle size. The intercept method, based upon the thick-layer theory, provides a weighted average particle size dependent upon the Kelvin effect.

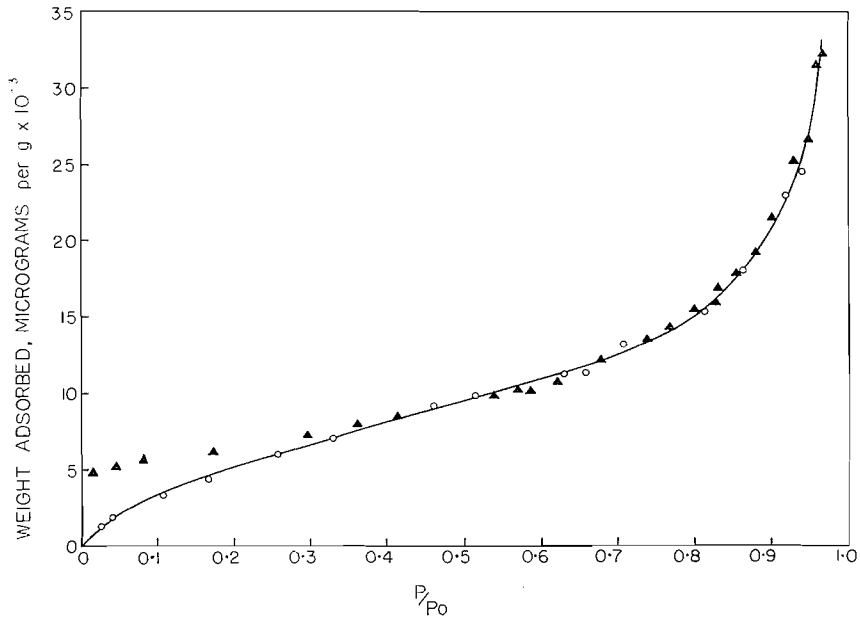

FIG. 5. Representation of the isotherms for samples 7 and 45 using an additive correction to amount adsorbed and a corrected value of p/p°.

Thirdly, there are undoubtedly other mechanisms which might be suggested to explain why the relative adsorption at high pressures is smaller for samples of relatively larger areas as these are normally determined by appeal to adsorption data up to relative pressures of about 0.4. The suggestion made here has the merit of simplicity, and is based upon the well-known phenomenon of enhanced vapor pressure of small droplets. It is important to observe that the adsorptions at high pressures are made to correspond well with one another by applying this idea. Further data are required to confirm its utility, but the initial results show promise.

Finally, on the basis of such data, it seems justified to employ the thick-layer adsorption theory for adsorption at high relative pressures. This conclusion is of importance in connection with the adsorption data for ethanol from which the lowering of surface free energy is calculated in Part II.

PART II. THE LOWERING OF SURFACE FREE ENERGY BY ADSORPTION OF ETHANOL

Four samples of sodium chloride were used in studying the adsorption of ethanol, and quite good agreement among the values of lowering of surface free energy was found. This agreement was somewhat fortuitous, however, since differences in the value of surface free energy lowering appeared over the three sections into which the data were subdivided. These sections were the low, the intermediate, and the high relative pressures, respectively. In our opinion the most reliable value was obtained with the sample designated NRC. There are two reasons for this view.

The first three samples were studied using an adsorption assembly which had less adequate temperature control along the column and within the chamber containing the sample. Moreover, the sample chamber was attached to the column by means of a greased taper joint, which might have caused some contamination of the surface. The assembly used to study sample NRC (and for the benzene adsorptions reported in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Part I), was free from any greased joints, as metal chambers or plates and indium gaskets were employed for those parts of the assembly which were removable.

To evaluate the Gibbs integral for the first region involving relative pressures less than 0.2, the equation

$$[2] \qquad \sigma_{so}-\sigma_{sv} = -\frac{RT}{(A+B)A_0}\ln\frac{B(p^\circ-p)}{Ap+Bp^\circ}$$

was employed.

This equation results from expressing the quantity adsorbed by the B.E.T. equation, and substituting the appropriate expression into equation [1]. The B.E.T. equation expressed the adsorption data admirably from 0.02 to 0.20 relative pressure. In equation [2] A is $(C-1)/(\Gamma_m C)$ and B is $1/(\Gamma_m C)$, where Γ_m is the number of moles required to complete a monolayer on 1 gram of adsorbent. A_0 is the area of the sample in square centimeters per gram. To check this procedure the Gibbs integral was also expressed as

$$\sigma_{so}-\sigma_{sv} = \frac{RT}{A_0}\int_0^{\Gamma} d\Gamma + \frac{RT}{A_0}\int_0^{p/\Gamma} \Gamma d \ln p/\Gamma,$$

and a plot of Γ versus $\ln p/\Gamma$ was integrated graphically from the extrapolated value of p/Γ at $\Gamma = 0$, up to the value at the relative pressure of about 0.2. The agreement between the two methods was, in the case of two separate experiments, 17.5 and 17.3 ergs cm^{-2}, and 20.5 and 18.7 ergs cm^{-2}, respectively.

Evaluation of the integral for the second section of data was performed graphically. The range of relative pressure over which graphical integration was performed was from about 0.2 to 0.97. In this range the contribution to the lowering of surface free energy fell between 13.8 and 15.6 ergs cm^{-2} for all runs, and as the limits of integration varied slightly for each run, the agreement was considered satisfactory.

Because of the conclusions derived from the study of the high relative pressure end of the benzene isotherms, the evaluation of the integral for the ethanol data from 0.97 to 1.0 of the relative pressure range was performed analytically. It should be noted that the value of the surface free energy lowering does not depend upon whether or not the Kelvin correction has been applied, but the upper limit of relative pressure at which Γ approaches infinity will exceed the experimental value of 1.0, and this fact should be considered if the limit of relative pressure is involved in the analytical form by which the evaluation is made.

Insufficient data at the very high experimental relative pressures above 0.97, introduced some uncertainty in the evaluation of the lowering of the surface free energy. With the data available three procedures were possible. These were: (1) To utilize the data obtained for relative pressures above 0.80 in the form of a Hill plot (i.e. $1/\Gamma^3$ vs. $\ln p/p^\circ$) and ignore the two values at the highest pressures (which might be considered incorrect, since they suggest that $\Gamma \rightarrow \infty$ at the experimental relative pressure 1.0) and thus obtain the slope a from the lower relative pressure data. This resulted in a value of $-\Delta\sigma$ from 0.97 relative pressure to Γ infinite of 2.1 ergs cm^{-2}. (2) To utilize the data for the four highest relative pressure points to obtain the slope a of the Hill plot. This yielded 0.35 ergs cm^{-2}. (3) To use the knowledge of the area determined with nitrogen to predict the required relative pressure to make Γ infinite, and employ this along with all data for relative pressures above 0.80 to obtain the slope a. This gives a value 1.2 ergs cm^{-2}.

If one separates the data obtained into two groups, namely those data found in the first adsorption run, and those found in subsequent adsorption runs after what appeared to be sintering of the salt by the ethanol, the total lowering of surface free energy would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

be 31.6 to 33.3 ergs cm^{-2} for the first adsorption before sintering occurred, or 35.6 to 37.3 for subsequent adsorptions. Taking the mean of these results, the lowering of surface free energy is 34.5 ± 2.9 ergs cm^{-2}. In the estimate of this value, in addition to the uncertainties arising from the procedures outlined above, there is the conversion of values to unit surface on the basis of an area to nitrogen reported as 52 $m^2 g^{-1}$. The area as measured by ethanol before sintering was 16.5 $m^2 g^{-1}$ on the basis of 20.7 $Å^2$ for the area of the ethanol molecule. The conversion factor of 0.317 was retained in dealing with the sintered sample, of ethanol area 11.2 $m^2 g^{-1}$. Van Zeggeren's and Benson's value of σ_{s1} was obtained at 25° C, while the value of 34.5 ± 2.9 ergs cm^{-2} was obtained at 35.3° C. However, these may be combined to give an approximate value of σ_{so} on assuming $\cos \phi = 1.0$; thus $\sigma_{so} \simeq 21.5 + 171 + 34.5 = 227$ ergs cm^{-2}. This value is consistent with the value 276 ergs cm^{-2} for the total surface enthalpy, and leads to a value of about 0.16 ergs cm^{-2} deg^{-1} for $\partial\sigma_{so}/\partial T$. Similar experiments to determine σ_{s1} and $\sigma_{so} - \sigma_{sv^*}$ for solvents other than ethanol are required to establish that the value derived for σ_{so} is independent of the solvent employed. For the moment the provisional value of 227 ergs cm^{-2} is suggested.

CATALYTIC ACTIVATION OF MOLECULAR HYDROGEN BY RUTHENIUM (III) CHLORIDE COMPLEXES[1]

J. F. HARROD,[2] STEFANIA CICCONE, AND J. HALPERN

ABSTRACT

Ruthenium(III) chloride, in aqueous HCl solution, was found to activate H_2 homogeneously and to catalyze the reduction by H_2 of Ru(IV) and Fe(III). The kinetics of these reactions were examined and, in each case, the rate law was found to be $-d[H_2]/dt = k_1[H_2][Ru^{III}]$ where $k_1 = 4.0\times10^{14}\exp[-23{,}800/RT]\ M^{-1}\ sec^{-1}$. The mechanisms of these reactions are discussed and compared to those of other homogeneously catalyzed reactions of hydrogen. A special feature of the present system is the resistance of the catalytic species itself (i.e. Ru^{III}) to reduction by H_2.

INTRODUCTION

Among the metal ions and complexes which have previously been reported to activate molecular hydrogen homogeneously in solution are the chloride complexes of two group VIII metals, Pd^{II} and Rh^{III} (1, 2, 3). In extending these studies we have now found that the chloride complexes of another member of this group, Ru^{III}, exhibits similar catalytic activity. Thus Ru^{III}, in aqueous HCl solution, catalyzes, under relatively mild conditions, the homogeneous reduction by hydrogen of Ru^{IV} and of Fe^{III}. The present paper describes a kinetic study of these reactions.

EXPERIMENTAL

In most of the experiments, the source of ruthenium was Johnson, Matthey $(NH_4)_2RuCl_6$ (99.7%). Essentially similar results, however, were obtained using Johnson, Matthey specpure $(NH_4)_2RuCl_5.H_2O$ or $RuCl_3.3H_2O$ as starting materials. When dissolved in concentrated HCl all of these gave solutions having essentially the same spectra and exhibiting similar reactivity toward H_2. The spectrum in each case corresponded with that reported by Wehner and Hindman (4) for Ru^{IV}. The presence of all the ruthenium in these solutions as Ru^{IV} was further confirmed (*a*) by titration with Sn^{II} and (*b*) by measuring the volume of H_2 taken up by the solution. The latter corresponded to one atom of hydrogen for each atom of ruthenium and the spectrum of the resulting reduced solution agreed with that reported by Jörgensen (5) for Ru^{III}. The concentrations of Ru^{IV} determined by these various methods were in excellent accord with each other and (to within 5%) with the total ruthenium concentration estimated by spectrophotometric determination of perruthenate, following distillation as RuO_4 using bismuthate as oxidant (6).

Solutions of Ru^{III}, used to study the catalyzed reduction of Fe^{III}, were prepared by reducing solutions of Ru^{IV} with H_2.

Kinetic measurements were made by following the uptake of hydrogen using the apparatus and procedure described earlier (7, 1).

RESULTS AND DISCUSSION

Solutions of Ru^{IV} were found to absorb H_2 in an autocatalytic manner as shown in Fig. 1. The stoichiometry of the total H_2 uptake (Table I) corresponds to complete

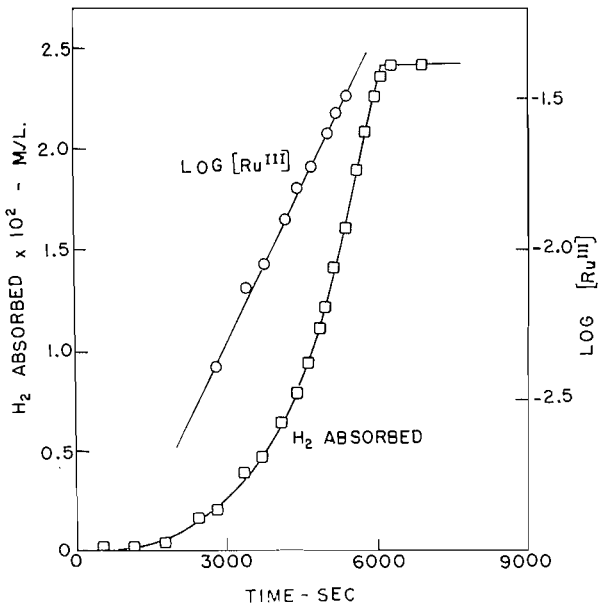

FIG. 1. Autocatalytic reduction of Ru^{IV} by H_2 at 80° C, 450 mm H_2, 3 M HCl.

TABLE I

Autocatalytic reduction of Ru^{IV}

(3 M HCl; 3.6×10^{-4} M H_2; 80° C)

Initial $[Ru^{IV}]$ (moles/l.)	Total H_2 uptake (moles/l.)	k_1 (l. $mole^{-1}$ sec^{-1})
0.037	0.019	1.07
0.048	0.024	1.08
0.055	0.030	0.91

reduction of Ru^{IV} to Ru^{III},

$$2Ru^{IV} + H_2 \rightarrow 2Ru^{III} + 2H^+ \qquad [1]$$

as do the spectra of the final solutions.

The autocatalytic behavior may be explained in terms of catalysis of the reaction by Ru^{III}, and fitted by a rate law of the form,

$$-d[H_2]/dt = \tfrac{1}{2}d[Ru^{III}]/dt = k_1[H_2][Ru^{III}]. \qquad [2]$$

With $[H_2]$ constant during the course of each experiment, this yields on integration,

$$\log [Ru^{III}] = \log [Ru^{III}]_{initial} + 2k_1[H_2]t/2.303. \qquad [3]$$

In accord with this, plots of log $[Ru^{III}]$ vs. time, such as that depicted in Fig. 1, were found to be linear over the major portion of each experiment and to yield consistent values of k_1 (Table I). About 3% of the Ru, initially present as Ru^{III}, sufficed to account for the initial rates observed in these experiments. Ru^{IV} itself appeared to be unreactive toward H_2 under these conditions. Thus the addition of a small amount of $Cr_2O_7^=$, which oxidizes the Ru^{III} initially present, inhibited completely the uptake of H_2. Conversely the initial rate of uptake of H_2 could be increased (and the total amount of H_2 taken up

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

correspondingly decreased) by prior reduction of a portion of the Ru^{IV} to Ru^{III} by Sn^{II}. These effects were completely reversible and the rate of uptake of H_2 under given conditions was found, in accord with equation [3], to depend only on the concentration of Ru^{III} and not on the method of attainment of the latter.

Although responsible for the activation of H_2 in this system, Ru^{III} itself showed little tendency to undergo reduction (i.e. to Ru^{II} or metallic Ru). Thus the uptake of hydrogen in the experiments described ceased abruptly when all the Ru^{IV} had been reduced to Ru^{III}. However, like Rh^{III} and Pd^{II}, which also activate hydrogen under these conditions, Ru^{III} proved to be an effective catalyst for the homogeneous reduction of Fe^{III}. (The latter, unlike $Cr_2O_7^=$, is not a sufficiently strong oxidant to oxidize Ru^{III} to Ru^{IV}.) Thus the reaction,

$$2Fe^{III} + H_2 \rightarrow 2Fe^{II} + 2H^+ \qquad [4]$$

proceeded readily in the presence of Ru^{III}. Since both $[H_2]$ and $[Ru^{III}]$ remained constant during the reaction, the uptake of H_2, while still conforming to equation [3], followed a pseudo zero-order rate law. Typical zero-order plots for such experiments are shown in Fig. 2. Values of k_1, computed from the slopes of these plots using equation [3] are listed

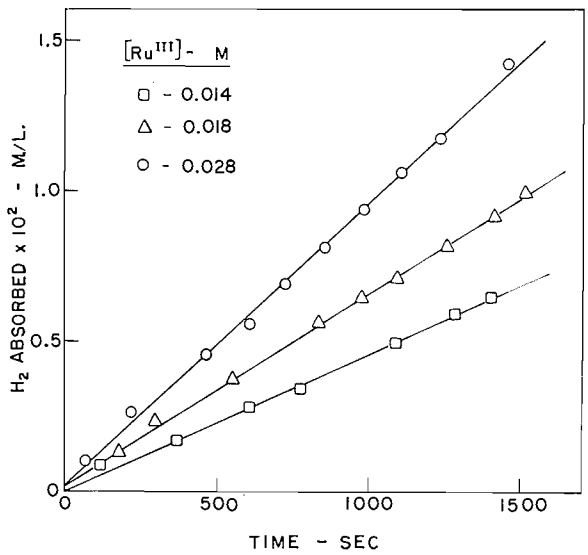

FIG. 2. Ru^{III}-catalyzed reduction of Fe^{III} by H_2 at 80° C, 450 mm H_2, 3 M HCl.

in Table II and are seen to be substantially independent of $[Ru^{III}]$, $[H_2]$, and $[Fe^{III}]$. At 80° C, in 3 M HCl these values range from 0.90 to 1.10 M^{-1} sec^{-1} and are thus in excellent agreement with the values of k_1 determined from the autocatalytic reduction of Ru^{IV} (Table I). There thus seems little doubt that the two reactions proceed by a common mechanism, the rate-determining step of which is a bimolecular reaction between H_2 and Ru^{III}. Since the kinetics of the Ru^{III}-catalyzed reduction of Fe^{III} are simpler than those of the autocatalytic reduction of Ru^{IV} and since both yield essentially the same information, most of the measurements were made on the former reaction.

Kinetic measurements over the temperature range 65° to 85° C yielded the values of k_1 listed in Table II. These gave a good Arrhenius plot fitted by the equation

$$k_1 = 4.0\times10^{14} \exp[-23{,}800/RT]\ M^{-1}\ \text{sec}^{-1}. \qquad [5]$$

*Based on solubility of H_2 in 3 *M* HCl estimated as described earlier (1).

The corresponding values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, 23.1 kcal/mole and +6 e.u., respectively, are remarkably close to those (24.5 kcal/mole and +9 e.u.) found earlier (2) for the kinetically similar reduction of Fe^{III} by H_2, catalyzed by Rh^{III}.

Little change in k_1 was noted when the HCl concentration was varied between 3 *M* and 6 *M* (Table II). Available data (8) on the formation constants of Ru^{III}-chloride complexes suggest that, at least at room temperature, $RuCl_4^-$, $RuCl_5^{2-}$, and $RuCl_6^{3-}$ are all present in appreciable concentrations in this region and that there is a significant displacement of the complexing equilibrium toward $RuCl_6^{3-}$ as the HCl concentration is increased from 3 *M* to 6 *M*. The constancy of the rate thus implies either similar reactivities for the various complexes or, alternatively, a displacement of the complexing equilibrium at the higher temperature (80° C) of the reaction so that formation of $RuCl_6^{3-}$ is substantially complete at 3 *M* HCl. The former alternative is considered the more likely one.

Below 3 *M* HCl, k_1 exhibited a marked inverse dependence on the HCl concentration, which was only partially offset by addition of LiCl to maintain a constant ionic strength and total Cl^- concentration. A possible explanation of these effects is in terms of hydrolytic equilibria of the type

$$Ru(OH)Cl_{n-1}^{3-n} + H^+ + Cl^- \rightleftharpoons RuCl_n^{3-n} + H_2O, \qquad [6]$$

where the hydrolyzed species has the lower reactivity.

A common feature of the mechanisms of many of the homogeneously catalyzed hydrogenation reactions thus far examined (3) appears to be a rate-determining heterolytic splitting of H_2 by the catalytic species with the formation of a metal-hydride complex which reduces the substrate in a subsequent (generally fast) step. It seems highly likely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

that the mechanism of activation of H_2 by Ru^{III} also is of this type and that the over-all reaction scheme in the system under consideration is as follows:

$$Ru^{III} + H_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ru^{III}.H^- + H^+ \quad [7]$$

$$Ru^{III}.H^- + 2Ru^{IV} \xrightarrow{k_2} 3Ru^{III} + H^+ \quad [8]$$

$$Ru^{III}.H^- + 2Fe^{III} \xrightarrow{k_3} Ru^{III} + 2Fe^{II} + H^+ \quad [9]$$

$$Ru^{III}.H^- + Ru^{III} \xrightarrow{k_4} 2Ru^{II} + H^+ \quad [10]$$

All the observations relating to these reactions are explained by this scheme, provided that,

$$k_2, k_3 > k_{-1} > k_1, k_4.$$

Thus step [7] is irreversible in the presence of Ru^{IV} or Fe^{III}, which react rapidly with $Ru^{III}.H^-$. However in the absence of such substrates most of the H_2 which reacts with Ru^{III} is regenerated since step [10] is too slow to compete effectively with reversal of step [7]. This situation is analogous in many respects to that already encountered in the Cu^I-catalyzed reduction of Cu^{II} (7).

KINETICS OF THE OXIDATION OF HYDRAZOBENZENE BY IODINE AND TRIIODIDE[1]

J. W. MAY[2] AND J. HALPERN

ABSTRACT

The oxidation of hydrazobenzene (AH_2) to azobenzene by iodine in aqueous ethanol solution was found to be very rapid and in order to render the kinetics measurable it proved necessary to reduce the concentration of free iodine by complexing with iodide. This revealed a parallel oxidation path, much slower than for iodine, involving the triiodide ion. The overall rate law thus is: $-d[AH_2]/dt = k_1[AH_2][I_2]+k_2[AH_2][I_3^-]$ where the rate constants, in 60 volume% ethanol, are given by, $k_1 = 4.2\times10^{11}\exp[-10{,}000/RT]\ M^{-1}\,\text{sec}^{-1}$ and $k_2 = 2.5\times10^{11}\exp[-16{,}400/RT]\ M^{-1}\,\text{sec}^{-1}$. These and other features of the kinetics, including the inverse dependence of the rate constants on the ethanol concentration and the absence of effects due to added quinone and various metal ions, are interpreted in terms of a simple bimolecular mechanism for each path. Some measurements of the thermodynamics of triiodide formation in aqueous ethanol also are reported.

INTRODUCTION

This paper describes a kinetic study of the oxidation of hydrazobenzene (AH_2) to azobenzene (A), in aqueous ethanol solution, by iodine and triiodide. The oxidation by iodine,

[1] $$C_6H_5NHNHC_6H_5 + I_2 \rightarrow C_6H_5N{=}NC_6H_5 + 2HI,$$

was found to be rapid and, in order to render the kinetics measurable, it proved necessary to reduce the concentration of free iodine to a very low level by complexing with iodide. This revealed a parallel oxidation path, involving the triiodide ion, I_3^-, the kinetics of which also were examined. Some measurements of the thermodynamics of the triiodide equilibrium, required for the interpretation of the kinetic results, also are reported.

EXPERIMENTAL

Materials

AR grade KI and Eastman Kodak hydrazobenzene were recrystallized from aqueous ethanol, in the latter case until white crystals (m.p. 127° C) were obtained. Formic and acetic acids (C.P.) were redistilled. Iodine and other chemicals were of reagent grade. Water and ethanol used as solvents were redistilled, the former from alkaline permanganate.

Determination of the Triiodide Formation Constant

Although the triiodide equilibrium,

[2] $$I_2 + I^- \rightleftharpoons I_3^-,$$

has been examined in aqueous solution (1, 2) no data were available for aqueous ethanol and the equilibrium constants, K ($= [I_3^-]/[I_2][I^-]$), required for interpretation of the kinetic results were therefore determined experimentally. A spectrophotometric procedure, similar to that of earlier workers (1, 2) was used. This involved, essentially, determination of the equilibrium I_3^- concentration in a solution of KI and I_2, by measuring the absorption in the 3500–3600 Å region where I_3^- absorbs strongly ($\epsilon_{max} \sim 2.7\times10^4$) and I_2 and I^-, negligibly. From the initially known KI concentration, the

[2]*Present address: Inorganic Chemistry Laboratory, Oxford, England.*

equilibrium I^- concentration (generally in the range $0.5\text{–}20\times10^{-4}$ M) could be computed, while the equilibrium I_2 concentration (generally $0.5\text{–}2.5\times10^{-5}$ M) was determined (after the measurement of the I_3^- concentration) from the *increase* in I_3^-, on addition of an excess ($\sim$0.1 M) of KI sufficient to displace equilibrium [2] far to the right and convert essentially all the free I_2 to I_3^-. The I_3^- absorption spectrum exhibited a slight dependence on the solvent composition and was determined for each of the solvent mixtures used. A Beckman DU spectrophotometer with a thermostated cell compartment was used for the spectrophotometric measurements. The normal precautions (e.g. deaeration of solvents, use of stoppered spectrophotometer cells to which solutions were transferred with a hypodermic syringe after flushing with N_2) were taken in preparing the solutions and in making the spectrophotometric measurements, to minimize air oxidation of iodide. The effectiveness of the resulting procedure was confirmed by running a parallel blank (with a solution containing KI only) for each experiment and determining the amount of iodine formed by air oxidation. The latter was always small and the correction to K from this source generally amounted to less than 3%. In some experiments, notably at the higher temperatures, a small decrease in the total iodine concentration (due presumably to reduction by the solvent or buffer) during the period required for thermal equilibration of the solution and for the spectrophotometric measurement was noted and, where necessary, corrected for; this correction also was small, in every case less than 3%.

Kinetic Measurements

To minimize zero-time errors the reaction was started by adding 10 ml of a standard hydrazobenzene solution to 90 ml of a solution containing all the other reagents (KI, I_2, and buffer) after both solutions had already reached the reaction temperature. The reaction vessel, a darkened stoppered flask, was immersed in a water bath, thermostated to $\pm0.03°$ C. Aliquots of the reacting solution were withdrawn periodically and after the reaction was quenched by addition of an excess of thiosulphate (to reduce the unreacted iodine) the concentration of azobenzene produced was determined spectrophotometrically by measuring the absorption at 4300 Å where interference from other species was negligible. The spectrum of azobenzene exhibited an appreciable solvent dependence and was determined for each of the solvent mixtures used.

The choice of a mixed solvent, aqueous ethanol, was dictated by the requirement for simultaneous solubility of hydrazobenzene, azobenzene, KI, and buffer (0.26 M HOAc – 0.047 M KOAc, unless otherwise stated). The latter served to buffer the solution against the HI produced in the reaction and thus prevent the acid-catalyzed benzidine rearrangement of hydrazobenzene. A few unbuffered experiments were made, however, to check the reaction stoichiometry. In these it was found (by potentiometric titration with NaOH) that, in accord with equation [1] and with the corresponding equation for the oxidation of hydrazobenzene by I_3^-,

$$[3] \qquad AH_2 + I_3^- \rightarrow A + 2HI + I^-,$$

two equivalents of acid were produced for each molecule of azobenzene. Further support for the proposed stoichiometry and for absence of side reactions was provided by the excellent agreement always observed (in experiments in which the initial iodine concentration exceeded that of hydrazobenzene) between the initial hydrazobenzene and final azobenzene concentrations.

The spectrum of the azobenzene product corresponded to that of the trans isomer.

RESULTS

Thermodynamics of I_3^- Formation

Values of the I_3^- formation constant, K, determined over a range of temperatures and solvent compositions, are listed in Table I. From the temperature dependence of K

TABLE I

Equilibrium constants for I_3^- formation

*Buffer composition: [HOAc]:[KOAc] = 5.7:1.

†Computed from the measured value at 16.8° C using $\Delta H^0 = -4.8$ kcal/mole (1).

‡The values in parentheses are adjusted to the normal buffer concentration of 0.31 M.

§Obtained by interpolation from the data at the other temperatures.

in 60 volume% ethanol, the values of ΔH^0 and ΔS^0 for the formation of triiodide (reaction [2]) were found to be -9.5 kcal/mole and -13 e.u., respectively; the corresponding values in water are -4.8 kcal/mole and -3 e.u. (1).

The marked dependence of K on the ethanol content of the solvent (corresponding to a 50-fold increase in going from pure water to 75 volume% ethanol) is in the direction expected from a consideration of the polarities of the two solvents. Water, being the more polar solvent, undoubtedly solvates and stabilizes I^- (relative to the larger I_3^- ion) to a greater degree than ethanol and thus favors dissociation of I_3^-, relative to ethanol. The more negative ΔH^0 and ΔS^0 values for I_3^- formation in the mixed solvent, relative to pure water, also find explanation in these terms.

In the series of experiments made to determine the temperature dependence of K, the buffer concentration was reduced to half its normal value (0.15 instead of 0.31 M) in an attempt to eliminate a possible cause of the instability (referred to earlier) which the iodine solutions sometimes exhibited on prolonged standing at the higher temperatures. Where they overlap, the measurements at the two different buffer concentrations reveal a slight inverse dependence of K on the buffer concentration. Thus at 14.9° C and 60 volume% ethanol, the values of K for buffer concentrations of 0.15 and 0.31 M (i.e. 3.13×10^4 and 2.57×10^4 M^{-1}, respectively) differ by a factor of 0.82. This factor was assumed to be temperature independent and was applied to the data at other temperatures to obtain values of K (given in parentheses in Table I) for 0.31 M buffer, which were used in the kinetic calculations. The correction factor is small enough that the introduction of an appreciable error from this source is unlikely.

Kinetics

The over-all rate law for the oxidation of hydrazobenzene was found to be,

$$[4] \qquad -d[AH_2]/dt = k_1[AH_2][I_2]+k_2[AH_2][I_3^-]$$

$$[5] \qquad = (k_1/K[I^-]+k_2)[AH_2][I_3^-].$$

Under the conditions pertaining in all the experiments the triiodide equilibrium [2] was displaced far to the right, hence $[I_3^-] \sim [I_2]_T$, where $[I_2]_T$ $(= [I_2]+[I_3^-])$ is the total (i.e. stoichiometric) iodine concentration. Equation [5] thus reduces to a pseudo second-order rate law,

$$[6] \qquad -d[AH_2]/dt = k_{exp}[AH_2][I_2]_T$$

where,

$$[7] \qquad k_{exp} = k_1/K[I^-]+k_2.$$

On integration, this gives,

$$[8] \qquad \log ([I_2]_T/[AH_2]) = \log ([I_2]_T/[AH_2])_{initial}+([I_2]_T-[AH_2])_{initial}k_{exp}\,t/2.303.$$

In accord with equation [8] each experiment yielded a good plot (generally extending over at least 90% of the reaction) of log $([I_2]_T/[AH_2])$ vs. time (Fig. 1) from the slope of which k_{exp} was determined. Values of k_1 and k_2 were determined from the slopes and intercepts of linear plots (Figs. 2 and 3) of k_{exp} vs. $[I^-]^{-1}$ according to equation [7] using the values of K in Table I. The latter are uncorrected for ionic strength effects due to the varying KI concentration and the values of k_1 are thus subject to some systematic influence from this source whose magnitude is difficult to assess.

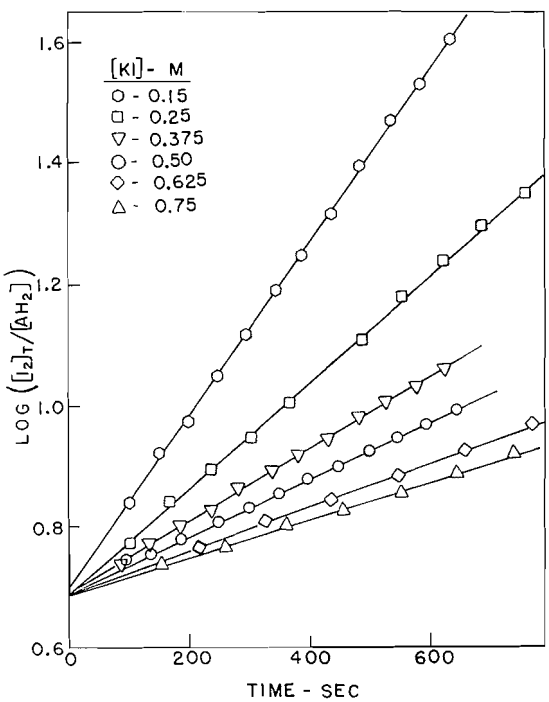

FIG. 1. Typical second-order rate plots. (15° C; 75 vol.% ethanol; 0.31 M buffer. Initial reactant concentrations: 1.20×10^{-3} M AH_2; 5.46×10^{-3} M total I_2.)

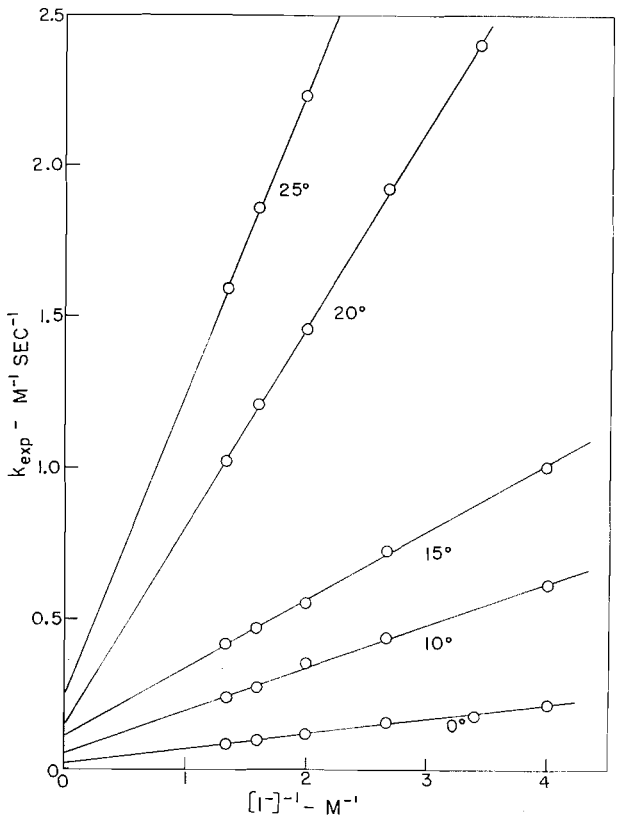

FIG. 2. Plots of k_{exp} vs. $[I^-]^{-1}$ according to equation [7]. Effect of temperature. (60 vol.% ethanol; 0.31 *M* buffer.)

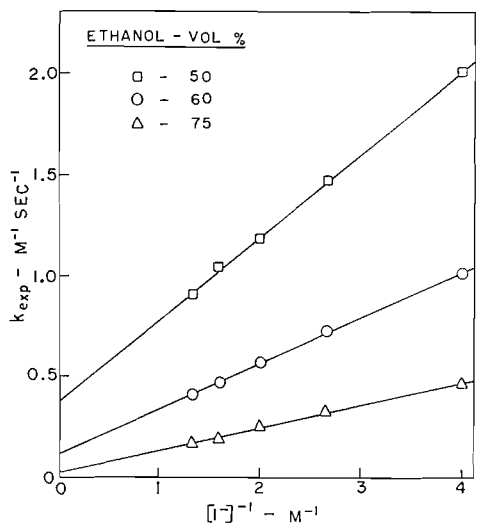

FIG. 3. Plots of k_{exp} vs. $[I^-]^{-1}$. Effect of solvent. (15° C; 0.31 *M* buffer.)

Values of k_{exp} listed in Table II are seen to be independent of the initial AH_2 concentration. Independence of the initial iodine concentration was observed only when the latter exceeded 3.0×10^{-3} *M*. At lower concentrations an apparent inverse dependence of k_{exp} on $[I_2]_T$ was noted which is believed to reflect the increasing *relative* importance of air oxidation of hydrazobenzene under these conditions. In view of this all the pertinent kinetic measurements were made with $[I_2]_T > 5\times10^{-3}$ *M*, i.e. in the region of constant k_{exp}.

At least over a limited pH range, in weakly acid solution, the rate of reaction appeared to be pH independent. Thus no variation in k_{exp} was noted in a series of experiments with formic acid – formate buffer ratios ranging from 1:1.85 to 4:1 (corresponding to a pH variation of 4.02 to 3.15, in aqueous solution).* With increasing pH, however, marked acceleration of the reaction was noted indicating the emergence of an additional, base-catalyzed path, in neutral and basic solution. This region was not investigated.

With acetic acid – acetate buffers of constant ratio, some dependence of the rate on the total buffer concentration was noted (Table II), presumably due to an ionic strength effect.

**Formate buffers were used in place of acetate buffers in these experiments in order to achieve as large a variation of* pH *as possible, without approaching the* pH *range where base catalysis might begin to play some part.*

Values of k_1 and k_2 in 60 volume% ethanol for various temperatures ranging from 0° to 25° C are listed in Table III and yield the Arrhenius expressions,

[9] $$k_1 = 4.2\times10^{11} \exp[-10{,}000/RT]\ M^{-1}\ \text{sec}^{-1},$$

[10] $$k_2 = 2.5\times10^{11} \exp[-16{,}400/RT]\ M^{-1}\ \text{sec}^{-1}.$$

Both frequency factors are in the normal range for simple bimolecular reactions.

TABLE III

Temperature dependence of the rate constants
(60 volume % ethanol; 0.31 *M* 5.7:1 HOAc–KOAc buffer)

Temp. (°C)	k_1/K (sec^{-1})	$k_1\times10^{-3}$ ($M^{-1}\ \text{sec}^{-1}$)	k_2 ($M^{-1}\ \text{sec}^{-1}$)
0.0	0.049	3.2	0.020

25.0	1.00	14.6	0.25

Measurements in different solvent mixtures ranging from 45 to 85 volume% ethanol reveal a marked inverse dependence of k_{exp} on the ethanol content (Fig. 3, Table IV).

TABLE IV

Solvent effects
(15.0° C; 0.31 *M* 5.7:1 HOAc–KOAc buffer)

Volume % ethanol	k_{exp} (0.25 *M* KI) ($M^{-1}\ \text{sec}^{-1}$)	$k_1\times10^{-3}$ ($M^{-1}\ \text{sec}^{-1}$)	k_2 ($M^{-1}\ \text{sec}^{-1}$)
45	3.40		
50	2.02	8.4	0.38
55	1.36		
60	0.984	5.7	0.12
65	0.775		
70	0.610		
75	0.472	4.8	0.021
80	0.342		
85	0.248		

While k_1 and k_2 both contribute to this trend the solvent effect is much greater for the latter. Thus, on going from 75 to 50 volume% ethanol, k_1 increases by a factor of 1.75 and k_2 by a factor of 18.1.

Addition of 10^{-4} *M* benzoquinone and comparable concentrations of salts of a number of metal ions including Co^{2+}, Fe^{2+}, UO_2^{2+}, Cr^{3+}, and Hg^{2+}, were without marked effect on the rate (Table II). The largest effect, exhibited by $FeSO_4$, was a reduction of 18% in the rate.

DISCUSSION

Although hydrazobenzene is known to be oxidized readily by many oxidants only in a few other cases, notably for $S_2O_8^=$ (3) and O_2 (4), have the reaction kinetics been examined. In connection with each of these reactions, including the present ones, there arises the question of whether oxidation of hydrazobenzene occurs by a "molecular" (i.e. one-step) mechanism or by a multi-step mechanism involving the α,β-diphenylhydrazyl radical (AH) as an intermediate. A mechanism of the latter type, involving

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

a chain reaction propagated by the AH and SO_4^- radicals, has been demonstrated by Whalley, Evans, and Winkler (3) for the oxidation of hydrazobenzene by persulphate,

[11a] $$AH_2 + S_2O_8^= \rightarrow AH + HSO_4^- + SO_4^-,$$

[11b] $$AH_2 + SO_4^- \rightarrow AH + HSO_4^-,$$

[11c] $$AH + S_2O_8^= \rightarrow A + HSO_4^- + SO_4^-,$$

[11d] $$2AH \rightarrow A + AH_2.$$

For the oxidation by O_2, on the other hand,

[12] $$AH_2 + O_2 \rightarrow A + H_2O_2,$$

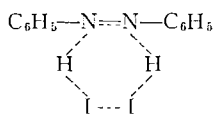
at least under certain conditions, a one-step mechanism has been suggested (4).

For the oxidation of hydrazobenzene by I_2 (and similarly by I_3^-), both a simple one-step mechanism (equation [1]) as well as a chain mechanism analogous to that for persulphate, i.e.

[13a] $$AH_2 + I_2 \rightarrow AH + HI + I,$$

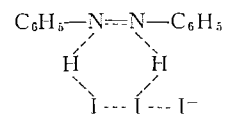
[13b] $$AH_2 + I \rightarrow AH + HI,$$

[13c] $$AH + I_2 \rightarrow A + HI + I,$$



[13d] $$2AH \rightarrow A + AH_2,$$

appeared at the outset to be reasonable possibilities. The evidence accumulated in the present study, among which the following in particular may be cited, is considered to favor strongly the former alternative:



1. The second-order kinetics and normal frequency factors for both the AH_2–I_2 and AH_2–I_3^- reactions are most readily reconciled with a simple bimolecular rate-determining step in each case. A chain mechanism such as that considered above would be expected to exhibit marked departures from second-order kinetics such as are observed for the AH_2–$S_2O_8^=$ reaction (3).

2. The absence of significant effects due to addition of quinone and of various oxidizing and reducing metal ions which commonly catalyze or inhibit chain reactions (5). Failure to observe any such effects in the present case makes it very unlikely that a chain mechanism is involved.

The very low activation energy, notably for the I_2 reaction, is most readily reconciled with a "cyclic" activated complex, such as (I), which is stabilized both by incipient formation of the relatively strong H—I bonds and by a substantial portion of the resonance energy of the incipient azobenzene molecule.

(I)

(II)

An alternative mechanism, namely hydride transfer from AH_2 to I_2, leading to the formation, initially, of I^-, HI, and AH^+ (i.e. the conjugate acid of azobenzene) is considered less likely in view of the absence of evidence (e.g. a low frequency factor) for a highly polar transition state which would be expected for such a mechanism. Both mechanisms are consistent with the formation of *trans*-azobenzene, the more stable isomer, as the initial product.

An analogous path (II) may be envisaged for the I_3^- reaction. The lower reactivity of I_3^-, relative to I_2, is reflected largely in the activation energy difference (16.4 vs. 10.0 kcal/mole) between the two reactions. The additional activation energy of 6.4 kcal/mole represents a substantial portion of, though not quite all, the energy of 9.5 kcal/mole required to remove the extra I^- ion completely (i.e. to dissociate I_3^- into I_2 and I^-); this suggests that the extra I^- ion is nearly dissociated in the activated complex. Also in accord with this interpretation is the much greater accelerating effect of water on k_2 than on k_1, which may be explained in terms of an additional contribution to stabilization of the activated complex by solvation of the incipient I^- ion.

THE PREPARATION OF ALKOXIDES AND TRIETHYLSILANOLATES OF Ti, Zr, V, Nb, Ta, AND Sn FROM THE DIALKYLAMIDES

I. M. THOMAS*

The chemical properties of the dialkylamides of titanium, zirconium, vanadium, niobium, tantalum, and tin have recently been studied in this laboratory (1), and it has been found that they are very reactive to reagents containing replaceable hydrogen atoms. Besides being extremely sensitive to moisture, they react smoothly and completely with alcohols and triethylsilanol at room temperature in benzene to give the corresponding alkoxides and triethylsilanolates with the liberation of the dialkylamine:

$$M(NR_2)_x + xR^1OH \rightarrow M(OR^1)_x + xR_2NH,$$
$$M(NR_2)_x + xEt_3SiOH \rightarrow M(OSiEt_3)_x + xR_2NH.$$

This method has been used by Gilman *et al.* (2) to prepare uranium^{IV} tetraalkoxides from tetrakis-diethylamido-uranium^{IV}.

Previous methods of preparation of transition metal alkoxides have utilized the metal chloride as starting material, and subsequent side reactions have reduced the yields in many cases. No niobium penta-*t*-alkoxides (3) or vanadium^{IV} tetraalkoxides have been reported.

The preparation of trialkylsilanolates from trialkylsilanols is also hindered by the ease with which the trialkylsilanols condense to a disiloxane and water under the influence of acidic or 'Lewis acidic' reagents (4), with subsequent hydrolysis of the product.

The absence of side reactions in this method enables near quantitative yields to be obtained in all cases, and it is particularly suitable for the preparation of all alkoxides of vanadium^{IV} and tin, and the tertiary alkoxides of zirconium and niobium.

It should be noted that niobium^{IV} tetra-dialkylamides on reaction with alcohols and triethylsilanol give pentavalent derivatives. Repeated attempts to prepare tetraalkoxides were unsuccessful, and it is evident that reduction of the alcohol by Nb^{IV} readily takes place even at 0° with subsequent formation of a pentavalent product. However, the comparative stability of vanadium in the tetravalent state enabled substantially pure tetra derivatives to be prepared from vanadium^{IV} tetra-dialkylamides.

EXPERIMENTAL

Special precautions, e.g. carefully dried all-glass apparatus, were adapted to avoid hydrolysis, and all experiments were conducted under an atmosphere of dry, oxygen-free nitrogen.

Analysis

Metals, except vanadium, were determined gravimetrically as the ignited oxides (4), and silicon as silica (4). An oxidation method (5) was used for the determination of ethoxy and isopropoxy groups, and basic nitrogen was estimated in a modified Kjeldahl apparatus (1). Estimation of vanadium and valency determination were carried out using a Jones reductor and ceric sulphate solution (6).

The alcohols and benzene were dried azeotropically prior to use.

The preparations of dialkylamido compounds of titanium, zirconium, and tantalum have been described (1, 7). Those of vanadium and niobium will be reported in another communication. Tetrakis-diethylamido-tin was prepared as described below.

Preparation of Tetrakis-diethylamido-tin

Stannic chloride (19.0 g) in benzene (50 ml) was added, over 20 minutes, to a stirred solution of lithium diethylamide in ether (300 ml of 1.18 *N* solution). The mixture was refluxed for 3 hours after the addition and then stirred overnight at room temperature. Evaporation of the solvent under reduced pressure, and distillation of the residue under high vacuum gave tetrakis-diethylamido-tin (8.90 g: 30% yield) as a pale yellow liquid, b.p. 90°/0.1 mm. Found: Sn, 29.1%; N, 13.4%; Cl, zero. Calc. for $Sn(NEt_2)_4$: Sn, 29.1%; N, 13.8%.

Since the technique used in the alcoholysis and silanolysis reactions was essentially the same in each experiment, the details are given for the preparation of zirconium tetra-*t*-butoxide and the other results summarized in Tables I and II.

NOTE: All products, except those of vanadium, were colorless liquids or solids. All products were analyzed for basic nitrogen content, which was found to be zero in every case.

Preparation of Zirconium Tetra-t-butoxide

t-Butanol (12 ml: ca. 100% excess) was added dropwise to tetrakis-diethylamido-zirconium (5.63 g) in benzene (30 ml). An exothermic reaction took place and the solution

was left at room temperature for 20 minutes after the addition. Evaporation of the solvent under reduced pressure and distillation of the residue under high vacuum gave zirconium tetra-*t*-butoxide (5.00 g: 88% yield) as a colorless liquid, b.p. 60°/0.1 mm. Found: Zr, 23.7%; N, zero. Calc. for $Zr(OBu^t)_4$: Zr, 23.8%.

THE ACIDITY OF 9-MONOALKYL- (OR ARYL-) FLUORENES

G. W. H. Scherf and R. K. Brown

In a previous publication (1) it was shown that the reaction between equivalent amounts of alkyl halide and 9-fluorenyl-potassium (or -sodium) in ether solvents gave not only the expected 9-monoalkyl fluorene but as much as 35% yield of 9,9-dialkylfluorene. This latter product was considered to occur as result of cross metalation between unreacted 9-fluorenyl-potassium (or -sodium) and the 9-alkylfluorene initially produced. For the 9-alkylfluorene to compete with the alkyl halide for the remaining 9-fluorenyl-potassium as successfully as it apparently did, the postulation was made that the C_9-monoalkylated fluorene was at least as acidic as, and probably more acidic than, the parent unsubstituted fluorene. It is known that 9-phenylfluorene is more acidic than is fluorene (2, 3), but that an *alkyl* substituent at C_9 of fluorene should also lead to enhanced acidity of the remaining hydrogen at carbon 9 is unexpected. The explanation given (1) was that of a tendency of the C_9 substituent to become coplanar with the planar fluorene moiety, hence assisting the tendency to rehybridization of carbon 9 from sp^3 to sp^2, in agreement with the known capability of fluorene for carbanion formation (4). Such coplanarity is quite possible if the carbon atom attached to C_9 of fluorene is methyl or methylene.

Some evidence has now been obtained that certain 9-alkylfluorenes do in fact possess somewhat greater acidity than that of the parent fluorene. Several reports concerning nuclear magnetic resonance studies show that the chemical shift observed for the proton signal is related to the electronic environment and hence the acidity of the proton (5, 6). Accordingly an examination was made of the N.M.R. spectra of fluorene, 9-benzylfluorene, 9-methylfluorene, and 9-phenylfluorene in chloroform solution. The position of the C_9 proton signal, referred to the proton signal of the solvent, is shown for each of these compounds.

Compound	Signal relative to solvent, c.p.s.	Shift relative to fluorene, c.p.s.
Fluorene	+193	0
9-Phenylfluorene	+130	−63
9-Methylfluorene	+181	−12
9-Benzylfluorene	+181	−12

The large shift of 63 c.p.s. found for the proton signal in 9-phenylfluorene relative to that of fluorene is clearly an indication of the marked acidity actually found for 9-phenylfluorene (2, 3). Both 9-methylfluorene and 9-benzylfluorene show a shift of only 12 c.p.s. relative to fluorene *but in the same direction* as that found for 9-phenylfluorene. This supports the view that the proton on carbon 9 of these monoalkylated fluorenes is also more acidic than the proton in unsubstituted fluorene.

NUCLEAR MAGNETIC RESONANCE SPECTRA OF A VINYL PHOSPHATE AND THIONOPHOSPHATE ISOMERS (PHOSDRIN AND 'thionoPHOSDRIN')*

J. B. Stothers and E. Y. Spencer

Some substituted vinyl phosphates, because of their high biological activity, have been the subject of a number of recent investigations (1, 2, 3, 4). One systemic insecticide of this type, methyl 3-(O,O-dimethylphosphoryloxy)but-2-enoate, (Phosdrin), exists in two geometric isomeric forms, I*a* and I*b*, one of which has a much higher anticholinesterase activity. An assignment of the configuration about the double bond has been made previously on rather weak arguments based on relative water solubility, chromatographic behavior, and selective toxicity (1). By analogy, a similar assignment had been tentatively suggested for the thiono derivatives, II*a* and II*b*, since their properties were somewhat similar to those of the Phosdrins. The thiono derivatives were prepared as part of a continuing investigation on the biological activity of phosphate esters, and their preparation is described herein. The results of the toxicity studies will be reported elsewhere.

Ia X = O
IIa X = S

Ib X = O
IIb X = S

Two methods utilized for the synthesis of Phosdrin yield different ratios of cis and trans isomers (1). One involving the reaction of trimethyl phosphite with methyl α-chloroacetoacetate (5) favors the "cis" isomer slightly while substituting benzyl α-chloroacetoacetate yields only the "cis" form (2). On the other hand, reaction of dimethyl phosphorochloridate with the sodium salt of methyl acetoacetate favors the "trans" isomer (1). It is of interest that in the synthesis of the thiono derivatives of Phosdrin, the latter method gave only the "trans" product from which the "cis" form was obtained by ultraviolet irradiation. Due to low solubilities, the Craig countercurrent extraction, employed in Phosdrin isomer separation (2), was replaced by selective elution from acid-washed activated alumina.

The earlier study had assigned the cis configuration, I*a*, to the more active isomer. (It should be noted that this assignment refers to the relative configuration of the carbomethoxyl and phosphoryloxy groupings.) Recently, Jackman (6) has shown that, in a number of β-methyl-α,β-unsaturated esters, an assignment of configuration can be made on the basis of a comparison of the N.M.R. spectra of cis and trans isomers. Therefore, the high-resolution proton magnetic resonance spectra of these four compounds have been determined in order to confirm or deny the original assignment.

Each compound was examined in dilute solution in carbon tetrachloride and the assignment of peaks from the observed chemical shifts was straightforward. The olefinic proton appeared at lowest field and the allylic methyl protons at highest field in each case. The methoxyl protons gave rise to three peaks, since the methoxyl groups on phosphorus are chemically shifted from the carbomethoxy group and are split into a doublet by spin–spin interaction with phosphorus. The distinction between the three peaks followed readily since the coupling constants, J_{H-P}, for both $CH_3OP \rightarrow O$ and $CH_3OP \rightarrow S$ are well known (7). The observed chemical shifts and J_{H-P} coupling constants are listed in Table I. It should be noted that the naming of these compounds arises from the previous assignment (1).

TABLE I

Proton chemical shifts and coupling constants (J_{H-P})

Compound	ν (cycles/sec)*				J (cycles/sec)
	Olefinic H	CH_3OP	CH_3OOC	CH_3	CH_3—OP→X
"cis" Phosdrin	347	232	222	145	10.4
"trans" Phosdrin	318	233	220	129	11.2
"cis" 'thionoPhosdrin'	341	233	222	142	14.6
"trans" 'thionoPhosdrin'	322	229	220	126	14.6

*Measured at 60 Mc/sec, expressed in cycles/sec from the single peak of tetramethylsilane.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

From these results, it can be seen that the allylic methyl group appears at lower field in the previously assigned "cis" forms. Since it is reasonable to assume that the phosphoryl group will exert a similar effect on this methyl group in both the cis and trans structures, the difference in chemical shift must arise from the orientation of the carbomethoxyl grouping. Jackman and Wiley (6) have clearly demonstrated that in similar systems the allylic methyl group is found at lower field in that isomer having the carbomethoxyl group and the β-methyl group in a cis relation than in the corresponding trans isomer. Therefore, the N.M.R. spectra of these four compounds show the original assignment to be incorrect. The more active isomer, the so-called "cis" Phosdrin must be that form in which the *allylic methyl and carbomethoxyl* groupings are in a cis relation.

There is one further point of interest in this study. It was expected that each of the multiplets observed in these spectra could be analyzed by first-order treatment, since the relative chemical shift between interacting protons is large compared to the coupling constants. In each case, however, the observed pattern was more complex than the simple doublet and quartet pattern expected for the allylic methyl and olefinic protons, respectively. Only one of these compounds, trans thionoPhosdrin, II*a*, is a solid and so amenable to rigorous purification. Its spectrum exhibited a well-resolved quartet for the allylic methyl group. This appears to be clear evidence for H^1—P^{31} spin–spin interaction through *four* bonds. From this pattern, however, it is not possible to assign a coupling constant unequivocally to each of the two observed interactions. The P^{31} spectra of this and related compounds will undoubtedly allow the assignment of J's and work is being directed to this end.

EXPERIMENTAL

N.M.R. Spectra

All spectra were obtained using dilute solutions (10–12% w/v) in carbon tetrachloride containing ca. 0.5% tetramethylsilane (TMS) as an internal reference. A Varian Associates V-4302 spectrometer operating at 60 Mc/sec was employed and the usual audio side-band technique was used to measure the relative chemical shifts from the TMS peak. The audio oscillator was calibrated with an H-P 522B frequency counter. The chemical shift data are reported in cycles per second from TMS and are judged to be accurate to within ± 1 cycles/sec.

"cis" and "trans" Phosdrin

These compounds were prepared as previously described (2).

"cis" and "trans" 'thionoPhosdrin'

The reaction product of 2.3 g of sodium and 11.6 g of methyl acetoacetate was heated in refluxing benzene with 16.0 g of dimethyl phosphorothionochloridate for 24 hours. Subsequent removal of the precipitate, evaporation of the solvent, and final vacuum distillation yielded a crude fraction boiling between 92° and 112° C at 0.6 mm. Crystals later formed and were filtered off and recrystallized to yield 5.1 g (21%), m.p. 49–50° C. Allowing for recovery of unreacted starting materials, the yield of purified product was 30%. The absence of the P → O linkage was indicated by the lack of a band between 1275 and 1300 cm^{-1} in the infrared spectrum, while absorption at 913 cm^{-1}, and none at 897 cm^{-1}, indicated the presence of only the "trans" isomer. Bromide–bromate titration confirmed the theoretical thiono sulphur content and a satisfactory analysis was obtained.

Twenty-nine hours of ultraviolet irradiation of 'thionoPhosdrin' in carbon tetrachloride by a Hanovia lamp was required to give maximum isomerization as indicated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

by the increase in absorption at 897 cm^{-1} and decrease at 913 cm^{-1}. Quantitative separation of the isomers was accomplished by absorption on Merck acid-washed activated alumina, triturated with 2% water, from hexane. This was followed by elution of the 'cis' isomer with carbon tetrachloride and then the 'trans' isomer by chloroform to yield 54% 'cis' isomer and 37% 'trans'. No absorption at 1285 cm^{-1} after ultraviolet irradiation indicated no P → S to P → O shift.

THE HEAT OF FORMATION OF THE FORMYL RADICAL

T. W. Shannon and A. G. Harrison

As discussed by Cottrell (1) the bond dissociation energy D(CHO—H) in formaldehyde and consequently the heat of formation of the formyl radical appear to be in some doubt. From investigations of the photolysis of formaldehyde Gorin (2) and Klein and Schoen (3) have suggested D(CHO—H) = 77 kcal/mole, leading to ΔH_f(CHO) = −2.8 kcal/mole. From a study of the photolysis of a number of aldehydes, as summarized by Calvert (4), a value D(CHO—H) = 91 kcal/mole (ΔH_f(CHO) = 11.2 kcal/mole) has been obtained.

Both the direct and indirect mass spectrometric methods have been applied by Reed and co-workers to the formyl radical. Reed and Brand (5) have reported the ionization potential of the formyl radical to be 9.83 to 10.03 v. This ionization potential, when combined with the appearance potential of CHO^+ from formaldehyde, 13.10 v (6), gives D(CHO—H) = 70.8 to 75.4 kcal/mole, corresponding to ΔH_f(CHO) = −4.4 to −9.0 kcal/mole.

In the indirect method Reed (6) has measured the appearance potential of CH_3^+ from acetaldehyde. On the assumption that the process occurring is $CH_3CHO + e \rightarrow CH_3^+ + CHO + 2e$ the reported appearance potential, 13.12±0.06 v, may be combined with $\Delta H_f(CH_3^+)$ = 262 kcal/mole (7) and $\Delta H_f(CH_3CHO)$ = −39.8 kcal/mole (8) to give ΔH_f(CHO) = −0.8 kcal/mole. As discussed below we have not been able to confirm in this work the reported appearance potential of CH_3^+ from acetaldehyde.

The present work reports the measurement of appearance potentials of ions of known heat of formation from a number of aldehydes in an attempt to obtain further information by the indirect mass spectrometric method for the heat of formation of the formyl radical. The results are given in Table I. Column six of Table I records values for

ΔH_f(CHO) + E calculated from the relation

$$A_p(R^+) \text{ from RCHO} = \Delta H_f(R^+) + \Delta H_f(\text{CHO}) - \Delta H_f(\text{RCHO}) + E$$

by substituting the known values for $\Delta H_f(R^+)$ and ΔH_f(RCHO), where E is any excess energy which may be associated with either the charged or uncharged fragment. The above relation assumes that the lowest energy process occurring is

$$\text{RCHO} + e \rightarrow R^+ + \text{CHO} + 2e.$$

The appearance potential of CH_3^+ from acetaldehyde obtained in this work is over 1 v higher than that reported by Reed and discussed above. The measured appearance potential, 14.51±0.1 v, is only slightly greater than that calculated for the process

$$CH_3CHO + e \rightarrow CH_3^+ + CO + H + 2e \qquad A_p = 14.3 \text{ v}.$$

No evidence was obtained for formation of methyl ions in any significant amounts below this appearance potential. Until further independent evidence is obtained, the appearance potential of CH_3^+ from acetaldehyde cannot be considered as providing convincing evidence concerning the heat of formation of the formyl radical.

The appearance potentials of the $C_3H_7^+$ ion from *n*-butyraldehyde and isobutyraldehyde, as well as the appearance potential of the $C_6H_5^+$ ion from benzaldehyde, lead to mutually consistent values for ΔH_f(CHO) + E. If one assumes that in these cases no excess energy is involved these results lead to ΔH_f(CHO) = −0.3±3 kcal/mole, in essential agreement with the low value obtained from chemical kinetics. If excess energy is involved then the true heat of formation will be even lower; in any case the results are not consistent with the high value, ΔH_f(CHO) = 11.2 kcal/mole, derived from chemical kinetics.

On the basis of $\Delta H_f(CHO) = -0.3$ kcal/mole the appearance potentials of CCl_3^+ from chloral and $C_2H_3^+$ from acrolein appear to involve excess energy in both cases. It should be noted that the result reported for acrolein is the only one which provides support for the high value for the heat of formation of the formyl radical. If one assumes this value then one must conclude that the appearance potentials measured for the $C_3H_7^+$ ions and the $C_6H_5^+$ ion are too low by approximately 0.5 v. Such a possibility appears highly unlikely; rather the results are more consistent with excess energy being associated with the formation of the CCl_3^+ and $C_2H_3^+$ ions.

In conclusion, the results reported in Table I provide support for the low value for the heat of formation of the formyl radical as derived from chemical kinetics. The results further suggest that excess energy is involved in the formation of the CCl_3^+ and $C_2H_3^+$ ions from the corresponding aldehydes.

EXPERIMENTAL

The appearance potentials were measured using an Associated Electrical Industries MS-2 mass spectrometer. The electron-accelerating voltage could be read to ± 0.02 volts with a precision voltmeter and was varied in 0.2-v steps while determining the ionization-efficiency curves. The voltage scale was calibrated by admitting either krypton or xenon with the sample. The appearance potentials were evaluated by extrapolating the voltage-difference curves to zero ion current. The limits of error given in column two of Table I represent the average deviations of three or more determinations.

Note added in proof: J. R. Majer, C. R. Patrick, and J. C. Robb (Trans. Faraday Soc. **57**, 14, 1961) have recently reported the appearance potential of CH_3^+ from CH_3CHO to be 14.55 v, in excellent agreement with the value obtained in this work.

As a result, information is now available concerning the rates of hydrogen abstraction by this polar radical from mercaptans (1, 2, 3), hydroaromatic compounds (4), amines (5, 6, 7), and phenols (7, 8). It has been confirmed in all these reactions that the major product is 2,2-diphenyl-1-picrylhydrazine, but only in the case of the hydroaromatic compounds has it been possible to isolate good yields of the dehydrogenation products (4). The kinetic results for hydroaromatic compounds do not, however, fit into the general pattern in that rates of reaction dependent upon the square of the DPPH concentration have been reported (4) in addition to activation energies as high as 33 kcal/mole. This note records the results of a new investigation of the kinetics of reaction of DPPH with 9,10-dihydroanthracene and 1,4-dihydronaphthalene.

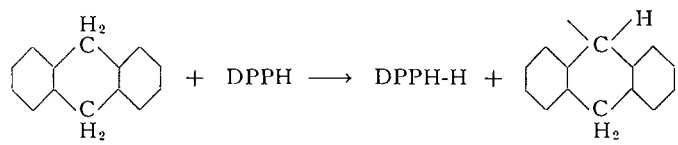

TABLE I

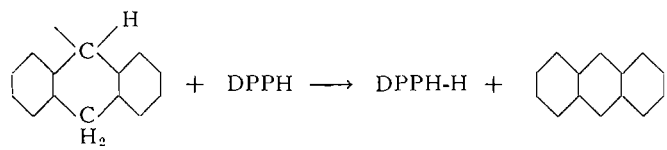
Rate constants (k_1) for the reaction of DPPH with 9,10-dihydroanthracene



DPPH, mole/l.	Dihydroanthracene, mole/l.	Solvent	Temp., °C	k_1, cc/mole sec
0.1	0.25	Benzene	50	0.37
0.025	0.25	"	50	0.38
0.025	0.0625	"	50	0.35
0.018	0.20	"	50	0.36*
0.025	0.25	"	30	0.124
0.025	0.25	"	40	0.20
0.025	0.25	"	60	0.60
0.0125	0.125	Carbon tetrachloride	30	0.26
0.0166	0.166	"	50	0.68
0.025	0.25	Dioxan	50	0.22
0.025	0.25	"	70	0.68

**In vacuo.*

9,10-Dihydroanthracene was prepared by the reduction of anthracene in boiling ethanol with sodium amalgam. Its reaction with DPPH in benzene solution obeys simple second-order kinetics as illustrated by the data in Table I, and the rate of reaction is not significantly affected by the presence of air or by the addition of diphenylpicrylhydrazine. High yields of anthracene and diphenylpicrylhydrazine (DPPH-H) are obtained (4) and the main reaction presumably involves the following steps.

[1]

[2]

Reaction [1] is rate determining, and reaction [2] is rapid compared with the reverse of reaction [1].

Rate constants at different temperatures lead to an activation energy of 10.4 ± 0.5 kcal/mole and an Arrhenius A factor of 4.0×10^6 cc/mole sec for reactions in benzene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solution. The activation energy is within the range 4–16 kcal/mole observed in other hydrogen-abstraction reactions involving DPPH, but the A factor is low compared with values of the order of 10^{10} cc/mole sec normally observed. The low value is not surprising in view of the high probability of steric hindrance to reaction [1]; a comparable A factor is observed in the reaction of DPPH with 2,6-di-*t*-butylphenol (8). For carbon tetrachloride as solvent the activation energy is 9.2 ± 1 kcal/mole and the A factor is 1.1×10^{6} cc/mole sec, and for dioxan as solvent the corresponding values are 12.4 ± 1 kcal/mole and 5.4×10^{7} cc/mole sec.

When 1,4-dihydronaphthalene (9) is used as the hydrogen donor, the kinetic results do not follow the expected pattern. In individual reactions the rate of disappearance of DPPH in solutions containing a large excess of 1,4-dihydronaphthalene falls off only to a small extent in the first 75% of reaction, in contrast to the first-order dependence observed with 9,10-dihydroanthracene as donor. Rates of reaction are higher in air than in degassed systems and the reproducibility is poor. Some typical results are given in Table II for the rates of disappearance of DPPH at 30° in carefully degassed benzene

TABLE II

Rates of reaction of DPPH with 1,4-dihydronaphthalene

DPPH, mole/l.	Dihydronaphthalene, mole/l.	Rate$\times10^{10}$, mole/cc sec
0.0226	0.1	8.3
0.0113	0.1	6.3
0.0057	0.1	5.3
0.0113	0.025	1.3

solutions. They are approximately represented by the expression

$$-d[\text{DPPH}]/dt = k_2[\text{dihydronaphthalene}][\text{DPPH}]^{0.3}.$$

Diphenylpicrylhydrazine (0.0113 M) causes a reduction in rate of about 20% in reaction mixtures containing DPPH at a concentration of 0.0113 M. The activation energy of the over-all process is estimated to be 12.5 ± 1.5 kcal/mole from rate measurements at 20° C, 30° C, 40° C, and 50° C. Since high yields of both diphenylpicrylhydrazine and naphthalene are obtained (4), a mechanism similar to that suggested for the dihydroanthracene reaction may be put forward; the activation energy of the primary hydrogen abstraction process would then be 12.5 kcal/mole. However, the low order of reaction with respect to DPPH shows that the reaction mechanism may be complex. A similar low order was observed in the early stages of the reaction of DPPH with mercaptans (1), but in that case the order increased to one for the major part of the reaction.

THE CONDENSATION OF RHODANINE AND DERIVATIVES WITH 4-ANTIPYRINALDEHYDE

FREDERICK J. ALLAN[1] AND G. GRAHAM ALLAN[2]

More than three-quarters of a century has elapsed since antipyrine (I*a*) was introduced into medicine by Knorr as an antipyretic and analgesic (1). Although pyrazolone analgesics have now virtually vanished from the scene in North America and the Scandinavian countries (2), they are still widely used in other areas and considerable efforts have been expended to improve their pharmacological properties (3, 4). In recent years some of this effort has been focused on 4-antipyrinaldehyde (I*b*)[3] and its derivatives (5–14), principally in connection with antineuralgic and febrifugal effects. While insecticidal pyrazolones have been described (15–17), other nonanalgesic applications of 4-antipyrinaldehyde or its derivatives have received little attention other than brief reports of tuberculostatic (18) and bacteriostatic activity (19).

therefore condensed with rhodanine, and its 3-ethyl, -allyl, -phenyl, and -carboxymethyl relatives, using sodium acetate in a mixture of acetic acid and anhydride as the condensing medium (24). The products,[4] (I*c*) to (I*g*), separated from the reaction mixture in an almost pure state.

EXPERIMENTAL[5]

5-[4-(1-Phenyl-2,3-dimethylpyrazol-5-onyl)methylene]rhodanine (Ic)

A mixture of 4-antipyrinaldehyde (216 mg, 0.001 mole) and rhodanine (133 mg, 0.001 mole) in acetic acid (1 ml) to which sodium acetate (200 mg) and acetic anhydride (0.1 ml) had been added, was refluxed for 30 minutes. The reaction mixture was allowed to cool when crystals separated. Recrystallization from dimethylformamide–ethanol gave (I*c*) as small golden yellow needles (102 mg, yield 31%) m.p. 325–327° with decomposition. Calc. for $C_{15}H_{13}N_3O_2S_2$ (331.402): C, 54.36; H, 3.95. Found: C, 54.21; H, 3.76%. The following compounds were similarly prepared.

3-Ethyl-5-[4-(1-phenyl-2,3-dimethylpyrazol-5-onyl)methylene]rhodanine (Id)

Orange plates (300 mg, yield 33%) m.p. 265–267°, crystallized from ethanol–benzene–dimethylformamide. Calc. for $C_{17}H_{17}N_3O_2S_2$ (359.462): C, 56.79; H, 4.77. Found: C, 56.48; H, 5.08%.

3-Allyl-5-[4-(1-phenyl-2,3-dimethylpyrazol-5-onyl)methylene]rhodanine (Ie)

Golden yellow blades (425 mg, yield 57%) m.p. 203–204°, crystallized from acetic acid. Calc. for $C_{18}H_{17}N_3O_2S_2$ (371.472): C, 58.18; H, 4.61. Found: C, 58.32; H, 4.72%.

3-Phenyl-5-[4-(1-phenyl-2,3-dimethylpyrazol-5-onyl)methylene]rhodanine (If)

Bright orange plates (435 mg, yield 54%) m.p. 266–268° with darkening, crystallized from ethanol–dimethylformamide. Calc. for $C_{21}H_{17}N_3O_2S_2$ (407.502): C, 61.9; H, 4.17. Found: C, 61.62; H, 4.03%.

3-Carboxymethyl-5-[4-(1-phenyl-2,3-dimethylpyrazol-5-onyl)methylene]rhodanine (Ig)

Orange-yellow needles (200 mg, yield 26%) m.p. 260–262°, crystallized from ethanol–dimethylformamide. Calc. for $C_{17}H_{15}N_3O_4S_2$ (389.442): C, 52.44; H, 3.88. Found: C, 52.65; H, 3.72%.

THE HYDROGEN ISOTOPE EFFECT IN THE PYROLYSIS OF CYCLOPROPANE[1]

ARTHUR T. BLADES

ABSTRACT

The hydrogen isotope effect in the thermal rearrangement of cyclopropane has been determined by the copyrolysis of cyclopropane and cyclopropane-d_6. The isotope effect in the temperature range 407–514° C and at pressures of about 60 cm Hg may be expressed by

$$k_H/k_D = 0.82 \exp(1300/RT).$$

The isotope effect is pressure dependent, decreasing from 1.98 at 76 cm Hg to 1.35 at 0.0178 cm Hg at 482° C.

The isotope effect and its temperature and pressure dependence are discussed in relation to the mechanism. The conclusion is reached that though trimethylene may be formed as an intermediate, the isotope effect is consistent only with an activated complex where a hydrogen atom is weakly bonded both to its original and ultimate carbon atoms, a situation which might also lead directly to propylene. A similar argument is presented to account for the previously described isotope effect in the decomposition of cyclobutane.

INTRODUCTION

The thermal rearrangement of cyclopropane to propylene is an unusually interesting reaction for a number of reasons. It is a unimolecular reaction wherein chain processes and heterogeneous behavior are readily eliminated, and it is the simplest of a group of cycloalkane reactions which exhibit a quasi-unimolecular behavior at relatively high pressures. Two completely different mechanisms have been proposed (1) for the reaction, one involving the intermediate formation of trimethylene diradical, and the other, formation of a transition state wherein one hydrogen atom is in the act of transferring from one carbon atom to another as the carbon–carbon bond breaks. While both mechanisms have some merit in explaining the accumulated experimental data, the latter is greatly favored on the basis of the theoretical treatment of the reaction by Slater (2).

A study of the hydrogen isotope effect in this reaction provides an important clue to the sequence of events which ultimately leads to reaction. The effect of pressure on the isotope effect may contribute to the understanding of the quasi-unimolecular behavior of unimolecular reactions at low pressures.

The tritium isotope effect in this reaction has been examined by Weston (3) and by Lindquist and Rollefson (4) by comparing the tritium content of a mixture of cyclopropane and cyclopropane-t_1 with that of propylenes produced by its isomerization. Lindquist and Rollefson found a relative rate constant expression $k/k_1 = 0.63 \exp(825/RT)$ at a pressure of 200 mm Hg in the temperature range 447–555° C, the isotope effect being 6–27%. Weston reports $k/k_1 = 0.86 \exp(385/RT)$ at the same pressure in the temperature range 406–492° C with an isotope effect up to only 17% despite the lower temperatures used. Weston also measured the isotope effect down to 0.4 mm Hg where it had decreased to approximately zero. While both of these studies suffer from

[1]*Manuscript received February 3, 1961.*
Contribution No. 147 from the Research Council of Alberta, Edmonton, Alberta.

the difficulty of tritium analysis, most uncertainty arises in the interpretation of the experimental results, i.e. the conversion of k/k_1 values to true isotope effects. Here the analysis by Weston seems preferable, but the temperature coefficients so obtained (5900±2000 and 8300 cal/mole) are impossibly high, as he states. In his appraisal of the pressure effect, Weston attempted to fit the data to two simple models. Both assumed that the isotope effect had fallen to its low-pressure limit at zero effect and the data fit both equally well. He pointed out that the zero effect at low pressure as found was coincidental since the isotope effect at low pressure is expected to be temperature dependent.

More recently, Schlag and Rabinovitch (5) have reported an isotope effect of 1.22 from a comparison of the rates of isomerization of cyclopropane and cyclopropane-d_2 at 718° K. Using Weston's conversion technique, this gives ($k_H/k_D = 2.18$) but this value did not decrease appreciably with pressure.

The present paper reports a study of the isotope effect in cyclopropane-d_6 as a function of temperature and pressure.

EXPERIMENTAL

The cyclopropane was Ohio Chemical Anesthetic grade and the cyclopropane-d_6 was supplied by Merck & Co. Both contained small amounts of impurities, especially propylene, which were removed by vapor phase chromatography. The deuterated compound was 93% d_6, the remainder being mainly d_5 and d_4.

The two cylindrical aluminum (2S) pyrolysis furnaces, accommodating 18- and 875-cc Pyrex reaction cells, were heated by directly applied asbestos-insulated Chromel "A" resistance wire and were lagged with 1.5-in. Marinite asbestos board with additional thicknesses at the ends. In each furnace, the reaction cell was surrounded on the sides by 1 in. of aluminum and on the ends by 1.5 in. The temperature of the small reactor was taken from the surrounding aluminum and of the large reactor from an axial thermocouple well extending to the center of the reactor. Temperatures were measured on a calibrated Pt: Pt – 10% Rh thermocouple.

The vacuum system utilized silicone-greased stopcocks throughout. No correction was attempted for reactor dead space as this was an insignificant percentage of the reactor volumes.

If two molecular species are copyrolyzed so that both have the same time and temperature history and if both exhibit first-order kinetics, then

$$k_1/k_2 = f_1/f_2 \cdot \frac{1 + 1/2f_1 + 1/3f_1^2 \ldots}{1 + 1/2f_2 + 1/3f_2^2 \ldots}$$

where f_1 and f_2 are the fractional conversions, i.e. the ratio of rate constants is the ratio of the fractional conversions modified by a correction term. If the conversions are kept below 0.1, the correction term remains small and great precision is not required in the individual conversions; the ratio of the two may be accurately determined from the ratios of the reactants and of the products. For present purposes a stock mixture of the normal and deuterated cyclopropanes was prepared and used in all subsequent experiments.

Separations of the two propylene products from reactants were carried out on a 15-ft dodecyl phthalate vapor phase chromatographic column at room temperature with hydrogen as carrier gas. The propylenes were collected in liquid-air traps, measured, and examined on a mass spectrometer. Isotope analysis of the first part of a vapor phase

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

chromatographic peak of a propylene sample indicated some fractionation; care was subsequently taken to collect the total chromatographic "peak".

In the mass spectrometric analysis of the propylene, the parent ions at mass 48 ($C_3D_6^+$) and 42 ($C_3H_6^+$) were taken as indicative of the relative proportions of the two isotopic species. Since the ion $C_3D_3^+$ makes a significant contribution at mass 42 at 50 v, a correction factor was determined from a sample of propylene-d_6 produced by the rearrangement of 10% of a sample of the deuterated cyclopropane. This procedure was also carried out at an ionization potential of 12 v where these corrections are considerably reduced but no significant or systematic difference was noted between the two analyses.

A similar procedure was followed in the analysis of the stock mixture of cyclopropane and cyclopropane-d_6.

In the study of the temperature coefficient, the small reactor was used throughout, conventional techniques being employed for introducing and retrieving the reactants. In the study of the pressure effect, the small reactor was used down to 50 mm Hg and the large reactor for lower pressures. In the very low pressure range, the pressure was calculated from the quantity of reactants introduced to the reactor. In experiments below 1 mm Hg, several successive runs were combined to provide sufficient sample for isotope-ratio analysis of the products.

RESULTS

The effect of pressure on the isotope effect is shown in Fig. 1 where k_H/k_D at 482° C

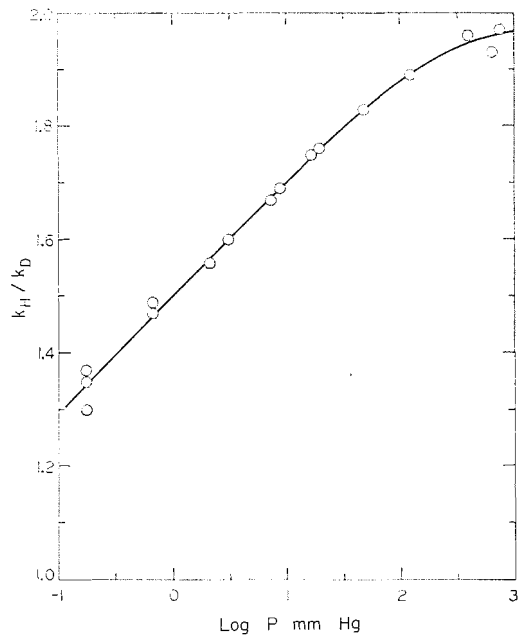

FIG. 1. The effect of pressure on the isotope effect at 482° C.

is plotted against the logarithm of pressure for comparison with the similar plot by Weston (3). To determine the isotope effect at infinite pressure, the best plot was that suggested by Schlag and Rabinovitch (5), k_D/k_H vs. $p^{-1/2}$; the value so obtained at 482° C is 1.96.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

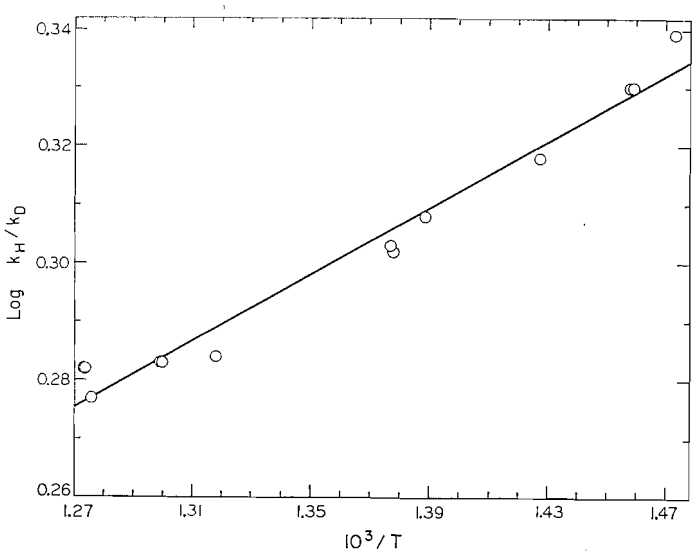

FIG. 2. The temperature dependence of the isotope effect.

The effect of temperature on the isotope effect is illustrated in Fig. 2 and the pertinent data are presented in Table I. A least-squares treatment of these data gives an isotope effect expression.

$$k_H/k_D = 0.82 \exp (1300 \pm 150/RT)$$

TABLE I
Data for the relative rate constants at high pressure

Expt. No.	Pressure, cm Hg	Temperature, °K	Conversion correction	k_H/k_D
16	67.6	720.0	1.026	2.03
17	66.8	700.4	1.017	2.08
18	64.4	783.3	1.032	1.89
25	63.6	758.6	1.027	1.92
27	62.2	725.7	1.034	2.00
28	62.1	726.1	1.037	2.01
30	59.6	678.6	1.006	2.18
31	58.7	785.1	1.034	1.91
32	58.1	785.4	1.034	1.91
33	58.3	769.4	1.037	1.92
34	57.5	769.6	1.037	1.92
35	56.6	685.8	1.009	2.12
36	56.4	685.3	1.009	2.12

Since these data were obtained in the pressure range 56–68 cm Hg, it would be expected that the pre-exponential term for the isotope effect at infinite pressure would be slightly higher.

DISCUSSION

The high-pressure hydrogen isotope effect reported here (2.04 at 445° C) compares favorably with effects observed in other gas phase reactions at the same temperature, for example the ethyl–ethyl-d_5 acetate decomposition (2.23) (6) and the abstraction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

reaction of CD_3 with acetone and acetone-d_6 (2.5) (7). The activation energy difference of 1300 cal/mole is slightly less than the values of 1515 cal/mole and 1670 cal/mole respectively for these two reactions but is still substantially above the maximum value of about 1150 cal/mole derivable from a single C—H stretching frequency being converted to a very weak vibration in the activated complex. It is therefore obvious that the hydrogen isotope effect in this reaction is a primary effect and that considerable carbon–hydrogen bond relaxation occurs during activation.

The decrease in the isotope effect with decreasing pressure confirms the observation of this same effect with cyclopropane-t_1 (3). Unlike that effect, which decreased to zero at 0.4 mm Hg, the present effect has not decreased to nearly the same extent at this pressure, nor is there any suggestion of its reaching a limiting value. Since this would happen only when the reaction has become truly second order, the present data must be considered as a more reliable measure of the variation of the effect with pressure.

Two quite distinct mechanisms have been proposed for the rearrangement of cyclopropane: the first, a mechanism wherein a hydrogen atom transfers from one carbon atom to another with the simultaneous breaking of the carbon ring; the second, involving the intermediate formation of a trimethylene diradical by the simple scission of the carbon ring, the propylene being subsequently formed by the transfer of a hydrogen atom from the middle carbon to a terminal one. This latter mechanism has recently been supported by the re-examination of data on the iodination of cyclopropane and on the rearrangement of cyclopropane-d_2 by Benson (8). Following the notation of Benson, the mechanism is given as

$$\triangle \underset{b}{\overset{a}{\rightleftharpoons}} \mathrm{T}: \overset{c}{\rightarrow} \mathrm{P}$$

and applying the steady-state treatment, the rate of formation of propylene becomes

$$\frac{d\mathrm{P}}{dt} = \frac{k_a k_c}{k_b} \triangle \Big/ \left(1 + \frac{k_c}{k_b}\right).$$

If the ratio k_c/k_b is small, then the over-all rate constant for the reaction becomes $k_a k_c/k_b$. Hence the hydrogen isotope effect observed must arise in one of these constants, and, since reaction (*c*) involves the transfer of a hydrogen atom, it must be assumed that k_c is the source of the primary effect, k_a and k_b probably having little, if any, isotope dependence.

The rate constant expressions derived by Benson for k_b and k_c indicate that at 444° C the reactions of trimethylene are so rapid that virtually no opportunity exists for collisions even at one atmosphere pressure. If true, this can only mean that the pressure effect in the isomerization occurs in the reaction (*a*), and, because the isotope effect is postulated to occur in (*c*) and not (*a*), then the isotope effect should not be pressure dependent. Since this is contrary to the experimental results, the mechanism must be incorrect unless either the instability of the trimethylene has been exaggerated, or the isotope effect in reaction (*a*) is of primary importance. Some assurance that the former is not the case may be gained from the results of Flowers and Frey (9), who found that at 100° C, trimethylene from the photolysis of cyclobutanone reacted with ethylene, but no such reaction occurred when cyclopropane was rearranged in the presence of excess ethylene. Both of these results are to be expected on the basis of half lives of the trimethylene radical at the two temperatures as calculated from Benson's rate-constant equations.

Two alternate interpretations may be put on a major isotope effect occurring in the reaction (*a*). It may be assumed that a transition state exists for the formation of trimethylene which involves a largely broken C—H bond, the hydrogen being in such a position as to considerably influence the carbon–carbon bond break. This would require that reactions (*b*) and (*c*) also have isotope effects and that they be of about the same magnitude. Since the geometric isomerization can be explained by the rotation in the trimethylene radical, it is unnecessary that the configuration of the activated complex allow for this alternate reaction. Secondly, it may be assumed that this transition state is such as to allow for geometric isomerism if it reverts to cyclopropane, and that it may go over directly to propylene. This would suggest an activated complex of the structure suggested by Smith (10) in which two hydrogens and the three carbon atoms are coplanar, with one of the hydrogens weakly bonded to its original carbon atom and to its ultimate acceptor. The postulate of a trimethylene intermediate from such a complex is unnecessary in explaining the experimental facts. The hydrogen isotope effect data does not conclusively decide between these two reaction schemes. It seems most reasonable to accept the latter, however, purely on the basis that, if the hydrogen does become bridged from one carbon to the next, as it must if it is to be of any assistance in the rupture of the carbon–carbon bond, then it will be most advantageous for it to continue on its path toward that carbon atom.

It is interesting to compare the isotope effect in this reaction with that observed for the decomposition of cyclobutane (11) to ethylene where the effect is 1.37 at 449° C, and the activation energy difference, 1400 cal/mole. The existence of this effect, despite the fact that the hydrogens do not transfer during the reaction, suggests that there is some similarity between the cyclopropane rearrangement and this decomposition. The similarity of the activation energy differences (1400 and 1300 cal/mole) suggests that the critical processes involved in reaching the activated complex are the same for each. If then, for the sake of argument, one proposes a mechanism for cyclobutane involving the tetramethylene diradical as an intermediate in the path to ethylene, and applies

$$\square \underset{b}{\overset{a}{\rightleftharpoons}} \mathrm{T} \xrightarrow{c} 2\mathrm{E}$$

the same steady-state treatment as for cyclopropane, it must be true that reaction (*a*) is the isotope-dependent step since the effect is again pressure dependent. The reaction (*c*) in cyclobutane does not involve a hydrogen transfer and would not be expected to involve a hydrogen isotope effect. In reaction (*b*), however, the activated complex is the same as for the forward reaction, and a roughly equivalent C—H bond weakening must occur as in reaction (*a*); hence a fairly large activation energy difference would be expected. Since this would tend to cancel the energy difference in (*a*), a relatively small temperature coefficient would have been expected in the isotope effect. The experimental value does not support this thesis, and it therefore seems reasonable to suggest that the decomposition of cyclobutane involves a transition state in which the carbon–carbon bond split is assisted by the partial bonding of one hydrogen to its neighboring carbon atom.

If this is a reasonable description of the mechanism of the reaction, some correlation must exist between the critical difference between the cyclopropane and cyclobutane mechanisms, i.e. the transfer and non-transfer of hydrogen atoms, and the considerable difference in the isotope effects, i.e. 2.04 vs. 1.37. The fact that the ratio of these two numbers is about 1.5 suggests that this difference arises from that part of the isotope

effect which is due to the relative reduced mass ratio in the reaction co-ordinate in the region of the transition state, which, for hydrogen isotope effects, is about 1.4. This implies that the difference in these isotope effects arises not in the mode of formation of the activated complex nor of its geometry, but rather in the unique way in which the hydrogen atom is concerned in that degree of freedom of the complex which results in reaction.

ACKNOWLEDGMENTS

The author wishes to thank Dr. B. S. Rabinovitch for his manuscript prior to publication and Dr. M. G. H. Wallbridge and P. W. Gilderson for fruitful discussions. Assistance in the form of a grant for fundamental research from the National Research Council is also gratefully acknowledged.

CONSTITUTION OF THE GALACTOMANNAN FROM THE KERNEL OF GREEN PALMYRA PALM NUT (BORASSUS FLABELLIFER LINN.)[1]

A. K. MUKHERJEE, D. CHOUDHURY, AND P. BAGCHI

ABSTRACT

The water-soluble polysaccharide extracted from the kernel of green palmyra palm nut (*Borassus flabellifer* Linn.) was shown to be composed of D-galactose and D-mannose in the proportion of 1:2.4. Hydrolysis of the fully methylated galactomannan yielded 2,3,4,6-tetra-*O*-methyl-D-galactose, 2,3,6-tri-*O*-methyl-D-mannose, and 2,3-di-*O*-methyl-D-mannose in the molar ratio of 1:1.4:0.95. Partial hydrolysis of the galactomannan afforded 4-*O*-β-D-mannopyranosyl-D-mannose, 6-*O*-α-D-galactopyranosyl-D-mannose, and two trisaccharides. Based on these results a structural formula for the galactomannan has been proposed, additional evidence for which was adduced from periodate-oxidation studies.

In 1956 Subrahmanyan *et al.* (1) reported the isolation of a polysaccharide from the kernel by extraction with 10% sodium hydroxide which gave, on hydrolysis, D-galactose and D-mannose in the ratio of 1:2.9 approximately. However, no detailed investigations seem to have been carried out on its structure.

This paper reports the structural studies on the polysaccharide obtained by precipitating the aqueous extract of the soft kernel with ethanol. Hydrolysis of the polysaccharide, $[\alpha]_D^{30}$ +8.5° (in 4% sodium hydroxide solution) gave D-galactose and D-mannose in the molar proportion of 1:2.4 as estimated by the periodate method (2).

The galactomannan was methylated first by repeated treatment with methyl sulphate and alkali (3) and then by Purdie's method (4). The resulting methylated galactomannan, which showed no hydroxyl absorption band in the I.R. spectrum, was a glassy solid —OCH_3 43.25%, $[\alpha]_D^{29}$ +29° (in chloroform). After methanolysis of the methylated polysaccharide and hydrolysis of the resulting mixture of methyl glycosides the mixture of methyl sugars, so obtained, on paper chromatographic examination using solvents B and D showed the presence of three methylated sugars together with a trace amount of another. The mixture of methylated sugars was separated on a cellulose column (5) using butanone–water azeotrope (6) as eluent.

Identification of the various methylated sugars obtained by column chromatography showed them to be 2,3,4,6-tetra-*O*-methyl-D-galactose (1 mole), 2,3,6-tri-*O*-methyl-D-mannose (1.35 moles), 2,3,6-tri-*O*-methyl-D-galactose (0.035 mole), and 2,3-di-*O*-methyl-D-mannose (1.03 moles).

The relative proportion of 2,3,4,6-tetra-*O*-methyl-D-galactose, 2,3,6-tri-*O*-methyl-D-mannose, and 2,3-di-*O*-methyl-D-mannose was estimated by hypoiodite titration (7) after separation on paper using solvent B and was found to be 1:1.4:0.95. This ratio is in good agreement with that obtained by weighing the different fractions obtained during column chromatographic examination of the mixture.

The tetra-*O*-methyl sugar fraction, $[\alpha]_D^{30}$ +109° (in water) obtained as a sirup, gave on demethylation (8) D-galactose only along with some partially demethylated sugars and was characterized to be 2,3,4,6-tetra-*O*-methyl-D-galactose through its anilide (9).

The tri-*O*-methyl-D-mannose $[\alpha]_D^{30}$ −9° (in water) was characterized as 2,3,6-tri-*O*-methyl-D-mannose through the crystalline 2,3,6-tri-*O*-methyl-D-mannose, 1,4-di-*p*-nitrobenzoate (10).

The fraction containing the trace quantity of the tri-*O*-methyl sugar gave D-galactose and D-mannose on demethylation and on paper chromatography using solvent B gave two spots corresponding to those of 2,3,6-tri-*O*-methyl-D-galactose and 2,3,6-tri-*O*-methyl-D-mannose the relative proportions of which were calculated from the observed specific rotation.

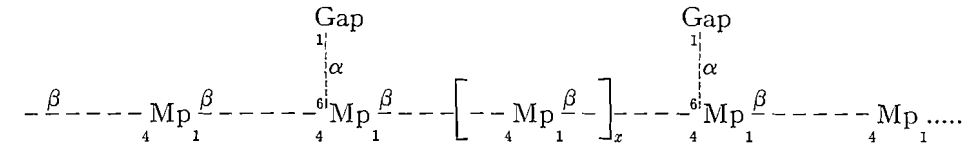
The dimethyl sugar fraction having $[\alpha]_D^{30}$ $-16.4°$ (in water) was chromatographically pure and was characterized to be 2,3-di-*O*-methyl-D-mannose by conversion to 2,3-di-*O*-methyl-D-mannonic acid phenyl hydrazide (11).

From the above results it is possible to assign a structure to the galactomannan. Demonstration of the existence of 2,3,4,6-tetra-*O*-methyl-D-galactose alone in the tetramethyl fraction of the hydrolyzate of the methylated polysaccharide shows that D-galactose in the pyranose form constitutes the non-reducing ends of the molecule.

That the backbone of the molecule is made up of $1 \rightarrow 4$-linked mannopyranose residues is proved by the characterization of 2,3,6-tri-*O*-methyl-D-mannose in the hydrolyzate of the methylated galactomannan.

The fact that 2,3-di-*O*-methyl-D-mannose is present in the hydrolyzate indicates that the polysaccharide is branched and that at branch points the mannose residues are linked through C_1, C_4, and C_6.

The trace amount of the tri-*O*-methyl-D-galactose might have originated from partial demethylation of the tetra-*O*-methyl-D-galactose fraction during methanolysis and hydrolysis of the methylated galactomannan (12) and is considered to have no structural significance.



Further support for the proposed structure for the galactomannan was obtained from the periodate oxidation of the galactomannan. It was found that one molar proportion of formic acid was liberated for every 3.7 hexose units in 25 hours and that 1.30 moles of periodate were consumed per hexose unit in 30 hours. If one galactopyranose residue is present as non-reducing terminal group for every 2.4 units of mannopyranose residues, on the average, in the chain, then theoretically the consumption of periodate works out to be 1.30 moles per hexose residue. The results of periodate uptake are thus in good agreement with the theoretically expected results.

When the periodate-oxidized polysaccharide was reduced with sodium borohydride and hydrolyzed, glycerol and erythritol were obtained from the non-reducing units and $1 \rightarrow 4$-linked mannose residues respectively in the molar proportion of 1:2.45. The linkages at the branch points through C_1, C_4, and C_6 as mentioned above were confirmed by the absence of mannose in this hydrolyzate. The length of the repeating unit (3.45) calculated from the amounts of glycerol and erythritol obtained is in good agreement with those obtained from methylation and periodate-oxidation studies.

In order to establish the stereochemistry of the linkages between the sugar units the galactomannan was subjected to graded hydrolysis. After separation by column and paper chromatography, two disaccharides, viz. 4-*O*-β-D-mannopyranosyl-D-mannose and 6-*O*-α-D-galactopyranosyl-D-mannose, and two trisaccharides, *O*-β-D-mannopyranosyl $(1 \rightarrow 4)$-*O*-β-D-mannopyranosyl$(1 \rightarrow 4)$-*O*-β-D-mannose and another triose having one galactose residue and two mannose residues with mannose residue at the reducing end, were isolated and, in pure form, studied.

The presence of mannobiose and mannotriose in comparatively larger amounts clearly shows a $1 \rightarrow 4$ β-linked mannose chain in the molecule. The existence of α-linked galactopyranose residues as non-reducing terminal units is confirmed by the isolation and characterization of 6-*O*-α-D-galactopyranosyl-D-mannose.

Based on the above results it can be concluded that the galactomannan has a structure of the following type:

where x has the value of 1 in one segment and 2 in the next, Gap = galactopyranose residue, Mp = mannopyranose residue.

The low specific rotation (+8.5° in 4% sodium hydroxide) of the galactomannan indicates the presence of both α and β linkages in the molecule.

During purification of the galactomannan through copper complex (13*a*, 13*b*) it was observed that the proportion of galactose gradually decreased. The ratio of galactose to mannose was found to change from 1:2.4 to 1:3.4 during five treatments with Fehling's solution. It was also noticed that only galactose residues were released when the galactomannan was hydrolyzed under very mild condition employing 0.02 *N* oxalic acid. The resulting galactomannan after 4 hours had galactose-to-mannose ratio of 1:3.7. Hence the increase in the mannose content during purification through copper complex may be attributed to the fact that some of the α-linked galactose residues, which are more labile, were removed during the acid treatment employed for destruction of the copper complex.

The galactomannan was acetylated in the usual way (14, 15). The triacetate, which showed an increased mannose content, was fractionally precipitated from a solution of the substance in a solvent containing *s*-tetrachloroethane and 95% ethanol in the ratio of 9:1, by gradual addition of methanol. The different fractions after deacetylation and hydrolysis were found to have galactose-to-mannose ratios between 1:2.4 to 1:3.2. It is significant to note that none of the fractions had the ratio of galactose to mannose more than 1:2.4. One of these fractions (fraction 5) having galactose-to-mannose ratio 1:3.2 was methylated directly (14) first by treating a solution of the triacetate in dry tetrahydrofuran with solid sodium hydroxide and methyl sulphate and then by Purdie's method. The resulting fully methylated polysaccharide, $-OCH_3$, 43.05%, $[\alpha]_D^{25}$ +24° (in chloroform) was subjected to methanolysis and hydrolysis. The mixture of the methyl sugars obtained, on paper chromatography, showed the presence of 2,3,4,6-tetra-*O*-methyl-D-galactose, 2,3,6-tri-*O*-methyl-D-mannose, and 2,3-di-*O*-methyl-D-mannose in the ratio of 1:2.11:1.08 as estimated by alkaline hypoiodite method. The mixture (ca. 200 mg) was separated on Whatman No. 3MM papers and the individual sugars were identified as above.

The isolation and characterization of the same methylated sugars from this fraction show that the original material was essentially homogeneous and that during acetylation some of the labile α-linked galactose units were eliminated.

The molecular weight of the methylated galactomannan as determined by light-scattering method was found to be 1.39×10^5.

The galactomannan obtained from palm kernel is similar in the essential structure to those obtained from fenugreek seed (16), carob seed (11, 17), and guar seed (18, 19, 20) but differs from that obtained from the kernel of coconut (*Cocos nucifera*) (paper in press).

EXPERIMENTAL

All specific rotations are equilibrium values. Unless otherwise stated, all evaporations were carried out *in vacuo* at 30°–40° C. The solvent mixtures (v/v) used for partition chromatography of sugars and their derivatives were:

(A) ethyl acetate:pyridine:water (8:2:1);
(B) methyl ethyl ketone – water azeotrope;
(C) butanol:acetic acid:water (4:1:5) upper layer;
(D) butanol:ethanol:water (40:11:19);
(E) butanol:ethanol:water (4:1:5) upper layer;
(F) ethyl acetate:acetic acid:water (9:2:2).

Whatman No. 1 filter papers were used for paper partition chromatography. The spray reagents used were:

(*a*) aniline hydrogen oxalate (saturated aqueous solution);
(*b*) *p*-anisidine hydrochloride (3% solution in butanol);
(*c*) ammoniacal silver nitrate solution.

Isolation and Purification of the Galactomannan

The kernel obtained from the market was peeled and the soft fleshy material was macerated in a high-speed "Kenmix 55" blender for 2 minutes in the presence of ethanol. The resulting slurry was kept overnight under ethanol and then was filtered through cloth. The residue was freed from ethanol by squeezing and then dried in air. The material (50 g) so obtained was allowed to swell with water (1500 ml) for some time and heated, while being stirred, on a boiling-water bath for 5 hours. After being kept overnight in a refrigerator the slurry was diluted with water (1500 ml) and the coarse suspended material was removed by filtration through cloth. The filtrate was passed through Cepa supercentrifuge at 25,000–30,000 r.p.m. for further clarification. The clear liquid was slowly added, with stirring, to acidified (pH 4–5) 95% ethanol when a white fibrous precipitate appeared. This was separated by centrifuge and triturated five times with absolute ethanol and finally with ether. The product was dried in air and then *in vacuo*. It was a white amorphous powder, yield: 12 g, moisture 10.9%, ash 0.36%, $[\alpha]_D^{30}$ +8.5° (in 4% aqueous sodium hydroxide solution, *c*, 0.5), intrinsic viscosity 1.25 dl/g (in 4% sodium hydroxide solution), pentosan (21) 0.5%, methoxyl group (22) 0.3%, nitrogen 0.7%, uronic acid (23) negligible. D-Galactose and D-mannose were detected by paper chromatography in the hydrolyzate of the polysaccharide using solvent A. A small portion of the hydrolyzate was separated quantitatively by paper chromatography using solvent A. The zones corresponding to each sugar were eluted in the usual way and estimated by the periodate method (2). D-Galactose and D-mannose were found in the ratio of 1:2.4.

The galactomannan was purified by complexing (13*a*, 13*b*) with Fehling's solution. The galactomannan (10 g) was dissolved in 4% sodium hydroxide solution (1 l.) in an atmosphere of nitrogen, and freshly prepared Fehling's solution (500 ml) was added to it while it was stirred in a cold bath (10° C). The flocculent blue precipitate so obtained was filtered through a piece of fine nylon cloth and washed with water till the filtrate was colorless. The precipitate was suspended in water (500 ml) in a cold bath (10° C) and 2 *N* HCl was added dropwise with stirring till the mixture was just acidic. The stirring was continued for 2 hours more when a homogeneous dispersion was obtained. This was then added slowly, with stirring, to ethanol (800 ml) when a white fibrous

precipitate separated out. This was centrifuged, washed with a mixture of 80% ethanol: HCl (100:1), and triturated with ethanol till free from acid and finally with ether. Yield 8.75 g, $[\alpha]_D^{30}$ +9° (in 4% sodium hydroxide solution, *c*, 0.5). On hydrolysis of the purified polysaccharide D-galactose and D-mannose were obtained in the ratio of 1:2.6.

Each repetition of the process led to a product showing higher mannose content. After five precipitations the ratio of galactose to mannose was found to be 1:3.4.

Mild Hydrolysis of the Galactomannan with Oxalic Acid

The galactomannan (1 g) was dispersed in water (50 ml) to which 0.04 *N* oxalic acid (50 ml) had been added and was heated on a water bath (90°–95° C). At intervals of 1 hour aliquots (25 ml) were withdrawn and precipitated with ethanol (30 ml). The supernatant liquids were concentrated to sirups. Each of these on paper chromatographic examination using solvent A indicated the presence of D-galactose only. The precipitated polysaccharide from the fourth stage was washed with alcohol and then hydrolyzed with 2 *N* sulphuric acid. The hydrolyzate was treated in the usual manner and the resulting sirup had D-galactose and D-mannose in the ratio of 1:3.7.

Hydrolysis and Identification of D-*Galactose and* D-*Mannose*

The galactomannan (0.5 g) was kept with 72% sulphuric acid (24) at room temperature overnight and diluted with water to give normal acid solution. The solution was heated for 8 hours on a boiling-water bath when the hydrolysis, followed iodometrically (25), was complete. The solution obtained after neutralization with barium carbonate and filtration, was deionized by passage through Amberlite I.R. 120(H)* and Amberlite I.R. 45(OH)* and was concentrated to a sirup. A portion of this sirup (200 mg) was separated on a Whatman No. 3MM filter paper using solvent A. The strips corresponding to D-galactose and D-mannose were each eluted with water (20 ml) and evaporated to give sirups, D-galactose, $[\alpha]_D^{30}$ +79° (in water, *c*, 1) and D-mannose, $[\alpha]_D^{30}$ +14° (in water, *c*, 1). Each of these components were refluxed with *p*-nitroaniline in methanol acidified with hydrochloride acid (26). The galactose component gave *p*-nitro-*N*-phenyl-D-galactosyl amine, m.p. and mixed m.p. 217°–218° C, $[\alpha]_D^{30}$ −245° (in dry pyridine, *c*, 0.5), lit. (26) −248°. D-Mannose component gave *p*-nitro-*N*-phenyl-D-mannosyl amine, m.p. and mixed m.p. 217°–218°, $[\alpha]_D^{30}$ −325° (in dry pyridine, *c*, 0.5) lit. (26) −325°.

Methylation of the Galactomannan

The galactomannan (10 g) was methylated by treatment first with methyl sulphate and alkali and then with methyl iodide and silver oxide according to the method of Falconer and Adams (27*a*, 27*b*) to yield a methylated derivative (3.22 g) showing no hydroxyl absorption band in the infrared spectrum. It had intrinsic viscosity 0.267 dl/g in chloroform and $[\alpha]_D^{29}$ +28.7° (in chloroform, *c*, 1). (Anal. Calc. for $C_9H_{16}O_5$, —OCH_3 44.7; found —OCH_3 43.25%.)

Molecular-Weight Determination of the Methylated Galactomannan

All measurements of the intensity of scattered light for molecular-weight determination of the methylated galactomannan were carried out with a Brice Phoenix light-scattering photometer (Model OM 1000A) using semioctagonal cells. Intensities of scattered light at four angles (viz. 0°, 45°, 90°, and 135°) over a concentration range of 0.5 to 4.5×10^{-3} g/ml were measured and working standard method was used to calculate turbidity (τ). The solutions used for the measurement were taken from a stock solution of known

**A product of Rohm & Hass Company, Pennsylvania, U.S.A.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

concentration in redistilled chloroform and diluted to a definite volume in a calibrated volumetric flask with the same solvent. Special precaution was taken to avoid dust and suspended particles by filtering the stock solution and solvent through sintered glass (G 4) and (G 5) respectively. The concentration of each solution was determined by dry-weight method. The refractive indices of the solutions were determined with Brice Phoenix differential refractometer at the same wave length and temperature. The turbidities and dissymmetries obtained by the above procedure were reproducible indicating absence of anomalous aggregation. The molecular weight of the methylated galactomannan was found to be 1.39×10^5 calculated by dissymmetry method (28*a*) assuming particle-scattering factor (P 90°) (28*b*, 28*c*) for random coil.

Methanolysis and Hydrolysis of the Methylated Galactomannan

The methylated galactomannan (1 g) was refluxed with 4% methanolic hydrogen chloride (100 ml) till the rotation reached a constant value (15 hours). The solution was evaporated to a sirup and the resulting mixture of methyl glycosides was hydrolyzed with N hydrochloric acid (75 ml) till the rotation reached constant value (14 hours). The hydrolyzate was neutralized (silver carbonate), filtered, and the resulting solution deionized by passage through Amberlite I.R. 120(H) and Amberlite I.R. 45(OH). The mixture of methylated sugars was evaporated to a sirup (0.85 g).

A preliminary analysis was made by paper partition chromatography using solvents B and D and spray reagent *a*. The following spots were identified.

Spot No.	R_f Solv. B	R_G* Solv. D	Sugars
1	0.69	0.91	2,3,4,6-Tetra-*O*-methyl-D-galactose
2	0.51	0.82	2,3,6-Tri-*O*-methyl-D-mannose
3	0.47	—	2,3,6-Tri-*O*-methyl-D-galactose (trace)
4	0.24	0.61	2,3-Di-*O*-methyl-D-mannose

*R_G values are with respect to *n*-tetra-*O*-methyl-D-glucose.

Separation of the Mixture of Methylated Sugars by Column Chromatography

The mixture of methylated sugars (825 mg) was separated on a cellulose column (5) (60×2.5 cm) using solvent B (6) on an automatic fraction collector. The total eluent was then divided into the following five fractions guided by the difference in the refractive indices of the solvent and solution in each test tube using a Brice Phoenix differential refractometer and also by examination by paper chromatography.

Fraction	Tube No.	Sugars	Molar ratio
A	21–25	2,3,4,6-Tetra-*O*-methyl-D-galactose	1
B	26	2,3,4,6-Tetra-*O*-methyl-D-galactose and 2,3,6-tri-*O*-methyl-D-mannose	
C	27–29	2,3,6-Tri-*O*-methyl-D-mannose	1.25
D	30–31	2,3,6-Tri-*O*-methyl-D-mannose and 2,3,6-tri-*O*-methyl-D-galactose	
E	35–44	2,3-Di-*O*-methyl-D-mannose	1.03

Identification of 2,3,4,6-Tetra-O-methyl-D-galactose

Fraction A on evaporation gave a sirup (245.7 mg) having $[\alpha]_D^{30}$ +109° (in water, *c*, 1) lit. (29) +109.5°. The sirup (5 mg) was demethylated (8) by heating for 5 minutes on a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

boiling-water bath with 48% hydrobromic acid (2 ml) in a sealed tube in an atmosphere of nitrogen. The resulting solution after usual treatment gave a sirup, which on paper chromatographic analysis using solvent A, indicated the presence of D-galactose only along with some partially demethylated sugars. The identity of 2,3,4,6-tetra-*O*-methyl sugar was confirmed by preparing the *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-galactosyl amine in the usual way, m.p. and mixed m.p. 187° C, lit. 188°–190° C (8), 186°–188° (30); $[\alpha]_D^{30}$ +38° (in acetone), lit. +39° (8), +40.7° (31).

Examination of Fraction B

This fraction on evaporation yielded a sirup (53.3 mg) having $[\alpha]_D^{30}$ +5° (in water). Demethylation of a small portion of this fraction gave D-galactose and D-mannose along with partially demethylated sugars. Paper partition chromatography using solvent D with authentic samples indicated that the mixture contained 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,3,6-tri-*O*-methyl-D-mannose by comparison with authentic samples. Specific rotation value showed that the tetramethyl galactose and the trimethyl mannose were present in the proportion of 1:7 approximately.

Identification of 2,3,6-Tri-O-methyl-D-mannose

The fraction C on evaporation gave a sirup (277 mg). This was chromatographically homogeneous and had $[\alpha]_D^{30}$ −9° (in water, *c*, 1) lit. −13° (9), −10° (11). It gave D-mannose along with some partially demethylated sugars on demethylation of a portion of it. The 2,3,6-tri-*O*-methyl-D-mannose was characterized through its crystalline 2,3,6-tri-*O*-methyl-D-mannose, 1,4-di-*p*-nitrobenzoate (10), m.p. and mixed m.p. 189°–190° C, lit. (9) 190°–191° C; $[\alpha]_D^{30}$ +32° (in chloroform), lit. (10) +33°.

Examination of Fraction D

This fraction yielded a sirup (33 mg) having $[\alpha]_D^{30}$ +13.5° (in water). Demethylation of a part of it yielded D-galactose and D-mannose along with other partially demethylated sugars. Examination of this sirup using solvent D with authentic samples indicated that it contained a mixture of 2,3,6-tri-*O*-methyl-D-galactose and 2,3,6-tri-*O*-methyl-D-mannose. Optical rotation value indicated that they were present in the ratio of 1:3 approximately.

Identification of 2,3-Di-O-methyl-D-mannose

Fraction E on evaporation gave a sirup (212.9 mg) having $[\alpha]_D^{30}$ −16° (in water) lit. (32) −15.8°. This fraction was chromatographically pure and gave D-mannose only along with partially demethylated sugars on demethylation of a part of it. The sirup (25 mg) was oxidized with bromine water at room temperature (10) for 68 hours. The bromine was removed by aeration and the solution after usual treatment yielded a thick sirup containing the lactone $[\alpha]_D^{29}$ +58° (in water, after 24 hours), which could not be induced to crystallization. This was converted to the phenylhydrazide by heating it with phenylhydrazine in ethanol on a boiling-water bath. The 2,3-di-*O*-methyl-D-mannonic acid phenylhydrazide was crystallized from methanol–ether (11), m.p. 158° C, lit. 156° (18), 168° C (10); $[\alpha]_D^{29}$ −24° (in water), lit. −24.2° (18), −25° (10).

Estimation of the Methyl Sugars

A small quantity of the mixture of methylated sugars (5 mg) was separated by paper chromatography using solvent B. Each sugar was eluted in the usual way and estimated by alkaline hypoiodite (7) method. The molar ratio of the different sugars found

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

were as follows: 2,3,4,6-tetra-*O*-methyl-D-galactose:2,3,6-tri-*O*-methyl-D-mannose:2,3-di-*O*-methyl-D-mannose as 1:1.4:0.95. The 2,3,6-tri-*O*-methyl-D-galactose was obtained in negligible amount.

Periodate Oxidation of the Galactomannan

The galactomannan (84.2 mg) was dispersed in water (50 ml) and oxidized by shaking with 0.1 *M* sodium metaperiodate (50 ml) in the dark at 15° C. The liberated formic acid and the amount of periodate consumed during the reaction were estimated in the usual way (33) at regular intervals of time. The liberation of formic acid became constant in 25 hours, 3.7 hexose residues liberating 1 mole of formic acid. The periodate uptake became constant after 30 hours corresponding to 1.30 moles of the oxidant per hexose residue.

Reduction of the Periodate-oxidized Galactomannan

The periodate-oxidized product (140 mg) was neutralized with barium hydroxide and filtered, and to the clear solution sodium borohydride (200 mg) was added. The reduction was allowed to proceed for 4 hours at room temperature. The resulting solution after usual treatment (34) yielded a sirup which, on paper chromatographic examination using solvent E and spray reagent *c*, indicated the presence of erythritol and glycerol.

The above sirup was separated on Whatman No. 3MM filter paper using solvent E. The zones corresponding to erythritol and glycerol were eluted and evaporated to sirups. They were characterized through their crystalline tetra- and tri-tosyl derivatives respectively. The tetratosyl erythritol had m.p. and mixed m.p. 163°–165° C, lit. (35) 165°–166°. The tritosyl glycerol had m.p. and mixed m.p. 102°–103° C, lit. (35) 103°–104° C.

Quantitative Estimation of the Polyhydric Alcohols

A small portion of the mixture was separated quantitatively by paper chromatography using solvent E, and the polyhydric alcohols were estimated by the method of Lambert and Neish (36). The ratio of glycerol to erythritol was found to be 1:2.45.

Acetylation of the Galactomannan

The galactomannan (8 g) was dispersed by stirring for 5 hours in formamide (100 ml). To this dispersion pyridine (150 ml) was added followed by the dropwise addition, with stirring, of acetic anhydride (120 ml) for a period of 4 hours at 20°. The stirring was continued for 3 days at room temperature and the galactomannan acetate was precipitated by pouring the dark viscous material into ice-cold water. The precipitate was washed first with water, then with methanol, and finally with ether. Completely dried material was once again acetylated by dissolving it in pyridine (150 ml) and adding acetic anhydride (120 ml) in a dropwise manner and then proceeding as above. Yield 6.8 g, $[\alpha]_D^{30}$ +11° (in chloroform, *c*, 1), intrinsic viscosity 5.65 dl/g (in chloroform), acetyl content (37) 43.07%. On deacetylation (38) and hydrolysis D-galactose and D-mannose were obtained in the ratio of 1:2.6.

Fractionation of the Acetylated Galactomannan

The acetylated galactomannan was fractionated according to the method of Hamilton and Kircher (14). The material (5.95 g) was dissolved in a solvent containing *s*-tetrachloroethane:95% ethanol in the ratio of 9:1 and fractionally precipitated by the gradual addition of methanol. Seven fractions could be collected in this way. The last two fractions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

were obtained on concentration of the solution after the fifth precipitation and after addition of petroleum ether. The results of studies on each of these fractions are shown in the following table.

Sample		Wt. (g)	$[\alpha]_D^{30°}$ in $CHCl_3$	I.V. (dl/g) in $CHCl_3$	Acetyl content (%)	Gal:Man
Original galactomannan acetate		5.95	+11°	5.65	43.07	1:2.6
Fraction	1	0.345	+11°	3.4	39.1	1:2.4
"	2	0.136	+11°	4.7	39.7	1:2.5
"	3	0.988	+11°	7.2	42.2	1:2.5
"	4	1.460	+11°	7.8	43.5	1:2.6
"	5	2.240	+12°	6.3	44.2	1:3.2
"	6	0.233	+11.5°	2.1	42.3	1:3
"	7	0.081	+11.5°	1.0	42.8	1:3

Methylation of the Acetylated Galactomannan (Fraction 5)

The fraction 5 (2 g) of the galactomannan triacetate was dissolved in dry tetrahydrofuran (40 ml) and methylated directly with methyl sulphate (35 ml) and solid sodium hydroxide (30 g) according to the method of Hamilton and Kircher (14). The product was methylated twice by Purdie's method. Yield 0.85 g, $-OCH_3$, 43.05%, $[\alpha]_D^{20}$ +24° (in chloroform).

Methanolysis and Hydrolysis of the Methylated Galactomannan

The methylated galactomannan was methanolyzed and the mixture of methyl glycosides was hydrolyzed as described earlier. On paper partition chromatography using solvent B the mixture of methyl sugars gave only three spots corresponding to 2,3,4,6-tetra-*O*-methyl-D-galactose, 2,3,6-tri-*O*-methyl-D-mannose, and 2,3-di-*O*-methyl-D-mannose. They were isolated and characterized as described earlier.

A portion of this mixture was quantitatively separated by paper chromatography using solvent B and each component estimated by the alkaline hypoiodite method (7). The 2,3,4,6-tetra-*O*-methyl-D-galactose, 2,3,6-tri-*O*-methyl-D-mannose, and 2,3-di-*O*-methyl-D-mannose were found in the molar ratio of 1:2.11:1.08.

Graded Hydrolysis of the Galactomannan

The galactomannan (15 mg) was dispersed in water (750 ml), 0.4 *N* sulphuric acid (750 ml) was added and the mixture was heated on a boiling-water bath for 2 hours. The solution was filtered and the residue was again hydrolyzed with 0.2 *N* sulphuric acid for 2 hours. The two solutions were combined and neutralized, filtered, and passed through ion exchange resins I.R. 120(H) and I.R. 45(OH). The resulting mixture of sugars was concentrated to 50 ml. Paper partition chromatography using solvent F indicated the presence of D-galactose, D-mannose, two disaccharides, and two trisaccharides.

Spot	R_{Gal} (in solvent F)	Sugars
1	0.62	4-*O*-β-D-Mannopyranosyl-D-mannose
2	0.54	6-*O*-α-D-Galactopyranosyl-D-mannose
3	0.34	A triose
4	0.30	*O*-β-D-Mannopyranosyl-(1 → 4) *O*-β-D-Mannopyranosyl-(1 → 4) *O*-β-D-Mannose

For personal use only.

Separation of the Oligosaccharides by Column Chromatography

The sugar mixture was allowed to soak into the top of a cellulose–charcoal (60–80 mesh) (39) column (35×4.2 cm). The column was first eluted with water and then subjected to stepwise elution (40) using 2.5%, 5%, 7.5%, and 10% aqueous ethanolic solutions successively. Eight liters of each fraction was collected and each was concentrated to small volume. The monosaccharides were eluted with water and the di- and oligo-saccharides with aqueous ethanol. All the alcoholic eluates were found to contain mixtures.

The mixture was separated on Whatman No. 3MM filter papers using solvent F into chromatographically pure fractions and the corresponding di- and tri-saccharide fractions were combined and evaporated to sirups. Thus two disaccharides and two trisaccharides were collected.

*Identification of 4-O-β-*D*-Mannopyranosyl-*D*-mannose*

The sirup (243.7 mg) having $[\alpha]_D^{30}$ −8° → −7° (in water), lit. $[\alpha]_D^{23}$ −7.7 → 2.2 (19), $[\alpha]_D^{25}$ −8.13° → −7.4° (14), −4.4° (41), gave on hydrolysis D-mannose only. The molecular weight determined by the alkaline hypoiodite method was found to be 329 (calc. for $C_{12}H_{22}O_{11}$, 342). The oxidation of mannobiose (65 mg) with 0.3 *M* sodium metaperiodate (10 ml) made up to 50 ml with water was followed by determining the formic acid liberated and uptake of periodate at various intervals of time. The corresponding values are 1.35 moles (10 hours), 2.45 moles (20 hours), and 2.90 moles (30 hours) and 2.40 moles (10 hours), 3.90 moles (20 hours), and 4.91 moles (35 hours). But when the same oxidation was carried out in acetate buffer (pH 3.7) the disaccharide (50 mg) consumed 4.06 moles of the oxidant per mole of the disaccharide in 3 hours (constant value). The periodate-oxidized product was freed from the oxidant in the usual way and reduced with sodium borohydride. After hydrolysis and usual treatments the mixture was found to contain glycerol and erythritol on paper chromatographic examination using spray reagent *c*.

A small portion of the disaccharide (30 mg) was converted to the phenylhydrazone in the usual way to give yellow crystals having m.p. 198°–199° C, lit. (42) 200°–201° C.

*Identification of 6-O-α-*D*-Galactopyranosyl-*D*-mannose*

The fraction 2 on evaporation gave a sirup (114.7 mg) having $[\alpha]_D^{30}$ +124° (in water), lit. (41) +123°. On hydrolysis it afforded D-galactose and D-mannose in equal proportion and the hydrolyzed sirup had $[\alpha]_D^{30}$ +49° (in water, *c*, 1). Hydrolysis of a portion after reduction with sodium borohydride indicated the presence of only D-galactose. The disaccharide (36 mg) was oxidized with sodium metaperiodate and the liberation of formic acid and consumption of periodate were recorded at various intervals of time. The corresponding values per mole of the disaccharide are, 1.95 moles (10 hours), 4.0 moles (20 hours), and 4.93 moles (30 hours) and 3.05 moles (10 hours), 4.75 moles (20 hours), and 5.95 moles (30 hours) respectively. On oxidation in the presence of acetate buffer (pH 3.7), however, the disaccharide (25 mg) consumed 5.14 moles of the oxidant per mole of the disaccharide in 2.5 hours (constant value). The oxidized product was reduced and hydrolyzed as before and the mixture was found to contain only glycerol. The 6-*O*-α-D-galactopyranosyl-D-mannose was characterized by preparing its phenylhydrazone, m.p. 168°–169° C, lit. (41) 170° C.

Examination of Fraction 3

This fraction on evaporation gave a sirup (48.3 mg) having $[\alpha]_D^{30}$ +33° (in water, *c*, 1).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

On hydrolysis it afforded D-galactose and D-mannose in the proportion of 1:2. On reduction and hydrolysis it indicated the presence of D-galactose and D-mannose on a paper chromatogram using spray reagent *a* indicating the presence of mannose residue at the reducing end. A portion (25 mg) was oxidized with sodium metaperiodate in acetate buffer (pH 3.7) and was found to consume 6.12 moles of the oxidant per mole of the sugar. The sugar thus seems to be a trisaccharide containing 1 mole of D-galactose residue and 2 moles of D-mannose residues.

Identification of the Mannotriose

This fraction yielded a sirup (82.6 mg) having $[\alpha]_D^{30}$ −15° (in water, *c*, 1), lit. −16° and −22° (41), −15° (19), −24.7° → −23.3 (43), −15.7° → −20.2° (42). On hydrolysis it afforded only D-mannose. The molecular weight of this sugar was determined by the alkaline hypoiodite method and was found to be 488 (calc. for $C_{18}H_{32}O_{16}$, 504). A portion of this fraction (30 mg) was oxidized with sodium metaperiodate in acetate buffer (pH 3.7). One mole of the trisaccharide was found to consume 5.08 moles of the periodate.

THE MERCURY-PHOTOSENSITIZED OXIDATIONS OF HYDROCARBONS

PART I. INTERACTION OF MERCURY WITH PRODUCTS FORMED IN THE REACTING MIXTURE[1]

K. M. BELL[2] AND C. A. MCDOWELL

ABSTRACT

The interaction of mercury with two hydrocarbon oxidation systems, namely those of oxygen and cyclohexene, and oxygen and isobutane, has been studied at 30° C in a conventional static photochemical apparatus. The removal of mercury from the gas phase in the mercury-photosensitized oxidation of isobutane is attributed to a reaction with ozone,

$$Hg + O_3 \rightarrow HgO + O_2,$$

whilst interaction with an intermediate of the oxidation chain is responsible for mercury removal in the cyclohexane oxidation reaction:

$$Hg + RO_2 \rightarrow HgO + RO.$$

INTRODUCTION

Several workers have observed the interaction of mercury with oxidation chain systems. Marshall (1), while studying the mercury-photosensitized hydrogen and oxygen reaction, found that HgO was deposited simultaneously on the vessel walls with the formation of water and hydrogen peroxide. Later Small and Ubbelohde (2) found the yield of peroxides in the thermal oxidation of *n*-hexane to be greatly reduced by the addition of small amounts of mercury vapor. Mercuric oxide was observed by Gray (3) to be deposited on the vessel walls during a study of the mercury-photosensitized oxidation of ethane, in a flow system at 25° C. Studying the same reaction in a similar manner Watson and Darwent (4) found that mercuric oxide was formed at 25° C, but that none was detected when the temperature was raised to between 40 and 45° C. Callear, Patrick, and Robb (5) have recently reported the removal of mercury as mercuric oxide from $Hg–O_2$ mixtures on illumination with 2537-Å radiation at 25° C.

In any mercury-photosensitized hydrocarbon oxidation system there are clearly two main possibilities for interaction of mercury with the products formed in the reacting mixture. It may react (i) with the products from the excited oxygen molecule reactions, or (ii) with the intermediates or final products of the hydrocarbon oxidation chain.

Two systems, isobutane–oxygen–mercury and cyclohexene–oxygen–mercury have been studied and found to illustrate these two types of interaction.

EXPERIMENTAL

A conventional static photochemical apparatus was used. A Cintel QVA 39 phototube, with a quartz envelope, was used in conjunction with a potentiometer circuit to give relative intensity variations in the parallel beam of radiation, transmitted through the reaction mixture. The reactions were carried out in a cylindrical quartz cell of 2-cm light path and 4-cm diameter. The light source was a water- and air-cooled Hanovia low-pressure mercury arc lamp, emitting 85–90% of its radiation at 2537 Å as determined by filters and the known spectral response characteristics of the phototube. Phillips

Petroleum Company cyclohexene of 99.98% purity was freed from peroxide by refluxing with copper stearate and subsequent distillation under nitrogen. The same firm also supplied Research Grade isobutane. Oxygen was piped from a cylinder to a storage bulb through a spiral cooled to −78° C.

Mercury vapor was introduced into a selected hydrocarbon–oxygen mixture by alternately raising and lowering the level of mercury in a premixing vessel several times. The reactants were passed into the evacuated cell through two U tubes, packed with small glass helices, surrounded by ice. The procedure of mixing and admittance to the cell was standardized, and reproducible light absorptions could be obtained. Results using greater than 24 mm Hg pressure of cyclohexene were obtained by dispensing with the traps cooled to 0° C.

PHOTOMETRY

The intensities of light transmitted through the reaction cell were related to the resistance needed to balance a potentiometer circuit, and calibrated by comparison with the potassium ferrioxalate actinometer of Hatchard and Parker (6).

If

I_t = intensity of transmitted radiation
I_o = intensity of incident radiation
I_a = intensity of radiation absorbed by reactants in the cell,

then

$$I_t/I_o = \exp\{-\epsilon[\mathrm{Hg}]l\}$$

and by differentiation

$$-d[\mathrm{Hg}]/dt = \frac{1}{\epsilon l}\frac{d\{\log (I_t/I_o)\}}{dt},$$

where ϵ = extinction coefficient and l = light path. If the quantum yield of mercury removal is Φ, then we have

$$\Phi = -\frac{\Delta[\overline{\mathrm{Hg}}]}{\Delta t}\cdot\frac{1}{I_a}$$

that is

$$\Phi = \frac{1}{\epsilon l}\frac{\Delta \log (I_t/I_o)}{\Delta t}\cdot\frac{1}{I_a}.$$

I_t and I_o were measured at the beginning of each experiment. As the concentration of mercury vapor [Hg] was known, it was possible to calculate the value of the extinction coefficient ϵ. Since Δt and I_a were known for each kinetic run, it was possible to calculate Φ. It was found that Φ was a useful parameter to give a measure of the interaction of mercury with the reactive species in the system, having a constant value (±5%), while more than 50% of the mercury vapor reacted. The measurable range of values for using the full intensity of the lamp ($\sim 3\times10^{14}$ quanta/sec) was from 1×10^{-4} to 9×10^{-3}.

RESULTS

The results of typical experiments are presented in Fig. 1. In the series of experiments using C_4H_{10}–O_2–Hg, Φ decreases from 7×10^{-3} to 9×10^{-4} in the isobutane pressure range 0–25 mm Hg (Fig. 2). The relative quenching cross sections of isobutane and oxygen are such that oxygen quenches more than 90% of the 6^3P_1 excited mercury atoms for partial pressures of isobutane of less than 25 mm Hg with P_{O_2} = 100 mm Hg.

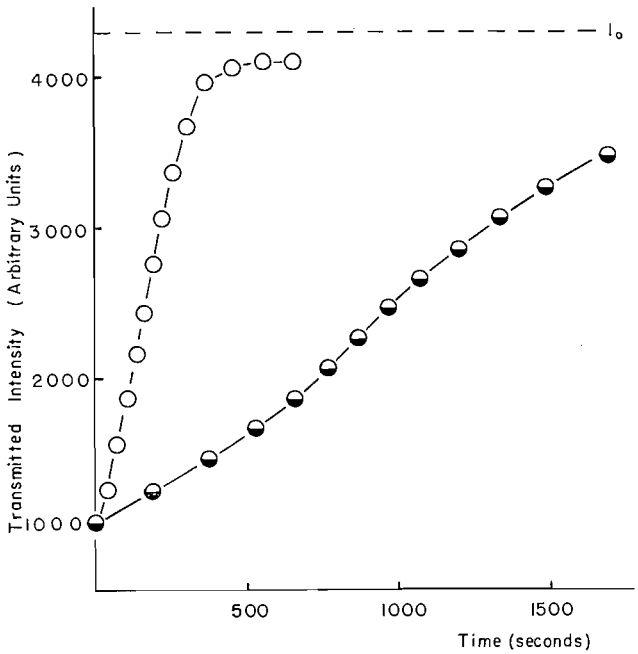

FIG. 1. Typical experiments showing variation in rate of removal of excited 6^3P_1 mercury atoms in the isobutane/oxygen and cyclohexene/oxygen systems at 30° C. ○ $p_{C_6H_{10}}$ = 24 mm Hg; p_{O_2} = 200 mm Hg. ◒ $p_{C_4H_{10}}$ = 50 mm Hg; p_{O_2} = 100 mm Hg. Arbitrary intensity units = potentiometer ohms.

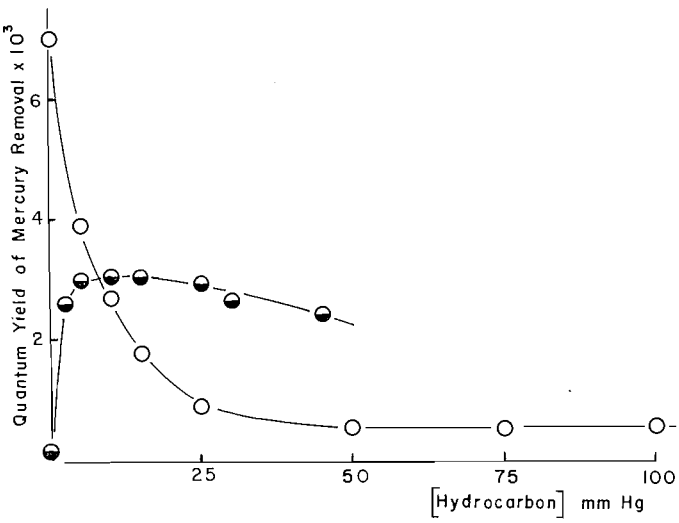

FIG. 2. Quantum yield of mercury removal as a function of partial pressure of hydrocarbon at constant oxygen pressure at 30° C. ○ Isobutane series p_{O_2} = 100 mm Hg. ◒ Cyclohexene series p_{O_2} = 200 mm Hg.

Mercury and oxygen react rapidly in a clean reaction vessel ($\Phi = 7\text{–}10\times10^{-3}$), but if an experiment using oxygen and mercury alone is performed after several using cyclohexene, oxygen, and mercury, the mercury–oxygen reaction is inhibited ($\Phi \sim 2\times10^{-4}$) presumably by involatile products having been deposited on the walls. In the presence of an increasing concentration of cyclohexene, Φ rapidly increases to a maximum value of 3×10^{-3} (Fig. 2).

DISCUSSION

The interaction of oxygen and mercury on illumination with 2537-Å radiation has recently been interpreted by Callear, Patrick, and Robb (5) in terms of the following series of equations [1]–[5]:

$$O_2 + Hg(6^3P_1) \rightarrow O_2^* + Hg(6^1S_0) \quad [1]$$

$$O_2 + O_2^* \rightarrow O_3 + O \quad [2]$$

$$O_2 + O_2^* \rightarrow O_2 + O_2 \quad [2']$$

$$O + O_2 + M \rightarrow O_3 + M \quad [3]$$

$$O_3 + Hg \rightarrow HgO + O_2 \quad [4]$$

$$O + O_3 \rightarrow O_2 + O_2. \quad [5]$$

In the presence of hydrocarbon, the products formed by the reactions indicated by equations [2] and [3] will react rapidly with the hydrocarbon, presumably by the following processes:

$$RH + O_3 \rightarrow RO + HO_2 \quad [6]$$

$$RH + O \rightarrow R + OH. \quad [7]$$

There will thus be a competition between the hydrocarbon molecules and mercury atoms for reaction with ozone. This will result in the observed decrease in Φ for increasing partial pressure of isobutane, since the rate of ozone production will not be appreciably altered on using a large excess of oxygen. Under the conditions of a large excess of isobutane ($p_{C_4H_{10}}/p_{O_2} = 600/30$), $\Phi < 2\times10^{-4}$, whilst the peroxide quantum yields were about 0.85, indicating a negligible interaction between mercury and the intermediates or final products of the reaction.

As mentioned earlier the mercury–oxygen reaction, i.e. reaction [4], seems to be inhibited in a vessel which has been used for several experiments with cyclohexene. This is illustrated in Fig. 2 from which we see that, under the circumstances mentioned, the quantum yield for the disappearance of mercury vapor in the presence of 200 mm Hg of oxygen has an initial value of about 2×10^{-4}. On adding cyclohexene the value of Φ increases until it reaches a maximum of about 3×10^{-3}. This maximum occurs when the pressure of cyclohexene is approximately 10 mm Hg. The reasons for the initial inhibition of the mercury–oxygen reaction are not clear. Reaction [4] would be expected to take place to some extent, but apparently the HgO is not stabilized on the walls of the reaction vessel after these have been exposed to the products from the cyclohexene reaction. Were this the case then it would, of course, be easy to understand the initial low value observed for Φ. The addition of increasing amounts of cyclohexene would reduce the rate of diffusion of the HgO to the walls of the vessel, and so we thus have some of the features of a wall-inhibited reaction. In this type of kinetic system, i.e. one with a step which is wall-inhibited, the rate of the over-all process studied increases with pressure because at the higher pressures the inhibiting influence of the walls becomes less important owing to the rate of diffusion of the active species being smaller at the higher pressures. The shape of the curve in Fig. 2 showing the variation of Φ with increasing cyclohexene pressure is in agreement with these requirements and so the suggested explanation would appear to be a reasonable one.

Since mercury does not react with cyclohexene in the absence of oxygen, our results suggest that the mercury vapor is removed by reaction with some product, or intermediate, of the oxidation. If the lamp was shielded midway through a run, the light

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

absorption was the same on reillumination as it was immediately prior to shielding, indicating that the mercury reacts with an active intermediate rather than a final product. Radicals produced in reaction [7], or by direct cleavage of the R—H bond in the hydrocarbon, will react rapidly with oxygen according to equation [8].

$$R\cdot + O_2 \rightarrow RO_2\cdot \qquad [8]$$

The subsequent reaction of the peroxy radical with mercury as indicated in equation [9]

$$RO_2 + Hg \rightarrow HgO + RO\cdot \qquad [9]$$

seems reasonable. This reaction was postulated by Small and Ubbelohde (2) as being responsible for the reduction of peroxide yield in the presence of mercury for the oxidation of *n*-hexane. Reaction [9] does not, however, necessarily lead to removal of $RO_2\cdot$ from the system if $RO\cdot$ reacts by the following scheme.

$$RO\cdot + RH \rightarrow ROH + R\cdot \qquad [10]$$

$$R\cdot + O_2 \rightarrow RO_2\cdot \qquad [8]$$

In the cyclohexene oxidation, low quantum yields of peroxide were obtained (< 0.08). The final amounts of products were very low owing to the limited period of initiation resulting from the rapid removal of mercury, the original concentration of which was about 5×10^{-10} g-mole liter^{-1}. As the quantities of products produced were extremely small the only analysis done was for peroxide. A modification of the sensitive ferrous thiocyanate method of Young *et al.* (8) was used. Cyclohexene will probably have a higher quenching cross section for excited 6^3P_1 mercury atoms than oxygen, and the decrease in Φ towards higher cyclohexene values where the cyclohexane is quenching an appreciable fraction of the excited mercury, suggests that each C_6H_{10}–Hg* quenching process has a lower radical-producing efficiency than the corresponding O_2–Hg* quenching process. The final radical yield would then be expected to be low since the yield of ozone in the O_2–Hg reaction was determined by Callear, Patrick, and Robb to be 0.14 (5). The final peroxide yield will also be low since the work of Burgess and Robb (7) indicates that it is unlikely that a hydrocarbon peroxide chain will be operative at 30° C.

MERCURY-PHOTOSENSITIZED OXIDATIONS OF HYDROCARBONS

PART II. THE MERCURY-PHOTOSENSITIZED OXIDATION OF ISOBUTANE[1]

K. M. BELL[2] AND C. A. MCDOWELL

ABSTRACT

The mercury-photosensitized oxidation of isobutane has been studied over a wide range of pressures of the hydrocarbon and oxygen, in a conventional static photochemical apparatus at the temperatures of 30° C and 100° C. The main products of the reaction are tertiary butyl hydroperoxide, together with tertiary butyl alcohol, acetone, and corresponding small quantities of formaldehyde and methyl alcohol. Isobutyraldehyde was also detected; ditertiary butyl peroxide being notably absent. Peroxide yields suggest that a reaction between an excited isobutane molecule and oxygen is important in the initiation processes and that peroxide is formed in the reaction

$$RO_2 + HO_2 \rightarrow ROOH + O_2.$$

INTRODUCTION

The mercury-photosensitized oxidations of methane, ethane, and propane have previously been studied in flow systems (1, 2, 3). The original classical concept of the peroxide chain reaction

$$RO_2\cdot + RH \rightarrow ROOH + R \qquad [19]$$

occurring at 25° C was modified in the most recently published work of this type by Watson and Darwent (4), who explained the low yields of peroxide obtained in the ethane oxidation by suggesting the following reaction

$$RO_2\cdot + HO_2 \rightarrow ROOH + O_2 \qquad [3]$$

as the source of hydroperoxide rather than reaction [19]. These workers found that the yields of peroxide decreased on raising the reaction temperature or on lowering the flow rate. They attributed these effects to thermal and photochemical decomposition of the peroxide. The hydroperoxide was characterized as ethyl hydroperoxide by Gray (1), and so this work provides no evidence on the nature of the mutual interaction of HO_2 radicals.

In an effort to elucidate further the nature of certain aspects of hydrocarbon oxidation mechanisms we have studied the mercury-photosensitized oxidation of isobutane in a static photochemical apparatus employing low light intensities.

EXPERIMENTAL

The apparatus and photochemical techniques employed were the same as those described in Part I (K. M. Bell and C. A. McDowell. Can. J. Chem. This issue). Using a modification of the ferrous thiocyanate method of Young, Voigt, and Nieuland (5), 5×10^{-9} mole of peroxides could be determined. The method is non-stoichiometric, and a calibration curve was prepared using purified solutions of tertiary butyl hydroperoxide. The hydroperoxide was also determined gas chromatographically, dinonyl phthalate on chromosorb being used as the column material. The other products were determined and identified by their characteristic elution times on different columns. Formaldehyde

was estimated by the method of Bricker and Johnson (6). In all cases the final yield of product was limited by the slow removal of the mercury vapor (see Part I). The rate of removal was greater at 30° C than 100° C. For a mixture of 50 mm Hg of isobutane and 100 mm Hg of oxygen, Φ (the quantum yield of *removal* of excited 6^3P_1 Hg atoms) was 6×10^{-4} at 30° C and 2×10^{-4} at 100° C.

RESULTS

The main product of the oxidation was tertiary butyl hydroperoxide, together with smaller yields of tertiary butyl alcohol, acetone, methyl alcohol, formaldehyde, and isobutyraldehyde. Evidence was also obtained for a trace of isobutyl alcohol. Tests were specifically made for ditertiary butyl peroxide but none could be detected under conditions where the lower limit of detection corresponded to a quantum yield of 0.02. It is also to be noted that we were unable to detect isobutylene oxide despite several attempts using our gas chromatographic apparatus. Close agreement was obtained between the total peroxide determined colorimetrically, and tertiary butyl hydroperoxide determined gas chromatographically.

The yield of peroxide was directly proportional to the integrated absorbed light intensity (Fig. 1) for constant incident intensity, and also to the average absorbed

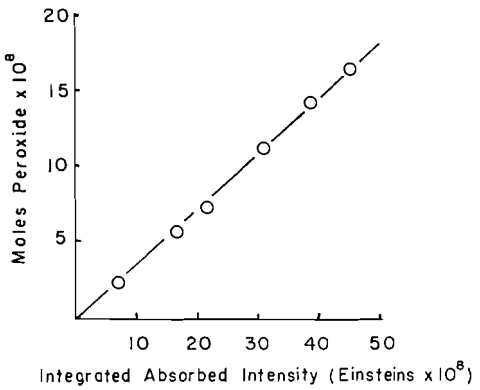

FIG. 1. Yield of peroxide as a function of the integrated absorbed intensity, for constant incident intensity, in the mercury-photosensitized oxidation of isobutane at 30° C, $p_{O_2} = p_{C_4H_{10}} = 100$ mm Hg.

intensity when a given isobutane–oxygen mixture was illuminated for a given time (500 seconds) at varying light intensities (Fig. 2). The integrated absorbed light intensity was obtained from the sum of the average numbers of quanta absorbed between determined short time intervals during the course of the reaction (see Part I). The time of illumination (500 seconds) for the intensity variation was the minimum required to obtain an accurately determinable quantity of peroxide at the lowest intensity, so minimizing the change in absorbed intensity, which in no case was greater than 15% of the total.

The quantum yield of peroxide was constant for a given isobutane–oxygen ratio for oxygen pressures in excess of 30 mm Hg, but increased as the fraction of isobutane in the mixture increased (Fig. 3). The yield of tertiary butyl alcohol underwent the same variation with varying light intensity as the peroxide (Fig. 4), and was constant in the region of constant peroxide (Fig. 5). The total yield of (tertiary butyl alcohol + acetone) was approximately proportional to the corresponding yield of peroxide (Fig. 6).

only by an increased yield of acetone relative to tertiary butyl alcohol, and an increased total yield of (tertiary butyl alcohol + acetone). With the increase in acetone, methanol and formaldehyde were detected. The variation with conditions for all products was the same at 100° C as at 30° C. Small quantum yields of isobutyl alcohol verging on the lower limit of detection ($\phi \simeq 0.02$–0.03) were observed at the higher isobutane–oxygen ratios.

Results showing the thermal stability of the peroxide to both homogeneous and heterogeneous decomposition during the course of an experiment, are given in Table III, the

TABLE III

Thermal stability of peroxide at 30° C and 100° C
($p_{O_2} = p_{C_4H_{10}} = 100$ mm Hg)

Period of illumination (seconds)	Period of shielding (seconds)	Peroxide	Temp. (°C)
500	—	0.36	30
500	1000	0.35	30
500	—	0.40	100
500	1000	0.39	100

products being left in the reaction cell for 1000 seconds, with the lamp shielded, after a 500-second period of illumination. The hydrocarbon conversion was never greater than 1%, and in the case of the colorimetric peroxide determination often less than 0.1%, thus minimizing photochemical decomposition with subsequent reaction of intermediate and final products.

DISCUSSION

Variation of the concentrations of the reactants in a mercury-photosensitized oxidation will possibly have an effect on the initiation reactions. The rate of initiation will depend upon the relative quenching cross sections of the two gases and also upon the numbers of radicals produced as a result of each quenching process. Values of the quenching cross section of oxygen have been variously reported in the literature lying in the range 13.2–19.9 Å² (7, 8). Burgess and Robb in a recent paper (9) adopted a value for $\sigma^2_{O_2,Hg(6^3P_1)}$ of 17.2 Å² and for $\sigma^2_{C_4H_{10},Hg(6^3P_1)}$ of 6.9 Å², both determined in the same way. Using these values the number of excited mercury atoms quenched by each gas is given by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$\frac{Z_{O_2,Hg(6^3P_1)}}{Z_{C_4H_{10},Hg(6^3P_1)}} = 3.2\,\frac{n}{(1-n)}$$

where n is the mole fraction of oxygen in the mixture (see Table I).

Radicals are produced from the hydrocarbon quenching reaction [*a*],

$$Hg(6^3P_1) + RH \rightarrow Hg(6^1S_0) + R + H. \qquad [a]$$

Radical yields in mercury-photosensitized decompositions are usually below unity. For isobutane a yield of 0.2 radicals has been determined by Darwent and Winkler (10), indicating that reaction [*b*] must occur.

$$RH^* + M \rightarrow RH + M \qquad [b]$$

In this equation RH* represents an excited RH molecule.

In the presence of oxygen it is possible that reaction [*c*] will occur.

$$RH^* + O_2 \rightarrow R + HO_2 \qquad [c]$$

Burgess and Robb (9) postulated that each O_2–Hg quenching collision led to three radicals in the sequence of reaction [*d*] to [*i*] since reaction [*e*] was stated to have an efficiency close to unity.

$$Hg(6^3P_1) + O_2 \rightarrow O_2^* + Hg(6^1S_0) \qquad [d]$$

$$O_2^* + O_2 \rightarrow O_3 + O \qquad [e]$$

$$RH + O_3 \rightarrow RO + HO_2 \qquad [f]$$

$$RO + RH \rightarrow ROH + R \qquad [g]$$

$$RH + O \rightarrow R + OH \qquad [h]$$

$$RH + OH \rightarrow R + H_2O \qquad [i]$$

In a subsequent paper Callear, Patrick, and Robb (11) while studying the O_2–$Hg(6^3P_1)$ reaction found the net efficiency of process [*e*] including reaction [*j*]

$$O + O_2 + M \rightarrow O_3 + M \qquad [j]$$

to be 0.14, due to deactivation of the active species in reaction [*k*]

$$O_2^* + O_2 \rightarrow O_2 + O_2. \qquad [k]$$

This seems to contradict the value adopted in their earlier paper. In hydrocarbon–oxygen mixtures the reactions [*l*] and [*m*]

$$RH + O_2^* \rightarrow R + HO_2 \qquad [l]$$

and

$$RH + O_2^* \rightarrow RO + OH \qquad [m]$$

are also possibilities.

The situation is obviously complex since efficiencies cannot be accurately assigned to all the above reactions. One simplification which can be made is to operate at a constant ratio of hydrocarbon to oxygen. Under these conditions the rate of initiation should not vary, provided the over-all gas pressures are adequate to provide complete quenching of all the excited mercury atoms. Using different ratios it is possible to assign efficiencies to some of the above reactions.

The fact that the quantum yields of peroxide were below unity and independent of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the hydrocarbon-concentration variation in a mixture containing a fixed hydrocarbon–oxygen ratio (Fig. 3) indicates the absence of a peroxide chain reaction at the temperatures studied. The operation of the simple mechanism below:

$$RH \xrightarrow{R_i} R + H \qquad [1]$$

$$R + O_2 \xrightarrow{k_2} RO_2 \qquad [2]$$

$$H + O_2 \xrightarrow{k_{2'}} HO_2 \qquad [2']$$

$$RO_2 + HO_2 \xrightarrow{k_3} ROOH + O_2 \qquad [3]$$

leads, on applying the stationary state hypothesis, to the kinetic equation

$$d[\mathrm{ROOH}]/dt = R_i = \phi I_a$$

where ϕ is the effective primary radical yield in all initiation processes.

For a given hydrocarbon–oxygen ratio the total yield of peroxide should be proportional to the absorbed light intensity as observed (Fig. 2). Yields of tertiary butyl alcohol vary in a manner parallel to those of the hydroperoxide (Figs. 4 and 5) suggesting that the tertiary butoxy radical, which must be the immediate precursor of the alcohol, in the absence of ditertiary butyl peroxide, originates in reaction [4]

$$RO_2 + RO_2 \rightarrow 2RO\cdot + O_2 \qquad [4]$$

with subsequent hydrogen abstraction from the parent hydrocarbon as follows,

$$RO + RH \rightarrow ROH + R. \qquad [5]$$

Reaction [4] is not a terminating step and, therefore, does not affect the rate equation for peroxide production. In addition to reaction [5] a similar type of process, namely [3′], merits some consideration.

$$RO + HO_2 \rightarrow ROH + O_2 \qquad [3']$$

It is difficult to decide definitively between the two reactions [3′] and [5]. If [3′] is assumed to be the process leading to the production of tertiary butyl alcohol this would imply a primary radical yield of greater than unity for those mixtures with an isobutane–oxygen ratio of 10:1, since [3′] is a terminating reaction. The value of 0.8 found for the quantum yield of tertiary butyl hydroperoxide suggests that [3] alone is the main terminating reaction. For these reasons, reaction [5] would seem to be a better suggestion for the production of tertiary butyl alcohol. Figure 5, however, shows that the quantum yield of tertiary butyl alcohol is constant and independent of pressure for a fixed ratio of isobutane–oxygen and this is predicted by equation [3′]. The inclusion of equation [5] and omission of [3′] would lead to a decrease in alcohol and an increase in acetone production for lower values of isobutane in the fixed isobutane–oxygen ratio. Either equation [5] or [3′] leads to the same expected change in the rate of formation of alcohol and acetone with variation in light intensity. The kinetic data we have obtained is in favor of reaction [3′] as being the process responsible for the formation of the tertiary butyl alcohol. It would, however, also be reasonable to include reaction [5] on the basis of the values and trends observed for the quantum yields of tertiary butyl alcohol. It must, however, be pointed out that the constant value found for the ratio tertiary butyl alcohol – acetone for varying values of the ratio [isobutane]–[oxygen] (see Table II) is predicted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

by neither [3′] nor [5] if either is in competition with equation [6], which is obviously the source of the acetone found.

$$(CH_3)_3CO \rightarrow CH_3COCH_3 + CH_3 \quad [6]$$

However, the process represented by equation [6] may not necessarily be so simple as there indicated. Should equation [6] be more complex than indicated it is possible that the inclusion of equation [5] may give the correct form of the variation of the quantum yields of tertiary butyl alcohol with hydrocarbon concentration.

The decomposition of the tertiary butoxy radical indicated in equation [6] is almost complete at temperatures about 190° C, even in the presence of an excess of a hydrocarbon containing a weak R—H bond (13, 14, 15, 16). At room temperature, it appears that the abstraction predominates because it requires a much lower activation than the decomposition. At 100° C the increasing yields of acetone are a measure of increasing extent to which the decomposition reaction [6] occurs. There is much uncertainty regarding the reaction of the resulting methyl radicals with oxygen to form methyl alcohol and formaldehyde (1, 16, 17, 18, 19, 20, 21). Below are listed some of the reactions considered possible at 100° C in the absence of significant yields of methyl hydroperoxide.

$$CH_3 + O_2 \rightarrow CH_3O_2 \quad [7]$$

$$CH_3O_2\cdot + HO_2 \rightarrow CH_3OOH + O_2 \quad [8]$$

$$CH_3O_2\cdot \rightarrow CH_2O + OH \quad [9]$$

$$CH_3OOH \xrightarrow{\text{surface}} CH_3O\cdot + OH \quad [10]$$

$$CH_3O_2\cdot + RO_2\cdot \rightarrow \underset{(R = CH_3 \text{ or } (CH_3)_3C)}{CH_3O\cdot + RO + O_2} \quad [11]$$

$$CH_3O\cdot + (CH_3)_3CH \rightarrow CH_3OH + (CH_3)_3C \quad [12]$$

$$CH_3O + O_2 \rightarrow CH_2O + HO_2 \quad [13]$$

It is not, of course, possible to assign individual efficiencies to reactions [7]–[13] given above. Tables I and II show that the peroxide yields and the variations of these with the composition of the reactants are about the same at 30° and 100°. Similar reactions as indicated in [7]–[13] must have about the same efficiencies at both these temperatures.

Close agreement between the total peroxide and tertiary butyl hydroperoxide indicates that neither the mutual interaction of hydroperoxy radicals nor abstraction from the parent hydrocarbon to form hydrogen peroxide occurs to any appreciable extent. The exothermicity for abstraction by the tertiary butyl peroxy radical from the isobutane molecule, equation [5′]

$$RO_2 + RH \rightarrow RO_2H + R, \quad [5']$$

is about 1.5 kcal mole^{-1}, and the activation energy has been determined by Burgess and Robb (9) to be 16 kcal mole^{-1}, thus accounting for the radical–radical reaction at 30° C. Abstraction from the isobutane molecule by the tertiary butoxy radical, equation [5], is exothermic by about 16 kcal mole^{-1}, and the activation energy is presumably less than for the peroxy abstraction, equation [5′], being sufficiently low to exclude the occurrence of the radical–radical reaction at 30° C.

The above isobutane–oxygen reaction scheme predicts that, providing $[HO_2] = [RO_2]$, the quantum yield of peroxide should be proportional to the sum of the reactions involving the RO· radical, i.e. tertiary butyl alcohol + acetone. Figure 6 shows that this is what our experimental results indicate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The yields of peroxide which are formed in the main terminating reaction [3] increase with the increasing role of hydrocarbon in the excited mercury quenching processes (Tables I and II) and suggest that reaction [*c*] in the initiation processes has an efficiency close to unity. Low peroxide yields ($\phi < 0.15$) for the oxygen–isobutane = 10:1 mixtures are attributed to a low efficiency of reaction [*e*]. The value for ϕ in this case is close to that determined by Callear, Patrick, and Robb (11) for the oxygen–mercury reaction.

The detection of small yields of isobutyraldehyde was surprising. This is regarded as being formed from the isobutoxy radical according to equation [14]

$$(CH_3)_2CHCH_2O + O_2 \rightarrow (CH_3)_2CHCHO + HO_2. \qquad [14]$$

In the absence of significant quantities of the corresponding hydroperoxide the isobutoxy radicals will probably be formed as primary products without going through the isobutyl peroxy stage, where the opportunity for formation of the hydroperoxide exists. The data in Table II show that the ratio isobutyraldehyde – tertiary butyl peroxide increases with the increase in the percentage of the excited mercury atoms quenched by molecular oxygen. This suggests that the reactions [15] and [16] may be of some importance:

$$(CH_3)_2CHCH_3 + O_3 \rightarrow (CH_3)_2CHCH_2O + HO_2 \qquad [15]$$

$$(CH_3)_2CHCH_3 + O_2^* \rightarrow (CH_3)_2CHCH_2O + OH. \qquad [16]$$

Both of these are very exothermic.

The occurrence of [14] and [15] maintains the balance of hydroperoxy radicals at high oxygen–hydrocarbon ratios where each effective oxygen quenching process has the potentiality of producing three $RO_2\cdot$ radicals and only one HO_2 radical (reactions [*c*] to [*i*]).

Hydrogen abstraction by oxygen from the isobutoxy radical must have a lower activation energy than abstraction by the isobutoxy radical from the parent hydrocarbon, in view of the low yields of isobutyl alcohol found. Hydrogen abstraction from the tertiary butoxy radical by oxygen does not occur to any extent because the product of this reaction, namely isobutylene oxide, was not detected. A small fraction of the formaldehyde yields is attributable to decomposition of the isobutoxy radical occurring at 100° C where the quantum yields of the aldehyde are lower. The over-all increase in the yield of (acetone + *t*-butyl alcohol) at 100° C suggests reaction [4] may have a small activation energy. The slight increase in peroxide at 100° C for oxygen-rich mixtures is explained if the efficiency of [*e*] increases with increasing temperature.

A pressure of $\sim$ 3 mm Hg of oxygen will give complete quenching in a system containing mercury vapor at its room temperature equilibrium vapor pressure. The tail-off in peroxide yield at oxygen pressures below 30 mm Hg may be attributable to a competition between deactivation processes and reaction with oxygen for removal of active isobutane molecules as portrayed by equations [17] and [18]

$$C_4H_{10}^* \rightarrow C_4H_{10} \qquad [17]$$

$$C_4H_{10}^* + O_2 \rightarrow C_4H_9 + HO_2. \qquad [18]$$

The slow, absolute rate of reaction of mercury with the isobutane oxidation system will not be significant in reducing the rate of production of radicals in the initiation processes (see Part I).

METAL OXIDE ALKOXIDE POLYMERS

PART I. THE HYDROLYSIS OF SOME PRIMARY ALKOXIDES OF ZIRCONIUM[1]

D. C. BRADLEY[2] AND D. G. CARTER[3]

ABSTRACT

Ebulliometric studies have been made on the hydrolysis of some zirconium alkoxides, $Zr(OR)_4$ where R = Et, Pr^n, Bu^i, and Bu^n. The variation of the degree of polymerization of the zirconium oxide alkoxides so produced was determined as a function of the degree of hydrolysis. The results are interpreted in terms of structural models based on octahedrally 6-co-ordinated zirconium.

INTRODUCTION

It is well established (1) that zirconium alkoxides $Zr(OR)_4$ are polymeric compounds involving metal–oxygen co-ordinate bonds. Although these alkoxides hydrolyze with great facility it is possible under rigorously controlled conditions to isolate the intermediate oxide alkoxides $ZrO_x(OR)_{4-2x}$. These products are of particular interest from the structural viewpoint because they may involve both condensation polymerization (giving ZrOZr systems) and co-ordination polymerization. In addition they are of interest as inorganic polymers which are intermediate between the relatively small polymers of the tetraalkoxide and the macromolecular metal oxide. Studies on the hydrolysis of titanium alkoxides (2, 3, 4) led to the suggestion of structural models for the titanium oxide ethoxides based on octahedrally 6-co-ordinated titanium. Since titanium exhibits a maximum co-ordination number of 6 but zirconium may expand its co-ordination to 7 or 8 it was important to determine whether or not the zirconium oxide alkoxides conformed to the same structural models as the corresponding titanium compounds. We now report the results of an ebulliometric study of the hydrolysis of four primary alkoxides of zirconium in which the degree of polymerization was determined as a function of the degree of hydrolysis.

EXPERIMENTAL AND RESULTS

Zirconium Alkoxides

These were prepared and analyzed using previously described (1) methods. The compounds were distilled at 0.1 mm pressure prior to the hydrolysis experiments.

Zirconium isobutoxide had not previously been described and it was prepared as follows. Freshly distilled zirconium tetraisopropoxide (9 g) was caused to react with isobutanol (125 cc), and the liberated isopropanol removed by fractional distillation. The solution was concentrated to ca. 30 cc and a mass (9 g) of crystals of the *solvate* $Zr(OBu^i)_4,Bu^iOH$ was deposited on cooling. At 100° C at 0.1 mm the crystals softened and lost isobutanol, and the tetraisobutoxide was distilled at 213° C at 0.3 mm. The gummy solid (found: Zr, 24.5; $Zr(OBu^i)_4$ requires: Zr, 23.8%) was recrystallized from isobutanol to reform the *solvate*. Found: Zr, 20.2. $Zr(OBu^i)_4,Bu^iOH$ requires: Zr, 19.9%. Heated under atmospheric pressure the *solvate* softened at 146° C and melted with dissociation at 154° C.

Ebulliometry

An all-glass ebulliometer, similar to that already described (5) and incorporating a differential water thermometer, was used. About 20 cc of dry alcohol was distilled into the ebulliometer in each experiment, the exact amount being determined by weighing to 0.01 g. The water levels in the differential thermometer were read to 0.01 mm using a travelling microscope. About 20 minutes were required after each addition of solute for thermal equilibrium to be re-established.

The following procedure was adopted for the ebulliometric hydrolysis studies. First a series of additions of weighed amounts (Δm) of zirconium alkoxide was made and the corresponding elevations of the boiling point (ΔT) were recorded. The slope of the linear plot of ΔT versus Δm was then found graphically. Next, several weighed amounts of the pure standard (either fluorene or azobenzene) were added and the ΔT's again plotted against weight of solute. The molecular weight of the zirconium compound was then calculated from a knowledge of the two slopes and the molecular weight of the standard. Finally, a series of additions of known aqueous alcohol were made. These solutions contained less than 10% w/w of water and were made up gravimetrically. The addition of aqueous alcohol caused an immediate decrease in the boiling point elevation due to the increase in molecular weight caused by hydrolysis of the zirconium compound. To obtain the correct degree of polymerization of the hydrolysis product an allowance was made for the additional solvent added, and for the amount of alcohol liberated by hydrolysis. These experiments were of several hours' duration and the ebulliometer was weighed at the end of the experiment to determine whether solvent had been lost by evaporation. The process being studied may be depicted by the following equation:

$$[ZrO_{x_1}(OR)_{4-2x_1}]n_1 + (n_2x_2 - n_1x_1)H_2O \rightarrow n_1/n_2[ZrO_{x_2}(OR)_{4-2x_2}]n_2 + 2(n_2x_2 - n_1x_1)ROH$$

where $n_2 > n_1$ and $x_2 > x_1$. In fact the system may contain a distribution of polymer sizes and the values of n determined are number-average degrees of polymerization. The degree of hydrolysis, namely the ratio of gram-molecules of water added per gram-atom of zirconium, is designated by h. In principle h may be varied from 0 to 2 but some experiments were terminated when insoluble products appeared in the ebulliometer.

Zirconium Ethoxide

Experiments were made at three initial concentrations of zirconium ethoxide. The results are given in the following tables.

(*a*) Initial concentration of $Zr(OEt)_4$: 0.186 g-mol./kg ethanol.

TABLE I

h	0.00	0.01	0.10	0.22	0.38	0.52	0.69	0.92	1.16	1.49	1.63	(1.87)
n	2.10	2.15	2.42	2.70	3.18	3.68	4.53	6.55	9.39	9.97	11.4	(10.9)

Precipitation of a white solid occurred 5 minutes after the addition corresponding to $h = 1.87$.

(*b*) Initial concentration of $Zr(OEt)_4$: 0.409 g-mol./kg ethanol.

TABLE II

h	0.000	0.060	0.148	0.273	0.422	0.630	0.825	1.027	(1.229)
n	2.17	2.47	2.83	3.12	3.60	4.81	6.65	10.3	(13.3)

Opalescence in the solution was just perceptible at $h = 0.630$ and became appreciable

at $h = 1.229$. The hydrolysis was continued to $h = 1.433$ before allowing the system to cool when about 0.1 g solid was deposited.

(*c*) Initial concentration of $Zr(OEt)_4$: 0.723 g-mol./kg ethanol.

TABLE III

h	0.000	0.037	0.080	0.121	0.182	0.248	0.344	0.463	0.612	0.766
n	2.24	2.42	2.61	2.81	3.01	3.22	3.54	3.94	4.66	5.79

Opalescence was first detected at $h = 0.612$ and became appreciable at $h = 0.888$.

Zirconium n-Propoxide

The concentration of $Zr(OPr^n)_4$ was 0.147 g-mol./kg *n*-propanol.

TABLE IV

h	0.000	0.159	0.400	0.711	1.118	1.469
n	2.44	2.79	3.30	4.21	7.27	13.9

The experiment was terminated at $h = 1.814$ because the thermometer reading was unsteady. This behavior is believed to indicate the presence of water in the system.

Zirconium n-Butoxide

The concentration of $Zr(OBu^n)_4$ was 0.0707 g-mol./kg *n*-butanol.

TABLE V

h	0.000	0.483	0.953	1.671
n	1.77	2.46	3.81	9.39

The experiment was terminated by fluctuations in the thermometer reading at $h = 2.606$.

Zirconium Isobutoxide

The concentration of $Zr(OBu^t)_4$ was 0.0766 g-mol./kg isobutanol.

TABLE VI

h	0.000	0.223	0.506	0.882	1.403	1.845
n	1.52	1.61	1.71	2.03	2.50	3.31

DISCUSSION

Before discussing the structural implications of the results on zirconium oxide alkoxides it is necessary to recapitulate briefly the structural models considered by Bradley, Gaze, and Wardlaw (3, 4) to explain the behavior of titanium oxide alkoxides. Three structural models were proposed, each involving 6-co-ordinated titanium. Model I was based on the unsolvated trimeric alkoxide $Ti_3(OR)_{12}$ (Fig. 1) and gave a series of trilinear polymers, e.g. $Ti_6O_4(OR)_{16}$ (Fig. 2) and the infinite polymer $[Ti_3O_4(OR)_4]_\infty$ (Fig. 3). These structures all fitted the general relationship $n = 12/(4-3h)$, where $h = 0$ to 1.333. A feature of the system is the fact that the number-average degree of polymerization n is uniquely determined by h and is thus independent of the distribution of polymer sizes. Model II was based on a solvated dimeric species $Ti_2(OR)_8,2ROH$ (Fig. 4) and gave bilinear

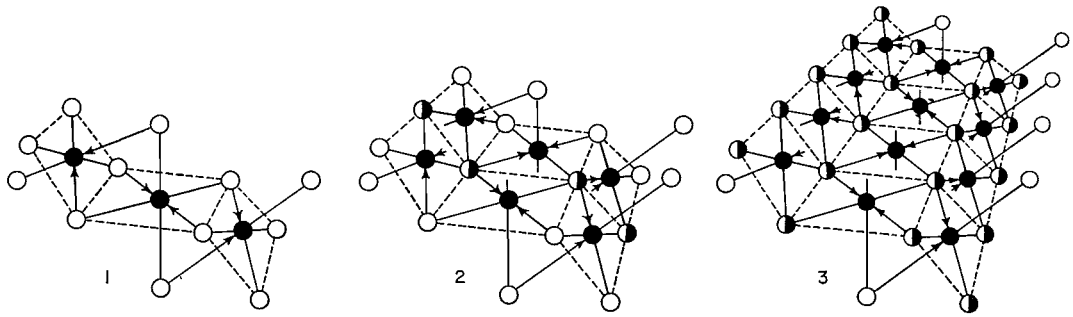

FIG. 1. $Ti_3(OR)_{12}$. ● = Ti; ○ = oxygen in OR groups; R groups omitted.
FIG. 2. $Ti_6O_4(OR)_{16}$. ● = Ti; ◑ = oxygen in Ti.O.Ti; ○ = oxygen in OR (some OR groups omitted for clarity); R groups omitted.
FIG. 3. Section of infinite trilinear polymer $Ti_{3(x+1)}O_{4x}(OR)_{4(x+3)}$. ● = Ti; ◑ = oxygen in Ti.O.Ti; ○ = oxygen in OR (some OR groups omitted for clarity); R groups omitted.

polymers (Fig. 5) corresponding to $n = 6/(3-2h)$, $h = 0$ to 1.5. A third model was based on a monomeric solvated species $Ti(OR)_4$,2ROH. This gave rise to the relation $n = 3/(3-h)$.

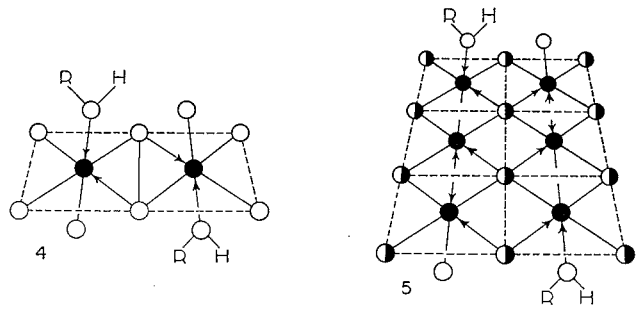

FIG. 4. Solvated dimer $Ti_2(OR)_8$,2ROH. ● = Ti; ○ = oxygen in OR.
FIG. 5. Section of infinite bilinear solvated polymer $Ti_2O_3(OR)_2$,2ROH. ● = Ti; ◑ = oxygen in Ti.O.Ti; ○ = oxygen in OR (some OR and R omitted for clarity); some ROH molecules omitted for clarity.

Accordingly, if the oxide alkoxides of zirconium conform to the same structural series, based on octahedrally 6-co-ordinated zirconium, then we should expect the variation of n with h to resemble one of the predicted relationships. For example, if the original alkoxide is trimeric in its boiling alcohol it should follow the requirements of model I and so forth.

Zirconium Oxide Ethoxides

In Fig. 6 we show a comparison between the experimental data for $Zr(OEt)_4$ and the predicted curves for models I and II. Two features are immediately apparent. Firstly it is noteworthy that practically all of the experimental points lie between the predicted curves for models I and II. Secondly it is clear that in the initial stages experimental points drift closer to the curve I, then remain fairly constant in distance from the curve before deviating towards curve II at h values >1.0. This general behavior is reminiscent of that shown by the hydrolysis products of $Ti(OEt)_4$ (3) and it seems reasonable to apply the principles developed by Bradley, Gaze, and Wardlaw. For a system containing species belonging to models I and II, if the degree of hydrolysis h is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

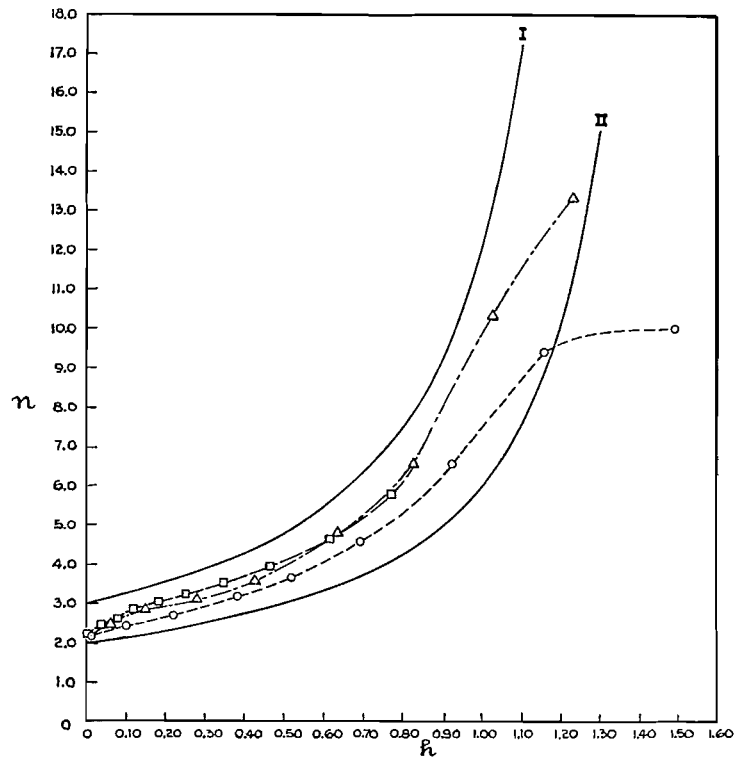

FIG. 6. The hydrolysis of $Zr(OEt)_4$ in boiling ethanol. □ = initial concentration 0.723 g-mol. $Zr(OEt)_4$/kg EtOH; △ = initial concentration 0.409 g-mol. $Zr(OEt)_4$/kg EtOH; ○ = initial concentration 0.186 g-mol. $Zr(OEt)_4$/kg EtOH.

the same for each model, it is readily deduced that the fraction of zirconium atoms in model I is α_I, where $\alpha_I = n_I(n - n_{II})/n(n_I - n_{II})$. In this expression n_I is the degree of polymerization if all the zirconium were in model I and n_{II} if all were in model II. In Fig. 7 is shown the variation of α_I with h for each experiment. Bearing in mind the sensitivity of α_I to experimental error the data still show clearly the rapid initial rise in α_I with increase in h followed by the attainment of a fairly constant value over a range of h and finally a decrease near the completion of the experiment. The latter phenomenon is probably the result of increasing solvation (model II) as the molar concentration of the polymeric species becomes low. This is a consequence of the experimental method since the mass of zirconium is constant throughout the experiment whereas the average molecular size of the zirconium oxide ethoxide species increases steadily with increasing degree of hydrolysis. The striking increase in α_I in the early stages of hydrolysis is more difficult to explain. Thus it is tempting to suggest that the original zirconium ethoxide ($h = 0$) exhibits a low value of n due to the steric effect of the ethyl groups opposing co-ordination polymerization. Then as hydrolysis proceeds and ethoxide groups are removed, co-ordination polymerization develops more fully. However, studies in the alkoxide field have shown (1) that n-alkyl groups exert relatively small steric effects in metal tetraalkoxides and it is surprising that such a large change could be due to this effect. Another puzzling feature is that zirconium ethoxide exhibits a slightly lower degree of polymerization in boiling ethanol than titanium ethoxide but a higher value in boiling benzene. In other words, in boiling ethanol, zirconium apparently has a greater

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

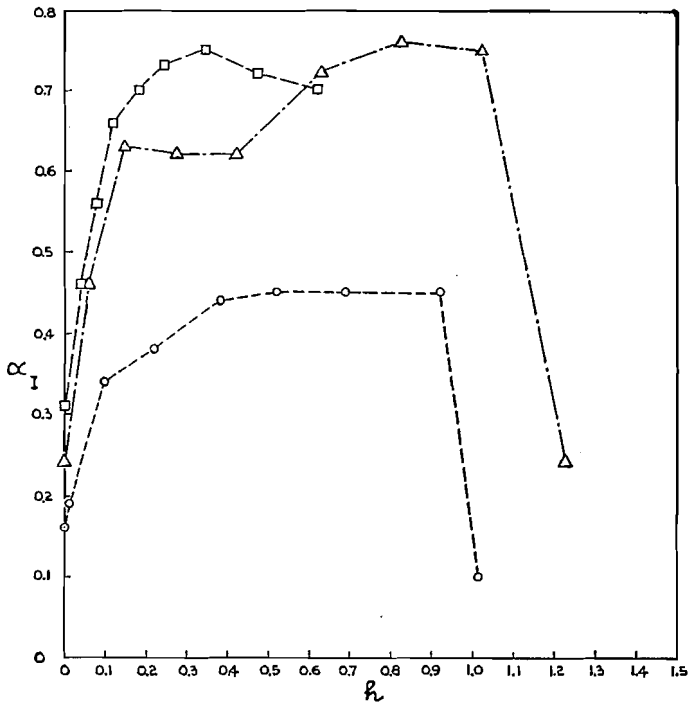

FIG. 7. The variation of α_I with h for zirconium oxide ethoxides. □ = initial concentration 0.723 g-mol. $Zr(OEt)_4$/kg EtOH; △ = initial concentration 0.409 g-mol. $Zr(OEt)_4$/kg EtOH; ○ = initial concentration 0.186 g-mol. $Zr(OEt)_4$/kg EtOH.

tendency to obtain 6-co-ordination by co-ordination with alcohol rather than by polymerization of the ethoxide. The electronic factors involved in bonding in these polymers must also be considered. For example, we should expect that the electron density on the oxygen will be greater for the oxygen in a ZrOZr system than in ZrOEt or EtOH because zirconium is more electropositive than hydrogen or carbon. Therefore the ZrOZr oxygen should be a stronger donor than ZrOEt or EtOH oxygens. Hence as hydrolysis is increased and the proportion of ZrOZr groups becomes significant this may lead to the favoring of polymerization at the expense of solvation and thus a change from model II to model I. The alternative polymers for $h = 1.0$ illustrate this point. In the molecule $Zr_{12}O_{12}(OEt)_{24}$ (model I) one half of the ZrOZr oxygens are utilized in co-ordination polymerization but in $Zr_6O_6(OEt)_{12}$,6EtOH (model II) only one third of the ZrOZr oxygens are so used. These proportions remain constant throughout the oxide ethoxide series and accordingly it would be expected that the values of α_I would rise rapidly at the initial stages of hydrolysis and then remain sensibly constant over a range of h values. Nevertheless, calculations show that this suggestion does not fully account for the rise in α_I with increase in h from 0.0 to 0.5. We are forced to conclude that zirconium tetraethoxide in boiling ethanol is not in true equilibrium with regard to trimer (unsolvated) and dimer (solvated) species but that the oxide ethoxide molecules act as catalysts in bringing the system nearer to equilibrium. There is other evidence which points to the suggestion that solutions of $Zr(OEt)_4$ in boiling ethanol are not in true equilibrium. For example in determining the molecular weight of $Zr(OEt)_4$ a number of additions of solute are made over a range in concentration yet the plot of ΔT (elevation of boiling point) vs. concentration of solute is linear, although a non-integral value for n suggests that more than one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

polymer species is present and hence the molecular weight should be concentration dependent. On the other hand we find that the elevation of boiling point at a given concentration remains constant over a period of hours suggesting that a pseudo equilibrium is set up. The sudden decline in α_I at $h > 1.0$ may be a dilution effect (decrease in polymer concentration) which favors solvation or alternatively it could be caused by the presence of ZrOH groups.

The structural model I reaches a limiting, infinite trilinear polymer at $h = 1.333$ and it would be expected that such a polymer would be insoluble. Our ebulliometric experiments were in fact limited by the onset of turbidity in the system. In the case of the experiment at the intermediate concentration of $Zr(OEt)_4$ a slight opalescence was detected at $h = 0.63$ and the experiment was terminated when precipitation occurred at $h = 1.43$. The precipitate was isolated and analysis showed that its composition was near to that for the infinite polymer $[Zr_3O_4(OEt)_4]_\infty$. Found: Zr, 51.2; EtO, 36.3. $Zr_3O_4(OEt)_4$ requires: Zr, 52.8; EtO, 35.0%. The degree of hydrolysis in the solid product corresponded to $h = 1.28$ and this would give a polymer with a number-average degree of polymerization of ~90. It is not surprising that such a large molecular species was sparingly soluble. However, it is interesting that it corresponded to a slightly lower degree of hydrolysis than that calculated from the known addition of water. This lends further support to the suggestion that hydrolysis may not be quantitative in the later stages of the experiment.

Zirconium Oxide n-Propoxides

The variation of n with h in this system is shown in Fig. 8. No precipitation occurred up to $h = 1.469$ but following the next addition of water (to $h = 1.814$) the behavior of the water thermometer suggested that hydrolysis was no longer quantitative. The shape of the hydrolysis curve suggests that polymers of the models I and II are present in the early stages of hydrolysis but for $h > 1.0$ solvation becomes more effective as the molar concentration of polymers decreases and hence the polymers are based on models II and III. In Table VII we report the values for α_I, $1 - \alpha_I$, α_{II}, and $1 - \alpha_{II}$ as a

TABLE VII

h	α_I	$1 - \alpha_I$	α_{II}	$1 - \alpha_{II}$	c
0.000	0.54	0.46	—	—	0.0602
0.159	0.72	0.28	—	—	0.0532
0.400	0.48	0.52	—	—	0.0445
0.711	0.24	0.76	—	—	0.0349
1.118	—	—	0.98	0.02	0.0197
1.469	—	—	0.88	0.12	0.0101

function of h and the average molar concentration of polymers c (g-mol./kg). α_{II} is defined by $\alpha_{II} = n_{II}(n - n_{III})/n(n_{II} - n_{III})$ where n_{II} and n_{III} are the calculated degrees of polymerization for models II and III respectively.

The interesting point about these data is the small rise in α_I in the early stages (compared with the zirconium oxide ethoxide system) and thereafter the steady increase in proportion of the more solvated species of models II and III. The relatively small rise in α_I at first suggests that the initial solution of $Zr(OPr^n)_4$ in boiling n-propanol is nearer to the true equilibrium between polymer species than was the solution of $Zr(OEt)_4$ and this may be due to the higher boiling point of n-propanol. The higher boiling point of the alcohol is probably responsible for the more rapid onset of solvation in the zirconium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

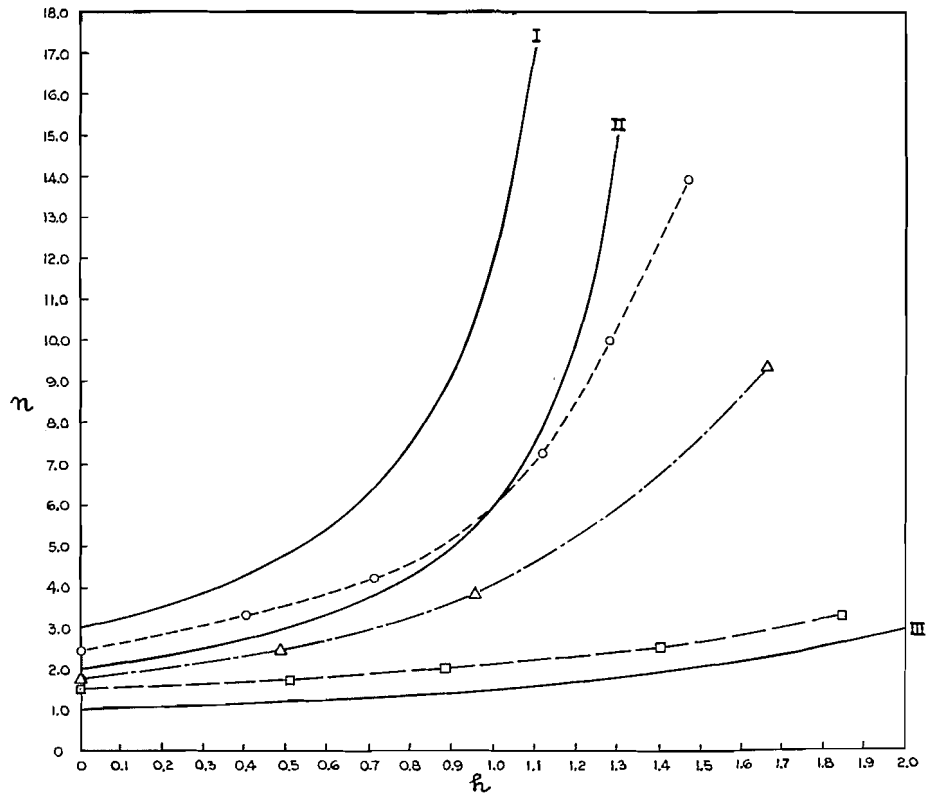

FIG. 8. The hydrolyses of $Zr(OPr^n)_4$, $Zr(OBu^n)_4$, and $Zr(OBu^i)_4$ in their respective alcohols. ○ = $Zr(OPr^n)_4$, initial concentration 0.147 g-mol./kg ROH; △ = $Zr(OBu^n)_4$, initial concentration 0.0707 g-mol./kg ROH; □ = $Zr(OBu^i)_4$, initial concentration 0.0766 g-mol./kg ROH.

oxide *n*-propoxide system. Thus Bradley, Gaze, and Wardlaw (4) suggested that solvation of the polymeric species would be promoted both by a decrease in molar concentration of polymer species and by increase in temperature. The data in Table VII suggest that the presence of polymers based on model III becomes increasingly significant with increase in h for $h > 1.0$. It is especially noteworthy that according to model III the highest polymer (at $h = 2.0$) possible is the trimer, whereas models I and II predict infinite linear polymers at $h = 1.33_4$ and 1.50 respectively. In our experiment no precipitation was observed although the reaction was terminated at $h = 1.814$ due to the presence of residual water in the system. The absence of a precipitate is thus in agreement with the presence of polymers based on model III in the final stages of hydrolysis. However, the presence of water at $h = 1.814$ also suggests that hydrolysis may be reversible at this stage due to the presence of Zr—OH groups and this offers an alternative means of producing low polymers.

Zirconium Oxide n-Butoxides

The high boiling point of *n*-butanol should promote the solvation process even more than *n*-propanol. The variation of n with h for the $Zr(OBu^n)_4$ system, shown in Fig. 8, agrees with this supposition. It appears that the polymeric species involve models II and III (with II predominating) and the dependence of α_{II} on h is shown in Fig. 9. It is extremely interesting to note that there is only a small initial rise in α_{II} at the early stages of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

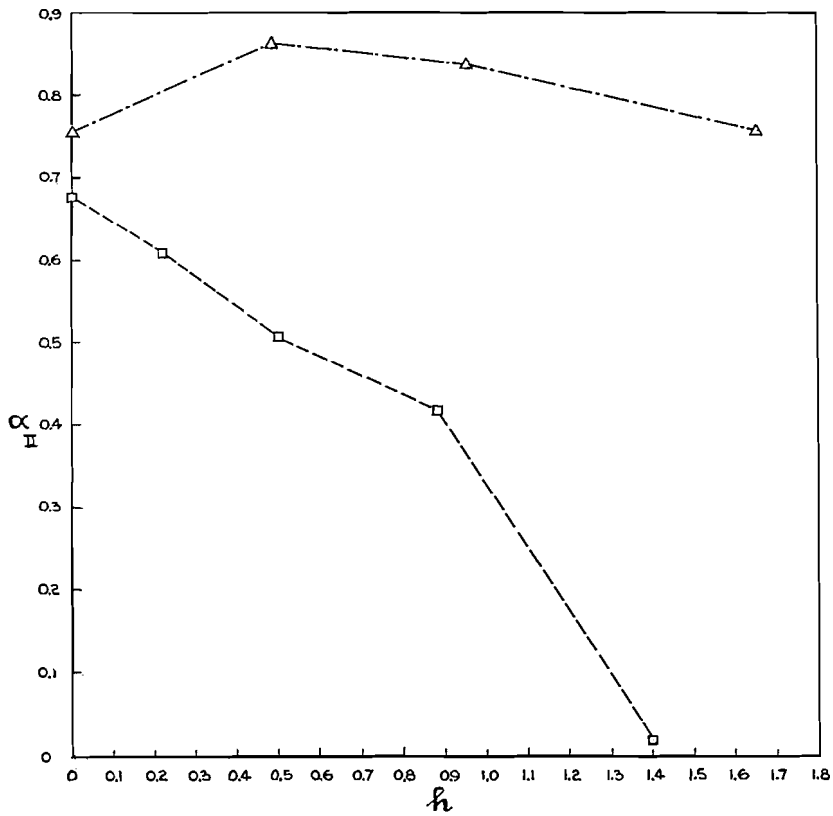

FIG. 9. The variation of α_{II} with h for zirconium oxide *n*-butoxides and zirconium oxide isobutoxides. △ = $Zr(OBu^n)_4$, initial concentration 0.0707 g-mol./kg ROH; □ = $Zr(OBu^i)_4$, initial concentration 0.0766 g-mol./kg ROH.

hydrolysis, followed by a steady decline in α_{II} as the decrease in polymer concentration with increase in n favors the model III species. No precipitation was observed and this suggests the predominance of model III in the final stages of hydrolysis. However, the detection of residual water at $h > 1.671$ means that hydrolysis may be reversible and incomplete in this region.

Zirconium Oxide Isobutoxides

The interesting feature of this system is that in spite of the lower boiling point of isobutanol compared with *n*-butanol, the solvation of $Zr(OBu^i)_4$ appears to be greater than for $Zr(OBu^n)_4$. This may well be due to the greater steric effect of the isobutoxide groups. It is well established (1) that branching of the alkyl groups in zirconium alkoxides opposes the formation of Zr—O intermolecular bonds and thus prevents co-ordination polymerization. The zirconium is thus forced to achieve its higher co-ordination by the process of solvation. Striking evidence in support of the preferential solvation of $Zr(OBu^i)_4$ was the isolation of the relatively stable solvate $Zr(OBu^i)_4,Bu^iOH$, in contrast to $Zr(OBu^n)_4$, which does not form a solvate. The variation of n with h for $Zr(OBu^i)_4$ is shown in Fig. 8. In Fig. 9 we show the steady decrease of α_{II} with increase in h, which suggests that model III species become favored as hydrolysis becomes extensive. No precipitation occurred up to $h = 1.845$ and this is in agreement with the predominance of model III species. Above $h = 1.845$ residual water was detected and this suggests that hydrolysis is reversible in this region.

CONCLUSIONS

The zirconium oxide alkoxides $ZrO_x(OR)_{4-2x}$, where R = Et, Pr^n, Bu^t, and Bu^n, exhibit low number-average molecular weights in solution in their progenitive alcohols at the boiling point. The variation of degree of polymerization with degree of hydrolysis is reasonably explained in terms of structural models based on 6-co-ordinated zirconium. With the exception of the ethoxides the zirconium compounds exhibited a greater degree of co-ordination polymerization than the corresponding titanium compounds.

THE INFLUENCE OF HYDROGEN ION CONCENTRATION ON THE MYOSIN-CATALYZED HYDROLYSIS OF ADENOSINE TRIPHOSPHATE[1]

GÉRARD E. PELLETIER[2] AND LUDOVIC OUELLET

ABSTRACT

The Michaelis constants for the system myosin–ATP have been measured at 5° C and 15° C from pH 7.0 to pH 10.5, in the presence of 0.4 *M* potassium chloride and 0.005 *M* calcium chloride. The experimental data point to the presence, in the active center, of two ionizable groups, with experimental acid p*K* of 7.35 and 8.6 respectively at 15° C. The apparent heats of ionization of these groups are about 9 kcal/mole for the first one and close to zero for the second. These data are interpreted as indication of the presence in the active center of myosin of a histidyl and a sulphydryl residue. A mechanism is proposed for the hydrolysis of ATP in the presence of myosin.

The kinetics of hydrolysis of adenosine triphosphate (ATP) in the presence of myosin has been described under several of its aspects. The reaction follows the Michaelis–Menten law. The influence of concentration of substrate, activator ions, ionic strength, and dielectric constants have been reported and have been summarized by Laidler (1). Recently Nihei and Tonomura (2) have observed an increase in the Michaelis constant at pH around 6.8. Blum (3) has also mentioned the variation of the Michaelis constant with the concentration of *p*-chloromercuribenzoate, an inhibitor probably reacting with sulphydryl residues.

The present paper describes the variation of the Michaelis constant of myosin as a function of the pH at two temperatures. The data so obtained will be used as information on the nature of the active groups of myosin.

DESCRIPTION OF THE DATA

The data reported in this paper were collected in terms of the usual system describing the influence of hydrogen ions on the rate of an enzymatic reaction. As the work progressed, however, it became evident that the simple usual scheme had to be modified to describe the experimental results.

The fundamental scheme is represented in Fig. 1. The enzyme is assumed to exist in

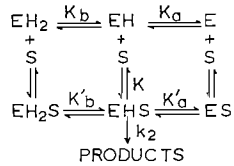

FIG. 1. Scheme representing the ionization states of an enzyme E and the enzyme substrate complex when the active center includes two acid groups.

three different ionic states EH_2, EH, E, in equilibria one with the other. The ionization constants K_b and K_a describe the ionization equilibrium. The charges and the hydrogen ions participating in the equilibrium have been left out. In the general case, these three

[1]*Manuscript received February 14, 1961.*
Contribution from the Department of Chemistry, Laval University, Quebec, Que.
[2]*Present address: Research Division, Imperial Oil Ltd., Sarnia, Ont.*

enzymic forms react with a substrate molecule S to give the complexes EH_2S, EHS, and ES. The complex EHS is usually assumed to give products.

Assuming the above system to be in equilibrium, the rate of hydrolysis V is given by the Michaelis–Menten equation:

$$V = \bar{V}_m[S]/(\bar{K}_m + [S]) \quad [1]$$

where $\bar{V}_m$, the rate at very high substrate concentration, assuming no substrate inhibition, is given by:

$$\bar{V}_m = V_m \Big/ \left(1+\frac{[H^+]}{K_b'}+\frac{K_a'}{[H^+]}\right) \quad [2]$$

and $\bar{K}_m$, the Michaelis constant, is:

$$\bar{K}_m = K_m\left(1+\frac{K_a}{[H^+]}+\frac{[H^+]}{K_b}\right) \Big/ \left(1+\frac{K_a'}{[H^+]}+\frac{[H^+]}{K_b'}\right). \quad [3]$$

The variation of $\bar{V}_m$ and $\bar{K}_m$ with pH provides information on the values of K_a, K_b, K_a', and K_b'. The techniques suggested by Dixon (5) and Massey and Alberty (6) have been used to estimate the ionization constants from the experimental data.

For a discussion of the various hypotheses involved in this representation, one is referred to Laidler (4).

EXPERIMENTAL PART

Myosin of the Weber–Edsall type (7) was used. Adenosine triphosphate (ATP) was the crystalline sodium salt purchased from Pabst Laboratories. All the other reagents were reagent grade.

In the determination of the Michaelis constants, all rates were measured by an electrometric titration method, as the hydrolysis of ATP liberates phosphoric acid according to the following equation.

$$ATP^{-4} + H_2O \rightarrow HPO_4^{=} + ADP^{-3} + H^+ \quad [4]$$

By continuously titrating standard alkali into the reaction mixture to maintain the pH constant, it is possible to follow the rate of formation of the acid.

The apparatus used consisted of a titrator (type TTT 1b) equipped with glass and calomel electrodes, a titrigraph (type SBR2b), and syringe microscrew burette (type SBU1a), from Radiometer (Copenhagen).

Nineteen milliliters of a 0.4 M solution of potassium chloride containing the required amount of ATP and calcium chloride (0.005 M) was pipetted into a double-jacketed reaction vessel. Circulation of water from a constant-temperature bath maintained the temperature within 0.1° C. Stirring was provided magnetically.

To minimize absorption of carbon dioxide from the atmosphere, air which had been twice washed in 30% potassium hydroxide solutions, followed by washing in water at the experimental temperature, was circulated over the surface of the reaction mixture. This proved effective up to pH 10, where a small blank correction was applied. One milliliter of the enzyme solution was injected to the above reaction mixture. The amount of alkali added was recorded as a function of time by the titrigraph. The total volume of sodium hydroxide added never exceeded 2% and was usually less than 1% of the reaction volume.

The rate at high substrate concentration was obtained from a series of runs, made in

1 day at one enzyme concentration. The results so obtained were then multiplied by $(\bar{K}_m + [S])/[S]$. At pH lower than 8, the rate at high concentration of substrate was obtained from analyses for orthophosphate by a colorimetric method (8).

RESULTS

Influence of pH on $\bar{V}_m$

Figure 2 shows the results obtained when the logarithm of the apparent maximum

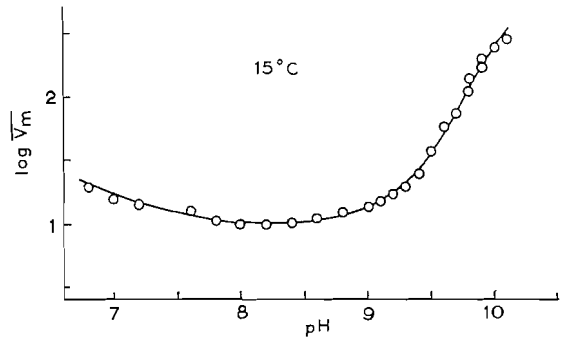

FIG. 2. Plot of the logarithm of the rate of hydrolysis of ATP at high concentration of substrate, $\bar{V}_m$, as a function of pH, at 15.1° C. The rates are in arbitrary units.

rate $\bar{V}_m$ was plotted against the pH at 15.1° C. The curve passes through a minimum in the neighborhood of pH 8.2. No true maxima could be obtained on the alkaline side of these curves, due in part to precipitation in the system and myosin inactivation (9). At 5.2° C, the alkaline branch of the curve was displaced toward higher pH values. Those results are consistent with observations reported by other investigators. Mommaerts and co-workers (10) as well as Tonomura and co-workers (11) have traced $\bar{V}_m$-vs.-pH curves under different conditions of temperature and ionic strength. In general, the curves passed through a minimum at low pH and reached a maximum in the vicinity of pH 9–10, after which a sharp drop resulted. By light-scattering experiments Blum (12) showed that this last phenomenon was due to an irreversible inactivation of the enzyme. Morales (13) has further shown that the concentration of calcium ions affects the position of the alkaline part of the curve, the curve shifting to lower pH values as the concentration of calcium ions is increased.

As no true maximum can be observed under our conditions, these curves cannot be used to estimate the pK of ionization of the myosin–ATP complex. All the experimental data pertaining to the ionization have perforce been obtained from a study of the variation of the Michaelis constant with pH.

The experimental Michaelis constants $\bar{K}_m$ were determined at two different temperatures over a range extending from pH 6.7 to 10.0 at 15.1° C and pH 7.0 to 10.4 at 5.2° C. Figure 3 represents examples of Lineweaver–Burk (14) plots of the reciprocal of the rate against the reciprocal of the ATP concentration. Each Michaelis constant was determined on the same day to eliminate errors due to possible loss in enzyme activity. The Michaelis–Menten law was found to hold under all the conditions studied. The usual determinations of $\bar{K}_m$ covered a ratio of 20 to 50 in concentrations of substrate.

Influence of pH on $\bar{K}_m$

For purposes of interpretation, the influence of pH on the apparent Michaelis constant is usually represented in the form of plots of p$\bar{K}_m$ ($-\log \bar{K}_m$) against pH. Figure 4

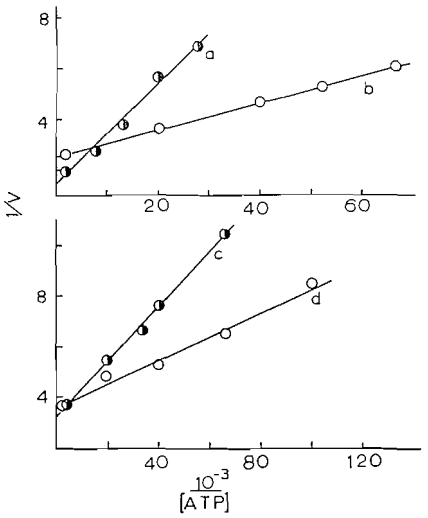

FIG. 3. Lineweaver–Burk plots of the reciprocal of the rate of hydrolysis in arbitrary units as a function of the reciprocal of the ATP concentration at 15.1° C. pH: a = 9.8; b = 7.2; c = 7.0; d = 8.0.

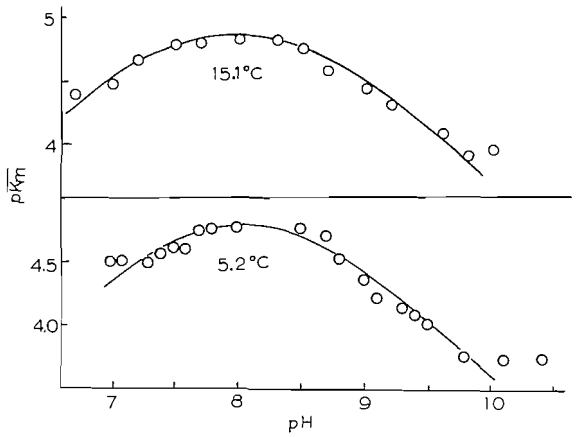

FIG. 4. Plots of $p\bar{K}_m$ ($-\log \bar{K}_m$) as a function of pH. The curves are theoretical curves drawn assuming $K_b' \gg K_b$ and $K_a' \ll K_a$ in equation [3] and pK_a = 8.6, pK_b = 7.34 at 15.1° C and pK_a = 8.6, pK_b = 7.6 at 5° C.

represents such plots at 15.1 and 5.2° C. Classical bell-shaped curves were obtained in both cases. These results are consistent with the observations of Nihei and Tonomura (2), who found that in buffered solutions containing 0.08 M THAM–maleate under two different ionic strength conditions, $\bar{K}_m$ hardly changed in the range of pH between pH 6.7 and 8.0 but increased with decreasing pH below 6.7. The ionization constants were calculated from these data by the method developed by Massey and Alberty (6). One assumes that the top part of the curve down to a point 0.3 $p\bar{K}_m$ units below the maximum is unaffected by any complication, and can be described by two ionization constants. Plots of $\bar{K}_m$ as a function of hydrogen ion concentrations or reciprocal of hydrogen ion concentrations, Figs. 5 and 6, gave approximately the same results, which have been tabulated in Table I.

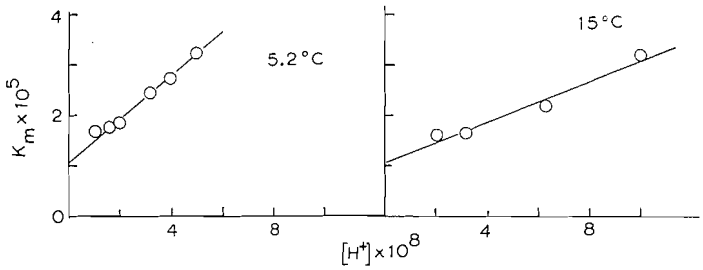

FIG. 5. Plots of $\bar{K}_m$ as a function of the hydrogen ion concentration.

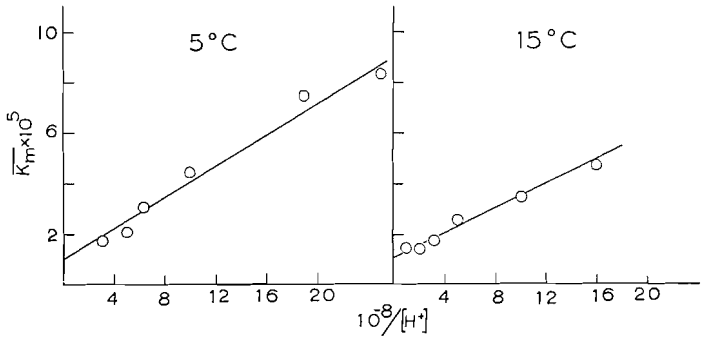

FIG. 6. Plots of K_m as a function of the reciprocal of hydrogen ion concentration.

TABLE I

pK_a and pK_b values for the active center of myosin at 15.1 and 5.2° C

	Temperature	pK_a	pK_b
Alberty and Massey's equation	5.2	8.60	7.60
	15.1	8.60	7.34
$\bar{K}_m$ vs. $[H^+]$ or $1/[H^+]$	5.2	8.53	7.60
	15.1	8.62	7.34

The two methods give similar values and an inspection of Fig. 4 indicates that these pK's correspond to pH where there are definite changes in direction in the $p\bar{K}_m$–pH curves (5).

The apparent heat of ionization of the group identified by pK_b is about 9 kcal/mole while that of the group identified by pK_a is close to zero with an indication that it might be an exothermic quantity.

The data represented in Figs. 5 and 6 show that the value of the pH-independent Michaelis constant is the same at 5.2 and 15.1° C at 1.05×10^{-5} mole/liter. This would suggest that the formation of the myosin–ATP complex is athermic, and is accompanied by an increase in entropy of about 23 e.u.

At high pH, the curves of $p\bar{K}_m$ vs. pH level off. Normally, this would be interpreted as a contribution of an ionizable group in the complex to the function representing $\bar{K}_m$. Such a function does not appear in the rate at high substrate concentration (Fig. 2), as there is no indication of a leveling of the curve. The experiments could not be carried to higher pH because of myosin inactivation (9).

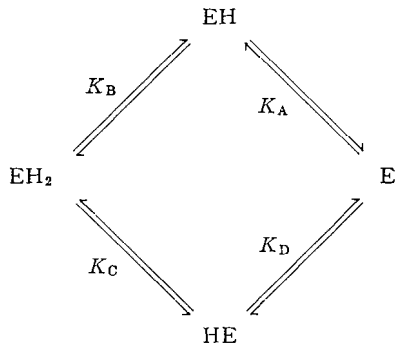
DISCUSSION

The data presented in this paper do not follow the pattern expected from a simple system like the one suggested in the description of the data. No really satisfactory explanation has been given for the minimum in the rate-vs.-pH curve (Fig. 2). Two possibilities will be mentioned here.

The description of the rate as a function of pH can be handled by assuming several complexes like EH_2S, EHS, ES, all yielding products. From a purely formal point of view, one can easily show that $\bar{K}_m$ is still described by equation [3]. On the other hand $\bar{V}_m$ can be described accurately, if one uses three complexes. One can criticize that hypothesis from two different points of view. First, it is evident that the inclusion of a sufficient number of constants will allow a good description of the data. The constants used, in our opinion, cannot be interpreted to give any information on the process. Second, the hypothesis implies several mechanisms in parallel for the transformation of one substrate into given products by one enzyme. So the hypothesis should not be considered, except as an explanation available if no other one is justified.

One may rather assume that the active complex is unique (e.g. EHS) and that the odd behavior of $\bar{V}_m$ as a function of pH is due to the influence of other factors, probably the electrostatic charge. It can certainly be argued that the presence of a negative ion such as ATP in the active center can reduce considerably the tendency of hydrogen ion to leave the protein molecule. This could move pK_B from about 7.3 in the enzyme, to values higher than 10 in the enzyme–substrate complex and inactivation becomes important before it can be determined. The fact that the rate of the hydrolytic reaction does not vary with the pH could then be explained by the variation of the ionization constant K_B with pH. As will be seen later, such an explanation assumes that the charge of the complex varies with pH. No data are available on that particular point.

Other hypotheses, such as acid–base catalysis of the hydrolysis of the complex, have been considered. In all cases it appeared impossible to obtain information on the ionizing groups in the active center from the rate at high substrate concentration.



According to Dixon (5), concave bends in the $p\bar{K}_m$-vs.-pH plots are due to ionizing groups of either the enzyme or the free substrate. Investigations on the calcium activation of ATPase (15) suggest that the substrate of ATPase is the calcium salt of adenosine triphosphate, $ATPCa^{-2}$, for which Smith and Alberty (16) have reported a pK_a value of 5.3 at 0.2 ionic strength at 25° C. In the present experiments the pK appearing in the maxima of the $p\bar{K}_m$-vs.-pH graphs are all above 7 and are therefore too high to be due to the substrate in the form of $ATPCa^{-2}$. Nihei and Tonomura (2) have, however, interpreted their results on the pH-dependence of $\bar{K}_m$, which indicated a pK in the neighborhood of 6.8 at 25° C, by assuming that the "true" substrate is ATP^{-4} since, according to Smith and Alberty (16), this substance has a pK of 6.95 at 25° C and 0.2 ionic strength. The pK of ionization which we have estimated from Nihei and Tonomura's data at 25° C is not inconsistent with our data at 5 and 15° C, although using it in the calculations would give a heat of ionization of about 12 kcal/mole. However, Alberty *et al.* (17) report pK values for ATP^{-4} of 6.48 at 25° C and 6.50 at 38° C in 0.15 *M* sodium chloride, giving a negligible heat of ionization. It therefore seems that the interpretation given by Nihei and Tonomura is incorrect and that the substrate of ATPase is the calcium salt form of ATP. On this basis, we can conclude that the dissociation constants appearing in the maxima in the $p\bar{K}_m$-vs.-pH curves refer to the enzyme and not to the substrate.

The simplest description of the curve of $p\bar{K}_m$ vs. pH (Fig. 4) involves two ionization constants, K_a and K_b. As equation [3] contains ionization constants of the enzyme in the

numerator and ionization constants of the enzyme–substrate complex in the denominator, the possibility of a third group of the active center ionizing within the pH area considered is not eliminated. In order to describe the experimental data, with three groups, the third one with a pK around 9, one has only to assume that pK_b' is also about 9. This type of evidence cannot be used to show the existence of three ionizable groups in the active center, but it shows that our data are not sufficient to eliminate the possibility that three, maybe more, acid groups participate in the catalyzed reaction.

Alternate Dissociation Paths

In the presence of two acid groups, there are two ionization paths, as suggested by Alberty (18).

If K_a and K_b are experimental constants, they are related to the true constants by:

$$1/K_a = 1/K_A + 1/K_D \quad [5]$$

$$K_b = K_B + K_C. \quad [6]$$

In the simplest case of no interaction between the acid groups, i.e. if $K_A = K_C$ and $K_B = K_D$

$$K_{A \text{ or } B} = \frac{K_b \pm \sqrt{(K_b^2 - 4K_bK_a)}}{2}. \quad [7]$$

This equation imposes a minimum value of 4 to the ratio K_b/K_a, giving identical true ionization constants, $K_A = K_B$. This case has been reported by Alberty (18) in the fumarase case where, in acetate buffer, pK's of 5.9 and 6.5 are found.

If the ionization of one group does not affect the ionization of the other group, equation [7] gives at 5.2° C pK_B = 7.65 and pK_A = 8.55, while at 15° C pK_B = 7.37 and pK_A = 8.57. The correction on the pK is, however, within the limits of the experimental error and the hypothesis of no interaction possibly renders it insignificant. The important conclusion to be drawn from consideration of the alternate paths is that the actual nature of the ionized group is not known, that is, the one with a low pK could be unionized and the one with a high pK ionized in the most "stable" complex.

Electrostatic Effects

The influence of the electric charge of the molecule on the ionization process is much more important than the effects discussed above.

The two groups ionizing in the active center could be identical, if they are close so that the electrostatic charge developed on the ionized group reduces the tendency of the

second one to lose a proton. Differences of 1 and 1.3 are observed between the pK of symmetric dicarboxylic acids such as glutaric and succinic acids (19). In the case of myosin, it could be argued that a distance of about 7 Å between protons, based on the distance calculated from electrostatic effects in glutaric acid (19), is a reasonable quantity. However, the fact that the two groups have different heats of ionization, or that the difference between the pK of ionization varies with temperature, would suggest that the groups are of a different nature.

In order to estimate the influence of the electrostatic charge the following data on myosin are to be considered. According to Mihalyi (20), myosin has an isoionic point of about 5.75 in potassium chloride. At 15° C the molecule has lost 33 hydrogen ions on the average at pH 8.6 while at 5° C it has lost 30.5 hydrogen ions at the same pH. At pH 7.6, at 5° C, it has lost 25.2 protons and 24.5 at pH 7.35 at 15° C. All these data are reported to a weight of 10^5 grams of protein.

On the other hand, Lewis and Saroff (21) have found that most of the hydrogen ions are replaced by potassium ions at concentrations higher than 0.1 M of potassium chloride. The protein is, under these conditions, negatively charged if the pH is higher than about 5.8 (19, 21). In the presence of calcium chloride, electrophoresis experiments show that the protein is positively charged at pH 8.7 in 0.06 M calcium chloride (22). Under our conditions 0.01 M calcium chloride, 0.4 M potassium chloride, the charge on myosin is probably small, although it could be either positive or negative.

A semiquantitative treatment of the influence of the electrostatic charge Z on the ionization constant of an acid group on a protein is given by Scatchard (23).

[8] $$pK = pK_0 - 2wZ/2.3,$$

where w is given by

$$w = \frac{e^2}{2DkT}\left(\frac{1}{b} - \frac{\kappa}{1+\kappa a}\right).$$

The expression for w involves e the electronic charge, D the dielectric constant of the medium, k the Boltzman constant, T the absolute temperature, b the radius of the protein molecule assumed to be a sphere, and $\kappa/(1 + \kappa a)$ is a Debye–Hückel term including ionic strength effects. The quantity pK_0 is the pK at charge zero.

In the case of myosin, the correction is probably small, as the charge is small.

However, this effect explains the low value of the apparent heat of ionization for the group with a pK of 8.6. Myosin has a large number of ϵ amino residues with a heat of ionization of about 11 kcal/mole, and a pK around 10 at 25° C (24). At pH 8.6 these groups contribute to the charge of the proteins. If the temperature is raised 10° C the pK of a lysyl ϵ amino group is lowered by about 0.3 pK units, making the protein molecule more negative, at pH 8.6. If a group in the active center, with a pK at 8.6, has a heat of ionization of 6 to 7 kcal/mole, its pK is displaced by 0.15 to 0.18 pK unit for the same rise in temperature. But at the pH equal to the new pK, the charge of the protein is more negative, increasing the pK of ionization, following equation [8]. In the case of myosin, it appears that the lowering of the pK of ionization due to rise in temperature from 5 to 15° C is compensated by an increase in negative charge (or decrease in positive charge) due to ionization of ϵ amino groups.

The above interpretation requires that the heat of ionization of the group with a pK at 8.6 be smaller than that of ϵ amino groups. A value of 6 to 7 kcal/mole would be reasonable. The fact that the mobility of the protein is small in electrophoresis experiments would indicate a small charge on the enzyme and, probably, a small variation of

Z with pH in the region of pH 8.6. At pH 10, the increase in negative charge could be sufficient to eliminate the influence of pH on $p\bar{K}_m$, as the pK of ionization could well increase as fast as the pH. Erdös (24) has reported that in the presence of 0.1 M calcium chloride the electrophoretic mobility of myosin becomes suddenly negative as the pH is increased above 9.3 at an unspecified temperature.

Around pH 7.3, at 15° C, carboxylate groups affect the charge and the same effect probably contributes a rise in the heat of ionization. According to Mihalyi (20), the average heat of ionization of groups in myosin at pH 7.5 at 10° C, is very slightly above 5 kcal/mole, that is, lower than the value for histidyl (24) or sulphydryl (26) residues. Then, as the temperature is increased, the charge would have a tendency to become more positive as the pK is lowered, increasing the apparent temperature effect. This would lead to a true heat of ionization somewhat smaller than 9 kcal/mole for the group with a pK of 7.34 at 15° C.

Group in the Active Center

The suggestions on the nature of the groups in the active center of myosin will use the following conclusions. The first ionizable group has a pK of 7.34 at 15° C (7.1 at 25° C) and a heat of ionization smaller than 9 kcal/mole. As the charge on the protein is probably small, this value would be close to pK_0. Such values could well be attributed to the imidazole group of histidine, which has a pK_0 of ionization of 7.0 and a heat of ionization of 7 kcal/mole at 25° C (23).

The second group, with a pK of 8.6 and a heat of ionization significantly lower than 11 kcal/mole, would be attributed to a sulphydryl residue of cysteine. In cysteine itself, the pK of ionization of the —SH group is 8.5 for the species carrying no net charge (26). The heat of ionization of the —SH group of thioglycolic acid has been given as 7 kcal/mole (26). This identification would take into account the fact that *p*-chloromercuribenzoate, one of the best —SH inhibitors, inhibits myosin ATPase activity (27, 3) and that cysteine has been separated recently from the active center of myosin (28).

Suggestion of a Mechanism

Taking into account the fact that the substrate at very high concentration inhibits myosin, the above two groups, and a mechanism recently proposed by Krupka and Laidler (29) for the action of cholinesterase, we would like to suggest the following mechanism. ATP is bound in a regular Michaelis complex to an imidazole group and an unionized sulphydryl group of myosin. In the following step, the unionized SH group of myosin is phosphorylated to give enzyme $-S-PO_3^=$. This intermediate is then hydrolyzed with the participation of the imidazole group. This step is required to take substrate inhibition into account together with the large increase in pK_b observed when the substrate is attached to the enzyme. The hydrolysis of enzyme $-S-PO_3^=$ intermediate would be rate limiting.

CONCLUSION

The influence of hydrogen ion concentration on the rate of hydrolysis of ATP in the presence of myosin suggests that the active center of the enzyme is made of at least one imidazole and one sulphydryl group. A two-step mechanism similar to that proposed for the enzyme cholinesterase would explain the experimental results presented.

THE EFFECT OF INITIAL ACID CONCENTRATION ON THE LIGNIN ISOLATED BY THE ACIDOLYSIS OF ASPEN WOOD[1]

J. M. Pepper and M. Siddiqueullah[2]

ABSTRACT

A further study has been made of the isolation, by acidolysis, of lignin from aspen wood meal (*Populus tremuloides* Michx.) using a dioxane–water (9:1) solvent medium containing hydrogen chloride and a low extraction temperature of 87±2° for a short extraction time of 0.5 hour. Lignins so isolated included those: (*a*) under different initial acid concentrations of 0.0, 0.05, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.8, and 1.7 equivalents of HCl/liter of solvent medium; (*b*) from successive extractions under increasing initial acid concentrations of 0.2, 0.4, 0.8, and 1.6 equivalents/liter; and (*c*) from successive extractions under constant initial acid concentrations of 0.2 equivalent/liter.

All the lignin fractions so isolated were studied with respect to their yield, methoxyl content, infrared absorption spectra, and the yields of vanillin and syringaldehyde obtained from them by oxidation using alkaline nitrobenzene.

Evidence is presented in support of the non-homogeneity of the whole protolignin. This may be the result of the presence of possibly two basic types. One fraction, comprising around 70–85%, is most readily extracted, has a consistently high methoxyl content (ca. 21%), and is capable of being oxidized to give high yields of syringaldehyde and vanillin in a ratio close to 2.5:1. The second fraction is characterized by a greater difficulty of extraction, lower methoxyl content, and significantly lower yields of the aldehydes in a ratio closer to 1:1.

In a previous communication, Pepper, Baylis, and Adler (1) reported a study of the effect of extraction time on the isolation and properties of the lignin fraction obtained by the acidolysis of spruce and aspen wood meals. The extractions were carried out under reflux for periods ranging from 0.5 to 48 hours using a constant initial hydrochloric acid concentration, namely 0.2 *N* with respect to the dioxane–water (9:1) solvent medium. As the time of extraction was increased, the yields of the isolated lignin fractions also increased, but the yields of phenolic aldehydes (vanillin from spruce or a mixture of vanillin and syringaldehyde from aspen) obtained from them by alkaline nitrobenzene oxidation gradually decreased. It was also shown that with increasing time of acidolysis of the aspen wood, a rise in the carbon-methyl to methoxyl ratio was observed for the isolated lignins. A similar finding had been made earlier for spruce lignin isolated under the same conditions (2). As a result of these studies, it was suggested that such a lignin fraction isolated under conditions of 1-hour extraction with the 0.2 *N* acid solvent may be only mildly modified during extraction and hence suitable for subsequent chemical investigation.

This report deals with a study of the effect of the initial acid concentration on the yield and nature of the lignin isolated by a similar acidolysis of aspen wood.

An extraction time of 0.5 hour was chosen and all extractions were effected at 87±2°, which represented a simmering state for all media. The lignin fractions so isolated are named by means of their association with the initial acid strengths of the solvent media, which were 0.0 *N*, 0.05 *N*, 0.1 *N*, 0.2 *N*, 0.4 *N*, 0.5 *N*, 0.6 *N*, 0.8 *N*, and 1.7 *N* expressed as equivalents of dry hydrogen chloride per liter of solvent medium. The yields of the lignins so isolated by this acidolysis procedure are given in Table I.

‡Media of concentrations of 0.4 and higher were two-phase systems at room temperature.

These results indicate that approximately 70–75% of the lignin is comparatively easily recoverable at lower acid concentrations, but that the isolation of the remainder requires higher initial acid concentrations. To study further the behavior of isolation of the lignin, extraction experiments were carried out along the following two lines: (1) lignin was isolated from the same wood meal by successive extractions under increasing initial acid concentrations (see Table II), and (2) lignin was isolated from the same wood meal by successive extractions under constant initial acid concentrations (see Table III).

TABLE II

Lignin isolation by successive extractions under increasing initial acid concentrations*

Initial HCl (N)	Isolated lignin	Recovery† (%)	Combined recovery† (%)

General Description of Isolated Lignins

It was quite evident that as the conditions of isolation became more drastic the isolated lignin fractions showed progressive deterioration of color, ranging from a light tan-colored, 0.2 N lignin to a dark brown, 1.7 N lignin. The explanation of this change is not clear, but there is good evidence that under increasing initial conditions of acidity

For personal use only.

a dark-colored material is isolated, in increasing amounts, which may be of rather different chemical composition* to the major lignin fraction (3). It is very probable that this change is caused by increasing condensation of the lignin.

A similar color change had been noted in the lignins isolated under similar acidolysis conditions with increasing time of extraction, and also in those lignin samples which were isolated originally by a 1-hour extraction and subsequently treated under similar conditions for varying times (1). This color change is not associated with any significant loss of methoxyl, but the conclusion that either some structural change is occurring or that lignin fractions having different structures are being isolated is borne out by the steadily decreasing yields of vanillin and syringaldehyde that are obtained by the alkaline nitrobenzene oxidation of these lignins.

Using approximately two milligrams of sample per 4 milliliters of solvent as a criterion of solubility, all the isolated lignins were found to be soluble in dioxane, glacial acetic acid, 80% ethanol, 80% methanol, and 80% acetone but insoluble in carbon tetrachloride, chloroform, acetone, ethanol, methanol, carbon disulphide, acetonitrile, and nitromethane. The various lignin samples were tested using the color reaction reported by Gierer (4) involving the coupling with quinone monochloroimide. An intense green-blue coloration, indicative of the presence of the *p*-hydroxybenzyl alcohol grouping, was obtained in all cases except for the 1.7 *N* lignin, lignin C, and lignin D. For these samples the test was very weak, or, if positive, was masked by the reddish-brown coloration of the original solution.

From the results of these isolation studies some conclusions may be drawn regarding the nature of the protolignin in the wood. From Table III, it is apparent that with successive extractions of wood meal using constant initial acid concentrations, the yields of recovered lignin decreased until on the fourth extraction only 1.2% of the original lignin was so recovered. It may be argued that if the protolignin were homogeneous, both with respect to its chemical structure and linkage to other cell components, and if no change were being effected under the conditions of isolation, a much more equal recovery by each extraction would have been expected. For aspen wood it may be that about seventy-five per cent of the total lignin is comparatively easily recoverable (see Tables I and III) but that the remaining part requires more drastic conditions for isolation. It is known that lignin is located both in the middle lamella and in other layers of the cell wall. According to Ritter (5) about seventy-five per cent is associated with the middle lamella and twenty-five per cent elsewhere. Even though this latter figure may be appreciably high, it is quite reasonable that the more easily isolated part, as obtained in these extraction experiments, may be the middle lamella lignin whilst the cell-wall lignins, if they are more intimately linked with carbohydrate, require the more drastic conditions for isolation.

All the isolated lignins described in Tables I, II, and III were analyzed for their methoxyl content and some representative samples were analyzed for carbon and hydrogen. These results are given in Table IV.

These few carbon and hydrogen analyses are sufficient to indicate that as the conditions of isolation become increasingly more drastic, the isolated lignins have increasing percentages of carbon and lower percentages of hydrogen. This is most simply explained by an increasing extent of an inter- or intra-molecular dehydration, but may in part

**It may be significant that these products had a methoxyl content ranging from 9.7 to 10.6%, which is half of that reported for the isolated lignins.*

be due to the extraction of increasing amounts of a second lignin-like component having a higher carbon percentage.

The consistently high methoxyl content (av. 20.7%) obtained for all lignins except 1.7 *N* lignin, lignin C, and lignin D is in general agreement with the values of 19.8 and 21.5% methoxyl reported for native aspen lignin (6) and milled wood aspen lignin (7) respectively, both of which are considered to be representative lignins. It must be realized that the methoxyl content alone serves only to show that other non-lignin components are absent and is not necessarily a good criterion of the unchanged quality of the lignin. For example Klason aspen lignin, although drastically modified chemically as shown by the only trace amounts of vanillin and syringaldehyde obtainable by alkaline nitrobenzene oxidation, has a methoxyl content of 21.4%. The significantly lower methoxyl content of the 1.7 *N* lignin and lignins C and D may best be explained by the presence of either non-lignin (carbohydrate) residues carried by the lignin through chemical bondage or lower methoxyl-containing lignins such as those mentioned earlier. If this is so then the ability to isolate at least seventy-five per cent of the protolignin with a constant methoxyl content supports the belief that the major part of the lignin is of a higher methoxyl content than the remainder. This distinction may be related to the observation discussed earlier concerning the ease of isolation from which a similar conclusion was drawn.

From a survey of recent studies (8, 9, 10) it would appear that the major infrared investigations on lignin have been carried out to evaluate lignins obtained from the same species by different processes or from different species by the same process. No detailed spectroscopic investigation has been conducted for a study of the lignin fractions obtained from a particular species using the same general extraction procedure but under a variety of conditions. This would permit of a better understanding of the changes taking place in the same lignin substance as a result of the controlled changes in reaction conditions. Once the nature of the major functional groups present and the changes undergone by them are known, a clearer interpretation with respect to the structure of the lignin molecule may be made.

With this general objective, the infrared absorption spectra were determined on all the isolated lignins described in Tables I, II, and III, as well as those described previously (1), which had been isolated from aspen wood at constant initial acid concentrations (0.2 *N*) under increasing times of reactions from 0.5 hour through 48 hours. For purposes of comparison, spectra were also obtained on both aspen and spruce Klason lignins. Since

For personal use only.

the spectra were determined on a qualitative basis only, minor variations, slight lessening or strengthening in the intensity of peaks, were not considered since they could arise due to the variation in the concentration of the sample. In their general nature all spectra for the hardwood (aspen) lignins were basically similar but were distinctly different from the spectrum of a typical softwood (spruce) lignin. This is in agreement with their known chemical differences and therefore adds support to the belief that an interpretation of such spectra may reveal chemical changes taking place in the lignin substance as a result of any series of studies on the effect of various chemical treatments such as those described in this investigation.

The sharpness of the strong, characteristic, aromatic ring vibrations absorption bands near 1600 cm^{-1} and 1500 cm^{-1} progressively decreased as the conditions of lignin isolation became more severe, until for the 48-hour lignin and for the aspen Klason lignin the bands had become distinctly broad. This indicates that a significant change is occurring involving the substitution pattern associated with the aromatic nuclei and is in agreement with the analytical data already discussed and with the decreasing yields of phenolic aldehydes obtained by alkaline nitrobenzene oxidation to be discussed later. A similar conclusion could be drawn regarding the observed progressive lessening in intensity of the 1225–1235 cm^{-1} band attributed to the aryl C—O (phenolic) stretching mode (10), indicative of some condensation involving phenolic hydroxyl groups.

The significant differences between the aspen and spruce infrared spectra are associated principally with the carbonyl band and the aromatic substitution pattern. For the spruce lignin a weak, broad band at 1660–1670 cm^{-1} was present but absent in all the aspen lignins, whilst the 1710–1725 cm^{-1} band was distinctly stronger for spruce than for aspen. These two bands have been associated with carbonyl groupings, the first according to Herger (10) being, "a ketone carbonyl alpha to an aromatic ring, with the *para*-position etherified and with an oxygen atom (as a hydroxyl group or etherified) in the two-position" and the second, a non-conjugated carbonyl group. Distinct, weak bands occurred in the spruce lignin spectrum at 855 cm^{-1} and 810–820 cm^{-1} and are characteristic of the guaiacyl nucleus and due to the monohydrogen and two adjacent ring hydrogen out-of-plane deformations respectively. For the aspen lignin, which contains both the syringyl (with only a monohydrogen deformation possible) and the guaiacyl nuclei, it is not surprising that only a weak, broad band at 830–850 cm^{-1} appeared as a result of a combination of the two types of nuclei.

All the isolated lignins recorded in Tables I, II, and III were oxidized using alkaline nitrobenzene and the yields of vanillin and syringaldehyde are recorded in Table V. The quantitative analytical procedure of Stone and Blundell (11) was used. It has been reported previously that the possible interference of acetovanillone and acetosyringone in the chromatographic procedure did not exist due to the absence of these compounds in the products obtained at 180° (12). No *p*-hydroxybenzaldehyde was detected in the lignin oxidation products.

Further evidence is hereby presented for the marked decrease in the percentage recoveries of both vanillin and syringaldehyde obtained by the oxidation of wood meal and calculated on the basis of the Klason lignin content. Some possible explanations of this observation have been discussed (13) but none is entirely satisfactory. Experimental evidence does support the belief that protolignin itself, or that lignin substance formed at the moment of liberation from its close association, either physical or chemical, with other cell-wall constituents, is very reactive and rapidly undergoes side-chain rearrangements and/or intramolecular condensations. The ease of such rearrangements in isolated

lignins whereby C-methyl groups are produced has been reported (1, 2). Such changes can be envisioned to destroy, at least in part, the linkages which give rise to the aldehydic group on oxidation. On the other hand, the rather consistent yields of both vanillin and syringaldehyde (Table V) obtained from those lignins isolated under increasing strengths of initial acid concentrations, at least up to until about seventy per cent of the lignin has been removed, suggest that, in the protolignin, two different structural units are present. Both such linkages may be cleaved to yield the phenolic aldehydes under the conditions of alkaline nitrobenzene oxidation but only one is destroyed by the more common processes of lignin isolation. Support for this suggestion is found in the decreasing yields of the phenolic aldehydes obtained from the 0.6 *N*, 0.8 *N*, and 1.7 *N* lignins and even more definitely in the yields obtained from lignins B, C, and D isolated by successive extractions under increasing initial acid concentrations (Table II).

Of equal interest and structural significance are the molar ratios of syringaldehyde to vanillin reported in Table V. For those fractions representing a total recovery of lignin of 80–85% (previously suggested as the middle lamella lignin) an average molar ratio of about 2.5 (2.1–2.7) is found; whereas for the remainder (previously suggested as cell-wall lignin) an average ratio of close to 1 is found. In a previous communication (1) the ratio of the yields of the phenolic aldehydes obtained by the oxidation of lignin samples isolated under increasing times of reaction using an initial acid concentration of 0.2 *N* have been reported. If these yields are calculated on a molar basis, similar ratios (2.0–2.6) to those found in this investigation are obtained. It was therein pointed out that it is difficult to correlate the average methoxyl content of approximately twenty-one per cent of at least the major part of the isolated lignin with this molar ratio of syringaldehyde to vanillin obtained by oxidation of these same lignins. On the basis of the widely believed assumption that hardwood lignin is of a complex polyconiferyl alcohol – polysinapyl alcohol nature, a molar ratio of these two different nuclei of from 2:1 to 1:1, depending on the extent of side-chain oxidation, would be required to analyze for about twenty-one per cent methoxyl. This is in direct contrast to the actual ratio of the phenolic aldehydes produced by oxidation. It may be that as a result of the chemical reactions occurring

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

during isolation, a greater proportion of vanillin-yielding nuclei than syringaldehyde-yielding nuclei are destroyed. However, the consistency of these experimental observations suggests that these ratios are of real structural significance. An attempt to correlate some of these data will be made in a forthcoming publication.

EXPERIMENTAL

Pre-extracted (alcohol–benzene) aspen sapwood meal (*Populus tremuloides* Michx.) similar to that in the work reported by Pepper, Baylis, and Adler (1) was used. It was dried to constant weight over P_2O_5. Anal: Klason lignin, 18.2%; methoxyl, 5.13%.

All dioxane was purified according to Fieser (14). All water was purified and carefully freed of oxygen prior to use. Gaseous hydrogen chloride was used to prepare the extraction solvents, the strength of the acidic media being obtained by titration against standard carbonate-free sodium hydroxide. All dioxane–water systems were prepared on a 9:1 v/v basis.

Lignin Isolation under Different Initial Acid Concentrations

Pre-extracted, vacuum-dried aspen wood meal (25 g) was placed in a 1-liter, four-necked, round bottom Pyrex flask, fitted with a reflux condenser, nitrogen inlet, dropping funnel, thermometer, and a three-way stopcock to a water pump. The flask was then evacuated. A pressure of 10–15 mm of mercury was maintained in the flask for 15–20 minutes. Then the stopcock leading to the pump was closed and the solvent (500 ml) was added from the dropping funnel slowly with caution so that no air entered the flask. When about half of the solvent had been added, the pressure was restored by slowly introducing nitrogen. The remaining half of the solvent was added. The contents of the flask were gradually heated over a period of 15–20 minutes with stirring to 87±2°. This temperature was maintained for 30 minutes. A slow stream of nitrogen, at the rate of 80–100 bubbles/minute was maintained throughout the period of heating and subsequent cooling.

After the reaction mixture had cooled down to 35–40°, it was filtered under a stream of nitrogen. The wood residue was washed with neutral dioxane–water (9:1) until the washings were colorless. The filtrate and washings were combined.

This red-brown filtrate was neutralized with solid sodium bicarbonate with stirring. It was then concentrated to 30–40 ml by distillation under reduced pressure (10–15 cm) to yield a dark syrupy liquid. The concentrate containing the bicarbonate sludge was transferred to a separatory funnel fitted to a 1-liter suction flask containing 500 ml of a 1% Na_2SO_4 solution in oxygen-free water.

By applying suction to the flask a partial vacuum was maintained inside it. The concentrate along with the sludge was then allowed to drop slowly into the sodium sulphate solution which was kept vigorously stirred. After the whole concentrate had been added, the precipitated lignin was recovered by centrifugation. It was then washed several times with a large excess of oxygen-free water until the washings were free from inorganic salts. Finally it was dried, while still lying in the centrifuge tubes, under vacuum over phosphorus pentoxide. It was then transferred to a weighing bottle and weighed.

Following this general procedure, lignin was isolated at the different initial acid concentrations of the solvent of 0.0 *N*, 0.05 *N*, 0.1 *N*, 0.2 *N*, 0.4 *N*, 0.5 *N*, 0.6 *N*, 0.8 *N*, 1.7 *N*.

Lignin Isolated by Successive Extractions under Increasing Initial Acid Concentrations

Pre-extracted wood meal (25 g) was first extracted with 0.2 *N* solvent and the lignin was recovered according to the procedure described above. The wood residue left after the precipitated lignin had been washed with neutral dioxane–water (9:1) was transferred to the previously used reaction flask. Again suction was applied for about thirty minutes and then the 0.4 *N* solvent was added and the extraction of the lignin and its recovery was carried out as usual. The wood residues were successively extracted in a similar fashion with the 0.8 *N* solvent and the 1.6 *N* solvent.

Lignin Isolation by Successive Extractions under Constant Initial Acid Concentrations

Pre-extracted wood meal (25 g) was successively extracted four times in a fashion similar to that described immediately above. In this case the initial concentration of the solvent for each extraction was the same (0.2 *N*).

Analytical Procedures

The methoxyl analyses were determined using the procedure of Gran (15). The infrared spectra were obtained using a Perkin–Elmer Model 21 spectrophotometer with sodium chloride optics and Nujol mulls. The alkaline nitrobenzene oxidations and quantitative estimations of the phenolic aldehydes were conducted according to the procedure of Stone and Blundell (11) with the recent modifications of Pepper and Siddiqueullah (12).

THE FIVE-COMPONENT SYSTEM: LITHIUM–SODIUM–POTASSIUM–SULPHATE–CHLORIDE–WATER, AT 25° C[1]

A. N. CAMPBELL, E. M. KARTZMARK, AND H. M. HUTTON[2]

ABSTRACT

The system consisting of the ions Li_2^{++}, Na_2^{++}, K_2^{++}, $Cl_2^{=}$, $SO_4^{=}$, and water at 25° C has been investigated by the chemical analysis of the solutions and of the wet residues. In the solid model eight volumes were found where the following solid phases were in equilibrium with solution: $Li_2SO_4.H_2O$, K_2SO_4, $Na_2SO_4.10H_2O$, $K_3Na(SO_4)_2$, $KLiSO_4$, solid solution of Na_2SO_4 and Li_2SO_4, KCl, and NaCl. Anhydrous Na_2SO_4 was found to exist only as a surface in the solid diagram. Another volume, $LiCl.H_2O$, was not obtained experimentally owing to its close proximity to the LiCl corner of the diagram.

Five invariant points were discovered. No ternary salt was found to exist in the interior of the phase model at the temperature of this study, 25° C.

This paper marks the completion of a study of Campbell, Kartzmark, and their associates of the five-component system named in the title. Hitherto no such complete study has existed. Earlier papers (1) have dealt with the subsystems which had not previously been studied. All the component binary, ternary, and quaternary systems, including the reciprocal salt pairs, are now known at 25° C. There remained only the five-component system proper, represented graphically by the interior of the solid model.

EXPERIMENTAL PROCEDURE

Since the five quaternary subsystems were now completed and represented as the five surfaces (two triangular and three rectangular) of the Jänecke prism, the procedure adopted was to trace the paths of univariant curves from the corresponding quaternary invariant points on the outside surfaces till they met in quinquenary invariant points in the body of the diagram. This was accomplished experimentally by saturating with the phases of the quaternary invariant equilibrium, then adding increasing quantities of ions not participating in the quaternary equilibrium, and thus delineating the space curves. Since quinquenary invariant points mark the intersection of four curves (four solid phases), it was possible to check all these invariant points by approaching them along independent curves and this was always done. The experimental test for invariance was found in the sudden occurrence of a new ion in the solid phase, which was, of course, analyzed every time. The occurrence in large amount of a fresh ion is definitive, except for the change of sodium sulphate decahydrate to anhydrous sulphate, but here the change of water content was conclusive.

As an aid to clear thinking we constructed, while the experimental work was in progress, a solid model of stout wire, and suspended our analyzed points in the body of the model at the appropriate distances from the ends of the prism. In this way the direction of a line in space could be visualized.

As to the technique of solubility work, this has been too frequently described for mention here. Chloride ion was determined gravimetrically as silver chloride but the direct determination of sulphate ion as barium sulphate was avoided since we have found this to be completely inaccurate in the presence of alkali metal ions. Sulphate ion was determined solely by difference. Flame photometry was used to determine the alkali metal cations: our instrument was the Perkin–Elmer flame photometer. The accuracy of cation estimation was about two per cent but this is much better than can be attained by any other method of alkali determination in mixtures of alkali cations.

Since it is important to know the nature of the solid phases in contact with saturated solutions, it would be very desirable to have unequivocal methods of doing this but the usual methods, viz. X-ray powder photography or measurement of optical properties could not be applied because of the necessity of keeping the solid phase wet with equilibrium solution. If the solid phases are allowed to dry, phase change may occur, even at room temperature. Furthermore, the strongest X-ray reflections of sodium chloride and of sodium sulphate happen to be very close together, so that the X-ray method is less sensitive than usual. Consequently, we were forced to rest our determinations of the nature of solid phases entirely on the identification of the new phase which appeared at an invariant point. When a new ion suddenly appears, in quantity, in the solid phase, there is usually no question regarding the nature of the new phase. Moreover, the intersection of two or more solubility curves left little doubt about the nature of the four solid phases present at the invariant point.

EXPERIMENTAL RESULTS

The experimental results are given in Table I, which gives the mole% of each of Li_2^{++}, Na_2^{++}, K_2^{++}, $Cl_2^{=}$, and $SO_4^{=}$ in both the solid phase and the liquid phase, as well as m, the number of moles of water per "mole" of salt, and the nature of the solid phase.

Pictures of the equilibrium diagrams are shown in Fig. 1, with the invariant points marked as outlined in the caption. These are the solids in equilibrium with solution at 25° C. The photographs in Fig. 1 show the approximate positions of the quinquenary invariant points. To help differentiate the various lines in the prism, the quaternary lines on the surface are grey, while the quinquenary lines inside the prism are black. Picture (*a*) is shown with the K_2SO_4 corner nearest the right front; in picture (*b*) the NaCl corner is forward, presenting a view diagonally opposite to the first picture. Due to the difficulties in assembling this solder-and-wire diagram, the lines and invariant points are positioned only approximately. With the experimental data obtained, the invariants marked 2 and 4 in the photographs, Fig. 1, should be closer than indicated, actually almost touching.

One other invariant point, $LiCl.H_2O$, $Li_2SO_4.H_2O$, NaCl, KCl, in equilibrium with solution, exists in this system, but could not be obtained experimentally or even represented on this diagram. It is situated in the LiCl corner of the prism and theoretically is represented by the expanded diagram, Fig. 2.

The small volume which the lithium chloride salt occupies is the result of the powerful action of this chloride in displacing other salts from solution. This was expected from the data of the quaternary systems.

To illustrate the existence of the volumes indicating solution saturated with one salt, approximate cross sections at constant anion composition were drawn, using the three-dimensional wire model as a guide. The 16 diagrams are represented in Figs. 3–18.

Figure 3 is the sulphate end of the prism. In this system all the sulphates, $Li_2SO_4.H_2O$, K_2SO_4, and $Na_2SO_4.10H_2O$, are present with Na_2SO_4 anhydrous represented by the lines *ab*, and *ab'*. Only two addition compounds, $KLiSO_4$ and $K_3Na(SO_4)_2$, exist; at this temperature solid solution occurs between the lithium and sodium sulphates. Figures 4 and 5 show the change of the $Li_2SO_4.H_2O$, solid solution, and $Na_2SO_4.10H_2O$ areas. In Fig. 6, at the quinquenary invariant point (No. 5), where $K_3Na(SO_4)_2$, $KLiSO_4$, Na_2SO_4, $Na_2SO_4.10H_2O$ are the solids in excess in solution, another small wedge of solid solution appears: Na_2SO_4 anhydrous is still represented on the surface of the solid solution, that is *ab*, *ab'*, and *ab''*. Past this quinquenary invariant, in Fig. 7, $Na_2SO_4.10H_2O$

is still evident, with the anhydrous form existing on the base below the solid solution. Finally in Fig. 8 the decahydrate volume has vanished. In this interval the $KLiSO_4$–$K_3Na(SO_4)_2$ surface has been tilted upward at the $KLiSO_4 - K_3Na(SO_4)_2$ – solid solution line, as evident in Fig. 9. The first appearance of a chloride, NaCl, is observed in Fig. 10, its area increasing in Figs. 11 and 12, at the expense of the solid solution region. Figure 13

is drawn through the quaternary invariant point $Li_2SO_4.H_2O$, solid solution, NaCl in the lithium–sodium–chloride–sulphate–water system. Solid solution here is completely in the body of the diagram and in Fig. 14 it is quickly disappearing as another quinquenary invariant is approaching. Figure 14 also represents the quinquenary invariant (No. 1) $KLiSO_4$, $K_3Na(SO_4)_2$, K_2SO_4, KCl; KCl appears for the first time, but cannot

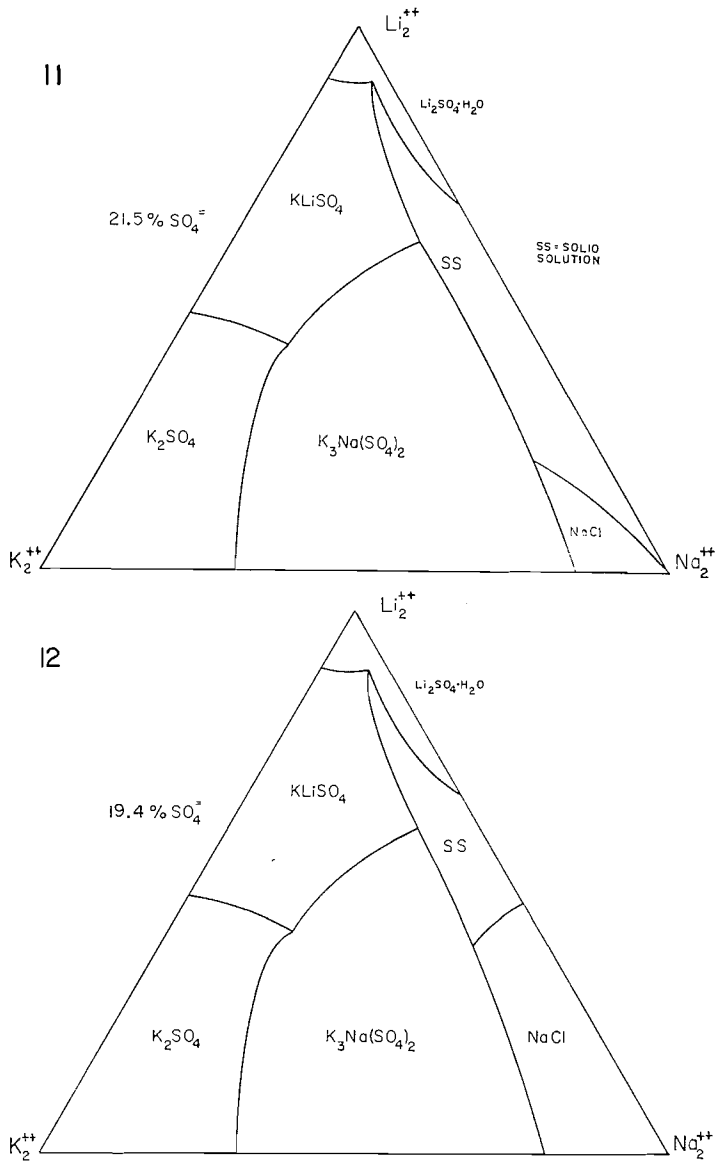
be represented since it is on the plane immediately behind Fig. 14. In Fig. 15, the invariant $K_3Na(SO_4)_2$, $KLiSO_4$, Li_2SO_4, $Li_2SO_4.H_2O$, NaCl (No. 4) has been reached, this being one extremity of solid solution, that is, lithium sulphate; K_2SO_4 has all but disappeared. This surface represents the last plane of existence of the double salts $KLiSO_4$ and $Na_3K(SO_4)_2$. Between Figs. 15 and 16, the $Li_2SO_4.H_2O$ – NaCl line has moved rapidly



FIGS. 9 AND 10.

upward. Two quinquenary invariants are evident in Fig. 16: the $Li_2SO_4.H_2O$, $KLiSO_4$, NaCl, KCl (No. 3) and $Na_3K(SO_4)_2$, $KLiSO_4$, NaCl, KCl (No. 2) invariants, although not all the salts can be represented. Figure 17 shows the existence of the chlorides of sodium and potassium and the sulphate of lithium. The last, Fig. 18, where only the chlorides are present, represents only the sodium and potassium chlorides. Lithium

EFFECT OF AMBIENT OXYGEN ON THE SEMICONDUCTIVITIES OF EVAPORATED FILMS OF MESONAPHTHODIANTHRENE AND MESONAPHTHODIANTHRONE[1]

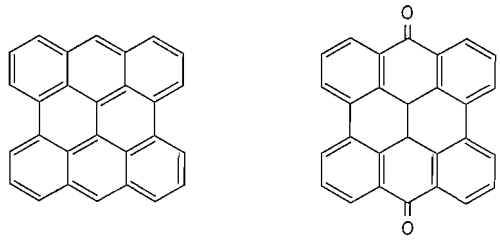
H. KURODA[2] AND E. A. FLOOD

ABSTRACT

The electrical conductivity of an "evaporated" film of mesonaphthodianthrene increases when the film is exposed to oxygen. The increase in conductivity is associated with changes in the semiconductivity activation energies. The activation energy for the oxygen-free anthrene (bulk conduction) is 0.74 ev while that associated with oxygen adsorption (surface conduction) is 0.40 ev. In marked contrast, the conductivity of an evaporated film of mesonaphthodianthrone decreases when exposed to oxygen. An oxygen-free film of the anthrone has different activation energies in different temperature regions, the activation energies being 0.73 ev and 0.43 ev in the higher and lower temperature regions, respectively. The conduction associated with the lower activation energy decreases when the film is exposed to oxygen.

The effect of oxygen on the semiconductivities of mesonaphthodianthrene and mesonaphthodianthrone are compared with the effect of oxygen on their electron spin resonance spectra.

INTRODUCTION



The adsorption of gas molecules on the surface of metals and semiconductors modifies the electrical properties associated with the surface (e.g. work function, contact potential, surface conductance, etc.) especially when the surface reaction involves an electron-transfer mechanism. While in the case of inorganic semiconductors there is a large body of scientific literature dealing with such effects, in the case of organic semiconductors comparatively few papers exist, in spite of the fact that adsorption on organic crystal surfaces can also involve electron-transfer mechanisms. Pick and Wissman observed that the electrical conductivity of a napthalene single crystal was affected markedly by ambient oxygen (1). The influence of ambient oxygen on the photoconductivity of the anthracene crystal has been studied by many investigators (2, 3, 4). The effect of oxygen on the photoconductivity of phthalocyanine is also known (5).

Recently Matsunaga found that a sharp absorption peak appeared in the electron spin resonance spectrum of mesonaphthodianthrene powder when it was exposed to air (6). This suggests that some kind of electron transfer is taking place between the hydrocarbon crystal and oxygen molecules adsorbed on the surface. It seemed, therefore, interesting to investigate the influence of ambient oxygen on the electrical conductivities of thin films formed by evaporation (evaporated films) of these compounds. A brief account of our findings on this subject has been presented in a previous note wherein it was pointed out that ambient oxygen does indeed exert an influence on the electrical conductivities of such films (7).

EXPERIMENTAL

Mesonaphthodianthrene (I) and mesonaphthodianthrone (II) were both purified by repeated sublimation in a high vacuum. Immediately after the final sublimation, a small amount of the powder of the sample was sealed in the conductivity apparatus,

which is schematically shown in Fig. 1. The powder of the sample was placed at the bottom of the small tube A. The cell was evacuated by means of a two-stage mercury diffusion pump together with two liquid nitrogen traps. The whole vacuum system except the region containing the sample was baked during the evacuation. The final vacuum attained after a long evacuation was 10^{-6} mm Hg. The sample was first evaporated to the upper part of the tube A and then re-evaporated from there to the flat surface B, which was equipped with two electrodes of platinum foil embedded in the glass as shown in Fig. 1. It was found necessary to carry out the sublimation rather

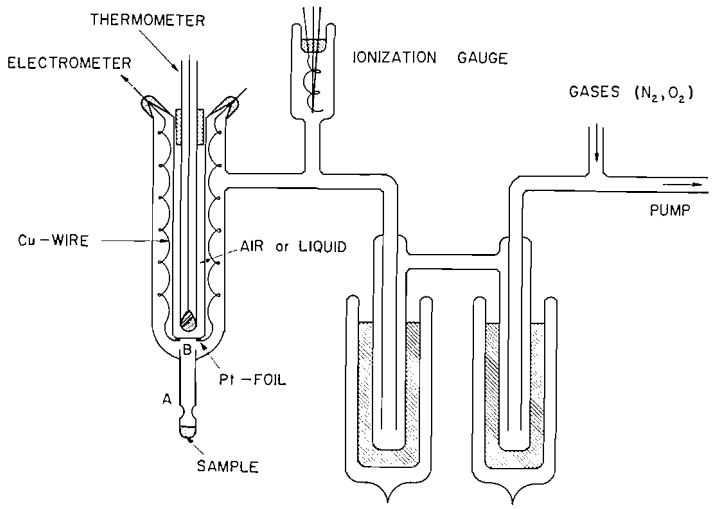

FIG. 1. The apparatus for the measurement of the conductivity.

slowly, in order to obtain a coherent film. The films so obtained were transparent and the order of 1 μ in thickness. The electrical conductivities of the oxygen-free films were studied immediately after the preparation of the films, without breaking the high vacuum.

Conductivity measurements were made using a d-c. method. Direct-current voltage of 135 v was applied between the two electrodes by means of dry cells. The distance between the two electrodes was 1–3 mm. The current through the film was measured with a Hewlett and Packerd DC Micro-volt-ammeter Model 425. The output of the electrometer was connected to a Varian G-10 recorder. The conductivity change was followed by the change in current.

RESULTS

(a) Mesonaphthodianthrene Film

The temperature dependence of the conductivity of a film of mesonaphthodianthrene is shown in Fig. 2. The current, i, through the film is plotted in logarithmic scale against $(1/T)$. In order to avoid any permanent change due to the evaporation of the compound from the film, the temperature of the measurement was not raised to more than 150° C when the measurement was made in vacuum. With an oxygen-free film a linear relation is obtained between log i and $(1/T)$. There is no appreciable deviation between the curve for the heating process and that for the cooling process.

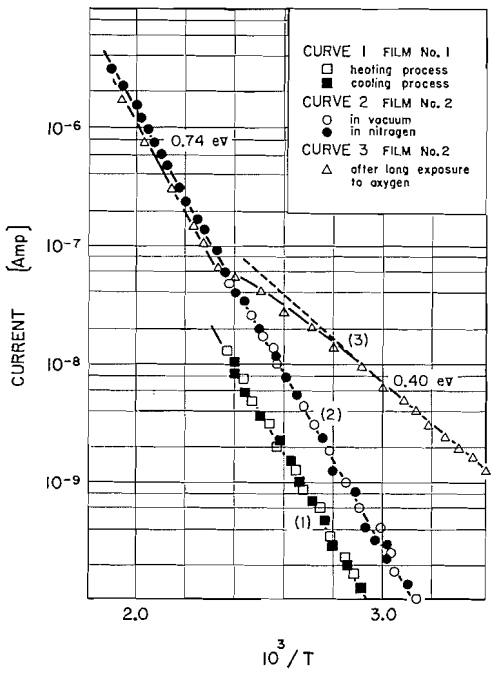

FIG. 2. Temperature dependence of the current through mesonaphthodianthrene films.

The temperature dependence of the conductivity in nitrogen was measured using the same film as that used previously for measurements in vacuum. The results are shown in Fig. 2, curve 2. The temperature range of the measurement was extended up to 250° C. The plot of log i vs. $(1/T)$ gives again a straight line, which coincides with the results measured in vacuum at temperatures below 150° C. This indicates that nitrogen does not influence the electrical conductivity of the film appreciably. The temperature dependence described above can be expressed by an exponential function as is usually found with semiconductors,

$$i = i_0 \exp(-E/kT) \quad [1]$$

where E is the activation energy for the semiconductivity. The value of E determined from the experimental results is 0.74 ev.

If an evaporated film of mesonaphthodianthrene is kept in oxygen or air for a long period, it shows quite a different behavior in respect to the temperature dependence of the electrical conductivity (cf. curve 3 of Fig. 2). In this case the slope of the log i vs. $(1/T)$ curve in the lower-temperature region differs distinctly from that in the higher-temperature region. The latter coincides exactly with the curve obtained in nitrogen.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The slope of the curve in the lower-temperature region corresponds to a smaller activation energy, 0.40 ev. At lower oxygen pressures the semiconductivity of the "anthrene" as a function of temperature shows considerable hysteresis due to adsorption–desorption effects.

If the evaporated film is placed in contact with oxygen at room temperature the conductivity increases gradually with time. The conductivity change at 24° C is shown in Fig. 3. This is a very slow process. The rate of the conductivity change is dependent upon

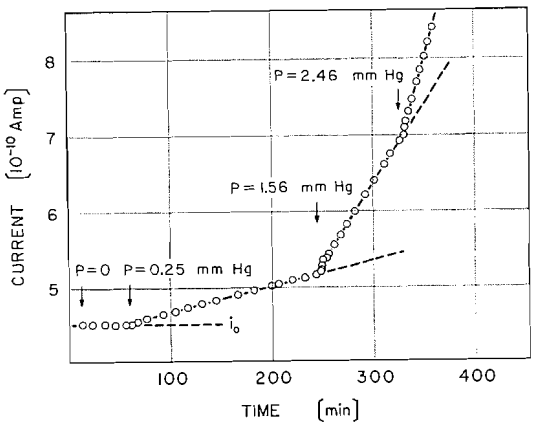

FIG. 3. Variation of the current through a mesonaphthodianthrene film in lower pressures of oxygen at 24° C.

the pressure of the ambient oxygen, being nearly proportional to the pressure when it is less than a few millimeters of mercury. This is illustrated in Fig. 4. If the pressure is high, the conductivity increases rapidly during a short initial period, after which the rate of increase falls off and the conductivity approaches constant values.

At a pressure about 100 mm Hg, the change in the conductivity practically ceases after a few days. When oxygen is pumped off, the conductivity of the film decreases slowly. This again is a very slow process. The change described above is evidently associated with the adsorption of oxygen molecules, and is reversible to a large extent.

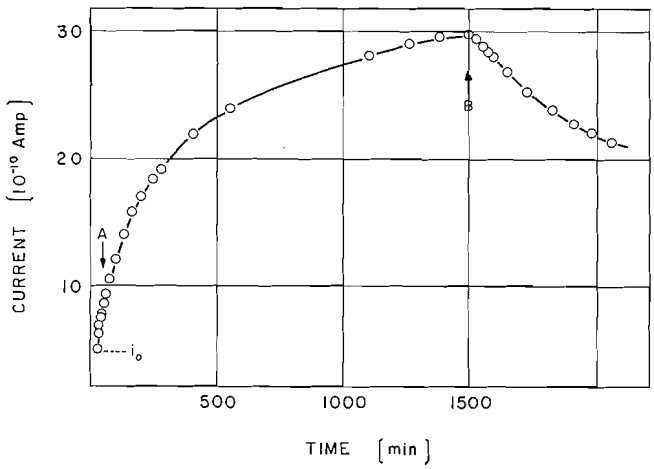

FIG. 4. Variation of the current through a mesonaphthodianthrene film in oxygen (10 mm Hg) at 24° C. The ambient oxygen is introduced into the cell at point A and pumped off at point B.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

The temperature dependence of the electrical conductivity was measured at different stages of the oxygen adsorption although some difficulties due to temperature adsorption–desorption effects were encountered. It was found that the rate of the conductivity increase associated with the oxygen adsorption, as well as that of the reverse change, is faster at higher temperatures. Accordingly, the measurements were made as quickly as possible at temperatures below 40° C, and reproducible results were obtained. The results are shown in Fig. 5 and indicate clearly that the conduction mechanism associated with the lower activation energy is the one which is created by oxygen adsorption. The log i vs. $(1/T)$ curve is not a straight line when the amount of adsorbed oxygen is small. The slope of the curve at the high-temperature end is almost equal to that of the oxygen-free film, and the slope at the low-temperature end corresponds to the activation energy of 0.40 ev. As the amount of oxygen adsorption increases, the region in which the activation energy is 0.40 ev becomes predominant at temperatures below 40° C.

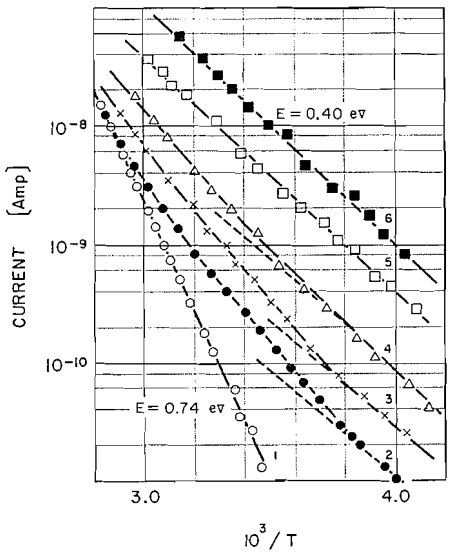

FIG. 5. Temperature dependence of the current through a mesonaphthodianthrene film which has been exposed to oxygen at various pressures for different lengths of time. (1) Oxygen-free state; (2) 1 mm Hg, ½ hr; (3) 3 mm Hg, ½ hr; (4) 10 mm Hg, ½ hr; (5) 50 mm Hg, 1 hr; (6) 300 mm Hg, 2 hr.

(b) Mesonaphthodianthrone Film

The temperature dependence of the conductivity of a mesonaphthodianthrone film is shown in Fig. 6. In marked contrast to the behavior of the mesonaphthodianthrene film, the activation energy of the oxygen-free film of mesonaphthodianthrone in the higher-temperature region differs distinctly from that in the lower-temperature region. In the latter region the activation energy is 0.43 ev while in the former it is 0.73 ev. Further if the film is exposed to air or oxygen the low-temperature activation energy of 0.43 ev disappears from the log i vs. $(1/T)$ curve, the activation energy becoming the same as at the higher temperature, i.e. it becomes 0.73 ev over the whole range thus resembling the oxygen-free anthrene.

The conductivity change due to ambient oxygen at 24° C is shown in Fig. 7 in which i_0 denotes the current in high vacuum; oxygen is introduced into the cell at point A and pumped off at point B. The conductivity of a mesonaphthodianthrone film decreases

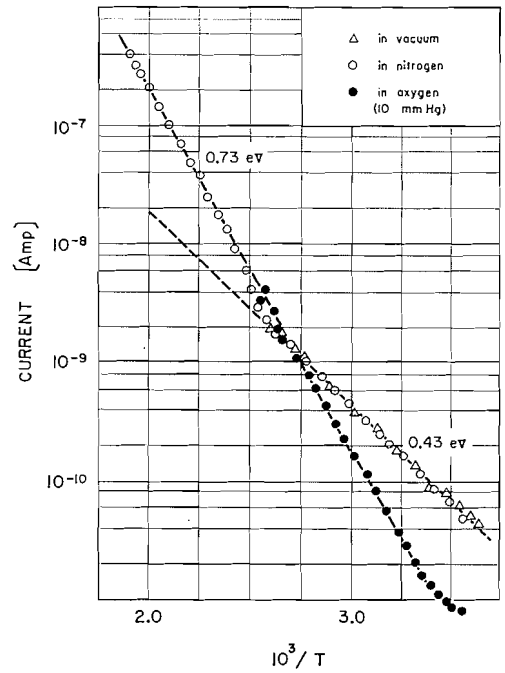

FIG. 6. Temperature dependence of the current through a mesonaphthodianthrone film.

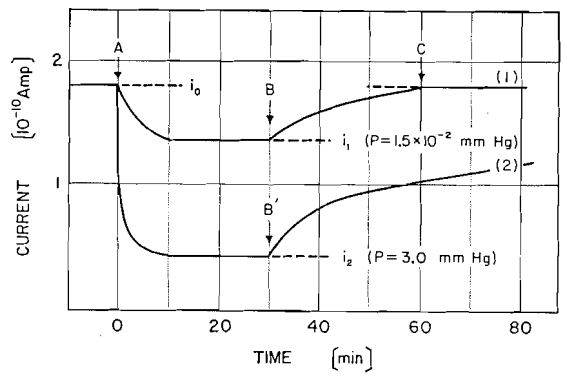

FIG. 7. Variation of the current through a mesonaphthodianthrone film caused by exposure to oxygen. Oxygen is introduced into the cell at point A and pumped off at point B (240° C).

rather rapidly when the film is exposed to oxygen, usually becoming constant within 10 minutes. As oxygen is pumped off the conductivity increases gradually with time, and goes back to the original value after evacuation during a long period. The magnitude of the conductivity at the equilibrium state is dependent upon the pressure of the ambient oxygen, as illustrated in Fig. 8 in which the current through a film with a constant applied potential difference is plotted against the pressure of oxygen.

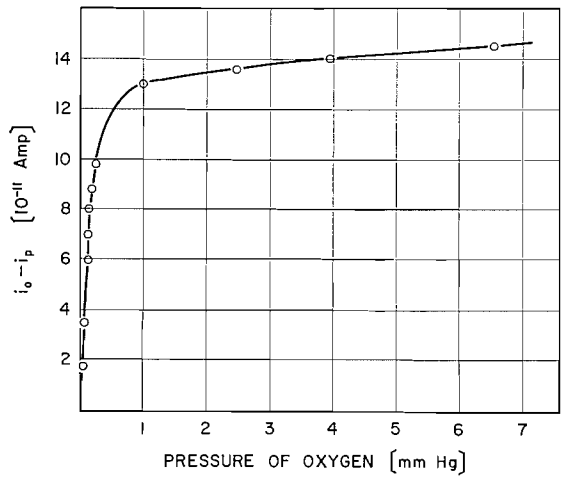

FIG. 8. Current through a mesonaphthodianthrone film at the equilibrium state in oxygen as a function of the oxygen pressure (24° C).

DISCUSSION

From the results described above it is evident that there are at least two mechanisms involved in the electrical conduction of mesonaphthodianthrene films as well as in the conduction of mesonaphthodianthrone films. One of them, in each case, is dependent upon the ambient oxygen while the other is independent. The oxygen-sensitive conduction is associated with a lower activation energy. It is known that the conductivity of the intrinsic semiconductor can be described by the following equation,

$$\sigma = \sigma_0 \exp(-\epsilon/2kT), \quad [2]$$

where σ_0 is a constant dependent upon the concentration of the electronic states and the mobility of the carrier, and ϵ is the energy gap in the band structure of the semiconductor. The semiconductivities of these compounds have been studied by Inokuchi using compressed-powder specimens (8). The energy gaps were estimated from the equation given above as 1.2 ev and 1.3 ev for mesonaphthodianthrene and mesonaphthodianthrone, respectively. Applying the same equation to our results the energy gaps corresponding to the two activation energies of the semiconductivity of mesonaphthodianthrene film are estimated as 1.48 ev and 0.80 ev, while those of the mesonaphthodianthrone film are 1.46 ev and 0.86 ev.

It is difficult to distinguish between bulk and surface conductivities where data refer to net conductivities of either compressed powders or to evaporated films, both of which may have fairly large surfaces. Surface effects might be expected to be particularly significant in the case of very thin evaporated films; of course surface states can control the semiconductivity. However, our results suggest that the activation energy, which is independent of the ambient oxygen, the higher activation energy, is associated with bulk conduction, i.e. independent of the surface.

The data given in Fig. 5, the temperature dependence of the electrical conductivity of mesonaphthodianthrene film in oxygen, can be described quite well by the following equation,

$$\sigma = \sigma_1 \exp(-E_1/kT) + \sigma_2 \exp(-E_2/kT), \quad [3]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where E_1 is 0.74 ev and E_2 is 0.40 ev. The value of σ_1 remains constant for all curves while σ_2 increases as the amount of oxygen adsorbed increases. The values of σ_1 and σ_2 are dependent upon the mobility of the charge carrier and the concentration of the electronic states, i.e. the concentration of the impurity levels in the case of extrinsic semiconduction. As is well known, the surface state can contribute to the electrical conductivity either by forming a surface band through which charge carriers can move, or by behaving as an impurity level which provides the charge carriers to the bulk conduction. It seems probable in the present case that the electron-acceptor levels are created by oxygen adsorption on the surface and that the increase in the magnitude of σ_2 is due to the increase in the concentration of such acceptor levels. According to this model, 0.80 ev is the energy gap between the acceptor level and the lower band.

According to Matsunaga (6), mesonaphthodianthrene powder shows an electron spin resonance spectrum with a fine structure consisting of at least seven peaks separated by 4.4 oersted when it is detected in vacuum. The spin concentration corresponding to this electron spin resonance is 3×10^{21} per mole, g-value being 2.0024. If the powder is exposed to air the central peak of the electron spin resonance spectrum grows slowly reaching the maximum intensity after a few days. The spin concentration corresponding to this sharp absorption is about one tenth of that of the broad absorption mentioned above. The intensity of the sharp absorption decreases with time when air is pumped off. This change is evidently due to the interaction between oxygen and mesonaphthodianthrene crystals. Matsunaga also studied the electron spin resonance of mesonaphthodianthrone powder. It gives an electron spin resonance spectrum similar to that of the hydrocarbon, its spin concentration being about one third of that of the latter. In this case, however, the oxygen effect was not detected.

It is interesting to compare the effect of oxygen on the electrical conductivity with that on the electron spin resonance. In the first place, both effects take place very slowly at room temperature, taking a few days to reach the equilibrium state in air, and both are reversible. In the second place, the creation of the acceptor level and that of the spin center are caused by the ambient oxygen only in the case of the hydrocarbon. These facts suggest that the impurity level created as a result of oxygen adsorption is associated with the formation of a free radical on the surface of the hydrocarbon crystal.

The change in the electrical conductivity of mesonaphthodianthrene film in oxygen is accelerated if the film is illuminated with visible light. Photooxidation is known to occur with anthracene, tetracene, and some other hydrocarbons when oxygen-containing solutions of these hydrocarbons are illuminated with ultraviolet light (9). The molecular structures of these photooxides are known, an oxygen molecule "bridging" two active positions of each hydrocarbon molecule. Since molecules are closely packed in the crystals of these hydrocarbons, it is hard for an oxygen molecule to penetrate into the crystal to form a photooxide. Thus photooxidation can not take place in the bulk of the crystal, as it is illuminated in the ambient oxygen. On the surface of the crystal, however, photooxidation can occur much more easily. The photoconductivity of anthracene increases remarkably in the presence of oxygen, and has been attributed to the formation of a peroxide layer on the surface of the anthracene crystal (2, 3, 4). A similar effect is expected with crystals of various aromatic hydrocarbons which have reactive positions for oxygen in the molecular structure. The two meso positions of the mesonaphthodianthrene molecule are generally considered to be strongly reactive toward oxygen. The photooxide of this hydrocarbon, however, has not been isolated from the solution illuminated with light (10). This might be due to the fact that the two reactive positions are too far apart

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

from each other for an oxygen molecule to "bridge" them without considerable strain, thus leading to a "photooxide" so unstable that it can not be isolated. However, this does not exclude the possibility of considerable photooxidation on the surface of the crystal since the photooxide could be stabilized by surface forces. It thus seems that the acceleration of the change in the electrical conductivity in oxygen, caused by the illumination with light, is due to photooxidation. We are not sure if this reaction product is a peroxide or not. Whatever the structure of the reaction product may be, the bond between the oxygen molecule and hydrocarbon molecule must be a loose one, since oxygen molecules can be liberated rather easily. Thus it seems probable that the reaction product is a molecular complex formed between an excited hydrocarbon molecule and an oxygen molecule.

A mesonaphthodianthrone molecule is not markedly reactive to oxygen, no oxygen effect having been detected by electron spin resonance. The presence of the oxygen-sensitive mechanism of conduction in the oxygen-free film of this quinone indicates that the surface state of the crystal of the quinone itself is making an important contribution to the electrical conduction. An oxygen molecule behaves generally as an electron acceptor. Thus, if the semiconductor is *p*-type, the conductivity would be expected to increase in oxygen. While we do not know the nature of the charge carrier in the semiconduction of this quinone, it appears possible that the conduction associated with the activation energy of 0.43 ev is due to a surface conduction in which the majority of carriers are electrons. While this would be consistent with our experimental results, evidently a good deal more experimental data are needed concerning the very interesting reaction of oxygen with the surfaces of quinones. Some interesting recent papers germane to these problems are listed in References (11, 12, 13, 14).

ACKNOWLEDGMENT

The authors wish to express their thanks to Dr. Y. Matsunaga for his valuable advice and discussion.

RADIOIODINE EXCHANGE BETWEEN IODOSTEARIC ACID MONOLAYERS AND SUBSTRATE IODIDE. III[1]

J. M. RAMARADHYA[2] AND R. F. ROBERTSON[3]

ABSTRACT

Further studies have been made of the isotopic exchange reaction between monolayers at the air/water interface of I^{131}-α-iodostearic acid and KI substrates. The dependence of the exchange velocity on substrate iodide ion concentration has been examined by employing KCl–KI mixtures of constant over-all molarity to minimize possible variations in film characteristics with substrate salt concentration. The order in substrate I^- ion concentration was found to be fractional at pH 2 and indeterminate at pH 3. The velocity of exchange at all KI concentrations was increased when KCl was added to the substrate. Surface potential measurements showed α-iodostearic acid to have a negative surface potential at high molecular areas which decreased to zero as the film was compressed. The apparent negativity of the surface potential increased as salt was added to the substrate. The surface potential was found to vary with the substrate pH, passing through a maximum between pH 2 and 3. The isotopic exchange velocity and the surface potential were found to be closely related. The variation of the surface potential with time during isotopic exchange has been examined both for monolayers and for collapsed films.

INTRODUCTION

The present investigation is an extension of earlier studies (1, 2) of the homogeneous isotopic exchange reaction

$$CH_3(CH_2)_{15}CHI^*COOH + KI \rightarrow CH_3(CH_2)_{15}CHICOOH + KI^*$$

occurring between I^{131}-labeled α-iodostearic acid, spread as a monolayer at the air/water interface, and iodide ion in the substrate.

In the earlier papers the temperature dependence of the reaction and the possible influence of film characteristics on the exchange rate were reported. The reaction was found to be first-order in surface concentration of film molecules but of indeterminate order in concentration of substrate KI. The impossibility of establishing the order of the exchange reaction in substrate concentration was attributed to changes in the film characteristics of α-iodostearic acid as the concentration of KI in the substrate was varied (1). The influence of pH on the exchange rate was also studied in detail (2). The rate was found to decrease almost 20-fold as the pH of the substrate was varied from 1 to 10 pH units. Between pH 2 and 3 the rate plot passed through a maximum.

In the present paper, further studies are reported on the influence of substrate iodide ion concentration on the exchange reaction, under conditions of constant film characteristics. The surface potential technique of Schulman and Rideal (3) has been employed to study α-iodostearic acid films on various substrates and I^{131}-α-iodostearic acid films during exchange.

EXPERIMENTAL PART

The trough, barriers, and radiochemical counting equipment employed have been described elsewhere (1, 2). The surface balance was the automatic, self-compensating, self-recording, vertical pull instrument described in another paper (4). The experimental

[1]*Manuscript received March 13, 1961.*
Contribution from the Department of Chemistry, McGill University, Montreal, Que.
[2]*Present address: Department of Chemistry, University of Alberta, Edmonton, Alberta.*
[3]*The Department of Chemistry, McGill University, Montreal, Que.*

techniques employed were essentially the same as in these earlier publications. However, the following changes in equipment and materials should be noted.

(1) The surface potential measuring equipment.—The air electrode was a 5 mc Po^{210}-plated source obtained from the Commercial Products Division, Atomic Energy of Canada. This electrode was used in conjunction with a standard calomel half-cell (Beckman) dipping into the film-free substrate solution behind a stationary barrier on the trough. The air electrode, when in use, was positioned approximately $\frac{1}{4}$ inch above the film surface. The potential was measured by a Beckman Model G pH meter connected to the electrodes by shielded and grounded leads. The trough was insulated from the supporting stand by a teflon sheet. The outer aluminum casing of the air bath served, when electrically grounded, as a most satisfactory Faraday screen.

(2) Radiochemically tagged I^{131}-α-iodostearic acid.—Some minor modifications in the preparation of I^{131}-α-iodostearic acid resulted in samples of consistently higher specific activity than obtained previously. A solution of 0.02 g of stock α-iodostearic acid in 5 ml of absolute ethanol was placed in the reaction flask described earlier (1), and 10 mc of carrier-free NaI^{131} in 1 ml of water was added to the solution with 2 drops of constant-boiling HCl. This solution was refluxed for $1\frac{1}{2}$–2 hours, allowed to cool, and 50–75 ml of 0.01 *M* HCl was added. The mixture was left for 10 to 12 hours to permit good crystal growth, filtered on a sintered glass filter, washed with 25 to 50 ml of 0.01 *M* HCl, and dried by suction for a further 12 hours. The spreading solution was prepared in a 10 ml volumetric flask by dissolving the acid from the filter with warm reagent grade benzene.

(3) Other materials.—The benzene, KCl, and KI employed were of reagent grade. Tests for surface-active contamination by the usual compression and surface pressure technique indicated these chemicals to be suitable for use without further purification. A trace of sodium bisulphite was added in the trough to all KI substrate solutions to remove any iodine formed by air oxidation.

RESULTS

1. *The Effect of Substrate KI Concentration on the Isotopic Exchange Rate*

Studies of the π–A isotherms of α-iodostearic acid on KI substrates (2) and on KCl substrates indicated that the curves were identical for the two salts at the same substrate concentration. Substrates of KCl–KI mixtures should then give isotherms characteristic of the total substrate molarity and independent of the relative amounts of the two salts present. Isotopic halogen exchange reactions examined on such substrates could be assumed to be studied under conditions of constant film characteristics for any given total substrate molarity.

Solutions were prepared by the addition of the appropriate amounts of dry KI and KCl to distilled water to give two series of substrate solutions. One series was of unit over-all molarity in KCl and KI but 0.25, 0.5, 0.75, and 1.0 *M* in KI alone and the other, 2 *M* in over-all molarity but 0.25, 0.5, 0.75, 1.0, 1.5, and 2 *M* in KI. Exchange reactions were studied on these substrate solutions at 25° C and at pH 2 and 3. The film of α-iodostearic acid was maintained at a constant surface pressure of 4 dynes/cm during the exchange. After the appropriate background corrections were made, the ratio of the initial count rate at time $t = 0$, $C(0)$, to the count rate at time $t = t$, $C(t)$, was determined from the paper trace of the surface count rate against time. A plot of log $C(0)/C(t)$ vs. time was made for each exchange experiment. The typical linear semilogarithmic plots obtained in all these experiments are illustrated in Fig. 1 for the 2 *M* KI–KCl mixture at

The equation for the specific rate constant, k_s, of the exchange reaction was given in the original paper (1) by the equation

$$V = k_s n\, m^y$$

where n is the surface concentration of monolayer; m, the concentration of I^- in the substrate; and y, the order of the reaction in substrate iodide ion. A plot of log k' vs. log m should be a straight line of slope y. Figure 2 gives these plots for 1 and 2 M sub-

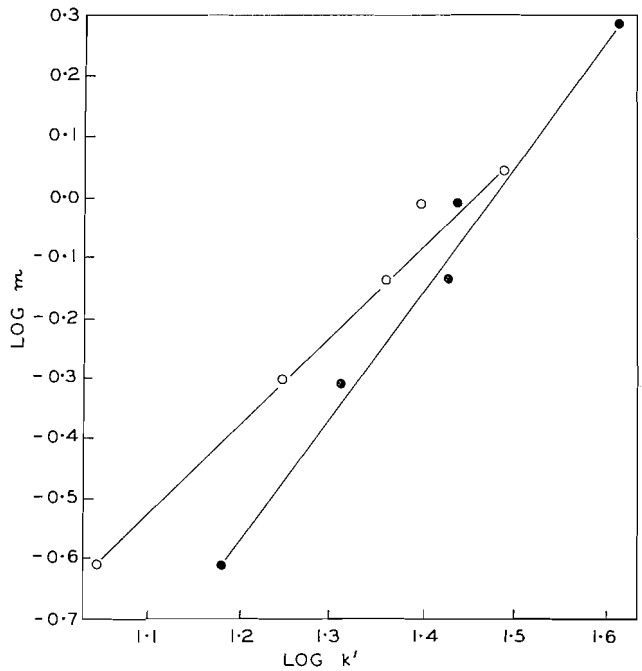

FIG. 2. Plot of logarithm of substrate KI concentration against logarithm of isotopic exchange rate constant. Temperature 25° C, substrate pH 2. Total molarity of substrate in KI and KCl: 1 M, open circles; 2 M, closed circles.

strates at pH 2. A value of y of 0.67 for 1.0 M and 0.48 for 2 M solution is calculated from these slopes. At pH 3 marked deviations from linearity appeared in the plot and calculations of the order could not be made (Table I).

2. The Surface Potential and the Isotopic Exchange Reaction

In an earlier publication (2) it was noted that in the range of pH 2 to pH 5 for 1 M KI substrates, the π–A isotherms of α-iodostearic acid remained essentially constant but the isotopic exchange rate varied markedly. Films of α-iodostearic acid were examined by the surface potential technique in this pH range to elucidate any relation between the surface potential (ΔV) and the rate constant for exchange.

The π–A–ΔV plots for 0.01 M HCl substrates are given in Fig. 3 and the corresponding plots for 1.0 M KI substrates at different values of the pH are given in Fig. 4. At both 17.5° C and 25° C the surface potential of the α-iodostearic acid monolayers on 0.01 M HCl was negative at high molecular areas and approached zero as the film was compressed to smaller areas per molecule. In the range 75 to 80 sq. Å/molecule the plot of ΔV vs. area showed a sudden increase in slope at both temperatures although no change in the

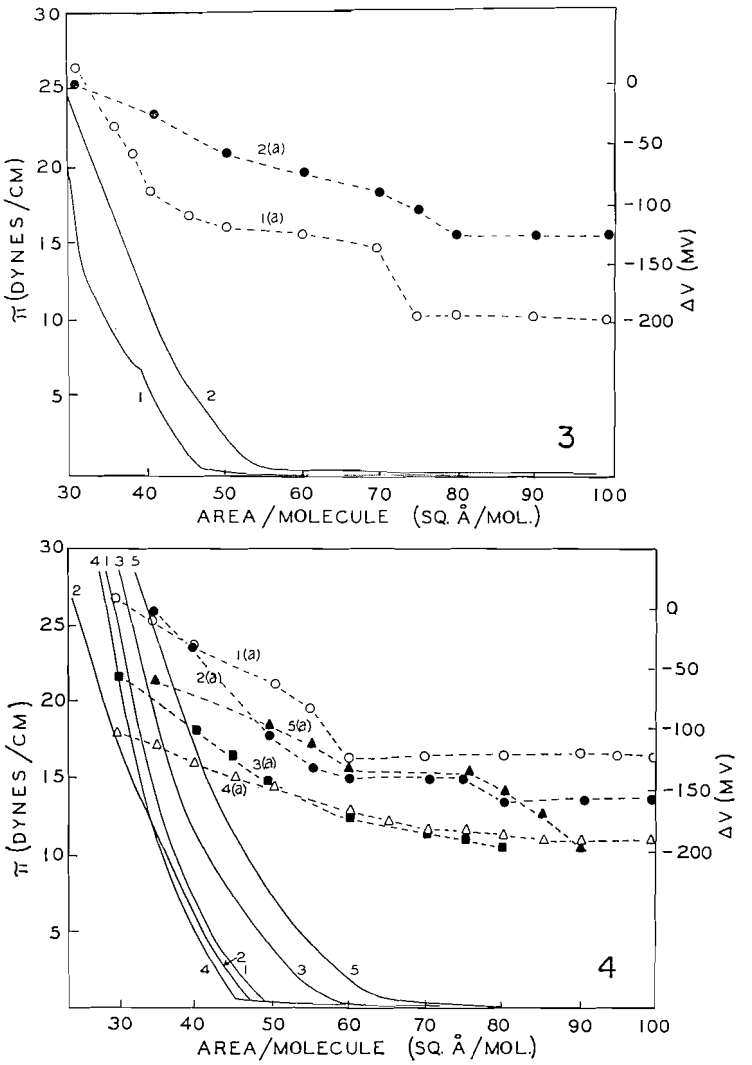

FIG. 3. Pressure–area isotherms and surface potential – area plots for α-iodostearic acid on 0.01 *M* HCl substrates. Curve (1) π–A isotherm 17.5° C; (2) π–A isotherm 25° C. Curves 1*a*, 2*a*, corresponding ΔV–A plots.

FIG. 4. Pressure–area isotherms and surface potential – area plots for α-iodostearic acid on 1.0 *M* KI substrates at 25° C. Curve (1) π–A, pH 1.2; (2) π–A, pH 2.0; (3) π–A, pH 2.8; (4) π–A, pH 3.2; (5) π–A, pH 3.8. Curves 1*a*, 2*a*, 3*a*, 4*a*, 5*a*, corresponding ΔV–A plots.

slope of the π–A isotherms could be detected in this region of molecular area. The transition to a liquid condensed film at 40 sq. Å/molecule in the 17.5° isotherm on 0.01 *M* HCl was markedly reflected in the ΔV-vs.-area plot. The surface potential approached zero very rapidly during compression once the transition point was crossed. The surface potentials of monolayers spread on 1.0 *M* KI substrates (Fig. 4) were decidedly more negative than for 0.01 *M* HCl at all values of the pH above 1.2. The same discontinuous change in slope of the ΔV-vs.-area plot was observed for all the isotherms on KI as on 0.01 *M* HCl except at pH 2.8 and 3.2. The range of area/molecule at which this discontinuity in slope appeared was considerably wider on KI substrates.

The variations of ΔV with pH are given in Fig. 5 for constant molecular areas of 100, 75, 50, and 35 sq. Å/molecule. Surface potential measurements made on I^{131}-α-iodostearic acid monolayers during exchange are given in Fig. 6 for a substrate pH of 2 and at 25 and 17.5° C with the corresponding semilogarithmic plots for the exchange reaction. The surface potential and semilogarithmic plots of an exchange reaction at 25° C in a collapsed film are also included in this figure.

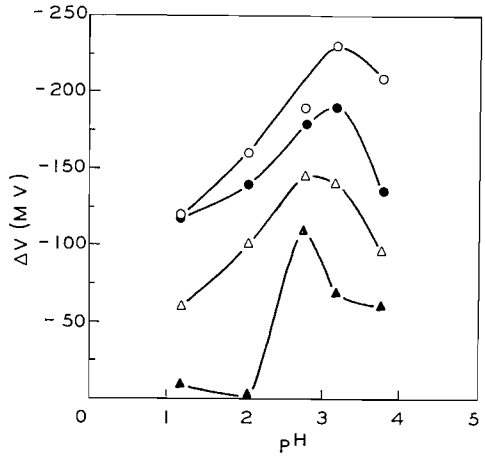

FIG. 5. Surface potential of α-iodostearic acid monolayer on 1 M KI at 25° C as a function of substrate pH at 35 sq. Å/molecule (▲); 50 sq. Å/molecule (Δ); 75 sq. Å/molecule (●); 100 sq. Å/molecule (○).

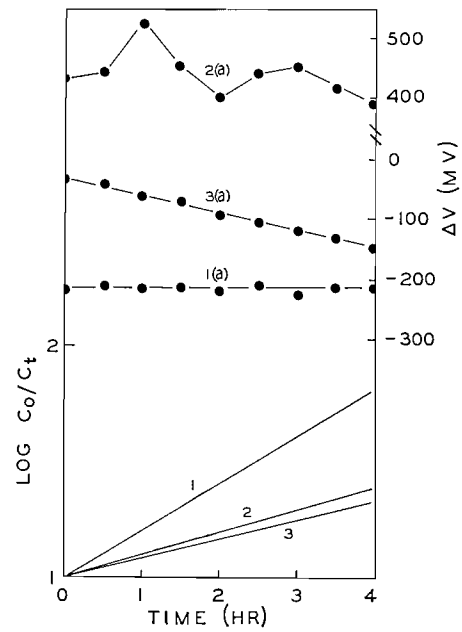

FIG. 6. Semilogarithmic plot of relative surface count rate against time and ΔV–time plot for I^{131}-α-odostearic acid during exchange on 1 M KI at pH 3. Curve (1), π = 4 dynes/cm, 25° C; (2) collapsed film 25° C; (3) π = 4 dynes/cm, 17.3° C. Curves 1a, 2a, 3a, corresponding ΔV– time plots.

DISCUSSION

The pseudo-first-order rate constants obtained in the presence of KCl at KI concentrations of 1.0 *M* or less were consistently higher than those obtained in KI substrates of the same molarity but with no KCl present (1). Since no exchange occurred on KCl substrates alone, the increase in the isotopic exchange rate in the presence of KCl is difficult to explain. Kinetic salt effects which have been reported for other monolayer reactions (5) seem hardly to be applicable to an exchange reaction of the type being studied. The kinetic accessibility of the I^- in the substrate to the I^{131} atom in the α-iodostearic acid monolayer can be assumed to remain constant on substrate solutions of constant total molarity in KCl and KI. No changes occur in the π–A isotherms for such substrates and consequently no reorientation of the film molecules would be expected which could change the accessibility and hence the rate of exchange. Possibly the addition of KCl to the substrate may increase the effective concentration of I^- in the surface region below the monolayer. The more rapid exchange on substrates 2 *M* in total salt concentration for all KI concentrations would tend to support this view.

The failure to determine the order in substrate I^- concentration at pH 3 might be related to the apparent discontinuity found in the Arrhenius plot for the activation energy at this same pH (2). Both the apparent discontinuity in the activation energy and the apparent deviations from linearity at pH 3 in the plots for the reaction order in substrate I^- may have a common origin in undetected minor variations of the pH, since close control of this factor in the monolayer trough is most difficult. It has been shown (2) that the isotopic halogen exchange rate constant becomes markedly sensitive to pH near the maximum of the pH-vs.-k' plot. Since this maximum occurs near pH 3, small changes in the pH could lead to significant variations in the reaction velocity and thus to the results observed in the activation energy and substrate I^- order plots.

The negative value of the surface potential obtained for α-iodostearic acid monolayers on HCl substrates is similar to that obtained by Frumkin (6) with monolayers of ω-bromohexadecanoic acid. This negative surface potential suggests that the negative end of the vertical component of the dipole moment of the molecule is uppermost. The iodine atom is then above the carboxyl group in the monolayer surface. On compressing the iodostearic acid monolayers the relative planes of the iodine atom and carboxyl group, parallel to the water surface, must approach one another on compression as the surface potential approaches zero. At higher molecular areas, the increased negativity of the surface potential as the temperature is lowered from 25° C to 17.5° C (−130 mv to −190 mv at 90 sq. Å/molecule) may be related to a decrease in the relative solubility of the film molecules in the substrate. This effect would tend to force the α-iodine atom to a position in the surface above the carboxyl group.

The surface potential of films on 1.0 *M* KI substrates at pH 2 (25° C) is more negative at all higher molecular areas than the corresponding curve on HCl substrates but the two curves approach one another as the area per molecule is decreased. The greater degree of negativity on KI substrates might be related to salting out of the film molecules on the addition of electrolyte to the substrate.

The variation of the surface potential with pH on 1.0 *M* KI substrates would be expected to be associated with the variation in the degree of dissociation of the carboxyl group of the monolayer acid as the acidity of the substrate is decreased. The surface potential would presumably increase as the degree of dissociation increased with numerically increasing pH. In the range of pH studied (1–5 pH units) the change in the

film characteristics of α-iodostearic acid is small, only a slight expansion being detectable (2). Consequently, in the absence of the characteristic marked expansion to a gaseous film which occurs as a monolayer acid approaches complete dissociation, only a small increase in the degree of dissociation must have occurred in traversing this pH range. Since the degree of dissociation can only increase with increasing pH, the maximum of Fig. 5, detectable over a wide range of molecular areas, cannot be accounted for on the basis of the degree of dissociation alone. It must be concluded that the variation of surface potential with pH must arise from other unknown factors as well as the degree of dissociation. That the maximum of Fig. 5 is real seems to be established when the rate constants for isotopic halogen exchange (2) and the present surface potential data are plotted against substrate pH as in Fig. 7. The similarity between the two curves is

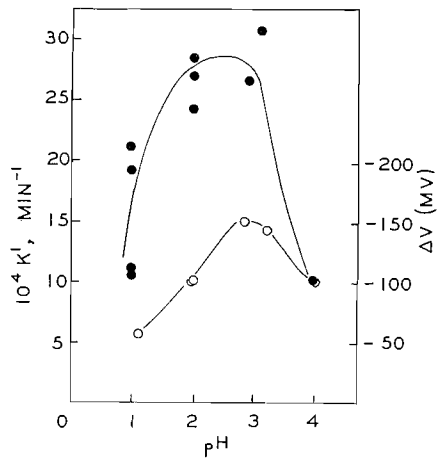

FIG. 7. Plot of isotopic exchange rate constant k' (closed circles) and ΔV (open circles) against substrate pH. Temperature 25° C, molecular area 35 sq. Å.

immediately evident, both the surface potential and the rate constant k' pass through a maximum near pH 3 for the same area/molecule in the monolayer. It seems reasonable to conclude that the variations in surface potential and k' with pH on 1.0 M KI substrates are closely related and are the result of changes in the degree of ionization of the stearic acid derivative and unknown changes, probably of both steric and electrical nature, occurring in the surface region.

The curves of the simultaneous relative surface count rate decrease and surface potential variations with time, taken during the course of an exchange reaction (Fig. 6) with I^{131}-α-iodostearic acid, indicate that at 25° C, pH 3, for a surface pressure of 4 dynes/cm, the surface potential remains essentially constant during the reaction and shows the same value of ΔV as obtained for the inactive films. When the temperature of exchange was lowered to 17.5° C, however, the surface potential was more erratic and slowly increased with time. At this temperature the apparent discontinuities appeared in the Arrhenius plot in earlier experiments and the liquid-intermediate monolayer was present in the π–A isotherms (1, 2). A progressive, slow change in the film characteristics of the monolayer itself might explain the variable surface potential and exchange rate constants in this region of temperature. The surface potential of the collapsed film changed from the negative or zero values found for homogeneous films to large positive

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

values. This probably indicates the formation of at least one layer of inverted α-iodostearic acid molecules above the original monolayer, out of the surface and, as indicated by the markedly reduced exchange rate, no longer available for exchange.

BACTERIOSTATS

V. THE PREPARATION AND BACTERIOSTATIC PROPERTIES OF AMIDINE DERIVATIVES[1]

D. L. GARMAISE,[2] R. W. KAY,[2] R. GAUDRY,[3] H. A. BAKER,[3] AND A. F. MCKAY[2]

ABSTRACT

A number of polyamidines, N-substituted amidines, and diamidines were prepared for evaluation as bacteriostats. N,N′-Bis-(3,4-dichlorobenzyl)-sebacamidine dihydrochloride was the most active compound prepared in this investigation.

Compounds with unsubstituted amidine groups have been employed as chemotherapeutic agents (1) but there have been relatively few investigations of N-substituted amidines. Some bacteriostatically active N-substituted monoamidines were found (2) to be too toxic for use in guinea pig infections. A series of N,N′-bis-(alkyl)-adipamidines and -sebacamidines has been patented (3) for use in disinfectant compositions, and high bacteriostatic activity has been claimed (4) for a number of polymeric amidines which were obtained by the reaction of diiminoethers with diamines. These polymers were highly toxic (5). The preparation and bacteriostatic evaluation of a number of N-substituted amidines, alkylenediamidines, arylenediacetamidines, and some new polyamidine hydrochlorides are described in the present paper.

The monosubstituted monoamidines (Table I) were prepared by reaction of amines with iminoether hydrochlorides, while the condensation of amines with imidic chlorides was the most convenient method for the preparation of N,N′-disubstituted monoamidines (Table I) and N,N′,N″,N‴-tetrasubstituted diamidines. The N,N′-bis-(aryl)-adipamidines (Table II) were readily prepared by condensation of adiponitrile with substituted aniline hydrochlorides, but no crystalline products could be obtained from the similar reaction of dinitriles with substituted benzylamine hydrochlorides.

The N,N′-bis-(benzyl)-diamidines (Table II) were prepared by heating dinitriles with benzylamine benzenesulphonic acid salts according to the general procedure described by Oxley and Short (6, 7). Conversion of the diamidine dibenzenesulphonates to the corresponding dihydrochlorides was accomplished by passing the dibenzenesulphonate in methanol through a column of Amberlite IRA-400 resin in the chloride form.

Three polyamidine salts (Table III) were prepared by the self-condensation of ω-aminonitrile hydrochlorides. The polymerization was effected by heating the molten hydrochloride in a nitrogen atmosphere until threads could be drawn from the melt. The polyamidine salts listed in Table IV were prepared in the same manner by heating hexamethylenediamine dihydrochloride with dinitriles. These polyamidine hydrochlorides with the exception of the polymer from 4-cyanobenzylamine hydrochloride, are water-soluble, hygroscopic solids with low melting points. The free polymeric bases could be precipitated from aqueous solutions of the hydrochlorides by addition of alkali.

The minimal growth inhibitory concentrations listed in Table V show that all the amidine derivatives are more effective against gram-positive than gram-negative organisms. In the polymeric series, the polymer derived from 10-cyanodecylamine hydrochloride was the most active. The β-(3,4-dichlorophenyl)-ethyl substituent was somewhat more effective than the 3,4-dichlorobenzyl group in the monoamidine derivatives.

N,N′-Di-(10-cyanodecyl-carbamyl)-hexamethylenediamine	90–100	223	9	Pale yellow glass, partially soluble in water

[a]Prepared by Hunt and Kirby (4).

In the alkylenediamidine series, N-aryl substituents were considerably less effective than N-benzyl groups. The 3,4-dichlorobenzyl derivative possessed the highest activity. A similar observation has been made in several other series of compounds (8). The most effective of the alkylenediamidines was N,N′-bis-(3,4-dichlorobenzyl)-sebacamidine dihydrochloride with a minimal growth inhibitory concentration of 1:5,120,000 for *Micrococcus pyogenes* var. *aureus* (penicillin resistant) and 1:10,240,000 for *Sarcina lutea*. Compounds possessing shorter or longer alkylene chains were less active. The introduction of additional 3,4-dichlorobenzyl substituents, as in N,N′,N″,N‴-tetrakis-(3,4-dichlorobenzyl)-sebacamidine dihydrochloride, caused a reduction in activity. In the related series of arylenediacetamidines, N,N′-bis-(3,4-dichlorobenzyl)-toluene-2,4-diacetamidine dihydrochloride was found to be highly active.

In general, the diamidines retained a fair degree of their bacteriostatic effectiveness in the presence of 10% serum. The arylenediacetamidine derivative was more sensitive to deactivation by serum protein than the alkylenediamidines. Among the latter, serum deactivation had a leveling effect on the activity of members of the homologous series, and the relationship between chain length and optimum bacteriostatic activity, which was observed in the absence of serum, was no longer apparent.

EXPERIMENTAL[4]

N-(3,4-Dichlorobenzyl)-3,4-dichlorophenylacetamidine

A solution of 3,4-dichlorobenzyl cyanide (20.67 g, 0.11 mole) and anhydrous methanol (3.56 g, 0.11 mole) in anhydrous ether (250 ml) was saturated with hydrogen chloride at 0°. The solution was allowed to stand at 5° for 4 days. Methyl 3,4-dichlorophenylacetimidate hydrochloride, m.p. 105° (decomp.), was recovered by filtration, yield 18.0 g (63.6%).

[a]Minimal inhibitory concentration determined by serial dilution tube technique, e.g., the value of 1,280 is equivalent to a concentration of 1 part in 1,280,000.
[b]Prepared by Hunt and Kirby (4).

The iminoether hydrochloride (3.40 g, 0.00134 mole) and 3,4-dichlorobenzylamine (2.34 g, 0.00134 mole) were dissolved in anhydrous methanol (30 ml) and the solution was allowed to stand at room temperature for 4 days. The residue from evaporation of the solution was added to 0.1 *N* sodium hydroxide solution (147.4 ml) and ether (100 ml). The dried ether extract was concentrated to a small volume and diluted with petroleum ether to give N-(3,4-dichlorobenzyl)-3,4-dichlorophenylacetamidine, m.p. 94–97°, yield 2.86 g (59%). Recrystallization from ether – petroleum ether raised the melting point to 96–98°.

The iminoether hydrochloride on treatment with 2-(3,4-dichlorophenyl)-ethylamine (9) by the above procedure gave N-(β-(3,4-dichlorophenyl)-ethyl)-3,4-dichlorophenylacetamidine (Table I).

N-(3,4-Dichlorobenzyl)-3,4-dichlorobenzamide

Sodium hydroxide (8.0 g, 0.20 mole) in water (100 ml) was added dropwise to a stirred mixture of 3,4-dichlorobenzylamine hydrochloride (21.25 g, 0.10 mole) and 3,4-dichlorobenzoyl chloride (20.9 g, 0.10 mole) in water (250 ml) at 25°. After the addition period of 2 hours, the mixture was stirred for 6 hours. The crude product (m.p. 118–123°) was recovered by filtration, yield 28.6 g (82.0%). Crystallization from ethanol raised the melting point to 131–132.5°, yield 21.5 g (61.6%). Anal. Calc. for $C_{14}H_9Cl_4NO$: C, 48.18; H, 2.60; Cl, 40.64; N, 4.01%. Found: C, 48.36; H, 2.65; Cl, 40.65; N, 3.89%.

N,N′-Di-(3,4-dichlorobenzyl)-3,4-dichlorobenzamidine

A solution of N-(3,4-dichlorobenzyl)-3,4-dichlorobenzamide (10.4 g, 0.03 mole) and phosphorus pentachloride (6.24 g, 0.03 mole) in benzene (60 ml) was refluxed for 3 hours. Evaporation of the solvent yielded N-(3,4-dichlorobenzyl)-3,4-dichlorobenzimidic chloride as an oil which gradually solidified, m.p. 83–86°. 3,4-Dichlorobenzylamine (5.3 g, 0.03 mole) in ether (25 ml) was added, and the solution was allowed to stand for 3 days. The precipitate (2.8 g, m.p. 200–220°) was filtered, and the filtrate was shaken with 2 *N* hydrochloric acid (100 ml), giving an additional precipitate of 4.8 g, m.p. 210–230°. The combined solids were extracted with boiling water (25 ml) and the residue was recrystallized from dimethylformamide (30 ml). N,N′-Di-(3,4-dichlorobenzyl)-3,4-dichlorobenzamidine hydrochloride, m.p. 243–244.5°, was recovered in 15.1% yield (2.3 g).

A sample of the hydrochloride (1.6 g, 0.0032 mole) in dimethylformamide (15 ml) was added to 5% sodium hydroxide solution (100 ml) and chloroform (50 ml). The aqueous layer was extracted with chloroform (2×50 ml) and the combined chloroform extracts were washed with water, dried, and evaporated. The residue (1.3 g), m.p. 92–97°, was crystallized from ether – petroleum ether, giving the free base melting at 117–118°, yield 1.0 g (10.1% based on the amide).

Reaction between the imidic chloride and 4-chlorobenzylamine gave N-(4-chlorobenzyl)-N′-(3,4-dichlorobenzyl)-3,4-dichlorobenzamidine (Table I).

Preparation of Dinitriles

p-Xylylenedicyanide (m.p. 95–97°) was prepared in 60% yield from *p*-xylylenedibromide by the method of Titley (10).

Toluene-2,4-diacetonitrile

2,4-Di-(chloromethyl)-toluene (150 g, 0.79 mole) in ethanol (200 ml) was added, with stirring, to sodium cyanide (100 g, 2.04 moles) in water (90 ml) at 76–80° during a period of 30 minutes. The mixture was refluxed for 2 hours, and then cooled and filtered. Most

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of the ethanol was removed by concentration of the filtrate at reduced pressure, and the oily residue was extracted with benzene (200 ml). The benzene layer was dried and evaporated, and the residue was distilled, giving the crude product, b.p. 162–170° at 0.1 mm, yield 91 g (68%).

The distillate was shaken with 50% sulphuric acid (100 ml) for 5 minutes, and the resulting emulsion was extracted with benzene (100 ml). The benzene layer was washed with sodium bicarbonate solution and water, dried, and evaporated. Distillation of the residue yielded the pure product, b.p. 182° at 0.7 mm, m.p. 38–42.5°, yield 64.8 g (49%). Anal. Calc. for $C_{11}H_{10}N_2$: C, 77.65; H, 5.88; N, 16.47%. Found: C, 77.73; H, 6.30; N, 16.43%.

1,12-Dicyanododecane

1,12-Dodecanedicarboxylic acid (20.7 g, 0.08 mole) was added to thionyl chloride (28.6 g, 0.24 mole) in benzene (100 ml) at room temperature. After being allowed to stand for 90 minutes, the solution was refluxed for 3 hours. The solvent and excess thionyl chloride were removed by concentration *in vacuo*, and the dark-brown residue was added dropwise to concentrated aqueous ammonia (67 ml) at 15°. The precipitated 1,12-dodecanedicarboxamide was recovered by filtration, m.p. 182–187°, yield 19.3 g (94.2%). After recrystallization from dimethylformamide, the diamide melted at 186–187°, resolidified, and remelted at 194–197°. Anal. Calc. for $C_{14}H_{28}N_2O_2$: C, 65.58; H, 11.01; N, 10.93%. Found: C, 65.44; H, 10.80; N, 10.79%.

The diamide (15.7 g, 0.061 mole) was refluxed with thionyl chloride (16.0 g, 0.134 mole) in benzene (100 ml) for 7 hours. The solution was evaporated and the residue was distilled, giving 1,12-dicyanododecane, b.p. 151–153° at 0.04 mm, m.p. 35.5–36°, yield 8.5 g (63.3%). Anal. Calc. for $C_{14}H_{24}N_2$: C, 76.31; H, 10.98; N, 12.71%. Found: C, 76.15; H, 10.83; N, 12.52%.

N,N′-Bis-(3,4-dichlorophenyl)-adipamidine Dihydrochloride

A mixture of 3,4-dichloroaniline hydrochloride (9.93 g, 0.05 mole) and adiponitrile 2.71 g, 0.025 mole) was heated to 210°. After 20 minutes at 205–210°, the melt solidified. Crystallization of the solid from hot water yielded material melting at 226–232° (decomp.), yield 8.62 g (68.2%). The pure dihydrochloride melting at 243–244° (decomp.) was obtained by recrystallization from methanol–ether solution, yield 4.82 g (38.0%).

N,N′-Bis-(4-chlorophenyl)-adipamidine dihydrochloride (Table II) was prepared by the same procedure.

N,N′-Bis-(3,4-dichlorobenzyl)-adipamidine

3,4-Dichlorobenzylamine (35.2 g, 0.20 mole) was added to a solution of benzenesulphonic acid (35.2 g, 0.22 mole) in methanol (600 ml). The solution was concentrated to 250 ml. 3,4-Dichlorobenzylamine benzenesulphonate (m.p. 244–248°) crystallized out on standing, yield 50.7 g (75.9%).

3,4-Dichlorobenzylamine benzenesulphonate (47.0 g, 0.141 mole) was stirred with adiponitrile (7.62 g, 0.0705 mole) at 235° for 35 minutes. The mixture was crystallized from methanol (150 ml) yielding some unchanged starting material (15.7 g, m.p. 206–235°). Concentration of the mother liquors yielded the crude product (14.7 g, m.p. 170–199°), which on recrystallization from water (600 ml), gave N,N′-bis-(3,4-dichlorobenzyl)-adipamidine dibenzenesulphonate (6.0 g, 11.4%), m.p. 210–213°. The analytical sample melted at 213.5–215° after recrystallization from methanol–ether solution.

A solution of the dibenzenesulphonate (3.83 g, 0.00493 mole) in methanol (80 ml) was passed through a column of Amberlite IRA-400 resin (50 ml), which had previously

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

been saturated with chloride ion. The column was washed with methanol (100 ml) and the combined eluates were evaporated, giving N,N′-bis-(3,4-dichlorobenzyl)-adipamidine dihydrochloride, m.p. 241–244°, yield 2.38 g (85.4%). Recrystallization from methanol–ether raised the melting point to 242–244°.

The other N,N′-diaralkyldiamidines described in Table II were prepared by the same method.

N,N′-Bis-(3,4-dichlorobenzyl)-p-phenylenediacetamidine

A mixture of *p*-xylylenedicyanide (14.3 g, 0.0915 mole) and 3,4-dichlorobenzylamine benzenesulphonate (61.3 g, 0.183 mole) was stirred in a nitrogen atmosphere at 230° for 90 minutes. The cooled reaction mixture was extracted successively with dimethylformamide (50 ml) and boiling methanol (100 ml), giving the product as the dibenzenesulphonic acid salt, m.p. 311–312°, yield 31 g (41%). The analytical sample melted at 313–314° after crystallization from dimethylformamide. Anal. Calc. for $C_{36}H_{34}Cl_4N_4O_6S_2$: C, 52.44; H, 4.16; Cl, 17.20; N, 6.74; S, 7.78%. Found: C, 52.30; H, 4.23; Cl, 17.45; N, 6.98; S, 7.88%.

The dibenzenesulphonate (30.0 g, 0.0364 mole) was dissolved in dimethylformamide (430 ml), and a solution of potassium hydroxide (30 g) in methanol (100 ml) was added. Dilution with water precipitated the product as the free base, m.p. 164–165°, yield 17.2 g (93%). The melting point was raised to 168–169° by recrystallization from dilute ethanol. Anal. Calc. for $C_{24}H_{22}Cl_4N_4$: C, 56.71; H, 4.36; Cl, 27.91; N, 11.02%. Found: C, 56.64; H, 4.68; Cl, 27.70; N, 10.77%.

N,N′-Bis-(3,4-dichlorobenzyl)-toluene-2,4-diacetamidine

Toluene-2,4-diacetonitrile (6.8 g, 0.04 mole) and 3,4-dichlorobenzylamine benzenesulphonate (26.8 g, 0.08 mole) were heated at 210–230° for 3 hours. The cooled mixture on crystallization from methanol and ether gave 8.4 g (31.4%) of unreacted 3,4-dichlorobenzylamine benzenesulphonate. Evaporation of the mother liquors yielded the product as an amorphous solid (yield 22 g, 66%) which gave a single spot, R_f 0.85, when chromatographed with butanol:acetic acid:water (50:40:10). A methanolic solution (200 ml) of the product was passed through a column of Amberlite IRA-400 resin (150 ml) in the chloride form, and the column was washed with methanol (200 ml). Evaporation of the eluate gave the product as the amorphous dihydrochloride (yield 14.7 g, 62%).

A sample of the dihydrochloride (4.5 g, 0.0086 mole) was added to fumaric acid (1.0 g, 0.0086 mole) in ethanol (30 ml). Addition of ether (20 ml) yielded the crystalline fumarate salt, m.p. 170–190°, which was recrystallized from dimethylformamide to a constant melting point of 190.5–193°, yield 1.95 g (35%). Anal. Calc. for $C_{29}H_{28}Cl_4N_4O_4.H_2O$: C, 53.06; H, 4.61; Cl, 21.61%. Found: C, 53.38; H, 5.13; Cl, 21.04%.

N,N′-Bis-(3,4-dichlorobenzyl)-sebacamide

Sebacyl chloride (23.9 g, 0.10 mole) in benzene (50 ml) was added dropwise to a solution of 3,4-dichlorobenzylamine (35.2 g, 0.20 mole) and pyridine (15.8 g, 0.20 mole) in dry benzene (300 ml) at 15–20° C. The solution was allowed to stand overnight and the precipitate was filtered and washed with water. Recrystallization from methanol gave the pure diamide, melting at 123–124°, resolidifying, and remelting at 135–136°, yield 38.0 g (69.5%). Anal. Calc. for $C_{24}H_{28}Cl_4N_2O_2$: C, 55.62; H, 5.44; Cl, 27.37; N, 5.41%. Found: C, 55.43; H, 5.50; Cl, 27.41; N, 5.37%.

N,N′,N″,N‴-Tetrakis-(3,4-dichlorobenzyl)-sebacamidine

N,N′-Bis-(3,4-dichlorobenzyl)-sebacamide (5.18 g, 0.010 mole) was refluxed with phosphorus pentachloride (4.20 g, 0.020 mole) in dry benzene (70 ml) for 3.5 hours. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

benzene solution, after being decanted from the resinous by-products, was added to 3,4-dichlorobenzylamine (6.02 g, 0.040 mole), and the solution was allowed to stand for 2 hours.

The residue obtained on evaporation of the benzene was partitioned between ether (100 ml) and 2 *N* sodium hydroxide (100 ml). The ether solution was dried and evaporated, and the residue was extracted repeatedly with petroleum ether. The residual oil gave a single spot, R_f 0.93, in a paper chromatogram with the solvent system butanol:acetic acid:water (50:40:10).

The product was dissolved in ethanol (50 ml) and acidified with aqueous hydrochloric acid. Evaporation of the solution yielded the dihydrochloride as an amorphous solid which resisted all attempts at crystallization, yield 3.8 g (42%). Anal. Calc. for $C_{38}H_{40}Cl_{10}N_4$: C, 50.31; H, 4.44; N, 6.18%. Found: C, 49.54; H, 4.75; N, 5.58%.

Polyamidines

A mixture of succinonitrile (3.06 g, 0.382 mole) and hexamethylenediamine dihydrochloride (7.23 g, 0.382 mole) was heated, with stirring, in a nitrogen atmosphere until a homogeneous melt was obtained. Immersion in a bath at 245° for 15 minutes was required to melt the mixture. The bath temperature was lowered to 190° and the heating was continued for 10 hours. The pressure was reduced to 10 mm and the heating was continued for 1 hour. On cooling, the viscous mass solidified to a brown hygroscopic glass melting at 45–55°.

The other polymers described in Tables II and III were prepared in the same manner. In each case the mixture or the aminonitrile hydrochloride was first melted and then heated at the bath temperature noted in the tables until threads could be drawn from the polymeric mass. The pressure was reduced toward the end of the reaction to remove volatile impurities.

INORGANIC SALTS DISSOLVED IN NON-AQUEOUS OR IN MIXED SOLVENTS

XIII. VISCOSITY STUDIES OF $SnCl_4.5H_2O$ AND $SnCl_2.2H_2O$ DISSOLVED SEPARATELY AND TOGETHER IN METHANOL – CARBON TETRACHLORIDE[1]

P. A. D. DE MAINE AND E. R. RUSSELL

ABSTRACT

Here is reported evidence from viscosity data for competitive, reversible complex formation between species of Sn(IV) or Sn(II) and Sn(IV) or methanol in methanol – carbon tetrachloride solutions of $SnCl_4.5H_2O$ and $SnCl_2.2H_2O$. Empirical relations between the viscosity parameter and the salt or methanol concentrations are also reported.

INTRODUCTION

Spectrophotometric and conductance data for $SnCl_4.5H_2O$ and $SnCl_2.2H_2O$ dissolved separately (1, 2, 3, 4, 5) and together (6, 7) in methanol or in methanol – carbon tetrachloride have shown that there is competitive, reversible complex formation between Sn(IV) and Sn(II) species, between two Sn(IV) species, between Sn(IV) species and methanol, and between Sn(II) species and methanol. The ratio, R (molar conductance at 45° C/molar conductance at 20° C), is independent of salt concentration for each solvent composition. Interactions between Sn(IV) species and Sn(II) or Sn(IV) species are favored by desolvation of methanolated Sn(IV) and Sn(II) (through elevation of the temperature or increase of the carbon tetrachloride concentration).

Here we report viscosity data for $SnCl_4.5H_2O$ and $SnCl_2.2H_2O$ dissolved separately and together in methanol – carbon tetrachloride at 25° and 45° C. These new data can be interpreted in terms of the four competitive, reversible complex formation modes noted in the preceding paragraph. Thus the spectral, conductance, and viscosity data all lead to the same interpretation.

EXPERIMENTAL

Fisher Spectrograde methanol and carbon tetrachloride were dispensed under an atmosphere of dry nitrogen (dew point less than −60° C). Fisher Certified Reagent Grade $SnCl_4.5H_2O$ and $SnCl_2.2H_2O$ were used without further purification. However analyses for tin and chlorine (4) showed that the actual composition of each salt is within 1% of the theoretical composition.

The techniques for preparation of solutions have been described (1, 6). Viscosities were measured with calibrated Ostwald–Fenske viscometers in thermostated baths at 25° and 45° C. Densities for each solution were calculated from density data for the pure solvents (8) and for tin chloride solutions of the highest concentrations, at both temperatures. In separate experiments we have shown that for methanol and methanol – carbon tetrachloride solutions of tin chlorides, densities calculated on the assumption of additive volumes agree to within 0.35% of actually measured densities over the range of concentrations used in this study.

Duplicated experiments showed that all measurements can be reproduced to better

NOTE: *a* denotes concentrations where systems formed two layers. Reference 4 is a study of these two-layer systems.

than 0.30% with another set of solutions. Table I indicates the ranges of solvent composition and salt concentration over which viscosity data was collected.

RESULTS

In this work we define salt molar viscosity (η_{salt}) thus:

$$\eta_{salt} = (\eta_s - \eta_o)/c = \eta_{sp}\eta_o/c$$

where η_s and η_o are the measured viscosity coefficients of the solution and solvent respectively, η_{sp} is the specific viscosity coefficient, and c is the salt concentration in moles/liter.

Systems with $SnCl_4.5H_2O$ as Solute

For all salt concentrations and both temperatures, plots of viscosity coefficient versus carbon tetrachloride concentration, for solutions with fixed $SnCl_4.5H_2O$ concentration, are linear (Fig. 1).

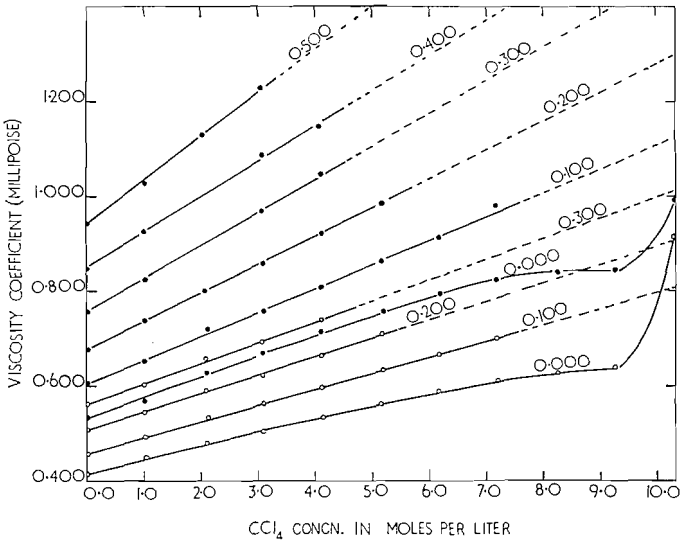

FIG. 1. Viscosity coefficient for $SnCl_4.5H_2O$ – methanol – carbon tetrachloride solutions versus carbon tetrachloride concentration (moles/liter) at the indicated temperatures and molar salt concentrations. ● 25° C; ○ 45° C.

Plots of $SnCl_4.5H_2O$ molar viscosity (η_{IV}) versus salt concentration for solutions with fixed solvent composition and temperature are linear with positive slope (Fig. 2). The ratio B (η_{IV} at 25°/η_{IV} at 45° C) appears to be independent of the salt concentration. Average B values and the square-root-mean-square deviations are given in Table II.

Systems with $SnCl_2.2H_2O$ as Solute

Plots of viscosity coefficient for solutions with fixed $SnCl_2.2H_2O$ concentration versus carbon tetrachloride concentration are illustrated in Fig. 3. Here linearity in the plots was observed only for the higher salt concentrations at both temperatures. The $SnCl_2.2H_2O$ molar viscosity (η_{II}) appears to be independent of salt concentration at each temperature and solvent composition. The average η_{II} values do increase on addition of carbon tetrachloride (Table III, data for 25° C).

The ratio B' (η_{II} at 25°/η_{II} at 45° C) is independent of salt concentration for each solvent composition. B' does depend on solvent composition. Table II lists average B' values together with square-root-mean-square deviations and the number of values averaged.

Systems with $SnCl_4.5H_2O$ and $SnCl_2.2H_2O$ as Solute

For solutions with a constant total salt concentration, plots of viscosity coefficient versus carbon tetrachloride concentration are similar in form to the plots in Fig. 3. The increase in measured viscosity coefficient ($\eta_s - \eta_o$) on addition of the mixed salts to solvents of fixed composition and temperature is noted in Table IV. Also given are the sums of increments of viscosity for separate solutions of each salt at the concentrations and temperature of the corresponding mixed-salt system in the same solvent.

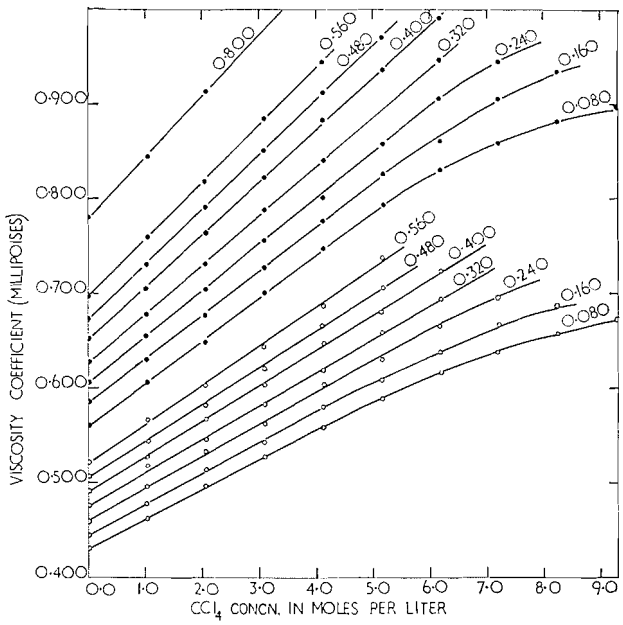

FIG. 3. Viscosity coefficient for $SnCl_2.2H_2O$ – methanol – carbon tetrachloride systems versus concentration of carbon tetrachloride at the indicated temperatures and salt concentrations (moles/liter). ● 25° C; ○ 45° C.

DISCUSSION

Acceptance of the hypothesis that partial reversible association of either covalent or ionic species will lead to a corresponding increase in the molar viscosity of the salt permits an analysis of the new viscosity data which are consistent with earlier conclusions from spectrophotometric and conductance data for the separate and mixed $SnCl_4.5H_2O$ and $SnCl_2.2H_2O$ – methanol – carbon tetrachloride systems. The hypothesis can be justified upon careful consideration of the Stokes' viscosity equation.

Systems with $SnCl_4.5H_2O$ as Solute

The linear dependence of the $SnCl_4.5H_2O$ molar viscosity on salt concentration for solutions with fixed solvent composition and temperature (Fig. 2) may be explained with the supposition that partial reversible dimerization of covalent tin(IV) species occur together with reversible methanolysis of monomeric tin(IV) species. Addition of carbon tetrachloride leads to partial demethanolysis of the monomeric species and a consequent increase in the concentration of the dimeric form. Thus the salt molar viscosity coefficient increases. The increase in positive slope of the straight-line plots in Fig. 2 on addition of carbon tetrachloride supports the competitive dimerization–methanolysis reaction invoked to explain spectrophotometric (1) and conductance (3, 5) data for this system.

Systems with $SnCl_2.2H_2O$ as Solute

As $SnCl_2.2H_2O$ molar viscosity (Table III) is independent of salt concentration for solutions of fixed solvent composition and temperature, partial reversible polymerization of Sn(II) species cannot be significant. There is reversible methanolysis of Sn(II) species. These same conclusions were obtained from spectral (1) and conductance data (3, 5). The gradual increase in the $SnCl_2.2H_2O$ molar viscosity on addition of carbon tetrachloride (Table III) indicates that ion-pair formation and demethanolation may both contribute to the salt molar viscosity.

Systems with $SnCl_4.5H_2O$ and $SnCl_2.2H_2O$ as Solute

If the interaction between tin(IV) and tin(II) species occurs only after demethanolation of the species, the measured $(\eta_s - \eta_o)$ should be greater than the corresponding value calculated with values for the salts in separate solutions. The difference should increase with increased total salt or carbon tetrachloride concentration. Data in Table IV confirm these predictions. Experiments for which the situation is reversed occur because of the relatively small salt molar concentrations and consequent greater experimental error.

Temperature Dependence of Salt Molar Viscosity

As the ratios B and B' are independent of salt concentration for fixed solvent composition for each salt system (Table II) it seems that the salt species in solution behave as Arrhenius–Guzman liquids (9).

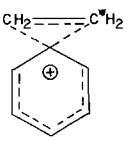
REARRANGEMENT STUDIES WITH C^{14}

XI. THE FORMOLYSIS OF 2-PHENYLETHYL-1-C^{14} *p*-TOLUENESULPHONATE WITH OR WITHOUT ADDED SODIUM *p*-TOLUENESULPHONATE-S^{35} [1]



J. W. CLAYTON[2] AND C. C. LEE

ABSTRACT

The formolysis of 0.350 *M* 2-phenylethyl-1-C^{14} *p*-toluenesulphonate (I) was carried out at 74±0.2° C with or without the presence of an equimolar amount of sodium *p*-toluenesulphonate-S^{35} (III). The over-all first-order rate constant, k_1, was found to be 2.6×10^{-5} sec^{-1} and 3.0×10^{-5} sec^{-1}, respectively, for the reaction with and without added III. The determination of the degrees of rearrangement of the C^{14}-labeled atoms from the C-1 to the C-2 positions in the 2-phenylethyl *p*-toluenesulphonate (I_r) recovered from the reaction mixture at various reaction times permitted the evaluation of k^{14}, the rate of return from ionic intermediates to covalent bonding. Using the experimental data, it was possible to calculate k_s and k_Δ, the rates, respectively, for the anchimerically unassisted and assisted solvolysis. As expected, formolysis of I proceeded principally by the anchimerically assisted process. Calculations also showed that the fraction of the anchimerically assisted ionization returning to covalent bonding was about 15% for the reaction in the presence of III, while in the absence of III, the return was about 9%. For the formolysis of I in the presence of III, the extents of incorporation of S^{35} in the recovered sulphonate I_r were also determined. The S^{35} incorporation in I_r, when considered in conjunction with the C^{14} rearrangement in I_r, led to the conclusion that the return from ionic intermediates to covalent bonding during the formolysis of I included both internal and external returns, the extent of external return being the greater of the two.

INTRODUCTION

In earlier publications (1, 2), isotope position rearrangements observed in the solvolysis of 2-phenylethyl-1-C^{14} *p*-toluenesulphonate (I) under various conditions were reported. When acetolysis and formolysis of I were interrupted at about 50% completion, the rearrangement of C^{14}-labeled atoms from the C-1 to C-2 positions in the recovered 2-phenylethyl-*x*-C^{14} *p*-toluenesulphonate (I_r) indicated some return to covalent bonding through the intermediate ethylphenonium ion (II) or its equivalent. Solvolysis of I

(II)

in the presence of sodium *p*-toluenesulphonate-S^{35} (III) made possible the simultaneous determinations of C^{14} rearrangement and S^{35} incorporation in the sulphonate I_r recovered from the partially solvolyzed mixture. The data obtained for formolysis (2) indicated that some of the *p*-toluenesulphonate anions involved in the return to give the isotopically rearranged 2-phenylethyl-2-C^{14} *p*-toluenesulphonate were derived from an intramolecular process, thus pointing to the occurrence of some internal return from an intimate ion pair (3–6) during the formolysis of I.

A drawback in the earlier work (1, 2) has been a lack of any concurrent kinetic data for consideration in conjunction with the observed C^{14} rearrangement and S^{35} exchange. In the present study, the formolysis of I was carried out at 74° C with or without the presence of an equimolar amount of III. At various stages of reaction, the rearrangements of the C^{14}-labeled atoms from the C-1 to C-2 positions were determined in the product, 2-phenylethyl-*x*-C^{14} formate (IV), and in the 2-phenylethyl-*x*-C^{14} *p*-toluenesulphonate (I_r) recovered from the reaction mixture. For the formolysis in the presence of III, the incorporations of S^{35} in I_r were also measured. Concurrent kinetic studies were made by potentiometric titration of the *p*-toluenesulphonic acid liberated, by isotope dilution of the product, IV, that was formed, and by isotope dilution of the reactant, I_r, that remained.

METHODS AND RESULTS

Formolysis of 2-Phenylethyl-1-C^{14} p-Toluenesulphonate (I) without Added Sodium p-Toluenesulphonate-S^{35} (III)

The reaction was carried out in an all-glass apparatus. The reaction vessel of about 75-ml capacity was provided with a cold-finger condenser at the top and a drain with stopcock at the bottom. The vessel was enclosed in a pyrex jacket which was fitted with a reflux condenser and connected to a pot of boiling liquid. The vapor from the boiling liquid heated the reaction mixture and maintained a constant temperature. The boiling liquid used in the present work was ethyl acetate, giving a jacket temperature of 74±0.2° C for all experiments.

Fifty-milliliter portions of 0.350 *M* solution of I in anhydrous formic acid were heated in the reaction vessel at 74±0.2° C for various lengths of time. Each experiment was stopped by draining the reaction mixture into an ice-cooled receiver. A 2-ml aliquot was pipetted into dry acetic acid for potentiometric titration of the liberated *p*-toluenesulphonic acid (7). A larger aliquot (40 ml) was added to ice water. Known weights of ordinary 2-phenylethyl formate and 2-phenylethyl *p*-toluenesulphonate were added as carriers. The diluted reaction product (IV) and remaining reactant (I_r) were isolated as

described previously (2). By isotope dilution calculations, the concentrations of IV and I_r were then ascertained. The results are tabulated in Table I.

Let a be the initial concentration of I, x the concentration at time t of the products, p-toluenesulphonic acid and IV, then $(a-x)$ would be the concentration of the recovered reactant I_r. From the titration and isotope dilution data, three separate values of $(a-x)$ could be calculated. In these calculations, a small correction on a was made because prolonged heating caused slight decreases in volume due to decomposition of the formic acid. For example, one of the reactions, stopped at a reaction time of 600 minutes, showed, by titration, a p-toluenesulphonic acid concentration of 0.245 M. From an independent trial, heating of the formolysis mixture at 74±0.2° C for 600 minutes caused a decrease in volume from 500 to 494 ml. The effective value of a for the aliquot titrated at 600 minutes of reaction time would be $(500/494)\times0.350 = 0.354$ M. Hence $(a-x)$ from potentiometric titration was $0.354-0.245 = 0.109$ M. Similarly, isotope dilution calculations showed that the concentration of IV was 0.236 M. Thus $(a-x)$ would be $0.354-0.236 = 0.118$ M. Again from isotope dilution, the concentration of I_r was 0.131 M. Correcting for the decrease in volume, $(a-x)$ would be $(0.350/0.354)\times0.131 = 0.129$ M. The mean value for $(a-x)$ is therefore $(0.109+0.118+0.129)/3 = 0.119$ M. Such mean values of $(a-x)$ corresponding to various reaction times are also given in Table I. From a semilogarithmic plot of the mean $(a-x)$ values vs. t (Fig. 1), a straight line was obtained

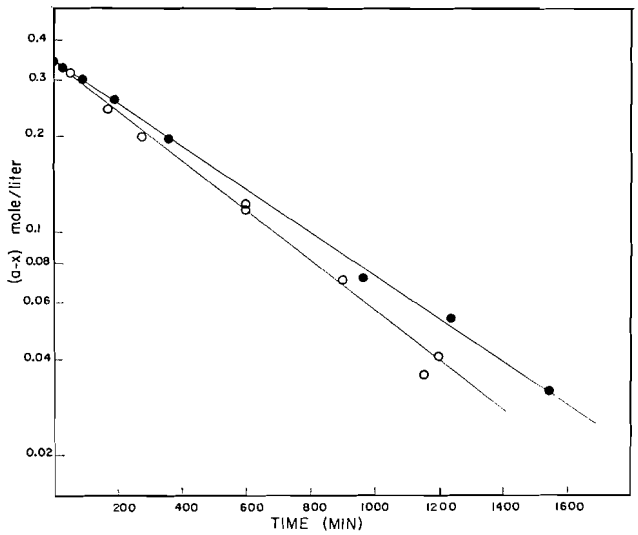

FIG. 1. Rate of formolysis of 2-phenylethyl-1-C^{14} p-toluenesulphonate. Open and closed circles, respectively, represent reaction without and with added sodium p-toluenesulphonate-S^{35}.

indicating a first-order reaction. The first-order specific rate constant, k_1, derived from Fig. 1 is 3.0×10^{-5} sec^{-1}.*

Besides the isotope dilution studies, the rearrangements of the C^{14} label from C-1 to C-2 were determined in the recovered reactant I_r, and in the product IV (2). Treatment of I_r with sodium iodide in acetone gave 2-phenylethyl-x-C^{14} iodide which was oxidized

**Winstein and co-workers (8) reported a k_1 of 3.59×10^{-5} sec^{-1} at 74.62° C for 0.074 M initial concentration of the sulphonate. The agreement appears satisfactory since other data given by these authors (8) showed that at a given temperature, an increase in initial concentration decreased k_1.*

with potassium permanganate (1) to yield benzoic acid whose activity gave a measure of the C^{14} content in the C-2 position of I_r. For the reaction product IV, alkaline permanganate oxidation also yielded benzoic acid whose activity showed the degree of rearrangement of C^{14} to the C-2 position of IV. The C^{14} rearrangements in I_r and IV corresponding to various reaction times are included in Table I.

Formolysis of 2-Phenylethyl-1-C^{14} p-Toluenesulphonate (I) with Added Sodium p-Toluenesulphonate-S^{35} (III)

p-Toluenesulphonic acid-S^{35} was prepared by sulphonation of toluene with concentrated sulphuric acid containing S^{35} (2). Instead of a simple neutralization as a means of obtaining the sodium salt (2), the following series of reactions was used to synthesize III so as to eliminate any possible presence of impurities. *p*-Toluenesulphonic acid was converted to the sulphonyl chloride. Reaction of the latter with ethanol in pyridine (9) gave ethyl *p*-toluenesulphonate-S^{35}, which, in turn, was treated with sodium iodide in acetone to give the desired sodium salt, III.

The formolysis was carried out in a reaction vessel of about 600-ml capacity enclosed in a pyrex jacket as described earlier. Five hundred milliliters of anhydrous formic acid solution, 0.350 *M* in I and in III, was heated in the reaction vessel by the vapor of refluxing ethyl acetate. At zero time, when the jacket temperature first reached 74±0.2° C, and at various time intervals thereafter, aliquots of the reaction mixture were withdrawn for potentiometric titrations of *p*-toluenesulphonic acid, for isotope dilution determinations of the concentrations of I_r and IV, and for the measurements of C^{14} rearrangement in I_r and IV as outlined in the previous section. In addition, the degrees of incorporation of S^{35} in the various samples of recovered reactant I_r were measured. The procedure (2) was based on the treatment of I_r with sodium iodide in acetone, which gave, besides 2-phenylethyl-*x*-C^{14} iodide, sodium *p*-toluenesulphonate whose S^{35} content represented the amount of S^{35} incorporated in I_r. The results obtained from formolysis of I in the presence of an equimolar amount of III are summarized in Table II. A semilogarithmic

plot of $(a-x)$ vs. t (Fig. 1) also gave a straight line from which k_1 was calculated to be 2.6×10^{-5} sec^{-1}.

DISCUSSION

With reference to the results tabulated in Tables I and II, the fact that there was rearrangement of the C^{14}-labeled atoms from the C-1 to C-2 positions in every sample of 2-phenylethyl-x-C^{14} p-toluenesulphonate (I_r) recovered from partially solvolyzed reaction mixtures definitely confirmed the earlier conclusion (2) that there was some return to covalent bonding involving an intermediate ethylphenonium ion (II) or its equivalent. The C^{14} rearrangement in I_r could be regarded as a simple isotopic exchange reaction, the rate of exchange being proportional to $Y_\infty - Y$, where Y is the fraction exchanged at time t, and Y_∞ the fraction exchanged at infinite time. This treatment has been applied by Jenny and Winstein (6) in the consideration of data from the solvolysis of 2-p-methoxyphenylethyl-1-C^{14} p-toluenesulphonate.

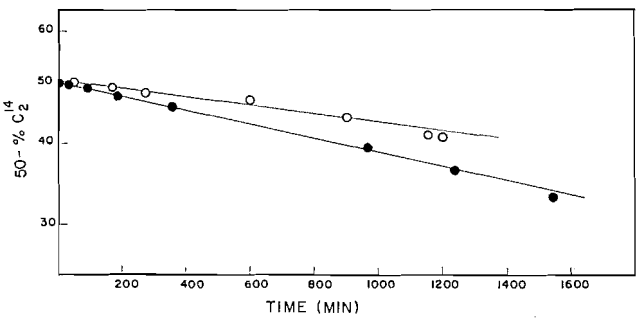
Thus

$$[1] \qquad \frac{d(\%\ C_2^{14})}{dt} = k^{14}(\%\ C_{2\infty}{}^{14} - \%\ C_2^{14})$$

where $\%\ C_2^{14}$ and $\%\ C_{2\infty}{}^{14}$ are, respectively, percentage rearrangement of C^{14} to C-2 at time t and at infinite time. Using the maximum rearrangement of 50% as $\%\ C_{2\infty}{}^{14}$, integration gave

$$[2] \qquad k^{14}t = 2.303 \log \frac{50}{50 - \%\ C_2^{14}}.$$

From semilogarithmic plots of $50 - \%\ C_2^{14}$ vs. t (Fig. 2), k^{14} could be evaluated. Values



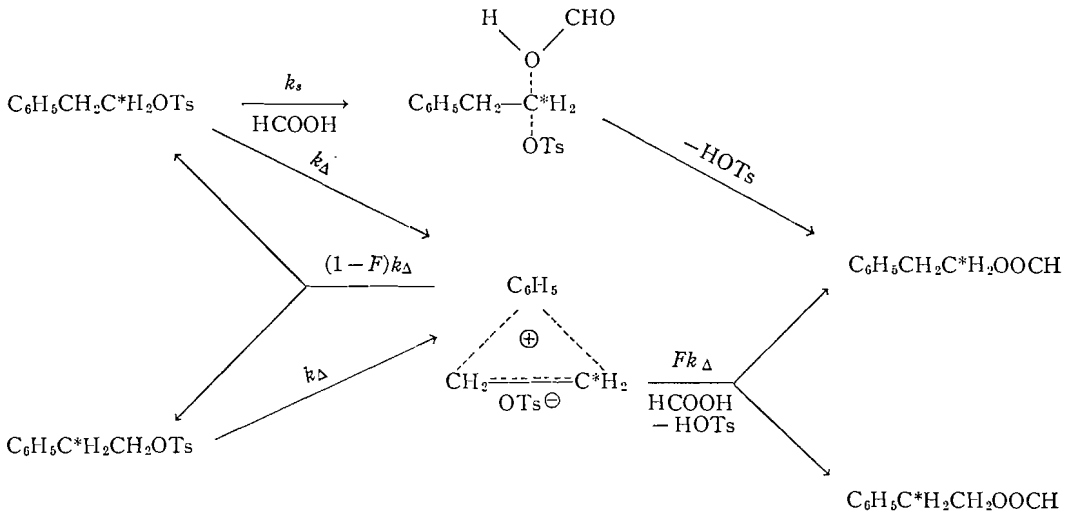


FIG. 2. Rate of C^{14} rearrangement in 2-phenylethyl p-toluenesulphonate recovered from partially solvolyzed mixtures. Open and closed circles, respectively, represent formolysis without and with added sodium p-toluenesulphonate-S^{35}.

of 4.2×10^{-6} sec^{-1} and 2.5×10^{-6} sec^{-1} were obtained, respectively, for k^{14} for formolysis of I with and without the presence of an equimolar quantity of III.

Using the symbolism of Winstein, with k_s and k_Δ designating, respectively, the anchimerically unassisted and assisted solvolysis, the following scheme may be written:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In this scheme, F is that fraction of the anchimerically assisted ionization which leads to solvolysis products, and $(1-F)$ is that fraction which returns to covalent bonding. With the aid of equations [3], [4], and [5], k_s, k_Δ, and F can be calculated (6). The results, together with values of k_1 and k^{14} derived from Figs. 1 and 2, are summarized in Table III.

[3] $$k_1 = Fk_\Delta + k_s$$

[4] $$k^{14} = (1-F)k_\Delta$$

[5] $$\frac{k_\Delta}{k_s} = \frac{\text{mean \% rearrangement in formate IV}}{50 - \text{mean \% rearrangement in formate IV}}$$

TABLE III

Summary of rate data for the formolysis of 2-phenylethyl-1-C^{14} *p*-toluenesulphonate (I) with or without the presence of an equimolar amount of sodium *p*-toluenesulphonate-S^{35} (III)

$NaOTs\text{-}S^{35}$	10^5k_1 (sec^{-1})	10^5k^{14} (sec^{-1})	10^5k_s (sec^{-1})	10^5k_Δ (sec^{-1})	F
None	3.0	0.25	0.4	2.9	0.91
Equimolar	2.6	0.42	0.2	2.8	0.85

From Table III, it may be noted that the relative values of k_s and k_Δ showed that the reaction proceeded chiefly by anchimerically assisted ionization as one would expect for solvolysis in formic acid, a highly ionizing solvent. The over-all formolysis rate, k_1, was some 13% slower when the reaction was carried out with added III. This could be explained on the basis of the so-called mass-law effect (10) with the common *p*-toluenesulphonate ion causing a rate depression. The data also demonstrated that this rate depression was attributable to a greater degree of return to covalent bonding when an excess of *p*-toluenesulphonate ion was present during the formolysis. This was indicated by a greater k^{14} for the formolysis in the presence of III. From the calculated F values, it can also be seen that the fraction of the anchimerically assisted ionization returning to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

covalent bonding was some 15% for the reaction in the presence of III as compared with a return of only 9% when III was absent.

In connection with returns to covalent bonding, it may also be of interest to point out that in a study of the rates of solvolysis of 2-phenylethyl-1,1-d_2 and 2-phenylethyl-2,2-d_2 *p*-toluenesulphonates (I_b and I_c), Saunders and co-workers (11) noted the absence of any drift of the rate constants toward a common value and concluded that "internal return from a phenonium–tosylate ion pair cannot be appreciable, since in its presence I_b and I_c would be interconverted and their rate constants would drift toward a common value as the reaction proceeded". This conclusion would be valid only if the rate of the return process were great enough to cause an almost complete scrambling of the C-1 and C-2 positions in I_r before the product-forming reaction proceeded to completion. Inspection of the data in Table I shows that after a reaction time of 1200 minutes (about 88% completion), the C^{14} rearrangement in I_r was 8.88%, far from a 50% rearrangement expected for a complete scrambling of the C-1 and C-2 positions. Thus the interconversion of I_b and I_c was not great enough during the formolysis of these compounds to cause an observable drift towards a common rate constant. The fraction $(1-F)$ from the present data indicated that a return to covalent bonding did occur to the extent of about 9% of the anchimerically assisted ionization.

The processes of return from ionic intermediates to covalent bonding may be differentiated as internal and external returns, with internal return designating return from the "intimate ion pair" and external return designating return from the "solvent-separated ion pair" or dissociated ions (4, 5). In such a differentiation, internal return would be pictured as an intramolecular process. It was hoped that the inclusion of S^{35}-labeled sodium *p*-toluenesulphonate (III) in the formolysis studies might provide data which could shed some light on the extent, if any, of the intramolecular return.

The degrees of incorporation of S^{35} in the various samples of I_r are given in Table II. These results could not be treated kinetically as data for a simple exchange reaction between 2-phenylethyl *p*-toluenesulphonate (I) and sodium *p*-toluenesulphonate-S^{35} (III) because one of the reactants, I, was being continually converted to 2-phenylethyl formate (IV). Moreover, the S^{35} incorporated in I_r, besides arising from external return, might have resulted also from a direct displacement reaction between I and the added *p*-toluenesulphonate-S^{35} anion, and (or) by exchange between the labeled *p*-toluenesulphonate anion and the *p*-toluenesulphonate anion of the intimate ion pair. However, a qualitative consideration of the S^{35} incorporation in I_r in conjunction with the C^{14} rearrangement in I_r can be made (2). If the C^{14} rearrangement in I_r were to arise entirely from reaction between ethylphenonium ions (II) and the added *p*-toluenesulphonate-S^{35} anions, in other words entirely from external return, the percentage of S^{35} incorporated in I_r would be twice the percentage of C^{14} rearrangement in I_r. A correction should be made because the added *p*-toluenesulphonate-S^{35} anions would be progressively diluted by the *p*-toluenesulphonic acid liberated from I during the course of the reaction. The S^{35} in I_r would be decreased by this dilution effect. For example, for a reaction stopped at 10% completion, on the average, the incorporation of S^{35} would be decreased by a factor of $100/(100+10/2)$. The values obtained from [100/(100+% reaction/2)] ($2\times$% C^{14} rearrangement in I_r) would be the calculated percentage of S^{35} in I_r if the return process were only external or intermolecular. These calculated values are given in column 7 of Table II. Compared with the observed percentage of S^{35} in I_r (column 6, Table II), it can be seen that during the earlier stages of the reaction, the observed S^{35} in I_r were slightly lower than the calculated S^{35} for pure external return, while at the later stages

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of reaction, the observed S^{35} in I_r were considerably lower than the calculated values. Since the observed S^{35} in I_r should be the sum of the S^{35} incorporated via external return, via direct displacement between I and the added *p*-toluenesulphonate-S^{35}, and possibly even via return from an intimate ion pair containing some exchanged *p*-toluenesulphonate-S^{35} anions, if the return process were only intermolecular between II and *p*-toluenesulphonate-S^{35}, one would expect the observed S^{35} in I_r to be at least equal to, or possibly greater than the calculated % S^{35} in I_r for pure external return. The fact that the observed percentage of S^{35} in I_r were smaller than the calculated values, even though only slightly smaller, indicated that very probably some intramolecular return also took place. It may, therefore, be concluded that the return from ionic intermediates to covalent bonding during the formolysis of I included both internal and external returns, with external return accounting for the major portion of the return processes.

CONDENSATION OF SPRUCE PERIODATE LIGNIN WITH FORMALDEHYDE[1]

EDGAR EISENBRAUN[2] AND C. B. PURVES

ABSTRACT

The use of 73% sulphuric acid at 41° for 1 hour or less caused the periodate lignin to condense with 32% by weight of formaldehyde, as shown by direct measurement and by employing C^{14}-formaldehyde. Analyses of the product, however, suggested that the elements of water had been expelled during the condensation and that the true yield was about 120%. Up to 106% was recovered as material insoluble in dilute sulphuric acid (Ross–Potter lignin), and about 9% as a more soluble form. The approximate equivalence in weight of the Ross–Potter lignin to the original periodate (or Klason) lignin thus originated in the cancellation of three large errors. Formaldehyde periodate lignin failed to yield vanillin when oxidized in alkali with nitrobenzene or cupric hydroxide. Oxidation with alkaline potassium permanganate, or with iodic acid at not more than 200°, yielded benzenepentacarboxylic acid and perhaps mellitic acid (total, 3.9%) but none of the 1,2,4,5-tetracarboxylic acid recovered (together with the pentacarboxylic acid) from similar oxidations of periodate lignin. Convenient semimicro-scale oxidations with cupric hydroxide and with iodic acid, and the chromatography of the benzene-penta- and -tetra-carboxylic acids on paper, were described.

INTRODUCTION

It is well known that the treatment of wood meal with 72% sulphuric acid near 20°, as in the Klason determination of lignin, soon degrades and dissolves all of the carbohydrates but leaves the lignin as a dark brown, amorphous powder insoluble in all liquids. In 1929, however, Ross and Hill (1) observed that when the wood meal was first soaked in formalin all dissolved in the sulphuric acid, and this solution had to be diluted with water in order to precipitate "formaldehyde lignin". The yield appeared to be quantitative from softwoods, but not from hardwoods, and the products were soluble in alcohol, acetone, or acetic acid containing a little water. Ross and Potter (2) modified the procedure to determine lignin in paper pulps, but the Klason method proved to be more reproducible (3). Since formaldehyde could be expected to condense freely with lignin (a phenolic material) it seemed anomalous that the yield of Ross–Potter lignin was not substantially greater than that of the Klason lignin. The solubility of formaldehyde lignin suggested (2) that the formaldehyde had substituted active centers in the lignin, which normally condensed with each other to form the insoluble Klason lignin. The present research was planned to gain information on these possibilities.

Borisek and Polcin (4) determined the amount of formaldehyde that condensed with sulphite waste liquor solids under various conditions. No condensation occurred in neutral solution, and in alkali the formaldehyde underwent the Cannizzaro reaction. In sulphuric acid, the amount condensed increased as the concentration of the acid was increased to 27%, and 2 hours were sufficient for the reaction. Samples pretreated with sulphurous or sulphuric acid failed to react under the conditions tried. The lignin used on the present occasion was isolated by alternately oxidizing spruce wood meal with sodium periodate near pH 4, and extracting the oxidized polysaccharides with cold, dilute alkali. Although free of carbohydrates and dissolving at almost the normal rate during a calcium bisulphite cook of the type used in pulping wood, the periodate lignin was somewhat oxidized. Nevertheless, it served as a good model substance for lignin

in situ. Periodate lignin, when saturated with formalin, proved to be completely soluble at 41° in sulphuric acid provided the concentration of acid in the final mixture was at least 69% by weight.

The simplest way of isolating the main product (method (*a*)) was to pour this solution into a large volume of cold water, which was kept near neutrality by the simultaneous addition of sodium hydroxide, and to purify the precipitated formaldehyde periodate lignin by dialysis. The yield was 104% by weight. To recover the soluble products, dialysis was avoided in method (*b*), in which the neutralized, concentrated liquors were freed of sodium sulphate by dilution with ethanol and acetone. Evaporation of the mother liquor gave a yellow glass highly contaminated with inorganic material and formaldehyde polymer, but extraction with organic solvents recovered 9% of product, which with 106% for the main fraction raised the total yield to 115%, free of ash and moisture. This figure was accepted as being close to the yield actually formed in the condensation. Both the major and the minor fractions retained ultraviolet absorption spectra in 0.1% solution of the type characteristic of most lignins, with a broad, prominent maximum near wave length 280 mμ. A third attempt at isolation (method (*c*)) involved pouring the original sulphuric acid solution into an excess of acetic anhydride and anhydrous sodium acetate more than sufficient to combine with all the water and acid present. After isolation by precipitation into water followed by dialysis, the acetylated periodate formaldehyde lignin was recovered in 92% yield as a dark, hard resin.

The consumption of formaldehyde in the condensation was estimated, by difference, from the initial and final amounts. The results showed that 100 g of the lignin condensed with 32 g of formaldehyde, but the true amount might be as high as 35 g, since Freudenberg and Sohns (5) obtained 2 to 3% of formaldehyde by distilling various lignins with sulphuric acid. Thus the expected yield of formaldehyde periodate lignin was at least 132% by weight, whereas 115% was the most that was ever recovered. According to the book by Walker (6), the strongly acidic conditions necessary to cause the condensation of formaldehyde with simple phenolic ethers or with ethylenic compounds were usually, although not always, sufficient to condense the hydroxymethyl derivatives initially formed to cyclic acetals, to ethers, or to derivatives of diphenylmethane. The above discrepancy in the yield of formaldehyde periodate lignin might thus originate in the condensation of hydroxymethyl groups with loss of the elements of water.

To investigate this possibility, the composition of an adduct from 100 parts by weight of periodate lignin and 32 parts of formaldehyde was calculated as shown in Table I, line C. A loss in weight of this adduct in the ratio 132:120 (instead of the observed ratio, 132:115) would result in the calculated composition given in line D, although the figures were no longer percentages. Comparison of line D with line E, the observed percentage composition of formaldehyde periodate lignin, showed that the latter retained all of the original carbon atoms and methoxyl groups but had lost hydrogen and oxygen in the ratio 1:8 characteristic of the composition of water. These calculations were approximate, because they were based on the major Ross–Potter fraction of the formaldehyde periodate lignin rather than on the entire amount, and ignored a sulphur content of 1% derived from the sulphuric acid used in the condensation.

Comparison of columns 4 and 5 in Table I showed that periodate lignin failed to respond to a methylation attempted with diazomethane, and therefore contained no hydroxyl groups of a phenolic nature; the increase of 1.8% observed in a similar methylation of the formaldehyde periodate lignin (line E) suggested that a few phenolic groups had been formed in the condensation, probably by the hydrolytic action of the 73% sulphuric

acid. Methylation with dimethyl sulphate caused practically the same increase (17.6–12.2%) and (15.2–9.9%) in the methoxyl contents of the two lignins (columns 4 and 6), and thus both had the same total number of phenolic and aliphatic hydroxyl groups. Since the formaldehyde periodate lignin seemed to contain a few phenolic groups, its content of aliphatic hydroxyl groups was probably less than that of the periodate lignin. The acetyl contents of the two acetylated lignins (column 7, lines A and E) also suggested that aliphatic hydroxyl groups had been diminished, rather than increased, by the condensation with formaldehyde.

Two small-scale condensations were carried out with radioactive C^{14}-formaldehyde to determine, by an independent method, the proportion of carbon in formaldehyde periodate lignin which was contributed by the formaldehyde. The procedure of Das Gupta and Nair (9) was adapted to oxidize the various samples quantitatively by combustion to carbon dioxide, the activity of which was measured after conversion to barium carbonate. The count rates given by layers of the carbonate varying in thickness were plotted in Fig. 1 to eliminate the self-absorption factor, and to give comparison for samples of identical superficial density. Individual measurements deviated from the plots by not more than 10%. The open and filled circles (upper plot, left-hand ordinates) represented duplicate combustions of the original C^{14}-formaldehyde, and yielded a single smooth plot. When the ordinate scale shown at the right of Fig. 1 was chosen, the data from duplicate combustions of one C^{14}-formaldehyde periodate lignin sample fitted the same plot (open and filled triangles). It followed that 900/6000, or 15% of the carbon in this sample was derived from the formaldehyde. The values obtained for the second preparation of C^{14}-formaldehyde periodate lignin (crosses) corresponded to 16% of C^{14}.

Downes (16), however, found that C^{14}-formaldehyde condensed with dimedon to form the insoluble bismenthone, $C_{17}H_{24}O_4$, at only 0.93 times the rate displayed by the C^{12} isotope; if a similar effect occurred in the condensation with lignin, the above results would become 16% and 17%, respectively. In the present experiments, some of the C^{14}-formaldehyde was converted quantitatively to the bismenthone to eliminate the isotope effect, and the carbon in the product was recovered as barium carbonate before being counted. The results (Fig. 1, lower plot, open and half-filled circles) showed that 5.0 to

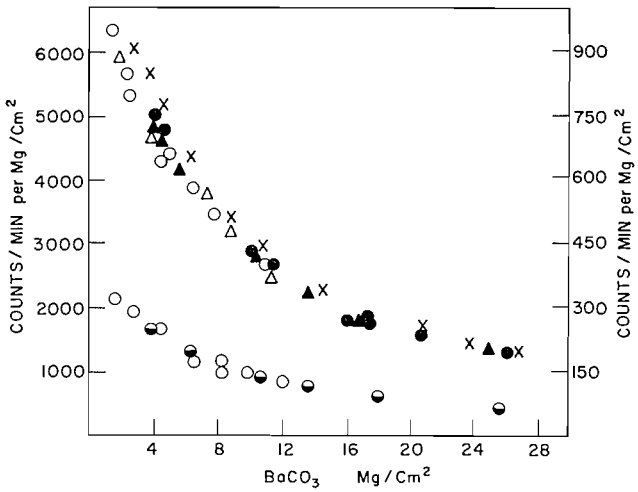

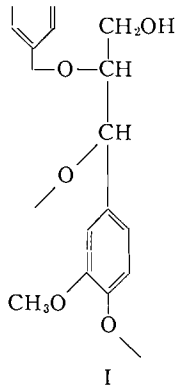

FIG. 1. Activity of C^{14}-compounds as mg barium carbonate per sq. cm. Left-hand ordinates, upper plots, open and filled circles, formaldehyde. Right-hand ordinates, open and filled triangles, formaldehyde periodate lignin; crosses, a duplicate preparation of the lignin; lower plot, open and half-filled circles, duplicate preparations of formaldehyde bismenthone.

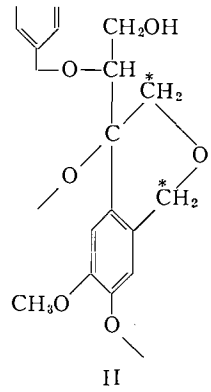
5.4% of the carbon was derived from the C^{14}-formaldehyde, whereas the value calculated for the bismenthone, 5.9%, was higher by about one-tenth. The cause of this discrepancy was not determined. Whether the C^{14}-formaldehyde count or that of its bismenthone derivative was accepted as the primary standard, the amount of C^{14} in the C^{14}-formaldehyde periodate lignin appeared to be between 15% and 18% of the total carbon content. This result agreed well with the value of 17.2% assumed in Table I.

Since the detailed structure of the lignin macromolecule remained unknown, that of the formaldehyde derivative could only be surmised. The greater part of the macromolecule, however, is currently supposed to resemble structure I, in which the ether links in the phenylpropane side chains were assigned to arbitrary positions (11, 12). Cross links rendered the lignin insoluble in all chemically indifferent liquids, but were not numerous enough to prohibit swelling. The action of sulphuric acid by itself would be to cleave some of the ether bonds, but autocondensation would simultaneously yield the insoluble, and presumably more highly cross-linked, Klason lignin. A loss of the elements of water probably occurred in such condensations (13). Perhaps the alpha positions in the side chains and the sixth positions in the nucleii were among those involved in condensation, because the former were probably sulphonated when lignin was heated in aqueous sodium bisulphite (12) and the latter could be chlorinated. A preferential condensation of each of these reactive sites with 1 mole of formaldehyde would increase the base molecular weight of the lignin from about 187 to about 247, or in the ratio 100:132 by weight, and the formaldehyde would contribute 16.7% of the carbon in the adduct. The loss of a molecule of water would lead to a new ether link (structure II) and reduce the yield by weight in the ratio 132:122. These figures were close to those observed. Carbon atoms originating as formaldehyde were denoted by asterisks in this and subsequent structures.



The ready solubility of formaldehyde lignin in several liquids suggested that condensation with formaldehyde did not bring about cross linking, and an intramolecular arrangement of the new ether group was chosen for structure II. Wherever this group was located, its existence reduced the number of the free hydroxyl groups to the original number, as

Mellitic acid

was found. Most lignins, including Klason lignin (14) and periodate lignin (15), when heated with nitrobenzene and alkali yielded vanillin, presumably by oxidative cleavage at the alpha carbon atom in structure I. The nitrobenzene could be replaced with cuprous hydroxide (16), whose use was adapted to a convenient semimicro scale. Neither oxidant produced a trace of vanillin from the Ross–Potter fraction, or the acid-soluble fraction, of formaldehyde periodate lignin, and attempts to isolate a carboxyvanillin from the oxidation liquor also failed. These failures were not inconsistent with structure II, since substitution of the alpha positions by formaldehyde might render the molecule more resistant at this point to oxidative cleavage.

Samples of the Ross–Potter fraction were then thoroughly oxidized with potassium permanganate in hot aqueous alkali to carbon dioxide, acetic acid, oxalic acid, and a mixture of benzenepolycarboxylic acids (17). Since the oxalic acid was radioactive when C^{14}-formaldehyde periodate lignin was used, the formaldehyde had formed a C—C bond, rather than a C—O—C bond, with the lignin, as shown in structure II. All aromatic rings directly substituted with oxygen, however, were known to be destroyed in this oxidation, and structure II would yield no benzenecarboxylic acids. As previously discussed (17), the production of these acids suggested that a minor part of the lignin macromolecule consisted of lignan elements in which the β-carbon atoms of the phenylpropane units were directly joined. Substitution of a hydroxymethyl group in the α-position of the lignan, followed by cyclization as shown by the broken line (structure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

III), would yield a cyclohexene ring (A) entirely substituted by carbon atoms. Benzenehexacarboxylic (mellitic) acid (IV) would result when this ring was oxidized, and also benzenepentacarboxylic acid by partial decarboxylation. A new paper chromatographic technique was used to isolate the benzenepentacarboxylic acid in a pure condition, but the mellitic acid, if present, stayed on the starting line, and no benzenetetracarboxylic acids were present. When C^{14}-formaldehyde periodate lignin was oxidized, the supposed mellitic acid had some activity, but the pentacarboxylic acid had none.

Although parallel oxidations of spruce Klason lignin yielded about the same amount, 4%, of benzenepolycarboxylic acids as did the formaldehyde periodate lignin, the mixture consisted exclusively of benzenepentacarboxylic acid and the 1,2,4,5-tetracarboxylic acid, and mellitic acid was absent (17). This sharp difference between the two lignins strongly supported the view that some of the formaldehyde substituted the alpha positions of the phenylpropane units of structure III, as well as those in structure I. Mellitic acid, benzene-penta-, -1,2,4,5-tetra-, and -1,2,3,5-tetra-carboxylic acid were oxidized to the extent of only 0.7, 2.2, 1.9, and 5.0%, respectively, by iodic acid in concentrated sulphuric acid at 180° to 190°, although Kleinert and Dlouhy (18) recently showed that these acids were quantitatively oxidized at 220° to carbon dioxide. Oxidation at the lower temperature proved to be a simple method of recovering the benzenepolycarboxylic acids from periodate and formaldehyde periodate lignin.

Another aldehyde capable of condensing with lignin was chloral hydrate in the presence of a little hydrochloric acid. Ogait (19) extracted most of the lignin from spruce wood meal with this reagent, and recovered about half as a thermoplastic "chloral lignin" soluble in chloroform and containing about 15% of chlorine. A repetition of this work with spruce periodate lignin yielded a "chloral periodate lignin" with only 9.2% of chlorine and soluble in acetone, but the results were otherwise too similar to those of Ogait to justify detailed reproduction here. They served to show, however, that the cleavage of lignin–carbohydrate bonds was not an essential step in the production of chloral lignin (19), since the periodate lignin was free of carbohydrates.

EXPERIMENTAL

Materials and Methods

Woodmeal of 20–30 mesh fineness was prepared from a log of black spruce which was free of bark and about 30 years old. The oxidation of a 2160-g batch with 660 g of sodium paraperiodate in 18 liters of water adjusted to pH 3.6–4.0 with acetic acid, and the subsequent extraction of the oxidized carbohydrates with cold 0.1 *N* sodium hydroxide, were as previously described (15, 20). After four or five oxidation–extraction cycles, the water-wet, gelatinous periodate lignin was solvent-exchanged first into acetone, which yielded a free-flowing, easily filterable suspension, and then through methyl ethyl ketone into ligroin, b.p. 30°–60°. Final drying, *in vacuo* over phosphorus pentoxide and solid paraffin, had to be thorough. Found: C (21), 60.1; H (21), 5.4; OCH_3 (22), 11.9; ash (21), 2.5; Klason lignin (23), 87%; holocellulose (24), trace. The product, and also samples isolated by freeze-drying the water-wet mass, were light-colored powders of low density, whereas samples dried directly from water were hard, darker resins. Periodate lignin had a low but noticeable cation-exchange capacity, and the acid form acquired sodium ion from aqueous sodium chloride.

Distilled water and organic liquids of C.P. or equivalent grade were used throughout

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the work. Evaporations were performed at not more than 45° in a rotary evaporator under vacuum; often the solutions or suspensions, especially when neutral, produced much froth initially and the pressure had to be reduced gradually. Unless stated otherwise, final drying was *in vacuo* over phosphorus pentoxide, and analyses were in duplicate, the averages of concordant determinations being quoted. Seamless cellulose dialyzer tubing, 0.00072 inch thick, was used in dialyses, which were against large volumes of water. Phenolic compounds were chromatographed on paper with *n*-butanol saturated with 2% aqueous ammonia (16) (solvent A) or with ligroin–dioxane–water in the ratio 4:2:1 by volume (solvent B) as eluents. The spray described by Barton, Evans, and Gardner (25) was made more sensitive by the use of a mixture of 1% ferric chloride, 10 ml; 1% potassium ferricyanide, 6 ml; saturated boric acid solution, 10 ml; and water, 20 ml. The eluent for organic acids was a 10:1:1 mixture of methyl isobutyl ketone, water, and formic acid (solvent C) with bromphenol blue as the spray. Prior to spraying, the paper was dried at 130° *in vacuo* to eliminate formic acid. Yields and analyses were quoted on a moisture- and ash-free basis.

Condensations with Formaldehyde (1, 2)

Many preliminary experiments showed the necessity of immersing the lignin in formalin *before* adding the sulphuric acid, which had to attain at least 69% concentration by weight in the mixture. The required concentration was reached by adding 88.5% sulphuric acid, since the use of the concentrated acid yielded a more highly sulphonated product.

In a typical experiment, 50 g of periodate lignin (47.1 g on a moisture- and ash-free basis) was soaked for 2 hours in changes of commercial 37% formalin, 224 g of which was retained when the swollen mass was recovered on a filter. The moist lignin was mixed in a 1.5-liter beaker with 250 g of solid carbon dioxide, and ice-cold 88.5% sulphuric acid (about 700 g) was slowly added with stirring until the final concentration was 73±1%, the composition being: lignin, 47.1 g; formaldehyde, 83 g; sulphuric acid, 620 g; and water, 227 g. The gummy mixture was then maintained near 41° and was worked with a glass rod until a uniform, dark red-brown solution was obtained. No more solid particles could be detected after 30 to 50 minutes; the solution was then cooled and the product isolated in one of the following ways.

Method (a)

The reaction mixture and about 8 liters of cold, 10% aqueous sodium hydroxide were simultaneously poured into 15 liters of cold water so that the pH remained between 5 and 9, the final value being 3.5. The precipitate was separated on a centrifuge and the liquors were extracted at pH 2 with methyl ethyl ketone, which removed 0.3 g of a dark, non-volatile, brittle solid. This solid was extracted from the ketone by 5% sodium hydroxide. The major product, 74 g including 30% of sodium sulphate, was mixed with 250 ml of water and was dialyzed for 3 days. Acidification of the dialyzate to pH 1.8 and extraction with methyl ethyl ketone removed 1.8% of a gum which was soluble in water and dilute alkali. Found: OCH_3, 9.2; sulphated ash, 3.9%. This gum remained partly on the starting line, and partly in the solvent front, when chromatographed on paper with solvents A or B.

The contents of the dialysis sac, when evaporated at pH 6, yielded 52.5 g of formaldehyde periodate lignin as dark brown lumps which were powdered in a mortar. Found: C, 59.3; H, 5.1; OCH_3, 9.4; S, 1.0; ash, 4.6%. The yield, ash-free, was 104% of the periodate lignin, and the two minor fractions increased this figure to 107.4%.

Method (b)

A solution of formaldehyde periodate lignin in 73% sulphuric acid, made from 9.7 g of periodate lignin, was poured into 400 ml of water at 0°, and the precipitated Ross–Potter lignin was washed on the centrifuge with four 250-ml volumes of water; a little sulphuric acid had to be added in the last washing to obtain a good separation. The liquors were neutralized with sodium carbonate and were evaporated at pH 8 to 700 ml, when crystalline sodium sulphate was removed at 4°. After acidification to pH 0.5 with sulphuric acid, the liquor was alternately concentrated to 50 ml and diluted with water several times to decompose and eliminate most of the formaldehyde polymers. The neutralized liquor, 40 ml, was highly diluted with acetone to precipitate inorganic material, and the portion soluble in dry acetone was recovered as a near-white, dry gum. Yield: 6.53 g. Found: ash, 27.1; loss in weight on heating in air for 70 minutes at 105°, 45.3%.

This loss of weight represented the decomposition of formaldehyde polymer. A suspension of the gum in 80 ml of water was continuously extracted first with ether and then with methyl ethyl ketone at 240 mm pressure. The ether extract yielded 0.57 g of material of which 0.17 g was non-volatile at 105°, while 0.72 g of the 0.76 g recovered from the ketone was non-volatile. Samples of both extracts were hydrolyzed in boiling 16% sulphuric acid and the formaldehyde liberated from the polymer was determined by the sodium sulphite method (4, 26). The aqueous residue from the extractions contained 2.7 g of a white, amorphous solid. Found: OCH_3, 20.5; S, 21.3; ash, 54.6%. Calc. for $H_2C(OCH_3)OSO_3Na$: OCH_3, 18.9; S, 19.5; ash as Na_2SO_4, 43.3%. The substance failed to give a positive test for sulphate ion with aqueous barium chloride, but the ash did so.

The Ross–Potter fraction was dissolved in dilute sodium hydroxide except for an 0.28-g residue with 45% of ash. Acidification of the brown filtrate reprecipitated the main product, which was washed with water and redissolved while still wet in much acetone. A residue separated on the centrifuge yielded 0.17 g of material insoluble in water (ash, 13.7%), and 0.29 g soluble in water (ash, 30.3%). The acetone solution was diluted with water, adjusted to pH 5.7, concentrated, and the product was isolated as a friable, brown powder by freeze-drying. Yield: 10.43 g: ash, 6.1%. The total recovery of organic material, excluding formaldehyde polymer, was (0.17+0.72+0.14+0.15+0.2 +9.8 g) 11.2 g, or 115% by weight.

Method (c)

A solution of formaldehyde periodate lignin, prepared in 73% sulphuric acid from 3.2 g of periodate lignin, was mechanically stirred into a mixture of glacial acetic acid, 81 ml; acetic anhydride, 540 ml; and anhydrous sodium acetate, 105 g. Although the flask was cooled externally with solid carbon dioxide, the temperature rose to 51°. The resulting slurry was kept near 2° for 18 hours, when the excess acetic anhydride was cautiously hydrolyzed with water and the liquor was thoroughly dialyzed against water. The non-dialyzed portion was isolated by evaporation at pH 6.5 followed by drying to constant weight. The dark brown resin weighed 3.21 g. Found: OCH_3, 7.8; acetyl (27), 4.2; ash, 13.4%.

Methylations of Ross–Potter Fraction

A portion of the product isolated by method (*a*) was suspended in dry tetrahydrofuran and an excess of dry diazomethane was added. Twelve hours later, the liquor was evaporated and the residue dried *in vacuo* over phosphorus pentoxide and solid sodium hydroxide. Found: OCH_3, 11.2; ash, 4.5%.

Another portion of the same Ross–Potter fraction was methylated with dimethyl sulphate and 30% sodium hydroxide in aqueous tetrahydrofuran, the atmosphere being oxygen-free nitrogen. Both the acetone-soluble and acetone-insoluble fractions of the product (yields 37% and 46%, respectively) had the same methoxyl content, not increased by remethylation. Found for the acetone-soluble fraction: OCH_3, 15.0; S, 0.44; ash, 2.0%. A sample of periodate lignin was completely methylated in the same way. Found: OCH_3, 17.5; ash, 1.2%.

Consumption of Formaldehyde

The apparatus consisted of a stout-walled glass bomb of 100-ml capacity with a side-arm dipping into water to trap any formaldehyde expelled when pressure increased. The top of the bomb was connected by a short piece of rubber hose to an air-tight, mercury-sealed stirrer consisting of a stout glass rod reaching almost to the bottom. The flexible connection made it possible to work the particles of lignin into solution. Paraformaldehyde, 42 g, and 68 ml of 0.05 *N* hydrochloric acid were boiled under reflux and the almost clear solution, when analyzed by the steam distillation – sodium sulphite method (4, 26), contained 36.2, 36.1% formaldehyde by weight. Three grams (2.86 g ash-free) of periodate lignin and 15 g of the formaldehyde solution were weighed into the apparatus; next day 44.8 g of 88% sulphuric acid was added and the condensation completed as previously described.

The resulting solution was cooled, diluted with water, and quantitatively transferred to a 1-liter flask arranged for steam distillation. The suspension, 400 ml, was kept just below the boiling point for 50 minutes to hydrolyze formaldehyde polymers, and was then steam-distilled for 3 to 4 hours, the distillate being exactly 1 liter. Aliquots, 100 ml, of the distillate were then analyzed by the sodium sulphite method, which employed *N* hydrochloric acid and a thymolphthalein indicator in the final titration (26). Found: CH_2O, 4.30, 4.26 g, whereas a blank containing no lignin yielded 5.28, 5.27 g. The difference, 0.99 g, had therefore condensed with 2.86 g of periodate lignin, or in the proportion of 34.5:100. Since any trace of sulphuric acid carried into the distillate would have registered as formaldehyde, independent experiments were carried out in which the distillates were neutralized to thymolphthalein before the determination of formaldehyde. Found: CH_2O, 4.38, 4.32 g, and 5.29, 5.26 g in the blank. In this case, 32 g of formaldehyde condensed with 100 g of the lignin. The still residues yielded 3.07, 3.09 g of the Ross–Potter fraction, or 104, 105%, and a further 0.22 g or 7.8% of formaldehyde periodate lignin was recovered from the mother liquors after removal of sulphate ion as the barium salt. The removal of sulphate ion by the cation-exchange resin "Amberlite IR-120" reduced the recovery of the acid-soluble lignin to 5.7% in the duplicate experiment.

C^{14}-Formaldehyde Periodate Lignin (Fig. 1)

A solution of radioactive formaldehyde was made by heating 18 mg of C^{14}-paraformaldehyde (obtained from Merck Company of Canada, Limited) and 5 g of inert paraformaldehyde with 8.5 ml of 0.05 *N* hydrochloric acid in a sealed glass bomb at 100° for several hours. Found for the clear solution by the bisulphite (4, 26) method: H_2CO, 35.8, 35.8, 36.2%. This result was checked by precipitating the formaldehyde in 0.5-g samples with 2 g of dimedon in 300 ml of water at pH 4.6. One gram of the bismenthone was equivalent to 0.1027 g of formaldehyde (26). Found: H_2CO, 35.7, 36.25%. Two batches of C^{14}-formaldehyde periodate lignin were prepared as described in method

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(*a*), each from 2.5 g of the above solution, 0.5 g of periodate lignin, and 8.5 g of 88.5% sulphuric acid. After the dialysis, solutions of the Ross–Potter fractions in dilute sodium hydroxide were filtered through sintered glass to remove insoluble but active material (15 mg or less), thoroughly dialyzed again, and freeze-dried. Yield: 470, 488 mg.

To determine C^{14}-carbon, 50-mg samples were burned to carbon dioxide in a conventional microcombustion furnace (28), those of the original formaldehyde solution being introduced in a fine glass tube sealed at one end. The carrier gas was purified oxygen, and the carbon dioxide was absorbed by passage through each of two 250-ml centrifuge tubes one-third filled with aqueous barium hydroxide free of carbonate. Each tube contained a small magnetic stirrer to make sure that the distribution of C^{14}-carbon in the precipitated barium carbonate would be uniform (29), and some samples were mixed with pulverized potassium dichromate to prevent any loss of carbon dioxide as sodium carbonate during the combustion. The precipitated barium carbonate was recovered by centrifugation and was magnetically stirred with changes of wash water (free of carbon dioxide) and finally exchanged into acetone, giving a fine-grained product suitable for counting.

A suspension of this precipitate in acetone was deposited in varying amounts on tared aluminum pans 3 cm in diameter; drying was under an infrared lamp and all samples were measured over the same area. A gas-flow proportional counter was used whose efficiency, compared with a 2π gas-flow windowless counter, was checked at 13% on several samples. Each measurement for formaldehyde and the Ross–Potter fraction totalled at least 30,000 and, with two exceptions, at least 11,000 for formaldehyde bismenthone. Each measurement was corrected for background, and the sensitivity and window position of the instrument were kept constant throughout.

Oxidations with Nitrobenzene and Cuprous Hydroxide

One gram of the lignin, 2.3 ml of pure benzaldehyde, and 20 ml of 4 *N* sodium hydroxide were heated together in a stainless steel bomb at 175° for 3 hours (30, 31). The contents were distilled in steam, the still residue was extracted with benzene, acidified to pH 3, and continuously extracted with ether. Portions of the residue from the ether extract were then chromatographed on paper with solvent A.

In the oxidations with cuprous hydroxide (16), 2 g of the lignin, 42 ml of 3 *N* sodium hydroxide, and 12 g of finely divided cuprous hydroxide were heated at 175° for 3 hours. The suspension was then filtered, and filtrate plus washings were acidified to pH 2 and continuously extracted with ether. When the extract from an oxidation of periodate lignin was re-extracted with saturated aqueous sodium bisulphite, a 20% yield of vanillin was recovered, some of which was isolated with the correct melting point and mixed melting point. Products from formaldehyde periodate lignin yielded ether extracts which deposited insoluble material continuously during extractions with aqueous sodium bisulphite, bicarbonate, or hydroxide. Every attempt to isolate vanillin, a carboxyvanillin, or vanillic acid failed.

The above oxidation was reduced to the semimicro scale previously described for oxidations with nitrobenzene (30), the 5-ml steel bombs being charged with lignin, 50 mg; cuprous hydroxide, 300 mg; and 2 ml of 2 *N* sodium hydroxide. During the heating in an air oven at 175° for 2.5 hours, the bomb was twice shaken vigorously by hand. The liquor could then be directly spotted on chromatograph paper; when the spots had been dried, they were exposed for a minute to the vapor of acetic acid to neutralize any free alkali and were then developed with solvent A.

Chromatography of Some Benzenepolycarboxylic Acids

Samples, 15 μg, of the authentic, pure acids were spotted on chromatograph paper, and were subsequently developed with solvent C for 4 hours, the spray being bromphenol blue. The R_F values observed were as follows: mellitic acid, 0.0; benzenepentacarboxylic, 0.035; benzene-1,2,3,4-tetracarboxylic acid, 0.12; the 1,2,4,5-isomer, 0.22; and the 1,2,3,5-isomer, 0.24. A mixture of the five acids in equal amount when chromatographed yielded the first three in a pure state, but the separation between the last two was unsatisfactory.

Oxidations with Potassium Permanganate

A suspension of 10 g of the formaldehyde periodate lignin in 1.6 liters of 1% potassium hydroxide was thoroughly oxidized near 97° by a total of 90 g of potassium permanganate added during 4 days. After the product had been isolated, first as barium salts and then as an aqueous solution of the free acids, in the way described (17), crystalline oxalic acid dihydrate was separated. The residual material after reoxidation with boiling, concentrated nitric acid yielded 0.39 g or 3.9% of a pale yellow solid shown by chromatography to contain benzenepentacarboxylic acid but none of the benzenetetracarboxylic acids.

The above oxidation was repeated with 0.8 g of C^{14} formaldehyde periodate lignin, but when the alkaline oxidation liquor was acidified the carbon dioxide was expelled and recovered as barium carbonate. This carbonate was radioactive, and so was the crystalline oxalic acid dihydrate, which had the correct melting point of 101°. Yield 0.14 g or 17.5%. After the final product had been chromatographed on paper, the spot containing the benzenepentacarboxylic acid was excised and placed in a counter, but no activity was observed. Some activity remained at the starting line of the chromatogram.

Oxidations with Iodic Acid (13, 18)

One gram of the lignin was mixed in an open 50-ml flask with 10 ml of a saturated solution of potassium iodate in concentrated sulphuric acid. When the initial violent reaction subsided, 10 g of powdered potassium iodate was cautiously added in small portions, more heat and iodine being evolved. Nitrogen was then bubbled through the solution, which was kept at 180° to 200°, for 40 minutes. An additional 10 ml of concentrated sulphuric acid was added, and 10 minutes later, 50 mg of paraformaldehyde, to reduce any remaining iodic acid. The solution was cooled 20 minutes later, cautiously diluted with 25 ml of water, and then boiled to expel free iodine. A second dilution with water brought the volume to 60 ml, and the solution was extracted continuously with ether. This extract was evaporated with water several times to expel free iodine that formed, and the final liquor, 8 ml, was ready for paper chromatography. Spots of R_F 0.14 and 0.23 to 0.24 indicated the presence of benzenepentacarboxylic acid and benzene-1,2,4,5-tetracarboxylic acid in the product from periodate lignin, but there was no trace of the latter spot in the products from various fractions of formaldehyde periodate lignin.

ACKNOWLEDGMENTS

The authors thank the National Research Council of Canada for the Research Grant that defrayed part of the costs, Dr. Leo Yaffe for great assistance in the work with radioactive carbon, and Dr. T. N. Kleinert for helpful discussions. One author (E.E.) gratefully acknowledges the award of a Union Carbide (Visking Division) Corporation Fellowship and of Summer Stipends from the Pulp and Paper Research Institute of Canada.

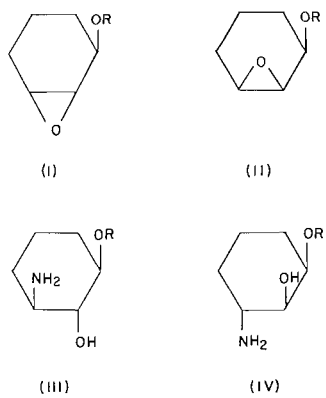
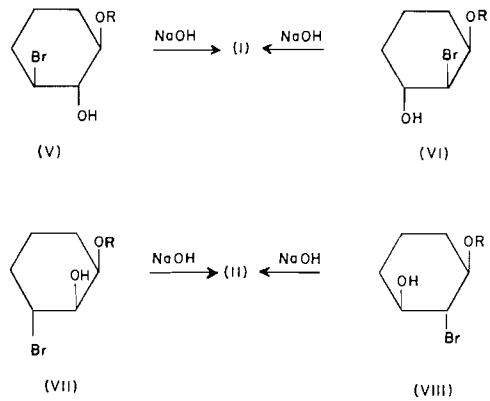
CYCLOHEXANE COMPOUNDS



III. THE 1-METHOXY- AND 1-ETHOXY-2-HYDROXY-3-BROMOCYCLOHEXANES[1, 2]

R. A. B. Bannard and L. R. Hawkins



ABSTRACT

1α-Methoxy-2β-hydroxy-3α-bromocyclohexane and 1α-methoxy-2α-hydroxy-3β-bromocyclohexane have been prepared by the action of hydrobromic acid on 1β-methoxy-2α,3α-epoxycyclohexane and 1α-methoxy-2α,3α-epoxycyclohexane respectively. Assignment of stereochemical configuration to 1α-methoxy-2β-hydroxy-3α-bromocyclohexane was made by catalytic debromination of the phenyl- and 1-naphthyl-urethanes to derivatives of 2β-methoxy-1α-cyclohexanol. An alternative proof of structure was obtained by de-etherification of the bromohydrin to 3α-bromo-1α,2β-cyclohexanediol, which was catalytically debrominated to 1α,2β-cyclohexanediol and oxidized via periodate to 2-bromoadipaldehyde, isolated as the bis-2,4-dinitrophenylhydrazone. The structure of 1α-methoxy-2α-hydroxy-3β-bromocyclohexane was established by de-etherification to 3β-bromo-1α,2α-cyclohexanediol, which was oxidized by periodate 10 times more rapidly than its isomer. The corresponding ethoxy compounds were prepared and their structures were elucidated in a completely analogous manner.

In an earlier paper (1) the mixtures of bromohydrins resulting from the action of aqueous N-bromosuccinimide on 1-methoxy- and 1-ethoxy-cyclohexene-2 were utilized for synthesis of the stereoisomeric 1-methoxy- and 1-ethoxy-2,3-epoxycyclohexanes I and II (R = CH_3 or C_2H_5) and led ultimately by ammonolysis of the latter to the 1-methoxy- and 1-ethoxy-2-hydroxy-3-aminocyclohexanes III and IV (R = CH_3 or C_2H_5). The formation of two oxides by the action of aqueous sodium hydroxide on each 1-alkoxy-cyclohexene-2 bromohydrin demonstrated the presence in each of at least two trans-oriented bromohydrins (2, 3), but the possibility existed that all four bromohydrins V–VIII were present. Attempts to separate the bromohydrin mixtures by fractionation *in vacuo* were unsuccessful, and attention was, therefore, directed toward preparation of pure bromohydrins from the pure oxides by the action of hydrobromic acid, since it was anticipated that knowledge gained concerning the physical and chemical characteristics of any of the possible components of the mixtures would facilitate the development of a method for separation and identification of all the components.

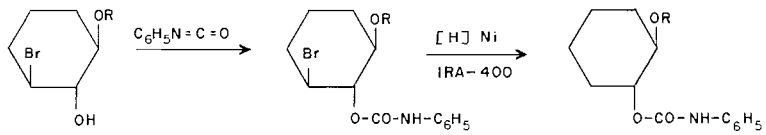
Theoretically, two bromohydrins can be formed from each oxide if ring scission occurs in both possible directions (4). However, our previous experience with ammonolysis of the oxides, in which derivatives of 3-amino-1,2-cyclohexanediol were formed exclusively (1), together with the results obtained by Lemieux, Kullnig, and Moir (5) on methanolysis of the oxides, suggested that 1-alkoxy-2-hydroxy-3-bromocyclohexanes would probably be the only bromohydrins formed. The work now to be described is concerned only with the synthesis and proof of structure of the 1-methoxy- and 1-ethoxy-2-hydroxy-3-bromocyclohexanes. Application of the information gained therefrom to solution of the problem of the composition of the bromohydrin mixtures referred to above is reserved for a subsequent communication.



1β-Methoxy-2α,3α-epoxycyclohexane (I, R = CH_3) on treatment with hydrobromic acid gave a solid bromohydrin, m.p. 68.5–69°, in 63% yield. The liquid fraction isolated from the reaction was shown to consist of 27% bromohydrin (by isolation of the 1-naphthylurethane, m.p. 185–186°) and 19% of a 1-methoxy-2,3-cyclohexanediol (identified by periodate cleavage followed by isolation of the bis-2,4-dinitrophenylhydrazone of 2-methoxyadipaldehyde, m.p. 192–193.5°, and by isolation of a 1-methoxy-2,3-cyclohexanediol bis-1-naphthylurethane, m.p. 224–226°) leaving approximately 50% of the oil unidentified. No further attempt was made to characterize this portion of the product but the suggestion is offered that it could well be a 2-methoxy-3-bromocyclohexanol formed by methoxyl migration (6). In support of this suggestion is the observation (see below) that the action of hydrobromic acid on the cis oxide II produces the corresponding bromohydrin in 93% yield with formation of only a very minor quantity of methoxydiol. The absence of a large fraction of unknown structure is to be expected in this instance because facile migration of the methoxyl group is hindered by virtue of the cis relationship of the methoxyl and its neighboring hydroxyl group.

The bromohydrin was characterized by preparation of its phenylurethane, m.p. 133–134° (86%), 1-naphthylurethane, m.p. 185–186° (94%), and its acetyl derivative, m.p. 56–56.5° (90%), and its structure was established as 1α-methoxy-2β-hydroxy-3α-bromocyclohexane (V, R = CH_3) by the following methods.

The phenylurethane of the bromohydrin (IX, R = CH_3) was debrominated according to the method of McCasland and Horswill (7) using hydrogen, Raney nickel, and an anion exchange resin, producing 2β-methoxy-1α-cyclohexanol phenylurethane (X, R = CH_3), m.p. 66–67.5°, in 78% yield. The identity of the latter compound was established by comparison with an authentic specimen obtained from 2β-methoxy-1α-cyclohexanol (8).

Prior to use of the debromination method it was shown that no concomitant reduction of the benzene or urethane groups occurred under the conditions employed, since debromination of 2β-bromo-1α-cyclohexanol phenylurethane, m.p. 85–87° (9) gave cyclohexanol phenylurethane, m.p. 83–84.5° (10), in 86.5% yield. The bromine atom must have occupied a position trans to the hydroxyl group in the original bromohydrin since the latter yields the oxide I (R = CH_3) on treatment with alkali (2, 3) and it therefore follows that the bromohydrin must be 1α-methoxy-2β-hydroxy-3α-bromocyclohexane (V, R = CH_3).

(V) (IX) (X)

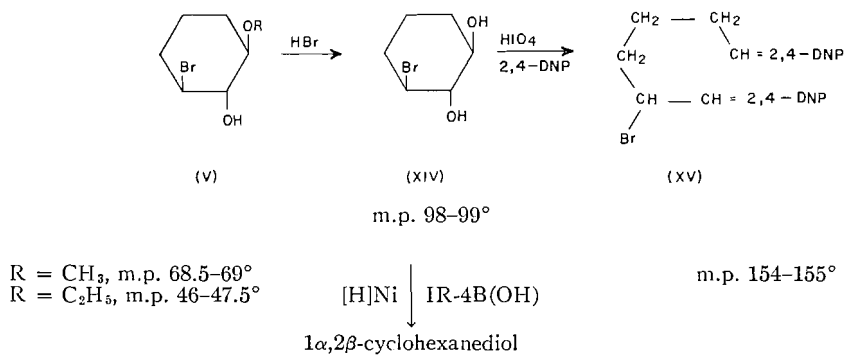
R = CH_3, m.p. 68.5–69° R = CH_3, m.p. 133–134° R = CH_3, m.p. 66–67.5°
R = C_2H_5, m.p. 46–47.5° R = C_2H_5, m.p. 132–133.5°

A similar proof of structure was obtained using the 1-naphthylurethane (XI, R = CH_3) rather than the phenylurethane. During debromination, however, simultaneous reduction of one of the benzenoid rings occurred, leading to the tetralin derivative (XII, R = CH_3). The latter substance was identified by comparison with an authentic specimen prepared by reduction of 2β-methoxy-1α-cyclohexanol 1-naphthylurethane (XIII, R = CH_3) under the same conditions as used for debromination.

(XI) (XII) (XIII)

R = CH_3, m.p. 185–186° R = CH_3, m.p. 89.5–91° R = CH_3, m.p. 111–112°
R = C_2H_5, m.p. 196–197° R = C_2H_5, m.p. 71–72.5° R = C_2H_5, m.p. 131–132°

It was also shown that debromination of 2β-bromo-1α-cyclohexanol 1-naphthylurethane by the hydrogen – Raney nickel method leads to a cyclohexanol tetrahydro-1-naphthylurethane identical with that obtained by reduction of cyclohexanol 1-naphthylurethane under the same conditions. These experiments did not establish which benzenoid ring was reduced. However, by analogy with work reported by Papa and Schwenk (11) it seems probable that reduction occurred in the unsubstituted ring.



The urethanes were used rather than the bromohydrin V (R = CH_3) itself to avoid the possibility of intermediate oxide formation, which would invalidate any structural assignment based on the debromination experiments since the oxide I (R = CH_3) could result just as readily from VI as from V (R = CH_3). It will be demonstrated in the sequel, however, that the use of derivatives is unnecessary because oxide formation is readily preventable and, moreover, if it is forced to occur the oxide is not reduced under the conditions of debromination.

De-etherification of the bromohydrin with fuming hydrobromic acid gave a bromodiol, m.p. 98–99°, in 89% yield, which was further characterized via its bis-1-naphthylurethane, m.p. 210–210.5°, and diacetate, m.p. 65.5–66.5°, and was shown to be a

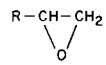
derivative of 1,2-cyclohexanediol, since periodate oxidation followed by treatment with 2,4-dinitrophenylhydrazine gave a 97% yield of the bis-2,4-dinitrophenylhydrazone of 2-bromoadipaldehyde (XV). The steric orientation of the 1,2-diol group was shown to be trans since debromination in the presence of Amberlite IR-4B (OH) resin gave *dl*-1α,2β-cyclohexanediol in 91% yield. Since the bromine and its adjacent hydroxyl group in the original bromohydrin are in a trans orientation, it follows that the bromodiol must be *dl*-3α-bromo-1α,2β-cyclohexanediol (XIV) and the bromohydrin must be *dl*-1α-methoxy-2β-hydroxy-3α-bromocyclohexane (V, R = CH_3) in agreement with the structural assignment reached on the basis of debromination of the urethanes. This proof of structure is based on two assumptions. First, that no inversion of configuration occurs during de-etherification and second, that elimination of bromine is not assisted by intermediate oxide formation. The first assumption was shown to be valid by de-etherification of 2β-methoxy-1α-cyclohexanol under conditions identical with those used for the bromohydrin, when 1α,2β-cyclohexanediol was obtained in 92% yield. It was also shown that the oxide cannot be an intermediate in the debromination reaction since 1β-methoxy-2α,3α-epoxycyclohexane and other oxides are not reduced by Raney nickel and hydrogen under the conditions used. In complete agreement with this result is the observation that debromination of the bromodiol XIV does not proceed in the presence of Amberlite IRA-400 (OH) resin, whereas the use of identical conditions with the phenyl- and 1-naphthyl-urethanes IX and XI (R = CH_3) had furnished high yields of the debrominated compounds X and XII (R = CH_3). Debromination of XIV is readily achieved, however, in the presence of Amberlite IR-4B (OH). This behavior was explained when the action of the two anion exchange resins on 1α-methoxy-2β-hydroxy-3α-bromocyclohexane (V, R = CH_3) was examined. In the presence of the weakly basic resin, IR-4B, the bromohydrin remains unchanged, but in the presence of the strongly basic resin it is converted to the oxide I (R = CH_3), which does not undergo reduction to a diol under the conditions used. These results underline the efficacy of the protection afforded against intermediate oxide formation by the presence of urethane groups in the earlier debromination experiments in which the strongly basic resin was used.

1α-Methoxy-2α,3α-epoxycyclohexane II (R = CH_3) on treatment with hydrobromic acid gave a 93% yield of a liquid bromohydrin VII (R = CH_3) b.p. 62–63° at 0.01 mm. This substance was quite different from the solid bromohydrin V (R = CH_3) obtained from the isomeric oxide, as demonstrated by comparison of their derivatives and infrared spectra. Conversion of the liquid bromohydrin to a 1-naphthylurethane, m.p. 122–124°, in 86% yield and to a liquid acetyl derivative, b.p. 63–65° at 0.01 mm in 95% yield

suggested that the compound was sterically pure. The proof of structure of this bromohydrin was not as exhaustively pursued as that of its stereoisomer and the simplicity of the de-etherification approach led us to follow this method. Ether cleavage of the bromohydrin gave a bromodiol, m.p. 70.5–71°, in 74% yield together with 8% of unchanged starting material. The new compound gave a liquid diacetyl derivative, b.p. 85–86° at 0.1 mm, in 95% yield and a bis-1-naphthylurethane, m.p. 176–178°, in 95% yield. The bromodiol was shown to be a 3-bromo-1,2-cyclohexanediol since periodate oxidation followed by treatment with 2,4-dinitrophenylhydrazine gave the bis-2,4-dinitrophenylhydrazone of 2-bromoadipaldehyde (XV) which had been obtained earlier from similar treatment of its isomer XIV. The orientation of the hydroxyl groups in the lower-melting bromodiol was shown to be cis since its rate of oxidation by periodate at 20° was 10 times more rapid than that of its isomer. Since the liquid bromohydrin yields the oxide II (R = CH_3) on treatment with alkali, it follows (2, 3) that the structure of the bromohydrin must be *dl*-1α-methoxy-2α-hydroxy-3β-bromocyclohexane (VII, R = CH_3) and the corresponding bromodiol must be *dl*-3β-bromo-1α,2α-cyclohexanediol (XVI).

(VII) (XVI)

A solid bromohydrin, m.p. 46–47.5°, was obtained in 61% yield by the action of hydrobromic acid on the trans oxide I (R = C_2H_5) and was further characterized by preparation of the phenylurethane, m.p. 132.5–133.5° (75%), 1-naphthylurethane, m.p. 196–197° (97%), and acetyl derivative, m.p. 29.5–30.5° (92%). Its structure was established as *dl*-1α-ethoxy-2β-hydroxy-3α-bromocyclohexane (V, R = C_2H_5) by debromination of the 1-naphthylurethane XI (R = C_2H_5) to the tetrahydronaphthylurethane of *dl*-2β-ethoxy-1α-cyclohexanol XII (R = C_2H_5) in 88% yield and by de-etherification of the bromohydrin to the bromodiol XIV in 86% yield.



As in the case of the cis methoxy oxide II (R = CH_3), the action of hydrobromic acid on the ethyl homologue produced a liquid bromohydrin, b.p. 71–72° at 0.01 mm, in 82% yield. This bromohydrin failed to yield a solid 1-naphthylurethane and gave a liquid acetyl derivative, b.p. 72–74° at 0.05 mm, in 90% yield. The substance was assigned the structure 1α-ethoxy-2α-hydroxy-3β-bromocyclohexane VII (R = C_2H_5) since de-etherification with hydrogen bromide gave the bromodiol XVI in 51% yield together with 26% of unreacted bromohydrin.

The n.m.r. spectra of the bromohydrin acetates and bromodiol diacetates were measured by Dr. R. R. Fraser of Ottawa University. Interpretation of these spectra according to the principles elaborated by Lemieux, Kullnig, Bernstein, and Schneider (12) fully confirmed the structural assignments made above on the basis of chemical evidence. An additional check on the purity of the two liquid bromohydrins (VII, R = CH_3 and C_2H_5) and their corresponding liquid acetyl derivatives was thereby provided, since there were no abnormalities in the spectra indicative of contamination of any of these substances with positional isomers or stereoisomers.

In recent years considerable attention has been focused upon mechanisms of oxide

For personal use only.

ring scissions and the mode of addition of nucleophiles to unsymmetrically substituted oxides. The results of these investigations have been summarized by Winstein and Henderson (4) and Parker and Isaacs (13) in extensive review articles, but no unifying theory capable of accurately predicting the products of such reactions has emerged. The stereoisomeric 1-alkoxy-2,3-epoxycyclohexanes I and II (R = CH_3 or C_2H_5), which were first prepared by McRae, Moir, and co-workers (14, 15, 16), provided, during and after elucidation of their structures (5, 1), useful models for examination of certain aspects of the mechanisms of oxide ring cleavages by careful product analysis. Investigations by McRae *et al.* (14), Lemieux, Kullnig, and Moir (5), and Bannard and Hawkins (1) made it evident that under alkaline conditions these oxides are attacked by nucleophiles such as methanol, water, and ammonia predominantly at position 3 (yields in excess of 70%). Although some work on the opening of the oxides under acidic conditions by water (17) and *p*-toluenesulphonic acid (5) was also reported earlier, yields of isolated products were not sufficiently high to permit a definite conclusion to be drawn regarding the preferred position of attack. The results of the present work make it quite clear, however, that position 3 is still the preferred point of attack under acidic conditions and that there is apparently no tendency toward reversal of the mode of opening of the oxide ring in 1-alkoxy-2,3-epoxycyclohexanes as has frequently been observed for unsymmetrical oxides of the type XVII (18, 13, 15, 21).

(XVII)

In the reactions cited above, opening of the oxide ring was attended by Walden inversion at position 3, which is suggestive that an S_N2 mechanism is operating (19). This result agrees with the majority of evidence in the literature (13, 15, 20, 21), which supports the S_N2 mechanism for oxide scissions. No indication of the presence of products formed by ring opening with retention of configuration was obtained in any of the work summarized above. This observation makes improbable the intervention of an S_N1 process as a major feature of the mechanism (see references 18, 4, 13, 20, 21) since under such circumstances at least some cis-2,3-oriented products would be expected (13, 19, 20, 21). The latter mechanism may occur to a minor extent, however, because in none of the reactions under consideration was a total material balance of completely characterized products obtained. The results of Lemieux, Kullnig, and Moir (5), obtained when the ring was opened with water under alkaline conditions and arrived at by a method of product analysis which was sensitive enough to reveal minor products formed by attack at position 2, suggests that further careful product analysis is required in all these reactions before intervention of the S_N1 mechanism to a minor extent can be ruled out. No clear picture of the role of polar and steric effects in determining the point of attack of nucleophiles on the 1-alkoxy-2,3-epoxycyclohexanes has resulted. On the basis of simple polar effects and the view that the important feature in S_N2 processes is the facilitation of reagent approach (18, 19, 20) (which is adequate for explanation of the mode of addition to oxides of type XVII), it would be predicted that attack should occur at position 2, which is not the case. Lemieux, Kullnig, and Moir (5) have pointed out however, that the observed result is in agreement with prediction if the governing factor in S_N2 mechanisms is ease of development of carbonium ion character in the transition state (22, 13, 20). Also, there is no uniformity in prediction of the position

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of attack by the nucleophile on the basis of Angyal's (23) extension of the Fürst–Plattner rule (24) which visualizes the more stable conformer undergoing reaction to produce a chair form by diaxial ring opening. This theory predicts the observed result for the cis oxides but not for the trans oxides. If the view is taken that steric ease of approach of the nucleophile determines the point of attack, the observed products are predicted for the trans oxides because attack at position 2 is inhibited by the presence of the methoxyl group at position 1 in a cis relationship to the entering nucleophile, as indicated by Lemieux, Kullnig, and Moir (5). However, such an effect would be absent from reactions involving the cis oxides and it might have been expected that attack would occur at positions 2 and 3 with equal facility. It seems evident from these observations that much work still remains to be done before the mechanisms of oxide ring openings can be placed on a firm basis.

EXPERIMENTAL*†

dl-1α-Methoxy-2β-hydroxy-3α-bromocyclohexane (V, R = CH_3)

dl-1β-Methoxy-2α,3α-epoxycyclohexane (42.5 g, 0.332 mole) was dissolved in acetone (100 ml) and the solution was cooled with mechanical stirring to −10°. Hydrobromic acid (48%, 56.0 g, 0.332 mole) was added dropwise at −10° to 0°, the solution was allowed to come to room temperature, the excess acid was neutralized by addition of sodium carbonate, the precipitated salt was removed by filtration, and the solution was evaporated to dryness *in vacuo*. The residue was recrystallized from ether, yielding 43.9 g (63.3%) of *dl*-1α-methoxy-2β-hydroxy-3α-bromocyclohexane, as colorless needles, m.p. 68.5–69°. Calc. for $C_7H_{13}O_2Br$: C, 40.22; H, 6.27; Br, 38.22%. Found: C, 40.10; H, 6.25; Br, 38.10%. A liquid fraction (13.1 g), b.p. 65–67° at 0.03 mm, was also obtained which was shown to contain more of the bromohydrin V (R = CH_3) and a 1-methoxy-2,3-dihydroxycyclohexane (see below).

Derivatives of dl-1α-Methoxy-2β-hydroxy-3α-bromocyclohexane

The phenylurethane (IX, R = CH_3) was obtained in 86.1% yield, m.p. 133–134°, after recrystallization from 95% ethanol. Calc. for $C_{14}H_{18}O_3NBr$: C, 51.23; H, 5.53; N, 4.27; Br, 24.35%. Found: C, 51.13; H, 5.35; N, 4.21; Br, 24.72%.

The 1-naphthylurethane (XI, R = CH_3) was obtained in 94.4% yield, m.p. 185–186°, after recrystallization from ether. Calc. for $C_{18}H_{20}O_3NBr$: C, 57.15; H, 5.33; N, 3.70; Br, 21.13%. Found: C, 57.16; H, 5.28; N, 3.91; Br, 21.12%.

The acetyl derivative was obtained in 90.0% yield as colorless needles, m.p. 56–56.5°, after recrystallization from ether–heptane. Calc. for $C_9H_{15}O_3Br$: C, 43.04; H, 6.02; Br, 31.82%. Found: C, 42.99; H, 6.13; Br, 32.08%.

dl-1α-Methoxy-2β,3α-cyclohexanediol Bis-1-naphthylurethane

A sample (1.00 g) of the liquid fraction from preparation of 1α-methoxy-2β-hydroxy-3α-bromocyclohexane was treated with 1-naphthylisocyanate (2.00 g) at 70°. The crude mixture of resultant 1-naphthylurethanes was washed with petroleum ether, then fractionally crystallized from ether, yielding 0.43 g (27%) of *dl*-1α-methoxy-2β-hydroxy-3α-bromocyclohexane 1-naphthylurethane, m.p. 185–186°—identified by mixed melting point and infrared spectrum, and 0.41 g (13%) of *dl*-1α-methoxy-2β,3α-cyclohexanediol bis-1-naphthylurethane, m.p. 224–226°. Calc. for $C_{29}H_{28}O_5N_2$: C, 71.88; H, 5.82; N, 5.78%. Found: C, 71.72; H, 5.84; N, 5.94%.

**All melting points are uncorrected.*

2-Methoxyadipaldehyde Bis-2,4-dinitrophenylhydrazone

A second portion (1.00 g) of the above-mentioned liquid fraction was dissolved in ethanol (20 ml) and treated with sodium metaperiodate (3 g in 50 ml water). The solution was kept for 4 hours at room temperature, evaporated to dryness *in vacuo*, and extracted with ether. After evaporation, the residue from the ether extract was treated with 2,4-dinitrophenylhydrazine reagent (25). The bis-2,4-dinitrophenylhydrazone of 2-methoxyadipaldehyde separated as a yellow solid and after recrystallization from ethyl acetate had m.p. 192–193.5°. Yield, 0.64 g (19%). Calc. for $C_{19}H_{20}O_9N_8$: C, 45.24; H, 4.00; N, 22.22%. Found: C, 45.31; H, 4.17; N, 21.80%.

Debromination of dl-2β-Bromo-1α-cyclohexanol Phenylurethane

dl-2β-Bromo-1α-cyclohexanol phenylurethane (cf. Bedos (9)), m.p. 85–87° (0.900 g, 3.02×10^{-3} mole), was debrominated by the same method as described below for *dl*-1α-methoxy-2β-hydroxy-3α-bromocyclohexane phenylurethane. The crude product after recrystallization from ethanol–heptane furnished 0.57 g (86.5%) of cyclohexanol phenylurethane, m.p. 83–84.5°, alone and in admixture with an authentic sample (cf. Stengl *et al.* (10)).

dl-2β-Methoxy-1α-cyclohexanol Derivatives

dl-2β-Methoxy-1α-cyclohexanol was prepared by the method of Winstein and Henderson (8) and converted to the phenylurethane in 82% yield, m.p. 66–67.5°, after recrystallization from aqueous ethanol. Calc. for $C_{14}H_{19}O_3N$: C, 67.45; H, 7.68; N, 5.62%. Found: C, 67.40; H, 7.54; N, 5.70%. The 1-naphthylurethane was obtained in 77% yield, m.p. 111–112°, after recrystallization from ether–heptane. Calc. for $C_{18}H_{21}O_3N$: C, 72.22; H, 7.07; N, 4.69%. Found: C, 72.31; H, 7.09; N, 4.74%.

Debromination of dl-1α-Methoxy-2β-hydroxy-3α-bromocyclohexane Phenylurethane

dl-1α-Methoxy-2β-hydroxy-3α-bromocyclohexane phenylurethane (0.900 g, 2.74×10^{-3} mole) was dissolved in ethanol (50 ml), Raney Nickel W-7 (26) catalyst (10 g) and Amberlite IRA-400 (OH) resin (2 ml) were added, and the mixture was shaken for 24 hours at room temperature at 40 p.s.i. hydrogen pressure. The mixture was filtered and the filtrate was evaporated to dryness *in vacuo* yielding a crystalline residue, which, after recrystallization from ether–heptane, furnished 0.53 g (78%) of *dl*-2β-methoxy-1α-cyclohexanol phenylurethane (X, R = CH_3), m.p. 66–67.5°, alone and in admixture with an authentic specimen. The infrared spectra of the two samples (KBr pellet) were also identical.

dl-2β-Methoxy-1α-cyclohexanol Tetrahydro-1-naphthylurethane (XII, R = CH_3)

dl-2β-Methoxy-1α-cyclohexanol 1-naphthylurethane (0.200 g, 6.7×10^{-4} mole) was reduced by the same method as described for *dl*-1α-methoxy-2β-hydroxy-3α-bromocyclohexane phenylurethane except that ethanol–benzene (2:1, v/v; 30 ml) was used as solvent. Recrystallization of the crude product from aqueous ethanol gave 0.199 g (98.5%) of fine colorless needles, m.p. 89.5–91°. Calc. for $C_{18}H_{25}O_3N$: C, 71.25; H, 8.31; N, 4.62%. Found: C, 71.26; H, 8.27; N, 4.67%.

Debromination of dl-1α-Methoxy-2β-hydroxy-3α-bromocyclohexane 1-Naphthylurethane

dl-1α-Methoxy-2β-hydroxy-3α-bromocyclohexane 1-naphthylurethane (1.00 g, 2.65×10^{-3} mole) was debrominated by the same method as given for *dl*-2β-methoxy-1α-cyclohexanol 1-naphthylurethane. The crude product was recrystallized from aqueous ethanol yielding 0.690 g (86%) of *dl*-2β-methoxy-1α-cyclohexanol tetrahydro-1-naphthylurethane,

m.p. 89.5–91°, alone and in admixture with an authentic specimen. The infrared spectra (KBr pellet) of the two substances were also identical.

dl-2β-Bromo-1α-cyclohexanol 1-Naphthylurethane

This compound was obtained in 75% yield from *dl*-2β-bromo-1α-cyclohexanol (27) after recrystallization from ether, m.p. 177–177.5°. Calc. for $C_{17}H_{18}O_2NBr$: C, 58.63; H, 5.21; N, 4.03; Br, 22.95%. Found: C, 58.54; H, 5.19; N, 4.19; Br, 22.74%.

Cyclohexanol Tetrahydro-1-naphthylurethane

Cyclohexanol 1-naphthylurethane (cf. Bickel and French (28)), m.p. 131–132.5° (1.10 g, 4.07×10^{-3} mole), was reduced by the same method as described for 2β-methoxy-1α-cyclohexanol 1-naphthylurethane. Recrystallization of the crude product from aqueous ethanol gave 1.01 g (90.2%) of cyclohexanol tetrahydro-1-naphthylurethane as fine colorless needles, m.p. 105–106.5°. Calc. for $C_{17}H_{23}O_2N$: C, 74.69; H, 8.48; N, 5.12%. Found: C, 74.77; H, 8.48; N, 5.15%.

Debromination of dl-2β-Bromo-1α-cyclohexanol 1-Naphthylurethane

dl-2β-Bromo-1α-cyclohexanol 1-naphthylurethane (0.340 g, 9.77×10^{-4} mole) was debrominated by the same procedure as described for *dl*-2β-methoxy-1α-cyclohexanol 1-naphthylurethane. Recrystallization of the crude product from aqueous ethanol gave 0.250 g (93.7%) of cyclohexanol tetrahydro-1-naphthylurethane as colorless needles, m.p. 105–106.5°, alone and in admixture with an authentic specimen. The infrared spectra (KBr pellet) of the two samples were also identical.

Conversion of dl-1α-Methoxy-2β-hydroxy-3α-bromocyclohexane to dl-1β-Methoxy-2α,3α-epoxycyclohexane via Amberlite IRA-400 (OH) Resin

dl-1α-Methoxy-2β-hydroxy-3α-bromocyclohexane (4.18 g, 0.02 mole) was placed in a 500-ml pressure bottle together with Amberlite IRA-400 (OH) resin (40 ml) and ether (200 ml) and the mixture was shaken for 24 hours at atmospheric pressure. The resin was collected, washed with ether (100 ml), and the filtrate and washings dried over anhydrous sodium sulphate. The ether was removed by distillation at atmospheric pressure, after which the residue was fractionated *in vacuo* yielding 2.18 g (85.1%) of *dl*-1β-methoxy-2α,3α-epoxycyclohexane as a colorless oil, b.p. 60–61° at 12 mm, n_D^{25} 1.4511. The substance was identified by its infrared spectrum (1).

Attempted Reduction of dl-1β-Methoxy-2α,3α-epoxycyclohexane with Raney Nickel and Hydrogen

dl-1β-Methoxy-2α,3α-epoxycyclohexane (6.00 g, 4.68×10^{-2} mole), dissolved in ether (100 ml), was shaken with Raney nickel catalyst (10 ml) at room temperature under 40 p.s.i. hydrogen pressure for 24 hours. The mixture was filtered, the filtrate was concentrated by removal of the ether at atmospheric pressure, and the residue was distilled *in vacuo* yielding 5.60 g (93.4%) of unchanged starting material, b.p. 54–55° at 10 mm, which was identified via its infrared spectrum (1).

Action of Amberlite IR-4B (OH) Resin on dl-1α-Methoxy-2β-hydroxy-3α-bromocyclohexane (V, R = CH_3)

dl-1α-Methoxy-2β-hydroxy-3α-bromocyclohexane (1.00 g, 4.78×10^{-3} mole), dissolved in 95% ethanol (100 ml), was shaken for 24 hours with Amberlite IR-4B (OH) resin. The mixture was filtered, and the filtrate was allowed to evaporate to dryness at room temperature in an evaporating dish. The residual crystals were collected, recrystallized from ether, and identified as *dl*-1α-methoxy-2β-hydroxy-3α-bromocyclohexane by their melting

For personal use only.

point of 68–69°, alone and in admixture with an authentic specimen. Recovery, 0.925 g (92.5%).

De-etherification of dl-1α-Methoxy-2β-hydroxy-3α-bromocyclohexane (V, R = CH_3) to dl-3α-Bromo-1α,2β-cyclohexanediol (XIV)

dl-1α-Methoxy-2β-hydroxy-3α-bromocyclohexane (1.05 g, 5.0×10^{-3} mole) was finely ground and heated for 1.5 hours in a sealed tube at 65° with fuming hydrobromic acid (1.0 ml, 68%, 1.57×10^{-2} mole). The pale yellow solution was transferred quantitatively to a 250-ml, round-bottomed flask (in ca. 50 ml of water), the excess acid was neutralized by addition of solid sodium bicarbonate, and the solution was evaporated to dryness *in vacuo*. The residue was transferred to a Soxhlet extractor, extracted for 4 hours with anhydrous ether, and the extract evaporated to dryness. Crystallization of the product from ether gave 0.861 g (88.8%) of *dl*-3α-bromo-1α,2β-cyclohexanediol as colorless prisms, m.p. 98–99°. Calc. for $C_6H_{11}O_2Br$: C, 36.94; H, 5.68; Br, 40.97%. Found: C, 36.96; H, 5.64; Br, 41.07%.

Derivatives of dl-3α-Bromo-1α,2β-cyclohexanediol (XIV)

The bis-1-naphthylurethane was obtained in 84.5% yield as fine colorless needles, m.p. 210–210.5°, after recrystallization from acetone. Calc. for $C_{28}H_{25}O_4N_2Br$: C, 63.04; H, 4.72; N, 5.25; Br, 14.98%. Found: C, 62.89; H, 4.93; N, 5.49; Br, 14.68%.

The diacetate was obtained in 95.1% yield as fine colorless needles, m.p. 65.5–66.5°, after recrystallization from ether–heptane. Calc. for $C_{10}H_{15}O_4Br$: C, 43.03; H, 5.42; Br, 28.63%. Found: C, 43.17; H, 5.62; Br, 28.73%.

dl-1α,2β-Cyclohexanediol from dl-2β-Methoxy-1α-cyclohexanol

dl-2β-Methoxy-1α-cyclohexanol (0.650 g, 5.0×10^{-3} mole) was heated for 1 hour at 75° with fuming hydrobromic acid (3.0 ml, 68%, 4.70×10^{-2} mole) in a sealed tube. The product was isolated by the same procedure as described for the de-etherification of *dl*-1α-methoxy-2β-hydroxy-3α-bromocyclohexane, except that final purification was effected by sublimation *in vacuo*. In this manner, 0.533 g (92.0%) of colorless crystals, m.p. 104.5–105.5°, alone and in admixture with an authentic specimen of *dl*-1α,2β-cyclohexanediol, were obtained.

Debromination of dl-3α-Bromo-1α,2β-cyclohexanediol (XIV)

dl-3α-Bromo-1α,2β-cyclohexanediol (0.400 g, 2.05×10^{-3} mole) was placed in a 500-ml pressure bottle together with ethanol (100 ml), Amberlite IR-4B (OH) resin (3 g), and Raney nickel catalyst and shaken for 24 hours under 40 p.s.i. hydrogen pressure at room temperature. The mixture was filtered and the crystalline residue, which resulted from evaporation to dryness of the filtrate, was sublimed *in vacuo*, yielding 213 mg (90.3%) of colorless crystals, m.p. 104.5–105.5°, alone and in admixture with an authentic specimen of *dl*-1α,2β-cyclohexanediol. The infrared spectra of the two specimens (KBr pellet) were also identical.

2-Bromoadipaldehyde Bis-2,4-dinitrophenylhydrazone (XV) from dl-3α-Bromo-1α,2β-cyclohexanediol (XIV)

dl-3α-Bromo-1α,2β-cyclohexanediol (1.00 g, 5.12×10^{-3} mole) and sodium metaperiodate (4.18 g, 2×10^{-2} mole) were dissolved in water and the solution was kept overnight at 25°, then evaporated to dryness *in vacuo* at room temperature. The residue was extracted with ether and the latter was removed *in vacuo*. The product was dissolved in ethanol and treated with 2,4-dinitrophenylhydrazine reagent (25). The yellow precipitate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was collected and washed three times with hot ethanol yielding 2.75 g (96.8%) of 2-bromoadipaldehyde bis-2,4-dinitrophenylhydrazone, m.p. 154–155° (with decomposition). Calc. for $C_{18}H_{17}O_8N_8Br$: C, 39.07; H, 3.10; N, 20.25; Br, 14.44%. Found: C, 39.35; H, 3.09; N, 19.90; Br, 14.41%.

dl-1α-Methoxy-2α-hydroxy-3β-bromocyclohexane (VII, R = CH_3)

The procedure was identical with that used for the preparation of *dl*-1α-methoxy-2β-hydroxy-3α-bromocyclohexane (V, R = CH_3) except that the cis oxide II (R = CH_3) (12.0 g, 9.37×10^{-2} mole) was employed as starting material. The crude liquid product was fractionated *in vacuo* yielding 18.3 g (93.3%) of a colorless viscous oil, b.p. 62–63° at 0.01 mm; n_D^{25} 1.5080. Calc. for $C_7H_{13}O_2Br$: C, 40.22; H, 6.27; Br, 38.22%. Found: C, 40.01; H, 6.17; Br, 38.27%.

Derivatives of dl-1α-Methoxy-2α-hydroxy-3β-bromocyclohexane

The 1-naphthylurethane was obtained in 86.5% yield, m.p. 122–124°, after recrystallization from acetone – petroleum ether (65–110°). Calc. for $C_{18}H_{20}O_3NBr$: C, 57.15; H, 5.33; N, 3.70; Br, 21.13%. Found: C, 57.27; H, 5.16; N, 3.80; Br, 20.83%.

The acetyl derivative was obtained in 95.5% yield as a colorless liquid, b.p. 63–65° at 0.01 mm; n_D^{25} 1.4828. Calc. for $C_9H_{15}O_3Br$: C, 43.04; H, 6.02; Br, 31.82%. Found: C, 43.00; H, 5.94; Br, 32.07%.

De-etherification of dl-1α-Methoxy-2α-hydroxy-3β-bromocyclohexane to dl-3β-Bromo-1α,2α-cyclohexanediol (XVI)

dl-1α-Methoxy-2α-hydroxy-3β-bromocyclohexane (2.09 g, 1.0×10^{-2} mole) was subjected to ether cleavage under conditions identical with those used for its stereoisomer. The resultant mixture of oil and crystals (1.82 g) was washed with anhydrous ether to dissolve the oil, and recrystallization of the residue from anhydrous ether gave 1.44 g (73.8%) of *dl*-3β-bromo-1α,2α-cyclohexanediol as colorless prisms, m.p. 70.5–71°. This substance was shown to be quite different from its stereoisomer, by comparison of their infrared spectra (KBr pellet). Calc. for $C_6H_{11}O_2Br$: C, 36.94; H, 5.68; Br, 40.97%. Found: C, 37.11; H, 5.43; Br, 40.78%. The oil fraction from this preparation was distilled in an air bath at 25–30° at 0.001 mm pressure yielding 170 mg (8.1%) of colorless oil, n_D^{25} 1.5085, identified via its infrared spectrum as *dl*-1α-methoxy-2α-hydroxy-3β-bromocyclohexane (VII, R = CH_3).

Derivatives of dl-3β-Bromo-1α,2α-cyclohexanediol

The bis-1-naphthylurethane was obtained in 95.3% yield as colorless crystals, m.p. 176–178°, after recrystallization from ethyl acetate. Calc. for $C_{28}H_{25}O_4N_2Br$: C, 63.04; H, 4.72; N, 5.25; Br, 14.98%. Found: C, 63.20; H, 4.73; N, 5.15; Br, 15.14%.

The diacetyl derivative was obtained in 95.0% yield as a colorless viscous oil, b.p. 85–86° at 0.1 mm pressure; n_D^{25} 1.4810. Calc. for $C_{10}H_{15}O_4Br$: C, 43.03; H, 5.42; Br, 28.63%. Found: C, 43.02; H, 5.20; Br, 28.93%.

2-Bromoadipaldehyde Bis-2,4-dinitrophenylhydrazone (XV) from dl-3β-Bromo-1α,2α-cyclohexanediol (XVI)

The procedure used was identical with that given for the periodate oxidation and subsequent 2,4-dinitrophenylhydrazone formation from *dl*-3α-bromo-1α,2β-cyclohexanediol (XIV). The bis-2,4-dinitrophenylhydrazone was obtained in 95% yield, m.p. 154–155°, and had an infrared spectrum (KBr pellet) identical with that of an authentic specimen of XV.

Periodate Oxidation of dl-3α-Bromo-1α,2β-cyclohexanediol (XIV) and dl-3β-Bromo-1α,2α-cyclohexanediol (XVI)

The experimental procedure used for periodate oxidation of the bromodiols XIV and XVI was identical with that described earlier for oxidation of the *p*-nitrobenzoyl derivatives of the 3-amino-1,2-cyclohexanediols (1), except that the determinations were performed at 20° and 14-mg samples of the bromodiols were used. The results showed uptake of 1 mole of periodate by the cis diol in 15 minutes and by the trans diol in 180 minutes. Comparison of the $t_{\frac{1}{4}}$ values (1.75 minutes for XVI and 18.0 for XIV) indicated that the rate of oxidation of the cis diol is approximately 10 times that of the trans diol.

dl-1α-Ethoxy-2β-hydroxy-3α-bromocyclohexane (V, R = C_2H_5)

dl-1β-Ethoxy-2α,3α-epoxycyclohexane (I, R = C_2H_5) (14.2 g, 0.100 mole) on treatment with hydrobromic acid in the same manner as described for its lower homologue gave 13.6 g (61.0%) of *dl*-1α-ethoxy-2β-hydroxy-3α-bromocyclohexane as colorless needles, m.p. 46–47.5°, after recrystallization from ether. Calc. for $C_8H_{15}O_2Br$: C, 43.07; H, 6.78; Br, 35.82%. Found: C, 42.91; H, 6.58; Br, 35.61%.

Derivatives of dl-1α-Ethoxy-2β-hydroxy-3α-bromocyclohexane

The phenylurethane (IX, R = C_2H_5) was obtained as fine needles in 75.3% yield, m.p. 132.5–133.5°, after recrystallization from ether–heptane. Calc. for $C_{15}H_{20}O_3NBr$: C, 52.64; H, 5.89; N, 4.09; Br, 23.35%. Found: C, 52.68; H, 5.84; N, 4.16; Br, 23.38%.

The 1-naphthylurethane (XI, R = C_2H_5) was obtained in 96.6% yield as fine needles, m.p. 196–197°, after recrystallization from ethyl acetate. Calc. for $C_{19}H_{22}O_3NBr$: C, 58.17; H, 5.65; N, 3.57; Br, 20.37%. Found: C, 58.32; H, 5.46; N, 3.88; Br, 20.04%.

The acetate was obtained as fine colorless needles in 92.4% yield, m.p. 29.5–30.5°, after recrystallization from *n*-hexane. Calc. for $C_{10}H_{17}O_3Br$: C, 45.29; H, 6.46; Br, 30.14%. Found: C, 45.28; H, 6.28; Br, 30.31%.

dl-2β-Ethoxy-1α-cyclohexanol 1-Naphthylurethane (XIII, R = C_2H_5)

dl-2β-Ethoxy-1α-cyclohexanol (b.p. 75–77° at 11 mm; n_D^{25} 1.4538) was prepared in 73% yield by the same method (8) as used for the corresponding methoxy compound (cf. Mousseron *et al.* (29)) and was converted in 94.2% yield to the 1-naphthylurethane, which was obtained as fine needles, m.p. 131–132°, after recrystallization from ethyl acetate. Calc. for $C_{19}H_{23}O_3N$: C, 72.81; H, 7.40; N, 4.47%. Found: C, 73.08; H, 7.39; N, 4.67%.

dl-2β-Ethoxy-1α-cyclohexanol Tetrahydro-1-naphthylurethane (XII, R = C_2H_5)

dl-2β-Ethoxy-1α-cyclohexanol 1-naphthylurethane (0.830 g, 2.66×10^{-3} mole) was reduced by the same method as described for *dl*-2β-methoxy-1α-cyclohexanol 1-naphthylurethane. Recrystallization of the crude product from aqueous ethanol gave 0.760 g (90.3%) of fine colorless needles, m.p. 71–72.5°, of the tetrahydro-1-naphthylurethane. Calc. for $C_{19}H_{27}O_3N$: C, 71.88; H, 8.57; N, 4.41%. Found: C, 71.80; H, 8.67; N, 4.58%.

Debromination of dl-1α-Ethoxy-2β-hydroxy-3α-bromocyclohexane 1-Naphthylurethane (XI, R = C_2H_5)

dl-1α-Ethoxy-2β-hydroxy-3α-bromocyclohexane 1-naphthylurethane (0.900 g, 2.88×10^{-3} mole) was debrominated by the same method as described for *dl*-2β-methoxy-1α-cyclohexanol 1-naphthylurethane. The crude product was recrystallized from aqueous ethanol yielding 0.640 g (87.9%) of *dl*-2β-ethoxy-1α-cyclohexanol tetrahydro-1-naphthylurethane as colorless needles, m.p. 71–72.5°, alone and in admixture with an authentic sample. The infrared spectra (5% in carbon tetrachloride) were also identical.

For personal use only.

dl-3α-Bromo-1α,2β-cyclohexanediol (XIV) from dl-1α-Ethoxy-2β-hydroxy-3α-bromocyclohexane (V, R = C_2H_5)

dl-1α-Ethoxy-2β-hydroxy-3α-bromocyclohexane (1.12 g, 5.0×10^{-3} mole) was subjected to ether cleavage under conditions identical with those described for the lower homologue. The crude product was recrystallized from ether yielding 831 mg (85.7%) of colorless prisms, m.p. 98–99°, alone and in admixture with an authentic specimen of *dl*-3α-bromo-1α,2β-cyclohexanediol.

dl-1α-Ethoxy-2α-hydroxy-3β-bromocyclohexane (VII, R = C_2H_5)

dl-1α-Ethoxy-2α,3α-epoxycyclohexane (II, R = C_2H_5) (14.2 g, 0.100 mole) was treated with hydrobromic acid in the same manner as described for *dl*-1β-methoxy-2α,3α-epoxycyclohexane. The crude liquid product was fractionated *in vacuo* yielding 18.3 g (82.0%) of *dl*-1α-ethoxy-2α-hydroxy-3β-bromocyclohexane, b.p. 70–71° at 0.01 mm; n_D^{25} 1.4971. Calc. for $C_8H_{15}O_2Br$: C, 43.07; H, 6.78; Br, 35.82%. Found: C, 43.11; H, 6.85; Br, 35.69%.

dl-1α-Ethoxy-2α-acetoxy-3β-bromocyclohexane

dl-1α-Ethoxy-2α-hydroxy-3β-bromocyclohexane (2.23 g, 1.00×10^{-2} mole) was heated under reflux for 1 hour with acetic anhydride (10 ml). The excess anhydride was removed by distillation *in vacuo* and the residue was distilled *in vacuo* yielding 2.39 g (90.2%) of colorless mobile oil, b.p. 64–64.5° at 0.01 mm; n_D^{25} 1.4760. Calc. for $C_{10}H_{17}O_3Br$: C, 45.29; H, 6.46; Br, 30.14%. Found: C, 45.13; H, 6.13; Br, 30.25%.

De-etherification of dl-1α-Ethoxy-2α-hydroxy-3β-bromocyclohexane to dl-3β-Bromo-1α,2α-cyclohexanediol (XVI)

dl-1α-Ethoxy-2α-hydroxy-3β-bromocyclohexane (2.23 g, 1.0×10^{-2} mole) was subjected to ether cleavage under conditions identical with those described for its homologue, yielding a mixture of oil and crystals (1.67 g) which, after recrystallization from anhydrous ether, gave 988 mg (50.6%) of colorless prisms, m.p. 70.5–71°, alone and in admixture with an authentic sample of *dl*-3β-bromo-1α,2α-cyclohexanediol (XVI). The residual oil was distilled in an air bath at 28–33° at 0.001 mm pressure yielding 588 mg (26.4%) of colorless oil, n_D^{25} 1.4981, which was identified as *dl*-1α-ethoxy-2α-hydroxy-3β-bromocyclohexane (VII, R = C_2H_5) via its infrared spectrum.

ACKNOWLEDGMENTS

We are indebted to Prof. R. U. Lemieux and Dr. R. R. Fraser for measurement and interpretation of the n.m.r. spectra of the bromohydrin acetates and bromodiol diacetates, to Dr. R. Y. Moir for a helpful discussion, to Mr. A. A. Casselman for preparation of quantities of the ethoxybromohydrins, to Dr. G. M. Brown for assistance, and to Mr. R. Gravelle for measurement of infrared spectra.

NOTES

DIFFUSION OF Zn IN ZnO

E. A. Secco

INTRODUCTION

The experimental results reported in the literature on the diffusion of Zn in ZnO appear conflicting and cannot be fitted to a single conventional defect model. There is also a discrepancy between the parabolic rate constant for zinc oxidation and the diffusion of Zn in ZnO if the Wagner equation (3, 17)

$$K = \int_{a_1}^{a_2} D \, d \ln a$$

relating the parabolic rate constant K and the diffusion coefficient D of the zinc metal is accepted. The diffusion of zinc has been suggested to occur via the interstitial sites. However, the apparent disagreement among the experimental results obtained to date, reviewed elsewhere (1, 2, 3), and reproduced in Table I in simple equation form, has led

TABLE I

		Temp., ° K	Ref.
Oxidation	Parabolic rate equation		
	$K = 3.3\times10^{-7} \exp(-29.0 \text{ kcal}/RT)$ cm² sec⁻¹	648–673	Moore and Lee (4)
	$K = 1.1\times10^{-5} \exp(-35.0 \text{ kcal}/RT)$ cm² sec⁻¹	873–973	Krupkowski and Balicki (5)
	$K = 2.5\times10^{-7} \exp(-25.0 \text{ kcal}/RT)$ cm² sec⁻¹	703–752	Gebhardt (6)
Exchange	Diffusion equation		
	$D = 4.8 \exp(-73 \text{ kcal}/RT)$ cm² sec⁻¹	1183–1300	Secco and Moore (7)
	$D = 1.8\times10^{5} \exp(-89 \text{ kcal}/RT)$ cm² sec⁻¹	1189–1540	Spicar (8)
	$D^* = 30 \exp(-75 \text{ kcal}/RT)$ cm² sec⁻¹	1189–1540	Moore (3)
	$D = 1.7\times10^{2} \exp(-76 \text{ kcal}/RT)$ cm² sec⁻¹	1073–1463	Lamatsch (9)
	$k_e = 4.0\times10^{5} \exp(-40 \text{ kcal}/RT)$ sec⁻¹	993–1113	Secco (14)
	$D = 10 \exp(73.0 \text{ kcal}/RT)$ cm² sec⁻¹	993–1113	Secco (14)
Tracer	Diffusion equation		
	$D = 1.3 \exp(-74 \text{ kcal}/RT)$ cm² sec⁻¹	1073–1600	Lindner (10)

Conductivity	Diffusion equation		
	$D = 1.6\times10^{-2} \exp(-39 \text{ kcal}/RT)$ cm² sec⁻¹	973–1603	Pohl (12)
	$D = 1.5\times10^{-2} \exp(-39 \text{ kcal}/RT)$ cm² sec⁻¹	1100–1370	Arneth (13)

*This diffusion coefficient is obtained from the one above it by correcting to constant zinc pressure on the basis of $D \propto P_{Zn}^{1/2}$.

to the speculation of other structural defects, such as oxide vacancies and Frenkel defects.

Recently, the exchange of zinc vapor with polycrystalline zinc oxide has been studied in a static system under different conditions of temperature and pressure (14). Plots of $\log_{10}\alpha^*$ (exchange fraction) versus time revealed two processes at the temperatures studied, 720°–840° C. The initial process was a rapid simple exchange whose data were fitted to a first-order rate law with the Arrhenius expression given by

$$k_e = 4.0\times10^{5} \exp(-40 \text{ kcal}/RT) \text{ sec}^{-1}.$$

This first-order rate law was found to persist to a depth of 20–25 molecular thicknesses

at 720° C, i.e. one half of particle radius, and to increasing depths at the higher temperatures. A second, slower process, which appeared to be diffusion-controlled, with the diffusion equation expressed by $D = 10 \exp (73.0 \text{ kcal}/RT)$ cm^2 sec^{-1}, followed the initial process. This diffusion equation is in agreement with diffusion equations obtained in other exchange studies using single crystals.

Close examination of the above data reveals that the diffusion coefficient as obtained from the exchange studies is equal to, within the limits of experimental uncertainty, the product of the parabolic rate constant or the diffusion coefficient from conductivity studies and the exchange constant k_e from polycrystalline studies. That is, the diffusion coefficient in the exchange work appears to be a composite quantity consisting of a mobility term and an exchange term, $D_e = D_i k_e$, namely, an interstitialcy type of diffusion mechanism.

Let us consider an interstitial particle of the non-Frenkel type (interstice occupied by a particle without the existence of a corresponding vacancy) diffusing through a lattice. From Fick's law the diffusion coefficient for the interstitial atom D_i is $D_i = \nu_i \lambda^2 \exp(-E_i/RT)$ cm^2 sec^{-1} where λ is the distance between the adjacent interstitial positions, and ν_i is the frequency of vibration or the number of attempts per second made by the interstitial atom to cross the energy barrier E_i. For diffusion of this type the over-all diffusion coefficient may be expressed as $D = D_i f_i$ where f_i = fraction of interstices available for occupancy by a mobile interstitial atom, i.e. $f_i = (N_i - n_i)/N_i$ where N_i = number of *effectively* available interstices and n_i = number of interstices occupied by atoms. The diffusion coefficient becomes $D = ((N_i - n_i)/N_i)D_i$. Under conditions of unsaturation, it is assumed that $n_i \ll N_i$, the diffusion coefficient becomes identical with the interstitial mobility, $D = D_i$. Whereas under equilibrium conditions, when $n_i \approx N_i$, the diffusion coefficient becomes zero, $D = 0$, which means that the simple interstitial mechanism of diffusion is impossible when all available interstices are occupied. Essentially, this condition is visualized when the direct interstice-to-interstice movement becomes energetically unfeasible because of the narrowing in the constriction separating the interstices at saturation caused by the large difference in radii, 1.4 Å for Zn atom and 0.7 Å for the octahedral interstice. Provided the latter condition obtains, the only other alternative would be a diffusion mechanism of the coupled, interstitial-lattice type.

An inspection of the ZnO lattice shows that an interstitial zinc has the same energy barrier E_i, judging solely from lattice dimensions, by the direct interstice path or via a vacant lattice site. In each case the interstitial atom must move through a similar constriction of the atoms constituting the host lattice. In the case of the interstitialcy mechanism the interstitial must possess an additional energy E_e if the lattice site is occupied. That is, the over-all energy required would be $E_e + E_i$. Now, if the rate of exchange of lattice atoms is given by $k_e = \nu_e \exp(-E_e/RT)$, and the interstitial mobility by $D_i = \nu_i \lambda^2 \exp(-E_i/RT)$, then the interstitialcy diffusion coefficient would be expected to be $D = \nu_i \nu_e \lambda^2 \exp((E_i + E_e)/RT) = D_i k_e$, where $\nu_i \nu_e$ represents the frequencies of vibration of the interstitial and lattice atoms. Thus diffusion occurs when the normal modes of vibration, with adequate energy, of the interstitial and lattice atoms come sufficiently into phase to give the vital configuration for its critical push. The diffusion equation would be $D = \nu_o \lambda^2 \exp(-(E_e + E_i)/RT)$ where ν_o is the over-all frequency of the linked process. Thus, the interstitialcy diffusion coefficient becomes $D = 10^{-2} - 10^{-1} \exp(-(E_e + E_i)/RT)$ cm^2 sec^{-1} for $\nu_o = 3 \times 10^{13}$ sec^{-1} and $\lambda = 3 \times 10^{-8}$ cm for the case of ZnO.

On the basis of the above discussion the interpretation to be given to the two processes observed in the exchange studies on polycrystalline zinc oxide is that the exchange reaction and zinc diffusion via interstices occur simultaneously. But if the interstitial mobility of the zinc is more rapid the exchange process predominates. As soon as the *effectively* available interstices become filled the transport or diffusion step becomes rate-controlling and supersedes the simple exchange process. The critical experiment to check the above hypothesis and empirical relationship is evidently the exchange reaction between zinc oxide, previously saturated with inactive zinc, and active Zn^{65} vapor.

EXPERIMENTAL

The polycrystalline ZnO used in this work was from the batch previously reported (14). The zinc oxide was exposed to excess inactive zinc vapor, ca. 0.15 atm, at 760° C for 5 hours. The exchange runs using this saturated zinc oxide were carried out in a static system which has already been described.

RESULTS

In Fig. 1 is given a plot of the logarithm of the exchange reaction against time for

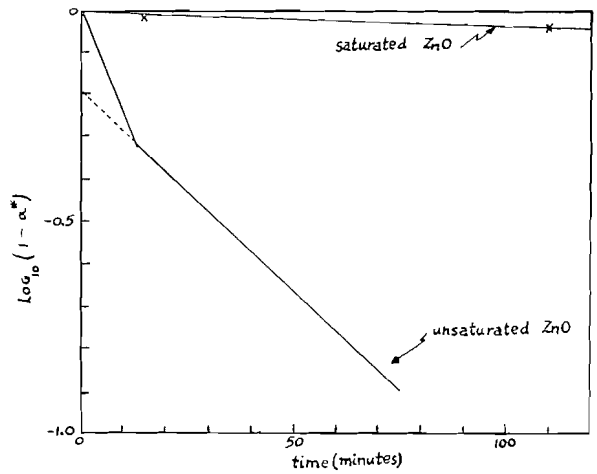

FIG. 1. Plot of logarithm of the unexchanged-fraction versus time at 760° C; saturated ZnO curve from present work, unsaturated ZnO from work already reported (14).

Zn^{65} exchange with the saturated ZnO and for Zn^{65} exchange with untreated ZnO, at 760° C. Figure 2 shows the plot of the non-dimensional (Dt/a^2) as a function of time for Zn^{65} exchange with the pretreated ZnO at temperatures 760° and 800° C. The values of Dt/a^2 were taken from Crank (16). The diffusion coefficients were evaluated as the product of the slope of the straight line in Fig. 2 and the square of the particle radius, a^2. The diffusion equation as obtained from these two temperatures is $D = 0.40 \exp(-76.5 \text{ kcal}/RT)$ $\text{cm}^2 \text{ sec}^{-1}$, which is in agreement with existing exchange data on zinc oxide.

It was thought in the pretreatment of ZnO with zinc vapor that sintering could have occurred resulting in a diminution of the surface area and hence increased particle size. The surface area of the oxide used could not be measured but another sample of oxide from the same batch heated in air at 760° C for 2 hours was found to drop from an original

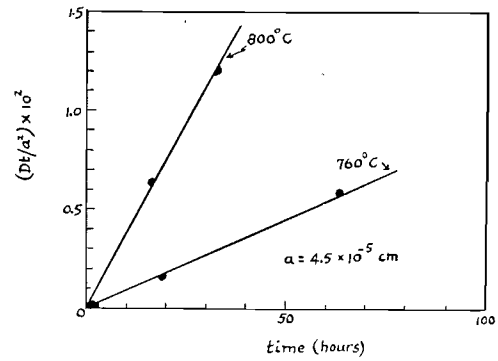

FIG. 2. Plot of non-dimensional (Dt/a^2) versus time at 760° and 800° C.

value of 3.50 m^2/g to 1.20 m^2/g. The change in surface area is negligible compared to the decrease observed in the exchange reaction rate.

DISCUSSION

It can be concluded that the hypothesis set forth in the introduction of this paper has been verified. The results, therefore, give strong support to the empirical relationship, $D_e = D_i \cdot k_e$, obtained from the reported data in Table I and the interstitialcy model of diffusion described above. The pre-exponential term for $D_e = D_i \cdot k_e$, using the mobility term from conductivity measurements, is at variance with the theoretical model by a factor of 10^3. D_i as calculated from the conductivity data is based on the assumption that the decay in conductivity was due solely to diffusion of interstitial zinc. The latter assumption may or may not be valid. A better fit to the theoretical interstitialcy model is obtained with the mobility term from the parabolic oxidation data.

If the sequence of rate-controlling steps as postulated for the observed processes in the exchange reaction on polycrystalline oxide were correct, then it is possible to calculate the diffusion coefficient of zinc via interstices if the time required for saturation of the oxide with interstitial zinc is taken as that time up to the onset of the interstitialcy diffusion (14). For temperatures 720°, 740°, 760°, and 780° C and using the simple relationship of $a^2 = 2Dt$, where a is the radius of the particle, the diffusion equation $D_i = 3 \times 10^{-7} \exp(-25 \text{ kcal}/RT)$ $cm^2\ sec^{-1}$ was obtained. This equation is concordant with the parabolic rate data, hence the mobility term.

An alternative interpretation of the data in Table I and the results reported herein could be given in terms of zinc vacancies. The existence of zinc vacancies would fit the theoretical model presented, where the mobility term would be diffusion via zinc vacancies under unsaturated conditions, while the exchange reaction under saturated conditions (no Zn vacancies) would consist of an interstitialcy mechanism. This interpretation would demand zinc oxide to be p-type instead of n-type semiconductor as observed. Furthermore, the diffusion constant would show an inverse dependence on zinc pressure, which is not the case.

The parabolic rate and diffusion equations as observed in the oxidation and conductivity studies are explained on the basis of a simple interstitial mechanism. Here, it is assumed that the diffusion coefficient was measured or determined while the excess zinc was diffusing through an unsaturated oxide lattice (oxidation) or out of a saturated oxide (conductivity). In the exchange experiments the diffusion coefficient on the other

For personal use only.

hand was determined while the zinc was diffusing through a saturated oxide lattice. The widely divergent results of Lindner on compressed sintered polycrystalline pellets of zinc oxide and of Moore and Williams on single crystals of zinc oxide are explained in a similar manner. That is, the drastic preannealing in the sintering stages of Lindner's experiments permitted saturation of the oxide powder by decomposition of the oxide as already reported (15), while the very moderate preannealing procedure by Moore and Williams produced only a very small concentration of interstitial zinc.

CONNAISSANCE DES *tert*-BUTYL-4 NITROMÉTHYL-1 CYCLOHEXANOLS-1 *cis* ET *trans*

H. Favre et D. Gravel

L'étude de la désamination nitreuse d'α-aminoalcools et plus particulièrement celle de la réaction de Tiffeneau (1) nous ont amenés à préparer les *tert*-butyl-4 nitrométhyl-1 cyclohexanols-1 *cis* (I*a*) et *trans* (II*a*) et à déterminer leurs configurations respectives. Nous posons que le groupe *tert*-butyle adoptera la conformation équatoriale (2, 3) dans les molécules étudiées.

I*a* R = CH_2NO_2 II*a* III
I*b* R = CH_2NH_2
I*c* R = $CH_2NC_5H_{10}$
I*d* R = CH_3 II*d*

L'action du nitrométhane sur la *tert*-butyl-4 cyclohexanone, en présence d'éthylate de sodium (4), conduit aux deux nitroalcools isomères I*a* et II*a*. Nous avons pu séparer facilement du mélange, par crystallisation fractionnée, l'isomère prédominant p.f. 86–87° et, plus difficilement, l'isomère p.f. 56–57°, qui ne représente que quelques pour-cents du mélange.

Nous attribuons la configuration cis au nitroalcool p.f. 86–87° après l'avoir transformé en méthyl-1 *tert*-butyl-4 cyclohexanol-1 *cis* (I*d*), p.f. 93–95°, en passant par l'α-aminoalcool I*b* et l'époxyde III. Cross et Whitham (5) viennent de décrire l'action de l'iodure de méthylmagnésium sur la *tert*-butyl-4 cyclohexanone et d'attribuer la configuration cis à leur isomère p.f. 89–90° et la configuration trans à l'isomère p.f. 70°; ils signalent toutefois que l'isomère cis n'est pas très pur. Dans nos mains les deux isomères purs fondent à 97–98° et 69–70°; nous leur attribuons les configurations cis et trans respectivement, après avoir mesuré les vitesses de saponification de leurs *p*-nitrobenzoates, à la manière de Hennion et O'Shea (3).

Le passage du nitroalcool I*a* à l'alcool I*d* s'est fait de la manière suivante. L'aminoalcool I*b*, obtenu de I*a* par réduction par le nickel de Raney (4), a été désaminé par l'acide nitreux; le produit brut de désamination a été réduit par l'hydrure de lithium et d'aluminium, puis oxydé par l'acide chromique et chromatographié: on isole la *tert*-butyl-4 cycloheptanone et l'alcool I*d*. Ces résultats font du produit de désamination de l'aminoalcool I*b* un mélange de *tert*-butyl-4 cycloheptanone et de l'époxyde III.[1] Cet époxyde n'a pas été isolé; outre sa transformation en alcool tertiaire I*d*, qui prouve son existence dans les produits de la désamination de I*b*, il a été caractérisé par un pipéridinoalcool (6) dont la formule probable est I*c*, à l'image de l'ouverture des époxydes dissymétriques par les amines (7, 8). La *tert*-butyl-4 cycloheptanone,[2] produit majeur de la désamination, a été caractérisée par sa dinitro-2,4 phénylhydrazone.

Pour que la preuve de configuration avancée ici soit valable il faut qu'il n'y ait aucune inversion de configuration en passant de I*a* à I*b* à III à I*d*. Les étapes I*a* $\rightarrow$ I*b* et III $\rightarrow$ I*d* n'offrent pas de difficultés d'interprétation; elles se font avec rétention de configuration; pour le passage de I*b* à III, nous avançons un mécanisme retenant la configuration, à l'image de la formation des époxydes dans l'agrandissement de cycle des cyclanones par le diazométhane (11) et dans la désamination nitreuse d'aminoalcools axiaux chez les stéroïdes (12, 13, 14).

PARTIE EXPÉRIMENTALE[3]

1. tert-Butyl-4 nitrométhyl-1 cyclohexanols-1 cis et trans (Ia et Ib)

En suivant fidèlement les indications opératoires de Dauben *et al.* (4) 25 g de *tert*-butyl-4 cyclohexanone conduisent à 25.8 g (74%) du mélange des deux nitroalcools, I*a* et I*b*, p.f. brut 65–75°. Après une recristallisation dans de l'éther de pétrole on isole 20 g de *tert*-butyl-4 nitrométhyl-1 cyclohexanol-1 *cis* (I*a*) (prismes incolores), p.f. 86–87°. Calculé pour $C_{11}H_{21}O_3N$: C, 61.37; H, 9.83; N, 6.51. Trouvé: C, 61.29; H, 9.91; N, 6.46%. L'isomère trans (II*a*) (paillettes incolores, 400 mg) p.f. 56–57°, s'obtient par 10 recristallisations fractionnées du résidu. Trouvé: C, 61.39; H, 9.84; N, 6.49%.

[1]*Il est bien connu que la cétone agrandie est le produit majeur de la désamination des aminométhyl-1 cyclanols-1 (1). Overberger et Katchman (9) ont signalé la formation d'époxydes dans la série hétérocyclique.*

[2]*Nozoe et ses collaborateurs (10) ont obtenu cette cétone en agrandissant la tert-butyl-4 cyclohexanone par le diazométhane.*

[3]*Les points de fusion (p.f.) ont été déterminés en tubes capillaires, avec un thermomètre étalonné avec des substances pures de p.f. connu, en provenance du Bureau des Standards de Washington.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

2. tert-Butyl-4 aminométhyl-1 cyclohexanol-1 cis (Ib)

En suivant fidèlement le mode opératoire de Dauben *et al.* (4) 25 g du nitroalcool I*a*, p.f. 86–87°, conduisent à 21.6 g (84%) du chlorhydrate du *tert*-butyl-4 aminométhyl-1 cyclohexanol-1 *cis* (I*b*), p.f. 235–236°. Calculé pour $C_{11}H_{24}ONCl$: C, 59.57; H, 10.91; N, 6.32. Trouvé: C, 59.40; H, 10.91; N, 6.37%.

3. Désamination du tert-butyl-4 aminométhyl-1 cyclohexanol-1 cis

À 1.2 g de chlorhydrate de *tert*-butyl-4 aminométhyl-1 cyclohexanol-1 *cis* dans 20 ml d'eau on ajoute 5.5 ml de soude 0.1 *N* pour libérer l'amine de son sel et 9.3 ml d'acide acétique glacial. La petite quantité de chlorure de sodium ne nuit pas à la réaction.

Le mélange est refroidi à 0° et une solution de 1.12 g de nitrite de sodium dans 4.5 ml d'eau est ajoutée goutte à goutte, en 45 minutes. Le mélange est ensuite agité à 0° pendant 2 heures, puis neutralisé par addition d'une solution de soude à 20%, sans que la température ne s'élève au dessus de 0°. On doit cesser l'addition de la soude au moment où l'aminoalcool non-réagi commence à se séparer sous forme de précipité blanc. On ajoute assez d'acide acétique glacial pour redissoudre le précipité, puis 15 gouttes en excès.

La solution acide est extraite à l'éther. Les solutions éthérées sont lavées au bicarbonate de sodium à 5%, à l'eau saturée de chlorure de sodium puis réunies, séchées et évaporées. On obtient une huile jaune pesant 795 mg. Des eaux acides on retire, à la manière habituelle l'aminoalcool qui n'a pas réagi (70 mg). Le produit brut de la réaction (795 mg) est repris par 10 ml de méthanol et 1 ml de pipéridine, puis chauffé à reflux pendant 2 heures. Le solvant est évaporé sous vide à 50°. Le résidu est repris par 100 ml d'éther anhydre; cette solution éthérée est lavée par de l'eau jusqu'à neutralité puis extraite par trois portions de 10 ml d'acide chlorhydrique aqueux 10%.

On examine (A) les solutions aqueuses et (B) la solution éthérée.

(A) Les solutions aqueuses acides sont réunies et évaporées sous vide. On obtient ainsi 82 mg de chlorhydrate de *tert*-butyl-4 pipéridinométhyl-1 cyclohexanol-1 *cis*, p.f. 242–243°. Calculé pour $C_{16}H_{32}ONCl$: C, 66.29; H, 11.13; N, 4.83. Trouvé: C, 66.18; H, 10.92; N, 4.87%.

(B) La solution éthérée est lavée au bicarbonate de sodium à 10%, à l'eau saturée de chlorure de sodium puis séchée et évaporée. On obtient ainsi 768 mg de *tert*-butyl-4 cycloheptanone sous forme d'huile jaune que l'on caractérise par sa dinitro-2,4 phénylhydrazone p.f. 146–147°. Calculé pour $C_{17}H_{24}O_4N_4$: C, 58.61; H, 6.94; N, 16.08. Trouvé: C, 58.58; H, 6.92; N, 16.19%.

4. Méthyl-1 tert-butyl-4 cyclohexanols-1 cis et trans (Id et IId)

Une solution de 10 g de *tert*-butyl-4 cyclohexanone dans 50 ml d'éther anhydre est traitée à 0° par de l'iodure de méthylmagnésium (préparé à partir de 2.37 g de magnésium et de 23.9 g d'iodure de méthyle dans 160 ml d'éther anhydre) à la façon habituelle. Le mélange des alcools tertiaires est un solide blanc (10.9 g) p.f. 40 à 58°.

Une partie du produit (9.7 g) est mise en solution dans 100 ml d'éther de pétrole (p. éb. 30–43°) et chromatographiée sur 388 g d'alumine Merck pour chromatographie.

L'élution de la colonne donne: (*a*) par de l'éther anhydre, une trace de cétone non réagie, identifiée par son spectre infrarouge; (*b*) par un mélange éther 95% – chloroforme 5%, 4.06 g de méthyl-1 *tert*-butyl-4 cyclohexanol-1 *trans* p.f. 69–70° (après sublimation); Cross et Whitham donnent (5) p.f. 70°; (*c*) par un mélange chloroforme 90% – méthanol 10%, 4.16 g de méthyl-1 *tert*-butyl-4 cyclohexanol-1 *cis* p.f. 97–98° (recristallisation dans l'éther de pétrole). Calculé pour $C_{11}H_{22}O$: C, 77.58; H, 13.02. Trouvé: 77.47; H, 13.20%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Les résultats de cette chromatographie montrent que l'isomère cis et l'isomère trans se sont formés dans un rapport de 1:1.

p-Nitrobenzoates des méthyl-1 tert-butyl-4 cyclohexanols-1 cis et trans

Préparation selon Hennion et Barrett (15).

Cis: p.f. 128–129° (EtOH–eau). Trouvé: C, 67.72; H, 7.94; N, 4.50%.

Trans: p.f. 115–116° (EtOH–eau). Trouvé: C, 67.66; H, 7.91; N, 4.48%. Calculé pour $C_{18}H_{25}O_4N$: C, 67.69; H, 7.89; N, 4.39%.

5. Preuve de configuration du nitroalcool Ia

Le produit brut (1.9 g) obtenu à la suite de la désamination nitreuse de 2.5 g de chlorhydrate du *tert*-butyl-4 aminométhyl-1 cyclohexanol-1 p.f. 235–236° (voir section 3) est immédiatement réduit par 1.9 g d'hydrure de lithium et d'aluminium dans 50 ml d'éther. Le produit de réaction est une huile incolore.

Une solution de 1.0 g de cette huile dans 25 ml d'acide acétique glacial est traitée, à 15°, par 500 mg d'anhydride chromique, ajoutée par petites portions. Le mélange est agité à la température de la pièce pendant 48 heures, puis versé dans 300 ml d'eau glacée et extrait par de l'éther de pétrole (p. éb. 30–43°). La couche organique est lavée par $NaHCO_3$ 10% et à l'eau, puis séchée et évaporée. Le produit brut de la réaction (600 mg) est chromatographié sur 15 g d'alumine Merck pour chromatographie. L'élution de la colonne par un mélange éther de pétrole – éther, donne la *tert*-butyl-4 cycloheptanone, identifiée par son spectre infrarouge et l'élution par de l'éther anhydre donne un solide blanc, p.f. 93–95°, dont le spectre infrarouge est identique à celui du méthyl-1 *tert*-butyl-4 cyclohexanol-1 *cis*, p.f. 97–98°. Point de fusion mixte avec un échantillon authentique: 95–96°.

6. Configuration des alcools tertiaires Id et IId

La configuration des alcools tertiaires est déterminée par l'étude des taux de saponification des *p*-nitrobenzoates à 24.8° dans le mélange acétone–eau, 4–1. La méthode employée est celle utilisée par Hennion et O'Shea (3).

Le *p*-nitrobenzoate de méthyl-1 *tert*-butyl-4 cyclohexanol-1 *trans*, p.f. 115–116°, a donné (deux essais): $k_2 = 4.9\times10^{-4}$ et 4.6×10^{-4}, moyenne: 4.75×10^{-4} litre mole^{-1} sec^{-1}. L'isomère cis, p.f. 128–129°, a donné (deux essais): $k_2 = 20.8\times10^{-4}$ et 19.5×10^{-4}; moyenne 20.2×10^{-4} litre mole^{-1} sec^{-1}.

Nous exprimons nos remerciements au Conseil National des Recherches du Canada, pour une bourse (D.G.) et un octroi de recherches (H.F.), ainsi qu'aux Établissements Dow Chemical of Canada Ltd., Montréal, pour la quantité généreuse de *tert*-butyl-4 cyclohexanols-1 mise à notre disposition.

A CHEMILUMINESCENT REACTION*

H. W. HOLDEN† AND K. O. KUTSCHKE

Recently, Vasil'ev *et al.* (1) observed weak chemiluminescence during the thermal decomposition of certain compounds. Several hydroperoxides were decomposed in their preparative solutions; benzoyl peroxide and azobisisobutyronitrile were studied in chlorobenzene solution. The temperature dependence of the luminescent intensity led the authors to suggest that the emission arose as a rare event which occurred during the combination of radicals. While the evidence for this interpretation is not yet conclusive, it has the corollary that stabilization by emission should be a more probable event in the gas phase where deactivating collisions occur less frequently.

We wish to report here the observation of luminescence in a system containing gaseous ethyl hyponitrite, undergoing thermal decomposition, upon the addition of acetaldehyde. The light was observed with a 1P21 photomultiplier tube in an Eldorado PH200 photometer at signal-to-noise ratios as high as 20 to 1 under some experimental conditions. The system was chosen since it was anticipated that it would contain large concentrations of acetyl radicals produced by the thermal reactions

$$C_2H_5ONNOC_2H_5 \rightarrow 2C_2H_5O + N_2, \qquad [1]$$

$$C_2H_5O + CH_3CHO \rightarrow C_2H_5OH + CH_3CO. \qquad [2]$$

In general terms it was hoped to produce the low-lying triplet state of biacetyl, which possesses a high phosphorescent efficiency (2), by the combination of acetyl radicals formed in [2]. The triplet state is well known in the photochemistry of biacetyl; details of the latter have been reviewed in considerable detail (3).

Ethyl hyponitrite was prepared by Partington and Shah (4) by the esterification of silver hyponitrite with ethyl iodide; they reported a rapid decomposition at 70° C. In our preparation a liberal excess (25–30 mole%) of the silver salt was used (we are indebted to Dr. L. C. Leitch for a supply of silver hyponitrite); this was required because of difficulties encountered in removing ethyl iodide from earlier preparations. The ester, dried over $CaCl_2$, was introduced into the vacuum system along with a small residue of ether solvent. While the ester was being outgassed at −85° C, it was observed to solidify gradually as the ether was removed. The ester was distilled at −10° C to a storage tube held at −85° C and was stored behind a mercury cutoff. It was crystalline in appearance and melted at a temperature slightly above the −85° C storage temperature.

The cell system consisted of a Pyrex vessel of 8-cm³ capacity having a thinned window. It was contained in an oven and connected by 6 mm i.d. tubing to a magnetically

operated glass circulation pump, a manometer, and a mercury cutoff. Earlier attempts were made to observe the luminescence in a cell designed for measurements of the photo-excited fluorescence. These attempts consumed reagent wastefully since about 75% of the cell system was heated to the decomposition temperature whereas only a small volume could be observed by the photocell.

Measurements of the luminescent intensity were made at several temperatures in the range 56 to 72° C; these yield an apparent activation energy of about 30 kcal/mole. This may be interpreted, following Vasil'ev *et al.* (1), as the activation energy for the decomposition of the ester. At least one alternative explanation involving the reactions

$$R + R \rightarrow R_2^*$$
$$R_2^* + B \rightarrow B^*$$
$$B^* \rightarrow B + h\nu$$

cannot be eliminated on the basis of measurements made thus far. Here R_2^* represents the initially excited dimer of the radicals R (which might be acetyl), and B and B^*, the unexcited and excited states of the product biacetyl. Much more intensive study is required, including identification of the emitting species, before a mechanism can be considered seriously.

The hyponitrite is a difficult compound with which to work and very little is known of the mechanism of its decomposition. The kinetics of the pyrolysis of ditertiarybutyl peroxide are well known. First trials with this initiator were unsuccessful, however, presumably because of the instability of acetyl radicals at the temperature necessary for its rapid decomposition (above 150° C), or because of the instability of the triplet state of biacetyl at that temperature (3).

It is hoped to follow this preliminary investigation with a more complete study in an attempt to determine the mechanism of the phenomenon.

THE SYNTHESIS OF 17α-FLUOROPROGESTERONE

R. Deghenghi and R. Gaudry

The biological activity of progesterone can be enhanced by the presence of appropriate substituents in positions α to the 20-carbonyl group. Thus 21-fluoro- and 17α-bromo-progesterone were shown to be twice as active as the natural hormone (1, 2). It was of interest therefore to prepare 17α-fluoroprogesterone and to compare its activity with that of the chloro and bromo analogues.

A previous attempt to introduce a fluorine in position 17 by opening a suitable 16,17-epoxypregnane with hydrogen fluoride, was reported to be unsuccessful (3); we chose, therefore, to investigate the reaction of a 20-cyano-17,20-epoxypregnane (I) with hydrogen halides. The latter pathway was recently used for the preparation of 17α-fluoro-11-dehydrocorticosterone acetate (4). Starting from 17α-bromopregnenolone we prepared readily the corresponding cyanoepoxide (I, R = H) by the action of alcoholic potassium cyanide at room temperature (5, 6). A proof of structure of (I) was obtained by its conversion to the known (7) 17α-chloropregnenolone acetate (III, R = Ac).

I II III

When 17α-bromoprogesterone was similarly allowed to react with potassium cyanide, a crystalline cyanoepoxide was obtained in high yield, the α,β-unsaturated 3-ketone being inert under our reaction conditions. This cyanoepoxide (IV), however, proved to be remarkably stable towards the action of anhydrous HF under the reaction conditions previously described in the 11-oxygenated series (4). It would seem that an 11-oxygen function facilitates the acid-catalyzed opening of the epoxide ring in 17,20 by anhydrous HF. In our case we found that treatment of IV with aqueous HF in a heterogeneous system resulted in the formation of the desired 17α-fluoro-20-cyanohydrin (V), smoothly and in good yield.

The resulting cyanohydrin (V) was found to be stable in non-hydroxylated solvents like ether, but it readily lost the elements of hydrogen cyanide when dissolved in an aqueous alcohol. Alternatively the regeneration of the 20-ketone function was effected by heating the cyanohydrin in organic bases, such as collidine, in a more conventional but less satisfactory manner. A proof of structure for the resulting 17α-fluoroprogesterone was obtained by removal of hydrogen fluoride upon prolonged treatment with refluxing dimethylformamide in the presence of LiBr and Li_2CO_3 (8), providing the known 16-dehydroprogesterone.

It was interesting to note that a substitution of fluorine at position 17α causes a positive increment in the rotation[1] (see Table I), contrary to the effect of a chlorine or bromine substituent. A hypsochromic displacement of the 20-ketone frequency in the infrared was observed due to the axial fluorine atom. There is only a slight shift with a 17α-chloro substituent, and no effect at all with a 17α-bromine atom. These shifts parallel those observed for an 11-ketone in the 9α-halogenated series (9). 17α-Fluoroprogesterone is slightly less active, in the Clauberg subcutaneous test, than the parent natural hormone.

TABLE I

	$[\alpha]_D$ $CHCl_3$	M_D	ΔM_D	$\Delta\nu$ 20-C=O $CHCl_3$ (cm^{-1})

EXPERIMENTAL[2]

Reaction between 17α-Bromopregnenolone and KCN

17α-Bromopregnenolone (5.00 g) (m.p. 158–159° C) was dissolved in 310 ml of 95% ethanol. A solution of 1.50 g of KCN and 2.20 g potassium acetate in 40 ml water was added and the resulting clear solution was stirred at room temperature for 19 hours. The product (4.0 g) was isolated by pouring the solution into 2 l. of ice water and filtering.

A 2-g portion of the crude bromine-free precipitate was suspended in benzene and chromatographed over 100 g of silica gel. Ethyl acetate – benzene 10:90 eluted 1 g of amorphous material, the infrared spectrum of which was consistent with the *cyanoepoxide* structure I (R = H): ν_{nujol} 3350 cm^{-1} (OH), 2240 cm^{-1} (—CN).

Increasing quantities of EtOAc in benzene eluted crystalline substances whose infrared spectra indicated the presence of a cyanohydrin group, m.p. 250–255° decomp., raised by crystallization from ethanol to 267–298° decomp. A sample was crystallized for analysis, m.p. 290° decomp. According to Barton's suggestions in the corresponding 11-oxygenated series (4) we assign to this substance the structure of a cyclopropanone cyanohydrin VII (or its epimer), intermediate in a Favorski rearrangement. Calc. for

VII

$C_{22}H_{31}O_2N$: C, 77.37; H, 9.15; N, 4.10%. Found: C, 77.67; H, 8.98; N, 3.91%. ν_{nujol} 3440 and 3240 cm^{-1} (OH), 2240 cm^{-1} (C≡N), 1053 cm^{-1} (C—O). Both hydroxyl groups were acetylated by acetic anhydride in pyridine at room temperature.

[1]*Professor Carl Djerassi kindly informed us that he observed a positive Cotton effect for 17α-fluoropregnenolone, prepared independently by Dr. Jensen of the University of Chicago.*

[2]*Melting points were determined in evacuated capillaries and corrected.*

17α-Chloropregnenolone Acetate (III, R = Ac)—Proof of Structure I

The amorphous cyanoepoxide I (0.500 g) was dissolved in 10 ml acetic acid. Anhydrous HCl was bubbled through the solution at room temperature for 30 minutes. A reddish-brown color developed. Ice water was added and the precipitate was collected on a filter and air-dried to give 0.514 g of a solid with a positive Beilstein test. One-half gram of this precipitate (II, R = Ac) was refluxed for 1 hour with 10 ml of toluene and 1 ml of a toluene solution containing 2.3% of collidine. The cooled solution was extracted with CH_2Cl_2, washed with iced dilute HCl, $NaHCO_3$ solution, and water, dried, and the solvent removed to give 0.495 g of a yellow oil which was reacetylated overnight at room temperature with 10 ml of pyridine and 2 ml of acetic anhydride. The usual working up gave 0.472 g of a crude product which was chromatographed on silica gel. EtOAc–benzene 3:97 eluted crystalline fractions (300 mg) which were recrystallized from ether–methanol for analysis, m.p. 142–144° C (III, R = Ac). Calc. for $C_{23}H_{33}ClO_3$: C, 70.30; H, 8.46; Cl, 9.02%. Found: C, 70.52; H, 8.01; Cl, 9.54%. This substance did not depress the melting point of an authentic sample of 17α-chloropregnenolone acetate (7). The infrared spectra were identical.

20-Cyano-17β,20-epoxy-4-pregnene-3-one (IV)

To 17α-bromoprogesterone (20.0 g) in 1200 ml commercial ethanol, there was added a mixture of 5.8 g KCN and 8.5 g CH_3COOK in 150 ml of water. The resulting solution was stirred at room temperature for 24 hours. At the end of this time 3.0 g of 20-cyano-17β,20-epoxy-4-pregnene-3-one crystallized out and was collected on a filter. The alcoholic filtrate was poured into ice water and the precipitate collected on a filter and washed with water. The combined dried precipitate weighed 17.0 g representing crude cyanoepoxide IV, m.p. 230–240° C. A sample was crystallized three times for analysis, m.p. 246–250° C (methanol). $[\alpha]_D^{25}$ +21.3 ($CHCl_3$ 1%); λ_{max} 241 mμ, ε 17,400. Calc. for $C_{22}H_{29}O_2N$: C, 77.84; H, 8.61; N, 4.13%. Found: C, 77.81; H, 8.46; N, 4.06%. ν_{CHCl_3} 2250 cm^{-1} (C≡N), 1665 and 1620 cm^{-1} (3-ketone-Δ^4). The structure of this substance was proved by conversion to the known 17α-chloroprogesterone (7), m.p. 165–167° C. The infrared spectra were identical and no depression of the melting point with an authentic sample was observed.

17α-Fluoroprogesterone (VI)

20-Cyano-17β,20-epoxy-4-pregnene-3-one (IV), 2.4 g, was slurried with 30 g of 48% aqueous HF at room temperature for 1 hour. The resulting oily substance was taken up in ether and washed to neutrality with $NaHCO_3$ solution and water. Evaporation of the solvent gave 2.45 g of a white solid, which crystallized from ether, m.p. 210–211° decomp. ν_{CHCl_3} 3360 cm^{-1} (OH), 2240 cm^{-1} (C≡N), 1663 and 1619 cm^{-1} (3-keto-Δ^4). When this substance, representing crude 17α-fluoro-4-pregnene-3-one-20-cyanohydrin, was refluxed in aqueous methanol overnight, HCN gas was evolved and crude 17α-fluoroprogesterone was recovered by evaporation of the solvent. Alternatively the cyanohydrin, 1.0 g, was refluxed for 1 hour in 5 ml of collidine. After the usual working up, 0.98 g of a yellow oil was obtained which was chromatographed on neutral alumina (Woelm III). The petroleum ether – benzene eluates contained 0.450 g of 17α-fluoroprogesterone, m.p. 170–174° C. A sample was recrystallized from acetone–hexane for analysis, m.p. 177–179° C, $[\alpha]_D$ +195.7° ($CHCl_3$). Calc. for $C_{21}H_{29}O_2F$: C, 75.87; H, 8.79; F, 5.71%. Found: C, 76.08; H, 8.85; F, 5.90%. ν_{CHCl_3} 1718 cm^{-1} (20-ketone, 17α-fluoro), 1665 and 1620 cm^{-1} (3-ketone-Δ^4).

Dehydrofluorination

To 17α-fluoroprogesterone, 130 mg, dissolved in 10 ml of dimethylformamide, there was added 130 mg of LiBr and 130 mg Li_2CO_3. The mixture was refluxed under N_2 for 24 hours. Usual working up gave 80 mg of a yellow oil which crystallized from acetone. The melting point did not depress upon admixture with an authentic sample of 16-dehydroprogesterone, m.p. 184–186° C. The infrared spectrum showed the characteristic Δ^{16} band at 1591 cm^{-1}.

Attempted Reaction of IV with Anhydrous HF

The cyanoepoxide IV, 5.0 g, was dissolved in 100 ml of dry tetrahydrofuran. To this solution, cooled into a dry ice – acetone bath, there was added 20 g of anhydrous HF. The resulting solution was stirred at room temperature for 18 hours. The usual working up (4) gave 5.0 g of a solid which crystallized from ether, m.p. 225–236° decomp. The infrared spectrum was identical with that of IV.

SOME REMARKS ON AGGREGATION OF POLYTHENE IN SOLUTION

H. P. Schreiber

INTRODUCTION

In a recent article Trementozzi (1) noted serious differences in the weight-average molecular weights, $\overline{M_w}$, obtained for high- and low-pressure polythene samples from light scattering in α-chloronaphthalene (α-CN) and tetralin solutions. He suggested that these differences were due to association of polythene molecules in α-CN solutions at the temperatures in question (~100–140° C). Thus, the α-CN data presumably gave the dimension of aggregates of polythene chains, rather than that of the average molecular chain. The suggested association was supported by data showing a decrease in $\overline{M_w}$ values obtained for one high-pressure polythene as the temperature of the α-CN solutions rose from 95–141° C. Subsequently Tung (2) noted similar differences in $\overline{M_w}$ values

SOME REMARKS ON AGGREGATION OF POLYTHENE IN SOLUTION

H. P. Schreiber

INTRODUCTION

In a recent article Trementozzi (1) noted serious differences in the weight-average molecular weights, $\overline{M_w}$, obtained for high- and low-pressure polythene samples from light scattering in α-chloronaphthalene (α-CN) and tetralin solutions. He suggested that these differences were due to association of polythene molecules in α-CN solutions at the temperatures in question (~100–140° C). Thus, the α-CN data presumably gave the dimension of aggregates of polythene chains, rather than that of the average molecular chain. The suggested association was supported by data showing a decrease in $\overline{M_w}$ values obtained for one high-pressure polythene as the temperature of the α-CN solutions rose from 95–141° C. Subsequently Tung (2) noted similar differences in $\overline{M_w}$ values

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

obtained for low-pressure polythenes from light scattering in α-CN solution and from calculations involving their intrinsic viscosities, $[\eta]$, in tetralin solution. Tung postulated the existence of long-chain branches in the supposedly linear polythenes used in his work. Long branching would reduce values of the intrinsic viscosity of the polymers (3) and result in calculations of erroneously low $\overline{M}_w$ values from an equation established on the basis of calibration data obtained for linear polythenes. This postulate gives internal consistency to the results, but does not explain the results of the earlier work (1), in which light scattering in α-CN and tetralin solutions of high-pressure polythenes (which are generally assumed to contain long-chain branches) also resulted in large $\overline{M}_w$ differences.

The possible aggregation of polythene in α-CN solution would cast doubt on a considerable body of published molecular weight data. Consequently comparisons of the temperature coefficients of intrinsic viscosity of two polythenes in α-CN and tetralin solutions were carried out to test further the possibility of association. This article reports the results of these comparisons.

THEORETICAL

The well-known theoretical treatment of Flory and Fox (4) gives the intrinsic viscosity $[\eta]$ of a polymer solution as

$$[\eta] = KM^{\frac{1}{2}}\alpha^3 \qquad [1]$$

where M is the molecular weight of the polymer, K is a temperature-dependent parameter, and α is the linear expansion coefficient which depends on the configuration of the polymer molecule in a specified solution.

The temperature dependence of $[\eta]$, discussed in detail by Flory (5) and more recently by Kawai and Ueyama (6), is due to the temperature coefficients of K and α in equation [1]. In general, K tends to decrease as the temperature rises, but its temperature dependence is generally small compared with that of α. The temperature dependence of α may be shown (5, 6) to reflect the solvent–polymer interaction in any system, the sign being settled by the heat of dilution in the pertinent system. As a rule, for nonpolar polymer–solvent systems this is positive (5). Thus in polythene solutions, α may be expected to increase with increasing temperature, especially in the vicinity of θ, the critical temperature for miscibility of the infinite polymer homologue in a given solvent.

If, in the investigated temperature range 100–150° C, appreciable association between polythene molecules occurs in α-CN solutions as compared with tetralin solutions, then the degree of solvent–solute interaction in α-CN is appreciably less than in tetralin solutions. The α-CN solutions are consequently closer to their characteristic θ temperatures and the temperature coefficient of $[\eta]$ in α-CN should be positive and significantly greater than that in tetralin. Further, if the assumption of aggregation is true, the greater tendency for expansion of the polythene molecules in tetralin solutions must result in $[\eta]_t > [\eta]_{\alpha\text{-CN}}$ at comparable temperatures (the subscript t is used to denote tetralin solution). These experimental consequences seem necessary to support the contention of association, although they are not sufficient to establish this behavior unequivocally.

EXPERIMENTAL

Materials

Two unfractionated polythenes were used in this work. One was a low-pressure linear polythene L, the other a high-pressure branched polythene B. Some of their physical properties are summarized below. Methyl group contents for the two samples were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

	Density (g/cc)	CH_3/1000 carbons	$\overline{M_w}$
Polythene L	0.960	1.1	13.5×10^4
Polythene B	0.920	22.7	12.8×10^4

obtained from infrared spectrophotometry and attest to the essential linearity of sample L, and the presence of branches in B. The $\overline{M_w}$ values were obtained from light-scattering measurements in α-CN solution at 120° C using a modified Bryce-Pheonix apparatus. In view of the uncertainty of the meaning of the values, however, the quoted molecular weights are not considered to be absolute. The two samples were in fact chosen because of similarities in their melt viscosities over an appreciable shear-stress range, which suggested that their molecular weights were not greatly different.

Viscosity Measurements

Solution viscosity measurements were carried out in modified Ubbelohde viscometers described by Schulken and Sparks (7), and no kinetic energy or shear corrections were applied. In the investigated range, 100–150° C, temperatures were controlled to about ±0.05° C. Polythene samples used to make up appropriate solutions were stabilized against oxidation by incorporating 0.1% by weight of a commercial antioxidant on a two-roll mill. Viscosity measurements on the redistilled solvents showed these to be thermally stable over periods which were long compared with the working life of a given solution. Minimum exposure of solutions to air was ensured by carrying out all viscosity determinations in a nitrogen atmosphere. Intrinsic viscosities were obtained from extrapolation to zero concentration (c) of plots of η_{sp}/c vs. c and $\ln \eta_r/c$ vs. c, where η_{sp} is the specific viscosity and η_r the relative viscosity of the solution. These plots were found to be linear in the range $0.1 < c < 0.6$ g/100 ml. Values of $[\eta]$ so obtained had a high degree of internal consistency, the precision being not less than ±2%.

RESULTS

The pertinent intrinsic viscosity data are given in Table I. The temperature coefficient

TABLE I

Intrinsic viscosities of polythene solutions at various temperatures

Temp. (°C)	$[\eta]$ (dl g^{-1})			
	Polymer L		Polymer B	
	Tetralin	α-CN	Tetralin	α-CN
100	1.91		1.21	
110		1.43		1.00
120	1.94	1.47	1.23	1.02
140	1.94	1.56	1.21	1.05
150	1.92	1.60	1.19	1.07

of $[\eta]$ in α-CN is positive and substantially greater for both polythenes than the corresponding coefficients in tetralin solutions. Further, the $[\eta]$ values in tetralin for both polymers are significantly greater than the corresponding α-CN values. This indicates a greater tendency for polymer expansion in tetralin, which is therefore thermodynamically the better solvent. The results are in keeping with the theoretical development outlined above; consequently they are consistent with the supposition of solute aggregation in α-CN solutions of polythene (1).

DISCUSSION

Differences between the $[\eta]$–temperature relationships of polythenes L and B are more readily seen from a plot of $[\eta]$ versus T, such as given in Fig. 1. The temperature

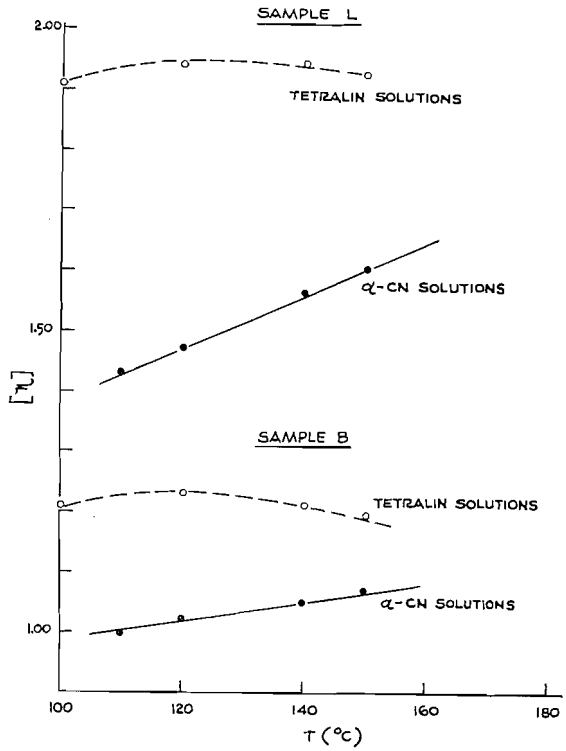

FIG. 1. Temperature dependence of intrinsic viscosity in polythene solutions.

coefficient of $[\eta]_{\alpha\text{-CN}}$ for polythene L is substantially greater than for polythene B, the respective slopes of the linear plots being 2.1×10^{-3} and 1.2×10^{-3}. Since the apparent $\overline{M}_w$ of these samples is roughly equivalent, it is suggested that the polymer L – α-CN pair may be closer to its characteristic θ temperature than the pair polymer B – α-CN at the temperatures involved in these experiments. In terms of a solute-association hypothesis, the molecules of polymer L thus have a greater tendency for aggregation than do those of polymer B. In view of the generally held opinion that linear polymers are more subject to segmental entanglements (8) than are branched polymers, an aggregation in α-CN solution could result simply from the inability of the weak solvent to disrupt these entanglements. The aggregation should therefore be increasingly evident with rising molecular weight, lowered temperature (in line with the findings of Trementozzi (1) and Tung (2)), and increasing linearity of the polythene, but should be partially reduced or eliminated in thermodynamically better solvents such as tetralin.

The $[\eta]_t$ values appear to attain a maximum near 120° C, more noticeably so for polythene B. Kawai and Ueyama (6) have recently suggested such a maximum to be generally expected in high-polymer systems and have noted its occurrence in polythene–xylene. The temperature at which this maximum occurs increases with the flexibility

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of the polymer chain (6); since the maximum for sample L should then occur at a somewhat higher temperature than that of sample B, its more pronounced manifestation in polythene B may be understood. The weak temperature coefficient of $[\eta]_t$ indicates a general balance of thermal effects due to changes in K and α of equation [1] and, as previously noted, suggests an appreciably stronger solvent–solute interaction than in the α-CN solution systems.

The temperature at which the solute molecule appears to expand to the same extent in α-CN as it does in a corresponding tetralin solution may be estimated from the $[\eta]$–T relationships in Fig. 1. Thus, if $[\eta]_t$ is assumed to attain a maximum near 120° C for both polythenes, then the linear $[\eta]_{\alpha\text{-CN}}$–$T$ plots may be extrapolated to the appropriate maximum value of $[\eta]_t$. For polythene L the temperature for "solvent equivalence" appears to be about 230° C; for B about 270° C. This admittedly gross procedure suggests that light-scattering experiments using α-CN solutions of polymers L and B at the above temperatures, and tetralin solutions at 120° C, should yield equal values of $\overline{M}_w$ for each of the two resins. Both of the suggested temperatures for α-CN experimentation would, of course, be well beyond limits of practicability.

CONCLUSIONS

Tetralin is thermodynamically a superior solvent for polythene than α-CN. At the temperatures normally utilized for light-scattering measurements of $\overline{M}_w$, α-CN solutions of polythene seem closer to their characteristic θ temperatures, and would therefore be the preferred solution systems for such measurements, provided no solute aggregation occurred. The present results, however, are fully consistent with the suggestion of polythene aggregation in α-CN solutions (1), although they do not unequivocally establish its existence. In view of this, further critical experimentation into the state of the polymer molecule in α-CN solution would appear to be called for.

ACKNOWLEDGMENTS

I am indebted to Messrs. R. Baxter and P. Kruus for much of the viscosity work, to Mr. A. W. Pross for infrared determinations, and to Dr. M. H. Waldman for light-scattering data.

STRUCTURE OF AN ARABINOGALACTAN FROM TAMARACK (LARIX LARICINA)[1]

S. HAQ[2] AND G. A. ADAMS

ABSTRACT

Partial acid hydrolysis of an arabinogalactan from tamarack wood yielded:
(I) L-arabinose,
(II) D-galactose,
(III) 3-*O*-β-L-arabinopyranosyl-L-arabinose,
(IV) 6-*O*-β-D-galactopyranosyl-D-galactose,
(V) 3-*O*-β-D-galactopyranosyl-D-galactose,
(VI) *O*-D-galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl(1 → 6)-D-galactose,
(VII) 3,6-di-*O*-(galactopyranosyl)-D-galactopyranose,
(VIII) *O*-D-galactopyranosyl(1 → 3)-*O*-D-galactopyranosyl(1 → 3)-D-galactose,
(IX) *O*-D-galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl(1 → 3)-D-galactose,
(X) *O*-D-galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl (1 → 3)-D-galactose,
(XI) *O*-D-galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl(1 → 3)-*O*-D-galactopyranosyl (1 → 3)-D-galactose.

A previously published structure for the tamarack polysaccharide was revised to show that not more than two consecutive 1 → 3 or 1 → 6 linkages respectively were present in the main core of the repeating unit. Some of the 6-*O*-β-D-galactopyranosyl-D-galactose units occurred as side chains as well as in the main body of the molecule.

It has been shown previously that the water-soluble polysaccharide of tamarack (*Larix laricina*) is a highly branched arabinogalactan composed of L-arabinose and D-galactose in the ratio of 1:3.8 (1). Evidence was presented to indicate that the galactose residues were joined predominantly by 1 → 3 and 1 → 6 glycosidic linkages. The original view (2) that arabinose was attached as a single molecule in the furanose form in ε-galactan polysaccharides was made untenable by the isolation of β-3-*O*-L-arabinopyranosyl-L-arabinose from a mild hydrolysis of both a larch ε-galactan (3) and an arabinogalactan from western larch (*Larix occidentalis*) (4). The present work which describes the fragmentation analysis of arabinogalactan from tamarack was undertaken to provide additional information on the fine structure of the polysaccharide.

The polysaccharide was subjected to a progressive, mild acidic hydrolysis, as it was observed previously (1) that such treatment released arabinose units almost completely from the main body of the polysaccharide, resulting in a degraded galactan. The chromatographic picture of the hydrolyzate (0.01 *N* H_2SO_4 for 3 hours and .02 *N* H_2SO_4 for 4 hours) revealed as the main components, L-arabinose, D-galactose, a disaccharide of arabinose, and a disaccharide of galactose. In addition, there were several minor spots of sugars giving pink or reddish-brown colors with *p*-anisidine hydrochloride spray reagent. Two of these moved on paper chromatograms faster than arabinose and two moved

[1]*Manuscript received April 6, 1961.*
Contribution from the Division of Applied Biology, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 6350.
[2]*N.R.C. Postdoctorate Fellow, 1959–1961.*

between galactobiose and arabinobiose and gave a reddish-brown color with *p*-anisidine hydrochloride. One of the faster-moving components had the same R_F value as L-rhamnose but it was not sufficient in amount to permit further characterization. The components moving between galactobiose and arabinobiose were probably the products of resynthesis because heating of a mixture of arabinose and galactose under the same conditions showed very faint spots having the same flow rates on the chromatogram.

After the foregoing mild hydrolysis, the degraded galactan was subjected to a more rigorous hydrolysis. From the hydrolyzates the various sugars were isolated through a combination of cellulose and charcoal–celite column chromatography. The results are shown in Table I. The preliminary hydrolysis released the monosaccharides, the disaccharides of arabinose, and galactobiose (IV). The more rigorous hydrolysis released D-galactose (II), additional galactobiose (IV), and all other oligosaccharides. L-Arabinose and D-galactose were crystallized and identified by their physical properties.

TABLE I

Sugars recovered from partial acid hydrolysis of arabinogalactan of tamarack

	Name	Yield (mg)
(I)	L-Arabinose	Not determined
(II)	D-Galactose	Not determined
(III)	3-*O*-β-L-Arabinopyranosyl-L-arabinose	500
(IV)	6-*O*-β-D-Galactopyranosyl-D-galactose	850
(V)	3-*O*-β-D-Galactopyranosyl-D-galactose	390
(VI)	*O*-D-Galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl(1 → 6)-D-galactose	17
(VII)	3,6-Di-*O*-(galactopyranosyl)-D-galactopyranose	32
(VIII)	*O*-D-Galactopyranosyl(1 → 3)-*O*-D-galactopyranosyl(1 → 3)-D-galactose	106
(IX)	*O*-D-Galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl(1 → 3)-D-galactose	93
(X)	*O*-D-Galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl (1 → 3)-D-galactose	35
(XI)	*O*-D-Galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl(1 → 3)-*O*-D-galactopyranosyl (1 → 3)-D-galactose	94

The disaccharide of arabinose on complete acidic hydrolysis and chromatographic examination gave arabinose as the only monosaccharide. On complete methylation and hydrolysis, the disaccharide gave (i) 2,3,4-tri-*O*-methyl-L-arabinose, (ii) 2,4-di-*O*-methyl-L-arabinose, and (iii) 2,5-di-*O*-methyl-L-arabinose. These sugars were characterized through their respective crystalline derivatives.

The presence of 2,4- and 2,5-di-*O*-methyl-L-arabinose in the hydrolyzate of the methylated disaccharide indicated that the disaccharide was a mixture of β-3-*O*-L-arabinopyranosyl-L-arabinopyranose and β-3-*O*-L-arabinopyranosyl-L-arabinofuranose. From the amount of 2,4-di-*O*-methyl-L-arabinose (93 mg) and 2,5-di-*O*-methyl-L-arabinose (14.2 mg) it was concluded that the two forms of the disaccharide were present in the mixture in the ratio of 6.5:1. Approximately the same ratio was found between the 2,4- and 2,5-di-*O*-methyl arabinoses by gas–liquid chromatography (5, 6). The lower specific rotation of the disaccharide and that of its methylated derivative compared to those reported by previous workers (3, 4) also indicated the possibility of a disaccharide present in furanose form. The 2,5-di-*O*-methyl-L-arabinose could not have arisen from incomplete methylation of the disaccharide because the methoxyl content of the methylated derivative agreed with the theoretical value and no adsorption corresponding to $(OH)^-$ group could be detected in the infrared spectrum.

The disaccharide of galactose, which was obtained by mild acid hydrolysis, was crystallized and identified as β-6-*O*-D-galactopyranosyl-D-galactose and was identical with

galactobiose (IV) described below. The amount released in the preliminary hydrolysis was approximately one quarter of the total amount that was recovered from all hydrolyses. Galactobiose (IV) was obtained in crystalline form and its specific rotation indicated a β-linkage. The mode of linkage in the disaccharide was established by the isolation of 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,3,4-tri-*O*-methyl-D-galactose from the hydrolyzate of fully methylated disaccharide. Thus the structure of galactobiose (IV) was confirmed as β-6-*O*-D-galactopyranosyl-D-galactose.

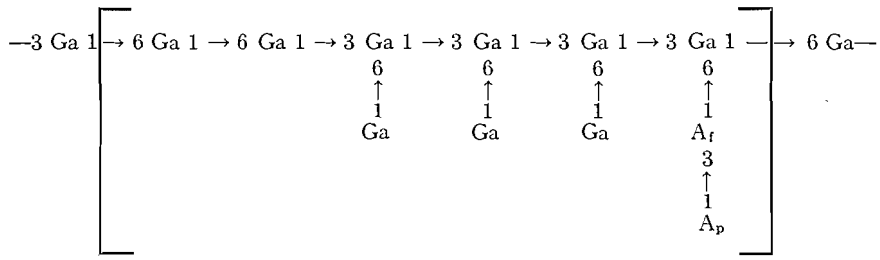
Galactobiose (V) on complete acidic hydrolysis gave only galactose and its flow rate on a chromatogram indicated that it was a disaccharide. On complete methylation and hydrolysis, the disaccharide gave 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,4,6-tri-*O*-methyl-D-galactose, and its structure was established as 3-*O*-D-galactopyranosyl-D-galactose.

Galactotriose (VI) and galactotriose (VII) were isolated in very small amounts and complete structural studies by methylation were not possible. However, some preliminary experiments revealed their probable structure. Galactotriose (VI) on partial hydrolysis gave galactose, galactobiose (IV), and the original sugar. On reduction and partial hydrolysis of the reduced product, galactose and galactobiose (IV) were obtained as reducing sugars. Therefore galactotriose (VI) is probably *O*-D-galactopyranosyl (1 → 6)-*O*-D-galactopyranosyl(1 → 6)-D-galactose. Galactotriose (VII) on partial acidic hydrolysis gave galactose, galactobiose (IV), galactobiose (V), and the original sugar. After reduction and partial hydrolysis of the derived glycitol, galactose was obtained as the only reducing sugar. Therefore the evidence suggests that galactobiose (VII) is probably a branched trisaccharide having the tentative structure 3,6-digalactopyranosyl-D-galactose.

Galactotriose (IX) on complete methylation and hydrolysis of the methylated product gave 2,3,4,6-tetra-*O*-methyl-D-galactose; 2,3,4-tri-*O*-methyl-D-galactose; and 2,4,6-tri-*O*-methyl-D-galactose in equimolar proportion. These results indicated that the trisaccharide was a straight chain containing 1 → 6 and 1 → 3 glycosidic linkages. The trisaccharide on partial acidic hydrolysis gave galactobiose (IV) and galactobiose (V). The sequence of glycosidic linkages was established by the reduction of the trisaccharide and partial hydrolysis of the derived glycitol. On reduction and hydrolysis the trisaccharide gave galactose and galactobiose (IV) as reducing sugars. This finding confirmed that the 1 → 3 linkage was at the reducing end of the molecule while the 1 → 6 linkage was penultimate to the reducing end. Therefore the structure of galactotriose (IX) was established as *O*-D-galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl(1 → 3)-D-galactose.

Galactotriose (VIII) was obtained in crystalline form for the first time. The sugar, after partial acidic hydrolysis, gave galactose, galactobiose (V), and the original trisaccharide. After reduction and partial hydrolysis it gave galactose and galactobiose (V) as reducing sugars. Therefore it was probably a straight-chain trisaccharide containing 1 → 3 glycosidic linkages. On methylation and hydrolysis of the methylated product, the trisaccharide gave 2,3,4,6-tetra-*O*-methyl-D-galactose (1 mole) and 2,4,6-tri-*O*-methyl-D-galactose (2 moles). Therefore the structure of galactotriose (VIII) was established as *O*-D-galactopyranosyl(1 → 3)-*O*-D-galactopyranosyl(1 → 3)-D-galactose.

Galactotetraose (X) on partial acidic hydrolysis produced galactose, galactobiose (IV), galactobiose (V), galactotriose (VI), galactotriose (IX), and the original sugar. On reduction and hydrolysis it gave galactose, galactobiose (IV), and galactotriose (VI). Therefore the structure of galactotetraose (X) was proposed as *O*-D-galactopyranosyl (1 → 6)-*O*-D-galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl(1 → 3)-D-galactose. Similarly,



on the basis of the products of partial hydrolysis of the sugar and its reduced product, the structure of galactotetraose (XI) was proposed as *O*-D-galactopyranosyl(1 → 6)-*O*-D-galactopyranosyl(1 → 3)-*O*-D-galactopyranosyl(1 → 3)-D-galactose. No other galactotetraoses were found. Figure 1 shows a diagrammatic representation of the oligosaccharide

$O_1 \rightarrow {}_6\emptyset$ galactobiose (IV)	$O_1 \rightarrow {}_3\emptyset$ galactobiose (V)

$O_1 \rightarrow {}_6O_1 \rightarrow {}_6O_1 \rightarrow {}_3\emptyset$ galactotetraose (X)	$O_1 \rightarrow {}_6O_1 \rightarrow {}_3O_1 \rightarrow {}_3\emptyset$ galactotetraose (XI)

FIG. 1. Diagrammatic representation of D-galactose oligosaccharides from tamarack arabinogalactan: O, galactose; Ø, galactose (reducing unit).

structures of the various sugars isolated from tamarack in the present study. Of these, (IV), (V), (VI), (VII), and (VIII) have been previously reported as products of partial hydrolysis of European larch galactan (8).

A possible structure for the tamarack arabinogalactan (Fig. 2) was proposed earlier

Structure I

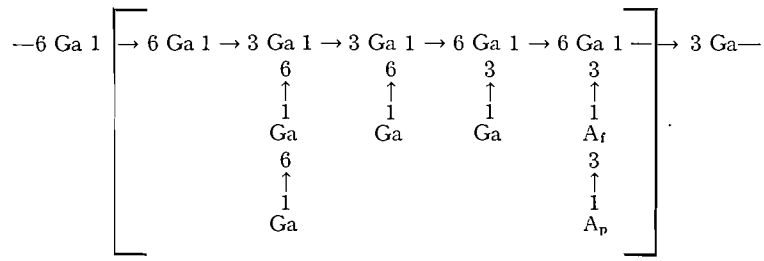

FIG. 2. Structure originally proposed for repeating unit of tamarack arabinogalactan.

(1) and was based on methylation and periodate oxidation evidence. The isolation and identification of the oligosaccharides obtained in the present study confirm, in general, most of the main features of this structure. Some revisions, as will be pointed out below, are required. The occurrence of 1 → 3 and 1 → 6 linked galactopyranose units in the core of the molecule was proved by the isolation of galactobiose (IV) and (V). Two galactose trisaccharides (VIII) and (VI) joined by 1,3- and by 1,6-linkages respectively were isolated and have established that two consecutive 1 → 3 and 1 → 6 linkages exist in the polysaccharide. In addition, two trisaccharides containing both 1,3- and 1,6-linkages were found. In these, galactotrioses (IX) and (VII), the galactose units constituting the reducing end of the chains were linked to the remainder of the molecule through C_3; in addition, the reducing terminal unit of galactotriose (VII) was branched through C_6. From the structure of galactotetraoses (X) and (XI), it appears that not more than two 1 → 3 or two 1 → 6 linkages occur consecutively in the polysaccharide.

Partial hydrolysis using very dilute acid yielded 1 → 6 linked galactobiose but no

For personal use only.

$1 \rightarrow 3$ linked galactobiose. Approximately one quarter of the $1 \rightarrow 6$ linked disaccharide was released by this treatment, the remainder being formed by more rigorous hydrolysis. The $1 \rightarrow 6$ and the $1 \rightarrow 3$ linkages are present in approximately equal proportions (1) and the preferential release of the $1 \rightarrow 6$ linked galactobiose units indicated that some of them were in side chains. This observation was further substantiated by recovery of most of the intact polysaccharide after the preliminary mild acid hydrolysis. The attachment of $1 \rightarrow 6$ linked galactose units as side chains has been proposed also for the ϵ-galactan of European larch (8). These findings have necessitated changes from structure I (Fig. 2) to structure II (Fig. 3). This latter structure accounts for the formation of all

Structure II

FIG. 3. Modified structure proposed for repeating unit of tamarack arabinogalactan.

the oligosaccharides shown in Fig. 1. In addition, the methylation and periodate oxidation found in a previous study (1) support this structure.

The structure as originally proposed for the tamarack arabinogalactan (1) and shown in Fig. 2 predicted that some of the L-arabinose units were attached in such a way as to yield 3-*O*-L-arabinopyranosyl-L-arabinofuranose on partial hydrolysis. This disaccharide has now been isolated and identified and found to be identical with that previously isolated from larch ϵ-galactans (3, 4). In addition, a much larger amount of arabinose occurred as 3-*O*-L-arabinopyranosyl-L-arabinopyranose. It is presumed that the disaccharide of arabinose existed in the original polysaccharide with its reducing unit in the furanose form and was attached directly to the D-galactose units in the main structure but no positive proof is presently available.

Possible structures for repeating units in galactans from other larch species have been proposed by White (7) and Aspinall (8). The structure proposed by White is characterized by a main chain of 1,6-linked galactose units substituted in position 3 by a secondary chain of three $1 \rightarrow 3$ linked D-galactose residues, the structure proposed by Aspinall consists of a $1 \rightarrow 3$ linked D-galactose main core with two $1 \rightarrow 6$ linked D-galactose units attached to it through position 6. Neither of these formulations would explain the formation of all the oligosaccharides isolated from tamarack arabinogalactan; nor could the proportion of methylated sugars obtained from fully methylated tamarack arabinogalactan be produced from these structures. Assuming the validity of these different proposed structures, it is apparent that some species differences in these polysaccharides must exist.

Further studies of the structural relationships of L-arabinose in the tamarack arabinogalactan are being undertaken through enzymic degradation.

EXPERIMENTAL

The organic phase of the following solvent systems (v/v) was used for chromatography:

(A) ethyl acetate – pyridine – water (2.5:1:2.5),
(B) butan-1-ol–ethanol–water (5:1:4),
(C) benzene–ethanol–water–ammonia (200:47:14:1),
(D) ethyl acetate – acetic acid – water (9:2:2).

Paper chromatography was carried out on Whatman No. 1 and No. 3MM papers for qualitative and quantitative separations respectively.

A 3% ethanolic solution of *p*-anisidine hydrochloride was used for detecting reducing sugars (9). All specific rotations were measured in water and at 25° C unless otherwise stated. Evaporations were done under reduced pressure at 32–34° C.

Hydrolysis of the Polysaccharide

Arabinogalactan (20 g) as previously prepared (1) was heated on a boiling-water bath with 0.01 *N* H_2SO_4 (500 ml) for 3 hours. After the solution had cooled, it was neutralized with barium carbonate, filtered, and concentrated to a small volume (100 ml). The concentrated solution was poured dropwise into 95% ethanol (2 l.), which was rapidly stirred. The precipitated polysaccharide was removed by filtration and the filtrate was evaporated to dryness (1.1 g). The precipitated polysaccharide was hydrolyzed twice more with 0.02 *N* H_2SO_4 (500 ml) for 2 hours and recovered as above. Chromatograms of all the hydrolyzates showed L-arabinose, D-galactose, a disaccharide of L-arabinose, a disaccharide of D-galactose, and traces of other sugars running faster on paper than L-arabinose.

The sugars (3 g) were separated on a cellulose column (40×6 cm) and eluted with a mixture of butanol–ethanol–water (40:11:19) at a rate of 7 ml per 18 min. The following fractions were collected.

A. (Tube 61–109).—This fraction gave a syrup (30 mg) which contained traces of arabinose and two other sugars, (i) R_{arab} 1.56, (ii) R_{arab} 2.32 in solvent A. L-Rhamnose has R_{arab} 1.56 in solvent A.

B. (Tube 110–114).—This fraction gave a syrup (777 mg) containing mainly arabinose and traces of galactose. The mixture crystallized from aqueous ethanol giving pure L-arabinose which, after three recrystallizations from the same solvent, had m.p. 159–160° C, $[\alpha]_D$ +105° (*c*, 1.74).

C. (Tube 145–275).—This fraction gave a mixture of sugars (1.63 g) containing L-arabinose, D-galactose, and a disaccharide of L-arabinose. The mixture was separated on a charcoal–celite (1:1) column (27×4.5 cm). The column was washed first with water (2 l.) to remove monosaccharides, and the disaccharide was removed by gradient elution (20% ethanol run into 1.5 l. of water). All the fractions (8–11) showing a single spot on paper chromatogram were combined and evaporated to dryness. A chromatographically pure disaccharide of L-arabinose (500 mg) was obtained.

D. (Tube 293–416).—This fraction on evaporation gave a sugar (220 mg) which contained mainly a galactobiose, R_{gal} 0.32 in solvent A with traces of galactose, a trisaccharide, and another sugar giving a reddish-brown color with *p*-anisidine reagent and moving on paper slightly faster than galactobiose. A crystalline sugar was obtained by keeping a methanolic solution of the syrup in the cold for 10 days. After recrystallization from methanol, the crystals had m.p. 168–170° C with swelling at 98–100° C and sintering at 120° C. The crystalline sugar was identical with β-6-*O*-galactopyranosyl-D-galactose (see later).

Identification of Arabinobiose

The syrup (500 mg) had $[\alpha]_D$ +193° (*c*, 3.77) and R_{arab} 0.74 in solvent A. It gave a characteristic pink color with *p*-anisidine hydrochloride spray reagent and on complete hydrolysis yielded L-arabinose.

The disaccharide (290 mg) dissolved in water (5 ml), was cooled in an ice bath, and dimethyl sulphate (1 ml) was added. The solution was stirred vigorously and 30% sodium hydroxide solution (2 ml) was added dropwise during 7 hours and the reaction mixture was further stirred for 5 hours. Then 30% sodium hydroxide solution was added 5 ml at a time and dimethyl sulphate (3 ml) was allowed to run in dropwise and the reaction mixture was further stirred for 14 hours. The solution was heated at 60° C for 1 hour to decompose any unreacted dimethyl sulphate, and then the partially methylated sugar was continuously extracted with chloroform for 4 days. After removal of the chloroform the sugar was once again methylated as above except that the sodium hydroxide solution was added first to keep the reaction mixture alkaline. The partially methylated products were then methylated twice with Purdie's reagent. The methylated disaccharide (300 mg) had $[\alpha]_D$ +160° (*c*, 0.76 in chloroform). (Found: MeO, 50.3%. $C_{16}H_{30}O_9$ requires: OMe, 50.6%.)

The methylated disaccharide (260 mg) was hydrolyzed by heating on a water bath at 100° C for 7 hours with 0.5 *N* HCl (20 ml). The solution was neutralized with silver carbonate, filtered, and the filtrate was evaporated to dryness. The syrup (240 mg), on examination by paper chromatography in solvent B, showed two spots with R_G 0.81 and R_G 0.63. The sugars were separated on paper in the same solvent.

Fraction I

This fraction proved to be 2,4-di-*O*-methyl-L-arabinose (93 mg), $[\alpha]_D$ +118° (*c*, 0.9). (Found: OMe, 33.3. $C_7H_{14}O_5$ requires: OMe, 34.8%.) A portion (32 mg) of the sugar was heated on a water bath with freshly distilled aniline (17 mg) in ethanol (2 ml) for 3 hours. The solvent was removed and the syrup was dissolved in hot butanol, and on cooling, crystals (plates) were formed. After recrystallization from the same solvent the crystals had m.p. and mixed m.p. 135–136° C. (On an uncovered glass plate the crystals melted at 145–147° C; the same behavior was observed with authentic samples of 2,4-di-*O*-methyl-*N*-phenyl-L-arabinosylamine.)

Another portion (40 mg) was oxidized with 2 drops of bromine in water (0.5 ml). Barium carbonate (20 mg) was added to the reaction mixture, which was stored in the dark for 72 hours. Bromine was removed by aeration and the acidified solution was extracted with chloroform. After removal of the chloroform the residual syrup was distilled (bath temperature 120–145° C at 0.02 mm). The distillate was dissolved in methanol (10 ml), saturated with ammonia, and kept in the cold overnight. On evaporation of methanol, the amide crystallized and after recrystallization from methanol in the cold the crystals had m.p. 158–159° C (reported m.p. of 2,4-di-*O*-methyl-L-arabonamide is 160–161° C) (4). (Found: MeO, 32.0%. $C_7H_{14}O_5N$ requires: MeO, 32.3%).

Fraction II (120.4 mg)

When this fraction was examined by paper chromatography in solvent C it was found to consist of two sugars. This observation was also confirmed when the sugar (2 mg) was refluxed with methanolic hydrogen chloride (2%), and examined by gas–liquid chromatography (5, 6). The sugars were separated on paper in solvent C.

(*a*) 2,5-Di-*O*-methyl-L-arabinose (14.2 mg), $[\alpha]_D$ −19.7° (*c*, 0.71). The sugar was oxidized as above with bromine and the corresponding arabonic acid was distilled (bath temperature 120–140° C at 0.02 mm). The lactone was dissolved in ammoniacal methanol and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

kept overnight in the cold. On evaporation of methanol the product crystallized and after recrystallization from ethanol the crystals had m.p. 130–131° C, undepressed on admixture with an authentic specimen of 2,5-di-*O*-methyl-L-arabonamide.

(*b*) 2,3,4-Tri-*O*-methyl-L-arabinose (42 mg) (there was some accidental loss of material). The sugar was oxidized with bromine as above and the resulting product was distilled (bath temperature 105–120° C at 0.02 mm). The lactone was heated with phenylhydrazine in methanol (3 ml) for 3 hours. Methanol was removed and the syrup crystallized on seeding. After recrystallization from ethyl acetate the phenylhydrazide of 2,3,4-tri-*O*-methyl-L-arabonolactone had m.p. and mixed m.p. 156–158° C.

Hydrolysis of the Degraded Polysaccharide

The degraded galactan (20 g) recovered from previous hydrolysis with dilute H_2SO_4 was further hydrolyzed on a boiling-water bath with 0.1 *N* H_2SO_4 (500 ml) for a total of 6 hours. Three hydrolysis periods of 2 hours each were used, with recovery of polysaccharide after each hydrolysis by precipitation with 92% ethanol. The hydrolysis procedure was again repeated with 0.2 *N* H_2SO_4 for 2 hours and with 0.5 *N* H_2SO_4 for 3 hours. The chromatographic picture of all hydrolyzates was similar, showing galactose and oligosaccharides of galactose.

The sugars (12 g) from the combined hydrolyzates were fractionated on a charcoal–celite (1:1) column (48×6.5 cm). The column was first washed with water (3 l.) to remove monosaccharides. Then gradient elution technique was applied in which 10% ethanol was allowed to run into water (4 l.) to elute the oligosaccharides. After 185 fractions had been collected (80–100 ml each), 10% ethanol was replaced by 20% ethanol.

The water eluate on evaporation gave mainly D-galactose (8.1 g) and traces of L-arabinose. D-Galactose was crystallized from aqueous ethanol and after recrystallization had m.p. 165–166° C, $[\alpha]_D$ +80.6° (*c*, 2.02).

The individual sugars were further purified by paper chromatography in solvent A. Galactotriose (VI) gave a single spot in all solvent systems, but when examined by paper electrophoresis in borate buffer at pH 10 it showed two sugars, galactotriose (VI) (M_G 0.81) and galactotriose (VII) (M_G 0.69). These sugars were separated on paper electrophoresis in borate buffer.

Identification of the Oligosaccharides

Galactobiose (IV)

The sugar (650 mg) crystallized from methanol with 2 moles of methanol as solvent of crystallization, m.p. 168–170° C with swelling at 98–100° C and softening at 120° C, $[\alpha]_D$ 28° (*c*, 1.43). (Found: C, 41.39; H, 7.57. $C_{12}H_{22}O_{11}$,$2CH_3OH$ requires: C, 41.30; H, 7.38.) After removal of the solvent of crystallization at 100° C *in vacuo* over P_2O_5, the disaccharide had m.p. 168–170° C with softening at 120° C, $[\alpha]_D$ 34.2° (*c*, 1.52). (Found: C, 41.94; H, 6.54. $C_{12}H_{22}O_{11}$ requires: C, 42.1; H, 6.48.) On complete hydrolysis it gave D-galactose.

The disaccharide (306 mg) was methylated initially with dimethyl sulphate (13 ml) and 30% sodium hydroxide solution (24 ml) as described above for arabinobiose, and subsequently by two methylations with Purdie's reagent. The methylated product (303 mg) crystallized from the syrup as needles but could not be crystallized from any solvent. It had m.p. 68–70° C, $[\alpha]_D$ −5.7° (*c*, 2.4 in methanol). (Found: C, 51.96; H, 8.28; MeO, 52.4%. $C_{20}H_{38}O_{11}$ requires: C, 52.42; H, 8.12; MeO, 54.6%.)

The methylated disaccharide (250 mg) was hydrolyzed with *N* HCl at 100° C for 5 hours. The solution was neutralized with silver carbonate, filtered, and evaporated to dryness. The individual methylated sugars were separated on paper in solvent C and two fractions were obtained.

*(a) 2,3,4,6-Tetra-O-methyl-*D*-galactose (86.7 mg).*—The sugar (40 mg) was heated with freshly distilled aniline (25 mg) in ethanol (3 ml) for 3 hours. When the solution was concentrated and cooled, crystals of 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-galactosylamine separated which, after recrystallization from ethanol, had m.p. and mixed m.p. 194–196° C.

*(b) 2,3,4-Tri-O-methyl-*D*-galactose (80.3 mg).*—A portion of the sugar (20 mg) was heated with freshly distilled aniline (15 mg) for 3 hours in ethanol (3 ml). Ethanol was removed by distillation and the residual syrup was extracted with hot ethyl acetate. After removal of the ethyl acetate the syrup was crystallized from acetone. On recrystallization from the same solvent the crystals (plates) had m.p. 165–167° C, undepressed on admixture with an authentic specimen of 2,3,4-tri-*O*-methyl-*N*-phenyl-D-galactosylamine. Another portion of the trimethyl galactose (22 mg) was oxidized with bromine for 48 hours. Bromine was removed by aeration and the acidified solution extracted with chloroform. After removal of the chloroform, the acid was distilled (bath temperature 150–160° C at 0.02–0.01 mm). The distillate was dissolved in methanol (10 ml), saturated with ammonia, and kept at +4° C overnight. After removal of methanol the product crystallized and on recrystallization from ethanol the 2,3,4-tri-*O*-methyl-D-galactonamide had a m.p. and mixed m.p. 166–167° C.

Galactobiose (V)

This fraction, $[\alpha]_D$ +60.3° (*c*, 2.1), was a chromatographically pure sugar (390 mg) but it could not be induced to crystallize even by seeding with authentic samples of 3-*O*-*β*-D-galactopyranosyl-D-galactose. On complete hydrolysis it gave D-galactose as the only monosaccharide.

The sugar (175 mg), on methylation as described above, gave a methylated product (145 mg). (Found: MeO, 52.37%. $C_{20}H_{38}O_{11}$ requires: MeO, 54.6%.) The methylated sugar (140 mg) was hydrolyzed by being heated on a boiling-water bath with *N* HCl (15 ml) for 7 hours. The acid was neutralized with silver carbonate, the precipitate was filtered off, and the filtrate was evaporated to dryness. The methylated sugars were separated on paper in solvent B and two fractions were obtained.

*(a) 2,3,4,6-Tetra-O-methyl-*D*-galactose (56.6 mg).*—The sugar was converted into its anilide derivative which, after crystallization, had m.p. 195–197° C, undepressed on admixture with an authentic specimen.

*(b) 2,4,6-Tri-O-methyl-*D*-galactose (51.7 mg).*—The sugar, on being heated with freshly distilled aniline (30 mg) in ethanol (3 ml) for 3 hours, gave a product which crystallized from acetone on cooling. After recrystallization, the crystals (needles) had m.p. 177–179° C, undepressed on admixture with an authentic sample of 2,4,6-tri-*O*-methyl-*N*-phenyl-D-galactosylamine, m.p. 176° C. On the basis of these findings the disaccharide was identified as 3-*O*-*β*-D-galactopyranosyl-D-galactose.

Galactotriose (VI) (17 mg)

Galactotriose (VI) was chromatographically pure sugar which had the same R_{gal} value (0.10) as galactotriose (VII) (0.10) in solvent A but which differed in M_G values in borate buffer. The sugar on partial acidic hydrolysis gave galactose, galactobiose (IV), and the original sugar. After reduction (potassium borohydride) and partial acidic

hydrolysis it gave galactose and galactobiose (IV) as reducing sugars. This trisaccharide is probably *O*-D-galactopyranosyl(1→ 6)-*O*-D-galactopyranosyl(1 → 6)-D-galactose.

Galactotriose (VII) (31.6 mg)

The sugar on partial acidic hydrolysis gave galactose, galactobiose (IV), and galactobiose (V). On reduction (potassium borohydride) and partial hydrolysis it gave galactose as the only reducing sugar.

Galactotriose (IX) (93 mg)

This was a chromatographically pure sugar, $[\alpha]_D$ +20.5° (*c*, 4.0). On partial acidic hydrolysis it gave galactose, galactobiose (IV), galactobiose (V), and the original sugar. On reduction of the trisaccharide (potassium borohydride) and partial acidic hydrolysis of the glycitol only galactose and galactobiose (IV) were found as reducing sugars.

The trisaccharide (80 mg) was methylated twice as described above with dimethyl sulphate (2.5 ml) and 30% sodium hydroxide solution (5 ml). After two further methylations with Purdie's reagent the methylated trisaccharide (66.5 mg) had MeO content 49.37%; $C_{29}H_{54}O_{16}$ requires: MeO, 51.8%. The methylated product was hydrolyzed with *N* HCl (10 ml) by being heated on a boiling-water bath for 5 hours. The acidic solution was neutralized with silver carbonate, filtered, and evaporated to a syrup (50 mg). The hydrolyzed product on a paper chromatogram in solvent B showed two sugars: (*a*) the faster-moving, corresponding to tetra-*O*-methyl-D-galactose, and (*b*) a slow-moving elongated spot. The mixture was separated on paper in solvent B.

(a) 2,3,4,6-Tetra-O-methyl-D-galactose (18.5 mg).—The sugar gave a crystalline anilide derivative, m.p. and mixed m.p. 195–197° C, when heated with aniline (10 mg).

(b) 2,3,4- and 2,4,6-Tri-O-methyl-D-galactose (29 mg).—Chromatographic separation was done using solvent C. The paper was irrigated and when the solvent front was near the bottom of the paper, the paper was dried and again irrigated. This operation was repeated four times but still gave an imperfect separation. However, about $\frac{3}{4}$ in. of the paper in the middle of the band of sugars was discarded and the top portion of the band was extracted with water to give a sugar (9.2 mg). When heated with a drop of aniline in ethanol the sugar gave a product which crystallized from acetone. After recrystallization, the crystals (plates) melted at 165° C, undepressed on admixture with an authentic specimen of 2,3,4-tri-*O*-methyl-*N*-phenyl galactosylamine. The lower portion of the paper gave a sugar (7.9 mg) which gave a crystalline (needles) anilide derivative, m.p. 176–178° C, undepressed on admixture with an authentic specimen of 2,4,6-tri-*O*-methyl-*N*-phenyl galactosylamine.

Galactotriose (VIII) (106 mg)

The sugar crystallized from aqueous ethanol, m.p. 240–245° C (decomposed), $[\alpha]_D$ +51° (*c*, 0.87). (Found: C, 42.00; H, 6.31. $C_{18}H_{32}O_{16}$ requires: C, 42.10; H, 6.34.) The trisaccharide after partial acidic hydrolysis gave galactose, galactobiose (V), and the original sugar. After reduction (potassium borohydride) and partial acidic hydrolysis it gave galactose and galactobiose (V) as reducing sugars.

The trisaccharide (75 mg) was methylated as above. The methylated product (75.6 mg) crystallized from ethanol on slow evaporation of the solvent at room temperature, m.p. 158–160° C, $[\alpha]_D$ −10.0° (*c*, 1.45 in methanol). (Found: MeO, 50.6%. $C_{29}H_{54}O_{16}$ requires: MeO, 51.8%).

The methylated trisaccharide (60 mg) was hydrolyzed in *N* HCl (10 ml) by being heated on a boiling-water bath for 5 hours. The acid was neutralized with silver carbonate, the precipitate was filtered, and the filtrate evaporated to dryness. The syrup on separation on paper in solvent B gave two fractions.

For personal use only.

*(a) 2,3,4,6-Tetra-O-methyl-*D*-galactose (17.2 mg).*—On being heated with aniline (10 mg) in ethanol (2 ml) for 3 hours the product crystallized from ethanol. After recrystallization from the same solvent it had m.p. and mixed m.p. 195–197° C.

*(b) 2,4,6-Tri-O-methyl-*D*-galactose (28.6 mg).*—The syrup was heated with aniline (16 mg) in ethanol (3 ml) for 3 hours. The solvent was removed and the product was crystallized from acetone. After recrystallization, the crystals (needles) had m.p. and mixed m.p. 177–178° C. On the basis of above findings this sugar was identified as *O*-D-galactopyranosyl(1 → 3)-*O*-D-galactopyranosyl(1 → 3)-D-galactose.

Galactotetraose (X) (35 mg)

On partial acidic hydrolysis with 0.1 *N* H_2SO_4 for 1 hour the sugar gave galactose, galactobiose (IV), galactobiose (V), galactotriose (VI), galactotriose (IX), and the original sugar. On reduction and hydrolysis it gave galactose, galactobiose (IV), and galactotriose (VI) as reducing sugars.

Galactotetraose (XI) (94 mg)

On partial acidic hydrolysis the sugar gave galactose, galactobiose (IV), galactobiose (V), galactotriose (IX), galactotriose (VIII), and the original sugar. After reduction of the tetrasaccharide, followed by partial acid hydrolysis, the derived glycitol gave galactose, galactobiose (IV), galactobiose (VI), and galactotriose (IX) as reducing sugars.

ACKNOWLEDGMENTS

The authors wish to thank Professor J. K. N. Jones, Queen's University, Kingston, and Dr. Hans O. Bouveng, Swedish Forest Products Research Laboratory, Stockholm, Sweden, for gifts of 2,4-di-*O*-methyl-*N*-phenyl-L-arabinosylamine. Thanks are also due Dr. G. O. Aspinall, Edinburgh University, and Dr. A. S. Perlin, National Research Council, Saskatoon, for crystalline specimens of 3-*O*-β-D-galactopyranosyl-D-galactose. Carbon, hydrogen, and methoxyl analyses were done by Mr. A. E. Castagne.

THE CRYSTAL STRUCTURE OF 1,4-DIBROMONAPHTHALENE[1]

J. TROTTER

ABSTRACT

Crystals of 1,4-dibromonaphthalene are monoclinic with eight molecules in a unit cell of dimensions $a = 27.45$, $b = 16.62$, $c = 4.09$ Å; $\beta = 91.9°$; space group $P2_1/a$. The high proportion of bromine in the crystal probably precludes location of the carbon atoms with sufficient precision to give accurate molecular dimensions, and it has therefore not been considered worth while proceeding beyond the detailed examination of the projection along the short c-axis. There are two molecules in the asymmetric unit, and the solution of the structure from $hk0$ Patterson and Fourier projections has indicated that these two molecules are related, at least in projection, by a pseudo center of symmetry. The projected bond distances indicate significant deviations of the bromine atoms from the aromatic plane. Approximate values of the bond lengths in the molecule have been deduced from the projected distances and estimated orientation angles.

INTRODUCTION

The crystal structure of 1,4-dibromonaphthalene has been determined as part of a series of investigations of derivatives of naphthalene (1).

EXPERIMENTAL

Crystals of 1,4-dibromonaphthalene, obtained by crystallization from aqueous ethanol, consist of colorless plates elongated along the c-axis with the (010) face developed. The approximate density was determined by flotation in standard heavy liquids. The unit-cell dimensions and space group were determined from rotation and oscillation photographs of a crystal rotating about the c-axis, $hk0$ and $hk1$ Weissenberg films, and an $h0l$ precession film.

Crystal Data

1,4-Dibromonaphthalene, $C_{10}H_6Br_2$; molecular weight = 286.0; m.p. = 83° C.

Monoclinic, $a = 27.45 \pm 0.08$, $b = 16.62 \pm 0.04$, $c = 4.09 \pm 0.01$ Å; $\beta = 91°55' \pm 10'$.

Volume of the unit cell = 1864.9 Å^3.

Density, calculated (with $Z = 8$) = 2.037 g cm^{-3}, measured ~2.0 g cm^{-3}.

Absorption coefficient for X-rays, $\lambda = 1.542$ Å, $\mu = 105.4$ cm^{-1}; $\lambda = 0.7107$ Å, $\mu = 94.2$ cm^{-1}.

Total number of electrons per unit cell = $F(000) = 1088$.

Absent spectra: $h0l$ when h is odd, $0k0$ when k is odd.

Space group is $P2_1/a$—C_{2h}^5.

The intensities of the $hk0$ reflections* were recorded on Weissenberg exposures for a crystal rotating about the c-axis, using Cu $K\alpha$ radiation, with multiple-film technique to correlate strong and weak reflections. The $h0l$ reflections were recorded on precession films with Mo $K\alpha$ radiation. All the intensities were estimated visually, the range being about 2000 to 1. The cross section of the crystal normal to the c-axis was 0.08×0.02 mm, so that absorption is negligible, and no corrections were applied. The structure amplitudes were derived by the usual formulae for a mosaic crystal, the absolute scale being established later by correlation with the calculated structure factors. Three hundred and sixty-eight independent $hk0$ reflections were observed, representing about 62% of the possible number observable with Cu $K\alpha$ radiation.

**The 200, 110, and 210 reflections were cut off by the beam stop.*

STRUCTURE ANALYSIS

The best approach to determining the complete structure was obviously by examination of the *c*-axis Patterson projection. The *hk*0 Patterson map is shown in Fig. 1. There are

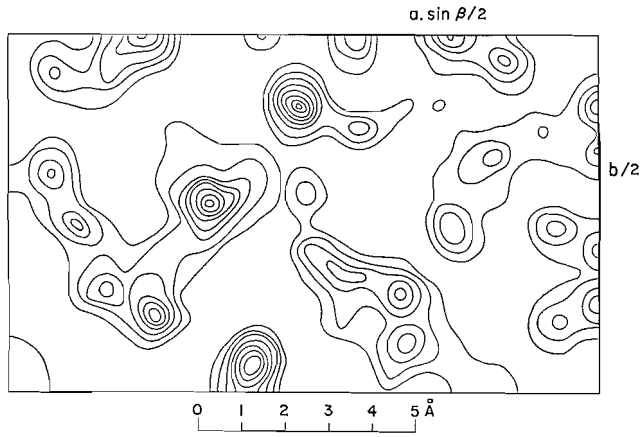

FIG. 1. *c*-Axis Patterson projection; contours at arbitrary intervals.

two molecules and hence four bromine atoms in the asymmetric unit and the plane group for this projection is *pgg*, so that the vector distribution is complex, with many multiple peaks. However, the four Harker peaks on each of the lines $x = \frac{1}{2}$ and $y = \frac{1}{2}$ were easily distinguished, and 16 possible positions (x_j, y_j, z_j) for the four bromine atoms readily deduced. A search was then made for single bromine–bromine vectors at positions $(2x_j, 2y_j, 2z_j)$; this eliminated several of the 16 possibilities but ambiguities still remained. However, it was possible to determine the most probable position for one of the bromine atoms, and a minimum function was then constructed by placing the origin of the Patterson function, in turn, at this bromine position and at the three symmetry-related positions. There were only four significant independent peaks on the resulting map, all of about the same height, and these were taken as corresponding to the four bromine atoms. It was noted that they were related in pairs by a pseudo center of symmetry, so that the larger peaks on the Patterson map correspond to fourfold coincidences of Br–Br vectors.

Structure factors were calculated for all the observed *hk*0 reflections using the scattering factor for bromine of the *Internationale Tabellen* (2) with $B = 3.8$ Å^2, and the discrepancy factor was 44.6%. A Fourier series was then summed, using as coefficients the measured structure amplitudes together with the calculated signs. On the resulting electron-density map all the bromine and carbon atoms were well-resolved, although the carbon contours were considerably distorted, as might be expected in the presence of the much heavier bromine atoms. New positions were chosen for the bromine atoms, and co-ordinates also obtained for all 20 carbon atoms in the asymmetric unit. Structure factors were recalculated using the scattering curve for carbon of Berghuis *et al.* (3) with $B = 3.8$ Å^2; the R value was 24.3%. A second Fourier synthesis was then computed, and on the resulting electron-density map (Fig. 2), the resolution of the carbon atoms was much improved. No changes were suggested in the positional parameters of the bromine atoms, but improved co-ordinates were obtained for the carbons. Since it was not considered worth

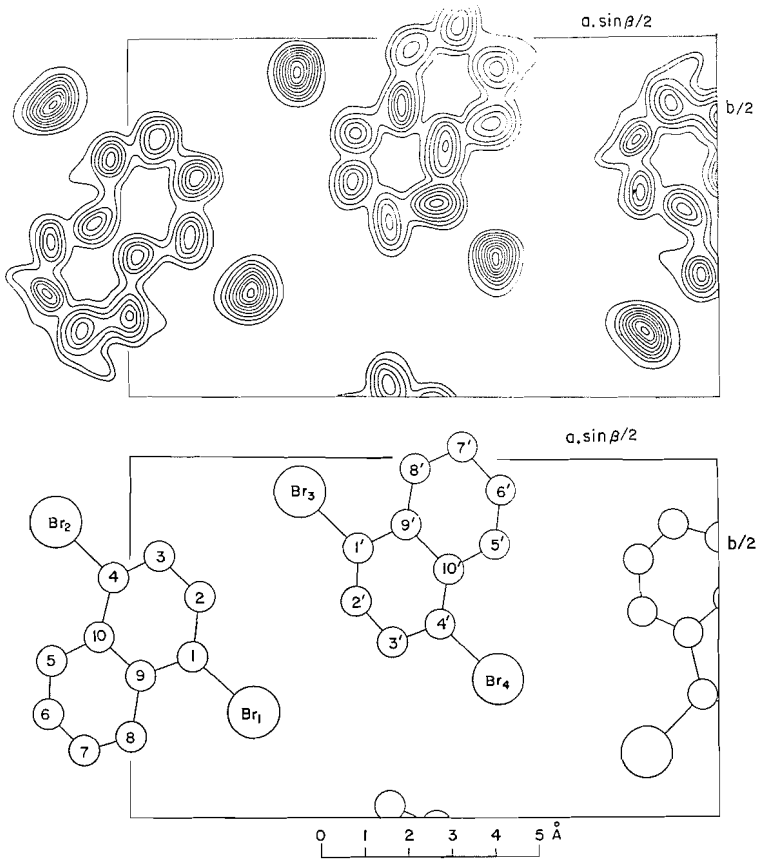

FIG. 2. Electron-density projection along [001] (contours on the carbon atoms at intervals of 1 e Å^{-2}, starting at 2 e Å^{-2}, and on the bromine atoms at intervals of 5 e Å^{-2}, starting at 5 e Å^{-2}), and projection of the structure along [001].

while carrying out further intensive refinement, structure factors were not recalculated; the values at the penultimate stage ($R = 24.3\%$) are not included here, to save space, but are available from the author.

It was apparent that no resolution of the individual atoms could be expected in the projections down the long *a*- and *b*-axes, so that three-dimensional methods would be required to determine the *z*-co-ordinates. It was not considered that the results which could be obtained from such an analysis would be sufficiently accurate, nor that the problem was sufficiently important, to justify the great amount of work involved, and so no effort has been made to determine the *z*-co-ordinates of the atoms.

Co-ordinates and Bond Distances

The final positional parameters are listed in Table I, referred to the crystal axes and expressed as fractions of the unit-cell edges. There is a pseudo center of symmetry at about (0.124, 0.300). The projected bond distances calculated from these co-ordinates are given in the first column of Table II. In order to deduce true bond lengths from these

projected distances the following assumptions were made:

(i) that the C—Br distances are equal to the normal single bond length (1.91 Å),

(ii) that the naphthalene skeletons are planar and have symmetry *mmm*,

(iii) that the average bond length for each of the three groups of parallel C—C bonds is equal to the corresponding average length in naphthalene (4, 5).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The inclinations of the various bonds from the plane of projection, derived from these assumptions, are listed in the second column of Table II, and the true bond distances in the third column. Although there are some large deviations from *mmm* symmetry, these cannot be considered as significant, and the mean bond lengths are given in the fourth column of the table.

Although it has been assumed, in deriving the true bond distances, that the average distances in the various directions are equal to the corresponding average distances in naphthalene, this does not imply that the individual distances must be equal, and so it is permissible to compare the mean bond lengths in 1,4-dibromonaphthalene with the distances in naphthalene. This comparison is included in Table II; the agreement is extremely good, suggesting, as we might expect, that the mean distances are more accurate than the individual values, and also that the assumptions made are plausible.

Comparison of the inclination angles for the C—Br bonds (12°) and for bonds such as 9—10 (23°) indicates that the bromine atoms are displaced from the naphthalene plane, the two bromine atoms in the molecule being displaced in opposite directions from the aromatic plane by about 0.4 Å. If it had been assumed that the bromine atoms were situated on the naphthalene plane, the true C—Br distances would have been 2.03 Å, considerably longer than the normal single bond length, so that the bromine atom displacements are probably real. The deviations are possibly the result of small steric interactions with the *peri* hydrogen atoms.

Projected distances indicate that all the intermolecular contacts correspond to normal van der Waal's interactions.

The author thanks the National Research Council for grants-in-aid for this work.

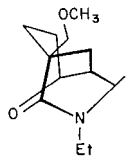
THE EPIMERIZATION OF DELCOSINE[1]

VINKO SKARIĆ[2] AND LÉO MARION

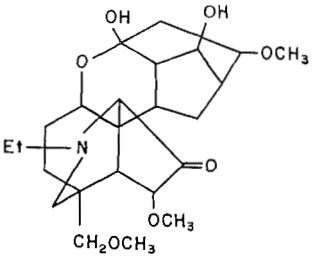


ABSTRACT

Delcosine has been assigned tentatively the same C—N skeleton as lycoctonine. In lycoctonine, ring A carries at C-1 a methoxyl group which is directed away from the nitrogen ring. In delcosine, C-1 carries a hydroxyl group which has the opposite configuration and is directed towards the nitrogen. An attempt to correlate the two structures first involves epimerization at C-1 in delcosine. This has been carried out by oxidation of desethyldelcosine to an azomethine, the ethiodide of which, by the action of methanolic potassium hydroxide, is converted to oxo-1-epidelcosine in two steps. Oxo-1-epidelcosine in an acid-catalyzed rearrangement is transformed to a pinacone which, after methylation, gives O,O-dimethyl-anhydro-oxo-1-epidelcosine. This compound was compared with O-methyl-anhydro-oxolycoctonine, prepared from oxolycoctonine, but was not identical. Removal of a methoxyl, which in each compound is ortho to a carbonyl, by the action of sodium amalgam, produced O,O-dimethyl-6-desmethoxy-anhydro-oxo-1-epidelcosine and O-methyl-6-desmethoxy-anhydro-oxolycoctonine, which are not identical, but show in their infrared spectra much less dissimilarity than the spectra of the pair of compounds from which they were derived. These results are discussed in terms of the structure of delcosine.

As a working hypothesis, the alkaloid delcosine ($C_{24}H_{39}O_7N$) has been assumed to possess the same C—N skeleton as lycoctonine ($C_{25}H_{41}O_7N$). All the chemical reactions of delcosine studied so far are in agreement with such an assignment. In order to prove or disprove that delcosine has the previously assigned (1, 2, 3) structure I, it has been

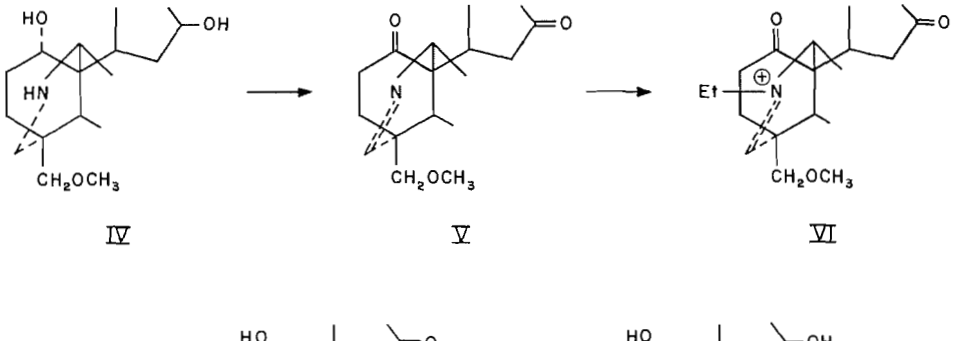
I



II

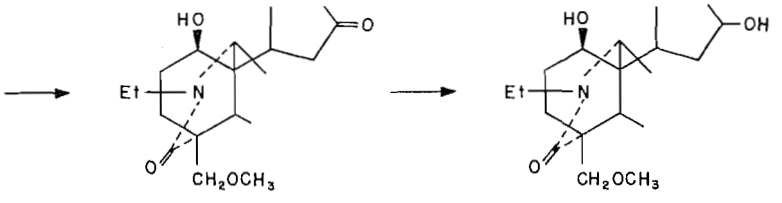
attempted in the work now reported to correlate it with lycoctonine. Although we have failed in our main objective, the results obtained firmly establish the position of all but two of the substituents on the C—N skeleton.

It has been shown earlier (2, 3) that delcosine contains a secondary hydroxyl substituted on the six-membered ring A. Oxidation of delcosine with either silver oxide or N-bromosuccinimide gives rise to a carbinolamine ether, anhydrohydroxydelcosine II (1, 3), the formation of which involves this secondary hydroxyl, which was assumed to occupy position C-1 by analogy with lycoctonine. This conclusion is also supported by the results of the oxidation of oxodelcosine with lead tetraacetate (3). Although the product of this reaction should contain a five-membered and a six-membered cyclic ketone, actually it is a ketohemiketal III in which cyclization has occurred between the secondary hydroxyl of ring A and the carbonyl of the six-membered cyclic ketone (3, 4). Position C-1 for the secondary hydroxyl of ring A is the only one that allows the formation



[1]*Manuscript received April 7, 1961.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 6358.
[2]*National Research Council of Canada Postdoctorate Fellow, 1957–1959.*

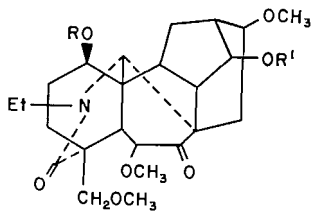
of a six-membered cyclic hemiketal and appears to be the only one where the formation of a ring is geometrically possible. To account for the formation of the carbinolamine ether it is further necessary that the C-1 hydroxyl be directed on the same side of ring A as the nitrogen ring (3). This configuration is different from that of the methoxyl at C-1 in lycoctonine (5).



III

Hence, any attempt to correlate delcosine with lycoctonine would initially involve epimerization at C-1. Sparatore, Greenhalgh, and Marion (6) have attempted this epimerization in delsoline, which is a monomethyldelcosine (2), but their reported result is in error, and the compound that they have described is not epidelsoline but Δ′-anhydrodelsoline ($C_{25}H_{39}O_6N$). Dvornik and Edwards (7) reported the epimerization of a hydroxyl in ajaconine, and Dr. Dvornik suggested to us an adaptation of the method by which it has now proved possible to prepare epidelcosine from N-desethyldelcosine, a previously described oxidation product of the base (1). N-Desethyldelcosine (IV) was oxidized by Sarett's reagent to a mixture of N-desethyl-1,10-didehydrodelcosine-azomethine (V) and the neutral N-desethyl-1,10-didehydro-oxodelcosine. The former was converted to the ethiodide (VI), which on being refluxed with 10% methanolic potassium hydroxide, yielded 10-dehydro-oxo-1-epidelcosine (VII). Reduction of VII with sodium boro-

IV V VI



VII VIII

hydride gave oxo-1-epidelcosine (VIII), m.p. 128–130°, $[\alpha]_D^{25}$ +19.8°, and this on treatment with lithium aluminum hydride produced 1-epidelcosine, m.p. 177–178°, $[\alpha]_D^{26}$ +38.9°, which formed a perchlorate, m.p. 199–201°.

For the purpose of correlating epidelcosine with lycoctonine it was necessary to methylate the primary hydroxyl group in the latter. Although this could be achieved, the yield was poor and it was more usual to obtain a dimethylated product in which one of the two vicinal tertiary hydroxyls had reacted. This complication made it necessary to use derivatives of the two alkaloids in which the tertiary hydroxyls were no longer present. Such derivatives are accessible via the pinacolic rearrangement which these alkaloids undergo readily (8, 9). Oxo-1-epidelcosine was, therefore, heated with acetic acid containing sulphuric acid according to the method described earlier (8, 9), and thus converted to the pinacone, anhydro-oxo-1-epidelcosine (IX, R = R′ = H), which was methylated to O,O-dimethyl-anhydro-oxo-1-epidelcosine (IX, R = R′ = CH_3), $C_{26}H_{39}O_7N$, m.p. 178–180°, $[\alpha]_D^{22}$ −56.3°, showing in the ultraviolet a maximum at 303 and a minimum at 263 mμ. In the infrared it showed no absorption in the hydroxyl region, but produced a band at 1727 cm^{-1} due to a six-membered cyclic ketone and a band at 1648 cm^{-1} attributable to the lactam carbonyl.

IX

By acid-catalyzed pinacolic rearrangement, oxolycoctonine (previously designated lycoctonam) was converted to anhydro-oxolycoctonine (9), which was methylated to O-methyl-anhydro-oxolycoctonine, $C_{26}H_{39}O_7N$, m.p. 126–128°, $[\alpha]_D^{25}$ +9.2°. In the ultraviolet it showed a maximum at 302 and a minimum at 267 mμ while in the infrared the spectrum contained bands at 1725 and 1642 cm^{-1}. The melting point and optical rotation of this compound are quite different from those of IX (R = R′ = CH_3), and, also, both compounds contain the same functional groups as shown by both the ultraviolet and infrared spectra; the fingerprint region of their I.R. spectra showed marked differences.

It has been shown by X-ray crystallography that the methoxyl at C-6 in lycoctonine is equatorial whereas in aconitine the methoxyl in the same position is axial (5). The non-identity of the two pinacones (IX (R = R′ = CH_3) and O-methyl-anhydro-oxolycoctonine) could be due to a similar difference between lycoctonine and delcosine. Since in the two pinacones the methoxyl at C-6 is vicinal, or α, to the carbonyl, it is removable by the action of sodium amalgam (10, 11). Both O,O-dimethyl-anhydro-oxoepidelcosine and O-methyl-anhydro-oxolycoctonine were, therefore, dissolved in absolute ethanol and demethoxylated at C-6 by treatment with sodium amalgam. O,O-Dimethyl-6-desmethoxy-anhydro-oxoepidelcosine thus produced, m.p. 152.5–154°, $[\alpha]_D^{25}$ −35.2°, showed a maximum at 282 mμ and a minimum at 262 mμ in the ultraviolet. Its infrared spectrum contained an absorption band at 1715 cm^{-1} due to the six-membered cyclic ketone and one at 1645 cm^{-1} due to the lactam carbonyl. The O-methyl-6-desmethoxy-anhydro-oxolycoctonine, m.p. 161–163°, $[\alpha]_D^{26}$ +3.4°, showed in the ultraviolet a maximum

at 282 mμ and a minimum at 262 mμ; and in the infrared, a band at 1716 cm^{-1} and one at 1638 cm^{-1}. The two desmethoxy compounds are not identical, but the fingerprint region of their infrared spectra are much more closely alike than the spectra of the preceding pair of compounds in the same region, which may indicate that the C-6 methoxyl in delcosine is axial.

The demethoxylating action of sodium amalgam establishes the location of the methoxyl at C-6. The presence of the two tertiary hydroxyls at C_7 and C_8 is firmly established by the formation of secodiketones from anhydrohydroxydelcosine (5), from oxodelcosine (3), and from the related oxodelsoline (6). The presence of a methoxyl at C-19 is indicated by the elimination of methanol and the formation of $\alpha\beta$-unsaturated ketones from the secodiketones derived from anhydrohydroxydelcosine (5) and oxodelsoline (6). It has not been established, however, whether the stereochemistry at C-19 is the same as in lycoctonine. None of the many oxidation reactions of delcosine that have been studied has yielded an acid product, thus indicating the absence of a primary alcoholic group. Since, however, according to the N.M.R. spectrum, no methyl group attached to carbon is present besides that of the N-ethyl group, it becomes highly probable that the third methoxyl in the molecule is present in a methoxy-methyl group at C-17. Delcosine contains a secondary hydroxyl attached to a five-membered ring (1, 3). This hydroxyl has been located at C-10 by analogy with lycoctonine, which contains a methoxyl at that position, but besides the fact that it must be a substituent on ring D, there is no proof of its exact location. It could be at C-10 and have a configuration different from that of the C-10 methoxyl in lycoctonine, or it could be at C-12. Although the derivatives of delcosine and lycoctonine that have been compared did not prove to be identical, it still remains that the chemical reactions of delcosine and its transformations all point to the alkaloid possessing the same carbon–nitrogen skeleton as lycoctonine. It is hoped, with work presently underway, to locate the position of the secondary hydroxyl on ring D, and to complete the correlation of delcosine with lycoctonine.

EXPERIMENTAL

Ultraviolet spectra were determined in 95% ethanol and recorded with a Beckman DU instrument. The infrared absorption spectra were recorded with a Perkin–Elmer double-beam model 21 spectrophotometer, and unless it is otherwise mentioned, the samples were suspended in nujol. Melting points were determined on a Kofler hot stage and were uncorrected. Optical rotations were determined in a dm microbore tube and, unless otherwise stated, in chloroform solution. The neutral alumina used for chromatography was standardized according to Brockmann, and the eluants were collected in fractions of 20 ml.

Δ′-Anhydrodelsoline

To a solution of delsoline (220 mg) in dried, chilled pyridine (5.5 ml), *p*-toluenesulphonyl chloride (440 mg) dissolved in pyridine (5.5 ml) was added, and the mixture allowed to stand at room temperature for 54 hours. It was then concentrated under reduced pressure at room temperature to a syrup which was dissolved in chloroform and extracted with 4% aqueous sodium carbonate. The chloroform solution was dried and evaporated to dryness. The residue was triturated in ether, and the ether-soluble fraction (176 mg) was crystallized from hexane, yield 84 mg, m.p. 135–140°. It was dissolved in benzene and chromatographed on alumina (activity II to III, 1.4 g). Elution with chloroform gave a product which, after crystallization from hexane, melted at 139–141°. For analysis

For personal use only.

this sample was sublimed at 145° at 5×10^{-4} mm. $[\alpha]_D^{24}$ +27.7±0.7° (*c*, 1.37). Found: C, 66.62; H, 8.81. Calc. for $C_{25}H_{39}O_6N$: C, 66.79; H, 8.75%. Ultraviolet: end absorption. IR: 3470 and 3390 cm^{-1} (hydroxyl).

Hydrogenation of 1-Dehydro-oxodelcosine

1-Dehydro-oxodelcosine (35 mg obtained by oxidation of monoacetyldelcosine, followed by hydrolysis (3)) in glacial acetic acid (5 ml) was hydrogenated over Adams' catalyst (17 mg) for 1 hour at 3.9 atm. The catalyst was filtered off and the filtrate evaporated to dryness; the residue was dissolved in chloroform and the solution extracted with 4% aqueous sodium carbonate; the chloroform layer was evaporated to dryness and the residue (35 mg) was crystallized from ether from which it separated as colorless prisms, 31 mg, m.p. 241–243.5° undepressed on admixture with authentic oxodelcosine. $[\alpha]_D^{24}$ +42.2±1.1° (*c*, 0.9). The infrared spectrum of the product and that of oxodelcosine were superimposable.

Oxidation of N-Desethyldelcosine

(a) N-Desethyl-didehydrodelcosine-azomethine (V).—To freshly distilled pyridine (10 ml) cooled to 0°, chromic anhydride (1.0 g) was added portionwise with stirring. To the precipitated yellow complex a solution of N-desethyldelcosine (1) (500 mg) in pyridine (18 ml) was added and the mixture allowed to stand at room temperature for 12 hours in a stoppered flask. Subsequently sulphur dioxide was bubbled into the reaction mixture and the solvent evaporated under diminished pressure. Ice and 3 *N* sulphuric acid were added to the residue, and the resulting green solution was extracted with chloroform. The chloroform extract containing the neutral component was set aside. The aqueous acid layer was neutralized by the gradual addition of powdered sodium carbonate and made alkaline by the further addition of 10% aqueous sodium hydroxide. It was then extracted with chloroform, the extract washed with water, dried, and evaporated to dryness. The residue (270 mg) was redissolved in dry, pure, chloroform, chromatographed on alumina grade III (6.0 g), and eluted with chloroform. The eluate, on evaporation, yielded 248 mg of the azomethine which was crystallized twice from acetone–ether from which it separated as rhombohedral prisms, m.p. 219–220°, $[\alpha]_D^{25}$ +257.5±1.3° (*c*, 0.8). Found: C, 63.15; H, 6.81. Calc. for $C_{22}H_{29}O_7N$: C, 62.99; H, 6.97%. Ultraviolet: λ_{max} 269 mμ, log ε 2.105; λ_{max} 290 mμ, log ε 2.123; λ_{min} 281 mμ, log ε 2.098. Infrared: 3420 cm^{-1} (hydroxyl), 1745 cm^{-1} (five-membered cyclic ketone), 1702 cm^{-1} (six-membered cyclic ketone), 1633 cm^{-1} (—CH=N—); in chloroform: 3520, 3470, 1753, 1715, 1635 cm^{-1}.

(b) N-Desethyl-1,10-didehydro-oxodelcosine.—The chloroform solution containing the neutral fraction of the product (mentioned above) was washed with 4% aqueous sodium carbonate, dried, and evaporated to dryness. The residue (114 mg) was triturated with ether and the material recrystallized from acetone–hexane from which it separated as colorless prisms, m.p. 274–275.5°, $[\alpha]_D^{28}$ +139±0.9° (*c*, 1.12). Found: C, 60.63; H, 6.53. Calc. for $C_{22}H_{29}O_8N$: C, 60.68; H, 6.71%. Ultraviolet: λ_{max} 300 mμ, log ε 2.039; λ_{min} 262 mμ, log ε 1.312. Infrared: 3430 cm^{-1} (hydroxyl), 3350 cm^{-1} (imine), 1740 cm^{-1} (five-membered cyclic ketone), 1703 cm^{-1} (six-membered cyclic ketone), 1665 cm^{-1} (lactamic carbonyl); in chloroform: 3460, 3380 cm^{-1} (hydroxyl), 3280 cm^{-1} (imino group).

Ethiodide of N-Desethyl-1,10-didehydrodelcosine-azomethine (VI)

Desethyldidehydrodelcosine-azomethine (290 mg) was dissolved in acetone (30 ml), and ethyl iodide (6 ml) was added to the solution. The mixture was left at room temperature for 24 hours in the dark, after which it was evaporated to dryness under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

reduced pressure. The crystalline residue (414 mg) was recrystallized repeatedly from acetone–hexane from which it separated as pale-yellow microcrystals, m.p. 168–171°, $[\alpha]_D^{28}$ +132.4±1.0° (*c*, 1.02 in methanol). Found: C, 50.27; H, 6.13. Calc. for $C_{24}H_{34}O_7NI$: C, 50.09; H, 5.96%. Ultraviolet: shoulders at λ_{max} 258 mμ, log ε 2.918 and λ_{max} 350 mμ, log ε 1.851; λ_{max} 300 mμ, log ε 2.498; λ_{min} 292 mμ, log ε 2.484. Infrared: 3440, 3220 cm^{-1} (hydroxyls), 1755 cm^{-1} (five-membered cyclic ketone), 1713 cm^{-1} (six-membered cyclic carbonyl), 1652 cm^{-1} (—C=N$^+$).

10-Dehydro-oxo-1-epidelcosine (VII)

The ethiodide of desethyldidehydrodelcosine-azomethine (85 mg) was dissolved in 10% methanolic potassium hydroxide (5 ml), and the mixture was refluxed for 90 minutes and evaporated to dryness under reduced pressure. The residue was dissolved in water, and the solution extracted with chloroform. The chloroform extract was washed first with 3 *N* sulphuric acid, then with water, dried, and evaporated to dryness. The residue (62 mg), which failed to crystallize, was dissolved in chloroform, chromatographed on alumina (activity III), and eluted with chloroform. The product obtained from the eluate could not be induced to crystallize, $[\alpha]_D^{27}$ +10.4±0.8° (*c*, 1.25). Ultraviolet: λ_{max} 295 mμ, log ε 1.456; λ_{min} 265 mμ, log ε 0.736. Infrared in chloroform: 3575, 3500, 3420 cm^{-1} (hydroxyls), 1750 cm^{-1} (five-membered cyclic ketone), 1640 cm^{-1} (lactamic carbonyl).

Oxo-1-epidelcosine (VIII)

(a) Sodium borohydride (300 mg) was added to a solution of 10-dehydro-oxo-1-epidelcosine (230 mg) in 80% methanol (20 ml), and the mixture allowed to stand at room temperature for 2 hours and then evaporated to dryness. The residue was dissolved in water and the solution extracted with chloroform. The chloroform extract was washed with 3 *N* sulphuric acid, with water, dried, and evaporated to dryness. There was left a residue (208 mg) which crystallized from ether, wt. 161 mg, m.p. 124–126°. The crystalline product was dissolved in benzene, chromatographed on alumina (5.0 g, activity III), and eluted with chloroform. From the eluate there was obtained a fraction, m.p. 126–130°, which was recrystallized from acetone–hexane. The colorless hexagonal prisms thus obtained, after being dried at 100° at 5×10^{-4} mm, melted at 128–130°, $[\alpha]_D^{25}$ +19.8±0.9° (*c*, 1.16). Found: C, 61.39; H, 8.14. Calc. for $C_{24}H_{37}O_8N$: C, 61.65; H, 7.98%. Infrared in chloroform: 3640, 3570, 3490 cm^{-1} (hydroxyls), 1638, 1628 cm^{-1} (double peak due to lactam carbonyl).

(b) The above product was also obtained as follows. 10-Dehydro-oxo-1-epidelcosine (65 mg), dissolved in glacial acetic acid (6.5 ml), was shaken under hydrogen with Adams' catalyst (50 mg) at 3.9 atm for 1 hour. The catalyst was filtered off and the filtrate evaporated to a syrup which was dissolved in chloroform and washed with 4% aqueous sodium carbonate. The dried chloroform solution was evaporated to dryness and the residue (60 mg) crystallized from acetone–ether–hexane, m.p. 126–128°, undepressed by admixture with the sample of oxo-1-epidelcosine obtained above. The infrared spectra of both samples were superimposable.

Didehydro-oxodelcosine from Oxo-1-epidelcosine

To a solution of oxo-1-epidelcosine (69 mg) in glacial acetic acid (5 ml), a solution of sodium dichromate (35 mg) in glacial acetic acid (5 ml) was added dropwise, and the reaction mixture set aside for 1 hour at room temperature. Sulphur dioxide was bubbled in to reduce the excess reagent and the solvent removed under reduced pressure. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

residue was dissolved in chloroform and the solution washed first with 3 *N* sulphuric acid, then with 4% aqueous sodium carbonate, dried, and evaporated under reduced pressure. It left a residue (63 mg) which crystallized from ether. Recrystallization from acetone–ether–hexane yielded 44 mg, m.p. 208–209° undepressed by mixture with an authentic sample of didehydro-oxodelcosine, $[\alpha]_D^{25}$ +128.0±1.0° (*c*, 1.0). The infrared spectra of both samples were superimposable.

Epi-1-delcosine

To a solution of oxo-1-epidelcosine (50 mg) in pure dioxane (5 ml), powdered lithium aluminum hydride (60 mg) was added in small portions under a nitrogen atmosphere. The suspension was refluxed and stirred for 1 hour. The excess of reagent was decomposed with methanol, water was added, the precipitated aluminum hydroxide was filtered with suction and washed with acetone and with methanol. The combined filtrate and washings was evaporated to dryness under reduced pressure and the residue dissolved in chloroform. The chloroform solution was washed with several portions of 3 *N* sulphuric acid, the acid solution made basic with sodium hydroxide and extracted with chloroform. This last chloroform solution when evaporated to dryness left a residue (40 mg) which crystallized from water (2 drops). The product was recrystallized twice from benzene–hexane, from which it separated as colorless prisms, m.p. 177–178°, $[\alpha]_D^{26}$ +38.9±1.0° (*c*, 0.95). Found: C, 63.69; H, 8.66. Calc. for $C_{24}H_{39}O_7N$: C, 63.55; H, 8.67%. Infrared: 3590, 3504, 3410, 3364 cm^{-1} (hydroxyls).

1-Epidelcosine (30 mg) dissolved in methanol (2 ml) was made just acid to Congo red by the dropwise addition of perchloric acid. The solution was evaporated to dryness under reduced pressure and the crystalline residue recrystallized from methanol–ether from which it separated as colorless hexagonal prisms, m.p. 197–200°. After several recrystallizations the salt melted at 199–201° when immersed in a bath at 193°, $[\alpha]_D^{28}$ +26.8±1.8° (*c*, 0.56 in methanol). Found: C, 52.15; H, 7.40. Calc. for $C_{24}H_{39}O_7N.HClO_4$: C, 52.03; H, 7.27%.

Anhydro-oxo-1-epidelcosine (IX, R = R′ = H)

Oxo-1-epidelcosine (150 mg) in glacial acetic acid (5 ml, containing 0.1% by volume of sulphuric acid) was heated at 75–80° for 70 minutes. The warm solution was poured onto crushed ice, neutralized with ice-cold 20% aqueous potassium hydroxide, and extracted with chloroform. The chloroform layer was evaporated to dryness and the residue refluxed for 1 hour with 10% methanolic potassium hydroxide (10 ml) and water (1.0 ml). The solution was evaporated to dryness, and the residue dissolved in water and extracted with chloroform. The extract was washed with 3 *N* sulphuric acid, with water, dried, and evaporated to dryness under reduced pressure. The residue (144 mg) was dissolved in benzene containing 15% of chloroform and chromatographed on alumina, activity III (2.7 g). Chloroform was used to elute the column, and the eluate yielded the pinacone which crystallized from ether, m.p. 225–229°. Recrystallization from acetone–ether–hexane raised the melting point to 227–231°, wt. 86 mg. For analysis the product was recrystallized once more and obtained as colorless long needles, m.p. 230–232°, $[\alpha]_D^{23}$ −23.8±2° (*c*, 0.55). Found: C, 64.13; H, 7.80; OMe, 20.53. Calc. for $C_{24}H_{35}O_7N$: C, 64.12; H, 7.85; 3OMe, 20.71%. Ultraviolet: λ_{max} 302 mμ, log ε 1.810; λ_{min} 265 mμ, log ε 0.993. Infrared: 3360 cm^{-1} (hydroxyl), 1725 cm^{-1} (six-membered cyclic ketone), 1625 cm^{-1} (lactam carbonyl); in chloroform: 3578, 3440 cm^{-1} (hydroxyls), 1727 and 1642 cm^{-1} (carbonyls).

For personal use only.

O,O-Dimethyl-anhydro-oxo-1-epidelcosine (IX, R = R′ = CH_3)

The pinacone described above (93 mg) was dissolved in dioxane (9 ml) and a slight excess of sodium hydride was added to the solution, which was brought to a boil and, after the addition of excess methyl iodide, was refluxed, with stirring, in a hydrogen atmosphere for 10 hours. The reaction product was filtered through a Hyflo-Supercel column, the filtrate evaporated to dryness, and the residue dissolved in water and extracted with chloroform. The chloroform solution was washed with 3 *N* sulphuric acid, with water, dried, and evaporated to dryness. The residue (quantitative yield) was dissolved in benzene containing 20% hexane and chromatographed on alumina (2.9 g, activity III). Elution of the column was done first with benzene and then with a benzene–chloroform (3:1) mixture. Both eluates yielded the same product, which crystallized from ether, m.p. 177–180°, wt. 71.5 mg. A sample for analysis was recrystallized from ether, m.p. 178–180°, $[\alpha]_D^{22}$ −56.3±1.3° (*c*, 0.80), and sublimed at 145° at 5×10^{-4} mm. Found: C, 65.64; H, 8.40; OMe, 32.41. Calc. for $C_{26}H_{39}O_7N$: C, 65.39; H, 8.23; 5OMe, 32.49%. Ultraviolet: λ_{max} 303 mμ, log ε 1.897; λ_{min} 263 mμ, log ε 1.423. Infrared: 1727 cm^{-1} (six-membered cyclic ketone), 1648 cm^{-1} (lactam carbonyl).

O,O-Dimethyl-6-desmethoxy-anhydro-oxo-1-epidelcosine

Sodium amalgam (5%, 680 mg) was added to a solution of the methylated pinacone, O,O-Dimethyl-anhydro-oxo-1-epidelcosine (74 mg), in absolute ethanol (1.6 ml). The mixture was shaken for 90 minutes, filtered through a Hyflo-Supercel column, and the filtrate diluted with water and extracted with chloroform. Evaporation of the chloroform extract left a residue (67 mg) which was dissolved in benzene–hexane (1:1) and chromatographed on alumina (2.4 g, activity III). From benzene and benzene containing 30% chloroform eluates, there was isolated a middle fraction (36 mg) which crystallized from ether, m.p. 149–154°. Recrystallized from ether–pentane, the product consisted of colorless prisms, m.p. 152.5–154°, $[\alpha]_D^{25}$ −35.2±1.8° (*c*, 0.54). Found: C, 67.26; H, 8.29. Calc. for $C_{25}H_{37}O_6N$: C, 67.09; H, 8.33%. Ultraviolet: λ_{max} 282 mμ, log ε 1.744; λ_{min} 261 mμ, log ε 1.533. Infrared: 1715 cm^{-1} (six-membered cyclic ketone), 1645 cm^{-1} (lactam carbonyl).

O-Methyl-anhydro-oxolycoctonine

Anhydro-oxolycoctonine was prepared from acetyl-oxolycoctonine by acid-catalyzed rearrangement followed by hydrolysis as described above for the corresponding oxoepidelcosine derivative. The pinacone (155 mg) was dissolved in dioxane (9 ml) and excess sodium hydride was added to the solution which was brought to a boil and, after the addition of excess methyl iodide, was refluxed, with stirring, for 7 hours under a hydrogen atmosphere. The reaction mixture was filtered through a Hyflo-Supercel column and the product worked up exactly as described above for the corresponding delcosine derivative. The crude product was dissolved in benzene–hexane (4:1), chromatographed on alumina (4 g, activity III), and eluted (*a*) with benzene, (*b*) with benzene–chloroform (4:1), and (*c*) with benzene–chloroform (1:1). The first two eluates (*a* and *b*) together yielded a fraction (104 mg) which crystallized from ether and after recrystallization from the same solvent consisted of colorless needles, m.p. 126–128°, $[\alpha]_D^{25}$ +9.2±0.8° (*c*, 1.2). Found: C, 65.57; H, 8.09; OMe, 32.40. Calc. for $C_{26}H_{39}O_7N$: C, 63.59; H, 8.23; 5OMe, 32.49%. Ultraviolet: λ_{max} 302 mμ, log ε 1.856; λ_{min} 267 mμ, log ε 1.471. Infrared: 1725 cm^{-1} (six-membered cyclic ketone), 1642 cm^{-1} (lactam carbonyl).

The third eluate (*c*) from the chromatogram yielded a by-product (20 mg) which crystallized from ether, m.p. 185–201°, $[\alpha]_D^{26}$ +85.9±1.6° (*c*, 0.63). Infrared: 1728 cm^{-1} (six-membered cyclic ketone), 1650 cm^{-1} and 1643 cm^{-1} (lactam carbonyl).

O-Methyl-6-desmethoxy-anhydro-oxolycoctonine

Sodium amalgam (5%, 610 mg) was added to a solution of the above methylated oxolycoctonine pinacone (67 mg) in absolute ethanol (1.8 ml) and the mixture shaken for 2 hours. It was afterwards filtered through a Hyflo-Supercel column and the filtrate diluted with water and extracted with chloroform. The extract was evaporated and the residue (quantitative yield) crystallized from ether, wt. 52 mg, m.p. 159–163°. After recrystallization from ether it consisted of colorless needles, m.p. 161–163°, $[\alpha]_D^{26}$ $+3.4\pm1.1°$ (*c*, 0.89). Found: C, 67.26; H, 8.30; OMe, 27.60. Calc. for $C_{25}H_{37}O_6N$: C, 67.09; H, 8.33; 4OMe, 27.73%. Ultraviolet: λ_{max} 282 mμ, log ϵ 1.643; λ_{min} 262 mμ, log ϵ 1.410. Infrared: 1716 cm^{-1} (six-membered cyclic ketone), 1638 cm^{-1} (lactam carbonyl).

ACKNOWLEDGMENTS

The authors wish to express their indebtedness to Dr. R. Norman Jones and Mr. R. Lauzon of these laboratories for the determination of the infrared absorption spectra and to Mr. H. Seguin for the microanalyses.

THE KINETICS OF REACTION OF 2,2-DIPHENYL-1-PICRYLHYDRAZYL WITH PHENOLS[1]

J. S. Hogg, D. H. Lohmann, and K. E. Russell

ABSTRACT

The kinetics of reaction between 2,2-diphenyl-1-picrylhydrazyl (DPPH) and a wide variety of phenols have been studied. The rate of disappearance of DPPH is of first order with respect to both the DPPH and the reacting phenol. The rates of reaction can be roughly correlated with the Hammett σ value of the phenol substituent in the range $-0.4 < \sigma < 0.2$, a ρ value of -6 being obtained. *t*-Butyl groups in both ortho positions of the phenol give rise to steric hindrance, the reduction in rate being largely due to a reduction in the A factor. Hydrogen abstraction from the less reactive phenols is strongly retarded by the product, 2,2-diphenyl-1-picrylhydrazine.

The rate-determining step probably involves the abstraction of a hydrogen atom from the phenol by the DPPH to give diphenylpicrylhydrazine and a phenoxy radical. The retardation by diphenylpicrylhydrazine is readily explained if this primary step is reversible.

Hydrogen-abstraction reactions involving 2,2-diphenyl-1-picrylhydrazyl (DPPH) as the acceptor molecule are relatively easily studied and a number of recent publications have been concerned with the rates of reaction of this radical with hydrogen donors. Information has been obtained concerning the reactivities of restricted ranges of donors containing C—H (1), N—H (2, 3), O—H (4, 5, 6), and S—H (7, 8) bonds. Phenols are well suited to an investigation of hydrogen abstraction from O—H-containing compounds (3). A wide range of phenols is available and a detailed study of the effect of substituents is possible.

During the course of the work, a paper by McGowan, Powell, and Raw was published (4) giving rate constants for the second-order reactions of DPPH with a large number of phenols, showing that substituents may exert considerable polar and steric influences on the reaction. Their measurements were normally made at room temperature using carbon tetrachloride as solvent, but with three phenols, measurements were made over a temperature range. In the work described here benzene was used as solvent, activation energies and A factors were obtained for all the phenols studied, and the effect of the product 2,2-diphenyl-1-picrylhydrazine on the rate of reaction was determined. Some additional evidence was obtained that the primary reaction involves the hydrogen atom of the O—H group, and the stoichiometry of the process was investigated.

EXPERIMENTAL

Materials

2,2-Diphenyl-1-picrylhydrazine was prepared by the reaction of picryl chloride and 1,1-diphenylhydrazine (9, 10). DPPH was prepared by the oxidation of diphenylpicrylhydrazine with lead dioxide (9). Complexed solvent was removed by heating *in vacuo* at 60° for several hours.

2-Methylanisole and 1- and 2-methoxynaphthalene (Eastman Kodak) were used without further purification.

Phenols were obtained from the Aldrich Chemical Company or from the Eastman Kodak Company. The liquids were distilled and the solids were either sublimed at reduced pressure or recrystallized; 2,6-di-*t*-butylphenol was used without further purification.

Procedure

The experimental method has been described elsewhere (3). The rates of disappearance of DPPH were normally followed in the presence of air. With phenol, experiments were performed at various concentrations using degassed solutions and a comparison of rates was made at corresponding extents of reaction. Initial DPPH concentrations were in the range $4–20\times10^{-5}$ *M*. Phenol concentration ranges were chosen to give convenient rates of reaction; a minimum value of 2×10^{-5} *M* was used with the very reactive 2,4-dichloro-1-naphthol and a maximum value of 2×10^{-2} *M* with 4-acetylphenol. Measurements were normally performed at 30° C and activation energies were derived from measurements taken over a temperature range of at least 20 degrees.

The stoichiometry of the reaction was investigated by making up solutions containing ratios of DPPH to phenol between 2.5:1 and 1:1 and determining the optical densities of the solutions diluted 10-fold with benzene after appropriate times. If optical density is plotted against DPPH-to-phenol ratio, a break in the curve is observed which gives the stoichiometry applying under the particular experimental conditions. The break is sharp for the more reactive phenols; Fig. 1 shows the results obtained with 1-naphthol

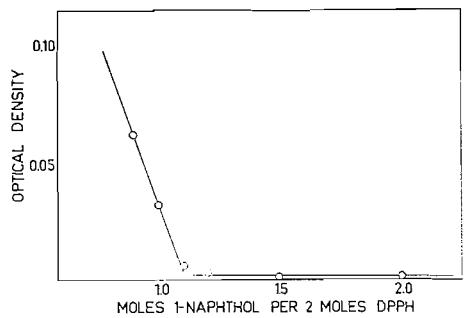

FIG. 1. Stoichiometry of the reaction of DPPH with 1-naphthol.

after 85 minutes at 50° C and an initial DPPH concentration of 2.5×10^{-3} *M*. With phenols whose reaction with DPPH is strongly retarded by diphenylpicrylhydrazine, the break in the curve is less sharp and the stoichiometric ratios are probably not known to better than 10% of their value.

Retardation by diphenylpicrylhydrazine was investigated by determining initial rates of reaction for solutions to which the hydrazine had been added at a concentration twice that of the initial DPPH concentration. With the very reactive phenols 4-methoxyphenol, 1-naphthol, and 2,4-dichloro-1-naphthol, the concentration of diphenylpicrylhydrazine was 8×10^{-5} *M* and with all other phenols it was 2×10^{-4} *M*.

The yield of diphenylpicrylhydrazine was determined for the reactions between DPPH and phenol and 1-naphthol. Reaction mixtures containing a slight excess of phenol were allowed to react until more than 99% of the DPPH had disappeared, and the products were separated on a column of alumina deactivated by the addition of 4% water. The diphenylpicrylhydrazine, identified by melting point and mixed melting point, was obtained in greater than 80% yield when phenol was the donor and in a yield of 90% to 95% when 1-naphthol was the donor.

Infrared spectra of mixtures obtained by the reaction of DPPH with various phenols in chloroform solution were examined. The high yields of diphenylpicrylhydrazine were confirmed but little information was obtained concerning the structures of the other products.

RESULTS AND DISCUSSION

Diphenylpicrylhydrazine (DPPH—H) is a major product of the reaction of DPPH with phenols, confirming that the main reaction is a hydrogen-abstraction process. The very low rates of reaction observed with the methylated phenols 1-methoxynaphthalene, 2-methoxynaphthalene, and 2-methylanisole indicate that the hydrogen of the O—H is attacked in the rate-determining step.

$$\text{DPPH} + \text{XOH} \rightarrow \text{DPPH—H} + \text{XO}\cdot \qquad [1]$$

The change in substituent from O—H to O—Me might affect the rate of hydrogen abstraction from C—H but relative rates greater than a thousand would not be expected. Further support is given by the observation that pentachlorophenol, which contains no C—H bonds, reacts with DPPH to give diphenylpicrylhydrazine as a major product, and the rate of reaction is approximately that predicted from reactions involving monochlorophenols. In addition, Bickel and Kooyman (6) observed a deuterium isotope effect in the second-order reaction of DPPH with 4-methyl-2,6-di-*t*-butylphenol and concluded that the rate-determining step involved the simple attack of DPPH on the O—H group. It is probable that a similar conclusion applies in the reactions of DPPH with all phenols.

In this study the rates of disappearance of DPPH were usually found to be of first order with respect to both the DPPH and the phenol. The only exceptions were the reactions involving phenol, pentachlorophenol, and 2,6-di-*t*-butylphenol where the order was slightly less than one with respect to the phenol. The reactions were normally studied in the presence of air and it is possible that oxygen has some effect on the rate of reaction and on the nature of the products. The effect on the rate of reaction of DPPH with phenol is small, for when degassed solutions are used a reduction in rate of a few per cent is observed.

The kinetic results are summarized in Table I. The rate constants (k) for the hydrogen-abstraction process of reaction [1] have been calculated from the observed initial rates of disappearance of DPPH at 30° C and the stoichiometry of the reaction. The activation energies (E) are probably correct to better than ± 1.0 kcal/mole with phenols which have very high rate constants or which undergo reactions which are strongly retarded by diphenylpicrylhydrazine; with other phenols the activation energies are probably correct to ± 0.5 kcal/mole. The uncertainty in the A factors is determined largely by the uncertainty in the corresponding activation energy.

The rate constant for hydrogen abstraction varies considerably with the nature of the substituent. 4-Methoxyphenol, for example, gives a rate constant some 20,000 times that given by 4-nitrophenol. In Fig. 2 values of $\log_{10}(k/k_0)$, where k is the second-order rate constant for the substituted phenol and k_0 is the rate constant for phenol at 30° C, are plotted against the Hammett σ value (11). For σ values less than 0.2 the relationship

$$\log_{10}(k/k_0) = -6$$

is very roughly obeyed but for values of σ greater than 0.2 the slope is much lower. The high negative value of the slope in the range $-0.4 < \sigma < 0.2$ has been compared with the smaller slopes of -3.7 for hydrogen-abstraction reactions involving phenols and alkylperoxy radicals (12) and of -2.5 for phenols and polystyryl radicals and is interpreted as evidence for the great importance of polar factors in the free-radical reactions between DPPH and phenols (5). However, the referee has pointed out that recent discussions of substituent effects (13, 14) indicate that the substituents from which the

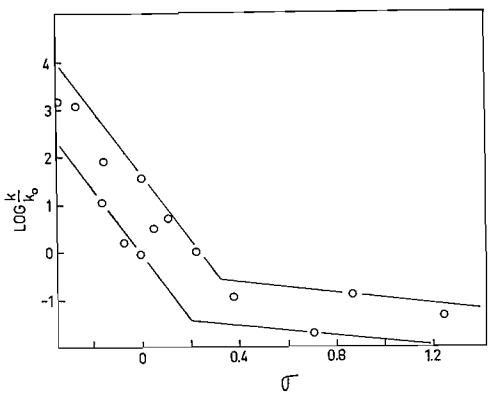

FIG. 2. Variation of rate constant with Hammett σ value of phenol substituent.

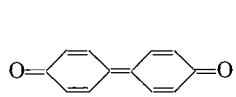
value of $\rho = -6$ is deduced are ones for which the unmodified Hammett equation is not valid. Taft (14) has shown that a meaningful measure of the inductive contribution of a substituent to the reactivity of a benzene derivative is the ρ_I value obtained from a Hammett σ plot using only selected meta substituents. The value of ρ_I for the DPPH–phenol reaction obtained from rate constants for phenol, *m*-chlorophenol, *m*-cresol, and *m*-nitrophenol is -2.1. Assuming that the inductive effect is the same for meta and para substituents, it is possible to estimate the resonance contributions of substituents to the reactivities of benzene derivatives. Taft defines a specific resonance parameter $\bar{\sigma}_R$ and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

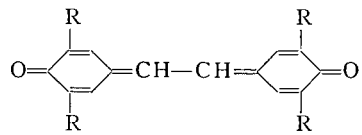
shows that deviations from the Hammett equation which result from a specific dependence of resonance effects on reaction type can usually be detected by deviation of the specific resonance parameter from its "normal" value. In the reaction of DPPH with phenols, considerably enhanced values of $\bar{\sigma}_R$ are observed for *p*-methoxy, *p*-methyl, and *p*-phenyl substituents. Both electrophilic and free-radical reactivities (14) give enhanced values of $\bar{\sigma}_R$ for these substituents and at this stage it is not possible to use $\bar{\sigma}_R$ values to place the DPPH–phenol reaction in one of these classes. More data for the present reaction, and for free-radical reactions generally, would be helpful, but the difficulty largely stems from our use of a highly polar free radical as a hydrogen acceptor. McGowan, Powell, and Raw (4) prefer an ionic mechanism for the DPPH–phenol reaction and suggest that the DPPH abstracts a hydride ion from the phenol. The main evidence for this suggestion is that the relative rates of hydrogen abstraction from phenols by DPPH are remarkably close to those for the solvolysis of dimethylbenzyl chlorides. We believe, however, that the rate-determining step of the reaction of DPPH with phenols is not significantly different from that generally put forward for the reaction of alkylperoxy radicals (12) and polystyryl radicals (5) with phenols and for the reaction of DPPH with hydroaromatic compounds (1), aromatic amines (4), and mercaptans (7).

The rate constants for the reaction of DPPH with phenols in carbon tetrachloride solution (4) are greater than those obtained using benzene as solvent under similar conditions; the ratio is of the order of three but varies with the phenol. The dielectric constant of the medium has been shown to be important in determining the rate of reaction of DPPH with mercaptans (8) but the similar values for carbon tetrachloride and benzene make it unlikely that the difference in rates can be accounted for in terms of dielectric constant alone. With mercaptans as hydrogen donors it was found that the reactions were approximately twice as fast in cyclohexane as in benzene (7) and it was suggested that the loose complex formed between benzene and DPPH could account for the slower reaction in benzene. This explanation may apply to the reaction of DPPH with phenols since carbon tetrachloride does not complex with DPPH to any great extent.



McGowan, Powell, and Raw have pointed out that alkyl substituents in the two ortho positions of the phenol can cause steric hindrance to the hydrogen-abstraction reaction (4). The effect is small for two methyl groups but the rate of reaction drops to approximately one hundredth of the expected rate when there are *t*-butyl groups in both ortho positions. The present work shows that the reduction in rate is caused largely by a reduction in the A factor rather than an increase in activation energy. The A factors are normally of the order of 10^9 cc/mole sec but higher values are usually observed in reactions of comparatively high activation energy and lower values in reactions of low activation energy. The expected values for the 2,6-disubstituted phenols would be of the order of 10^8 cc/mole sec and the lower values observed for 2,6-dimethylphenol and 2,6-diisopropylphenol may indicate that some steric hindrance is occurring in these cases. The value of 3.8×10^5 cc/mole sec observed for 2,6-di-*t*-butylphenol is much lower than the expected value and there is little doubt that steric hindrance is the main factor involved. Some caution must be exercised in arguments of this type as the A factor found for the reaction involving 2,6-di-*t*-butyl-4-methylphenol is considerably larger (3.2×10^6 cc/mole sec), yet it is not significantly different from that found for di-*t*-butylphenol because of the wide limits of experimental uncertainty.

The effect of the product 2,2-diphenyl-1-picrylhydrazine on the rate of reaction is shown in Table I. The values recorded are the ratios of the rate constants k_1/k where k



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

applies to the normal reaction and k_1 to the reaction retarded by the addition of diphenylpicrylhydrazine at a concentration twice that of the initial DPPH concentration. For the less reactive phenols the values of k_1/k are generally small and in these cases the accumulation of diphenylpicrylhydrazine as the product of a normal reaction will cause a considerable decrease in rate. It is clear that accurate kinetic analyses can only be made using initial rates of reaction where the concentration of retarding product is low. The retardation can be simply explained if reaction [1] is reversible; the rate of production of dehydrogenation products of the phenols is determined by the concentration of XO· radicals and any lowering of this concentration by a reversal of reaction [1] results in a decreased rate of production of dehydrogenation products and a decreased rate of disappearance of DPPH. The quantitative effect of the diphenylpicrylhydrazine on the rate of reaction depends on the reactivity of XO· towards diphenylpicrylhydrazine and also on the further reactions of XO· radicals with themselves, and with DPPH. In many cases these further reactions become rate controlling even at low concentrations of diphenylpicrylhydrazine, and detailed kinetic studies of the retarded reactions may be useful in distinguishing between the alternative secondary processes.

Some indication of the nature of the secondary reactions is given by the stoichiometric results; these are recorded in Table I as the number of moles of phenol reacting with 2 moles of DPPH. In most cases the ratio of DPPH to phenol consumed is approximately 2:1.1 and since the yields of diphenylpicrylhydrazine are high, an average of almost two hydrogen atoms is abstracted from each phenol molecule. The second hydrogen atom is probably in the ortho or para position because if these positions are blocked as in 2,4-dichloro-1-naphthol the DPPH-to-phenol ratio is closer to 1:1. Products of the type I and II are suggested by the stoichiometry and by previous work on the oxidation of

I

II

phenols (15, 16). The infrared spectra of the product mixtures do not show a strong absorption in the carbonyl stretching region, however, and there is no direct evidence for the formation of quinonoid compounds. With all phenols examined the OH stretching absorption of the reacting phenol decreases in intensity as the reaction proceeds, but in the case of 1-naphthol a new absorption at a frequency some 40 cm^{-1} below that of the 1-naphthol is observed in the products. It appears that the paths followed in the further reactions of the phenoxy radicals may vary with the phenol.

AN ALTERNATIVE SYNTHESIS OF 5-*O*-METHYL-L-ARABINOSE[1]

I. R. SIDDIQUI,[2] C. T. BISHOP, AND G. A. ADAMS

ABSTRACT

5-*O*-Methyl-L-arabinose has been synthesized by an unambiguous route in which *O*-benzyl groups were used to block positions 2 and 3 in the L-arabinose molecule. In addition to the usual indirect proofs of structure, a direct proof is described involving isolation of the product from periodate oxidation of the 5-*O*-methyl-L-arabinose. Two new derivatives, the phenylhydrazide and amide of 5-*O*-methyl-L-arabonic acid, were prepared.

The probable occurrence of 5-*O*-methyl-L-arabinose among the hydrolysis products of methylated wheat bran hemicellulose (1) prompted the synthesis of this compound by Dutton *et al.* (2). These authors used *O*-acetyl groups to block positions 2 and 3 in ethyl α-L-arabinofuranoside during methylation by Purdie's reagents and stated that "although sugar acetates may undergo acetyl migration even in the presence of such a weak base as silver oxide there was no indication of such migration in the preparation described here" (2). This result indicated that *O*-acetyl migrations, which are known to occur in the hexopyranoside series (3–6) and in D-glucose diethyl thioacetal tetracetate (7), may not happen in the pentofuranoside series.

Authentic samples of mono- and di-*O*-methyl ethers of L-arabinose were required in connection with another problem (8) and were obtained from various laboratories. Examination of the methyl glycosides of these compounds by gas–liquid partition chromatography (9, 10) revealed that all of the samples that were syrups contained more than one component. These samples had been obtained by chromatography on cellulose and the results showed that pure methyl ethers of arabinose may be difficult to isolate by that method.

Because of the unexpected absence of *O*-acetyl migration in the synthesis of Dutton *et al.* (2), the apparent difficulties in purification of these compounds by cellulose chromatography, and the urgent need for an authentic sample of this important reference sugar, an alternative synthesis of 5-*O*-methyl-L-arabinose seemed desirable. The present paper reports such a synthesis together with a proof of structure and two new derivatives of this sugar, namely the phenylhydrazide and the amide of 5-*O*-methyl-L-arabonic acid.

The route followed in this synthesis was similar to that used by Dutton *et al.* (2) except that *O*-benzyl rather than *O*-acetyl groups were used to block positions 2 and 3 in the L-arabinose molecule. The sequence of reactions was as follows. Ethyl α-L-arabinofuranoside was tritylated and the product was benzylated to yield ethyl 2,3-di-*O*-benzyl-5-*O*-trityl-α-L-arabinoside. This compound was successively detritylated, methylated, debenzylated, and hydrolyzed to yield 5-*O*-methyl-L-arabinose. Purities of the compounds obtained in each step of the synthesis were checked by analysis and, where possible, by gas–liquid partition chromatography and paper chromatography.

Confirmation that the syrupy mono-*O*-methyl-L-arabinose from the above synthesis was 5-*O*-methyl-L-arabinose was obtained from the following evidence. Complete methylation of the methyl glycosides, prepared by refluxing the mono-*O*-methyl-L-arabinose in methanolic hydrogen chloride, yielded methyl 2,3,5-tri-*O*-methyl α- and β-L-arabinosides,

[1]*Manuscript received February 23, 1961.*

[2]*N.R.C. Postdoctorate Fellow, 1958–1960.*

readily distinguished from the methyl glycosides of 2,3,4-tri-*O*-methyl-L-arabinose by gas–liquid partition chromatography (8). Oxidation of the mono-*O*-methyl-L-arabinose by bromide yielded a lactone that crystallized from the chloroform extract of the reaction mixture. This lactone showed a very slow change in rotation in aqueous solution and had carbonyl absorption at 1773 cm^{-1} in the C=O stretching frequency of its infrared spectrum. Barker *et al.* (11) have shown that γ-lactones of aldonic acids have their carbonyl absorption bands in the range 1765–1790 cm^{-1} while those of δ-lactones are between 1726 and 1760 cm^{-1}. This was confirmed here by observation of the infrared spectra of the following lactones, which showed carbonyl absorption as indicated: D-gluconic acid δ-lactone (1720 cm^{-1}); 2,5-di-*O*-methyl-L-arabonic acid-γ-lactone (1777 cm^{-1}); and 3,5-di-*O*-methyl-D-galactonic acid-γ-lactone (12) (1786 cm^{-1}). The results of methylation and the isolation of the γ-lactone showed that the parent mono-*O*-methyl-L-arabinose was capable of existing in the furanose form and therefore that the *O*-methyl group could not be located at C_4.

The mono-*O*-methyl-L-arabonic acid-γ-lactone provided a crystalline phenylhydrazide and a crystalline amide on reaction with phenylhydrazine and ammonia respectively. The amide gave a positive Weerman (13) reaction showing the presence of a free hydroxyl at C_2. This conclusion was supported by isolation of an osazone from the mono-*O*-methyl-L-arabinose without loss of methoxyl and by the large M_G value of the parent sugar on paper electrophoresis in borate buffer (14).

On oxidation by periodate the methyl glycosides of the mono-*O*-methyl-L-arabinose consumed one molar proportion of oxidant and released neither formic acid nor formaldehyde. This result could not have been obtained from methyl 3-*O*-methyl-L-arabinoside, which would not be oxidized in either the furanoside or pyranoside form, and showed that C_3 in the mono-*O*-methyl-L-arabinose must carry a free hydroxyl.

The foregoing evidence showed that free hydroxyls existed on C_2, C_3, and C_4 of the mono-*O*-methyl-L-arabinose and constituted indirect proof that the *O*-methyl group was located on C_5. On periodate oxidation the mono-*O*-methyl-L-arabinose yielded methoxyacetaldehyde, isolated by azeotropic distillation with water and identified as its *p*-nitrophenylhydrazone (15, 16). The isolation of this product, which could have arisen only from the 5-*O*-methyl isomer, constituted a direct proof of structure.

The physical constants of the 5-*O*-methyl-L-arabinose, 5-*O*-methyl-L-arabonolactone, and 5-*O*-methyl arabinosazone isolated in the present study are in reasonable agreement with the values reported for these derivatives by Dutton *et al.* (2) except for the specific rotations of the free sugar and of its osazone. Although certain partially methylated reducing sugars are known to give anomalous results when oxidized by periodate (17, 18), Dutton *et al.* (2) have shown that 5-*O*-methyl-L-arabinose behaves normally under these conditions, a conclusion supported by the present work.

EXPERIMENTAL

Paper chromatograms were run by the descending method on Whatman No. 1 paper using the organic phase of butanone saturated with water containing 2% of concentrated ammonium hydroxide. Paper electrophoresis was done on Whatman 3MM paper at 700–800 v for 2 hours using 0.2 *M* borate buffer, pH 10. Sugars were detected on the papers by the *p*-anisidine hydrochloride spray reagent (19). Infrared spectra were measured in the frequency range 3800–699 cm^{-1} either on chloroform solutions or by the Nujol mull technique. Gas–liquid partition ch romatograms were done on a Pye Argon

Chromatograph using straight, 4-ft columns with the following packings:

(*a*) butanediol succinate polyester on Chromosorb W, 60–80 mesh (1:9 w/w),

(*b*) polyphenyl ether, *m*-bis(*m*-phenoxyphenoxy)-benzene, on Celite 545, 80–100 mesh (1:6 w/w).

Flow rates and temperatures were as cited for individual analyses. Evaporations were carried out at 35° C under diminished pressure unless otherwise stated and melting points are corrected.

Ethyl 5-O-Trityl-α-L-arabinoside

Ethyl α-L-arabinofuranoside (10.8 g, m.p. 48–49° C, $[\alpha]_D^{26}$ −117°±1.5° (*c*, 1.7% in water) (20)) was dissolved in dry pyridine (100 ml) and triphenylchloromethane (16.85 g) was added. After the solution had been kept at room temperature (25–26° C) for 41 hours isolation of the product (21) yielded ethyl 5-*O*-trityl-α-L-arabinoside as a syrup (yield 25.0 g or 98%), $[\alpha]_D^{22}$ −51.4° (*c*, 3.1% in methanol). Anal: Calc. for $C_{26}H_{28}O_5$: trityl, 59.8%; C, 74.26%; H, 6.71%. Found: trityl (22), 59.67%; C, 74.99%; H, 6.92%.

Ethyl 2,3-Di-O-benzyl-5-O-trityl-α-L-arabinoside

Ethyl 5-*O*-trityl-α-L-arabinoside (23 g) was benzylated according to the procedure of Dennison and McGilvray (23). The syrupy product showed very weak hydroxyl absorption in its infrared spectrum but the high yield (35.0 g, 106%) indicated incomplete removal of benzyl chloride or benzyl alcohol from the reaction mixture. $[\alpha]_D^{22}$ −40.5° ±1° (*c*, 1.7% in chloroform). Anal: Calc. for $C_{40}H_{40}O_5$: C, 80.0%; H, 6.71%. Found: C, 81.1%; H, 6.71%.

Ethyl 2,3-Di-O-benzyl-α-L-arabinofuranoside

Ethyl 2,3-di-*O*-benzyl-5-*O*-trityl-α-L-arabinoside (34.8 g) was dissolved in dry chloroform (100 ml) and the solution was saturated at 0° C with dry hydrogen chloride. After 1 hour, the solution was neutralized with silver carbonate, silver salts were filtered, and the filtrate was evaporated to a syrup. A methanolic solution of this syrup yielded crystals of triphenylcarbinol when kept at 0° C. The crystals (4.0 g) were removed and the filtrate was evaporated to dryness. The residue, slurried in petroleum ether (65–110° C), was added to a column of alumina (3.5×28 cm) which was then eluted with petroleum ether (700 ml) to remove triphenylmethane (10 g, m.p. 93° C). Elution of the column with methanol (500 ml) and evaporation of the eluate then yielded the syrupy product (14.66 g, 74.5%), $[\alpha]_D^{24}$ −28.5°±0.5° (*c*, 2.4% in chloroform). Anal: Calc. for $C_{21}H_{26}O_5$: C, 70.37%; H, 7.31%. Found: C, 70.53%; H, 7.10%.

Ethyl 2,3-Di-O-benzyl-5-O-methyl-α-L-arabinoside

Ethyl 2,3-di-*O*-benzyl-α-L-arabinofuranoside (14 g) was methylated with methyl iodide (125 ml) and silver oxide (19 g). Filtration and evaporation of the filtrate yielded a product which still had hydroxyl absorption in its infrared spectrum. One more methylation yielded a product (14.1 g, 96%) with no hydroxyl absorption in the infrared and having $[\alpha]_D^{24}$ −22.3°±0.5° (*c*, 2.0% in chloroform). Anal: Calc. for $C_{22}H_{28}O_5$: C, 70.94%; H, 7.58%. Found: C, 71.58%; H, 7.08%.

Ethyl 5-O-Methyl-α-L-arabinoside

Ethyl 2,3-di-*O*-benzyl-5-*O*-methyl-α-L-arabinoside (13.0 g) was debenzylated by reduction with sodium in alcohol (24) to yield a syrupy product (4.66 g, 78.5%). Analysis of this product by gas–liquid partition chromatography, column A, 170° C, 300 ml argon/min, showed the presence of one major component (68.9%) and four minor

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

components. The minor components were undoubtedly partially benzylated products that were soluble in water. Because of this evidence of a mixture, no analyses or measurement of specific rotation were done.

Hydrolysis of Ethyl 5-O-Methyl-α-L-arabinoside

The syrupy glycoside obtained above (2.5 g) was heated with 0.05 *N* sulphuric acid (50 ml) at 100° C and the hydrolysis was followed by gas–liquid partition chromatography using the conditions just described for examination of the products from debenzylation. The glycosides gradually disappeared and none could be detected after 2 hours of hydrolysis. The hydrolyzate was neutralized with barium carbonate, filtered, and the filtrate was evaporated to dryness yielding a syrup (1.9 g, 91.2%). Paper chromatography of this material showed the presence of a major component of R_G 0.39 and minor components of R_G values 1.1, 1.0, 0.77, 0.22, and 0.12 (R_G = movement relative to 2,3,4,6-tetra-*O*-methyl-D-glucose).

Isolation of 5-O-Methyl-L-arabinose

The syrupy mixture from the hydrolysis (1.9 g) was resolved by chromatography on 22 sheets of Whatman No. 3MM paper (46×57 cm) and elution of the appropriate areas yielded the major component (R_G 0.39), which was recovered as a syrup (0.90 g, 47.4%). The yield was corrected for material lost on the guide strips used to locate the sugars.

Dutton *et al.* (2) reported $[\alpha]_D^{25}$ −32.0° (*c*, 0.484% in water) for 5-*O*-methyl-L-arabinose. The sugar isolated in the present work had $[\alpha]_D^{25}$ −25.3°±1.5° (*c*, 1.0% in water) and a methoxyl content of 18.7%; a mono-*O*-methyl pentose requires a methoxyl content of 18.9%. On paper chromatography and paper electrophoresis this sugar gave R_G, R_F, and M_G values of 0.39, 0.32, and 0.74 respectively. Gas–liquid partition chromatography of a methanolyzate of this compound on column B showed only two peaks, which corresponded to the anomeric glycosides of 5-*O*-methyl-L-arabinose. These results show that 5-*O*-methyl-L-arabinose is readily purified by chromatography on cellulose despite the apparent difficulties, referred to in the discussion, in obtaining pure samples of arabinose methyl ethers by that procedure.

Methylation of 5-O-Methyl-L-arabinose

The mono-*O*-methyl pentose (ca. 2 mg) was heated at 100° C in a sealed tube with 2% methanolic hydrogen chloride (1.0 ml) for 12 hours. Acid was neutralized with silver carbonate, and the filtrate from removal of silver salts was evaporated to a syrup which was shaken overnight with silver oxide (20 mg), methyl iodide (0.2 ml), and dimethyl formamide (0.2 ml) (25). The reaction mixture was examined by gas–liquid partition chromatography using column B, 200° C, 85 ml argon/min. Two components were found, in the methylation reaction, with retention volumes (V_R), which were made relative to methyl 2,3,5-tri-*O*-methyl-α-L-arabinoside, of 1.00 and 1.28 corresponding to the α- and β-methyl glycosides respectively of 2,3,5-tri-*O*-methyl-L-arabinose. Under the conditions used, the α- and β-methyl glycosides of 2,3,4-tri-*O*-methyl-L-arabinose ran as one component with V_R = 1.75 and none was found in the methylated product.

5-O-Methyl-L-arabonolactone

A mixture of 5-*O*-methyl-L-arabinose (300 mg), water (3 ml), barium carbonate (300 mg), and bromine (30 drops) was kept in the dark at room temperature for 70 hours. Bromine was removed by aeration and the aqueous solution was extracted continuously with chloroform for 5 days. The lactone crystallized from the chloroform solution and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

evaporation of the solution left more of the lactone as a crystalline residue. Recrystallization from ethanol – petroleum ether (30–60° C) yielded 5-*O*-methyl-L-arabonolactone (170 mg), m.p. 137–138° C; $[\alpha]_D^{25}$ $-79.1°\pm1° \rightarrow -71.3°\pm1°$, 6 days incomplete (*c*, 1.0% in water); ν_{max}^{Nujol} 1773 cm^{-1}. Reported (2) values are m.p. 135° C, $[\alpha]_D^{25}$ $-76.2°$ (*c*, 0.22% in water). Anal: Calc. for $C_6H_{10}O_5$: C, 44.44%; H, 6.22%; OCH_3, 19.3%. Found: C, 44.12%; H, 5.99%; OCH_3, 19.1%.

5-O-Methyl-L-arabonamide

5-*O*-Methyl-L-arabonolactone (50 mg) was dissolved in saturated methanolic ammonia and stored at 5° C for 20 hours. Evaporation of the solution and recrystallization from ethanol–ether yielded the amide, m.p. 141–143° C, $[\alpha]_D^{25}$ $+40.7°\pm2°$ (*c*, 0.8% in methanol). Anal: Calc. for $C_6H_{13}O_5N$: C, 40.22%; H, 7.31%; N, 7.82%. Found: C, 39.98%; H, 7.09%; N, 7.76%.

A portion of the amide (ca. 5 mg) was oxidized with sodium hypochlorite and on addition of semicarbazide hydrochloride (13) gave a white precipitate of hydrazodicarbonamide.

5-O-Methyl-L-arabonic Acid Phenylhydrazide

5-*O*-Methyl-L-arabonolactone (40 mg) was dissolved in methanol (3 ml), and freshly distilled phenylhydrazine (30 mg) was added. The solution was refluxed for 3 hours and then evaporated to a syrup which crystallized from ethanol–ether to give the phenylhydrazide, m.p. 176.5–178° C, $[\alpha]_D^{25}$ $+23.6°\pm3°$ (*c*, 0.38% in methanol). Anal: Calc. for $C_{12}H_{18}O_5N_2$: N, 10.37%. Found: N, 10.58%.

5-O-Methyl-L-arabinose Phenylosazone

A mixture of 5-*O*-methyl-L-arabinose (50 mg), 20% acetic acid (3 ml), sodium bisulphite (50 mg), and phenylhydrazine (0.5 ml) was heated for 1 hour at 80° C and was then left for 24 hours at room temperature. The yellow, crystalline precipitate (25 mg) was recrystallized from aqueous acetone to give 5-*O*-methyl-L-arabinose phenylosazone, m.p. 153–155° C, $[\alpha]_D^{25}$ $+3°\pm1°$ (*c*, 0.97% in methanol). Reported (2) values are m.p. 154.5° C, $[\alpha]_D^{25}$ $-16.6°$ (*c*, 0.4% in methanol). Anal: Calc. for $C_{18}H_{22}O_3N_4$: C, 63.14%; H, 6.48%; N, 16.4%; OCH_3, 9.05%. Found: C, 63.08%; H, 6.51%; N, 16.57%; OCH_3, 9.11%.

Periodate Oxidation of 5-O-Methyl-L-arabinose

5-*O*-Methyl-L-arabinose (90 mg) was dissolved in 0.10 *M* sodium metaperiodate (20 ml) and the solution was stored in the dark at room temperature for 24 hours. The solution was then distilled and to the distillate was added an aliquot (4 ml) of a solution of *p*-nitrophenylhydrazine (0.4 g) in water (25 ml) and concentrated hydrochloric acid (0.4 ml) (15). The dense yellow precipitate was filtered after 5 minutes and recrystallized from ethanol:water (2:3) to yield methoxyacetaldehyde-*p*-nitrophenylhydrazone, m.p. 114–116° C. Reported (15, 16) values are m.p. 116° C and 115–115.5° C. Anal: Calc. for $C_9H_{11}O_3N_3$: C, 51.67%; H, 5.30%; N, 20.09%. Found: C, 51.30%; H, 5.39%; N, 19.95%.

Periodate Oxidation of Methyl 5-O-Methyl-(α,β)-L-arabinoside

5-*O*-Methyl-L-arabinose (40 mg) was refluxed with 2% methanolic hydrogen chloride (3 ml) for 6 hours. The solution was neutralized with silver carbonate, filtered, and the filtrate was evaporated to a syrup. The syrup (33.7 mg) was oxidized in aqueous solution (25 ml) containing 0.3 *M* sodium metaperiodate (10 ml); a blank was run concurrently. The consumption of periodate, estimated by the arsenite method (26), was 0.96 mole

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

THE REACTION OF NITROGEN ATOMS WITH OXYGEN ATOMS IN THE ABSENCE OF OXYGEN MOLECULES[1]

C. MAVROYANNIS[2] AND C. A. WINKLER

ABSTRACT

The reaction has been studied in a fast-flow system by introducing nitric oxide in the gas stream with excess active nitrogen. The nitrogen atom consumption was determined by titrating active nitrogen with nitric oxide at different positions along the reaction tube. The rate constant is found to be $k_1 = 1.83\ (\pm 0.2) \times 10^{15}$ cc^2 mole^{-2} sec^{-1} at pressures of 3, 3.5, and 4 mm, and with an unheated reaction tube.

The homogeneous and surface decay of nitrogen atoms involved in the above system were studied using the nitric oxide titration method, and the rate constants were found to be $k_3 = 1.04 \pm 0.17 \times 10^{16}$ cc^2 mole^{-2} sec^{-1}, and $k_4 = 2.5 \pm 0.2$ sec^{-1} ($\gamma = 7.5 \pm 0.6 \times 10^{-5}$), respectively, over the range of pressures from 0.5 to 4 mm with an unheated reaction tube.

INTRODUCTION

The emission spectrum of the blue nitric oxide afterglow has been studied recently by Kaplan and his associates (1). From the sensitivity of its vibrational intensity distribution to the addition of helium, it has been postulated that the spectrum arises from the three-body recombination of a ground-state oxygen atom and a ground-state nitrogen atom, by way of some intermediate state, into the excited upper states of the beta, gamma, and infrared bands,

$$N(^4S) + O(^3P) + He \rightarrow NO\ (\text{intermediate}) + He \rightarrow NO(A^2\Sigma, B^2\Pi) + He.$$

The lifetime of the intermediate, relative to the duration of the collision, is not known. Kaufman and Kelso (2) have obtained support for the above mechanism.

In the present paper, the kinetic characteristics of the reaction between nitrogen atoms and oxygen atoms have been studied, using a fast-flowing system.

EXPERIMENTAL

Active nitrogen was produced by a microwave generator. A quartz tube of 12-mm i.d., and 10 cm long, was used as a discharge tube, and the reaction vessel consisted of a pyrex tube of 20-mm i.d., and 30 cm long. Nitrogen (>99.9% pure) was passed into the discharge tube through a liquid-air trap to remove water, while purified nitric oxide was passed into the reaction tube through small jets, located at four different points along the reaction tube.

Oxygen atoms were produced by addition of nitric oxide at the first jet, to an excess of active nitrogen, at pressures of 3, 3.5, and 4 mm and with an unheated reaction tube. The nitrogen atom consumption, after the first jet, was determined by titrating active nitrogen with nitric oxide (2, 3) at subsequent jet positions along the reaction tube.

The same procedure was used to study the homogeneous and surface decay of nitrogen atoms, that is, the disappearance of nitrogen atoms along the reaction tube was determined by titration with nitric oxide at the different jet positions.

RESULTS AND DISCUSSION

The following reactions may be involved:

$$N + O + M \xrightarrow{k_1} NO + M \quad [1]$$

$$NO + N \xrightarrow{k_2} N_2 + O \quad [2]$$

$$N + N + M \xrightarrow{k_3} N_2 + M \quad [3]$$

$$N + \text{wall} \xrightarrow{k_4} \tfrac{1}{2}N_2 + \text{wall} \quad [4]$$

$$O + O + M \xrightarrow{k_5} O_2 + M \quad [5]$$

$$O + \text{wall} \xrightarrow{k_6} \tfrac{1}{2}O_2 + \text{wall}. \quad [6]$$

The reaction

$$NO + O + M \rightarrow NO_2 + M \quad [7]$$

was not taken into account, since NO_2 would react rapidly with oxygen atoms to produce NO (4) and, moreover, reaction [2] is very fast (5) in comparison with reaction [7]. Since the system was free from O_2, except for small amounts formed by reactions [5] and [6], it was assumed that there would be negligible influence from the reactions

$$O + O_2 + M \rightarrow O_3 + M \quad [8]$$

$$O + O_3 \rightarrow 2O_2 \quad [9]$$

$$N + O_2 \rightarrow NO + O. \quad [10]$$

The disappearance of nitrogen atoms in reactions [1] to [4] is given by

$$\frac{-d(N)}{dt} = 2k_1(N)(O)(M) + k_3(N)^2(M) + k_4(N)$$

and

$$k_1 = k_5 \frac{\log \dfrac{(N)_{t_1}}{(N)_{t_2}} - \dfrac{k_4 \Delta t}{2.303} - \log\left[1 + \dfrac{k_3(M)(N)_{t_1}}{k_4}(1 - e^{-k_4 \Delta t})\right]}{\log\left[1 + \dfrac{2k_5(M)(O)_{t_1}}{k_6}(1 - e^{-k_6 \Delta t})\right]}.$$

The rate constant for reaction [5] was assumed to be $k_5 = 1.6 \times 10^{15}$ cc^2 mole^{-2} sec^{-1}, with $\gamma = 1.65 \times 10^{-5}$ (6) which, for the conditions used, corresponds to a value of $k_6 = 0.516$ sec^{-1}. Several values of k_3 and k_4 have been reported; the value of k_4 in particular presumably depends on the condition of the wall of the reaction vessel used. Reinvestigation of reactions [3] and [4], with the procedure described above, gave the results shown in Fig. 1, on the assumption that only homogeneous decay of nitrogen atoms occurred, i.e. that the rate constant, over the pressure range 0.5 to 4 mm, is given by

$$k_3 = \frac{1}{(M)\Delta t}\left[\frac{1}{(N)_{t_2}} - \frac{1}{(N)_{t_1}}\right]. \quad [11]$$

The data indicate that the value of k_3 decreases as the pressure is increased up to about 2.5 mm, then remains essentially constant with further increase of pressure. Hence, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

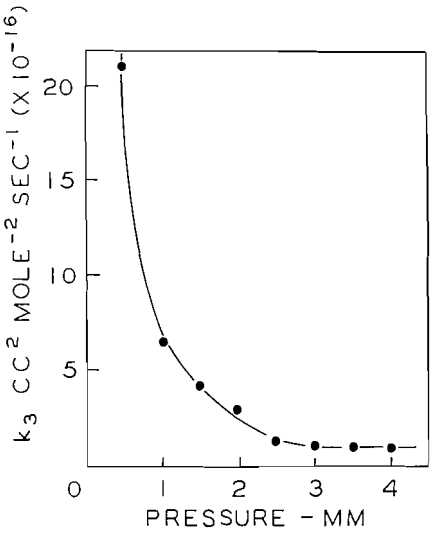

FIG. 1.

surface decay of nitrogen atoms is practically negligible at pressures above about 2.5 mm. A typical plot of $1/((N)_t(M))$ against reaction time at 2.5 mm pressure yields a straight line (Fig. 2).

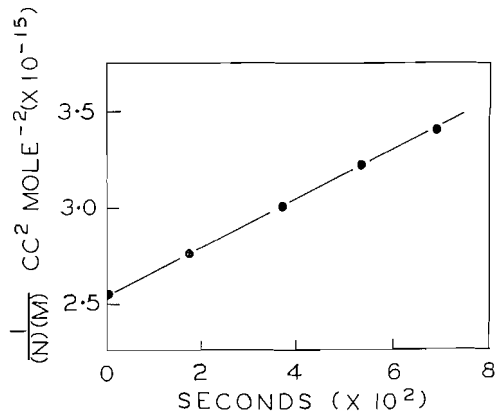

FIG. 2.

To separate the homogeneous and surface decay of nitrogen atoms, plots were made of ln (N) against time. Approximately straight lines were obtained, the slopes of which depended, of course, on (M). The average slopes of these lines are plotted against (M) in Fig. 3. For pressures of 2.5 mm and above, an extrapolation of the line passes through zero, indicating the small effect of the surface decay at these pressures. For pressures lower than 2.5 mm, an extrapolation gives an intersection corresponding to $k_4 = 2.5 \pm 0.2$ sec^{-1}. The recombination coefficient is given (7) by $\gamma = (2rk_4)/\bar{c}$, where r is the radius of the reaction vessel and $\bar{c}$ is the root mean square atomic velocity, and is found to be $\gamma = (7.5 \pm 0.6) \times 10^{-5}$. The value of γ, and that of k_3 (Table I), are in good agreement

with those of other investigators (8, 9, 10, 11) but not with those previously reported from this laboratory (12, 13).

Since the reaction of nitrogen atoms with oxygen atoms was studied at pressures of 3, 3.5, and 4 mm, the effect of reaction [4] is very small, and has been neglected. The integrated equation for k_1, with $k_4 = 0$, is given by

$$k_1 = k_5 \frac{\log \frac{(N)_{t_1}}{(N)_{t_2}} - \log\,(1+k_3(M)(N)_{t_1}\Delta t)}{\log\left[1+\frac{2k_5(M)(O)_{t_1}}{k_6}\,(1-e^{-k_6\Delta t})\right]}. \qquad [12]$$

The results are shown in Table II, with an average value of $k_1 = 1.83(\pm 0.2)\times 10^{15}$ cc^2 mole^{-2} sec^{-1}.

COMPARISON WITH THEORY

Using the hard sphere collision model, and assuming the reaction scheme to be

$$N + O \underset{k_{-1}'}{\overset{k_1'}{\rightleftarrows}} NO^*$$

$$NO^* + M \xrightarrow{k_2'} NO + M,$$

the stationary concentration of the binary complex NO* may be taken approximately as $(NO)^* = Z_{N.O}\tau_{NO}(N)(O)$, where $Z_{N.O}$ is the collision frequency of N and O, and τ_{NO} is the mean lifetime of the complex NO*.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The over-all rate is

$$\frac{d(\text{products})}{dt} = k_1(\text{N})(\text{O})(\text{M}) = k_2'(\text{M})(\text{NO}^*)$$
$$= k_2'(\text{M})(\text{N})(\text{O})Z_{\text{N.O}}\tau_{\text{NO}}$$

from which, by substituting $k_2' = PZ_{\text{NO}^*.\text{M}}e^{-E_2/RT}$, the experimental specific rate constant may be written as $k_{\text{exp}} = PZ_{\text{NO}^*.\text{M}}\tau_{\text{NO}}e^{-E_2/RT}$; τ_{NO} is the reciprocal of a unimolecular rate constant, and it should be about 10^{-13} sec, if we neglect activation energy. If there is any activation energy, it may be absorbed in the exponential term, thus, $Z_{\text{ter}} = Z_{\text{NO}^*.\text{M}}Z_{\text{N.O}}\tau_{\text{NO}}$. The collision frequencies can be calculated, assuming collision diameters of 3.5, 3.75, 2.95, and 1.8×10^{-8} cm for NO, (M) = N_2, N, and O respectively. For $T = 300°$ K, $Z_{\text{ter}} = 1.65\times10^{15}$ cc^2 mole^{-2} sec^{-1}.

The calculated value of Z_{ter} is in good agreement with that given experimentally by $k_1 = 1.83\ (\pm0.2)\times10^{15}$ cc^2 mole^{-2} sec^{-1}.

Wigner (14) has developed an expression which gives an upper limit for the rate of association reactions, by determining the probability of decrease of the relative energy of the two atoms below zero, under the influence of a third body. For the atomic reaction $A_1 + A_2 + A_3 \rightarrow A_1A_2 + A_3$ the rate constant is given by

$$k' = -2\pi\frac{g_{12}}{g_1g_2}\left(\frac{2\pi m_r}{kT}\right)^{1/2}\int_{V_0<0}V_0q_{12}\,[(a_{13}^2-a_{23}^2)(a_{13}/m_1-a_{23}/m_2) \qquad [13]$$
$$+2(a_{13}^2/m_1+a_{23}^2/m_2)q_{12}+(a_{13}/m_1+a_{23}/m_2)q_{12}^2]dq_{12}$$

where k' is the rate constant, k the Boltzmann constant; V_0 is the relative potential energy of the atoms A_1 and A_2 for infinite separation of A_3; m_r, m_1, m_2 are the reduced mass and the masses of A_1 and A_2; g_{12}, g_1, and g_2 are the statistical weight factors of A_1A_2, A_1, and A_2; q_{12} is the separation of the atoms A_1 and A_2; a_{13} and a_{23} are the sum of the collision radii of A_1A_3, and A_2A_3 respectively. The term $T^{-\frac{1}{2}}$ will cause a small fall-off in rate with increasing temperature.

For V_0, the Hulburt–Hirschfelder (15) potential energy curve was used, given by the equation

$$V(r) = 6.609[(1-e^{-x})^2+0.0678x^3(1+2.663x)e^{-2x}-1]\text{ ev},$$

where $x = 3.1579\ (r-r_e)/r_e$, $V(\infty) = 0$, and $r_e = 1.1508$ Å, which, according to Vanderslice (16), fits better than a Morse curve for the $X^2\Pi$ state of NO. The adopted radii were 0.89 (17), 1.49, and 1.875 Å (derived from viscocity data) for O, N, and N_2 respectively. The ratio of the statistical weights may be taken as

$$\frac{g_{\text{NO}}}{g_{\text{N}}g_{\text{O}}} = \frac{3.1}{4\times8.7},$$

taking into account the separation of the levels. The final result, for $T = 300°$ K, is $k' = 3.4\times10^{16}$ cc^2 mole^{-2} sec^{-1}. The agreement between the observed and calculated value might be taken as satisfactory, since equation [13] gives an upper limit for the reaction rate, when only atoms are involved.

HELMINTHOSPORAL, THE TOXIN FROM HELMINTHOSPORIUM SATIVUM

I. ISOLATION AND CHARACTERIZATION[1]

P. DE MAYO,[2] E. Y. SPENCER,[3] AND ROBERT W. WHITE[3]

ABSTRACT

The toxin produced by *Helminthosporium sativum* P.K. and B.[4] has been isolated in crystalline form. It has the formula $C_{15}H_{22}O_2$ and has been shown to contain one saturated aldehyde function, one α,β-unsaturated aldehyde, and two carbocyclic rings.

The significance of toxins as agents in plant pathology is now generally recognized, and these substances may be of considerable economic significance. *Helminthosporium sativum*[4] is a fungus which produces a seedling blight, foot and root rot, head blight, and leaf spot of cereals and grasses. The disease is widespread in North America and elsewhere and in particular affects wheat and barley crops. It has been estimated that the loss of the wheat crops in Western Canada caused by the action of this fungus has ranged from 3 to 13% during the past 25 years (2); an estimated loss of the order of $50,000,000.00.

Recently Ludwig (3) has demonstrated that the action of the fungus is dependent on the presence of a toxin produced by the fungus. Means were found for the artificial growth of the fungus, and the cell-free culture filtrates were able to produce many of the general symptoms characteristic of seedling blight, the degree of damage being related directly to the dosage. However, the combined action of spore suspensions, themselves reported innocuous (3), and culture filtrate resulted in the plants becoming diseased and the plants generally died. Ludwig concluded that the nonspecific toxin predisposed the plants to invasion of the organism.

For the preparation of the toxin on a large scale, the fungus was grown (see Experimental) in a 25-gal jacketed fermenter on sucrose–potato infusion. The culture filtrate was then stirred with charcoal upon which the active principle was absorbed. It was eluted with chloroform, and after filtration through alumina it was then distilled at low pressure. The distillate crystallized, and was purified by recrystallization.

The substance so obtained, helminthosporal, showed characteristic absorptions in the ultraviolet (λ_{max} 266 mμ) and infrared (ν_{max} 1715 and 1685 cm^{-1}). The original crude toxin concentrate before heat treatment either did not show these bands or (in certain batches where perhaps inadvertent heating had occurred) they were present but very weak, but, weight for weight, showed essentially the same biological activity. It would seem, therefore, that helminthosporal exists in the fungus as a precursor, from which it is formed by the fungus. This change can also be effected by heat, acid or base.

Helminthosporal analyzed in accordance with the empirical formula $C_{15}H_{22}O_2$. It is unstable to air, even at low temperature, and at room temperature takes up oxygen in a quantity equivalent to half an atom in 5 days. The presence of two bands in the carbonyl region of the infrared at 1715 and 1685 cm^{-1} suggested that these accounted for both oxygen atoms. This was supported indirectly by the absence of any bands in the infrared attributable to hydroxyl or ether groupings. It was demonstrated directly by the preparation of a bis oxime.

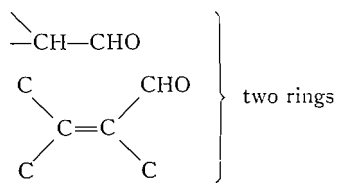
The ultraviolet absorption spectrum indicated the presence of conjugation of some sort. That this was due to conjugation of a double bond with one or both of the carbonyl functions and was not to be attributed to a diene system was shown by reduction of helminthosporal with lithium aluminum hydride to the glycol, the latter being characterized as the crystalline bis-3,5-dinitrobenzoate. The glycol showed no high-intensity absorption in the ultraviolet above 210 mμ.



A band in the infrared at 2720 cm^{-1} was suggestive of the presence of an aldehyde. That this was so was shown directly by oxidation of helminthosporal with alkaline silver oxide in good yield to the corresponding monoacid, further characterized as the acid oxime. The acid showed bands in the infrared at 1705 and 1670 cm^{-1}, indicating that the conjugated carbonyl had not been affected. This was confirmed by the fact that the ultraviolet absorption (λ_{max} 265 mμ) was also essentially unchanged.

Attempts at further oxidation, of the remaining carbonyl group, led to intractable material, and a decision between an (second) aldehyde and a ketone function was arrived at by two methods. First, although the presence of a carboxyl group obscured the 2750 cm^{-1} region and rendered the C—H aldehyde stretch undetectable, there was present in the near infrared a band at 4480 cm^{-1} characteristic of aldehydes and very strongly suggestive of a conjugated aldehyde (4).

Secondly, the proton resonance spectrum of helminthosporal (in CCl_4) showed a singlet equivalent to one hydrogen at $\tau = 0.1$ and a doublet, also equivalent to one hydrogen at $\tau = 0.5$ ($J \sim 4$ c.p.s.). In the corresponding monoacid the doublet was replaced by a singlet at $\tau = 1.48$ (carboxyl hydrogen), the singlet being unaffected. This provided strong evidence that the remaining carbonyl was aldehydic, and this was confirmed by the spectrum of the derived oxime in which the singlet at $\tau = 0.1$ had been replaced by a singlet at $\tau = 1.93$ in accord with expectance for the grouping —CH=N·OH (5).

Of the five double-bond equivalents indicated by the empirical formula of helminthosporal and its derivatives, three have been accounted for as two carbonyl groups and a double bond. The latter is required to be tetrasubstituted since no bands attributable to vinyl hydrogen appear in the N.M.R. spectrum of helminthosporal or any of its simple derivatives. This was confirmed by the fact that the bis-3,5-dinitrobenzoate already referred to reacted with one molecule of osmium tetroxide to give a tetraol bis-3,5-dinitrobenzoate which was recovered unchanged on attempted acetylation.

That no other tetrasubstituted double bond was present was shown as follows. Reduction of the aldehyde acid with sodium borohydride gave, directly, a lactone. This reacted with one molecule of osmium tetroxide to give a diol which was optically transparent in the ultraviolet above 200 mμ. It must therefore be concluded that helminthosporal contains two carbocyclic rings. This, together with the observation that the band at $\tau = 0.5$ in helminthosporal is a doublet, allow the functions of this substance to be expressed as in I.

I

The results of the further work in progress will be reported in due course.

EXPERIMENTAL

Infrared spectra and nuclear magnetic resonance spectra were determined in carbon tetrachloride solution, ultraviolet spectra in ethanol, and optical rotations in chloroform unless otherwise stated. Light petroleum refers to the fraction of b.p. 35–60°. Melting points were taken on the Köfler hot stage.

The N.M.R. spectra were determined in ca. 10% w/v solution with 1% tetramethylsilane using a Varian V-4302 spectrometer. The peak positions were determined using an audio oscillator calibrated with a Hewlett Packard 522-B frequency counter.

Isolation

The same strain of *H. sativum* as used earlier (3) was employed in the production of toxin for isolation and characterization studies. Inoculum for the fermenter tank was prepared by inoculating four 500-ml Erlenmeyer flasks, each containing 150 ml of medium (prepared from 100 ml infusion of 100 g potatoes and 10 g sucrose) with 5 ml of spore suspensions from agar slants of the fungus and incubating the cultures at 27° C on a shaker for 3 to 5 days. The inoculum was then transferred aseptically to 8 l. of sterilized medium similar to the above. The suspension was aerated at room temperature for 3 to $3\frac{1}{2}$ days. This was then used to inoculate 100 l. of a sterilized infusion from 5000 g potatoes and 1500 g sucrose in a 35-gal jacketed fermenter. Aeration with stirring was continued for $3\frac{1}{2}$ days followed by separation of the mycelium from the culture filtrate in a Tolhurst basket centrifuge. The filtrate was adjusted to pH 2 and activated charcoal (Nuchar C 145-A; 400 g) was added and stirred. The charcoal with the absorbed toxin was separated from the liquid in a Tolhurst centrifuge and suspended in ethanol (1500 ml). After filtering on a Buchner funnel the charcoal cake was suspended in chloroform (1200 ml), stirred, and filtered. This process was repeated three times. The chloroform extracts were combined and the solvent removed *in vacuo* to yield between 25 and 35 g of crude extract.

The oil (58 g) was heated under nitrogen at 120° for 12 hours. During this time small amounts of water, ethanol, and chloroform were lost, leaving a residue of 47 g which was dissolved in light petroleum (b.p. 60–80°, 150 ml) and applied to a column of alumina (Merck, acid-washed; 400 g). Elution with the same solvent (4 l.) gave a trace (100 mg) of oil. Elution with ether (8 l.) gave, after evaporation, a brown oil (38 g). Distillation of this oil (b.p. 115–120/0.015 mm) afforded a yellow oil (18 g) which slowly set. A portion was crystallized twice from light petroleum to give helminthosporal, m.p. 56–59°; $[\alpha]_D$ −49° (*c*, 1.18); λ_{max} 266 mμ (ϵ 11,000); ν_{max} 1715, 1685, and 1618 (C=C) cm^{-1}. Calc. for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46; C—Me (2), 12.83%; M.W. 234. Found: C, 76.72; H, 9.27; C—Me, 12.56%; M.W. (isopiestic, av.) 232, (Rast, av.) 247. Biological tests showed little difference in activity between the crude distillate and the recrystallized material.

The bis-*oxime* (hydroxylamine hydrochloride – pyridine at room temperature) had m.p. 177–182° (from aq. EtOH). Calc. for $C_{15}H_{24}O_2N_2$: C, 68.15; H, 9.15; N, 10.60%. Found: C, 68.0; H, 8.87; N, 10.69%.

Reduction of Helminthosporal with Lithium Aluminum Hydride

To lithium aluminum hydride (50 mg) in ether (50 ml) was added slowly with stirring a solution of the aldehyde (50 mg) in ether (100 ml) over 30 minutes. The mixture was refluxed for 30 minutes, after which the excess hydride was decomposed with ice water, and the product isolated in the usual way. The glycol was obtained as a colorless oil showing no high-intensity absorption in the ultraviolet above 210 mμ.

The glycol (40 mg) in pyridine (1 ml) containing 3,5-dinitrobenzoyl chloride (230 mg) was allowed to stand for 24 hours. Isolation of the neutral material with ether, followed by washing the ether with 0.5 *N* HCl, aqueous $NaHCO_3$ and water, successively, gave, after evaporation of the solvent, a yellow semisolid (78 mg). This was percolated in ethyl acetate solution through a short column of alumina, and the solvent evaporated. The product was crystallized from ethanol to give the bis-3,5-dinitrobenzoate (69 mg), m.p. 151–152.5°. Calc. for $C_{29}H_{30}O_{12}N_4$: C, 55.59; H, 4.83%. Found: C, 55.41, 55.66; H, 4.79, 4.72%.

The glycol diester (39 mg) in dioxan (3 ml) solution with osmium tetroxide (38.5 mg) was allowed to stand 5 days. Pyridine (1 ml) was then added and the mixture allowed to stand a further 5 days. Decomposition of the osmic ester with hydrogen sulphide, filtration, followed by concentration gave the tetraol diester as an amorphous powder. Calc. for $C_{29}H_{32}O_{14}N_4$: C, 52.73; H, 4.73%. Found: C, 52.68; H, 4.96%. Attempted acetylation (acetic anhydride – pyridine) gave back material, the infrared spectrum of which was superposable on that of the diester.

Oxidation with Silver Oxide

To the aldehyde (200 mg) in ethanol (8 ml) was added in one portion, a solution of silver nitrate (320 mg) in water (4 ml). The mixture was stirred while sodium hydroxide (113 mg) in water (2 ml) was added dropwise. After completion of the addition the stirring was continued for 2 hours.

After removal of the silver oxide by filtration the solution was diluted with water and neutral material removed by extraction with ether previously used to wash the silver oxide residue. The aqueous phase was then acidified with sulphuric acid (6 *N*; 5 ml) and the acidic material isolated with ether. Evaporation of the solvent gave a partly solidified oil (203 mg). This was chromatographed on silica gel (6 g). The material eluted with ether:benzene (1:19) was crystallized from light petroleum (b.p. 60–80°) to give the acid, m.p. 127–128°; λ_{max} 265 mμ (ϵ 7000); ν_{max} 1705, 1670 cm^{-1}; $[\alpha]_D$ −64° (*c*, 1.07). Calc. for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%. Found: C, 72.05; H, 8.98%.

The acid (50 mg) was converted into the oxime (hydroxylamine hydrochloride – pyridine). Crystallized from light petroleum (b.p. 60–80°) it had m.p. 142–143°. Calc. for $C_{15}H_{23}O_3N$: C, 67.89; H, 8.74; N, 5.28%. Found: C, 68.11; H, 8.63; N, 5.47%.

Reduction of the Aldehyde-Acid with Sodium Borohydride

To the monoacid (695 mg) in aqueous ethanol (50%; 200 ml) was added, in portions, sodium borohydride (1.0 g). The mixture was allowed to stand at room temperature with occasional swirling for 2 hours, after which it was acidified with H_2SO_4 (6 *N*), allowed to stand 30 minutes, diluted with water (500 ml), and extracted with ether. The ether extracts were then extracted with 5% sodium carbonate solution. This alkaline solution was then acidified with dilute H_2SO_4, allowed to stand 30 minutes, and again extracted with ether.

This process was repeated four times and the combined neutral material washed with water, dried, and evaporated to dryness. The product thus obtained (539 mg) was crystallized from light petroleum to yield the lactone (459 mg), m.p. 133.5–135°; ϵ_{200} 6000; ν_{max} 3080, 1780, 1615, 905 cm^{-1}; $[\alpha]_D$ +136° (*c*, 1.14). Calc. for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%. Found: C, 77.00; H, 9.46%. The compound showed bands at τ = 4.74 and 5.03 (doublets, $J \sim 5$ c.p.s.) (exomethylene group).

Ozonolysis in carbon tetrachloride solution at −15° gave formaldehyde, characterized as the dimedone derivative, in 25% yield.

For personal use only.

Reaction of the Lactone with Osmium Tetroxide

To the lactone (320 mg), dissolved in ether (2 ml) was added pyridine (0.5 ml) and osmium tetroxide (383 mg). This mixture was kept in the dark at room temperature for 23 days when it was diluted with ethanol and the osmic ester decomposed with hydrogen sulphide. The precipitate was filtered off on Celite and washed thoroughly with ethanol. The combined filtrate and washings were evaporated to dryness to leave an oil which solidified on standing. Chromatography on silica gel (20 g) gave, on elution with ether–benzene (1:19), unchanged lactone (70 mg). Elution with ether–benzene (1:1) gave a product (250 mg) which on crystallization from ether – light petroleum gave the lactone diol (190 mg), m.p. 159–164°; ϵ_{190} <200; ν_{max} 3600, 3500, and 1785 cm^{-1}; $[\alpha]_D$ +64° (*c*, 1.01). Calc. for $C_{15}H_{24}O_4$: C, 67.13; H, 9.02%. Found: C, 66.97; H, 8.59%.

ACKNOWLEDGMENTS

The authors would like to thank Mr. L. G. Crawford for able assistance, and Dr. R. A. Ludwig for advice, in growing the toxin. They would also like to express their appreciation to Dr. J. B. Stothers for the determination of the N.M.R. spectra.

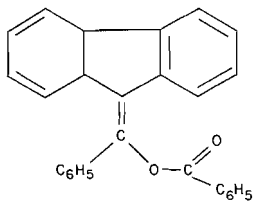
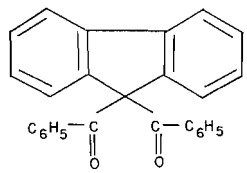
THE REACTION OF BENZOYL CHLORIDE AND ETHYL BENZOATE WITH SOME ALKALI METAL SALTS OF FLUORENE[1]

G. W. H. Scherf and R. K. Brown



ABSTRACT

In hydrocarbon or ether solvents, the sodium or potassium salt of fluorene or of 9-benzoylfluorene reacts with an equimolar amount of benzoyl chloride to form 9,1′-benzoyloxybenzylidenefluorene (I). The reaction of equimolar quantities of the lithium salt of fluorene or of 9-benzoylfluorene and benzoyl chloride in ether solvents gives rise to a mixture of 9,9-dibenzoylfluorene (II) and 9,1′-benzoyloxybenzylidenefluorene (I), but in hydrocarbon solvents produces only 9,9-dibenzoylfluorene (II).



Only 9-benzoylfluorene is isolated from the reactions of the monometal salts of fluorene or of 9-benzoylfluorene with ethyl benzoate.

INTRODUCTION

The dibenzoylation of fluorene at carbon 9 gives rise to two products, the enol ester (I) and the β-diketone (II). The first recorded synthesis of 9,9-dibenzoylfluorene (II) was

(I)

(II)

that of Schlenk and Bergmann (1, 2), who, from the reaction between 9-fluorenyllithium and benzoyl chloride in benzene, isolated di-(9-fluorenyl)-phenylcarbinol along with a small amount of a compound, m.p. 180°, of unknown structure. This compound, obtained only by painstaking effort, was later identified by Kliegl *et al.* as the β-diketone (II) (3). Subsequent preparations of II have followed this (4) or similar procedures (5). The enol ester (m.p. 189.5–190°) was first obtained by Kliegl and co-workers (3) from the reaction of benzoyl chloride with 9-fluorenylsodium in ether. The only other product reported from this reaction was unchanged fluorene. No mention was made that 9-benzoylfluorene was obtained as one of the products from the reaction of benzoyl chloride with either 9-fluorenyllithium (1, 2) or 9-fluorenylsodium (3). However, recent work (5) shows that 9-propionylfluorene can be prepared in 10% yield by the reaction of 9-fluorenyllithium with propionyl chloride in ether if the reaction is carried out at reflux temperature, whereas at room temperature 9,9-dipropionylfluorene is obtained. The 9-benzoylfluorene can be synthesized quite conveniently by the reaction of fluorene with potassium metal and ethyl benzoate (6, 7).

In view of the finding that the relative amount of mono- and di-alkylation at C_9 of fluorene obtained from the reaction of equimolar quantities of alkyl halide and monometalated fluorene depended upon the metal and solvent employed (8), a study was undertaken of the reaction of benzoyl chloride with some of the alkali metal salts of fluorene in ether and in hydrocarbon solvents.

RESULTS

Unless otherwise stated, all experiments involved equimolar proportions of fluorene, metal, and benzoyl chloride or ethyl benzoate in hydrocarbon or ether solvent.

The Reaction of Benzoyl Chloride with 9-Fluorenyl-lithium, -sodium, or -potassium

When 9-fluorenylpotassium (9) was treated at room temperature with benzoyl chloride in either dioxane or diethyl ether, wherein the salt is only partly soluble, the major product consisted of 9,1′-benzoyloxybenzylidenefluorene, I. The expected 9-benzoylfluorene was obtained only as a minor product and could be removed quite readily, along with much unreacted fluorene, by boiling the solid reaction product with ethyl alcohol, in which the enol ester is insoluble. The same results were obtained when the solid 9-fluorenylpotassium, freed from dioxane (9), was suspended in pentane and treated with benzoyl chloride. Similar results were obtained when 9-fluorenylpotassium, completely dissolved in dimethoxyethane, or 9-fluorenylsodium dissolved in dimethoxyethane or diethoxyethane (8, 10) was allowed to react with benzoyl chloride.

On the other hand, the reaction of 9-fluorenyllithium and benzoyl chloride gave results quite different from those obtained with the sodium or potassium analogues. Under the heterogeneous conditions obtained in the suspension of the lithium salt in pentane, 9,9-dibenzoylfluorene was produced in 28% yield, uncontaminated by the enol ester (I). The unreacted fluorene, along with a small amount of monobenzoylfluorene, was easily removed by extraction from the insoluble β-diketone (II) with hot ethanol. However, equimolar amounts of 9-fluorenyllithium and the acid halide in diethoxyethane or dimethoxyethane yielded, after removal of unchanged fluorene and some monobenzoylfluorene, a mixture of 9,9-dibenzoylfluorene and 9,1′-benzoyloxybenzylidenefluorene. Efforts to separate this mixture were unsuccessful. The infrared spectra obtained for both I and II showed clearly the presence of this mixture.

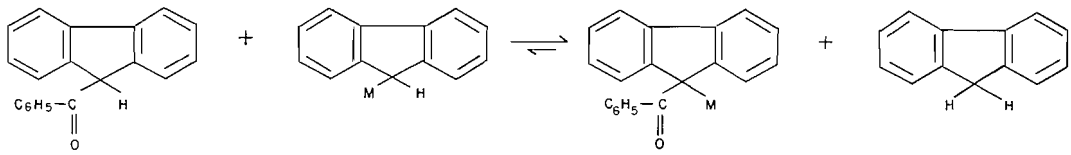
The infrared spectrum of the enol ester, I, in carbon disulphide showed a strong band at 1738 cm^{-1}, typical of a conjugated ester carbonyl group and a band of medium strength at 1650 cm^{-1} due to the enol double bond (11). The enol ester showed no absorption at 1688 cm^{-1}. The spectrum of the diketone, II, exhibited a strong doublet at 1688 cm^{-1} and 1660 cm^{-1}, but no absorption at 1738 cm^{-1}. The presence of one isomer as an impurity in the other was thus easily detected by the bands at 1738 cm^{-1} and 1688 cm^{-1}. A further distinct difference occurred in the region of aromatic C—H out-of-plane bending frequencies. The β-diketone showed one sharp band of medium intensity at 762 cm^{-1} whereas the enol ester gave two sharp bands, one at 762 cm^{-1}, the other at 775 cm^{-1}.

The spectrum of 9-benzoylfluorene also showed a doublet at 1670 cm^{-1} and 1688 cm^{-1}, though it was not as well resolved as that found for the diketone. In addition, a strong band at 1273 cm^{-1} and a weak band at 1723 cm^{-1} occurred in the spectrum of the monobenzoylfluorene but not in that of the diketone. The 9-benzoylfluorene is considered to exist in the more stable keto form (12). The double carbonyl band of the keto form of 9-benzoylfluorene is not unusual since this phenomenon has been observed in a number of compounds containing only one carbonyl group (13).

The Reaction of Ethyl Benzoate with 9-Fluorenyl-lithium, -sodium, and -potassium

The reaction of 9-fluorenylpotassium, either in dioxane or in pentane, with ethyl benzoate gave a 40% yield of 9-benzoylfluorene. This is considerably better than the yield of 28% of the monobenzoylated fluorene obtained by Wislicenus and Fehrle (7) from the reaction of fluorene, potassium, and ethyl benzoate mixed in the ratio 1:1:1. The reaction of 9-fluorenyllithium, either partly dissolved in dimethoxyethane or as an

insoluble suspension in pentane, when treated with ethyl benzoate, gave 40–45% of 9-benzoylfluorene. In all cases much fluorene was isolated, but no evidence was found for the formation of the enol ester, I, or the diketone, II.

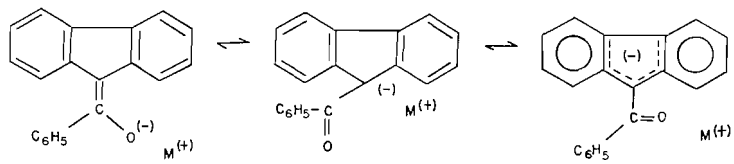


The Reaction of 9-Benzoyl-9-fluorenyl-lithium, -sodium, or -potassium with Benzoyl Chloride or Ethyl Benzoate

The compound 9-benzoylfluorene was converted readily to the lithium, sodium, or potassium salt, and then brought into reaction with benzoyl chloride or ethyl benzoate. In the ether solvents, dimethoxyethane or diethoxyethane, 9-benzoyl-9-fluorenyllithium and benzoyl chloride produced 55–65% of an inseparable mixture of enol ester and diketone. But when pentane was the solvent, a 54% yield of diketone was obtained, uncontaminated by enol ester. The sodium salt in dimethoxyethane or diethoxyethane, and the potassium salt in dimethoxyethane gave a 50–60% yield of the enol ester uncontaminated by the diketone.

The potassium or sodium salt of 9-benzoylfluorene in dimethoxyethane, reacting with ethyl benzoate, produced only unchanged 9-benzoylfluorene.

DISCUSSION



The results obtained clearly indicate that the following equilibrium occurs in the reaction of 9-fluorenyl-lithium, -sodium, or -potassium with benzoyl chloride in ether or in hydrocarbon solvents and under homogeneous or heterogenous conditions.

M = Li, Na, K

The enhanced acidic character of the remaining hydrogen at C_9 causes 9-benzoylfluorene to react with the remaining monometalated fluorene much more readily than the latter does with the benzoyl chloride.

The sodium and potassium salts of 9-benzoylfluorene will be largely, if not completely, ionic and stabilized by contributing structures A, B, and C. When the reaction with

A B C

benzoyl chloride occurs, the carbon–metal bond, highly ionic in both hydrocarbon and ether solvents, permits the accumulation of negative charge preferentially on the oxygen atom, the most electronegative atom in the anion. Reaction thus produces the enol ester, I, exclusively.

On the other hand, the carbon–*lithium* bond has considerable covalent character,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

especially so in hydrocarbon solvents (14–16). In pentane the attack of benzoyl chloride therefore occurs at the carbon–metal bond directly, yielding only the diketone, II. However, in ether solvents, particularly dimethoxyethane and diethoxyethane, some association occurs between the metal and the unshared electron pairs of the oxygen atoms of the ethers (8), enhancing the ionic character of the carbon–lithium bond. Benzoyl chloride will then have two alternative competitive courses of reaction. Approach to the carbonyl oxygen atom produces the enol ester, with the assistance of the ether associated with the metal. Approach to the carbon–lithium bond results in facile displacement of the ether with consequent reaction directly at the carbon–lithium bond, thus yielding the diketone. The infrared spectra of the inseparable mixture of these two products obtained from the reaction of 9-benzoyl-9-fluorenyllithium and benzoyl chloride in the ethers mentioned indicate that the enol ester and the diketone are formed in the ratio of nearly 1:2.

The formation of only 9-benzoylfluorene along with unchanged fluorene from the reaction of ethyl benzoate and 9-fluorenyl-lithium, -sodium, or -potassium in ether or hydrocarbon solvents is no doubt due to the lower nucleophilic character of the resonance-stabilized anion ABC as compared with that of the ethoxide ion. The ethoxide ion, which must be formed if this anion reacts with ethyl benzoate, readily reacts with the enol ester or β-diketone to reconvert it to the more stable monobenzoylfluorenyl anion ABC. Such a decomposition of an enol ester or diketone by a strong base has been shown previously (4, 7). The failure of the Grignard reagent to form the expected tertiary alcohol from 9-methyl-9-benzoylfluorene also demonstrates the labile nature of 9-benzoylfluorene under basic conditions (17). A similar explanation has been offered for the failure of metalated diphenylmethane to react with more than one equivalent of ester (18).

EXPERIMENTAL

The experimental procedure is generally quite similar in all the reactions performed. A typical experiment for the reactions carried out in ether solvent and one for the reaction conducted with pentane as solvent are shown below. The essential details for the remainder of the experiments carried out are shown in the accompanying table.

All preparations involving organometallic compounds were carried out under nitrogen. Products were identified by mixed melting points with authentic specimens and (or) by comparison of the infrared spectra.

The Reaction of 9-Fluorenylpotassium with Benzoyl Chloride

(1) In dioxane.—Fluorene (16.6 g, 0.1 mole) and potassium (3.9 g, 0.1 mole) were kept for 4 hours in 160 ml of pure, dry, refluxing dioxane. Under these conditions all the potassium was consumed. The mixture was allowed to cool to room temperature and then benzoyl chloride (14 g, 0.1 mole), dissolved in 50 ml of dioxane, was slowly added. The dark red color of the original solution turned to light orange and a viscous solution was formed. Addition of ether and water followed by several washings of the ether layer with water permitted removal of the inorganic salts and the dioxane. At room temperature the ether layer contained yellow crystals which were separated. A second crop of crystals was obtained when the mother liquor was reduced in volume. The yield of crude material was 11.7 g (31%). After unreacted fluorene and 9-benzoylfluorene were removed by trituration with hot ethyl alcohol, pure 9,1′-benzoyloxybenzylidenefluorene, m.p. 189°, was obtained.

(2) In pentane.—Fluorene (8.3 g, 0.05 mole) and potassium metal (1.95 g, 0.05 mole)

TABLE I

Original compound	Metal	Metalation medium[a]	Solvent medium for benzoylation	Benzoylating agent[b]	Product[c]; yield
Fluorene	K	Dioxane	Dioxane	Ethyl benzoate	39% 9-benzoylfluorene + unchanged fluorene
Fluorene	K	Dioxane	Pentane	Ethyl benzoate	42% 9-benzoylfluorene + unchanged fluorene
Fluorene	Li	DEE (10)	DEE	Benzoyl chloride	31% of a mixture of I and II + unchanged fluorene
Fluorene	Li	DEE (10)	Pentane	Benzoyl chloride	28% of II + unchanged fluorene
Fluorene	Li	DEE (10)	DEE	Ethyl benzoate	45% of 9-benzoylfluorene + unchanged fluorene
Fluorene	Li	DEE (10)	Pentane	Ethyl benzoate	41% of 9-benzoylfluorene + unchanged fluorene
9-Benzoylfluorene	Li	DEE (10)	DEE	Benzoyl chloride	67% of a mixture of I and II + unchanged 9-benzoylfluorene
9-Benzoylfluorene	Li	DME	DME	Benzoyl chloride	56% of a mixture of I and II + unchanged 9-benzoylfluorene
9-Benzoylfluorene	Li	DEE	Pentane	Benzoyl chloride	54% of II + unchanged 9-benzoylfluorene
9-Benzoylfluorene	Li	DEE	DEE	Ethyl benzoate	Only unchanged 9-benzoylfluorene
9-Benzoylfluorene	Li	DEE	Pentane	Ethyl benzoate	Only unchanged 9-benzoylfluorene
9-Benzoylfluorene	Na	DME	DME	Benzoyl chloride	60% of I + unreacted 9-benzoylfluorene
9-Benzoylfluorene	Na	DEE	DEE	Benzoyl chloride	Only I (amount undetermined) + unreacted 9-benzoylfluorene
9-Benzoylfluorene	Na	DME	DME	Ethyl benzoate	Only unchanged 9-benzoylfluorene
9-Benzoylfluorene	K	DME	DME	Benzoyl chloride	48% of I + unchanged 9-benzoylfluorene
9-Benzoylfluorene	K	DME	DME	Ethyl benzoate	Only unchanged 9-benzoylfluorene

[a]Metalation was complete in all cases, although the time varied between 0.5 and 2 hours for complete reaction with 9-benzoylfluorene and 4 to 5 hours for the metalation of fluorene. DEE = diethoxyethane. DME = dimethoxyethane.
[b]The slower reaction with ethyl benzoate was allowed to continue overnight, with stirring, to ensure complete reaction. Benzoyl chloride reacted more rapidly but was given a 1- to 3-hour reaction time to ensure completeness.
[c]The 9-benzoylfluorene was freed from fluorene by crystallization from ethanol. Hot ethanol removed fluorene and 9-benzoylfluorene from the alcohol-insoluble enol ester and/or diketone.

were kept for 4 hours in 40 ml of pure, refluxing dioxane. The cooled solution, containing no unreacted potassium, was poured into 500 ml of dry pentane, whereupon the 9-fluorenylpotassium precipitated. The liquid was decanted and the precipitate washed by decantation using pentane, and then suspended in 100 ml of pentane. To this was added slowly a solution of 7 g (0.05 mole) of benzoyl chloride in 50 ml of dry pentane. Reaction occurred immediately but was allowed to continue for 3 hours, with stirring, to assure maximum reaction of the suspended solid. After removal of inorganic substances by water washes, there remained a solid material suspended in the pentane layer. When this was removed and dried it weighed 9.9 g. Contaminating fluorene and 9-benzoylfluorene were removed by extraction of the crude material with hot ethanol, in which both the 9,1′-benzoyloxybenzylidenefluorene and 9,9-dibenzoylfluorene are insoluble. There was obtained 5.1 g (27%) of material analyzing correctly for the enol ester and melting at 189°.

The pentane mother liquor, upon evaporation, yielded a small amount of 9-benzoylfluorene and a considerable quantity of unreacted fluorene.

INTERMOLECULAR FORCES AND LIQUID STRUCTURE IN SOME METAL ALKOXIDES[1]

D. C. BRADLEY,[2] CALLIOPE C. A. PREVEDOROU,[2] AND W. WARDLAW[3]

ABSTRACT

The viscosities of some alkoxides of titanium, zirconium, cerium (IV), thorium, and tin (IV) have been measured in the temperature range 25–40° C. The liquid structure in these compounds is discussed in terms of the activation energy, free energy, and entropy of activation for viscous flow, and the energies of cohesion and vaporization.

INTRODUCTION

Previously (1) we investigated the liquid-state properties of a number of germanium tetraalkoxides (alkyl orthogermanates) in order to establish a basis for comparison with similar properties of a number of metal alkoxides. The germanium alkoxides are monomeric whereas some of the metal alkoxides studied in this research are known to be polymeric. It was of interest, in connection with the theory of intermolecular forces in the liquid state, to study the behavior of both monomeric and polymeric metal alkoxides since these large molecules are believed to have globular or quasi-spherical structures. We now report some results on the viscosities of a number of alkoxides of the group IV metals and discuss these in conjunction with related properties of the liquid state.

EXPERIMENTAL

Preparation of the Alkoxides

The alkoxides of titanium (2), zirconium (2), cerium (3), thorium (4), and tin (5) were prepared, purified, and analyzed by the previously described methods. Titanium tetraethoxide is a supercooled liquid at room temperature but it did not change in viscosity when kept in the apparatus over 8 hours.

Viscosity Measurements

All-glass Ostwald viscometers were calibrated using pure benzene at 25, 30, 35, and 40° C. The sample of alkoxide was distilled into the rigorously dried viscometer at 0.1 mm pressure and dry nitrogen was then admitted at atmospheric pressure. The temperature of the viscometer was controlled to ±0.01° C and three separate determinations were carried out on each compound. The reproducibility was of the order of ±0.0001 poises for the least viscous and ±0.01–0.02 poises for the most viscous compounds. The results (viscosity in poises) are presented in Table I.

The activation energies of viscosity E_{visc} (kcal/mole) were evaluated graphically from the plot of $\log \eta$ versus $1/T°$ K. The free energies of activation of viscous flow $\Delta F^{\ddagger}$ (kcal/mole) were calculated from Eyring's (6) equation:

$$\eta = (hN/V) \cdot e^{(\Delta F^{\ddagger}/RT)}.$$

The molar volumes were taken from our previous work (8) and the molar heats of vaporization from the results of vapor pressure studies (2).

$Th(OCEt_3)_4$	0.492	0.387	0.322	0.269

DISCUSSION

The data on E_{visc}, $\Delta F^{\ddagger}$, and $\Delta S^{\ddagger}$ (cal/deg mole), at 25° C, are presented in Table II.

TABLE II

Compound	E_{visc} (kcal/mole)	$\Delta F^{\ddagger}$ (kcal/mole)	$\Delta S^{\ddagger}$ (cal/°C mole)
$Ti(OEt)_4$	7.9	5.9	+6.7
$Ti(OPr^n)_4$	8.4	6.9	+5.3
$Ti(OBu^n)_4$	7.1	6.5	+2.0
$Ti(OBu^t)_4$	4.1	4.8	−2.4
$Zr(OBu^t)_4$	4.4	4.8	−1.4
$Ti(OCMe_2Et)_4$	5.2	5.4	−0.7
$Zr(OCMe_2Et)_4$	5.4	5.4	0
$Sn(OCMe_2Et)_4$	6.4	5.8	+2.0
$Ti(OCMeEt_2)_4$	6.1	6.3	−0.7
$Zr(OCMeEt_2)_4$	6.6	6.2	+1.3
$Ce(OCMeEt_2)_4$	7.0	6.1	+3.5
$Sn(OCMeEt_2)_4$	8.2	6.7	+5.0
$Ti(OCMe_2Pr^n)_4$	3.8	5.2	−5.0
$Zr(OCMe_2Pr^n)_4$	4.0	5.2	−4.0
$Ce(OCMe_2Pr^n)_4$	12.6	8.1	+15.1
$Sn(OCMe_2Pr^n)_4$	5.6	5.6	0
$Ce(OCEt_3)_4$	6.3	6.6	−1.3
$Th(OCEt_3)_4$	7.6	6.6	+3.5

The errors in E_{visc} and $\Delta F^{\ddagger}$ were of the order of ± 0.5–1.0%, whilst for $\Delta S^{\ddagger}$ the errors probably range from about $\pm 5\%$ for values around 5 cal/deg mole to about $\pm 15\%$ for values around 1 cal/deg mole.

Considering first the *n*-alkoxides of titanium, $Ti(OR)_4$, where R = Et, Pr^n, and Bu^n, it is noteworthy that for both η and E_{visc} there is a maximum value at the *n*-propoxide. This is in marked contrast to the behavior of the corresponding germanium *n*-alkoxides where E_{visc} increases steadily with molecular size (1). Moreover, the values of E_{visc} for the titanium derivatives are two to three times greater than for the corresponding germanium derivatives. There is little doubt that this "anomalous" behavior of the titanium compounds is a consequence of their polymeric nature. For example, Caughlan *et al.* (7)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

showed cryoscopically that the number-average degree of polymerization of titanium *n*-alkoxides in benzene increased with increasing concentration to a limiting value of three. They suggested that the trimer was of structural significance and deduced two possible structures based on octahedral titanium atoms in which 6-co-ordination was attained by intermolecular bonds from oxygen to titanium. It seems reasonable to assume that these alkoxides would also be trimeric in the pure liquid state. Concerning the mechanism of viscous flow, there seem to be two alternatives for the polymeric derivatives. Either the trimers migrate individually or they may dissociate into more mobile monomer units which then migrate. We have already observed that for the germanium *n*-alkoxides, which are monomeric, E_{visc} increases steadily with increase in molecular size. It is also clear from the data in Table II that for the monomeric tertiary alkoxides of titanium (and zirconium) E_{visc} again increases steadily with molecular size. Hence it might reasonably be expected that E_{visc} for the trimer $Ti_3(OR)_{12}$ would be almost triple that for the monomer $Ti(OR)_4$ if the trimer migrates as a whole. We have estimated, by extrapolation from the values of E_{visc} for the monomeric tertiary alkoxides, that the values of $(E_{visc})_{mon}$ for "monomeric" normal alkoxides of titanium should be approximately: $Ti(OEt)_4$, 2.2; $Ti(OPr^n)_4$, 3.2; $Ti(OBu^n)_4$, 4.1 kcal/mole. These figures are reasonably close to the corresponding values for the work of cohesion W_c (see later) and W_c should be $\simeq E_{visc}$ for simple molecules (9). The ratios $E_{visc}/(E_{visc})_{mon}$ are as follows: $Ti(OEt)_4$, 3.6; $Ti(OPr^n)_4$, 2.6; $Ti(OBu^n)_4$, 1.7. Bearing in mind the approximations involved, it might be agreed that the figures for $Ti(OEt)_4$ and $Ti(OPr^n)_4$ are consistent with these compounds exhibiting flow by migration of trimeric molecules, but such is not the case for $Ti(OBu^n)_4$. Moreover, the alternative mechanism of flow involving depolymerization of the trimers and migration of monomers would also require anomalously high values of E_{visc} because the activation energy for viscous flow would include the energy of depolymerization ΔE. Assuming that $E_{visc} = (E_{visc})_{mon} + \Delta E$, the following values for ΔE are derived: $Ti(OEt)_4$, 5.7; $Ti(OPr^n)_4$, 5.2; $Ti(OBu^n)_4$, 3.0 kcal/mole. The observed order of E_{visc} would then be a consequence of the decrease in depolymerization energy (ΔE) with increase in length of the alkyl chains. We are inclined to the view that the second mechanism, i.e. depolymerization followed by migration of monomers, is the correct one because of the entropies of activation $\Delta S^{\ddagger}$ shown in Table II. Thus the monomeric germanium *n*-alkoxides had negative entropies of activation and the monomeric titanium tertiary alkoxides also have negative entropies of activation. Hence we should expect the migration of trimeric molecules to involve a similar negative entropy of activation. However, the titanium *n*-alkoxides have relatively large positive entropies of activation and this is consistent with the proposition that depolymerization is involved in the mechanism of flow since such a process should cause a considerable degree of disorder in attaining the activated configuration. It is noteworthy that the positive $\Delta S^{\ddagger}$ values decrease in the same order as the values of ΔE.

Turning now to the monomeric alkoxides of titanium and zirconium, we note that η and E_{visc} increase with molecular size from $M(OCMe_3)_4$ to $M(OCMe_2Et)_4$ to $M(OCMeEt_2)_4$, with the titanium derivative having a slightly higher viscosity but slightly lower E_{visc} than the corresponding zirconium derivative. The $\Delta S^{\ddagger}$ values are slightly more positive for the zirconium compounds. However, the E_{visc} values for the $M(OCMe_2Pr^n)_4$ derivatives of Ti and Zr are remarkably low and suggest that the mechanism of flow must differ in these molecules from the mechanism of "molecular jumps" which probably occurs in the other tertiary alkoxides. This is reflected in the large negative $\Delta S^{\ddagger}$ values for the $M(OCMe_2Pr^n)_4$ molecules. The behavior of the stannic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

alkoxides is surprising since the values for η and E_{visc} are higher and $\Delta S^{\ddagger}$ more positive than in the corresponding titanium and zirconium derivatives. Previous work (8) showed that the stannic compounds also had anomalously low parachors compared with the Ti and Zr compounds. The reason for this is still not clear. The effect of polymerization is strikingly revealed in the viscosity data for the cerium derivatives of dimethyl *n*-propyl carbinol and methyl diethyl carbinol. On the other hand the triethyl carbinol derivatives of cerium and thorium, which are monomeric, seem to have η and E_{visc} values of the correct order of magnitude.

Grunberg and Nissan (9) have shown that important structural information on liquids may be deduced from a comparison of the internal energy of vaporization $E_v(\Delta H_v - RT)$, the work of cohesion W_c ($2\gamma N^{1/3} V_l^{2/3}$, where γ is the surface tension and V_l the molar volume of the liquid), and the activation energy of viscosity E_{visc}. Eyring (6) has shown that for many liquids, $E_v/\Delta F^{\ddagger} \simeq 2.5$ and E_v/E_{visc} is 3–4, and has interpreted deviations from these values in terms of structural abnormalities. We have calculated the values for W_c (kcal/mole) (8) and the ratios E_v/E_{visc} etc. for some liquid metal alkoxides and the data are given in Table III.

TABLE III

Compound	E_v (kcal/mole)	W_c (kcal/mole)	$E_v/\Delta F^{\ddagger}$	E_v/E_{visc}	E_v/W_c	E_{visc}/W_c
$Ti(OEt)_4$	21.0	2.84	3.55	2.50	7.39	2.95
$Ti(OPr^n)_4$	15.1	3.78	2.18	1.71	3.99	2.33
$Ti(OBu^n)_4$	19.5	4.39	3.00	2.71	4.44	1.63
$Ti(OBu^t)_4$	14.0	4.92	2.91	3.41	3.00	0.83
$Zr(OBu^t)_4$	14.6	4.47	3.04	3.32	3.27	0.98
$Ti(OCMe_2Et)_4$	16.1	6.03	2.98	3.10	2.67	0.86
$Zr(OCMe_2Et)_4$	15.7	5.46	2.90	2.91	2.88	0.98
$Ti(OCMeEt_2)_4$	18.4	6.92	2.92	3.01	2.66	0.88
$Zr(OCMeEt_2)_4$	18.4	6.30	2.96	2.80	2.92	1.05
$Ti(OCMe_2Pr^n)_4$	18.9	6.75	3.63	4.97	2.73	0.57
$Zr(OCMe_2Pr^n)_4$	18.4	6.28	3.54	4.60	2.93	0.64

In addition, the values of W_c and the ratio E_{visc}/W_c have been calculated for some alkoxides whose latent heats of vaporization are not known: $Sn(OCMe_2Et)_4$: W_c 4.96, E_{visc}/W_c 1.31; $Sn(OCMe_2Pr^n)_4$: 4.99, 1.13; $Ce(OCMeEt_2)_4$: 6.23, 1.12; $Ce(OCEt_3)_4$: 7.03, 0.90; $Th(OCEt_2)_4$: 6.09, 1.25.

Grunberg and Nissan (9) showed that for various monomeric liquids, $E_{visc} = W_c$, and it is clear that in these cases the energy requirements for translating a molecule from one equilibrium position to another in viscous flow are the same as in displacing a molecule to expose fresh surface of the liquid. They also noted that for "associated" liquids, $E_{visc} > W_c$, and suggested that the difference $E_{visc} - W_c$ could be attributed to the energy of dissociation of the associated molecules since W_c does not contain the dissociation energy but E_{visc} does. This difference presumably arises because E_{visc} is determined from a rate process whereas the determination of W_c involves an equilibrium system. In principle, a higher value of W_c including the energy of dissociation might be obtained by using a dynamic method in which the surface tension was measured during a time interval which was short compared with the lifetime of a "dissociated" molecule. The results for the monomeric tertiary alkoxides $M(OCMe_nEt_{3-n})_4$, where M = Ti or Zr and n = 3, 2, or 1, and also for some of the tertiary alkoxides of tin, cerium, and thorium, show that the ratio E_{visc}/W_c is indeed close to unity. Evidently these large

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

globular molecules behave similarly to simple molecules in the processes of viscous flow and surface formation. No doubt this is because the intermolecular forces between the monomeric tertiary alkoxides are mainly determined by the peripheral alkyl groups and these forces will be of the dispersion type. It is quite clear that the central metal atom has little influence on the magnitude of these forces and this is in accordance with the earlier theory of Bradley *et al.* (2, 3, 4, 5) that the highly branched tertiary alkoxide groups effectively screen the metal and prevent intermolecular bonding involving the metal. The behavior of the monomeric alkoxides $Ti(OCMe_2Pr^n)_4$ and $Zr(OCMe_2Pr^n)_4$ is extremely interesting. In both cases the ratio E_{visc}/W_c is considerably less than unity and it appears, from a comparison with the data for the other monomeric titanium and zirconium alkoxides, that for $M(OCMe_2Pr^n)_4$ the values of W_c are normal but values of E_{visc} are abnormally low. This suggests that the mechanism of flow for $M(OCMe_2Pr^n)_4$ liquids does not involve the discrete movement of the whole molecule but, more probably, migration occurs by a "molecular wriggle" mechanism. It is noteworthy that these compounds also have fairly large negative entropies of activation for viscous flow and this recalls the mechanism of flow postulated by Moore, Gibbs, and Eyring (10) for straight-chain hydrocarbons. They noted that these compounds had low values of E_{visc} in the low-temperature region and gave negative $\Delta S^{\ddagger}$'s. It was suggested that these liquids had a quasi-crystalline structure and that viscous flow involved a co-operative movement analogous to the movement of dislocations in the lattice of a metal.

It is extremely interesting to note that for the polymeric *n*-alkoxides of titanium, the values of E_{visc}/W_c are much greater than unity due to the abnormally high values for E_{visc}. In fact, the values of W_c for the *n*-alkoxides are remarkably close to the values calculated for hypothetical "monomeric" derivatives by extrapolation from the data on the monomeric tertiary alkoxides. From this we deduce that the intermolecular forces which are overcome in the creation of fresh surface are the same in nature for both the polymeric and the monomeric alkoxides and hence must involve predominantly the dispersion forces between the peripheral alkyl groups. Hence the values of W_c for the polymeric alkoxides do not involve the dissociation energy of the polymers whereas we have argued earlier that E_{visc} does include the dissociation energy. Therefore, the difference $E_{visc} - W_c \simeq \Delta E$ and provides an alternative measure for ΔE. The values of ΔE so calculated are: $Ti(OEt)_4$, 5.1 (5.7); $Ti(OPr^n)_4$, 4.6 (5.2); $Ti(OBu^n)_4$, 2.7 (3.0); the values in parentheses are the ones deduced earlier in the paper by the other method.

For the monomeric tertiary alkoxides which exhibit the "molecular jump" mechanism of flow it appears that $E_v/\Delta F^{\ddagger}$ is 3.0 rather than 2.5 as found by Eyring (6) for "normal" liquids. This discrepancy may well be due to the fact that Eyring's values of E_v were calculated from heats of vaporization at the normal boiling point whereas in the metal alkoxides our values of E_v are derived from vapor pressure results at lower pressures (where ΔH_v will be larger). For the same compounds E_v/E_{visc} is around 3.0 whereas for the "abnormal" polymeric alkoxides E_v/E_{visc} is low and for $M(OCMe_2Pr^n)_4$ (M = Ti, Zr) the values are rather high.

Finally, it is interesting to explore the application of Grunberg and Nissan's (9) ideas on the structure of liquids to our data. For liquids composed of simple molecules they suggested that there is a statistical structure in which each molecule is surrounded by *n* nearest neighbors and that intermolecular forces may be considered as localized in "bonds" between nearest neighbors. In the process of vaporization all of these "bonds" must be disrupted before a molecule is free to escape into the vapor. However, in surface formation the number of "bonds" which need to be disrupted in order to expose a

"central" molecule depends on the quasi structure in the liquid and this is why $E_v > W_c$. They deduced that the ratio $E_v > W_c$ would be determined by the co-ordination number and the structure of the liquid as follows: for hexagonal (c.p.), cubic (c.p.), and cubic (b.c.) packing, $E_v/W_c = 4$; for octahedral packing, $E_v/W_c = 3$; and for tetrahedral packing, $E_v/W_c = 2$. For the monomeric tertiary alkoxides the data in Table III show that the zirconium compounds have E_v/W_c values about 10% greater than the corresponding titanium derivatives. This is a reflection of the fact that the zirconium compounds have lower values of W_c but about the same values of E_v as the titanium compounds. Nevertheless, the value of E_v/W_c for all of these compounds is around 3.0 and suggests that the molecules have an average co-ordination number of 6. This figure must be treated with caution since the molecules under consideration are large and complicated in structure and hence may not conform to the requirements of the theory.

CONCLUSIONS

1. From considerations of the energies of intermolecular attraction as deduced from the processes of vaporization, viscous flow, and surface formation, it appears that the monomeric tertiary alkoxides behave rather like simple covalent molecules which are bound by dispersion forces in the liquid state. This agrees with the conclusions from other work that the steric effect of the branched alkoxide groups largely precludes the central metal atom from being involved in intermolecular interaction.

2. In the *n*-alkoxides of titanium, which are polymeric due to intermolecular bonding between titanium and oxygen, it appears that the mechanism of viscous flow involves dissociation of the polymers with consequent abnormally high activation energy. On the other hand the process of surface formation appears to involve only the relatively weak dispersion forces between the molecules.

MOLECULAR INTERACTIONS

I. INFRARED SPECTRA OF SOME CARBOXYLIC ACIDS IN CARBON TETRACHLORIDE AND BENZENE SOLUTIONS[1]

F. E. MURRAY[2] AND S. SUNDARAM

ABSTRACT

Infrared spectra of benzoic, *o*-chlorobenzoic, and salicylic acids in the range 700 to 3800 cm^{-1} have been studied. Measurements have been made on the three acids in carbon tetrachloride and benzene solutions, at a number of concentrations in each case. The results are interpreted in terms of the molecular species present in each solution and the effect of the solvents on these species. Assignments have been made of the observed bands to the various vibrational modes characteristic of the COOH group.

INTRODUCTION

Dimeric carboxylic acids have been the subject of study by a number of investigators in the past. The infrared and Raman spectra have been used to show the presence of strong hydrogen bridges between the carbonyl and the hydroxyl groups of the two molecules. Even in dilute solutions in certain solvents, the association between the molecules persists.

The abnormally strong hydrogen bonds in these acids is an advantage in correlating the characteristic distortions of the O—H stretching modes with the association. There are also other regions of the spectra that are equally important. The C=O region (1700 cm^{-1}) gives indications of the immediate environment of the COOH group. The other regions that provide additional useful data are 1300–1400 cm^{-1}, corresponding to C—O stretching and O—H in-plane deformation, and near 950 cm^{-1}, attributed to the O—H out-of-plane mode.

The infrared spectra of benzoic acid in solution in carbon tetrachloride have been studied by Davies and Sutherland (1), Harris and Hobbs (2), and Bratoz *et al.* (3). Hadzi and Sheppard (4) have also observed the infrared spectrum of solid benzoic acid below 1500 cm^{-1}. Among others, Murty and Seshadri (5) have reported the Raman spectrum of benzoic acid in solution in benzene and indicated the presence of ring dimers. Brooks *et al.* (6, 7) have recently investigated the C=O and O—H frequencies in the infrared spectra of benzoic and *o*-chlorobenzoic acid in ether–CCl_4 and CCl_4 solutions respectively and of substituted salicylic acids and their esters in CCl_4 solutions. The Raman spectrum of salicylic acid in benzene solution has been studied by Murty and Seshadri (8). They concluded that some chelate monomer is present in benzene solution but the major molecular species is a polymer, the structure of which was not clear.

The present study was begun to obtain information on the effect of the ortho substituents in benzoic acid on the tendency of this compound to form dimers in solution. The presence of an ortho substituent in benzoic acid makes possible the formation of chelate monomers. This tendency for chelation depends on the donor or acceptor strength of the ortho substituent group. Thus, for these compounds there are two competing processes for the formation of donor–acceptor bonds leading to the production of chelate monomers or to associated polymers. The effect of the solvent on the type of the molecular species present in solution has also been investigated.

Three acids, benzoic, *o*-chlorobenzoic, and salicylic were chosen for study. The spectra for these three compounds were obtained at various concentrations in solution in carbon tetrachloride and in benzene.

EXPERIMENTAL

All the spectra were recorded using a Perkin–Elmer Model 21 double-beam spectrometer equipped with sodium chloride optics. The instrument was calibrated against atmospheric absorption bands and a polystyrene film. The accuracy in the O—H stretching band region is estimated at ± 10 cm^{-1}. Measurements were made using 5-mm matched cells. The solvents used, carbon tetrachloride and benzene, were spectrograde and the acids used were analytical reagent grade. All of the above compounds were used without any attempts at further purification.

RESULTS

(*a*) Infrared spectral data for benzoic acid in carbon tetrachloride solution at a concentration of 8.2 millimoles per liter.—Principal absorption bands (cm^{-1}): 3650, 3545, 3060, 3020, 3005, 2875, 2658, 2590, 2540, 2080, 1970, 1927, 1912, 1815, 1780, 1737, 1692, 1620, 1455, 1420, 1352, 1320, 1287, 1177, 1125, 1090, 1065, 1025, 935.

(*b*) Infrared spectral data for benzoic acid in benzene solution at a concentration of 17.2 millimoles per liter.—Principal absorption bands (cm^{-1}): 3660, 3630, 3470, 3220, 3000, 2780, 2665, 2630, 2540, 2345, 2300, 2197, 2080, 1902, 1725, 1690, 1650, 1640, 1355, 1290, 1272.

(*c*) Infrared spectral data for salicylic acid in carbon tetrachloride solution at a concentration of 6.58 millimoles per liter.—Principal absorption bands (cm^{-1}): 3535, 3060, 2918, 2870, 2590, 2530, 1690, 1660, 1612, 1482, 1462, 1442, 1382, 1297, 1180, 1162, 1152, 1135, 1072, 1033, 903.

(*d*) Infrared spectral data for salicylic acid in benzene solution at a concentration of 4.4 millimoles per liter.—Principal absorption bands (cm^{-1}): 3655, 3450, 3240, 3000, 2820, 2635, 2570, 2540, 1787, 1687, 1655, 1642, 1417, 1342, 1330, 1290, 1265.

(*e*) Infrared spectral data for *o*-chlorobenzoic acid in carbon tetrachloride solution at a concentration of 12.8 millimoles per liter.—Principal absorption bands (cm^{-1}): 3585, 3080, 3030, 3000, 2910, 2655, 2555, 1977, 1947, 1755, 1700, 1565, 1480, 1442, 1410, 1297, 1180, 1165, 1145, 1130, 1100, 1050, 1042, 925.

(*f*) Infrared spectral data of *o*-chlorobenzoic acid in benzene solution at a concentration of 12.8 millimoles per liter.—Principal absorption bands (cm^{-1}): 3655, 3460, 3210, 2775, 2670, 2530, 1717, 1690, 1332, 1270.

DISCUSSION

In the following discussion of the spectra observed, the absorption bands in the various regions are assigned to the molecular species which appear to exist for each of the acids in the two solvents. The assignments are based on the position of the band and on the behavior of the intensity of the band with changing concentration of the solute. In some cases, the positions of the bands change significantly as the concentration of the solute is changed. This effect, which must be caused by an interaction between solvent molecules and the functional group which gives rise to the vibrational band, has not been considered in any detail.

1. Region of the O—H Stretching Fundamental

The results obtained in the region of the O—H stretching vibrational frequency are shown in Fig. 1. The acids in solution in carbon tetrachloride show sharp monomer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

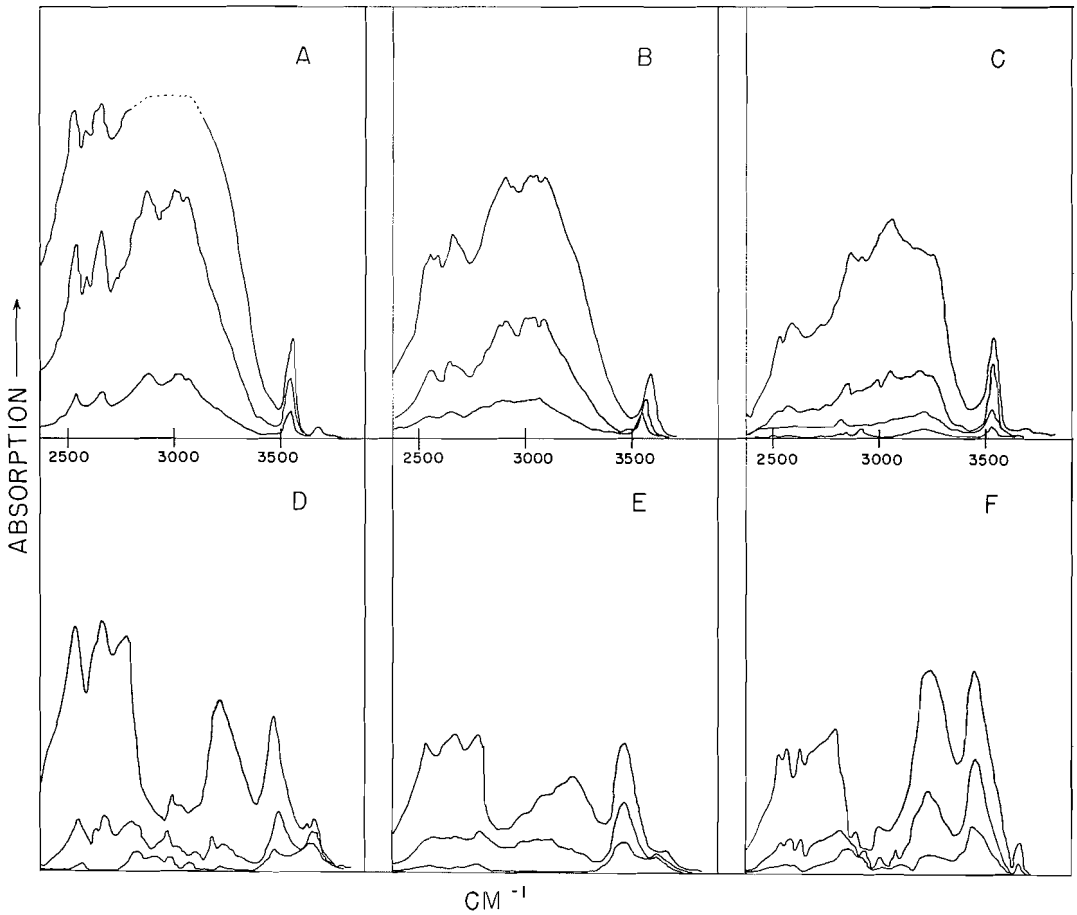

FIG. 1. Region of the O—H stretching fundamental bands: A, benzoic acid in carbon tetrachloride at concentrations 32, 8.2, and 1.3 millimoles per liter; B, orthochlorobenzoic acid in carbon tetrachloride at concentrations 12.8, 3.84, and 1.15 millimoles per liter; C, salicylic acid in carbon tetrachloride at concentrations 6.58, 1.98, 0.59, and 0.18 millimoles per liter; D, benzoic acid in benzene at concentrations 17.2, 3.4, and 0.68 millimoles per liter; E, orthochlorobenzoic acid in benzene at concentrations 12.8, 3.84, and 1.15 millimoles per liter; F, salicylic acid in benzene at concentrations 14.5, 4.4, and 1.32 millimoles per liter.

O—H bands at 3545, 3585, and 3535 cm^{-1} for benzoic, *o*-chlorobenzoic, and salicylic acids, respectively. In this solvent, the band of the associated form is strong and broad with the actual position of the peaks obscured by the overlapping C—H bands.

In benzene solution, the monomeric bands appear at lower frequencies than the bands for the same acids in carbon tetrachloride solution. The monomer bands are at 3470, 3460, and 3450 cm^{-1} respectively for the benzoic, *o*-chlorobenzoic, and salicylic acids. The bands for the associated species are clearly defined for each acid and appear at 3220, 3210, and 3240 cm^{-1} for the benzoic, *o*-chlorobenzoic, and salicylic acids.

Subsidiary maxima, with somewhat narrower half-band widths, have been observed in all the solutions in the region 2500–3000 cm^{-1}. These bands have been very satisfactorily accounted for by a summation-band hypothesis by Hadzi and Sheppard (4).

2. Region of the C=O Stretching Fundamental

The spectra obtained for the three acids in both the solvents, in the region of the C=O stretch, are shown in Fig. 2. The effect of the solvent change on the C=O stretching

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

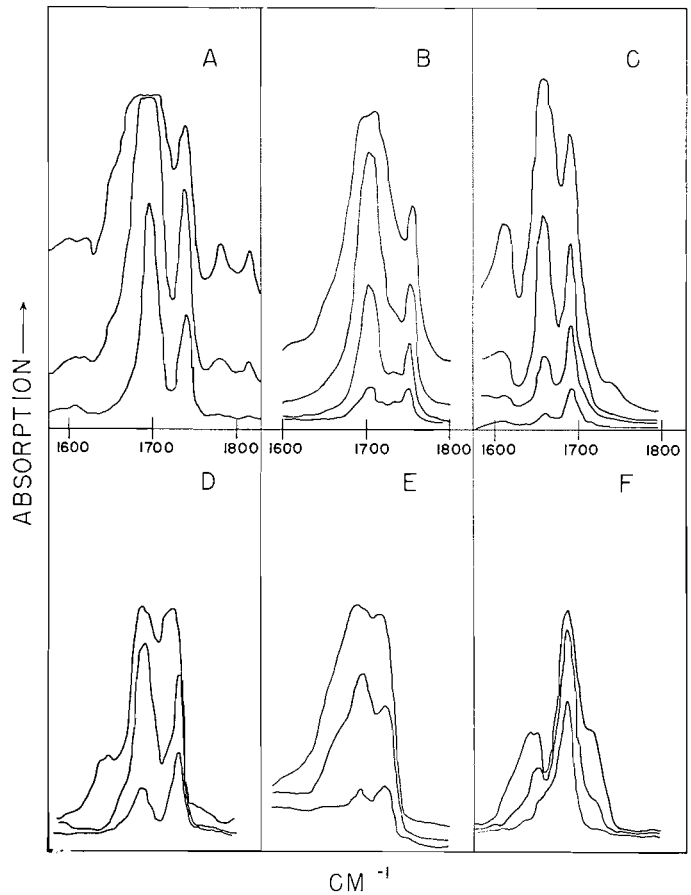

FIG. 2. Region of the C=O stretching fundamental bands: A, benzoic acid in carbon tetrachloride at concentrations 32, 8.2, and 1.3 millimoles per liter; B, orthochlorobenzoic acid in carbon tetrachloride at concentrations 12.8, 3.84, 1.15, and 0.35 millimoles per liter; C, salicylic acid in carbon tetrachloride at concentrations 6.58, 1.98, 0.59, and 0.18 millimoles per liter; D, benzoic acid in benzene at concentrations 17.2, 3.4, and 0.68 millimoles per liter; E, orthochlorobenzoic acid in benzene at concentrations 12.8, 3.84, and 1.15 millimoles per liter; F, salicylic acid in benzene at concentrations 14.5, 4.4, and 1.32 millimoles per liter.

vibration is not nearly as great as it is on the O—H stretching vibration. Thus, the C=O bands are shifted only slightly in changing from the solvent carbon tetrachloride to benzene. This region yields considerable information regarding the molecular species present in each case.

Monomer bands for the benzoic, *o*-chlorobenzoic, and salicylic acids in carbon tetrachloride appear at 1737, 1755, and 1690 cm^{-1} respectively. In the case of the salicylic acid, the peak at 1690 cm^{-1} is characteristic of the chelated form of the acid as shown in Figs. 5*e* and 5*f*, and the small shoulder at 1730 cm^{-1} arises from the presence of some unchelated monomer. The peaks for the associated forms of the benzoic, *o*-chlorobenzoic, and salicylic acids in carbon tetrachloride solution appear at 1692, 1700, and 1660 cm^{-1} respectively.

In benzene solution, the benzoic acid shows a monomer band at 1725 cm^{-1} and the bands for the associated forms of the acid at 1690 and 1650 cm^{-1}. The monomer peak for the *o*-chlorobenzoic acid in benzene solution appears at 1717 cm^{-1} with the peak for the associated species at 1690 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The chelated form of salicylic acid in benzene solution shows an absorption band at 1687 cm^{-1} with a shoulder arising from the unchelated monomer at 1710 cm^{-1}. The band for the associated species appears at 1655 cm^{-1}.

3. Region of the O—H In-plane Bending and the C—O Stretching Vibrations

Figure 3 shows the spectra observed in the region 1250 to 1500 cm^{-1} for the three acids

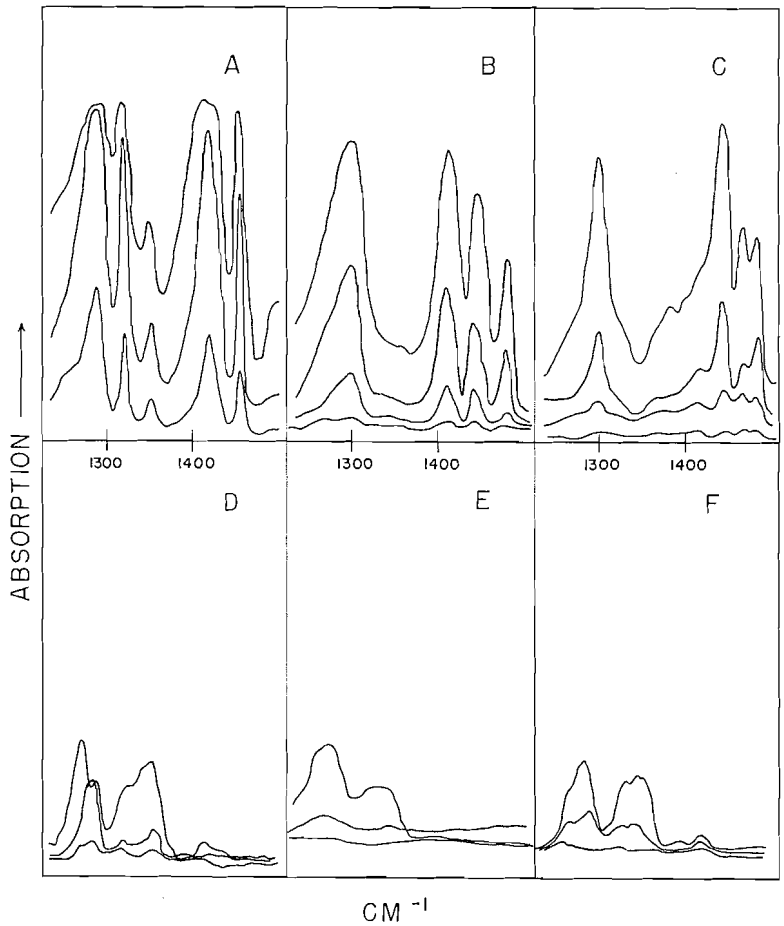

FIG. 3. Region of the O—H in-plane bending and C—O stretching: A, benzoic acid in carbon tetrachloride at concentrations 32, 8.2, and 1.3 millimoles per liter; B, orthochlorobenzoic acid in carbon tetrachloride at concentrations 12.8, 3.84, 1.15, and 0.35 millimoles per liter; C, salicylic acid in carbon tetrachloride at concentrations 6.58, 1.98, 0.59, and 0.18 millimoles per liter; D, benzoic acid in benzene at concentrations 17.2, 3.4, and 0.68 millimoles per liter; E, orthochlorobenzoic acid in benzene at 12.8, 3.84, and 1.15 millimoles per liter; F, salicylic acid in benzene at concentrations 14.5, 4.4, and 1.32 millimoles per liter.

in both the solvents. The spectra in benzene are rather poorly defined in this region as a result of the solvent absorption. It is noteworthy, however, that the bands appearing between 1400 and 1500 cm^{-1} in carbon tetrachloride solution are essentially absent for the acids in benzene solution. Hadzi and Sheppard (4) have reported 1420 and 1287 cm^{-1} in this region for the characteristic frequencies of the COOH group of solid benzoic acid.

The internal co-ordinates of the COOH group which might account for the frequencies in the region between 1500 and 800 cm^{-1} are the C—O stretching, O—H motion perpendicular to the plane of the dimer, or the torsional motion of the O—H band about the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

C—O linkage for the monomeric molecule. The assignment of these modes to this frequency range has been confirmed by Hadzi and Sheppard (4), who observed the behavior of the two bands corresponding to the in-plane and the out-of-plane O—H bending on deuteration. One is, however, left with the ambiguity with regard to distinguishing the C—O stretching and the O—H in-plane bending frequencies in the region of 1450–1300 cm^{-1}. They both belong to the same symmetry species and might be expected to interact appreciably. While there is a marked disagreement in the literature concerning their precise assignments, and Hadzi and Sheppard (4) have also concluded that a clear-cut assignment in terms of the C—O stretching and O—H in-plane bending vibrations is not possible, the present results, as discussed below, favor the assignment of the band $\backsim$1400 cm^{-1} to the O—H in-plane bending mode. This is also compatible with the unambiguous assignment, by Hadzi and Sheppard (4), of the band at 1050 cm^{-1} in the COOD group to the O—D in-plane bending.

4. Region of the O—H Out-of-plane Bending Vibration

Figure 4 shows the region of the O—H out-of-plane bending vibration for the three

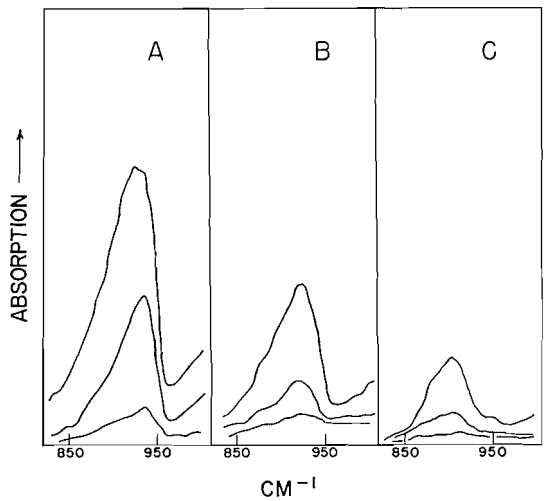

FIG. 4. Region of the O—H out-of-plane bending: A, benzoic acid in carbon tetrachloride at concentrations 32, 8.2, and 1.3 millimoles per liter; B, orthochlorobenzoic acid in carbon tetrachloride at concentrations 12.8, 3.84, and 1.15 millimoles per liter; C, salicylic acid in carbon tetrachloride at concentrations 6.58, 1.98, and 0.59 millimoles per liter.

acids in carbon tetrachloride solution. That this region is definitely that of the O—H out-of-plane bending has been suggested on less direct experimental evidence by Davies and Sutherland (1) and confirmed by Hadzi and Sheppard (4). The changes in this band caused by dilution in carbon tetrachloride solutions are as spectacular as those occurring for the O—H stretching frequencies. The interest in the study of this band also stems from the energy change implied by the deviation from a linear hydrogen bond configuration. This band was absent in benzene solution.

The absence of these bands in the benzene solution may be caused by the relatively strong absorption of the solvent in this region. However, data from the region of the O—H stretching vibration indicate that benzene interacts with the O—H sufficiently to shift the monomer O—H bands by about 100 cm^{-1} on changing from carbon tetrachloride to benzene solution. This interaction may also act to suppress the O—H bending vibrations in both the in-plane and the out-of-plane modes. This possible explanation for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

absence of appreciable bands for all the three acids in benzene solution at about 900 cm^{-1} and at 1400 cm^{-1} requires further study but appears reasonable.

On the basis of the above explanation for the absence of the O—H in-plane and out-of-plane bending modes in benzene solution, it appears that the absorption peaks appearing in the region of 1400 to 1500 cm^{-1} (Fig. 3A, B, and C) in carbon tetrachloride solutions arise from the O—H in-plane bending modes for the various molecular species. The bands at $\backsim$1300 cm^{-1} therefore can be reasonably assigned to the C—O stretching mode.

CONCLUSIONS

The data presented in Figs. 1 to 4 cannot be considered accurate enough to yield quantitative intensity values. However, the results are semiquantitative and conclusions may be drawn on the basis of the intensity changes with concentration.

An examination of Figs. 1 and 2 indicates that the ratio of associated to monomer form is appreciably higher for all the three acids in carbon tetrachloride than in benzene solutions. Thus, it appears that benzene interacts more strongly with the solute molecules in every case and suppresses to some extent the tendency of the acids to form associated species.

It has been established by cryoscopic methods (9) that benzoic acid exists primarily as a dimer (Fig. 5*b*) in benzene solution. The peaks appearing at 1692 cm^{-1} in carbon

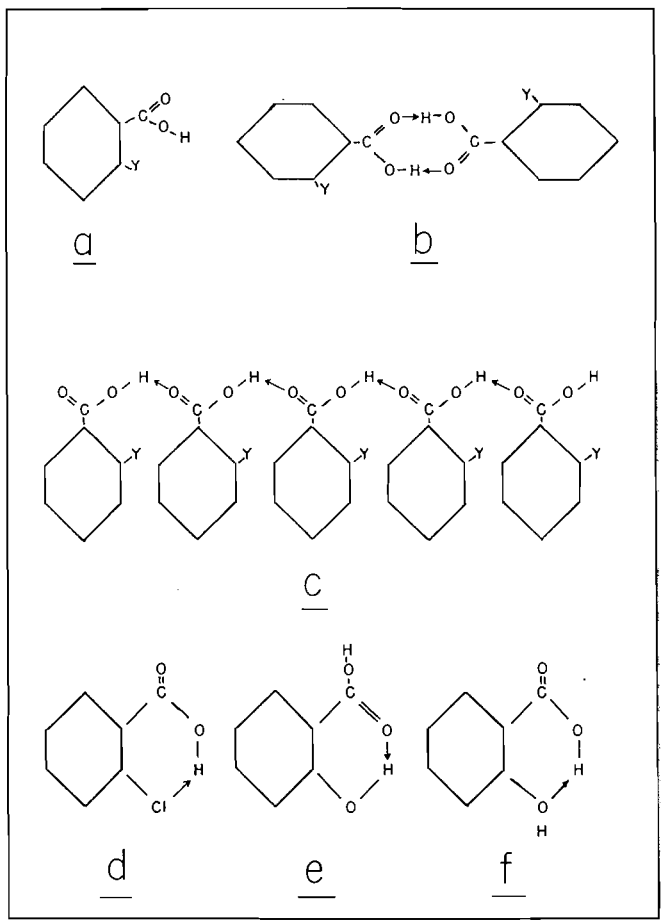

FIG. 5. Various molecular species which may be present in the ortho-substituted benzoic acids.

tetrachloride solution (Fig. 2A), and at 1690 cm^{-1} in benzene solution (Fig. 2D), appear to be the dimer peaks. The results shown in Figs. 1D and 2D indicate that appreciable amounts of the monomer are also present in benzene solution and the C=O peak at 1650 cm^{-1} (Fig. 2D) indicates that some polymer (Fig. 5*c*) or open dimer is also present.

Only two molecular species are present in the *o*-chlorobenzoic acid solution in carbon tetrachloride or benzene. The associated form is most probably a dimer. The results obtained in carbon tetrachloride solution are in agreement with those of Brooks *et al.* (6).

It is noteworthy that the position of the monomer band for the *o*-chlorobenzoic acid in benzene solution is lower by about 40 cm^{-1} than the corresponding band in carbon tetrachloride solution. This large decrease in frequency that occurs on changing the solvent is not apparent in the case of the benzoic or the salicylic acids and may well indicate that the monomer of *o*-chlorobenzoic acid in benzene solution is a chelate form such as that shown in Fig. 5*d*.

The results shown in Fig. 2F indicate that the most stable form of salicylic acid at low concentrations in benzene is the chelate form (Fig. 5*e* or *f*). As the acid concentration is increased, the appearance of the peak at 1655 cm^{-1} indicates the formation of some polymer and the appearance of the shoulder at 1710 cm^{-1} indicates the presence of some unchelated monomer. This unchelated monomer would be expected as an intermediate species arising from the equilibrium

$$\text{chelated monomer} \leftrightharpoons \text{unchelated monomer} \leftrightharpoons \text{polymer.}$$

The strong band at 1660 cm^{-1} for the salicylic acid in carbon tetrachloride solution indicates the presence of large amounts of polymer in this solvent. The presence of unchelated monomer is shown by the shoulder at 1730 cm^{-1}.

As pointed out by Murty and Seshadri (7), the peaks for the associated form of the salicylic acid (Figs. 2C and F) occur at appreciably lower frequency than the dimer peaks for the benzoic acid or for the *o*-chlorobenzoic acid. This raises some question of whether these peaks at about 1655 cm^{-1} arise from dimers or polymers. The occurrence of a polymer peak in the case of the benzoic acid in benzene solution (Fig. 2D) at 1650 cm^{-1} seems to favor the conclusion that the associated species in salicylic acid solution is a polymer form probably of the type shown in Fig. 5*c*.

INFRARED SPECTRA AND THE STRUCTURES OF XANTHATES AND DIXANTHOGENS[1]

M. L. SHANKARANARAYANA AND C. C. PATEL[2]

ABSTRACT

The infrared spectra of representative dialkyl dixanthogens and a few xanthates have been examined. All these compounds have two strong absorption bands in the regions 1140–1265 and 1010–1080 cm^{-1}. On the basis of the shift of the bands with the changes in the substituents in the xanthic acid, the former band is assigned to the C═S group, while the latter to the CO group. Except in the ionic compounds, the canonical structure $-\bar{S}_2C{=}\dot{O}R$ contributes very little to the structures of dixanthogens and covalent metal complexes.

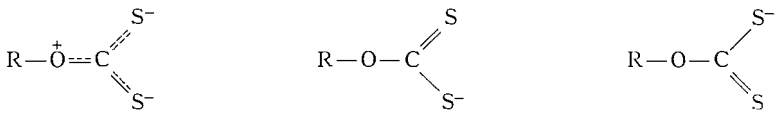
Although infrared spectra of some of the xanthates and dixanthogens have been reported (1–5), an interpretation of the vibration frequencies of C═S and C—O groups of these compounds has not been attempted. The assignment of these group frequencies is somewhat difficult since both of them lie in the same region 1000 to 1275 cm^{-1}. Further, the absorption bands of both these groups are intense and very susceptible to the environmental changes in the molecules. In fact, Bellamy (6, p. 355) has pointed out that the location of the C═S absorption frequency has been a matter of some difficulty in organic thio compounds. Bak (7) *et al.* have assigned the band close to 1200 cm^{-1} to the C═S stretching mode of vibration in dithioesters, while Bellamy and Rogasch (8) have assigned the frequencies between 1000 and 1200 cm^{-1} for different types of thio compounds. These examples point out that the CO and C═S group frequencies fall in the same region. The CO symmetrical stretching vibration takes place around 1030 cm^{-1} in alkyl esters, alcohols, and silicon ethers and around 1200 cm^{-1} in aryl esters (9). In the present paper, it is assumed that the higher frequency around 1200 cm^{-1} is due to the C═S group, while the lower one around 1030 cm^{-1} is due to the CO group. The validity of this assumption is considered later.

Felumb (1) reported the infrared spectra of dimethyl, diethyl, and di-*n*-propyl dixanthogens and arbitrarily located the C═S frequency in the region 1210–1230 cm^{-1}. Little and Leja (2) gave the spectra of diethyl dixanthogen and some xanthates but could not make assignments to the frequencies because of the lack of information of infrared data. The infrared spectrum of potassium ethyl xanthate has been lately reported by several investigators (3–5) but they have not located the group frequencies for C═S and CO groups.

Gordy's Relation and C═S and CO Group Frequencies

Gordy's relation (10), in combination with the equation for the simple harmonic oscillator, has been helpful in assigning the P—S and PO frequencies (11). The same relations have been tried here to get the probable spectral regions for the C═S and CO vibrations. Gordy's relation [1] (10) gives the bond-stretching force constant, $k \times 10^{-5}$ in dynes/cm, as follows:

$$[1] \qquad k = 1.67N\left(\frac{\chi_A \cdot \chi_B}{d^2}\right)^{3/4} + 0.30,$$



where χ_A and χ_B are respectively the electronegativities (in Pauling's scale) of the atoms

[1]*Manuscript received March 6, 1961.*
Contribution from the Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 12, India.
[2]*To whom the correspondence may be addressed.*

involved, d is the internuclear distance between the atoms in Å, and N is the bond order. The values of $k\times10^{-5}$ for C═S and CO are 6.88 and 5.26 dynes/cm respectively (d for C═S is 1.6 Å) (12). By substituting these values in the equation for the simple harmonic oscillator, the frequencies for C═S and CO are 1161 and 1147 cm^{-1} respectively. In the above calculation for CO, d is taken as 1.43 Å, as given by Pauling (12). If, however, the average value of d for CO (1.38 Å) is taken, as deduced by Carrai and Gottardi (13), the ν_{CO} falls at 1170 cm^{-1}. These values of $\nu_{C=S}$ and ν_{CO} are so close to each other, and overlapping, that it is difficult to make assignments to C═S and CO groups when they occur in the same molecule, as in the derivatives of xanthic acids. In the following discussion, an alternative approach is, therefore, made to assign the frequencies on the basis of the effect of the substituents in xanthic acid.

Assignment of C═S and CO Frequencies of Xanthates

The xanthate ion can be represented in the following three forms.

(I) (II) (III)

Dithiocarbamate ion, which is similar to the xanthate ion, is also represented in the same way (14). Analogous to the structure of ionic salts of carboxylic acids, investigated in detail by Lecomte and co-workers (15) from the infrared studies, the structure of xanthate ion in ionic compounds can mainly be represented as a canonical structure (I). In such a case, the π-bond character of C═S will be lowered while the σ bond of CO will acquire a partial π-bond character. This is expected to result in the lowering of the C═S frequency and the enhancing of the CO frequency. This expectation has come true when the corresponding absorption frequencies of sodium ethyl xanthate are compared with those of the symmetrical compound di-*n*-butyl dixanthogen (Table I). The C═S frequency in sodium xanthate is lowered to 1179 cm^{-1}, while that of CO is raised to 1040

TABLE I

Characteristic frequencies of C═S and CO groups of the derivatives of xanthic acid

Substance	Medium	C═S frequency (cm^{-1})	CO frequency (cm^{-1})
Sodium ethyl xanthate (2)	Nujol mull	1179	1040
Potassium ethyl xanthate (3–5)	KCl disk (3) / KBr disk (4)	1143	1055
Potassium *n*-butyl xanthate (2)	Nujol mull	1153	1077
Cuprous ethyl xanthate (2)	"	1200	1037
Zinc ethyl xanthate (2)	"	1212	1035
Lead ethyl xanthate (2)	"	1220	1020
Diethyl dixanthogen	CCl_4 solution	1242 / 1262 (split band)	1026
Diisopropyl dixanthogen	"	1258	1010
Di-*n*-butyl dixanthogen	"	1258	1026
Diisoamyl dixanthogen	"	1258	1024
Ethyl xanthic S-ethyl ester (5)	—	1190	1053–1000 (triply split band)

cm^{-1}, as compared to the respective frequencies of the dixanthogen at 1258 and 1026 cm^{-1}. Now, if sodium is replaced by potassium in the ethyl compound, the ionic character of the xanthate ion will increase according to the Fajan's rule and also according to the lower electronegativity of the bigger potassium ion. We thus expect the π-bond character of C═S to decrease further while that of CO to increase, resulting in further lowering of the C═S frequency and enhancement of the CO frequency. This expectation has also been realized, which is evident from the comparison of the C═S and CO frequencies of the sodium and potassium ethyl xanthates (Table I). The frequency for C═S in the potassium salt is lowered to 1143 cm^{-1} while that for CO is raised to 1055 cm^{-1}. When the ethyl group is replaced by the *n*-butyl group in the potassium xanthate both the C═S and CO bands move to higher frequencies (Table I), probably due to the greater electron-releasing tendency of the *n*-butyl group.

In a covalent compound such as cuprous ethyl xanthate, resonating structures (II) and (III) predominate. No bonding is expected between the covalent copper and π-bonded sulphur. This non-bonding is similar to the behaviors of arsenic (III) (13) and lead (II) (16) in their xanthates, studied by X-ray and electron diffraction respectively. Under such circumstances, the π-bond character of C═S and σ-bond character of CO are greatly enhanced in cuprous xanthate, as compared to those in the alkali metal xanthates. A shift of the C═S to the higher frequency and of the CO to the lower one could be expected for cuprous xanthate. A comparison of the C═S and CO frequencies of cuprous xanthate and of alkali metal xanthates confirms the above reasoning. It is seen from the above discussion that as the metal–sulphur bond strengthens, the CO vibration frequency and its bond order are lowered.

Much experimental data are not available on the spectra of the divalent metal xanthates. The relative shifts of C═S and CO frequencies of zinc and lead ethyl xanthates (Table I) are not in accordance with the electronegativities of their metal atoms. It is possible that other considerations such as the thermodynamic stability and the stereochemistry of the metal xanthates may also be contributory factors in determining the shifts of the C═S and CO frequencies in such compounds.

Apart from the discrepancy encountered in the divalent metal xanthates, the results of the alkali metal and cuprous xanthates are sufficient to indicate that the strong band around 1200 cm^{-1} is due to C═S and the band around 1030 cm^{-1} is due to CO absorption.

C═S and CO Group Frequencies of Dixanthogens

The dixanthogen absorption spectra (Table I and Fig. 1) do not show any appreciable change in the C═S and CO frequencies, even though the alkyl groups of different dixanthogens vary. The C═S group frequency is practically constant at 1258 cm^{-1} while that of CO, at 1025 cm^{-1}. A small shift of CO frequency to 1010 cm^{-1} in the case of diisopropyl dixanthogen is probably due to the vibrational coupling of the CO group with the C—C skeletal stretching vibration. Diisoamyl dixanthogen has also a similar branched alkyl group, but its remoteness from the CO group probably prevents the analogous interaction. The constancy of the C═S group frequency at 1258 cm^{-1} in the dixanthogens is due to the symmetry of the groups in either parts of the molecules. It is interesting to note that the asymmetric ethyl xanthic S-ethyl ester gives the C═S frequency at 1190 cm^{-1}. The splitting of the C═S band of diethyl dixanthogen (Fig. 1) is interesting and peculiar to this dixanthogen. Such a splitting has been observed with this compound both in the solid state (2) and in the carbon tetrachloride solution.

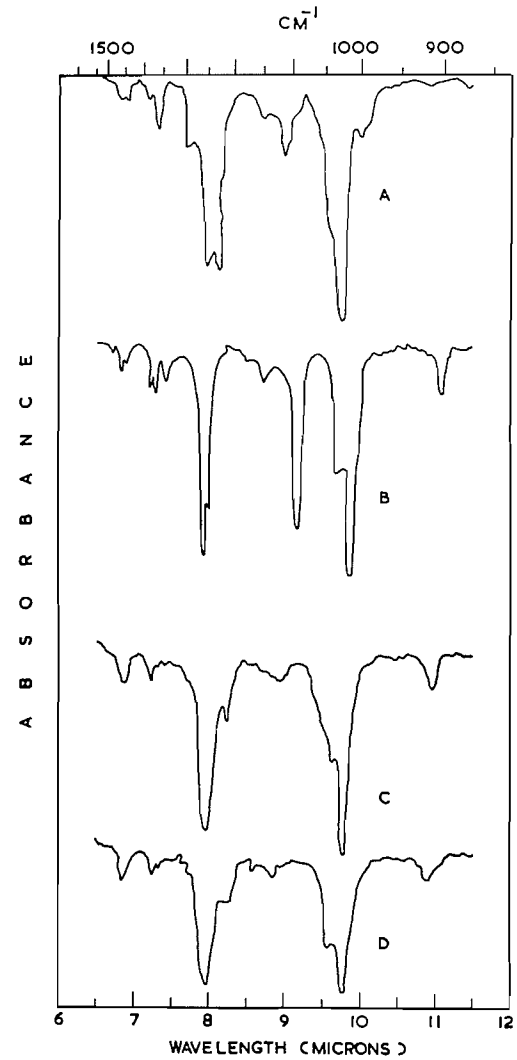

FIG. 1. Infrared spectra of dialkyl dixanthogens. A, diethyl dixanthogen; B, diisopropyl dixanthogen; C, di-*n*-butyl dixanthogen; D, diisoamyl dixanthogen.

EXPERIMENTAL

Dixanthogens

Diethyl, diisopropyl, di-*n*-butyl, and diisoamyl dixanthogens were prepared by oxidation of the respective high-purity potassium alkyl xanthates by iodine and were purified by extraction with petroleum ether (b.p. 40–60° C). The purity of the dixanthogens was over 99.7% as analyzed by the method developed in this laboratory (17).

Spectra

The spectra of the dixanthogens in the region 700–4000 cm^{-1} were obtained in carbon tetrachloride solution (0.1 *M*), with a Perkin–Elmer double-beam recording Infracord spectrophotometer, Model 137. The spectra in the range 850–1500 cm^{-1} with NaCl prism are reproduced in Fig. 1. The infrared spectrum of diethyl dixanthogen in carbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tetrachloride solution agrees well with that of the solid substance given by Little and Leja (2).

Diisopropyl dixanthogen gives rise to a characteristic intense band at 1087 cm^{-1}. This band is peculiar to this dixanthogen and may be due to the rocking mode of vibration of methyl groups, coupled strongly with the skeletal vibration of isopropyl group. A similar band is found around 1100 cm^{-1} in the derivatives of isopropyl alcohol as in isopropyl nitrate (6, p. 368) and diisopropyl ether (18). In the spectrum of the diethyl dixanthogen alone a medium band occurs at 1105 cm^{-1} owing to the rocking mode of vibration of C—CH_3.

ACKNOWLEDGMENT

The authors thank Prof. M. R. A. Rao for his keen interest in this work.

THE CRYSTAL AND MOLECULAR STRUCTURES OF *m*-DINITROBENZENE AND *p*-DINITROBENZENE[1]

J. TROTTER

ABSTRACT

The structures of *m*-dinitrobenzene and *p*-dinitrobenzene have been refined by three-dimensional (F_o—F_c) syntheses. The results indicate that both nitro groups in each molecule are twisted 11° out of the aromatic plane, about the C—N bonds, in contrast to nitrobenzene, where the whole molecule is completely planar. These molecular configurations are shown to be in accord with those which might be expected from intramolecular steric effects. The dimensions of the three molecules have also been compared.

INTRODUCTION

The crystal structure of *m*-dinitrobenzene has recently been reinvestigated using new three-dimensional data, the refinement of positional and anisotropic temperature parameters proceeding by use of the block diagonal least-squares method (1). This analysis yielded a reasonably precise account of the geometry of the molecule: all the carbon and nitrogen atoms are situated on one plane, but each of the oxygen atoms is displaced from this plane by about 0.2 Å, the deviations being in such a sense that the molecular symmetry is *m* within the limits of experimental error. The nitro groups are thus rotated about the C—N bonds out of a completely planar configuration, the angles of rotation being about 11°.

The results of this least-squares refinement are, however, unsatisfactory in several respects. Firstly, there was a large increase (of about 20%) in the over-all scale factor during the three cycles of refinement. Secondly, the final anisotropic temperature parameters vary widely, haphazardly, and do not appear to correspond to any physically reasonable rigid-body vibrations of the molecule. Thirdly, although the deviations of the oxygen atoms from coplanarity suggest that the molecule has symmetry *m*, detailed study of the bond lengths and valency angles indicates that this is very far from being so, the measured values of two chemically identical bonds, for example, differing by 0.12 Å. It seems unlikely that these large bond length differences and large temperature factor variations can be real, and probably they result from some inadequacy of the refinement process. One possible source of error is unsuitability of the weighting system, but the weights used were those normally adopted, and there would appear to be no reason for supposing that they are unsuitable in this case. A second source of error is termination of the refinement process before shifts become negligible, but again the positional and temperature parameter changes in the final cycle were very small, and were not generally in directions which indicated that continued refinement would make the final results more reasonable. Thirdly, introduction of anisotropic thermal parameters at too early a stage in the refinement might introduce errors in positional parameters, but it is difficult to comment on this possible source of inaccuracy; the DEUCE least-squares program used automatically produces anisotropic temperature parameters, although it is, of course, possible to reinsert isotropic ones manually. Another obvious source of error might be inaccuracies in the measured structure factor data, but it is considered that this can be completely discounted, as the photographic records were

[1]*Manuscript received April 7, 1961.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia.

all very good, and inaccuracies in visual intensity estimation are unlikely to produce such wide variations in molecular dimensions and temperature factors as are observed.

In view of all these uncertainties it seemed that some useful information might be obtained by repeating the whole refinement process, using a different method. In order that the results might be comparable with those obtained for nitrobenzene (2), it seemed that differential syntheses would be most convenient, but since no program was available for computing these, it was decided to proceed, instead, by calculating three-dimensional $(F_o—F_c)$ syntheses. The final results should then be equivalent to those which would be obtained from differential syntheses with backshift corrections.

It also seemed that some useful information might be derived from a similar refinement of the crystal structure of *p*-dinitrobenzene. This structure had been investigated previously (3) and the molecular geometry had been established with considerable precision (4), but it was decided that it would be useful to refine it further so that the results would be directly comparable with those obtained for nitrobenzene and *m*-dinitrobenzene.

REFINEMENT OF THE STRUCTURES

m-Dinitrobenzene

Structure factors were calculated for all the observed reflections from the previous final positional parameters of the carbon, nitrogen, and oxygen atoms, but using an isotopic temperature factor $B = 4.5$ Å^2 for all the atoms. The discrepancy factor R was 22%, and the over-all scale factor had returned to the value prior to the anisotropic least-squares refinement. Further refinement proceeded by computing successive $(F_o—F_c)$ syntheses and altering the positional and isotropic temperature parameters to minimize the difference–density slopes and magnitudes at the atomic centers. After two cycles, R had been reduced to 19% and no further significant changes in atomic co-ordinates or temperature factors were indicated. Refinement was terminated at this point so that the results would be directly comparable with those for nitrobenzene. Any further work would require introduction of a contribution from the hydrogen atoms and of anisotropic thermal parameters for the heavier atoms, and in view of the unsatisfactory results which had already been obtained with the only program available to us for carrying out the refinement of anisotropic temperature factors, it was not considered worth while proceeding any further with the refinement. The measured structure factor data previously listed (1) should be multiplied by a scale factor 0.822 to convert them to an absolute scale.

p-Dinitrobenzene

No new structure factor data were collected for *p*-dinitrobenzene, but structure factors were calculated for all the reflections measured by Llewellyn (3), using the positional parameters of the carbon, nitrogen, and oxygen atoms listed by Abrahams (4), with $B = 4.6$ Å^2 for all the atoms. R was 25%. Refinement proceeded as for *m*-dinitrobenzene, and after two cycles of three-dimensional $(F_o—F_c)$ syntheses, R had been reduced to 19% and no further changes were indicated in any of the parameters.

CO-ORDINATES AND MOLECULAR DIMENSIONS

m-Dinitrobenzene

The positional and temperature parameters of the carbon, nitrogen, and oxygen atoms are listed in Table I. The atomic co-ordinates are referred to the principal crystallographic

co-ordinates referred to the principal crystallographic axes and expressed as fractions of the unit-cell edges.

The equation of the plane through the six carbon atoms of the aromatic ring is

$$0.5285X' - 0.6577\,Y + 0.5367Z' = 0,$$

where X', Y, Z' are co-ordinates expressed in Å units and referred to orthogonal axes a, b, and c'; the deviations of the atoms from this plane are given in the last column of Table II. The equation of the nitro group plane is

$$0.6697X' - 0.6313\,Y + 0.3911Z' = 0.1123,$$

and the angle between this plane and the plane of the aromatic ring is 11.8°.

The bond lengths and valency angles in the molecule were calculated from the co-ordinates of Table II, and are shown in Fig. 1*b*. The standard deviations of the atomic positions are about 0.02 Å for all the atoms.

DISCUSSION

The molecule of nitrobenzene in the crystalline state is completely planar within the limits of experimental error, the maximum deviation from the mean molecular plane being 0.03 Å, and the root mean square deviation, 0.016 Å (in comparison with an e.s.d. in atomic position of 0.014 Å). This suggests that the most stable configuration of a typical aromatic nitro compound, with only hydrogen atoms ortho to the nitro group, is a completely planar one. This is, of course, the configuration required by resonance theory, since maximum resonance interaction between the aromatic π-electrons and the substituent nitro group is obtained when the nitro group is coplanar with the aromatic ring. This situation may be contrasted with that in a molecule which has bulky substituents ortho to the nitro group; in a molecule of this type the steric effects of the bulky ortho groups cause the nitro group to be twisted markedly out of the aromatic plane, about the C—N bond. In nitromesitylene, for example, the angle of twist is 66° and the oxygen atoms lie one above and one below the aromatic plane at perpendicular distances of 0.95 Å from it.

The six-membered ring of carbon atoms in the *m*-dinitrobenzene molecule is completely planar within the limits of experimental error, the maximum deviation from the mean plane (Table I) being 0.02 Å and the root mean square deviation, 0.015 Å (e.s.d. of atomic position 0.02 Å). The nitrogen atoms also lie on this aromatic plane (deviations only

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

-0.02 Å for N_1 and $+0.01$ Å for N_2), but the oxygen atoms of each nitro group lie one above and one below the plane, so that each group is twisted about the C—N bond, out of the plane of the carbon and nitrogen atoms, the angles of twist being 12.4° for $N_1O_1O_2$ and 10.3° for $N_2O_3O_4$. The small difference between these two angles is probably not significant, so that each nitro group may be considered to be rotated out of the aromatic plane by 11.4°. The mean oxygen atom displacement from this plane is 0.21 Å, and these displacements are in directions such that the symmetry $mm—C_{2v}$ which would pertain in a completely planar model is reduced to $m—C_h$ (neglecting, for the moment, variations in bond distances and valency angles).

In the *p*-dinitrobenzene molecule all the carbon atoms lie in one plane, within experimental error, the maximum and root mean square deviations being 0.01 Å (Table II). The nitrogen atoms also lie on this aromatic plane, but the oxygen atoms of a nitro group are displaced one above and one below the plane, so that the group is rotated about the C—N bond 11.8°, out of the plane of the carbon and nitrogen atoms. The differences between the oxygen atom displacements are probably not significant, the mean value being 0.21 Å. The displacements are in directions such that the symmetry $mmm—D_{2h}$ possessed by a planar model is reduced to $2/m—C_{2h}$ (only a center of symmetry being required from space group considerations).

We see then that while the nitrobenzene molecule is completely planar, in *m*-dinitrobenzene and *p*-dinitrobenzene the groups are all twisted out of the aromatic planes by about 11°. Since the most stable configuration for the nitrobenzene molecule is apparently a completely planar one, and since the steric considerations in all three molecules are very similar, the author has previously considered that the deviations from planarity in *m*-dinitrobenzene and *p*-dinitrobenzene are probably the result of intermolecular forces (1, 2). However, it is now evident that all the nitro groups in *m*- and *p*-dinitrobenzenes are twisted out of the aromatic planes by about the same amount, although their environments in the crystals are not similar, and this suggests that perhaps some intramolecular steric effects, which are similar for both these molecules but absent in nitrobenzene, are operative.

In order to investigate intramolecular steric effects, planar models were constructed for all three molecules, using for the values of the van der Waal's radii: 1.40 Å for the oxygen atoms and 1.20 Å for hydrogen (Fig. 2). In all three molecules there is apparently

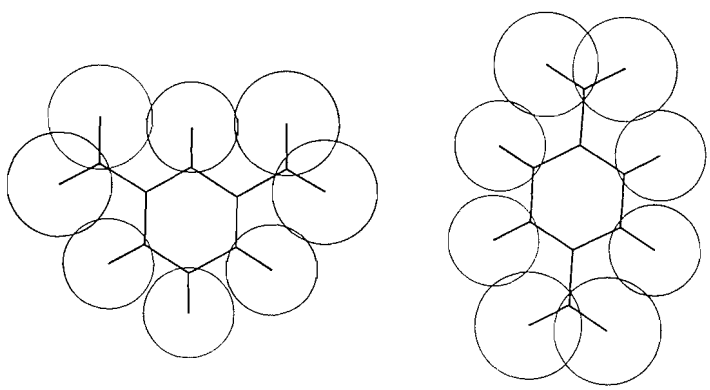

FIG. 2. Coplanar configurations of *m*-dinitrobenzene and *p*-dinitrobenzene, drawn to scale with van der Waals radii: oxygen = 1.40 Å, hydrogen = 1.20 Å.

a small steric interference between the oxygen atoms and the neighboring ortho hydrogen atoms. For nitrobenzene, however (the model is similar to that for *p*-dinitrobenzene, but with one nitro group replaced, of course, by a much smaller hydrogen atom), this steric repulsion can be relieved by small in-plane displacements of the hydrogen atoms, and no displacements of the oxygen atoms from the aromatic plane are necessary. In-plane displacements would clearly be inadequate in the *m*-dinitrobenzene molecule (Fig. 2), where relief of steric repulsions between the oxygen atoms and that hydrogen atom which is ortho to both nitro groups can be accomplished only by out-of-plane displacements. The steric effects in *p*-dinitrobenzene are apparently very similar to those in nitrobenzene, but closer examination of Fig. 2 indicates that any in-plane displacements of the hydrogen atoms would result in steric interferences between these atoms, so that relief of oxygen–hydrogen steric effects would again have to involve deviations of the oxygen atoms from the aromatic plane. These simple considerations of the steric effects are certainly in accord with the experimentally determined molecular configurations.

The variations in the measured bond lengths for *m*-dinitrobenzene (Fig. 1*a*) are smaller than those previously noted in the least-squares refinement, but there is still quite a large difference between the values for two chemically identical bonds. However, a χ^2 test of the differences between the chemically equivalent bonds (Table III) shows

TABLE III

χ^2 test

	Least-squares refinement	Fourier refinement
$\Sigma\,[\Delta(l)]^2$	0.0219 Å^2	0.0107 Å^2
$\sigma^2(l) = [\sqrt{2}\sigma(x)]^2$	<0.0004 Å^2	0.0008 Å^2
$\chi^2 = \Sigma\,\Delta^2/\sigma^2$	>55	13.4
Degrees of freedom	6	6
Probability P	$0.001 > P$	$0.05 > P > 0.01$
Significance level	Highly significant	Possibly significant

clearly that these differences were in the highly significant range in the least-squares refinement, but have now been reduced to the possibly significant range. This improvement is still evident even if $\sigma(x)$ is taken as 0.02 Å for both sets of results. For *p*-dinitrobenzene the measured molecular dimensions (Fig. 1*b*) suggest that the molecule does not deviate from symmetry $2/m$. When the mean bond distances in nitrobenzene (Fig. 1*c*), *m*-dinitrobenzene, and *p*-dinitrobenzene are compared, the most significant feature is that all the C—N distances are greater than the value usually quoted for the C(sp^3)—N single-bond length (1.475 Å). The measured molecular configurations indicate that some force, possibly resonance interaction, is tending to keep the molecules planar, or as nearly planar as steric effects will allow, so that the non-observance of any reduction of the C—N bond distances below the single-bond lengths might be due to the fact that any such reduction would further increase the steric repulsions.

THE OXIDATION OF NITRITE AND IODATE IONS BY HYPOCHLORITE IONS[1]

M. W. Lister and P. Rosenblum

ABSTRACT

The oxidation of nitrite ions and of iodate ions by hypochlorite ions in aqueous solution has been examined. The oxidation of nitrite is really a reaction of hypochlorous acid, with the slow stage $HOCl + NO_2^- + H_2O \rightarrow H_3O^+ + Cl^- + NO_3^-$. The rate constant is given by $\log k = 7.36 - 6450/RT$ (time in minutes, and the activation energy in calories). The oxidation of iodate is chiefly a reaction of hypochlorite ions, probably $ClO^- + IO_3^- \rightarrow Cl^- + IO_4^-$, although the rate is somewhat increased by a higher concentration of hydroxide ions. The rate constant is given by $\log k = 16.15 - 26{,}100/RT$. These results are compared with other oxidations by hypochlorite ions, to see if any general trends are apparent.

Sodium hypochlorite solution will oxidize many substances, and the mechanisms of these oxidations have been the subject of considerable investigation, e.g. ref. 1–4. Some of these reactions have, in fact, turned out to be reactions of free hypochlorous acid, but at present it does not seem possible to predict whether any particular reaction will go through hypochlorite ions or the free acid. On the other hand, there does seem to be a rough correlation between the heats of these reactions and their rates; for instance, the very exothermic oxidation of sulphite ions is very fast, while the slightly endothermic oxidation of iodate ions is slow. This is certainly what might be expected; however, there are one or two notable exceptions, and this matter will be briefly discussed later. The present work was undertaken in order to increase the information on which any generalizations about the reactions of hypochlorites could be based.

1. REACTION OF NITRITE AND HYPOCHLORITE IONS

This reaction has been known in relatively acid solution for a long time, and is the basis of one method for estimating nitrites. Some measurements on the reaction under these conditions have been made by Shilov (5), who found a considerable dependence of the rate on pH over the range 5 to 8. However, he gives very little detail about his results.

The present work was on the reaction in alkaline solution, where it was thought that a reaction of two ions might occur. As will be seen in what follows, this also proved to be a reaction of hypochlorous acid.

Experimental Method

Mixtures in solution of sodium hypochlorite, sodium nitrite, and sodium hydroxide of various concentrations were made up; these were then kept at constant temperature, and analyzed at intervals as described below.

The sodium hypochlorite was made in the usual way from sodium hydroxide and chlorine. The solutions consequently contained sodium chloride in amounts at least equimolar to the sodium hypochlorite. Sodium nitrite and hydroxide stock solutions were made from reagent grades of these chemicals. Reagent grade sodium chloride was added to control the ionic strength.

The solutions were kept stirred in a water thermostat, and, at intervals, 10-ml samples were pipetted out and analyzed as follows. The cooled sample was diluted to a known

[1]*Manuscript received April 13, 1961.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

volume in a volumetric flask, and the optical density of the diluted solution was measured at 292 mμ, where there is a maximum in the absorption spectrum of hypochlorite ions, and at 360 mμ, which is close to the maximum in the absorption spectrum of nitrite ions. A Beckmann DU spectrophotometer was used. The known extinction coefficients for the various ions at these wave lengths were checked on separate samples, and the following values were used in the calculations:

Ion	λ = 292	360 mμ
OCl^-	345	10.2
NO_2^-	8.8	21.8
NO_3^-	6.4	0.01

It was assumed that all nitrogen was present either as nitrite or nitrate; hence, if the original concentration of nitrite is known, measurements at these two wave lengths suffice to determine the concentrations of hypochlorite, nitrite, and nitrate ions. This assumption was justified by the consistency of the results. Most of the disappearance of hypochlorite ions is due to reaction with nitrite, but a small part (between 0.1 and 0.5%) is due to their decomposition to chlorate and chloride ions. This is shown by the slow increase of the difference, $[NO_2^-]-[OCl^-]$. Results from a typical run are given in Table I. The

TABLE I

(Run 1; at 60° C; ionic strength 1.46; [NaOH] = 0.3901 *M*)

Time, min	$[OCl^-]$, *M*	$[NO_2^-]$, *M*	Difference, *M*	$\log [OCl^-]/[NO_2^-]$

481.2	0.0392	0.2698	0.2306	$\bar{1}.162$
692.2	0.0281	0.2587	0.2306	$\bar{1}.036$
1411.6	0.0100	0.2407	0.2307	$\bar{2}.619$

last column gives $\log [OCl^-]/[NO_2^-]$, which should give a straight line when plotted against time if the reaction is first order in hypochlorite and in nitrite ions. This was found to be the case for all runs.

The evaluation of the rate constants was done as follows. Two reactions are occurring simultaneously in the mixture:

$$NO_2^- + OCl^- \rightarrow NO_3^- + Cl^-, \quad k_1,$$

$$2OCl^- \rightarrow ClO_2^- + Cl^-, \quad k_2,$$

where the rate constants are respectively k_1 and k_2. The second reaction is followed by further oxidation of chlorite to chlorate ions. Then if $[OCl^-] = x$, and $[NO_2^-] = y$, these equations require that

$$\frac{dx}{dt} = -k_1xy - \frac{3}{2}k_2x^2,$$

$$\frac{dy}{dt} = -k_1xy.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The rigorous solution of these equations is difficult; but since k_2 is small, an approximate solution can be obtained as follows.

If $k_2 = 0$, it is easily shown that the solution is

$$\ln \frac{x_0 y}{y_0 x} = -k_1(x_0 - y_0)t,$$

where x_0 and y_0 are the initial concentrations. Under these conditions a plot of $\ln(x/y)$ against time would give a straight line of slope $k_1(x_0 - y_0)$.

If k_2 is not zero, the equations above give

$$\frac{d \ln(x/y)}{dt} = k_1(x-y) - \frac{3}{2} k_2 x,$$

and since $(x-y)$ is very nearly constant and k_2 is small, in practice a plot of $\ln(x/y)$ against time does in fact give a virtually straight line. Table I, for instance, shows that in run 1, $(x-y)$ varied by only 0.13%; and the slope of the graph is such that k_1 is of the order of 100 times as large as k_2. If s is the slope of the graph of $\ln(x/y)$ against time, then approximately

$$s = k_1(\overline{x-y}) - \frac{3}{2} k_2 \bar{x},$$

where the bar over the symbols indicates the average value during a run. The rate constant k_1 was calculated from this equation, with the results given in Table II; k_2 was

TABLE II

taken from reference 1, the following values being used:

T, °C	50	60	70
$k_2 \times 10^5$, (g-mol./l.)$^{-1}$ min^{-1}	1.5	5.0	15.5

The values in Table II show that the rate is dependent on the hydroxide concentration; and, in fact, [OH^-].k_1 is approximately constant, as shown by the following values, all for 60° C:

Runs	1, 2	5, 6	7, 8
[OH^-].$k_1 \times 10^3$	2.40	3.11	3.11

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

This is equivalent to saying that the rate is proportional to the hydrogen ion concentration, and the most probable explanation is that this is really a reaction of hypochlorous acid, with

$$\text{rate} = k[\text{HOCl}].[\text{NO}_2^-].$$

Nitrous acid is a much stronger acid than hypochlorous, so it is much more likely that the H^+ is attached to the hypochlorite. On this assumption, the true rate constant, k, is given by

$$k = \frac{k_1[\text{OH}^-]}{K_h},$$

where K_h is the equilibrium constant for the hydrolysis of hypochlorite ions:

$$\text{OCl}^- + \text{H}_2\text{O} \rightleftharpoons \text{HOCl} + \text{OH}^-.$$

The ionization constant of hypochlorous acid is 3.8×10^{-8} at 27° C (6), and combining this with the ionization constant of water, K_h is 3.1×10^{-7} at 27° C. At 25° C, ΔH for this hydrolysis is 11.0 kcal; if we assume that this value holds up to 60° C, then K_h is 1.92×10^{-6} at 60° C. This value cannot be claimed to be very accurate, but is the best available on the present data. Hence $k = 1.61\times10^3$ (g-mol./l.)$^{-1}$ min^{-1} at 60° C.

The data in Table II make the apparent activation energy 17.4 kcal/g-mol. However, since the heat of hydrolysis of hypochlorite ions is 11.0 kcal, the true activation energy is 6.4 kcal. If k is given by the usual formula $k = Ae^{-E/RT}$, then $\log A = 7.41$. This is a rather small value, but there are others as small (see e.g. ref. 7).

Runs 7 and 8, in conjunction with the others, show that the rate constant increases with ionic strength, though the change is fairly small.

2. REACTION OF HYPOCHLORITE AND IODATE IONS

The total reaction here is

$$\text{NaOCl} + \text{NaIO}_3 + 2\text{NaOH} \rightarrow \text{NaCl} + \text{Na}_3\text{H}_2\text{IO}_6.$$

It was checked, by analytical methods given below, that the number of gram-molecules of periodate formed was within 1/2% of the number of gram-molecules of iodate disappearing. This confirms the stoichiometry of the reaction, and also checks the analytical methods. In alkaline solution a precipitate of sodium periodate forms. This was analyzed and found to be $Na_3H_2IO_6$, in agreement with the phase diagram for the system sodium hydroxide, periodic acid, water, as found by Hill (8).

The reaction was followed by mixing solutions of sodium hypochlorite and reagent grade sodium iodate and sodium hydroxide, with sodium chloride added to keep the ionic strength constant. The mixture was kept at constant temperature, and samples for analysis were taken at intervals. It was found that both hypochlorite and periodate ions absorb light strongly at about 300 mμ, so spectrophotometric analysis was not possible. The following titrations were therefore used.

Methods of Analysis

A sample was taken, cooled in ice for a short time, and any sodium periodate was filtered off. The solution was then allowed to warm up to room temperature, and aliquots were pipetted out for analysis. This procedure was necessary, as, otherwise, sodium periodate crystallized from the solution after pipetting. The aliquots were analyzed by the following methods.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(*a*) The aliquot was diluted and mixed with a known volume of standardized arsenious oxide solution and a large excess of sodium bicarbonate. Then 3 g of potassium iodide was added, and the excess arsenious oxide was titrated with standard iodine solution. In this titration the hypochlorite first oxidizes the arsenite to arsenate; and then, on adding potassium iodide, the periodate liberates iodine (which reacts with the arsenite):

$$Na_3H_2IO_6 + 2KI + H_2O \rightarrow NaIO_3 + 2KOH + 2NaOH + I_2.$$

Hence this titration measures hypochlorite plus periodate. It is essential to allow the sodium hypochlorite to react before adding potassium iodide.

(*b*) The aliquot was mixed with excess dilute (about 0.7 *N*) sulphuric acid and boiled for 10 minutes. This treatment destroys hypochlorite, but did not affect the iodate and periodate present. The solution was then cooled, excess potassium iodide was added, and the liberated iodine was titrated with sodium thiosulphate. This titration measures iodate plus periodate.

(*c*) The aliquot was boiled with dilute sulphuric acid as in (*b*). Borax was added in considerable excess (the pH being about 8); then potassium iodide was added and the liberated iodine was titrated with arsenious oxide. This measures the periodate alone.

From these titrations the concentrations of hypochlorite and iodate ions in the solution could be calculated. The constancy found for the difference, $[OCl^-]-[IO_3^-]$, besides being evidence of the stoichiometry of the reaction, is a check on the reliability of the analytical methods. In this reaction, chlorate formation accounted for less than 0.1% of the total decomposition.

The results show that the reaction is first order in hypochlorite and iodate ions; hence the equations that governed the reaction with nitrite apply here also. The results of a typical run are given in Table III.

The values of the rate constant, k_1, are given in Table IV. Inspection of these values shows that there is little change of the rate constant with hydroxide concentration. Apart from a degree of scattering in the constants, there seems to be a definite upward drift of the rate constant with hydroxide concentration. Roughly the constants at 60° C obey the equation

$$k_1 = 5.08\times10^{-2}(1+0.195[NaOH]_0).$$

The main reaction is therefore one of hypochlorite ions, presumably

$$OCl^- + IO_3^- \rightarrow Cl^- + IO_4^-,$$

but there is some third-order reaction with hydroxide ions as well.

The dependence on temperature corresponds to an activation energy of 26.1 kcal/g-mol. Expressing k_1 as $Ae^{-E/RT}$, $\log A = 15.83$. This is a relatively high value, though not unprecedentedly high.

3. DISCUSSION OF RESULTS

A number of oxidations by hypochlorite have now been examined by various workers, and it is of interest to see whether any generalizations can be made. Table V gives a

TABLE V

†This rate is proportional to $[H_3O^+]^2$.

summary of these reactions. The first column gives the reagents indicating whether hypochlorous acid or hypochlorite ions are involved. The activation energies and log A values refer to the reactions as written, allowing for hydrolysis to HOCl where necessary. The ΔH^0 values also refer to the reactions as written, and assume that the reagents and products are all in aqueous solution. The last four entries are for reactions producing, respectively, perchlorate, sulphate, cyanate, and iodate ions. Here only qualitative observations on the rates are available, but the rates are either very fast or very slow.

Table V perhaps chiefly emphasizes our limited knowledge of the reactions of hypochlorites, but slight indications of trends are apparent. In the first place, log A generally falls when E does, so the actual rate constants are not as different as the activation energies would suggest. The fall in log A is not great enough to offset the change in activation energy; in fact it is about half as large as would be necessary for this. At present no general explanation is suggested.

There is some indication that, if the reaction is relatively exothermic, the activation energy is lower. This is perhaps to be expected, since if the new bond to oxygen is strong, this would tend to lower the energy of the activated complex as it is formed. However, this trend is not universal; for instance, the very exothermic oxidation of oxalate has quite a high activation energy. This particular reaction may be a little different from the others, since it is apparently not an oxygen transfer but an electron transfer; although it could be formulated either way. A more puzzling case is the reluctance of hypochlorite ions to oxidize chlorate ions to perchlorate, although this would be a fairly exothermic process. Some of these reactions involve hypochlorous acid, and some hypochlorite ions, but at present no general explanation can be offered for this distinction.

THE ELECTRONIC STATES OF LINEAR METHYLENE[1]

G. W. KING AND G. L. MALLI[2]

ABSTRACT

The electronic energy levels of the linear methylene radical, with r(C—H) = 1.0295 Å, have been calculated by the LCAO/MO/CI procedure. The state of lowest energy has $^3\Sigma_g^-$ symmetry, and is accompanied by low-lying $^1\Delta_g$ and $^1\Sigma_g^+$ states. Allowed intravalence shell transitions from the ground state ($^3\Pi_u$–$^3\Sigma_g^-$, $^3\Sigma_u^-$–$^3\Sigma_g^-$) are too high in energy to account for the observed transition at 8.6 ev, indicating that the latter is of Rydberg type if it is between linear combining states.

INTRODUCTION

A spectroscopic transition in absorption at 8.6 ev, obtained during the flash photolysis of diazomethane, has been assigned to the elusory methylene radical by Herzberg and Shoosmith (1), who showed that the lower combining state has a bond angle between 140° and 180° and is non-totally symmetrical. Although experimental data did not permit a complete analysis, it appeared very likely (2) that the spectrum arises from a $^3\Sigma_g^-$ linear ground state, with r''(C—H) in the range 1.029–1.034 Å. Photolysis of diazomethane in solid inert gas matrices at low temperatures has also yielded a product, tentatively identified as methylene, with absorption bands in the near ultraviolet (3, 4). More recently, further flash photolysis work on diazomethane vapor has revealed an extensive absorption spectrum between 6000 and 9000 Å, which may also be due to methylene (2). This spectrum resembles the α-band system of NH_2 (5) and is probably due to an analogous transition ($^1B_1$–$^1A_1$) between states differing in geometry, but with the $^1A_1$ state lying above the triplet ground state.

Theoretical predictions of the shape and electronic structure of methylene present a divergence of views (6, 7, 8). Apart from these and other qualitative discussions on the nature of the ground state (9, 10), quantitative LCAO/MO/SCF calculations by Padgett and Krauss (11) indicated a $^3B_1$ ground state with an equilibrium bond angle of 120°, while more extensive calculations by Foster and Boys (12) gave the same ground state with an angle of 129°; but in the latter work, the calculated energy of the corresponding $^3\Sigma_g^-$ linear state was greater by only 0.3 ev, a difference that is not significant when compared with the accuracy of the calculation. In both these papers, electronic energy was determined as a function of bond angle, the results confirming Walsh's prediction (13) that if the ground state is a triplet it has linear, or nearly linear, geometry. Walsh also concluded that for such a ground state, the allowed transition at longest wavelengths would occur in the far ultraviolet, but could be either intra- or extra-valence shell in character. However, Padgett and Krauss predicted a low-energy $^3\Pi_u$ state permitting a non-Rydberg ($^3\Pi_u$–$^3\Sigma_g^-$) allowed transition at 1.5 ev; for slightly bent states, the corresponding ($^3B_1$–$^3A_1$) transition would also be expected to lie at fairly long wavelengths.

It is clear that further theoretical work on methylene is desirable. Padgett and Krauss and Foster and Boys have both calculated the energies of a few excited states. We report here the values of a much larger number of these for the linear molecule, obtained by procedures which, on the basis of previous work, give useful semiquantitative results.

By the Franck–Condon principle, calculated energies for transition in absorption should give the positions of vibrational bands of maximum intensity in such excited states as may prove to be bent.

THEORETICAL

The LCAO/MO/CI method is outlined in previous papers (14, 15), whose notation is followed here. Accurate wave functions $\Psi'_k(q_{O\ldots N})$ for the stationary states of a molecular system can be constructed as sums of Slater determinants Φ_p only if a complete set of basic single-electron molecular spin orbitals $\phi_{iv}(\mathbf{r}_v)$ are available. In practice it is necessary to use a restricted number of MSO's as the basic set for approximating to the wave functions of a system. Foster and Boys (12) used exponential functions expanded into a limited number of configurational determinants. On the other hand, in the SCF calculations of Padgett and Krauss (11), Ψ_k was approximated by a single Slater determinant or by a small number of these in linear combination, a modified Hartree–Fock procedure being used to obtain the best MSO's. In general, minimization of the expectation values E_k and E_l for the energies of two states Ψ_k and Ψ_l (necessarily obeying the orthogonality restriction $\int \Psi^*_k \Psi_l d\tau = \delta_{kl}$) will lead to different values of parameters and scaling factors within a restricted set of MSO's from which wave functions are constructed, and energy minimization for each separate state presents a formidable problem in computation. Best SCF ground-state orbitals cannot be assumed suitable for calculating excited-state energies; Padgett and Krauss made this assumption, although they introduced a limited perturbation treatment to compensate for errors.

In the calculation reported here, the basic MSO's were symmetry orbitals constructed from Slater AO's with fixed parameters, and had the same form for all the electronic states considered. This relatively crude approximation simplifies the orthogonalization of wave functions and reduces computation for a large number of electronic states to manageable proportions: errors are reduced by allowing for the interactions between large numbers of configurations. In view of the difficulty of evaluating multicenter integrals over AO's that occur in the calculation, a more sophisticated procedure does not seem justified at present.

Application to Methylene

A linear centrosymmetric geometry was assumed for the radical, with r(C—H) = 1.0295 Å. With Cartesian axes centered on the carbon atom and hydrogen atoms H′ and H″ on the positive and negative z-axis respectively, the basic Slater AO's have the following form:

$$\begin{aligned}
h' \equiv \mathrm{H}'(1s) &= (\delta_{\mathrm{H}}/\pi)^{1/2} \exp(-\delta_{\mathrm{H}} r') \\
h'' \equiv \mathrm{H}''(1s) &= (\delta_{\mathrm{H}}/\pi)^{1/2} \exp(-\delta_{\mathrm{H}} r'') \\
1s \equiv \mathrm{C}(1s) &= (\delta'_c/\pi)^{1/2} \exp(-\delta'_c r_c) \\
s \equiv \mathrm{C}(2s) &= (\delta_c^{5/3}\pi)^{1/2} r_c \exp(-\delta_c r_c) \\
\left.\begin{aligned} \pi \equiv \mathrm{C}(2p_x) &= \\ \bar{\pi} \equiv \mathrm{C}(2p_y) &= \\ \sigma \equiv \mathrm{C}(2p_z) &= \end{aligned}\right\} &\quad (\delta_c^5/\pi)^{1/2} r_c \exp(-\delta_c r_c) \left\{\begin{aligned} x_c \\ y_c \\ z_c \end{aligned}\right.
\end{aligned}$$

with $\delta_{\mathrm{H}} = 1$, $\delta'_c = 5.70$, $\delta_c = 1.57$. The latter value and that for r(C—H) were chosen together to facilitate interpolation in tables of molecular integrals (16); the internuclear separation is itself only defined approximately by experiment. The carbon $2s$ orbital was used in the orthogonalized form,

$$s^0 = (s - 0.20848.1s)/0.97803,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

in evaluating all carbon mononuclear integrals (14). The AO's h', h'', s, π, $\bar{\pi}$, and σ form a reducible representation of the $D_{\infty h}$ point group for the linear molecule

$$\Gamma = 2\Sigma_g^+ + 2\Sigma_u^+ + 2\Pi_u,$$

and the set of orthogonal LCAO/MO's, which form bases for the irreducible representations and were used in the calculation, are given in Table I.

TABLE I

LCAO/MO's for linear methylene

	Symmetry	Analytical form
ϕ_0	σ_g^+	$0.5280s+0.3400(h'+h'')$
ϕ_1	σ_u^+	$0.5300\sigma+0.4200(h'-h'')$
$\phi_2 = \phi_3^*$	π_u	$2^{-\frac{1}{2}}(\pi+i\bar{\pi})$
$\phi_3 = \phi_2^*$	π_u	$2^{-\frac{1}{2}}(\pi-i\bar{\pi})$
ϕ_4	σ_g^+	$1.5500s-0.9995(h'+h'')$
ϕ_5	σ_u^+	$1.4990\sigma-1.1875(h'-h'')$

The carbon 1s electrons were taken as screening the nucleus, leaving a total of 924 different ways of distributing the remaining six electrons among the MSO's ϕ_i to satisfy the Pauli principle. Since each way of doing this gives one determinantal function Φ_p, a very large secular equation would have to be solved for the energy, but the order can be reduced in various ways. A somewhat similar procedure to that used here has been outlined by Slater (17) for the diatomic oxygen molecule. We need only select in the first place those determinantal functions Φ_k with eigenvalue $M_S = 0$ (three α and three β spins for the electrons) of S_z, the z-component of the spin operator, since every electronic state has a component with this eigenvalue. The MSO's ϕ_i and the determinants Φ_k constructed from them are eigenfunctions of the symmetry operators i and C_ϕ of the $D_{\infty h}$ point group, which commute with the Hamiltonian for the system and each other, thus factorizing the secular determinant. Further factorization is achieved by recombining the Φ_k as eigenfunctions of S^2; suitable linear combinations Ω^S are readily found for states with up to four singly occupied MO's, but the 20 states with six singly occupied orbitals were not included owing to the complexity of the wave functions resulting from their spin degeneracy. These states, energetically high in LCAO/MO approximation, should only contribute negligibly to the wave functions $\Psi_k{}^S$ of the states considered below. Finally, for configurations containing partly filled orbitals ϕ_2 and ϕ_3, the Ω^S are not eigenfunctions of the operator σ_v (reflection in a plane through the nuclei), and fresh linear combinations are taken to remedy this. Thus the original secular determinant can be factored into blocks, each referring to one particular symmetry class and multiplicity. These reduced equations were rigorously solved on a Bendix D-15G computer to obtain their lowest roots.

Evaluation of Matrix Elements

The elements of the secular determinants expand into sums of integrals over the AO's, on either one, two, or three nuclear centers. Mononuclear and two-center integrals were obtained from analytic expressions (18, 19) and tables (16, 20), each integral being calculated by more than one method where possible, to minimize errors.

Of the various approximations available, the Ruedenberg–Mulliken method (21) was used for evaluating three-center integrals, by which the latter are expanded as sums of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

one- and two-center integrals. The nuclear attraction integrals $(\sigma:h'h'')$ and $(H'':h'\sigma)$, of form

$$(A:\chi_b\chi_c) = \int \chi_b^*(1)\ |Z_a/r_a|\ \chi_c(1)d\tau_1,$$

were evaluated by the method of Barker and Eyring (22). The Ruedenberg–Mulliken approximation for the integral

$$(h'\pi:h''\pi) = \iint h'(1)\pi(1)\ |1/r_{12}|\ h''(2)\pi(2)d\tau_1 d\tau_2$$

fails here, giving the value zero. Gray, Ross, and Yates (23) found an analogous situation in their work on benzene, and give an approximate formula for the integral which was used in this calculation.

RESULTS

The relative energies of all the states considered are given in Table II. These include: the three states $^3\Sigma_g^-$, $^1\Delta_g$, and $^1\Sigma_g^+$ of lowest energy; the $^3\Pi_u$ and $^3\Sigma_u^-$ states, which can

TABLE II

Calculated energy levels

Symmetry	Calculated energy (ev)		
	This work	Padgett and Krauss	Foster and Boys
$^3\Sigma_g^-$	0.00	0.00	0.00 ev
$^1\Delta_g$	2.17	2.0	2.6
$^1\Sigma_g^+$	3.30	3.7	
$^5\Sigma_g^-$	15.94		
$^3\Delta_g$	19.99		
$^3\Pi_u$	20.35	1.5	
$^3\Sigma_g^+$	21.60		
$^1\Pi_u$	25.56		
$^1\Sigma_g^-$	27.17		
$^3\Sigma_u^-$	27.65		
$^1\Sigma_u^-$	34.46		

spectroscopically combine with the ground $^3\Sigma_g^-$ state; and a number of other states differing in multiplicity from these, whose calculation used many of the same basic integrals. Detailed energy calculations were not carried out for the Π_g states, which cannot combine with any of the three low-lying states, or for the Σ_u^+ states, which cannot combine with the ground state and which, preliminary LCAO/MO calculations showed, were some 40 ev higher in energy.

The low-lying group of states $^3\Sigma_g^-$, $^1\Delta_g$, and $^1\Sigma_g^+$ all arise, in LCAO/MO approximation, from the configuration $(\sigma_g^2\sigma_u^2\pi_u^2)$; similar states occur in the oxygen and boron molecules which also have two electrons in degenerate π-orbitals. The calculated energies agree well with those found by Padgett and Krauss (11) and by Foster and Boys (12), which are also shown in Table II. However, the $^3\Pi_u$ state is found to be 20 ev above the ground state, much higher energetically than in the former authors' calculations, and in accordance with Walsh's predictions (13).

In calculations such as these, the basic set of MSO's does not include extravalence shell orbitals, formed from AO's with quantum number $n > 2$, since values for all the necessary integrals are not readily available. Experimentally it is known that many simple organic molecules have Rydberg states some 10 ev above the ground state, leading

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

to ionization potentials in the 10–15 ev region. These Rydberg states should properly be included in a configuration interaction scheme. In the methylene radical, there are no low-lying excited states which can combine with the ground state; and since the ionization potential is 11.7 ev (24), it must be concluded that the lowest excited states of many species shown at high energy in Table II are in fact largely Rydberg in character, and occur at lower energies. In particular the observed transition at 8.6 ev, if it indeed arises from the $^3\Sigma_g^-$ linear ground state, must be of Rydberg type, as has been suggested (2).

If the absorption spectrum of methylene in the visible region is similar to that of NH_2, then it may well be between the two components ($^1A_1$ and $^1B_1$) into which the $^1\Delta_g$ state transforms on bending. If, as in NH_2, the upper state is linear, the electronic origin of the transition cannot be at energies greater than 2.2 ev, else the actual ground state of the molecule will be bent ($^1A_1$). Both CH_2 and NH_2 show this type of transition in the same spectral region, and detailed analysis for the latter molecule gives the origin at 1.24 ev (5). An origin of similar value for the methylene spectrum is therefore consistent with a linear ground state.

SULPHONIUM SALT SOLVOLYSIS

PART II. COMMON-ION EFFECT AND THE ION-PAIR MECHANISM IN THE SOLVOLYSIS OF DIMETHYL-*t*-BUTYL SULPHONIUM SALTS[1]

J. B. HYNE and J. W. ABRELL[2]

ABSTRACT

The kinetic effect of added common anion in the solvolysis of dimethyl-*t*-butyl sulphonium halides in ethanol–water mixtures is analyzed in terms of a mechanism involving solvolysis through an ion-pair intermediate. The simple ion-pair role, however, does not account for the kinetic behavior at higher added common-anion concentrations. A normal salt effect and further involvement of the ion pair in S_N2 attack by common anion are compared as possible explanations for the observed kinetic behavior.

INTRODUCTION

Evidence presented in the previous paper of this series (1) was interpreted as indicative of the increasing role of an ion-pair mechanism in the solvolysis of dimethyl-*t*-butyl sulphonium salts as the dielectric constant of the medium is reduced. Further experimental

[1] $$\begin{array}{ccc} R_3S^+ + X^- & \overset{K_A}{\rightleftharpoons} & R_3S^+X^- \\ \downarrow k_+ & & \downarrow k_{ip} \end{array}$$

evidence in support of this proposed mechanism is presented in this paper. It is clear from equation [1] that such a mechanism should be affected by the concentration of common anion X^-. Higher concentrations should favor ion-pair formation and a higher proportion of the over-all solvolysis should proceed through the ion-pair intermediate. The over-all rate of solvolysis (k_{obs}) of dimethyl-*t*-butyl sulphonium iodide and chloride has therefore been measured as a function of both added common anion and solvent composition.

In the previous paper of this series it was shown that if the ion-pair mechanism is correct, $k_{ip} > k_+$. Consequently, added common anion should increase the over-all rate of solvolysis (k_{obs}) since a greater proportion of the solvolytic process will proceed through the faster ion-pair pathway. As the dielectric constant of the solvolytic medium is reduced, the ion-pair association constant (K_A) will increase and together with increasing concentration of common anion these factors will result in virtually complete conversion of the sulphonium ion to the ion-pair state. The over-all rate of solvolysis should therefore increase with added common anion and lower dielectric constant but should approach an upper limiting value as the degree of ion pairing approaches 100%.

EXPERIMENTAL METHOD AND RESULTS

All rates were measured by the radiochemical flow counting technique of Hyne and Wolfgang (2). C^{14}-labelled dimethyl-*t*-butyl sulphonium iodide was prepared as described previously (2) and converted to the chloride by metathesis with freshly prepared silver chloride. Solvent mixtures were prepared by weight from doubly distilled water (10^{-7} mhos) and redistilled absolute ethanol. Reagent grades of lithium chloride and iodide

were used as sources of the common anion. The concentration of sulphonium salt used throughout was 1×10^{-3} M except in a few cases noted where rates at concentrations of anion less than 10^{-3} M were required. Observed rates as a function of concentration of added anion and solvent composition are shown in Tables I (a)–(e) for the sulphonium iodide and II (a)–(c) for the sulphonium chloride. All rates were measured at 75.75° C.

The rate data plotted in Figs. 1 and 2 show the predicted increase in rate as common anion is added. The observed initial increase, furthermore, becomes more pronounced as the dielectric constant of the solvent decreases. These phenomena are in keeping with the mechanism proposed in equation [1] since the ion-pair association constant increases as the dielectric constant decreases and consequently the effect of added common anion in displacing the equilibrium to the ion pair will also be greater. However, it is seen from these plots that the k_{obs} does not approach a limiting value as the added anion concentration is increased but becomes linearly dependent upon the anion concentration. Two possible explanations of this effect are offered and the relative merits of each considered in the subsequent sections of this paper. Both interpretations involve the equilibrium between free sulphonium ions and sulphonium ion pairs with the anion as postulated in equation [1]. The values of the ion-pair association constant K_A, obtained by analysis of the kinetic data, are both similar in magnitude and in variation with solvent composition to those obtained conductimetrically for similar sulphonium salt systems. There appears to be little doubt, therefore, that such an ion-pair equilibrium is involved in the solvolysis.

MECHANISM INVOLVING S_N2 ATTACK BY THE ANION ON THE ION PAIR

In this interpretation of the observed kinetic behavior the following extended form of equation [1] is proposed.

[2] $$\begin{array}{ccccc} R_3S^+ + X^- & \overset{K_A}{\rightleftharpoons} & R_3S^+X^- & \xrightarrow[k_{ip}']{+X^-} & \text{products} \\ \downarrow k_+ & & \downarrow k_{ip} & & \\ \text{products} & & \text{products} & & \end{array}$$

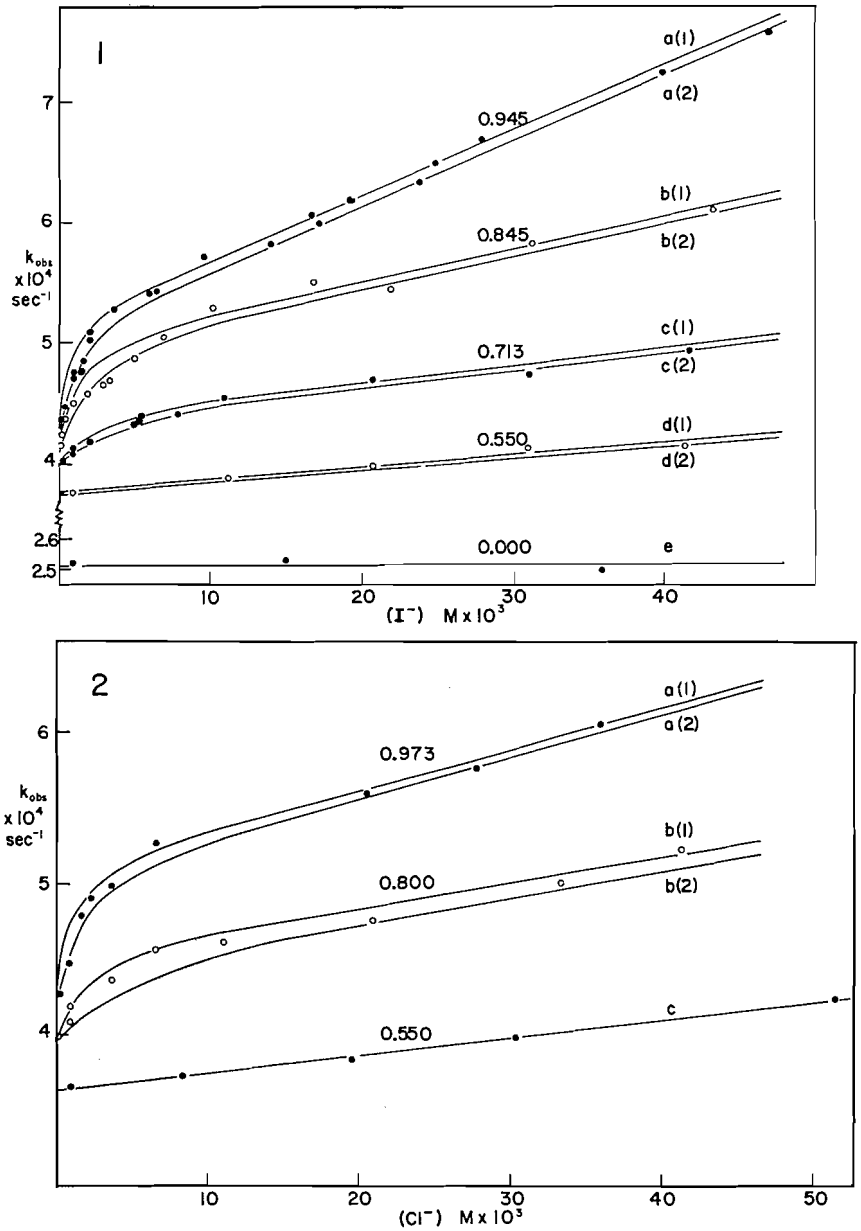

FIG. 1. Fit of experimentally determined k_{obs} (Table I) for dimethyl-*t*-butyl sulphonium iodide solvolysis to calculated curves from kinetic-expression equations [10] or [17]. (See Table III for values of constants for each calculated line.)

FIG. 2. Fit of experimentally determined k_{obs} (Table II) for dimethyl-*t*-butyl sulphonium chloride solvolysis to calculated curves from equations [10] or [17]. (See Table III for values of constants for each calculated line.)

This mechanism differs from that proposed in equation [1] in that a third rate-determining step, k_{ip}', has been added, which is a bimolecular attack of a free halide ion on the ion pair.

Derivation of Rate Equation

Assuming the mechanism proposed in equation [2] above, a rate expression for k_{obs} can be derived. Consider the three paths available for the reaction of the sulphonium salt to dimethyl sulphide and other products; in each case the only assumption made is that dimethyl sulphide is produced in the rate-determining step of each path. From equation [2] the observed rate of production of dimethyl sulphide is

$$r = k_+[R_3S^+]+k_{ip}[R_3S^+X^-]+k_{ip}'[R_3S^+X^-][X^-]. \quad [3]$$

However,

$$[R_3S^+X^-] = K_A[R_3S^+][X^-], \quad [4]$$

and substituting [4] in [3],

$$r = k_+[R_3S^+]+k_{ip}K_A[R_3S^+][X^-]+k_{ip}'K_A[R_3S^+][X^-]^2. \quad [5]$$

The observed pseudo first-order over-all rate of production of dimethyl sulphide, r, must be equal to the rate of removal of the salt (total) if dimethyl sulphide is produced in the rate-determining step of all paths, hence

$$r = k_{obs}[R_3SX]_T. \quad [6]$$

Substituting [6] in [5] and rearranging,

$$k_{obs} = \{[R_3S^+]/[R_3SX]_T\}\{k_+ + k_{ip}'K_A[X^-]+k_{ip}K_A[X^-]^2\}. \quad [7]$$

But at all times,

$$[R_3SX]_T = [R_3S^+]+[R_3S^+X^-] \quad [8]$$

$$= [R_3S^+]+K_A[R_3S^+][X^-]. \quad [9]$$

Substitution of [9] for $[R_3SX]_T$ in [7] and rearranging,

$$k_{obs} = \frac{k_+ + k_{ip}K_A[X^-]+k_{ip}'K_A[X^-]^2}{1+K_A[X^-]}. \quad [10]$$

Equation [10] requires that k_{obs} increases as $[X^-]$ increases due to the k_{ip} and k_{ip}' terms. However, it does not predict a leveling off of the rate at high $[X^-]$ as in equation [1] since when $K_A[X^-]$ becomes large compared with unity and k_+, equation [10] reduces to

$$k_{obs} \doteq k_{ip}+k_{ip}'[X^-], \quad [11]$$

showing a continued linear dependence of k_{obs} on $[X^-]$.

Analysis of Data by Equation [10]

Equation [10] may be rearranged to

$$k_{obs} = k_+ + K_A\{k_{ip}[X^-]-k_{obs}[X^-]+k_{ip}'[X^-]^2\}, \quad [12]$$

which has the general form of a straight line with slope K_A and intercept k_+.

From equation [12] it is seen that k_{obs} is a linear function of a complex term involving $[X^-]$. Thus in order for k_{obs} to follow first-order kinetics, as indeed it does, the $[X^-]$ must be assumed to be constant throughout a given run (i.e. a given determination of k_{obs}). It is now necessary to examine the validity of this assumption for, during the course of a given run, the amount of halide involved in ion pairing will change. On solvolysis

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the sulphonium salt liberates halide, previously tied up in ion pairs, as HX; as a result the free [X^-] does not remain constant over the entire run. However, inspection of the plots of the basic experimental data (see e.g. ref. 2) shows that first-order behavior of the rate is not observed until some three half lives of reaction have elapsed. This is due to an artifact of the method and not a fundamental change in reaction order (2). Consequently, some 88% of the sulphonium salt has reacted by this point, freeing the halide from ion pairs, and the following half lives over which the rate is determined liberate such a small amount of X^- that the concentration change cannot be detected as affecting the rate of reaction. This concentration effect was corrected for by assuming the total halide concentration present in a given run to be the amount of added lithium halide *plus* 88% of the initial concentration of the sulphonium salt. This corrected halide ion concentration is shown in Tables I and II. It is obvious that this correction is most important at low concentrations of added halide.

An additional complication arises in the computation of the anion concentration, due to the incomplete dissociation of the lithium halide in low dielectric media. Data of sufficient detail is not available to enable precise corrections to be made for this effect. However, the dissociation of lithium chloride in ethanol has been studied (3) and these results show that the salt is still 90% dissociated at 10^{-2} M. Although the neglect of this effect will introduce errors in the analysis presented here these errors will not affect the internal consistency of the treatment although they will be reflected in the absolute values of the constants computed.

The values for k_{ip} and k_{ip}' must be known if K_A and k_+ are to be found graphically. Upon inspection of the data given in Tables I and II and plotted in Figs. 1 and 2, it is noted that after an initial steep rise in k_{obs} with added X^- the relationship approximates linearity. After addition of a sufficient amount of common ion (LiX) the sulphonium ion is present almost entirely in the form of an ion pair, especially in the lower dielectric media where K_A is large. At this point equation [11] should hold. Thus, upon back extrapolation of the linear sections of the plot to zero [X^-], the intercept gives an approximate value for k_{ip} and the slope yields a value for k_{ip}'. Approximate values for k_+ were obtained by back extrapolation of the initial steep section of the plots to zero X^- concentration. As noted in Tables I and II several rate determinations were made at salt concentrations less than 10^{-3} M in order to permit more accurate back extrapolations. Using the approximate values of k_+, k_{ip}, and k_{ip}' so obtained, and arbitrarily chosen values of K_A, best-fit curves, as shown in Figs. 1 and 2, were calculated by successive approximation. In some cases the values of k_{ip} and k_{ip}' had to be altered slightly to obtain better fits. It should be noted that k_+ and K_A are theoretically obtainable from a plot of the experimentally determined values of k_{obs}, [X^-], k_{ip}, and k_{ip}' according to equation [12]. It was found, however, that a plot of this type is extremely sensitive to [X^-] and that the value of the bracketed term in equation [12] is a very small difference between very large numbers. The experimental errors in k_{obs} and [X^-] are therefore too great to permit analysis on the basis of a plot of the function as described in equation [12]. Consequently, resort to the technique of successive approximation to a best fit was necessary.

Figure 1 is a composite of the experimental data for the sulphonium iodide (Table I) and the upper and lower limiting theoretical curves for each set of points computed from equation [10] using the values for the constants shown in Table III. Figure 2 is a similar composite for the sulphonium chloride data (Table II), the values for the constants being shown in Table III.

Discussion of Analysis by Equation [10]

The fit of experimental data to curves calculated from equation [10], as shown in Figs. 1 and 2, supports the kinetic model for the solvolysis from which equation [10] was derived. The formal similarity of the rate behavior in this case to that observed by Fainberg and Winstein (4) for the special salt effect in alkyl halide and benzene sulphonate solvolysis is immediately obvious. The similarity arises from the fact that in this case an initial-state ion can solvolyze by ion-pair formation whereas in the alkyl halide and benzene sulphonates a covalent initial state can solvolyze by passing to the ion-pair intermediate.

The ion-pair association constants (K_A) obtained from the kinetic analysis and shown in Table III exhibit the same form of dependence on solvent dielectric as those reported from conductance measurements on the trimethyl sulphonium iodide system (5, 6). The orders of magnitude are also comparable. This observation can be interpreted as further support for the proposed mechanism. It is also noted that K_A (I^-) > K_A (Cl^-) in a given solvent medium, which is in keeping with the observed order of ion-pair association constants for lead (7) and lithium halides (8). The probable error associated with the K_A values determined by the kinetic analysis is large compared with the accuracy attainable in modern conductimetric methods. It should be noted, however, that in cases such as the sulphonium salt under study here the kinetic method is the only available technique for K_A determination since the salt reacts with the solvent.

In Table IV the percentages of the sulphonium salt (10^{-3} M) present as ion pairs in various solvents with 10^{-2} M added common anion are shown. These values are calculated

0.550	1.5×10^2	60
0.000	~20	~25

from the median values of K_A for each solvent composition shown in Table III for the iodide case. A similar table may be constructed for the chloride system but the iodide case suffices for illustration. The concentration of added common anion of 10^{-2} M was chosen since inspection of Fig. 1 will show that in all solvent compositions the dependence of k_{obs} on added common anion has become linear at this point. It is seen from Table IV that in all solvent compositions above 0.550 mole fraction ethanol more than half of the sulphonium salt is present as ion pairs at this concentration of added common anion. It is beyond this concentration of added anion that the S_N2 attack of the anion on the ion pair is postulated to be important. The fact that most of the sulphonium salt is present as the ion pair and that there is at least a 10-fold excess of anion over sulphonium salt establishes that the necessary species for such a mechanism are present in abundance.

The early interest in the solvolysis of sulphonium salts was primarily due to the fact that such systems represent the case where charge is dispersed on passing to the transition state and the rate would be expected to increase with decreasing dielectric constant. It is clear from the data presented here, however, that the observed rate (k_{obs}) is not the rate of solvolysis of the ion in lower dielectric media. Hence previous attempts to correlate the observed rate with dielectric constant have been unsuccessful. In this analysis, however, values for k_+ are obtained (as shown in Table III) over the whole solvent composition range. These values are plotted versus dielectric constant in Fig. 3 and describe a linear relationship. The additional points in Fig. 3 at $D = 37$ (0.324 mole

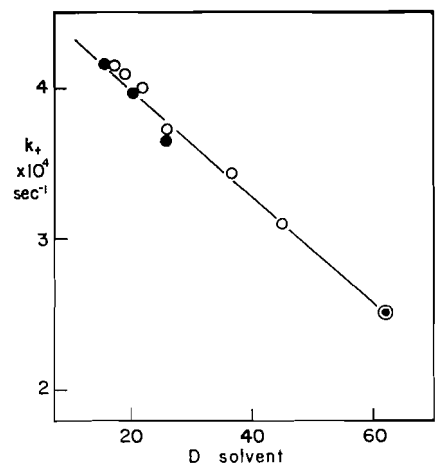

FIG. 3. k_+ versus dielectric constant of solvent: ○, iodide; ●, chloride.

fraction ethanol) and $D = 45$ (0.203 mole fraction ethanol) are computed from rates for the solvolysis of dimethyl-*t*-butyl sulphonium iodide at 50.3° and 78.4° (9). Figure 3 also shows that the k_+ values for both the chloride and iodide salts lie on the same line, an observation consistent with the kinetic model proposed, since k_+ is a measure of the rate of solvolysis of the free sulphonium ion and does not involve the anion in the rate-determining step.

The dependence of k_{ip} and k_{ip}' on dielectric constant of the solvent is shown in Fig. 4(*a*

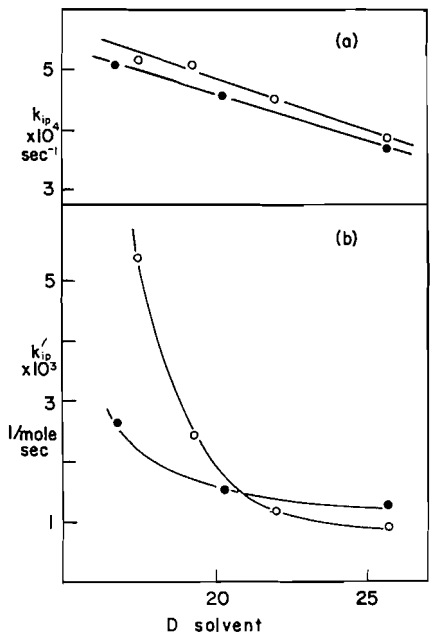

FIG. 4. (*a*) k_{ip}, (*b*) k_{ip}' versus dielectric constant of solvent: ○, iodide; ●, chloride.

and *b*). According to the kinetic model presented previously, both rates should show a dependence on the nature of the anion since this species is involved in the rate-determining step. Such a dependence is noted in both cases but is considerably greater in the k_{ip}' than in the k_{ip} rate. Furthermore the dielectric-constant dependence of k_{ip}' is larger than that of k_{ip}. The mechanism proposed to account for these observations together with the other features of the over-all solvolytic process are summarized in Fig. 5.

The S_Ni-type mechanism proposed for the rate process k_{ip} is in keeping with the first-order character of the rate constant. Formal charge is presumably partially dispersed in the initial ion-pair state so that little change in charge character results on passing to a transition state involving intramolecular nucleophilic attack of the halide component of the ion pair on the adjacent *t*-butyl carbon atom; hence the relative insensitivity of k_{ip} to solvent dielectric constant changes. Dimethyl sulphide is liberated in the rate-determining step as assumed in the kinetic analysis and *t*-butyl halide is also formed. Subsequent solvolysis or elimination of the *t*-butyl halide to yield alcohol or olefin will not be rate determining since the rates of such reactions under the experimental conditions used in this work are considerably greater than those of the sulphonium salt rates (10, 11). It is perhaps a little surprising that the rate differences between the iodide and chloride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

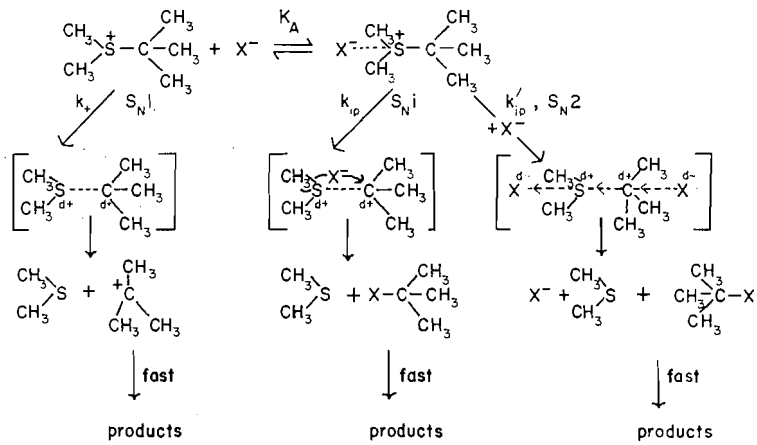

FIG. 5.

salts are not greater than those observed in Fig. 4(*a*). The small differences, however, are in the expected order since the iodide ion is more nucleophilic than the chloride ion and should react somewhat more readily in the S_Ni mechanism.

The bimolecular mechanism proposed for the rate process k_{ip}' is in accord with the second-order form of this constant. In low-dielectric media the bulk of the sulphonium ions are readily converted to ion pairs by initial addition of small amounts of common anion (see Table IV) so that further additions provide halide ions which participate in S_N2-type attack on the ion pair. The marked dependence of k_{ip}' on dielectric constant (Fig. 4(*b*)) is characteristic of reactions involving the dispersal of ionic charge in the formation of the transition state. Such would be the case in the mechanism proposed here where a halide ion and an ion pair form a charge-dispersed transition state. The greater nucleophilicity of the iodide ion is also reflected in the relative magnitudes of k_{ip}' for the two salts. It is questionable whether the apparent crossover in Fig. 4(*b*) is real, due to the accuracy with which k_{ip}' can be determined from the best-fit analysis. Dimethyl sulphide is again liberated in the rate-determining step and the subsequent *t*-butyl halide solvolysis is fast.

MECHANISM INVOLVING NORMAL SALT EFFECT

The alternative explanation for the linear dependence of k_{obs} on added common anion at higher concentrations is based on the possible role of normal salt effects. The derivation of the rate expression in this case is exactly similar to that shown previously in equations [3] through [10] except for the omission of the additional k_{ip}' term. The resulting rate equation obtained is

$$k_{obs} = \frac{k_+ + k_{ip} K_A[X^-]}{1 + K_A[X^-]}. \qquad [13]$$

If a normal salt effect is considered, however, k_+ and k_{ip} are not constants independent of $[X^-]$. Using the approximation favored by Fainberg and Winstein (13) for salt effects in other than pure aqueous media these effects can be expressed as a linear function of anion concentration, i.e.

$$k_+ = k_+^0 (1 + a[X^-]) \qquad [14]$$

$$k_{ip} = k_{ip}^0 (1 + b[X^-]). \qquad [15]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Hence

$$[16] \qquad k_{obs} = \frac{k_+^0 + k_{ip}^0 K_A[X^-] + k_+^0 a[X^-] + k_{ip}^0 b K_A[X^-]^2}{1 + K_A[X^-]}.$$

In the derivation of this equation we have made no simplifying assumptions regarding the nature of the normal salt effect. It would be unjustifiable to assume that the constants a and b are equal since they represent the salt effect on two different processes: one, the solvolysis of an ion and the other, of an ion pair. However, from the experimental data plotted in Fig. 1 it is seen that in the more aqueous media, where the bulk of the solvolysis proceeds via the ion (k_+), the slope of the linear section is very small and in pure water virtually zero. This is the region of solvent composition where the salt effect is largely determined by the term $k_+^0 a[X^-]$ in equation [16]. Consequently it seems reasonable to assume that a is small compared with b since in more ethanolic solvents, where the proportion of the solvolysis proceeding through the ion (k_+) is small compared with that through the ion pair (k_{ip}), the salt effect is much greater and is determined by the term $k_{ip}^0 b K_A[X^-]^2$ in equation [16]. As a first approximation, therefore, equation [16] may be written as

$$[17] \qquad k_{obs} = \frac{k_+^0 + k_{ip}^0 K_A[X^-] + k_{ip}^0 b K_A[X^-]^2}{1 + K_A[X^-]}.$$

This approximation is tantamount to the assumption that the normal salt effect on the free sulphonium ion reaction may be neglected (equation [14]) due to the smaller magnitude of this effect compared with that on the ion pair and the diminishing role of the free-ion reaction in lower dielectric media. It should be noted that a simplifying assumption of this kind is necessary at this stage since equation [16] has more unknowns than can be evaluated from the data presently available. The possible errors inherent in this assumption are considered in the discussion of the b values in a subsequent section.

It is seen immediately that equation [17] has the same form as equation [10] derived for the alternative S_N2-type mechanism explanation for the non-limiting rate behavior. Consequently $k_{ip}' = k_{ip}^0 b$, and since $k_{ip}^0 = k_{ip}$ of equation [10], $b = k_{ip}'/k_{ip}$. Values of b so calculated are shown in Table III.

Discussion of Analysis by Equation [17]

The normal salt effect b values obtained from analysis of the experimental data by equation [17] and shown in Table III indicate that a normal salt effect would be one of acceleration since all values are positive. It is further seen that the b values decrease as the dielectric constant of the medium increases. It should be noted, however, that at mole fractions of ethanol of 0.550 and lower, the first-order approximation made in order to simplify equation [16] may become invalid since the $k_+^0 a[X^-]$ term may now be significant compared with the $k_{ip}^0 b K_A[X^-]^2$ term. This suspicion is warranted since in the more aqueous media a larger contribution to the over-all k_{obs} is made by the k_+ term and furthermore, we have no knowledge of how the normal salt effect constant, a, varies with solvent composition. Consequently, while the contribution to k_{obs} from the free-ion pathway (k_+) is still significant, the assumption that the salt effect on this pathway (viz. a) is negligible is a dubious one. This error may be the reason for the apparent similarity of the b values at 0.713 and 0.550 mole fraction ethanol in the iodide case and at 0.800 and 0.550 mole fraction in the chloride case. In both systems the b values at 0.550 mole fraction may be in error due to the increasing significance of the a value.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

There can be no doubt, however, that if a normal salt effect is responsible for the linear dependence of k_{obs} on added anion concentration then this effect is one of acceleration, i.e. a positive salt effect. The prediction of the sign of normal salt effects depends upon a knowledge of the relative charge character of the initial and transition states in the rate-determining step. It is known, however, that for reactions in aqueous media, positive salt effects are observed for reactions between two ions of like sign where the transition state has a higher charge density than the initial state while negative salt effects are noted for reactions between oppositely charged ions where the transition state has a lower charge density due to partial neutralization of the two charges. Since all kinetic evidence indicates that the solvolysis of sulphonium salts involves charge delocalization in going to the transition state, it therefore seems reasonable to expect a *negative* normal salt effect and not a positive one. The validity of extension of these principles to systems in non-aqueous media is supported in the work of Fainberg and Winstein on the solvolysis of toluenesulphonates (4) in ethanol and acetic acid, which demonstrated a positive salt effect, in keeping with the fact that charge is created in moving from the polar initial state to a more ion-like transition state. The b values obtained here refer to the salt effect on a reaction proceeding from an ion-pair initial state to a charge-dispersed transition state. Here the difference in charge character between the two states is presumably even smaller than that between a free sulphonium ion initial state and a charge-dispersed transition state. Yet the b value for the ion-pair process appears to be greater than the a value for the solvolysis from the free ion, as indicated by the virtual independence of k_{obs} on anion concentration in water. There is every indication, therefore, that if our interpretation of the charge character of the sulphonium salt solvolysis is correct, then the observed linear dependence of the rate on salt concentration has the wrong sign for an explanation based on a normal salt effect. Regarding the observed increase in b with lowering of dielectric constant, it is clearly impossible to offer an explanation for this behavior until the more fundamental question of the sign of the effect can be answered.

CONCLUSIONS

There seems little doubt that in the solvolysis of sulphonium salts in media of dielectric constant less than 25, a reaction pathway involving ion pairs plays a significant role. The correspondence between ion-pair association constants obtained from the kinetic analysis and those for similar systems determined conductimetrically appears to be too close to be fortuitous. There still remains considerable doubt, however, about the explanation for the observed linear dependence of the over-all rate of solvolysis on added salt at higher concentrations when the sulphonium salt is largely in the form of ion pairs. The evidence at the moment would appear to favor an explanation based upon the onset of a third S_N2-type attack by anion on the ion pair but there is as yet insufficient evidence to exclude conclusively an explanation based on a normal salt effect. Further work on the effect of added non-common ions and investigation of the stereochemistry of the solvolysis of salts with optically active alkyl groups should provide the necessary information to enable a distinction or an assignment of relative roles of the two phenomena to be made.

THE VELOCITY OF RATE-CONTROLLING SURFACE DIFFUSION REACTIONS IN THE ELECTRODEPOSITION OF METALS AS A FUNCTION OF DISLOCATION DENSITY[1]

H. KITA, M. ENYO, AND J. O'M. BOCKRIS

ABSTRACT

The rate constant for the surface diffusion velocity of Cu adions in the deposition of Cu appears to depend on the current density of measurement. An interpretation is suggested in which it is proposed that the number of growth sites during the deposition of Cu under "monolayer" conditions depends upon potential, owing to the dependence of the critical radius for growth upon supersaturation. Calculations based upon this hypothesis are compared with experiment. The dependence of the shape of the Tafel relation in metal deposition (transient conditions) is related to the effect of changing the number of "active" growth sites.

1. INTRODUCTION

It has been recently suggested (1, 2) that in the buildup of the first few layers of a metal surface at low current densities in electrodeposition, the surface diffusion of adions (2), from the sites at which they land on the metal from the solution to growth steps on the metal surface, is the rate-determining step in the over-all reaction $M^{z+}+ze_0^- = M$. Evidence for a similar rate-determining step in dissolution is available (1). The velocity of surface diffusion may be expressed approximately by

$$V_{\text{diff}} = v_0\left(\frac{c_x - c_0}{c_0}\right) \qquad [1]$$

where $v_0^* = D(c_0/x_0^2)$, c_x is the concentration of adions at distance x from a growth step, c_0 is their concentration at $x = 0$ or the concentration at equilibrium, D is the surface diffusion coefficient, and x_0 is the half distance between growth steps. If the concentration of growth steps is independent of the current density, i, of deposition and dissolution, x_0 and hence v_0 should be independent of i, and this was the approximation made in the first quantitative theory of surface diffusion control for metal deposition or dissolution (1).

Evidence is now available (3, 4) which shows that on Cu and Ag, v_0 increases with i; at low current densities, there is a rough proportionality between v_0 and i. It will be shown here that this result is consistent with the model of rate-controlling surface diffusion already discussed, if the dependence on potential of the number of dislocations which may form growth steps is taken into account.

The assumption of the independence of dc/dx with x, implicit in [1], may be dropped (4); whereupon $\partial^2 c_x/\partial x^2 \neq 0$, so that, during steady-state deposition at a constant overpotential, and assuming a surface far from saturation in respect to adion concentration,

$$D\left(\frac{\partial^2 c_x}{\partial x^2}\right) + \frac{i_0}{ZF}\exp(-\alpha_c F\eta/RT) - \frac{i_0}{ZF}\exp(\alpha_a F\eta/RT) = 0, \qquad [2]$$

[1]*Manuscript received March 27, 1961.*
Contribution from the John Harrison Laboratory of Chemistry, University of Pennsylvania, Philadelphia 4, Pa.

**In moles cm^{-2} sec^{-1}. It is the rate of the surface diffusion when the surface adion concentration is that at equilibrium.*

where i_0 is the exchange current density, α_c and α_a the transfer coefficients for the electrochemical reaction, and η the overpotential; F, R, and T have their usual meaning and x is counted from the growth step.

The rate of surface diffusion at $x = 0$ is also equal to the rate of the over-all reaction of deposition and dissolution. In mass per unit area per unit time it is given by

[3] $$V_{x=0} = \frac{D}{x_0}\left(\frac{\partial c}{\partial x}\right)_{x=0}.$$

2. DEPENDENCE OF "EQUILIBRIUM SURFACE DIFFUSION FLUX" UPON CURRENT DENSITY

The critical diameter (5), l_c, which must be exceeded before a nucleus can grow on a surface, is related to the surface free energy of the edge, γ, and the degree of supersaturation, $RT \ln c/c_0$, by (6)

[4] $$l_c = \frac{2A\gamma}{\rho RT \ln \frac{c}{c_0}}$$

where A is the atomic weight, ρ the density, c the concentration of surface adions at the condition considered, and c_0 that at equilibrium. The surface of a real crystal contains a certain concentration of screw dislocations, which constitute surface steps. All steps of length l, the distance between pairs of dislocations, which provide steps having $l > l_c$, will grow when they receive material by means of surface diffusion. Assuming a random distribution of steps of various lengths, it may be shown that (6)

[5] $$\frac{dN_l}{N_0} = 2\frac{l}{\bar{l}^2}\exp\left[-\left(\frac{l}{\bar{l}}\right)^2\right]dl$$

where dN_l is the number of steps of length between l and $l+dl$, $\bar{l}$ is the average length of a step, and N_0 is the total number of steps per unit area. Further, on the assumption of a random distribution, one has that

$$\left(\frac{1}{N_{\text{dls}}}\right)^{1/2} = \bar{l}$$

where N_{dls} = mean number of dislocations cm^{-2}. Hence $\bar{l}^2 N_{\text{dls}} = 1$. But $2N_0 = N_{\text{dls}}$ and hence $\bar{l}^2 2N_0 = 1$, or

[6] $$\bar{l}^2 N_0 = \tfrac{1}{2}.$$

Thus, the number of steps which are active in crystal growth is

$$N_{l>l_c} = \int_{l=l_c}^{l=\infty} 2N_0 \frac{l}{\bar{l}^2}\exp\left[-\left(\frac{l}{\bar{l}}\right)^2\right]dl = N_0 \exp\left[-\left(\frac{l_c}{\bar{l}}\right)^2\right].$$

Using [4] and [6],

[7] $$N_{l>l_c} = N_0 \exp\left[-\left(\frac{2\sqrt{2}A\gamma N_0^{1/2}}{\rho RT \ln \frac{c}{c_0}}\right)^2\right].$$

This number, $N_{l>l_c}$, of steps which will take part in lattice growth influences the rate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of surface diffusion because increase of $N_{\iota>\iota_c}$ decreases x_0 and hence increases v_0 (cf. equation [1]).* A relation between i and v_0 arises because, in steady-state metal deposition or dissolution,

$$V_{\text{diff}} = \frac{i}{ZF}. \qquad [8]$$

Or, using [1],

$$\ln \frac{c}{c_0} = \ln\left(1+\frac{i}{ZFv_0}\right). \qquad [9]$$

Further,

$$v_0 = \frac{Dc_0}{x_0^2} = 8Dc_0N_{\iota>\iota_c} \qquad [10]$$

$$= 8Dc_0N_0 \exp\left[-\left\{\frac{2\sqrt{2}A\gamma N_0^{1/2}}{\rho RT \ln\left(1+\frac{i}{8ZFDC_0N_{\iota>\iota_c}}\right)}\right\}^2\right] \qquad [11]$$

from which v_0 can be determined for a given N_0, $N_{\iota>\iota_c}$ being determined graphically from [7], [9], and [10].

3. THE TAFEL RELATION AS A FUNCTION OF DISLOCATION DENSITY

It has been shown (Mehl and Bockris (1)) that the i–η relation for a metal exchange reaction (adion coverage far from saturation) is

$$i = \frac{i_0[\exp(-\alpha_c F\eta/RT)-\exp(\alpha_a F\eta/RT)]}{1+\frac{i_0}{ZFv_0}\exp(\alpha_a F\eta/RT)}. \qquad [12]$$

Correspondingly, the expression for the concentration of adions as a function of x can be found from [2] for certain boundary conditions. Thus, if

$$c = c_0, \qquad x = 0$$

$$\partial c/\partial x = 0, \qquad x = x_0$$

then (4)

$$\frac{c_x}{c_0} = \exp[-(\alpha_a+\alpha_c)F\eta/RT] + \frac{1-\exp[-(\alpha_a+\alpha_c)F\eta/RT]}{1+\exp[-2X]}\left[\exp(-2X)\exp\left(X\frac{x}{x_0}\right)+\exp\left(-X\frac{x}{x_0}\right)\right], \qquad [13]$$

where

$$X = \left(\frac{i_0}{ZFv_0}\right)^{1/2}\exp(\alpha_a F\eta/2RT). \qquad [14]$$

Hence, from [3] and [13],

$$\frac{i}{ZF} = V_{x=0} = \frac{Dc_0}{x_0^2}\cdot X\cdot[1-\exp(-2F\eta/RT)]\left[1-\frac{2}{1+\exp(-2X)}\right]. \qquad [15]$$

Equation [15] reduces to the normal Butler–Volmer equation for transfer control if $v_0 \gg i_0$, i.e. the rate-controlling reaction is transfer. Hence, qualitatively, it is clear

**The model is applicable only under the condition total quantity of electricity passed ≡ less than one monolayer under which the measurements recorded here were taken.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

from [11] and [15] that if surface diffusion is the rate-controlling reaction at low current densities, transfer control will tend to be rate determining at some higher current density,* as has indeed been experimentally found (1, 4). (It is assumed that the experimental conditions are such that diffusion in solution is always "fast".)

4. COMPARISON WITH EXPERIMENT

Comparison will be made for experimental material on Cu (3). Thus, $A = 63$, $z = 2$, $\rho = 8.9$ g cc^{-1}. Values of c_0D, γ, and N_0 require discussion and no measured values of D for surface diffusion on metals in contact with aqueous solutions exist at room temperature.

One can take the value of c_0, in order of magnitude terms, to be 10^{-10} mole cm^{-2}. The value depends sensitively on surface conditions: an intermediate value of those known experimentally (3, 7) was taken here.

D may be roughly estimated by extrapolation from high-temperature values obtained in the gas phase on Cu (8) by using an activation energy† of the order of 1/20th of the heat of sublimation (6). By this method, one obtains $10^{-6} \sim 10^{-7}$ cm^2/sec. The values thus calculated are, however, concerned with *adatom* movement whilst in the electrodeposition case one is concerned with the movement of adions which have a fractional charge (2). The activation energy for the adions is expected to be higher than that of adatoms, and from considerations of an energy cycle, similar to that described by Conway and Bockris (2); the value of D is found to be reduced by about 10^{-1} from the adatoms to the adion case.

Values of the number of dislocations per square centimeter of metal surface recorded in the literature vary from about 10^8–10^{12} dislocation lines cm^{-2}, the upper limit being for cold-worked material (9). The value of N_0 on a quenched surface would be likely to be some 100 less than that on a cold-worked surface. On the latter type of surface, for Cu, the mean number of dislocation from two methods (energy and density measurements) is about 4×10^{11} cm^{-2} (10). Hence it sounds reasonable to accept 4×10^9 cm^{-2}. In the present calculation, 10^{10} cm^{-2} for N_0 was taken. This higher value seems possible to accept for the following reasons. (i) The basis of the estimate of 4×10^9 cm^{-2} is very approximate (i.e., it is the generally observed order of magnitude for the ratio of the number of dislocations for a quenched, compared with a cold-worked, material). (ii) In the preparation of the specimens, SiO_2 or SiO may evaporate from the Vycor tube or diffuse from the glass sheath of the electrode and introduce increased dislocations into the surface. (iii) According to Hirsch and Silcox (11), 10^{10} dislocations cm^{-2} was observed on the rapidly quenched Al.

γ for Cu has been determined by Udin *et al.* (12), who found 1800 ergs cm^{-2} for a Cu surface at 1100° K. The value for Cu at 300° K can be approximately estimated by use of the Ramsey-Shields equation, using $T_C = 0.6\times T_B$ (cf. *Textbook of physical chemistry* by Glasstone). The value is 2250 ergs cm^{-2}. However, this value refers to surface atoms and it is necessary to have a value of γ corresponding to atoms in the edges to which the surface adions diffuse. The value of γ for a site at which the co-ordination number

**An earlier explanation of the change in the rate-controlling step at higher current densities (1) involved a qualitative interpretation in terms of potential-dependent* nucleation. *This process does not seem a likely path in metal deposition or dissolution on surfaces such as those discussed here until current densities are much higher than those used (except on metals, e.g. vapor-phase dendrites, in which the dislocation density is particularly low).*

†Obtained from calculation of the intersection points of potential energy – distance curves using both a Lennard Jones potential (Burton and Cabrera (6)) or a Morse function (Conway and Bockris (2)).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

is $c_{S,1}$ may be related to that of a surface atom through Stefan's relation, according to which one finds

$$\frac{\gamma_{S,1}}{\gamma_{S,2}} = \frac{1-\frac{c_{S,1}}{c_B}}{1-\frac{c_{S,2}}{c_B}},$$

where $c_{S,2}$ is the co-ordination of the surface atoms and c_B is that of the bulk liquid. Taking $c_{S,1} = 7$, $c_{S,2} = 9$, and $c_B = 12$, one obtains $\gamma_{S,1} = 3750$ ergs cm^{-2}.

Comparison with experiment is shown in Fig. 1. It is seen that, having the above deduced parameters, we can achieve a moderate agreement with experiment.

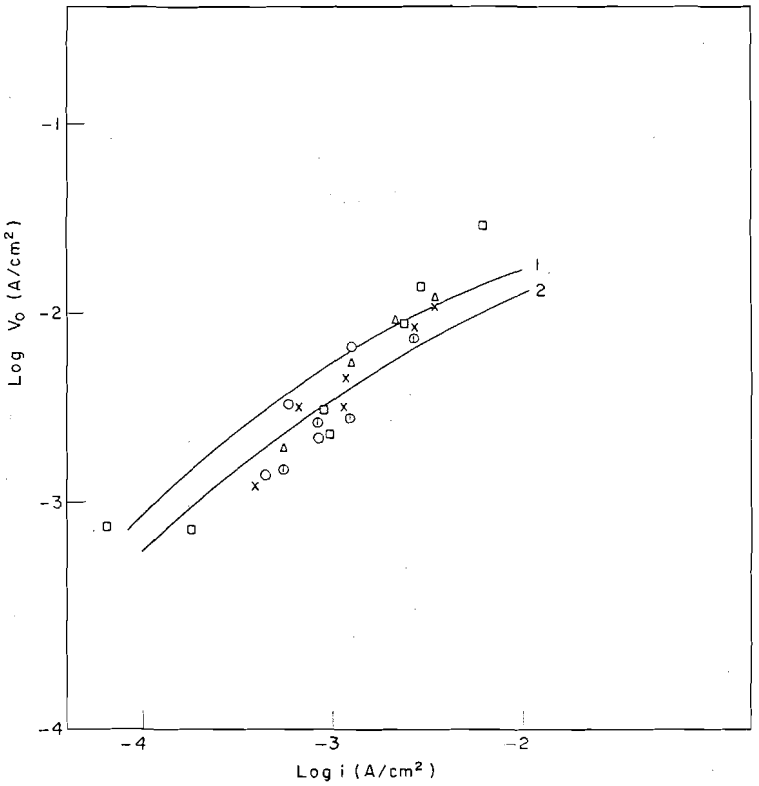

FIG. 1. Change of observed (3) and calculated v_0 with i.
Electrode: quenched electrode in He.
Solution: 0.5±0.1 mole/l. H_2SO_4 and ×, 0.46; ○, 0.30; □, 0.096; △, 0.073; ⊙, 0.012 mole/l. $CuSO_4$.
——: Calculated v_0 using numerical values of $N_0 = 10^{10}$/cm^2, $DC_0 = 10^{-18}$ mole/sec; (1) $\gamma = 2250$ ergs/cm^2, (2) $\gamma = 3750$ ergs/cm^2.

The existence of deviations from the Butler–Volmer equation at low current densities that are due to rate-determining surface diffusion is also well rendered (Fig. 2). With an increasing number of dislocations, the Tafel lines at a given current density (Fig. 2) become increasingly coincident with those for the Tafel equation expected from transfer control. The disappearance of diffusion control with increase of current density, previously reported (1, 7), is thus satisfactorily described.

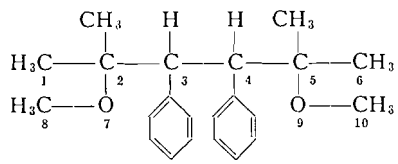
THE PROTON RESONANCE SPECTRA OF THE 2,5-DIMETHYL-2,5-DIMETHOXY-3,4-DIPHENYLHEXANES[1]

S. BROWNSTEIN

ABSTRACT

The relative free energies of the various conformations for the diastereomeric 2,5-dimethyl-2,5-dimethoxy-3,4-diphenylhexanes have been determined. Hindered and free rotation about the various bonds has been observed and assignments of the proton resonance signals to specific conformations have been made.

Proton resonance spectroscopy has been found well suited to the study of hindered rotation in substituted ethanes (1, 2). Hindered rotation in the 2,5-dimethyl-2,5-dimethoxy-3,4-diphenylhexanes has been demonstrated by dipole moment studies (3). The present investigation extends the previous work and provides some quantitative data.

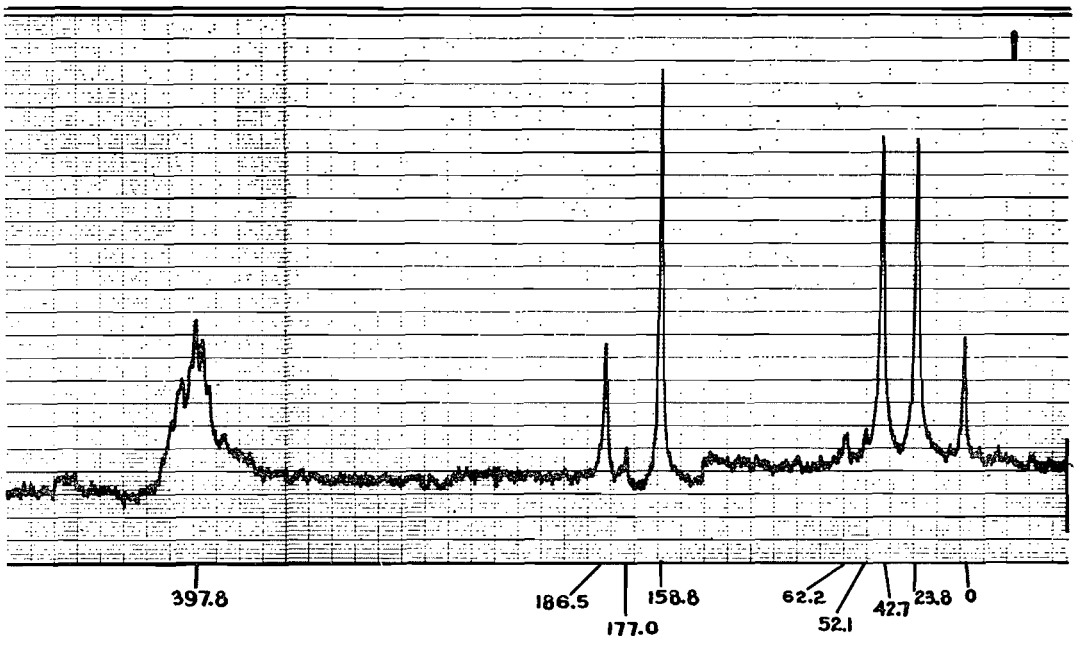


For a substituted ethane with the symmetry CHXY—CHXY there are two non-equivalent conformations for the meso diastereomer and three non-equivalent conformations for the *d,l* diastereomer. In one of the conformations of the meso diastereomer the two hydrogens will be non-equivalent. In the other they will both be equivalent, but will not be in the same environment as either of the hydrogens which are non-equivalent. Therefore if rotation about the central carbon–carbon bond is sufficiently hindered one could theoretically observe one signal from one conformation and a pair of peaks from the other conformation. This assumes that there is a sufficient population of molecules in each of the conformations. However, with rapid rotation, only a single signal will be observed, whose position is the weighted average of the individual signals. All three conformations of the *d,l* diastereomer have the hydrogens of a given conformation equivalent; but each conformation has them in a unique environment. Therefore with hindered rotation one signal should be observed for each conformation. The same conclusions apply to the groups X and Y if they also contain protons.

The relative populations in any two conformations of a given diastereomer will be given by

$$\frac{P1}{P2} = e^{-\frac{\Delta E}{RT}}$$

where ΔE is the free energy difference between the two conformations. Therefore if rotation is sufficiently hindered so that proton resonance signals are observed for the individual conformations, but sufficiently rapid so that thermal equilibrium of the populations is obtained in a reasonable time, then the variation in relative intensities of the signals as the temperature is varied will yield the free energy differences between the conformations.



The rotations and conformations will be discussed with respect to the numbering shown in the following formula.

[1]*Manuscript received April 26, 1961.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 6388.

The methyl groups attached to carbon atoms 2 and 5 may be considered as part of a system of symmetry CX_2Y—CPQR. It has been shown that regardless of the rate of rotation about the central carbon–carbon bond the two groups X will always be magnetically non-equivalent (4). However, if rotation is hindered it may be possible to observe two peaks for each conformation.

The spectra of the meso and *d,l* isomers at 296° K are shown in Figs. 1 and 2. Some of the peaks of the less abundant conformations are too weak to be observed at this temperature but become apparent in spectra obtained at higher temperatures. The chemical

shifts which may be assigned to definite conformations are listed in Table I. The conformations are designated as shown in Fig. 3.

TABLE I

Peak positions of the 2,5-dimethyl-2,5-dimethoxy-3,4-diphenylhexanes

Assignment	meso		Conformation	*d,l*		Conformation
Intense CH_3	23.8	42.7	A	52.0	63.1	D
Weak CH_3	52.1	62.2	B	25.8	42.9	C
Intense OCH_3	158.8		A	178.1		D
Weak OCH_3	177.0		B	160.6		C
Intense CH	186.5		A	191.6		D
Weak CH	179.9	188.9*	B	188.5*		C

*Position likely due to a hydrogen which is between the dimethylmethoxy group and the hydrogen attached to the opposite carbon atom of the central carbon–carbon bond.

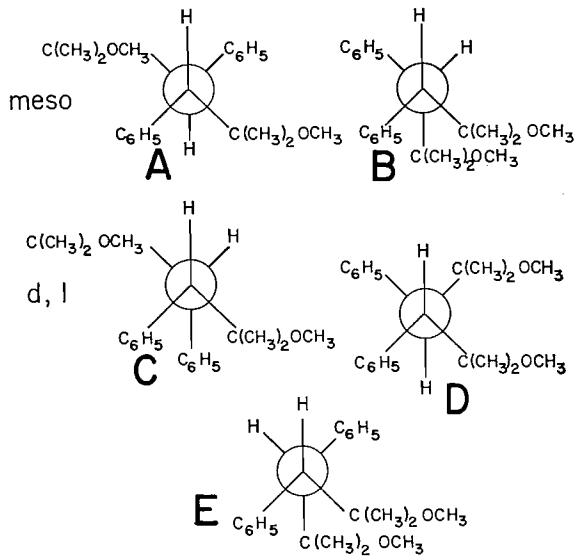

FIG. 3. Conformations of the diastereomeric 2,5-dimethyl-2,5-dimethoxy-3,4-diphenylhexanes.

The assignment to the individual conformations was done according to the following reasoning. Conformation B is the only one with non-equivalent hydrogens on the central carbon atoms; therefore the weak CH peaks must arise from this conformation. The assignment of the other peaks of the meso isomer necessarily follows. The positions reported for the weak CH peaks are those they would have in the absence of spin coupling. Actually, a four-line *AB*-type spectrum is obtained. Analysis yields the peak positions shown and a spin coupling constant of 1.55±0.2 cycles/sec (5). The dihedral angle between these protons in conformation B is 60°. For this angle the Karplus theory of spin coupling predicts a coupling constant of 1.7 cycles/sec, which agrees nicely with this observation (6).

For the *d,l* isomer, the dimethylmethoxy group in conformation C is located between the phenyl and the hydrogen attached to the opposite carbon atom of the central carbon–carbon bond. It is in a similar environment for conformation A of the meso isomer.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Therefore the peaks in the *d,l* isomer which occur in the same position as those of conformation A may be assigned to conformation C. In conformation D the dimethylmethoxy group is located between the hydrogen and the dimethylmethoxy group attached to the opposite carbon atom of the central carbon–carbon bond. It is in a similar environment for conformation B of the meso isomer. Therefore the remaining methyl and methoxyl peaks of the *d,l* isomer are in good agreement with an assignment to conformation D.

Because it is impossible to assign the C—H peaks of conformation B to a given hydrogen of that conformation, one cannot compare the agreement with the position for the C—H peak of conformation C. However, because of the close similarity in chemical shifts it seems likely that the positions marked with an asterisk in Table I are both due to a hydrogen which is between the dimethylmethoxy group and the hydrogen attached to the opposite carbon atom of the central carbon–carbon bond. In both conformations A and D the C—H is located between the phenyl group and the dimethylmethoxy group attached to the opposite carbon atom of the central carbon–carbon bond. In this case there is not very good agreement between the chemical shifts in the two isomers. The assignment of the peaks to conformations C and D cannot be considered as proved; however, excellent agreement in the positions of 14 of the 16 peaks makes the assignment quite probable. No peaks were observed which could be attributed to conformation E.

So far one can say that there is strongly hindered rotation about the 3—4 bond and free rotation about the 1—2, 5—6, 7—8, and 9—10 bonds. There could be either free or hindered rotation about the 2—3, 2—7, 4—5, or 5—9 bonds. However, if rotation is hindered, only one conformation about the bond in question can be present in any appreciable amount. As the temperature is raised it is observed that the peaks due to the methyl groups in conformation B are not of equal intensity. Above 345° K another peak appears at 56.0 cycles/sec. These results may be explained on the basis of strongly hindered rotation about the 2—7 and 5—9 bonds with conformation F of Fig. 4 as the most stable. As the population of conformation G increases with temperature, the relative intensity of the peak at 52.1 decreases and that at 62.2 increases. Eventually the peak at 56.0 is observed. Therefore the peaks at 52.1 and 62.2 may be assigned to conformation F of conformation B, and the peaks at 56.0 and 62.2 to conformation G of conformation B.

These conclusions about free and hindered rotation agree with the results obtained by dipole moment studies (3). Although it is not possible to determine the freedom of rotation about the 2—3 and 4—5 bonds, examination of Fisher–Hirschfelder models indicates that free rotation is likely.

The variation in the relative intensities of the peaks with temperature is shown in Table II. From this, one can calculate that conformation A is more stable than conformation B by 1.72±0.11 kcal/mole. Similarly conformation D is more stable than

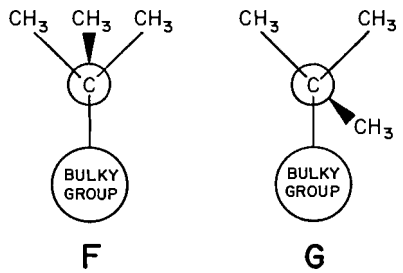

FIG. 4. Conformations about the carbon–oxygen bonds 2—7 and 5—9.

meso	345	—O—CH_3	.083	1.70
meso	371	—O—CH_3	.074	1.91
meso	389	—O—CH_3	.091	1.85

conformation C by 1.92 ± 0.13 kcal/mole. It is also possible to say that conformation F is more stable than conformation G. Because of the low intensities involved it was not possible to get quantitative information. However, it is possible to state that the energy difference between these two conformations, F and G, is much greater for conformation A than for conformation B. No contribution from conformation G was detected in the spectra attributed to conformations C and D. However, it is very likely that the energy difference between F and G in conformation D is also greater than for conformation B since no lines due to G are observed even though the lines from conformation D are quite intense. Because of the greater energy difference of the *d,l* conformations compared to those of the meso diastereomer it is impossible to extend this comparison to conformations B and C.

Only a single signal was seen for the C—H protons in both meso- and *d,l*-1,2-dibromo-1,2-diphenylethane. Their limited solubility did not allow observations below 350° K for the meso isomer and 225° K for the *d,l* isomer. Replacement of the dimethylmethoxy group by bromine, or other less bulky groups, would lower the energy of the barrier to rotation, but would not be likely to decrease the energy difference between conformations. At a temperature low enough for hindered rotation it is quite possible that the more stable conformation would predominate to such an extent that no signals could be observed for the other conformation. Therefore this system does not seem to be a suitable one for determining the relative sizes of groupings by determining the change in the barrier to rotation as these groupings replace dimethylmethoxy.

EXPERIMENTAL

The proton resonance spectra were obtained on a Varian Associates high-resolution nuclear magnetic resonance spectrometer Model V4300C operating at 56.4 Mc/sec. The spectra were calibrated using side-band modulation (7) counted with a Hewlett Packard

For personal use only.

Model 521C frequency counter. The thermostated probe assembly has been described previously (8). The chemical shifts are listed in cycles per second to low field from tetramethylsilane as an internal reference. Solutions in carbon tetrachloride, saturated at room temperature, were used throughout, except for meso-1,2-dibromo-1,2-diphenylethane which was dissolved in bromoform. Since comparisons of intensity were only made for the same grouping in a somewhat different environment, peak heights rather than peak areas were used to determine intensities. For a given grouping the line width at half height was the same in both conformations. The line width for the C-methyl group was significantly greater than for the O-methyl group. This is unlikely to arise from hindrance to rotation about the 1—2 and 5—6 bonds since the line width did not decrease significantly at the higher temperatures. Both diastereomers of 1,2-dibromo-1,2-diphenylethane were prepared as reported in the literature (9).

AN EXTRACELLULAR POLYSACCHARIDE FROM GIBBERELLA FUJIKUROI (FUSARIUM MONILIFORME)[1]

I. R. SIDDIQUI[2] AND G. A. ADAMS

ABSTRACT

Growth of *Gibberella fujikuroi* (*Fusarium moniliforme*) on a glucose medium produced an extracellular polysaccharide containing D-glucose, D-mannose, D-galactose, D-glucuronic acid (molar ratio 1.0:1.1:1.3:0.6), and possibly D-mannuronic acid. Protein was retained tenaciously by the polysaccharide and several deproteinization methods reduced the nitrogen content only slightly. Methylation studies showed that the polysaccharide was highly branched with D-glucose and D-mannose forming the non-reducing ends in the molecule. Most of the D-mannose and D-galactose units were joined by $1 \rightarrow 2$ and $1 \rightarrow 6$ linkages with some branching also at C_2 and C_6 positions; D-galactose occurred exclusively in the furanose form. D-Glucose units were joined by $1 \rightarrow 2$ and $1 \rightarrow 3$ linkages. The D-glucuronic acid residues were mainly non-terminal and were attached to both D-galactose and D-mannose units. Periodate oxidation studies supported the foregoing conclusions.

Although there are many reports in the literature dealing with the isolation of polysaccharides from a variety of fungi (1–4), few investigations of the structural features of fungal polysaccharides have been made. Galactocarolose, a polysaccharide elaborated by *Penicillium charlesii*, has been shown to contain 9–10 β-galactofuranose units linked through the $1 \rightarrow 5$ position (5). A polysaccharide (varianose) containing $1 \rightarrow 4$ linked galactose units terminated by glucose and idose or altrose has been isolated from *Penicillium varians* (6). Barker *et al.* (7) have shown that an extracellular polyglucosan isolated from *Aspergillus niger* consisted of D-glucose units linked α $1 \rightarrow 4$ and α $1 \rightarrow 3$. A recent survey by Martin and Adams (8) of the polysaccharides produced by 31 species of fungi showed a wide variation in sugar components in both the intracellular and extracellular polysaccharides. In this laboratory, four strains of *Fusarium* (*Fusarium lini* NRC 666, 9593; *Fusarium moniliforme* NRC F73; *Fusarium* species NRC 68) and one strain of *Trichoderma viride* NRC v139 were examined for polysaccharide production, using procedures described by Martin and Adams (8). Following this preliminary study, a more intensive investigation was made of the preparation, isolation, and structural features of the polysaccharide from *Gibberella fujikuroi* (*Fusarium moniliforme*) NRC F73, ATCC 10052. The results of this investigation form the basis for the present communication.

G. fujikuroi was grown on buffered enriched salts medium with glucose as the carbon source. The crude polysaccharide was precipitated from the concentrated culture medium by ethanol after the removal of the cells and salts. Addition of 'Cetavlon' (9) to an aqueous solution of the acidic polysaccharide gave a small oily precipitate, an acid hydrolyzate of which showed equal amounts of the same sugar components as were in an acid hydrolyzate of the Cetavlon-soluble fraction. Since no amino sugars were detectable in an acid hydrolyzate of the polysaccharide, it was assumed that the nitrogen content (3.96%) represented mainly protein contaminants. This observation was confirmed by the presence of amino acids (ninhydrin test) in the acid hydrolyzates. Attempts to remove or reduce the protein content of the crude polysaccharide material by the Sevag method (10) were not practicable since considerable quantities of the polysaccharide were removed

[1]*Manuscript received May 4, 1961.*

along with the denatured protein. The conclusion that the protein was firmly bound to the polysaccharide was substantiated by the failure of prolonged tryptic digestion (11) to remove it. The use of phenol–water partition (12), however, produced some purification as shown by the lower nitrogen content of the water-soluble fraction (2.9%) as compared with that of the phenol-soluble fraction (3.8%).

The sugar components of the partially purified acidic polysaccharides were glucose, mannose, galactose, and hexuronic acid (1.0:1.1:1.3:0.6). This sugar ratio was determined in an acid hydrolyzate of the polysaccharide obtained by heating the mixture at 100° C for 3 hours with 2 *N* sulphuric acid, and does not take into account the sugars bound in the uronic acid complexes. Boundary electrophoresis (13) of the polysaccharide in borate buffer showed one major peak along with a smaller stationary peak (Fig. 1) which was

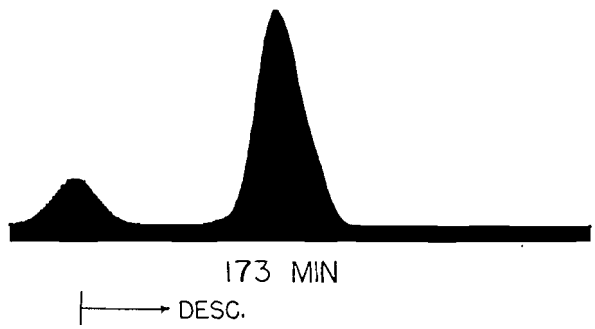

FIG. 1. Electrophoretic pattern of polysaccharide in acetate buffer (pH 5).

presumably a boundary anomaly. The major peak, however, was not symmetrical and hence the polysaccharide may not be homogeneous. The infrared spectrum confirmed the presence of carboxylic acid groupings. The spectrum of the sodium salt showed absorption at 1615 cm^{-1} and 1405 cm^{-1}, which is characteristic of the carboxylate ion. Amide bands (C=O, 1650 cm^{-1}; and —N—H, 1520 cm^{-1}), such as those given by proteins, were also detected. The absence of absorption at 1735 cm^{-1} in the spectrum of the sodium salt of the acidic polysaccharide precluded the existence of *O*-acetyl groups. The ultraviolet absorption spectrum showed an absorption peak at 275 mμ which is characteristic of proteins containing aromatic amino acids (14).

The mixture of sugars produced by heating the polysaccharide with 2 *N* sulphuric acid at 100° C for 3 hours was fractionated first on an anion exchange resin and subsequently on paper chromatograms. From the hydrolysis products, D-glucose, D-mannose, and D-galactose were recovered and characterized either in crystalline form or as crystalline derivatives. The acidic components were identified as D-glucuronic acid, and an aldobiouronic acid which was a glucuronosyl-galactofuranose as established by reduction, methylation, and hydrolysis. Two aldotriouronic acids were isolated in amounts too small to establish their structure; one contained galactose, mannose, and glucuronic acid, the other, galactose, mannose, and a hexuronic acid, which appeared to be mannuronic acid.

The polysaccharide was methylated and the hydrolysis products were separated by chromatography on an anion exchange column and then on paper chromatograms. The weights of the fractions finally isolated, together with that of the di-*O*-methyl uronic acid, corresponded to the following approximate molar ratios: tetra-*O*-methyl hexose, 3;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tri-*O*-methyl hexose, 2; di-*O*-methyl hexose, 2. The components of each of the above fractions along with their relative ratios are listed in Table I. All of these sugars, with the

TABLE I

Yield of methylated sugars

Fraction	Weight (mg)	Components	Molar ratio
Tetra-*O*-methyl hexose	680	2,3,4,6-Tetra-*O*-methyl-D-glucose 2,3,4,6-Tetra-*O*-methyl-D-mannose	3
Tri-*O*-methyl hexose	390	2,4,6-Tri-*O*-methyl-D-glucose 3,4,6-Tri-*O*-methyl-D-glucose 3,5,6-Tri-*O*-methyl-D-galactose 2,3,5-Tri-*O*-methyl-D-galactose 2,3,4-Tri-*O*-methyl-D-mannose 3,4,6-Tri-*O*-methyl-D-mannose	2
Di-*O*-methyl hexose	380	3,5-Di-*O*-methyl-D-galactose 3,4-Di-*O*-methyl-D-mannose 3,6-Di-*O*-methyl-D-mannose	2

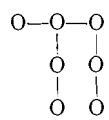
exception of 3,5,6-tri-*O*-methyl-D-galactose and 3,6-di-*O*-methyl-D-mannose, were obtained either in crystalline form or were characterized by the isolation of crystalline derivatives.

The ratio of glucose:mannose:galactose, calculated from the weights of the methylated sugars, was 1.0:1.4:1.1, in reasonable agreement with that found for the original polysaccharide (1.0:1.1:1.3).

The number and proportion of methylated sugars indicated, in general, that the molecule was highly branched. The relatively large amount of tetra-*O*-methyl sugars represented a high proportion of non-reducing terminal units in the molecule. Of these, there was a predominance of glucose over mannose end groups; galactose units were apparently not present on the periphery of the molecule.

A considerable proportion of the main body of the molecule was made up of D-mannose units linked $1 \rightarrow 2$ and $1 \rightarrow 6$ as shown by the occurrence of 3,4,6-tri-*O*-methyl-D-mannose and 2,3,4-tri-*O*-methyl-D-mannose. Lesser amounts of glucose were linked $1 \rightarrow 2$ and $1 \rightarrow 3$. Galactose was recovered as 2,3,5-tri-*O*-methyl-D-galactose and 3,5,6-tri-*O*-methyl-D-galactose on hydrolysis and showed that the D-galactofuranose units were linked glycosidically $1 \rightarrow 6$ and $1 \rightarrow 2$. The presence of 3,5-di-*O*-methyl-D-galactose showed that some of the galactofuranose units formed branch points through C_2 and C_6. Smaller amounts of 3,4-di-*O*-methyl-D-mannose likewise showed that some of the mannopyranose units formed branch points through C_2 and C_6. The tentative identification of 3,6-di-*O*-methyl-D-mannopyranose indicated that some D-mannose units had some minor branching through C_2 and C_4.

Mild acid hydrolysis of the polysaccharide as provided by heating in 0.01 *N* sulphuric acid at 100° C for periods as long as 6 hours did not release any sugars, showing that no more than two furanoside units were contiguous and that no terminal furanoside ring forms were present. This latter observation was further substantiated by the fact that no 2,3,5,6-tetra-*O*-methyl-D-galactose was detected in the cleavage products of the methylated polysaccharide.



Evidence that the major portion of the D-glucuronic acid residues were non-terminal was provided by the identification of 2,3-di-*O*-methyl-D-glucose as a hydrolysis product of the reduced methylated uronic acid isolated from the fully methylated polysaccharide. A small amount of D-glucuronic acid was identified also as 2,3,4-tri-*O*-methyl-D-glucose

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

after separation, reduction, and hydrolysis of the methylated uronic acid components of the fully methylated polysaccharide. The conclusion that some of the uronic acid was attached to the galactose unit was provided by the isolation of a glucuronosyl galactose by partial hydrolysis of the polysaccharide. Hydrolysis of a methylated aldobiouronic acid fraction yielded 3,4-di-*O*-methyl-D-mannose and a methylated uronic acid, showing that some of the uronic acid was attached to D-mannose through C_2 or C_6. Following methanolysis, reduction, and hydrolysis, the uronic acid portion appeared as 2,3-di-*O*-methyl-D-glucose. Hydrolysis of a methylated aldotriouronic acid yielded 3,4-di-*O*-methyl-D-mannose, 3,5-di-*O*-methyl-D-galactofuranose, and 2,3,4-tri-*O*-methyl-D-glucuronic acid. This observation showed that some D-glucuronic units were attached terminally to either unit of contiguous D-galactose and D-mannose residues.

On periodate oxidation, the acidic polysaccharide consumed 1.3 moles of periodate and produced 0.5 mole of formic acid. Acid hydrolysis of the periodate-oxidized polysaccharide gave large amounts of galactose and small amounts of acidic components. Examination of the oxidized polysaccharide by the procedure of Smith *et al.* (15) showed, in addition to the components detected in the acid hydrolyzate, small amounts of arabinose, traces of two components ($R_{glucose}$ 1.01 and 1.23), glycerol, but no erythritol. The absence of erythritol precluded 1,4 linkages in the polysaccharide but the presence of arabinose clearly indicated that at least some of the galactose residues were in the furanose form with C_5 and C_6 unsubstituted. This is in accord with the isolation of 3,5,6-tri-*O*-methyl-D-galactose from the methylated polysaccharide. Galactose units in the furanose form that were not oxidized by periodate were linked through C_2 and C_6 and gave rise to 3,5-di-*O*-methyl-D-galactofuranose as a product of methylation and hydrolysis. The yield of 0.5 mole of formic acid indicated that 50% of the sugar units (pyranose form) were either linked $1 \rightarrow 6$ or were present in non-reducing end groups. Approximately 30% of the residues consumed periodate but did not produce formic acid; such units could be either in the pyranose or furanose form and could be linked $1 \rightarrow 2$. The remainder of the sugar residues did not consume periodate; of these, the pyranose sugars must be linked $1 \rightarrow 3$ or be branched, and the furanose forms must be attached through C_2 and C_6. Such an attachment of the galactofuranose units would account for the relatively high yield of 3,5-di-*O*-methyl-D-galactofuranose obtained on hydrolysis of the fully methylated polysaccharide.

Present data do not permit formulation of a unique structure for the polysaccharide, although certain structural features have been established. However, no certainty exists that the polysaccharide examined was a homogeneous molecule. Electrophoretic examination indicated that minor amounts of other materials were present. On the basis of methylation and periodate oxidation results, it is suggested that an average general repeating unit consisted of seven sugar units arranged in the following pattern.

Such a formulation would not only account for the molar ratio (3:2:2) obtained for the tetra-, tri-, and di-*O*-methyl ethers but would also yield the periodate oxidation result of 1.3 moles periodate consumed, and 0.5 mole formic acid produced. It is suggested that the polysaccharide may consist of repeating units conforming to the general pattern

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

shown above and containing various sugars. Fragmentation studies now being planned are necessary to reveal further fine features of this polysaccharide.

EXPERIMENTAL

The following solvents (v/v ratios) were used for chromatographic separations: (A) *n*-butanol:ethanol:water (5:1:4); (B) butanone saturated with water containing 2% ammonia; (C) benzene:ethanol:water:ammonia (200:47:14:1); (D) *n*-butanol:acetic acid:water (40:1:5); (E) pyridine:ethyl acetate:water (1:2.5:2.5); (F) *n*-butanol:ethanol:water (40:11:19). Sugars, as their borate complexes, were separated by electrophoresis in 0.2 *M* borate buffer (pH 10) and uronic acids were analyzed in acetate buffer (pH 5) (17). All electrophoretic examinations were made on Whatman No. 3MM paper at 700–800 v. Uronic acid content was determined by the method of Barker *et al.* (17). Reducing sugars were detected on paper chromatograms or electrophoretograms with *p*-anisidine hydrochloride spray (18); non-reducing sugars were detected by alkaline silver nitrate (19). Evaporations were carried out at 35° C on a rotary film evaporator. Melting points are corrected and rotations are equilibrium values unless otherwise stated.

Cultural Conditions

The organism *G. fujikuroi* was grown on a culture medium as described by Martin and Adams (8), the glucose solution (20 l.) and the other nutrients were sterilized separately and then mixed aseptically in a bottle of 40-l. capacity. The culture was grown on a malt–agar slant and the spores were used to prepare successively larger batches of inoculum. The final inoculated medium was grown at 29° on a rotary shaker with aeration provided by an air stream of about 1 l. per minute passing over the surface of the solution. The cultures were harvested when 80–85% of the sugar had been consumed.

Isolation of the Polysaccharide

The mycelium was removed by filtration through paper and the filtrate was concentrated about 10-fold at 30° C in a Majonnier evaporator and then dialyzed against cold water (2° C) for 2 days. The non-dialyzable material was poured into 3 volumes of ethanol with vigorous stirring. The precipitate was removed by centrifugation, washed with ethanol and ether, and dried *in vacuo* over phosphorus pentoxide (yield 300 mg/l., 7% based on glucose consumed).

The crude polysaccharide (12 g) was extracted with water to yield a water-soluble fraction (6.4 g) and a water-insoluble residue (5.6 g). Chromatographic and electrophoretic examination of hydrolyzates of each fraction showed that the water-soluble material contained glucose, galactose, mannose, and uronic acid components; the residue contained only traces of glucose and mannose, and was discarded.

Attempted Removal of Protein from the Polysaccharide

The crude, water-soluble polysaccharide had a nitrogen content of 3.96%. Since its acid hydrolyzate gave a negative test for amino sugars (20) and a positive test (ninhydrin) for amino acids, it was concluded that the contaminant was protein.

Fractionation by Cetavlon (9) gave a small oily precipitate which on electrophoretic examination in borate buffer gave the same pattern as the unprecipitated material. Examination, by chromatography, of hydrolyzates of the two materials showed that the same sugars were present in each.

Fractionation by phenol (12) gave a water-soluble fraction having a nitrogen content

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of 2.9% while that of the phenol-soluble material was 3.8%, but the two fractions had identical sugar components.

Digestion with trypsin (11) for 5 days at 35° C did not lower the nitrogen content of the polysaccharide preparation significantly.

Analysis of Acidic Polysaccharide

The polysaccharide ($[\alpha]_D^{28}$ $+12.7\pm1°$ (*c*, 1.02 in water)) on analysis gave the following: N, 2.9%; ash, 3.9%; P, nil; and uronic acid, 15%. Electrophoretic examination in a Spinco apparatus model H in 0.5 *M* borate buffer (pH 9.2) showed a single asymmetric peak (Fig. 1). The polysaccharide (10 mg) was hydrolyzed with 2 *N* sulphuric acid for 4 hours at 100° C. The sugars were recovered and determined quantitatively according to Nelson (21), giving a ratio of glucose:mannose:galactose of 1.0:1.1:1.3.

Acid Hydrolysis of the Polysaccharide

Polysaccharide (1.5 g) was hydrolyzed with 2 *N* sulphuric acid (30 ml) for 3 hours at 100° C. After neutralization ($BaCO_3$) and filtration, the filtrate was slurried with ion exchange resin Dowex 1 (carbonate form, 35 g) for 24 hours. The resin was then washed with water (1 l.) in a column to remove the neutral sugars (0.95 g). The uronic acid fraction was eluted with *N* ammonium carbonate (500 ml) and recovered (0.250 g) by removing excess ammonium carbonate by distillation *in vacuo* at 65–70° C and the remainder with Amberlite IR-120 (H) resin.

A. Neutral Sugars

A portion of the neutral sugars was separated on Whatman 3MM paper using solvent E. Elution with water yielded glucose, mannose, and galactose as syrups.

(i) D-*Glucose*

The syrup was refluxed for 15 minutes with an aliquot (1 ml) of a solution containing *p*-nitroaniline (9 g), methanol (200 ml), and concentrated hydrochloric acid (0.14 ml). The mixture was filtered while hot and after it had cooled, crystallization occurred. Two recrystallizations from methanol gave *N*-*p*-nitrophenyl-D-glucopyranosylamine dihydrate having m.p. and mixed m.p. 184° C. Reported (22): m.p. 184° C.

(ii) D-*Mannose*

The syrup was similarly characterized as *N*-*p*-nitrophenyl-β-D-mannopyranosylamine dihydrate having m.p. 219° C and $[\alpha]_D^{26}$ $-330°$ (*c*, 0.112 in dry pyridine). Reported (22): m.p. 219° C.

(iii) D-*Galactose*

The sugar crystallized from methanol to give m.p. 164–167° C and $[\alpha]_D^{26}$ $+80.2\pm1°$ (*c*, 0.445 in water), and was therefore D-galactose.

B. Uronic Acid Fraction

The acidic sugars (0.25 g) were separated on Whatman No. 1 paper with solvent A. Three main components were recovered corresponding to hexuronic (A), aldobiouronic (B), and aldotriouronic acid (C) respectively. Two very minor components, one (D) near the starting line and another (E) which moved ahead of (A), were recovered in trace amounts.

(i) Hexuronic Fraction (A)

This fraction (20 mg) was converted to its methyl ester glycoside form by refluxing with methanolic hydrogen chloride (2%) for 6 hours. Reduction with lithium aluminum hydride (23) (80 mg) in tetrahydrofuran:ethyl ether solution (4:1) yielded the corresponding methyl hexoside. Acid hydrolysis and paper chromatography showed glucose

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with traces of mannose and galactose. The main hexuronic acid was therefore glucuronic acid.

(ii) Aldobiouronic Acid Fraction (B)

A portion of this fraction (7.5 mg) was hydrolyzed with 2 *N* sulphuric acid for 3 hours at 100° C. Paper chromatography in solvent A showed glucuronic acid, galactose, and some original material. A portion of the acid (70 mg) was converted to its methyl glycoside methyl ester and reduced with lithium aluminum hydride as described above. Examination of the acid hydrolyzate (solvent E) showed glucose and galactose. The methyl bioside (43 mg) was dissolved in tetrahydrofuran (5 ml) and methylated by the Falconer and Adams procedure (24). The product was recovered by extraction with chloroform. Three methylations by this method followed by one methylation by Purdie's method (methyl iodide, 10 ml; silver oxide, 1 g) gave a fully methylated product, as indicated by its infrared spectrum. Hydrolysis of the methylated disaccharide and separation of the sugars by paper chromatography (solvent B) yielded 2,3,4,6-tetra-*O*-methyl-D-glucose and a tri-*O*-methyl galactose (R_g 0.86).

(iii) Aldotriouronic Acid Fraction (C)

Paper chromatography of this fraction in solvent A for 4 days showed the presence of two components C_I ($R_{glucose}$ 0.23) and C_{II} ($R_{glucose}$ 0.17). Acid hydrolysis (2 *N* sulphuric at 100° C for 3 hours) and chromatographic examination of the hydrolyzates (solvents A and E) showed the components of C_I to be galactose, mannose, and hexuronic acid (which appeared to be mannuronic acid); the components of C_{II} were galactose, mannose, and glucuronic acid.

Spectra of the Polysaccharide

The ultraviolet absorption spectrum of an aqueous solution (0.5%) of the polysaccharide showed a peak at 275 mμ. The infrared spectrum was determined in potassium chloride disks on the free acid form and also the sodium salt of the polysaccharide. The main characteristics of the spectra of both forms were bands ν_{max} 1615, 1405, 1520, and 1650 cm^{-1}; the free acid had an additional band at 1735 cm^{-1}.

Periodate Oxidation

The polysaccharide was oxidized according to the method of Jeanes and Wilham (25). The number of moles of periodate consumed and formic acid produced per 162 g of polysaccharide are given in the following table:

Time (hours)	24	48	72	96	112
Periodate consumption	0.93	1.00	1.20	1.33	1.36
Formic acid production	0.36	0.47	0.54	0.58	0.60

Extrapolation of these values to 0 time showed a ratio of periodate consumed:formic acid produced of 1.3:0.5 mole per 162 g of polysaccharide.

The remaining solution of oxidized polysaccharide was treated with ethylene glycol, dialyzed against tap water, and the product recovered by freeze-drying. A portion was hydrolyzed and on paper chromatographic examination showed large amounts of galactose and small amounts of uronic acid. The remainder of the periodate-oxidized material (40 mg) was dissolved in water (4 ml) and after deionization with Amberlite ion exchange resins IR-45 and IR-120, a solution of potassium borohydride (150 mg in 1 ml of water) was added. After 24 hours, the solution was neutralized with acetic acid, dialyzed for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

24 hours, and the reduced product was recovered by freeze-drying. A small amount was hydrolyzed with 2 *N* sulphuric acid for 3 hours at 100° C. After neutralization, the hydrolyzate was examined by paper chromatography in solvent E and contained galactose, arabinose, and two spots ($R_{glucose}$ 1.01 and 1.23) which gave a light green color with *p*-anisidine spray reagent. A chromatogram of the same hydrolyzate in solvent F and sprayed with silver nitrate reagent (19) showed glycerol but no erythritol.

Methylation

The polysaccharide (3.0 g), dissolved in water (30 ml), was methylated by the dropwise addition of 30% sodium hydroxide (160 ml) and dimethyl sulphate (60 ml) and was stirred for 24 hours. The reagents were added at such a rate that the reaction mixture was always alkaline. The addition of the methylating agents was repeated twice. The methylation mixture was heated for 75 minutes at 80° C, then cooled, and finally neutralized with sulphuric acid. The precipitated salts were dissolved in water, and the partly methylated polysaccharide was extracted with chloroform. The recovered methylated polysaccharide (2.78 g) showed a definite hydroxyl band at 3500–3600 cm^{-1} in its infrared spectrum. The partially methylated polysaccharide was dissolved in tetrahydrofuran (150 ml) containing pulverized sodium hydroxide (15 g), and dimethyl sulphate (18 ml) was added dropwise over 6 hours with constant stirring. The mixture was stirred for 18 hours, and then sufficient water was added to dissolve the solids. The pH was adjusted to 9.0 and the solution was extracted with chloroform. The recovered methylated polysaccharide still contained free hydroxyl groups as shown by its infrared spectrum: consequently, the previous methylation was repeated twice more. The methylated product still showed a small hydroxyl group in the infrared spectrum and was methylated further by Purdie's method (methyl iodide, 100 ml; silver oxide, 20 g). After two Purdie methylations there were no free hydroxyl groups shown in the infrared spectrum. Yield 3.1 g, methoxyl content 39.0%.

Hydrolysis of Methylated Polysaccharide

The methylated polysaccharide (3.1 g) was refluxed with 4% methanolic hydrogen chloride (100 ml) for 24 hours. The solution was neutralized with silver carbonate, filtered, and evaporated *in vacuo* to a syrup, which was hydrolyzed with *N* sulphuric acid for 30 hours at 100° C. Periodic analysis of aliquots of the hydrolyzate by gas–liquid partition chromatography (26) showed that the prolonged hydrolysis period was necessary to hydrolyze the glycosides completely. The hydrolyzate was neutralized with barium carbonate, filtered, and concentrated to about 100 ml.

Separation of Acidic and Neutral Sugars

The above hydrolyzate (100 ml) was stirred for 30 hours with Dowex 1 (carbonate form) (35 g). The resin was then poured into a column and washed with water (1.5 l.) to elute neutral methyl sugars (1.99 g) and with *N* ammonium carbonate (700 ml) to elute the methylated uronic acid fraction (0.34 g). The latter was recovered by removing most of the ammonium carbonate by sublimation *in vacuo* at 65–70° C and the remainder by passing the solution over Amberlite resin IR-120.

A. Separation of Tetra-, Tri-, and Di-O-methyl Sugars

The mixture of neutral methyl sugars (1.6 g) was separated on large sheets of Whatman No. 3 MM papers using solvent A. The three bands located on the papers corresponded to tetra-*O*-methyl, tri-*O*-methyl, and di-*O*-methyl sugars having R_g values of 1.0, 0.84,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and 0.64 respectively. The weights were: tetra-*O*-methyl, 680 mg; tri-*O*-methyl, 390 mg; and di-*O*-methyl, 380 mg, which corresponds to an approximate molar ratio of 3:2:2.

B. Examination and Identification of Tetra-O-methyl Fraction

The syrupy tetra-*O*-methyl fraction had $[\alpha]_D^{25}$ +48.8° (*c*, 2.06% in water) and a methoxyl content 50.8% (theoretical value for $C_{10}H_{20}O_6$, 52.5%). Demethylation with boron trichloride (27) gave glucose and mannose as the parent sugars. The tetra-*O*-methyl fraction (2–3 mg) was heated in a sealed tube with 2% methanolic hydrogen chloride for 12 hours and neutralized with silver carbonate. The mixture of glycosides was examined by gas–liquid partition chromatography (26) using a 4-ft column of 20% Apiezon M on Celite 545 at 150° C and an argon flow rate of 150 ml/min. The examination showed the presence of the methyl glycosides of 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3,4,6-tetra-*O*-methyl-D-mannose in a ratio of 58.9:41.1. Optical rotation measurements of the original mixture indicated a ratio of 2,3,4,6-tetra-*O*-methyl-D-glucose:2,3,4,6-tetra-*O*-methyl-D-mannose of 57.3:42.7.

(i) 2,3,4,6-Tetra-O-methyl-D-glucose

The foregoing tetra-*O*-methyl fraction (550 mg) was dissolved in ethyl ether, small amounts of impurities were centrifuged off, and petroleum ether was added drop by drop. On being cooled, the solution deposited crystals (70 mg) which, after several recrystallizations from ether – petroleum ether (1:1), gave 2,3,4,6-tetra-*O*-methyl-D-glucose, m.p. 95–96° C; $[\alpha]_D^{25}$ +82.6±2° (*c*, 0.605% in water). An aliquot of the mother liquor (27 mg) was heated with aniline (15 mg) in methanol (2 ml) and the solution refluxed for 2 hours. The anilide crystallized on partial removal of the solvent and on recrystallization from ethanol gave 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-glucosylamine, m.p. 134–137° C. Reported value: 137–138° C (28).

(ii) 2,3,4,6-Tetra-O-methyl-D-mannose

A portion of the original tetra-*O*-methyl hexose mixture was run on sheets of Whatman No. 1 paper using solvent B until the solvent front reached the bottom of the papers. The sugars were located on the papers, the appropriate strips cut out and attached to the top of new sheets of paper, and the chromatograms again run with solvent B. The sugar band was located and the slower-moving fourth of the area was cut out and eluted with water. The syrupy product (20 mg) in methanol (2 ml) was refluxed with aniline (10 mg) to yield crystalline 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-mannosylamine, which was recrystallized from ethyl ether to give a melting point of 144–146° C, undepressed on admixture with an authentic specimen. Reported (29): m.p. 142–143° C. The X-ray diffraction pattern of the crystals was identical with that of the authentic specimen of 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-mannosylamine.

C. Examination and Identification of Tri-O-methyl Fraction

The tri-*O*-methyl fraction (390 mg) ($[\alpha]_D^{26}$ +12.6° (*c*, 2.53 in water)) yielded galactose, mannose, and a minor amount of glucose on demethylation by boron trichloride (26). Paper electrophoresis (17) (borate buffer, pH 10) separated the sugars into two borate-complexing fractions (0.154 g and 0.0125 g respectively) and a non-complexing fraction (0.126 g).

(i) Borate Non-complexing Fraction

This fraction, when demethylated as before, showed the presence of galactose, mannose, and a small amount of glucose. Paper chromatography in solvent B separated three components, two of which had the same R_g values (0.57 and 0.65) and color reactions with

p-anisidine hydrochloride as 2,4,6-tri-*O*-methyl-D-glucose and 2,3,4-tri-*O*-methyl-D-mannose respectively. The third component had an R_g of 0.74.

2,4,6-Tri-O-methyl-D-glucose.—The syrup (5 mg) was refluxed with aniline (3 mg) in methanol (1 ml) for 3 hours. The product crystallized on partial evaporation of the solvent and on recrystallization from ether gave 2,4,6-tri-*O*-methyl-*N*-phenyl-D-glucosylamine, m.p. 159–162° C. Reported value: 162–166° C (30).

2,3,4-Tri-O-methyl-D-mannose.—The syrup (33.5 mg) was oxidized with bromine (0.1 ml) in the presence of barium carbonate (30 mg) for 70 hours. Bromine was removed by aeration and the acidified solution was extracted with chloroform for 2 days. The chloroform extract was dried with anhydrous sodium sulphate and concentrated to a syrup, which was distilled (bath temperature 130–160° C at 0.01 mm). The distilled syrup was dissolved in methanol saturated with ammonia (5 ml) and allowed to stand for 24 hours at 5° C. Removal of the solvent gave a syrup which crystallized from ethanol:ethyl ether solution giving 2,3,4-tri-*O*-methyl-D-mannosamide, m.p. and mixed m.p. 143° C. Reported (31): m.p. 143° C.

2,3,5-Tri-O-methyl-D-galactose.—The syrup (33 mg) (R_g 0.74, solvent B) was oxidized by bromine as described above. The syrupy lactone showed a strong C=O stretching peak at 1786 cm^{-1} in its infrared spectrum and was therefore a γ lactone. Treatment with methanolic ammonia gave a crystalline amide, m.p. 145–146° C; $[\alpha]_D^{26}$ $-5.1\pm1.5°$ (*c*, 0.72 in methanol). Anal. Calc. for $C_9H_{19}O_6N$: C, 45.5%; H, 8.02%; N, 5.9%; OMe, 39.2%. Found: C, 45.15%; H, 8.3%; N, 6.04%; OMe, 38.9%. Since the galactose was in the furanose form this sugar was either 2,3,5- or 2,5,6-tri-*O*-methyl-D-galactose. Periodate oxidation of its amide by the method of Baddiley *et al.* (32) showed a negative test, thus eliminating 2,5,6-tri-*O*-methyl-D-galactofuranose, and hence the sugar was tentatively identified as 2,3,5-tri-*O*-methyl-D-galactofuranose.

(ii) Borate-complexing Fraction I

This fraction on demethylation gave mannose and glucose as the parent sugars. Paper chromatography in solvent C separated two components having R_t values and color reactions with *p*-anisidine spray reagent (18) identical with 3,4,6-tri-*O*-methyl-D-mannose (75 mg) and 3,4,6-tri-*O*-methyl-D-glucose (10 mg).

3,4,6-Tri-O-methyl-D-mannose.—The syrup (75 mg) crystallized on seeding with an authentic specimen of 3,4,6-tri-*O*-methyl-α-D-mannose. On recrystallization from ether: hexane the sugar had a melting point of 102–103° C (undepressed on admixture with an authentic sample) and $[\alpha]_D^{25}$ $+32\pm2°$ (*c*, 0.875 in methanol). Reported values (33): m.p. 101–102° C; $[\alpha]_D$ +36° (methanol).

3,4,6-Tri-O-methyl-D-glucose.—On seeding with an authentic specimen of 3,4,6-tri-*O*-methyl-D-glucose, the syrup (10 mg) crystallized. Recrystallization from ether:hexane at 0° C gave 3,4,6-tri-*O*-methyl-α-D-glucose, m.p. 76–77°. Reported value (34): m.p. 76–77° C.

(iii) Borate-complexing Fraction II (12 mg)

3,5,6-Tri-O-methyl-D-galactose.—The syrup had $[\alpha]_D^{25}$ $-16.2\pm1.5°$ (*c*, 1.23 in water). Demethylation by boron trichloride showed galactose as the only parent sugar. Movement on electrophoresis in borate buffer showed that C_2 was unsubstituted and the sugar was tentatively identified as 3,5,6-tri-*O*-methyl glucose. An aliquot (2 mg) was converted to the methyl glycoside by heating in 2% methanolic hydrogen chloride. The glycoside was methylated by the Kuhn procedure (35), and examination of the product by gas–liquid chromatography yielded the glycoside of 2,3,5,6-tetra-*O*-methyl-D-galactose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

D. Examination and Identification of Di-O-methyl Sugars

The fraction had $[\alpha]_D^{20}$ −12.5° (*c*, 1.35 in water); OMe, 28.7%. Calculated for $C_8H_{16}O_6$: OMe, 29.8%. Demethylation by boron trichloride (26) and examination of the sugars showed mainly galactose with small amounts of mannose. Paper electrophoresis in borate buffer showed the presence of two components (M_G values, 0.66, 0.52). Paper chromatography in solvent B showed three components (R_g values, 0.28, 0.33, and 0.41). The syrup (0.35 g) was separated on Whatman No. 1 paper using solvent B to give the three fractions (R_g 0.28, 14 mg; R_g 0.33, 28 mg; and R_g 0.41, 242 mg).

*(i) 3,5-Di-O-methyl-*D*-galactose*

This new sugar (R_g 0.41) was characterized, and the results have been published previously (36).

*(ii) 3,4-Di-O-methyl-*D*-mannose*

The syrup (R_g 0.33) (28 mg) crystallized from ethyl acetate, giving 3,4-di-*O*-methyl-D-mannose, m.p. and mixed m.p. 70–73° C. Reported (37): m.p. 70–73° C.

*(iii) 3,6-Di-O-methyl-*D*-mannose*

Demethylation of a portion of the sugar (R_g 0.28) and examination of the products showed mannose as the parent sugar. Paper electrophoresis in borate buffer showed three components; two of these were in trace amounts and had the same M_g values as 2,3- and 2,4-di-*O*-methyl-D-mannose. The main component was assumed to be 3,6-di-*O*-methyl-D-mannose since its M_g value did not correspond to that of either 2,6- or 4,6-di-*O*-methyl-D-mannose. A small sample (1–2 mg) was converted to its methyl glycoside by heating for 12 hours in 2% methanolic hydrogen chloride. The glycoside was methylated by Purdie's reagents (methyl iodide, 2 ml, and silver oxide, 20 mg). Examination of the fully methylated sugar by gas–liquid partition chromatography (26) showed the glycosides of 2,3,4,6-tetra-*O*-methyl-D-mannose. On the basis of the foregoing evidence, the sugar was tentatively identified as 3,6-di-*O*-methyl-D-mannose. Scarcity of material precluded further identification.

E. Examination of Methylated Uronic Acid Fractions

The methylated uronic fraction, separated from the neutral sugars, weighed 300 mg. Separation on filter paper using solvent D gave three fractions (R_g 0.85, 0.61, and 0.50).

(i) Fraction 1

Yield 30 mg, R_g value 0.85. A small portion (2 mg) was hydrolyzed with *N* sulphuric acid (0.5 ml) for 8 hours at 100° C. Chromatographic examination of the hydrolyzate in solvent B failed to show the presence of any neutral sugars. The remainder of the fraction was then converted to its methyl ester methyl glycoside by being heated in 2% methanolic hydrogen chloride in a sealed tube for 12 hours. After reduction with lithium aluminum hydride in ether solution, the disaccharide was recovered and hydrolyzed with *N* sulphuric acid. Paper chromatography (solvent B) and paper electrophoresis (borate buffer) showed one spot having R_g and M_g values of 0.30 and 0.13 respectively. These values corresponded to those of 2,3-di-*O*-methyl glucose. Demethylation of the sugar yielded glucose. The methylated uronic acid was therefore 2,3-di-*O*-methyl-glucuronic acid.

(ii) Fraction 2

Yield 22 mg, R_g value 0.61. Paper chromatography and paper electrophoresis (solvent B and borate buffer, pH 10) of an acid hydrolyzate of this material showed the presence of 3,4-di-*O*-methyl mannose as the only neutral sugar. As described above, the sugar acid was converted into the methyl ester methyl glycoside, reduced with lithium aluminum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

hydride, and hydrolyzed with acid. The sugars, identified by chromatography and electrophoresis, were 2,3-di-*O*-methyl-D-glucose and 3,4-di-*O*-methyl mannose with traces of 2,3,4-tri-*O*-methyl-D-glucose. Demethylation of the reduced sugar produced glucose and mannose.

(iii) Fraction 3

Yield 28 mg, R_g 0.50. Acid hydrolysis and chromatographic examination of the sugars showed 3,4-di-*O*-methyl mannose, 3,5-di-*O*-methyl galactose, and trimethyl glucuronic acid. Methanolysis, reduction, and hydrolysis as described for earlier fractions produced 2,3,4-tri-*O*-methyl-D-glucose, 3,4-di-*O*-methyl mannose, and 3,5-di-*O*-methyl galactose. Demethylation of the reduced trisaccharide yielded glucose, mannose, and galactose.

ACKNOWLEDGMENTS

The authors wish to thank Mr. F. P. Cooper for assistance with the gas–liquid chromatography, Mr. A. E. Castagne for performing the microchemical analyses, and Miss M. T. Clement for preparing the cultures of the organisms.

THE REDUCTION OF NITROBENZENE BY SODIUM SULPHIDE IN AQUEOUS ETHANOL[1]

O. J. Cope and R. K. Brown

ABSTRACT

The reduction of nitrobenzene by sodium sulphide in aqueous ethanol has been examined. Hydrosulphide and hydrodisulphide ions give rise to quite similar, though slow, rates of reduction. Sulphide ion appears to be two to three times as effective as the hydrosulphide ion. Both the sulphide and hydrosulphide species are considered to be responsible for the initial, very slow reduction with possibly some contribution from traces of polysulphide ions. The reduction is markedly accelerated by the addition of elemental sulphur to form di- and polysulphide, a much more reactive reducing species. The formation of "active" elemental sulphur during the course of the reduction produces disulphide and thus gives rise to an autocatalytic reaction. Some of this elemental sulphur is lost as thiosulphate by reaction with hydroxyl ions produced by the reduction itself, and by hydrolysis of sulphide and disulphide ions. The addition of base increases the rate of reduction due to a shift in the equilibria $S^{=} + H_2O \leftrightharpoons HS^- + OH^-$ and $S_2^{=} + H_2O \leftrightharpoons HS_2^- + OH^-$, but this is offset somewhat by greater loss of the active elemental sulphur as thiosulphate, thus decreasing the autocatalytic acceleration of rate.

Although, from its absorption at 265 mμ, nitrobenzene concentration could be accurately measured, no satisfactory method was found for estimating the concentration of disulphide ions during the course of the reduction.

INTRODUCTION

In order to understand the variable results obtained in this laboratory in the alkaline sulphide reduction of nitro compounds and to rationalize the well-known selectivity observed in the sulphide reduction of mono- and poly-nitro compounds (1–4), a detailed study of the sulphide reduction of nitrobenzene was undertaken.

Reduction of aromatic nitro compounds by such reagents as titanous chloride or stannous chloride under acidic conditions has been followed by measurement of the consumption of reducing agent (5–7). Since the disappearance of the nitro compounds was not followed directly, one must either determine or assume that certain definite changes occur in the reducible substance and that all the reducing agent has been consumed by this process and no other. This approach has revealed that the reaction is first order with respect to both nitro compound and reducing agent, and agrees with the generally accepted course of the reaction suggested by Haber (8) and shown as follows.

$$RNO_2 \xrightarrow{\text{slow}} RNO \xrightarrow{\text{fast}} RNH(OH) \xrightarrow{\text{fast}} RNH_2 \qquad (a)$$

There is a considerably greater difficulty in following the reduction by measuring change in concentration of reducing agent when sulphide ions are employed, since the composition of the reduction mixture is more complex than it is in the case of stannous chloride. It is known that a solution of sodium sulphide contains a number of species including sulphide, hydrosulphide, disulphide, hydrodisulphide, and thiosulphate ions, the relative composition of which depends upon the source of the sodium sulphide used for its preparation and the conditions under which the solution is made. The particular species responsible for the reduction, as well as its concentration, must be determined.

Since a method which measured the disappearance of nitrobenzene directly would

Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta. Taken from the thesis of O. J. Cope to be submitted to the Graduate School of the University of Alberta in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

possess obvious advantages, attention was directed to the development of a spectrophotometric method which followed the change in extent of absorption at λ_{max} 265 mμ with change in nitro concentration. Such a method was indeed obtained. However, during the course of our experiments, Ogata *et al.* (9) reported an investigation of the kinetics of the reduction of aromatic nitro compounds by sodium disulphide in aqueous methanol (40% volume methanol:water). The choice of sodium disulphide stemmed from their observations that reduction with the monosulphide was too slow for satisfactory kinetic study. These authors followed the course of the reaction by measurement of the changes in the absorption of nitrobenzene at λ_{max} 270 mμ, although in cases where a large excess of nitrobenzene was employed, the spectrophotometric method was checked by an electrometric titration of the sodium disulphide with silver ion. Their results showed that the reduction was first order in nitrobenzene. A second-order dependence upon disulphide ion was found also, but when allowance was made for hydrolysis, the reaction was reported to be first order with respect to disulphide ion as well.

Bullock and Forbes (10) have also studied the reduction of certain nitrobenzene sulphonates in aqueous solution by sulphide, disulphide, and polysulphide ions. From their measurements of polysulphide concentration by iodometric titration, they concluded that the reduction was first order in both nitro compound and polysulphide, although no allowance for the extent of hydrolysis of the polysulphide appeared to have been made.

The present work describes the results of a study of the reduction of nitrobenzene with sodium sulphide in aqueous ethanol by following the change in absorption of the nitrobenzene at λ_{max} 265 mμ.

EXPERIMENTAL

Chemicals and Solvents

Sodium sulphide ($Na_2S.9H_2O$), obtained from the Nichols Chemical Company, was of reagent grade. It was colorless and apparently free from the yellowish polysulphide impurities found in sodium sulphide obtained from some other sources.

Nitrobenzene was Fisher certified reagent grade material. This was distilled, before use, at 85–86° C at 10 mm.

Sulphur was Merck sublimed material, used without further purification.

Aqueous ethanol (40%) was prepared by addition of the requisite amount of distilled water to 95% ethanol. This solution was deaerated before use by gentle reflux and subsequent cooling under an atmosphere of oxygen-free nitrogen.

Solutions

The stock solution of sodium sulphide was prepared by the addition of sufficient $Na_2S.9H_2O$ (neglecting the change in the water concentration due to the water of hydration) to the 40% aqueous ethanol to make the solution 0.960 molar with respect to the Na_2S. This stock solution was then diluted appropriately with the 40% aqueous ethanol in the preparation of a 0.160 *M* solution of sodium sulphide. A 0.160 *M* solution of sodium sulphide made in this manner contained 61.2% of water and 38.8% of ethanol.

Apparatus

A Beckman Model DU spectrophotometer, equipped with a power pack, was used to make the absorption measurements. Matched, glass-stoppered quartz cells of 10-mm light path were used for all measurements.

The pH determinations were made with a Beckman Zeromatic meter equipped with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

a high pH electrode. The standardization was made with a saturated solution of pure calcium hydroxide which has a pH of 12.45 at 25° C (11), and also with standard buffers at lower pH.

The reaction was carried out in a 500-ml, four-necked flask fitted with an efficient, water-cooled reflux condenser, a stirrer, an inlet for the addition of sodium sulphide solutions, and an inlet for a nitrogen bleed. In addition, a tube dipping below the surface of the solutions held a 1-ml pipette and thus permitted sampling so that there was a minimum of exposure of the solution surface to air. The apparatus was thermostatted at 50.0° C.

A calibrated dropping funnel was used to introduce the solution of sodium sulphide into the reaction vessel.

Procedure

The reaction vessel was first flushed with nitrogen and subsequently a slight positive pressure of nitrogen was maintained in the apparatus above the solution throughout the entire reaction period.

About 50 ml of the stock solution (0.960 *M* sodium sulphide in aqueous ethanol) was added to the reaction vessel, followed by a sufficient volume of the mixed solvent to give a final concentration of 0.160 *M* sodium sulphide. For the cases which required the addition of sodium hydroxide or elemental sulphur, the necessary quantity of the reagent was added before the diluting solvent had been completely added, followed by the remainder of the solvent needed to make up the required volume. The solutions made by the addition of sodium hydroxide or sulphur were allowed to stand for $\frac{1}{2}$ hour to ensure equilibration of the species in the solution. No change in absorption was noted in such an equilibrated solution, even upon prolonged standing. Finally the nitrobenzene was introduced by means of a Victor Meyer bottle into the rapidly stirred solution.

For following the change in absorption at 450 mμ, the Beckman DU cell container was thermostatted at 50.0° C. The glass-stoppered cell was completely filled with freshly prepared initial reaction solution obtained from the reaction flask and the change in absorbance was measured continuously and directly. This eliminated errors due to cooling and air oxidation which would occur if fresh samples were taken periodically from the reaction flask.

To follow the change in nitrobenzene concentration, 1-ml samples were withdrawn from time to time and immediately diluted to 100 ml with a standard mixture of 40% aqueous ethanol containing four times the calculated amount of hydrochloric acid required to convert all the sodium sulphide to H_2S and the amine to the hydrochloride. These solutions, properly protected and capped, were allowed to stand for the duration of the experiment (2–4 hours) before measurements were made, and then the absorbances were obtained at 25° C at 265 mμ. The period of standing produced no alteration in absorption and thus permitted the choice of a more convenient time for the absorption measurements. Interfering absorption at 265 mμ due to polysulphide was subtracted from the total absorption at this wave length to give a measure of the nitrobenzene concentration. The magnitude of this interfering absorption due to polysulphide was evaluated by measurement of the polysulphide concentration from its absorbance at 450 mμ at 50° C and conversion of this reading to the corresponding (and lower) one at 25° C using calibration plots of concentration of polysulphide versus absorbance at 450 mμ at these two temperatures. From this value of absorption at 450 mμ, the corresponding interfering absorption

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

at 265 mμ was obtained from a plot relating absorption at 450 mμ to absorption of the same solution at 265 mμ after having been diluted 100-fold and acidified with the standard aqueous ethanolic solution of hydrochloric acid. These measurements were all made at 25° C.

The solutions required for the comparative absorption of disulphide and hydrodisulphide ions were made up as follows. All preparations were carried out in an atmosphere of nitrogen. To the stock solution of 0.960 *M* sodium sulphide was added the requisite amount of elemental sulphur. Ten-milliliter aliquots of the resulting solution were then separately treated with base, acid, or bicarbonate as required and then diluted to 60 ml with the 40% aqueous ethanol. The aliquot which was to supply the solution of disulphide was first basified by addition of the necessary amount of solid sodium hydroxide to give a concentration of added base equal to 4 *M* and then the volume made up to 60 ml. One of the aliquots which was to supply the solution of hydrodisulphide was acidified by careful addition of the requisite quantity of constant-boiling hydrochloric acid to the rapidly stirred solution. The pH of the solution was followed during this addition and found to be 10.7 when all the necessary hydrochloric acid had been added. To the other aliquot was added sufficient solid sodium bicarbonate to convert all the sodium sulphide and sodium disulphide to the corresponding hydrosulphide and hydrodisulphide (12) and then the volume made up to 60 ml. This solution was cooled to 0° C and the sodium carbonate allowed to precipitate. The supernatant solution of sodium hydrosulphide and sodium hydrodisulphide (pH = 10.7) was removed from the flask, under nitrogen pressure, through a porous plate.

The solutions of sodium hydrosulphide, and sodium hydrosulphide containing hydrodisulphide, were prepared from the 0.960 *M* sodium sulphide stock solution, by appropriate addition of elemental sulphur in the latter case, and then suitable acidification with hydrochloric acid during the dilution, to give the final concentration of 0.160 mole per liter.

Iodometric titrations were carried out by standard procedures.

RESULTS AND DISCUSSION

A method similar to that devised by Ogata *et al.* (9) was used to follow the reduction of nitrobenzene.

The absorption of nitrobenzene in aqueous ethanol was found to follow Beer's law over the concentration ranges studied.

Although reduction of nitrobenzene in alkaline media is known to yield bimolecular reduction products (azoxybenzene and azobenzene), a careful examination of a typical reaction at the λ_{max} at which these compounds absorb showed conclusively that bimolecular reduction products were not present nor were they involved in the reaction. Azoxybenzene has been converted to azobenzene by sulphide (13, 14). We have found that a 0.005 *M* solution of azoxybenzene in aqueous ethanol made 0.150 *M* in sodium sulphide gave approximately 1% conversion to azobenzene in 200 minutes, but only when elemental sulphur was added to form the more actively reducing polysulphide species. Hence, had such bimolecular reductions been involved in our sulphide reductions, azobenzene would surely have accumulated and been detected. Thus the only organic products found at any time during the reaction were nitrobenzene and aniline, in agreement with the observations of previous investigators (9, 10) and with the scheme of reduction given by Haber (8).

Bullock and Forbes (10) have suggested that the over-all reaction for the reduction of nitrobenzene as expressed by equation (*b*):

$$RNO_2 + S_2^{=} + H_2O \rightarrow RNH_2 + S_2O_3^{=}, \qquad (b)$$

can be broken into three separate reactions as follows:

$$RNO_2 + 3S_x^{=} + 4H_2O \rightarrow RNH_2 + 3S_x^{0} + 6OH^{-} \qquad (c)$$

$$S^0 + S^{=} \rightarrow S_2^{=} \qquad (d)$$

$$4S^0 + 6OH^{-} \rightarrow S_2O_3^{=} + 2S^{=} + 3H_2O. \qquad (e)$$

Of these products, only polysulphide interfered at 265 mμ. However, this could be estimated from suitable Beer's law plots (see Experimental).

Ogata's method (9) of allowance for polysulphide absorption was considered unsatisfactory for our work since polysulphide does not absorb to the same extent at 265 mμ and 240 mμ. This is illustrated in the following table for different concentrations of sodium disulphide.

Absorption at 265 mμ	Absorption at 240 mμ
0.098	0.125
0.213	0.260
0.361	0.412
0.510	0.580

Hence for the present work the actual absorption of the disulphide at 265 mμ was determined in each case.

On the assumption that a 10-fold excess of sodium sulphide over nitrobenzene would give a pseudo-first-order reaction, data for the disappearance of nitrobenzene with time were obtained for the reaction of 0.015 *M* nitrobenzene with 0.160 *M* sodium sulphide in aqueous ethanol (approximately 61:39 water:alcohol, by weight) at 50° C, carefully protected by an atmosphere of nitrogen. The data is shown conveniently in Fig. 1, plot I, and in Fig. 2. The existence of an induction period and an autocatalytic reaction, clearly shown here, has been observed previously by Bullock and Forbes (10) in their experiments on sulphide reduction of nitro compounds in aqueous solution. They discovered that, of the products obtained from these reactions (equations (*c–e*)), only polysulphide was responsible for the autocatalytic reaction. This has been supported by our observation that replacement of some of the sodium sulphide by disulphide shortened or practically eliminated the induction time (Fig. 1, plots II–IV). When 2% of the sodium sulphide was present as disulphide, the induction period was reduced to about 25 minutes, while a molarity of added elemental sulphur greater than 0.0075 (4.7%) gave a reaction practically devoid of an induction period.

Corroboration that the reactive species is, in fact, an increasing quantity of polysulphide was found by simultaneously following the change in polysulphide concentration during the course of the reduction. Polysulphide absorbs quite strongly over a broad region but is quite measurable at 450 mμ. In a plot of concentration of sulphur as polysulphide in 0.160 *M* sodium sulphide in aqueous ethanol versus absorption at 450 mμ at 25° and at 50° C, it was found that Beer's law held remarkably well even up to a molarity of 0.08 for elemental sulphur.

The exact composition of a combination of elemental sulphur with sodium sulphide,

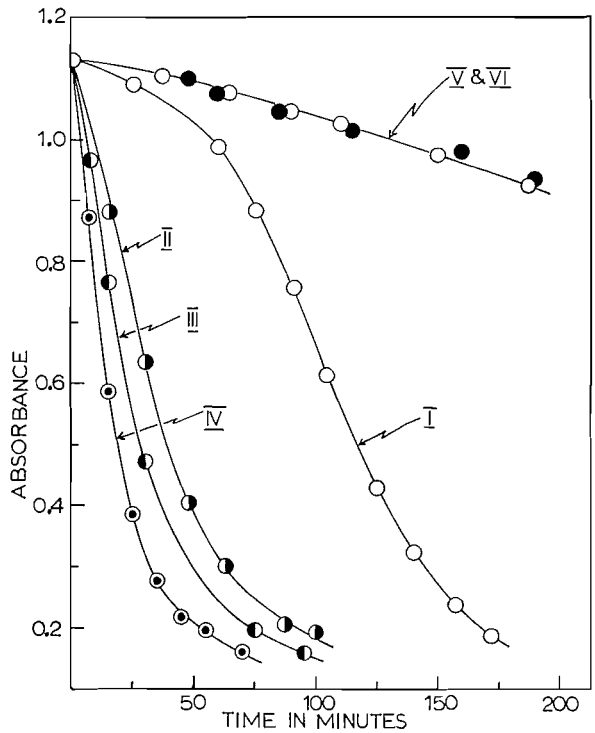

FIG. 1. The change in absorbance of nitrobenzene at 265 mμ with time during the reduction at 50° C of 0.015 *M* nitrobenzene by aqueous ethanolic sodium sulphide. I to IV have a Na_2S concentration of 0.160 *M*; II, III, and IV are 0.0075 *M*, 0.015 *M*, and 0.030 *M* respectively in dissolved sulphur; V and VI plots both contain 0.160 *M* NaHS, VI (●) being also 0.015 *M* in sulphur.

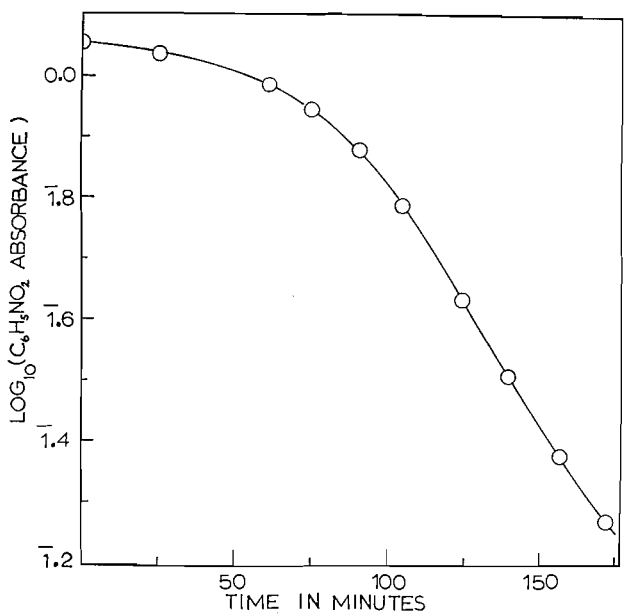

FIG. 2. A plot of $\log_{10}$ of the nitrobenzene absorbance at 265 mμ vs. time for the reduction of 0.150 *M* nitrobenzene by 0.160 *M* Na_2S in aqueous ethanol at 50° C.

and hence the nature of the absorbing species, is uncertain (15–18). The adherence to Beer's law noted above, and our finding that the intensity of absorption of Na_2S_3 in the aqueous ethanol employed is nearly *three* times that of Na_2S_2 under the same conditions, favors the view that $S_2^=$ is essentially the species present when the concentration of sulphur is considerably less than that of the sodium sulphide. However, in view of the uncertainty of the composition of our polysulphide, for convenience the term *disulphide* will be used.

From Fig. 3, plot I, it is seen that in the initial stage of the reaction between sodium

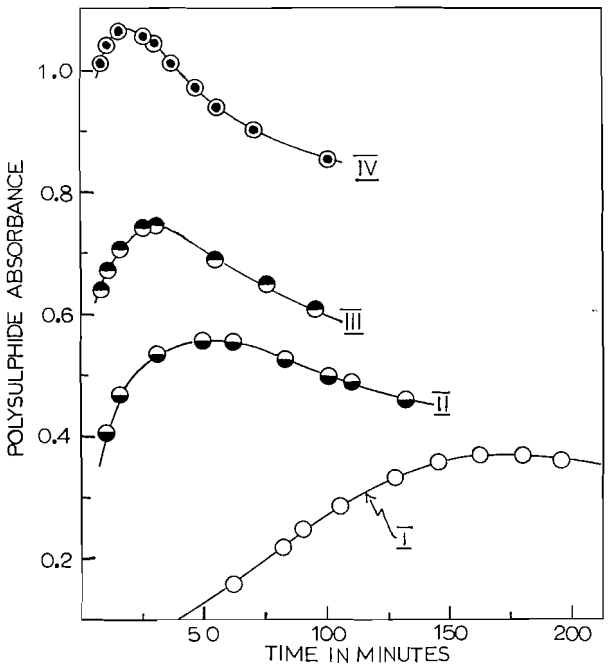

FIG. 3. The change in absorbance at 450 mμ with time during the reduction at 50° C of 0.015 *M* nitrobenzene in aqueous ethanolic sodium sulphide. I to IV have a Na_2S concentration of 0.160 *M*; in addition II, III, and IV are 0.0075 *M*, 0.015 *M*, and 0.030 *M* respectively in dissolved sulphur.

sulphide and nitrobenzene, the disulphide concentration was indeed quite small, but increased to a maximum at about 175 minutes of reaction, slowly decreasing thereafter. This value became constant when the reduction had been completed, a fact not shown in the plot but actually determined in two separate cases. When sulphur was added initially, not only was the rate of increase of disulphide greater with larger initial concentration of disulphide, but so was the rate of loss of disulphide. Furthermore, from the pseudo-first-order logarithmic plot (Fig. 2) it is seen that no truly linear section occurred.

In an attempt to rationalize these findings the following aspects of the reaction were considered.

The Probable Extent of Hydrolysis of Sodium Sulphide in Aqueous Ethanol

An aqueous solution of sodium sulphide is considered to be extensively hydrolyzed (17). Kuster and Heberlein (19, compare also 17) indicate that a 1 *M* solution of sodium sulphide is hydrolyzed to about 50%. Ogata (9) has used a figure of 10 for the hydrolysis constant for a solution of sodium sulphide in aqueous media. However, disagreement

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

concerning the value of the second ionization constant of hydrogen sulphide (20, 21) makes the value of the concentration of sulphide and hydrosulphide ions, calculated by the use of the value 10, somewhat uncertain.

Little is known about the extent of hydrolysis of sodium sulphide in aqueous ethanol. The reasoning presented by Ogata *et al.* (9) indicates that the hydrolysis constant of sodium sulphide in aqueous methanol at room temperature is somewhat less than the value of 10.[2] It is reasonable that a similar decrease in magnitude of the hydrolysis constant applies to the aqueous ethanol employed in our work. But, in view of the lack of more precise knowledge of the hydrolysis constant of sodium sulphide in aqueous ethanol, particularly at 50° C, an estimation of the extent of hydrolysis was made by pH measurements according to the following procedure.

In a comparison of pH readings obtained from equimolar solutions (at 50° C) of sodium hydroxide in water and in the stock aqueous ethanol, ranging from 0.050 to 0.500 M in sodium hydroxide, it was found that an apparent constant difference of 0.60 pH units occurred, and could be expressed as

$$pH_{H_2O} = pH_{H_2O-alc} - 0.60.$$

This "alcohol effect" on pH readings obtained for solutions in aqueous alcohol has been recorded previously (22). It is seen that a knowledge of the concentration of sodium hydroxide in water and the pH to which it corresponds can be used to estimate the concentration of sodium hydroxide in an alcohol–water mixture by measurement of the pH of the latter solution. In this manner, advantage can be taken of the known values of pK_w in water for conversion of pH to pOH and hence to hydroxyl ion concentration. For example, a pH of 12.60 found for a certain amount of sodium hydroxide dissolved in aqueous ethanol at 50° C corresponded to an equivalent pH of 12.00 in water. Using $pK_w = 13.26$, the value reported for a temperature of 50° (23), one obtained the hydroxyl ion concentration of 5.5×10^{-2} M. The pH readings were considered to be accurate to ± 0.02 units, hence the hydroxyl ion concentration was expressed as 0.055 ± 0.002 M.

A further complication arose from the fact that the pH measures *activity* of the hydrogen ion and not the actual hydrogen ion concentration directly. A knowledge of the activity values would permit calculation of the hydrogen ion, and hence hydroxyl ion, concentration. The lack of such data led to the following evaluation.

A 0.050 M solution of sodium hydroxide in *water* at 50° C gave a pH reading of 11.90 whereas the calculated figure, using pK_w at 50° C = 13.26, was 11.96—a difference of 0.06 units. Sodium hydroxide solutions, 0.1 and 0.5 M in strength, showed respectively the difference of 0.160 and 0.260 between calculated and observed values of pH. Thus the pH value found for aqueous alcoholic solutions of sodium hydroxide, even though corrected for the alcohol effect, gave an apparent hydroxyl ion concentration which was, in the region of 0.050 molarity, about 0.06 pH units lower than that actually present.

The foregoing considerations and observations were then applied to the problem of determining the sulphide ion concentration of a 0.160 M sodium sulphide solution in aqueous ethanol at 50° C. The pH of this solution was found to be 12.60 ± 0.02. When corrected for the alcohol effect, the value was 12.00 ± 0.02. This was identical with the pH found for a 0.160 M solution of the same concentration of sodium sulphide in water

[2]*These authors show a ratio of hydrolysis constants in aqueous media of* $K_{S^-}/K_{S_2^-} = 4$. *Since* S_2^- *should hydrolyze less than does* S^-, *either in water or in aqueous ethanol, and since Ogata obtained a value of 1.4 for the hydrolysis constant,* K_h, *of* S_2^- *in aqueous methanol, the* K_h *of sodium sulphide in aqueous methanol may also be approximately four times this figure, i.e. 5.6. If aqueous ethanol and aqueous methanol are comparable, the* K_h *of* Na_2S *in aqueous ethanol then might be about 5.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

at 50° C. Using the pK_w value of 13.26, the hydroxyl ion concentration was estimated at 0.055 ± 0.002 *M*. Allowing for the "activity measurements" indicated above, the hydroxyl ion concentration was estimated to be 0.063 ± 0.002 *M*.

On the basis of the above calculations of the hydroxyl ion concentration, the extent of hydrolysis of a 0.160 *M* solution of sodium sulphide in the aqueous ethanol at 50° C was $39 \pm 2\%$. The sulphide ion concentration was therefore 0.097 ± 0.002 *M*. From these figures a value of 4.1×10^{-2} was obtained for the hydrolysis constant of sodium sulphide in the aqueous ethanol at 50° C. It is realized that these calculations are approximations. However, they do supply us with a rough estimate of the sulphide ion concentration.

The Initial Slow Reduction

The initially slow reaction between sodium sulphide and nitrobenzene (Figs. 1 and 2, plot I) might be attributed to one or a combination of the species present as a result of hydrolysis of sodium sulphide. These are principally the sulphide and hydrosulphide ions with possibly small concentrations of disulphide and hydrodisulphide ions as contaminants. It was originally thought that the slow reaction was due largely, if not completely, to the small concentration of contaminating disulphide ion. Support for this view was obtained by the observation that this initial rate was found occasionally to be considerably greater than that usually observed, depending upon the source (and hence extent of contamination by $S_2^=$) of the sodium sulphide. This apparent doubling of the initial rate could hardly be attributed to significant change in the monosulphide ion concentration due to hydrolysis, since the concentration of 0.160 *M* in sodium sulphide was adhered to as closely as possible. The species which could change sufficiently in concentration to effect this twofold increase in initial rate was more reasonably the contaminating disulphide ions. However, because of the reasons indicated below, the view is now held that the initial slow reduction is at least to a large extent due to sulphide and hydrosulphide species.

The extent of hydrolysis, obtained from pH measurements, gives for a 0.160 *M* solution of sodium sulphide, at the beginning of the reduction, a concentration of sulphide and hydrosulphide ions of 0.097 ± 0.002 *M* and 0.063 ± 0.002 *M* respectively. It is reasonable to assume that of these two ions, the sulphide ion should possess the greater capability for reduction. But the fact that the initial reduction rate by a solution which contains only hydrosulphide ions (Fig. 1, plot V) is not much different from that found when more than half of the hydrosulphide is converted to sulphide ion (Fig. 1, plot I) indicates that the sulphide and hydrosulphide (and also hydrodisulphide, Fig. 1, plot VI) ions are all of the same order of reducing power.

The extremely slow reduction by the sulphide ion might be due to the fact that it is much more strongly hydrated than is the hydrosulphide ion (23). The displacement of the water to allow association of the sulphide ion with the nitro group for the subsequent electron transfer occurs with difficulty. In contrast, disulphide and polysulphide ions reduce nitrobenzene much more rapidly, no doubt due in part to the lower degree of hydration of these ions (18). Furthermore, it is not unreasonable to assume that the conversion $:\dot{\underset{\cdot\cdot}{\overset{\cdot\cdot}{S}}}:\dot{\underset{\cdot\cdot}{\overset{\cdot\cdot}{S}}}:^{=} \rightarrow 2e + \dot{\underset{\cdot\cdot}{\overset{\cdot\cdot}{S}}}:\,:\dot{\underset{\cdot\cdot}{\overset{\cdot\cdot}{S}}}$ is more facile than is the analogous change of $:\dot{\underset{\cdot\cdot}{\overset{\cdot\cdot}{S}}}:^{=} \rightarrow 2e + \dot{\underset{\cdot\cdot}{\overset{\cdot\cdot}{S}}}:$ on the basis that the combination of the two sulphur atoms yields a more stable product.

In this connection it is of interest to record the observation that the rate of reduction of nitrobenzene by a dilute, aqueous ethanolic solution of sodium *tri*sulphide was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

approximately the same as, although constantly slightly lower than, that found for an equal concentration of sodium *di*sulphide under otherwise identical conditions. This agrees with the view expressed by Ogata (9) that attack by disulphide ion is on the nitrogen atom of the nitro group. The bulkier trisulphide ion would find such an approach somewhat more difficult.

The Autocatalytic Reaction

Since the effective reducing species is the disulphide ion, and this is present in a concentration less than or comparable with that of the nitrobenzene, although increasing as the reaction progresses, it is obvious that a pseudo-first-order reaction cannot be obtained. The data shown in Figs. 1 and 3 indicate an autocatalytic reaction; hence it might be possible to apply the equation for such a reaction (24) and thus evaluate the rate constant, providing the concentrations of both reactants are known or can be measured.

The concentration of one reactant, nitrobenzene, is easily and accurately determined by absorption measurements, and is found to decrease continually with time. However, the concentration of disulphide ion is governed by several factors. The process of reduction itself (equation (*c*)) with simultaneous production and reaction of elemental sulphur (equations (*d*) and (*e*)) is one factor which must be considered. When this is coupled with the unknown extent of hydrolysis of the disulphide ion, which, in turn, is affected by the change in hydroxyl ion concentration,[3] the task of measuring the disulphide ion concentration is indeed quite formidable. Since, to our knowledge, the hydrolysis constant of the disulphide ion is unknown either in aqueous media or in aqueous ethanolic solution at 50° C, the determination of the disulphide ion concentration by this route is not feasible.

The Relative Absorbances of Disulphide and Hydrodisulphide Species and the Attempt at Estimation of Disulphide Ion Concentration by Absorption Measurements

During the course of these experiments it was also shown that the absorption of "disulphide ion" at 450 mμ does not give a direct measure of the disulphide ion concentration since both disulphide and hydrodisulphide species contribute to this absorption, although to different extents.

An attempt was made to convert a solution of sodium disulphide, on the one hand, to one containing entirely unhydrolyzed disulphide ion (and sulphide ion), and, on the other hand, to a solution containing only hydrodisulphide ion (and hydrosulphide ion). Measurement of the absorption would then provide a means of estimating the extent of hydrolysis of sodium disulphide in our reduction mixture.

A series of aqueous ethanolic solutions, 0.160 *M* in sodium sulphide, containing 21.4% of sulphur as disulphide, were made up to contain progressively greater concentrations of sodium hydroxide. The results of absorbance measurements, made at 25° C at 450 mμ, are shown in Fig. 4. The absorbance rose from 1.013 units for the unbasified equilibrium mixture to a maximum of 1.820 units when the molarity of added base reached 4.0. Further addition of base produced no change in absorbance. The most reasonable explanation of these results is that of repression of hydrolysis by the added base to produce essentially disulphide ion, which must then absorb to a greater degree than does an equal amount of hydrodisulphide ion.

When the aqueous ethanolic solution, 0.160 *M* in sodium sulphide and containing

[3]*In one experiment involving the reduction of nitrobenzene by sodium sulphide at 50° C, the changes in* pH *were found to be: initial* pH, *12.60; after 45 minutes of reaction, a maximum* pH *of 12.95; and after 130 minutes, well beyond one half life, a* pH *of 12.50.*

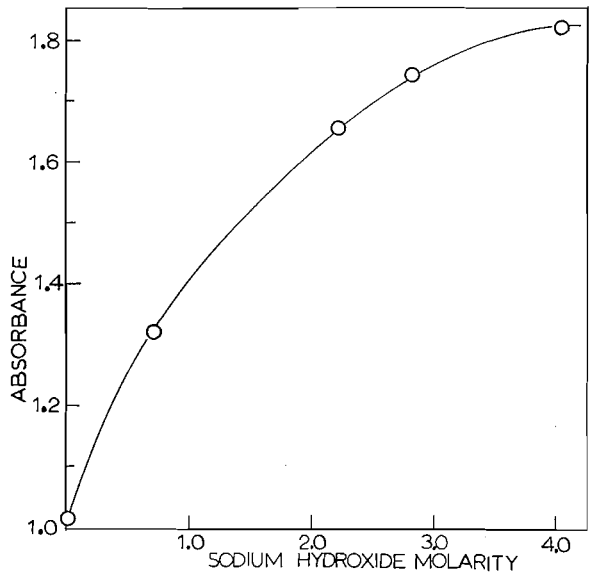

FIG. 4. The effect of the addition of NaOH on the absorbance at 450 mμ of a solution of sulphur in 0.160 *M* Na_2S (in aqueous ethanol).

elemental sulphur as disulphide, was treated so as to convert sulphide and disulphide ions to hydrosulphide and hydrodisulphide ions (see Experimental) the absorption *increased* rather than decreased as would be expected from the results of the work involving basified solutions. No constant value for absorption was obtained since the extent of absorption increased with increasing amounts of hydrochloric acid added. No explanation could be found for this phenomenon.

From these experiments, it is obvious that the ratio $HS_2^-/S_2^=$ could not be calculated from absorbance measurements. Hence the concentration of disulphide ion could not be found, thus making a satisfactory kinetic study of the reduction of nitrobenzene by sodium sulphide under our conditions quite difficult.

The Effect of Addition of Base on the Reduction of Nitrobenzene by Sodium Sulphide

The addition of sodium hydroxide increased the rate of reduction of nitrobenzene by sulphide (Fig. 5, plots I–IV), but not in proportion to the amount of base added. Eventually a state was reached where further addition of base actually had the reverse effect (Fig. 5, plot V). The increased rate was no doubt due to the conversion of the relatively unreactive HS_2^- to the much more reactive species, $S_2^=$. A large concentration of base would convert essentially all the polysulphide to the unhydrolyzed state and result in a maximum rate of reduction. However, the increased concentration of base caused greater reaction between hydroxyl ion and the "active sulphur" (10), hence less disulphide was formed, thus leading to a lower acceleration of rate. With sufficiently high concentration of base it is expected that most if not all of the active sulphur would be lost as thiosulphate and no autocatalysis would be observed. This could not be tested in our solutions since a concentration of base significantly greater than 4 *M* resulted in a salting out of the ethanol.

The changes in "polysulphide concentration" accompanying the reductions in each of these cases are shown in Fig. 6. It has been shown that this absorption is due to both

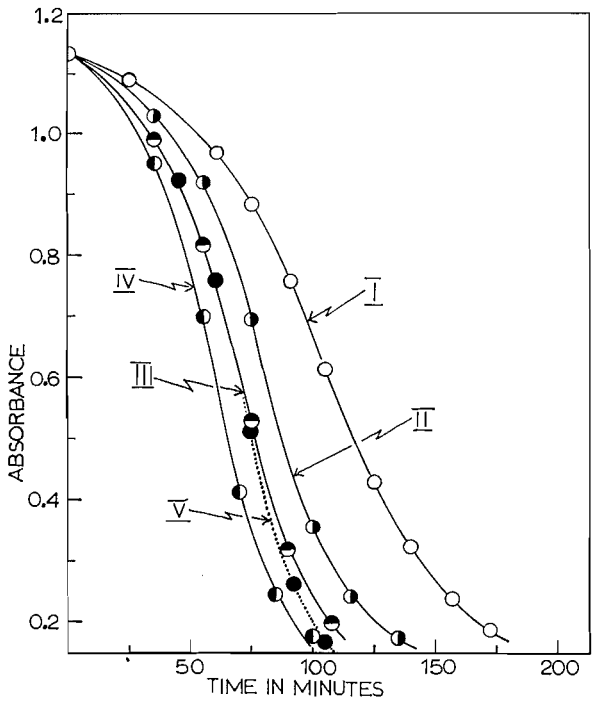

FIG. 5. Absorbance at 265 mμ vs. time during the reduction of 0.015 *M* nitrobenzene in aqueous ethanol at 50° C by 0.160 *M* Na_2S. I contains no added NaOH; II, III, IV, and V are 0.160 *M*, 0.320 *M*, 0.800 *M*, and 1.600 *M* in NaOH respectively.

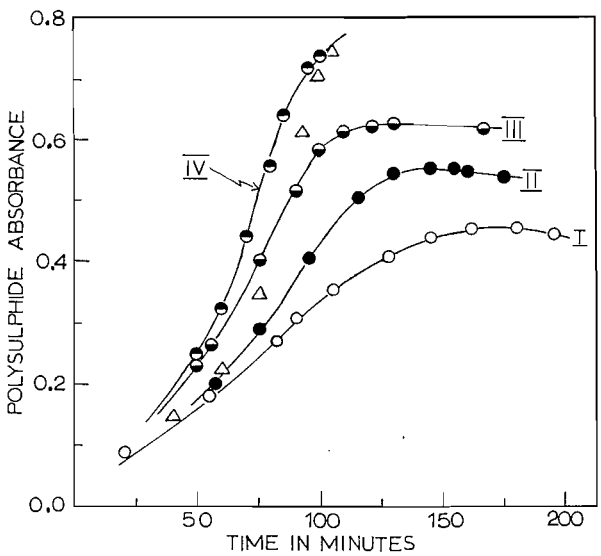

FIG. 6. The absorbance at 450 mμ vs. time during the reduction of 0.015 *M* nitrobenzene in aqueous ethanol at 50° C by 0.160 *M* Na_2S. I contains no added NaOH; II, III, IV, and V (△) are 0.160 *M*, 0.320 *M*, 0.800 *M*, and 1.600 *M* in NaOH respectively.

hydrodisulphide and disulphide species, and that addition of base changes their relative proportion and hence the total absorption (Fig. 4). In the preparation of solutions of sulphur in 0.160 *M* sodium sulphide, containing up to 0.160 *M* sulphur, it was found that the pH changed negligibly,[4] hence it was concluded that the ratio of disulphide ion to hydrodisulphide ion remained essentially constant in these solutions. Absorption of the 0.160 *M* sodium sulphide solutions containing various amounts of sulphur as polysulphide then reflected reasonably well the *concentration* of elemental sulphur, although not the *ratio* of disulphide ion to hydrodisulphide ion. This is embodied in the linear relation between absorbance and elemental sulphur found in the calibration plot which followed Beer's law.

The absorption shown in Fig. 6 must then be a composite of increased polysulphide concentration as result of reduction, and a larger ratio of disulphide to hydrodisulphide ion, the magnitude of which depends upon the hydroxyl ion concentration. Hence, calculation of the polysulphide sulphur from these absorption measurements, using the calibration data from the Beer's law plot would give erroneous results. With the aid of Fig. 4, the absorbances at various base concentrations have been converted to those where no base was added and thus it was possible to show the real increase of polysulphide sulphur which occurred during these reductions in basified solutions. Figure 7 shows more

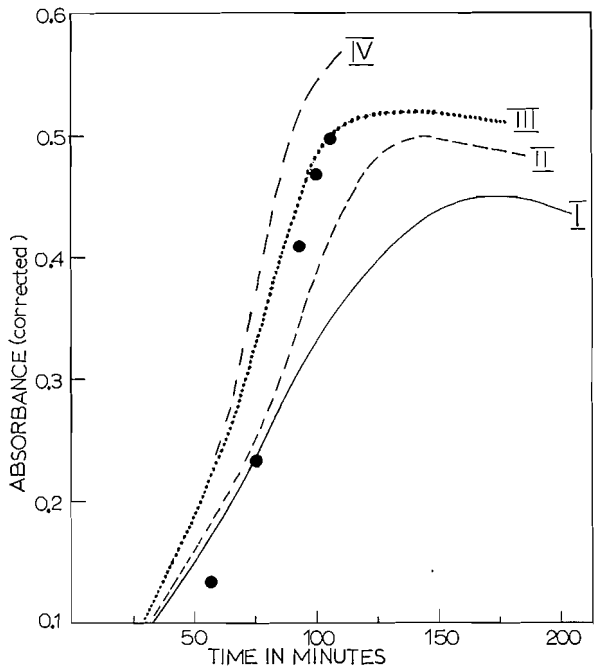

FIG. 7. The corresponding absorbances at 450 mμ from Fig. 6 corrected for the effect of increased OH ion concentration on the absorbance at 450 mμ (here ● represents 1.600 *M* NaOH).

clearly the diminishing increase of polysulphide sulphur as the initial concentration of base is increased and thus the greater extent of loss of sulphur by reaction with base.

Figure 4 was obtained by progressive basification of a sodium sulphide solution

[4]*A decrease in* pH *was expected since the disulphide ion should hydrolyze to a lower extent than does the sulphide ion (9). However, these results were repeatable using several different electrodes to avoid the chance that an electrode might have become contaminated or unreliable.*

For personal use only.

containing *one* specific concentration of polysulphide, and gave a figure of 1.80 for the ratio of absorbance of basified (4 *M*) solution to that of the unbasified solution. The same figure of 1.80 was obtained when a number of solutions were prepared, differing only in concentration of polysulphide, and made 4 *M* in sodium hydroxide. Hence the use of Fig. 4 and the ratio 1.80 for conversion of absorbances of the basified polysulphide solutions shown in Fig. 6 is justified.

The Formation of Thiosulphate during the Course of the Reduction

The possibility of air oxidation of sulphide to thiosulphate was avoided by careful deaeration of all solutions and by use of a nitrogen atmosphere. Iodometric titration of thiosulphate (25) requires preliminary removal of both sulphide and hydroxide ions. The addition of cadmium sulphate, rather than cadmium carbonate (10), accomplished this satisfactorily. However, it was found that the precipitated cadmium sulphide adsorbed some of the thiosulphate, thus giving low results in spite of attempts at recovery of adsorbed thiosulphate by extractions. Hence small changes in thiosulphate concentration during a reaction might easily be missed.

There existed the possibility of thiosulphate formation in our solutions due to the interaction of polysulphide sulphur with hydroxyl ions formed as a result of hydrolysis, especially since the pH of the solutions were well above 8 (10). This could not be determined satisfactorily by iodometric titrations for the reason cited above. However, an oxygen-free solution of 0.160 *M* sodium sulphide, containing 10% of sulphur as polysulphide, when kept at room temperature or at 50° C under nitrogen for 12 hours, showed no change in absorption or in pH. This is consistent with the view that little or no formation of thiosulphate occurred via reaction (*e*) by interaction of polysulphide sulphur and hydroxyl ion.

However, in contrast, much thiosulphate was formed *during* the reduction of nitrobenzene by sulphide solutions, in agreement with the observation of Bullock and Forbes (10). Iodometric titrations, after removal of hydroxyl and sulphide ions with cadmium sulphate, in spite of the loss due to adsorption, showed at least a ninefold increase of thiosulphate during the first 70 minutes of a typical reaction. That the base should react with sulphur formed *during* the reduction but not with the sulphur in polysulphide when nitrobenzene is absent can be reasonably explained. The negative charge on both hydroxyl and polysulphide ions prohibits their mutual interaction. On the other hand, the sulphur released during nitrobenzene reduction is uncharged and therefore can react readily with hydroxyl ions or with sulphide ions according to equations (*e*) and (*d*). This form of sulphur has been termed "active sulphur" by Bullock and Forbes and appears to be much more readily soluble in the sulphide solution than is elemental sulphur, ordinarily used for the preparation of polysulphide solutions.

Reduction of Nitrobenzene with Sodium Hydrosulphide and Sodium Hydrodisulphide

Reduction of nitrobenzene (0.015 *M*) by solutions of sodium hydrosulphide and sodium hydrodisulphide were carried out at 50° C. The results, shown in Fig. 1, plot V, indicate that during the initial stage of the reduction by hydrosulphide the rate was only $\frac{1}{2}$ to $\frac{1}{3}$ that found for the reduction with sodium sulphide. The marked autocatalytic effect observed in the latter case did not occur in hydrosulphide reduction of nitrobenzene. The addition of enough sulphur to convert about 10% of the sodium hydrosulphide to the hydrodisulphide gave no apparent increase in initial rate of this slow reaction and thus shows that sodium sulphide, sodium hydrosulphide, and the hydrodisulphide have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

apparently the same order of reducing capacity. The slow increase in rate shown in Fig. 1, plot V, could be ascribed to a gradual shift in the equilibrium $S_2^= + H_2O \leftrightarrows HS_2^- + OH^-$ to the left due to the increase in hydroxyl ion concentration resulting from the slow reduction. The observation that the pH rose from 10.0 to 10.9 over a period of 630 minutes of reaction supports this point of view. This is further supported by the observation of a greater rate of reaction in one preparation of hydrosulphide wherein only enough hydrochloric acid had been added to reduce the pH of the solution to 12.1 rather than the usual 10.0 to 10.2.

Summary of the Course of Reduction of Nitrobenzene by Sodium Sulphide in Aqueous Ethanol

The studies described in the preceding sections assist in clarifying the course of the reduction of nitrobenzene by sodium sulphide solution.

As the reaction progresses, to the initial, slow reduction by sulphide and hydrosulphide ions is added the much faster reduction due to polysulphide formed by the sulphur produced during the reduction. Since the conversion of *one* molecule of nitrobenzene to aniline forms *three* atoms of sulphur, which then rapidly react preferentially with sulphide or hydrosulphide ions present, an exponential increase of polysulphide occurs, accounting for the rapid autocatalysis. At the same time some of this active sulphur reacts with the hydroxyl ions to form thiosulphate. This reaction must be considerably slower than is the combination of sulphur with sulphide ions, otherwise the autocatalytic effect would be less pronounced. The increase in absorption at 450 mμ reflects an increase in polysulphide species. Eventually a state is reached where the rate of reduction appears to be constant, as a result of a balance between the increasing concentration of active polysulphide ions, the drop in nitrobenzene concentration, and the removal of some of the active sulphur as thiosulphate by the increasing concentration of hydroxyl ions. Following this, the reduction rate decreases as expected.

After the peak of the reduction rate has passed, the loss of polysulphide as thiosulphate, through preliminary reaction with nitrobenzene to produce active sulphur and its subsequent combination with base, becomes more competitive. This is no doubt due to the fact that only a 10-fold excess of sodium sulphide over nitrobenzene was employed as well as the fact that three sulphide (or polysulphide) ions are necessary to reduce one molecule of nitrobenzene to aniline. Thus, as reaction proceeds, there is a rapid decrease in the concentration of the charged sulphide species, which will react with the active sulphur formed by the reduction, to such a low level that the competitive reaction of sulphur with the hydroxyl ions becomes more important.

When the nitrobenzene has been practically completely reduced, the formation of thiosulphate and polysulphide ceases, as indicated by the constancy of the absorption of the polysulphide solution noted in at least two instances where such measurements were made over a period of 24 hours.

HYDROGEN BONDING IN SOLUTIONS OF SUBSTITUTED ACETIC ACIDS[1]

LEONARD W. REEVES

ABSTRACT

The changes in chemical shift of the acid proton in some simple carboxylic acids on dilution in four solvents has been studied. The existence of chainlike hydrogen-bonded polymers in solution is suggested by the results. The association of the monomer molecules in dilute solution with donor centers in the solvent molecules is suggested from a study of the —O—H monomer stretching bond in the vapor and in two solvents. There is a difference in the behavior of acetic and trifluoroacetic acid in N-methyl and N,N-dimethyl formamide, which has been explained in terms of protonation of the amides in trifluoroacetic acid solutions.

INTRODUCTION

The proton resonance technique has been a useful tool in measuring changes in the amount of hydrogen bonding in fluid systems (1, 2, 3, 4). The changes in chemical shift with the amount of hydrogen bonding are often very large. Recent improvements in standardization of chemical shifts and their measurement and the introduction of 60 Mc/s as a proton high-resolution frequency have made the sensitivity for detection of very weak interactions of the hydrogen-bonding type superior to any other technique (5, 6). The short lifetime of the hydrogen bond association compared to the inverse frequency shift due to various environments results in an averaging of the varying proton-shielding parameter, and one signal is observed (1, 7). The position of this signal corresponds to the average environment of the various equilibrium processes involved in the hydrogen bonding. This is a particular disadvantage in a system in which polymeric association via hydrogen bonds occurs, since the variation of averaged nuclear-shielding parameter with concentration or temperature does not provide enough information for the obtaining of a true association chemical shift, or equilibrium constants (8, 9). Some attempt has been made to calculate equilibrium constants for the monomer–dimer equilibrium in dilute alcohol solutions in CCl_4 using a region of concentration known to involve only monomers and dimers (10, 11).

The study of strong dimer associations such as carboxylic acids or intramolecular hydrogen bonds has been pursued in an attempt to avoid some of the above difficulties (12, 13, 14, 15). It has been suggested that acetic acid forms polymeric hydrogen-bonded associations in concentrated nonpolar solutions (15) while longer-chain acids show only dimer associations in the same concentration regions (13). The present study of substituted acetic acids was undertaken to investigate possible polymeric hydrogen bonding and to try to provide an explanation for the difference in behavior of acetic acid (15).

EXPERIMENTAL

Dichloroacetic acid, trifluoroacetic acid, and α-bromo- and α-chloro-proprionic acid were purified by fractional distillation in a dry atmosphere. A small middle cut was taken in each case. Monochloroacetic, trichloroacetic, trimethyl acetic, phenyl acetic, bromoacetic, and β-bromoproprionic acids were either recrystallized from chloroform or taken as reagent grade chemicals. The acids which are deliquescent were handled in a dry box.

The solvents used, carbon tetrachloride and 1,2-dichloroethane, were fractionally distilled in a dry atmosphere. The dilution chemical shift studies were made using 0.5

mole% cyclohexane in each solvent as an internal reference signal. The mole fraction of solute was computed using the total moles of solvent, solute, and internal standard.

The measurements were made with a V-4300 Varian 40-Mc spectrometer with field stabilizer V.K. 3506. An audio-oscillator was calibrated using Lisajoux figures at multiples of 60 c.p.s. mains frequency and the later measurements of audio frequencies were calibrated by a Hewlitt Packard Electronic Counter. The side-band technique of measurement was used in all cases. Chemical shifts are accurate to ± 1.5 c.p.s. in this work. Solutions were made up by weighing the liquids in capped vials.

RESULTS

Chemical shift measurements of the carboxyl proton resonance, using an internal cyclohexane reference, are plotted in Fig. 1 for various concentrations of acid in carbon tetrachloride. The acids measured were mono-, di- and tri-chloroacetic, α-chloro- and α-bromo-proprionic, trifluoroacetic, and trimethyl acetic acid. As the solid acids were not completely soluble at 28° C, the dilution shift curves are not complete for these acids. Monochloroacetic acid is soluble to about 10 mole% and the dilution shift curve is coincident as far as it goes with dichloroacetic acid. Trichloroacetic acid shows distinct behavior (see curve 2) in dilute solution but, between 8 mole% acid and the solubility limit, 20 mole%, the dilution shift curve is the same as that for the other chloroacetic acids. All dilution chemical shifts except that for trimethyl acetic acid showed a low-field movement with decreasing acid concentration. The change in chemical shift to low-field ranges from 19 cycles in dichloroacetic to 9 cycles in trifluoroacetic. Figure 1 also shows the carboxyl proton resonance in trifluoroacetic acid as a function of concentration in *n*-methyl formamide (curve 7), and the dilute regions are continued and shown as curve 7 in Fig. 2. In even more dilute solutions, the carboxyl proton in this system is found at -170 c.p.s. in 3.00 mole% solution compared to the proton resonance in cycloC_6H_{12}. This constitutes a shift of 320 c.p.s. (8 p.p.m.) from the chemical shift of the same proton in a 50:50 mole mixture with N-methyl formamide (Fig. 1). The N-methyl peak is a doublet in the amide because of indirect spin–spin coupling with the N-proton; and the other peak in the spectra of these mixtures corresponded to the aldehyde proton (16). Significant changes in chemical shift were obtained in the chemical shift of these protons; this is shown in an inset of Fig. 2(*b* and *c*). The chemical shift scale is the same but the concentration axis is halved in length for the same concentration change. Figure 2 also shows the dilution chemical shifts for three acids in 1,2-dichloroethane. Figure 3 shows a comparison of the dilution chemical shifts for the acid proton in acetic and trifluoroacetic acid dissolved in N-methyl and N,N-dimethyl formamide.

The infrared spectra of the —OH stretching region was investigated for CCl_3COOH and CF_3COOH in various solvents and in the vapor phase. The spectra for CCl_3COOH are shown in Fig. 4(*a*) and those for CF_3COOH are shown in Fig. 4(*b*). The frequency shifts from the vapor phase monomer frequency are shown in Table I together with values of the half widths of the single peak and details of concentration. In addition to these, reliable values for the vapor phase frequency from the literature (25, 26) for the —OH stretching in monomeric acetic and formic acid are shown, and the value for this frequency for iodoacetic acid in CCl_4 is also measured and quoted in this work. Spectra were recorded on a Perkin–Elmer 21 double-beam spectrometer with sodium chloride optics on the normal automatic 927 program. The wavelength calibration was carefully performed with the water vapor spectrum in this same region. Wave numbers quoted are accurate to ± 2 cm^{-1}. Solution spectra were taken using balanced 0.1-mm cells or a

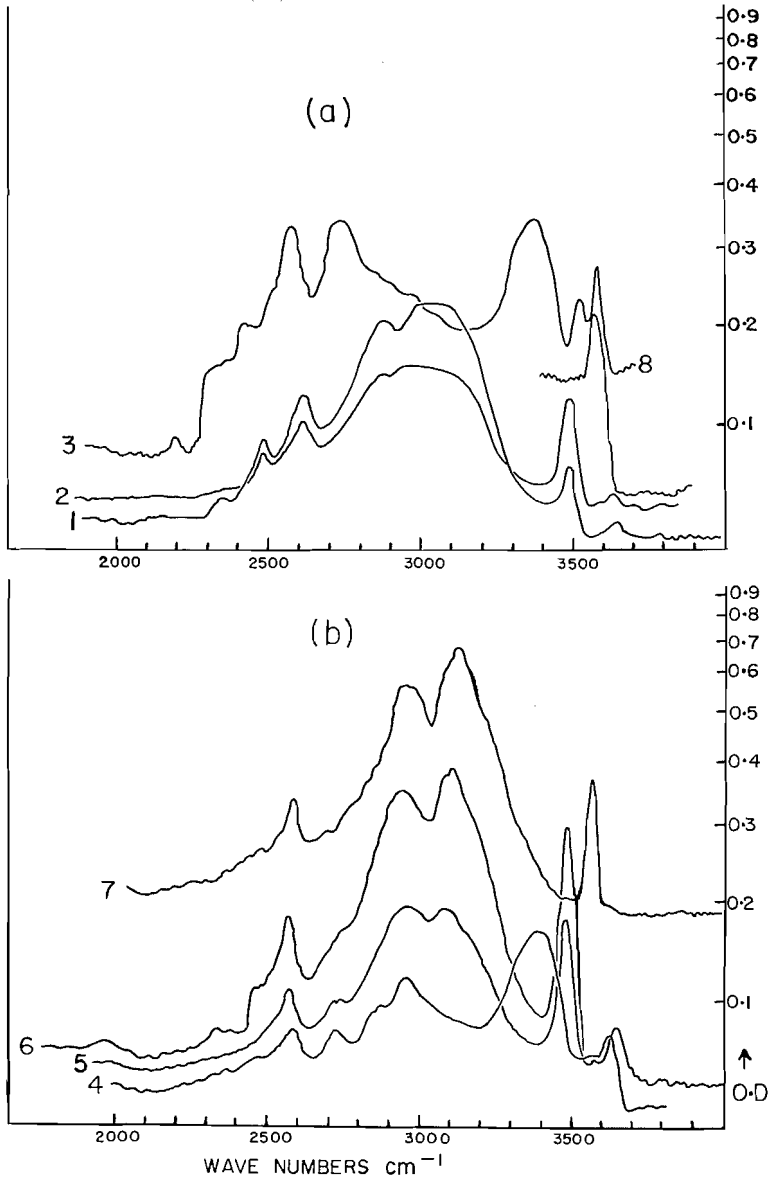

FIG. 4. (*a*) Infrared spectra of the —O—H stretching region for CCl_3COOH. Curves are identified by numbers: (1) 4.2×10^{-3} mole fraction in CCl_4, 0.1-mm cell; (2) 6.4×10^{-4} mole fraction in CCl_4, 3.0-mm cell; (3) 1.4×10^{-3} mole fraction in 1,2-dichloroethane, 3-mm cell; (8) vapor spectrum CCl_3COOH at 35° C, 5-m gas cell.

(*b*) Infrared spectra of —O—H stretching region for $CF_3CO.OH$. Curves are identified by numbers: (4) 1.7×10^{-2} mole fraction in 1,2-dichloroethane, 0.1-mm, cell; (5) 1.904×10^{-3} mole fraction in CCl_4, 3.0-mm cell; (6) 2.9×10^{-3} mole fraction in CCl_4, 3.0-mm cell; (7) vapor spectrum of CF_3COOH at 25° C, 10-cm gas cell.

The —OH monomer stretching frequency occurs in the vapor phase for all acids measured at 3574 ± 6.5 cm^{-1}. The frequency difference from acid to acid is significant but quite small compared to a shift of 85–90 cm^{-1} to the monomer absorption in CCl_4

solution for all acids. An even larger shift of 180–202 cm^{-1} occurs when the acid monomer absorbs in $CH_2Cl—CH_2Cl$ solution. Each of these solvent shifts is accompanied by large changes in the absorption half widths, $\Delta\nu_{\frac{1}{2}}$.

DISCUSSION

Consideration of the Case for Open-chain Hydrogen-bonded Polymers

In Fig. 1, the low-field dilution shift obtained for the acid proton resonance in the following acids: trifluoroacetic, trichloroacetic, dichloroacetic, monochloroacetic, and α-bromo- and α-chloro-proprionic acids, will be interpreted as resulting from the occurrence of open- and polymeric-chain association in equilibrium with the cyclic dimer form of these acids in concentrated solution. The result is similar to that obtained by Reeves and Schneider (15) with acetic acid solutions although not similar to the curves obtained for the acids C_3 to C_{17} (13).

The polymeric hydrogen-bonded form of acetic acid in solution suggested by dielectric measurements (23, 28), Raman spectra (19), and nuclear magnetic resonance (15) is probably related to the polymeric form in the crystal of acetic acid (18). The order introduced by cyclic or chainlike polymers in solution as opposed to cyclic dimer formation must be compensated by an increased strength of the individual hydrogen bonds. The occurrence of proton resonance at higher field for the carboxyl proton and the fact that the hydrogen bonds are individually stronger can only be reconciled by chainlike polymerization as opposed to a cyclic structure.

The proton resonance occurs at higher field because a chainlike structure involves one terminal acetic acid molecule which has one non-hydrogen-bonded proton. It is possible that the rapid averaging of the proton shielding gives rise to a net displacement to high field for the acid proton. In Table II, the chemical shifts relative to water of various O—H - - - O hydrogen bonds is given together with the O—H - - - O distance where data is available. It can be seen from this table that there is good correlation between the

TABLE II

Comparison of chemical shifts in O—H - - - O hydrogen-bonding systems and bond distances when available

Compound	Concentration dependent?	Chemical shift, H_2O, p.p.m.	O—H - - - O distance in crystal, Å	Reference to chemical shifts
Pure acetic acid	Yes	−6.8	—	15
Pure substituted acetic acids	Yes	−6.9	—	Present work
Pure C_3–C_{10} acids	No	−7.2	—	13
Pure trimethyl acetic acid	No	−7.5	—	Present work
$CF_3CO.OH$ – N-methyl formamide 1:1 complex	Yes	−8.7	—	Present work
Calculated acetic acid dimer shift from K_{dimer}	No	−9.7	2.76+	24
Acetylacetone-enol form	No	−10.0	—	12
Calculated benzoic acid dimer shift	No	−10.25	2.64+	24
$CF_3CO.OH$–N,N-dimethyl formamide, lowest field position acid proton	Yes	−12.0	—	Present work
Triacetylmethane-enol form	No	−12.6	—	25
Potassium hydrogen maleate	No	−15.4		26
Sodium hydrogen maleate	No	−15.03	2.41+ to 2.43	26
Potassium hydrogen phthalate	No	−15.15		26

NOTE: Uncertainties of ±0.2 p.p.m. exist in any given chemical shift due to varying referencing procedures. "+" bond distances obtained from reference 20.

hydrogen-bond strength and the paramagnetic chemical shift of the hydrogen-bonded proton. This supports the suggestions of Pople and Marshall (31) that the strongest hydrogen bonds have the largest negative chemical shifts, and the experimental measurements of Reeves, Allan, and Strømme (14, 27).

The suggestions of Pitzer and Davis (24) that the reduction of the O—O distance across the hydrogen bond eventually causes increased shielding due to electrons of the noncovalently bonded oxygen is not experimentally proved. The only explanation therefore of the low-field shift on dilution of some carboxylic acids is the occurrence of chainlike polymers.

The careful experimental work of Pitzer and Davis (24) warrants some discussion since the calculated dimer chemical shift in their work lies considerably to low field with respect to the dimer shifts assumed in the work of Reeves and Schneider (15) and, later, Reeves (13). The occurrence of abnormally large variations of monomer chemical shift with temperature (24) using equilibrium constants obtained from infrared measurements and the extremely large absolute magnitude of the monomer–dimer chemical shifts must reflect some uncertainty in either the equilibrium constants used or the basic assumptions that only monomers and cyclic dimers exist at the concentrations studied. A variation of 400 cycles in chemical shift due to a neighboring ring current effect (24) over an 80° C range is almost one order of magnitude too large (5). Even when the equilibrium constants are adjusted so as to obtain constant values of δ_{monomer} and δ_{dimer} with temperature, the uncertainty about the existence of open dimers, trimers, or higher polymers renders this adjustment of the value of δ_{monomer} somewhat artificial. Recent dielectric measurements (28) suggest the existence of polymers of the open-chain type in concentrated solutions of *n*-caproic and cyclohexane carboxylic acid in nonpolar solvents. The complicated question of species present in nonpolar solutions of long-chain acids is not resolved but in acetic acid and the substituted acetic acids measured here, the occurrence of open-chain polymers is indicated.

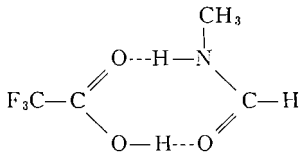
Association of the Monomer Form of Carboxylic Acids with Solvents

A weak hydrogen-bond acceptor such as chloroform forms hydrogen-bonded complexes with donor solvents such as acetone (4) and even with weak donor systems such as benzene or olefins (5). It is to be expected that a much stronger acceptor such as the acid proton of the monomer form of carboxylic acids will form a stronger hydrogen-bond association than chloroform, with the same donor solvents. The position of the monomer acid proton chemical shift is shown to be strongly temperature dependent in the work of Pitzer and Davis (24) but the calculated position of the signal is subject to large systematic errors. The interpretation suggested by several workers (13, 15, 17) that the monomer form appears in solutions of higher dielectric constant merely because of the higher dipole moment of the monomer is not entirely true. Recent work on the infrared spectra of solute molecules has shown conclusively that spectral shifts can be associated with specific association with a solvent molecule through a hydrogen bond (30, 29). The figures in Table I are evidence for the specific association of the acid monomers with solvent molecules on this basis. The frequency shift of the monomer —O—H stretching frequency between the vapor phase and essentially infinite dilution in CCl_4 is about 80–90 cm^{-1}. This is too large to be accounted for on the basis of dispersion forces alone. At the same time the half width of the single line observed increases markedly between the vapor and the solution as seen from Table I. The frequency shift and increase in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

half width of the monomer —O—H absorption is much more marked in 1,2-dichloroethane (Fig. 4 and Table I), indicating a stronger hydrogen-bonded complex with the monomer in this case. The frequency shift of the monomer absorption in the vapor phase amongst a series of acids is quite small, ± 6.5 cm^{-1}, compared with the change between vapor and solvent. The variation of monomer absorption frequency in CCl_4 amongst three acids measured (Table I) is also quite small. The weak hydrogen-bond association of carbon tetrachloride with carboxylic acid monomers is to be expected since this molecule is a very weak donor.

The dimer band is considerably more intense than the monomer even at the concentrations studied, but an intensification factor of 37× on dimer formation suggested by Pimentel and McClellan (32, Table 3-VIII) indicates that little dimer is present.



The Chemical Shift Changes in 1,2-Dichloroethane

The dilution chemical shifts of three acids in 1,2-dichloromethane indicate that the polymeric hydrogen-bonded forms and the dimer form are dissociated appreciably at much higher acid concentrations. The situation at infinite dilution of acid will correspond to some kind of hydrogen-bonded complex between the acid monomer and dichloromethane. The behavior of the substituted acids in this solvent is very similar to that reported previously for other carboxylic acids in dichloroethane, acetone, and acetonitrile. The dissociation at higher concentrations of acid is encouraged in a solvent of higher dielectric constant.

The Behavior of Carboxylic Acids in Basic Solvents

The changes in chemical shift of the acid proton of trifluoroacetic acid in N-methyl and N,N-dimethyl formamide (Figs. 1, 2, and 3) are of some interest since the low-field extremes of these shifts are quite remarkable. Such a low-field shift is consistent only with the formation of a very strong hydrogen bond. There is considerable heat evolution on making up the solutions, which is not usually detectable when there is a change in the strength and number of hydrogen bonds formed.

The formation of a stronger hydrogen bond in a 1:1 complex could conceivably occur between trifluoroacetic acid and N-methyl formamide in a configuration similar to an acid dimer, as shown below.

This particular form of a 1:1 complex depends on the existence of both donor and acceptor ends of the hydrogen bond in the correct spatial arrangement on the amide molecule. This is excluded in N,N-dimethyl formamide but the extreme low-field chemical shift of the acid proton becomes greater in these solutions as shown in Fig. 3. The form of the 1:1 complex above is not therefore the cause of this extreme low-field shift.

The form of these dilution chemical shift curves are explicable in terms of proton transfer to the amide.

$$CF_3CO.OH + NMe_2CHO \rightleftharpoons CF_3COO^- + NMe_2CH_2O^+$$

The strength of trifluoroacetic acid is sufficient to cause proton transfer to the amide,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

although in such concentrated solutions the medium effects prohibit quantitative prediction of the extent of protonation. The addition of amide to the acid causes the chemical shift of the acid proton to move to low field. This can be explained in terms of the protonation of almost all amide molecules and the formation of a very strong hydrogen bond between the conjugate acid of the amide and the trifluoroacetate anion. This is equivalent to the formation of ion pairs in moderately concentrated solution. The chemical shift of the acid proton observed is an average of the various environments since rapid proton exchange is evident from the single sharp line observed. In a 1:1 mole ratio of acid to amide it is expected that almost all the molecules present are involved in ion-pair formation. Addition of further amide will raise the dielectric constant of the solution and cause dissociation of the ion pairs. The breaking of the strong hydrogen bond in the ion pairs in dilute solution causes the very large chemical shift change in the high-field direction. The nature of the amide conjugate acid is not indicated by these results.

The dilution chemical shift of acetic acid in the N,N-dimethyl formamide is quite small and not detectable until dilute acid solutions. The strength of acetic acid is much smaller so it is expected that protonation of the amide is inappreciable.

The chemical shift in dilute solutions of acetic acid in N,N-dimethyl formamide is not measurable (~15 mole% acid) because of broadening of the acid proton resonance below noise level. This is indicative of proton exchange in the critical region for n.m.r. measurements (7). Further studies of these processes are being made.

NOTES

SAPONINS AND SAPOGENINS

XI. ON THE PRESENCE OF ECHINOCYSTIC ACID AND QUERCETIN IN FLOWERS OF ALBIZZIA LEBBEK BENTH.*

I. P. VARSHNEY AND MOHD. S. Y. KHAN

Seeds of *Albizzia lebbek* Benth. from Utter Pradesh have previously been reported to yield saponin from which oleanolic acid and echinocystic acid have been obtained (1), while the complete beans of *A. lebbek* Benth. from Bengal yield, in addition to these two acids, another isomer of echinocystic acid named albigenic acid (2). Another species, *Albizzia anthelmintica* (3), yields echinocystic acid alone. *Albizzia procera* from Madhya Pradesh (4) and *Albizzia odoratissima* seeds from Maharashtra (5) yield machaerinic acid.

Although much work has been done on the seeds from various species, no work seems to have been done on the flowers of any of the species of *Albizzia* and therefore the work on the flowers of *A. lebbek* Benth. was undertaken.

The flowers of *A. lebbek* Benth., collected locally from the university campus, yielded, by alcoholic extraction and subsequent treatment, a colorless hygroscopic powder giving all the tests for saponins. The sulphuric acid hydrolysis of the saponin gave the sapogenin (acid), m.p. 297–301°. It gave a diacetate, m.p. 257–262°, and diacetyl methyl ester, m.p. 201–202°. It is a pentacyclic triterpenic acid belonging to the β-amyrin group and has been identified as echinocystic acid ($3\beta,16\alpha$-dihydroxy-Δ^{12}-oleanene-28-oic acid) by mixed melting point with authentic samples of echinocystic acid and derivatives (c.f. echinocystic acid, m.p. 305–312°; acetate, m.p. 272–275°; acetyl methyl ester, m.p. 200–201° (1, 6)). The infrared spectra of the acetyl methyl ester, which is superimposable with that of an authentic sample, confirmed its identity as echinocystic acid.

The flowers also yield an anthoxanthin glycosidic fraction. The product did not crystallize and therefore was hydrolyzed. The aglycone obtained was then chromatographed on filter paper. The chromatogram showed the presence of at least three components quite different from each other. One of the components was identified as quercetin by chromatography with an authentic sample of quercetin.

EXPERIMENTAL

All the melting points recorded have been taken on a Kofler hot microscopical stage and are corrected. The infrared spectra have been taken in these laboratories by one of the authors (I. P. V.) using a Perkin–Elmer spectrometer model 137 (Infracord) in nujol mull.

Saponin and sapogenin.—The flowers (200 g), after being exhausted with light petroleum ether, were extracted with 95% alcohol and the saponin (10.5 g) was obtained as a colorless hygroscopic powder in the usual manner (4). It gave all the tests for saponin, i.e. it foams copiously when shaken with water, is toxic to fishes in dilute concentrations, and haemolyzes red blood corpuscles in dilute solutions (7). The saponin (5 g) was hydrolyzed with sulphuric acid (7%) (4) and the genin obtained (1.5 g) was then transformed into the potassium salt by being refluxed with methyl alcoholic potassium

**Part X. Arch. Pharm. In press.*

hydroxide. The solution of the potassium salt was extracted with ether to remove any neutral sapogenin present. Hydrochloric acid, added to the alkaline solution remaining after ether extraction, precipitated the acid sapogenin, which was filtered, washed free of the acid, and dried.

Acetate.—The genin (200 mg) was acetylated hot, in the usual manner, with pyridine and acetic anhydride. The acetate obtained was crystallized from methyl alcohol as colorless needles, m.p. 257–262° (cf. diacetyl echinocystic acid, m.p. 272–275° (6); 248–249° (1)). The melting point was not depressed when a mixed melting point was taken with an authentic sample of diacetyl echinocystic acid. I.R. spectra: λ_{max}^{nujol} 5.81, 5.90, 8.09 μ.

Genin.—The acetate (100 mg) was deacetylated with methyl alcoholic potassium hydroxide (10%) and the free genin (80 mg) obtained was crystallized from isopropyl alcohol as colorless crystals, m.p. 297–301° (cf. echinocystic acid, m.p. 305–312° (6); 291–293° (1)). No depression was noted when a mixed melting point was taken with an authentic sample of echinocystic acid. I.R. spectra: λ_{max}^{nujol} 2.87, 5.97 μ.

Acetyl methyl ester.—The acetate (100 mg) was methylated with diazomethane and the methyl ester obtained was crystallized from methyl alcohol as colorless fine needles (90 mg) melting at 201–202°. It was found to be identical with acetyl methyl echinocystate as no depression was observed in the mixed melting point with an authentic sample of diacetyl methyl echinocystate and the infrared spectra were identical (cf. echinocystic acid diacetyl methyl ester, m.p. 200–201° (1, 6); I.R. spectra: λ_{max}^{nujol} 5.75, 8.09 μ). I.R. spectra: λ_{max}^{nujol} 5.75, 8.09 μ.

Anthoxanthin glycosides.—The residue obtained after the evaporation of the alcoholic extract was dissolved in water and the solution extracted with *n*-butyl alcohol. The recovery of the butyl alcohol gave a mixture of the saponin and the glycoside. It was dissolved in alcohol, filtered, and then added dropwise into a large volume of acetone to precipitate the saponin. The saponin was filtered off and the acetone solution was evaporated to dryness and then again dissolved in alcohol and reprecipitated with acetone. This operation was repeated twice to remove the saponin completely. The acetone, after the removal of the saponin, was evaporated to dryness and the product obtained gave a salmon-pink coloration with magnesium and hydrochloric acid (8). All attempts to crystallize the glycoside were fruitless.

Aglycone.—The aqueous solution of the glycoside containing a little alcohol was hydrolyzed by refluxing with sulphuric acid (10%) for 3 hours. The aglycone obtained was filtered and washed free of acid. It was dissolved in alcohol and two drops of dilute lead acetate solution added to it precipitated the impurities. It was then filtered and the filtrate was treated with hydrogen sulphide to remove any lead which might have passed into the filtrate. The solution thus obtained was evaporated to dryness under reduced pressure. The product (aglycone) obtained gave acidic cyanidin and Wilson's boric acid tests (8, 9).

Paper chromatography.—The aglycone dissolved in a few drops of alcohol was deposited on Whatman filter paper No. 1 and chromatographed beside an authentic sample of quercetin (L. Light & Co. Ltd., England). An acetic acid:water (60:40) (10) solvent mixture and the ascending technique were used. The chromatogram was run for 16 hours and then dried and sprayed with sodium carbonate solution, ferric chloride solution, or examined under ultraviolet light and ultraviolet light and ammonia (10, 11) vapors. It showed three clear spots, one of which was found to be identical with quercetin. All attempts to crystallize the aglycone failed.

PREPARATION OF UNDECENOL AND UNDECENYL BROMIDE

D. G. M. DIAPER

Although complex hydrides have revolutionized the preparation of primary alcohols from acids and esters, the Bouveault–Blanc procedure may still be preferable for preparative work on the grounds of expense, especially when catalytic hydrogenation cannot be employed. To prepare undecenol (undec-10-en-1-ol) in quantity (1), sodium–ethanol reduction of ethyl undecylenate (undec-10-enoate) was used. Yields previously reported for this and other Bouveault–Blanc reductions vary widely, and rarely exceed 80%. Smith (2) obtained undecenol in 76% yield by sodium and ethanol reduction and only 30% was obtained (3) in butanol. Poor yields have been attributed to the presence of water, which gives sodium hydroxide, destroying the ester by conversion to the sodium salt, which is not attacked by the reagent. In long-chain ester reductions this concurrent production of the sodium salt of the acid is doubly serious since it not only reduces the yield but complicates isolation of the alcohol which is entrained in the soapy aqueous layer. Intensive drying of the ethanol is the customary solution of this problem—a tedious affair which must be repeated at intervals if the stock of ethanol is exposed to air in intermittent use. Even so, Darzens (4) contends that reaction of the ester with sodium thus,

$$R.COOEt + 2H_2 \rightarrow RCH_2OEt + H_2O, \qquad [1]$$

inevitably produces some water and thus sodium salt. This interpretation implies a stoichiometric equivalence of ethyl ether production, water formation, and ester destruction.

In an attempt to assess the effects of traces of water (such as are removed in an intensive drying operation) upon the reaction, progressive amounts were added to the solvent in successive reductions under standard conditions. The saponification yield was found by titration and the results are represented in Fig. 1, curve A. The first part of the curve is steep, demonstrating that the effect of water upon the saponification reaction is catalytic

PREPARATION OF UNDECENOL AND UNDECENYL BROMIDE

D. G. M. DIAPER

Although complex hydrides have revolutionized the preparation of primary alcohols from acids and esters, the Bouveault–Blanc procedure may still be preferable for preparative work on the grounds of expense, especially when catalytic hydrogenation cannot be employed. To prepare undecenol (undec-10-en-1-ol) in quantity (1), sodium–ethanol reduction of ethyl undecylenate (undec-10-enoate) was used. Yields previously reported for this and other Bouveault–Blanc reductions vary widely, and rarely exceed 80%. Smith (2) obtained undecenol in 76% yield by sodium and ethanol reduction and only 30% was obtained (3) in butanol. Poor yields have been attributed to the presence of water, which gives sodium hydroxide, destroying the ester by conversion to the sodium salt, which is not attacked by the reagent. In long-chain ester reductions this concurrent production of the sodium salt of the acid is doubly serious since it not only reduces the yield but complicates isolation of the alcohol which is entrained in the soapy aqueous layer. Intensive drying of the ethanol is the customary solution of this problem—a tedious affair which must be repeated at intervals if the stock of ethanol is exposed to air in intermittent use. Even so, Darzens (4) contends that reaction of the ester with sodium thus,

$$R.COOEt + 2H_2 \rightarrow RCH_2OEt + H_2O, \qquad [1]$$

inevitably produces some water and thus sodium salt. This interpretation implies a stoichiometric equivalence of ethyl ether production, water formation, and ester destruction.

In an attempt to assess the effects of traces of water (such as are removed in an intensive drying operation) upon the reaction, progressive amounts were added to the solvent in successive reductions under standard conditions. The saponification yield was found by titration and the results are represented in Fig. 1, curve A. The first part of the curve is steep, demonstrating that the effect of water upon the saponification reaction is catalytic

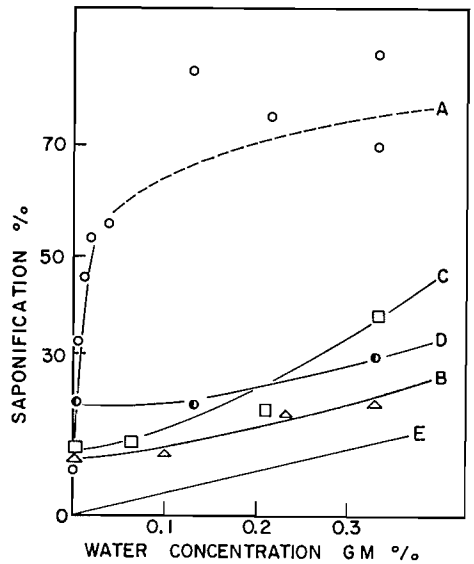

FIG. 1. Saponification of ethyl undecylenate during Bouveault–Blanc reduction as a function of water concentration. Curve A (open circles), ethanol alone; curve B (triangles), ethanol (30 ml) and acetic anhydride (1 ml); curve C (squares), ethanol (30 ml) and acetic acid (0.5 ml); curve D (half-filled circles), ethanol (30 ml) and acetic acid (1 ml); curve E, theoretical saponification yield.

and not stoichiometric. Curve E represents stoichiometric utilization of water in saponification (by calculation). It is suggested that the latter part of curve A (dotted) is indefinite for the following reason. The Bouveault–Blanc reaction is performed extremely rapidly and there must be a competition between two rapid reactions. Reduction probably occurs principally at or near the sodium surface; saponification, in all regions of the ethanol phase. The competition will therefore be controlled by the effective surface area of the molten metal and therefore by the degree of turbulence of the mixture during a brief critical period of time. This condition is hard to control or reproduce.

The use of ammonium chloride (5) and trialkyl borates (6) as additives to suppress saponification in sodium reductions has been advocated. We find that acetic anhydride (curve B, Fig. 1) and acetic acid (curves C and D) have similar effects. Such a result for acetic anhydride is not unexpected, for this reagent can effectively diminish water concentration by conversion to acetic acid. The product, acetate ion in this case, would attack the ester starting material much more slowly than the hydroxide ion. The acetic acid result is more surprising, for it must react with hydroxide ion as follows:

$$OH^- + CH_3.COOH \rightarrow H_2O + CH_3.COO^-. \qquad [2]$$

On this basis, a mole of water is regenerated for a mole of hydroxide ion destroyed. This can react further with sodium giving a mole of hydroxide back again, so the effect of acetic acid is not expected to destroy water or hydroxide but to keep the amounts of these constant in a cyclic process. Possibly the acetic acid functions, with its ion, as a buffer, diminishing hydroxide concentration during the early critical part of the reaction. An increased acetic acid concentration (curve D, compare C) actually leads to a poorer result with traces of water. This is attributed to precipitation of sodium salts on the sodium surface, hindering migration of ester to the site of reduction and exposing it for a relatively longer time to saponification.

The Darzens hypothesis (equation [1]) would require that the crude undecenol should contain some of its ethyl ether as an impurity. It was found that a single peak was obtained in gas chromatographic analysis and it was shown that an authentic sample of 1-ethoxy-10-undecene can be separated from undecenol under the conditions employed. To prepare the ether, undecenyl bromide was made by an improved method which incorporates removal of starting material (which boils close to the product) as acidic phosphate esters.

While the evidence now available confirms catalytic rather than stoichiometric participation of water and rules out significant formation of ethyl ether as a side reaction, it sheds little light on the mechanism of the reduction process. It is demonstrated, however, that the necessity for "super-dry" ethanol as a solvent in this instance may be avoided.

EXPERIMENTAL

Undecenol—Preparative Method

Ethyl undecylenate (46 g, 0.22 mole, n_D^{20} 1.4390) was mixed with ethanol (200 ml) which had been drawn from the stock of absolute ethanol without special drying. Acetic acid (3 ml) was added. The solution was poured, as rapidly as possible without loss, down an inclined condenser attached to a flask containing sodium (40 g, 1.7 moles, cut in several large pieces under xylene and melted under nitrogen) and heated in a salt bath at 160°. After the reaction had moderated, the solution was boiled under reflux for 5 minutes in a dry nitrogen atmosphere. A steam inlet was then quickly attached and the bulk of the ethanol was removed by steam distillation while the unreacted sodium was simultaneously destroyed. It is important that air is not allowed to enter the system until all the sodium has been destroyed. The residual liquid was extracted with ether, washed once with water, and dried. Upon distillation, undecenol was obtained in three runs of similar scale in yields of 78, 84, and 82%, b.p. 134–139° at 12 mm. Scale-up to 100 g of ester diminished this to 74%. The discrepancy between these yields and those indicated in Fig. 1, curve C, may be due to scale-up or distillation loss. The undecenol in each case gave a single peak in gas chromatographic analysis as described below.

Undecenol—Estimation of Concurrent Saponification

A 500-ml three-necked flask was fitted with an inlet tube for dry nitrogen, a large-liquid-capacity Allihn condenser, arranged for reflux somewhat inclined from the vertical, and a stopper. The condenser was capped with a drying tube. All apparatus was standard taper glassware, oven dried at 120° and quickly filled with nitrogen after assembly, while still hot. Sodium metal (approximately 9 g, 0.39 mole) was cut in a single lump, under xylene, with a knife and a large, warm, lightly greased cork borer. It was pressed out of the cork borer directly into the flask while a vigorous stream of nitrogen emerged. The flask was then immersed in a salt bath at 170°. The sodium should melt to give a bright globule with a thin broken black film. There should be no visible pieces of white crust. Dry ethyl undecylenate (10 g, 0.047 mole) was quickly weighed into a flamed flask while still hot, and dry ethanol (30 ml) was siphoned in. The ethanol stock had been dried by the magnesium ethoxide method; it was then collected in hot glassware previously filled with dry nitrogen, and stored in a ground-joint apparatus fitted with a siphon and drying tube. Immediately before being poured onto the sodium, the required additives (acetic acid, water, or acetic anhydride (see Fig. 1)) were added by pipette in the form of freshly prepared ethanol or benzene solutions of accurately known concentration in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

1–10% range. The nitrogen stream was interrupted while the solution was poured down the condenser and restarted immediately after. A few minutes were allowed to elapse after the reaction subsided and the apparatus was then quickly fitted with a steam inlet, care being taken to avoid ingress of air. When all the sodium had been destroyed, the solution was acidified with sulphuric acid and ice, and continuously extracted with ether. The ether extract was made up to 100 ml with ethanol and an aliquot was neutralized to bromcresol green. Sodium hydroxide (0.0486 *N* in ethanol) was added from a burette in excess, and, after it had been allowed to stand several hours under nitrogen to ensure saponification of ester, the alkali was back-titrated with standard acid. Solvent blank reactions were performed (ethanol, sodium, acetic acid or anhydride, but no ethyl undecylenate), giving titration values within 0.2 ml of the theoretical figures. Curves B, C, and D were plotted using titration values corrected for acetic acid content. All points represent single determinations, except the first point (water concentration = 0) on curve A, which was the mean of a triplicate determination (7.0, 7.6, and 8.3%).

Undecenyl Bromide (11-Bromo-1-undecene)

Conversion of undecenol to the bromide (6) is complicated by the fact that starting material and product boil at nearly the same temperature. The following modification ensures freedom from undecenol. After undecenol (86 g, 0.51 mole) was treated with phosphorus tribromide (50 g, 0.18 mole) in toluene (250 ml) at −5° and then at 90° for 3 hours, toluene was removed under reduced pressure and the solution was diluted with dry ether (150 ml). It was treated with phosphorus pentoxide (two 20-g portions) and next day decanted into 250 ml of 50% aqueous methanol. Ammonia was quickly added until the mixture was alkaline to phenolphthalein and, after it was washed with a similar portion of aqueous methanolic ammonia and with water, the ether solution was dried and distilled, giving 57 g (48%) of undecenyl bromide, b.p. 136–141° at 15 mm, n_D^{20} 1.4638. By vapor phase chromatography in hydrogen at 160 ml/minute and 183° on an Apiezon grease column the bromide came through as a single peak with a retention time of 15.6 minutes. Under similar conditions undecenol had a retention time of 8.4 minutes and a sample of undecenyl bromide, prepared as above but omitting the phosphoric anhydride – ammonia purification, showed two peaks. The infrared absorption spectrum of this sample had a peak in the O—H region, absent from the purified sample.

1-Ethoxy-10-undecene

By condensation of undecenyl bromide with one equivalent of sodium ethoxide in dry ethanol or by condensation of ethyl bromide with one equivalent of sodium undecenoxide in dry benzene, a liquid product was obtained, boiling at 114–115° at 4 mm, n_D^{21} 1.4344. Although it analyzed correctly for $C_{13}H_{26}O$ (found: C 79.1, H 12.9; calc: C 78.8, H 13.1%), the vapor chromatogram (in hydrogen at 160 ml/minute over Apiezon at 220°) showed two peaks at 3.25 and 4.0 minutes. The latter was identified as undecenol by admixture with an authentic sample and accounted for about 5% of the product. The fact that both methods of preparation gave a similar proportion after distillation indicates that an azeotropic mixture is formed. Separation was achieved by column chromatography over alumina and the purified ethoxy undecene gave a single vapor phase chromatograph peak. After distillation it had n_D^{21} 1.4336.

Support for this research was received from Defence Research Board under Grant No. 9530-17 and is gratefully acknowledged.

THE CRYSTALLIZATION OF POLYAMINO POLYACETIC ACIDS IN AN ION EXCHANGE MEMBRANE CHAMBER

R. A. KUNTZE

Ethylenediamine tetraacetic acid (EDTA) as represented by the formula $(HOOCCH_2)_2N(CH_2)_nN(CH_2COOH)_2$, where $n = 2$, has received considerable attention because of its ability to form highly stable chelates with a variety of metal ions. It is generally synthesized by condensation of sodium chloracetate and ethylenediamine (1) or by modifications of the Strecker-type synthesis (2). The free acid can be crystallized from the alkaline reaction mixtures by acidification to pH 1.5–2 with a mineral acid.

In the course of an investigation of the properties of polyamino polyacetic acids as inhibitors of the precipitation of calcium salts, the methods of synthesis and crystallization of several acids similar to EDTA were examined. It was found that diethylenetriamine pentaacetic acid (DTPA), with the formula $(HOOCCH_2)_2N(CH_2)_2NCH_2COOH(CH_2)_2$-$N(CH_2COOH)_2$, can be synthesized by both the Strecker-type synthesis and the chloracetate method, although it has been claimed that the latter method cannot be used for this purpose (3). The chloracetate method is preferred since the accompanying impurities are well known, whereas those of the Strecker-type synthesis have not been determined (4).

Attempts to obtain the free acid of DTPA by crystallization from the reaction mixture on acidification with a mineral acid were unsuccessful. Similarly, no success was encountered with crystallization methods used for other polyamino polyacetic acids (5). It is apparently necessary to remove the majority of the sodium ions from the reaction mixture before crystallization can take place.

Subsequently, an ion exchange membrane method was developed which permits crystallization in a simple and efficient manner. The apparatus employed (Fig. 1) was

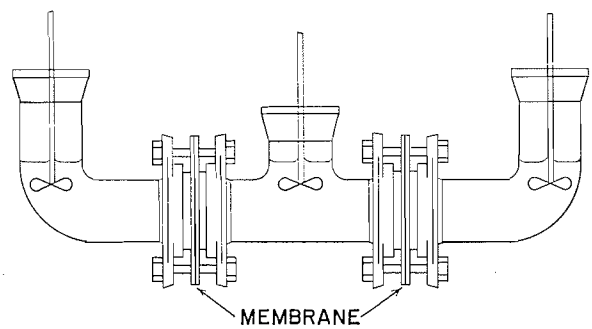

FIG. 1. Ion exchange membrane vessel.

assembled from standard 3-in. glass pipe using two 90° elbows and one T piece. This results in a W-shaped vessel whereby each of the two elbows are on the outside separated from the T piece in the center by a No. 3142 Permutit cation exchange membrane inserted between two polyethylene gaskets. Thus, three compartments in series are formed, the outer two containing dilute hydrochloric acid and the center compartment containing the alkaline reaction mixture. The membranes permit the passage of sodium ions from the center compartments into the outer compartments but prevent migration of chloride, chloracetate, or polyamino polyacetate ions from one compartment into the other. In this way, sodium ions are gradually removed from the reaction mixture, the speed of which depends upon the amount of sodium ions and the strength of the hydrochloric acid solution. For example, if 0.75 liter $N/5$ hydrochloric acid is used in each outer compartment (renewed every 4 hours), and if the concentration of the reaction mixture is adjusted to contain 2.5 mole NaOH, the crystallization of DTPA can be expected to occur within 24 hours. The DTPA obtained in this manner melted with decomposition at 224° C. Calculated for $C_{14}H_{23}O_{10}N_3$: C, 42.75; H, 5.89; N, 10.68%. Found: C, 42.81; H, 5.93; N, 10.63; Cl, <0.05; Na, <0.05%. This crystallization is quantitative, as shown by control experiments, and can be accelerated by renewing the hydrochloric acid solution at shorter intervals and by applying a potential across the compartments.

The higher homologues of EDTA such as trimethylenediamine to hexamethylenediamine tetraacetic acids (n = 3–6) were also prepared by the chloracetate method and crystallized in the ion exchange vessel.

A RECORDING GLASS SPIRAL MANOMETER

F. H. C. Edgecombe and D. A. Jardine

INTRODUCTION

In a study of the kinetics of a reaction in which a pressure change occurred, it was found necessary to devise a pressure-measuring device which could be used in an atmosphere corrosive to mercury and which would be robust and accurate and able to provide a continuous record of the changing pressure.

METHOD

The glass spoon gauge (1) and its recording counterpart devised by Hooley (2) were not sufficiently robust, when designed, to be sensitive, and hence the stronger glass spiral manometer described by Johnson and McIntosh (3) was modified to make a recording instrument.

In Fig. 1, a schematic representation of the manometer, B and C form the plates of a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

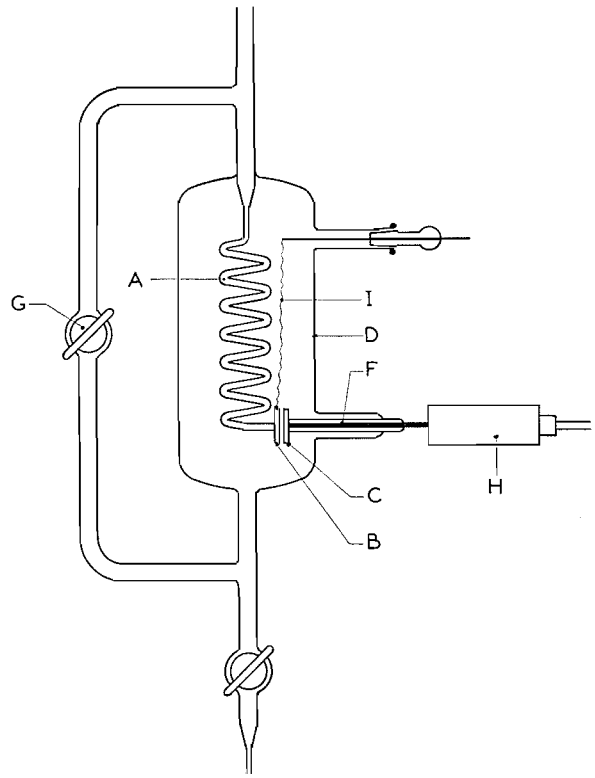

FIG. 1. Schematic diagram of the recording glass spiral manometer.

simple parallel condenser; B, a thin brass plate attached to the glass spiral, is grounded through a wire I. I should be preferably very flexible, e.g. Litz wire, in order to eliminate, so far as possible, drag on the spiral. C is another brass plate attached to a metal rod which, in turn, is sealed in wax to permit adjustment of the distance between the plates. Connected to C through the metal rod is H, the capacitance transducer, obtained from the Decker Corporation of Bala-Cynwyd, Pennsylvania. D is a vacuum-tight glass envelope and G a shorting stopcock through which the envelope may be evacuated when the gauge is used as a differential manometer. The transducer probe, H, is described in detail by Lion (4). Every variation of the gauge capacitor causes a corresponding change in the output voltage of the transducer. In our application of the system the plates C and B of Fig. 1 form the variable capacitance. The voltage output of the transducer is fed through an attenuator to a continuously operating recorder.

The spiral is calibrated by referring the voltage applied to the recorder to the pressure on the spiral, as measured on a mercury manometer by a cathetometer.

PERFORMANCE

The glass spiral used is capable of withstanding the sudden application of a differential pressure of one atmosphere. The sensitivity of such a manometer when used in the system described is very high. By fabrication of thinner spirals, increased sensitivity may be obtained but only at the expense of increasing the "noise level" caused by vibration of the building, which is transmitted to the spiral.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Over small pressure ranges there exists a linear relationship between pressure applied and output voltage. As the applied pressure increases, the calibration curve becomes hyperbolic in form since the plates no longer approximate a parallel relationship due to increased angular displacement of the spiral. This fact cannot be counted as too great a disadvantage, since once an accurate calibration curve has been obtained it remains valid for a considerable period of time.

The zero drift of the instrument is less than 1% over a period of 24 hours and its stability to ambient temperature changes is sufficient not to require any thermostatic control.

Over a pressure range from 0 to 10 cm of mercury the average voltage output from the transducer is 0.2 v per cm of mercury pressure. When this voltage is applied through an attenuator to a 10-mv, full-scale recorder it is evident that very high sensitivities can be obtained. The usable sensitivity is limited by the noise produced by vibration of the spiral. The maximum noise level is equivalent to 0.05 cm of mercury, and by suitable location and mounting of equipment could be reduced to less than that equivalent to 0.01 cm. The experiments in which we used the spiral manometer did not require pressure measurements of precision greater than 0.05 cm and hence no special mounting of the gauge was necessitated although, on occasion, when heavy motors were operating in the vicinity of the gauge, the noise brought about by building vibration was troublesome.

APPLICATION OF THE VARRENTRAPP REACTION TO THE PREPARATION OF LONG-CHAIN DICARBOXYLIC ACIDS

R. G. Ackman, M. A. Bannerman, M. E. Retson, and F. A. Vandenheuvel

Aliphatic dicarboxylic acids with 11 or more carbon atoms were required for gas–liquid chromatographic identification of similar materials produced by ozonolysis of marine-oil fatty acids. Aside from brassylic acid, prepared by oxidative fission of erucic acid, these acids are not conveniently available. As an alternative to individual syntheses, modification of the Varrentrapp reaction (1–4) by limiting it to redistribution of the 13:14 double bond in erucic acid into adjacent positions, followed by oxidative fission and recovery of the dicarboxylic acids, offered a means of obtaining a number of these acids in one preparation.

The product of alkali fusion at 320° C was selected for oxidative fission as the iodine value of 60 indicated that the Varrentrapp reaction proper, production of the saturated acid two carbon atoms shorter than the original monounsaturated acid, had proceeded only to a limited extent. Since double bonds migrating to the 6:7 or 7:8 positions rapidly participate in the final stages of this reaction (2), it was expected that the residual double bonds in the fusion product would be in positions more remote from the carboxyl group.

APPLICATION OF THE VARRENTRAPP REACTION TO THE PREPARATION OF LONG-CHAIN DICARBOXYLIC ACIDS

R. G. Ackman, M. A. Bannerman, M. E. Retson, and F. A. Vandenheuvel

Aliphatic dicarboxylic acids with 11 or more carbon atoms were required for gas–liquid chromatographic identification of similar materials produced by ozonolysis of marine-oil fatty acids. Aside from brassylic acid, prepared by oxidative fission of erucic acid, these acids are not conveniently available. As an alternative to individual syntheses, modification of the Varrentrapp reaction (1–4) by limiting it to redistribution of the 13:14 double bond in erucic acid into adjacent positions, followed by oxidative fission and recovery of the dicarboxylic acids, offered a means of obtaining a number of these acids in one preparation.

The product of alkali fusion at 320° C was selected for oxidative fission as the iodine value of 60 indicated that the Varrentrapp reaction proper, production of the saturated acid two carbon atoms shorter than the original monounsaturated acid, had proceeded only to a limited extent. Since double bonds migrating to the 6:7 or 7:8 positions rapidly participate in the final stages of this reaction (2), it was expected that the residual double bonds in the fusion product would be in positions more remote from the carboxyl group.

For personal use only.

The petroleum-ether-soluble ozonolysis product contained chiefly monocarboxylic acids such as palmitic, stearic, and arachidic, with appreciable amounts of odd-numbered monocarboxylic acids of 11 or fewer carbon atoms. The methanol-soluble ozonolysis product contained approximately 60% of roughly equal amounts of the dicarboxylic acids with 7 to 16 and 17 carbon atoms and 40% of monocarboxylic acids with 7 to 16 carbon atoms (Fig. 1).

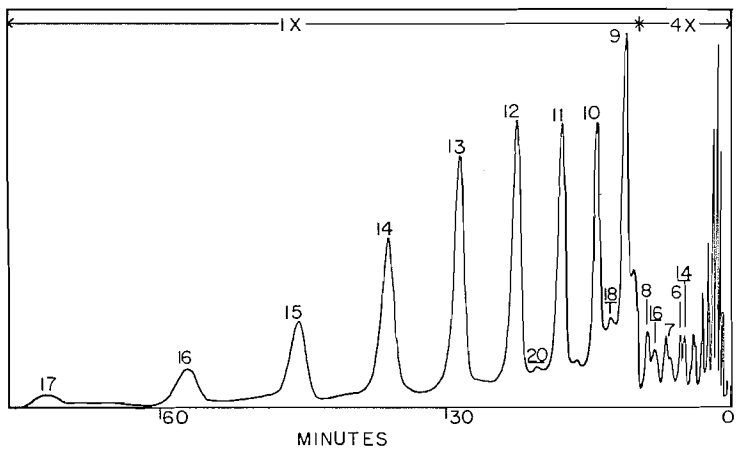

FIG. 1. Gas–liquid chromatogram of methyl esters of dicarboxylic acids. Column, 10 ft×¼ in., packed with 25% LAC-3R-728 on 60–80 mesh Chromosorb. Analysis of 0.005 ml at 200° C with hydrogen carrier gas flowing at 80 ml/minute. Numerals indicate the number of carbon atoms in the acid chains, monocarboxylic acids being underlined.

Since double bonds are increasingly less susceptible to the Varrentrapp reaction when more remote from the carboxyl group, a higher proportion of long-chain dicarboxylic acids with 15 or more carbon atoms could be obtained by prolonged fusion at lower temperatures. The over-all dicarboxylic acid yield would, however, be diminished as a consequence of further completion of the Varrentrapp reaction.

EXPERIMENTAL

A technical erucic acid, iodine value 85, was employed in this reaction. Gas–liquid chromatography indicated a composition of 72.8% erucic acid, 12.4% eicosenoic acid, 6.7% oleic acid, and minor amounts of palmitic, stearic, linoleic, and arachidic acids. Alkali fusions were carried out in a covered iron vessel fitted with a nitrogen inlet and a stirrer of iron pipe. Equal weights of erucic acid, sodium hydroxide, and potassium hydroxide were placed in this vessel, and it was then placed in a Wood's metal bath preheated 40° C above the reaction temperature. The mixture was stirred continuously for ½ hour and intermittently for a further half hour. The cooled reaction mass was dissolved in water, acidified, and the fatty acids extracted with petroleum ether. Weight recoveries were approximately 80%, with iodine values of 38, 60, and 69 from fusions at, respectively, 360, 320, and 300° C for 1 hour. Gas–liquid chromatography indicated almost complete destruction of the oleic, linoleic, and eicosenoic acids, the products thus consisting chiefly of saturated acids and docosenoic acids.

The alkali fusion product of iodine value 60 (5 g) was ozonized in glacial acetic acid and the ozonide decomposed with hydrogen peroxide (2). The final solution was diluted

to 400 ml with water and extracted with diethyl ether (400 ml). The ether solution was washed with water (50 ml), and the aqueous phases discarded. The ether was removed and the product (5.7 g) was dissolved in 90% methanol (200 ml) and extracted with petroleum ether (b. p. 40–60° C, 200 ml). The petroleum-ether-soluble material (0.9 g) and the methanol-soluble material (4.8 g) were converted to methyl esters with diazomethane. Identification of certain components was effected through mixed gas–liquid chromatograms with authentic materials employing both silicone grease and polyester substrates. The identification of the remainder was confirmed by plots of logarithm retention time vs. number of carbon atoms.

AMINO ACID DISTRIBUTION IN BIOLOGICALLY ACTIVE PEPTIDES
II. DIPEPTIDES HAVING LOW STATISTICAL SIGNIFICANCE

SAUL B. NEEDLEMAN

In the previous publication of this series (1), the amino acid sequences of a number of biologically active proteins were examined for the occurrence of relative chain position preferences of the individual constituent amino acids and for statistically significant repeating amino acid sequences comprising dipeptidic couplet units. Thirty-five dipeptide structures were found for which the chi-square values exceeded the 90% confidence limits for one degree of freedom (2.706). The study is now extended to dipeptide sequences which occur at a very low level of statistical significance.

A total of 10 couplets, listed in Table I, occurred only once in the proteins included in

this study. All had chi-square values of less than 0.00393 at the 0.95 probability level and for one degree of freedom.

If the data are randomly or normally distributed and agree with the null hypothesis, one should expect to get χ^2 values greater than 0.00393 95% of the time. Since these values are much lower, it is possible that the data for these couplets, as well as for the 106 dipeptide combinations (of 400 possible combinations for 20 amino acids) which did not appear at all, are not random, or, that the couplets, somehow, have been preselectively avoided in the natural synthesis of these biologically active proteins.

An additional 18 dipeptide couplets had chi-square values of less than 0.025.

SOME NEUTRAL AND ACIDIC EXTRACTIVES FROM CEANOTHUS AMERICANUS L.

R. A. ABRAMOVITCH AND G. TERTZAKIAN

The extractives from *Ceanothus americanus*, also known as New Jersey tea, have been the subject of many investigations (for a survey of the literature on this subject see ref. 1). A number of alkaloidal and acidic constituents have been isolated from the root bark, and some of the fatty and dicarboxylic acids have been identified (2). Bertho and Liang (3) reported the isolation of an alkaloid, ceanothin, for which they gave the molecular formula $C_{29}H_{36}N_4O_4$. On the other hand, Julian, Pikl, and Dawson isolated a high-melting monohydroxydicarboxylic acid which they called ceanothic acid and to which they assigned the molecular formula $C_{29}H_{44}O_5$ (4). The fact that both this acid and the above alkaloid were reported to be C_{29} compounds might indicate a possible structural relationship between them and it was thought to be of interest to examine systematically the composition of the neutral and acidic extractives from *Ceanothus americanus* root bark.

When the ground root bark (kindly supplied by Flint, Eaton and Co., Decatur, Illinois) was percolated and worked up as described by Julian, Pikl, and Dawson (4) no ceanothic acid could be isolated. A crude acid mixture was in fact isolated from which betulic acid was obtained as the main component (the fatty acids and simple dicarboxylic acids being eliminated in the work-up procedure). The same mixture of acids could be obtained by ether extraction. Betulic acid was characterized further as the methyl ester, the methyl ester acetate, and the acetate. A red pigment, believed to be a tannin, can also be isolated in relatively large quantities (11.5% based on dry root bark). Chromatography of the crude high-melting acids on silica gel gave betulic acid as well as a yellow amorphous acid, m.p. 250–260° (decomp.), which could not be purified but whose infrared spectrum indicated the presence of a $\diagdown\!\!\diagup C{=}CH_2$ group.

The root bark was continuously extracted with ether and the brown oil obtained was saponified with aqueous ethanolic potassium hydroxide (ammonia was evolved during the saponification and identified as ammonium picrate). Steam distillation gave a very small quantity of a saturated aliphatic alcohol which has been tentatively identified as 2-nonanol by comparison of its relative retention time (relative to ethanol) on vapor phase chromatography on two different columns (silicone on firebrick and Apiezon "N" on firebrick) with that of an authentic sample, as well as by a comparison of their infrared spectra. From the steam distillation residue a small amount of β-sitosterol glucoside could be extracted out. Working up the non-saponifiable fraction led to the isolation of (*a*) β-sitosterol, characterized as its acetate and its benzoate, and (*b*) lupeol, characterized further as lupeol acetate and dihydrolupeol acetate. A mixture of saturated hydrocarbons was also isolated chromatographically but not characterized further as were also a number of minor compounds.

EXPERIMENTAL

Melting points are uncorrected. Petroleum ether refers to the fraction, b.p. 40–50°, which had been freed of unsaturation. All yields are given as a per cent of dry root bark.

Isolation of the Acidic Components

Dry root bark (2.25 kg) was continuously extracted with ether (8 l.) in a Soxhlet extractor for 3 days. The solution was concentrated to 1 l. and kept in the refrigerator for a few days. The white, oily solid which separated was filtered and extracted exhaustively with petroleum ether. The residue was a tan-colored powder (A). This was dissolved in ether (250 ml), extracted with 10% sodium carbonate solution, and the ether layer dried (Na_2SO_4) and evaporated to give whitish crystals (15.3 g; 0.69%), which after numerous recrystallizations from methanol yielded betulic acid,* m.p. 312°, $[\alpha]_D^{25}$ +6.04° (pyridine). Found: C, 78.71; H, 10.85. Calc. for $C_{30}H_{48}O_3$: C, 78.89; H, 10.59. Robertson, Soliman, and Owen give m.p. 317°, $[\alpha]_D$ +7.8° (pyridine) for betulic acid (5). The melting point was undepressed on admixture with an authentic sample of betulic acid. This acid gave the acetate, m.p. 290° (reported (5) m.p. 289–291°); the methyl ester with diazomethane, m.p. 222–223°, $[\alpha]_D^{25}$ +3.5° (pyridine) (reported (5) m.p. 223–224°, $[\alpha]_D$ +8.01° (pyridine)) (found: C, 78.88; H, 10.68; calc. for $C_{31}H_{50}O_3$: C, 79.10; H, 10.71); and the methyl ester acetate, m.p. 203° (reported (5) m.p. 201–202°).

The crude mixture of acids (A) (2.55 g) was chromatographed on a column of silica gel (70 g). Elution with petroleum ether–benzene (1:2) (3900 ml) gave betulic acid (1.078 g), m.p. 295–300° after recrystallization from aqueous acetone. The infrared spectrum of this acid was identical with that of authentic betulic acid. Elution with benzene–ether (1:1) (2500 ml) gave an amorphous yellow powder (369 mg) m.p. 250–260° (decomp.). Infrared spectrum (main peaks): 3400 (br)(m), 1680 (s), 1635 (m), 1603 (w), 1508 (w), 1280 (br)(m), 1230 (br)(s), 1190 (br), 1105 (m), 1030 (m), and 880 (m) cm^{-1}. This product could not be purified by recrystallization and was not examined further at this stage.

Saponification of the Ether Extractives—The Non-saponifiable Fraction

The viscous, brown ether extractives after removal of betulic acid (16.81 g) were boiled under reflux with 7% aqueous ethanolic (2:3) potassium hydroxide solution (250 ml) for 24 hours. The solution was concentrated at atmospheric pressure at 80° and water was then added and the mixture steam distilled. The distillate was saturated with salt,

**Betulic acid is insoluble in sodium carbonate solution.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

extracted with ether, and the dried ether layer evaporated. Distillation of the residue gave 2-nonanol, b.p. 82° at 12 mm, $[\alpha]_D^{25}$ +0.74° (methanol), n_D^{21} 1.4320. Vapor phase chromatography on 6-ft columns of silicone on firebrick and Apiezon "N" on firebrick respectively indicated that this product had the same relative retention times as authentic 2-nonanol. The infrared spectra of the two samples were identical. The reported (6) boiling point of 2-nonanol is 81–83° at 15 mm.

The residue from the steam distillation was continuously extracted with ether. White, needle-like crystals (40 mg), m.p. 310°, separated in the extraction flask and were shown to be identical with β-sitosterol glucoside by comparison of the infrared spectrum with that of an authentic specimen and by a mixed melting point determination. Evaporation of the ethereal extract gave a yellow wax (1.75 g, 0.13%) which crystallized from methanol to give β-sitosterol, m.p. 133.5–135.5°, $[\alpha]_D^{25}$ −31.2° (chloroform). The melting point was undepressed on admixture with an authentic specimen of β-sitosterol. Found: C, 83.55; H, 12.16. Calc. for $C_{29}H_{50}O$: C, 83.99; H, 12.15. The sterol gave the acetate, m.p. 123.5–124.5°, $[\alpha]_D^{26}$ −39.2° (chloroform) (found: C, 81.72; H, 11.07; calc. for $C_{31}H_{52}O_2$: C, 81.52; H, 11.48) (lit. (7) m.p. 126.5–127.5°, $[\alpha]_D$ −36.56°) and the benzoate, m.p. 142–143°.

The crude, non-saponifiable, non-steam-volatile fraction (5 g) after extraction with ether was chromatographed on a column of alumina (28 cm × 2.2 cm). Elution with petroleum ether gave a colorless oil (309 mg), b.p. 200–240° at 0.5 mm (with darkening), n_D^{25} 1.4795, $[\alpha]_D^{26}$ +1.16° (chloroform). Found: C, 86.82, 86.12; H, 13.11, 13.77; mol. wt. (ebullioscopic), 226. Calc. for $C_{20}H_{36}$: C, 86.86; H, 13.14; mol. wt., 276. Calc. for $C_{18}H_{34}$: C, 86.32; H, 13.68; mol. wt., 250. Infrared spectrum (liquid film): 2900 (s), 2860 (s), 1462 (m), and 1371 (m) cm^{-1}. This oil did not take up hydrogen on shaking in the presence of Adams' catalyst even in dioxane – glacial acetic acid solution (20:1) at 2 atm. It did not consume any peracid on treatment with monopherphthalic acid but did decolorize bromine water. In view of the inconsistent analyses this product was not examined further at this stage.

Elution with petroleum ether – benzene (1:2) gave at first a mixture (587 mg) of a ketonic and a non-ketonic compound. The ketonic portion was removed with Girard's reagent "T" giving the non-ketonic portion (493 mg) as a yellow solid which, on recrystallization from methanol, gave lupeol, m.p. 203–204°, $[\alpha]_D^{26}$ +29.5° (chloroform). Found: C, 84.66; H, 12.06; mol. wt. (Rast), 437. Calc. for $C_{30}H_{50}O$: C, 84.44; H, 11.81; mol. wt., 427. The melting point was undepressed on admixture with an authentic specimen of lupeol kindly supplied by Dr. T. R. Govindachari. It formed an acetate, m.p. 204–205°. Found: C, 82.03; H, 11.07. Calc. for $C_{32}H_{52}O_2$: C, 81.99; H, 11.18. Heilbron, Kennedy, and Spring (8) give m.p. 214–215° for lupeol acetate. This acetate was hydrogenated over Adams' catalyst to give dihydrolupeol acetate, m.p. 241–242° (lit. (8) m.p. 245–246°).

Further elution with petroleum ether – benzene (1:2) gave β-sitosterol (980 mg). Elution with somewhat more polar solvents gave intractable materials. Finally, methanol (6750 ml) eluted a brown solid (1.063 g), m.p. 250° (decomp.), which could not be recrystallized.

ACKNOWLEDGMENTS

This work was carried out during the tenure (by G. T.) of a University Research Demonstratorship and with the financial assistance of the National Research Council. The authors wish to express their gratitude to Flint, Eaton and Co. for a generous

DECARBOXYLATION OF AROMATIC CARBOXYLIC ACIDS IN ISOTOPIC STUDIES

F. B. FISHER AND A. N. BOURNS[1]

It is occasionally necessary in C^{13}-isotopic studies to isolate in a form suitable for mass spectrometric analysis a carbon atom attached directly to an aromatic nucleus. This may be accomplished by oxidation of the compound in question to an aryl carboxylic acid which, on decarboxylation, furnishes carbon dioxide derived exclusively from the carbon whose isotopic abundance is to be determined. When precise isotopic ratios are required, as in kinetic isotope effect studies, it is essential that these degradative reactions proceed with high conversion, otherwise they may give rise to isotopic fractionation which could introduce a serious error in the results.

The two principal decarboxylation methods used in isotopic studies are the copper chromite – quinoline reaction and the Schmidt reaction. The former has given variable yields (1) and, in our hands, contamination from extraneous carbon has been difficult to avoid. The Schmidt reaction has been reported (2) to give carbon dioxide in 55% yield from benzoic acid. By making certain modifications in the original procedure, we have been able to increase the yield to 95% for benzoic and *p*-anisic acid. When, however, the method was applied to aromatic acids containing electronegative substituents the yield of carbon dioxide fell drastically.

A further method of decarboxylation of value in preparative organic chemistry is the Hunsdecker reaction involving the action of bromine on the silver salt of a carboxylic acid. The higher yields of aryl halide reported for the nitrobenzoic acids compared to benzoic acid (3, 4, 5) suggested that this reaction might be satisfactorily applied to the production of carbon dioxide from aromatic carboxylic acids containing electron-withdrawing groups. This has indeed proved to be the case, yields of over 90% having been obtained from *m*-nitrobenzoic acid and *p*-trifluoromethylbenzoic acid. The two reactions, therefore, provide complementary methods for the decarboxylation of aromatic carboxylic acids in isotopic investigations.

DECARBOXYLATION OF AROMATIC CARBOXYLIC ACIDS IN ISOTOPIC STUDIES

F. B. FISHER AND A. N. BOURNS[1]

It is occasionally necessary in C^{13}-isotopic studies to isolate in a form suitable for mass spectrometric analysis a carbon atom attached directly to an aromatic nucleus. This may be accomplished by oxidation of the compound in question to an aryl carboxylic acid which, on decarboxylation, furnishes carbon dioxide derived exclusively from the carbon whose isotopic abundance is to be determined. When precise isotopic ratios are required, as in kinetic isotope effect studies, it is essential that these degradative reactions proceed with high conversion, otherwise they may give rise to isotopic fractionation which could introduce a serious error in the results.

The two principal decarboxylation methods used in isotopic studies are the copper chromite – quinoline reaction and the Schmidt reaction. The former has given variable yields (1) and, in our hands, contamination from extraneous carbon has been difficult to avoid. The Schmidt reaction has been reported (2) to give carbon dioxide in 55% yield from benzoic acid. By making certain modifications in the original procedure, we have been able to increase the yield to 95% for benzoic and *p*-anisic acid. When, however, the method was applied to aromatic acids containing electronegative substituents the yield of carbon dioxide fell drastically.

A further method of decarboxylation of value in preparative organic chemistry is the Hunsdecker reaction involving the action of bromine on the silver salt of a carboxylic acid. The higher yields of aryl halide reported for the nitrobenzoic acids compared to benzoic acid (3, 4, 5) suggested that this reaction might be satisfactorily applied to the production of carbon dioxide from aromatic carboxylic acids containing electron-withdrawing groups. This has indeed proved to be the case, yields of over 90% having been obtained from *m*-nitrobenzoic acid and *p*-trifluoromethylbenzoic acid. The two reactions, therefore, provide complementary methods for the decarboxylation of aromatic carboxylic acids in isotopic investigations.

EXPERIMENTAL

Hunsdecker Reaction

The silver salts were prepared by the method outlined by Cason and Rapoport (6), collected on a sintered-glass funnel, and dried in a vacuum desiccator. Yields were 90% for benzoic acid and better than 95% for the substituted benzoic acids.

The apparatus for the decarboxylation consisted of a 200-ml three-necked flask fitted with a dropping funnel, nitrogen-inlet tube, and a reflux condenser. Nitrogen gas, used to sweep carbon dioxide from the reaction mixture, was purified by passing through Fieser's solution and concentrated sulphuric acid and was led to the top of the dropping funnel as well as to the inlet tube. The condenser was connected to a CO_2-absorption train consisting of a dry ice – acetone trap and a CO_2 absorber described by Calvin *et al.* (7).

Silver salt, sufficient to produce approximately 100 mg of barium carbonate, and 60–80 ml of dry carbon tetrachloride were placed in the reaction flask, which was fitted temporarily with a downward distillation assembly in place of the reflux condenser and CO_2-absorption train. The system was flushed with nitrogen and about one third of the carbon tetrachloride removed by distillation. The condenser and absorption train were quickly replaced and, with a slow stream of nitrogen passing through the apparatus, the suspension was heated to the boiling point and stirred magnetically. Bromine (10% in carbon tetrachloride) was added a few drops at a time to the reaction mixture, with time being allowed between successive additions for the solution to decolorize. When the reaction was essentially complete, as usually indicated by the flocculation of silver bromide, a further three to five drops of bromine solution were added and heating continued for an additional 20–30 minutes. Barium carbonate was precipitated by the usual procedure (7). Blank experiments carried out in the absence of silver salt gave less than one milligram of precipitate.

Schmidt Reaction

The procedure described by Doering *et al.* (2) was used with minor modification. Ethylene dichloride was used as solvent instead of chloroform and the effluent carbon dioxide was passed through a dry ice – acetone trap and 5% permanganate in 1 *N* sulphuric acid (8) and absorbed in sodium hydroxide (7). Sodium azide was added over a period of 40 minutes at 40° C, and stirring and heating were continued an additional 50 minutes. Contamination with extraneous carbon dioxide was found in blank experiments to be less than one per cent.

RESULTS

The per cent yields of barium carbonate from each of four acids using the two methods of decarboxylation are shown in the following table:

	Per cent yield of $BaCO_3$	
Acid	Hunsdecker*	Schmidt
p-Anisic	61	95
Benzoic	90	95
p-Trifluoromethylbenzoic	93	28†
m-Nitrobenzoic	98	9

*Based on silver salt.
†Reaction temperature of 56–60° C.

THE POTASSIUM SALTS OF FUMARIC ACID: PREPARATION, UNIT CELL CONSTANTS, SPACE GROUPS, AND X-RAY DIFFRACTION POWDER IDENTIFICATION DATA[1]

M. P. GUPTA[2] AND W. H. BARNES

ABSTRACT

The preparation of the three crystalline potassium salts of fumaric acid, "acid" potassium hydrogen fumarate ($2KHC_4H_2O_4.H_2C_4H_2O_4$), potassium hydrogen fumarate ($KHC_4H_2O_4$), and dipotassium fumarate dihydrate ($K_2C_4H_2O_4.2H_2O$), is discussed, and suitable pH values for the growth of single crystals of each are given. Unit cell, space group, and X-ray diffraction powder identification data for the three salts are presented.

INTRODUCTION

There are three crystalline potassium salts of fumaric acid, $K_2C_4H_2O_4.2H_2O$, $KHC_4H_2O_4$, and $2KHC_4H_2O_4.H_2C_4H_2O_4$. The first two were prepared by Rieckher in 1844 (1), and all three were obtained by Carius in 1867 (2). Rieckher (1) saturated fumaric acid in water with potassium carbonate and allowed the aqueous solution to evaporate, thus obtaining the normal salt which he found to be a dihydrate from the loss in weight at 100° C; by incineration to potassium carbonate he determined the formula as "KO,C_4HO_3+2Aq" (i.e., $K_2C_4H_2O_4.2H_2O$). Potassium hydrogen fumarate was prepared from the neutral salt and acetic acid, from fumaric acid and potassium carbonate followed by the addition of more fumaric acid, and from the neutral salt and fumaric acid. Rieckher showed that crystals of potassium hydrogen fumarate are anhydrous, and, by conversion to potassium sulphate, he established the formula as "$KO,C_4HO_3+C_4HO_3,HO$" (i.e., $KHC_4H_2O_4$). Carius (2), apparently unaware of Rieckher's work, treated solutions of barium fumarate with potassium sulphate and various concentrations of sulphuric acid, and thus obtained not only the two salts to be expected of a dibasic acid but, in addition, an "acid" potassium hydrogen fumarate, $2KHC_4H_2O_4.H_2C_4H_2O_4$, which he first considered to be a monohydrate (2) but later (3) decided was anhydrous. His analysis of dipotassium fumarate was carried out after the compound was dried at 100° C so that his formula corresponds to that of the anhydrous salt and not to that of the dihydrate. Carius also observed, like Rieckher, that $KHC_4H_2O_4$ could be crystallized from a solution of $K_2C_4H_2O_4$ and fumaric acid, but he also reports (3) that it is not obtained from a solution of the former and "acid" potassium hydrogen fumarate, which recrystallize separately.

Dehn and Merling (4) prepared $K_2C_4H_2O_4$ (presumably anhydrous) from fumaric acid and potassium hydroxide in anhydrous ether. Zechmeister and Szécsi (5) obtained "acid" potassium hydrogen fumarate from an alcohol extract of *Capsella bursa-pastoris*, and also from the appropriate molar proportions of fumaric acid and potassium hydroxide.

Finally, Sabalitschka and Kubisch (6) prepared potassium hydrogen fumarate from fumaric acid and $N/2$ KOH solution. All three salts are included in the 1893 and 1942 editions of Beilstein's *Handbuch* (although the latter gives the normal salt in its anhydrous form) but $2KHC_4H_2O_4.H_2C_4H_2O_4$ does not appear in the edition of 1920 (7).

Crystals of $K_2C_4H_2O_4.2H_2O$ are described by Rieckher (1) as "brilliant, short, striated prisms" and by Carius (3) as "bright, monoclinic prisms and plates". Rieckher (1) refers to crystals of $KHC_4H_2O_4$ variously as "clear and regular", and as "irregular needles", while Carius (3) describes them as "thick, monoclinic (?) plates". Crystals of $2KHC_4H_2O_4.H_2C_4H_2O_4$ are said by Carius (3) to be "needle-like prisms" and are referred to as "elongated and tapering" by Zechmeister and Szécsi (5). Optical crystallographic data are given by Repossi (8) (see also Groth (9)) for crystals of $KHC_4H_2O_4$ said to have been obtained from aqueous solution. Stafford (10) reports refractive indices for dipotassium fumarate but fails to indicate whether they are for the anhydrous salt or the dihydrate. Gupta (11) describes a preliminary investigation of the crystal structures of "acid" potassium hydrogen fumarate and of "acid" rubidium hydrogen fumarate which were prepared by the addition of fumaric acid to aqueous solutions of the appropriate hydroxides; the composition of the potassium salt was verified by an analysis for carbon and hydrogen. As Gupta points out, the composition of the potassium salt may be expressed as $2KC_4H_3O_4+C_4H_4O_4$ or as $K_2C_4H_2O_4+2C_4H_4O_4$ but the two-dimensional structure analysis did not enable a choice to be made between the two formulations, if indeed there is any real difference between them. In the present paper the "acid" potassium hydrogen fumarate is designated by the first formula, namely $2KHC_4H_2O_4.H_2C_4H_2O_4$.

In anticipation of crystal structure investigations of $KHC_4H_2O_4$ and $K_2C_4H_2O_4.2H_2O$, crystals of all three salts have been grown from aqueous solutions of KOH or K_2CO_3 and fumaric acid, but it immediately became apparent that the particular salt obtained was dependent on the pH of the solution. An extensive series of crystallization experiments, therefore, have been carried out to establish suitable pH ranges within which satisfactory crystals of the various salts may be grown. Unit cell and space group data for $KHC_4H_2O_4$ and $K_2C_4H_2O_4.2H_2O$ have been collected, and indexed X-ray diffraction powder data for all three salts have been obtained.

PREPARATION

The potassium salts first were prepared by the addition of weighed amounts of pure fumaric acid to solutions containing previously weighed amounts of KOH or K_2CO_3. The potassium fumarate solutions were boiled, filtered, and set aside to crystallize spontaneously and slowly in an air-conditioned room at 19 to 21° C and $<50\%$ relative humidity. The uncertain proportion of carbonate in solid KOH, and a significant proportion of hydrate (shown by X-ray powder photographs) even in fresh, unopened bottles of the highest grade of "anhydrous" K_2CO_3, made it preferable to add measured volumes of a standardized solution of KOH (free from carbonate) to weighed samples of the fumaric acid; KOH is more satisfactory than K_2CO_3 because there is a tendency for $KHCO_3$ to crystallize first from the more strongly acid solutions. As soon as the approximate range of pH appropriate for the appearance of each fumarate had been determined, solutions were prepared by dissolving fumaric acid in $N/10$ KOH solution (carbonate free) and adjusting the pH to within the range desired. Universal indicator papers (such as Cenco pHydrion) are adequate for following the changes in pH although a Beckman pH meter with external electrodes is more satisfactory.

When crystals appeared, the solutions were tested for pH and the crystals were removed with tweezers, rolled gently on absorbent (bibulous) paper, and allowed to air-dry.

Distilled water was added to the solution, which was warmed to accelerate solution of unremoved crystals, and the beaker was set aside until the next small crop of crystals was obtained. This procedure was repeated until the volume had been reduced usually to a few drops. The solution was then allowed to evaporate to dryness and the solid residue was ground and mixed thoroughly. Representative crystals from each crop, and samples of the final residues, were identified by X-ray powder photographs.

The standard powder patterns employed for identification purposes were authenticated as follows: $2KHC_4H_2O_4.H_2C_4H_2O_4$, from data given by Gupta (11) for material analyzed for carbon and hydrogen; $KHC_4H_2O_4$, material analyzed for carbon and hydrogen; $K_2C_4H_2O_4.2H_2O$, crystallized from solution containing excess KOH, 4 g (air-dried at 19° C and 60% relative humidity) showed a loss in weight of 15.80% after heating to constant weight at 150° C (calculated for conversion of dihydrate to anhydrous salt, 15.78%). The authenticity of the standard patterns for $KHC_4H_2O_4$ and $K_2C_4H_2O_4.2H_2O$ later was confirmed by successful indexing on the basis of the unit cell and space group data.

No difficulty was experienced in the preparation of $K_2C_4H_2O_4.2H_2O$. The solubility was determined gravimetrically as approximately 62.4 g *anhydrous* $K_2C_4H_2O_4$ per 100 ml H_2O at 21° C; the pH of a saturated solution at this temperature is about 10. Because of the high solubility, several recrystallizations under conditions of greatly reduced evaporation at room temperature were frequently necessary to obtain well-formed single crystals of reasonably small dimensions.

"Acid" potassium hydrogen fumarate is much less soluble in water (approximately 2.01 g $2KHC_4H_2O_4.H_2C_4H_2O_4$ per 100 ml H_2O at 21° C), and the pH of a saturated solution at 21° C is about 3.2_3. If the appropriate volume of standard KOH added to a weighed amount of fumaric acid is not sufficient for complete solution of the fumarate, water may be introduced until all solid has dissolved. Spontaneous crystallization by slow evaporation at room temperature usually gave good acicular single crystals. An annoying feature of solutions of this salt, however, was a propensity for nurturing the growth of mold over the sometimes long periods of evaporation necessary for the growth of the best crystals; this can be prevented by the addition of one or two drops of dilute formaldehyde solution. On a few occasions, crystals of fumaric acid (easily recognizable as opaque, feathery clusters) preceded the appearance of the first crystals of "acid" potassium hydrogen fumarate, particularly when the initial pH of the solutions was less than 3.0. The solubility of fumaric acid was determined gravimetrically as approximately 0.51 g $H_2C_4H_2O_4$ per 100 ml H_2O at 21° C; the pH of a saturated solution at this temperature is about 2.2_2.

On the evaporation of a solution containing the proper proportions of fumaric acid and KOH (or K_2CO_3) to give $KHC_4H_2O_4$, the first crystals to appear are those of $2KHC_4H_2O_4.H_2C_4H_2O_4$. As crystallization of this salt proceeds, the pH of the solution rises until it approaches about 3.7_5 when crystallization of "acid" potassium hydrogen fumarate is replaced by that of $KHC_4H_2O_4$, which continues until the pH has risen to about 5. As evaporation proceeds to dryness, and the pH continues to rise, crystals of $K_2C_4H_2O_4.2H_2O$ appear. Similarly, when crystals of $KHC_4H_2O_4$ are dissolved in water, and the solution is allowed to evaporate, the same sequence of crystal identities and increasing pH is observed. Mold growth was troublesome in the acidic stages of these tests also until a drop or two of dilute formaldehyde was added to the initial solutions.

For the preparation of the potassium salts of fumaric acid, therefore, it is recommended that pure fumaric acid be dissolved in measured volumes of a standard KOH solution (free from carbonate) and that the pH of the solutions be adjusted to, and maintained at,

about 3.3 for $2KHC_4H_2O_4.H_2C_4H_2O_4$, about 4 for $KHC_4H_2O_4$, and about 8 for $K_2C_4H_2O_4.2H_2O$. The first and last may be recrystallized directly from water, but, after dissolving $KHC_4H_2O_4$ in water, the pH must be increased to about 4 in order to suppress crystallization of "acid" potassium hydrogen fumarate. The great difference in the solubilities of "acid" potassium hydrogen fumarate and dipotassium fumarate dihydrate should be kept in mind when one is selecting the initial volume of KOH solution for a

given preparation. Adjustment of pH upwards may be effected by the addition of KOH solution; if the solutions are not to be evaporated to dryness, dilute acetic acid may be employed for lowering the pH. In all cases, a few representative crystals from each crop should be ground and an X-ray powder photograph taken, for identification purposes, and to confirm that crystals of one salt only are present.

The foregoing notes throw light on some of the statements appearing in the early literature. Thus when Carius (3) recrystallized mixed solutions of $K_2C_4H_2O_4.2H_2O$ and $2KHC_4H_2O_4.H_2C_4H_2O_4$, he must have recovered not only these two salts separately as he reports, but crystals of $KHC_4H_2O_4$ must also have been present. Rieckher's description (1) of crystals of the normal salt actually suggests $KHC_4H_2O_4$, while his varied comments on crystals of the latter sometimes suggest $2KHC_4H_2O_4.H_2C_4H_2O_4$. If the crystals which Repossi (8) employed for his optical crystallographic study of $KHC_4H_2O_4$ were recrystallized from water, without any adjustment of the pH of the solution, they may actually have been those of $2KHC_4H_2O_4.H_2C_4H_2O_4$.

UNIT CELL AND SPACE GROUP DATA

The unit cell constants and the space group of $KHC_4H_2O_4$ and of $K_2C_4H_2O_4.2H_2O$ were determined by the Buerger precession method using Mo $K\alpha$ (λ = 0.7107 Å) radiation for the first and Cu $K\alpha$ (λ = 1.5418 Å) radiation for the second. Film shrinkage corrections were applied to all film measurements. Corresponding data for $2KHC_4H_2O_4.H_2C_4H_2O_4$ have been reported by Gupta (11) and, therefore, were not redetermined in the present

investigation. Densities (at about 20° C) were measured by flotation in binary solutions of toluene and ethylene dibromide in the case of "acid" potassium hydrogen fumarate, and toluene and methylene iodide in the other two cases. Data for the three salts are summarized in Table I.

The unit cell of $2KHC_4H_2O_4.H_2C_4H_2O_4$ represented in Table I(A) was derived by Delaunay reduction from that of Gupta (11), $a = 8.64$ Å, $b = 7.48$ Å, $c = 6.96$ Å, $\alpha = 78.1°, \beta = 112.9°, \gamma = 107.9°$, although the latter is the more convenient structurally. The transformation matrix from the original cell (1) to the reduced cell (Table I) is $010/101/00\bar{1}$.

In the case of $KHC_4H_2O_4$ the reciprocal lattice elements of two different cells were measured and both were reduced to that represented in Table I(B). The direct cell elements of the first were $a = 6.92_2$ Å, $b = 6.95_2$ Å, $c = 17.95_7$ Å, $\alpha = 36° 44'$, $\beta = 32° 11'$, $\gamma = 53° 31'$; transformation matrix to give the reduced cell of Table I(B),

$010/\bar{2}\bar{1}1/1\bar{1}0$. The direct cell elements of the second were $a = 12.70_9$ Å, $b = 13.13_7$ Å, $c = 18.03_0$ Å, $\alpha = 161° 33'$, $\beta = 163° 07'$, $\gamma = 27° 56'$; transformation matrix to give the reduced cell of Table I(B), $110/\bar{1}\bar{2}\bar{2}/\bar{1}01$. Numerical values for corresponding reduced-cell constants agreed to better than 0.01_5 Å in linear dimensions, and 20′ in the angles; the values selected for Table I(B) are those for the first cell because they gave slightly better agreement with the powder data.

POWDER IDENTIFICATION DATA

The powdered samples were taken up in thin-walled glass capillary tubes as described elsewhere (12), and cylindrical cameras of 114.6-mm diameter were employed. The photographs were taken with Co $K\alpha$ radiation ($\lambda = 1.790$ Å), Straumanis film mounting, and the apparatus "cut-off" was about 20 Å. Film shrinkage corrections were $<1/1000$, and were not applied to the measurements. Intensities were estimated visually with the aid of a calibrated strip. The patterns were indexed on the basis of the unit cell and space group data of Table I, with the exception of $2KHC_4H_2O_4.H_2C_4H_2O_4$ for which the constants of the unreduced cell (11) were employed. The results are given in Tables II, III, and IV, where B and BB in the columns of I/I_1 indicate lines which were broader and much broader, respectively, than the general average for a given pattern, and an asterisk in the columns of d (obs.) indicates that the reflection probably was present but with $I/I_1 < 1$, thus making a reasonably accurate measurement of 2θ impractical.

ON THE SOLUBILITY OF ANHYDROUS CALCIUM SULPHATE AND OF GYPSUM IN CONCENTRATED SOLUTIONS OF SODIUM CHLORIDE AT 25° C, 30° C, 40° C, AND 50° C[1]

E. Bock

ABSTRACT

The solubilities of anhydrous $CaSO_4$ and $CaSO_4.2H_2O$ in concentrated aqueous solutions of NaCl at a series of temperatures—25° C, 30° C, 40° C, and 50° C, have been determined. It was found that the transition temperature for the reaction

$$CaSO_4.2H_2O \rightarrow CaSO_4 + 2H_2O,$$

which in pure water has a value of 42° C, is shifted progressively to lower temperatures with increasing NaCl concentration. It was also found that the variation of the transition temperature with NaCl concentration could be adequately represented by the equation

$$\Delta G = \Delta H - T\Delta S + 2RT \ln P/P_0,$$

where ΔG, ΔH, and ΔS are the Gibbs free energy, enthalpy, and entropy of the reaction and P_0 and P are the vapor pressures of pure water and the solution respectively at the absolute temperature T.

INTRODUCTION

It has long been known that the gypsum–anhydrite transition point is depressed by addition of strong electrolytes. However, it appears that no systematic study of this aspect of this system has ever been made, and only isolated experiments are reported in the literature (1).

Since many naturally occurring gypsum deposits which are used as raw material for the commercial production of plaster of paris and building plaster are contaminated with various amounts of sodium chloride, it was decided to carry out a systematic study of the behavior of the system gypsum–anhydrite in the presence of varying amounts of sodium chloride. The results of such a study should afford a clearer understanding of the factors that govern the deposition of anhydrite or gypsum, as the case may be, from a slurry of hemihydrate ($CaSO_4.\frac{1}{2}H_2O$) and water, contaminated with NaCl.

EXPERIMENTAL

The salts used in this research, i.e. $CaSO_4$ anhyd., $CaSO_4.2H_2O$, and NaCl, were all Fisher certified reagents of high purity. No recrystallization of the salts was attempted since it was felt that nothing would be gained by it in view of the high initial purity of the materials. An ignition analysis of $CaSO_4.2H_2O$ showed a loss in weight equal to the theoretically expected value of 20.8%. The anhydrous $CaSO_4$ was heated at 900° C for 1 hour and subsequently kept in a desiccator at a temperature of 60° C.

Saturated solutions of gypsum and anhydrite were obtained as follows. Excess solid was added to an aqueous solution of sodium chloride of known composition. The latter was contained in an all-hard-pyrex-glass solubility cell (Fig. 1). The cell and contents were then immersed in a water bath the temperature of which was controlled by an electronic relay and was constant to within 0.05° C. The temperature of the water bath was read by means of a Beckmann thermometer. The latter was calibrated against a standard platinum resistance thermometer. The solutions were agitated for at least 48 hours by means of a pyrex-glass stirrer. This time interval was found to be quite

[1]*Manuscript received April 17, 1961.*
Contribution from the Department of Chemistry, University of Manitoba, Winnipeg, Manitoba.

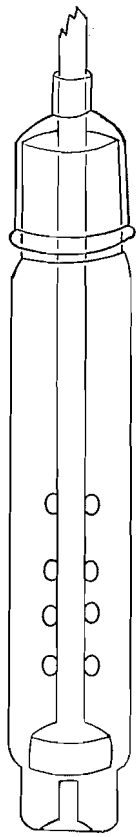

FIG. 1. Solubility cell.

satisfactory in the case of the more stable solid phase. Thus periodic checks in which the solution was stirred for 48 hours, 72 hours, and 96 hours showed no difference in the solubility, i.e. the solubility was identical within the limits of experimental error of $\frac{1}{2}\%$. In the case of the less stable solid phase some difficulties were encountered. It was found that the solubility decreased with longer periods of stirring. It was necessary to make several solubility determinations for different durations of stirring. The maximum solubility value was taken as the "true" solubility of the phase.

After it was deemed that the solution had been stirred for a sufficient length of time, the excess solid was separated from the liquid phase by quickly emptying the contents of the solubility cell into a large sintered-glass filter and applying suction to the suction flask by means of a water aspirator. The act of filtration never lasted longer than 1 minute, thus making any possible loss of water due to evaporation from the saturated solution negligible.

The analysis of the saturated solution was carried out as follows. Two 50-ml samples of the solution were put into two previously weighed Erlenmeyer flasks. The latter were immediately stoppered with rubber stoppers. The flasks and contents were weighed on an analytical balance. Next, the calcium ion concentration was determined by titration with standard E.D.T.A. using "Calred" as indicator. The sodium chloride content was similarly determined on two different samples by titration with standard $AgNO_3$ solution following Mohr's method. Blanks were run in each case.

EXPERIMENTAL RESULTS

The experimental results are summarized in Table I. In this table is recorded the solubilities of gypsum and anhydrite at various temperatures and sodium chloride concentrations. In Figs. 3 and 4 the solubilities are represented in a graphical manner. Figure 3 shows the solubilities of the two salts in pure water. Lastly, Fig. 2 shows the variation of the transition-point temperature with sodium chloride content of the solution.

TABLE I

Solubility of $CaSO_4$ and $CaSO_4.2H_2O$ in sodium chloride solutions

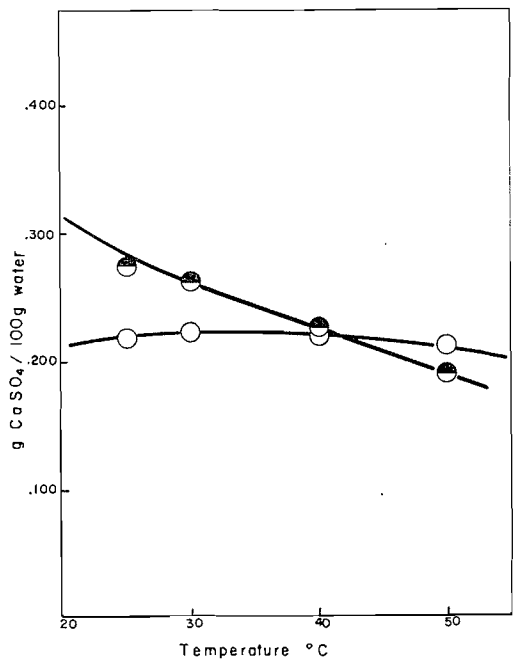

FIG. 3. Solubility in pure water: ◓ $CaSO_4$ anhyd., ○ $CaSO_4.2H_2O$.

DISCUSSION OF RESULTS

From the phase rule it is known that the number of degrees of freedom F, i.e. the number of undetermined variables of a system consisting of C components which are in mutual equilibrium and exist in P phases, is given by the expression

$$F = C - P + 2. \qquad [1]$$

An aqueous solution of gypsum or anhydrite, containing, in addition, dissolved sodium chloride, constitutes a system of three components: $CaSO_4$, NaCl, and H_2O. If the temperature and pressure are fixed at some arbitrary value, the vapor phase may be disregarded. Hence if all sodium chloride is in solution there are only two phases present: the liquid phase—solution, and the solid phase—$CaSO_4$ anhyd. or $CaSO_4.2H_2O$. From eq. [1] it is apparent that F, the number of degrees of freedom, is unity. However, as soon as a second solid phase appears, the system will become invariant, i.e. $F = 0$. It is clear that when $F = 0$ the solution must be saturated with respect to both solid phases, $CaSO_4$ anhyd. and $CaSO_4.2H_2O$. In other words, the two solids will be in equilibrium with one another. By determining the solubility of both salts separately and constructing a plot of solubility versus sodium chloride content of solution, it is possible from the intersection of the two corresponding isotherms to obtain the transition-point temperature of the two salts. That is, the point of intersection of the two curves represents that state of affairs in which both salts have the same solubility and this, as has been shown above, is just the condition for equilibrium. Hence the temperature of the isotherm is the transition temperature for the system in the presence of a certain definite quantity of sodium chloride, the actual quantity of which is defined by the intersection of the two isotherms. By plotting the temperature of the isotherms versus the sodium chloride

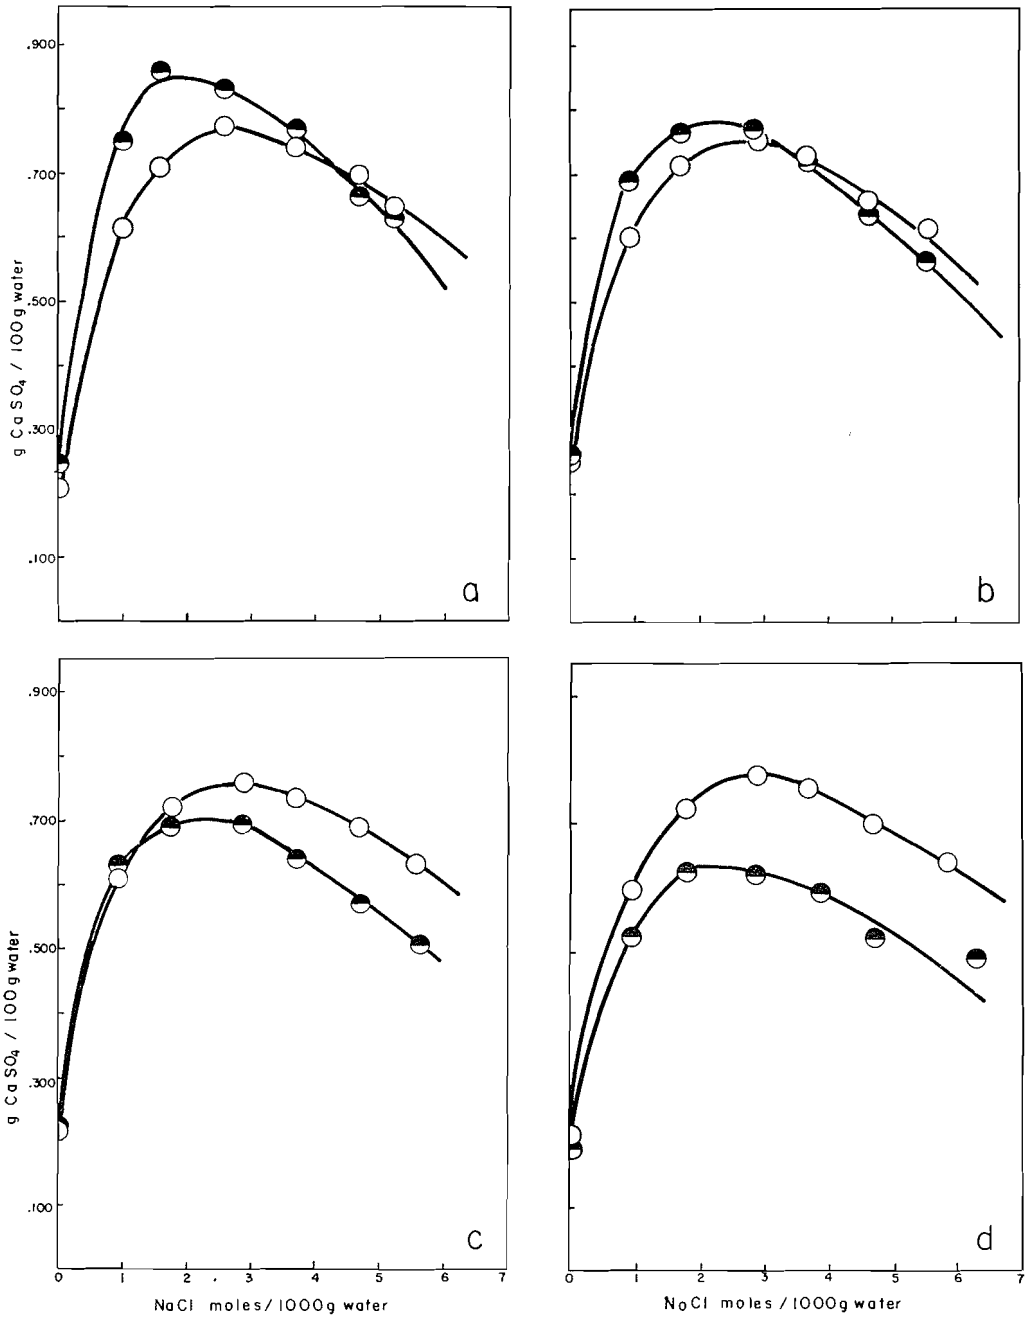

Fig. 4. Isotherms: (*a*) 25° C, (*b*) 30° C, (*c*) 40° C, (*d*) 50° C; ◓ $CaSO_4$ anhyd., ○ $CaSO_4.2H_2O$.

content of the solutions corresponding to the intersection points a graph is obtained which represents the variation of the transition-point temperature with sodium chloride content of solution. By means of this graph (Fig. 2) one can predict the nature of the precipitate that will result from an evaporation of a solution of $CaSO_4$ containing a known quantity of sodium chloride. Thus, for all solutions of a given sodium chloride content, $CaSO_4$

anhyd. will be deposited provided the temperature is above the curve in Fig. 2 or, alternatively, gypsum will be the solid thrown out if the temperature is below the curve.

The variation of the transition-point temperature with sodium chloride content may be also derived from theoretical considerations. The problem is to derive an expression for the variation of the equilibrium constant with temperature for the reaction

$$CaSO_4.2H_2O \rightarrow CaSO_4 + 2H_2O. \quad [2]$$

Employing the known relationships

$$\Delta G^0 = -RT \ln K, \quad [3]$$

$$\Delta G^0 = \Delta H^0 - T\Delta S^0, \quad [4]$$

where ΔG^0, ΔH^0, and ΔS^0 are the standard Gibbs free energy, enthalpy, and entropy and K the equilibrium constant for the reaction, it is possible to arrive at a value of K for any temperature T provided the other quantities involved are known. This procedure was employed by Macdonald (2) in the calculation of the transition point for the above system. A few words should be said concerning the water term on the right-hand side of eq. [2]. This term refers to pure water. But in presence of NaCl the water is no longer pure; its activity is said to be depressed by the presence of NaCl. The extent of this depression may be calculated approximately from vapor pressure values of aqueous sodium chloride solution. These are extensively recorded in the *International Critical Tables* (3). Inserting the numerical values for ΔH, ΔS, and R the gas constant (4), and recognizing that at equilibrium, $\Delta G = 0$, one obtains

$$\Delta G = 163.89T + 0.0215T^2 - 65.17 \log_{10} T - 2495 + 2RT \times 2.303 \log_{10} (P/P_0). \quad [5]$$

Table II shows a number of calculated transition-point temperatures along with those

TABLE II

THE RELATIVE BASICITIES OF WATER, METHANOL, AND ETHANOL[1]

C. E. NEWALL AND A. M. EASTHAM

ABSTRACT

From the kinetics of the reaction of ethylene oxide with aqueous ethanol and methanol, catalyzed by perchloric acid, the relative basicities of water, methanol, and ethanol have been determined. The value of K_1 in the expression

$$K_1 = \frac{[H_3O^+][ROH]}{[H_2O][ROH_2^+]}$$

has been found to be 1.2×10^2 for methanol and 2.1×10^2 for ethanol, in good agreement with previous values.

In alcohol solution a number of acid-catalyzed reactions are known to be strongly retarded by traces of water (1, 2, 3). The generally accepted explanation of this effect, first put forward by Goldschmidt about 1900 (2), attributes the decrease in rate to the great affinity of water for protons, with a resulting conversion of the acid ROH_2^+ to the weaker H_3O^+. This view has received strong support in recent years from measurements of the relative basicity of water with respect to alcohols, notably by Braude and Stern (4), Koskikallio (5), and others (6). The results indicate that K_1, where

$$K_1 = \frac{[H_3O^+][ROH]}{[ROH_2^+][H_2O]},$$

has a value of about 100 for methanol and 200 for ethanol at ordinary temperatures.

Our studies of the acid-catalyzed reaction of ethylene oxide with alcohols have prompted us to attempt an estimation of K_1 for methanol and ethanol from kinetic data. This reaction seems particularly well suited to the purpose not only because it shows a large and easily measured retardation by water, but because the uncatalyzed reaction is negligibly slow, and because it now seems quite certain that the reaction mechanism involves a preliminary rapid proton transfer to equilibrium, followed by a slow reaction of the protonated epoxide with the solvent.

$$HA + \underset{\diagdown O \diagup}{CH_2{-}CH_2} \rightleftharpoons \underset{\diagdown OH^+ \diagup}{CH_2{-}CH_2} + A^- \qquad \text{rapid} \qquad [1]$$

$$\underset{\diagdown OH^+ \diagup}{CH_2{-}CH_2} + \begin{matrix}ROH\\ \text{or}\\ H_2O\end{matrix} \xrightarrow{k_1} \begin{matrix}ROCH_2CH_2OH\\ \text{or}\\ HOCH_2CH_2OH\end{matrix} \qquad \text{slow} \qquad [2]$$

Furthermore, water and alcohols react at rather similar rates with the protonated epoxide so at low water concentrations the value of k_1 can be assumed to be independent of the solvent over a workable range of solvent compositions.

From the equilibrium expressions

$$K_2 = \frac{[\text{oxide.H}^+][ROH]}{[\text{oxide}][ROH_2^+]} \quad \text{and} \quad K_3 = \frac{[\text{oxide.H}^+][H_2O]}{[\text{oxide}][H_3O^+]} = K_2/K_1$$

and from the reasonable approximations: (*a*) that the sum of the concentrations of ROH_2^+ and H_3O^+ equals the concentration of added acid (i.e. that ionization is complete and the concentration of protonated epoxide very small), and (*b*) that $[H_3O^+]$ is small

[1]*Manuscript received May 10, 1961.*

Issued as N.R.C. No. 6406.

compared to $[H_2O]$, one can derive, as the rate expression for the reaction at low water concentrations, the equation

$$-d(\text{oxide})/dt = k_1K_2[\text{HA}][\text{oxide}]\left\{\frac{[\text{ROH}]}{K_1[H_2O]+[\text{ROH}]}\right\} \quad [3]$$

which in anhydrous solution reduces to the usual rate expression

$$-d(\text{oxide})/dt = k_1K_2\,[\text{HA}][\text{oxide}].$$

K_1 can then be estimated either by measuring k_1K_2 in anhydrous alcohol and solving equation [3] at various water concentrations or by plotting $1/k_{sp}$ against $[H_2O]$, where

$$k_{sp} = \frac{-d(\text{oxide})/dt}{[\text{HA}][\text{oxide}]} = \frac{k_1K_2[\text{ROH}]}{K_1[H_2O]+[\text{ROH}]}, \quad [4]$$

$$1/k_{sp} = \frac{K_1[H_2O]}{k_1K_2[\text{ROH}]}+\frac{1}{k_1K_2}.$$

Since, at low water concentrations, [ROH] is approximately constant, the plot is a straight line of slope $K_1/k_1K_2[\text{ROH}]$ and intercept $1/k_1K_2$.

EXPERIMENTAL

Rate measurements were made dilatometrically, evaluated by the Guggenheim method (7), and expressed in terms of moles per liter per minute at 25° C, essentially as previously described (3). Ethylene oxide was measured out as the vapor in a vacuum system and sealed into ampoules which were then broken into the reaction mixture. Methanol was dried with magnesium turnings in the usual way and used to dilute a stock solution of perchloric acid in dry methanol. The stock solution was prepared from the commercial 70% acid ($HClO_4.2H_2O$). For a few experiments in which an attempt was made to reduce the water content below the 0.01 *M* limit imposed by the 70% acid, anhydrous perchloric acid was prepared in the vacuum apparatus as described elsewhere (8) and diluted at low temperature with dry methanol.

Data for ethanol were taken from the previous paper (3).

RESULTS

The average values of k_{sp} for a series of mixtures of methanol and water are shown in Table I.

TABLE I

$[H_2O]$	$[CH_3OH]$	k_{sp} (av.) (l. mole^{-1} min^{-1})	Glycol in product (mole%)	H_2O in solvent (mole%)

It is apparent from the product analysis that, over most of the range of solvent mixtures, methanol is somewhat more reactive than water. The deviations at low water concentrations are believed to be due to experimental errors in determining the small amounts of glycol present, errors resulting from some oxidation of the methanol. Certainly there is no indication in the analyses that k_1 cannot be considered constant over small changes in solvent composition.

Attempts to determine k_1K_2 by direct measurement of the rate in anhydrous methanol were not very successful, apparently because the reaction is so sensitive to traces of water. Improved techniques could doubtless reduce the error but as the final results show that an error of 1% in the rate corresponds to an error of less than 0.002 M in the concentration of water, this approach does not appear very promising. The best values of k_1K_2 appear to be those obtained by extrapolating the plot of $1/k_{sp}$ against $[H_2O]$ to zero water concentration (Fig. 1). The plots are linear up to 1–2 M water and yield the following constants:

	Methanol	Ethanol
k_1K_2	13.7	6.7
K_1	1.2×10^2	2.1×10^2

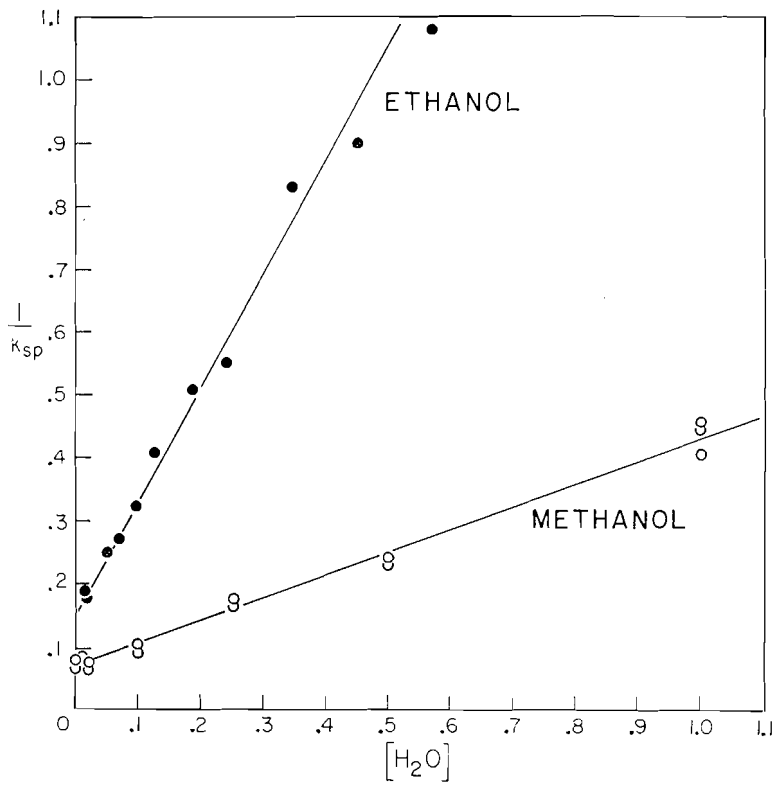

FIG. 1. Plots of $1/k_{sp}$ against water concentration: ● in ethanol (data of Brown and Eastham (3)); ○ in methanol.

The value of K_1 for ethanol is in good agreement with the value of 220 obtained by Braude and Stern (4) from indicator measurements, presumably at about 20° C, while the value for methanol is consistent with values from 110 to 140 obtained by various workers and by a variety of methods, at 25° (5).

While the agreement of the present values of K_1 with other work seems good, inspection of the data suggests that the probable error in our values may be as high as $\pm 10\%$. The error lies largely in the value for k_1K_2 since the extrapolation is by no means precise. There is, however, one rather disturbing feature of the results, namely the relative values of k_1K_2 for the two alcohols. If K_1 is twice as large for ethanol as for methanol then one might expect the same to be true for K_2, and it follows that k_1 should be about four times as large for methanol as for ethanol. The glycol analyses, however, suggest that k_1 cannot be more than twice as large for methanol as for ethanol. A comparison of this kind is perhaps dangerous since the two sets of constants were obtained in different solvents (methanol and ethanol) but does suggest that the results should be treated with caution.

In Fig. 2, values of k_{sp} calculated from the above constants have been plotted, along

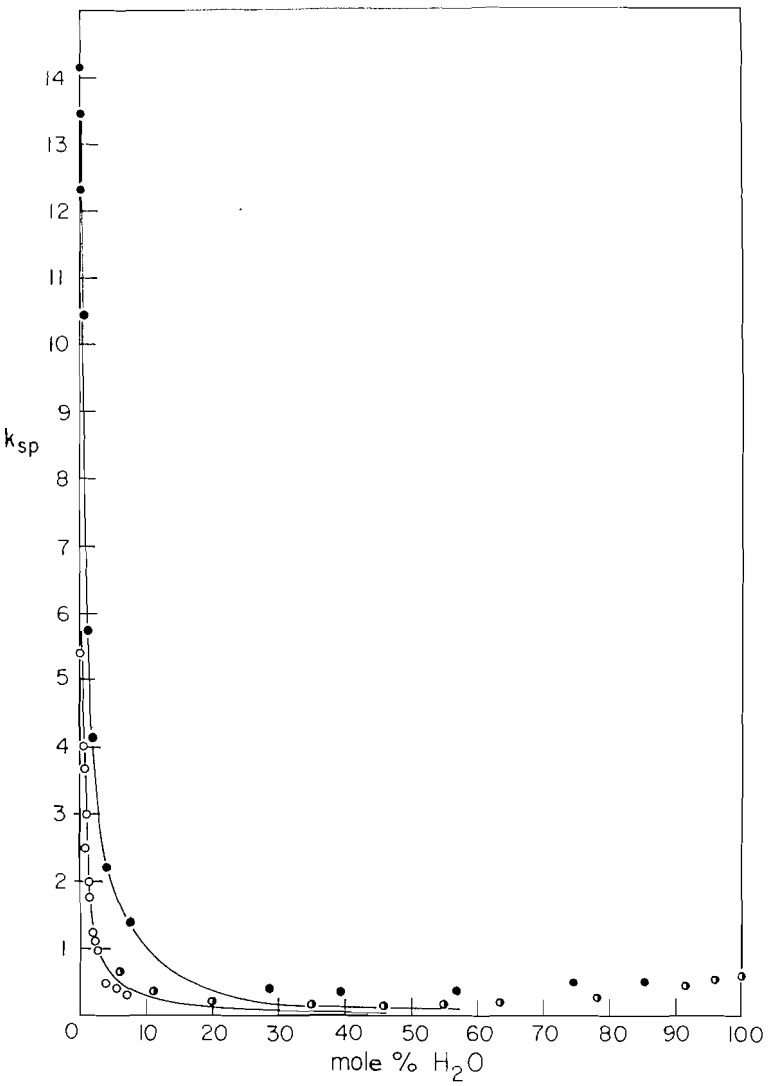

FIG. 2. Plots of k_{sp} against solvent composition. Solid lines are rates calculated for methanol and ethanol from the values of k_1K_2 and K_1 obtained in this work. Circles are experimental values: ● methanol–water; ○ ethanol–water; ◑ ethanol–water at constant ionic strength (ClO_4^- = 0.055 M).

with the experimental data, against the solvent composition. As the proportion of water in the solvent increases, deviations from the calculated rates become severe at about 10–15 mole% water, while at about 50 mole% water the rate starts to increase again. These changes may be due in part to general medium effects such as changes in the dielectric constant but there are also a number of specific causes which have not been taken into account here. In particular we may note (*a*) that salt effects are about five times larger in ethanol than in water so a small rate decrease should occur with increasing water, (*b*) that equation [3] treats the solvent as pure alcohol and does not allow for an increase in molarity (from 17 to 55 in the case of ethanol–water) as the water concentration increases, and (*c*) over a wide range of concentrations the value of k_1 will not be constant in methanol–water mixtures because of the lower reactivity of water.

CORRELATIONS OF INFRARED GROUP FREQUENCIES AND BAND INTENSITIES IN ORGANIC MOLECULES WITH SUBSTITUENT CONSTANTS: A STATISTICAL EVALUATION[1]

C. N. R. RAO[2] AND R. VENKATARAGHAVAN[3]

ABSTRACT

A statistical evaluation of the empirical linear correlations of infrared group frequencies and band intensities in aliphatic and benzene derivatives with substituent constants has been carried out. The correlations of frequencies with substituent constants generally give low standard deviations and acceptable correlation coefficients, and may thus be employed for the estimation of substituent constants. The correlations of band intensities with substituent constants show an interesting trend of the sign and magnitude of the slopes (ρ values) with the electrical property of the bond or group involved in the vibration. The ρ value decreases with the increasing electron-withdrawing power of the group.

INTRODUCTION

Although the various substituent constants were devised to correlate the structure of organic molecules with their chemical reactivity, many physical properties of the molecules may also be correlated with these constants (1, 2). Such empirical or semiempirical relations give a better insight into the structure and behavior of organic molecules, particularly when the chemist cannot yet disentangle the various structural factors into finer and more fundamental contributions. Considerable interest has been exhibited, in recent years, in correlating the infrared group frequencies and band intensities of related groups of organic molecules with substituent constants (3–9). The infrared frequencies and intensities are controlled by different factors. While the frequency is mainly determined by the bond force constants, the intensity is controlled by dipole derivatives with respect to bond length, $(\delta\mu/\delta r_{ij})$. Change of substituent group may affect the force constants, static dipole moments, or $(\delta\mu/\delta r_{ij})$, through inductive or (and) resonance effects. Substituent groups generally affect both the frequency and the intensity, though not always in the same direction. Sometimes the frequency shift is very small and the change in band intensity is large or vice versa. It is therefore important to correlate the frequencies and intensities of groups with substituent constants to understand the mechanism(s) involved. Although there have been several reports of such correlations with substituent constants in the literature (3–9), there has been no systematic evaluation of these correlations. We have now carried out a statistical evaluation (10) of the correlations of group frequencies and band intensities of aliphatic and benzene derivatives, in order to test the validity and utility of the correlations. Such an evaluation is justified by the high precision and accuracy of the recent infrared data on related groups of organic molecules, used in these correlations.

RESULTS AND DISCUSSION

A linear relation of the infrared group frequencies in meta- and para-disubstituted benzene derivatives with the Hammett σ constants (11) has been suggested by several workers (3, 8, 12). The relation may be expressed by a Hammett-type equation,

$$\nu = \nu_0 + \rho\sigma, \quad [1]$$

where ν is the observed group frequency in the meta- or para-disubstituted benzene, ν_0 is the group frequency in the monosubstituted derivative, and σ and ρ have their usual significance. Thompson *et al.* (3) have expressed doubt about the roughly linear plots of ν against σ having much significance and have considered the possibility of plotting ν^2 versus σ. A linear relationship of the group frequencies in the meta- and para-benzene derivatives has also been proposed (4) with the electrophilic substituent constants, σ^+ (13, 14).

$$\nu = \nu_0^+ + \rho^+\sigma^+ \quad [2]$$

The σ^+ values differ from the σ values by an extra resonance factor resulting from greater opportunity for resonance in electrophilic reactions. The results of the statistical treatment of the correlations of the available data on the infrared group frequencies of benzene derivatives, with the σ and σ^+ constants, have been summarized in Table I. The σ constants were taken from the recent compilation by McDaniel and Brown (27) and σ^+ constants from the compilations by Brown and Okamoto (14). For the 18 sets of frequencies of meta- and para-substituted benzene derivatives correlated with the σ and σ^+ constants, the average standard deviations for the $\nu-\sigma$ and $\nu-\sigma^+$ correlations are 3.3 and 3.3 cm^{-1} respectively, while the correlation coefficients are 0.938 and 0.924 respectively. It may be concluded that both the substituent constants correlate the frequencies equally well. This is not completely unexpected, because the vibrational frequencies, being associated with mechanical properties of bonds, may not show any preference between σ and σ^+ constants.

A linear relationship of the infrared group frequencies in aliphatic derivatives with the σ^* constants of Taft (28) has been proposed.

$$\nu = \nu_0^* + \rho^*\sigma^* \quad [3]$$

The results of the statistical evaluation of the correlations of the available data with the σ^* constants have been summarized in Table II. The average standard deviation is rather high (14.1 cm^{-1}), compared to the value of 3 cm^{-1} in the case of benzene derivatives (Table I).

Several possible correlations of infrared band intensities in meta- and para-substituted benzene derivatives with σ and σ^+ constants have been suggested (3, 4, 5, 9, 36). The best correlation is probably between the logarithm of the vibrational band intensities, $\log A$, and the substituent constants. Thompson and co-workers (3, 8) have correlated $\log A$ with Hammett σ constants:

$$\log A = \log A_0 + \rho\sigma. \quad [4]$$

Rao (4, 9, 22) has suggested a similar linear relation with the σ^+ constants:

$$\log A = \log A_0^+ + \rho^+\sigma^+. \quad [5]$$

A statistical evaluation of the correlations of log A with σ and σ^+ constants (Table III) seems to indicate that σ^+ constants are probably better suited for the correlations. In some cases, like benzonitriles and anilines, the correlations with σ^+ constants are far superior. Such a preference to σ^+ constants is understandable, since band intensities are related to electrical properties of bonds. Excellent linear correlations have also been

found between the logarithms of molar extinction coefficients, log ϵ, and σ^+ constants in the case of C—O—C stretching vibrations of anisoles (22) and NH stretching overtones of anilines (21).

The infrared band intensities in aliphatic derivatives may be correlated with σ^* constants:

$$\log A = \log A_0{}^* + \rho^*\sigma^*, \quad [6]$$

but the correlations are not satisfactory (Table IV).

GENERALIZATIONS

In the correlations of group frequencies with substituent constants, there is no particular relation between the sign and the magnitude of ρ and the nature of the bond or group involved in the vibration as might be expected. However, in the correlations of band intensities, there is a systematic variation of the sign of ρ with the nature of the bond involved. A negative slope of the log $A-\sigma$, log $A-\sigma^+$, or log $A-\sigma^*$ plot is always found when the bond or the group involved is electron-withdrawing in nature, as in carbonyl derivatives and nitriles. A positive slope is found when the bond or group involved is electron-donating in character. The magnitude of ρ seems to vary in proportion to the extent to which the groups can withdraw or donate electrons. The slope of the log $A-\sigma$ or log $A-\sigma^+$ plot decreases with the increasing electron-withdrawing power of the group. These generalizations may be clearly seen from Table V.

This relation of the sign of ρ in the log $A-\sigma$, log $A-\sigma^+$, or log $A-\sigma^*$ plot to the electrical property of the bond or group is found because the band intensity is itself dependent

TABLE V

Generalizations regarding the correlation of infrared spectra of organic molecules with substituent constants

Series	Frequency	Group	para-σ of the group	$\frac{\log A - \sigma}{\rho}$	$\frac{\log A - \sigma^+}{\rho^+}$
Anilines (20)	ν_{NH}	$-NH_2$	−0.66	0.166	0.130
Phenols (15)	ν_{OH}	—OH	−0.37	0.137	0.106
Ethyl benzoates (3)	$\nu_{C=O}$	$-COOC_2H_5$	0.45	−0.08	−0.055
Nitriles (24)	$\nu_{C\equiv N}$	—CN	0.66	−0.26	−0.509

on $(\delta\mu/\delta r_{ij})$. Substituents favoring a dipole of a bond always increase its band intensity. Thus, the OH band intensity in phenols increases with electron-withdrawing ability of the group in the para or meta position (positive slope), while the C≡N band intensity in benzonitriles increases with the increasing electron-donating ability of the para or meta substituent (negative slope). This type of generalization is extremely useful in identifying the prominent resonance forms in aromatic systems. For example, the most prominent resonance structures in phenols (I) and anisoles (II) should be similar since

I

II

the slopes of the log $A - \sigma$ plots are positive in both cases (22). The most prominent resonance structure of the organic isothiocyanates has been proposed to be III (38) or IV (39). This proposal may now be supported by the band intensity measurements of Caldow

III

IV

and Thompson (26) in para- and meta-substituted phenyl isothiocyanates. The —NCS band intensity increases with the electron-withdrawing power of the substituents.

UTILITY OF THE CORRELATIONS IN ESTIMATING REACTIVITIES OF GROUPS

An obvious application of these different linear relations would be in the estimation of substituent constants of groups. The frequency correlation would be more useful for this purpose because frequencies can be measured very easily with high precision and accuracy. The measurement of band intensities, on the other hand, is rather tedious. One could, however, make use of extinction coefficient data, to a certain extent. If one were to employ the frequency correlations (Tables I and II) for estimating the substituent constant for a group, one has to determine the characteristic frequency of a functional group in the unsubstituted and substituted derivatives and then calculate the substituent constant by making use of the ρ values given in the tables (employing the same solvent). One should choose a functional group which has the most structure-sensitive frequency. Carbonyl stretching vibration is probably best for the purpose.

NOTE ADDED IN PROOF: Brown (40) has recently suggested that the substituent constants should be linearly related to the square roots of the infrared absorption intensities in substituted benzene derivatives. We have now carried out the statistical evaluation of the linear relations of $A^{\frac{1}{2}}$ with σ and σ^+ constants and have found that the $A^{\frac{1}{2}}$–σ^+ correlations are as good as the log A – σ^+ correlations. The average standard deviation and correlation coefficient of $A^{\frac{1}{2}}$–σ^+ correlations for the six series of benzene derivatives (Table III) are found to be 0.081 and 0.957 respectively.

THE PREPARATION OF SOME MERCAPTO MONOSACCHARIDES[1]

N. C. JAMIESON AND R. K. BROWN

ABSTRACT

Methyl 4,6-O-benzylidene-2-benzylthio-2-deoxy-α-D-altropyranoside and methyl 4,6-O-benzylidene-3-benzylthio-3-deoxy-α-D-altropyranoside have been prepared by the reaction of sodium benzylmercaptide with methyl 2,3-anhydro-4,6-O-benzylidene-α-D-allopyranoside and methyl 2,3-anhydro-4,6-O-benzylidene-α-D-mannopyranoside respectively.

These two thio ethers were successfully reduced by sodium in liquid ammonia to methyl 2-deoxy-2-mercapto-α-D-altropyranoside and methyl 3-deoxy-3-mercapto-α-D-altropyranoside. An attempted replacement of the tosyl group in 1,2;5,6-di-O-isopropylidene-3-O-tosyl-α-D-glucofuranose by benzyl mercaptan was unsuccessful.

INTRODUCTION

The preparation of monosaccharides in which an oxygen atom has been replaced by a sulphur atom has received renewed attention in recent years, primarily due to the fact that these compounds provide a route to the synthesis of deoxy sugars. A review by Raymond covering the literature on thio sugars to 1944 (1) refers to the preparation of a number of thioglycosides and ω-deoxy-ω-alkylthio-hexoses and -pentoses. The only monosaccharide mentioned which contained a free mercapto group on a carbon atom other than the anomeric carbon (2–4) was a substance described as "3-deoxy-3-mercapto-D-glucose" obtained by Freudenberg and Wolf (5) in their attempt to apply the Tschugaeff reaction (6) to the preparation of an unsaturated monosaccharide.

Since 1944, a considerable amount of work has appeared in this area, but primarily concerning the preparation of the thioglycosides and thio ethers of monosaccharides (7–12). A few reports have been made of the preparation of monosaccharides with a free mercapto group. An improved synthesis of 1-thio-D-glucose by the reaction of hydrogen sulphide with 1,2-anhydro-D-glucose and its 3,4,6-tri-O-acetate in dimethylformamide has been described (13). The reduction with lithium aluminum hydride of 5,6-dideoxy-5,6-epithio-1,2-O-isopropylidene-β-L-idose has yielded 5,6-dideoxy-5-mercapto-L-idose (14). There has also been reported the preparation of 5,6-dideoxy-1,2-O-isopropylidene-5,6-(thiocarbonyldithio)-β-L-idose, a compound which, no doubt, can be reduced readily to 5,6-dideoxy-1,2-O-isopropylidene-5,6-dimercapto-β-L-idose with lithium aluminum hydride in accordance with similar reductions carried out on the trithiocarbonates of some hexitols (14, 15).

Since a number of mercapto monosaccharides were required in this laboratory, a program for their preparation was begun. This paper presents some results obtained in this direction.

RESULTS AND DISCUSSION

The debenzylation of S-benzylcysteine has been accomplished by the use of sodium in liquid ammonia (16) and this technique has been successfully applied in this laboratory to the preparation of mercaptoindoles (17). These results suggested that mercapto monosaccharides might be prepared by the reaction of benzyl mercaptan with suitable anhydro monosaccharides followed by the reductive cleavage of the resulting benzylthio ethers with sodium in liquid ammonia. This did indeed prove to be the case.

When methyl 2,3-anhydro-4,6-O-benzylidene-α-D-allopyranoside (18, 19) was treated with sodium benzylmercaptide in methanol as solvent an almost quantitive yield of crystalline methyl 4,6-O-benzylidene-2-benzylthio-2-deoxy-α-D-altropyranoside was obtained. Similarly, methyl 2,3-anhydro-4,6-O-benzylidene-α-D-mannopyranoside (19), when treated with sodium benzylmercaptide, gave crystalline methyl 4,6-O-benzylidene-3-benzylthio-3-deoxy-α-D-altropyranoside. The direction of opening of the anhydro ring agreed with observations recorded in the literature (7–9) and with the requirement that ring opening proceed preferentially via the more stable trans diaxial transition state according to Furst and Plattner's rule (20, 21). The position of the benzylthio group was verified by desulphurization of the benzylthio ethers with Raney nickel (9, 22) to produce the corresponding deoxy monosaccharides. These were compared with authentic specimens prepared by the reduction with lithium aluminum hydride of methyl 2,3-anhydro-4,6-O-benzylidene-α-D-mannopyranoside and methyl 2,3-anhydro-4,6-O-benzylidene-α-D-allopyranoside (23).

When treated with sodium in liquid ammonia, methyl 4,6-O-benzylidene-2-benzylthio-2-deoxy-α-D-altropyranoside gave a good yield of solid methyl 2-deoxy-2-mercapto-α-D-altropyranoside which readily crystallized from alcohol. Reduction of methyl 4,6-O-benzylidene-3-benzylthio-3-deoxy-α-D-altropyranoside under the same conditions gave a colorless syrup which solidified on trituration with water. Attempts at purification by direct crystallization from a wide variety of solvents and solvent pairs were abortive. However, chromatography of the crude mercapto sugar on neutral alumina yielded bibenzyl in the initial fractions followed by a viscous colorless syrup which again readily solidified on trituration with water. Crystallization of this solid from ethyl propionate was slow, but large prismatic crystals were produced whose analysis agreed with the formulation of this substance as methyl 3-deoxy-3-mercapto-α-D-altropyranoside. It is thus seen that sodium in liquid ammonia removes not only the benzyl group from the sulphur atom but also provides a convenient route for the removal of the benzylidene group without affecting the glycosidic linkage. Simultaneous cleavage of the benzylidene group and desulphurization have been obtained by the use of a large excess of Raney nickel (8, 9). However, when no more than a fourfold excess of Raney nickel was employed, reductive desulphurization occurred unaccompanied by removal of the benzylidene group (9). Since 1,2;5,6-di-O-isopropylidene-α-D-glucofuranose (24) was quite unaffected by sodium in liquid ammonia, this reductive cleavage may be specific for the benzylidene group.

Hydrolysis of methyl 2-deoxy-2-mercapto-α-D-altropyranoside and the 3-mercapto isomer with *N* sulphuric acid gave yellow solids which charred on heating but would not melt. Infrared spectra showed the substances to be quite impure and afforded no information as to their structures. Neither they, nor the products obtained from attempts to prepare their acetyl, benzoyl, or 3,5-dinitrobenzoyl derivatives, could be obtained in crystalline form.

Freudenberg and Brauns (25) reported that treatment of 1,2;5,6-di-O-isopropylidene-3-O-tosyl-α-D-glucofuranose with hydrazine replaced the 3-tosyloxy group by the hydrazine moiety. The resulting compound has recently been shown unequivocally to have the allo configuration (26). Although Reichstein *et al.* (9, 27) have shown that both sodium methoxide and sodium methylmercaptide did not replace the tosyloxy group but merely caused detosylation, it was thought that the greater nucleophilic character of the benzylmercaptide might induce a reaction analogous to that obtained by Freudenberg and Brauns and thus lead to the formation of 3-deoxy-3-mercapto-D-allose. However, here again, reaction of sodium benzylmercaptide with 1,2;5,6-di-O-isopropylidene-3-O-tosyl-α-D-glucofuranose resulted only in detosylation with retention of configuration about C_3.

EXPERIMENTAL

All melting points are uncorrected.

Methyl 4,6-O-Benzylidene-2-benzylthio-2-deoxy-α-D-altropyranoside

Sodium (2 g) was dissolved in methanol (40 ml) containing benzyl mercaptan (2.6 g, 0.022 mole) (28). Methyl 2,3-anhydro-4,6-O-benzylidene-α-D-allopyranoside (5 g, 0.019 mole) (18, 19) was added and the mixture then refluxed under nitrogen for 2 hours. The solution, left standing overnight at room temperature, deposited crystalline material which was removed and recrystallized from ethanol. The methanolic mother liquor was diluted with water and extracted with chloroform. The chloroform extract was washed with water until neutral and dried with sodium sulphate. Elimination of the solvent gave a further quantity of crystalline material. Total yield of methyl 4,6-O-benzylidene-2-benzylthio-2-deoxy-α-D-altropyranoside was 7 g (95%). M.p., 136–137° C; $[\alpha]_D^{CHCl_3}$ at 22°, +90.6° (c = 1.668). Anal. Calc. for $C_{21}H_{24}O_5S$: C, 64.93; H, 6.23; S, 8.25. Found: C, 64.97; H, 6.22; S, 8.30.

Methyl 4,6-O-Benzylidene-3-benzylthio-3-deoxy-α-D-altropyranoside

Methyl 2,3-anhydro-4,6-O-benzylidene-α-D-mannopyranoside (19) was treated in a manner similar to that given the allo isomer with the exception that the reaction time was extended to 15 hours. Crystallization did not occur when the solution stood at room temperature overnight; therefore the reaction mixture was diluted with water and extracted with chloroform. The chloroform solution was washed until neutral and then dried with sodium sulphate. Removal of the solvent left a viscous syrup which solidified after trituration with ether. Recrystallization from methanol afforded colorless crystals. M.p., 105–106° C; yield, 88%; $[\alpha]_D^{CHCl_3}$ at 22°, −112°. (c = 1.436). Anal. Calc. for $C_{21}H_{24}O_5S$: C, 64.93; H, 6.23; S, 8.25. Found: C, 64.90; H, 6.44; S, 8.18.

Methyl 2-Deoxy-2-mercapto-α-D-altropyranoside

Finely powdered methyl 4,6-O-benzylidene-2-benzylthio-2-deoxy-α-D-altropyranoside (5 g) was added to liquid ammonia (150 ml) in an Erlenmeyer flask cooled in dry ice. Small pieces of sodium metal were added to the solution, constantly stirred by a magnetic stirrer, until the blue color persisted for 10 minutes. At the end of this time, ammonium chloride was added until the blue color was discharged, whereupon the ammonia was allowed to evaporate, under a blanket of nitrogen to prevent oxidation of the mercaptan. The residue was extracted with chloroform (N_2) which, upon evaporation, left a colorless solid possessing a sweetish odor. Yield of crude product, 90%; m.p., 140–145° C. Recrystallization from ethanol, in which the compound was found to be quite soluble, yielded small colorless needles, m.p., 145–146° C; $[\alpha]_D^{CHCl_3}$, +95.2° (c = 0.9352). Anal. Calc. for $C_7H_{14}O_5S$: C, 39.99; H, 6.71; S, 15.25. Found: C, 39.95; H, 6.71; S, 15.14.

Methyl 3-Deoxy-3-mercapto-α-D-altropyranoside

Finely powdered methyl 4,6-O-benzylidene-3-benzylthio-3-deoxy-α-D-altropyranoside was subjected to a sodium-in-liquid-ammonia reduction under the same conditions as outlined above for the 2-isomer. On removal of the solvent from the chloroform extract, a colorless viscous syrup remained which solidified on trituration with water. A solution of this material in a benzene–methanol mixture (5:1) was passed through a column of neutral alumina prepared in benzene. The initial fractions contained bibenzyl and were discarded. Subsequent fractions yielded a colorless viscous syrup which solidified when triturated with water.

Several recrystallizations from ethyl propionate gave pure methyl 3-deoxy-3-mercapto-α-D-altropyranoside as large prismatic crystals. M.p., 85–87° C; $[\alpha]_D^{H_2O}$, +68.6°

(c = 1.428). Anal. Calc. for $C_7H_{14}O_5S$: C, 39.99; H, 6.71; S, 15.25. Found: C, 40.08; H, 6.80; S, 15.44.

ACKNOWLEDGMENT

The authors wish to thank the National Research Council of Canada for its generous financial support throughout the course of this work.

THE RADIOLYSIS OF CYCLOHEXANE

IV. BINARY MIXTURES IN THE VAPOR PHASE[1]

J. M. RAMARADHYA[2] AND G. R. FREEMAN

ABSTRACT

The variation of the hydrogen yield with the composition of binary gaseous mixtures containing cyclohexane and benzene, cyclohexene, or propylene is qualitatively similar to that in the liquid phase.

The quantitative experimental data were tested against several possible reaction mechanisms and two mechanisms gave straight-line plots.

One mechanism involved scavenging of hydrogen atoms. The values of the kinetic parameters derived from this mechanism might not be unreasonable in the mixtures of cyclohexane with cyclohexene or propylene. The values for benzene, however, seem less likely.

The second mechanism involved the transfer of energy (excitation or ionization) from cyclohexane to the second substance. The values of the ratio of the rate constants, k_7/k_6, of the reactions

$$C_6H_{12}^{**} \rightarrow H_2 + \text{products}, \qquad [6]$$

$$C_6H_{12}^{**} + P \rightarrow C_6H_{12} + P^* \qquad [7]$$

is about 10^3 times greater in the gas than in the liquid phase. Consideration of possible detailed mechanisms of reactions [6] and [7] indicates that this difference is reasonable if $C_6H_{12}^{**}$ is a positive ion rather than an excited molecule.

INTRODUCTION

The study of binary systems has helped considerably in the investigation of the primary chemical processes involved in radiation chemistry. When a solute is dissolved in a solvent and the solution irradiated, the yields of the products are frequently quite different than they would have been if the substances had been irradiated separately. If the solvent product yields are lowered, the solute is said to "protect" the solvent. Thus the amount of hydrogen from cyclohexane radiolysis is considerably lowered by the presence of benzene.

Such a protective action of the solute might be caused either by trapping the free radicals produced from the primarily excited and ionized molecules or by trapping the energy from these molecules.

Our aim was to study the protection role played by benzene, cyclohexene, and propylene in the decomposition of cyclohexane during irradiation in the vapor phase.

EXPERIMENTAL

Cyclohexane and benzene were Eastman-Kodak spectrograde. Cyclohexene was obtained from Matheson, Coleman and Bell. Propylene was Phillips Research Grade material. All the materials were used as obtained.

The apparatus and techniques employed in this investigation were the same as those previously described (1). Binary mixtures of cyclohexane with benzene, cyclohexene, or propylene were irradiated at 108° C with Po^{210} α-particles. The concentration of these protectors ranged from 0.8 to 100 mole% in each case.

The mixtures of cyclohexane with benzene or cyclohexene were prepared as follows. Liquid solutions of various concentrations of protector in cyclohexane were made. Two milliliters of a given solution was thoroughly degassed and then volatilized into a liter bulb, heated electrically to 108° C.

[1]*Manuscript received April 14, 1961.*
Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta. Paper presented at the 138th Meeting of the American Chemical Society, New York, September, 1960.
[2]*Present address: Consolidated Mining and Smelting Company, Trail, B.C.*

The mixtures of cyclohexane with propylene were prepared by volatilizing the appropriate amount of cyclohexane into the liter bulb and then injecting the required amount of propylene, such that the total pressure in the bulb was about the same as in the preceding mixtures (ca. 360 mm).

The liter bulb contained a calibrated Po^{210}-plated source (nominally 100 mc). The source was calibrated by Fricke dosimetry, using $G(Fe^{+++}) = 5.5$ (1). The irradiation time was 2 hours. Approximately 0.01% of the sample was decomposed. The pressure of the vapors in the bulb was such that all the energy was absorbed from the α-particles (1).

The products were analyzed by a Toepler pump – McLeod gauge combination and by gas chromatography.

The major product was hydrogen, with smaller amounts of ethylene, ethane, acetylene, propylene, propane, a C_4 hydrocarbon, cyclohexene, and dicyclohexyl. Under the conditions used, only the hydrogen could be measured accurately as a function of protector concentration. The precision of the measurements was 3% or better.

RESULTS

The results are presented in Fig. 1. In these plots, the observed values of $G(H_2)$, the number of molecules of hydrogen produced per 100 ev absorbed, are plotted against the "electron fraction" of the protector. The broken lines in the plots indicate the hydrogen

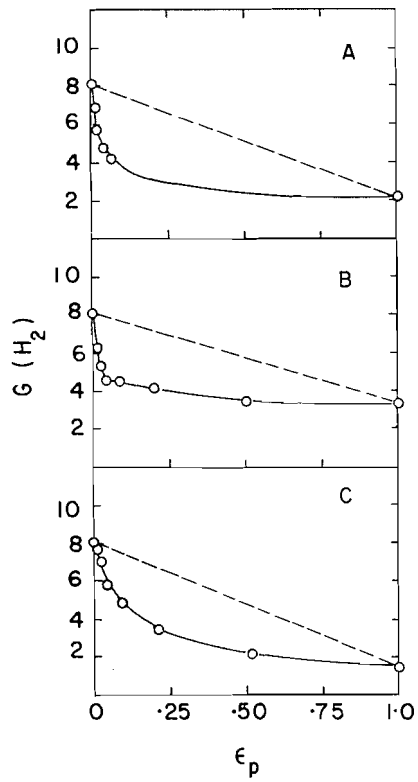

FIG. 1. Hydrogen yield as a function of protector concentration. ϵ_P = electron fraction of protector, P; (A) P = propylene; (B) P = cyclohexene; (C) P = benzene.

yield that might have been expected if there had been no interaction between the components and if the energy absorption were directly proportional to the electron fraction of the component (2, 3).

The variation of the hydrogen yield with the composition of the binary gaseous mixtures is qualitatively similar to that observed in the liquid phase (2, 3, 4). The hydrogen yield decreases quite rapidly with increasing protector concentration.

DISCUSSION

The experimental results were tested against several reaction mechanisms and two mechanisms were found to give straight-line plots. One mechanism involved scavenging of hydrogen atoms and the other involved energy transfer from cyclohexane to the protector. The two mechanisms will be treated separately.

I. Scavenging Mechanism

$$C_6H_{12} \xrightarrow{I} C_6H_{12}^* \quad [1]$$

$$C_6H_{12}^* \rightarrow H + C_6H_{11} \quad [2]$$

$$H + C_6H_{12} \rightarrow H_2 + C_6H_{11} \quad [3]$$

$$H + P \rightarrow PH \quad [4]$$

$$H + P \rightarrow H_2 + P- \quad [5]$$

In the above equations, I represents the rate of formation of $C_6H_{12}^*$, which subsequently decomposes to produce a hydrogen atom; P represents the protector; and PH and P− represent the corresponding radicals. Since the kinetic treatment is based on the hydrogen yield and since the formation of other products does not appreciably affect the hydrogen yield under the present conditions, the steps for the formation of other products have not been included. It may, however, be mentioned that a more complete mechanism involving some of the other products has been suggested by Freeman for the liquid-phase γ-radiolysis of cyclohexane–benzene (3) and cyclohexane–cyclohexene (4) systems.

By steady-state treatment of the above mechanism, it can be shown that

$$\frac{d(H_2)}{dt} = I\left\{\frac{1+k_5(P)/k_3(C_6H_{12})}{1+(k_4+k_5)(P)/k_3(C_6H_{12})}\right\}, \quad [i]$$

which may be rearranged to

$$\left\{1+w\frac{(P)}{(C_6H_{12})}\right\}\frac{I}{d(H_2)/dt} = 1+v\frac{(P)}{(C_6H_{12})} = \rho, \quad [ii]$$

where $w = k_5/k_3$, $v = (k_4+k_5)/k_3$, and ρ represents the left-hand side of equation [ii].

The numerical values of $I/[d(H_2)/dt]$ can be determined from the experimental data (3). The experimental G values were corrected for the hydrogen produced by direct excitation of the protector (3).

By giving arbitrary values to w, sets of values of ρ can be calculated. A wide range of these sets of values were plotted against the ratio $(P)/(C_6H_{12})$ to see if a straight line with an intercept of unity could be obtained for each of benzene, cyclohexene, and propylene. Such a line was obtained in each case (see Fig. 2). The values of the various ratios of rate constants derived from these plots are shown in Table I.

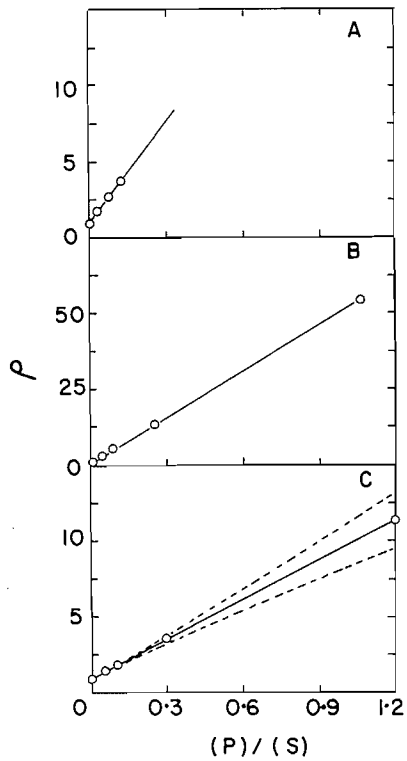

FIG. 2. Kinetic plots of mechanism I. $\rho = \{1 + w[(P)/(C_6H_{12})]\}I/[d(H_2)/dt]$; (A) P = propylene; (B) P = cyclohexene; (C) P = benzene (the upper and lower broken lines correspond to values of w of 3.0 and 2.0 respectively).

TABLE I

Values of rate-constant ratios obtained from mechanism I

P	k_5/k_3	k_4/k_3	k_4/k_5
C_6H_6	2.5±0.2	5.9±0.5	2.4
C_6H_{10}	25±10	31±19	1.2
C_3H_6	>10	>105	11

These values of the rate-constant ratios might not be unreasonable in the cases of cyclohexene and propylene. The value of k_5/k_3 obtained for benzene, however, is surprisingly high, even if the hydrogen atoms were epithermal. It implies that abstraction of hydrogen from benzene is 2.5 times faster than from cyclohexane. The smaller amount of hydrogen in benzene, and the stronger C—H bond in benzene than in cyclohexane, make this seem unlikely. It thus appears doubtful that the scavenging mechanism alone can account for the observed results.

Now let us consider the energy-transfer mechanism.

II. Energy-Transfer Mechanism

$$C_6H_{12} \xrightarrow{I'} C_6H_{12}^{**} \qquad [1']$$

$$C_6H_{12}^{**} \rightarrow H_2 + \text{products} \qquad [6]$$

$$C_6H_{12}^{**} + P \rightarrow C_6H_{12} + P^* \qquad [7]$$

$$P^* \rightarrow xH_2 + \text{products}, \quad 0 \leqslant x \leqslant 1. \qquad [8]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The x signifies that perhaps not every P* results in the formation of an H_2. Reactions [6] and [8] represent over-all processes and might comprise several steps each. Steady-state treatment of this mechanism yields

$$\{1+y(\mathrm{P})\}I'/[d(\mathrm{H_2})/dt] = 1+z(\mathrm{P}) \qquad [iii]$$
$$= \rho',$$

where $y = xk_7/k_6$, $z = k_7/k_6$, and ρ' represents the left-hand side of equation [iii]. Assuming arbitrary values for y, sets of values of ρ' were calculated and plotted against the protector concentration, (P), in an attempt to obtain a straight line with an intercept of unity (Fig. 3). The value of y that gave the desired line in each system, along with the slope of the line, z, and corresponding value of x, is presented in Table II.

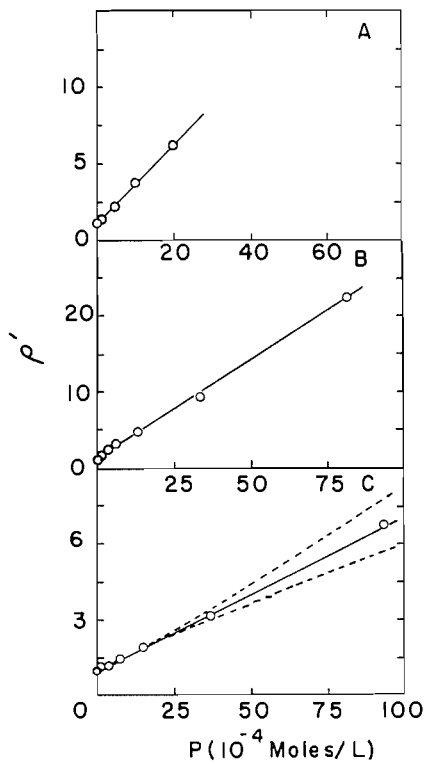

FIG. 3. Kinetic plots of mechanism II. $\rho' = \{1+y(\mathrm{P})\}I/[d(\mathrm{H_2})/dt]$; (A) P = propylene; (B) P = cyclohexene; (C) P = benzene (the upper and lower broken lines correspond to values of y of 180 and 120 liter/mole respectively).

TABLE II

Values of kinetic parameters obtained from mechanism II

P	y (liter/mole)	x	z (k_7/k_6, liter/mole)
C_6H_6	150±18	0.25±0.01	610±25
C_6H_{10}	1200±420	0.44±0.01	2700±800
C_3H_6	>1200	0.47±0.01	>2570

The value of the ratio k_7/k_6 gives an indication of the ratio of the rate of energy transfer to the rate of decomposition of the excited cyclohexane species. The value of the ratio

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

k_7/k_6 in liquid cyclohexane + benzene was 0.78 liter/mole (3) and in liquid cyclohexane + cyclohexene, 0.54 liter/mole (4). Thus the value of this ratio in the gas phase is of the order of 10^3 greater than that in the liquid phase. This has three possible causes: (*a*) k_6 is much smaller in the gas than in the liquid phase; (*b*) k_7 is much larger in the gas than in the liquid phase; or (*c*) both.

Assuming that mechanism II is the correct one, the exact nature of $C_6H_{12}^{**}$ is not known. It is probably a positive ion or an electronically excited molecule.

Consider the possibility that $C_6H_{12}^{**}$ is a positive ion. If reaction [6] corresponds to the dissociative recombination of the ion and electron, k_6 would be several orders of magnitude smaller in the gas than in the liquid phase. It is believed that the lifetime of a positive ion in an irradiated liquid is of the order of 10^{-13} sec (5). However, under the present conditions of gas-phase irradiation (10^{13} ev absorbed/ml sec, k (ion–electron recombination) $\approx 10^{-6}$ ml/ion sec (6)), the lifetime of the positive ion is about 10^{-3} sec. Thus k_6 might be smaller by a factor of the order of 10^{-10} in the gas phase than in the liquid phase. It also seems likely that k_7 would be much smaller in the gas phase than in the liquid phase (reference 7 combined with reference 8). Thus it is possible that the value of the ratio k_7/k_6 in the gas phase would be several orders of magnitude larger than in the liquid phase (about 10^{10} divided by the appropriate ratio of k_7 values in the two phases).

If $C_6H_{12}^{**}$ were an electronically excited molecule, the rate of its decomposition might be the same in both the liquid and gaseous states. This would be especially true if the internal conversion of some of the electronic energy into vibrational energy occurs as rapidly as it is presently thought to occur (in the order of 10^{-13} sec (9)). Thus k_6 might be expected to be of the same order of magnitude in the gas and liquid phases. Most theories of electronic excitation transfer imply that the value of k_7 in the gas phase would be similar to or much smaller than the value in the liquid phase. The exciton theory (10) and the sensitized fluorescence theory (11) imply much smaller rate constants in the gas phase. If $C_6H_{12}^{**}$ were an electronically excited molecule, it appears that the value of the ratio k_7/k_6 in the gas phase should have been the same as or smaller than that in the liquid phase.

If the second mechanism applies, the observed increase in the value of k_7/k_6 by a factor of about 10^3, when the phase is changed from liquid to gas, may be taken as an indication that $C_6H_{12}^{**}$ is a positive ion.

In the liquid-phase cyclohexane–benzene system, two 'protection' processes occur to comparable extents (3). The lack of resolution between the two gas-phase mechanisms in the present paper might be due to the occurrence of both. It is possible that the rate constants and concentrations are such that the two mechanisms cannot be resolved in the gas phase by the present technique. However, the apparent value of k_5/k_3 in the benzene–cyclohexane system is so high that the occurrence of only the scavenging mechanism is doubtful. Even if the energy-transfer mechanism contributed only a portion, say one half, of the over-all protection, the calculated values of k_7/k_6 would be of the same order of magnitude as those in Table II. The conclusion that the activated species taking part in the energy-transfer mechanism is probably a positive ion would still hold.

THE LUMINESCENCE OF COMPLEX MOLECULES IN RELATION TO THE INTERNAL CONVERSION OF EXCITATION ENERGY

PART III. THE TOTAL EMISSION SPECTRA OF 1-NAPHTHOIC ACID[1]

ROBIN M. HOCHSTRASSER

ABSTRACT

After excitation by 3130-Å light the anion of 1-naphthoic acid in ethanol solution internally converts to the triplet form of the acid. The excited-state equilibrium can be shifted by the addition of a base or an acid. Numerous total emission spectra of 1-naphthoic acid in various solvents can be understood in terms of some well-established principles governing non-radiative energy transfer processes within and between complex molecules.

No quantitative equilibrium studies are presented. The results indicate that the lowest excited states of the acid, singlet and triplet, are of π,π^* character. The lowest excited singlet state of the anionic form is most probably n,π^*, while the lowest triplet level is π,π^*.

INTRODUCTION

Parts I and II of this series were concerned with the influence of the excitation energy on the luminescence of complex molecules (1, 2). In this part the technique of total emission spectroscopy, i.e. the simultaneous measurement of fluorescence and phosphorescence and the relative yields of these processes, is applied to 1-naphthoic acid. In a previous paper (3) the emission spectra of 1,1-binaphthyl were examined in various media as a function of temperature. If the electronic levels of 1-naphthoic acid are considered to be weakly perturbed versions of the levels of naphthalene, then the acid dimer structure is analogous to 1,1′-binaphthyl with the naphthalene rings about three times farther apart. The total emission spectra of the acid resemble, in their spectral location, the spectra of both naphthalene and the binaphthyls but the phosphorescence and fluorescence efficiencies are found to be quite different and strongly solvent dependent. Changes of this type must be related to variations of the non-radiative processes which occur after light absorption in the complex molecule.

The fluorescence and absorption spectra of 1-naphthoic acid and the 1-naphthoate ion have been used by Weller (4) to measure the pK of the acid and of the protonated acid. El-Bayoumi and Kasha (5) have measured solvent spectral shifts for the monomer and dimer acid. Preliminary observations of the emission spectrum of the dimer and monomer indicated that the exiton model of Kasha and McRae (6) could not explain satisfactorily the spectra of 1-naphthoic acid in various solvent systems. Both the ground state and excited molecules can undergo solvolysis reactions, the products of which have considerably modified electronic structures.

This part is a study of the photochemical processes which occur during the electronic excitation lifetime of an organic acid, and provides an interesting example of how the established principles of molecular spectroscopy may be employed to deduce the detailed mechanism of a photochemical reaction.

EXPERIMENTAL

The experimental details have been published previously (3). A monochromatic source was used to excite the luminescence. All the spectra were recorded spectrophotometrically on a modified Hilger E2 spectrograph. The solvents had optical densities of less than

[1]*Manuscript received May 25, 1961.*
Contribution from the Chemistry Department, the University of British Columbia, Vancouver 8, B.C. This research was financially supported by the National Research Council of Canada.

0.01/cm, and no emission was detectable from the pure solvents, on excitation with 3130-Å light. The coolant was ice-free liquid nitrogen. The spectra are not corrected for the response of the 1P28(RCA) photomultiplier. In order to estimate absolute phosphorescence–fluorescence yield ratios from the figures, the phosphorescence curves should be magnified by about 1.5 times.

Table I shows the estimated probable 0–0 transition energies for 1-naphthoic acid and its conjugate base in various media. The phosphorescence to fluorescence yields in the last column of Table I are corrected for photomultiplier response.

TABLE I

Solvent	Temp., °K	Origin of emission, cm^{-1} ±40		ϕ_P/ϕ_F*
		Fluorescence	Phosphorescence	
Methylcyclohexane	300	28,330	—	—
Methylcyclohexane	77	29,680	19,880	0.10
Ethanol	300	26,950	—	—
Ethanol	77	30,340	19,830	1.36
Ethanol – KOH (0.05 *M*)	77		20,540	20

*ϕ_P/ϕ_F is the *intersystem crossing ratio*, being the ratio of the fluorescence and phosphorescence quantum yields. The values in the table were obtained by comparing the areas of the corrected emission spectra.

Luminescence of Alkaline Solutions

The pK_a of 1-naphthoic acid is 3.7 units at 290° K. The ΔH of ionization in protic solvents for acids of this strength is usually very small (~1000 cal); therefore, pK_a may increase by about 1 unit when the temperature is reduced to 77° K. The acid should therefore be 50% ionized in a rigid ethanol glass at a concentration of about 2×10^{-4} mole/liter. In 0.05 *M* KOH – ethyl alcohol the acid is completely ionized at 77° K.

The pK_S (K_S, acid dissociation constant of the lowest singlet excited level) is 2–4 units higher than pK at 300° K (7). At 77° K, pK_S should be at least 7.8; therefore the acid is completely ionized in 0.05 *M* KOH at this temperature.

Figure 1 therefore represents the total emission spectrum of the acid anion. The

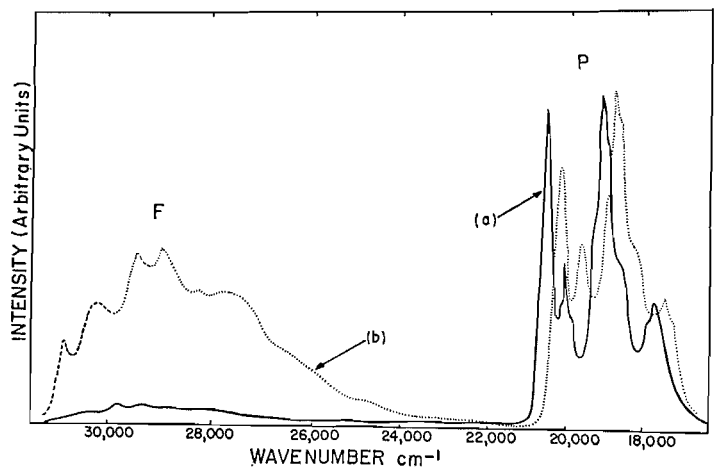

FIG. 1. Total emission spectrum of 1-naphthoic acid at 77° K. F and P indicate the fluorescence and phosphorescence regions.
(*a*) 1.1×10^{-5} mole/liter; solvent, ethanolic KOH (0.05 *M*).
(*b*) 2.0×10^{-4} mole/liter; solvent, ethanol.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

outstanding feature of this spectrum is the extremely high ratio of phosphorescence to fluorescence yield. This is typical of the class of molecules whose lowest excited singlet levels are reached by $n \rightarrow \pi^*$ promotional transitions. For molecules with singlet ground states, fluorescence from $^1(n,\pi^*)$ levels is always weak because of the forbidden character of the transition. Non-radiative intercombinations with upper triplet levels of the molecule can proceed at the usual rate for polyatomic molecules (10^{+7} sec^{-1}) so that the phosphorescent level is populated in favor of fluorescence (8). The spectrum of 1-naphthoic acid in ethanol is shown in Fig. 1 for comparison.

In view of the large gap between the origins of fluorescence and phosphorescence (10,000 cm^{-1}), it is probable that the lowest triplet level of the anion is of $^3(\pi,\pi^*)$ character. Such a gap would be much larger than any previously measured splitting between an n,π^* singlet and triplet state. Further, qualitative estimates have proved that the half-life of phosphorescence for the acid and the anion are about equal. Thus there is good indication that states of the same nature are involved.

Luminescence of Ethanolic Solutions

As mentioned previously there are two absorbing species in solutions of the acid at low concentrations in ethanol. Absorption by the anion and the acid will give rise to two different emissions so the systems will be treated independently.

Primary Light Absorption by the Anion

The excited singlet (n,π^*) anion can undergo two reactions in solution at 77° K. Firstly, intersystem crossing to the triplet anion may occur; the half-life for this process is about 10^{-7} sec. The newly formed triplet is rapidly thermally equilibrated and the reverse reaction has a vanishing probability at 77° K. The singlet anion is also involved in the solvolysis reaction

$$R^*COOH \underset{^1k_2}{\overset{^1k_1}{\rightleftharpoons}} R^*COO^- + H^+_{solv.} \qquad (A)$$

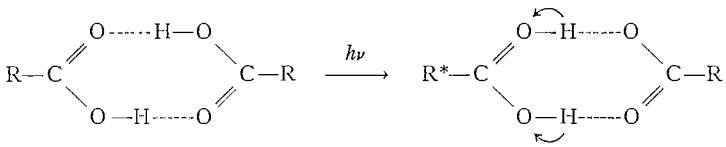
The equilibrium constant for this dissociation is at most 1.3×10^{-8} (see previous section) and the hydrogen ion concentration is 2×10^{-4} mole/liter at 50% ionization in the ground state. The rate constant $^1k_2$ for the proton recombination reaction is diffusion controlled and should be within an order of magnitude of 10^{10} liters mole^{-1} sec^{-1}. Thus the half-life of recombination is about 5×10^{-7} sec. Once reformed, the acid could not ionize again within times comparable to its half-life of fluorescence. The anion may therefore form the excited acid by proton recombination *or* it may form the triplet anion; for the example chosen, these processes have about equal probability although at lower acid concentrations the latter alternative will be strongly favored.

The triplet anion may now undergo one of two courses: either radiative intercombination with the ground state (phosphorescence), with a half-life of close to 1 sec, *or* the proton recombination

$$^3(R^*COOH) \underset{^3k_2}{\overset{^3k_1}{\rightleftharpoons}} {}^3(R^*COO^-) + H^+_{solv.} \qquad (B)$$

The phosphorescence 0–0 transition of the ion is shifted by 1.8 kcal/mole to higher energy than the corresponding transition of the acid at 77° K. The value of pK_T (acid dissociation of the triplet) at 77° K is therefore 5.1 units.

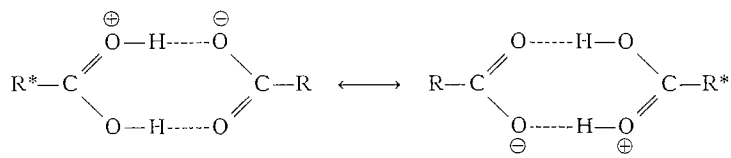
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



As for $^1k_2$, the value of $^3k_2$ is about 10^{10} liters mole^{-1} sec^{-1} and therefore the half-life of recombination is 5×10^{-7} sec; $^3k_1$ is therefore 8.7×10^4 sec^{-1}. The half-life of emission for each of the triplet molecules in (B) is 1 sec, which means that less than 1.0% of the phosphorescence observed in ethanol solution is from the triplet anion. Figure 1(*b*) shows the total emission spectra from ethanolic solutions of 1-naphthoic acid. The fluorescence is from the acid singlet level and the phosphorescence is from the acid triplet level, both attained after primary light absorption by the anion, as described above. Some of the fluorescence may have originated from directly excited acid but under the present experimental conditions these could not be separated.

The phosphorescence–fluorescence yield ratio in ethanolic solution is high and could be altered by adding acid (e.g. H_2SO_4) in accordance with the above scheme.

The Luminescence of 1-Naphthoic Acid in Methylcyclohexane



In this solvent the acid is dimerized completely at 10^{-3} mole/liter at 300° K (9). The heat of dimerization of carboxylic acids is usually around 10 kcal/mole so at concentrations as low as 10^{-6} mole/liter the acid will be completely dimeric at 77° K. It was not possible to glassify solutions more concentrated than 10^{-6} *M* without forming microcrystals which themselves have an intense emission in the blue region of the spectrum.

Weller has shown that the carbonyl oxygen becomes more basic in the lowest excited singlet state of the acid (10). The acidic oxygen also becomes more basic in this excited state, i.e., the acid is weaker. The protons in the hydrogen bridges of the dimer must therefore both be attracted towards the half of the dimer in which the excitation energy is localized.

It is unlikely that the protonated acid (excited) and the anion (unexcited) will separate completely as the former is still a very strong acid and the latter a very strong base.

Strictly, the excitation energy is not initially localized in one of the naphthalene rings. The electronic states of the separated conjugated systems are weakly coupled in the dimer and the excitation energy may be transferred non-radiatively between the two configurations. The half-life of transfer may be about 10^{-11} sec for weak coupling situations of this type. In the excited state the dimer is therefore stabilized by a resonance force interaction which may be represented as follows.

The total emission in Fig. 2(*b*) is interpreted as dimer emission. Owing to the very weak coupling between the rings, the emission spectra in Fig. 2 should not differ appreciably from the pure monomer emission. The phosphorescence to fluorescence yield ratio is very low for the dimer (1:10) and is similar to the value for unsubstituted naphthalene.

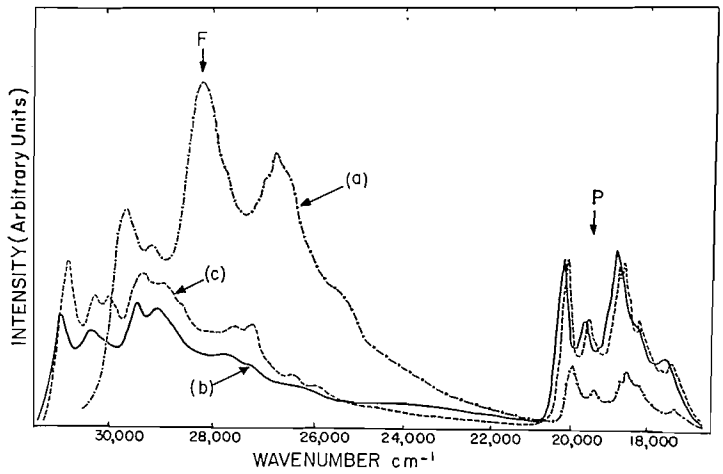

FIG. 2. Total emission spectrum of 1-naphthoic acid at 77° K. F and P indicate the fluorescence and phosphorescence regions.
(*a*) 4.6×10^{-6} mole/liter; solvent, methylcyclohexane.
(*b*) 4.6×10^{-6} mole/liter; solvent, methylcyclohexane – ether (0.25 *M*).
(*c*) 4.6×10^{-6} mole/liter; solvent, methylcyclohexane – ethanol (0.026 *M*).

Low values for the phosphorescence yield are characteristic of molecules with lowest excited singlet states of π,π^* character. The transition moment for the singlet–singlet emission of 1-naphthoic acid is known to lie in the plane of the molecule (11). Thus the fluorescence observed from the dimer is $^1(\pi,\pi^*) \rightarrow {}^1$(ground state) emission.

An enhancement of phosphorescence was expected on dimerization. The lowest excited electronic state of the dimeric acid has zero combination probability with the ground state of the dimer—if the structure of the planar dimer is the same as that in the crystal (12). The low probability of fluorescence should cause increased probability of non-radiative processes such as intersystem crossing and hence an increase in the ratio of phosphorescence to fluorescence yields compared to the monomer (6). However, this would not arise if *either* the dimer were twisted *or* if the dimer splittings were of the order of kT. Both of these conditions are possibly upheld in the present case (11).

Emission in Mixed Solvents

(I) The addition of a small amount of ethanol (0.5 *M*) to the dimeric solution in methylcyclohexane caused a marked increase in phosphorescence yield. This is shown in Fig. 2(*c*). The ethanol presumably breaks up the dimer and the previously discussed sequence of reactions in the excited state may occur.

(II) Figure 2(*b*) shows the effect of diethyl ether (0.5 *M*) on the dimer emission spectrum. As in (I) the fluorescence is decreased and the phosphorescence is increased. This experiment indicates that a hydrogen bond to the acid oxygen of naphthoic acid is the sole requirement for the establishment of ionization in the ground state, and suggests that the electronic environment of the carboxylic oxygen does not seriously affect the acid–base reaction in the neighborhood of the acidic oxygen.

(III) Figure 3(*b*) shows the effect of adding a small quantity of acetic acid (0.04 *M*) to the dimeric methylcyclohexane solution. The spectrum is broadened but the phosphorescence to fluorescence yield ratio is hardly altered from the dimer value. The acetic acid

(*b*) 4.6×10^{-6} mole/liter; solvent, methylcyclohexane – acetic acid (0.04 *M*).

is likely to be strongly hydrogen bonded to the naphthoic acid and the resulting species is a mixed dimer which is mainly undissociated in the ground state. In the excited state

the bridged protons would shift toward the basic and acidic sites of the naphthoic acid. It is unlikely that the mixed dimer would actually split into an excited protonated acid and an acetate ion, although the effect of excitation would be the reduction of the energy of dimerization. The influence of acetic acid on the emission spectrum is exactly what is expected on the basis of the explanations given in previous sections. Very similar results have been obtained for β-naphthoic acid. However, it was possible to obtain more concentrated solutions of the β-isomer in methylcyclohexane as no precipitation occurred in this case. The phosphorescence–fluorescence yield ratios were slightly lower than those for 1-naphthoic acid.

ACKNOWLEDGMENT

The author would like to thank Professor Jack Halpern for some stimulating discussions.

INFRARED SPECTRA OF XANTHATE COMPOUNDS

III. ORGANIC SOLVENT EFFECT ON THE C=S FREQUENCY[1]

L. H. LITTLE,[2] G. W. POLING, AND J. LEJA

ABSTRACT

The previously made absorption-band assignment (1) for the C=S stretching mode in xanthate-type compounds, 1020–1070 cm^{-1}, has been confirmed by the characteristic behavior of the C=S dipole in a range of different solvents (Bellamy and Rogasch (2)).

Assignments for the C=S stretching mode in xanthates, proposed by various investigators, cover the frequency range from 1000–1400 cm^{-1} and conflict with the assignments for the stretching vibrations of the C—O groups. It was felt necessary, therefore, to seek additional evidence to confirm our recent C=S band assignment (1) by solvent effects. Bellamy and Rogasch (2) found that a linear relationship exists between the frequency displacements ($\nu_{vapor} - \nu_{solution}$) of the C=S stretching vibrations in cyclic trithiocarbonates (dithioesters and some thioamides) and the frequency displacements of the C=O band in acetophenone, when studied in a particular sequence of solvents.

The same solvent sequence as that employed by Bellamy and Rogasch was used in the study of xanthate-type compounds. However, owing to the very low vapor pressures of solid xanthate compounds, their vapor-state spectra could not be obtained and the band displacements in the various solvents had to be represented relative to the frequency in cyclohexane. In the work of Bellamy and Rogasch cyclohexane solutions gave band frequencies close to those of the respective vapors. The behaviors of the two strong "xanthate bands", 1020–1070 cm^{-1} and 1200–1280 cm^{-1}, both of which had been assigned by various investigators (1, 3) to the C=S stretching mode, were contrasted; the shift of the 1020–1070 cm^{-1} band to lower frequencies (positive shift) in the solvent sequence from cyclohexane to tetrabromoethane confirms the fact that this band had been correctly assigned to the C=S stretching vibration.

EXPERIMENTAL

Materials.—Zinc *n*-butyl xanthate, *n*-butyl dixanthogen, and O-octadecyl,S-octadecyl dithiocarbonate were the same reagents which were previously used for the assignment of frequencies (1) and all analyzed 99%+ in purity. Solvents used were Eastman Kodak Company materials, designated "Specially pure for infrared spectroscopy", with the exception of dioxane, which was a C.P. grade reagent.

Procedure.—The spectra were recorded differentially (relative to pure solvent in the reference beam) on a Perkin–Elmer 221G spectrophotometer. The rotational lines of the ammonia-gas spectrum were used for frequency calibration (accuracy ±1 cm^{-1}). Due to the intense absorption bands of many solvents in the spectral region of interest and due to the asymmetrical nature of the xanthate bands themselves, the accuracy of the frequencies determined in some solvents was probably of the order of ±3 cm^{-1}.

RESULTS

Table I lists the frequencies and the relative displacements, $\Delta\nu = (\nu_{cyclohexane} - \nu_{solvent})$ cm^{-1}, of the two characteristic intense absorption bands, 1020–1070 and 1200–1280 cm^{-1},

B. *n*-Butyl dixanthogen in: (*a*) capillary film, (*b*) cyclohexane, (*c*) carbon tetrachloride, (*d*) tetrabromoethane.

DISCUSSION

The frequency shifts ($\Delta\nu$) of the 1020–1070 cm^{-1} bands, reported in Table I, are all positive and of the order of 0–9 cm^{-1}. The corresponding data of Bellamy and Rogasch, recalculated relative to cyclohexane, give a progressive change of $\Delta\nu$ from 0 to 7 cm^{-1} for dithioacetates and $\Delta\nu$ = 0–17 cm^{-1} for ethylene trithiocarbonate. The frequency displacements of *n*-butyl dixanthogen and O,S-dioctadecyl dithiocarbonate exhibit more scatter (i.e. deviate more from linearity) than do those reported for dithioacetates and ethylene trithiocarbonates by Bellamy and Rogasch. However, since the general shifts of the 1200–1280 cm^{-1} band are toward higher frequencies (negative) in the same solvent sequence, the evidence clearly indicates that the 1020–1070 cm^{-1} band follows the typical C=S behavior while the 1200–1280 cm^{-1} band does not. This evidence confirms the assignment of the 1020–1070 cm^{-1} band to the C=S stretching mode in xanthate-type compounds and not the 1210–1230 cm^{-1} band as assigned by Felumb (3).

THE ACIDITY OF NITROGUANIDINE AND ITS HOMOLOGUES[1]

A. A. Amos, P. D. Cooper, E. Nishizawa, and George F Wright

ABSTRACT

It has been shown that nitroguanidine, nitriminoimidazolidine, and 1-benzyl-2-nitriminoimidazolidine behave like urea by formation of potassium salts which completely hydrolyze in water. By contrast to true primary nitramines with which they might be considered to be tautomeric, the nitrimines are classed like urea as practically neutral compounds. Despite this ostensible tautomerism which was formerly evoked to explain the survival of nitroguanidine and nitriminoimidazolidine in alkaline solution it is now believed that the salts of nitroguanidine and nitraminoimidazolidine, from which the original nitrimines are regenerated upon acidification, are not intermediates, but rather end products, in the slow reaction with alkali. The intermediate is now postulated as an hydroxyisonitraminate anion from which the several products of the reaction are formed by appropriate fission. Presumably this anionic intermediate also is operative when tetraethylnitroguanidine or 1,3-dibenzyl-2-nitriminoimidazolidine is converted by alkali into tetraethylurea and 1,3-dibenzyl-2-imidazolidine respectively.

The chemistry of nitroguanidine and its homologues with alkalies seems to have been left in a state of confusion which may in part be due to an error appearing in one of our publications. In this paper we shall correct this error and shall suggest instead a more consistent explanation for the reaction with alkalies.

It is now recognized that nitroguanidine exists commonly as the nitrimine, $H_2NC(NNO_2)NH_2$, rather than as the tautomeric primary nitramine. Nitroguanidine does not react appreciably with alkali in aqueous solution in contrast to primary nitramines for which $K_a \simeq 10^{-5}$ to 10^{-6} (1). Its electric moment is much lower (μ = 6.95 D) than would be expected (2) if the substance were a nitramine, especially since the latter would be expected to have zwitterion characteristics. Also the ultraviolet absorption spectrum does not resemble those of known nitramines (2, 3) (which absorb at 225–240 mμ) but its strong absorption at 265 mμ is near the 268 mμ absorption found to be characteristic of *sym*-tetraethylnitroguanidine (4) which certainly is a nitrimine. Essentially by the same criteria, the studies with 2-nitriminoimidazolidine (1), 1-nitro-2-nitriminoimidazolidine (5), and azobisnitroformamidine (6, 7) have shown that with few exceptions (8) most of the homologues of nitroguanidine have nitrimino structures.

Nitrimines like these are formally analogous with urea and, indeed, there are similarities. Like urea, the acidity of nitrimines in water, as shown by potentiometric (2) and spectroscopic (9) examination, is negligible (pK 12–14). The basicity of nitroguanidine has been reported as $pK_b = 14.5$ (10). Indeed the existence of salts such as the hydrochloride (11) in media minimal in content of water would indicate that the basicity is comparable with that of urea (K_b at 25°, 1.5×10^{-14}).

With bases, in nonaqueous media (potassium amide in liquid ammonia), urea will form a potassium salt. Under the same conditions potassium nitroguanidine (m.p. 155–156° C) is obtained in 49% yield. A salt of lesser purity (m.p. 149° C) is obtained in lower yield from molar potassium methoxide in methanol. These salts regenerate nitroguanidine when they are dissolved in water, but they can be crystallized satisfactorily from methanol containing potassium methoxide. The potassium nitroguanidine is recovered unchanged after a few hours in boiling dimethylformamide or acetonitrile, but alone it decomposes at 100° C (0.3 mm Hg pressure); cyanamide and dicyanamide have been found in the strongly basic residue.

[1]*Manuscript received March 20, 1961.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

The potassium nitroguanidine has been characterized, like its urea analogue, by reaction with benzyl chloride in absolute ethanol or in dimethylformamide. The yields of benzylnitroguanidine are 39% and 43% respectively, the remainder of the product being nitroguanidine. No trace of a benzylisonitramine, a characteristic product of primary nitramines, has been detected.

The acidimetric titration of benzylnitroguanidine in 50% aqueous ethanol (curve I, Fig. 1) shows that it is a nitrimine, since it does not react with 1 equivalent of alkali

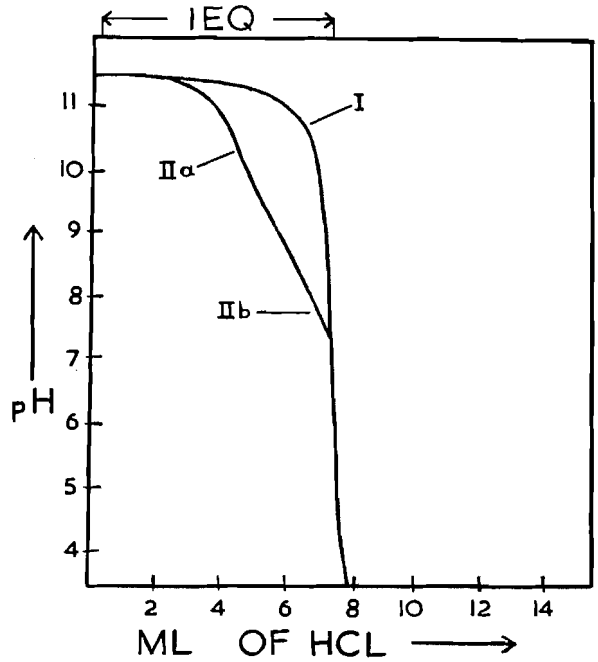

FIG. 1.

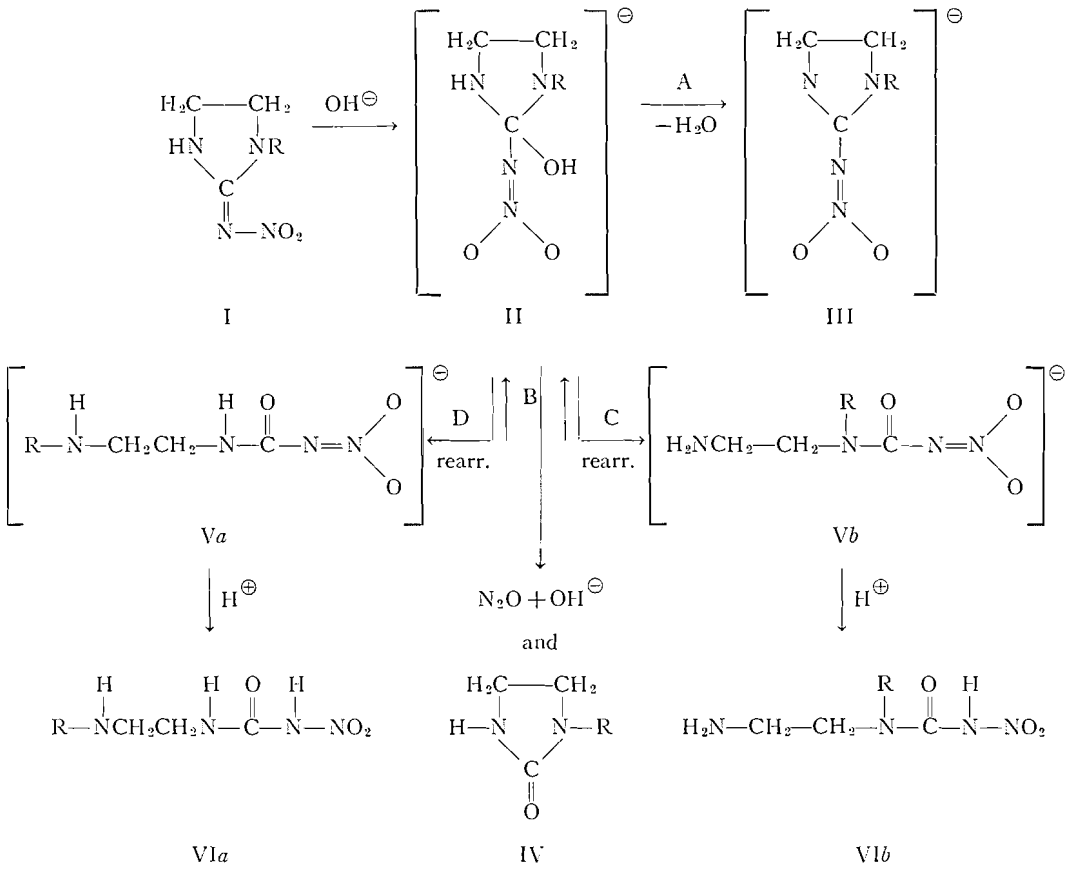
immediately after addition. However, when such a solution is aged for 62 hours its properties are altered according to titration curve II of Fig. 1. This curve shows two inflections: II*b* is indicative of about 10% decomposition to an amine, while II*a* shows that about 50% of the nitrimine has been converted to an acidic substance. Since 78% of benzylnitroguanidine is recoverable from the system, compared with 90% recovery from a freshly prepared solution, it is evident that the acidic substance must be present as the salt of isomeric benzylnitroguanidine.



In a former publication (1) from this laboratory, the isomer of non-salt-forming nitroguanidine (which isomer must have been present as the sodium salt in an aged alkaline solution) was designated as the nitramino form, $NH_2C(NH)NHNO_2$. Likewise the sodium salt of nitraminoimidazoline had to be present, together with the sodium salt of 3-β-aminoethylnitrourea, after neutral nitriminoimidazolidine was aged in alkaline solution. From this experimental evidence it was postulated that nitraminoimidazoline was intermediate in the formation of 3-β-aminoethylnitrourea or its cyclic isomer, 2-hydroxy-2-nitraminoimidazoline.

This postulation is absurd. Nitraminoimidazoline cannot be an intermediate in the formation of 3-β-aminoethylnitrourea and, in the same system, be the source of recovered

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

starting material when the components of that system have neutralized an entire equivalent of alkali, since it has been shown that 3-β-aminoethylnitrourea in alkali does not yield any nitriminoimidazolidine when the latter system is acidified. Although the recovery of nitriminoimidazolidine by acidification of its aged alkaline solution definitely indicates that the salt of the nitramino tautomer is present, the latter cannot be an intermediate.

We suggest that the intermediate is the anion 2-hydroxy-2-imidazolidinylisonitraminate, II. The alkaline aging reaction may therefore be formulated as shown in the accompanying scheme (where R = H). After the isonitraminate ion, II, is formed

slowly from nitriminoimidazolidine, I, it may react by paths A, B, C, or D. Loss of water (path A) leads to the salt of the nitramine, III, from which I may be regenerated by acidification. Or the ion may decompose along path B, losing nitrous oxide and hydroxyl ion, to give the imidazolidone, IV (R = H). Finally the anion II (R = H) may rearrange by either path C or D to give the anions V*a* or V*b* of 3-β-aminoethylnitrourea, VI*a* or VI*b*. When R = H, paths C and D are identical.

The same four paths will be involved in the alkaline reactions of nitroguanidines. Although all three products (urea, nitrourea, and nitroguanidine) have been detected from nitroguanidine, path A seems to be predominant. The large recovery of benzylnitroguanidine likewise indicates that path A is followed. On the other hand alkaline

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

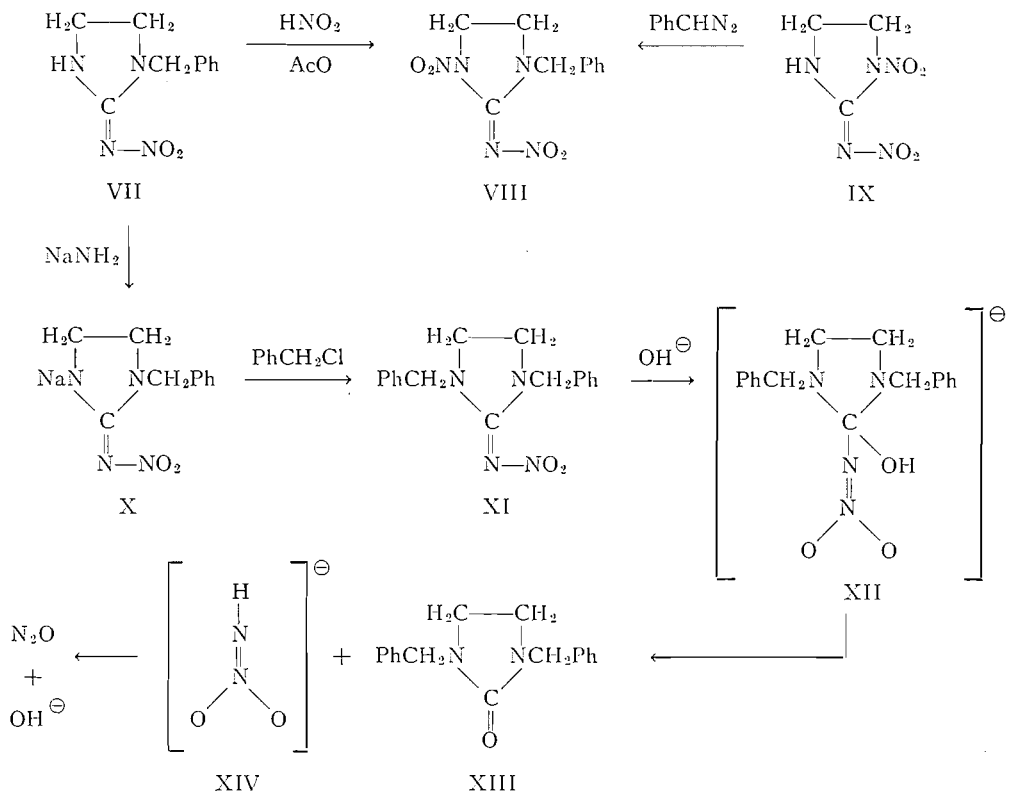
treatment of nitriminoimidazolidine seems to follow chiefly path C, less along path A, and negligibly along path B.

It would seem then that the course of reaction is determined by the substituent groups. In conformity with this expectation we have now found that only paths B and D are followed when 1-benzyl-2-nitriminoimidazolidine (I, R = benzyl) is aged with alkali.

This substance may be prepared by treatment with benzyl chloride in hot ethanol of potassium nitriminoimidazolidine which is obtained in 47% yield by the method of Franklin and Stafford. The remainder of the reaction system is accounted as 2-nitriminoimidazolidine, and no trace of benzyl imidazolinylnitraminate or isonitraminate can be detected.



A 0.1 *N* solution of sodium hydroxide in water does not dissolve 1-benzyl-2-nitriminoimidazolidine (I, R = benzyl), but the solution may be made homogeneous by addition of ethanol. When the system is acidified within an hour, the starting material is recovered quantitatively. On the other hand, when the system is aged for 72 hours, a mixture is obtained in which none of the starting material is present. The mixture is comprised of 1-benzylimidazolidone (IV, R = benzyl) and a substance, the hydrochloride of which has been isolated, which we consider to be 3-β-benzylaminoethyl-1-nitrourea, VI*a* (R = benzyl). This latter assignment has been made because nitrous acid reacts to give the dinitrosamine $PhN(NO)CH_2CH_2N(NO)CONHNO_2$ but no nitrogen. Since the alternative VI*b* contains a primary amino group it is excluded by this test.

In previous publications (12, 13, 14) we have avoided a specific designation of structure for substances such as 3-β-benzylaminoethyl-1-nitrourea because of evidence showing that tautomeric forms (so-called ring-chain isomers typified in the present instance as 1-benzyl-2-hydroxy-2-nitriminoimidazolidine) are operative in this chemistry. Essentially the same reservation is implied in the formulations of equilibria between VI*a*, VI*b*, and II (R = benzyl); indeed this implication is supported by the instability of the substance designated as VI*a*. In 10% alkali this substance is slowly converted to 1-benzylimidazolidone, presumably via the anion II. The conversion of a nitriminoimidazolidine to an imidazolidone (IV) may thus lead to a somewhat complicated rate expression in which IV is formed both directly and indirectly from II. It is possible that difficulties of this sort have been encountered previously (15).

It may be true that I and VI*b* are present in quantities too small to be detected by our methods of isolation. Within the limits of these methods, paths A and C are excluded in favor of paths B and D, and this direction may be attributed to the substituent benzyl group in the intermediate anion II. However, it would be surprising if variations in ionic strength of the system did not divert the reaction into the other paths. Insufficient work has been done to make an assessment of this possibility.

The chemical reactions of 1-benzyl-2-nitriminoimidazolidine VII conform with those of analogous nitrimines. Thus it may be nitrated to 1-benzyl-2-nitrimino-3-nitroimidazolidine, VIII, which has also been prepared by treatment of 1-nitro-2-nitriminoimidazolidine (IX) with phenyldiazomethane. As has been shown above, benzylnitriminoimidazolidine (VII) does not itself form a stable alkali salt in aqueous solution. However, in nonaqueous media it reacts with sodamide to give a sodium salt, X, which, with benzyl chloride in ethanol, gives 1,3-dibenzyl-2-nitriminoimidazolidine, XI.

When this unquestionable nitrimine, XI, is treated with aqueous alkali the substance loses the elements of nitramide and becomes 1,3-dibenzyl-2-imidazolidone, XIII. It is

reasonable to postulate that the isonitraminate ion, XII, is intermediate in this conversion to the ketone and the anion, XIV, corresponding to nitramide. This ion, XIV, is known to decompose to nitrous oxide and hydroxyl ion. But this reaction series is only a special case of the alkaline aging reaction described over the formulation series I → VI inclusive which is shown above. In this special instance substituent groups on nitrogen prevent reaction along paths A, C, and D, leaving only path C available. The same explanation applies to the alkaline conversion of *sym*-tetraethylnitroguanidine to *sym*-tetraethylurea (4).

Probably the two errors in our original publication on the acidity of nitroguanidines have by inadvertence led to criticism which has tended to obscure rather than clarify the chemistry of these substances. It is of interest that neither of these errors was actually detected by the critics.

The first error was quickly detected by us and it was reported shortly (6, 13) that, although neutral substances of appropriate constitution must be classified as nitrimines, it does not follow that the isomeric nitramino structure is applicable if the substance is moderately acidic. Such acidity may be induced by electron-withdrawing groups (such as the 1-nitro group in 1-nitro-2-nitriminoimidazolidine) without the occurrence of any atomic shift of a tautomeric nature.

Unfortunately the correction outlined above was not generally acknowledged (9). The evaluation of very weak acidities by spectroscopic means has obscured our definition of neutrality. In the sense that we used it, neutrality applies to the practical basis whereby a substance like nitroguanidine or nitriminoimidazolidine can be separated from an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

aqueous alkaline solution without any evidence of sodium salt formation. Such compounds may be called neutral in the same sense that Hantzch called the pseudo acid nitromethane a neutral form in order to contrast it to the *aci* form of this substance. Such a classification does not eliminate the pseudo acid nitromethane from its proper place in the pK_a scale. One can also write a resonance hybrid structure for ordinary nitromethane, but it has no direct relationship to the pseudo-*aci* behavior of this substance.

The situation is now unambiguous if in the publication by De Vries and Gantz (9) the term "nitramine" is read as "nitrimine" and all of the substances listed in their Table I are considered to be nitrimines. Also it should be realized that these valuable data by De Vries and Gantz do not contribute to the question of slow tautomerism because their analyses were not carried out under conditions which would reveal the isomeric process.

Our second error in stipulation of a tautomeric shift of nitrimine to nitramine as the first step in the reaction with alkali has now been corrected in terms of the initial formation of hydroxyaminate ion from which the sodium salt of the nitramine is formed subsequently. Therefore the slow tautomerism is an over-all experimental observation of a process in which the intermediate steps can lead to products additional to the nitrimine that is recoverable by acidification from the sodium salt of the nitramine. It is to be hoped that this clarification will eliminate the confusion about the reactions of nitroguanidine and its homologues with alkali.

EXPERIMENTAL

Melting points have been corrected against reliable standards.

Potassium Nitroguanidine

A solution was prepared of potassium metal (1.95 g, 0.05 g-atom) in 80 ml of anhydrous ammonia. Formation of potassium amide was allowed to proceed spontaneously. When the solution was colorless, 5.20 g (0.05 mole) of nitroguanidine was added, and the system was stirred while the substance dissolved. During the next 2 hours the white potassium salt precipitated. It was filtered off, m.p. 153.5–154° C, and then washed thrice with liquid ammonia, m.p. 155.5–156° C, 3.46 g (49.5%). Anal. Calc. for $CH_3KN_4O_2$: N, 39.4; K, 27.5. Found: N, 38.5; K, 27.1.

When the salt was heated for 1 hour at 65° C in 20 ml of anhydrous dimethylformamide and cooled, 75% (m.p. 145–146° C) was filtered off. The filtrate, after vacuum evaporation to half volume and dilution with diethyl ether, yielded 23% more, m.p. 133–137° C. Crystallization of the whole from 5 *M* methanolic potassium hydroxide gave a total yield of 98%, m.p. 152–153° C, not lowered by admixture with the original salt.

When the potassium salt was heated during 20 hours at 100° C (0.3 mm), gas was continually evolved. The residue in aqueous 10% nitric acid was filtered to remove nitroguanidine. Subsequent treatment of the filtrate with silver nitrate yielded yellow silver cyanamide.

Potassium 2-Nitriminoimidazolidine

This salt was prepared in 47% yield as described above. Admixture of the salt, m.p. 215–216° C, with 2-nitriminoimidazolidine gave a melting point depression. The salt was hydrolyzed by water to yield nitriminoimidazolidine. Anal. Calc. for $C_3H_5KN_4O_2$: K, 23.2. Found: K, 23.2.

For personal use only.

Potassium 1-Benzyl-2-nitriminoimidazolidine

The reagent was not very soluble in liquid ammonia, but an 85% yield of salt was obtained, m.p. 226–227° C. Its hydrolyzate with water yielded 112% of the expected potassium content according to titration with acid.

1-Benzyl-2-nitroguanidine

To 0.57 g (0.004 mole) of potassium nitroguanidine in 20 ml of anhydrous dimethylformamide was added 0.75 ml (0.005 mole) of benzyl chloride. After 12 hours at 80° C this stirred system was filtered hot to remove sodium chloride. The vacuum-evaporated filtrate left a sticky solid which, extracted with diethyl ether and then water, left 0.365 g (43%), m.p. 170–172° C. Three crystallizations from absolute ethanol raised this melting point to 182–183° C, not lowered by admixture with authentic material (16).

A solution of 0.116 g (0.0006 mole) of this substance in 15 ml of hot absolute ethanol was cooled to 25° C, and 10 ml each of water and 0.1340 *N* sodium hydroxide were added. Back-titration with 0.1010 *N* hydrochloric acid showed exact equivalence with the alkali. When the system was evaporated to a 1-ml volume it yielded 0.104 g (90%) of benzylnitroguanidine, m.p. 178–179° C.

A similar solution was aged for 62 hours. Potentiometric titration with 0.1010 *N* hydrochloric acid showed, by the inflection on the curve, that ½ equivalent of free alkali had been consumed in neutralization of a weak acid. From this system 78% of benzylnitroguanidine, m.p. 178° C, was recovered.

1-Benzyl-2-nitriminoimidazolidine

To 35 ml of dry benzene was added 5.2 g (0.04 mole) of 2-nitriminoimidazolidine and 2.0 g (0.051 mole) of sodium amide. The system was stirred for 8 hours at 70° C. The excess of amide was then destroyed carefully with absolute ethanol and then treated with 5.0 ml (0.044 mole) of benzyl chloride. After 8 hours of further stirring the system was cooled and the solvent was vacuum-evaporated. The residue was eluted with absolute ethanol and filtered to remove salts. The filtrate was decolorized with Darco and then evaporated to a 20-ml volume. The benzylnitriminoimidazolidine which precipitated was crystallized from ethanol, 3.6 g (41%), m.p. 148–149° C, not depressed by admixture with an authentic sample (17).

1-Benzyl-2-nitrimino-3-nitroimidazolidine

(a) From Benzylnitriminoimidazolidine

To a mixture of 7 ml (0.073 mole) of acetic anhydride, 7 ml of acetic acid, and 1 ml (0.024 mole) of 99% nitric acid stirred at 5° C was added slowly 0.5 g (0.0023 mole) of 1-benzyl-2-nitriminoimidazolidine. After an additional hour at 5° C the system was filtered to remove 0.5 g (88%), m.p. 150–152° C, decomp. After three crystallizations from 95% ethanol the melting point was raised to 154–154.5° C, decomp.

(b) From 1-Nitro-2-nitriminoimidazolidine

To a methanolic solution containing 0.003 mole of phenyldiazomethane (17) was added 0.5 g (0.0027 mole) of 1-nitro-2-nitriminoimidazolidine (III), and the system was warmed slightly to complete the evolution of nitrogen. Upon cooling to 4° C, 0.35 g of III precipitated. Upon evaporation to half volume, 0.15 g (72% of III consumed), m.p. 150–153° C, was obtained. Three crystallizations from ethanol raised this melting point to 154–155° C, not depressed by admixture with product from procedure (*a*). Anal. Calc. for $C_9H_{11}N_4O_4$: C, 45.2; H, 4.63. Found: C, 45.0; H, 4.41.

1,3-Dibenzyl-2-nitriminoimidazolidine

The treatment with benzyl chloride of the potassium salt from 8.8 g (0.04 mole) of 1-benzyl-2-nitriminoimidazolidine was carried out exactly in the manner of the benzylation of nitriminoimidazolidine. The product, 5.2 g (42%), m.p. 120–121° C, was thrice crystallized from chloroform (1.5 ml per g, +20° C to −75° C), m.p. 125–125.5° C. Some dibenzylimidazolidone, in one instance as much as 44%, was found in the crystallization mother liquors. Anal. Calc. for $C_{17}H_{18}N_4O_2$: C, 65.8; H, 5.81. Found: C, 65.5; H, 5.82. The five strongest spacings, in Angstroms, by X-ray diffraction using Cu K_α radiation (Ni-filtered) are expressed as intensities: $[I/I_1]$ as [10] 2.79 [8] 5.04 [7] 4.11 [6] 2.10 [5] 2.29.

1,3-Dibenzyl-2-imidazolidone

To 0.176 g of 1,3-dibenzyl-2-nitriminoimidazolidine was added 7 ml of 20% aqueous sodium hydroxide. The solution was refluxed for 10 minutes, then chilled and extracted with 40 ml of diethyl ether. The extract, dried with magnesium sulphate, was evaporated, leaving 0.14 g, m.p. 85–90° C. Three crystallizations from absolute ethanol (4 ml per g) raised the melting point to 93–93.5° C, not depressed by admixture with the compound prepared by the method of Lob (19), yield 94%.

1-Benzyl-2-nitriminoimidazolidine (I, R = Benzyl) with Alkali

(a) Recovery of I (R = Benzyl)

To a cooled solution of 1.16 g (0.0053 mole) of 1-benzyl-2-nitriminoimidazolidine in 150 ml of absolute ethanol was added 187 ml of water containing 5.33 ml (0.012 mole) of 2.5 *N* aqueous sodium hydroxide solution. A 25-ml portion of this well-mixed system was extracted with three 20-ml portions of chloroform. The extract was dried by use of sodium sulphate and then was vacuum-evaporated to leave 0.089 g (100%) of I (R = benzyl), m.p. 146–148° C, authenticated by mixture melting point.

After several intervals of time, 25-ml portions were extracted and otherwise treated identically with that described above. The chloroform-extracted aqueous solution was acidified and again extracted with chloroform. The melting points of the evaporated extracts are recorded in the table below.

Reaction time (hr)	Recovered from alkaline solution		Recovered from acid solution	
	Wt. (g)	M.p. (°C)	Wt. (g)	M.p. (°C)
0	0.089	146–148	Omitted	
24	0.056	145–148	0.056	136–143
72	0.051	115–125	0.049 (gum)	

(b) Isolation of 1-Benzyl-2-imidazolidone and 3-β-Benzylaminoethyl-1-nitrourea

A well-mixed system was prepared identical with that of procedure (*a*). The system was allowed to age for 62 hours at 25° C. After evaporation at 40° C (15 mm) to a volume of 30 ml the crystals were filtered off, twice washed with 2-ml portions of water, and dried at 40° C (15 mm), giving 0.432 g of 1-benzylimidazolidone, m.p. 126.5–128° C. The aqueous filtrate and washings were combined and extracted with 30 ml of chloroform. Evaporation of the extract left 1.60 g of the same substance, m.p. 126–128° C. The total yield, 64%, was identified by mixture melting point with an authentic sample (17).

The extracted aqueous filtrate was then acidified with 3 ml of 20% hydrochloric acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and then was extracted with 20 ml of chloroform. The extract (containing 0.007 g of gum) was discarded while the aqueous phase was evaporated at 35° C (15 mm) to a 5-ml volume. The crystals were filtered off, 0.363 g (24%), m.p. 155–182° C. This 3-β-benzylaminoethyl-1-nitrourea hydrochloride was crystallized from methanol – methyl acetate and then from cold methanol–acetone mixture, m.p. 192–194° C (decomp.). The substance gave a strong Franchimont (20) and a positive Beilstein test. Anal. Calc. for $C_{10}H_{15}N_4O_3.HCl$: C, 43.7; H, 5.50; N, 20.5. Found: C, 43.9; H, 5.54; N, 20.5.

The pH of the filtrate from which this hydrochloride was removed was adjusted to 5.5 and some silica was filtered off. After 17 hours at 25° C stubby needles separated, which were filtered off and washed with 1 ml of ethanol to leave 0.075 g (6%), m.p. 170–171° C. This 3-β-benzylaminoethyl-1-nitrourea was recrystallized twice from hot water, m.p. 175–175.5° C. Anal. Calc. for $C_{10}H_{15}N_4O_3$: C, 50.4; H, 5.93; N, 23.6. Found: C, 50.7; H, 6.01; N, 23.1.

1-Benzylimidazolidone

A solution of 0.10 g (0.00036 mole) of 3-β-benzylaminoethyl-1-nitrourea hydrochloride in 10 ml (0.025 mole) of 10% aqueous sodium hydroxide solution was thrice extracted with 15-ml portions of diethyl ether. The ethereal extract contained about 10 mg of brown gum. After 2 days the aqueous phase deposited stubby needles which were filtered off and washed with 5 ml of water to leave 20 mg, m.p. 126–128° C, mixture melting point with authentic material not lowered.

When this 1-benzylimidazolidone was boiled 5 minutes with 2.5 *N* sodium hydroxide it was recovered unchanged. Also, when its solution in 6% hydrochloric acid was allowed to age at 25° C for 12 hours, and then evaporated at 40° C (15 mm) to a volume of 0.5 ml and neutralized with aqueous sodium bicarbonate, the substance was quantitatively recovered unchanged, m.p. and mixture m.p. 126–128° C.

3-β-N-Benzyl-N-nitrosaminoethyl-3-nitroso-1-nitrourea

To a solution of 0.274 g (0.001 mole) of 3-β-benzylaminoethyl-1-nitrourea (VI*a*, R = benzyl) in 8 ml (0.004 mole) of 1.8% aqueous hydrochloric acid at 0° C and under nitrogen was slowly added 0.276 g (0.004 mole) of sodium nitrite in 2 ml of water. This nitrite solution was added during 200 minutes from a mechanically driven hypodermic syringe. No gas was evolved and the solution remained clear and colorless until the last 30 minutes of the addition period.

When addition was complete a solid was filtered off and methanol-washed (0.083 g, 35%); it was unchanged starting material, m.p. 174–176° C, mixture m.p. not lowered. The filtrate was evaporated at 35° C (15 mm) to dryness and the residue was extracted with 5 ml of hot acetone. This extract was evaporated to a 2-ml volume and then was chilled to −80° C to precipitate 0.06 g (cold-acetone-washed), m.p. 172–175° C (decomp.). This 21% yield of dinitroso derivative was crystallized from absolute methanol, m.p. 184.5–185° C. The substance gave a strong Liebermann nitroso test (while the Liebermann test for the starting material was negative) and a positive Franchimont nitramine test. Anal. Calc. for $C_{10}H_{12}N_6O_5$: C, 40.6; H, 4.08. Found: C, 40.6; H, 4.05.

METHYLATION OF SUGAR MERCAPTALS

II. L-ARABINOSE DIETHYL MERCAPTAL[1]

G. G. S. Dutton and Y. Tanaka

ABSTRACT

Methylation of L-arabinose diethyl mercaptal in tetrahydrofuran with methyl iodide and silver oxide yielded mainly 2-*O*-methyl-L-arabinose and a trace of 5-*O*-methyl-L-arabinose. The identity of the major component was inferred by its behavior on electrophoresis and confirmed by the preparation of the crystalline amide. The polymethylated components were not examined. 2-*O*-Methyl-L-arabono-γ-lactone, previously known as a sirup, has now been obtained crystalline.

In Part I it was reported (1) that in the Purdie methylation of D-glucose diethyl mercaptal the 2-position was methylated exclusively but no methylation took place with other sugar mercaptals. This was attributed to the insolubility of the other mercaptals in methyl iodide. When the methylation was carried out in tetrahydrofuran not only D-glucose mercaptal but also other sugar mercaptals were found to be reactive towards Purdie's reagents; the qualitative investigation of these mercaptals has been described previously (1).

The present paper is the second in a series on the relative reactivities of hydroxyl groups in sugar mercaptals and describes the methylation of L-arabinose diethyl mercaptal in tetrahydrofuran. As with D-glucose diethyl mercaptal, the hydroxyl on C_2 of L-arabinose diethyl mercaptal is the most reactive to methylation in tetrahydrofuran. The primary C_5-hydroxyl group is also reactive but to a much lesser extent. No monomethylarabinoses were found other than the 2-*O*- and 5-*O*-methyl isomers, and a colorimetric estimation showed these to be present in the approximate ratio of 30:1.

L-Arabinose diethyl mercaptal was shaken at room temperature in tetrahydrofuran in the presence of silver oxide and drierite, in a quantity of methyl iodide adjusted so that a reasonable amount of monomethylarabinoses was obtained. Acid hydrolysis of the methylation mixture gave a mixture of methylated L-arabinoses which was shown by paper chromatography to contain, *inter alia*, two mono-*O*-methyl isomers. These two components were isolated by paper chromatography using butanone–water azeotrope as the developing solvent.

The fast-running component (R_f 0.30 in butanone–water azeotrope) was assumed first to be 5-*O*-methyl-L-arabinose (2), since it ran at the same rate as the latter on paper chromatography in butanone–water azeotrope. However, paper electrophoresis of this component showed that it was a mixture of 5-*O*-methyl-L-arabinose (M_g 0.80, faint) and a polymethylated arabinose (M_g 0.00, strong), the structure of which was not investigated. Since the amount of 5-*O*-methyl-L-arabinose produced in this methylation was very small, as shown by a faint spot on electrophoresis, it was not possible to isolate it and identify it by the preparation of a crystalline derivative.

The slow-running component (R_f 0.15 in butanone–water azeotrope) was shown to be electrophoretically homogeneous (M_g 0.33), and the crystalline amide was prepared (m.p. 131–132° C) from the sirup by oxidation with bromine followed by treatment with methanolic ammonia. Both 2- and 3-*O*-methyl-L-arabonamides have been reported

[1]*Manuscript received June 27, 1960.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver 8, B.C. Presented at the 138th American Chemical Society meeting in New York, September, 1960.

(m.p. 131° C and 132° C, respectively (3)), but our amide was assumed to be the 2-*O*-methyl derivative from the fact that substitution of the 2-hydroxyl with a methyl group results in retardation of migration in electrophoresis (4). Admixture of our amide with an authentic sample prepared by the method of Jones, Kent, and Stacey (5) and of Hirst and Jones (6) showed no depression of the melting point.

Confirmation of the identity of the slow-moving component as 2-*O*-methyl-L-arabinose was obtained by showing that (*a*) the derived amide gave a negative Weerman test (7), (*b*) the infrared spectra of the amide of the unknown sugar and of the synthetic 2-*O*-methyl-L-arabonamide were superimposable, and (*c*) a mixed melting point of the unknown amide with an authentic sample of 3-*O*-methyl-L-arabonamide (m.p. 131–132° C) was 80–105° C. During the preparation of the authentic 2-*O*-methyl-L-arabonamide the 2-*O*-methyl-L-arabono-γ-lactone was obtained in crystalline form, m.p. 88° C.

In addition to these two monomethylarabinoses, a number of polymethylarabinoses and unreacted arabinose were also detected on paper chromatography, but they were not investigated further.

EXPERIMENTAL

Methylation of L-*Arabinose Diethyl Mercaptal*

L-Arabinose diethyl mercaptal (500 mg) was dissolved in 50 ml of dry tetrahydrofuran, and 500 mg of silver oxide and 3 g of drierite were added to the solution. Methyl iodide (10 ml) was added to the mixture which was then shaken at room temperature for 20 hours, during which time 30 ml of methyl iodide were added in aliquots of 10 ml at 5-hour intervals. The reaction mixture was filtered and evaporated *in vacuo* to a sirup which was then dissolved in 30 ml of chloroform, and a small amount of inorganic impurities was removed by filtration. The chloroform solution was evaporated *in vacuo*, and the sirup (564.3 mg) thus obtained was dissolved in a mixture of ethanol (10 ml) and concentrated hydrochloric acid (2.5 ml) and refluxed in boiling water for 5 hours. After neutralization with Duolite A-4 resin, the solution was evaporated *in vacuo* to give a light brown sirup (290.8 mg).

Chromatographic Separation of the Methylated L-*Arabinoses*

The sirup showed the following spots by paper chromatography: R_f 0.91 to 0.75 (two (?) components); 0.59, 0.47, 0.36, 0.30, 0.15, and 0.05 (butanone–water azeotrope); R_f 0.84 to 0.77 (two (?) components); 0.66, 0.57, 0.52, 0.45, 0.37, and 0.18 (ethyl acetate – formic acid – acetic acid – water, 18–1–3–4).

The sirup was chromatographed using butanone–water azeotrope for about 13 hours on Whatman No. 3MM paper previously washed with the same solvent. The components which corresponded to R_f 0.30 and R_f 0.15 (butanone–water azeotrope) were detected on both edges of the chromatogram, and the strips containing these components were extracted with boiling methanol. After three extractions the extract gave a very faint Molisch test. Yields of the fast- and slow-running compounds were 7.0 mg and 32.6 mg respectively. These two components were examined by electrophoresis (750–1000 v, 1.5 hours, 0.05 *M* sodium borate solution) and showed the following M_g values: slow-running component (R_f 0.15), M_g 0.33; fast-running component (R_f 0.30), M_g 0.80 (faint) and 0.00 (strong); synthetic 5-*O*-methyl-L-arabinose, M_g 0.80; (D-glucose, M_g 1.00).

A quantitative analysis of the fast-running component by the phenol – sulphuric acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

method (11) showed a ratio of 6:1 for the components with M_g 0.00 and 0.80. This gives approximately 30:1 for the ratio of 2-*O*-methyl-L-arabinose to the 5-*O*-methyl isomer.

Identification of the Slow-running Component as 2-O-Methyl-L-arabinose

The sirup (20.7 mg) was oxidized with bromine for 24 hours according to the ordinary procedure and the lactone (11.0 mg) was dissolved in 10 ml of ethanol (absolute), saturated with dry ammonia, and kept overnight at room temperature. Evaporation of the solvent gave 9.0 mg of sirup which was crystallized from ethanol – light petroleum ether. Yield: 45%, based on the monomethylarabinose. M.p. and mixed m.p. 131–132° C. Mixed m.p. with 3-*O*-methyl-L-arabonamide 80–105° C.

Synthesis of 2-O-Methyl-L-arabinose

This was prepared by the published method (6) from methyl β-L-arabopyranoside (m.p. 168° C, 4 g), anhydrous copper sulphate (50 g), and acetone (200 ml). The sirupy isopropylidene derivative (3.29 g) was methylated three times by Purdie's method and the product (2.45 g) hydrolyzed with *N* sulphuric acid for 4 hours on the steam bath. Neutralization (Duolite A-4 resin) and evaporation gave a sirup (1.67 g) which on chromatographic examination showed two strong spots (R_{arab} 3.76 and 10.7) and one weak spot (R_{arab} 1.0, butanone–water). Separation of the sirup on a cellulose–hydrocellulose column (9) using butanone–water yielded 691 mg of chromatographically pure 2-*O*-methyl-L-arabinose (R_{arab} 3.76, $[\alpha]_D^{22}$ 94.0° (*c*, 0.26 in water)).

When the preparation of this compound was attempted by refluxing for 24 hours a mixture of the sirupy glycosides (10 g) with anhydrous copper sulphate (50 g) and acetone (250 ml), the yield of chromatographically pure 2-*O*-methyl-L-arabinose was only 438 mg.

2-O-Methyl-L-arabono-γ-lactone

Synthetic 2-*O*-methyl-L-arabinose (173.2 mg) was oxidized with bromine, and the lactone (153.0 mg, 89.5%), obtained initially as a sirup, was crystallized from acetone or ethyl acetate as needles, m.p. 88° C; $[\alpha]_D^{20}$ −49.1° → −46.3° (24 hours, *c*, 0.128 in water); λ_{max}^{nujol} 5.73 μ (8). Anal. Calc. for $C_6H_{10}O_5$: OMe, 19.2%. Found: OMe, 19.2, 19.5%. The lactone (111 mg) was converted to the amide (92 mg, 76%), which was recrystallized from ethyl acetate – acetone or ethyl acetate – methanol as fine needles; m.p. 131° C, lit. (6) m.p. 131° C. The infrared spectra of this amide and that obtained from the slow-running component were identical.

3-O-Methyl-L-arabinose

This was prepared by the courtesy of Mr. A. E. Barlay according to the method of Hirst, Jones, and Williams (10). The sugar had $[\alpha]_D^{22}$ 107° (*c*, 1.4 in water), and the derived 3-*O*-methyl-L-arabonamide, after recrystallization from ethyl acetate – petroleum ether, had m.p. 131–132° C.

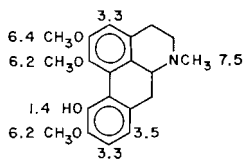
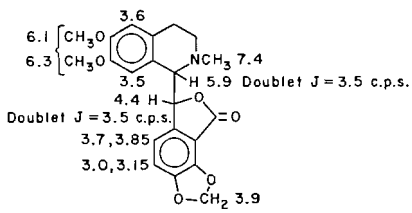
THE ALKALOIDS OF CORYDALIS GOVANIANA[1]



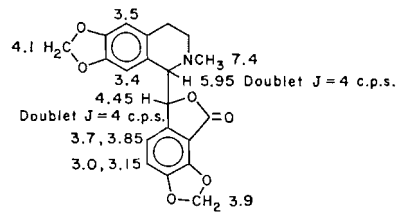
O. E. Edwards and K. L. Handa[2]

ABSTRACT



The Himalayan plant *Corydalis govaniana* (Wall. Tent.) has been shown to contain the alkaloids protopine, corlumine, bicuculline, and isocorydine, as well as fumaric acid and choline.

The alkaloids of the genus *Corydalis* have been the subject of intensive investigation (1). The species *govaniana* (Wall. Tent.), however, appears to have escaped chemical examination until the present work. It is native to the western Himalayas, where the inhabitants use the roots in treating skin diseases.



An alcohol extract of the dried ground root was concentrated to a syrup under reduced pressure, and the alkaloids extracted into dilute sulphuric acid. They were then separated using the general procedure devised by Manske (2) (see Flow Sheet I). Only known alkaloids were encountered: protopine, isocorydine (I), corlumine (II), and bicuculline (III) in the approximate ratio of 1:1:8:3. The latter two ran together with several solvent systems on paper, were not separated by chromatography on alumina, but could be partially separated by fractional crystallization. However, countercurrent distribution between benzene and buffer of pH 3 effected a clean separation of the two bases.

I

II

III

We were surprised to find the phthalide isoquinoline base corlumine (II) appearing, in part, among the phenolic bases. The lactone rings in it and bicuculline are hence readily opened by alkali, a fact supported by the fairly rapid shift of their ultraviolet absorption spectra in alkaline ethanol. The identity of the bases was surmised after study of their ultraviolet, infrared, and N.M.R. spectra and comparison of empirical formula and melting point with literature values. Finally, comparison was made with authentic samples kindly supplied by Dr. Léo Marion and Dr. R. H. F. Manske. The ultraviolet spectra and description of new salts of the alkaloids are documented in the experimental part. Our assignment of the main bands of the N.M.R. spectra have been indicated on the formula in τ ($CDCl_3$ solutions) (3). The infrared spectra of the alkaloids are reproduced in Fig. 1. Two features of the spectra of general interest are the N—CH_3 bands near 2800 cm^{-1} and the OCH_3 bands near 2850 cm^{-1}. These supplement the sometimes

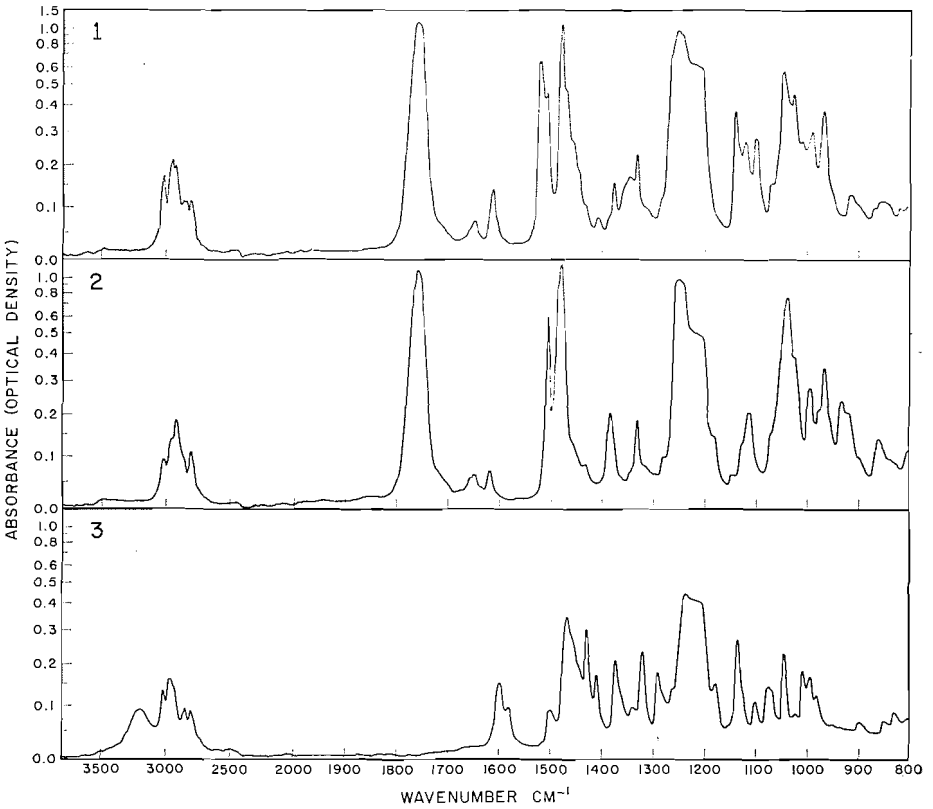

FIG. 1. Infrared spectra in chloroform in a 0.1-mm cell: 1, corlumine; 2, bicuculline; 3, isocorydine.

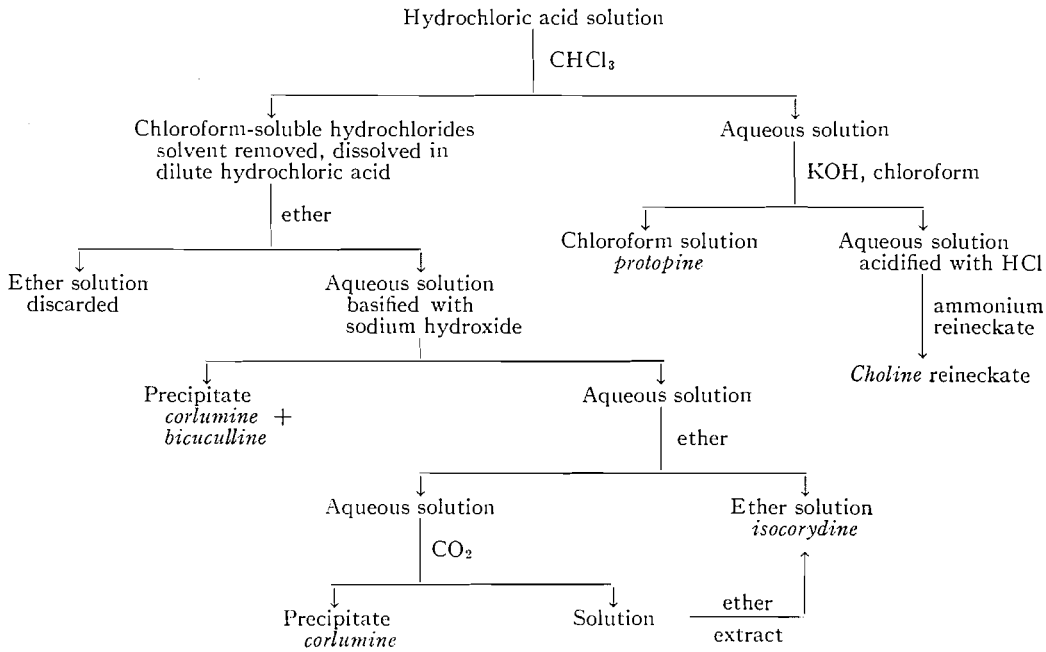
ambiguous evidence from analyses and N.M.R. spectra. The acidic material from the plant yielded fumaric acid, while the water-soluble part of the ethanol extract gave choline reineckate when treated with ammonium reineckate.



EXPERIMENTAL

Ultraviolet spectra were determined in 95% ethanol (intensities in ϵ are cited in parentheses), rotations in chloroform, and N.M.R. spectra in deuterochloroform with tetramethylsilane as internal standard. The pK_a' values were determined in the aqueous alcohol mixtures specified, by titration with *p*-toluenesulphonic acid in the same solvent. Melting points were determined on a Kofler hot stage.

Extraction and Separation

Roots of *Corydalis govaniana* (Wall. Tent.) were collected in September 1960, air-dried, and ground. An exhaustive ethanol extraction of 5 kg of this material was made at room temperature. The extract was concentrated to a syrup under reduced pressure. The alkaloids were extracted from the syrup into dilute sulphuric acid. The acid solution was basified with ammonia and the alkaloids recovered by extraction into chloroform. After removal of the chloroform the residue was dissolved in 300 ml of 10% hydrochloric acid. After standing overnight, this solution was extracted six times with 200-ml portions of chloroform. The subsequent operations are shown on Flow Sheet I.

FLOW SHEET I

The corlumine–bicuculline mixture was not separated by chromatography on 20 times its weight of alumina, activity III. Five grams of the mixture was loaded in five Craig tubes (capacity, 10 ml of each phase) in benzene. It was then subjected to 100 transfers past phosphate–citrate buffer of pH 3. Tubes 15–45 contained one substance with peak concentration in tube 30. The contents of tubes 20 to 40 were combined and 3.6 g alkaloid recovered. After one recrystallization from methanol it melted at 160–161° and proved to be corlumine. Tubes 55–75 were mainly one alkaloid (peak concentration at tube 65) but a tailing out toward higher tube number suggested the presence of another. The contents of tubes 60 to 75 were combined. The alkaloid from these (1.3 g) melted at 197–198° after one recrystallization from methanol, and proved to be bicuculline. No pure alkaloids were obtained from the remaining tubes.

Corlumine

Yield, 17.2 g (0.36%). After four recrystallizations from methanol it melted at 162°; $[\alpha]_D^{25}$ 77° (*c*, 1.0); pK_a' (50% aqueous methanol) 6.3. Ultraviolet spectrum: λ_{max} 222 (30,640), 287 (3980), and 326 (5260) mμ, unchanged on addition of acid. In alkaline ethanol it had λ_{max} 219 (53,600) and 287 (7280) mμ. It did not depress the melting point of an authentic sample with m.p. 160°. The base formed a crystalline picrate, m.p. 204°. Found: C, 52.32; H, 3.71; N, 10.09. Calc. for $C_{27}H_{24}O_{13}N_4$: C, 52.92; H, 3.90; N, 9.14. Its perchlorate melted at 180–181° C. Found: C, 51.70; H, 4.70. Calc. for $C_{21}H_{21}O_6N.HClO_4$: C, 52.11; H, 4.56. Its picrolonate melted at 225°.

Bicuculline

Yield, 5.3 g (0.106%). After five recrystallizations from methanol this base melted at 199° and had $[\alpha]_D^{25}$ 131° (*c*, 1.6) and pK_a' (50% aqueous methanol) 6.2. It did not depress the melting point of an authentic sample of bicuculline, m.p. 198°. It had λ_{max} 225 (36,700),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

296 (6390), and 324 (5870) mμ, unchanged in acidified ethanol. In alkaline ethanol it had λ_{max} 222 (48,440) and 293 (9540) mμ. Its picrate melted at 202°. Found: C, 52.40; H, 3.31. Calc. for $C_{26}H_{20}N_4O_{13}$: C, 52.35; H, 3.35. Its picrolonate melted at 195°.

Isocorydine

Yield, 2.1 g (0.04%). After recrystallization from methanol this base melted at 186° and had $[\alpha]_D$ 195° (*c*, 1.0) and pK_a' (80% methanol) 6.3. It did not depress the melting point of an authentic sample of isocorydine, m.p. 185°. It had λ_{max} 220 (51,500), 266 (18,760), and 304 (6650) mμ. In alkaline ethanol it had λ_{max} 342 (19,440) mμ. Its methiodide melted at 224° (lit. 224 (4)).

Protopine

Yield, 3.4 g (0.068%). After recrystallization from methanol this melted at 210° and showed no mixed melting point depression with authentic protopine, m.p. 211°. Its pK_a' was 8.2 in 90% methanol. It had λ_{max} 290 (10,170) mμ unchanged on addition of alkali. In a 1 *N* solution of hydrogen chloride in 95% ethanol it had λ_{max} 290 (9180) and 240 (9880) mμ.

Choline

The reineckate was converted to the chloroaurate (0.215 g), m.p. 242°, undepressed when mixed with choline chloroaurate, m.p. 244°.

Fumaric Acid

The acid-insoluble part of the ethanol extract was extracted with hot water. On being cooled the solution deposited crystals of fumaric acid which sublimed above 200° and melted at 297° (sealed capillary); mixed m.p. with authentic fumaric acid, 297°.

ACKNOWLEDGMENTS

We thank Mr. H. Seguin for the microanalysis, Mr. R. Lauzon for the infrared spectra, and Mr. J. Nicholson for the N.M.R. spectra. One of us (K. L. H.) is grateful to the Canadian Colombo Plan authorities for financial assistance.

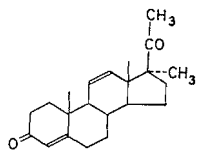
STEROIDS AND RELATED PRODUCTS



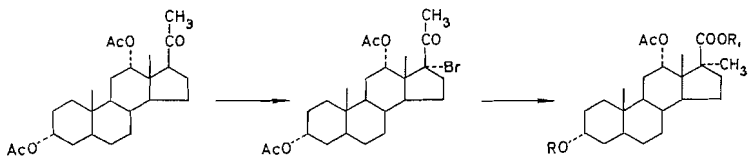
XVI. AN IMPROVED SYNTHESIS OF 11-DEHYDRO-17α-METHYLPROGESTERONE[1,2]

CH. R. ENGEL,[3] G. JUST, AND R. BUTTERY

ABSTRACT

An improved synthesis of 11-dehydro-17α-methylprogesterone, previously synthesized by this group, has been devised. The new hormone analogue has the same luteoid activity as 17α-methylprogesterone; in this case, the 11,12-unsaturation has no potentiating effect on the progestational activity. Some stereochemical aspects of the Faworsky rearrangement of 17α-halo-20-keto steroids are discussed in a preliminary fashion.

In a recent paper (2) this group reported the synthesis of a new progestational agent, 11-dehydro-17α-methylprogesterone (I), in which were combined two chemical features



I

that independently increase the luteoid activity of the natural hormone, i.e. an 11,12-double bond and a 17α-methyl group. While we had established that the new hormone analogue possessed marked activity, more material was needed for a quantitative biological evaluation.

Since the yields of two reaction sequences of the previously reported synthesis (2) had proved unsatisfactory, we devised an improved pathway for the preparation of the desired progestin.

One of these unsatisfactory sets of reactions had been the transformation of the starting material, 3α,12α-diacetoxypregnane-20-one (II), to the 17α-bromo derivative III and thence, by a Faworsky rearrangement, to ester derivatives of the 17α-methyl etianic acid IV. Since it is known (compare ref. 3) that a Faworsky rearrangement of impure

17α-bromo-20-ketones gives a poor yield of 17α-methylated etianic acid derivatives, we considered that at least part of our difficulties stemmed from the fact that the amorphous

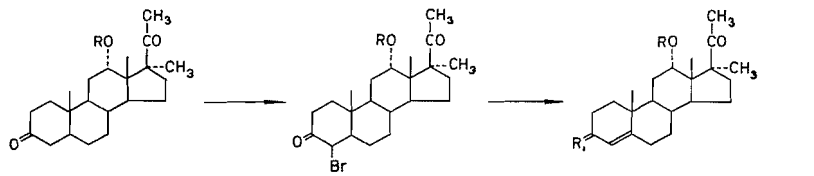
17α-bromide III could not be isolated in the pure state. We were able to improve the yield of this reaction sequence by replacing the acid-catalyzed bromination of II with molecular bromine by a free-radical bromination with N-bromosuccinimide, using the procedure of Schock and Karpel (4). Furthermore, we simplified and improved the method of isolation of the desired rearrangement product by using a series of operations schematized in Flowsheet I and described in detail below under *Experimental*. Thus it was possible to raise the yield of the transformation of II to IV*b* by almost 50%, namely from 30–35% to 45–50%.

FLOWSHEET I

Isolation of methyl 3α,12α-diacetoxy-17α-methyletianate (IV*b*)



It is noteworthy that, as in the case of the previously reported Faworsky rearrangement of crude bromide III, we were not able to isolate any 17-epimeric rearrangement products, in spite of the fact that large amounts of material were used and carefully worked up. This is in accord with the results obtained when 17α-bromopregnenolone acetate is treated with bicarbonate (3), and in contrast to those of the rearrangement with bicarbonate of 17α-bromo-3α-acetoxypregnane-11,20-dione (5) (compare also the rearrangement of this compound with sodium ethylate, reported by Wendler *et al.* (6)). In the case of Faworsky rearrangements of 17α-bromo-20-keto steroids without carbonyl functions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

in ring C, by the action of bicarbonate, the mechanism proposed by Loftfield (7) seems unacceptable. Indeed, this mechanism consists in the concerted formation of a cyclopropanone intermediate which is opened by base; hence the reaction should proceed with inversion in 17 and result, in the case of a 17α-bromo-20-ketone, in a 17β-methyl-17-isoetianic acid derivative. A synionic transfer of bromine from position 17 to 21, prior to the formation of the cyclopropanone intermediate, as postulated by Wendler *et al.* (6) (compare also an earlier proposal by Richard (8)), seems likewise improbable, at least in this instance, since the rearrangement of 21-halogenated 20-ketones gives a mixture of 17-epimeric etianic acid derivatives (compare ref. 9). A detailed discussion of this problem, together with new experimental data, will be reported in a forthcoming paper of this series.

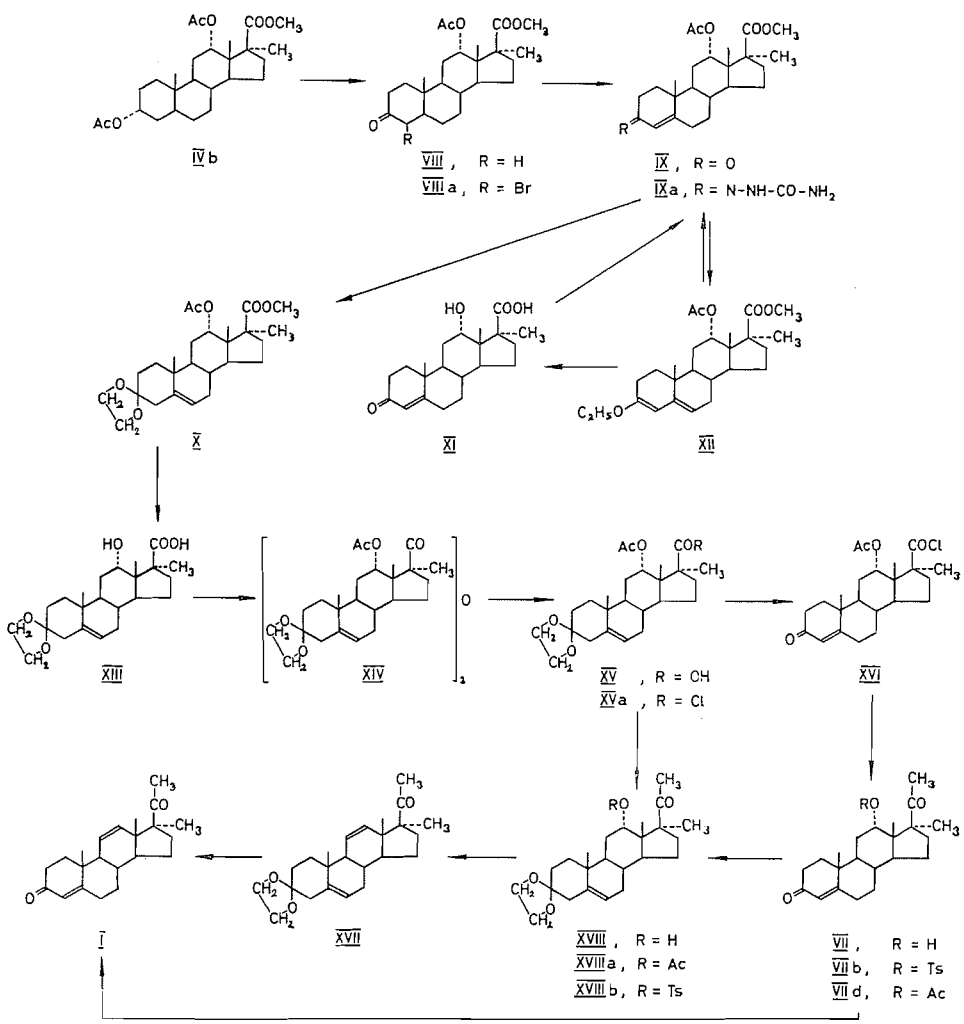
A second unsatisfactory set of transformations in our previous synthesis of 11-dehydro-17α-methylprogesterone was the penultimate sequence of reactions, consisting in the introduction of the Δ^4-double bond into 12α-tosyloxy-17α-methylpregnane-3,20-dione (compare V*a* $\rightarrow$ VI*a* $\rightarrow$ VII*c* $\rightarrow$ VII*b* (2)). The introduction of this double bond into the corresponding free 12α-hydroxy derivative V (compare the transformations V $\rightarrow$ VI $\rightarrow$ VII*a* $\rightarrow$ VII) had also proved unsatisfactory. Since the analogous sequence of reactions

V , R = H
Va , R = Ts

VI , R = H
VIa , R = Ts

VII ,R = H , R1 = O
VIIa,R = H , R1 = N-NH-CO-NH2
VIIb,R = Ts , R1 = O
VIIc,R = Ts , R1 = N-NH-CO-NH2

proceeded in much better yields in the case of methyl 12α-tosyloxy-3-oxo-17α-methyletianate (2), we decided to introduce the Δ^4-double bond at an early stage of our new synthesis, prior to the elaboration of the methyl ketone side chain.



We transformed methyl 3α,12α-diacetoxy-17α-methyletianate (IV*b*) to methyl 12α-acetoxy-3-oxo-17α-methyletianate (VIII), as previously described (2). The 3-keto ester VIII was converted in high yield to the 4-bromide VIII*a* by bromination with bromine in acetic acid, and the Δ^4-double bond was introduced by McGuckin and Kendall's method (10), via the 4-unsaturated 3-semicarbazone IX*a*, in almost quantitative yield.

The Δ^4-3-keto moiety of the resulting methyl Δ^4-12α-acetoxy-3-oxo-17α-methyletienate (IX) was protected against the vigorous alkaline treatment necessary for the saponification of 17-methylated etianic esters, by formation of an ethylene ketal (X). Prolonged treatment of ester X with methanolic potassium hydroxide under pressure and at elevated temperature led, in 90% yield, to the 3-ethylenedioxy acid XIII.

Protection of the α,β-unsaturated ketone by the formation of an enol ether, which had proved satisfactory in previous experiments of this series (11, 12), gave somewhat disappointing results: the yield of the formation of enol ether XII was lower than anticipated and its conversion to the Δ^4-3-keto etienic acid XI was not as simple as in the analogous cases which we described previously.

The 12α-hydroxy-3-ethylenedioxy acid XIII was transformed to its acetate XV by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

treatment with acetic anhydride in pyridine at reflux temperature and by hydrolysis with potassium carbonate of the 12α-acetoxy anhydride XIV thus formed.

Whereas the carbonyl function of acid XV reacts readily with oxalyl chloride and whereas the acid chloride formed gives an excellent yield of a 17α,21-dimethyl-20-ketone upon treatment with dimethyl cadmium, the protecting ketal function in position 3 tends to be removed during this sequence of reactions, particularly in the course of the preparation of the acid chloride. Thus, the acetoxy ketal acid XV can be transformed in 87% yield to crystalline 12α-acetoxy-17α-methylprogesterone (VII*d*) without a separate hydrolysis step. If every trace of moisture is excluded during the preparation of the acid chloride, it is possible to obtain the 3-ethylenedioxy-20-ketone XVIII*a* as the main reaction product (approximately 70% yield of crude and 45% yield of purified product), from which the concomitantly formed Δ^4-3,20-diketone VII*d* can be separated in the pure state in an approximate yield of 10% by crystallization and chromatography. This unsaturated diketone VII*d* can in turn be converted in over 50% yield to the monoketal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

XVIII*a* by the usual treatment with ethylene glycol and *p*-toluenesulphonic acid in boiling benzene. The retention of the ketal group in position 3 is desirable because alkaline hydrolysis of the 12α-acetate requires, in the presence of a 17-methyl group, relatively drastic conditions (compare ref. 2) to which a free Δ^4-3-ketone should not be exposed.[4]

The hydrolysis of acetate XVIII*a* with methanolic potassium hydroxide proceeded in almost quantitative yield. Tosylation of the resulting hydroxy adduct XVIII was slow, but the desired 12α-tosylate XVIII*b* was obtained in 78% yield when care was taken to avoid hydrolysis of the ketal function during the working up. Dehydrotosylation was achieved in good yield by chromatography on activated aluminum oxide at elevated temperature, as described in the previous paper of this series (1) (compare also ref. 13), and the Δ^4-3-keto moiety was set free by an exchange reaction with acetone in the presence of *p*-toluenesulphonic acid at room temperature (compare ref. 14). The resulting product was identical with authentic 11-dehydro-17α-methylprogesterone (I), previously prepared by our group (2).

Doctors P. Perlman and M. Eisler of the Schering Corporation, Bloomfield, N.J., kindly tested the new hormone analogue I for progestational activity, in the Clauberg assay. They found that the product was, upon parenteral administration, two to three times as active as progesterone, hence of the same activity as 17α-methylprogesterone (3). Evidently, the additional presence of the Δ^{11}-double bond, which raises the progestational activity of progesterone by a factor of 3 (15), had in this instance no potentiating effect. This is interesting because it is well established that in the majority of cases the inclusion in one molecule of more than one chemical feature which independently raises the same hormonal activity leads to potentiation of the biological effect. However, the finding is not entirely unexpected since Meystre and Wettstein (16) reported that 11-unsaturation of 17α-ethinyltestosterone even lowered the progestational activity. It may be tempting to speculate that the enhancement of progestational activity brought about by an 11-double bond is confined to progesterone itself, or possibly to progestins with an unmodified methyl ketone side chain; that is to say, that this activity-enhancing effect of the 11-double bond could be due to an indirect effect on the interaction of the side chain with the receptor. However, more experimental data on 11-unsaturated progestins are needed before any valid conclusion can be reached concerning the mechanism by which this double bond exerts its effects on progestational activity, in the case of 11-dehydroprogesterone.

EXPERIMENTAL[5, 6, 7]

17α-Bromo-3α,12α-diacetoxypregnane-20-one (III)

To a hot solution of 49.872 g of 3α,12α-diacetoxypregnane-20-one (II) in 500 cc of dry carbon tetrachloride, 35.8 g of N-bromosuccinimide was added. The mixture was stirred, and irradiated for 9 minutes with a 660-watt photo flood lamp at reflux temperature. The product was cooled and filtered over sodium sulphate and the filtrate was washed

[4]*It is possible to transform the Δ^4-3-keto-hydroxy acid XI without protection of the alcohol function directly to Δ^4-12α-hydroxy-17α-methylpregnene-3,20-dione (VII), which in turn can be converted to the tosylate VIIb and thence to 11-dehydro-17α-methylprogesterone; however, as one would expect, the yield of this transformation is low.*

[5]*The melting points were taken in evacuated capillaries and the temperatures were corrected.*

[6]*The microanalytical work was performed by Mr. J. F. Alicino, Metuchen, N.J., and Drs. F. and O. Schwarzkopf, Woodside, N.Y.; we wish to express our sincere appreciation to them.*

[7]*For chromatography, Merck aluminum oxide was treated as described in footnote 18 of reference 13; cf. also footnote 18 of reference 11. We sincerely thank Merck and Company, Montreal, for the generous gift of aluminum oxide.*

For personal use only.

with cold 10% sodium bisulphite solution and with water. After having been dried over sodium sulphate, the solvent was removed *in vacuo*. The remaining crude amorphous bromide III (73 g) was used without further purification in the following reaction.

Methyl 3α,12α-Diacetoxy-17α-methyletianate (IVb)[8]

To a solution of the above-mentioned crude bromide III (73 g) in 2.47 l. of methanol, a solution of 138 g of potassium bicarbonate in 480 cc of water was added. The mixture was refluxed for 4 hours and its volume was reduced *in vacuo* to 600 cc. The product was poured into 6 l. of water and the precipitate was extracted with ether. The ethereal solution was washed with water, dried over sodium sulphate, and taken to dryness, thus affording 47.46 g of "*neutral fraction I*". The aqueous alkaline phase remaining after the extraction was acidified with sulphuric acid to a congo blue reaction and the resulting mixture was extracted with chloroform. The organic solution was washed with water, dried over sodium sulphate, and the solvent was removed. Thus 5 g of "*acid fraction I*" was isolated.

"Neutral fraction I" was dissolved in 750 cc of acetic acid and 75 cc of water. Then, at 60°, 75 g of zinc powder was added, portionwise and with repeated shaking, and the mixture was subsequently heated to 85° for 45 minutes with repeated shaking. The product was cooled and filtered and the filtrate was extracted with ether; the ethereal solution was washed repeatedly with dilute hydrochloric acid, with sodium carbonate and sodium bicarbonate solutions, and with water, and was then dried over sodium sulphate. Evaporation of the solvent afforded 46.06 g of a light yellow oil.

To a solution of this product in 460 cc of absolute ethanol and 46 cc of acetic acid, 51.5 g of freshly recrystallized Girard T reagent was added. The mixture was refluxed for 45 minutes, allowed to cool, and subsequently poured into 4.22 l. of an iced 0.15 *N* sodium hydroxide solution. The product was extracted with ether, the ethereal solution was washed with water and dried over sodium sulphate, and the solvent was removed. Thus there was obtained 28.16 g of the "*non-ketonic fraction*". The alkaline solution was acidified with sulphuric acid and the resulting product was extracted with ether. The ethereal solution was washed with iced sodium bicarbonate solution and with water and was dried over sodium sulphate. Evaporation of the solvent gave 23.87 g of the "*ketonic fraction*".

A solution of the "ketonic fraction" (23.87 g) in 82 cc of pyridine was refluxed for 90 minutes with 41 cc of acetic anhydride with the exclusion of moisture. The usual working up gave 24.1 g of an amorphous product. Chromatographic purification on aluminum oxide afforded 16.234 g of authentic starting material, *3α,12α-diacetoxypregnane-20-one* (II), m.p. 117–120°.

"Acid fraction I" (5.0 g) was dissolved in 80 cc of absolute methanol and 119 cc of absolute ether. To this solution was added, at 0°, 130 cc of a 2% ethereal diazomethane solution. The mixture was allowed to stand overnight at room temperature. The excess diazomethane was neutralized with acetic acid and the solvents were removed. The resulting methylated product (5.7 g) was combined with the "non-ketonic fraction". This mixture was refluxed for 4 hours in 570 cc of a 6.8% methanolic potassium hydroxide solution. After addition of 140 cc of water, the volume was reduced *in vacuo* to 200 cc and another 70 cc of water was added. The solution was now reduced *in vacuo* to 170 cc and then poured into 2.6 l. of distilled water. The mixture was extracted with ether and the ethereal solution was washed with water, treated with sodium sulphate, and taken to dryness. Thus 20.2 g of "*neutral fraction II*" was obtained. The aqueous alkaline residue

[8]*Compare Flowsheet I.*

of the ether extraction was acidified with sulphuric acid to a congo blue reaction and was extracted with chloroform. The organic solution was washed with water and dried over sodium sulphate. Evaporation of the solvent afforded 10.1 g of "*acid fraction II*", containing 17-non-methylated acids.

A solution of "neutral fraction *II*" (20.2 g) in 65 cc of pyridine was refluxed for 90 minutes with 33 cc of acetic anhydride with the exclusion of moisture. The usual working up gave 25.35 g of a partly crystalline product. Recrystallization from methanol gave 11.987 g of *methyl 3α,12α-diacetoxy-17α-methyletianate* (IV*b*), m.p. 159–161°. Chromatographic purification of the mother liquors on aluminum oxide gave another 5.126 g of IV*b*, m.p. 158–160°. The identity of this product was established by mixed melting point with an authentic sample and by comparison of the infrared spectra. In consideration of the recovery of starting material, the yield of methyl 3α,12α-diacetoxy-17α-methyletianate (IV*b*) from 3α,12α-diacetoxypregnane-20-one (II) amounted to 47.5%. No 17β-methyl-17-isoetianate could be obtained.

Methyl Δ⁴-12α-Acetoxy-3-oxo-17α-methyletienate (IX)

(*a*) Methyl 3α,12α-diacetoxy-17α-methyletianate (IV*b*) was transformed to methyl 12α-acetoxy-3-oxo-17α-methyletianate (VIII) as previously described (2). To a solution of 2 g of this keto ester VIII, m.p. 149–150°, in 40 cc of acetic acid were added a drop of hydrogen bromide solution in acetic acid and subsequently, dropwise and with stirring, over a period of 30 minutes, 5.9 cc of a 0.845 *M* bromine solution in acetic acid. The mixture was stirred for another 10 minutes and then poured into 500 cc of ice water. The precipitate was extracted with ether and the ethereal solution was washed with iced potassium bicarbonate solution and with water and was dried over sodium sulphate. Removal of the solvent *in vacuo* gave 2.56 g of crude crystalline methyl *4β-bromo-12α-acetoxy-3-oxo-17α-methyletianate* (VIII*a*). Recrystallization from methanol–ether yielded 1.463 g of bromide VIII*a*, melting between 177.5 and 179.5°, and 169 mg of slightly less pure bromide VIII*a*, melting at 172–175°.

The mother liquors (900 mg) were debrominated in the usual fashion (see above) with 2 g of zinc dust in 22 cc of 90% acetic acid. Thus 636 mg of crude saturated 3-keto ester VIII, m.p. 115–125°, was recovered; recrystallization from ether–hexane gave 330 mg of pure ester VIII, m.p. 142.5–144.5°. In consideration of this recovery of pure starting material, the yield of bromide VIII*a* amounted to 81.8%.

A solution of 1.369 g of bromide VIII*a*, m.p. 177.5–179.5°, in 43 cc of absolute chloroform and 71 cc of *t*-butyl alcohol was flushed with carbon dioxide. Freshly recrystallized semicarbazide (434 mg) was added and the reaction mixture was again flushed with carbon dioxide and the flask was sealed. The mixture was occasionally shaken during 150 minutes. The usual color changes (compare ref. 10) were observed. After filtration, the solvents were removed *in vacuo* at 40° and the solid residue was taken up in a mixture of 60 cc of ethanol and 3.5 cc of water. This solution was concentrated *in vacuo* to 30 cc and then poured into 280 cc of cold water. The mixture was stored for 2 hours at −10° and the crystalline precipitate was filtered and dried. The *methyl Δ⁴-12α-acetoxy-3-oxo-17α-methyletienate-3-semicarbazone* (IX*a*) thus obtained (1.227 g) melted with decomposition at 193–196°; λ_{max}^{EtOH} 270 mμ (log ε 4.7).

To a solution of the semicarbazone IX*a* (1.227 g) in 37 cc of acetic acid and 13.3 cc of water, 3.3 cc of a 1.64 *N* aqueous pyruvic acid solution was added. The mixture was flushed with carbon dioxide and the flask was sealed. After 19 hours the product was poured into 300 cc of ice water and the precipitate was extracted with ether. The organic

solution was washed with cold sodium carbonate solution, with iced dilute hydrochloric acid, with bicarbonate solution, and with water, and was then dried over sodium sulphate. Removal of the solvent afforded 1.104 g (96.9% yield from VIII*a*) of *methyl* Δ^4-*12α-acetoxy-3-oxo-17α-methyletienate* (IX), m.p. 164–167.5°. A sample was recrystallized twice from ether–hexane for analysis; colorless needles, m.p. 165.5–167.5°, $[\alpha]_D^{22}$ 242.5° (*c*, 0.756 in $CHCl_3$), λ_{max}^{EtOH} 239 mμ (log ε 4.46). Anal. Calc. for $C_{24}H_{34}O_5$: C, 71.61; H, 8.51. Found: C, 71.56; H, 8.42.

(*b*) In another series of experiments, 3.59 g of the acetoxy keto ester VIII was transformed in a similar manner to 4.457 g of crude bromide VIII*a* which afforded, upon crystallization from ether–methanol, 2.41 g of pure bromo ketone VIII*a*, m.p. 181–183°. This bromide was transformed, as described above, to 2.424 g of semicarbazone IX*a*, m.p. 186–194° decomp., which gave upon hydrolysis with aqueous acetic acid and pyruvic acid (compare above) 1.934 g of the 4-unsaturated ester IX, m.p. 164–166°. The mother liquors from the crystallization of the crude bromide (2.043 g) were treated in the same way as the pure bromide. Purification by chromatography and recrystallization of the resulting Δ^4-3-ketonic material gave 1.106 g of slightly less pure ester IX, m.p. 157–163°. In this run the total yield of the transformation of the saturated ester VIII to the unsaturated ester IX amounted to 85.1%.

Methyl $\Delta^{3,5}$*-3-Ethoxy-12α-acetoxy-17α-methyletiadienate (XII)*

By the procedure described by Julian and co-workers (17), 1.934 g of the Δ^4-3-keto ester IX was transformed to the enol ether XII. Recrystallization of the crude crystalline reaction product from acetone–methanol in the presence of traces of pyridine gave 1.428 g (69%) of beautiful needles, m.p. 180.5–182°. From the mother liquors, 119 mg (5.8%) of a product of lesser purity, m.p. 169–173°, was isolated. A sample was recrystallized four times for analysis; m.p. 183–184.5°, $[\alpha]_D^{24}$ −12.2° (*c*, 1.04 in pyridine), λ_{max}^{EtOH} 240 mμ (log ε 4.4). Anal. Calc. for $C_{26}H_{38}O_5$: C, 72.52; H, 8.90. Found: C, 72.71; H, 9.03.

Hydrolysis

A sample of 65 mg of enol ether XII was dissolved in 5 cc of acetone and treated for 12 hours, at room temperature, with 1 cc of 2 *N* hydrochloric acid. Ether extraction gave an amorphous product which yielded, after crystallization from ether–hexane, 32 mg of the Δ^4-3-keto ester IX, m.p. 166.5–168.5°, not depressed upon admixture of an authentic sample.

Δ^4*-12α-Hydroxy-3-oxo-17α-methyletienic Acid (XI)*

(*a*) In a sealed tube, 1.428 g of enol ether XII was heated for 48 hours to 169° with 60 cc of a 6.9% methanolic potassium hydroxide solution. The product was cooled, diluted with 400 cc of water, and acidified with 40 cc of 2 *N* sulphuric acid. Filtration of the precipitate afforded 1.063 g of a crude product which melted between 192.5 and 196.5°. Repeated crystallization from acetone afforded 808 mg (70.3% yield) of Δ^4-3-keto acid XI, m.p. 274–280°. The product was recrystallized for analysis; short, fine needles, m.p. 277–280°, $[\alpha]_D^{25}$ 123° (*c*, 0.934 in methyl cellosolve). Anal. Calc. for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73. Found: C, 72.70; H, 8.67.

(*b*) In another run, 705 mg of enol ether XII was saponified as described under (*a*). The reaction product was acidified with concentrated hydrochloric acid and the mixture was diluted with chloroform. The product was kept for 30 minutes at room temperature, with repeated shaking. Subsequently, the organic solution was washed until neutral and the solvent was removed. Thus 520 mg (91.7% yield) of acid XI, m.p. 272.5–276°, was obtained.

Remethylation and Reacetylation

A solution of 60 mg of the hydroxy keto acid XI, m.p. 275–277°, in 10 cc of absolute methanol was treated at 0° with 15 cc of a 2% ethereal diazomethane solution. The mixture was stored for 8 hours at 0° and the solvents were removed *in vacuo*. The crude reaction product was dissolved in 5 cc of pyridine and refluxed for 90 minutes with 2.5 cc of acetic anhydride. The usual working up gave 96 mg of an oil which was chromatographed on 2.5 g of aluminum oxide. Petroleum ether – benzene (1:1, 1:4), benzene, and benzene–ether (4:1) eluted 71 mg of acetoxy keto ester IX, m.p. 155–162°. Recrystallization raised the melting point to 163–166°; the melting point was not depressed upon admixture of authentic ester IX.

Methyl Δ^5-3-Ethylenedioxy-12α-acetoxy-17α-methyletienate (X)

A solution of 2.759 g of methyl Δ^4-12α-acetoxy-3-oxo-17α-methyletienate (IX), m.p. 162.5–165°, in 206 cc of absolute benzene was reduced to 150 cc. Freshly distilled ethylene glycol (40.6 cc) and *p*-toluenesulphonic acid (112 mg) were added. The mixture was refluxed for 13.5 hours, with exclusion of moisture and with repeated removal of moist benzene. The reaction product was cooled and poured into an iced, saturated sodium bicarbonate solution, and the precipitate was extracted with ether. The organic solution was washed with iced 1% sodium carbonate solution and with water and was dried over sodium sulphate. Upon removal of the solvent, 3.02 g (98.7% yield) of ketal ester X, m.p. 176–180°, was obtained. The product was recrystallized twice from ether–hexane for analysis; colorless needles, m.p. 181.5–183°, $[\alpha]_D^{23}$ 51.9° (*c*, 0.847 in $CHCl_3$). Anal. Calc. for $C_{26}H_{38}O_6$: C, 69.92; H, 8.58. Found: C, 69.92; H, 8.66.

Δ^5-12α-Hydroxy-3-ethylenedioxy-17α-methyletienic Acid (XIII)

In a sealed tube, 4.984 g of acetoxy ketal ester X, m.p. 177–180°, was treated for 48 hours with 102 cc of a 6.8% methanolic potassium hydroxide solution at 170°. The reaction product was poured into 1 l. of water and the mixture was extracted with ether. The usual working up of the ethereal solution gave 7 mg of an amorphous product. The aqueous alkaline solution was carefully acidified with 1 *N* sulphuric acid to the congo blue reaction, and the mixture was extracted with chloroform. The organic solution was washed until neutral and then dried over sodium sulphate. Removal of the solvent afforded 4.49 g of a crystalline residue which gave, upon recrystallization from ether–methanol, 3.572 g of acid XIII, m.p. 125–130°/209–212°, and a second crop of 471 mg, m.p. 125–130°/207–209° (yield of recrystallized product 93%). A sample was recrystallized four times from ether–methanol for analysis; plates, m.p. 211–214°, $[\alpha]_D^{26}$ −10° (*c*, 0.700 in $CHCl_3$). Anal. Calc. for $C_{23}H_{34}O_5$: C, 70.74; H, 8.78. Found: C, 70.82; H, 8.59.

Δ^5-12α-Acetoxy-3-ethylenedioxy-17α-methyletienic Acid (XV)

A solution of 513 mg of the hydroxy ketal acid XIII, in 9 cc of pyridine and 4.5 cc of acetic anhydride, was refluxed for 1.5 hours. After the solution had been cooled, 30 cc of ice water was added and the mixture was allowed to stand for 30 minutes. Subsequently, it was diluted with another 200 cc of ice water and shaken repeatedly during 15 minutes. Extraction with ether afforded 566 mg of crude crystalline *Δ^5-12α-acetoxy-3-ethylenedioxy-17α-methyletienic acid anhydride* (XIV), which was dissolved in 30 cc of methanol and 7 cc of benzene. A solution of 750 mg of potassium carbonate in 5 cc of water was added and the mixture was refluxed for 1 hour. After dilution with 300 cc of ice water and extraction with ether, the remaining aqueous alkaline solution was carefully acidified in the cold with 0.5 *N* sulphuric acid to give a congo blue reaction. The mixture was extracted

with ether and the organic solution was washed until neutral and dried over sodium sulphate. Removal of the solvent gave 558 mg (98.2% yield) of crystalline Δ^5-*12α-acetoxy-3-ethylenedioxy-17α-methyletienic acid* (XV), m.p. 223–224.5°. A sample was recrystallized four times from methylene chloride – hexane for analysis; very fine, short needles, m.p. 231.5–233.5°, $[\alpha]_D^{25}$ 39.8° (*c*, 0.775 in $CHCl_3$). Anal. Calc. for $C_{25}H_{36}O_6$: C, 69.42; H, 8.39. Found: C, 69.70; H, 8.44.

Δ^4-12α-Acetoxy-17α-methylpregnene-3,20-dione (VIId)

At 0°, a solution of 4.05 cc of oxalyl chloride in 19.3 cc of absolute benzene was added dropwise to a suspension of 513 mg of well-dried Δ^5-12α-acetoxy-3-ethylenedioxy-17α-methyletienic acid (XV) in 23 cc of absolute benzene. During the addition, which took 5 minutes, the flask was shaken vigorously. The agitation was continued for another 30 minutes at room temperature, and subsequently the solvent was removed *in vacuo* at 20–30°. The residue was redissolved in absolute benzene and taken to dryness *in vacuo*; this operation was repeated twice in order to rid the compound completely of oxalyl chloride. The product showed a strong absorption at 240 mμ and represented crude *Δ^4-12α-acetoxy-3-oxo-17α-methyletienic acid chloride* (XVI). A solution of this chloride in 25 cc of absolute ether and 5 cc of absolute benzene was added, with stirring, to an ethereal solution of dimethyl cadmium prepared, as previously described (2), from 1.29 g of magnesium, 5.3 g of cadmium chloride, and the amounts of methyl bromide and ether equivalent to those used in previous experiments (2). The mixture was refluxed for 1 hour and the excess dimethyl cadmium was destroyed by careful addition of a 10% acetic acid solution. The product was extracted with ether and the ethereal solution was washed with cold, dilute sulphuric acid, with cold sodium bicarbonate solution, and with water, and was then dried over sodium sulphate. Removal of the solvent afforded 397 mg (86.6%) of crude crystalline *Δ^4-12α-acetoxy-17α-methylpregnene-3,20-dione* (VII*d*), m.p. 162–171°, λ_{max}^{EtOH} 239 mμ (log ε 4). Recrystallization from ether–hexane raised the melting point to 177.5–183.5°. The analytical sample was prepared by three further recrystallizations from methylene chloride – hexane, from ether–methanol, and finally from pure methanol; colorless prisms, m.p. 189–190°, $[\alpha]_D^{23}$ 165° (*c*, 0.809 in $CHCl_3$), λ_{max}^{EtOH} 240 mμ (log ε 4.2); ν_{max}^{KBr} 1722 and 1248 cm^{-1} (12α-acetate), 1690 cm^{-1} (17-methyl-20-ketone), 1667 and 1616 cm^{-1} (Δ^4-3-keto doublet). Anal. Calc. for $C_{24}H_{34}O_4$: C, 74.58; H, 8.87. Found: C, 74.55; H, 8.92.

Δ^5-12α-Acetoxy-3-ethylenedioxy-17α-methylpregnene-20-one (XVIIIa)

(a) From Δ^5-12α-Acetoxy-3-ethylenedioxy-17α-methyletienic Acid (XV)

A quantity of Δ^5-12α-acetoxy-3-ethylenedioxy-17α-methyletienic acid (XV) was dried by repeated evaporation of its benzene solution and by subsequent prolonged heating to 130° in high vacuum. A portion of 2.73 g of this product was suspended in 124 cc of absolute benzene. A solution of 21.6 cc of oxalyl chloride in 103 cc of absolute benzene was added dropwise and with agitation, at 0°, within 5 minutes. The agitation was continued for another 25 minutes. Subsequently, the resulting clear solution was allowed to stand for 30 minutes at room temperature and the product was taken to dryness *in vacuo* at 20–30°. The residue was further dried by repeated evaporation *in vacuo* of its benzene solution and by being kept for 18 hours in high vacuum. The resulting product, which was practically transparent to ultraviolet light in the region of 240 mμ, and which represented *Δ^5-12α-acetoxy-3-ethylenedioxy-17α-methyletienic acid chloride* (XV*a*), was dissolved in 134 cc of absolute ether. This solution was added, as described above for the preparation of the diketone VII*d*, to an ethereal dimethyl cadmium solution prepared from 6.96 g

of magnesium, 29 g of cadmium chloride, and the quantities of methyl bromide and ether equivalent to those used in previous experiments (2). The mixture was refluxed for 1 hour and worked up in the usual way. Thus 2.762 g of a crystalline solid, melting between 115 and 140°, was obtained. The product was filtered over aluminum oxide. The crystalline fractions eluted with ether (2.174 g) were recrystallized from ether–hexane to give 822 mg of a substance melting between 137 and 147°. Further recrystallization from ether–hexane gave 254 mg (10.4%) of pure *Δ^4-12α-acetoxy-17α-methylpregnene-3,20-dione* (VII*d*), m.p. 184–188°, identified by mixed melting point and infrared analysis.

The mother liquors of the first crystallization of this product weighed 1.312 g (48.3%) and crystallized readily from methanol; after one recrystallization they melted at 163–166° and showed, in the ultraviolet, no absorption maximum typical of an α,β-unsaturated ketone.

The methanol fraction of the aluminum oxide filtration (849 mg) was filtered again over aluminum oxide. The resulting crystalline fraction eluted with ether was combined with the crystalline mother liquors of the diketone VII*d*, showing no ultraviolet absorption in the 240 mμ region (see above), and with mother liquors of further recrystallizations of the unsaturated diketone VII*d*. This product (1.8 g, 73.8%), representing crude ketal XVIII*a* contaminated with some Δ^4-3-keto derivative VII*d*, was chromatographed on 54 g of aluminum oxide (pH 8.5). Petroleum ether – benzene mixtures, benzene, and benzene–ether mixtures eluted 1.104 g (45.3%) of purified *Δ^5-12α-acetoxy-3-ethylenedioxy-17α-methylpregnene-20-one* (XVIII*a*), melting between 159 and 170°. The majority of the fractions melted between 168 and 171°. A sample was recrystallized four times from ether–hexane for analysis; small, fine needles, m.p. 171–172°, $[\alpha]_D^{23}$ 36° (*c*, 1.055 in $CHCl_3$). Anal. Calc. for $C_{26}H_{38}O_5$: C, 72.52; H, 8.90. Found: C, 72.40; H, 8.92.

(b) From Δ^4-12α-Acetoxy-17α-methylpregnene-3,20-dione (VIId)

A solution of 254 mg of the Δ^4-3,20-diketo acetate VII*d* in 310 cc of absolute benzene was refluxed for 3 hours with 8 cc of ethylene glycol and 22 mg of *p*-toluenesulphonic acid. During this period the mixture was stirred vigorously and the moist benzene was removed periodically by the use of a water trap. The usual working up afforded 294 mg of a product which crystallized upon trituration with methanol; m.p. 132–140°. Recrystallization from ether–hexane gave 94 mg (33.1%) of monoketal XVIII*a*, m.p. 164–166°, not depressed upon admixture of authentic 3-monoketal XVIII*a*. The mother liquors were chromatographed on aluminum oxide. Petroleum ether – benzene (1:1) eluted 11 mg of a product (m.p. 168–170°) which showed no ketonic absorption in the infrared and to which the structure of *Δ^4-12α-acetoxy-3,20-bisethylenedioxy-17α-methylpregnene* is tentatively assigned. Further elutions with petroleum ether – benzene gave 54 mg of authentic monoketal XVIII*a*, m.p. 158–161° (total yield of monoketal XVIII*a* from diketone VII*d*: 52.4%).

Δ^5-12α-Hydroxy-3-ethylenedioxy-17α-methylpregnene-20-one (XVIII)

A solution of 239 mg of the 12α-acetoxy monoketal XVIII*a*, m.p. 164–167°, in 15 cc of 6.6% methanolic potassium hydroxide was refluxed for 4 hours. The product was cooled and poured into cold water, the precipitate was extracted with ether, and the ethereal solution was washed until neutral and dried over sodium sulphate. Evaporation of the solvent afforded 215 mg (99.7%) of a product which crystallized upon addition of a drop of hexane; m.p. 172.5–173.5°. A sample was recrystallized three times from ether–hexane for analysis; colorless prisms, m.p. 174.5–175.5°, $[\alpha]_D^{23}$ −23.8°, (*c*, 0.875 in $CHCl_3$); ν_{max}^{KBr} 3525 cm^{-1} (12-hydroxy), 1684 cm^{-1} (17-methyl-20-ketone)

1102 cm^{-1} (ketal). Anal. Calc. for $C_{24}H_{36}O_4$: C, 74.20; H, 9.34. Found: C, 74.31; H, 9.19.

Δ^5-12α-Tosyloxy-3-ethylenedioxy-17α-methylpregnene-20-one (XVIIIb)

To a solution of 221 mg of hydroxy ketal XVIII, m.p. 164–167°, in 2.6 cc of absolute pyridine, 332 mg of *p*-toluenesulphonyl chloride, m.p. 67–69°, was added. The flask was flushed with nitrogen and sealed, and the mixture was heated for 14 days to 55°. The product was cooled and poured into 100 cc of an ice-cold, saturated sodium bicarbonate solution containing 10 cc of pyridine. This mixture was shaken for 1 hour at room temperature. Subsequently, the product was extracted with ether. The ethereal solution was washed with cold sodium bicarbonate solution and with water and was dried over sodium sulphate. Removal of the solvent *in vacuo* gave 242 mg (78.4%) of a product which crystallized upon addition of a drop of methanol; m.p. 129–131°, λ_{max}^{EtOH} 225 mμ (log ε 4.1). One recrystallization from methylene chloride – methanol raised the melting point to 135–137°, a second recrystallization, to 140–141°; $[\alpha]_D^{25}$ −10.1° (*c*, 0.957 in $CHCl_3$). For the subsequent experiment crude crystalline tosylate XVIII*b* was used.

$\Delta^{4,11}$-17α-Methylpregnadiene-3,20-dione (11-Dehydro-17α-methylprogesterone) (I)

A quantity of 198 mg of crude tosyloxy ketal XVIII*b* was dissolved in a small quantity of benzene and absorbed on 40 g of aluminum oxide (activity 1, pH 8). The column was drained and then heated for 6 hours to 45°. The column was allowed to cool, and elutions with benzene – petroleum ether (4:1) were made; they afforded 100 mg of crude crystalline *$\Delta^{5,11}$-3-ethylenedioxy-17α-methylpregnadiene-20-one* (XVII), m.p. 167–174°, giving a positive tetranitromethane test. Chromatography of the non-crystalline fractions, under similar conditions, yielded another 13 mg of the same product (total yield: 83.6%). Purification afforded 69 mg (60% yield) of purified ketal XVII, m.p. 171–174°. A solution of this product (69 mg) and of 22 mg of *p*-toluenesulphonic acid in 17 cc of absolute acetone was allowed to stand for 42 hours in a carbon dioxide atmosphere. Ice and aqueous potassium bicarbonate solution were added and the precipitate was extracted with ether. The ethereal solution was washed with potassium bicarbonate and sodium carbonate solutions and with water, was dried over sodium sulphate, and was taken to dryness. The resulting crude crystalline *$\Delta^{4,11}$-17α-methylpregnadiene-3,20-dione (11-dehydro-17α-methylprogesterone)* (I) weighed 58 mg and was purified by chromatography on aluminum oxide. Thus 37 mg of pure, authentic 11-dehydro-17α-methylprogesterone (I), m.p. 125–139°, was obtained. One further chromatographic purification gave a product melting at 137–138°.

ACKNOWLEDGMENTS

We express warm thanks to Mrs. J. Capitaine for her devoted assistance in these experiments, to Mr. R. W. White, Science Service Laboratory, London, Ontario, for the infrared analyses, and to Drs. P. Perlman and M. Eisler, Schering Corporation, Bloomfield, N.J., for the biological tests. We are indebted to the Federal–Provincial Departments of National Health and Welfare, Ottawa and Toronto, the Ciba Ltd., Montreal, the Schering Corporation, Bloomfield, N.J., the Schering Corporation Ltd., Montreal, and the Canadian Life Insurance Officers Association, for financial support; and to Canada Packers Ltd., Toronto, for a gift of starting material. Sincere thanks are expressed to Dean J. B. Collip for his constant encouragement and for financial assistance extended to one of us (G. J.), and to Dr. J. A. Gunton for his kind interest. We are greatly indebted to the authorities of Laval University, in particular to Professors P. A. Giguère and J. Risi, for their generous help during the installation of our new laboratory.

METAL OXIDE ALKOXIDE POLYMERS

PART II. THE HYDROLYSIS OF TANTALUM PENTAETHOXIDE[1,2]

D. C. BRADLEY[3] AND H. HOLLOWAY[4]

ABSTRACT

The hydrolysis of tantalum pentaethoxide has been studied in boiling benzene and in boiling ethanol. Soluble tantalum oxide ethoxides were obtained over a considerable range of hydrolysis. Infrared studies suggest that Ta—OH groups are absent in these products. Ebulliometric studies have shown that the number-average degree of polymerization varies with the degree of hydrolysis in a characteristic manner and this has been quantitatively explained in terms of fundamental structural models based on octahedrally 6-co-ordinated tantalum.

INTRODUCTION

Recent work on the hydrolysis of titanium (1, 2) and zirconium (3) alkoxides has revealed that some of the metal oxide alkoxide polymers conform reasonably well to structural models based on the 6-co-ordinated metal. In these inorganic macromolecules, polymerization is based on two fundamental processes, namely "condensation" involving M·O·M bridges and co-ordination involving intermolecular metal–oxygen bonds. The previous work in this field (1, 2, 3) has involved the quadrivalent states of titanium and zirconium but the fundamental principles mentioned above should make the structural theory applicable to metals in other valence states. Tantalum forms a pentaethoxide which is essentially dimeric $Ta_2(OEt)_{10}$ (4) and is believed to involve 6-co-ordinated tantalum. Assuming this to be true it seemed that the polymeric tantalum oxide ethoxides $TaO_x(OEt)_{5-2x}$ should provide a good test for the aforementioned structural theory. In particular the system should be considerably simpler from the structural point of view than the titanium and zirconium compounds because the number of possible solvated species is fewer and there should be less possibility of ambiguity in the interpretation of the results. Accordingly, we have made a detailed investigation, mainly by the ebulliometric technique, of the hydrolysis of tantalum pentaethoxide under rigorously controlled conditions.

EXPERIMENTAL AND RESULTS

Tantalum Pentaethoxide

The compound was prepared by the previously described method (4) involving the reaction of $TaCl_5$ with ethanol and anhydrous ammonia in benzene. The $TaCl_5$ was prepared by chlorination of tantalum (99.9% purity metal) at about 400° C. The pentaethoxide (found: Ta, 44.6%; $Ta(OEt)_5$ requires: Ta, 44.6%) was distilled under reduced pressure immediately prior to an experiment and was obtained as a colorless distillate (b.p. 147° C at 0.2 mm).

Ebulliometric Measurements

The technique adopted in this work was similar to that described in our earlier studies (1, 3) and an all-glass ebulliometer involving a differential water thermometer was used.

[1]*Manuscript received March 10, 1961.*

Two refinements were developed. One was the use of a silicone-fluid heating bath instead of the flame of a microburner. The heating bath gave steadier ebullition. It was also found that the slight loss of solvent during a long experiment could be obviated by greasing the standard joints of the ebulliometer with a fluorocarbon grease.

Molecular Weight of Tantalum Pentaethoxide in Boiling Ethanol

An accurate knowledge of the degree of polymerization of tantalum pentaethoxide in boiling ethanol was essential for the accurate determination of the degree of polymerization of the tantalum oxide ethoxide produced by hydrolysis in the ebulliometer. Bradley, Wardlaw, and Whitley (4) reported a value of 1.78 compared with 1.98 in boiling benzene. The lower value in boiling ethanol was believed to be due to the presence of a solvated monomeric species, $Ta(OEt)_5$,EtOH, which still involved 6-co-ordinated tantalum. It was important therefore to investigate the degree of polymerization of the pentaethoxide in boiling ethanol over a wide range in concentration since a simple dimer–monomer equilibrium should show a concentration dependence of molecular weight. Five separate determinations were made, each involving several additions of freshly distilled pentaethoxide over the concentration range of approximately 0.01–0.25 g-mol. (dimer)/1000 g solvent. The method of "internal calibration" (5) using fluorene as standard substance was used. In each experiment there was a linear dependence of the elevation of boiling point with concentration within the probable experimental error of the measurements, and the following values for the degree of polymerization were obtained: 1.85, 1.83, 1.87, 1.81, and 1.88. The mean value of 1.85 was therefore adopted for the degree of polymerization of tantalum pentaethoxide in boiling ethanol. An interesting and puzzling point is the absence of the expected concentration dependence of the molecular weight. The method was quite sensitive enough for detection of a change in degree of polymerization with concentration of the order required by a dimer–monomer equilibrium. It is possible that the system is not in true equilibrium. However, the values obtained in several experiments were quite consistent and it appears that over 90% of the tantalum is present in the dimeric state.

Hydrolysis in Boiling Ethanol

The addition of known quantities of aqueous ethanol (3.70% H_2O, w/w) to boiling ethanolic solutions of tantalum pentaethoxide caused immediate decreases in the elevation of the boiling point due to the increase in degree of polymerization which resulted from the hydrolysis. The correct degree of polymerization of the tantalum oxide ethoxide species was deduced by applying the small correction for the ethanol added with the water. The results of four separate experiments involving different initial concentrations of tantalum ethoxide are recorded in Tables I–IV. The number-average degree of polymerization is denoted by n and the degree of hydrolysis (ratio of moles H_2O added/g-atom of Ta) by h.

Hydrolysis in Benzene

In an attempt to avoid the complications of solvation we determined the degree of polymerization of some tantalum oxide ethoxides in boiling benzene in which tantalum pentaethoxide is dimeric within probable experimental error. The main problem in this aspect of the work is the complete removal of ethanol from the hydrolysis product. The following procedure was believed to be reliable. A known amount of water (as 5% aqueous ethanol) was slowly added with stirring to a known amount (ca. 5 g) of $Ta_2(OEt)_{10}$ in benzene (ca. 100 cc) at room temperature. The solution was then refluxed for $\frac{1}{2}$ hour, allowed to cool under dry nitrogen, and then evaporated at room temperature and 0.1 mm pressure to remove benzene and ethanol. To ensure removal of ethanol the product was redissolved in dry benzene (ca. 50 cc) and the solution again evaporated. This procedure was repeated twice and finally the product was maintained under 0.1 mm at room temperature for about 16 hours. The product was then analyzed for tantalum and ethoxide and its molecular weight was determined ebullioscopically in benzene using the "internal calibration" method involving fluorene. The results are presented in Table V where n_{calc} is obtained by substituting the appropriate value of h in the theoretical equation $n = 6/(3-2h)$ and M is the molecular weight.

Disproportionation of a Tantalum Oxide Ethoxide

Tantalum ethoxide in benzene, when hydrolyzed to $h = 1.20$ as in the aforementioned manner, gave a gummy oxide ethoxide. (Found: Ta, 57.3; OEt, 36.2. $TaO_{1.2}(OEt)_{2.6}$ requires: Ta, 57.1; OEt, 37.0%.) This was heated at 290–300° C at 0.01 mm for 3 hours during which time a volatile liquid distilled over and a light brown solid residue remained. (Found: Ta, 78.4%.) The liquid proved to be tantalum pentaethoxide. (Found: Ta, 44.9. $Ta(OEt)_5$ requires: Ta, 44.6%.) This experiment demonstrated that tantalum oxide ethoxides undergo disproportionation when heated *in vacuo*.

Infrared Spectra of Tantalum Oxide Ethoxides

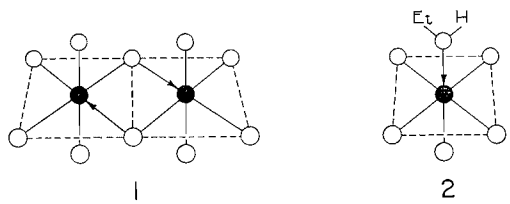
The absorption spectra of the oxide ethoxides corresponding to $h = 0.55$ and 1.20 were measured in CS_2 solution and compared with the spectrum for tantalum ethoxide. The spectra are too complex to permit a complete interpretation at this stage but it was interesting to find no evidence for hydroxyl bands in the hydrolysis products. Another feature was the steady decrease in intensity of the bands around 3.5 μ, 7 μ, and 18 μ with increase in degree of hydrolysis and these bands presumably involve the ethoxide groups. Simultaneously there was a strengthening of the broad bands in the 19–22 μ region and the appearance of broad, ill-defined bands in the 12–14 μ region. These bands presumably involve the Ta·O·Ta groups. (We are indebted to C. G. Barraclough of University College, London, England, for measuring these spectra.)

DISCUSSION

The hydrolysis of tantalum ethoxide in ethanol was shown by the ebulliometric studies to be an extremely rapid process. The analyses of the products of the hydrolyses carried out in benzene (Table V) and the infrared spectra show that tantalum oxide ethoxides $TaO_x(OEt)_{5-2x}$ are produced and not tantalum hydroxide ethoxides. Our experiments, under rigorously controlled conditions, have shown that a continuous series of tantalum oxide ethoxides may be produced and that the number-average degree of polymerization increases steadily with the degree of hydrolysis (Tables I–V). Let us now examine these results in the light of the structural theory developed by Bradley, Gaze, and Wardlaw (1, 2) to explain the behavior of titanium oxide alkoxides.

Polymeric Species in Boiling Ethanol

Assuming that tantalum attains octahedral 6-co-ordination in the pentaethoxide, then there are two probable structures, the dimeric unsolvated species (Fig. 1) and the solvated monomer (Fig. 2). These are clearly related to model II (based on $Ti_2(OR)_8,2ROH$)



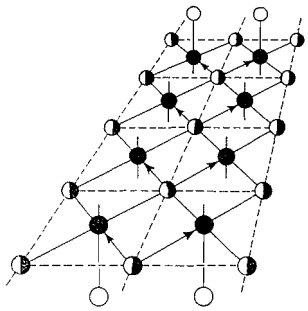


FIG. 1. The dimer $Ta_2(OEt)_{10}$. ● = Ta, ○ = oxygen in OEt (Et groups omitted).
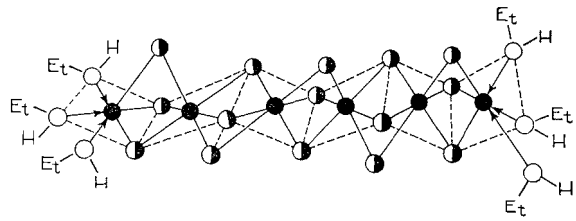
FIG. 2. The solvated monomer $Ta(OEt)_5,EtOH$. ● = Ta, ○ = oxygen in OEt (Et groups omitted).



and model III (based on $Ti(OR)_4,2ROH$) respectively in the titanium tetraalkoxide structures. If the tantalum pentaethoxide were entirely dimeric in boiling ethanol we should predict that the tantalum oxide ethoxides would conform to a structural series

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

based on model II for which $n = 6/(3-2h)$ but which have the general formula $Ta_{2(x+1)}O_{3x}(OEt)_{2(2x+5)}$, where $x = 0, 1, 2, 3 \ldots \infty$. The limiting bilinear polymer would thus be $[Ta_2O_3(OEt)_4]_\infty$ (Fig. 3) corresponding to $h = 1.5$. If the pentaethoxide were entirely monomeric its hydrolysis products might be expected to conform to the analogue of model III for which $n = 3/(3-h)$, and whose formulae would be given by $Ta_{(x+1)}O_{3x}(OEt)_{(5-x)},(EtOH)_{(x+1)}$. We note that the ultimate polymer in this series ($x = 5$, Fig. 4) corresponds to a hypothetical solvated form of tantalum pentoxide. The

molecular-weight studies in boiling ethanol showed that the number-average degree of polymerization of tantalum pentaethoxide was 1.85 ± 0.035 and it is thus reasonable to propose that the tantalum oxide ethoxides should exhibit a dependence of number-average degree of polymerization on degree of hydrolysis rather close to the predictions of model II. In Fig. 5 is shown the variation of n with h for all the data included in Tables I–IV in comparison with the theoretical curves for the model II and model III systems. The experimental points are close to the theoretical curve II for $h = 0$–1.3 but deviate at $h > 1.3$ towards curve III. It must be remembered that for the relation $n = 6/(3 - h)$ the value of n becomes very sensitive to errors in h at values of $h > 1.0$. For example, at $h = 0.5$ an error of 10% in h would result in an error of only 5% in n, but at $h = 1.0$ a 10% error in h causes a 25% error in n, whilst at $h = 1.25$ a 10% error in h causes a 100% error in n. Hence it is not surprising to find greater scatter in the experimental points at the higher values of h. There is the added factor that the probable experimental error in measuring n is greater at the higher values of n. If we rearrange the expression $n = 6/(3-2h)$ to $1/n = 0.5000-0.3333_4h$, it follows that a plot of $1/n$ versus h should be linear. Similarly the equation representing the theoretical curve III may be transformed to $1/n = 1.0000-0.3333_4h$. It is easily shown that in any system involving, simultaneously, models II and III with a constant value for α_{II} (the proportion of metal atoms in model II), then an equation of the form $1/n = 1.0000-0.5\alpha_{II}-0.3333_4h$ should be obeyed. We have taken all of the experimental data for $h = 0$–1.270 and determined by the method of least squares the best straight line for the plot of $1/n$ versus h. The results are shown in Fig. 6 where the straight line represents the least-squares equation $1/n = 0.5458-0.3389h$. Assuming that values of h are correct, the coefficient of variation for errors in n is ±4.5% and there are 30 changes in sign in the errors when the 52 results are arranged in ascending order of h. The errors are, of course,

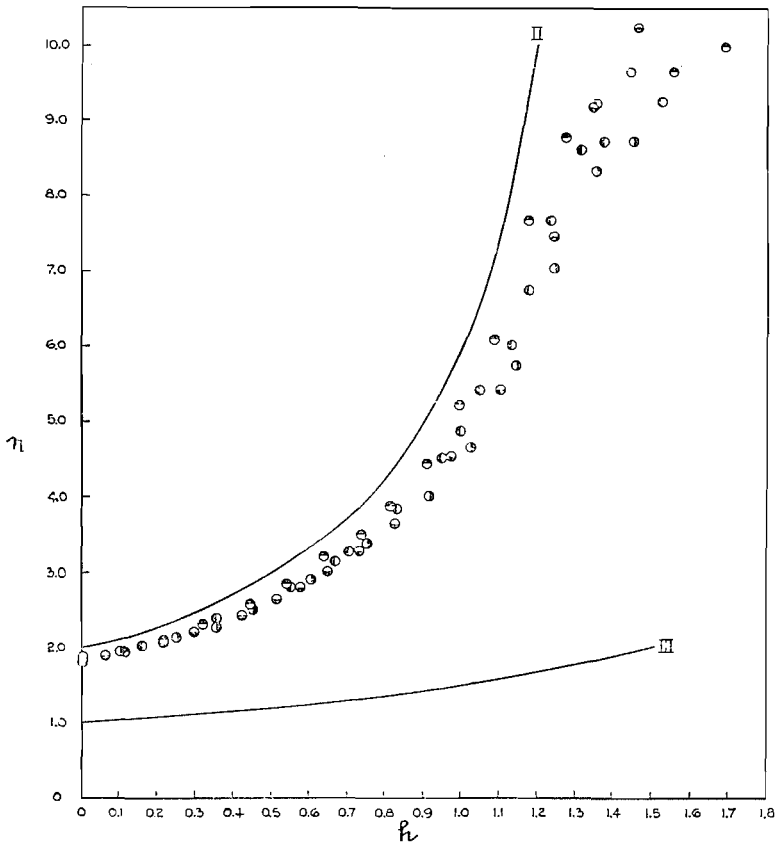

FIG. 5. The variation of n with h for tantalum oxide ethoxides in boiling ethanol. ◓ = data from expt. 1, ◐ = data from expt. 2, ◑ = data from expt. 3, ◒ = data from expt. 4.

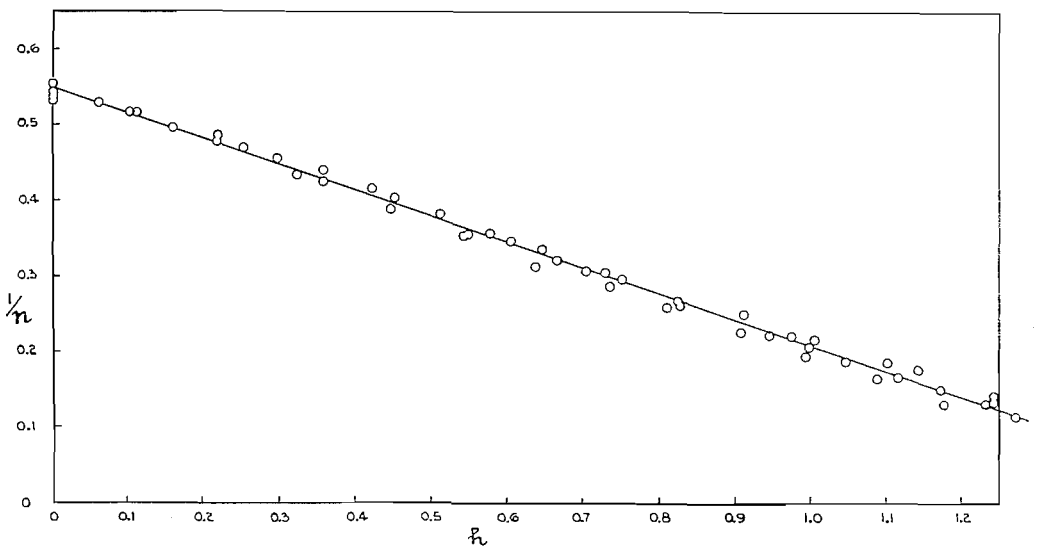

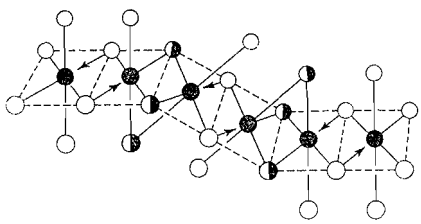

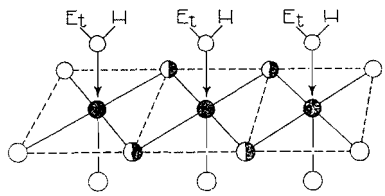

FIG. 6. The plot of $1/n$ versus h for tantalum oxide ethoxides in boiling ethanol.

higher at the higher values of h and the coefficient of variation for the first 24 points (h = 0–0.602) is only $\pm 1.76\%$ and this is slightly less than the percentage deviation in determining the degree of polymerization of tantalum pentaethoxide. It is interesting to note that the value of α_{II} derived from our least-squares equation is 0.908 and corresponds to a value of n = 1.83 for the pentaethoxide compared with the value n = 1.85 ± 0.035 obtained from the five experiments on the pentaethoxide alone. In addition, the least-squares slope of 0.339 is quite close to the "theoretical" value of 0.333. The experimental values of n for $h > 1.3$ show increasing deviations from n_{calc} with increase in h. This may correspond to a decrease in α_{II} as solvation becomes more developed at the lower molar concentrations of polymers, although we cannot rule out the alternative possibility that hydrolysis is incomplete at high values of h due to the presence of relatively stable Ta—OH groups in solution. Before leaving the ebulliometric studies, mention must be made of some alternative structural models which have been considered for the tantalum oxide ethoxide polymers. In model II the repeating units in the bilinear polymer (Fig. 3) involve three oxygen atoms bridging four tantalum atoms along the common edge of four octahedra. This results in the unusual example of a quaternary oxygen bonded to four tantalums in a plane. However, by allowing dimer units to be joined by three oxygens between two tantalums sharing a common face of two octahedra we arrive at another structural model having exactly the same variation of n with h as model II. The alternative model is illustrated by the structure for $Ta_6O_6(OEt)_{18}$ shown in Fig. 7. A zigzag arrangement of the dimers would result in the formation of an infinite linear polymer $[Ta_2O_3(OEt)_4]_\infty$ containing no quaternary oxygens. Our present technique cannot distinguish between these two alternatives. We have also considered an alternative to structural model III. The latter may be criticized in having, in some of its species, tantalum atoms which are formally exhibiting oxidation numbers higher or lower than five although the average valency is always five. This problem may be averted by causing the octahedra to share edges as illustrated by the trimer $Ta_3O_4(OEt)_7,(EtOH)_3$ (Fig. 8).

7

8

FIG. 7. The hexamer $Ta_6O_6(OEt)_{18}$. ● = Ta, ○ = oxygen in OEt (Et groups omitted), ◑ = oxygen in Ta·O·Ta groups.
FIG. 8. The trimer $Ta_3O_4(OEt)_7,(EtOH)_3$. ● = Ta, ○ = oxygen in OEt (Et groups omitted), ◑ = oxygen in Ta·O·Ta groups.

The general formula for this series, which we term model IV, is $Ta_{(x+1)}O_{2x}(OEt)_{5+x}$, $(EtOH)_{x+1}$ and this leads to a new equation: $n = 2/(2-h)$, and an infinite linear polymer; $[TaO_2(OEt),EtOH]_\infty$. If the tantalum oxide ethoxides involve models II and IV it is readily shown that a linear equation $1/n = 1.000 - 0.500\alpha_{II} - (0.5000 - 0.1667\alpha_{II})h$ should obtain. This gives exactly the same intercept for $1/n$ at $h = 0$ as the equation given by the combination of models II and III. However, the two equations differ in slope. Using the least-squares value for $\alpha_{II} = 0.908$, a slope of -0.349 is predicted for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the model II – model IV combination compared with the value of -0.333 required by the model II – model III combination. The least-squares value of the slope is -0.339 and this evidently favors the model II – model III system, although the result is hardly decisive.

Insoluble Tantalum Oxide Ethoxides

According to the model II series $n = 6/(3-2h)$, infinite polymers should form as $h \rightarrow 1.5$, whereas for model III the highest possible polymer is the hexamer Ta_6O_{15}, 6EtOH, and model IV predicts an infinite polymer at $h = 2.0$. Therefore, insoluble products would be expected somewhere in the region $h = 1.5$–2.5. In fact, solution of the least-squares equation $1/n = 0.5458-0.3389h$, which satisfactorily described the results up to $h = 1.3$, suggests that n will be infinite at $h = 1.61$. In our ebulliometric experiments we obtained precipitates at $h = 1.60$; at the three higher concentrations of tantalum pentaethoxide, 1.56 and 1.59, whilst at the lowest concentration no precipitate was formed up to $h = 1.69$. The formation of precipitates in the region of $h \sim 1.6$ is thus reasonable but the presence of species for $h > 1.5$ where model II predicts an infinite polymer requires some comment. If the polymers, even in this region, do conform to models II and III, then soluble species for $h > 1.5$ could obtain if the degree of hydrolysis in model II were less than in model III. This may be illustrated by the following example. Let us imagine that at an over-all average value of $h = 1.55$ the value of α_{II} is 0.8. Then the polymer equation will be $1/n = 0.6-h/3$ and for $h = 1.55$ we find $n_{calc} = 12.0$. Now, let us further assume that the average value of h_{II} for the species adopting model II is 1.45; this would correspond to $n_{II} = 60$ and these polymers could well be soluble. It follows that if the over-all average h for both species is 1.55 then the average h_{III} for the species in model III must be 1.95, for which $n_{III} = 2.85$. Finally, it is easily shown that if 80% of the tantalum has an average degree of polymerization $n_{II} = 60$ while the remaining 20% has $n_{III} = 2.85$, then the over-all average value of n is 12, which is the value predicted from the original equation. Therefore it follows that for all the polymer species to remain soluble at $h > 1.5$, $\alpha_{II} < 1$ and $h_{III} > h_{II}$.

The Molecular Weights of Tantalum Oxide Ethoxides in Benzene

If the tantalum pentaethoxide were not solvated it would be expected to conform exclusively to model II based on the dimer, and the number-average degree of polymerization of the oxide ethoxides would follow the requirements of the equation $1/n = 0.5000-0.3333h$. In boiling benzene, tantalum pentaethoxide is dimeric and hence it was important to determine molecular weights of the oxide ethoxides in benzene. Some results at five values of h between 0 and 0.750 are reported in Table V. It is clear that the observed values of n are reasonably close to n_{calc} evaluated from the theoretical equation. The coefficient of variation in n (assuming h is correct) is $\pm 5.5\%$ and this is a satisfactory value, bearing in mind the difficulties mentioned in the experimental section.

CONCLUSIONS

1. The hydrolysis of tantalum pentaethoxide in either ethanol or benzene solution under controlled conditions leads to the formation of polymeric oxide ethoxides.

2. The number-average degree of polymerization of these polymers can be accounted for with the assumption that these compounds are condensation – co-ordination polymers in which the tantalum achieves the co-ordination number of 6 in an octahedral configuration.

3. These octahedral structures are of fundamental significance since they are applicable to either titanium (IV) oxide ethoxides or tantalum (V) oxide ethoxides.

THE REVERSIBILITY OF AROMATIC MERCURATION[1]

M. Malaiyandi, H. Sawatzky, and G. F Wright

ABSTRACT

The ratio of isomeric bisperchloratomercuribenzenes obtained from the monomercurial and mercuric perchlorate in perchloric acid varies slightly with concentration of the acid, but is preponderantly meta. However, more para than meta isomer is obtained under conditions where the para isomer is insoluble in the system. This indicates a mobile equilibrium among the isomers, which is found to extend to all of the polymercuration products. The postulated intermediate for the equilibration, which is 1,2,4-trichloratomercuribenzene, is indicated by the isolation of the similarly oriented 1,2,4,5-perchloratomercuritetrakisbenzene. Although none of the ortho-diperchloratomercuribenzene can be found from this reaction in perchloric acid, it is the principal isomer when phenylmercuric acetate is acetoxymercurated neat.

The literature of aromatic mercuration is marked by many inconsistencies. Thus, although Dimroth (1) at 170° C converted mercuric benzoate to anhydro-*o*-hydroxybenzoic acid, an equivalent mixture of benzoic acid and mercuric acetate at 130° C was found to yield the *o*-, *m*-, and *p*-mercurated benzoic acids in the ratio 25:57:18 (2). On the other hand, the same equivalence in acetic acid (2.5 hours at 110° C) gave a ratio of 80:20:0 (3).

Several workers have suggested that the discrepancies are due to isomerization. The various results of Table I have in part been explained by Jackson and Frant (2) by the

possibility that equilibrium is not always attained at once in systems where the mercurated nitrobenzenes are not equally stable. Likewise, as is shown for toluene mercuration in Table II, Brown and McGary (9) have suggested that isomerization of the initially

formed mercurials seems to be occurring, and that mercuration, like sulphonation (11), is reversible. A similar opinion (12) had been affirmed earlier.

I

The ionization of mercuric salts is sufficiently incomplete that one may presume aromatic mercuration to involve initially a cationic transition state of appreciable stability. If the decomposition of the intermediate cation is fast, first order, and rate independent of the reaction system, the occurrence of monomercurial isomerization is unexpected, whether or not the reaction is reversible. The intermediate, I, may be expected to be deprotonated along paths related directly with the free energy of the products in the system. Either the activation energy for this final step of mercuration is greater than seems to prevail for other aromatic substitutions or else the isomerization must be related to another mechanism.

Reversible polymercuration provides an alternative path leading to isomerization. Indeed, the substitution of more than one anionomercuri group is so likely that most workers have been troubled by it. Attempts to avoid it (9) are understandable since aromatic polymercurials are difficult to manipulate because of low solubility. Nevertheless, we have deliberately chosen polymercuration of benzene in order to clarify the quandary of variable isomer ratios. By this expedient the directing and the entering group are identical.

At first we started with benzene in aqueous perchloric acid containing mercuric perchlorate. However, we were unable to get consistent results, despite the success of others (13), with this two-phase system. Subsequently we have obtained results that are reproducible by mercuration of mercuric perchlorate with mercuric perchlorate (prepared *in situ* from mercuric oxide) in perchloric acid. The results of a series of experiments in which the water – perchloric acid ratio has been varied are shown in Table III.

TABLE III

Mercuration of 0.0017 mole of phenylmercuric perchlorate with 0.0017 mole of mercuric perchlorate in perchloric acid for 2.5 hours at 25° C

The analyses of the products have been accomplished, after solvent-extractive separation of phenylmercuric chloride from the physically intractable benzenepolymercuric chlorides, by quantitative conversion to the polybromobenzenes. The methods used previously (14, 15) have been modified slightly. The distillable dibromobenzenes have been identified by infrared absorption using the intense bands relating to out-of-plane wagging modes. The results have been checked by thermal analyses and by isolation of *m*-dibromophenylchlorophenylsulphonamide when the ortho isomer is absent.

The series of experiments which are outlined in Table III show that in perchloric acid none of the ortho isomer can be detected with certainty. In the more dilute perchloric acid (expts. 1–4 inclusive) the meta isomer is preponderant; there are lesser amounts of para isomer and of symmetrical trimercurated benzene. Since the sum of these polymercurated products together with unchanged phenylmercuric perchlorate does not constitute a quantitative yield one may expect that other polymercurated benzenes, in small amount, have been missed. Also some benzene must have been formed, and lost, if aromatic mercuration is reversible. This reversibility is apparent when 50% perchloric acid is used in large excess as the reaction medium (expt. 2, Table III). The low yield of polymercurials may be contrasted to 4.6 times as much as that obtained from expt. 1. Since separate experiments show that these are equilibrium states which were attained after 150 minutes, and the amount of recovered monomercurial is essentially the same for expts. 1 and 2, the difference must be attributed to the formation of benzene.

In this connection it is of interest that at 25° C the solubility in 50% aqueous perchloric acid of phenylmercuric hydroxide (20 g/l.) is 10 times as great as in 70% perchloric acid. Thus it would appear that the phenylmercuric salt was more highly ionized or hydrated (or both) in the more aqueous medium.

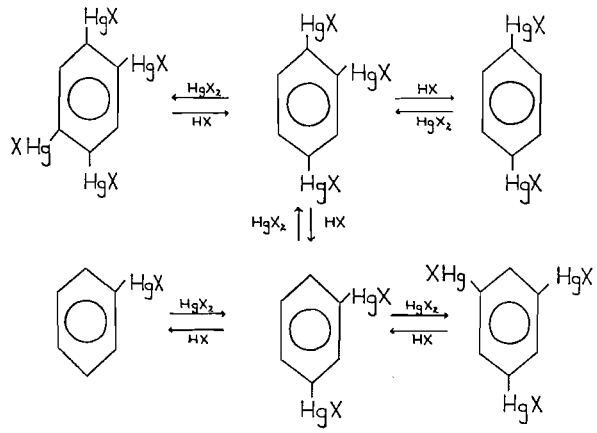
Addition of sodium perchlorate to the reaction systems described in Table III does not alter appreciably either the yields or the isomer ratio of substitution products. Neither does the acid concentration (see expts. 1, 3, and 4) up to a level of 61%, but in the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

amount of more concentrated perchloric acid (expts. 5 and 6) the relative yield of meta isomer decreases. The reason is quite apparent: after 20 minutes from 65% or after 4 minutes from 70% perchloric acid a precipitate appears which is nearly pure 1,4-diperchloratomercuribenzene. The amount of this precipitate increases when the total volume of 70% perchloric acid is decreased, or (expt. 7) much less of the precipitate appears when the volume of the system is greater.

Inspection of Table III shows that when this precipitation occurs (expts. 5 and 6) the meta isomer decreases in quantity and only slightly in favor of some 1,3,5-trimercurial which appears. It would seem that this meta isomer, which may be the initial polymercuration product, is converted to para isomer which then can precipitate. Indeed, when a system identical with that of expt. 6 is quenched after 4 minutes of reaction time (and before precipitation has commenced), the product contains only 25% of 1,4-bismercurial instead of the 57% obtained after the 150-minute reaction period of expt. 6 during which precipitation occurs. Moreover, the initial formation of the meta isomer must be rapid, because the polymercurial yield after 4 minutes is 60% of that obtained after 150 minutes of reaction time.

In order to test further the possibility that the meta isomer is the initial perchloratomercuration product we have prepared 1,3-hydroxymercuribisbenzene from 1,3-benzenedisulphinic acid and have dissolved it in 70% perchloric acid. After 2 hours the reaction system is drowned with aqueous sodium chloride. Besides a 20% yield of phenylmercuric chloride the mixture has been shown to contain 1,4-chloromercuribisbenzene as well as a small amount of 1,3,5-trismercurial. Thus a profound disproportionation of 1,3-bismercurial has occurred, undoubtedly to give benzene as well.



Except when it precipitates from solution, the 1,4-perchloratomercuribisbenzene is not inert toward the reaction system. When it is treated with a 12 molar excess of mercuric perchlorate in 70% perchloric acid for 2 hours the yield of mono- and di-mercurials is very small. Bromination of the remainder shows that *sym*-trismercurial is the principal product although a 5% yield of 1,2,4,5-tetrabromobenzene indicates the presence of this tetramercurial.

The perchloratomercuritrisbenzene also must not be considered to be an ultimate end product. When it is treated with monoperchloratomercuribenzene in 70% perchloric acid the system, after 2 hours, contains only 40% of the trismercurial while 40% of the two dimercurials has appeared.

On the basis of these findings the mode of reaction given below has been drawn up (X = ClO_4), although one important piece of evidence is lacking. In all of the systems which have been analyzed, the key substance, 1,2,4-tribromobenzene, indicative of the analogous trismercurial, has been sought assiduously, but never found. Despite the fact that the low melting point (44°) of 1,2,4-tribromobenzene makes isolation difficult, we are inclined to attribute the apparent absence of 1,2,4-triperchloratomercuribenzene to its high reactivity. Certainly it cannot be excluded because ortho perchloratomercuration is involved since the isolation of 1,2,4,5-tetrabromobenzene shows that ortho substitution can occur. Therefore, the transition to and from meta and para dimercurated benzenes seems to be explicable better by postulation of the 1,2,4-trisubstituted intermediate than by simple "isomerization".

The absence of evidence for initial ortho mercuration in the studies with perchloric acid should not be construed as proof that it does not occur. The perchloratomercuration of 1,2-perchloratomercuribisbenzene and the alternative reversal from the 1,2,4-trismercurial to 1,3-perchloratomercuribisbenzene may be so rapid that only the appearance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of the latter substance is first observed. However, initial ortho mercuration need not be a necessary condition of the reaction. Meta substitution may be a very rapid reaction, as is observed when phenyltrimethylammonium salts are nitrated to give exclusively the meta nitro compound in high yield (16, 17). No postulation of prior ortho–para substitution can be made in this event since nitration is essentially irreversible.

Actually a preponderance of ortho substitution is observed when phenylmercuric acetate is fused with mercuric acetate at 145–150° C. The reaction does not seem to be amenable to detailed study because of the complication that the acetato group also is mercurated (18) even though a reasonable separation of the mercurated acetic acid can be made (19). Although the yields vary unaccountably between 35 and 50% the ratio of bismercurials, *o*:*m*:*p*, is consistent at 65–66:23.5–24.5:11. An otherwise comparable experiment, in which mercuric acetamide replaces the acetate, yields 43% of bismercurials in *o*:*m*:*p* ratio of 69:18:12.

EXPERIMENTAL

Mercuration of Phenylmercuric Perchlorate

This procedure was used when various concentrations of perchloric acid were compared in mercuration. A sample of phenylmercuric hydroxide (m.p. 226–228° C) (20) weighing 0.50 g (0.0017 mole) was dissolved in perchloric acid (usually 417 ml) of the desired concentration. To this stirred solution at 25° was added 0.37 g (0.0017 mole) of mercuric oxide. The closed system was stirred only gently (to minimize loss of benzene) for 150 minutes.

Subsequently the system was poured into 1 liter of crushed ice, and 20% aqueous sodium hydroxide was added until the mixture was slightly basic. Then 1 g of sodium bromide was added. Acidification with acetic acid produced a precipitate which was allowed to settle while the remainder of the ice was melting. The precipitate was filtered off and washed thoroughly with water to remove soluble salts. Then it was washed with boiling ethanol and boiling benzene to remove phenylmercuric bromide, leaving the insoluble polymercurated benzenes.

p-Chloromercuribisbenzene

Following the procedure outlined above with 70% perchloric acid (d_{20} 1.67, 417 ml) the original system was stirred for 20 minutes. Then 0.05 g (0.00017 mole) of phenylmercuric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

hydroxide and 0.037 g (0.00017 mole) of mercuric oxide were added. Subsequently, nine more such additions were made every 20 minutes with continued stirring. Twenty minutes after the last addition the solid was filtered off and dissolved in water, then treated with sodium chloride. The purity of the infusible *p*-chloromercuribisbenzene (0.65 g, 32%) is indicated by the melting point (74–82°) of the *p*-dibromobenzene, which may be prepared from it quantitatively (21).

Treatment of the remainder of the reaction system (the filtrate) with ice and then with sodium bromide yielded 0.56 g of polymercurated benzenes which contained 22% of 1,4-bromomercuribisbenzene according to the prescribed bromination analysis described below.

Isomerization of p-Dimercurated Benzene

The 1,4-perchloratomercuribisbenzene was filtered from a reaction system such as has just been described; it was washed thoroughly with ethanol and then was dried *in vacuo* at 25° C. A mixture of 0.50 g (0.00074 mole) of 1,4-perchloratomercuribisbenzene in 200 ml of 70% perchloric acid containing 0.238 g (0.0011 mole) of mercuric oxide was stirred at 25° C. After 180 minutes the clear solution was drowned and treated as described above to give 0.04 g (17%) of phenylmercuric bromide and 0.40 g (25%) of polymercurated benzenes. Analytical bromination showed that this mixture contained 10% of the *p*-isomer, 57% of the *m*-isomer, and 24% of the 1,3,5-perchloratomercuritrisbenzene.

In a variation of this procedure 0.25 g (0.00037 mole) of 1,4-perchloratomercuribisbenzene in 50 ml or 70% perchloric acid containing 1.00 g (0.0046 mole) of mercuric oxide was stirred at 25° C for 2 hours and then was processed according to the earlier description to remove *p*-isomer (filtration) and then phenylmercuric salt (benzene–ethanol extraction). The remainder (0.31 g) when treated with bromine gave 0.09 g of solid polybromobenzenes. A hot ethanol (2.5 ml) solution, upon cooling, yielded 0.004 g (5%) of 1,2,4,5-tetrabromobenzene, m.p. 165–173° C. After crystallization from ethanol (m.p. 179–180° C) a mixture melting point with an authentic sample (22) was not depressed.

The ethanolic mother liquors were concentrated to yield 0.07 g, m.p. 65–92° C. Crystallization from petroleum ether (b.p. 40–60° C) showed that this material was largely 1,3,5-tribromobenzene, m.p. 118–119° C.

1,3-Chloromercuribisbenzene

A suspension of 4.70 g (0.0238 mole) of *m*-benzenedisulphinic (23) acid in 10 ml of water was made alkaline by addition of 50% aqueous sodium hydroxide and the whole was added to a boiling solution of 16.35 g (0.06 mole) of mercuric chloride in 50 ml of water. A curd appeared after 30 seconds and the system thickened to a paste on the steam bath. After 20 minutes the strongly acidic system was diluted with 50 ml of water and was maintained on the steam bath for 6 hours. The precipitate was filtered off and washed with hot water until free from mercuric salts (of which 0.015 mole was washed out), and then with boiling ethanol and boiling benzene. The remainder weighed 70.7 g or 82% of theoretical. Anal. Calc. for $C_6H_4Hg_2Cl_2$: C, 13.15; H, 0.73. Found: C, 13.0; H, 1.2. Upon treatment with bromine in excess the *m*-dibromobenzene, b.p. 85–90° C (15 mm), which was obtained in 65% yield, was converted to 2,4-dibromobenzenesulphonyl chloride, m.p. 75–78° C, mixed m.p. not depressed.

1,3-Hydroxymercuribisbenzene

A suspension of 10.7 g (0.0196 mole) of 1,3-chloromercuribisbenzene in 2 liters of 0.65%

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

aqueous sodium hydroxide was heated to boiling and filtered hot. The filtrate was evaporated to a 200-ml volume and cooled, precipitating 3.76 g (38%) of chlorine-free product. Treatment with bromine according to the procedure described below gave a quantitative yield of pure 1,3-dibromobenzene, b.p. 86–90° C (15 mm), according to freezing point (−2° C) and to the 2,4-dibromobenzenesulphonyl chloride, m.p. 77–78° C, which was derived from it.

Isomerization of 1,3-Perchloratomercuribisbenzene

Some heat is evolved when 0.50 g (0.00096 mole) of 1,3-hydroxymercuribisbenzene is dissolved in 150 ml of 70% perchloric acid. The solution was cooled to 25° C and let stand for 2 hours and then was drowned in ice, neutralized with alkali, and treated with sodium chloride. Extraction with hot benzene–ethanol removed 0.06 g of phenylmercuric chloride, m.p. 248° C. The alcohol- and benzene-insoluble part (0.36 g) was found by the analytical bromine technique to contain 25% of the *p*-isomer and less than 1% of bromotrisbenzene.

1,3,5-Chloratomercuritrisbenzene

A solution of 0.20 g (0.00068 mole) of phenylmercuric hydroxide in 100 ml of 70% perchloric acid was treated at 25° C with 1.70 g (0.00785 mole) of mercuric oxide. The system became and remained clear, unlike systems without excess of mercuric perchlorate. After 2 hours the system was poured into 2 kg of ice, and 20% aqueous sodium hydroxide was added to slight basicity. Then 1 g of sodium bromide was added, together with sufficient acetic acid for slight acidity. The precipitate, essentially bromomercuritrisbenzene, weighed 0.62 g (100%) and when brominated gave 0.21 g, m.p. 97° C. Crystallization from petroleum ether raised this melting point to 118–119° C; mixed m.p. not lowered.

Demercuration of Chloratomercuritrisbenzene

A quantity of material which was chiefly chloromercuritrisbenzene according to the bromination method of analysis was converted to the hydroxymercurial by washing it exhaustively with alkali. A suspension of 0.49 g (0.00067 mole) of this hydroxymercurial with 0.16 g (0.00054 mole) of phenylmercuric hydroxide was stirred with 150 ml of 70% perchloric acid for 3 minutes until the system was homogeneous. After 2 hours the system was drowned and processed as is outlined above. The recovered phenylmercuric chloride and the polymercurial portion weighed 0.07 g and 0.41 g respectively. Analysis of the latter by the bromination technique showed that 48% was dimercurated benzenes while 52% was trimercurated. This amount of trismercurial is 42% of that originally used, so that at least 58% has been demercurated. Likewise, the recovery of monomercurial is 44% of that first introduced to the system.

Acetoxymercuration of Phenylmercuric Acetate

A finely ground mixture of 10.0 g (0.03 mole) of phenylmercuric acetate and 12.78 g (0.047 mole) of purified mercuric acetate was heated in a large test tube and was immersed in a sulphuric acid bath at 150° C during 30 minutes. The clear melt became quite viscous. The system was allowed to cool gradually, then was finely ground and exhaustively washed with boiling ethanol and benzene to remove 1.2 g of unchanged phenylmercuric acetate. The remainder was washed five times with 200-ml portions of 5% aqueous sodium hydroxide containing 10% sodium bromide. After each washing the material was dried and reground. Finally it was washed with dilute acetic acid and with water. There remained after drying 9.5 g (58%) of infusible solid. Analysis by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the bromination method (spectral analysis) showed that it contained 64.8% ortho, 24.4% meta, and 10.8% para isomer. Duplication gave 65.8% ortho, 23.3 meta, and 10.8 para.

An otherwise identical experiment with mercuric acetamide gave a product with an *o*:*m*:*p* ratio of 69.3:18.4:12.3.

Identifications and Analyses

Because of the large atomic weight of mercury, an elemental analysis for carbon is chiefly, and for hydrogen or mercury entirely, meaningless. For this reason the mercurials and mixtures of them that are described in this report have largely been characterized by conversion to brominated benzenes. For a quantity of mercurial not to exceed 0.70 g the following procedure is used.

Bromination of Mercurials

The sample is added to a stirred two-phase system comprised of 5.0 ml of carbon tetrachloride with a solution of 3.0 g of potassium bromide in 15 ml of water. Bromine is added at such a rate that its color is just maintained. When the solid has disappeared the brominated benzenes are in the non-aqueous phase and the mercuric salts are in the aqueous phase.

The non-aqueous phase is vacuum-evaporated and the residue is distilled under 13 mm. The dibromobenzenes distill at 85–87° C while the residue consists of polybromobenzenes, 96–108° C. A single crystallization from 95% ethanol raises this melting point to 118–119° C, not depressed by admixture with 1,3,5-tribromobenzene. Since the weight of the distillation residue is 5% higher than the known amount from a calculated mixture of dibromobenzenes and 1,3,5-tribromobenzene, this residue weight less 5% is taken as presumptive for anionomercuritrisbenzene.

The method of Ferguson and Levant (24) for infrared spectral analysis of chlorobromobenzenes was simplified by use of the same cell for all determinations of 7–10% solutions in carbon disulphide so that optical density instead of extinction coefficient could be employed. The wag frequencies chosen include the three corresponding (but at lower frequencies) to those chosen by Whiffen *et al.* in their analysis of cresols (25) although the number has been extended (607 and 742 cm^{-1} for ortho; 664, 723, and 765 cm^{-1} for meta; 805 cm^{-1} for para). The optical densities of 12 known mixtures over the entire range of concentrations have been plotted for each frequency. Since these plots are practically linear and there is little overlap of the key frequencies, the percentages of isomer are read directly and (in the case of ortho and meta) averaged for the several frequencies used for these isomers. Although part of the *p*-dibromobenzene may be separated as such (m.p. 85–86° C) by chilling the distilled mixture of dibromobenzenes they are usually analyzed *in toto*.

When the ortho isomer is practically absent a two-component thermal analysis may be made for percentages of the meta and para dibromobenzenes. The hot oil is transferred by means of small capillaries to melting-point tubes about 1 mm in diameter. The disappearance of the last crystal is recorded while the sample is stirred by reciprocal motion of the capillary. The rate of heating is about 1° C per 5 minutes in a thaw-point apparatus (26). The diagram is shown in Fig. 1.

Meta–para mixtures of dibromobenzene also may be analyzed by the method of Huntress and Carten (27) because 1,4-dibromobenzene does not react with chlorosulphonic acid. For example, 0.30 g (0.0012 mole) of dibromobenzenes (from which part of the para isomer had been removed by filtration at 4° C) was treated at 0° C with 2.50 g (0.0215 mole) of chlorosulphonic acid (distilled at 147–149° C in a stream of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

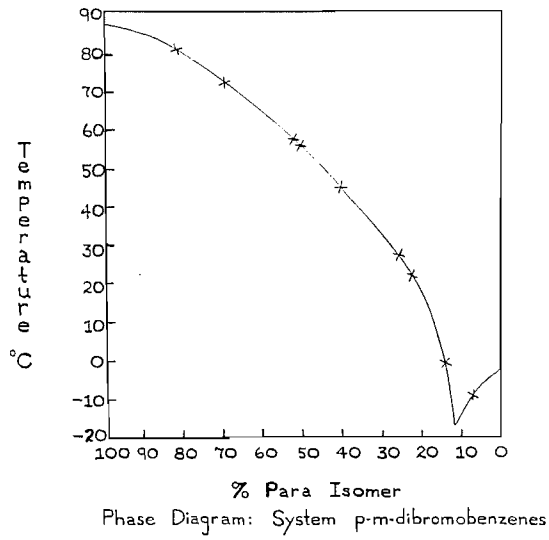


FIG. 1.

hydrogen chloride). After the reaction had subsided the system was warmed and held for 20 minutes at 20–25° C and then was drowned in ice. The white solid, 0.36 g, m.p. 57–73° C, was crystallized from 4 ml of petroleum ether (b.p. 40–60° C), yielding 0.33 g, m.p. 80–82° C, not depressed by admixture with authentic 2,4-dibromobenzenesulphonyl chloride. Refluxing with concentrated ammonia converts this product to 2,4-dibromobenzenesulphonamide, m.p. 189–190° C.

THE RADIOLYSIS OF ETHANOL

I. VAPOR PHASE[1]

J. M. RAMARADHYA[2] AND G. R. FREEMAN

ABSTRACT

The alpha radiolysis of ethanol vapor at 108° C produced hydrogen as the major single product, with smaller amounts of methane, carbon monoxide, ethylene, ethane, acetaldehyde, formaldehyde, water, 2,3-butanediol, 1,2-propanediol, propanol, and butanol. The initial yield of hydrogen was $G(H_2) = 8.9 \pm 0.4$, which is much higher than the values reported for the liquid phase ($G(H_2) \approx 4$).

A mechanism is proposed to account for the formation of the products. However, the observed value of $G(H_2O) = 5.4$ is over four times larger than can be explained by the mechanism.

There is a good material balance in the observed reaction products, which indicates that little polymerization occurred during the radiolysis. This is in marked contrast with the vapor phase radiolysis of cyclohexane.

INTRODUCTION

Although the radiolysis of liquid ethanol has been studied using helium ions (1, 2) and Co^{60} gamma rays (3), very little attention has been paid to the vapor phase radiolysis of ethanol. In the liquid phase radiolysis of ethanol, the gaseous products were hydrogen, carbon monoxide, methane, ethylene, and ethane and the liquid products were formaldehyde, acetaldehyde, and vicinal glycols.

One previous study of ethanol vapor by cathode-ray bombardment has been reported by McLennan and Patrick (4). The products reported were hydrogen, carbon monoxide, carbon dioxide, methane, ethane, formaldehyde, and acetaldehyde. In this paper, an investigation of the radiolysis of ethanol vapor by Po^{210} alpha particles is described.

EXPERIMENTAL

The apparatus and the general experimental technique used in this investigation are similar to those described in an earlier paper (5).

The ethanol was from Reliance Chemical Ltd., containing about 0.11 mole% water. Three and one-half grams of sodium was dissolved in 500 ml of ethanol and 14 g of diethyl phthalate was added to the solution (6). This solution was refluxed for 2 hours and was distilled in a system protected from moist air by passing dry hydrogen through it. The hydrogen was dried by passing it through a trap containing silica gel, immersed in liquid nitrogen. Only the middle one-third of the distillate was retained. After the purification the ethanol contained only 0.005 mole% water.

The purified ethanol was degassed and stored under vacuum in a reservoir. Prior to irradiation, 1.6 ml of the ethanol was distilled into a calibrated tube, where its volume was accurately measured at 0° C, and then volatilized into the reaction chamber.

The reaction chamber was a 1-liter bulb, heated to 108° C, containing a nominally 100-mc Po^{210} source (5). The polonium source was calibrated by Fricke dosimetry, using $G(Fe^{+++}) = 5.5$ (5). All the energy of the alpha particles was absorbed by the ethanol vapor during an experiment.

The products of the ethanol vapor radiolysis were analyzed by low-temperature distillation and by gas chromatography. The fraction of gaseous products that was volatile

[1]*Manuscript received May 23, 1961.*
Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta.
[2]*Present address: Consolidated Mining and Smelting Co., Trail, B.C.*

at −196° C consisted of hydrogen, carbon monoxide, and methane. It was collected and measured in a McLeod–Toepler apparatus and then analyzed on a 1-m activated charcoal column. Another gaseous fraction, noncondensable at −112° C and consisting of residual methane and C_2, C_3, and trace amounts of C_4 hydrocarbons, was analyzed using a 2.5-m silica gel column. The analyses of the various liquid products were performed using 2.5-m carbowax 1500, 2.5-m didecyl phthalate, and 1-m ucon columns.

Anhydrous ethanol is very hygroscopic. Water was also a reaction product. When the yield of water was being determined, samples of unirradiated ethanol were put through the entire analytical procedure and then analyzed for water on a 2.5-m carbowax 1500 column. The differences between the blanks and the irradiated samples were used to calculate the G of water.

The acetaldehyde yield was determined polarographically (7).

The amount of formaldehyde was measured by the chromotropic acid method. Analyses were done in triplicate and three standard samples and a blank were done concurrently with the unknowns. The procedure for an individual analysis was as follows. Chromotropic acid (110±1 mg) was weighed into each of seven 10-ml Erlenmeyer flasks and 0.80 ml of distilled water was added to each. Only a small portion of the chromotropic acid dissolved. Then 0.20 ml of irradiated ethanol, or of pure ethanol or standard ethanolic solution of formaldehyde, was added to the various flasks. Three different standard concentrations of formaldehyde were used to bracket the concentration in the unknowns. The solutions were then evaporated to dryness by suspending the flasks for 25 minutes in an oil bath at 110±2° C. The oil was stirred to obtain a uniform temperature for all the flasks in the bath. The flasks were then removed from the bath and allowed to cool for 3 or 4 minutes. Five milliliters of concentrated sulphuric acid was pipetted into each flask and they were then heated for 30 minutes in an oil bath at 130±2° C. After the flasks were removed from the bath and cooled, the acid solutions were transferred into 50-ml, glass-stoppered flasks. The solutions were diluted with 15.0 ml of distilled water, cooled, and their optical densities measured at 570 mμ. The temperatures and times in the analytical procedure should be kept as constant as possible and the diluted solution should not stand more than 1 hour before being measured in a spectrophotometer (the color fades). The sensitivity of the method decreases markedly if the water/ethanol ratio in the initial chromotropic acid solution decreases below 4/1. Acetaldehyde does not interfere with the analysis.

RESULTS

Pure ethanol was subjected to alpha radiation and the gaseous-product yield distribution was studied as a function of dose over the range 0.50×10^{19} ev to 3.77×10^{19} ev. The total yield of gases noncondensable at −196° C, $G(-196)$, appears to be constant at 10.1±0.4 over this dose range, while that of gases volatile at −112° C, $G(-112)$, decreases with increasing dose.

The products that constituted the fractions volatile at −196° C and −112° C were measured and their G values are presented as a function of dose in Fig. 1.

The yields of methane are the combined yields obtained from the two gas fractions. The portion of the total methane, derived from the −112° C fraction, increased from 21% at the lowest dose to 58% at the highest dose. However, the methane yield obtained from the gases volatile at −196° C remained approximately constant with a G of 1.1±0.1 except for the lowest-dose experiment.

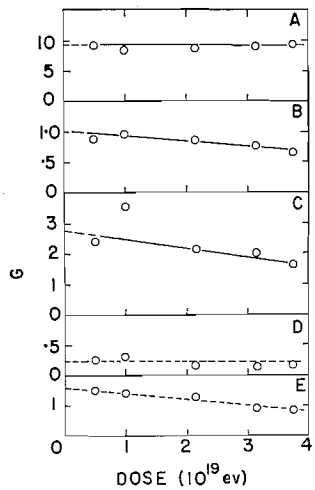

FIG. 1. G values of products volatile at −196° C and −112° C, as a function of dose: (A) hydrogen, (B) carbon monoxide, (C) methane, (D) ethane, (E) ethylene. The sample was 1.6 ml liquid ethanol volatilized into a 1-l. bulb at 108° C.

Since the amounts of liquid products were too small to be measured in these dose-function experiments, appreciably higher doses, about 8×10^{20} ev, were given to three ethanol samples and the liquid products were measured. The average yields are given in Table I along with the yields of the gaseous products obtained at the same dose. Comparison of the gaseous product yields in Table I and Fig. 1 indicates little change in the dose region from about 4 to 80 $\times10^{19}$ ev.

TABLE I

G values of products obtained by irradiating ethanol vapor
(Irradiation temperature 108° C, dose ≈ 8×10^{20} ev)

Product	G	Product	G
Hydrogen	7.6	Formaldehyde	0.9
Carbon monoxide	1.1	Acetaldehyde	4.5
Methane	1.66	Propanol	0.6
Ethane	0.23	Butanol	0.19
Ethylene	0.72	1,2-Propanediol	0.15
Acetylene	0.03	2,3-Butanediol	1.2
C_3 and C_4 hydrocarbons	Trace	Total glycols	1.6
Water	5.4		

There is fair agreement between the total glycols (ucon column) and the sum of the vicinal glycols (carbowax column). Ethylene glycol, 1,3-butanediol, and 1,4-butanediol were not present in detectable amounts.

DISCUSSION

The values of $G(H_2)$ obtained in the previous investigations of liquid ethanol (1–3) are around 4. The present vapor phase radiolysis of ethanol has yielded an average value of $G(H_2) = 8.9\pm0.4$ in the dose region from 0.5 to 3 $\times10^{19}$ ev/g. In hydrocarbon

radiolyses, the 100-ev hydrogen yields are also larger in the gas phase reactions than in the liquid phase reactions (5).

The following mechanism is suggested to account for the observed reaction products:

$$CH_3CH_2OH \sim\sim\rightarrow CH_3CH_2OH^* \quad [1a]$$

$$\sim\sim\rightarrow CH_3CH_2OH^+ + e \quad [1b]$$

$$CH_3CH_2OH^* \rightarrow CH_3CHOH + H \quad [2a]$$

$$\rightarrow CH_3 + CH_2OH \quad [2b]$$

$$CH_3CH_2OH^* \rightarrow CH_3CHO + H_2 \quad [3a]$$

$$\rightarrow CH_2O + CH_4 \quad [3b]$$

$$\rightarrow C_2H_4 + H_2O \quad [3c]$$

$$CH_3CH_2OH^+ + CH_3CH_2OH \rightarrow CH_3CH_2OH_2^+ + CH_3CHOH \quad [4]$$

$$CH_3CH_2OH_2^+ + e \rightarrow CH_3CH_2 + H_2O \quad [5a]$$

$$\rightarrow CH_3CH_2O + H_2 \quad [5b]$$

$$H + CH_3CH_2OH \rightarrow H_2 + CH_3CHOH \quad [6]$$

$$CH_3 + CH_3CH_2OH \rightarrow CH_4 + CH_3CHOH \quad [7]$$

$$C_2H_5 + CH_3CH_2OH \rightarrow C_2H_6 + CH_3CHOH \quad [8]$$

$$CH_3CH_2O + CH_3CH_2OH \rightarrow CH_3CH_2OH + CH_3CHOH \quad [9]$$

$$C_2H_4 + H \rightarrow C_2H_5 \quad [10]$$

$$CH_3 + CH_3CHOH \rightarrow \begin{matrix} CH_3CHOH \\ | \\ CH_3 \end{matrix} \quad [11a]$$

$$\rightarrow CH_4 + CH_3CHO \quad [11b]$$

$$C_2H_5 + CH_3CHOH \rightarrow \begin{matrix} CH_3CHOH \\ | \\ C_2H_5 \end{matrix} \quad [12a]$$

$$\rightarrow C_2H_6 + CH_3CHO \quad [12b]$$

$$\rightarrow C_2H_4 + C_2H_5OH \quad [12c]$$

$$2CH_3CHOH \rightarrow CH_3CHOHCHOHCH_3 \quad [13a]$$

$$\rightarrow CH_3CH_2OH + CH_3CHO \quad [13b]$$

$$CH_3CHOH + CH_2OH \rightarrow CH_3CHOHCH_2OH \quad [14a]$$

$$\rightarrow CH_3CH_2OH + CH_2O \quad [14b]$$

$$\rightarrow CH_3CHO + CH_3OH \quad [14c]$$

$$CH_3CHOH + CH_3CH_2O \rightarrow CH_3CHO + C_2H_5OH \quad [15a]$$

$$\rightarrow \begin{matrix} CH_3CHOH \\ | \\ OC_2H_5 \end{matrix} \rightarrow CH_3CHO + C_2H_5OH. \quad [15b]$$

Reactions [4] and [5*a*, *b*] are quite speculative but they are being considered in an investigation of the radiolysis of liquid ethanol in this laboratory. It is assumed that the positive charge on the species in reactions [4] and [5*a*, *b*] is localized on the oxygen atom.

Acetaldehyde may be formed by reactions [3*a*], [11*b*], [12*b*], [13*b*], [14*c*], and [15*a*, *b*]. The radicals involved in these reactions are CH_3, C_2H_5, CH_3CH_2O, CH_3CHOH, and CH_2OH. From the *G* values of products which require these radicals for their formation, the amounts of CH_3, C_2H_5, ($CH_3CHOH + CH_3CH_2O$), and CH_2OH radicals can be calculated to be respectively 1.1–2.3 (depending on the mechanism of formation of CO), 0.43, 12.35, and 1.05 *G* units. Since the amount, and therefore the concentration, of ($CH_3CHOH + CH_3CH_2O$) radicals is much greater than that of any other radical, the disproportionation reaction of these radicals (reactions [13*b*] and [15]) might be considered as a major source of acetaldehyde. The steady-state concentration of CH_3CH_2O will probably be much smaller than that of CH_3CHOH because of reaction [9] and because the latter radicals can be generated in many more reactions than can the former radicals (see the above mechanism).

Since the C—C bond is the weakest bond in the ethanol molecule, one might have expected a large yield of products resulting from CH_3 and CH_2OH radicals in the gas phase. In the liquid phase, there may be recombination of the CH_3 and CH_2OH radicals in the Franck–Rabinowitch cages and hence the yields of the corresponding products would be low. Low yields of methane (0.43) and formaldehyde (0.3) were experimentally observed by McDonell and Newton (1). In the gas phase, where the cage effect is not operative, larger yields of methane (1.7) and formaldehyde (0.9) were observed in the present work.

Carbon monoxide might be formed by decomposition of formaldehyde and acetaldehyde.

Propanol and butanol are probably formed by the addition of methyl and ethyl radicals to CH_3CHOH radicals (reactions [11*a*] and [12*a*]).

The vicinal glycols (2,3-butanediol and 1,2-propanediol) that were measured in the present investigation were probably formed by combination of CH_3CHOH radicals with themselves and with CH_2OH radicals (reactions [13*a*] and [14*a*]). From the relative yields of these two glycols it may readily be calculated that the yield of ethylene glycol would be negligible. If CH_2CH_2OH radicals were present in appreciable concentration during the decomposition of ethanol, the combination of CH_2CH_2OH radicals with each other and with CH_3CHOH would have led to the formation of 1,4-butanediol and 1,3-butanediol. Since these products were not produced to a measurable extent, the concentration of CH_2CH_2OH radicals was negligible in the present system.

The ethyl radicals produced by reactions [5*a*] and [10] might abstract (reaction [8]) or disproportionate to give ethane.

$$2C_2H_5 \rightarrow C_4H_{10} \qquad [16a]$$

$$\rightarrow C_2H_4 + C_2H_6 \qquad [16b]$$

Since the value of the ratio of disproportionation to combination of ethyl radicals is about 0.12 (9), the amount of ethane from reaction [16*b*] would be about one-eighth of the amount of butane. The yield of butane in the present work was only a trace, and thus a negligible amount of ethane originates from the disproportionation reaction. Therefore the major source of ethane is probably reaction [8].

Ethylene, which has an appreciable yield, is assumed to be formed by reactions [3*c*], [12*c*], and [16*b*]. Since [16*b*] was precluded as a significant source of ethane, it may also be neglected as a source of ethylene.

It is not known whether the acetylene is a primary or a secondary product but it will be assumed to be mechanistically as well as stoichiometrically equivalent to ($C_2H_4 - H_2$).

The preceding mechanism can be reduced to the following stoichiometric equations:

$$\begin{aligned} n\mathrm{C_2H_5OH} &= \mathrm{H_2} + \mathrm{CH_3CHO} \\ &= \mathrm{H_2} + \mathrm{CH_4} + \mathrm{CO} \\ &= \mathrm{H_2} + (\mathrm{CH_3CHOH})_2 \\ &= \mathrm{H_2} + \mathrm{C_2H_2} + \mathrm{H_2O} \\ &= \mathrm{H_2} + \mathrm{C_3H_7OH} + \mathrm{CH_2O} \\ &= \mathrm{C_2H_4} + \mathrm{H_2O} \\ &= \mathrm{C_3H_7OH} + \mathrm{CH_3OH} \\ &= \mathrm{CH_4} + \mathrm{CH_3CHO} + \mathrm{CH_3OH} \\ &= \mathrm{CH_4} + \mathrm{CH_3CHOHCH_2OH} \\ &= \mathrm{CH_4} + \mathrm{CH_2O} \\ &= \mathrm{C_4H_9OH} + \mathrm{H_2O} \\ &= \mathrm{C_2H_6} + \mathrm{CH_3CHO} + \mathrm{H_2O} \\ &= \mathrm{C_2H_6} + (\mathrm{CH_3CHOH})_2 + \mathrm{H_2O}, \end{aligned}$$

where $n = 1$, 2, or 3. The products can be written in several equivalent combinations. Equations such as

$$3\mathrm{C_2H_5OH} = \mathrm{CH_4} + (\mathrm{CH_3CHOH})_2 + \mathrm{CH_3OH}$$

can be included without altering the over-all picture or the calculations that follow.

From the above equations, the yields of hydrogen, water, and methane were correlated to the yields of other products.

$$G(\mathrm{H_2}) = G(\mathrm{CH_3CHO}+\mathrm{CO}+(\mathrm{CH_3CHOH})_2+\mathrm{C_2H_2}+\mathrm{C_3H_7OH}-\mathrm{CH_3OH}-\mathrm{C_2H_6})$$

Using Table I, the sum of the G values of the products on the right-hand side of this equation is equal to $7.2-G(\mathrm{CH_3OH})$.

Similarly

$$\begin{aligned} G(\mathrm{H_2O}) &= G(\mathrm{C_2H_2}+\mathrm{C_2H_4}+\mathrm{C_4H_9OH}+\mathrm{C_2H_6}) \\ &= 1.2, \\ G(\mathrm{CH_4}) &= G(\mathrm{CO}+\mathrm{CH_3OH}+\mathrm{CH_3CHOHCH_2OH}+\mathrm{CH_2O}-\mathrm{C_3H_7OH}) \\ &= 1.55+G(\mathrm{CH_3OH}). \end{aligned}$$

The values of $G(\mathrm{H_2}) = 7.2-G(\mathrm{CH_3OH})$ and $G(\mathrm{CH_4}) = 1.55+G(\mathrm{CH_3OH})$ are in approximate agreement with the observed values, $G(\mathrm{H_2}) = 7.6$ and $G(\mathrm{CH_4}) = 1.66$, if $G(\mathrm{CH_3OH})$ is small.

From the above, an approximate expected yield of methanol would be $G(\mathrm{CH_4})-1.55 \approx 0.1$. In the liquid phase radiolysis of ethanol (1), the value of the ratio of the yields of formaldehyde to methanol is 0.2. If this ratio had the same value in the vapor phase, the expected yield of methanol would be about 0.2. Thus the methanol yield is probably quite small, although methanol could not be measured by the present analytical system.

The predicted value of $G(\mathrm{H_2O}) = 1.2$ is much lower than the observed value of 5.4. The source of this excess water is not obvious. It might have been formed by reactions not considered in the mechanism, or the sample might have absorbed water from the atmosphere during the analytical procedure. However, the analysis of the blank samples should have compensated for the latter possibility. An unaccountable excess of water was also observed by McDonell and Newton (1) in the liquid phase radiolysis of ethanol.

A mass balance for carbon, hydrogen, and oxygen has been worked out from the products and is presented in Table II. This mass balance corresponds to an empirical

TABLE II

Mass balance of carbon, hydrogen, and oxygen in the products obtained in the radiolysis of ethanol vapor

Product	G	Mass balance C	H	O
Hydrogen	7.6	—	15.2	—
Carbon monoxide	1.1	1.1	—	1.1
Methane	1.66	1.7	6.6	—
Ethylene	0.72	1.4	2.9	—
Ethane	0.23	0.5	1.4	—
Acetylene	0.03	0.1	0.1	—
Water	5.4	—	10.8	5.4
Formaldehyde	0.9	0.9	1.8	0.9
Acetaldehyde	4.5	9.0	18.0	4.5
Propanol	0.6	1.8	4.8	0.6
Butanol	0.19	0.8	1.9	0.2
1,2-Propanediol	0.15	0.5	1.2	0.3
2,3-Butanediol	1.2	4.8	12.0	2.4
	Total	22.2	76.7	15.4

NOTE: The numbers under C, H, and O in the table were obtained by multiplying the G value of the product by the respective number of atoms of C, H, or O in that product.

formula $C_{2.00}H_{6.76}O_{1.36}$, which has slightly more hydrogen and oxygen in it than does ethanol, C_2H_6O.

If water is generated only by reactions [3*c*] and [5*a*], then $G(H_2O)$ should be equal to 1.2. The excess water in G units is $(5.4-1.2) = 4.2$. If the corresponding amounts of H (8.4) and O (4.2) are subtracted from the mass balance in Table II, the empirical formula of the total products becomes $C_{2.00}H_{6.02}O_{0.99}$.

This good mass balance indicates that little or no polymer was formed during irradiation, unless polymer was a coproduct of the observed excess of water. It was also observed that the Po^{210}-alpha-particle source intensity showed no decrease during the ethanol irradiations. In the radiolysis of hydrocarbons (5, 8), there was a poor mass balance and a decrease in source intensity due to the deposition of polymer on the surface of the source. The lack of decrease in source intensity and a good mass balance in the ethanol products corroborate little or no polymer formation during the radiolysis of ethanol.

It might be mentioned that the decrease in the yields of CO, CH_4, and C_2H_4 between 0.5 and 4×10^{19} ev does not appear to be accompanied by a comparable decrease in the hydrogen yield (Fig. 1). Thus the decrease does not appear to be entirely a scavenging effect.

THE RADIOLYSIS OF ETHANOL

II. BINARY VAPOR MIXTURES[1]

J. M. RAMARADHYA[2] AND G. R. FREEMAN

ABSTRACT

Benzene and cyclohexene cause a marked decrease in the hydrogen yield from the vapor phase radiolysis of ethanol.

The experimental data were tested against the two reaction mechanisms that gave straight-line plots for the corresponding cyclohexane–protector systems. Both of these mechanisms also gave straight-line plots for the ethanol–protector systems.

One mechanism involved scavenging of hydrogen atoms. The values of the kinetic parameters derived from this mechanism are quite similar in the cyclohexane and ethanol systems.

The second mechanism involved the transfer of energy (excitation or ionization) from ethanol to the protector. The values of the kinetic parameters derived from this mechanism showed some differences between the ethanol and cyclohexane systems.

One possible reason for the lack of resolution between the two reaction mechanisms might be that they both occur to comparable extents. Two mechanisms appear to occur to comparable extents in the liquid cyclohexane system.

INTRODUCTION

In the isolation of steps in radiolytic mechanisms, the study of binary systems should be very helpful. In that connection, the radiolyses of mixtures of hydrocarbons have been frequently investigated (1–5). However, the radiolyses of organic compounds with functional groups and of their mixtures with other compounds are less common. As a part of a general program, we have investigated the vapor phase radiolysis of ethanol by Po^{210} alpha particles (6). Newton and McDonell (7) were the first to report the protection of liquid ethanol by acetaldehyde and by hexene. The present paper reports the results of a study of the protective effect of benzene and of cyclohexene on ethanol during radiolysis in the vapor phase.

EXPERIMENTAL

The ethanol used in these investigations was obtained from Reliance Chemical Ltd. and contained about 0.11 mole% water. The benzene was Eastman Kodak spectrograde and cyclohexene was from Matheson, Coleman and Bell. All the compounds were used without any further purification.

The apparatus used was a conventional vacuum manifold and the general techniques used in this investigation have been previously described (8, 9).

Binary vapor mixtures of ethanol and benzene or cyclohexene were irradiated at 108° C with Po^{210} alpha particles. The Po^{210} source (nominally 100 mc) was calibrated by Fricke dosimetry, using $G(Fe^{+++}) = 5.5$. The concentration of the protector in the vapor mixtures ranged from 2 to 100 mole% in each case. A quantity (1.6 ml) of well-degassed liquid solution was volatilized into a heated 1-liter reaction vessel that contained the Po^{210} source. The irradiation time was 2 hours. Approximately 0.01% of the sample was decomposed.

RESULTS

The radiolysis of pure ethanol vapor has been studied as a function of dose (6). The major single product was hydrogen, with smaller amounts of carbon monoxide, methane, ethane, ethylene, acetaldehyde, formaldehyde, vicinal glycols, and water. Under the conditions of the present work, only the total fraction volatile at −196° C (comprised of about 80% H_2, 10% CO, and 10% CH_4) could be measured accurately as a function of protector concentration.

The results are presented in Fig. 1. In these plots, the observed values of $G(-196)$,

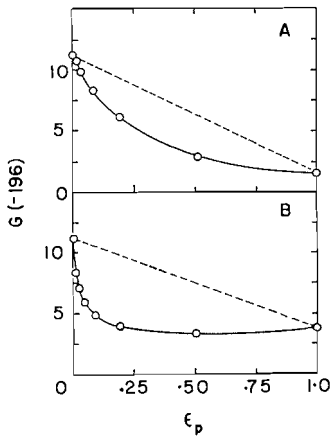

FIG. 1. G(−196), gas fraction volatile at −196° C, as a function of protector concentration: ϵ_p = electron fraction of protector P; (A) P = benzene; (B) P = cyclohexene.

the 100-ev yield of the gas fraction volatile at −196° C, are plotted against the "electron fraction" of the protector, ϵ_p. The value of $G(-196)$ decreases with increasing inhibitor concentration in both the systems. It is clear from Fig. 1 that cyclohexene reduces the yield of the −196° C fraction more rapidly than does benzene. The broken lines in the plots indicate the yield that might have been expected if there had been no interaction between the components and if the energy absorption were directly proportioned to the electron fraction of the compounds.

DISCUSSION

The experimental data were tested against the two reaction mechanisms that gave straight-line plots for the binary vapor mixtures of cyclohexane and benzene, cyclohexene, or propylene (9). The two mechanisms will be treated separately, making the simplifying assumption that the variation of the total gas fraction volatile at −196° C is a measure of the variation of the hydrogen yield.

I. Scavenging Mechanism

$$C_2H_5OH \xrightarrow{I} C_2H_5OH^* \quad [1]$$

$$C_2H_5OH^* \rightarrow H + C_2H_5O \text{ or } C_2H_4OH \quad [2]$$

$$H + C_2H_5OH \rightarrow H_2 + C_2H_4OH \quad [3]$$

$$H + P \rightarrow PH \quad [4]$$

$$H + P \rightarrow H_2 + P- \quad [5]$$

In the above, I represents the rate of formation of $C_2H_5OH^*$, P represents the protector, and PH and P— represent the corresponding radicals. The following equation can be derived by steady-state treatment of the above mechanism:

$$\left\{1+w\frac{(P)}{(C_2H_5OH)}\right\}\frac{I}{d(H_2)/dt} = 1+v\frac{(P)}{(C_2H_5OH)} = \rho,$$

where $w = k_5/k_3$, $v = (k_4+k_5)/k_3$, and ρ represents the left-hand side of the equation. The numerical values of $I/[d(H_2)/dt]$ were determined from the experimental data (4). By giving arbitrary values to w, sets of values of ρ were calculated. These sets of values were plotted against the ratio $(P)/(C_2H_5OH)$ to see whether a straight line with an intercept of unity could be obtained for each of benzene and cyclohexene. Such a line was obtained in each case (see Fig. 2). The values of the various ratios of rate con-

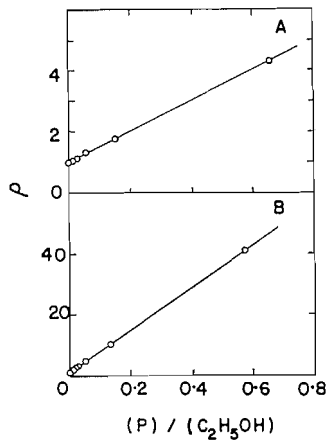

FIG. 2. Kinetic plots of mechanism I: $\rho = \{1+w[(P)/(C_2H_5OH)]\}I/[d(H_2)/dt]$; (A) P = benzene; (B) P = cyclohexene.

stants derived from these plots are shown in Table I. The corresponding values obtained in the cyclohexane systems (9) are given in parentheses.

TABLE I

Values of rate-constant ratios obtained from mechanism I

P	k_5/k_3	k_4/k_3	k_4/k_5
C_6H_6	0.9±0.3 (2.5±0.2)[a]	4.2±0.5 (5.9±0.5)	4.7 (2.4)
C_6H_{10}	20±5 (25±10)	50±10 (31±19)	2.5 (1.2)

[a]Corresponding cyclohexane system values given in parentheses.

It is apparent that the values obtained for the rate-constant ratios are rather similar in the cyclohexane and ethanol systems. While this similarity between the reactivities of ethanol and cyclohexane is not surprising (the rates of reaction of methyl radicals with cyclohexane and ethanol are approximately equal at 182° C and their activation energies are similar (10)), the same comments that were made in the earlier paper (9) can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

repeated here. The values of the rate-constant ratios obtained with cyclohexene might not be unreasonable. However, the value of k_5/k_3 obtained from benzene is surprisingly high, even if the hydrogen atoms are epithermal. It implies that abstraction of hydrogen atoms from benzene is as easy as from ethanol. The much stronger C—H bonds in benzene than in ethanol make this seem unlikely.

Now consider the second mechanism.

II. Energy (Ionization or Excitation) Transfer Mechanism

$$C_2H_5OH \xrightarrow{I'} C_2H_5OH^{**} \quad [1]$$

$$C_2H_5OH^{**} \rightarrow H_2 + \text{products} \quad [6]$$

$$C_2H_5OH^{**} + P \rightarrow C_2H_5OH + P^* \quad [7]$$

$$P^* \rightarrow xH_2 + \text{products}, \ 0 \leqslant x \leqslant 1 \quad [8]$$

The x signifies that perhaps not every P* results in the formation of a hydrogen molecule. Reactions [6] and [8] represent over-all processes and might comprise several steps each. Steady-state treatment of this mechanism yields

$$\{1+y(P)\}I'/d(H_2)/dt = 1+z(P) = \rho'$$

where $y = xk_7/k_6$, $z = k_7/k_6$, and ρ' represents the left-hand side of the equation. Assuming arbitrary values for y, sets of values of ρ' were calculated and plotted against the protector concentration (P), in an attempt to obtain a straight line with an intercept of unity. Figure 3 shows the lines that were obtained. The value of y that gave the desired

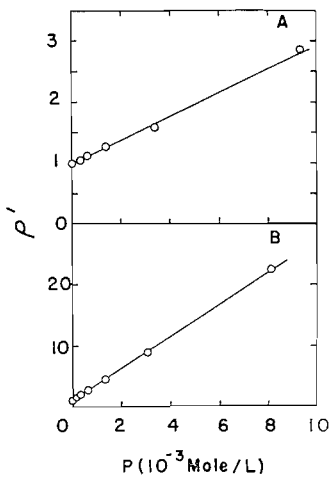

FIG. 3. Kinetic plots of mechanism II: $\rho' = \{1+y(P)\}I'/d(H_2)/dt$; (A) P = benzene; (B) P = cyclohexene.

line in each system, along with the slope of the line, z, and the corresponding value of x, are presented in Table II. The values obtained in the corresponding cyclohexane systems (9) are given in parentheses.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

TABLE II

Values of kinetic parameters obtained from mechanism II

P	y (liter/mole)	x	z (k_7/k_6 (liter/mole))
C_6H_6	6±6 (150±18)[a]	0.03±0.03 (0.25±0.01)	190±20 (610±25)
C_6H_{10}	720±180 (1200±420)	0.28±0.01 (0.46±0.01)	2600±600 (2700±800)

[a]Corresponding cyclohexane system values given in parentheses.

Table II shows certain differences between the cyclohexane and ethanol systems. The apparent value of x (the fraction of the P*, activated by energy transfer from the substrate, that decomposes to yield H_2) is smaller in the ethanol systems than in the cyclohexane systems. Also, the apparent value of the ratio k_7/k_6 (the ratio of the rate of energy transfer to the rate of decomposition of the activated substrate species) is smaller in ethanol–benzene than in cyclohexane–benzene, while it is the same in the two systems containing cyclohexene.

It does not seem useful to speculate here upon the possible reasons for these similarities and differences. Further work, especially using compounds with widely differing ionization potentials and hydrogen-atom activities, is required.

It may be remarked, however, that one possible reason for the present lack of resolution between the scavenging and energy-transfer mechanisms might be that they both occur to comparable extents. Two mechanisms appear to occur to comparable extents in the liquid cyclohexane systems (4). It is possible that the rate constants and concentrations are such in the gas phase that the two mechanisms will be difficult to resolve.

NOTES

β,β,β-TRIFLUOROLACTIC ACID[1]

SUMNER H. BURSTEIN AND H. J. RINGOLD

In a search for inhibitors of lactic acid dehydrogenase it was of interest to prepare and evaluate the hitherto unknown β,β,β-trifluorolactic acid. Our synthesis was effected by a straightforward route patterned after the preparation of α-methyl-β,β,β-trifluorolactic acid (1). Trifluoroacetaldehyde (2) was treated with hydrogen cyanide and the intermediate cyanohydrin was hydrolyzed by vigorous treatment with sulphuric acid to yield the desired *dl*-acid as a crystalline solid.

Trifluorolactic acid and its sodium salt were not oxidized by a crystalline rabbit muscle lactic dehydrogenase in the presence of DPN nor did they inhibit the enzymatic oxidation of sodium lactate or the reduction of sodium pyruvate. The procedure used was similar to that described by Busch and Nair (3) and by Baker and co-workers (4).

EXPERIMENTAL

The infrared spectrum was determined with a Beckman model IR4 instrument, while ultraviolet determinations were made with a Carey model 14 recording spectrophotometer.

β,β,β-Trifluorolactic Acid

Cold 16 *N* sulphuric acid (108 ml) was added dropwise over a period of 1 hour to a solution of trifluoroacetaldehyde hydrate (2) (39.2 g), potassium cyanide (21.6 g), and water (83 ml), held at 0–5°. The mixture was then allowed to come to room temperature and stand for 16 hours. Extraction with ether (4×125 ml), removal of solvent after sodium sulphate drying, and distillation of the residue at reduced pressure gave 33.3 g of intermediate cyanohydrin,[2] b.p. 75–76° (45 mm). The cyanohydrin (30 g) was added dropwise over a 10-minute period to concentrated sulphuric acid (29 ml) with a considerable evolution of heat ensuing as well as the appearance of a thick precipitate. The temperature was slowly raised to 120° and held there for 15 minutes before the mixture was cooled and cautiously diluted with ice water (150 ml). The resulting solution was boiled for 10 hours under reflux and then cooled, saturated at room temperature with sodium sulphate, and extracted with ether (4×125 ml). The ether extract was washed once with saturated sodium sulphate and then dried, and the solvent removed at atmospheric pressure. The residue was distilled at 60–95° (1–2 mm) through a short-path condenser and yielded 23.6 g of β,β,β-trifluorolactic acid as a solid, m.p. 64–67°. An analytical specimen was obtained by recrystallization from methylene chloride – pentane, m.p. 68–69°. Infrared: λ_{max}^{KBr} 5.69 μ. Anal. Calc. for $C_3H_3F_3O_3$: C, 25.01; H, 2.10; F, 39.57. Found: C, 25.42; H, 2.28; F, 39.35.

Attempted Enzymatic Oxidation of Trifluorolactic Acid and Inhibition Studies

The following solutions were added successively to a cuvette: 0.1 *M* phosphate buffer, pH 8.5 (2.7 ml), lactic dehydrogenase[3] (5γ in 0.1 ml of buffer), DPN (1.2 mg in 0.1 ml

[1]*This work was aided by grant No. T-185 from the American Cancer Society.*
[2]*A sample of cyanohydrin allowed to stand for 1 week at room temperature polymerized.*
[3]*Purchased from Worthington Biochemical Corporation.*

of water), and trifluorolactic acid or sodium trifluorolactate (1–40 mg in 0.1 ml phosphate buffer). Readings were taken at 15-second intervals in the spectrophotometer at 340 mμ to follow the appearance of DPNH but no oxidation of substrate occurred over a 30-minute period. When sodium *dl*-lactate (2.2 mg in 0.1 ml of phosphate buffer) was substituted for trifluorolactate, DPNH appeared at an initial rate of 0.05 optical density units per 15 seconds and the addition of varying amounts of trifluorolactate (1–40 mg) did not influence the rate of oxidation.

The reduction of pyruvate to lactate was carried out by the addition to a cuvette of 0.1 *M* phosphate buffer, pH 7.4 (2.7 ml), lactic dehydrogenase (5γ in 0.1 ml of buffer), DPNH (0.3 mg in 0.1 ml of water), and sodium pyruvate (0.55 mg in 0.1 ml of buffer). Readings at 340 mμ showed an initial decrease of 0.2 optical density units per 15 seconds. The addition of up to 10 mg of sodium trifluorolactate in buffer solution, previous to the addition of sodium pyruvate, did not inhibit the reduction of pyruvate.

CARBONIUM PERCHLORATES IN CHLOROFORM SOLUTION

A. L. Gatzke and Ross Stewart

In connection with other work on the spectra of carbonium ions, we have examined the behavior of triarylmethyl perchlorates in chloroform solution. The lowering in the apparent degree of ionization (1–12) of triarylmethyl salts dissolved in organic solvents has been the subject of some speculation. Several reactions might occur, including: (*a*) repression of the ionization of carbonium salts in the organic medium (1) (eq. [1]); (*b*) co-ordination of the carbonium ion with a solvent molecule, for example ether (4, 12) or acetone (7) (eq. [2]); and (*c*) solvolysis reactions (10) which would include both the reaction of the carbonium ion with an organic solvent molecule, for example nitromethane (9) (eq. [3]), and hydrolysis to the carbinol by traces of water remaining in the imperfectly dried solvents (11) (eq. [4]).

$$Ar_3C^+Y^- \rightleftharpoons Ar_3C{-}Y \qquad [1]$$

$$Ar_3C^+Y^- + (CH_3)_2CO \rightleftharpoons Ar_3C{-}\overset{+}{O}{=}C(CH_3)_2 \; Y^- \qquad [2]$$

$$Ar_3C^+Y^- + CH_3NO_2 \rightarrow Ar_3CCH_2NO_2 + HY \qquad [3]$$

$$Ar_3C^+Y^- + H_2O \rightleftharpoons Ar_3C{-}OH_2^+Y^- \rightleftharpoons Ar_3COH + HY \qquad [4]$$

We have examined chloroform as a solvent since it is unlikely to co-ordinate with carbonium ions. Unlike carbon tetrachloride, however, it will dissolve reasonable amounts of carbonium salts.

EXPERIMENTAL

Solvents

Reagent grade chloroform was washed with 95% sulphuric acid followed by repeated washings with distilled water and was then dried over $CaCl_2$ and P_2O_5. Distillation under nitrogen from Drierite through a 30-cm fractionating column yielded a fraction which was stored in a dark bottle under nitrogen over anhydrous potassium carbonate. The bottle was equipped with a drying tube and a siphoning arrangement. Partially dried solvents were prepared in the same manner but were dried for shorter periods. "Wet" chloroform was prepared by saturating this material with water at 10°. Its water content was estimated from solubility data to be 3.5×10^{-2} *M*.

Reagents

Triphenylmethyl perchlorate and tris-*p*-methoxyphenylmethyl perchlorate were prepared essentially as described by Hofmann and Kirmreuther (13). Tri-*p*-tolylmethyl perchlorate was prepared by the addition of perchloric acid and dry ether to an acetic anhydride solution of the carbinol. The product was recrystallized from acetic anhydride – ether and freed from solvent under vacuum. Titration with standard potassium hydroxide gave a molecular weight of 389; calculated, 384. Tri-*p*-tolylcarbinol was prepared by the Grignard reaction of *p*-tolylmagnesium bromide on di-*p*-tolyl ketone. The crude product was purified through the chloride which was then hydrolyzed by sulphuric acid to the carbinol. Recrystallization from petroleum ether gave the product, m.p. 94–96°.

Measurements

A sample of the perchlorate (5–15 mg) was weighed into a dry volumetric flask and dissolved in acetic anhydride. Aliquots (0.05–0.5 ml) of this solution were transferred to 5-ml volumetric flasks and evaporated to dryness under vacuum. Dry air was then admitted to the flask. The succeeding operations of filling the flask with solvent and then filling the glass-stoppered absorption cells with solvent were carried out in a dry box. Light absorption measurements were made on a Beckman DU or a Cary, Model 14 spectrophotometer. Since the color intensities in the chloroform were temperature dependent (except for the *p*-methoxy compound) the cell compartment was kept at 25.0±0.2°. Optical densities of more-concentrated solutions were measured using 0.1-cm cells. A very rapid initial partial fading, which could not be followed, occurred with the tri-*p*-tolyl and triphenyl compounds. This was followed by a slow fading reaction which obeyed exact second-order kinetics. This was corrected for by extrapolation to zero time.

RESULTS

The absorption spectra of the triarylmethyl perchlorates in chloroform in the visible region were very similar to those obtained in 50–70% sulphuric acid* except that the absorption maxima were shifted from 2–8 mμ to the red. The quantity $D_{\lambda_{max}}/\int Dd_\lambda$, the

**We have observed that the carbonium ion spectrum for each of these compounds is altered in more-concentrated sulphuric acid. These changes, which are still being investigated, become marked in regions above 80%, 100%, and 102% sulphuric acid for tris-p-methoxyphenylmethyl, tri-p-tolylmethyl, and triphenylmethyl cations, respectively, and may account for some of the discrepancies in carbonium ion spectra reported in the literature.*

For personal use only.

optical density at the wavelength maxima divided by the area under the curve, was identical to within 2% in sulphuric acid and chloroform.

The variation of optical density with concentration of dissolved salt is shown in Fig. 1

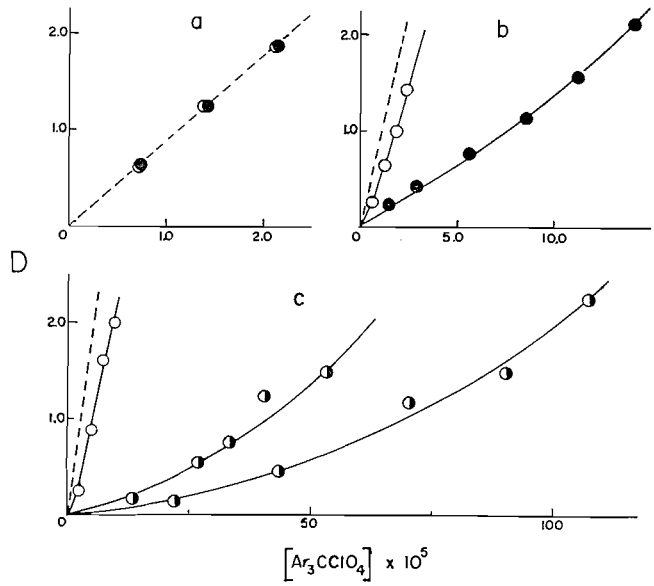

FIG. 1. Variation of optical density with molarity of dissolved triarylmethyl perchlorate. (*a*) $(p\text{-}CH_3OC_6H_4)_3C^+ClO_4^-$, (*b*) $(p\text{-}CH_3C_6H_4)_3C^+ClO_4^-$, (*c*) $(C_6H_5)_3C^+ClO_4^-$; ○ dry $CHCl_3$, ◑ partially dried $CHCl_3$, ● wet $CHCl_3$; the broken line corresponds to the extinction coefficient found for the carbonium ions in H_2SO_4 (Table I).

TABLE I

for the three carbonium perchlorates dissolved in both "dry" and "wet" chloroform. It can be seen that the ionization of tris-*p*-methoxyphenylmethyl perchlorate is complete in both wet and dry chloroform and that hydrolysis of this highly resonance stabilized carbonium ion does not proceed to a measurable extent. (The excellent agreement in Fig. 1*a* between the experimental points for chloroform solution and the line for 56.8% sulphuric acid may be fortuitous since a somewhat *higher* extinction coefficient has been reported for this ion in nitrobenzene (3).)

Tri-*p*-tolylmethyl perchlorate and triphenylmethyl perchlorate both show a reduction in the concentration of carbonium ion, particularly the triphenyl compound in the partially dried solvent (Fig. 1*c*). A wet chloroform solution of the latter could not be studied since a turbid solution resulted when sufficient perchlorate was used to produce a measurable color. The difficulty in obtaining reproducibly "dry" samples of chloroform precludes any exact comparison between the three perchlorates in the dried and partially dried solvents.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Since all the triarylmethyl perchlorates are highly colored in the solid state, it is generally believed that covalent forms of these compounds are unimportant. The approach, in the present cases, to complete ionization, which accompanies rigorous drying of the solvent is in accord with this. The slow fading of the carbonium ion color may be due to a solvolysis reaction corresponding to eq. [3] or to ether formation, but it seems unlikely that the very fast initial decrease in color could be due to this. We believe, in fact, that the latter effect is due to the rapid hydrolysis of the carbonium perchlorate ion pair by the small amount of water present and that the curves in Fig. 1 are explained by the equilibria shown in eq. [4]. (Traces of acid present in the chloroform would reverse these reactions but we believe that acids are absent since prolonged treatment with anhydrous potassium carbonate always *increased* the apparent extinction coefficient.)

There are several possible structures for the colorless hydrolysis product, and their relative concentrations should depend on the amount of water present.

Specific solvation effects such as those shown above involving hydrogen bonding (14, 15) will be most important in the low dielectric solvent chloroform. With a limited amount of water it seems likely that I would be formed whereas in the wetter solutions the carbinol would be expected to become less and less important in the dispersal of the positive charge. That is, the ion pairs II, III, and eventually IV, the carbinol plus the normal hydrated form of perchloric acid (16, 17), should become the principal cations in solution.

THE POLARIZATION OF THE FLUORESCENCE OF 1- AND 2-NAPHTHOIC ACID[1]

ROBIN M. HOCHSTRASSER

The naphthoic acids have received considerable spectroscopic attention within recent years. Weller (1) and, more recently, Porter and Jackson (2) have determined pK values for the lowest excited states of the molecule. Kasha and El Bayoumi (3) have measured solvent spectral shifts in solution. Hochstrasser examined the fluorescence and phosphorescence spectra in various solvents (10).

Porter and Jackson concluded that excitation to the lowest excited singlet level of the acids involves an orbital promotion of the type $n \rightarrow \pi^*$. This conclusion was based on the vastly different pK values for the molecule in its ground and first excited singlet state. The large difference in pK (pK^* − pK = 8 units) quoted by these authors applies to the protonated acid − acid equilibrium and not, as stated, to the acid–anion equilibrium (1). The value of ΔpK for the anionic system is about 2–4 units (5). Therefore the conclusions regarding the orbital nature of the lowest excited singlet level are not convincing.

On the basis of absorption intensity and solvent effects, El Bayoumi and Kasha assumed that the first excited singlet state is of π,π^* character, for which only slight changes of acid strength would be predicted.

Absorption spectra need not always provide proof of the character of the *lowest excited level* of a molecule. If absorption to this state is very weak, as for example would be the case for an $n \rightarrow \pi^*$ transition, a nearby strong transition, e.g. $\pi \rightarrow \pi^*$, could mask the weak transition. This is especially true for organic acids since the absorption spectra are characteristically diffuse.

Fluorescence originates from the lowest excited singlet level for essentially all common polyatomic molecules. Thus only by means of emission studies of diffuse spectra can conclusive date be obtained for extremely weak bands which lie very close to stronger bands. In this note some results on the polarized emission spectra of thin crystals of 1- and 2-naphthoic acid are presented in order to determine the direction of the transition moment connecting the ground and emitting levels.

The crystal structures of 1-naphthoic acid (6) and of 2-naphthoic acid (7) are known and these provide the exact orientations of the molecules in the unit cell. For both acids the crystal is composed of planar dimeric units and for 1-naphthoic acid the normal to the dimer plane is nearly coincident with the crystallographic b-axis. Very thin ($\sim$30 μ), microscopically perfect plates were prepared by sublimation. The crystals were mounted on quartz disks with the b-axis vertical and the blue fluorescence (excited by Hg 3130 Å) was observed normal to the *100* face. The emission was analyzed by a polaroid sheet

and detected by our modified Hilger E2 spectrograph (4). The emitted intensities polarized parallel to the crystallographic axes were either maximal or minimal. The spectra was measured with the crystals at 300° K.

Crystallographic Data

The data of Trotter (6, 7) were used for the descriptions that follow. 'Oriented gas' intensity ratios were calculated from known atomic co-ordinates.

1-Naphthoic acid.—The crystal is monoclinic (space group $P2_1/a$) with $\beta = 92.2°$. The unit-cell dimensions are $a = 31.12$, $b = 3.87$, $c = 6.92$ Å. The acid crystallizes, either from solution or after sublimation, in prisms which are elongated along the b-axis with (*100*) developed. The aromatic rings of the centrosymmetric dimer and the carboxyl (hydrogen-bonded) ring are not in the same plane. The deviation from coplanarity amounts to approximately 11°. The 'oriented gas' intensity ratio for a transition polarized perpendicular to the carboxyl plane is $I_b/I_c = 2.6$ while the value of this ratio for moments perpendicular to the aromatic ring planes is 4.2. The molecules are so arranged in the crystal that a line with any direction, but lying on the molecular plane (aromatic *or* carboxyl), always has a larger projection on the c than on the b crystallographic axis. This line need only deviate by a small angle from the plane for I_b/I_c to exceed unity. For example, the values of I_c/I_b (in parenthesis) for the lines joining certain carbon atoms of the 1-naphthyl group are as follows: 1,4 (4.5); 2,7 (6.9); 1,5 (1.4); 2,6 (6.3). Thus, for this crystal, a measurement of the dichroic ratio in absorption or the intensity ratio in emission normal to the (*100*) face should indicate unambiguously whether or not the electronic transition is polarized in or out of plane.

2-Naphthoic acid.—The crystal is monoclinic ($P2_1/a$) with $\beta = 92.6°$; $a = 30.59$, $b = 5.00$, $c = 5.63$ Å. The acid crystallizes as prisms elongated along the b-axis and sublimation flakes are developed on (*100*). The aromatic and carboxyl planes are parallel within experimental limits. The intensity ratio normal to (*100*) cannot give nearly so much information in this case. Both in-plane and out-of-plane transitions may be b-polarized. Values of I_b/I_c are as follows: 1.43 (normal to the plane of the dimer); 4.0 (longest axis of naphthyl); 3.6 (shortest axis of naphthyl). If the measured value is greater than 1.43 yet less than 3.6 there is good indication that the transition moment lies in the molecular plane.

The Fluorescence of 1-Naphthoic Acid

The emission spectrum is a broad band with a peak intensity at 4415 Å. The intensity ratio I_c/I_b was 1.8:1. The polarization ratio is consistent with a transition moment in the molecular plane, directed along a line which joins the bisectors of 1—2 and 5—6 bonds of a naphthalene ring. However, this conclusion neglects crystal-induced mixing of oppositely polarized states which could considerably modify the presently assumed 'oriented gas' model.

The Fluorescence of 2-Naphthoic Acid

The fluorescence was broad and structureless with an intensity maximum at 4565 Å. The polarization ratio was $I_b/I_c = 1.7$, which suggests a transition moment in the plane of the molecule.

The Assignment of the Nature of the Transitions

$n \rightarrow \pi^*$ promotional transitions correspond to the promotion of an electron from the lone-pair orbital of the carbonyl oxygen (or the acidic oxygen) into an antibonding π-orbital which is mainly localized on the carbonyl group. Such transitions between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

orbitals which are respectively symmetric and antisymmetric to reflection in the molecular plane are necessarily polarized perpendicular to the molecular plane. $\pi \rightarrow \pi^*$ transitions are polarized in the molecular plane. The allowed levels in the C_{2h} symmetry of the dimer are B_u (x- and y-polarized) and A_u (z or $\perp$ polarization). Therefore the vibronic symmetry of the emitting level is B_u and the nature of the transition from this level to the ground state is $B_u \rightarrow A_g$ ($n^2\pi\pi^* \rightarrow n^2\pi^2$).

The excited states of the monomer are probably split by exciton interaction (8) in the dimer. If the monomeric lowest excited level is considered to lie in the plane and along the long axis of the aromatic ring, the resulting dimer states are A_g and B_u in order of increasing energy. Fluorescence from a dimer of this type would be an electronically forbidden transition. The order of dimer states is inverted for short-axis transition moments in the monomer. It is very likely that the lowest transition of the monomer involves contributions from both polarizations as in the case of unsubstituted naphthalene (9).

The transition-moment direction calculated from the observed polarization ratio for 1-naphthoic acid should correspond to the resultant of the monomeric moments. A theoretical computation (dipole–dipole approximation) of the dimer levels which arise from the interaction of two monomeric states of this nature yields the result that the lowest excited dimer level has B_u symmetry. This is consistent with the notion that the observed emission involves an allowed electronic transition $B_u \rightarrow A_g$ and is not mainly a vibronically allowed combination as would have to be the case if the lowest dimer excited state had the symmetry A_g.

Further results of the 1-naphthoic acid crystal are in preparation.

IMPROVED PREPARATION OF BISTRIFLUOROMETHYLARSINE*

W. R. Cullen

Bistrifluoromethylarsine was first prepared by reducing iodobistrifluoromethylarsine with either lithium aluminum hydride (16% yield) or zinc and hydrochloric acid (43% yield) (1). The reduction of chlorobistrifluoromethylarsine with lithium aluminum hydride has been reported to proceed smoothly at ca. −25°, giving a higher yield of bistrifluoromethylarsine (70%) (2). It has now been found that this method is unreliable

and can result in complete failure. However, bistrifluoromethylarsine can be prepared by the reaction of chlorobistrifluoromethylarsine with excess hydrogen chloride, in the presence of mercury. The yield is high and the arsine can be easily separated from unreacted hydrogen chloride and the only other volatile reaction product, tetrakistrifluoromethyldiarsine.

Analogous reactions have been used to prepare alkyl- and aryl-trifluoromethylarsines (3, 4):

$$R_2AsI + Hg + CF_3I \rightarrow R_2AsCF_3.$$

Burg and Mahler (5) have reported that bistrifluoromethylphosphine can be prepared in 35% yield from the reaction of iodobistrifluoromethylphosphine with hydrogen chloride in the presence of mercury: other protic acids such as trifluoroacetic acid and phosphoric acid can be used. However, no bistrifluoromethylarsine is obtained when trifluoroacetic acid is used instead of hydrogen chloride. Burg and Mahler have suggested that the phosphine is formed through the following sequence:

$$(CF_3)_2PI + 2Hg \rightarrow (CF_3)_2PHg_2I \xrightarrow{HCl} (CF_3)_2PH,$$

but this does not easily account for the low yield of bistrifluoromethylphosphine or for the formation of chlorobistrifluoromethylphosphine. This scheme could apply to the present reaction though an alternative seems as likely:

$$(CF_3)_2AsCl + Hg \rightarrow (CF_3)_2As{-}As(CF_3)_2 \xrightarrow{HCl} (CF_3)_2AsH + ClAs(CF_3)_2.$$

Both these steps are possible since the reaction of chlorobistrifluoromethylarsine with mercury produces the diarsine quantitatively (2), and shaking the diarsine with excess hydrogen chloride and mercury produces bistrifluoromethylarsine in high yield. Such a mechanism, if it were the only one operating, would limit the yield of bistrifluoromethylphosphine to a maximum of 50% since chlorobistrifluoromethylphosphine does not react with mercury (6).

EXPERIMENTAL

Volatile reactants and products were manipulated in a glass vacuum system out of contact with oxygen and moisture. Chlorobistrifluoromethylarsine was prepared by reacting the corresponding iodoarsine with silver chloride (1). The product was distilled in a nitrogen atmosphere and boiled at 47° (lit. value, 46° (by extrapolation) (7)). Tetrakistrifluoromethyldiarsine was prepared by reducing chlorobistrifluoromethylarsine with mercury (2).

Reaction of Chlorobistrifluoromethylarsine with Hydrogen Chloride in the Presence of Mercury

The arsine (0.673 g), dry hydrogen chloride (0.729 g), and mercury (82 g), in a sealed tube (50 ml), were shaken at 23° for 17 hours. Trap-to-trap distillation gave only three fractions: tetrakistrifluoromethyldiarsine (0.067 g), which condensed at −78° and which was identified by its low vapor pressure (<20 mm at 23°) and by its infrared spectrum (1); bistrifluoromethylarsine (0.505 g, 86% yield), which condensed at −130° and which was identified by its molecular weight (found: 214, calc: 214) and by its infrared spectrum (1); hydrogen chloride (0.614 g), which condensed at −196°. No permanent gas was produced.

Reaction of Chlorobistrifluoromethylarsine with Trifluoroacetic Acid in the Presence of Mercury

The arsine (0.713 g), trifluoroacetic acid (7.6 g), and mercury (60.5 g), in a sealed tube (50 ml), were shaken at 23° for 40 hours. A slow reaction took place and eventually a considerable amount of white solid was deposited. Trap-to-trap distillation and infrared examination of the fractions isolated showed that no bistrifluoromethylarsine had been produced.

Reaction of Tetrakistrifluoromethyldiarsine with Hydrogen Chloride in the Presence of Mercury

The diarsine (1.128 g), hydrogen chloride (0.614 g), and mercury (63 g), in a sealed tube (50 ml), were shaken at 23° for 22 hours. Trap-to-trap distillation gave only three fractions: unreacted tetrakistrifluoromethyldiarsine (0.149 g), which condensed at −78°; bistrifluoromethylarsine (0.943 g, 84% yield), which condensed at −132°; and hydrogen chloride, which condensed at −196°. The fractions were identified as above. No permanent gas was produced.

INTEGRAL HEATS OF MIXING OF C_6-ALKANES IN PERFLUOROTRIBUTYLAMINE AND IN PERFLUOROCYCLIC OXIDE ($C_8F_{16}O$) AT 60° C

Dan E. Nicholson

In connection with studies of the thermodynamic properties of solutions of isomeric C_6-hydrocarbons, the integral heats of mixing of these compounds have been determined in a perfluoroamine and a perfluoroether. The calorimeter and accessory apparatus were described previously (1). Provision was made in the calorimeter design for investigations of energy changes at elevated pressures and temperatures. Earlier studies of the experimental and theoretical heat effects involved in other fluorocarbon–hydrocarbon systems have been reported (2, 3, 4). Spectroscopic grade hydrocarbons obtained from the American Petroleum Institute were used without further purification. Perfluorocyclic oxide and perfluorotributylamine were purchased from the Minnesota Mining and Manufacturing Company under the designation FC-75 and FC-43, respectively. Both samples were purified by distillation in a 50-plate column so that the initial 20% and the final 20% portions were discarded.

Eight calorimetric experiments for each of the 10 binary solutions of the five hydrocarbons in the two solvents were performed covering the concentration range from 0.1

2,3-Dimethylbutane–$C_8F_{16}O$	−2133	285	701

reproduce the calorimetric measurements within about ±1%. The maximum endothermic integral heat of mixing calculated from the equation above is approximately 550 cal per mole of mixture in solutions equimolar in *n*-hexane and perfluorotributylamine.

One of the objectives of the present investigation was to determine whether or not useful empirical relationships involving the group-equivalent concept could be formulated to correlate the heats of mixing. For example, one may consider the heat of mixing of 2,3-dimethylbutane with a solvent to arise from contributions of two isopropyl groups. Likewise, for 2-methylpentane the observed heat effects could be attributable to isopropyl and *n*-propyl groups. An internally consistent set of relationships based upon this approach could not be developed. As an illustration of the application of the group-equivalent concept the values shown in Table II were estimated for the $C_8F_{16}O$–C_6H_{14}

TABLE II

Structural unit	Contribution to the heat of mixing in $C_8F_{16}O$ as solvent at infinite dilution, cal/mole
$H_3C—CH_2—CH_2---$	1055
$H_3C—\underset{\displaystyle H}{\overset{\displaystyle CH_3}{\overset{\vert}{\underset{\vert}{C}}}}---$	930
$H_3C—CH_2---$	703
$H_3C—CH_2—CH_2—CH_2---$	1406
$H_3C—CH_2—\overset{\displaystyle CH_3}{\overset{\vert}{CH}}---$	1295
$H_3C—\underset{\displaystyle CH_3}{\overset{\displaystyle CH_3}{\overset{\vert}{\underset{\vert}{C}}}}---$	1087

systems. The heats of mixing at infinite dilution were obtained by means of large-scale plots. The group-equivalent quantities for propyl, ethyl, and *n*-butyl structures were assigned from the heats of mixing of *n*-hexane. The value for the isopropyl group was derived from the appropriate quantities for 2-methylpentane and the propyl group. Similarly, for the *sec*-butyl structure, the group-equivalent value was obtained from 3-methylpentane while the *tert*-butyl structure was estimated from heats of mixing for 2,2-dimethylbutane. For 2,3-dimethylbutane the calculated heat of mixing is, therefore, 2×930 or 1860 cal/mole of hydrocarbon. The observed value for the heat of mixing is 2040 cal/mole.

Some comparisons between the experimental heat changes from the current work and those from regular solution theory (equation 17, p. 124, reference 5) have also been made. From solubility parameters and the appropriate molar volumes (3, 6) the values given in Table III are found for solutions in $C_8F_{16}O$ (solubility parameter = 5.9).

picric acid and 1,3,5-trinitrobenzene. The derivative with 1,3,5-trinitrobenzene is a well-defined crystalline compound with a sharp melting point and may be of use in the classification and identification of trioxan. Trioxan did not form addition compounds with picrolonic acid or 1,2,7-trinitrofluorenone. Other cyclic ethers, e.g., dioxan and paraldehyde, did not form compounds with 1,3,5-trinitrobenzene or picric acid.

EXPERIMENTAL

Reaction of Trioxan with 1,3,5-Trinitrobenzene

Two grams of 1,3,5-trinitrobenzene was dissolved in slightly over the minimum quantity of boiling ethanol and 1.75 g of trioxan was added. Cooling of the solution caused the separation of pale yellow crystalline needles (2.6 g) which, on recrystallization from ethanol, yielded a compound of m.p. 94–97°. It was necessary to add a small amount of trioxan during the recrystallization; otherwise crystals of 1,3,5-trinitrobenzene separated. The addition compound could be similarly obtained in carbon tetrachloride, chloroform, or benzene. The derivative, however, did not readily precipitate from these solvents, but an apparently purer compound was obtained from carbon tetrachloride as pure white needles, m.p. 97°. Analysis: Found: C, 35.74; H, 2.92; N, 14.20; CH_2O, 30.16. $(CH_2O)_3.C_6H_3(NO_2)_3$ requires: C, 35.65; H, 2.99; N, 13.86; CH_2O, 29.70. The analysis indicates a 1:1 molecular compound of trioxan and 1,3,5-trinitrobenzene.

Reaction of Trioxan with Picric Acid

A hot saturated solution of picric acid in ethanol was added to an almost saturated solution of trioxan in boiling ethanol. When the mixture was cooled, a bulky yellow mass which consisted mainly of trioxan, separated. The trioxan was removed by evaporation in air at room temperature, leaving a pale yellow residue, presumably a picrate of trioxan. This derivative decomposed on attempted recrystallization so no analysis was made. The melting point was 58°, and mixtures with trioxan and with picric acid melted at 40–60° and 60–90° respectively, suggesting that the derivative was indeed a compound of trioxan and picric acid.

All melting points are uncorrected.

of excess pyridine, has been described recently by Motl *et al.* (1, 2), who obtained a mixture of isomeric hydrocarbons from both selin-4-ol and dihydro-α-cadinol. When this reagent was used in the current study with α-terpineol, dipentene (70%) and terpinolene (21%) were obtained and no other isomeric hydrocarbon was detected by gas–liquid chromatography (GLC). This is a considerable reduction in the number of isomers formed over that obtained when acidic reagents were used (3). However, because of the large excess of pyridine used with this reagent, the reaction is cumbersome. A much more convenient, and in some instances more specific, dehydration has now been obtained by heating the alcohol under reflux at 200 to 230° from 1 to 6 hours in the presence of twice its weight of neutral alumina (Woelm, activity grade I) to which 1 to 2% of pyridine or quinoline had been added. This reagent gave highly satisfactory results with α-terpineol, dihydro-α-terpineol, menthol, borneol, cedrol, and dihydroeudesmol, although the products obtained from linalool and isopulegol were more complex.

The amount of α-terpineol which had reacted with the reagent during 1 hour at 180°, 200°, and 220° C was 10%, 40%, and 82% respectively. The dehydration was virtually complete after 6 hours at 220° C, when dipentene (83%) and terpinolene (6%) were the only compounds detected by GLC. When α-terpineol was heated under reflux with neutral alumina alone, the steam-volatile product was found to be composed of α-terpinene (13%), dipentene (31%), *p*-cymene (16%), γ-terpinene (9%), terpinolene (26%), and *p*-mentha-2,4(8)-diene (5%), a composition very similar to that obtained with aqueous acidic reagents (2).

With dihydro-α-terpineol this base-modified alumina gave *trans*- (47%) and *cis*- (44%) *p*-menth-8-ene and *p*-menth-4(8)-ene (7%) after 1 hour reaction time. Since the ratio of cis to trans isomers in the starting material was 1:1 there appears to be no preferential reaction of either of the two isomers. Using the reagent of Motl *et al.* (1) the same mixture of hydrocarbons was obtained, but the yield of the *p*-menth-8-ene isomers was only 70%. Menthol, when treated with the new reagent for 1 hour, gave *p*-menth-2-ene (40%) and *p*-menth-3-ene (6%), whereas borneol was dehydrated to a mixture of camphene (68%) and tricyclene (16%). These results are very similar to those described by Pines and Pillai (4), who carried out the dehydration reaction of menthol, borneol, and neopentyl alcohol over ammonia-modified alumina in the gas phase. These authors propose that the dehydration takes place by a concerted mechanism involving both acidic and basic sites on the catalyst, whereas isomerization is suppressed by the preferential poisoning of the "strong acid sites" (5). Neutralization of acidic sites was confirmed in this study by evacuating the pyridine-treated alumina for 6 hours, when about 0.8% base was retained and no change in the reaction with α-terpineol was observed. Recently, Beranek *et al.* (6) have studied the dehydration of 4-methylcyclohexanol in the gas phase with a pyridine-modified alumina and have demonstrated that the active centers of the catalyst responsible for dehydration differ from those causing olefin isomerization. These authors also showed that, with unmodified alumina, isomerization is extensive and subsequent to dehydration. Thus there appears to be no difference in the reaction of tertiary or secondary alcohols over alumina catalysts in either the gas or liquid phase. The main feature of the base-modified alumina catalyst is the suppression of isomerization of the primary dehydration products by inhibiting carbonium-ion formation.

Dehydration of sesquiterpene alcohols with the new dehydrating agent also proceeds smoothly. Cedrol was converted to α-cedrene (85%) in 1 hour at 230° with only traces of an isomeric hydrocarbon being detected by GLC. When cedrol was treated with the thionyl chloride – pyridine reagent these two isomers were obtained in the ratio of 5:3. Dihydroeudesmol was similarly converted in high yield to a single hydrocarbon. Its

infrared spectrum had strong bands at 1645 and 880 cm^{-1}, showing it to be the isomer with the isopropenyl group. The dehydration of dihydroeudesmol with other reagents, as studied by Ruzicka *et al.* (7), produced invariably a mixture of dihydroeudesmene isomers. Thus it appears that the new reagent inhibits the formation of an exocyclic double bond, and it forms, therefore, an excellent complement to the common acidic reagents, which produce the exocyclic double bond preferentially in the early stages of the reaction.

The simplicity of the reaction with base-modified aluminas, however, does not seem to be general. Whereas the major reaction product with linalool was myrcene, four other hydrocarbons were detected in the reaction product. With isopulegol an even more complex mixture was obtained, nine hydrocarbon peaks and five peaks in the oxygenated terpene range being recorded by GLC. Since both of these alcohols are unstable at their boiling points, the formation of a complex mixture may be due to thermal decomposition or rearrangement rather than to the dehydration reaction itself. The reaction is being studied in more detail and the results obtained will be reported elsewhere.

EXPERIMENTAL

The gas chromatographic analyses were carried out with a modified Beckman GC-2 chromatograph. Quantitative data were obtained on the 12 ft$\times\frac{1}{4}$ in. (O.D.) rapeseed oil and 6 ft$\times\frac{1}{4}$ in. adipate and azelate polyester and polyethylene glycol columns described previously (2, 8, 9). The percentage composition was obtained by the triangulation method ($\pm 3\%$) and the average values are reported. The retention times of the sesquiterpenes and the *p*-menthenes are shown in Tables I and II. Those of the other compounds

For personal use only.

have been reported earlier (9). Preparative runs were carried out as before on a 10- to 20-mg scale (2). The infrared spectra were recorded with a Perkin–Elmer model 21 double-beam spectrophotometer. Borneol, menthol, linalool, and isopulegol were commercial products, whereas dihydro-α-terpineol (50% trans and 50% cis) was prepared by hydrogenation of redistilled α-terpineol (99% pure), using platinum oxide as catalyst and methanol as solvent. Dihydroeudesmol, m.p. 85–86° C, $[\alpha]_D^{25}$ +18.0° ($CHCl_3$), was obtained by a similar hydrogenation of eudesmol.

A typical dehydration experiment was carried out as follows. Neutral alumina (Woelm, activity grade I) (2.0 g) was placed into a 25-ml flask having two necks with ground-glass joints. To this was added pyridine (0.02 to 0.04 g) and α-terpineol (1.00 g) and the mixture was heated under reflux at 220° C (oil bath) for 6 hours. The mixture was then steam-distilled and the volatile product was taken up in a small volume of ether. After the ethereal solution had been dried over anhydrous sodium sulphate, it was transferred quantitatively to a flask having a long neck (2) and the ether was evaporated on a steam bath. The residue (0.79 g, 89% of theory) was analyzed by GLC. The composition of the hydrocarbons obtained was determined on the different columns at 80° C, and the amount of unreacted α-terpineol (in relation to the amount of hydrocarbons formed), at 110° or 130° C. The data obtained showed less than 1% unreacted alcohol, 93% dipentene, and 7% terpinolene. When quinolene was used as base instead of pyridine the respective yields of hydrocarbons were 92 and 6%.

In another experiment, neutral alumina (100.0 g) was thoroughly mixed with pyridine (2.0 g) and the mixture was evacuated to 0.5 mm Hg at room temperature for 6 hours. The residue (100.8 g) was used as such in the dehydration of α-terpineol, when practically identical results were obtained.

All other alcohols mentioned, except dihydroeudesmol, were dehydrated in the manner described in the first instance. Dihydroeudesmol (0.05 g) was weighed into a 10 cm × 5 mm glass tube. To this was added pyridine-modified alumina (0.20 g) and the lower end of the tube was immersed into an oil bath at 230° C in such a manner that the upper half of the tube acted as an air condenser. After 1 hour the tube was cooled and the mixture was extracted with ether. The residue (0.03 g), after evaporation of the ether, was analyzed on the polyester columns at 160° and 180° C, when only a single hydrocarbon peak was recorded. The infrared spectrum was, therefore, recorded directly without further purification.

The dehydrations with thionyl chloride were carried out as follows. To the alcohol (1.00 g) was added dry pyridine (40 ml) and the solution was cooled to about 5° C. Thionyl chloride (3.0 g) was then added dropwise with shaking. After the mixture had been shaken for another 5 minutes, sodium carbonate (3 g) in water (15 ml) was added slowly. The mixture was extracted thrice with ether and the ethereal solution was washed with a saturated tartaric acid solution until all pyridine had been removed; pyridine was found to interfere with the GLC analysis. It was then washed with water and worked up as described above.

The author is grateful to Mr. M. Granat for technical assistance and to Miss I. M. Gaffney for recording the infrared spectra.

SOLVENT EFFECTS ON THE RING PROTON MAGNETIC RESONANCE SPECTRA OF SOME SUBSTITUTED QUINOLINES

T. SCHAEFER

Proton resonance spectra of unsaturated ring compounds are strongly solvent dependent. The spectra of substituted benzenes and heterocyclic compounds are affected both by the nature of the solvent and the degree of dilution (1, 2). The variation of the "internal" chemical shifts in these compounds in different solvents is surprisingly large since these systems are not generally regarded as involving either hydrogen bonding or other specific molecular association. Comparison of the shifts of the ring protons in these aromatic compounds in *n*-hexane, acetone, and benzene solvents leads to the conclusion that highly specific solute–solvent interactions are involved, at least in the benzene solutions. This note extends the experimental results to some substituted quinolines.

EXPERIMENTAL AND RESULTS

Dilute solutions of the compounds were made up to a uniform concentration of 5 mole% in *n*-hexane, benzene, and acetone. All measurements were made at 60 Mc/sec and peak positions were measured relative to an external chloroform reference.* Bulk susceptibility corrections were applied.

In Table I the shifts of the ring protons, corrected for bulk susceptibility differences, are tabulated relative to an external chloroform reference. The shifts are given only to the nearest cycles/sec because in many cases the analysis of the complex spectra did not allow a closer estimation. In some cases the benzene solvent peak obscured a few solute peaks but sometimes the preferential shifts caused by benzene allowed analysis of the spectra in benzene but not in *n*-hexane or acetone. An aid in the assignment of peaks was the fact that the ring protons ortho to a methyl or methylene group couple weakly to the latter protons. However, this also decreased the accuracy with which shifts and coupling constants could be extracted.

In Fig. 1 the proton shifts in *n*-hexane are taken as a reference point and the alterations of the shifts in the acetone and benzene solutions are plotted for all compounds. In Table II are given the coupling constants which could be obtained from the spectra. The estimated errors are relatively large because of the effects mentioned above.

**The calibrated spectra of the pure compounds and of the solutions are available upon request.*

SOLVENT EFFECTS ON THE RING PROTON MAGNETIC RESONANCE SPECTRA OF SOME SUBSTITUTED QUINOLINES

T. SCHAEFER

Proton resonance spectra of unsaturated ring compounds are strongly solvent dependent. The spectra of substituted benzenes and heterocyclic compounds are affected both by the nature of the solvent and the degree of dilution (1, 2). The variation of the "internal" chemical shifts in these compounds in different solvents is surprisingly large since these systems are not generally regarded as involving either hydrogen bonding or other specific molecular association. Comparison of the shifts of the ring protons in these aromatic compounds in *n*-hexane, acetone, and benzene solvents leads to the conclusion that highly specific solute–solvent interactions are involved, at least in the benzene solutions. This note extends the experimental results to some substituted quinolines.

EXPERIMENTAL AND RESULTS

Dilute solutions of the compounds were made up to a uniform concentration of 5 mole% in *n*-hexane, benzene, and acetone. All measurements were made at 60 Mc/sec and peak positions were measured relative to an external chloroform reference.* Bulk susceptibility corrections were applied.

In Table I the shifts of the ring protons, corrected for bulk susceptibility differences, are tabulated relative to an external chloroform reference. The shifts are given only to the nearest cycles/sec because in many cases the analysis of the complex spectra did not allow a closer estimation. In some cases the benzene solvent peak obscured a few solute peaks but sometimes the preferential shifts caused by benzene allowed analysis of the spectra in benzene but not in *n*-hexane or acetone. An aid in the assignment of peaks was the fact that the ring protons ortho to a methyl or methylene group couple weakly to the latter protons. However, this also decreased the accuracy with which shifts and coupling constants could be extracted.

In Fig. 1 the proton shifts in *n*-hexane are taken as a reference point and the alterations of the shifts in the acetone and benzene solutions are plotted for all compounds. In Table II are given the coupling constants which could be obtained from the spectra. The estimated errors are relatively large because of the effects mentioned above.

**The calibrated spectra of the pure compounds and of the solutions are available upon request.*

DISCUSSION

The preferential shifts of the ring protons at various positions relative to the polar group still await a satisfactory explanation. It is clear that a specific solute–solvent interaction is present, at least in benzene. In contrast to the substituted toluenes (1), however, we can observe the solution shifts of protons in both the meta (β) and para (γ) position (protons 3 and 4) to the nitrogen. From Table I and Fig. 1 it is clear that although proton 4 occurs to a much lower field than proton 3 in *n*-hexane solutions (resonance effect) its behavior in benzene and acetone solution parallels that of proton 3. Hence there is no simple relationship between charge density at the carbon to which the proton is bonded and the magnitude of the solvent shift for the proton. Qualitatively it is clear that the solvent effects increase as the distance between the negative nitrogen atom and the protons increases, but again there is no simple relationship since protons 5, 6, 7 are shifted less than protons 3 and 4 in benzene solutions. The shifts to high field of protons 5, 6, 7 are about 30 cycles/sec and this is about the value expected for the ordinary dilution shift in benzene due to the ring current effect (see reference 1). It follows that the higher shift for protons 3 and 4 must somehow be connected with the presence of the polar nitrogen although this connection is obscure. Since the π electrons of the benzene molecules are repelled by the negative nitrogen, it may be that the planar benzene molecules pack about the planar quinoline molecules in such a way as to avoid the nitrogen. This would explain why protons 2 and 8 are shifted to high field by a lesser amount than would be expected on the ring current effect of about 25–30 cycles/sec.

With one exception, the coupling constants in Table II have the values expected for ring protons. J_{23} is found to have a value of 4.0 ± 0.2 cycles/sec for all compounds, about half the value for a normal coupling constant between protons in the ortho position. This

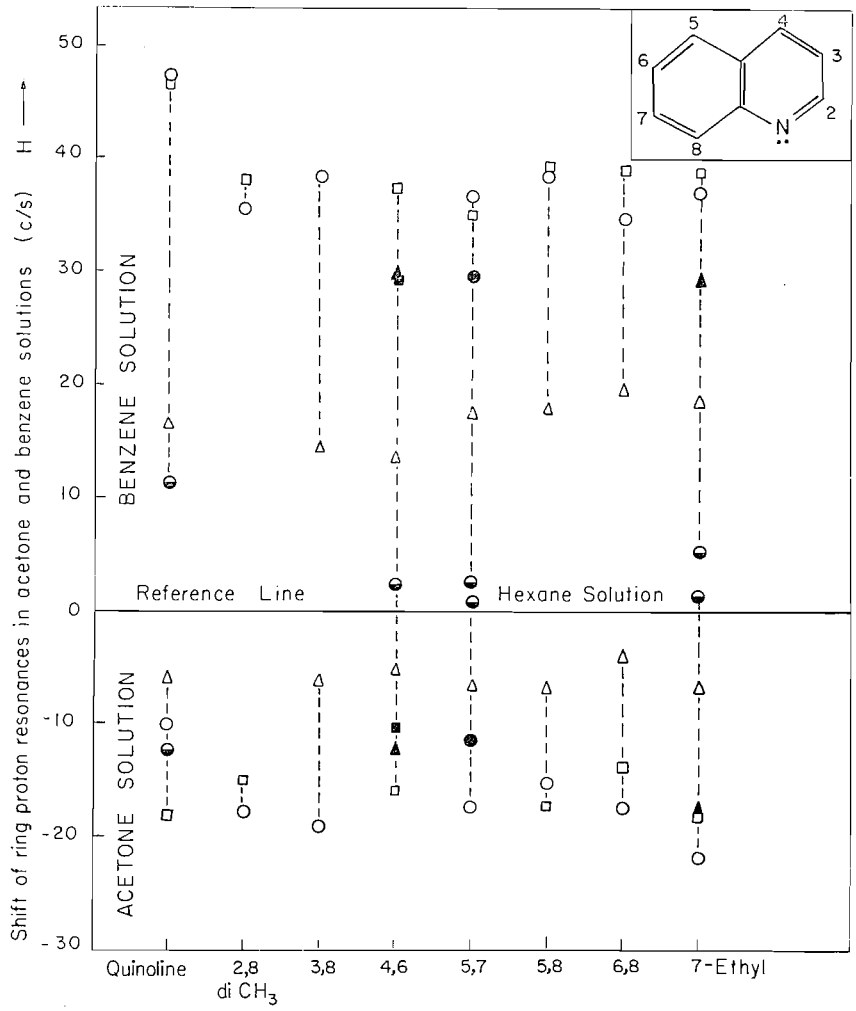

FIG. 1. Shifts of the ring protons of substituted quinolines in dilute acetone and benzene solutions relative to their position in the field for a dilute *n*-hexane solution. The shifts are given in cycles/sec for a measuring frequency of 60 Mc/sec. △, 2; □, 3; ○, 4; ▲, 5; ●, 6; ■, 7; ◒, 8.

value can be compared with one of 5.0 cycles/sec obtained from a spectrum of quinoline at 40 Mc/sec under somewhat lower resolution than was available in these experiments at 60 Mc/sec (3). Coupling of protons across the ring at positions 4 and 8 was found to be about 1 cycle/sec. Valence-bond calculations indicate coupling due to π electrons of less than 0.1 cycle/sec for the similar protons in naphthalene (4). Similar values have been found by Anet in 5,7-dimethylquinoline and 5,7-dichloroquinoline. As noted by Anet, such long-range coupling is limited to the 4- and 8-hydrogens and is comparable to coupling between hydrogen separated by five bonds in some olefins (5).

Finally, one might point out that in spectra as complex as these, preferential solvent shifts are extremely helpful in assignment of peaks as well as in the detailed analysis of groups of strongly coupled nuclei.

SURFACE EXCHANGE REACTIONS OF SILVER AND ITS IONS[1]

J. E. SANDOR[2]

ABSTRACT

The exchange reactions between silver and its ions in solution have been investigated by the use of radioactive tracers. Silver of highest purity was cleaned carefully and immersed into a radioactive silver nitrate solution. The course of the early absorption process and subsequent diffusion of the ions into the interior of the metal was followed in detail, and the diffusion coefficient at room temperature was calculated. The penetration depth was determined by controlled electropolishing of the metal, and the reverse movement of active ions from the metal into inactive solutions was also observed.

INTRODUCTION

The exchange reaction between metallic silver and its ions in solution has been investigated by several authors. This metal is of particular interest because it is available in high purity, is chemically inert, and has a convenient radioactive isotope with a half-life of 270 days.

Rollin (1) found that metallic silver, shaken with a silver nitrate solution containing radioactive silver, acquired an activity corresponding to more than 100 apparent atomic layers of silver. Baerg and Winkler (2) found that "abraded" and etched foil exchanged to different depths. They measured the "true" area by the Bowden–Rideal method (3) and tried to correlate surface area and exchange, but concluded that "the metal surfaces were poorly reproducible in respect to both exchange and area". Gerischer and Vielstich (4) observed that after a rapid initial exchange, which depended on the surface treatment, a second, slower increase in observed activity took place, and they attributed this increase to solid-state diffusion.

Tingley, Henderson, and Coffin (5) concluded from their work that generally there are two mechanisms acting in silver exchange reactions, one "kinetic" and the other a "true exchange"; which one of these was acting depended on the state of the surface.

King and McKinney (6) recently also found evidence that solid-state diffusion occurs in silver, accompanying the exchange reaction. A theoretical study of the heterogeneous reaction was done by Zimens (7). He devised equations relating the progress of the solid–liquid exchange with time, assuming that one of the following processes is the rate-determining one: (1) diffusion across the interface, (2) chemical reaction at the phase boundary, and (3) diffusion of the exchanging atoms into the interior of the solid. The rate laws for these processes are formally similar and are usually of an exponential nature.

It was the purpose of the present experiments to study the exchange between silver and its ions, following Zimens' model.

[1]*Manuscript received November 10, 1960.*
Contribution from the Mineral Sciences Division, Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada.
[2]*National Research Council Postdoctorate Fellow 1958–1960. Present address: Semiconductor Products Department, General Electric Company, Syracuse, N.Y.*

The main questions to be solved were: (1) the probable mechanism for a fast exchange to a depth of more than 100 atom layers, (2) the cause of the slow increase in observed activity after the initial exchange, and (3) a decision as to which of the three processes in Zimens' model were the rate-controlling ones. Gerischer and Vielstich (4) assumed that self-diffusion is the controlling step in the exchange; King and McKinney found some penetration of the radioisotope after the exchange. To confirm or deny these authors' findings and assumptions, an electropolishing technique was developed to measure the penetration of the radioisotope inside the solid.

Three major practical factors were considered essential to the success of the experiments: (1) use of high purity materials, (2) avoidance of oxidation and corrosion, and (3) careful preparation of the surfaces.

It should be stressed that small variations in technique can affect markedly the results of all such exchange experiments.

EXPERIMENTAL DETAILS

The radioisotope utilized for all the experiments was silver-110, obtained from Atomic Energy of Canada Ltd. It has a half-life of 270 days, and a complex beta- and gamma-ray spectrum with a maximum beta energy of 2.8 Mev and a maximum gamma-ray energy of 1.516 Mev.

All the activity measurements were done with a well-type NaI(Tl) scintillation counter. A statistical analysis of the counting assembly was done using a known source of Ag-110; the test indicated a satisfactory operation of the unit.

A 10^{-2} M silver nitrate solution was prepared with a specific activity of 6.5 μc/cc and a pH of 6.6. Metal foils were prepared from Johnson-Matthey 99.999% silver. Rods of 1.9-cm diameter and 2.5-cm length were alternately cold-rolled to 50% reduction and annealed 15 minutes at 500° C, to a final thickness of 0.0025 cm.

From these foils, samples of 1.5 cm^2 area were cut in such a way as to leave a short tip on one of the sides to use as a holder during the handling of the samples. (Silver-plated tweezers were used during all the experiments.)

These foils were cleaned in boiling ethanol for 1 hour, electropolished in a cyanide bath for 10 minutes, annealed for 20 minutes at 400° C, and finally electropolished again for 10 minutes. Samples prepared in this way showed no surface deformation when X-ray diffraction pictures were taken. These samples also stayed bright and untarnished when stored for considerable periods.

It was found that high annealing temperatures or long annealing periods produced some thermal etching, and that the pits were noticeably broadened during electropolishing.

EXPERIMENTS ON EXCHANGE AS A FUNCTION OF TIME

To find out if there was a continuous increase in activity after long periods of immersion,* 12 samples were left in a 100-cc Petri dish containing 50 ml of radioactive solution. The Petri dish was kept, for the duration of the experiments, in a well-shielded lead castle.

To simplify the handling of the specimens, they were attached by their tips to a ring of Lucite with a drop of paraffin. In this way some samples were immersed for as long as 37 days. This arrangement was adopted to avoid concentration changes in the solution

*By "long" is understood more than 1 day.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

by evaporation, and at the same time to make it possible to subject at least 12 samples simultaneously to exchange processes.

The solution was not stirred; it was assumed that even without agitation the diffusion through the diffusion layer in the liquid was much faster than the solid-state diffusion in the metal and so this factor would not influence the final results. (The ratio $D_l/D_s = 10^{12}$.)

The samples were taken out at regular intervals, rinsed carefully with cold water and alcohol, dried, and counted in the scintillation counter. The first counting was done after 9 days of immersion. No counting was done at the beginning of the exchange, because previous experiments had established a very rapid increase in activity during the first few minutes of the exchange. In the work described here the emphasis was on the longer-term exchange, particularly to show whether there is a continuous increase in activity in the samples, and whether this slow increase is due to solid-state diffusion.

A small correction had to be made to take into account the decay of the radioisotope.

EXPERIMENTAL RESULTS

Activity Increase as a Function of Time

The results of the long-term immersion tests are plotted in Fig. 1 in terms of apparent

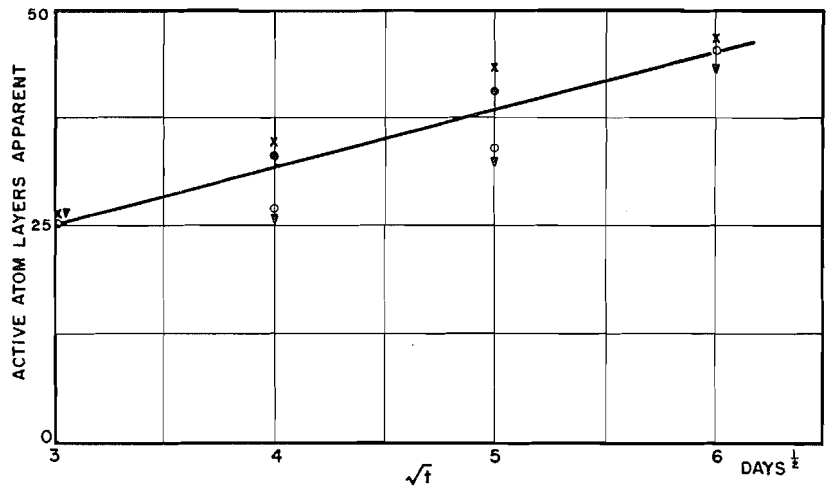

FIG. 1. Exchange as a function of time of immersion: ×, ●, ▼, ○ represent different samples.

layers of exchanged atoms as a function of time of immersion. The relation between adsorbed activity and equivalent atom layers had been established in an auxiliary electropolishing experiment. The first count was obtained after 9 days of immersion, and subsequent ones at intervals of 3 or 4 days.

The points correspond to different samples, but it seemed better to plot the average curve of the different samples than to draw a curve for each sample. There is some scatter in the points, but this was not the case when each sample was counted individually.

From this curve it can be seen that the activity increases approximately as a function of the square root of time, as expected if a diffusion process is the rate-determining process.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In the case of three samples the activity pickup was much higher than for the others. The reason for this divergence is not clear, but it may have been caused by some disturbance of the adsorption equilibrium, or by a deformation of the surfaces during the handling, which interfered with the reaction exchange – solid-state diffusion. This curve does not fit the equation $A_t = f(\sqrt{t})$.

Measurement of Penetration Depths

To find out if there was a measurable penetration of the radioactive isotope, and to calculate a self-diffusion coefficient for silver, the "exchanged" specimens were electropolished under reproducible conditions. It was ascertained that the same period of electropolishing removed the same weight of silver each time. In addition to this, before electropolishing, the samples were immersed in the electrolyte for short periods of time—ranging from 1 second to 1 minute—without applying electrical current, to see which portion of the activity was "re-exchangeable". The remaining activity in the samples was then counted.

In Table I are summarized the results of the immersion of the samples in the electrolyte

TABLE I

Exchanged samples immersed in the electropolishing solution without applying current

Sample No.	History	Time of immersion in electrolyte, sec	Initial activity, c.p.m.	Remaining activity, c.p.m.	Loss of activity, %
1	Exchanged 34 days, stored 60 days	1	14,000	8,900	36
		60		7,000	50
2	Exchanged 34 days, stored 30 days	1	12,000	7,700	36
		60		6,100	49
4	Exchanged 37 days, stored 60 days	1	25,000	18,000	28
		60		14,300	43
6	Exchanged 31 days, stored 60 days	1	13,600	7,700	43
		60		6,800	50
8	Exchanged 25 days, immediately after	1	25,000	19,200	23
		60		14,600	42
9	Exchanged 25 days, immediately after	1	24,600	18,000	27
		60		10,600	57

without applying current. It is evident that more than 40% of the activity is "exchangeable", and that between 20 and 45% of the activity is lost after the first second of immersion; in addition to this, the samples that picked up higher activity have a higher fraction of "exchangeable" atoms.

The results of the experiments done by progressively electropolishing the exchanged samples show that there is a measurable penetration of the radioactive tracer.

In Fig. 2*a* are plotted the penetration curves of some of the samples listed in Table I. The logarithm of the activity in c.p.m. is plotted as a function of the time of electropolishing. It was established by previous experiments that, under the operating conditions used, in the exchanged samples 1 minute of electropolishing was equivalent to removing an amount of silver equivalent to a thickness of 1μ.

It was observed that there was a large decrease of activity after removing the first 0.13 to 0.25 μ, and then a much smaller decrease in activity when a subsequent comparable thickness was removed.

It can be seen in Fig. 2*b* that the penetration curves are clearly the combination of two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

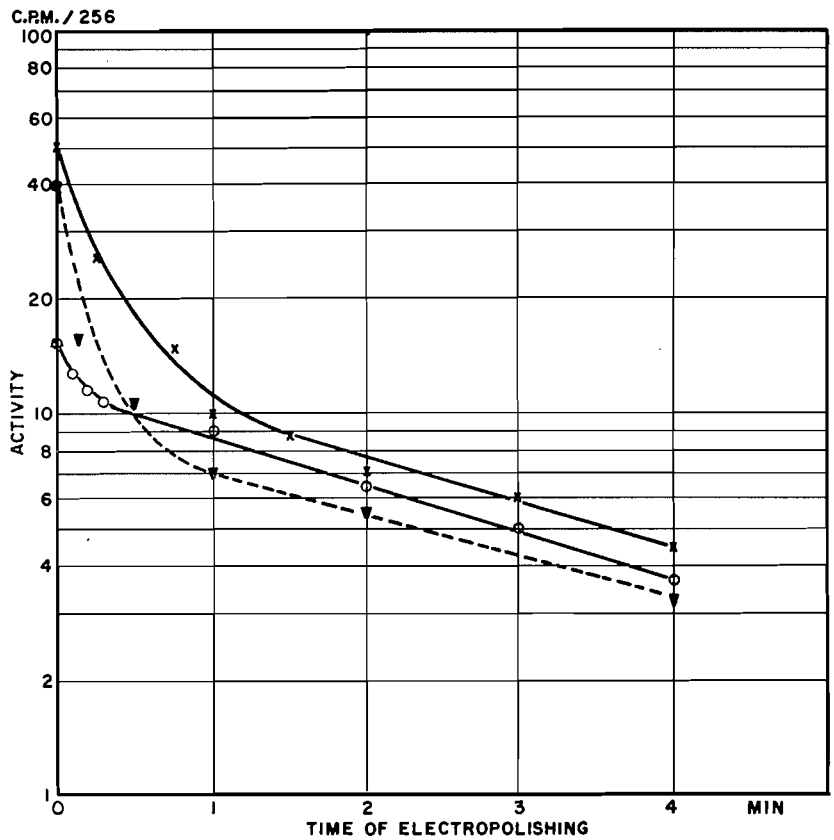

FIG. 2*a*. Penetration curves for fresh samples: ○, sample No. 2; ×, sample No. 8; ▼, sample No. 9.

independent exponential functions representing two processes proceeding at different rates.

It was observed that long storage of the foils after the exchange process affected the slope of the second part of the curves, and it made some difference in their initial slope. This effect is shown in Fig. 3. Longer storage times tended to flatten this first part.

CALCULATION OF DIFFUSION COEFFICIENT

From the data of the penetration curves the self-diffusion coefficient of silver at room temperature was calculated.

Fisher (8) made a mathematical analysis of the relation between grain boundary diffusion D_b and volume diffusion D_v by assuming that grain boundary diffusion is analogous to the diffusion of heat along a thin copper foil embedded in cork. He arrived at an expression

$$D_b = 2D_v^{1/2}(\log e)^2 \Big/ \delta\left(\frac{d\log a_x}{dx}\right)^2 (\pi t)^{1/2},$$

where e is the logarithm base and δ the grain boundary thickness. The same author

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

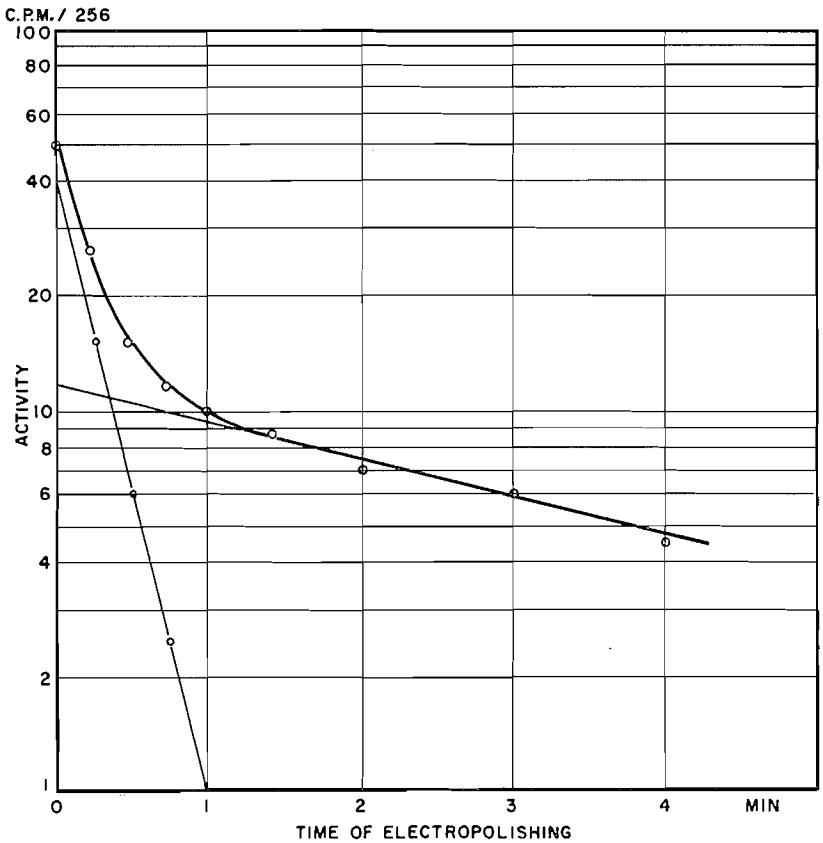

FIG. 2*b*. Penetration curves: analysis of typical curve.

assumed for δ a value of 5×10^{-8} cm that has since been criticized (9) because it is very hard to establish a uniform thickness for the grain boundaries of metals, but it can be used as an approximation. D_v can be calculated from the formula of Hoffman and Turnbull (10):

$$D_v = 0.895\exp(-49{,}500/RT)\ \text{cm}^2/\text{sec};$$

the value at 25° C is $D_v = 9.8\times10^{-38}$ cm²/sec. Inserting this value into the equation for D_b gives

$$D_b = 6\times10^{-11} \Big/ \left(\frac{d\log a_x}{dx}\right)^2 t^{1/2}$$

$$= 1.37\times10^{-20}\ \text{cm}^2/\text{sec},$$

where a_x = activity, x = penetration, and t = time of exchange. The slope of the straight part of the curves of Fig. 2*a* and a value of t = 34 days were used for the calculation.

DISCUSSION AND CONCLUSIONS

The results of this work confirm the conclusions from previous work that self-diffusion of silver is the rate-controlling step in the exchange reaction, and show clearly that there is fast diffusion in the uppermost atomic layers (approximately 300 layers). In the absence of corrosion, oxidation, or local cell action, in the case of silver a rapid exchange takes place between the surface atoms of the metal and the ions in the liquid on immersing the electropolished foils in the exchange solution. At the same time, some local cell action due to the presence of different crystal faces may take place, but in a polycrystalline material the electromotive force resulting from this difference must be negligible.

To measure the extent of reversibility of this exchange reaction, the reverse experiment was carried out. It was found that close to 50% of the activity of the samples was lost after a few seconds of immersion in an inactive silver nitrate solution. This would indicate that the adsorbed (chemisorbed and ionic double-layer) atoms re-exchange readily with the solution; the results are plotted in Fig. 4.

The results of the long-term experiments on the increase of activity with time gave a clear indication that a diffusion process was involved. The penetration curves confirmed this supposition. It was found that fast exchange at the surface is followed by diffusion of the atoms inside the solid.

For personal use only.

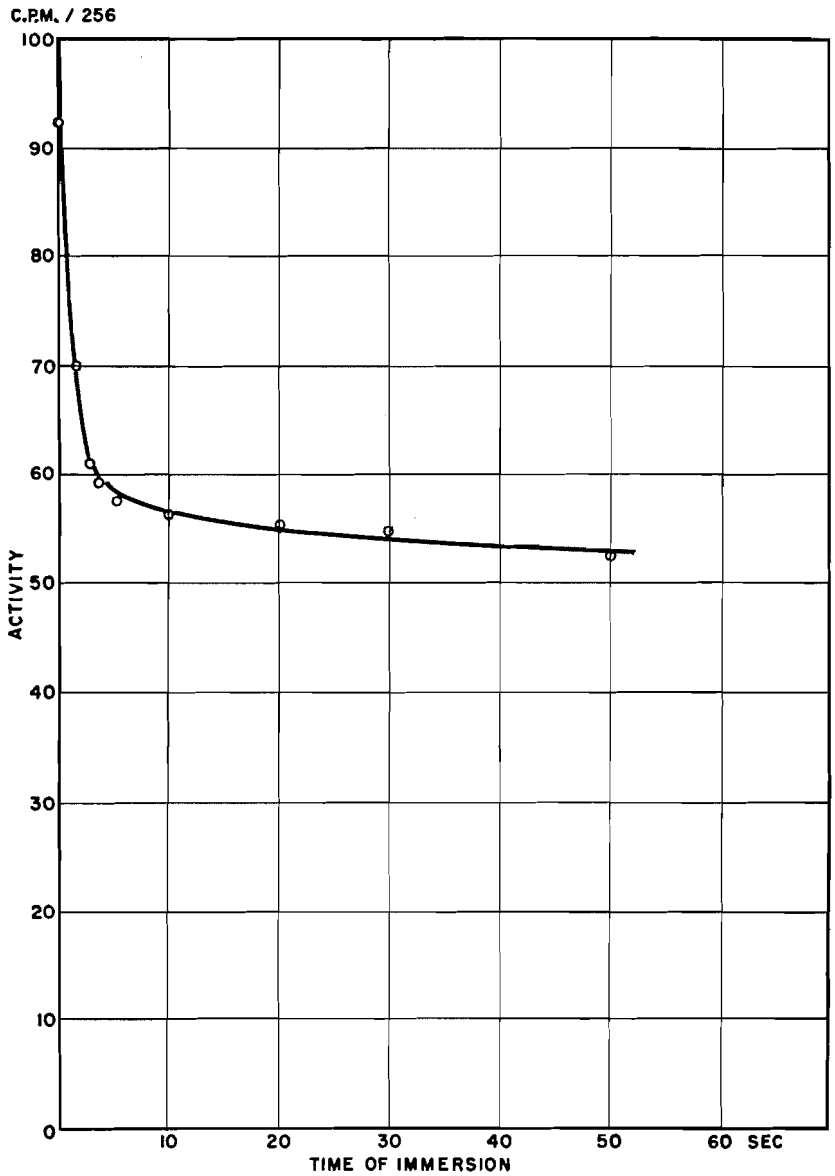

FIG. 4. Reverse exchange, active metal immersed in inactive solution.

It follows that two different mechanisms are acting, a fast diffusion process down to a depth of 300 atomic layers, followed by a much slower one at greater depth.

The diffusion coefficient found in the present study for this second process is $D_b = 1.37 \times 10^{-20}$ cm^2/sec. This compares with a value of $D_b = 6.14 \times 10^{-22}$ cm^2/sec, using Hoffman and Turnbull's formula and calculating for 25° C of temperature.

The difference of two orders of magnitude can be explained either as a result of extrapolation, because the work of Hoffman and Turnbull was done at high temperatures, or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

because there is a difference in the activation energy, indicating that another mechanism is acting at low temperatures.

Other authors found a difference of 4 or 5 orders of magnitude; this can be attributed to less-pure samples, or to less-well-polished surfaces.

It is an accepted theory that self-diffusion in face-centered cubic metals takes place by a lattice-vacancy mechanism. It has already been shown that in diffusion curves for polycrystals unusually high activity was noted at small penetration depths (11). The same result is found in the present study, so it is probable that there is a much more disordered and loose structure of atoms close to the surface exposed to the solution.

This would explain the high rate of adsorption at the beginning of the exchange reaction. It also accounts for the fact that in cold-rolled samples there is a faster diffusion than in annealed specimens, and for the observation that pretreating the surfaces in inactive silver before the exchange experiments tends to decrease the exchange rate.

The whole process can be pictured as in Fig. 5, i.e., similar to the interdiffusion of two solids.

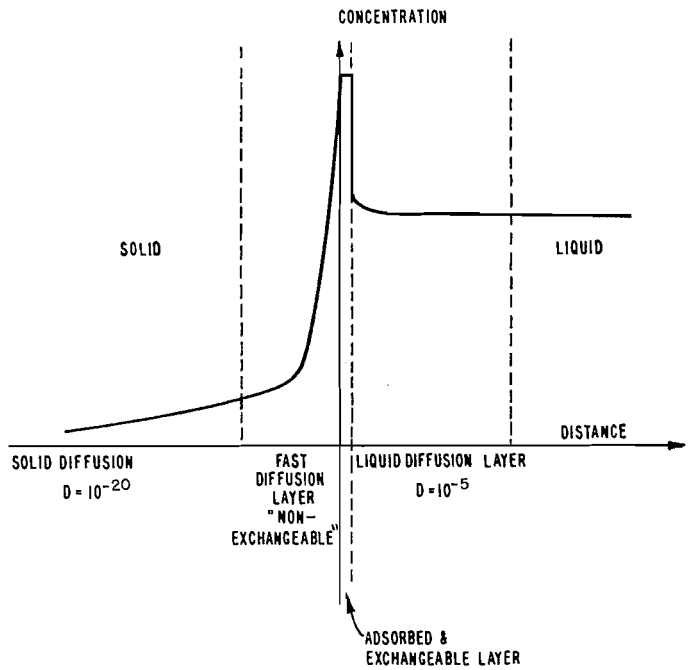

FIG. 5. Diagram of exchange layers.

The smallest diffusion coefficient is in the solid phase and it is the rate-determining factor in the whole exchange process under near-equilibrium conditions at the surface.

The atoms move from a solid lattice structure through a "fast diffusion" layer, through a phase boundary, through the liquid diffusion layer, and finally to the bulk of the liquid.

Summary

(1) A continuous increase in activity was found by immersing electropolished and annealed silver foils in a silver nitrate solution containing radioactive silver, for periods of 9 to 37 days. The adsorption process was a square root function of time.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(2) Close to 50% of the activity was lost by reverse exchange when the exchanged samples were immersed in inactive silver nitrate solution; the remainder was removed from the contact area by diffusion into the interior of the metal.

(3) The measurement of the penetration of the radioactive isotope after exchange was carried out using an electropolishing technique and showed an exponential distribution with depth.

It is concluded that a fast diffusion occurs close to the surface, followed by a slower one inside the metal. The calculated diffusion coefficient in the bulk of the solid does not differ much from the one calculated from Hoffman and Turnbull's results.

(4) A model of the whole exchange process is proposed, assuming that self-diffusion in the solid is the rate-determining process.

CLAM POISON

II. PURIFICATION OF CLAM POISON RESIDUES OF LOW TOXICITY BY A HEAVY-PAPER TECHNIQUE[1]

R. A. B. Bannard and A. A. Casselman

ABSTRACT

The usefulness of Whatman seed-test and No. 17 papers has been examined for purification and recovery on a preparative scale of the toxin present in residues of low toxicity from the Schantz alumina chromatographic method for purification of clam poison. A method was developed to minimize introduction of impurities from the papers into fractions recovered after chromatography when *t*-butanol:acetic acid:water (2:1:1) was used as developer. Seed-test paper gave better separation of the toxin from other components of the residues than did No. 17 paper. Residues of bio-assay as low as 300 MU/mg were found to be capable of enrichment by the method. On a scale of 500 mg per 18×22-in. sheet of pretreated seed-test paper, using residues of toxicity 1400 MU/mg, a 67% recovery of toxin enriched fourfold to 5800 MU/mg was achieved in four passes. Increased loading of the paper led to a decrease in both enrichment per pass and over-all recovery of toxin. The paper chromatographic properties, toxicity, and infrared spectrum of the recovered poison agree with those reported by Schantz and co-workers for pure clam poison dihydrochloride, but the specific rotation is lower by 25%. Four possible alternative explanations for the observed anomalous rotation are discussed.

INTRODUCTION

In the method devised by Schantz and co-workers (1) for purification of clam poison, the final step involves chromatography of clam poison dihydrochloride of 55–70% purity on acid-washed alumina, employing absolute and aqueous ethanol as eluants. In this step, 25–45% of the toxin applied is recovered in pure form and an over-all recovery of 70–90% is achieved, but some of the toxin remains on the column and must be removed by elution with water. Some of the fractions resulting from the process proved capable of further enrichment by recycling in the same manner, but it was not found profitable to attempt enrichment of samples of purity less than 30–50% in this way (2). In recent years, considerable quantities of clam poison residues of low toxicity from this process (hereinafter referred to as clam poison tailings) have accumulated, and it has been estimated (3) that as much as 25 g of toxin could be made available for study if a suitable method of purification could be devised. Several attempts were made to enrich clam poison tailings by chromatography on paper, cellulose columns, cation exchange resins, and acid-washed alumina, but these proved fruitless (4). The successful application of paper chromatography to this problem on a semimicro scale, which we recently reported (5), led us to attempt extension of the method to a preparative scale by the use of heavy paper. The present communication describes a method whereby clam poison tailings of toxicity 1400 MU/mg can be enriched to toxicity 5800 MU/mg in 67% yield on a scale of 500 mg.

RESULTS AND DISCUSSION

The purification of clam poison dihydrochloride and clam poison tailings by chromatography on a semimicro scale on Whatman No. 1 paper using *t*-butanol:acetic acid:water (2:1:1) as developer has recently been described (5). In this work extensive pretreatment of the paper was necessary to minimize the introduction of impurities into the recovered toxin. Brownell, Hamilton, and Casselman (6) previously established the usefulness of

chromatography on Whatman seed-test paper for the purification of amino acids and pyrophosphate esters on a preparative scale and found extensive pretreatment of the paper unnecessary since no appreciable quantities of impurities were introduced into the recovered substances by the neutral solvent systems which they employed. We were committed to use of the acidic solvent system mentioned above because of its ability to separate the components present in clam poison tailings and it seemed to us that the effectiveness of the heavy-paper technique would depend largely on the quantities of impurities introduced into the various fractions during chromatography. The other factor upon which the usefulness of the method would primarily depend is the degree of resolution of components attainable relative to the loading of the paper.

Attention was first directed to the question of impurities introduced during chromatography and the steps required to minimize them. Untreated Whatman No. 17 and seed-test papers were developed in *t*-butanol:acetic acid:water (2:1:1) by the descending method and air-dried; rectangular strips corresponding to preselected R_F ranges were removed and eluted with water; and the quantities of extractable impurities were determined by weighing, after lyophilization. Papers were then pretreated by the chromatographic washing procedure which had proved to be most effective for the removal of impurities from Whatman No. 1 paper (5) and the quantities of residues recovered by aqueous elution were determined as described above. Finally, the residues thus obtained were taken up in water and the quantities of impurities remaining after (*a*) filtration through a fritted glass filter and (*b*) elution through Amberlite IRA-400 (Cl) resin were determined.

It is evident from Table I that, as anticipated, unwashed seed-test paper yields much

larger quantities of impurities than does No. 17 paper. The quantity of impurity in both unwashed papers increases rapidly with increasing R_F, in agreement with results obtained earlier with unwashed Whatman No. 1 paper. Pretreatment reduces the quantities of impurities extracted from both papers to the same order of magnitude and leads to greater uniformity in the weight of impurity as the R_F is increased. In the R_F range 0.14–0.39, which is the region in which clam poison was expected to be located in actual

chromatograms, pretreated No. 17 and seed-test paper gave quantities of impurities which were respectively three and four times as large as those found for Whatman No. 1 paper by simple elution. Portions of these impurities can be eliminated from the reconstituted aqueous eluates by filtration through a fritted disk. The relative improvement thereby produced is in the following order: pretreated No. 17 ≈ pretreated seed-test > unwashed No. 17 ≈ unwashed seed-test. These results indicate that pretreatment produces a relatively larger quantity of insoluble fibrous debris than was present in the unwashed paper, but effectively removes the majority of the impurity initially present, which was mainly soluble rather than fibrous. More impurities can be eliminated from the reconstituted aqueous eluates from the filtration treatment by passing the solution through Amberlite IRA-400 (Cl) resin. The relative improvement was approximately identical for all but unwashed seed-test paper. These results suggest that the type of anionic impurity which is being removed from all but unwashed seed-test paper is uniform and this impurity could well be acetate ion which had been introduced by the pretreatment. The type of anionic impurity present in unwashed seed-test paper would be expected to be less uniform since the paper received no pretreatment.

By combined pretreatment, filtration, and elution through resin, the impurities in the R_F range 0.14–0.39 for No. 17 and seed-test papers were reduced respectively to one and one-half and twice the quantities obtained from pretreated Whatman No. 1 paper. Attempts were made to reduce the quantities of impurities still further by the use of millipore filters but no improvement resulted. Huffman and co-workers (7) found during alternate successive aqueous extraction and drying of Whatman No. 1 paper that no further reduction in the water-soluble carbohydrate impurities recovered occurred after the third extraction. This phenomenon was considered (7) to be related to the deterioration of cellulose caused by alternate wetting and drying of the paper and by the action of ozone at high moisture levels. Since the pretreatment method which was used for the purification of Whatman No. 1 paper (5) and the papers in the present investigation involved air-drying prior to water-washing after treatment with each irrigant, it seemed worth while to investigate the effect of eliminating the drying steps by using a continuous washing procedure. The quantities of residues found by this method after subsequent filtration and resin treatment were approximately one-third larger than given by the intermittent washing procedure and therefore no improvement resulted. Continuous washing did have the advantage, however, of reducing the time required for washing the papers from 39 to 30 days.

As a result of the purification of the heavy papers it was estimated that if a toxin fraction as large as 100 mg could be confined to a rectangular band 1×18 in., only 0.3 to 0.4% of impurity would be introduced by the paper, and this level of impurity was considered to be quite acceptable for our purposes.

Preliminary chromatograms were performed on Whatman No. 1, No. 17, and seed-test papers using clam poison tailings of toxicity 1400 MU/mg (25%) and $[\alpha]_D^{25}$ +26.3°. The results given in Table II indicate the presence of six components, only three of which are Weber-positive (8). The atypical Sakaguchi (9) and ninhydrin reactions shown by component 2 were observed earlier (5) to be characteristic of clam poison and it was concluded that this was the desired material. The components were sufficiently well separated in these chromatograms to suggest that successful separations could be achieved at considerably heavier loading.

A sample of clam poison tailings (100 mg, toxicity 1400 MU/mg, $[\alpha]_D^{25}$ +26.3°) was applied to a $4\frac{3}{4}$×22-in. sheet of specially pretreated Whatman seed-test paper and

developed with *t*-butanol:acetic acid:water (2:1:1). The components were located on the air-dried chromatogram by their fluorescence under ultraviolet irradiation and were recovered by elution with water, and the eluates lyophilized, weighed, and bio-assayed as described in the experimental section. In this manner, fractions 1–6, given in Table III, were obtained. All the toxic material was confined to fractions 1, 2, and 3 and although

*100 mg tailings (1400 MU/mg) applied (total MU = 140,000).

the percentage recovery on both a weight (102%) and toxicity (104%) basis was slightly greater than theoretical, the values found are within the experimental error of the method. The procedure is clearly capable of effecting a significant enrichment of clam poison present in the tailings since, judging from its toxicity, fraction 2 has been enriched threefold and contains 73% of the toxin originally applied to the paper. Fractions 1 and 3, on the other hand, are less pure than the original tailings and provided suitable material for examination of the effectiveness of the procedure for enrichment of tailings containing toxin approximately half as pure as that in the original sample. Fractions 1 and 3, after repurification as described above, gave fractions 7, 8, and 9. As before, the majority of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the toxicity (80%) was confined to the fraction of R_F 0.24, which had been enriched 3.5-fold to a toxicity of 2900 MU/mg. Although the degree of enrichment was slightly greater than that obtained in the first pass, the purity of fraction 8 is considerably less than that of fraction 2 because of the differential in purity of the two samples employed. Fractions 7 and 9 contain only 8000 MU of poison, which is little more than 1 mg of pure toxin (assuming the toxicity of pure clam poison to be 5500 MU/mg), and these fractions were discarded. In a subsequent experiment, however, in which 166 mg of tailings of bio-assay 300 MU/mg was purified by the same method, a 70% recovery of poison enriched approximately sevenfold to 2000 MU/mg was obtained, indicating that the procedure is effective even for concentration of tailings which contain as little as 5% of the poison. Fraction 8 was repurified in the same manner, yielding fractions 10, 11, and 12. In this pass, only an approximately twofold enrichment resulted and both the over-all recovery (64%) and percentage recovery in the most toxic band (47%) decreased sharply. By means of passes 2 and 3, however, the over-all recovery of poison of toxicity 4400 MU/mg or greater was increased to 85% from 73%. Fractions 2 and 11 were combined for a final purification to determine whether poison of toxicity identical with that reported by Schantz *et al.* (1) for pure clam poison dihydrochloride could be obtained by the method. The results given for fractions 14, 15, and 16 demonstrate that this objective was achieved.

In four treatments on seed-test paper it was thus possible to effect a fourfold enrichment of the toxin in 67% yield and to recover a further 17% of the poison in a less pure condition. Translating these results from $4\frac{3}{4}\times22$-in. strips to 18×22-in. sheets indicated that the method should be capable of treating 500 mg of tailings per sheet. In a subsequent experiment 500 mg of tailings was purified in the same manner as described above and produced identical results.

In another experiment the loading was increased to 200 mg per $4\frac{3}{4}\times22$-in. strip (i.e. 1.0 g per 18×22-in. sheet). In the first pass, 87% of the toxicity was recovered in the band of R_F 0.24, but the enrichment achieved was only 1.9-fold from 1400 MU/mg to 2600 MU/mg. After the fourth pass, 56% of the toxin applied in the first step was recovered, enriched 3.6-fold to 5000 MU/mg, and an additional 25% of the poison was recovered at lower enrichment levels. Thus, the lighter loading (500 mg per 18×22-in. sheet) is capable of producing more efficient enrichment than the heavier loading.

The usefulness of pretreated Whatman No. 17 paper in this method of purification was also examined, but was found less satisfactory than seed-test paper on the basis of both degree of enrichment and over-all recovery of toxin.

Previously, it was shown that clam poison dihydrochloride which had been purified by the semimicro paper chromatographic method (5) possesses a toxicity and rotation within the range of values reported by Schantz and co-workers (1, 10, 13) (5500 ± 500 MU/mg, $[\alpha]_D^{25}$ $+130°\pm5°$) for the pure material. Also the infrared spectrum (KBr pellet) of toxin purified by the paper chromatographic method (5) was indistinguishable from that found by Schantz and co-workers. Samples of clam poison which bio-assayed at 5000–5800 MU/mg after purification by the heavy-paper technique described above were also found to exhibit an infrared spectrum indistinguishable from that previously reported for clam poison dihydrochloride (5) and we were therefore surprised to find that the specific rotations of these samples fell within the range 94–101°, which is well below the limit accepted for pure clam poison. Rechromatography of these samples on pretreated Whatman No. 1 paper gave only one Weber-positive spot, R_F 0.32 (cf. Table II). When ninhydrin was used as the chromogenic agent, however, very faint purple spots, R_F 0.26 and 0.38, were also revealed and very faint red spots with the same R_F's

were observed with Sakaguchi reagent. It thus appears that traces of components 1 and 3 (Table II) still remain in toxin (component 2) purified by the heavy-paper technique even when the bio-assay exceeds 5000 MU/mg. The intensities of the spots revealed by ninhydrin and Sakaguchi reagents were very weak, however, and it was considered unlikely that sufficient of these materials were present to markedly depress the rotation of the samples unless these components possess a high negative rotation. That such is not the case was determined by examination of side bands from the purification which are rich in the ninhydrin-positive components 1 or 3 and also contain a small amount of the Weber-positive toxin (component 2). The first fraction examined had toxicity 600 MU/mg and $[\alpha]_D^{25}$ +18.5°. On rechromatography on Whatman No. 1 paper it gave a strong ninhydrin-positive spot at R_F 0.26, and a faint Weber-positive toxin spot at R_F 0.32, indicating the majority of this band to be component 1. The second fraction examined had toxicity 600 MU/mg and $[\alpha]_D^{25}$ +14.5°. On rechromatography on Whatman No. 1 paper it gave a faint Weber-positive toxin spot at R_F 0.32 and a strong ninhydrin-positive spot at R_F 0.38, indicating the majority of this band to be component 3. Judging from the toxicity assays on the two fractions, not more than 10% of each can be toxin. It was therefore concluded that the minor amounts of components 1 and 3 which are present in highly toxic samples recovered from the tailings are not responsible for the low optical rotations observed. It was also established that the low rotations do not owe their origin to an impurity extracted from the paper during recovery of the toxin. Measurements on 1% aqueous solutions of the impurity recovered from seed-test paper in the R_F range 0.14–0.25 exhibited negligible optical activity and in the actual purification of tailings the concentration of the impurity in the recovered toxin is approximately 100-fold more dilute.

Four alternative explanations for the observed rotations are possible. (*a*) Paper chromatography has eliminated some impurity with a rotation higher than +100° which was not removed from clam poison by the methods of Schantz *et al.* (*b*) The toxin present in the tailings is not clam poison but another toxin of closely related structure which has a lower positive rotation. (*c*) The tailings contain two toxins, clam poison and another toxin of lower positive rotation, which are not separated by paper chromatography. (*d*) The tailings contain a non-toxic impurity with a high negative rotation which is not separated from clam poison by paper chromatography.

Alternative (*a*) appears unlikely because Schantz *et al.* (1, 10) obtained clam poison of identical toxicity and rotation (5500±500 MU/mg and $[\alpha]_D^{25}$ +130°±5°) by three different methods of purification, viz. by chromatography on alumina, by chromatography on Norit A followed by crystallization as the helianthate, and by countercurrent distribution. Also, we have observed the same physical constants for clam poison purified by semimicro quantitative paper chromatography (5). It should be emphasized, however, that the chromatographic properties of the clam poison sample purified earlier (5) by the semimicro method and the clam poison tailings purified by the macro method reported herein do not correspond in all respects. It seems reasonable, therefore, to assume that the abnormal optical rotations encountered in the present work owe their origin to some material in the tailings which was absent from the sample purified earlier by the semimicro method and that the nature of the unknown material is explicable by one of the alternatives (*b*), (*c*), or (*d*) mentioned above. Alternative (*b*) at first appears unlikely because of the infrared spectral data. However, the infrared spectrum of clam poison contains little fine structure and may be relatively insensitive to minor structural changes involving, for example, stereoisomerism or tautomerism. In this connection it has been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

shown by Schantz *et al.* (10, 13) that little change in the spectrum results from conversion of clam poison to dihydro clam poison by catalytic hydrogenation, even though all the toxicity is lost in the process and the chromatographic properties change markedly (10). Mold *et al.* have obtained evidence from countercurrent distribution studies at pH 8 that clam poison can exist in two tautomeric forms, both of which are highly toxic (10). It may therefore be that the reason for retention of the tailings toxin by the alumina during the original purification is that its structure differs in some subtle manner from clam poison. That minor structural changes can cause significant differences in ease or order of elution of compounds in adsorption chromatography is well known (11). The possibility should also not be overlooked that the toxin recovered from the tailings is a partially degraded clam poison. Dr. E. J. Schantz has recently informed us in a private communication that studies in his laboratory have shown that the optical rotation of clam poison decreases to +50° without concomitant reduction in toxicity by treatment with aqueous alkali under anaerobic conditions. Also, evidence has been obtained by Dr. Schantz and his co-workers that the portion of the molecule responsible for toxicity is not responsible for the optical activity.

If the tailings toxin does differ from clam poison it is possible that the toxicity of the former could be significantly greater than the limits observed by Schantz *et al.* (1) for pure clam poison. Samples of tailings toxin of toxicity 5400±400 MU/mg and $[\alpha]_D^{25}$ +98°±4° were repurified repeatedly by the heavy-paper technique but neither the toxicity nor the specific rotation was significantly increased. It was therefore concluded that either the maximum purity for the material had been attained or that paper chromatography was incapable of effecting further purification. These results make it impossible to differentiate among alternatives (*b*), (*c*), and (*d*) at the present time and an answer to these questions must await further examination of the homogeneity of the tailings toxin by development of other methods of purification.

This work has established the feasibility of enriching and recovering by preparative paper chromatography on seed-test paper a toxin from hitherto intractable residues of low toxicity from the Schantz alumina chromatographic method for purification of clam poison. Residues of bio-assay as low as 300 MU/mg can be enriched by multiple batch treatments. On a 500-mg scale, tailings of toxicity 1400 MU/mg and $[\alpha]_D^{25}$ +26° can be enriched fourfold to 5400±400 MU/mg and $[\alpha]_D^{25}$ +98°±4° in 67% yield by four passes. Further work is required to elaborate the identity of the recovered toxin.

EXPERIMENTAL

Pretreatment of Papers

Whatman No. 17 and seed-test papers were trimmed to 18×22 in. and ½-in. serrations were cut along one 18-in. edge. To the other 18-in. edge was attached a stirrup and two wicks of Whatman 3MM paper (6). Eight such sheets supported by glass rods in a Model A 300 Chromatocab equipped with solvent troughs and reservoirs (6) were washed chromatographically by the procedure described earlier (5) for Whatman No. 1 paper.

Blank Runs on Pretreated Paper

After removal of one wick, the pretreated paper was developed by the descending method with *t*-butanol:acetic acid:water (2:1:1) until the solvent front was 1 to 1½ in. from the serrated edge. This operation required 16 hours for No. 17 paper and 40 hours for seed-test paper. The paper was air-dried at room temperature and rectangular strips were cut from the papers at the R_F ranges specified in Table I. To each strip a stirrup and two wicks of pretreated Whatman No. 1 paper were attached, after which the strips

were eluted with water (20 ml). The eluates were concentrated *in vacuo*, then lyophilized and weighed (5). To determine the quantity of particulate impurity in the residues, the latter were reconstituted in water (3 ml), filtered through a fine-porosity fritted-glass funnel, and the combined filtrate and washings (8 ml) were concentrated, lyophilized, and weighed. To determine the anionic impurity removable from the latter residues, they were reconstituted in water (3 ml) and eluted through Amberlite IRA-400 (Cl) resin (3 ml). The combined eluate and washings (15 ml) were concentrated, lyophilized, and weighed.

Preliminary Purification and Chromatography of Clam Poison Tailings

A sample of clam poison hydrochloride tailings approximately 25% pure was kindly provided for study by the U.S. Army Chemical Research and Development Laboratories. When samples of the aqueous alcoholic solution (14 mg/ml total solids, 18,700 MU/ml, specified by sender) were lyophilized, the total solids found was 14.7 mg/ml and the presence of oily droplets in the lyophilizates, which were water insoluble, was observed. Accordingly, the entire aqueous alcoholic solution was lyophilized and the mixture of oil and solid extracted with 5×2 ml of water to separate the water-soluble material from the oil. The oil and water-soluble fractions were lyophilized after filtration, and bio-assay confirmed that all the toxicity was confined to the water-soluble fraction, which weighed 2.02 g, and had toxicity 1400 MU/mg and $[\alpha]_D^{25}$ +26.3° (1% aqueous solution). Solutions used for chromatography were prepared directly from this material. For chromatograms on pretreated Whatman No. 1 paper, 20 λ of a 1% aqueous solution (200 γ), and on the pretreated heavy papers, 10 λ of a 30% aqueous solution (3 mg), were applied and developed in glass chromatographic tanks by the descending method. The air-dried chromatograms were examined under ultraviolet light and sprayed with Weber reagent (8), Sakaguchi reagent (9), or ninhydrin for location of the components.

Purification of Clam Poison Tailings on Seed-test Paper

A sample of clam poison tailings solution was lyophilized, weighed, and made up to exactly 2 ml in a volumetric flask. Aliquots (0.2 ml) of this solution were applied as a streak $3\frac{1}{2}$ in. long to a strip of pretreated seed-test paper $4\frac{3}{4}$×22 in., air-drying between each application until the desired quantity of tailings had been applied. The paper was developed by the descending method in a glass chromatographic tank (or in a Model A 300 Chromatocab when 18×22-in. sheets were used) containing *t*-butanol:acetic acid:water (2:1:1) for 40 hours, using a single wick of Whatman 3MM paper. The chromatogram was air-dried and examined under ultraviolet light for location of the components. The bands containing the fluorescent materials were cut from the paper and a stirrup and single wick of pretreated Whatman No. 1 paper was attached to each strip. The strips were eluted with water (20 ml) and the eluates were concentrated *in vacuo* to a volume of 3–5 ml. The concentrates were passed through Amberlite IRA-400 (Cl) resin (3–4 ml), filtered through a fine-porosity fritted-glass disk, concentrated *in vacuo* to a volume of ca. 1 ml, lyophilized, and weighed on the microbalance. From the weights of fractions thus obtained the weights of impurities known to be introduced as a result of blank runs on the same batch of pretreated paper were subtracted to give the corrected weight of each fraction. When side bands from purifications (e.g. fractions 1 and 3, Table III) were reprocessed, the size of the strip of paper to which such material was applied was decreased so that a loading equivalent to 500 mg per 18×22-in. sheet was employed. For bio-assay, solutions of concentration 20 γ/ml were prepared using water of pH 3.00 (hydrochloric acid). Rotations were measured on 1% aqueous solutions.

Bio-assay

Bio-assays were performed on male mice weighing 19–21 g by the method of Schantz *et al.* (12), using ten mice per assay. The conversion factor (C.F. value) for the strain of mice used in these experiments was determined using a standard sample of clam poison provided by Dr. Schantz and was found to be 0.160 γ per MU.

ACKNOWLEDGMENTS

We wish to thank the U.S. Army Chemical Research and Development Laboratories for providing the clam poison tailings used in these studies and Dr. E. J. Schantz of the U.S. Army Biological Laboratories for supplying a sample of pure clam poison for standardization of the bio-assay results.

We are greatly indebted to Dr. A. D. Tennant and Mr. R. Tuszynski of the Laboratory of Hygiene, Department of National Health and Welfare, Ottawa, for performing the bio-assays and to Dr. R. N. Jones and Mr. R. Lauzon, Division of Pure Chemistry, National Research Council, Ottawa, for measurement of infrared spectra.

THE FRACTIONATION OF POLYTHENE[1]

W. R. BLACKMORE[2] AND W. ALEXANDER[3]

ABSTRACT

An apparatus is described for fractionating large quantities (400 g) of polythene into five roughly equal fractions using a fractional precipitation technique. Application of this method of fractionation to a linear polythene has shown that the width of the molecular-weight distribution of the successive fractions decreases as the fractionation proceeds. Consequently, the initial high-molecular-weight fractions require refractionation to produce equally narrow distributions in them as are found in later fractions. Good agreement is obtained with the experimentally determined values of the number-average and weight-average molecular weight for the parent polymer when the measured values of M_n and M_w for each fraction are used to calculate the values for the parent. The differential molecular-weight distribution function of the parent polymer was calculated on a Bendix G-15 computer from the data for the fractions by using the weight, number-average and weight-average molecular weight, measured for each fraction in conjunction with an assumed log-normal or negative binomial molecular-weight distribution function in each fraction.

INTRODUCTION

The preparation of polythene samples with narrow molecular-weight distributions is more conveniently done by fractionation than by synthesis. Two techniques are most commonly used, fractional solution and fractional precipitation. Both methods appear to be equally efficient when used in dilute solution at or above the melting point of the polymer (1). The present study used a precipitation technique in which the polymer was dissolved in a suitable solvent (*p*-xylene) and then partially precipitated by adding a non-solvent (triethylene glycol) (2). In this way, a large-scale fractionator was used to divide a 400-g polymer charge into five 80-g fractions. The fractions were then stored until enough material had been collected in each fraction to warrant refractionation.

EXPERIMENTAL

Apparatus

The large-scale fractionator consisted of an upper borosilicate glass separator vessel of 50-liter capacity and a lower 40-liter metal storage tank, both immersed in a 200-gal, totally enclosed oil bath maintained at an operating temperature of 130° C by six thermistor-controlled 1000-w electric heaters. The temperature of the bath was measured by means of six precision thermometers placed at different locations in the bath. Temperature fluctuations were held to within ±0.05° C of the operating temperature throughout the entire bath by employing a highly efficient stirring arrangement and by using two specially designed ultrasensitive thermistor controllers (3) to control the temperature. The bath fluid, a water-white mineral oil maintained under an atmosphere of CO_2 to prevent oxidation, could be used for 2 months before it darkened and had to be discarded. Phase boundaries in the separator vessel were illuminated by means of three strategically placed, sealed-beam automobile head lamps submerged in the oil bath, and could be viewed through several glass observation ports in the side of the bath. The solvent, *p*-xylene, and the non-solvent, triethylene glycol, were separately preheated to 130° C in steam-jacketed, glass-lined kettles which were connected by steam-traced lines to the separator vessel. A specially designed burette was used to determine the quantities of hot triethylene glycol added to the separator. The layout of the apparatus is shown in Fig. 1. The selection

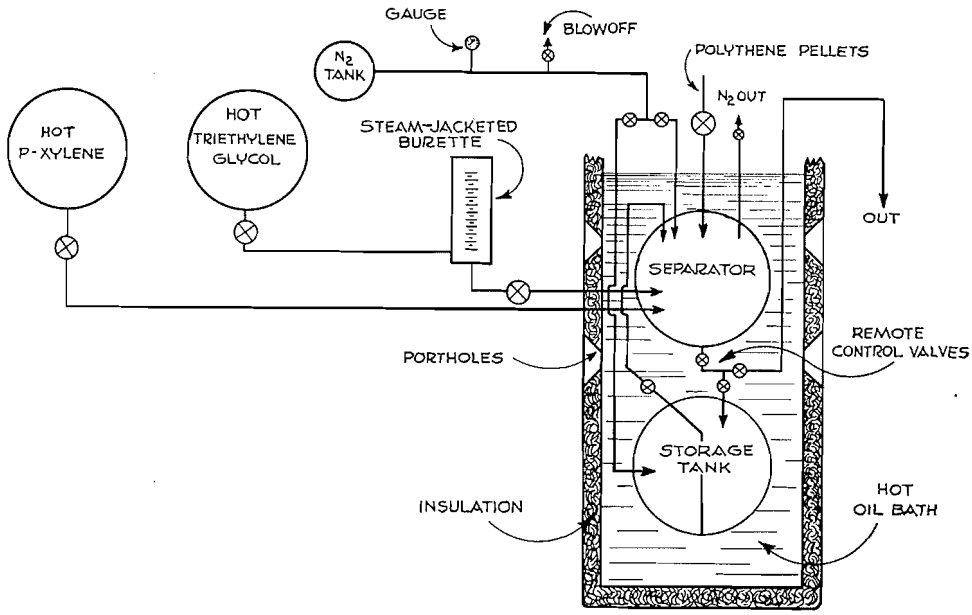

FIG. 1. Apparatus for large-scale fractionation of polythene.

of the operating temperature was determined by the melting point of the polymer and was chosen so that the precipitated material would be liquid and crystallization would not interfere with the equilibrium distribution of polymer between the two phases.

Procedure

The polymer was fractionated by partial precipitation in a manner similar to that described by Tung (2). A 1.6% solution (w/v) of the polythene in *p*-xylene (containing 0.1% w/v 2,6-ditertiary-butyl-*p*-cresol as antioxidant) was vigorously stirred under dry nitrogen in the separator and the non-solvent, triethylene glycol, slowly added until the first signs of opacity appeared in the solution. Sufficient non-solvent (determined by trial and error) was then added to precipitate out approximately 20% (80 g) of the total charge of polythene in the solution. After a period of vigorous agitation followed by a settling period, the upper gel phase was separated from the lower solution in the following manner: the lower solution was drained into the storage tank, then enough fresh *p*-xylene was added to form a clear solution of the gel phase, finally the gel was redissolved, and the fresh solution was siphoned out of the separator and into 10 gal of vigorously stirred cold methanol.

The solution in the storage tank was then transferred to the separator vessel by applying nitrogen pressure to the storage tank. Subsequent fractions were then precipitated by following the same procedure. In general the first fraction required 3 hours to settle; however, later fractions required longer settling times, fraction 4 requiring at least 12 hours. The fifth fraction was obtained by siphoning off the solution from the gel phase of fraction 4 and adding it directly to cold methanol. Each 80-g fraction was filtered off and then washed five times with cold methanol before being transferred to a special washing vessel in which the filtrate was stirred in contact with cold methanol (containing 0.05% antioxidant) for at least 24 hours before being filtered off and dried to constant weight in a vacuum oven. The yield efficiency of these partial precipitations was found

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to be about 95%. Studies indicated that polymer losses in filtration and washing amounted to 2.5%, leaving a further 2.5%, or 10 g, of polymer unaccounted for. This loss may have been due to low-molecular-weight material present in the polythene dissolving in the cold methanol/xylene mixture. However, cooling the methanol/xylene mixture to −72° C and allowing the material to warm up slowly until the xylene crystals melted failed to yield any precipitate.

DISCUSSION

Results

As an indication of the extent of fractionation actually achieved with the above system, measurements on fractions obtained from a linear polythene are given in Table I.

TABLE I

Typical fractionation results with a linear polythene

Run	Fraction	Cumulative wt. (g)	Cumulative % recovered	M_n (Me/1000)	M_n (vinyl)	η (120° C, tetralin)	Calc. M_w	M_w/M_n (vinyl)

Columns 5 and 6 list number-average weights (M_n) for each fraction, based on the assumption that each polymer molecule is terminated by a methyl group at one end and a vinyl group at the other. Both groups were measured by infrared spectroscopy, to within an accuracy of 20% in the methyl group determination (4) and 5% in the case of the vinyl group determination. Vinyl group measurements were based on the change in intensity of the 908 cm^{-1} band which arises when the sample is brominated (5). The weight-average molecular weights (M_w) were calculated from the intrinsic viscosities (η) for each fraction using the Duch and Kuchler relationship (7). The intrinsic viscosities were measured at 120° C in tetralin solutions using Schulken and Sparks (6) viscometers. The good agreement between (M_n) values determined by the two methods verifies the assumption that the molecule is terminated by a methyl and a vinyl group. The decreasing values of the ratios of the molecular weights, M_w/M_n, indicate that the width of the distribution in each consecutive fraction decreases and that refractionation is necessary if fractions of equally narrow molecular-weight distribution are required. Cragg and Hammerschlag (1) have pointed out that refractionation more than thrice is inefficient and this number of refractionations has been accepted as the limit. The value of the number-average molecular weight for the parent polymer was calculated using the measured number-average molecular weights of the fractions and the formula $M_n = \sum n_i m_i / \sum n_i$ and showed good agreement with the experimentally determined value for the unfractionated polymer (Table I). Likewise, the weight-average molecular weight of the parent polymer calculated from the expression $M_w = \sum m_i w_i / \sum w_i$ also showed good agreement with the value calculated from the measured intrinsic viscosity of the

For personal use only.

unfractionated polymer. This agreement suggests that the parent polymer had not been chemically changed by the fractionation procedure.

Calculation of the Molecular-Weight-Distribution Curves

Pre-1939 molecular-weight-distribution curves were obtained by making some estimate of the molecular weight of each fraction and then plotting the cumulative weight of the first n fractions against the estimated molecular weight of the nth fraction to yield the integral weight-distribution curve. This procedure assumed incorrectly that there was no overlap between fractions and also that every species present in the nth fraction had a molecular weight between the average measured for the $(n-1)$th and nth fractions. A somewhat more realistic approach was made by Schulz (8), who assumed the fraction to be symmetrically distributed about its average molecular weight. In this calculation, the total weight of the first $(n-1)$ fractions plus half the weight of the nth fraction is plotted against the molecular weight of the nth fraction; however, this still neglects the overlapping between fractions.

In the last decade, serious attempts have been made to allow for the overlap of the fractions by assuming a differential distribution function for each fraction, summing these functions to obtain the differential distribution curve for the parent polymer, and then forming the integral distribution curve (9, 10, 11). More recently two independent studies (12, 13) have suggested that the most satisfactory results are obtained when the amount of each fraction and the number- and weight-average molecular weight are also known. The differential distribution function for the parent polymer may then be calculated using these three parameters and assuming a relatively simple form for the distribution functions of the fractions. A program for the calculation of the molecular-weight distribution of the parent polymer was written for the Bendix G-15 computer, given the three parameters and assuming either a log-normal or a negative binomial distribution for the fractions. Results are given in Table I.

ACKNOWLEDGMENTS

The authors wish to acknowledge discussions of this work with Mr. A. M. Birks; to thank Dr. D. C. West for having programed the calculation of the polymer molecular-weight-distribution function on the Bendix computer; and to thank Mr. T. Finn, who performed most of the experimental work. The authors also wish to thank Mr. A. W. Pross for the infrared measurements and Dr. H. P. Schreiber for the intrinsic viscosity results.

THE GAS–LIQUID PARTITION CHROMATOGRAPHY OF CARBOHYDRATE DERIVATIVES

PART I. THE SEPARATION OF GLYCITOL AND GLYCOSE ACETATES[1]

S. W. GUNNER, J. K. N. JONES, AND M. B. PERRY

ABSTRACT

Gas–liquid partition chromatography has been used to separate the fully acetylated derivatives of tetritols, pentitols, hexitols, heptitols, octitols, and anomeric glycoses.

DISCUSSION

Gas–liquid partition chromatography (G.L.P.C.) has already been shown to be a powerful technique for the preparative separation and for the qualitative and quantitative analysis of carbohydrate derivatives. Bishop and his co-workers (1, 2) were the first to report the separation of methyl *O*-methyl glycosides by G.L.P.C. and have since demonstrated the use of such separations in the analysis of these derivatives obtained from the fission of methylated polysaccharides (3, 4, 5). Kircher (6) has also described the G.L.P.C. separation of methylated methyl glycosides employing other types of liquid phases. *O*-Methyl aldonolactones (7), *O*-methyl-*O*-acetyl glycitols (8), *O*-acetyl glycitols (9), and other carbohydrate derivatives (10) have also been successfully resolved using the G.L.P.C. technique.

In view of its potential use in the field of carbohydrate chemistry, a systematic program was undertaken in this laboratory to explore the conditions under which favorable separations of a variety of carbohydrate derivatives might be undertaken using G.L.P.C. This paper records the results obtained in investigations into the separation of glycitol and glycose acetates. Until recently the methods available for the separation of acetylated glycitols and glycoses involved column chromatography on a Magnesol–Celite or Silene EF – Celite (11*a*) mixture using benzene – *tert*-butyl alcohol as the mobile phase, cellulose column chromatography, or paper chromatography (11*b*). It is considered that the G.L.P.C. method of separation will provide a more rapid and refined procedure.

The recorded separations were carried out using samples of the acetate derivatives (2–5 γ) developed on a Pye Gas Argon Chromatograph fitted with an ionization detector (12), and in cases where larger amounts of material (20–200 mg) were used for preparative work, the Burrell Kromo-Tog, Model K-2 apparatus was used. Experience with other types of chromatographic equipment showed that it was necessary for the sample to be injected directly onto the column packing material in order to prevent the decomposition of the samples, which was observed when a dead space existed between the injection site and the beginning of the column packing material. In this connection it is important to note that small gaps in the packing material itself should be avoided and that the detector should be placed as close as possible to the end of column packing for satisfactory results.

Acid-washed Chromosorb W or silver-coated Chromosorb W proved to be a suitable inert support which did not show excessive adsorption of the acetate derivatives. The non-polar liquid phases chosen were Apiezon M vacuum grease or Dow Corning stopcock grease, and the polar phase selected was butanediol succinate polyester. Columns prepared containing 20% w/w of the non-polar liquid phases gave fair separations of the

For personal use only.

acetate derivatives with only slight adsorption-tailing effects. Columns prepared using 20% w/w of the polar phase on Chromosorb W gave increased resolution of the derivatives but had the disadvantage of markedly increasing their retention times. It was considered that mixtures of the packing materials made up of a non-polar and polar liquid phase component might combine the advantages of each individual liquid phase to give a column packing which would have a high resolving power and would give reasonable retention times for the glycitol and glycose acetates. In practice it was found that the ideal combinations were (*a*) a 1:1 w/w mixture of 20% w/w Apiezon M grease on silver-coated Chromosorb W and 20% w/w butanediol succinate polyester on Chromosorb W (column packing A) and (*b*) a 1:1 w/w mixture of 20% w/w Dow Corning grease on Chromosorb W and 20% w/w butanediol succinate polyester on Chromosorb W (column packing B).

In attempts to find a column packing material suitable for the separation of oligosaccharide acetates (13), H. G. Jones, in this laboratory, developed a packing material of 0.1 to 0.3% Apiezon M vacuum grease on silver-coated glass beads (column packing D). It was found that the retention times for monosaccharide acetates on this column were extremely short. The previously mentioned mixed column packings (A and B) gave satisfactory separations for the glycitol and glycose acetates up to those derived from the C_6 compounds but those derivatives of higher molecular weight showed considerable broadening of the peaks with increasing retention times. This latter difficulty was overcome by using a column made from a 1:1 v/v mixture of column packings A and D (column packing C), which gave satisfactory separations of the acetates derived from the C_7 and C_8 glycitols and glycoses, as well as retaining the ability to resolve the lower molecular weight derivatives. The glass bead column (column packing D) provided a rapid separation of the acetates derived from C_4 to C_8 glycitols in order of their increasing molecular weights, but under the conditions used it did not separate the individual glycitol acetates having the same molecular weights.

Typical separations of the glycitol acetates on column packing A are shown in Fig. 1, on column packing C in Fig. 2, and on column packing D in Fig. 3. Typical separations of anomeric glycose acetates on column packing A are shown in Fig. 4.

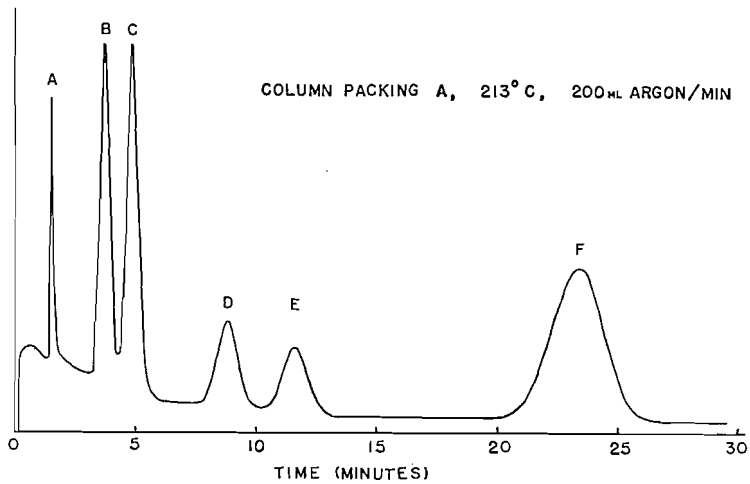

FIG. 1. Separation of glycitol acetates: (A) tetra-*O*-acetylerythritol, (B) penta-*O*-acetylribitol, (C) penta-*O*-acetylxylitol, (D) hexa-*O*-acetylallitol, (E) hexa-*O*-acetyl-D-iditol, and (F) hepta-*O*-acetyl-D-*glycero*-D-galactoheptitol.

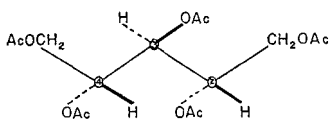
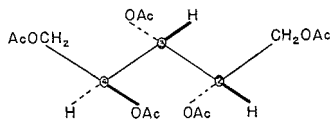
the three pentitol derivatives, penta-*O*-acetylribitol, penta-*O*-acetyl-L-arabitol, and penta-*O*-acetylxylitol, were obtained. All the hexitol acetate derivatives, with the exception of hexa-*O*-acetyl-D-glucitol and hexa-*O*-acetylgalactitol could be separated from each other. All the heptitol acetate derivatives could be separated from each other as well as the two octitol acetate derivatives which were examined. The order of emergence of the glycitol acetates was found to be independent of the nature of the column packing materials used, although some differences in the relative retention times for the compounds were observed. It was also found that the same order of emergence of the compounds was retained using column temperatures ranging from 200° to 250° C. At 250° the retention times for the glycitol acetates were very much decreased, and sharper peaks than those recorded in Figs. 1, 2, and 3 were obtained. No decomposition of the derivatives was detected using column temperatures up to 250° and the derivatives were recovered unchanged from preparative-scale separations.

The results collected so far indicate that a relationship exists between the retention times of the glycitol acetates and their stereochemical structure described in the conventional zig-zag conformations. The retention times of the glycitol acetates having the same molecular weight depends on the arrangement of acetoxy groups attached to the non-terminal carbon atoms. The greater the number of these acetoxy groups which are arranged on one side of the molecule, the greater is the affinity of the compound for the liquid phase and hence the greater its retention time. Thus, tetra-*O*-acetylerythritol (I) has a shorter retention time than tetra-*O*-acetyl-D-threitol (II), which has the two acetoxy groups attached to the non-terminal carbon atoms arranged on one side of the molecule.



(I)



(II)

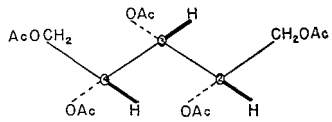
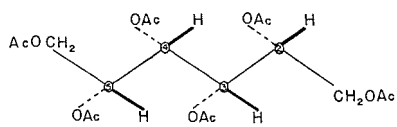
For personal use only.

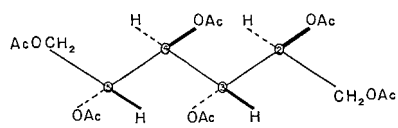


In the case of the three pentitol acetate derivatives, both penta-*O*-acetylribitol (III) and penta-*O*-acetyl-L-arabitol (IV) have a maximum of two acetoxy groups attached to non-terminal carbon atoms arranged on one side of the molecule. It would appear that in this case as well as the case of hexitol acetate and heptitol acetate derivatives, where there are two or more glycitol acetates of the same molecular weight and having the same maximum number of acetoxy groups arranged on one side of the molecule, the closer these acetoxy groups are to each other the greater is the affinity of the compound for the liquid phase and hence the greater its retention time. Thus, penta-*O*-acetylribitol (III) has a lower retention time than penta-*O*-acetyl-L-arabitol (IV). Penta-*O*-acetylxylitol (V), with the maximum of three acetoxy groups attached to non-terminal carbon atoms arranged on one side of the molecule, has the longest retention time of the three pentitol acetate derivatives.

(III)

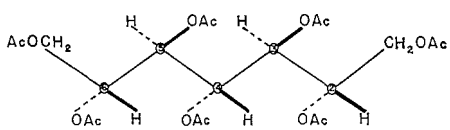


(IV)

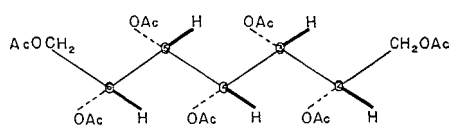


(V)

On the basis of the empirical rules set out above it would be predicted that hexa-*O*-acetyl-D-iditol (VI), which has all four of its acetoxy groups attached to non-terminal carbon atoms arranged on one side of the molecule, should be the hexitol acetate derivative having the longest retention time, and hexa-*O*-acetylallitol (VII), which has a maximum of two acetoxy groups attached to non-terminal carbon atoms arranged on one side of the molecule, and having the maximum possible separation, should be the hexitol acetate derivative having the shortest retention time. This prediction has proved correct in practice.



(VI)



(VII)

In agreement with the above statements, it was found that hepta-*O*-acetyl meso-*glycero*-alloheptitol (VIII), which has a maximum of three acetoxy groups attached to non-terminal carbon atoms arranged on one side of the molecule and having the maximum possible separation, has the shortest retention time of all the heptitol acetate derivatives, whereas hepta-*O*-acetyl-meso-*glycero*-idoheptitol (IX), which has all the acetoxy groups attached to the non-terminal carbon atoms arranged on one side of the molecule, has the longest retention time. The chromatographic behavior of the glycitol acetate derivatives having relative retention times between the extremes cited above is in agreement with

(VIII)

(IX)

that predicted from a consideration of the spatial distribution of the acetoxy groups attached to the non-terminal carbon atoms.

The acetate derivatives of the deoxyglycitols, 6-deoxy-L-talitol, L-rhamnitol, and D-fucitol, can be separated by G.L.P.C., and their order of elution from the columns used is the same as those of their parent hexitol derivatives (L-talitol, L-mannitol, and galactitol).

The anomeric acetates of D-xylopyranose, D-galactopyranose, D-glucopyranose, and D-mannopyranose were separated by G.L.P.C. as were the tetra-*O*-acetyl derivatives of α-D-ribopyranose and α-D-ribofuranose. It is probable that the retention times for these derivatives depend upon the relative positions of the axial and equatorial *O*-acetyl groups but with the limited results available at this time it is not possible to rationalize their chromatographic behavior.

G.L.P.C. has also been shown to afford a method for the separation of acetylated glycosides.

EXPERIMENTAL

Apparatus

The recorded separations were carried out using a Pye Argon Chromatograph fitted with an ionization detector (80 μc radium D) and employing straight glass columns (120×0.5-cm I.D.) packed with the appropriate support enclosed at each end by small glass wool plugs. The samples (2–5 γ) in dry chloroform solution were placed on the top of the column packing using a micropipette and development was made using dry argon as the carrier gas.

Preparative-scale separations (20–200 mg) were made on U-shaped glass columns (255×1.3-cm I.D.) filled with the support material, using the Burrell Kromo-Tog, Model K-2 apparatus fitted with a thermal detector and employing helium as the carrier gas.

Column Packing

Chromosorb W (Johns-Manville), 60–80 mesh, was washed with 2 *N* hydrochloric acid and then with distilled water until the washings were neutral, was dried at 110°, and was then screened to remove fines. Silver-coated Chromosorb W was prepared by treating acid-washed Chromosorb W (60–80 mesh) (10 g) with 120 ml each of two solutions A and B. Solution A was prepared by just adding sufficient dilute ammonium hydroxide solution to a solution of silver nitrate (15.8 g) in water (300 ml) to produce a clear solution. Solution B was prepared by adding a solution of Rochelle salt ($NaKC_4H_4O_6$, 2.5 g) in water (25 ml) to a boiling solution of silver nitrate (3 g) in distilled water (350 ml) and, after filtration, the volume of the solution was adjusted to 350 ml. After treatment of the stirred Chromosorb W with the first two portions of solutions A and B the supernatant was removed after 10 minutes, and the residue was further treated with the same amounts of these two solutions. The resulting silver-coated Chromosorb was filtered off, washed with distilled water followed by acetone, and finally dried in an oven at 140°. The weight of silver deposited was 3 g.

Silver-coated glass beads were prepared in a manner similar to that used in the preparation of silver-coated Chromosorb by treating glass beads (60 plus mesh; MS-H; Microbeads Inc., Jackson, Mississippi) (500 g), previously washed with dilute nitric acid and distilled water, with the same quantities of solutions A and B.

The following liquid phases were used: (*a*) Apiezon M vacuum grease (Fisher Scientific Company), (*b*) Dow Corning stopcock grease (Fisher Scientific Company), and (*c*)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

butanediol succinate polyester (Craig) prepared according to the directions of Bishop *et al.* (2). The packing materials were prepared by stirring a slurry of a weighed amount of the liquid phase dissolved in chloroform with a weighed amount of the inert support in an open beaker at room temperature while the bulk of the solvent was removed by aeration. The last traces of the solvent were removed by heating the material *in vacuo* at 140°.

The packing materials prepared are described below.

(1) Column packing A.—1:1 w/w mixture of (*a*) 20% w/w butanediol succinate polyester on 60–80 mesh Chromosorb W and (*b*) 20% w/w Apiezon M grease on 60–80 mesh silver-coated Chromosorb W.

(2) Column packing B.—1:1 w/w mixture of 20% w/w butanediol succinate polyester on 60–80 mesh Chromosorb W and (*b*) 20% w/w Dow Corning grease on 60–80 mesh Chromosorb W.

(3) Column packing C.—1:1 v/v mixture of (*a*) column packing A and (*b*) column packing D.

(4) Column packing D.—0.3% w/w Apiezon M grease on 60 plus mesh silver-coated glass beads.

The dried column packing materials were run into the glass columns under gravity with gentle tapping to ensure even packing and the absence of any cavities. The packed columns were purged for 3 hours at 240° with dry nitrogen gas before use. It was found that the columns could be used for several hundred analyses at 213° C before any significant deterioration in their resolving power became apparent.

ACKNOWLEDGMENTS

We wish to thank Dr. Nelson K. Richtmyer, National Institutes of Arthritis and Metabolic Diseases, National Institutes of Health, Bethesda, for the gift of the parent heptitols and octitols. FREE RADICALS BY MASS SPECTROMETRY

XXVI. PRIMARY STEPS IN THE MERCURY-PHOTOSENSITIZED DECOMPOSITION OF METHYL ACETATE[1]

R. F. POTTIE[2] AND F. P. LOSSING

ABSTRACT

The Hg($^3P_1$)-photosensitized reaction of methyl acetate at micron pressures in the presence of 8 mm of helium has been examined in a flow system by mass spectrometry. At 55° C the primary dissociation is mainly into acetyl and methoxy radicals. An alternative dissociation into CO_2 and two CH_3 radicals occurs with a frequency of about one fifth of the principal reaction. A small amount of $COOCH_3$ radical is also formed. No CH_3CO_2 radicals could be found. Since the yield of H_2 is less than 2% of the methyl acetate decomposed, a primary dissociation to give H atoms and CH_3COOCH_2 or CH_2COOCH_3 radicals is quite small.

INTRODUCTION

The photolysis of methyl acetate in the wavelength region 2200–2600 Å was investigated some years ago by Roth and Rollefson (1). From the products of the photolysis at 20° C and 14 mm pressure they concluded that a primary dissociation into acetyl and methoxy radicals accounted for about 95% of the total reaction. A dissociation into CO_2 and, presumably, two methyl radicals accounted for the remainder. They also examined the Hg($^3P_1$)-photosensitized decomposition under similar conditions and found that the decomposition proceeded by essentially the same paths. The direct photolysis has been investigated in further detail by Wijnen (2, 3, 4), and briefly by Ausloos (5). Wijnen found, in agreement with the earlier work, that the main primary dissociation was to form acetyl and methoxy radicals. A dissociation to give CO_2 also occurred, but to a larger extent than found by Roth and Rollefson. As will be discussed below, Wijnen's data lead to a ratio of about 4:1 for the two modes of dissociation at 30° C.

In the present work, the relative importance of the primary dissociation steps in the mercury-photosensitized decomposition has been reinvestigated.

EXPERIMENTAL

The Hg($^3P_1$)-photosensitized reactions were carried out using a fast-flow system coupled to a mass spectrometer. This apparatus and its characteristics have been described in earlier publications in this series (6, 7, 8). The reactant and mercury vapor at partial pressures of a few microns were carried in a stream of helium at 8 mm through a tubular fused-silica reaction cell strongly illuminated by a low-pressure mercury lamp of high intensity. A representative portion of the stream entered the ionization chamber of a mass spectrometer through a small orifice at the end of the illuminated zone. The temperature of the cell was maintained at 55° C by circulation of water from a thermostatted bath. The contact time in the illuminated zone was about 0.001 second. The intensity of 2537-Å radiation absorbed was sufficient to decompose acetone, for example, to the extent of about 22% in this period. In effect, the reaction conditions resemble those of flash photolysis, since radical–radical reactions greatly predominate over radical–substrate reactions (8).

RESULTS AND DISCUSSION

The yields of products in the mercury-photosensitized decomposition of methyl acetate are given in Table I. The yield of H_2 was less than 2% of the methyl acetate decomposed.

In addition to the products listed, a considerable amount of a polymeric substance was formed, which deposited on the walls of the reactor as a yellowish-brown stain. The formation of this material is presumably responsible for the low carbon, oxygen, and hydrogen balances. The low mass balances cannot be attributed to the formation of polymers of formaldehyde. In the photosensitized decomposition of dimethyl ether the carbon and oxygen balances were 95%, although large amounts of formaldehyde were formed (9). Moreover, the near equality of the carbon, oxygen, and hydrogen balances in Table I indicates that the material unaccounted for must have a C:O:H ratio essentially the same as in methyl acetate itself. Since some 25% of the methyl acetate disappears to form an unidentified and presumably non-volatile product, the conclusions reached as to the relative importance of various primary modes of dissociation are necessarily approximate.

The variations in the percentage of methyl acetate decomposed in the four runs in Table I result from the difficulties encountered in keeping the reactor walls reasonably free from opaque deposits.

The presence of substantial yields of products such as $(CH_3CO)_2$, CH_3COCH_3, and CH_3CHO indicates that acetyl radicals are formed in abundance in the decomposition. The corresponding fragment, CH_3O, is clearly the precursor of such products as CH_3OCH_3,

CH_3OH, and CH_2O. The formation of CO_2 and $HCOOCH_3$, on the other hand, must result from an alternative primary step in which a CH_3 radical or possibly two CH_3 radicals are lost from the methyl acetate molecule. Evidently two, and possibly four, primary decomposition steps must be taken into account:

$$CH_3\overset{\overset{O}{\|}}{C}OCH_3 + Hg^* \rightarrow CH_3CO + OCH_3 + Hg \quad [1]$$

$$CH_3\overset{\overset{O}{\|}}{C}OCH_3 + Hg^* \rightarrow CH_3 + \overset{\overset{O}{\|}}{C}OCH_3 + Hg \quad [2]$$

$$CH_3\overset{\overset{O}{\|}}{C}OCH_3 + Hg^* \rightarrow CH_3\overset{\overset{O}{\|}}{C}O + CH_3 + Hg. \quad [3]$$

If the CH_3CO_2 or $COOCH_3$ radicals decompose almost immediately, reactions [2] and [3] will be equivalent to the following reaction:

$$CH_3\overset{\overset{O}{\|}}{C}OCH_3 + Hg^* \rightarrow 2CH_3 + CO_2 + Hg. \quad [4]$$

The secondary reactions of radicals formed in these steps will be (*a*) from reaction [1]:

$$2CH_3CO \rightarrow (CH_3CO)_2 \quad [5]$$

$$2CH_3CO \rightarrow CH_3CHO + CH_2{=}CO \quad [6]$$

$$CH_3CO \rightarrow CH_3 + CO \quad [7]$$

$$CH_3CO + Hg^* \rightarrow CH_2{=}CO + H + Hg \quad [8]$$

$$CH_3CO + CH_3 \rightarrow CH_3COCH_3 \quad [9]$$

$$CH_3CO + CH_3 \rightarrow CH_2{=}CO + CH_4 \quad [10]$$

$$2CH_3O \rightarrow CH_3OH + CH_2O \quad [11]$$

$$CH_3O + CH_3 \rightarrow CH_3OCH_3 \quad [12]$$

$$CH_3O + CH_3 \rightarrow CH_2O + CH_4 \quad [13]$$

$$CH_3O + CH_3CO \rightarrow CH_3OH + CH_2{=}CO \quad [14]$$

$$CH_3O + CH_3CO \rightarrow CH_2O + CH_3CHO \quad [15]$$

$$CH_3COCH_3 + Hg^* \rightarrow CH_3CO + CH_3 + Hg \quad [16]$$

$$CH_3OCH_3 + Hg^* \rightarrow CH_3O + CH_3 + Hg \quad [17]$$

$$CH_3OCH_3 + Hg^* \rightarrow CH_3OCH_2 + H + Hg \quad [18]$$

$$CH_3OCH_2 + OCH_3 \rightarrow CH_3OCH_2OCH_3, \quad [19]$$

and (*b*) from reactions [2]–[4]:

$$2CH_3 \rightarrow C_2H_6 \quad [20]$$

$$CH_3\overset{\overset{O}{\|}}{C}O \rightarrow CH_3 + CO_2 \quad [21]$$

$$\overset{\overset{O}{\|}}{C}OCH_3 \rightarrow CH_3 + CO_2 \quad [22]$$

$$\overset{\overset{O}{\|}}{C}OCH_3 + CH_3O \text{ (or } CH_3CO) \rightarrow H\overset{\overset{O}{\|}}{C}OCH_3 + CH_2O \text{ (or } CH_2{=}CO). \quad [23]$$

Since many of these products can be formed in several ways it is not possible to establish the relative importance of these secondary reactions. The reactions of radicals such as CH_3CO and CH_3O with a second excited mercury atom under conditions of intense illumination in the present apparatus cannot be entirely neglected (7). The reaction of secondary products such as CH_3OCH_3 with excited mercury must also occur. For example, $CH_3OCH_2OCH_3$ is most probably formed by the sequence of reactions [12], [18], and [19].

The relative importance of the primary step [1] can be estimated from the amount of products derived from CH_3O and from CH_3CO radicals according to the following relations:

$$R_{CH_3O} = 2R_{(CH_3O)_2CH_2} + R_{CH_3OCH_3} + R_{CH_2O} + R_{CH_3OH} \quad [24]$$

$$R_{CH_3CO} = 2R_{(CH_3CO)_2} + R_{CH_3CHO} + R_{CH_2=CO} + R_{CH_3COCH_3}. \quad [25]$$

The yield of CO cannot be included in either of these relations, since CH_3O and CH_3CO radicals may both give CO by reaction with Hg^*. As shown in Table I, the yield of CH_3O amounts to 50–53% of the methyl acetate decomposed. The yield of CH_3CO is, however, only 34–38%. The difference presumably results from CH_3CO radicals which have disappeared to form products other than those listed in equation [25], that is, by reaction [7]. Since CH_3CO radicals would be thermally stable at 55° C, it is possible that some of the acetyl radicals carry over from the primary step sufficient energy to cause them to dissociate. Alternatively, reaction [7], like reaction [8], may be brought about by collision with an excited Hg atom.

An attempt was made to obtain an upper limit to acetyl production by introducing CH_3 radicals into the reaction stream and measuring the limiting yield of CH_3COCD_3. In this experiment, $Hg(CD_3)_2$ was added to the carrier gas as described in earlier publications (9, 10). The mercury-photosensitized decomposition of the $Hg(CD_3)_2$ then provided a large concentration of CD_3 radicals. According to Wijnen (2), the ratio of disproportionation to combination for $CH_3 + CH_3CO$ is about 0.06, and for the present purposes reaction [10] can be neglected compared to reaction [9]. The limiting yield of CH_3COCD_3 formed in the presence of a large excess of CD_3 should then provide an indication of the number of CH_3CO radicals which survive the primary step long enough to react with CD_3 radicals. The yields of CH_3COCD_3 obtained in this way are given in Table II. A plot of CH_3COCD_3 against added $Hg(CD_3)_2$ is given in Fig. 1. Although the yield is

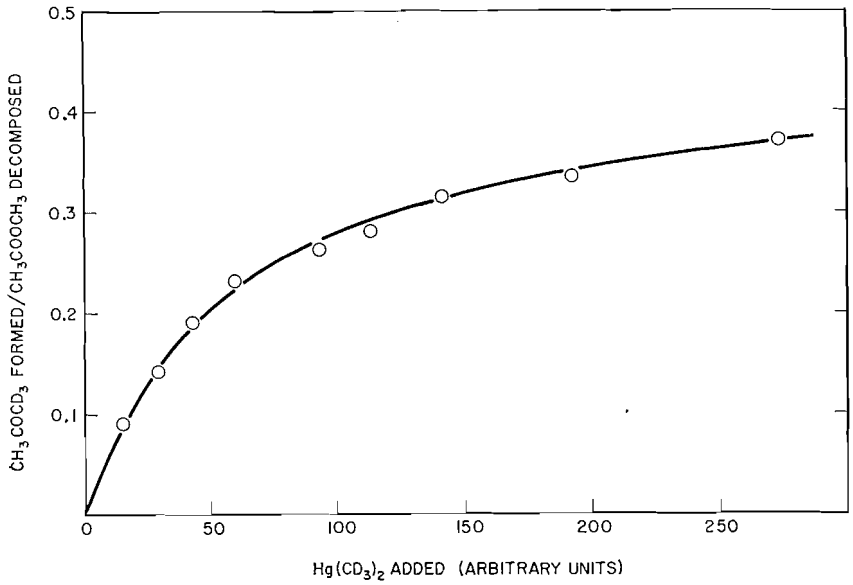

FIG. 1. Yield of CH_3CO radicals as shown by addition of CD_3 radicals to reaction stream.

still rising slowly even with the largest amount of added $Hg(CD_3)_2$, it is apparent that the limiting yield of CH_3CO is appreciably less than the 53% yield obtained for CH_3O. It is, in fact, not much higher than the CH_3CO yield in Table I as obtained from equation [28]. The difference between the values of 53% and of about 40% suggests that an appreciable fraction, possibly about one fifth, of the CH_3CO radicals formed in [1] decomposes to CH_3 and CO before the CH_3CO radicals have time to react with the other radicals present.

A slightly higher limit for the occurrence of reaction [1] can be obtained on the basis that

$$\text{total reaction [1]} = \tfrac{1}{2}(R_{CH_3O} + R_{CH_3CO} + R_{CO}). \qquad [26]$$

As shown in Table I, reaction [1] on this basis accounts for about 58% of the methyl acetate disappearing or about 82% of the total oxygen recovered.

The relative importance of the primary steps [2] and [4] can also be estimated from the yields in Table I. The only product other than CO_2 which could be formed only by reactions [2] and [4] was a small amount of methyl formate. In a separate experiment, a sample of reaction products was condensed from the gas stream in a liquid-nitrogen trap. G.L.P.C. fractionation of this sample yielded a fraction which by the retention time and by the mass spectrum was shown to be methyl formate and not the isomeric acetic acid. This points to the presence of $COOCH_3$ radicals resulting from reaction [2]. Confirmation of the presence of this radical was provided by the addition of CD_3 radicals to the reaction stream by means of $Hg(CD_3)_2$. The formation of a small peak at mass 77 (CD_3COOCH_3) supports the view that methyl formate was formed from $COOCH_3$ radical by reaction [23] rather than by combination of HCO and CH_3O radicals. The $COOCH_3$ radical was found in earlier work (8) to be reasonably stable at 55° C. The CH_3CO_2 radical, on the other hand, if formed at all, must dissociate immediately. The

For personal use only.

extent of the primary steps [2] and [4], then, can be estimated from the sum of the yields of CO_2 and methyl formate in Table I to be 13% of the methyl acetate decomposed. This is 18% of the total oxygen recovered.

A search was made for the CH_2COOCH_3 and CH_3COOCH_2 radicals which would result from removal of a hydrogen atom in a primary step. In the presence of a large excess of added CH_3 radicals no ethyl acetate or methyl propionate could be detected. The CH_2COOCH_3 radical, if present, should have been detected in this experiment, since it must have an appreciable lifetime at 55° C. Wijnen found $CH_3OCH_2COOCH_3$ from the combination of CH_2O and CH_2COOCH_3 to be a product of the photolysis even at 217° C (2). In this case the CH_2COOCH_3 radical was formed by a hydrogen-atom abstraction by CH_3 or CH_3O. The absence of these radicals in the present experiments, together with the low yield of H_2 mentioned above, indicates that the amount of decomposition proceeding by removal of a hydrogen atom was quite small.

In view of the 25% of methyl acetate which disappears to form unidentified products, any conclusions as to the ratios of various primary modes of dissociation are rather unreliable. It appears, however, that of that fraction which does give identifiable products, about 82% decomposes by reaction [1] and the remainder by reactions [2] and [4]. The ratio $R_1/(R_2+R_4)$ is about 4.4:1. This is not greatly different from the ratio observed by Wijnen (2) in the direct photolysis using a S-500 Hanovia arc. Using the data in Wijnen's Table 1 (excepting runs No. 13, 14, and 20 for which the CO_2 yield is anomalously low), one obtains values for the ratio of CH_3CO production to CO_2 production ($2R_{(CH_3CO)_2}+R_{CH_3COCH_3}+R_{CO}/R_{CO_2}$) ranging from 3.6 to 5.1. Ausloos (5) also found that CO production predominated in the photolysis of esters with unfiltered light, but that the formation of CO_2 became equally important at longer wavelengths.

FURTHER EVIDENCE FOR CYCLIC MONOMERS IN HEATED LINSEED OIL[1]

A. G. McInnes,[2] F. P. Cooper, and J. A. MacDonald[3]

ABSTRACT

The distillable esters of heated linseed oil contain a fraction, designated NAFD, which fails to form an adduct with urea. NAFD itself has now been separated into three fractions by gas–liquid partition chromatography. The chemical structure of these component esters was investigated by means of their infrared spectra and by analysis of the products obtained on oxidation of the esters with periodate–permanganate. It is concluded that all the components have the same carbon skeleton, namely, 1-propyl-2-alkenecarboxycyclohexene, but differ in the position of the double bond in the side chain.

INTRODUCTION

Wells and Common (1) have shown that the distillable (monomeric) ethyl esters obtained by ethanolysis of heated linseed oil contain a fraction, designated NAFD, that fails to form an adduct with urea. These authors suggested that NAFD contains a non-terminal ring structure preventing urea-adduct formation. Subsequently, MacDonald (2) obtained evidence for the presence of a six-membered non-terminal ring structure when he isolated phthalic anhydride following aromatization and oxidation of NAFD. MacDonald (2) also established that NAFD consisted of ethyl esters of C_{18} monocarboxylic acids containing an average of two double bonds per molecule. The double bonds did not contribute to the failure of NAFD to form a urea adduct because hydrogenated NAFD also failed to form an adduct (2). However, the low yield (about 1% of theory) of phthalic anhydride obtained (2) indicated that further investigation was necessary in order to determine the positions of the ring and the double bonds in the NAFD carbon chain.

In the present work, oxidation of NAFD by the periodate–permanganate oxidative procedure of Lemieux and von Rudloff (3) yielded a complex mixture of products, suggesting that NAFD was itself a mixture of C_{18} esters differing in the positions of the double bonds, of the ring, or both. On subjecting the methyl esters of NAFD acids to gas–liquid partition chromatography (G.L.P.C.), at least three components were detected. Two of the components were collected from the effluent gas stream and their structures were investigated separately by the periodate–permanganate oxidative procedure (3).

EXPERIMENTAL

Preparation of NAFD

NAFD was prepared from two distillation fractions of ethyl esters of heated linseed oil collected at 60° and 70°, respectively (2). The oxidation experiments were carried out with NAFD prepared from the fraction collected at 60° (NAFD 60°). Since this material was used up in these experiments, subsequent studies, e.g., fractionation of NAFD by G.L.P.C., were carried out with NAFD prepared from the fraction collected at 70° (NAFD 70°). The use of NAFD 70° was justified by the fact that (*a*) its refractive index (n_D^{20}, 1.47200) differed only slightly from the value (n_D^{20}, 1.47195) reported for NADF

60° (2); (*b*) both preparations contained the same component esters (Fig. 1, Table I); and (*c*) their infrared spectra were identical (Fig. 2).

Oxidation of NAFD

Total NAFD (ethyl esters) or NAFD fractions (methyl esters) obtained by G.L.P.C. were converted to free acids by saponification with ethanolic 0.5 *N* potassium hydroxide, followed by removal of the ethanol *in vacuo*, acidification, and extraction with ethyl ether. The free acids were dissolved in sodium bicarbonate solution at pH 7.6 (prior conversion to soaps by titration with 1 *N* sodium hydroxide hastened solution of the acids) and were oxidized with periodate–permanganate according to the procedure of Lemieux and von Rudloff (3). In a typical experiment, 1.03 g (3.69 mmoles) of NAFD acids consumed 17.0 mmoles of periodate (115% of theory for oxidation of two double bonds) after 30 hours, and yielded 1.22 g (theory 1.50 g) of oxidation products containing 3.12 equivalents (theory 5.0 equivalents) of acid per mole of NAFD oxidized.

A portion of the oxidation products of NAFD 60° was methylated with diazomethane in ethyl ether, and the resulting methyl esters were partially fractionated by distillation at 0.05 mm Hg; 75% of the products was collected up to 134° and this fraction is designated as "volatile" products; the remaining material is designated as "non-volatile" products.

Analysis of Oxidation Products

(a) Gas–Liquid Partition Chromatography (G.L.P.C.)

G.L.P.C. was carried out by the method of James and Martin (4) using a Podbielniak "Chromacon" (series 947-3V) which was modified to take glass chromatographic columns and to improve the pressure regulator, temperature control, and injection and collection systems. Helium was used as carrier gas, and a katharometer was used as detector.

Analyses of the methyl esters of oxidation products were made at 197° on a 4-ft column of Apiezon M – Celite 545 (1:4, w/w) (5). Separation of the methyl esters of NAFD was carried out at 240° on an 8-ft column of the same stationary phase.

(*b*) *Paper Chromatography*

Oxidation products were chromatographed as free acids by the method of Kolbe (6) for the separation of dicarboxylic acids, on Schleicher and Schuell 2043B paper using ethanol – 6 *N* ammonia – 3 *N* ammonium carbonate (6:1:1, v/v) as solvent. The chromatograms were developed for 20 hours at room temperature, dried, and sprayed with a solution of methyl red in borate buffer (6) to detect the acids. To isolate the separated acids, the mixture was applied as a band to sheets of Schleicher and Schuell paper (ca. 43 mg/sheet) and chromatographed as described above. The separated components were located on a guide strip cut from the middle of the sheet, and were eluted from the remaining paper with 3 *N* ammonia solution. The acids were isolated by acidifying the concentrated eluates with 0.1 *N* HCl and extracting with ethyl ether.

It is important to note that paper chromatography will analyze the total oxidation products, whereas G.L.P.C. will analyze only the volatile products.

RESULTS

Fractionation of NAFD by G.L.P.C.

The methyl esters of NAFD 60° or NAFD 70° were resolved by G.L.P.C. at 240° into three fractions (Fig. 1), the concentrations and relative retentions of which are given in Table I. The three fractions from both preparations of NAFD had the same relative retentions but differed in their relative proportions. As might be expected, NAFD 70°

contained a higher proportion of fraction III and a lower proportion of fraction I than did NAFD 60°. Samples of each of the fractions (from NAFD 70°) were collected from the effluent gas stream for further investigation.

Examination of the infrared spectra of the fractions (Fig. 2) showed that the band at 660 cm^{-1}, considered characteristic of NAFD (2), was completely absent in the spectrum of fraction I, moderately intense in fraction II, and greatest in fraction III. Since fraction II appeared to be contaminated with both fractions I and III, only the latter fractions were subjected to further analysis. Anal. were identified as azelaic, *n*-propyl-succinic, suberic, and pimelic acids (in decreasing concentration). The products from fraction III consisted mostly of a tricarboxylic acid together with small amounts of dicarboxylic acids, some of which were identified as suberic, azelaic, adipic, pimelic, and glutaric acids (in decreasing concentration). The major dicarboxylic acid methyl esters from total NAFD 60°, after separation by G.L.P.C., were collected from the effluent gas stream, converted to free acids, and characterized by analysis and melting point.

n-Propyl-succinic acid.—This component, after recrystallization from benzene–petroleum ether (b.p. 40–60°), had m.p. 90–91°, alone or when admixed with authentic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

n-propyl-succinic acid (m.p. 92–93°). Anal. Calc. for $C_7H_{12}O_4$: C, 52.49%; H, 7.55%; neutral equiv., 80.0. Found: C, 52.41%; H, 7.68%; neutral equiv., 79.8.

Suberic acid.—This component was recrystallized from water and had m.p. 139.5°, alone or when admixed with authentic suberic acid (m.p. 140–141°). Anal. Calc. for $C_8H_{14}O_4$: C, 55.16%; H, 8.10%; neutral equiv., 87.4. Found: C, 55.40%; H, 8.38%; neutral equiv., 87.4.

Azelaic acid.—This component, after recrystallization from benzene, had m.p. 104.5–105°, alone or in admixture with authentic azelaic acid (m.p. 106.5°). Anal. Calc. for $C_9H_{16}O_4$: C, 57.43%; H, 8.57%; neutral equiv., 94.0. Found: C, 57.67%; H, 8.42%; neutral equiv., 93.6.

The "volatile" fraction of the oxidation products of NAFD 60° on analysis by G.L.P.C. showed the same components as the total oxidation products of NAFD 60° given in Table II. The "non-volatile" products showed no peaks up to methyl sebacate under the same conditions, but on paper chromatography showed two components with R_F values (relative to sebacic acid) of 0.204 and 0.298 (Table III). These acids were almost completely absent from the oxidation products of fraction I, but were the predominating products from fraction III (Table III). Since these "non-volatile" products had low R_F values on paper chromatography, and had longer retention times than methyl sebacate on G.L.P.C., it was tentatively concluded that they were tricarboxylic acids of molecular weight greater than sebacic acid.

The tricarboxylic acid components were isolated by large-scale paper chromatography of 435 mg of the "non-volatile" fraction of total NAFD 60°; 32.9 mg of the acid with R_F 0.204 and 402.0 mg of the acid with R_F 0.298 were obtained as oily residues which failed to crystallize. Only the component with R_F 0.298 was investigated further. Its methyl ester showed strong ester absorption in the infrared at 1730 cm^{-1}, as well as a weak lactone band at 1775 cm^{-1}. Chromatography of the methyl ester on silicic acid with chloroform as eluant yielded a fraction (170 mg), the infrared spectrum of which showed only the ester band at 1730 cm^{-1}. The ester gave only one peak, with retention relative to methyl myristate of 3.09, when analyzed by G.L.P.C. on Apiezon M at 240°. The relative retention of the ester indicated that it had a molecular weight not less than that of methyl heptadecanoate (M.W., 284; relative retention, 3.20). Anal. Found: C, 61.55%; H, 8.89%; C—CH_3 (11), 7.20%; OCH_3, 24.1%; saponification equivalent, 117. Calc. for $C_{16}H_{19}(COOCH_3)_3$: C, 60.7%; H, 8.92%; C—CH_3, 8.55%; OCH_3, 29.4%; saponification equiv., 105.4. Calc. for $C_{11}H_{21}(COOCH_3)_3$: C, 61.8%; H, 9.14%; C—CH_3, 8.18%; OCH_3, 28.1%; saponification equiv. 110.0.

The analytical and chromatographic data suggest that the ester is a trimethyl ester of a C_{13} or C_{14} tricarboxylic acid with one terminal methyl group.

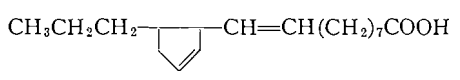
DISCUSSION

The analysis of NAFD by G.L.P.C. showed that it contained at least three components (Fig. 1, Table I), the relative retentions and analyses of which were consistent with those of methyl esters of diunsaturated C_{18} fatty acids (5). These esters cannot be simple open-chain diunsaturated compounds since it has already been shown that NAFD (1) and hydrogenated NAFD (2) fail to form an adduct with urea. The failure of NAFD to form a urea adduct might be due either to the presence of a non-terminal ring (1, 2) or to the presence of branching in the fatty-acid chain. However, the oxidation products of NAFD or of fractions I and III contained only traces of lower fatty acids (propionic through caproic, Table II) and failed to form oximes or hydrazones, indicative of the absence of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

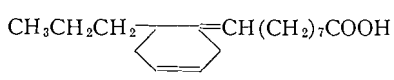
ketones. Furthermore, terminal methyl values for fractions I and III indicated the presence of only one C—CH_3 group per molecule. Since a branched-chain unsaturated fatty acid would yield either a ketone or a monocarboxylic acid on oxidation, and would have more than one terminal methyl group per molecule, it follows that none of the NAFD components can be branched, and therefore, that they contain a non-terminal ring.

Examination of the infrared spectra of the components of NAFD (fractions I, II, and III; see Fig. 2) revealed that the band at 660 cm^{-1}, attributed to the C—H out-of-plane deformation of a cis-disubstituted double bond in a six-membered ring (2), was present in III (and to a lesser extent in II) but not in I. Furthermore, the intensity of the band at 970 cm^{-1}, attributed to a trans-disubstituted double bond (8, 9), increased in the order I < II < III, and the weak absorption at 1650 cm^{-1}, due to the C=C double-bond stretching vibration (9), also increased in the same order. Finally the absorption at 715 cm^{-1}, characteristic of the methylene rocking vibration (9), decreased in intensity in the order I > II > III.



These data suggest that fraction III contains one trans-disubstituted double bond, one cis-disubstituted double bond (probably in a six-membered ring), and short methylene chains, whereas fraction I contains no trans-disubstituted double bonds and longer methylene chains. The weak absorption at 970 cm^{-1} (trans double bond) in fraction I is probably due to the presence of a small amount of fraction II.

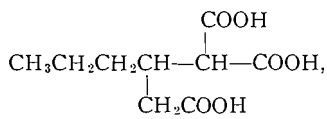
Separation of the components of NAFD by G.L.P.C. on Apiezon M may be attributed largely to differences in stereochemistry at the unsaturated centers, since compounds with trans double bonds have longer retention times than the cis isomers (see James (10)). The operation of other factors, such as the position of the ring and the lengths of the methylene chains, may be responsible for the incomplete separation and overlapping of the components, as evidenced by the complexity of the mixtures of oxidation products obtained from fractions I and III (Tables II and III). Nevertheless, the data in Tables II and III show that the major oxidation products of fraction I are azelaic and *n*-propyl-succinic acids, together with smaller amounts of suberic, pimelic, and an unknown acid, and those of fraction III are the tricarboxylic acid, suberic acid, and azelaic acid, together with smaller amounts of adipic, pimelic, and an unidentified acid. On the basis of the formation of these major oxidation products, one can suggest possible structures which would at least account for a major part of the material in fractions I and III.



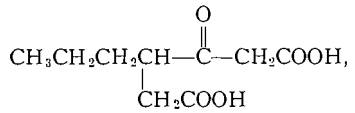
Thus the formation of *n*-propyl-succinic and azelaic acids from fraction I indicates that the latter contains the two fragments

$$CH_3CH_2CH_2—\underset{\displaystyle CH_2—C=}{\overset{\displaystyle |}{CH}}—C= \quad \text{and} \quad =CH(CH_2)_7COOH.$$

These fragments account for 16 carbon atoms and 3 double bonds, whereas fraction I contains 18 carbon atoms and only 2 double bonds. Formation of azelaic acid fixes the carboxyl end of the structure and also the position of one double bond, while the *n*-propyl-succinic acid fixes the methyl end of the structure. Two possible structures, A or B, could account for these products.



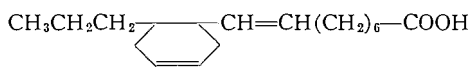
A



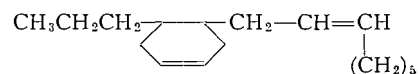
B

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Structure A, on oxidation, would give rise to azelaic acid and an acid,

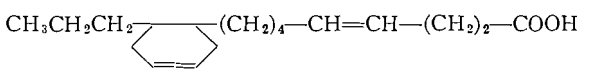


which would be oxidatively decarboxylated to *n*-propyl-succinic acid. Structure B would yield azelaic and a β-keto acid,

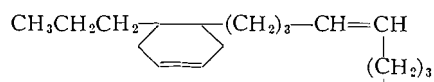


which would also be oxidatively decarboxylated to *n*-propyl-succinic acid. However, structure B fits the infrared data better than A, since B would not be expected to absorb strongly at 970 cm^{-1} (characteristic of a trans-disubstituted double bond) whereas the double bond in the side chain of A would be in the more thermodynamically stable trans conformation, as a result of the conditions of formation (2), and would thus absorb strongly at 970 cm^{-1}.

Formation of suberic acid and pimelic acid from fraction I might be accounted for by the presence of compounds (C and D) with a modified structure B, in which the exocyclic double bond is displaced by one or two carbon atoms towards the carboxyl group.



C



D

Oxidation of C and D would yield, in addition to suberic and pimelic acids, C_{10} and C_{11} tricarboxylic acids, respectively, possibly accounting for the small amount of tricarboxylic acids detected on paper chromatograms of the oxidation products of fraction I (Table III). It is quite likely that the bulk of fraction II consists of these two acids (C and D), incompletely resolved from the component with structure B present in fraction I.

To account for the formation of large amounts of C_{13} or C_{14} tricarboxylic acid from fraction III, structures E and F are postulated.

E

F

Oxidation of structures E and F would yield a C_{14} tricarboxylic acid and succinic acid, and a C_{13} tricarboxylic acid and glutaric acid, respectively. The presence of glutaric acid in the oxidation products of fraction III (Table II) adds additional support for structure F. Suberic and pimelic acids in the oxidation products of fraction III probably arise from structures C and D, which were not completely separated from fraction III.

The proposed structures should account for the fact that fraction I does not absorb at 660 cm^{-1}, the region attributed to C—H out-of-plane deformation of a cis double bond in a six-membered ring. All the structures proposed (B, C, D, E, and F) contain a cis double bond in a six-membered ring, but in structure B (the major component of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

fraction I), the second double bond is attached directly to the ring. It is possible that this double bond hinders the C—H out-of-plane deformation of the ring double bond to the extent that no absorption at 660 cm^{-1} occurs, whereas the exocyclic double bonds in structures C, D, E, and F, being further removed, offer no such hindrance.

Finally, the proposed structures should be consistent with the finding (2) that NAFD gave low yields of phthalic anhydride after allylic bromination, dehydrohalogenation, and oxidation of the side chains. The steric requirement for dehydrohalogenation in a six-membered ring is that the halogen and hydrogen atoms must be trans-diaxially oriented in the transition state (12). This requirement could not easily be fulfilled by an unsaturated six-membered ring such as in the proposed structures (particularly structure B), and therefore low yields of phthalic anhydride would be expected from any of these structures.

ACKNOWLEDGMENTS

The infrared spectra were taken by Mr. C. F. Rollin, and the microanalyses were carried out by Mr. A. E. Castagne. The generous help of Dr. M. Kates in preparation of the manuscript is acknowledged.

THE DIFFERENTIAL THERMAL ANALYSIS OF WOOD[1]

D. F. ARSENEAU

ABSTRACT

Differential thermal analysis was used to study the thermal breakdown of balsam fir and its components in air from 50° to 420° C. In this range, the thermogram of balsam fir is simply a composite of the individual thermograms of the components of the wood, with little, if any, interaction between the components.

INTRODUCTION

Wood is a multicomponent, molecularly non-homogeneous material in which part of the components exist in continuous separate intermingling structures. Balsam fir is reported (1) to contain about 27.7% lignin, 49.4% alpha-cellulose, 15.4% hemicelluloses, 1.5% acetyl, 0.5% ash, and 4.6% extractives. These extractives comprise an extraordinary diversity of substances and could include fats, fatty acids, resin acids, resins, waxes, tannins, phlobaphenes, coloring matters, gums, starches, and many others. All of these components contribute certain physical and chemical properties to the wood substance. Differential thermal analysis (D.T.A.) is able to determine to some degree what contributions some of these components make to the thermal decomposition characteristics of the wood.

Previous workers have used D.T.A. to study lignin (2), cellulose (3), and the carbonation of wood (2, 4). One study (2) indicated that the pyrolysis of birchwood was accompanied by considerable interaction between its components. Since preliminary work on balsam fir did not indicate this same interaction, a further study was undertaken.

EXPERIMENTAL

Apparatus

The apparatus for this study consisted of a vertical-type brass furnace (Fig. 1) in which three identical holes were drilled to a depth of $2\frac{3}{4}$ inches. Great care was taken to see that these were equidistant from the perimeter of the furnace. Two of these holes were to receive the sample holders, the third was to receive the thermocouple that feeds a signal to the temperature controller. The furnace was wound with 20 ft of 24 gauge Chromel 'A' wire, wrapped in asbestos, and placed in a metal container 5 in. in diameter. Glass wool between the furnace and the container provided further heat insulation. The sample holders were brass tubes fitted with iron–constantan thermocouples and had a capacity of 0.7 ml, although their total capacity was not always utilized. These holders were inserted vertically through the bottom of the furnace.

The temperature of the furnace was regulated using an F and M Model 40 Linear Temperature Programmer with an iron–constantan thermocouple. A heating rate of 5.8° C per min was used in all determinations in this study. The signal from the differential thermocouples was preamplified by a Leeds and Northrup Model 9835-B Stabilized D-C Microvolt Indicating Amplifier and was recorded with a Varian Graphic Recorder Model G-10 with a span of 10 mv. Stable, reproducible results were obtained using this arrangement.

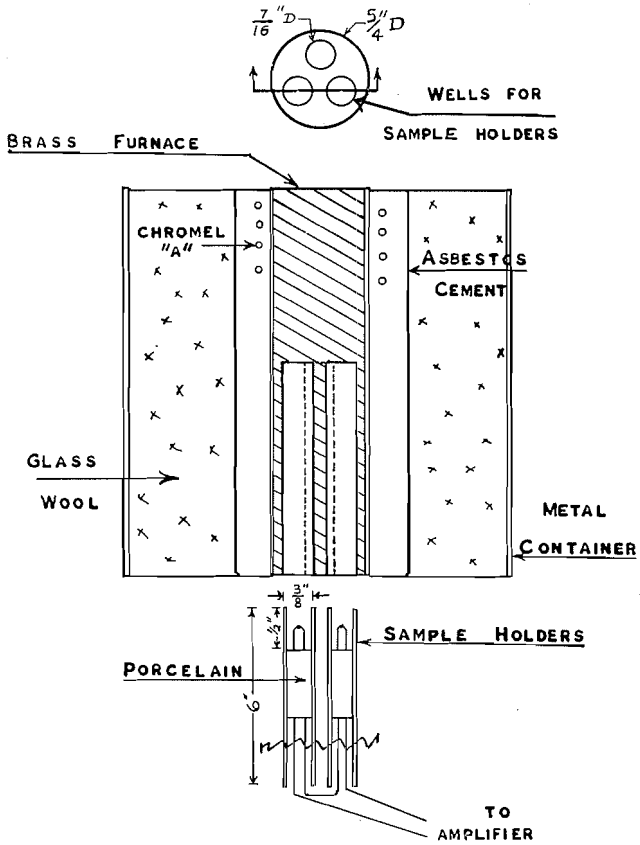

FIG. 1. Essentials of furnace and sample holders.

Wood Preparation

Air-dry balsam fir (*Abies balsamea* (L.) Mill.) was powdered using a metal file and then screened. That fraction passing mesh No. 70 but retained by mesh No. 200 was used in this work.

Removal of Extractives

Wood powder was extracted for 8 hours at room temperature with a mixture of 65 parts benzene, 35 parts ethanol, and 15 parts water. This mixture resulted in two layers. Upon evaporation, the benzene–alcohol layer yielded a brown, tarry material which was believed to contain resins. The alcohol–water layer was allowed to evaporate to near dryness at room temperature and was then further dried at 110° C. It yielded a gray material which was easily powdered. Some of the mixture appeared crystalline, and was very hygroscopic. A water solution of this material, acidified with acetic acid, gave a white precipitate with a solution of lead acetate, indicating the presence of tannins.

After the benzene–alcohol–water extraction, the wood powder was dried, and further extracted with 65 parts benzene and 35 parts ethanol. No extract was obtained. The wood was washed with water at 60° C and vacuum-dried at 100° C for 48 hours. This wood was designated as "free of extractives".

Isolation of Lignin

Two grams of wood free of extractives was added to 25 ml of 72% sulphuric acid at 10° C and stirred for 1 minute. The temperature was allowed to rise to 21° C. This mixture was allowed to stand for 2 hours with frequent stirring. The mixture was then diluted to 3% acid concentration, and boiled for 4 hours. The lignin residue was then filtered off using a fritted-glass crucible and washed with a liter of hot water until acid free. The lignin was dried at 110° C under vacuum for 24 hours.

Isolation of Some Hemicelluloses

One gram of wood powder free of extractives was treated with 50 ml of 20% potassium hydroxide for 18 hours under an inert atmosphere. Sufficient water was added to reduce the concentration of the potassium hydroxide to 3%, and the mixture was allowed to stand at 65 to 70° C for 2 hours before filtration. Excess acetic acid was added to neutralize the potassium hydroxide, and the hemicelluloses precipitated, twice the volume of methanol being used. After settling for about 2 hours, the precipitate was filtered off using a fritted-glass crucible, washed free of acid, washed with acetone, and vacuum-dried in a desiccator at room temperature.

Preparation for an Analysis

Calcined alumina, kept at 400° C until needed, was placed in both holders, the inert-sample holder being completely filled, the active-sample holder being filled to about $\frac{1}{8}$ of an inch of the thermocouple junction. Five milligrams of the active sample mixed with an equal volume of alumina was packed around the junction. Alumina was used to complete the filling of the sample holder. The two sample holders were inserted vertically into the furnace and a very slow current of air was circulated around the sample.

RESULTS AND DISCUSSION

Figure 2 shows eight thermograms over a range of 50° to 420° C. The interesting portions of the thermogram for air-dry wood powder have been lettered. Although some are very minor endotherms or exotherms, they reoccurred in all of the thermal analysis runs on the air-dry wood. As shown in Table I, all of the inflections except C can

TABLE I

Summary of peaks and their causes

Peak from air-dry wood	Fraction
A, endotherm at 145° C	Alcohol–water extract
B, endotherm at 163° C	Alcohol–water extract
C, 210° C	Unaccounted
D, 265° C	Possibly acid lignin
E, exotherm at 285° C	Benzene–alcohol extract
F, exotherm at 300° C	Sum of benzene–alcohol extract and acid lignin
G, exotherm at 330° C	Cellulose
H, exotherm at 360° C	Same as F

be attributed to reactions in the various fractions that go to make up the wood substance.

Thermogram II of the alcohol–water extract of wood discloses two endotherms at 144° and 163° C which could account for endotherms A and B. The extract melts at the former temperature and decomposes into a gas and a white powder at the latter.

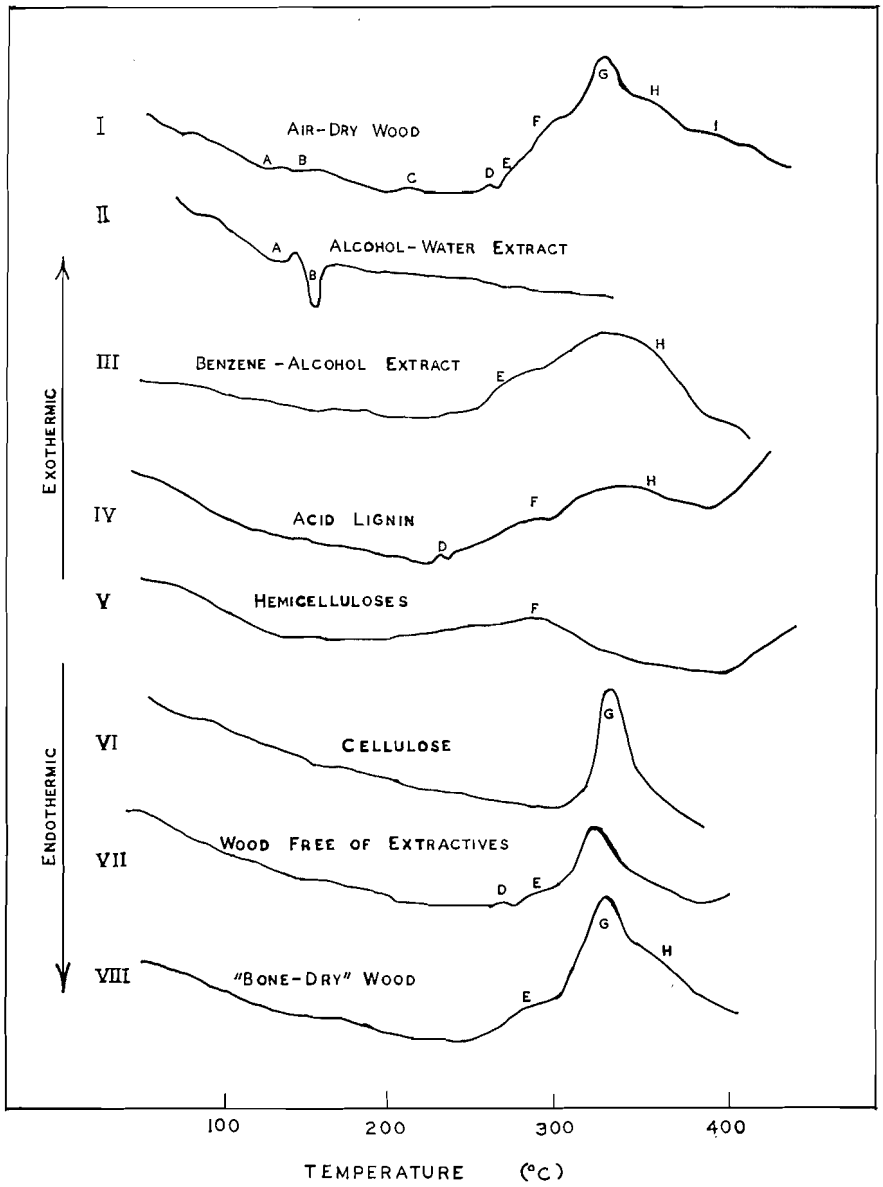

FIG. 2. Thermograms of balsam fir and its components.

The isolated acid lignin (IV) shows activity around 230° C quite similar to the variations D at 265° C in the thermogram for wood. This displacement could result from physical or chemical changes occurring in the lignin during the isolation procedure.

The main system of exothermic peaks from 270° to 400° C is actually a composite of several exothermic reactions. The shoulder E can be traced to the first portion of the main exothermic reaction of the benzene–alcohol extract (III). Section F is the sum of the tailing portion of the foregoing exotherm plus the 290° C exotherm of the acid lignin (IV).

Peak G is quite clearly the cellulose exotherm (VI) superimposed on the less intense exotherms of the lignin and the benzene–alcohol extract.

The hemicelluloses isolated by the procedure outlined above gave an exothermic peak which gradually reached a maximum at 285° C.

Morita and Rice (3) report that cellulose is characterized by an endotherm at 340° C when heated in an atmosphere of nitrogen. This present work shows that in air the endotherm becomes an exotherm at 330° C. The minor temperature shift can be attributed to the slower heating rate used here.

It is interesting to compare the thermograms of acid lignin and of the benzene–alcohol extract. Their marked similarity would suggest the presence of native lignin in the extract. In fact, a small amount (8 to 10%) of the protolignin in wood can be extracted in an unchanged form using indifferent solvents. Such lignin is termed "native" lignin. An acetone extract of wood, which would contain mainly resins, gave a thermogram identical with that of the benzene–alcohol extract. This similarity between the thermograms of lignin and resins could be expected because of a similarity in their basic structures.

These two thermograms do differ above 400° C, however. The acid lignin indicates the beginning of an intense exotherm, while the benzene–alcohol extract does not, nor does the unextracted wood powder show an exotherm in this range. Obviously the lignin has undergone some changes upon its isolation.

For thermogram VIII the original wood powder was vacuum-dried over drierite at 80° C for 48 hours. It was then left over drierite for 3 months at room temperature. Five milligrams of it was mixed with an equal volume of alumina and thermogramed. Many of the previously mentioned peaks were missing or decreased in intensity. It is difficult to account for these differences unless adsorbed water assists the breakdown of wood in a hydrolytic manner.

As would be expected, the thermogram of wood powder free of extractives (VII) displays the characteristic exotherm of cellulose at 330° C, and to a lesser extent, the exotherm of lignin, but not the peaks characteristic of the extractives.

It would appear, therefore, that over the range from 50° to 420° C the differential thermogram for balsam fir when heated in air is simply a composite of the individual thermograms of the various components of the wood, with little, if any, interaction between these components.

THE REACTION BETWEEN METHYL RADICALS AND ISOBUTANE[1]

A. R. BLAKE,[2] J. F. HENDERSON,[3] AND K. O. KUTSCHKE

ABSTRACT

It has been confirmed that the apparent rate constant for the reaction between methyl radicals, produced by the photolysis of deuterated acetone, and isobutane increases with decreasing isobutane pressure. An explanation is proposed to account for this observation suggesting that the production of methane by disproportionation between methyl and *t*-butyl radicals was not negligible as has been assumed previously.

INTRODUCTION

Observations made recently in this laboratory indicated that values of the apparent rate constants for the abstraction of hydrogen by methyl radicals, calculated using conventional methods, depended on the pressure of the added hydrogen donor. The reaction of methyl radicals with isobutane using the pyrolysis of di-*t*-butyl peroxide as a source of methyl radicals is an example of such a system (1). When mixtures of deuterated acetone and hydrogen were photolyzed, the rate constant for the reaction of methyl radicals with hydrogen was found to be a function of the hydrogen pressure (2). In view of the apparent similarities between the two systems, an investigation of the photolysis of deuterated acetone – isobutane mixtures was made.

EXPERIMENTAL

The apparatus and methods of analysis were similar to those employed in the photolysis of the deuterated acetone – hydrogen mixtures (2, 3). The deuterated acetone consisted of 98.2% acetone-d_6 and 1.8% acetone-d_5. Phillips Research Grade isobutane was outgassed by bulb-to-bulb distillations at $-160°$ C. The temperature of the reaction cell was $471 \pm 0.5°$ K for all experiments.

RESULTS AND DISCUSSION

In the photolysis of mixtures of deuterated acetone and isobutane, it is usually assumed that methane and ethane are formed by the following reactions:

$$CD_3 + CD_3 \rightarrow C_2D_6 \qquad [a]$$

$$CD_3 + CD_3COCD_3 \rightarrow CD_4 + CD_2COCD_3 \qquad [b]$$

$$CD_3 + i\text{-}C_4H_{10} \rightarrow CD_3H + t\text{-}C_4H_9. \qquad [c]$$

When the deuterated acetone was photolyzed alone (2), small amounts of CD_3H were formed due to the presence of acetone-d_5 in the sample, and its yield was given by

$$R_{CD_3H}/R_{C_2D_6}^{1/2} = 0.014[A] \times 10^{-12} \text{ (molecules/cc sec)}^{1/2}, \qquad [1]$$

where $[A]$ is the acetone concentration in molecules/cc. Allowance for this CD_3H was made when calculating values of $k_c/k_a^{1/2}$.

$$\rho = (k_c/k_a^{1/2})_{app} = R_{CD_3H}/R_{C_2D_6}^{1/2}[i\text{-}C_4H_{10}] \qquad [2]$$

Values of ρ are shown in Table I and it is evident that the apparent rate constant

169	7,241	1.09	1.08	3.22	3.76	5.30	0.495	9.60	97.7	6.73	63.2
173	6,300	3.23	1.07		7.52	10.1	1.22	23.3	98.1	6.69	65.3

determined by equation [2] varies with the isobutane pressure, which confirms the earlier observation (1). Unlike the addition of hydrogen (2), however, the addition of isobutane to acetone-d_6 did not affect the ratio $R_{CD_4}/R^{1/2}_{C_2D_6}[A]$ in any way. Finally, ρ did not appear to be influenced by the addition of perfluoro-*n*-butane which indicates the absence of excited species in the system.

To account for these observations, it is proposed that the disproportionation reaction between methyl and *t*-butyl radicals was important in the systems discussed here, and that the observed variation of ρ with isobutane pressure is due to the assumption that this reaction was negligible. By inclusion of the following radical–radical reactions in the mechanism, allowance for this additional source of CD_3H can be made in the following manner:

$$CD_3 + t\text{-}C_4H_9 \rightarrow CD_3H + i\text{-}C_4H_8 \qquad [d]$$

$$\rightarrow CD_3C_4H_9 \qquad [e]$$

$$t\text{-}C_4H_9 + t\text{-}C_4H_9 \rightarrow i\text{-}C_4H_{10} + i\text{-}C_4H_8 \qquad [f]$$

$$\rightarrow C_8H_{18} \qquad [g]$$

$$CD_3 + CD_2COCD_3 \rightarrow C_2D_5COCD_3 \qquad [h]$$

$$t\text{-}C_4H_9 + CD_2COCD_3 \rightarrow (CH_3)_3CCD_2COCD_3 \qquad [i]$$

$$CD_2COCD_3 + CD_2COCD_3 \rightarrow CD_3COCD_2CD_2COCD_3. \qquad [j]$$

The abstraction of deuterium from acetone-d_6 by t-C_4H_9 radicals is neglected on thermochemical grounds. On the basis of statistics, it is assumed that

$$2k_a = (2k_f + k_g) = 2k_j = k_d + k_e = k_h = k_i = k. \qquad [3]$$

Although this expression is not entirely correct due to differences in masses and entropies of the collision complexes, the error will be small (see Appendix I).

By the use of [3] and the mass balances in CD_3, t-C_4H_9, and CD_3COCD_2 radicals, the following expressions for m were derived (see Appendix II):

$$m_{\mathrm{I}} = 1 - [\beta\lambda_E^{1/2}(1 - \lambda_D - \lambda_E^{1/2})/\lambda_H] \qquad [4]$$

$$m_{\mathrm{II}} = ([1 + \beta(1 - \lambda_D)]/2\beta\lambda_H)\{1 - [1 - (4\beta\lambda_H)/(1 + \beta(1 - \lambda_D))^2]^{1/2}\} \qquad [5]$$

$$m_{\mathrm{III}} = (1 - \lambda_D - \lambda_E^{1/2})/\lambda_H \qquad [6]$$

$$m_{\mathrm{IV}} = 1/(1 + \beta\lambda_E^{1/2}), \qquad [7]$$

where $\beta = k_d/(k_d + k_e)$, $\lambda_D = R_{CD_4}/2R_{CO}$, $\lambda_H = R_{CD_3H}/2R_{CO}$, $\lambda_E = R_{C_2D_6}/R_{CO}$, and m is the yield of CD_3H from [*c*] relative to the total yield of CD_3H (i.e., $m = k_c[CD_3][i\text{-}C_4H_{10}]/R_{CD_3H}$).

Values of m were calculated for $\beta = 0.446$ corresponding to $k_d/k_e = 0.806$. This was calculated from the data of Kerr and Trotman-Dickenson (4) using [3] rather than [3*a*] (Appendix I), which was employed by the original authors. This procedure is logically more consistent with the present work than the use, directly, of the value $k_d/k_e = 0.699$ as reported by the original authors. In the recalculation, k_f/k_g was taken as 4.44, being the average of the values reported by Kraus and Calvert (5). It is interesting to note that the recalculated value is in better agreement than the original with the less precisely but more directly determined value $k_d/k_e = 0.9$ found by McMillan (6) using a method which did not require the assumption of either [3] or [3*a*]. Frey's value (7) is also based on the assumption of [3*a*] but no data are given to permit recalculation.

It was assumed throughout that CH_3 and CD_3 behave identically in respect to their reactions with t-C_4H_9 radicals.

not surprising in view of the algebraic identity which can be shown to exist (Appendix II), is, nevertheless, very gratifying when the algebraic complexity of some of the expressions is considered. Values of $k_c/k_a^{1/2}$ were determined using m_{IV} and equation [8]; they are independent of the pressure of isobutane (Table II and Fig. 1).

$$k_c/k_a^{1/2} = \rho m_{IV} \qquad [8]$$

By equating any two of the expressions [4], [5], [6], and [7] it is found that β is given by the relation

$$\beta = [\lambda_H - (1 - \lambda_D - \lambda_E^{1/2})]/\lambda_E^{1/2}(1 - \lambda_D - \lambda_E^{1/2}). \quad [9]$$

Because of the many subtractions involved, measurements of β made in this way cannot be regarded as highly precise; this is shown by the considerable scatter of its values (Table II).

Inspection of equation [7] indicates that m decreases with increasing λ_E, i.e. with increasing light intensity or decreasing isobutane pressure, and tends to $1/(\beta+1)$ in the limit. In Fig. 2, m_{IV} is plotted against the logarithm of λ_E (equation [7]) and approaches

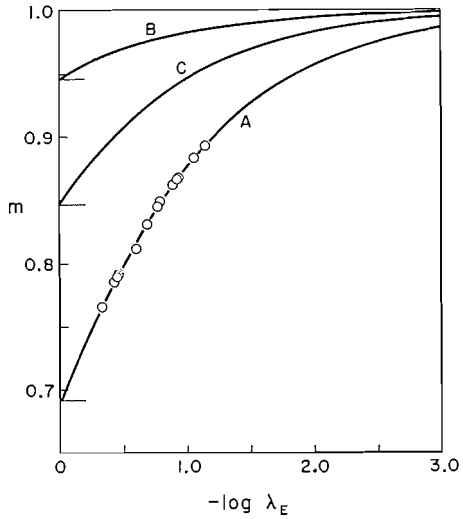

FIG. 2. Variation of m_{IV} with λ_E. A: m_{IV}, $\beta = 0.446$; B: m_{IV}, $\beta = 0.057$; C: m_{IV}, $\beta = 0.18$. The points on A are taken from Table II.

unity only when λ_E becomes exceedingly small; e.g. $m = 0.95$, 0.98, and 0.99 when $\lambda_E =$ 0.0139, 0.0021, and 0.0005 respectively. Consequently, to carry out experiments under conditions where the disproportionation reaction [*d*] would be negligible, the formation of ethane would have to be virtually completely suppressed.

If the earlier data, obtained by the pyrolysis of di-tertiary-butyl peroxide in the presence of isobutane (1), can be represented by a mechanism composed of reactions [*l*] and [*m*],

$$\text{DTBP} \rightarrow 2(CH_3)_3CO \quad [l]$$

$$(CH_3)_3CO \rightarrow CH_3 + CH_3COCH_3, \quad [m]$$

along with [*a*], [*c*], [*d*], [*e*], [*f*], and [*g*], an expression may be obtained which is identical in form with m_{IV}. However, in this application $\lambda_E = 2R_{C_2H_6}/R_{CH_3COCH_3}$. Acetone was not determined in those experiments but its rate of formation may be calculated with sufficient accuracy from the Arrhenius equation for the decomposition of the peroxide. Figure 1 also shows these data, in the original units, and indicates that application of the extended mechanism, with $\beta = 0.446$, gives essentially constant values of $k_c/k_a^{1/2}$. This is in contrast to the curvature observed in $R_{CH_4}/R_{C_2D_6}^{1/2}[i\text{-}C_4H_{10}]$ also shown in Fig. 1.

It is useful to note how the systematic error which arises from the neglect of reactions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the type [*d*] varies, through the value of β, with various hydrocarbons. Values of m_{IV} were calculated for $\beta = 0.057$ ($k_d/k_e = 0.06$ as found (7) for $CH_3 + C_2H_5$) and $\beta = 0.18$ ($k_d/k_e = 0.22$ as found (4) for $CH_3 + sec\text{-}C_3H_7$), and are shown in Fig. 2 as curves B and C respectively. The very much lower values of β encountered in these systems allow the taking of data without significant error at considerably larger values of λ_E.

The question also arises as to what effect neglect of the disproportionation reaction [*d*] has on the activation energy of the hydrogen-transfer reaction [*c*] when $m < 1.0$. It becomes immediately obvious when equation [2] is rewritten as follows that, provided m is kept independent of the temperature, the apparent and true activation energies will be identical.

$$\rho = m^{-1}(R_{CD_3H})_c/R^{1/2}_{C_2D_6}[i\text{-}C_4H_{10}] = (k_c/k_a^{1/2})_{app} \qquad [10]$$

If, owing to a decrease in λ_E, m increases with increasing temperature, the apparent value will be less than the true value, but the difference will be small in most instances. For example, it will be approximately 0.5 kcal mole^{-1} if m increases by 0.20 between 100° C and 250° C; this is comparable to the uncertainty often quoted in determinations of activation energy.

In conclusion, the variation with isobutane pressure of ρ (or $R_{CH_4}/R^{1/2}_{C_2D_6}[i\text{-}C_4H_{10}]$ in the DTBP system) can be accounted for by assuming the disproportionation reaction [*d*] to be a significant source of methane in these systems under some conditions. It is possible to relate the contribution of [*d*] to the known or measurable quantities β, λ_H, λ_D, and λ_E and thus to correct the data for that contribution. Some assumptions were necessary in the development of the relevant expressions but it is doubtful that the quantitative conclusions are seriously in error.

ACKNOWLEDGMENTS

We wish to thank Dr. E. W. R. Steacie for his interest in this work, Dr. R. J. Cvetanovic for some useful discussion of its interpretation, and Mrs. Bernice Riem for mass spectrometric analyses.

APPENDIX I

The referee of the present paper has asked us to comment on our use of [3] rather than [3*a*], the analogue of which occurs frequently in the literature.

$$k_e/k_a^{1/2}k_g^{1/2} = 2 \qquad [3a]$$

Kerr and Trotman-Dickenson (4, 9) and Trotman-Dickenson (10) have cited several systems in which [3*a*] appears to be verified experimentally.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Perhaps the simplest discussion can be given if the more general case is considered.

$$R_1 + R_1 \rightarrow \text{alkane}_1 + \text{alkene}_1 \quad [A]$$
$$\rightarrow R_1R_1 \quad [B]$$
$$R_1 + R_2 \rightarrow \text{alkane}_1 + \text{alkene}_2 \quad [C]$$
$$\rightarrow \text{alkene}_1 + \text{alkane}_2 \quad [D]$$
$$\rightarrow R_1R_2 \quad [E]$$
$$R_2 + R_2 \rightarrow \text{alkane}_2 + \text{alkene}_2 \quad [F]$$
$$\rightarrow R_2R_2 \quad [G]$$

The formulations corresponding to [3] and [3*a*] are, respectively,

$$(k_C+k_D+k_E)/(k_A+k_B)^{1/2}(k_F+k_G)^{1/2} = 2, \quad [i]$$

and

$$k_E/k_B^{1/2}k_G^{1/2} = 2. \quad [ii]$$

[A] and [D] are not observed when R_1 is a methyl radical.

It should be emphasized that [i], and thus [3], is the correct statistical formulation provided that each collision results in either disproportionation or combination of the colliding pair of radicals. The latter assumption, of course, underlies all the development in the body of this paper. If the steric factor is much less than unity for the sum of mutual disproportionation plus combination for some radical species, no theoretical relationship exists when a methyl radical is taken with that radical in a cross combination; this follows from the fact that the steric factor for the combination of methyl radicals is very close to unity (11). In that case, then, there is no a priori reason to expect either [i] or [ii] to hold.

If [i] is a correct formulation and the experimental data lead to [ii], it follows that the right side of [iii] must very nearly be unity.

$$(1/2)k_E/k_B^{1/2}k_G^{1/2} = [1+(k_B/k_A)]^{1/2}[1+(k_F/k_G)]^{1/2}/[1+(k_C/k_E)+(k_D/k_E)] \quad [iii]$$

Data are available to check [iii] for the systems tabulated.

R_1	R_2	k_A/k_B	k_F/k_G	k_C/k_E	k_D/k_E	[iii]

**Calculated from $k_D/k_C = 0.15$ and $k_C/k_E = 0.43$ given in footnote §.

Thus, within some 20%, the cancellation to unity is observed. This uncertainty is not much greater than that of the experimental values reported for $R_1R_2/(R_1R_1)^{1/2}(R_2R_2)^{1/2}$ used to support the use of [ii] and [3*a*].

It should be noted that the values of k_C/k_E reported in reference 4 for the systems CH_3, i-C_3H_7 and CH_3, t-C_4H_9 cannot be used to check [iii], since those values were obtained indirectly in that the equivalent of [ii] was used to calculate unmeasured products. The

ratios of rate constants reported by Boddy and Robb (12) were not considered here; reasons for questioning the reliability of those data have been advanced elsewhere (4, 10).

APPENDIX II

A brief description is given of the derivation of the expressions for m which appear in the text as equations [4], [5], [6], and [7]. To simplify the nomenclature, the following abbreviations are used: $[CD_3COCD_3] = a$, $[i\text{-}C_4H_{10}] = b$, $[CD_3] = v$, $[t\text{-}C_4H_9] = u$, $[CD_3COCD_2] = w$, and $\sigma = v+u+w$.

The balances for v, w, and u respectively are:

$$2R_{CO} = 2k_a v^2+k_b av+k_c bv+(k_d+k_e)uv+k_h wv \quad [i]$$

$$R_{CD_4} = k_b av = k_h vw+k_i uw+2k_j w^2 \quad [ii]$$

$$mR_{CD_3H} = k_c bv = (k_d+k_e)uv+2(k_f+k_g)u^2+k_i uw. \quad [iii]$$

If it is assumed that

$$2k_a = 2(k_f+k_g) = 2k_j = (k_d+k_e) = k_h = k_i = k, \quad [3]$$

the addition of [i], [ii], and [iii] and substitution of [3] yields [iv].

$$\sigma = (2R_{CO}/k)^{1/2} \quad [iv]$$

Combination of equations [ii] and [iv] gives

$$w = \sigma R_{CD_4}/2R_{CO} = \sigma\lambda_D. \quad [v]$$

Similarly, from equations [iii] and [iv],

$$u = m\sigma R_{CD_3H}/2R_{CO} = m\sigma\lambda_H. \quad [vi]$$

Because $(2R_{C_2D_6})^{1/2} = k^{1/2}v$, [iv] may be used to show that

$$v = \sigma(R_{C_2D_6}/R_{CO})^{1/2} = \sigma\lambda_E{}^{1/2}. \quad [vii]$$

Rearrangement of the relation

$$R_{CD_3H} = k_c bv+k_d uv = mR_{CD_3H}+k_d uv$$

and application of equation [iv] yields the following expression for m:

$$m = 1-(\beta uv/\sigma^2\lambda_H), \quad [viii]$$

where

$$\beta = k_d/(k_d+k_e). \quad [ix]$$

However,

$$u = \sigma-v-w = \sigma(1-\lambda_D-\lambda_E{}^{1/2}), \quad [x]$$

and the expression for m_I is obtained by substitution of [x] into [viii]. Similarly,

$$v = \sigma(1-\lambda_D-m\lambda_H), \quad [xi]$$

and, substituting in [viii], the expression for m_{II} is obtained. Substitution of uv in [viii] by

$$uv = m\sigma^2\lambda_H\lambda_E{}^{1/2} \quad [xii]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

gives the relation for m_{IV}. In addition, [iii] can be rewritten using [x] as

$$mR_{CD_3H} = k\sigma u = k\sigma^2(1-\lambda_D-\lambda_E^{1/2}).$$

The expression for m_{III} follows after substitution of [iv].

If any pair of the relations for m are equated, the same expression for β is obtained. The manipulation is easy except when m_{II} is one of the expressions in the pair taken. Furthermore, substitution of this expression for β into the relations for m_I, m_{II}, or m_{IV} yields that for m_{III}. This provides good evidence for the existence of the algebraic identity $m_I = m_{II} = m_{III} = m_{IV}$. Consequently, when calculating values of m the relation which gives the most precise result can be used.

Finally, because λ_E tends to unity as light intensity is increased and isobutane pressure is decreased, it can be shown that m will tend to $1/(1+\beta)$ at high light intensity and low isobutane pressure and that m will tend to unity under the opposite conditions, i.e. $\lambda_E \rightarrow 0$ (equation [7]).

DESIGN AND CALIBRATION OF AN INEXPENSIVE FREE-FLOW ELECTROVISCOMETER[1]

P. A. D. DE MAINE AND E. R. RUSSELL

ABSTRACT

Here are reported the design and calibration of a new inexpensive free-flow electroviscometer for rapid and accurate measurement of the viscosity coefficients for conducting and non-conducting solutions. Flow times of 30 seconds are easily reproduced to within 0.02 second.

INTRODUCTION

In the past, several comprehensive review articles about viscometers have been published (1–5). An automatic viscometer designed to measure flow times accurately without constant attention by the operator has been reported by Goldfinger and Greatbatch (6). This viscometer used a photoelectrically triggered timing device to measure flow times to within 1 part in 10,000. Stock (7) has designed an electric resistance stream gauge type viscometer.

Measurements with free-flow type viscometers are limited in accuracy by the response time of the observer and the flow time of the viscometer. Rotary cone and the Goldfinger–Greatbatch types are relatively expensive and create problems where temperature control is desired.

Here is described a new modification of the Ostwald–Fenske viscometer which can be immersed in the usual thermostated bath. Even the low flow times, less than 30 seconds, are measured electronically to better than 1 part in 1000.

DESCRIPTION OF APPARATUS

Electrodes of No. 24 gauge platinum were sealed into an Ostwald–Fenske viscometer at the locations shown in Fig. 1. Platinum-to-glass or Hysol cement seals are satisfactory. Special care should be taken to locate the lowest electrode (No. 3) away from the capillary entrance. The top two electrodes (Nos. 1 and 2) are located centrally to minimize holdback of the solution. Lead wires are soldered to the three electrodes and then are coated with Dupont Duco cement for electrical insulation. Cover assemblies were cut from solid Plexiglass and were cemented directly onto the viscometer with Dupont Duco cement. These cover assemblies fit into openings in the lid of the Precision Temp-trol kinematic viscosity bath (Precision Scientific Company, Chicago, Illinois), and thus correct positioning of the viscometer is assured at all times.

Two Model 30 Fisher transistor relays (Fisher Scientific Company, New York, N.Y.) were connected to the platinum electrodes on the viscometer (Fig. 2) through variable resistances (0 to 0.50 meg) and to a Precision Time-it timer (Precision Scientific Company, Chicago, Illinois) graduated in 1/10 seconds. Viscosity measurements at constant, desired temperatures were achieved by placing the viscometers in the Temp-trol kinematic viscosity bath or in a similar laboratory-constructed unit.

OPERATION AND CALIBRATION

Methanol – carbon tetrachloride solutions of $SnCl_4.5H_2O$ and methanol solutions of iron group metal chlorides were used in the calibration of the modified Ostwald–Fenske

viscometers. $CaCl_2$, $CrCl_3.6H_2O$, $MnCl_2.4H_2O$, $CoCl_2.6H_2O$, $CoCl_2.2H_2O$, $NiCl_2.6H_2O$, $NiCl_2.2H_2O$, $CuCl_2.2H_2O$, and $ZnCl_2$ were used. Accurate viscosity data for these solutions as measured with normal Ostwald–Fenske viscometers at 20° C or 25° C and 45° C have been reported (8, 9). It has also been shown that molar conductance values for these solutions are in the range 0.80 to near 160 (10, 11, 12). Densities accurate to four decimal places have also been reported (8, 12).

Ten milliliters of solution was pipetted into the electroviscometer. The resistance (R) between electrodes 1 and 2 or between 2 and 3 (Fig. 1) with the viscometer immersed in the thermostated bath, and the immediate change in resistance (ΔR) as the solutions flowed past the two top electrodes, were measured directly with a Simpson Avometer. The maximum resistance ($\bar{R}$) required to operate the contact circuits for each of the two relays, C and D (Fig. 2), was determined by varying resistances A and B respectively. For the four relays used in this work, $\bar{R}$ lies between 200,000 and 310,000 ohms. The variable resistances A and B were set at a value $\mathring{R}$ so that $\mathring{R}+\Delta R = \bar{R}+10{,}000$. Experiments have shown that for all the conducting solutions studied, $\mathring{R}$ can be set at any value between 50,000 and $(\bar{R}-20{,}000)$ ohms. $\bar{R}$ usually lies between 200,000 and 310,000 ohms. Values for $\mathring{R}$ between these limits do not give any change in flow-time values.

The solution was drawn up in the viscometer so as to cover electrodes 1, 2, and 3. As the falling solution passed the top electrode the timer was switched on automatically and then the timer was switched off as the liquid passed the second electrode. Typical data collected for solutions of $SnCl_4.5H_2O$ are given in Table I. The factor limiting the accuracy appears to be the 0.1-second units (readable to 0.05 second) on the timer.

TABLE I

In Figs. 3 and 4 are plotted viscosity coefficients, determined with the usual Ostwald–Fenske viscometer (flow time 400 to 1100 seconds), versus the product of density (8, 12)

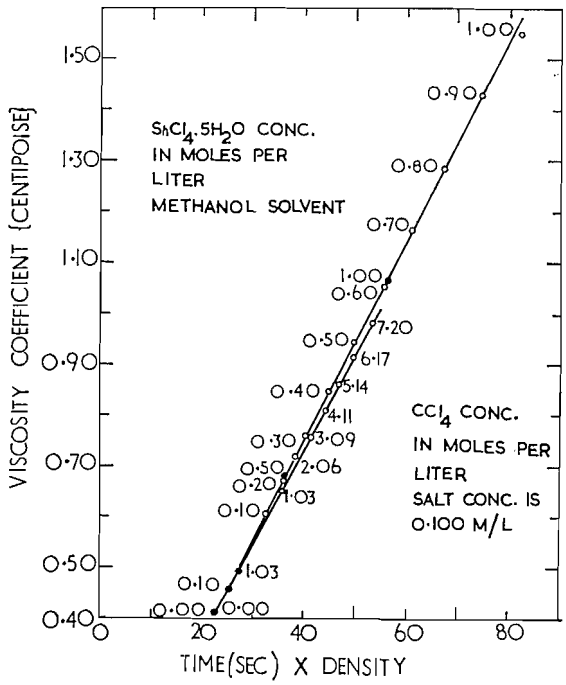

FIG. 3. Plots of viscosity coefficient, determined with normal Ostwald–Fenske viscometers, versus the product of density×time, measured with the electroviscometer, for $SnCl_4.5H_2O$ dissolved in pure methanol or in methanol – carbon tetrachloride: ○ 25° C; ● 45° C. (Except for the 1.000 *M* $SnCl_4.5H_2O$ solution, the maximum deviation from each straight line is near 1 part in 1000.)

and flow time (in seconds) measured with the new electroviscometer. The linear relations (maximum deviation 0.10%) found for the methanol solutions (Figs. 3 and 4) indicate that the flow characteristics of the modified Ostwald–Fenske viscometer do not change significantly with temperature or with the viscosity of the solution. For $SnCl_4.5H_2O$ solutions, similar linear relations exist for each solvent composition studied. The deviation for the plot for systems of high carbon tetrachloride concentration is just 1% from the plot for solutions with pure methanol as solvent (Fig. 3). This deviation probably arises from the gross changes in the surface tension and density as one passes from pure methanol to methanol – carbon tetrachloride, with the latter of high concentration.

Thus with calibration plots for each solvent and a modified Ostwald–Fenske viscometer, the viscosity coefficient of conducting solutions can be rapidly and accurately determined at any temperature. In our laboratory 200 measurements for 20 different solutions at two temperatures were made in less than 6 hours. Moreover, this inexpensive electroviscometer has been adapted to measure flow times for non-conducting liquids by addition of small amounts of a conducting compound, by use of higher resistances in parallel, or by different spacing of the electrodes.

HYDROGEN EXCHANGE BETWEEN CELLULOSE AND WATER

I. MEASUREMENT OF ACCESSIBILITY[1]

O. SEPALL[2] AND S. G. MASON

ABSTRACT

Estimates of the extent of the hydrogen exchange reaction between cellulose and water vapor determined by an improved method using tritiated water and by the use of heavy water were usually in good agreement. With certain samples, surface roughness had a small effect upon the measurement of tritium radioactivity in cellulose.

The accessibility or limiting extent of the exchange increased slightly with relative humidity in the range 20 to 100% and was attributed to the reduction of crystalline order reported recently in similar experiments.

In contrast to cellulose whose accessibility corresponds approximately to the amorphous fraction, a partially crystalline amylose was 100% accessible while an amorphous xylan was 52% accessible, indicating that in these substances the accessibility and the fraction of amorphous material are not identical.

INTRODUCTION

Although valuable contributions to the knowledge of the fine structure of cellulose have been made by studies of the hydrogen exchange reaction with water (1, 2, 3), work based on this technique has not been extensive because the experimental methods are time consuming and of limited applicability. This paper describes measurements of exchange using tritiated water (HTO) by an improved method which permits greater scope in studies of the reaction.

In most investigations, the exchange of deuterium with D_2O has been measured either by determining isotopic dilution (3) or the infrared absorption of deuterated and unreacted hydroxyl groups (1). The present results were obtained by the tritium exchange method devised by Lang and Mason (2) but using an improved apparatus (4) which is simpler and gives a more precise measurement. To calibrate the method and corroborate the results, the exchange of deuterium with pure D_2O was also determined by infrared (1) and gravimetric (5) techniques.

The accessibility, A^0, defined as the limiting extent of the exchange, was determined for various cellulose samples, starch, and xylan. The influence upon A^0 of the crystallinity of the sample and relative humidity was also investigated in a preliminary study of the factors governing hydrogen exchange in cellulose and similar polymers.

EXPERIMENTAL PART

Materials

The samples listed below were used.

1. Amylopectin: commercial grade, manufactured from potato starch from Stein Hall and Co.

2. Amylose: as for sample 1.

3. Cellophane: air-dried viscose film without additives, supplied by Dupont of Canada Ltd.

4. Wood cellulose: softwood, acetate grade wood pulp; 96% alpha cellulose (TAPPI method).

[1]*Manuscript received June 14, 1961.*
Contribution from the Physical Chemistry Division, Pulp and Paper Research Institute of Canada, and the Department of Chemistry, McGill University, Montreal, Que.
[2]*Holder of a Canadian Industries Limited Fellowship, 1960–61.*

5. Bacterial cellulose: kindly supplied by Dr. J. R. Colvin of the National Research Council, Ottawa.

6. Cotton linters: dewaxed by alcohol–benzene extraction.

7. Commercial paper grade woodpulps by Anglo Paper Products Ltd., Quebec, Que.

8. Xylan: birch (*Betula papyrifera*) xylan prepared by the method of Glaudemans and Timell (6).

9. Milled wood cellulose: sample 4 milled in an Intermediate Model Wiley Cutting Mill using three passes with a 150-mesh screen.

Methods

1. Deuterium Exchange: Gravimetric (A_1)

The method is based on that of Morrison (5) and involves determining the increase in mass of the sample following exchange with pure D_2O.

The apparatus used (Fig. 1) consisted of a 100-ml Pyrex flask (G) with two outlets

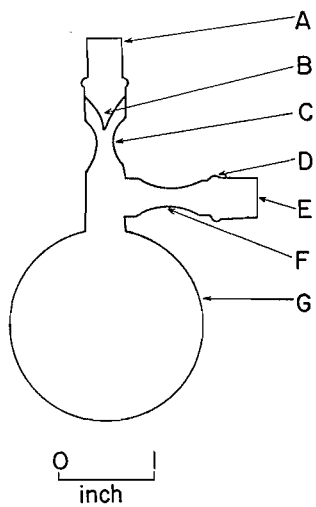

FIG. 1. Cell for gravimetric measurement of deuterium exchange. A, outlet to fit Veeco Quick Vacuum Coupling (No. C-50); B, break-seal; C and F, constrictions for sealing; D, expanded section for vacuum seal with O-ring; G, 100-ml flask.

(A and E) of suitable diameter to fit a Veeco Quick Vacuum Coupling on a vacuum system. The expanded section in the outlet as at D helped to form the vacuum seal created by an O-ring. The vessel could be sealed by fusing at the constrictions C and F. The break-seal (B) eliminated the need for a stopcock.

About 6 g of sample was placed in the flask of tared weight W_1 and dried by evacuating through outlet E for 48 hours at 75° C and at 1 μ Hg vacuum. The flask was sealed and weighed (W_2). The break-seal was opened by inserting a steel rod in A, and the apparatus shown in Fig. 2 was used to react the sample with pure D_2O. Dry air, obtained from the evaporation of liquid air in a Dewar flask shown at H in Fig. 2, was bubbled through liquid D_2O in J at constant temperature and then conducted into the sample in flask L (immersed in a thermostat) by a stainless steel tube (K). After the desired reaction time, the sample was dried by evacuating the flask for 48 hours at 75° C and at 1 μ Hg vacuum.

The flask was weighed (W_3) and the difference in weight ($W_3 - W_2$) was corrected for

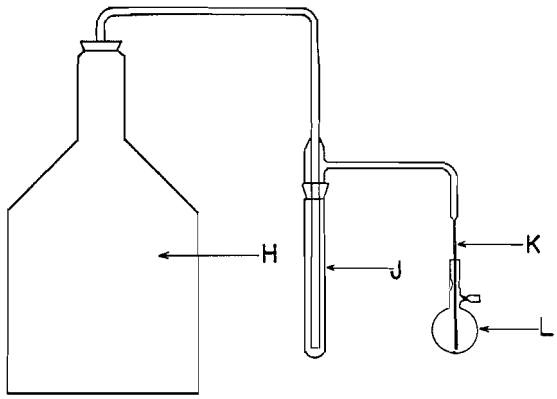

FIG. 2. Apparatus for conducting exchange with D_2O. H, Dewar flask with liquid air; J, vessel containing D_2O liquid; K, stainless steel tube; L, vessel shown in Fig. 1.

changes in air buoyancy to give the increase of mass ΔW corresponding to exchange of hydrogen by deuterium. The mass S of the sample was determined similarly from $(W_2 - W_1)$. The percentage of accessibility A_1 was calculated from

$$[1] \qquad A_1 = 100(\Delta W)/F \times S.$$

The factor F is the fractional increase in mass of the same substance after the hydroxyl hydrogens have been completely exchanged by deuterium. For cellulose and starch, $F = 0.0185$; for birch xylan, F was calculated to be 0.0140, assuming a linear chain of β-D-xylopyranose residues, linked by 1,4-glycosidic bonds and having a single terminal side chain of the potassium salt of 4-O-methyl-α-D-glucuronic acid attached glycosidically to C_2 of every 11th xylose residue (7).

No correction for the isotopic purity of the D_2O (99.7%) was necessary.

In contrast to Morrison's experiments (5), the exchange was conducted at constant relative humidity. This was done to avoid the partial reaction with inaccessible hydroxyl groups, shown to occur if the sample moisture was varied during the exchange (8).

The results reported are for single measurements only and were reproducible to 1%.

2. Tritium Exchange: Radioactivity (A_2)

The method used for measuring tritium exchange between cellulose and tritiated water (HTO) vapor has already been described (4), and consisted of (*a*) exposing the sample to tritiated water vapor, (*b*) drying, and (*c*) determining tritium radioactivity in the sample using a methane-filled, windowless proportional counter of special design in which all three operations were carried out.

During the treatment with tritiated water vapor, the relative humidity (RH) was kept constant to ±3% by suitably controlling the temperature of the liquid-HTO reservoir, and the sample temperature, to ±0.5° C. The samples were dried at 75° C in a vacuum of 1 μ Hg for 15 hours to remove sorbed water (2).

The samples were used in sheet form of superficial density of about 3 mg/cm².

Amylose was dissolved in water at 160° C and a film was deposited from the solution on a polished, chromium-plated surface by drying at room temperature. An aqueous amylopectin solution was prepared at room temperature, and, since the unsupported film tended to crack during drying, it was deposited onto a cellophane supporting film. Handsheets were prepared from fibrous materials such as wood cellulose by the TAPPI

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

procedure which consisted of (*a*) depositing the wet sheet of fibers from a water suspension on a fine screen, (*b*) pressing to remove moisture, and (*c*) drying the sheet at room temperature in contact with a polished, chromium-plated surface. The cotton linters required a preliminary beating before a satisfactory handsheet could be formed; this was done in a PFI Laboratory mill. Cellophane film was used as received.

The accessibility A_2 was determined from the relation

$$[2] \qquad A_2 = \frac{Rf}{c}\left(\frac{c_0}{R_0 f_0}\right) A_{1,0},$$

where R is the sample count rate; c, the activity of the tritiated water (about 1.5 μc/mg in these experiments); and f, the vapor/liquid partition ratio of tritium at the temperature of the liquid-HTO reservoir. The factor f is a known correction factor for the principal isotope effect (9). Quantities with the subscripts "0" are those of a standard sample whose accessibility $A_{1,0}$ was determined by the gravimetric D_2O exchange method under the identical conditions of temperature and relative humidity used in measuring R_0. Cellophane at 75% relative humidity and at 25° C was used as the standard sample.

The results are averages of four determinations on cellophane, and of two on wood cellulose and other materials; they were reproducible to 1%.

The principal difference between A_2 and the quantity A_s measured by Lang and Mason (2) was that the samples were dried rigorously after the exchange reaction by thoroughly evacuating at 75° C instead of room temperature. In addition, the precision of R was greater.

3. Deuterium Exchange: Infrared (A_3)

The accessibility of amylose and amylopectin was estimated by the infrared absorption method used by Marrinan and Mann for deuterated cellulose (1). An infrared cell (Fig. 3) suitable for investigating evacuated samples was constructed for use with the

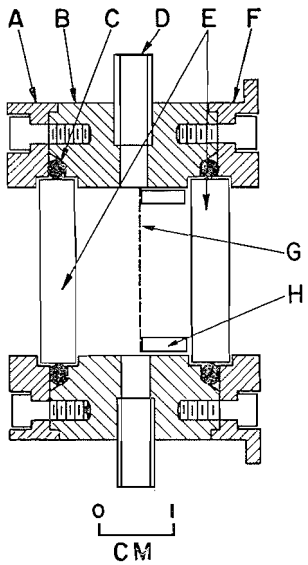

FIG. 3. Vacuum infrared absorption cell. A, front cover (stainless steel); B, cell body (stainless steel); C, O-ring; D, D_2O vapor circulation line; E, calcium fluoride windows; F, back cover to fit mounting on Perkin–Elmer model 21; G, sample film; H, annular sample holder.

For personal use only.

Perkin–Elmer model 21 spectrometer. Samples were inserted by removing cover plate A, which was sealed by O-rings to the standard calcium fluoride windows and to the body (B) of the cell. D_2O vapor was circulated through tube D, which was sealed by vacuum valves (not shown).

Sample films having a superficial density of 0.8 mg/cm^2 were prepared by evaporating aqueous solutions of amylose and amylopectin on a mercury surface. The film (G in Fig. 3) was attached to the annular sample holder (H) by a small amount of vacuum grease.

The sample film was reacted with D_2O vapor while in the absorption cell. A stream of air containing the vapor was produced with the arrangement shown in Fig. 2 and was circulated through the cell for 8 hours. The cell was evacuated for an hour to remove most of the sorbed water and sealed.

The absorbance was measured at $\nu_1 = 2530$ cm^{-1}, corresponding to an absorption peak for the OD group, and at $\nu_2 = 3360$ cm^{-1}, for OH (1). Assuming Beer's law to apply

$$[3] \qquad \frac{\log (I_0/I)\nu_1}{\log (I_0/I)\nu_2} = \frac{k_{OD}\, c_{OD}}{k_{OH}\, c_{OH}} = 1.11 \frac{c_{OD}}{(1-c_{OD})}$$

$$[4] \qquad = 1.11 \frac{A_3}{1-A_3}.$$

I_0 and I are the intensities of the incident and transmitted radiation; c is the mole fraction of absorbing groups and k the extinction coefficient; A_3 ($= c_{OD}$) is the corresponding accessibility. It was assumed that in starch $k_{OD}/k_{OH} = 1.11$, the same value used for cellulose (1), so that A_3 could be evaluated by equation [4].

As in the gravimetric measurement, the correction for isotopic purity of the heavy water was neglected.

RESULTS

Reaction Time

The time required to achieve limiting values of A_1 and A_2 was investigated at 75% RH and 25° C for cellophane and wood cellulose. The results given in Table I show that A_1

TABLE I

Effect of reaction time upon A_1 and A_2 (75% RH, 25° C)

Sample	Reaction time (days)	A_1 (%)	Sample	Reaction time (hours)	A_2 (%)

			,,	32	58.3

was approximately constant after 4 days and A_2, after about 8 hours. The long time required for deuterium exchange was undoubtedly due to the low rate of transfer of D_2O to the sample in the presence of air.

The influence of relative humidity in the range 20 to 75% RH upon the time required for A_2 to approach a limit A_2^0 was investigated for cellophane. Values of A_2 for different reaction times are plotted in Fig. 4 and show that after the initial rapid reaction reported

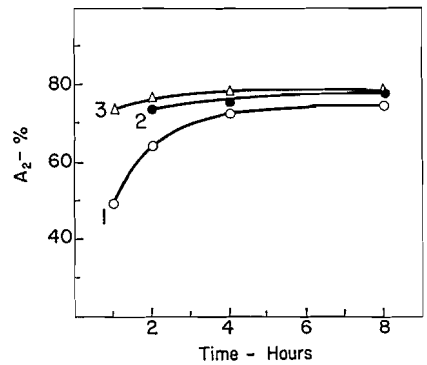

FIG. 4. Tritium exchange versus time for cellophane in HTO vapor. Curves 1, 2, and 3 correspond to relative humidities of 20, 50, and 75% respectively at 25° C.

earlier (1), the extent of the exchange tended to an asymptotic limit after about 8 hours. The reaction was slower at lower relative humidity and A_2 approached a smaller value. The decreased rate of reaction was probably due to slower diffusion of water vapor in cellulose at the lower moisture content (10). The lower limiting exchange, indicating that fewer reactive hydroxyls were available, is discussed later.

For amylopectin, a limiting value of $A_2^0 = 98\%$ at 75% RH and 25° C was also found after 8 hours. It was assumed that the rate of exchange with the other cellulose samples was similar to that with cellophane and wood cellulose.

For measurements of the limiting extent of the exchange denoted by the superscript "0", at least 4 days' exposure to D_2O was allowed in measuring A_1^0 and at least 8 hours' exposure, in measuring A_2^0. For A_3^0, an exposure of 8 hours was used, although it has been shown that little further reaction is detected in cellulose film after 1 hour in D_2O vapor (1).

Comparison of A_1^0, A_2^0, and A_3^0 for Different Samples

Values of A^0 were measured by the different methods for a number of samples at 75% RH and 25° C (Table II). The differences between A_2^0 and measurements of A_3 on

similar samples of Lang and Mason (2) ranged from 2 to 8% and were probably due to the slightly different experimental conditions employed.

In most cases, A_1^0 and A_2^0 were in good agreement (Fig. 5), except for +4% difference

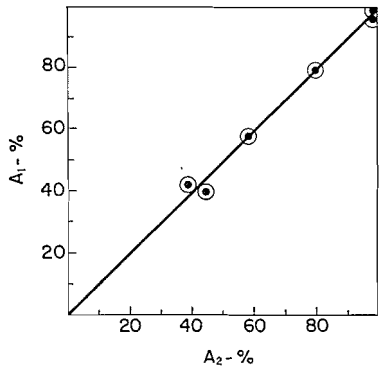

FIG. 5. Comparison of deuterium exchange (gravimetric) and tritium exchange methods of measuring A^0 (75% RH, 25° C).

for cotton linters and -3% for bacterial cellulose. It is believed that these discrepancies arose from surface roughness of the samples. The influence of surface roughness upon the measurement of tritium in tritiated cellulose, considered by calculating counting rates for simple models for the samples listed in Table II, is discussed elsewhere (11). It was concluded that the shape of surface irregularities influenced the measurement while the bulk density had negligible effect; the analysis made it possible to account for the differences observed here. The error can be avoided by using smooth samples or by independently calibrating the tritiation method for each material.

The high accessibility of amylose and amlyopectin was confirmed by the three methods. It is possible that here $A^0 = 100\%$, but that the measured values were influenced by factors such as (*a*) impurities in the samples, (*b*) deviations from Beer's law, and (*c*) contamination of D_2O by atmospheric moisture during the exchange reaction. Limited exchange in fully deuterated amylose and amylopectin from potato starch has recently been reported from infrared absorption measurements (12). The extent of the reaction was measured by the ratio (area of OD absorption band)/(area of OH absorption band), which was about 2.6 for both deuterated samples (12), while in the present measurements, the ratio was 55 for deuterated amylose. The reason for the difference is not clear; possibly the method of isolation can affect the properties.

Only A_1^0 was measured for xylan and milled wood cellulose because contact with water, as during preparation of sheet samples, has been found to produce recrystallization in similar materials (13). Milling increased A_1^0 as expected since a similar treatment has been shown to increase the amorphous fraction in cellulose determined by X-ray diffraction (13). The crystallinity parameter K_{002} (13) was found to be 1.25 for the original material and 1.13 for the milled samples, indicating some destruction of crystalline regions. The radial photometer traces for the samples showed that the crystallinity was not entirely destroyed by milling; this is presumably the reason for A_1^0 being less than 100%.

X-ray diagrams of amylose exhibited distinct diffraction rings while those of birch gave a diffuse halo, indicating that the former was partially crystalline and the latter wholly amorphous. The results were unexpected because complete accessibility of amylose, by analogy with cellulose, implied the absence of crystallinity. Evidently the analogy is not necessarily valid and other factors which are presently unknown determine the accessibility of amylose and xylan.

Relative Humidity

Values of A_2^0 were measured for wood cellulose and cellophane from 0.6 to 100% RH and at 25, 50, and 100° C. The results, summarized in Table III, indicate that A_2^0, at

25° C, of wood cellulose, and to a lesser extent of cellophane, increased slightly with increasing relative humidity. At 50 and 100° C the results appeared to be unaffected by relative humidity. It is not known whether the higher values at 100° C indicate a higher accessibility or a temperature-dependent isotope effect in the partition of tritium between HTO vapor and the hydroxyl groups in cellulose. Attempts to measure A_1^0 at 100° C were unsuccessful mainly because no satisfactory correction could be made for the loss in mass of cellulose occurring during contact with air under these conditions. The decrease in mass may have resulted from chemical degradation which has been observed in cotton linters as a reduction of degree of polymerization and of carboxyl groups after only 20 minutes in air at 100° C (14).

There is a possible error in the measurements of tritium exchange at different relative humidities because the tritium is concentrated in the residue during evaporation as in drying the sample. However, the effect was probably small because drying was rapid and the equilibrium separation would not have occurred. The higher values of A_2^0 with increasing relative humidity are therefore believed to indicate a greater number of reactive hydroxyls. The significance of the result is discussed below.

Comparison of Commercial Woodpulps

Values of A_2^0 were measured for commercial woodpulps prepared by alkaline (kraft and soda) and sulphite processes from Canadian softwoods and hardwoods. Since the samples also contained lignin and hemicelluloses in addition to cellulose, the values of A_2^0 are not necessarily the percentage of hydroxyl groups reacted. The results indicate only the relative abundance of reactive hydroxyls in the different samples compared with cellulose.

The results (Table IV) show only small differences between the samples. Wood fibers

*TAPPI method. (The permanganate number is a measure of lignin content and is approximately zero in bleached pulps.)

with higher lignin content appeared to have fewer accessible hydroxyls, as would be expected, since the hydroxyl content of lignin is lower than that of cellulose. The slightly lower values for hardwood fibers may have similarly indicated a higher content of xylan.

DISCUSSION

The results demonstrate the validity, versatility, and convenience of the tritium exchange method of measuring A, particularly for sheet cellulose samples.

The results for amylose and amylopectin differ from those of Ceh and Hadzi (12), and suggest the interesting possibility that starch can exist in stable forms which are either completely or only partially accessible. The xylan from birch wood is a linear polysaccharide like cellulose and similarly was only partially accessible. The differences between commercial wood fibers were small, suggesting that pulping processes have little effect upon the properties of cellulose.

It was surprising that A^0 did not increase to a greater extent with increasing relative humidity since reactive hydroxyl groups are believed to be formed as a result of disrupting hydrogen bonds by water (15). However, X-ray diffraction studies have indicated that the fraction of crystalline material is the same in wet and dry cellulose (16), although recently it was reported that a small reduction of the molecular order in crystalline regions occurred with increasing relative humidity (17). The similarity of the effect of relative humidity upon the crystalline and inaccessible portion supports the concept of stable, discrete crystallites which largely do not participate in the swelling or in many chemical reactions of cellulose. There is evidence, however, that crystallites tend to migrate in the structure during changes of relative humidity (2) as described further in the following paper (8).

The most interesting results were the apparently anomalous properties of amylose and birch xylan which implied that accessibility was not necessarily dependent upon the crystallinity. It is likely that steric effects dominate the extent of exchange of hydrogen in cellulose as found with other reactions (18), and that the conditions which preclude exchange can exist independently of crystallinity. The extent of exchange may therefore be expected to vary in different crystals.

HYDROGEN EXCHANGE BETWEEN CELLULOSE AND WATER

II. INTERCONVERSION OF ACCESSIBLE AND INACCESSIBLE REGIONS[1]

O. SEPALL[2] AND S. G. MASON

ABSTRACT

Exchange of hydrogen between water and some of the inaccessible hydroxyl groups in cellulose resulted from changes in the relative humidity and was most pronounced near 0 and 100% RH. A similar exchange occurred during prolonged immersion in liquid water. The extent of the reaction varied in different samples, increased with temperature, and was reproducible. By repeatedly wetting and drying cellophane, the exchange was cumulative and all the hydroxyl groups became exchanged after up to 100 cycles. The accessibility decreased slightly after repeated drying. The measurements were made by exchange with deuterated and tritiated water.

The behavior was interpreted as an interchange of ordered and disordered regions resulting from molecular rearrangement caused by interaction between cellulose and water.

INTRODUCTION

When cellulose is dried from heavy water (D_2O) (1) or tritiated water (HTO) (2), some of the hydrogen isotope becomes incorporated in inaccessible hydroxyl groups, i.e., hydroxyls which will not exchange hydrogen when the cellulose is re-exposed to water. Mann and Marrinan (1) suggested that the phenomenon was partly due to a reduction in the number of reactive hydroxyls by drying. However, Lang and Mason (2) showed by repeatedly wetting and drying cellophane in HTO that inaccessible hydroxyl groups were progressively exchanged with little change in the accessibility. The theory was proposed that during wetting and drying, a rearrangement of molecules occurs in cellulose and results in a partial interchange of accessible and inaccessible regions (2).

The present investigation was undertaken to study the causes of the changes in molecular order. It was also of interest to determine if all crystallites could be disrupted by repeatedly wetting and drying cellulose a sufficient number of times as appeared likely from the previous studies (2). The work included a study of the influence of temperature, relative humidity, and the number of cycles upon the irreversible exchange during drying.

The quantities measured were similar to those investigated by Lang and Mason (2) and are defined as follows. The accessibility A_n is the extent of the exchange reaction with water at 75% relative humidity (RH) and 25° C after n drying cycles. The quantity $\delta\omega_n$ represents the inaccessible hydroxyl groups reacted with water during the nth cycle while W_n is the net inaccessible hydroxyl groups reacted during n cycles. The three quantities were expressed as percentage of the total hydroxyls. Measurements were made by both tritium and deuterium exchange.

EXPERIMENTAL PART

Methods

1. Measurement of Accessibility

The accessibility (A_n) was determined by the HTO exchange method described previously (3). The measurement was calibrated for each material by determining the exchange of deuterium with D_2O by the gravimetric method (3); this was done to eliminate

[1]*Manuscript received June 14, 1961.*
Contribution from the Physical Chemistry Division, Pulp and Paper Research Institute of Canada, and the Department of Chemistry, McGill University, Montreal, Que.
[2]*Holder of a Canadian Industries Limited Fellowship, 1960–61.*

the small error resulting from the effect of surface roughness upon the measurement of tritium radioactivity (3). The results were averages for two determinations and were reproducible to $\pm 1\%$.

Since it was known (3) that A_n varies slightly with relative humidity (RH), standard conditions for the measurement were arbitrarily selected as 75% RH and 25° C.

2. Drying Cycles Using HTO

Three types of cycles, designated as D_1, D_2, and D_3 and representing regions of intermediate, low, and high RH respectively, were employed to study limited ranges of RH. Shorter drying times than required for equilibrium conditions (e.g., 23 hours to achieve moisture equilibrium in cellophane (4)) were used to permit the study of the effects of large numbers of cycles within a reasonable time.

The procedure for each type of cycle is outlined below.

Cycle D_1 (partial drying).—The treatment consisted of exposing the sample to HTO vapor during a cyclic change of RH and was conducted in a special counter designed for use of tritiated sheets (5). Only single cycles were studied. The initial exposure was to H_2O followed by HTO at the same RH. The vapor pressure of the HTO was then altered by changing the temperature of the HTO liquid reservoir. The duration of each exposure was 4 hours.

Cycle D_2 (rigorous drying).—The cycle consisted of exposing the sample, as in D_1, to HTO vapor and then vacuum-drying for 15 hours at 1 μ Hg and various temperatures. The exposure to HTO was usually for 8 hours at 75% RH and 25° C. For repeated treatments, one cycle, including the determination of tritium in the sample after drying, was performed each day.

Cycle D_3 (immersion and partial drying).—The sample was immersed in HTO liquid and partially dried at different temperatures kept constant during the experiment. The procedure devised by Lang and Mason (2) was used. The sample and a quantity of HTO liquid (30:1), large enough so that dilution effects could be neglected, were sealed in an evacuated, inverted U tube with the sample held at one end. During drying, the HTO arm was placed in an ice-water bath and the other in a water thermostat at the desired temperature. The wetting step was performed by tilting the U tube and allowing the HTO to flow to the sample end. Two hours were usually allowed for each step; preliminary experiments with cellophane showed that the exchange was over 80% completed during this period. For repeated treatments, three cycles were performed each day; one wetting step (conducted overnight) took 14 hours.

3. Reacted Inaccessible Hydroxyls by HTO Exchange

During each of the drying cycles, tritium became incorporated in both inaccessible and accessible hydroxyl groups. For example, after n successive D_2 cycles, the total tritium activity corresponded to (A_n+W_n). By exposing the sample to H_2O and thus removing the labile tritium (A_n), W_n alone was determined by the following procedure. The treated sample was placed in a 2-cm glass tube through which air at 75% RH and 25° C was circulated for 8 hours; 16 hours gave the same result. The residual tritium activity in the sample was measured in a counter (5) identical with that used for accessibility measurements but without the accessories for conducting the exchange reaction. The fraction of tritiated hydroxyl groups (W_n), corrected for isotope effects, was calculated from the measured counting rate as previously described for A_n (3).

It would have been desirable to end all drying cycles at 75% RH to avoid further change of sample moisture content during removal of labile tritium. Although this was done only in certain cases, the cycles were always terminated at a RH $< 95\%$ and, as will be shown later, the difference in RH during the final drying had little effect.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

For the measurement of $\delta\omega_n$ a similar procedure was used. The $(n-1)$ cycles were performed in H_2O and the nth cycle in HTO. The labile tritium was removed as described above and the residual tritium activity corresponded to $\delta\omega_n$. It should be noted that, by definition, $\delta\omega_1 = W_1$.

The results were usually reproducible to $\pm 5\%$ or less. In cellophane, however, differences were as large as 50% and may have been due to a lack of uniformity in the properties as a result of manufacturing conditions.

The quantities $\delta\omega_n$ and W_n defined by Lang and Mason (2) were determined after immersing the sample in H_2O liquid and air-drying, and are therefore lower than the present values because, as will be shown, a large fraction of the inaccessible hydroxyl is reacted during drying.

4. Reacted Inaccessible Hydroxyls by D_2O Exchange

To corroborate the experiments using HTO, a method of measuring (A_n+W_n) for cycle D_3 was devised based on the gravimetric measurement of A using D_2O (3). The method has the advantage that the samples are not required in sheet form. The apparatus is shown in Fig. 1 and served the same purpose as the U tube described above in the

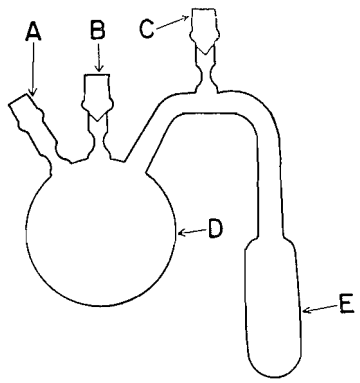

FIG. 1. Cell for measuring A_n+W_n by D_2O exchange. A, outlet; B and C, outlet with break-seals; D, 50-ml glass flask; E, 20-ml receiver.

corresponding experiment with HTO. It consisted of a 50-ml glass flask (D) connected by an inverted U tube to the 20-ml vessel (E). The three outlets (A, B, and C) were of suitable diameter to fit a Veeco Quick Vacuum Coupling on a vacuum manifold and B and C contained break-seals. The expanded sections in the outlets helped to form the vacuum seal created by an O-ring. The vessel could be sealed by fusing at the constrictions.

To correct for air buoyancy during weighings, the volume of the apparatus was determined by weighing the flask empty (M_0), and filled with water. A 3-g sample of cellulose was placed in the flask and dried rigorously by evacuating through outlet A for 48 hours at 75° C and 1 μ Hg (6). The flask was sealed by fusing at the constriction and weighed (M_1). The break-seal in B was opened by thrusting a steel rod in the outlet. To reduce subsequent dilution effects, the sample was exchanged with pure (99.7%) D_2O vapor by circulating a mixture of D_2O and air, at 75% RH, through the vessel for 4 days. The procedure resulted in a limiting exchange corresponding to the accessibility A_0*. A quantity (15.0 ml) of D_2O liquid was then added to the flask, which was sealed after evacuation,

**The limiting or equilibrium accessibility was previously (3) denoted by A^0. In this paper it is more convenient to designate this quantity as A_0 since it corresponds to A_n when $n = 0$.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with the flask immersed in liquid air to prevent loss of D_2O. The sample was subjected to the desired number of D_3 cycles as in the corresponding HTO experiment. The break-seal in outlet C was opened and the flask evacuated to dry the sample, then sealed under vacuum, and weighed (M_2).

The increase of mass ΔM, corresponding to exchange of H atoms on hydroxyl groups by D atoms, was determined from the difference of the weight (M_2-M_1) corrected for changes in air buoyancy. The mass M of the sample was determined similarly from (M_1-M_0).

To determine (A_n+W_n) it was necessary to correct for the dilution of D_2O resulting from exchange with ($A_n+W_n-A_0$) of the hydroxyl groups which did not react during the exposure to D_2O vapor. For a sample of mass M the dilution effect corresponded to ($0.167W_nM$) g H_2O; it was reasonable to assume that ($A_n+W_n-A_0$) = W_n because the correction was small and, as will be shown, $A_n = A_0$ (approx.). The final purity P of D_2O was therefore given by

$$P = 99.7 - \frac{100(0.167W_nM)}{(15.0\times.997)+(0.185A_0M)}.$$

In this relation, 99.7% is the initial purity; the second term represents the percentage dilution by H_2O.

The quantity (A_n+W_n) was then calculated from the relation

$$A_n+W_n = \frac{100}{P} \times \frac{100(\Delta M+\Delta M_B)}{0.0185M}$$

where 0.0185 represents the fractional increase in mass for cellulose after all hydroxyl groups have been exchanged by deuterium and ΔM_B is the change in mass in the same experiment but conducted in H_2O. ΔM_B was a correction for a loss in mass probably due to degradation of the cellulose.

The value of (A_n+W_n) was estimated first by assuming no dilution of D_2O (P = 99.7%). P was then calculated and a second approximation of (A_n+W_n) gave the desired accuracy.

Materials

The samples listed below were used.

1. Cellophane (supplied by Dupont of Canada Limited) was air-dried viscose film containing no additives.
2. Wood cellulose was a softwood acetate grade woodpulp with 96% alpha cellulose (TAPPI method).
3. Cotton linters were dewaxed by alcohol–benzene extraction.
4. Bacterial cellulose was kindly supplied by Dr. R. J. Colvin of the National Research Council, Ottawa.
5. Amylose was the commercial grade supplied by Stein Hall and Co. The samples were prepared as before (3).

RESULTS

Comparison of Cycles

Various modifications of the three drying cycles were tried to establish the conditions under which the interconversion of accessible and inaccessible hydroxyls occurred most readily. The experimental conditions and results for wood cellulose are listed in Table I;

TABLE I

W_1 for various drying cycles for wood cellulose

Expt. No.	Cycle	Temp. (°C)	Conditions	W_1 (%)
1	Control	30	(1) Conditioned in H_2O, 8 hr at 65% RH (2) Exposed to HTO, 8 hr at 65% RH (3) Exposed to H_2O, 8 hr at 65% RH (as for measurement of W_1)	0.6
2	Control	100	(1) Conditioned in liquid H_2O, 4 hr (2) Immersed in liquid HTO, 4 hr (3) Immersed in liquid H_2O, 8 hr (4) Air-dried	0.9
3	D_1	30	(1) Conditioned in H_2O, 4 hr at 60% RH (2) Exposed to HTO, 4 hr at 60% RH (3) RH changed to 14% for 2 hr (4) RH returned to 50% for 2 hr (5) Exposed to H_2O, 8 hr at 60% RH (as for measurement of W_1)	1.7
4	D_1	30	(1) Same as No. 3 except in step (3) RH changed to 90% for 2 hr	1.
5	D_2	25	(1) Exposed to HTO, 4 hr at 75% RH (2) Dried 15 hr at 1 μ Hg (3) Exposed to H_2O, 8 hr at 75% RH (as for measurement of W_1)	2.
6	D_2	25	(1) Dried 15 hr at 1 μ Hg (2) Exposed to HTO, 8 hr at 75% RH (3) Exposed to H_2O, 8 hr at 75% RH (as for measurement of W_1)	2.7
7	D_2	See conditions	(1) Dried 15 hr at 1 μ Hg, 75° C (2) Exposed to HTO, 8 hr at 75% RH, 25° C (3) Exposed to H_2O, 8 hr at 75% RH, 25° C, as for measurement of W_1	4.1
8	D_3	25	(1) Immersed in liquid HTO, 2 hr (2) Dried 2 hr at 20% RH (3) Exposed to H_2O, 8 hr at 75% RH (as for measurement of W_1)	5.0

two control experiments in which the sample was exposed to HTO and subsequently to H_2O without changing the RH are included.

In both control experiments (Nos. 1 and 2), W_1 was small but significant. Experiment 2 was similar to one described by Mann and Marrinan (1), who found that cellophane retained small quantities of deuterium after immersion in liquid D_2O followed by H_2O. The same experiment performed by Lang and Mason (2) in HTO liquid at 25° C gave values of 0 and 0.2% for W_1.

In expts. 3 and 4, cyclic changes of RH in a range from 15 to 95% yielded larger values of W_1 than expt. 1 although the time of exposure to HTO vapor was the same.

In expt. 5 (cycle D_2) the sample was exposed to HTO vapor only during desorption and in 6, only during adsorption; the values of W_1 were larger than in Nos. 3 and 4, presumably because of the lower RH during drying, and were approximately equal, showing that the change occurred with both increasing and decreasing moisture content.

Experiment 7 (cycle D_2) was similar to No. 6 with the exception that the sample was dried at 75° C to remove strongly bound moisture (6). A pronounced increase in W_1 occurred which was undoubtedly associated with adsorption of HTO at zero regain. The corresponding desorption experiment, in which the sample was dried from HTO to zero regain at 25° C, could not be studied because all the sorbed water could not be removed at this temperature under the conditions of evacuation used.

The greatest W_1 was formed in No. 8 in which the sample was immersed in HTO liquid and dried in contact with HTO vapor at 20% RH; the large effect apparently occurred in the range of relative humidity from 95 to 100%.

It was concluded from the experiments that (*a*) tritiated inaccessible hydroxyls were formed on changing the RH up or down and (*b*) the effect was most pronounced at the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

extreme ends of the drying cycle, i.e., at 0 and 100% RH. As found earlier (1, 2), a smaller but significant amount of reacted inaccessible cellulose resulted from exposure at constant RH.

The influence of other variables was studied with cycles D_2 and D_3 because they incorporated the two extreme conditions which produced the greatest changes.

Effect of Temperature

The influence of temperature upon W_1 in wood cellulose and cellophane was investigated between 25 and 100° C for cycles D_2 and D_3. The specified temperature for cycle D_2 was for the vacuum-drying only, whereas in cycle D_3, it was for both immersion and partial drying.

The results (Fig. 2) show that W_1 increased with temperature in both cycles.

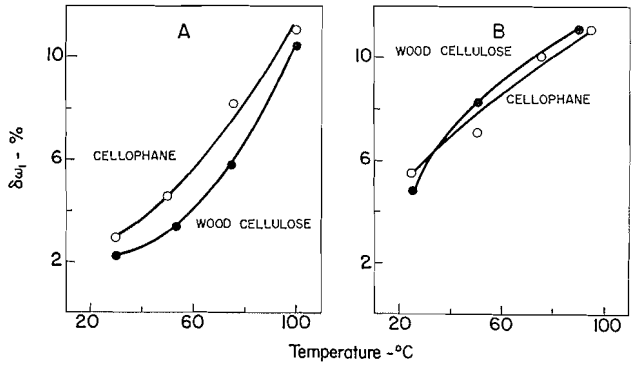

FIG. 2. Effect of temperature upon W_1. A, cycle D_1; B, cycle D_3.

Apart from the temperature during drying, two secondary factors may have contributed to the increase of W_1 with temperature, namely, heating the sample from 25° C to the higher temperature in cycle D_2 and the lower RH when drying at higher temperature in cycle D_3. To determine if the temperature of drying was of importance, the modified cycles described in Table II were conducted on wood cellulose.

TABLE II

W_1 for modifications of cycles D_2 and D_3 on wood cellulose

Expt. No.	Cycle	Conditions	W_1* (%)
9	D_2	(1) Exposed to HTO, 8 hr at 75% RH, 25° C (2) Dried 15 hr at 1 μ Hg, 75° C	5.8
10	D_2	(1) Exposed to HTO, 2 hr at 2.3% RH, 75° C (2) Dried 15 hr at 1 μ Hg, 75° C	6.6
11	D_2	As for expt. 9 with drying at 100° C	12.1
12	D_2	As for expt. 9 with drying at 100° C for 40 hr	11.7
13	D_3	(1) Immersed in liquid HTO, 2 hr, 50° C (2) Dried 12 hr at 95% RH, 50° C	8.3
14	D_3	As for expt. 13 with drying for 2 hr at 15% RH	8.5
15	D_3	As for expt. 13 with drying for 2 hr at 1 μ Hg	8.5

*In each experiment, W_1 was measured after the sample was exposed to H_2O for 8 hours at 75% RH and 25° C, as described in the text.

Cycle D_2 at 75° C, as described above, is presented for comparison as expt. 9. In expt. 10 (cycle D_2), the temperature (75° C) was constant throughout and the RH was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

lower (2.3%) during exposure to HTO. The comparable values for W_1 in Nos. 9 and 10 show that the temperature during drying at low RH determined the value of W_1 in cycle D_2. Continued heating of the dried sample produced no additional change (expts. 11 and 12).

In expts. 13 to 15 (cycle D_3) the RH during drying ranged from 10^{-3} to 95% and similar values of W_1 were found. Therefore the temperature during soaking, or drying, from 100 to 95% RH determined the magnitude of W_1 in cycle D_3.

Comparison of Samples

Values of W_1 for cycles D_2 and D_3 are listed in Table III for different types of cellulose

TABLE III

W_1 for different samples

Sample	A_0* (%)	W_1 (%)	
		Cycle D_2 at 75° C	Cycle D_3 at 50° C
Cellophane	79	8.3	7.1
Wood cellulose	58	5.8	8.5

Bacterial cellulose	42	2.6	8.5
Amylose	98	<0.1	<0.1

*From ref. 3.

and amylose. With cycle D_2, W_1 for cellulose increased with increasing A_0 whereas with cycle D_3 there appeared to be no correlation. With amylose, $W_1 = 0$ in both cycles as would be expected if the substance were completely accessible. Although the measured accessibility of amylose was consistently a little lower than 100% the difference probably did not indicate the presence of unreactive hydroxyls but an impurity in the sample, as discussed previously (3).

Repeated Cycles (HTO)

(a) Effect upon A_n and $\delta\omega_n$

Table IV lists values of A_n and $\delta\omega_n$ for samples which have undergone $(n-1)$ drying cycles (D_2 and D_3) in H_2O.

TABLE IV

Effect of repeated drying upon A_n and $\delta\omega_{n+1}$ by HTO exchange

Sample	Drying history*			A_n (%)	$\delta\omega_{n+1}$	
	Cycle	n	Temp. (°C)		Cycle D_2 at 75° C	Cycle D_3 at 50° C
Wood cellulose		0		58	5.8	8.5
,,	D_2	2	100	58	6.4

*Before the present experiments, cellophane and bacterial cellulose had been air-dried while wood cellulose had probably been dried at >100° C during manufacturing.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The accessibility was decreased slightly by drying, e.g., from 58 to 55% for wood cellulose after 50 D_3 cycles at 50° C, but the change in A_n during the first few cycles was negligible. Values of $\delta\omega_n$ for cycle D_2 increased with n, while for cycle D_3 the value decreased. The greatest change (from $\delta\omega_1 = 7.1\%$ to $\delta\omega_{51} = 4.9\%$ after 50 D_3 cycles at 50° C) occurred in cellophane and was similar to the earlier result (2).

(b) Effect upon W_n

The previously reported (2) increase of W_n with n was investigated under various conditions to determine if exchange with all hydroxyl groups, corresponding to $(A_n+W_n) = 100\%$, would occur when n was made large. Figures 3 and 4 show the results for cycles

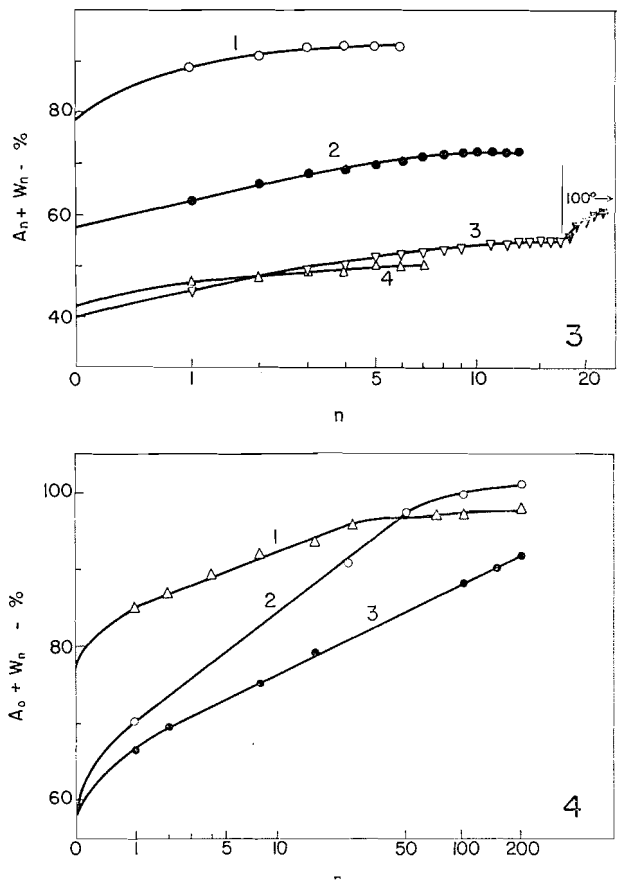

FIG. 3. A_n+W_n for cycle D_2 at 75° C. Curve 1, cellophane; 2, wood cellulose; 3, cotton linters; 4, bacterial cellulose.

FIG. 4. A_0+W_n for cycle D_3. Curve 1, cellophane at 50° C; 2, wood cellulose at 100° C; 3, wood cellulose at 50° C.

D_2 and D_3. In the latter experiments W_n was determined, and the data are shown as (A_0+W_n); this procedure is reasonable since A_0 and A_n are approximately equal. In both figures, log $(n+1)$ is plotted to include results for large n's while still showing the large changes occurring in the early cycles.

For cycle D_2 at 75° C, (A_n+W_n) was found to increase to a characteristic limiting value (Fig. 3) which remained constant to $\pm 0.1\%$ after several further cycles. By

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

increasing the drying temperature, as shown with cotton linters, a higher value was obtained. However, complete exchange was not achieved and higher temperatures than 100° C could not be studied with the present apparatus.

Using cycle D_3, (A_0+W_n) for wood cellulose and cellophane increased linearly with log $(n+1)$ until approximately 100% and then leveled off, indicating that complete exchange had occurred. The further increase in (A_0+W_n) above 100% was undoubtedly due to the continued increase of W_n as A_n decreased slowly with n (see Table IV). The quantity (A_n+W_n) would have been expected to remain constant at 100%.

The rate of increase of (A_0+W_n) with n was greater at higher temperature; it appeared that more than 20 times as many cycles would have been required at 50° C than at 100° C to reach $(A_0+W_n) = 100\%$.

(c) Effect of Prolonged Soaking in HTO upon W_n

Each of the D_3 cycles involved a period of immersion in liquid HTO. At large n the total immersion period, although not continuous, became large and, on the basis of the control experiment (No. 2, Table I), may have accounted for some of the increase in W_n reported above. The magnitude of the effect was estimated by measuring the variation of W_1 for cycle D_3 using soaking times from 2 hours to 135 days and the usual drying time of 2 hours.

Results for wood cellulose are given in Table V for temperatures from 25 to 100° C.

TABLE V

Effect of prolonged soaking upon W_1 in cycle D_3 for wood cellulose

Soaking time	Temperature (°C)	W_1 (%)
2 hours	25	5.0
64 days	,,	8.9
135 days	,,	10.2
2 hours	50	8.5
64 days	,,	16.4
135 days	,,	17.8
2 hours	100	12.2
15 days	,,	26.6
64 days	,,	28.9

The value of W_1 increased with soaking time and temperature. For large numbers of D_3 cycles, the exchange due to soaking undoubtedly constituted a large part of W_n. For example, the increase in W_1 due to the first 15 days of soaking at 100° C was 14.4% (Table V) while $(W_{50}-W_1)$ for 49 D_3 cycles, which included a total of 17 days' soaking, was 27.2%. The experiments with D_3 cycles thus measured the combined effects of repeated drying and of soaking.

Repeated Cycles (D_2O)

Two values of (A_n+W_n) were measured for cycle D_3 using D_2O with cellophane and wood cellulose to check the above results with HTO.

The results listed in Table VI are in satisfactory agreement with cellophane but not with wood cellulose. The error is believed to be in the measurement of deuterium exchange and in the correction term ΔW_B (see Experimental Part) which represents the loss in mass of cellulose probably due to chemical degradation. Since the degradation could be estimated only in H_2O and would be expected to be different in D_2O, the correction was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

TABLE VI
Comparison of results for cycle D_3 by exchange with D_2O and HTO

Sample	n	ΔM (%)	ΔM_B (%)	(A_n+W_n) (%), D_2O exchange	(A_0+W_n) (%), HTO exchange
Cellophane	50	1.57	−0.15	94	97
Wood cellulose	185	1.09	−0.31	76	90

probably invalid. Evidence of chemical reaction in cellulose after the cyclic drying was the distinct yellowing of the sample which had occurred, particularly where it was in contact with glass.

The gravimetric measurement of deuterium exchange with D_2O has, however, been used with excellent results for the measurement of accessibility (3). It appears that the degradative processes in cellulose have a significant effect upon the mass of cellulose only at high temperature (3) and during prolonged exposure to water.

DISCUSSION

The results may be summarized as follows:

1. exchange with the inaccessible hydroxyl groups in cellulose accompanied a change of relative humidity, either up or down;
2. the effect was most pronounced near 0 and 100% RH and increased with temperature;
3. the magnitude of the exchange was characteristic for different forms of cellulose;
4. when cellulose was wetted and dried repeatedly, the exchange increased until, as previously predicted, all hydroxyl groups had reacted;
5. the accessibility A of cellulose decreased slowly with large numbers of drying cycles; and
6. reaction with inaccessible hydroxyls also occurred during prolonged soaking and increased with temperature.

The formation of reacted inaccessible hydroxyls is assumed to result from the conversion of accessible regions to the inaccessible form, and thus implies localized changes in the degrees of molecular order. According to more recent concepts (7), the fine structure of cellulose can be described by a distribution of lateral order, the highly ordered regions corresponding to crystallites and the low-ordered, representing amorphous cellulose. Some evidence suggests that the inaccessible regions are highly ordered cellulose such as the interiors of crystallites, and perhaps also strongly hydrogen-bonded amorphous regions. For example, samples are graded in the same order by measurements of both accessibility and amorphous fraction by X-ray diffraction (7). Furthermore, the inaccessible hydroxyls in cellulose and crystalline cellopentaose give similar infrared absorption bands (1). It was also found that the change in accessibility with relative humidity is small (3) and similar to the effect upon the amorphous fraction determined by X-ray diffraction (8, 9). However, recent studies suggest that the accessibility of regenerated cellulose and of single crystals (10) of cellulose II may be similar (11). Anomalous behavior is also shown by substances other than cellulose. For example, a partially crystalline amylose was completely accessible while an amorphous xylan was only 52% accessible (3). It is evident, therefore, that one cannot unequivocally assume that inaccessible cellulose corresponds to the crystalline part although the two properties appear to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

be related in some way. In the present discussion it will be assumed for simplicity that the disruption of inaccessible regions represents destruction of crystallites.

To explain the accessible–inaccessible transformations during drying it was suggested previously that a molecular rearrangement occurred at an intermediate moisture content favorable for the formation of hydrogen bonds and for mobility of molecular chains (2). Under these conditions a dynamic equilibrium was believed to exist between accessible and inaccessible cellulose. It was assumed that at lower moisture content the cellulose chains became immobilized by interchain hydrogen bonding, while the swelling in the wet state prevented the formation of hydrogen bonds between cellulose molecules. Since the present results show that transformations occurred in cellulose over a wide range of moisture contents corresponding to relative humidities from 0 to 100%, this hypothesis does not appear to be valid. Furthermore, the changes were greatest at very low and high relative humidity when conditions were least favorable for the proposed equilibrium. The slight decrease of accessibility with decreasing relative humidity (3) may partly account for the formation of inaccessible cellulose during drying. However, the same effects were observed during sorption of water and have not been fully explained.

It is now proposed that molecular rearrangements, which have previously been assumed to occur only in the amorphous regions, with changes in the quantity of sorbed water (12), are also responsible for disrupting and reforming ordered regions. The destruction of the crystallite can be attributed to molecular stresses created in amorphous regions by the swelling action of sorbed water or by hydrogen bonds tending to draw cellulose molecules together when water is removed. Since the molecules extend through many regions of different order, the stresses, which on a molecular scale must become exceedingly high, are transmitted throughout the structure. The pronounced changes occurring in W_1 near 0 and 100% RH can be associated with characteristic interactions of cellulose and water at these relative humidities. At zero regain, water is very strongly bonded to cellulose, and Urquhart (13) has suggested that each H_2O molecule is bound to two hydroxyl groups. The resultant linking by the sorbed water can be conceived as drawing cellulose molecules together and causing a rearrangement. At the other extreme, the pronounced swelling near 100% RH could have the same result. The increasing transformation with temperature may be attributed to greater mobility of cellulose molecules; the reduction of sorption hysteresis with temperature has been ascribed to the same effect (14).

With the present rudimentary concepts it is not possible to consider the significance of the magnitude of the changes under various conditions. Presumably the results reflect the interplay between the network geometry of the molecular chains and the drying treatment. It is possible that the magnitude of these effects may characterize the fine structure and indicate, for example, the ease of molecular rearrangements in different samples.

The disruption of crystallites by molecular stresses suggests that similar effects may arise by mechanical deformation. It is known that by stretching cellulose, an orientation is created in the structure. However, little change in crystallinity was noted; cellulose acetate filaments, however, stretched up to 20 times their original length and when saponified underwent an increase in crystallinity (15). Whether crystallites were disrupted during the stressing was not known. With wool fibers, stretching was found to increase the reactivity of the disulphide bonds and was interpreted as a configurational change influencing the extent of the reaction (16). This effect appears to be somewhat analogous to the exchange with inaccessible hydroxyl groups in cellulose during drying.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The small effect of drying upon the accessibility and upon the values of $\delta\omega_n$ suggests that there is little permanent change in the cellulose. Other investigators have similarly reported only small changes in cellulose reactivity to nitration (17), hydrolysis (18), and exchange with D_2O (19) by repeated wetting and drying. The effects are not always the same; for example, accessibility to iodine absorption increased after drying (20) while accessibility to thallation decreased (19). It is therefore not clear whether the degree of molecular order is affected by drying, but in any event the change cannot be large. The reduction of accessibility after large numbers of drying cycles in the present work indicated an increase of the crystalline fraction. Recrystallization may have resulted from hydrolysis, since the DP of cellulose has been found to decrease in similar experiments (21).

A result of interest was the increasing exchange in the inaccessible regions with higher temperature during prolonged immersion in water. It appeared that at some temperature greater than 100° C, the cellulose may be completely accessible for the usual reaction time of several hours allowed in the measurement. The result suggests that crystallites may be continuously being disrupted and reformed by the thermal energies of the molecules. The effect may be greater in the presence of liquid water because, like other plasticizers (22), it would be expected to lower the second-order transition temperature and thereby permit the molecular rearrangement to occur more readily.

The transient existence of crystallites, as suggested by the present results, would also be expected to play a role in other chemical and physical changes in cellulose.

OZONOLYSIS OF UNSATURATED FATTY ACIDS

I. OZONOLYSIS OF OLEIC ACID[1]

R. G. ACKMAN, M. E. RETSON, L. R. GALLAY, AND F. A. VANDENHEUVEL[2]

ABSTRACT

Ozonolysis of oleic acid in methanol, a reacting solvent, with subsequent decomposition of the ozonide products by hydrogen peroxide in formic acid, gives yields of principal dicarboxylic acid fission products exceeding 95% with a minimum of secondary acidic products. The method is highly reproducible and offers unique advantages in the total recovery of the dicarboxylic acids and the elimination of peroxidic materials. The principal non-acidic by-products were tentatively identified as the C_8 alcohols and their formyl esters.

INTRODUCTION

The study of the position of the ethylenic double bonds in long-chain fatty acids is important in connection with the isolation of various naturally occurring fatty acids, and even more important in fields where the chemical treatment of the fatty acid by partial hydrogenation, alkali fusion, or other prototropic reactions leads to the formation of positional isomers. In the former instance, any reasonable yield of principal fission products resulting from the scission of the double bond is satisfactory for bond location, particularly as naturally occurring fatty acids are usually homogeneous in bond position and impurities will differ enough structurally to be recognized as such. In the case of mixtures of positional isomers, the over-all yield is less important than two other factors which must be considered. Firstly, the occurrence of abnormal fission products such as lower homologues of the principal fission products must be reduced to a minimum, and secondly, the method of recovery and analysis of the products must be such that the analysis reflects the true proportions of these products.

Scission of the double bonds is usually achieved by oxidative fission. Some work has been done to give aldehydes as primary products (1–9), but the more extensive application of this technique has always been in the direction of obtaining the more tractable acidic fission products. Ozonolysis is an attractive technique owing to the complete reaction of ozone with the starting material (8) and the simplicity of the reagents and procedures generally adopted. The chief disadvantages, other than the necessity of an ozone generator, have always been the nominal yields (70–85%) (10–16) of primary acidic fission products, the associated formation of carbonyl, peroxidic, and polymeric materials (1, 7, 17), and the presence of one or more secondary acidic oxidation products. The latter can cause considerable uncertainty where minor amounts of positional isomers are being determined, while by-products hinder both separation and analysis of the products (10, 18). Certain procedures do give high yields of products, but the silver oxide oxidation method of Asinger (3, 12, 19) and the procedure of Klenk and Bongard (20) are somewhat complex, while that of Pryde *et al.* (8) yields aldehydes as principal products.

The most common alternatively employed oxidizing agent, potassium permanganate, also gives only moderate yields of acidic products and considerable secondary oxidation (11, 12, 18, 21–24). The recently introduced permanganate-catalyzed periodate method of von Rudloff (3, 25–28) is much more attractive owing to the simplicity of the method

and the very high yields of primary products. These techniques do suffer from a disadvantage in that recovery of the primary products, in particular the dicarboxylic acids, must be made by extraction from a highly mineralized aqueous solution, with consequent risk of losses of the more soluble lower dicarboxylic acids. In the past this factor has led to erroneous results in determining the relative proportions of positionally isomeric double bonds (13, 24, 29, 30).

If ozonolysis is to be considered as a useful method for the sensitive determination of double-bond position in long-chain fatty acids it must satisfy the following requirements:

1. the method should have a high yield of primary products and should give rise to the least possible amounts and variety of "abnormal" products;
2. the procedure of working-up should give the highest possible recoveries of related products even when these have differing physical properties;
3. the method should be simple and reproducible;
4. the method of analysis should be sensitive and accurate.

It was deemed desirable that the principal products should be acidic in order to capitalize on the stability and low volatility of the desirable dicarboxylic acids. The method outlined below, based on ozonolysis in methanol, a reacting solvent, with decomposition of the ozonide product with hydrogen peroxide in formic acid, satisfies the above requirements. The yield of principal dicarboxylic acid product averages 95%, accompanied by only 2–4% lower homologous dicarboxylic acids and 2–4% other materials. The principal non-dicarboxylic acid by-product has been tentatively identified as the alcohol formed from the principal acidic product through the loss of one carbon atom, occurring both as the alcohol and as its formyl ester. Since only volatile solvents and reagents are employed, and the monocarboxylic acids are removed by steam distillation, total recovery of the dicarboxylic acids present is possible. The method is relatively simple and while some variation is found in the proportion of non-dicarboxylic products to dicarboxylic acids, the ratio of total secondary dicarboxylic acid products to principal dicarboxylic acid product is remarkably stable. The mixture of products is readily analyzed with a high degree of accuracy by gas–liquid chromatography. The methanol – formic acid procedure is derived from that employed by Bailey (31, 32) for the production of adipic acid by ozonolysis of cyclohexene, by Perry (33) in the ozonolysis of norbornylene, and by Pryde *et al.* (8) in the ozonolysis of methyl oleate to give carbonyl products. Methanol has also been employed recently by other workers in the ozonolysis field (34–37), although not necessarily in exploitation of the same type of reaction.

EXPERIMENTAL

Pure oleic acid was prepared from filbert oil (38) via the methyl esters by established procedures (39, 40). The following properties were determined: iodine value 91.2 (Wijs), 89.1 (by precision semimicro hydrogenation (41)) (calc. 89.9); n_D^{25} 1.45785 (cf. n_D^{25} 1.45792 (42)). Ultraviolet spectrophotometry showed no diene or triene content prior to alkali isomerization* and the latter procedure showed a diene content of 0.1% or less. Gas–liquid chromatography of the methyl ester showed only an oleate peak.

It has been reported that an oleic acid prepared from olive oil by standard methods contained appreciable amounts of positional isomers (29). The present and other studies (13, 14) have confirmed that oleic acid homogeneous in bond position can be readily

**Modification of the method of Vandenheuvel and Richardson (43); 21% KOH in ethylene glycol, effective heating time 15 minutes.*

prepared. The ultimate criterion of purity in all cases must be the analysis of both mono- and di-carboxylic acid fission products. Thus the presence of small amounts of suberic acid in the dicarboxylic acid product does not signify the presence of octadec-8-enoic acid unless decanoic acid can be found in the complementary monocarboxylic acids. In the present studies the occurrence of both mono- and di-carboxylic acid products containing 10 carbon atoms has been noted in amounts of $\leqslant 0.1\%$. Thus the amounts of octadec-8- and octadec-10-enoic acids cannot have exceeded this level.

Ozone was furnished by a pyrex corona discharge tube (4). At an oxygen flow rate of 1.1 l./hr, the ozone content was determined as 2.2% (w/w) by decomposition of potassium iodide (44). A dry-ice trap supplemented chemical drying of the oxygen.

1. Ozonolysis in Methanol

Pure oleic acid (ca. 1 g) was weighed in a long-necked, 100-ml standard taper flask. Absolute methanol (Fisher Spectrophotometric Grade, 40 ml) was added and the solution was chilled to $-30°$ C and treated with ozone-containing oxygen until complete absorption ceased. The flask was fitted with a distilling head in order to admit a capillary tube (nitrogen) and was connected through a dry-ice trap to a mechanical vacuum pump system. The flask was immersed in water at room temperature and vacuum applied in stages until all the methanol was removed and the pressure was less than 1 mm. Formic acid (98%, 25 ml) was added to dissolve the syrupy residue and hydrogen peroxide (30 or 50% aqueous solution, 10 mole-equivalents) added. A reflux condenser was immediately fitted to the flask and gentle warming induced an exothermic reaction, on completion of which the mixture was heated for 1 hour on a steam bath. The peroxide and peracid content fell rapidly below measurable limits.

Water (20 ml) was added and the solution transferred to a continuous steam-distillation unit, a few drops of acetone serving as rinse. In this case, 200 ml of distillate was collected for recovery of the nonanoic and associated monocarboxylic acid products. The dicarboxylic acid solution was transferred to a distillation unit and evaporated nearly to dryness under aspirator vacuum. Toluene was added in small lots (ca. 10 ml) and removed under reduced pressure until the distillate was free of water and formic acid (45). Further vacuum treatment eliminated residual toluene. The product was dissolved in acetone (100 ml) and aliquots were taken for determination of yield by weight and titration. The balance of the material was freed of solvent and esterified with distilled diazomethane (18) in ether solution. The ether was removed and the product examined by gas–liquid chromatography. The results are presented in Table I.

The steam distillate was extracted with hexane (100 ml). The hexane solution was dried over sodium sulphate, and after removal of solvent the monocarboxylic acids were converted to methyl esters with diazomethane. Analysis of these methyl esters is presented in Table II.

The methanol in the cold trap was diluted with water and extracted with hexane. The bulk of the solvent was removed and the remaining solution examined by gas–liquid chromatography. Only traces of nonaldehyde were observed.

2. Ozonolysis in Acetic Acid and Other Solvents

Ozonolyses were carried out as described above employing 40 ml of a mixture of acetic acid and methyl formate (3:1), acetone, or methyl formate, with cooling in an ice-water bath. After complete ozone absorption had ceased, aqueous hydrogen peroxide (30%, 5 ml) was added and the flask was fitted with a reflux condenser. After standing overnight at room temperature, the mixtures were heated on a steam bath for 1 hour.

Monocarboxylic acids were removed by extraction with hexane (100 ml) after addition of water (100 ml). The aqueous solution containing the dicarboxylic acids was freed of solvents and volatile acids as described above, yields were determined, and the product was converted to methyl esters. Gas–liquid chromatographic analyses of the products are presented in Table I for the acetic acid and acetone products. The methyl formate product did not differ appreciably from the acetone product.

3. Control Oxidation of Azelaic Acid

Pure azelaic acid (100% by gas–liquid chromatography of the dimethyl ester) was refluxed for $1\frac{1}{2}$ hours with hydrogen peroxide solution in formic acid in the proportions used in the ozonolysis procedure. After removal of the solvent the recovery was 97.7% by weight. The esters were examined by gas–liquid chromatography and gave dicarboxylic acid chromatograms almost identical with those obtained from ozonolysis (Table I). The only significant feature appears to be the lower amounts of pimelic and adipic acids formed and the absence of the alcohol by-product.

4. Control Oxidation of Azelaic Acid Methyl Ester Semialdehyde Acetal

Azelaic acid methyl ester semialdehyde was prepared from methyl oleate by ozonolysis in acetic acid and reduction with zinc (8, 9). After a preliminary distillation, a concentrate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was converted to the acetal by refluxing with methanolic HCl (46). The acetal methyl ester was treated with sodium bisulphite solution and after removal of solvent was purified by preparative gas–liquid chromatography (47). The product was not completely pure (cf. ref. 8), but on treatment with hydrogen peroxide in formic acid, a vigorous exothermic reaction took place, and working-up of the products, as in section 2 above, gave a product the gas–liquid chromatogram of which was virtually identical with that obtained by oxidation of azelaic acid.

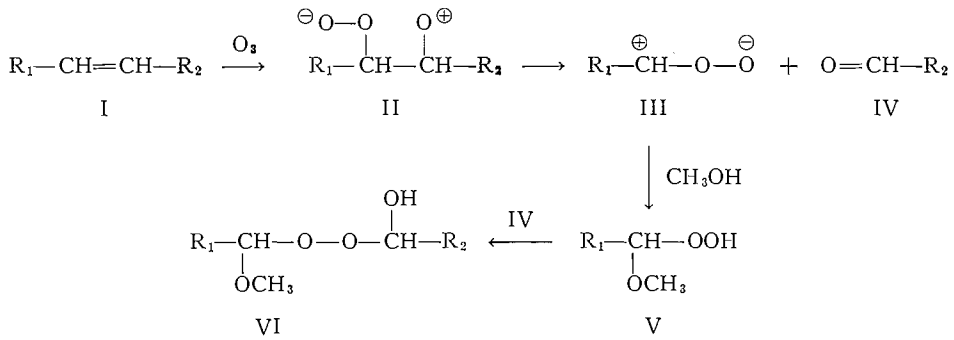
5. Determination of Peroxidic Materials

An aqueous solution of hydrogen peroxide (30%, 5 ml) was added to the solvent under consideration (40 ml) in a round-bottomed standard taper flask fitted with a reflux condenser. The solution was heated on a steam bath, aliquots being withdrawn at intervals for analysis. Determination of hydrogen peroxide was made with ceric sulphate, and of peracids, with potassium iodide and sodium thiosulphate (48). Only formic acid showed an appreciable peracid content at any time, and only with formic acid or mixtures containing formic acid was rapid destruction of all active oxygen evident.

6. Gas–Liquid Chromatography

The apparatus employed was a Podbielniak Chromacon. Columns were 10 ft in length and $\frac{1}{4}$ in. in diameter, packed with 30% of either high-vacuum silicone grease (Dow Corning), especially treated (49), or diethylene glycol – adipic acid polyester (LAC-2-R-446), on 60–80 mesh Chromosorb. Analyses of monocarboxylic esters were carried out at 100° C with hydrogen flow rates of 55 ml/min for the polyester column and 100 ml/min for the silicone column. Dicarboxylic esters were analyzed at 160° with hydrogen flow rates of 85 ml/min for the polyester column and 38 ml/min for the silicone column. Areas were determined by a ball-and-disk-type integrator. The errors associated with the small peaks ($\sim$0.1%) may be $\pm$30% owing to the few counts available (50).

The monocarboxylic acid chromatograms showed, in addition to minor amounts of octanoic and heptanoic methyl esters, three other components. The minor one was identified as nonanal and the others as octanol and octyl formate, the latter predominating. These identifications are assigned on the basis of complete coincidence of small additions of authentic materials added to the ozonolysis product, carried out on both polyester and silicone substrates.



In addition to a large number of very minor peaks, the dicarboxylic acid ester chromatograms showed one major non-dicarboxylic acid by-product. Methyl 8-hydroxyoctanoate was not available, but methyl 9-hydroxynonanoate was prepared by the method of Diaper and Mitchell (51). Calculations of the equivalent chain lengths (52) of methyl 8-hydroxyoctanoate were made from the retention times of methyl 9-hydroxynonanoate. These indicated that the retention times, relative to dimethyl azelate, would be 0.605 on the silicone column and 1.16 on the polyester column. Minor peaks were in fact observed at 0.610 and 1.20 respectively. The formyl ester of the alcohol methyl ester could be similarly shown to have relative retention times, calculated from those of the formyl ester of methyl 9-hydroxynonanoate, of 0.680 on the silicone grease column and 0.905 on the polyester column. These values correlate with the relative retention times of the major non-dicarboxylic acid product, 0.706 and 0.902 respectively. The value of the relative retention time for the by-product peak on the silicone grease column could not be accurately determined as it was overlapped by the dimethyl suberate peak. Mixed runs with small amounts of methyl azelaaldehyde (9) did not coincide with any component on either silicone or polyester analyses.

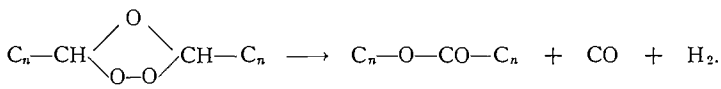
DISCUSSION

The Criegee ozonolysis mechanism (1, 53, 54) suggests that the zwitterion (III) in the presence of a reacting solvent, in this case methanol, leads to a methoxy hydroperoxide (V). There is a possibility that this may then react with the aldehyde (IV) to give a hemiperacetal (VI). If the latter step were not complete (cf. ref. 33), some loss of volatile aldehyde would be expected when the methanol is removed under vacuum, whereas only a trace of free aldehyde (nonaldehyde) has been observed in this step. Reaction of the aldehydes with methanol to give hemiacetals or acetals is also a possibility (37).

The decomposition of the hydroperoxides, hemiperacetals, hemiacetals etc. is readily accomplished by treatment with hydrogen peroxide and formic acid, the active agent probably being performic acid (55) formed *in situ*. Peracetic acid has been employed in similar cases (15, 16, 37). Performic acid decomposes readily on heating, ensuring the rapid destruction (31, 32) of all peroxidic materials, to leave inert products. Regardless of the nature of the material being oxidized, less than 1% nonaldehyde and only traces of azelaic semialdehyde are found in all cases. This can be taken as a reliable indication that oxidation is virtually complete.



The quality of the reagents is significant. Thus results 2-A and 2-B, Table I, where ordinary reagent grade methanol was employed, show slightly higher amounts of both dicarboxylic acid and non-dicarboxylic acid by-products than results 2-C and 2-D where spectrophotometric grade methanol was used.

The acidic composition of the monocarboxylic acid fraction (Table II) parallels, in certain respects, that of the dicarboxylic acid product. However, since the recovery is only about 90% and losses of lower materials are high, the results are less significant.

The close duplication of the ozonolysis results by the control oxidations of azelaic acid and azelaic acid methyl ester semialdehyde acetal (see Table I, also above), not only in terms of secondary dicarboxylic by-products, but also partly in the miscellaneous by-products, indicates that these materials result from true secondary oxidation by the hydrogen peroxide in formic acid, and do not form during the ozonolysis step.

The occurrence of the presumed alcohol by-products in both the monocarboxylic and dicarboxylic acid products suggests a symmetrical reaction characteristic of isolated double bonds, and since they are not found in the control oxidation reactions (see above), their formation must take place during the ozonolysis or decomposition of the ozonide. Two possible mechanisms may be considered. In the first instance Pasero *et al.* (56–58)

have observed the formation of appreciable amounts of esters during the ozonolysis of monoethylenic acids, and ascribe this to simple decomposition of the ozonide:

Thus monooctyl azelate is one of the two potential products in the ozonolysis of oleic acid, and in the presence of formic acid and water, might be expected to hydrolyze or transesterify to give both octanol and octyl formate, together with azelaic acid.

Lefort *et al.* (59, 60) have observed the formation of similar esters (C_n—O—CO—C_n) when aliphatic peracids are heated, although under anhydrous conditions, suggesting a complex reaction of peracids during the ozonide decomposition with hydrogen peroxide in formic acid. On the present evidence either mechanism might be applicable.

Complete elimination of by-products is a highly desirable but rarely attained end in all oxidative fission procedures. The methanol – formic acid procedure reduces the by-product level to a point where gas–liquid chromatography is greatly facilitated, while at the same time retaining the advantage of total recovery of the dicarboxylic acids. The by-products do not, therefore, detract from the advantages of this technique, combined with gas–liquid chromatography, as a quantitative means of analysis of the position of ethylenic double bonds in long-chain monounsaturated fatty acids.

ACKNOWLEDGMENTS

The authors are indebted to Mrs. M. Bannerman for carrying out gas–liquid chromatographic analyses and to Mr. P. M. Jangaard for the ultraviolet and alkali isomerization studies.

THE CRYSTAL STRUCTURE OF 1,3-DICHLORONAPHTHALENE[1]

J. TROTTER

ABSTRACT

Crystals of 1,3-dichloronaphthalene are monoclinic with four molecules in a unit cell of dimensions $a = 15.11$, $b = 3.92$, $c = 14.86$ Å; $\beta = 96.0°$; space group $P2_1/n$. The x and z parameters of the chlorine and carbon atoms have been determined from Patterson and Fourier projections along the b-axis. The bond distances in the molecule, determined from the lengths projected on (010) together with estimated orientation angles, are very similar to the corresponding distances in naphthalene.

INTRODUCTION

One of the molecules being studied during investigations of the crystal structures of some naphthalene derivatives was previously reported as 1,2-dichloronaphthalene (1). During the course of the analysis, however, it became evident that the b-axis Patterson projection corresponded not to 1,2-dichloronaphthalene, but to the 1,3-derivative, and melting-point studies revealed that, while the main bulk of the sample was rather impure 1,2-dichloronaphthalene, the well-formed sublimed crystals used in recording the X-ray data were pure 1,3-dichloronaphthalene (2). The present communication gives details and results of the analysis of these sublimed crystals.

EXPERIMENTAL

Crystals of 1,3-dichloronaphthalene, which were formed by sublimation over a period of several months, consist of colorless prisms elongated along the b-axis. The density was measured by flotation in aqueous potassium iodide solution. The unit-cell dimensions and space group were determined from rotation and oscillation photographs of a crystal rotating about the b-axis, $h0l$ and $h1l$ Weissenberg films, and $hk0$ and $0kl$ precession films.

Crystal Data

1,3-Dichloronaphthalene: $C_{10}H_6Cl_2$; molecular weight = 197.1; melting point = 61° C.

Monoclinic; $a = 15.11 \pm 0.04$, $b = 3.92 \pm 0.01$, $c = 14.86 \pm 0.04$ Å; $\beta = 96°00' \pm 10'$.

Volume of the unit cell = 875.4 Å^3.

Density: calculated (with $Z = 4$) = 1.495 g cm^{-3}, measured = 1.494 g cm^{-3}.

Absorption coefficient for X rays: $\lambda = 1.542$ Å, $\mu = 60.6$ cm^{-1}.

Total number of electrons per unit cell = $F(000) = 400$.

Absent spectra: $h0l$ when $(h+l)$ is odd, $0k0$ when k is odd. Space group is $P2_1/n$—C_{2h}^5.

The intensities of the $h0l$ reflections[2] were recorded on Weissenberg exposures for a crystal rotating about the b-axis, using Cu $K\alpha$ radiation, with multiple-film technique to correlate strong and weak reflections. The intensities were estimated visually, the range being about 1500 to 1. The crystal cross section normal to the b-axis was fairly uniform, and no absorption corrections were applied. The structure amplitudes were derived by

[1]*Manuscript received June 12, 1961.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver 8, B.C.

the usual formulae for a mosaic crystal, the absolute scale being established later by correlation with the calculated structure factors. Two hundred and twenty-nine independent $h0l$ reflections were observed, representing about 78% of the possible number observable with Cu $K\alpha$ radiation.

STRUCTURE ANALYSIS

The b-axis Patterson projection exhibited no peak corresponding to the Cl–Cl vector in a 1,2-derivative. Taking the two largest peaks on the map as corresponding to Cl–Cl interactions, positions were derived for the two chlorine atoms in the asymmetric unit, and by setting the origin of the Patterson function in turn at these two positions and at the positions related to them by the center of symmetry at the origin of the cell, a vector convergence (minimum) function was plotted. This map indicated quite clearly that the molecule was 1,3-dichloronaphthalene, all 10 carbon atoms being well-resolved, and co-ordinates were obtained for all the chlorine and carbon atoms. Structure factors were calculated for all the observed $h0l$ reflections, using the scattering factor for chlorine of Tomiie and Stam (3) with $B = 4.8$ Å^2, and the curve of Berghuis *et al.* (4) for carbon with $B = 4.8$ Å^2. The discrepancy factor was 28.2%.

Refinement proceeded by computing successive $(F_o—F_c)$ syntheses, and by altering the positional and temperature parameters to minimize the slopes and difference electron densities at the atomic centers. After two cycles the R value had been reduced to 15.5%; observed and calculated structure factors are not listed, but are available from the author. The final F_o synthesis, computed with measured structure amplitudes and calculated signs, is shown in Fig. 1.

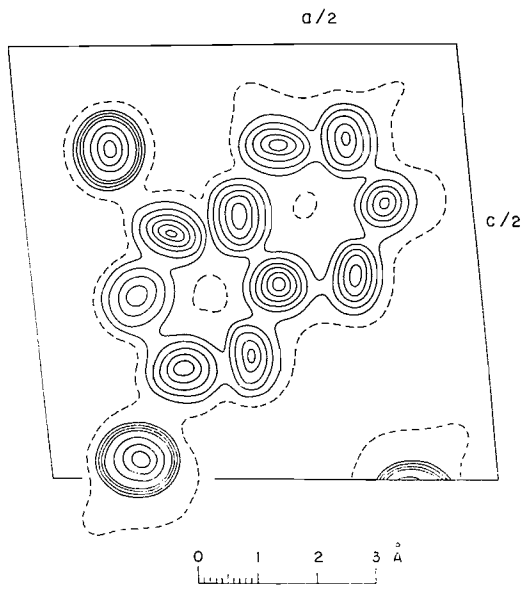

FIG. 1. Electron-density projection along the b-axis. Contours at intervals of 1 e Å^{-2} except at the chlorine atoms, where contours above 5 e Å^{-2} are at intervals of 5 e Å^{-2}; the one-electron line is broken.

No effort has been made to determine the y co-ordinates, since three-dimensional methods would be required, and it is not considered that the problem is sufficiently important to justify the great amount of work which would be involved.

the various sets of parallel bonds to the plane of projection, the true bond lengths, and the mean distances were derived as for 1,4-dibromonaphthalene (5), and the values are included in Table II. The agreement between the mean lengths and those in naphthalene (6, 7), which are listed in the final column of the table, is extremely good, indicating that the mean distances are more accurate than the individual values.

Comparison of the inclination angles for the C—Cl bonds and for parallel C—C bonds indicates that Cl_1 is displaced from the naphthalene plane by 0.28 Å. This displacement

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

is probably real, and is a result of steric interaction with the *peri* hydrogen atom. The deviation of Cl_2 from the aromatic plane is smaller (0.09 Å) and probably not significant.

Projected distances indicate that all the intermolecular contacts correspond to normal van der Waals interactions.

RADICAL RECOMBINATION REACTIONS

PART II. TRIFLUOROMETHYL AND HEPTAFLUORO-*n*-PROPYL RADICALS[1,2]

G. O. PRITCHARD,[3] G. H. MILLER,[3] AND J. R. DACEY[4]

ABSTRACT

Mixtures of hexafluoroacetone and perfluoro-di-*n*-propyl ketone were photolyzed, and the ratio of the rates of formation of the three fluorocarbons, $R_{C_4F_{10}}/R^{1/2}_{C_2F_6}R^{1/2}_{C_6F_{14}}$, was found to equal 1.77 ± 0.10 over a 107° temperature range.

INTRODUCTION

In this paper we are concerned with the photolytic cogeneration of $CF_3\cdot$ and $C_3F_7\cdot$ radicals in a gas-phase system, and the temperature dependence, if any, of the three recombination reactions:

$$CF_3\cdot + CF_3\cdot \xrightarrow{k_{1-1}} C_2F_6, \qquad [1\text{-}1]$$

$$CF_3\cdot + C_3F_7\cdot \xrightarrow{k_{1-2}} C_4F_{10}, \qquad [1\text{-}2]$$

$$C_3F_7\cdot + C_3F_7\cdot \xrightarrow{k_{2-2}} C_6F_{14}, \qquad [2\text{-}2]$$

with respect to each other.

In a steady-state condition we have

$$k_{1\text{-}2}/k^{1/2}_{1\text{-}1}\,k^{1/2}_{2\text{-}2} = R_{C_4F_{10}}/R^{1/2}_{C_2F_6}R^{1/2}_{C_6F_{14}}, \qquad [I]$$

provided these reactions are the only sources of the three fluorocarbons.

At the pressures used there are no third-body restrictions affecting the recombinations, and the small temperature dependence associated with the collision number will cancel out in expression [I]. Thus any temperature variation of this ratio must be due to differing activation energies for one or all of the processes.

EXPERIMENTAL

The apparatus has essentially been described previously (1). The 3130-Å radiation was collimated by a single quartz lens and a stop, passed through a blue glass (Corning 9863), and into a 157-ml, cylindrical, 10-cm-long quartz reaction cell, fully illuminating it. The cell was surrounded by an outer steam jacket. Refluxing liquids used to attain temperatures other than 100° were xylene, 140°; *o*-dichlorobenzene, 180°; and tetralin, 207°.

The radical sources were the two ketones, $(CF_3)_2CO$ and $(C_3F_7)_2CO$, purified as described previously (2, 3). No detectable impurities were found in the mass spectra. Photolysis of the ketones individually in the temperature range of our experiments yields CO and the corresponding fluorocarbon in a 1:1 ratio via a free-radical mechanism (2, 3).

[4]*Royal Military College.*

A Toepler pump was attached to the reaction cell to ensure complete mixing of the ketones before irradiation. After photolysis, the CO was separated at −195° and measured in a gas burette. The remainder of the reaction mixture was condensed into a tube containing thoroughly outgassed distilled water. After the contents had warmed up, the tube was shaken vigorously and reattached to the vacuum system. Blank experiments showed that this procedure removed all of the $(CF_3)_2CO$ and most of the $(C_3F_7)_2CO$ as hydrates. C_2F_6 was then separated on Ward – Le Roy stills at −160°, and C_4F_{10} at −120°. The purity of all the products was checked mass spectrometrically. A fraction collected at −80° was slightly larger than that required by radical balance and contained C_6F_{14} and some unreacted $(C_3F_7)_2CO$. Perfluorohexane was identified unambiguously from the relative peak heights at masses 119 ($C_2F_5^+$), 131 ($C_3F_5^+$), and 169 ($C_3F_7^+$) in the mass spectrum (4).

The ultraviolet spectrum of the heavier ketone was taken on a Cary Model 14 recording spectrophotometer. There is strong absorbance between 2500 and 3600 Å, with structure between 3000 and 3500 Å. The absorbance maximum is at 3130 Å; molar extinction coefficient 32.0 l. mole^{-1} cm^{-1}. This is about four times as large as that for $(CF_3)_2CO$ at 3130 Å (2). Mixtures of the ketones gave additive spectra.

RESULTS

The data are collected in Table I. Due to the clear-cut nature of the photolysis mechanisms, C_6F_{14} has been calculated from CO − $(C_2F_6 + C_4F_{10})$. Consideration of runs 4 to 10 indicates the constancy of the ratio $k_{1\text{-}2}/k_{1\text{-}1}^{1/2}k_{2\text{-}2}^{1/2}$ over 107°, so that further experimentation did not appear worth while.

No experiments below 100° were envisaged due to the temperature and pressure dependence of the quantum yields, especially for $(CF_3)_2CO$, in this range. However, even at 100° in the early experiments (run 3 is given as an example), a suppression of $CF_3\cdot$ products was found. Ratios deduced from them were not considered reliable due to the small amounts of C_2F_6 obtained. Runs 1 and 2 give data for the ketones when they were photolyzed separately. The percentage decompositions are in accord with the high-pressure quantum yields, 0.6 for $(CF_3)_2CO$ and 1.0 for $(C_3F_7)_2CO$ at 100°, and the enhanced absorbance of the heavier over the lighter ketone at 3130 Å. Examination of runs 3, 4, and 5 shows suppression of the $(CF_3)_2CO$ photodecomposition with increasing $(C_3F_7)_2CO$ concentration. This can only be due to the very efficient deactivation of the excited species $(CF_3)_2CO^*$ by the heavier ketone. As expected, this effect lessens with rising temperature.[5] Decrease in the initial $(C_3F_7)_2CO$ concentrations enabled us to approximate to the ideal fluorocarbon product ratio of 1:2:1.

Percentage decompositions were calculated from the ratios $(C_2F_6 + \frac{1}{2}C_4F_{10})/(CF_3)_2CO$ and $[CO - (C_2F_6 + \frac{1}{2}C_4F_{10})]/(C_3F_7)_2CO$. On a time basis the latter are not entirely self-consistent as the voltage to the lamp was not stabilized. For the short period of a particular experiment constant light intensity can be assumed. In any case small sporadic intensity fluctuations are of no consequence. Expression [I] is not subject to stationary-state limitations, and will remain constant until either ketone is completely consumed. We conclude that expression [I] = 1.77±0.10.

[5]*The other possibility of losing* $CF_3\cdot$ *products,*

$$CF_3\cdot + (C_3F_7)_2CO \rightarrow [CF_3(C_3F_7)_2CO\cdot] \rightarrow C_3F_7\cdot + CF_3COC_3F_7,$$

would lead to excess $C_3F_7\cdot$ *products, which was not observed, and contrary to the experimental findings, the effect would increase with temperature as such reactions require an activation energy of about 6–7 kcal/mole (see reference 10).*

DISCUSSION

(a) Pre-exponential Ratios

Assuming identical activation energies and steric factors for radical recombination reactions we have $k_{1\text{-}2}/k_{1\text{-}1}^{1/2}k_{2\text{-}2}^{1/2} = Z_{1\text{-}2}/Z_{1\text{-}1}^{1/2}Z_{2\text{-}2}^{1/2}$. By simple collision theory this reduces to approximately 2 in radical–radical systems. (The picture is somewhat more complicated if disproportionation reactions occur.) Using $\sigma CF_3\cdot = 4.0$ Å and $\sigma C_3F_7\cdot = 6.5$ Å, we obtain 2.2.

Kerr and Trotman-Dickenson (5) have shown that the experimental values for the combination of unlike radicals, in many cases, lie close to 2, and are independent of temperature, indicating that combination occurs on every collision. Calvert (6) has pointed out while this may be so for simple alkyl radicals, it is not true where one of the radicals is highly polar as a potential barrier to recombination exists. In the $CH_3\cdot + CF_3\cdot$ system (1) we noted a decrease from 3.0 to 1.8 over 140°, which was attributed to the polarity of the $CF_3\cdot$ radical, leading to a value of $E_{1\text{-}1} = 2$ kcal/mole. It has been pointed out (6, 7) that radicals formed in photolytic systems may not be thermally equilibrated, as evidenced in some cases by increasing disproportionation/recombination ratios with rising temperatures and falling pressure. If the disproportionation,

$$CF_3\cdot + CH_3\cdot \rightarrow CF_3H + CH_2\cdot,$$

occurred to a large extent, increasing with temperature, it could account for the observed decrease in $k_{1\text{-}2}/k_{1\text{-}1}^{1/2}k_{2\text{-}2}^{1/2}$. There was no positive evidence for it (1); also, the reaction has not been suggested in other $CH_3\cdot + CF_3\cdot$ systems (8, 9). The polar effect appears to be real.

Data from other similar systems are scant, as the determination of expression [I] was not the objective of the experiments. For $C_2H_5\cdot + C_3F_7\cdot$, it is 3.0, and admittedly scattered (5), and 2 ± 1 for $CH_3\cdot + C_2F_5\cdot$ (10), both ratios being temperature independent. Other gas-phase values at room temperature are 2.2 for $CF_2Cl\cdot + CF_2ClCF_2\cdot$ (11) and 1.9 for $CF_2Cl\cdot + CFCl_2\cdot$ (12).

Polar effects are being further studied by the cophotolysis of $(CH_3)_2CO$ and $(C_3F_7)_2CO$; the results will be presented in a later publication.

(b) Activation Energies

In the present system we have $E_{1\text{-}2} - \frac{1}{2}E_{1\text{-}1} - \frac{1}{2}E_{2\text{-}2} = 0$. The only reasonable assumption is that all three activation energies are equal. We may infer that there is a barrier to recombination of about 2 kcal/mole for all simple perfluoroalkyl radicals.

If we consider the system

$$X\cdot + R\text{—}H \rightarrow X\text{—}H + R\cdot$$
$$X\cdot + X\cdot \rightarrow X_2,$$

where $X\cdot$ is $CF_3\cdot$, $C_2F_5\cdot$, or $C_3F_7\cdot$, the activation energy of the first reaction will be determined mainly by the R—H and X—H bond strengths, and the repulsive forces between $X\cdot$ and R—H, and X—H and R. (13). As the activation energy for the second reaction remains constant, we may assume that the repulsive forces in the first do not vary significantly with $X\cdot$. If D(X—H) is constant, the activation energy should not vary with $X\cdot$.

Price and Kutschke (10) have summarized the available data for $CF_3\cdot$, $C_2F_5\cdot$, and $C_3F_7\cdot$ radicals. For CH_4 we have the following $E - \frac{1}{2}E$ values (±0.5 kcal): 10.3, 10.6, and 9.5 kcal, and for H_2: 8.8, 11.9, and 12.3 kcal. For $CF_3\cdot$ and $C_3F_7\cdot$ radicals only, we

have for D_2: 9.7 and 13.8 kcal, and for C_2H_6: 7.5 and 9.2 kcal. However, the last figure may be high by 1–2 kcal (14). Some correlation does exist, although $CF_3\cdot + H_2$ and $CF_3\cdot + D_2$ are exceptions.

ACKNOWLEDGMENTS

We wish to thank Mr. K. R. Chang for performing some of the photolyses, and Mr. J. K. Foote for taking the ultraviolet spectra and for helpful discussions. Our thanks are due to the National Science Foundation for a grant-in-aid (G.O.P. and G.H.M.), and to the Defence Research Board of Canada, under Grant 9530/13, for financial assistance (J.R.D.).

OCTAHALOGENODIBENZO-*p*-DIOXINS[1]

MARSHALL KULKA

ABSTRACT

Pentahalogenophenols have been converted to 1,2,3,4,6,7,8,9-octahalogenodibenzo-*p*-dioxins in almost quantitative yields using the halogens or halogen-producing compounds as initiators of the reaction. It is suggested that an intermediate in this reaction is the pentahalogenophenoxy radical.

In 1872, Merz and Weith (1) heated the potassium salt of pentachlorophenol and obtained a high-melting compound which they called perchlorophenylenoxyd. This compound was also obtained when pentachloroanisole was treated with concentrated sulphuric acid (2). A few years later it was shown that when "α-heptachloroketotetrahydrobenzol" (I) was heated at 180°, it yielded 2,3,4,4,5,6-hexachloro-2,5-cyclohexadienone (II) and when the temperature was raised over 200° the product was the "perchlorophenylenoxyd" (3, 4). Although the formula $(C_6Cl_4O)_x$ was assigned to "perchlorophenylenoxyd" there is little doubt that it was 1,2,3,4,6,7,8,9-octachlorodibenzo-*p*-dioxin (III).

I II III VII IV V VI + IV

[1]*Manuscript received July 7, 1961.*
Contribution from the Research Laboratories, Dominion Rubber Company Limited, Guelph, Ontario.

Can. J. Chem. Vol. 39 (1961)

About fifty years later, Denivelle and his co-workers (5) condensed a salt of pentachlorophenol with 2,3,4,4,5,6-hexachloro-2,5-cyclohexadienone (II) in an inert solvent to form 4-*p*-chlorophenoxy-2,3,4,5,6-pentachloro-2,5-cyclohexadienone. This compound then underwent a number of reactions, including cyclization, to form 1,2,3,4,6,7,8,9-octachlorodibenzo-*p*-dioxin (III).

Finally Sandermann, Stockmann, and Casten (6) were able to prepare III in poor yield directly from pentachlorophenol (IV) by heating it at 300°. The yield was poor because two simultaneous reactions occurred and the main product was hexachlorobenzene (VI). The formation of VI was explained in the following manner. Dehydration of two molecules of pentachlorophenol (IV) yielded the intermediate decachlorodiphenyl ether (V), which underwent cleavage in the presence of hydrogen chloride to form hexachlorobenzene (VI) and pentachlorophenol (IV). In the second reaction, two molecules of pentachlorophenol (IV) formed III with the elimination of two molecules of hydrogen chloride.

The writer has now developed a method for the conversion of pentachlorophenol (IV) to 1,2,3,4,6,7,8,9-octachlorodibenzo-*p*-dioxin (III) in almost quantitative yield by heating the phenol in the presence of an initiator. First of all, the work of Biltz (4) was repeated and it was found that when 2,3,4,4,5,6-hexachloro-2,5-cyclohexadienone (II) was heated over 200°, chlorine gas was liberated and the octachlorodibenzo-*p*-dioxin (III) was formed in high yield. From this observation the following mechanism of the reaction II → III became evident. Under the influence of heat, II dissociates to chlorine and the pentachlorophenoxy radical VII. Two of the radicals then associate, eliminate two chlorine atoms, and form III.

In view of the fact that hindered phenols can be oxidized to the corresponding phenoxy radicals (7, 8) it was decided to search for an oxidant which would convert pentachlorophenol (IV) to the pentachlorophenoxy radical VII and thus provide a method of preparing III from pentachlorophenol. 2,3,4,4,5,6-Hexachloro-2,5-cyclohexadienone (II) filled the requirements of such an oxidant because it not only liberated an oxidizing agent (chlorine) on being heated but also was converted to III. When an equimolecular mixture of pentachlorophenol (IV) and 2,3,4,4,5,6-hexachloro-2,5-cyclohexadienone (II) was heated under reflux for 16 hours in 1,2,4-trichlorobenzene as solvent, or at 250–300° for 15 minutes without solvent, octachlorodibenzo-*p*-dioxin (III) was formed in 85% yield. Furthermore, the amount of II could be decreased to the point where almost catalytic quantities were sufficient to initiate the reaction of IV → VII → III. The reason for this becomes evident when one realizes that the chlorine liberated in the reaction VII → III can be used in the oxidation of IV to VII. An outside source of chlorine is necessary only to initiate the reaction and to replenish undue losses from the internal source. It is interesting to note that in the reaction VII → III, the ortho chlorines are eliminated, and little, if any, para elimination occurs. No poly(1,4-phenylene oxide) of the type described by Price (8) could be detected.

Although 2,3,4,4,5,6-hexachloro-2,5-cyclohexadienone (II) is a very convenient initiator of the reaction IV → VII → III, it can be replaced by elementary halogens. When chlorine gas was bubbled slowly into a boiling solution of pentachlorophenol (IV) in 1,2,4-trichlorobenzene, the octachlorodibenzo-*p*-dioxin (III) was formed in 82% yield. Bromine and iodine were not as effective initiators as chlorine.

1,2,3,4,6,7,8,9-Octabromodibenzo-*p*-dioxin and 1,2,4,6,7,9-hexabromo-3,8-dichlorodibenzo-*p*-dioxin were prepared similarly from the corresponding phenols, showing that the method may have general application.

EXPERIMENTAL

2,3,4,4,5,6-Hexachloro-2,5-cyclohexadienone (II)

A reaction mixture of pentachlorophenol (500 g), *sym*-tetrachloroethane (400 ml), and iron powder (0.5 g) was stirred and heated at 90–100° while a slow stream of chlorine gas was passed in. When the weight increased by 80 g (12 hours) the dark reaction mixture was filtered and the filtrate concentrated *in vacuo* and allowed to cool overnight. The heavy, yellow crystals were filtered, washed with petroleum ether and with methanol, and dried. The yield from three successive crops was 444 g or 79%, and the product melted at 105–106°. The reported melting point is 106–107° (9).

1,2,3,4,6,7,8,9-Octachlorodibenzo-p-dioxin (III)

(a) From 2,3,4,4,5,6-Hexachloro-2,5-cyclohexadienone (II)

The hexachlorocyclohexadienone (II) (20 g) was heated at 270–280° in an atmosphere of carbon dioxide for ½ hour. The resulting cake was crystallized twice from 1,2,4-trichlorobenzene, yielding white needles (11 g or 73%) melting at 330–332°. Anal. Calc. for $C_{12}Cl_8O_2$: C, 31.30; Cl, 61.75. Found: C, 31.74, 31.61; Cl, 62.26, 61.74. This compound sublimed readily *in vacuo* (12 mm pressure). It was very stable and crystallized from hot, concentrated sulphuric acid without charring.

(b) From Pentachlorophenol Using II as Initiator

A solution of pentachlorophenol (IV) (40 g), 2,3,4,4,5,6-hexachloro-2,5-cyclohexadienone (II) (2 g), and 1,2,4-trichlorobenzene (80 ml) was heated under reflux for 16 hours. Hydrogen chloride and chlorine were evolved. The solution was allowed to cool and the white crystalline precipitate was filtered, washed with methanol, and dried. The product weighed 30 g (86%) and melted at 330°.

In another experiment an equimolecular mixture of pentachlorophenol (IV) and II was treated as above. The yield of III, based on the combined weights of II and IV, was 85%.

(c) From Pentachlorophenol Using Chlorine as Initiator

A solution of pentachlorophenol (IV) (25 g) in 1,2,4-trichlorobenzene (75 ml) was heated under reflux for 6 hours while chlorine gas was bubbled slowly into the reaction mixture. Then the refluxing was continued for another 10 hours without the introduction of chlorine. The resulting solution was allowed to cool, the white crystals were filtered, washed with methanol, and dried, m.p. 325–328°. The yield was 18 g or 83%.

(d) From Pentachlorophenol Using Bromine as Initiator

The experiment was carried out as in (*c*) but instead of the chlorine, 2 drops of bromine were added every 2 hours for the first 6 hours. The yield of III was 52%.

(e) From Pentachlorophenol Using Iodine as Initiator

The experiment was carried out as in (*c*) but instead of the chlorine, solid iodine (0.2 g) was added to the reaction mixture. Iodine vapors were visible in the reaction flask throughout the whole reaction time of 16 hours. The yield of III was 23%.

1,2,3,4,6,7,8,9-Hexabromodibenzo-p-dioxin

A mixture of pentabromophenol (35 g) and 2,3,4,4,5,6-hexachloro-2,5-cyclohexadienone (II) (0.2 g) was heated at 310–320° for ½ hour and then at 360° for a few minutes. Hydrogen bromide and bromine were evolved. The cooled product, on crystallization from 1,2,4-trichlorobenzene, yielded white plates (15 g or 52%) melting at 403–406°. Anal. Calc. for $C_{12}Br_8O_2$: Br, 78.43. Found: Br, 78.95, 79.02.

2,3,5,6-Tetrabromo-4-chlorophenol

Bromine (320 g) was added dropwise over 6 hours to a stirred solution of *p*-chlorophenol (64 g) in *sym*-tetrachloroethane (200 ml) and iron powder (0.2 g), in a reaction flask fitted with a condenser, stirrer, and dropping funnel. The temperature was kept at 90–100° by heating the mixture. Then the dark reaction mixture was heated at 100–120° for 15 hours and allowed to cool. The white precipitate was filtered and crystallized from benzene. The product (135 g) melted at 210–212°. A small portion, when crystallized from benzene–methanol, melted at 213–214° (lit. (10) m.p. 215°). Anal. Calc. for C_6HClBr_4O: C, 16.20; H, 0.23. Found: C, 16.12, 16.79; H, 0.70, 0.80.

1,2,4,6,7,9-Hexabromo-3,8-dichlorodibenzo-p-dioxin

A mixture of 2,3,5,6-tetrabromo-4-chlorophenol (30 g) and 2,3,4,4,5,6-hexachloro-2,5-cyclohexadienone (II) (0.2 g) was heated at 300–310° for 15 minutes and then at 350° for 15 minutes. The cooled product was crystallized from 1,2,4-trichlorobenzene, yielding 15 g (62%) of almost white crystals melting at 385–388°. Anal. Calc. for $C_{12}Cl_2Br_6O_2$: C, 19.5. Found: C, 19.84, 19.75.

In another experiment, 1,2,4-trichlorobenzene was used as solvent. After the solution had been heated for 16 hours the reaction was not complete because a considerable amount of the starting 2,3,5,6-tetrabromo-4-chlorophenol was recovered, and the yield of the product melting at 385–388° was only 36%.

α-KETOETHERS

II. INFRARED SPECTRA AND ROTATIONAL ISOMERISM OF PHENACYL ETHERS[1,2]

PETER YATES,[3] SHERRY LIPINSKY, AND DOROTHEA VOSSIUS

ABSTRACT

Bifurcation of the carbonyl-stretching bands in the infrared spectra of several phenacyl ethers has been observed and is interpreted in terms of rotational isomerism.

The infrared spectra of α-haloketones have been the subject of intensive study during the past decade. As a result of the work of Jones, Corey, Brutcher, and others, the dependence of the carbonyl-stretching frequency of cyclic α-haloketones on their geometry has been elucidated (2). Recently Bellamy and his collaborators (3) have studied the infrared spectra of acyclic α-chloroketones and have observed that these frequently show the presence of two carbonyl-stretching bands. Jones and Spinner (4) have also observed such bifurcation in the spectra of certain other types of α-substituted ketones. We report here a cognate phenomenon in the case of several α-ketoethers.

The positions of the carbonyl-stretching bands of these compounds in carbon disulphide solution are shown in Table I, together with those of the parent ketones and of two

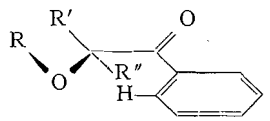
β-ketoethers. Several features of these data may be noted.

(i) The α-ketoethers of type $C_6H_5COCH_2OR$ (compounds 2–6) show a band close in position to the single band of acetophenone, together with a second band at lower wave length; the band separation of 0.07–0.08 μ is identical to that observed by Bellamy for compounds of type $ArCOCH_2Cl$ in solution in carbon tetrachloride.

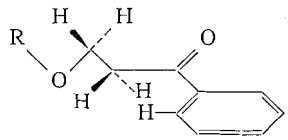


(ii) The two β-ketoethers of type $C_6H_5COCH_2CH_2OR$ (compounds 7 and 8) each show a single band close in position to that of acetophenone.

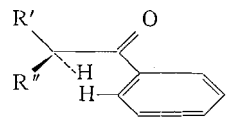
(iii) The remaining α-ketoethers (compounds 10 and 12) show splitting of the carbonyl band; the splitting is smaller, however, than that observed for the compounds of type $C_6H_5COCH_2OR$, and the parent ketones (compounds 9 and 11) also show a small splitting of their carbonyl bands.

The splitting of the carbonyl bands of the ketoethers of type $C_6H_5COCH_2OR$ can best be interpreted in terms similar to those suggested by Bellamy in the case of the phenacyl halides. The band at lower wave length is assigned to a rotational isomer in which the dipole associated with the CH_2—O—R group is in the same plane as that of the carbonyl group and acts in approximately the same direction, while the other band is assigned to a rotational isomer in which the CH_2—O—R dipole lies appreciably out of this plane. Although detailed interpretation in the present case is made more difficult by the greater multiplicity of rotational isomers, examination of scale molecular models indicates that the two types of rotational isomers most likely to be present are I and II. The isomer

I, R′ = H, R = alkyl or C_6H_5
VIII, R′ = C_6H_5, R = CH_3



II, R′ = R″ = H, R = alkyl or C_6H_5
VI, R′ = C_6H_5, R″ = H, R = CH_3
VII, R′ = H, R″ = C_6H_5, R = CH_3



I in which the CH_2—O bond is cis to the C=O bond is considered to give rise to the carbonyl band at lower wave length because of dipole interaction, while the gauche isomer II is assigned the higher wave-length band, which is close in position to the band of acetophenone.* It was found that the spectra of these ketoethers in solvents of increased polarity show an increase in the relative intensity of the lower wave-length band, as would be predicted on the basis of these assignments, and as observed previously in the case of the phenacyl halides (3).

The occurrence of a single carbonyl-stretching band in the spectra of the two β-ketoethers, $C_6H_5COCH_2CH_2OR$, may be attributed both to the attenuation of the field effect of the CH_2—O—R dipole upon the C=O dipole with increasing separation and to the probable large preponderance of the single type of rotational isomer III. It is of interest that the CH_2—O—R dipole in this species is directed approximately in the trans sense relative to the C=O dipole and thus any residual field effect would tend to increase the wave length of its carbonyl-stretching band relative to that of acetophenone. The fact that the single band of these two β-ketoethers falls very close to that of acetophenone implies that either this residual effect is negligible or that it is compensated by an inductive effect, which would operate in the opposite sense (cf. refs. 3 and 4).

House and Blaker (5) have interpreted the presence of two carbonyl bands in the infrared spectra of glycidic esters in related terms.

III

IV, R′ = C_6H_5, R″ = H
V, R′ = H, R″ = C_6H_5

The splitting of the carbonyl band of the parent ketone, deoxybenzoin (compound 9), is again most probably due to the presence of two types of rotational isomers,* i.e. IV and V. The fact that the related α-ketoether (compound 10) shows two bands in closely similar positions to those of the parent suggests that it exists in carbon disulphide solution mainly as rotational isomers of types VI and VII, but not VIII, which is analogous to I and would be expected to give rise to a band at a significantly lower wave length.† Similar considerations apply to the cases of phenylacetone (compound 11) and the related α-ketoether, compound 12; here, the increased number of possible types of rotational isomers prohibits detailed discussion, but again the close similarity of the positions of the bands of the ketoether to those of the parent ketone suggests that rotational isomers in which the C—O—CH_3 group is disposed with respect to the C=O group, as in I and VIII, do not make a major contribution to the rotational isomer mixture.

EXPERIMENTAL

Sources and Purification of Compounds

The sources of the compounds, other than the α-alkoxyacetophenones, are given in Table I. The α-alkoxyacetophenones were prepared by the acid-catalyzed decomposition of α-diazoacetophenone in alcoholic solutions by a method exemplified by the case of α-butoxyacetophenone below. The compounds were purified by distillation, molecular distillation, or crystallization, and their physical properties were checked with those reported in the literature or with those of samples prepared by standard methods in our laboratory.

α-Butoxyacetophenone‡

α-Diazoacetophenone (0.500 g) was added to a solution of *p*-toluenesulphonic acid monohydrate (0.045 g) in butanol (10 ml) maintained under a nitrogen atmosphere. Gas evolution began immediately. The mixture was heated under reflux at 98° for 2.75 hours. The excess of 1-butanol was removed under reduced pressure and the residue was subjected to molecular distillation at 78° (2 mm). The product was obtained as a pale yellow liquid in 70% yield. A second molecular distillation provided a colorless sample whose infrared spectrum was indistinguishable from that of the once-distilled product. This was characterized as its 2,4-dinitrophenylhydrazone which was recrystallized from methanol and had m.p. 136–137°.

Anal. Calc. for $C_{18}H_{20}N_4O_5$: C, 58.06; H, 5.41; N, 15.05. Found: C, 58.33; H, 5.49; N, 15.02.

**Jones and Spinner (4) have previously reported the splitting of the carbonyl-stretching band of deoxybenzoin in carbon tetrachloride solution and attributed it to rotational isomerism.*

†Examination of scale molecular models suggests that steric factors might well favor the preponderance of isomers of type VI and VII over those of type VIII.

‡This method is a modification of that of Newman and Beal (6).

THE EFFECT OF THE AMBIENT OXYGEN ON THE ELECTRICAL PROPERTIES OF AN EVAPORATED FILM OF PENTACENE[1]

HARUO KURODA[2] AND E. A. FLOOD

ABSTRACT

The "oxygen effect" on the dark current as well as that on the photocurrent was investigated using thin evaporated films of pentacene, 1,2-benzpentacene, 1,2,8,9-dibenzpentacene, 6,13-diphenylpentacene, and 5,7,12,14-tetraphenylpentacene. No oxygen effect could be detected in the dark current.

From the photocurrent dependence on oxygen pressure and from the rate of photocurrent decay, it is concluded that additional charge carriers are produced on illumination by photo-excitation of a surface complex.

INTRODUCTION

Ambient gases exert a considerable influence on the surface photoconductivities and semiconductivities of a number of organic crystals. In the case of anthracene crystals, the electron "acceptor" type gases O_2, NO, SO_2, HCl, BF_3, etc. increase the photoconductivity while the donor gases NH_3, $(CH_3)_2O$, $(CH_3)N$, etc., which are usually less strongly adsorbed, decrease the photoconductivity (1).

Chynoweth has suggested that ambient oxygen forms a surface peroxide with anthracene which decreases the rate of recombination of the charge carriers (2). Bree and Lyons (3) have adduced evidence that unstable surface peroxides are formed on exposure of anthracene to oxygen and they have suggested that an "anthracene peroxide biradical" is largely responsible for the increased conductivity.

In previous papers we have shown that the semiconductivities of films of mesonaphthodianthrene formed by sublimation are increased markedly by exposure to oxygen (4, 5). It was further shown that oxygen produces a new conduction mechanism with a lower activation energy, and we have attributed the effect to the formation of a complex between oxygen and the surface molecules. A similar oxygen effect might be expected in the case of crystals of other aromatic molecules which are reactive to oxygen. However, although pentacene is relatively highly reactive towards oxygen and readily forms an addition compound when solutions of pentacene are exposed to air, oxygen has but little effect on the dark-current semiconductivity of pentacene films.

In what follows we present the results of some exploratory experiments on the effect of ambient oxygen on the electrical properties of "evaporated films" of pentacene and of some pentacene derivatives. As will be seen, the effect of oxygen on these films is quite different from its effect on the mesonaphthodianthrene film.

EXPERIMENTAL

The experimental procedures and the equipment used were essentially the same as described previously (5), except for the addition of the photoconductivity cell which is shown in Fig. 1. The evaporated films were prepared by high-vacuum sublimation onto a teflon substrate carrying two carbon electrodes which had been painted on previously using a water suspension of graphite (Aquadag). The evaporated films of hydrocarbon

were of the order of a few microns in thickness. A tungsten-filament lamp was used as a light source. Direct-current voltage was applied between the two electrodes and the current through the film was measured by means of a Hewlett and Packard d-c. microvoltammeter model 425, together with a suitable recorder.

Pentacene, 1,2-benzpentacene,[3] and 1,2,8,9-dibenzpentacene[3] were obtained from L. Light and Company. 6,13-Diphenylpentacene and 5,6,12,14-tetraphenylpentacene were kindly supplied by Dr. R. N. Jones of the National Research Council, Ottawa.

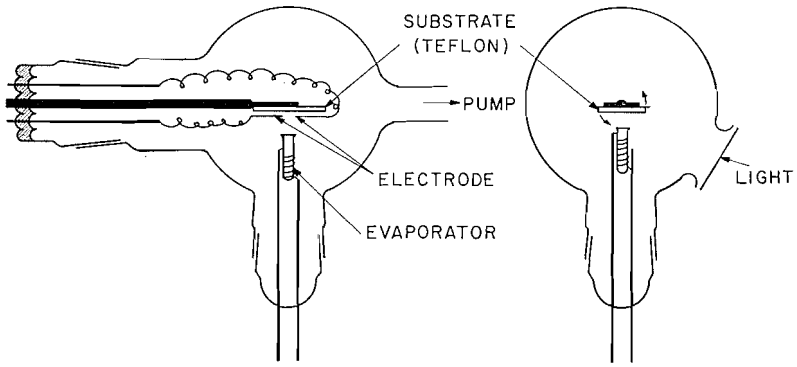

FIG. 1. Cell for the measurement of the oxygen effect on photoconduction.

RESULTS AND DISCUSSIONS

A. Dark Current

The temperature dependence of the dark current was determined, in nitrogen, with each film immediately after its preparation. In the temperature range 0° C to 150° C, the temperature dependence of the dark current was found to obey the exponential law

$$[1] \qquad i_{\text{dark}} = i_0 \exp(-E/kT),$$

where E is the activation energy for the semiconduction. No break was found in the $\log i$ vs. $(1/T)$ curves corresponding to any of the films of pentacene and pentacene derivatives studied. The values of the activation energies determined from experimental results are listed in Table I.

TABLE I

Activation energy of semiconduction

Compound	E (ev)
Pentacene	0.81
Diphenylpentacene	0.80
Tetraphenylpentacene	0.81
Dibenzpentacene	0.75
Benzpentacene	0.86

Although the reactivity of pentacene toward oxygen is as high as that of mesonaphthodianthrene, no appreciable change in either the dark current or the dark-current temperature dependence could be detected on exposure of pentacene films to oxygen. This

[3]*According to A. M. Patterson, L. T. Capell, and D. F. Walker ("The ring index". 2nd ed. American Chemical Society. 1960) the preferred names of these compounds are benzo[a]pentacene for 1,2-benzpentacene and dibenzo[a,l]pentacene for 1,2,8,9-dibenzpentacene.*

behavior is in marked contrast to the effect of oxygen adsorption on the dark current observed with mesonaphthodianthrene. Films of the other pentacene derivatives studied in this work behaved in a manner similar to that of pentacene films.

Of course we cannot conclude from this behavior that the surface reactions between these organic crystals and oxygen are purely physical adsorption or Van der Waals interactions, since the activation energy required to liberate a charge carrier from the surface complex could be higher than that of the semiconduction process in the bulk of the crystal or in the bulk of the microcrystalline mass. This seems not improbable in view of the reactivities of these pentacenes toward oxygen.

B. Change in Photocurrent on Exposure to Oxygen

The change in photocurrent of a freshly deposited pentacene film on exposure to oxygen is shown in Fig. 2. On exposure of the film to oxygen under 200 mm Hg pressure,

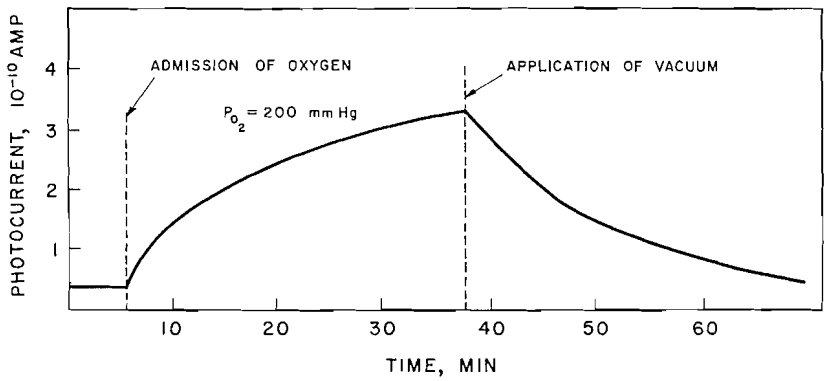

FIG. 2. Change in photocurrent through a pentacene film on exposure to oxygen.

the photocurrent rises slowly from the high-vacuum value and reaches a considerably higher stationary value in something over an hour. On evacuation, the photocurrent decreases, gradually approaching the original high-vacuum photocurrent.

Evidently the oxygen effect is reversible and the interaction between the surface and the oxygen molecule is not very strong. These rates of change are temperature dependent, the rates being higher at the higher temperatures.

Oxygen adsorption influences not only the magnitude of the photocurrent but also the rate of response to illumination. In the absence of oxygen the current through a pentacene film rises rapidly on exposure to light, taking less than a minute to reach its stationary value. In the presence of oxygen, however, the behavior is quite different. On exposure to light, the current rises rapidly to about the same value as in the case of the oxygen-free film, but the current continues to rise slowly until a considerably higher stationary value is obtained. When the light is extinguished, a rapid decrease in photocurrent is shown, the magnitude of its decrease being equal to that of the initial rapid rise; the photocurrent then decays slowly. The behavior is illustrated in Fig. 3. The rates of rise and fall of the current are temperature dependent, being higher at the higher temperatures.

If the photocurrent is observed with a light pulse of short duration (5–6 seconds) in place of the long continuous illumination, the height of the photocurrent pulse is not changed appreciably by exposure to oxygen. These facts suggest that two distinct

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

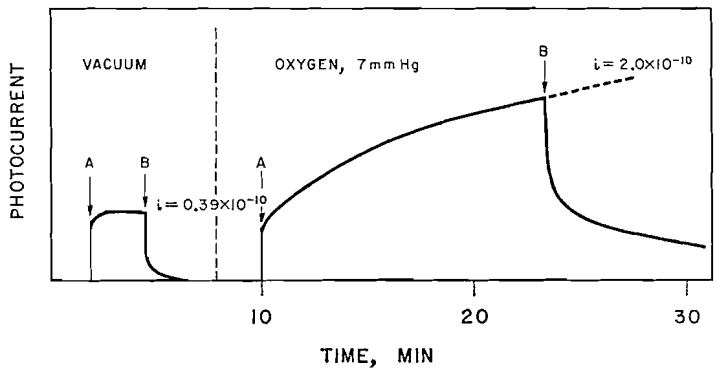

FIG. 3. Response of photocurrent to illumination. Light is admitted at A and shut off at B.

mechanisms are involved in the photoconduction process. In order to illustrate this situation more clearly, the following experiment was carried out. A pentacene film was exposed to oxygen for a long enough period for adsorption equilibrium to be attained. The film with ambient oxygen was then illuminated continuously until the stationary photocurrent was reached. At this point the continuous illumination was shut off and the sample subjected to short light pulses at 1-minute intervals. The photocurrent responses corresponding to the above experiment are shown in Fig. 4.

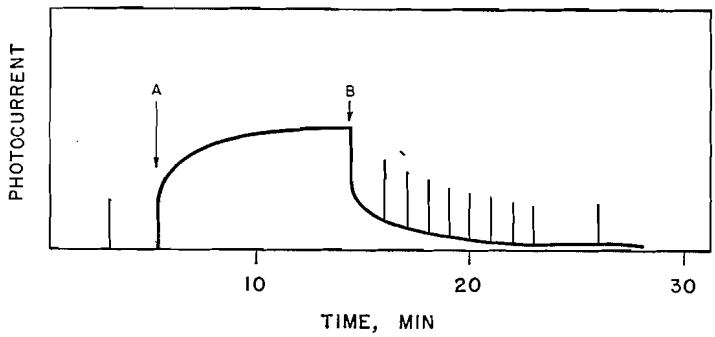

FIG. 4. Response of photocurrent to illumination in ambient oxygen. Continuous illumination is given between A and B.

It is interesting to note that the "heights" of the photocurrent pulses observed during the slow decay process are of almost the same magnitude as that of the pulse observed either for an oxygen-free film or for a film in oxygen before continuous illumination. This strongly suggests that the photocurrent observed in ambient oxygen consists of two more or less independent components, one of which has a short lifetime and is not sensitive to ambient oxygen while the other component has a relatively long lifetime and is oxygen sensitive. We shall represent the first of these photocurrent components by i_1 and the second, oxygen-sensitive component by $i_2(p)$, and write for the total photocurrent[4]

$$i = i_1 + i_2(p). \qquad [2]$$

[4]*Under our experimental conditions i_1 corresponds very approximately to an apparent conductivity of the order of 10^{-11} to 10^{-12}. The intrinsic conductivity of pentacene (30°) is of the order of 10^{-14}; anthracene, 10^{-18}; carbons, 10^{-7} to 1; graphite, $\geqslant 10^{3}$.*

For personal use only.

Films of 1,2-benzpentacene, 1,2,8,9-dibenzpentacene, and 6,13-diphenylpentacene exhibit oxygen-sensitive photoconductivities which are quite similar to those of the pentacene films.

Molecules in the pentacene crystal are closely packed as they are in crystals of anthracene and tetracene; hence, it is unlikely that the oxygen molecule can penetrate deeply into these crystals. In the case of aromatic molecules having substituent groups as large as rubrene (6,5,11,12-tetraphenylnaphthacene) we might expect a somewhat different situation, and, in fact, it is known that photooxidation can take place in the bulk of the rubrene crystal (6). Although the phenyl groups in 5,7,12,14-tetraphenylpentacene are not adjacent, as they are in rubrene, we might expect the crystals of the tetraphenylpentacene to be also rather loosely packed and that a transannular peroxide could be formed either by direct oxidation or by photooxidation. On this basis one might expect the "oxygen effect" on the photoconductivities of tetraphenylpentacene films to be larger than those on films of the other pentacenes. However, surprisingly enough, no oxygen effect could be detected at all, either in the photocurrent or in the dark current when films of 5,7,12,14-tetraphenylpentacene were examined experimentally.

While in solution, pentacene can be oxidized by exposure to oxygen, forming a transannular peroxide; in the case of the solid, the oxygen molecule cannot penetrate the closely packed crystal and appreciable oxidation of the solid does not normally occur on exposure to oxygen. It seems, therefore, safe to assume that under our experimental conditions, "oxide" formation is limited to the surface of the pentacene crystal. Thus in equation [2], i_1 is considered to be bulk photoconductivity while $i_2(p)$ is considered to be associated with surface states and hence sensitive to surface "oxide" formation.

C. Stationary Photocurrent and Oxygen Pressure

The stationary photocurrent determined after a long, continuous illumination is dependent on the oxygen pressure, as shown in Fig. 5.

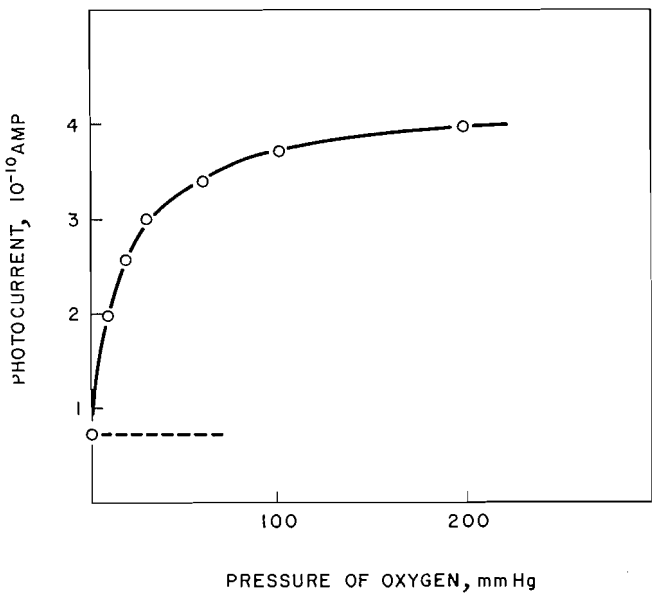

FIG. 5. Dependence of photocurrent on oxygen pressure.

Assuming that the adsorption of oxygen can be expressed by means of a Langmuir-type equation, we can write,

$$\frac{\theta}{1-\theta} = k_1 p, \quad [3]$$

where θ is the fractional surface area covered with oxygen at the pressure p, and k_1 the appropriate proportionality constant. When it is assumed that

$$i_2(p) = k_2\theta, \quad [4]$$

then

$$\frac{k_2}{i_2(p)} = (1/k_1)(1/p)+1 \quad [5]$$

and

$$i_2(p) = \Delta i(p) = i_{\text{photo}}(p) - i_{\text{photo}}(0). \quad [6]$$

Thus equation [5] can be expressed as

$$(1/\Delta i) = (1/k_1k_2)(1/p) + (1/k_2), \quad [7]$$

i.e., $1/\Delta i(p)$ is a linear function of the reciprocal of the oxygen pressure. In Fig. 6 the

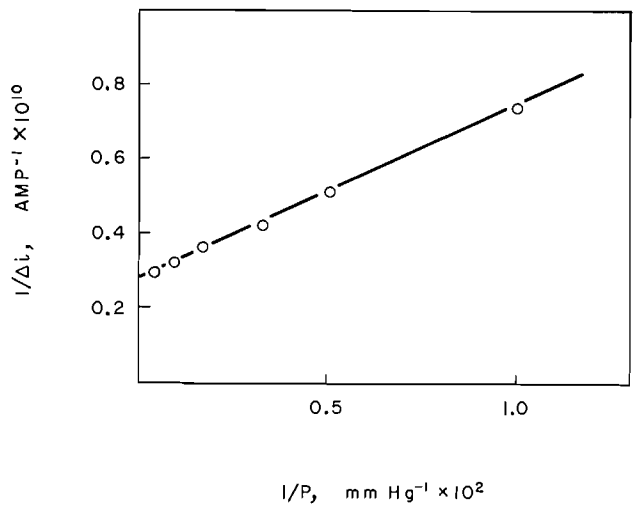

FIG. 6. Plot of reciprocal of photocurrent against reciprocal pressure.

reciprocals of the observed values of $\Delta i(p)$ are plotted against the reciprocals of the oxygen pressures and, as will be seen, $1/\Delta i(p)$ is indeed a linear function of $1/p$. Thus the evidence seems to indicate the validity of equation [4].

A relation similar to that of equation [7] has been reported for the effect of ambient gases on the photoconductivity of the anthracene crystal and has been attributed to the change in surface mobility of the charge carriers caused by adsorption (1). Recently Rosenberg (7) has also attributed the effect of oxygen on the photoconductivity of β-carotene to increased mobilities of charge carriers. While an increase in photocurrent caused by adsorption can be attributed either to an effective increase in the number of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

charge carriers, or to an increase in their mobilities, or to a combination of both these mechanisms, the proportionality between $i_2(p)$ and θ can be explained much more directly if we assume the photoinjection of additional charge carriers from the surface complex. Further, this latter mechanism leads quite naturally to an explanation of the influence of ambient oxygen on the rates of the photocurrent responses.

D. Mechanism of Slow Photocurrent Decay

A photoconductive response of the type shown in Fig. 4 is usually associated with traps. As is well known, the decay of the photocurrent response in many cases can be described by an exponential decay law. The slow decay of Fig. 4, however, does not obey an exponential law.

If we assume that the photocurrent consists of two more or less independent components, namely bulk photocurrent and surface photocurrent, the decay will occur through the fast recombination in the bulk of the crystal, presumably according to an exponential decay law and this will be followed by the slower surface decay.

The oxygen molecule usually behaves as an electron acceptor toward the surface of a number of semiconductors and usually increases the electrical conductivity of p-type semiconductors, presumably by injection of additional p-type charge carriers. If the increase in the photocurrent of the pentacene films on exposure to oxygen is also due to the injection of additional p-carriers, as a result of photoinduced electron transfer to surface oxygen atoms, negatively charged surface complexes must remain on the surface and they will behave as traps for p-type carriers in the surface recombination process. This behavior would be consistent with the known chemistry of pentacene. On this basis, the decay of the photocurrent, after cessation of illumination, will take place by fast recombination in the bulk of the crystal and also by the relatively slow trapping of the injected p-type carriers by the negatively charged surface complexes, the two mechanisms being more or less independent.[5]

According to the model given above, the carriers at the tail of the photocurrent decay must be p-type carriers in the surface region and the number of these carriers must be equal to the net number of negatively charged traps on the surface. Thus for this part of the decay we can write

$$-\frac{dn}{dt} = Kn(N_t - n_t), \tag{8}$$

where N_t is the total number of negatively charged surface traps formed initially and n_t the number of trapped carriers. Hence $n = N_t - n_t$ and equation [8] becomes a second-order reaction equation, namely

$$-\frac{dn}{dt} = Kn^2 \tag{9}$$

or

$$1/n - 1/n_0 = Kt. \tag{10}$$

Since $i(t)$ is proportional to n, equation [10] can be written as

$$1/i(t) - 1/i(0) = K't,$$

[5]*If the bulk decay is truly exponential and very rapid, it suggests that the recombination is essentially a "trapping" mechanism in which the number of "traps" is relatively large and independent of the number of carriers. If this is indeed the case, these bulk recombination "traps" must be ineffective in trapping the additional p-type carriers.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

that is, $1/i(t)$ becomes a linear function of time. That this is actually the case may be seen from Fig. 7.

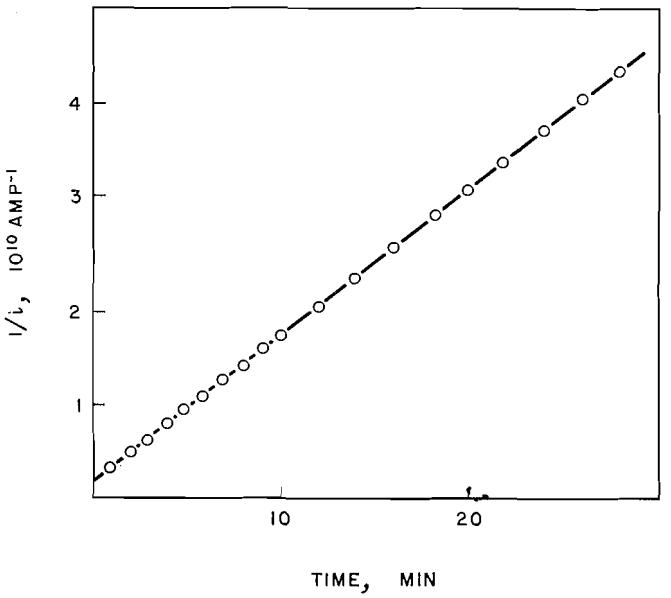

FIG. 7. Photocurrent decay in ambient oxygen (200 mm Hg).

While the above is a very unsophisticated description of the effect of oxygen on the photoconductivity of films of pentacene and some of its derivatives, both the dependence of the stationary photocurrent on the oxygen pressure as well as the decay of the photocurrent have been explained in terms of a very simple, plausible model, namely the formation of a surface "oxide" capable of providing additional *p*-type charge carriers on illumination. This model is reasonably consistent with the known tendency of some of these complex hydrocarbons to form biradical addition complexes and is reasonably consistent with the effect of oxygen on their absorption spectra. While, in the case of pentacene, the nature of the surface oxide is not known, the reversibility of the "oxygen effect" suggests that comparatively weak bonds are involved. Presumably the surface "oxide" is a "molecular" compound involving some resonance with a transient ionic form or biradical. On illumination, electrons are transferred and localized on the relatively immobile oxygen atoms, leaving unlocalized positive holes capable of acting as charge carriers.

ACKNOWLEDGMENTS

The authors would like to express their gratitude to Dr. W. G. Schneider for helpful suggestions and discussions, and to Dr. R. N. Jones for his kindness in supplying some of the pentacenes.

DEUTERIUM KINETIC ISOTOPE EFFECTS

V. TEMPERATURE DEPENDENCE OF β-DEUTERIUM EFFECTS IN WATER SOLVOLYSIS OF ISOPROPYL COMPOUNDS[1]

K. T. LEFFEK,[2] R. E. ROBERTSON, AND S. E. SUGAMORI

ABSTRACT

The secondary β-deuterium isotope effect (k_H/k_D) has been measured over a range of temperature for the water solvolysis reactions of isopropyl methanesulphonate, *p*-toluenesulphonate, and bromide. In these cases the isotope effect is due to a difference in entropies of activation of the isotopic analogues rather than a difference in the enthalpies of activation. It is suggested that the observed isotope effect is due to internal rotational effects of the methyl groups in the isopropyl radical, and the lack of an isotope effect on the enthalpy of activation is accounted for by a cancellation of an effect from this source and one from zero-point energy.

Secondary β-deuterium isotope effects in solvolytic reactions have been studied by several groups of workers (1–12). In all cases, replacement of hydrogen on β-carbon atoms of the alkyl radical by deuterium led to a reduction in the rate of solvolysis. The rate ratio (k_H/k_D) was found to vary from close to unity, for primary compounds (11, 12), to about 2.5, for tertiary compounds (1, 11). The source of this reduction in rate with deuterium substitution has usually been discussed in terms of the effect of changes in hyperconjugation associated with the activation process. The resulting weakening of C—H and C—D bonds implies a corresponding change in the difference in the zero-point energies. If this is the main source of the observed isotope effect, then an analysis of the temperature dependence of this effect should show a difference in the corresponding enthalpies of activation and any difference in the entropies and heat capacities of activation should be small. This explanation is in accord with the results reported by Shiner and Verbanic (2, 13) and by Lewis and Coppinger (5), who found in three solvolytic reactions that deuteration led to a change in both enthalpy and entropy of activation, the former being the major factor.

As a continuation of our general survey of β-deuterium isotope effects in the water solvolysis of alkyl halides and sulphonates (11), we have examined to what extent the above assumption is valid for the isopropyl system.

RESULTS AND DISCUSSION

Rate data over a range of temperature are given in Table I for the hydrolysis of isopropyl methanesulphonate, *p*-toluenesulphonate, and bromide, and their fully β-deuterated analogues. The rate data for the normal compounds were calculated from the three constant rate – temperature relationships previously determined in this laboratory (14). These relationships have been shown to reproduce the rate constants to better than the experimental error, and agreement between the rates so derived and experimentally determined for the protium compound was demonstrated for each of the above compounds, immediately prior to rate determinations on the deuterated

	0.3123	0.2371	40.005	1.31_7

compound. The rate ratios (k_H/k_D), given in the final column, are seen to be almost independent of temperature. The results were fitted to the transition-state relationship

$$[1] \qquad \log_{10}(k_H/k_D) = \frac{(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})}{2.303RT} - \frac{(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})}{2.303R}$$

by the method of least squares, and the resulting enthalpy and entropy differences are given in Table II. Thus the rate decrease resulting from β-deuteration in this system is

TABLE II

Changes in enthalpy and entropy of activation produced by β-deuteration in the solvolysis of isopropyl compounds in water

Compound	$(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})$ ±std. error (cal mole^{-1})	$(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ ±std. error (cal mole^{-1} deg^{-1})
Isopropyl methanesulphonate	7±28	−0.84±0.1
Isopropyl *p*-toluenesulphonate	−21±14	−0.93±0.05
Isopropyl bromide	−35±15	−0.65±0.05

due almost entirely to a difference between the entropies of activation of the isotopic analogues. This is in marked contrast to the earlier work and cannot be explained in terms of zero-point energy effects alone.

When equation [1] is used, it is assumed that the heat capacities of activation ($\Delta C_p^{\ddagger}$) for the protium and deuterium compounds are the same. Since it has been observed that $\Delta C_p^{\ddagger}$ is much more sensitive to changes in the anionic group than to changes in the alkyl radical (15), this assumption probably would not introduce a significant error in the general case. If such an error were detectable it would appear as a curvature in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

a plot of $\log_{10}(k_H/k_D)$ versus T^{-1}. For the present case of the isopropyl compounds, $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})$ is approximately zero and, therefore, $(\Delta C_{p,D}^{\ddagger} - \Delta C_{p,H}^{\ddagger})$ must also be very close to zero (less than -0.5 cal mole^{-1} deg^{-1}).

Any explanation of the results in Table II must be capable of producing the entropy of activation difference and at the same time account for the lack of an enthalpy of activation difference. The probable sources of secondary deuterium isotope effects will be examined in the light of these requirements.

Zero-Point Energy Effects

It has been generally claimed that the formation of a positive charge in the transition state of a solvolytic reaction proceeding via a carbonium ion brings about an increase in hyperconjugation in the activation process. The vibrational frequencies of the β-C—H (or β-C—D) bonds are, therefore, reduced in the transition state relative to the initial state. As a result, the difference between the zero-point energies of the β-C—D bonds and the β-C—H bonds is less in the transition state than in the initial state, leading to a higher enthalpy of activation for the deuterated compound. This argument is well established (1–12) and was applied in an earlier paper (11) to isopropyl compounds solvolyzing in water. Our present results show that if such an effect is present in the isopropyl case, it must be cancelled by another enthalpy effect of the opposite sign. The earlier work of Shiner *et al.* (2, 13) and Lewis *et al.* (5) on the temperature dependence of the secondary deuterium isotope effect seems to indicate that, in general, enthalpy of activation differences do occur. It is concluded, therefore, that the lack of an enthalpy difference in our system is probably due to a fortuitous cancellation of two (or more) effects.

Solvation Effects

Specific solvation effects as a source of secondary β-deuterium isotope effects in solvolytic reactions were considered by Shiner (1, 2), although Lewis and Coppinger (5) and later Streitwieser *et al.* (7) produced evidence against such an explanation.

Indirect evidence against solvation effects as a major contributor to the isotope effect is also available from the derived kinetic parameters for hydrolysis reactions. Briefly, a consideration of the changes in the entropy of activation ($\delta_R \Delta S^{\ddagger}$) accompanying the structural change ethyl to isopropyl for a series of halides and sulphonates leads to the conclusion that no appreciable solvent reorganization has taken place about the alkyl group at the transition state (14). Even stronger evidence is the lack of significant differences in the solvent isotope effect (15). The lack of correlation between $\delta_R \Delta S^{\ddagger}$ and $\delta_R \Delta C_p^{\ddagger}$ is also consistent with this conclusion.

Finally, there is the evidence from the work of Maccoll *et al.* (17) that an isotopic effect very similar to those reported here has been observed in the absence of solvent. In the gas-phase pyrolysis of normal and β-deuterated isopropyl bromide, a reaction which is postulated to have a quasi-carbonium-ion transition state, an isotope effect $(k_H/k_D) = 2.5$ was obtained. This rate ratio was also not greatly dependent on temperature. The result, by its marked similarity to those results given in Table I, supports the conclusion that solvation effects are not an important source of the isotope effect in this system, although the evidence is not strong enough to rule them out entirely.

Internal Effects

Isotope effects from this source arise as a result of differences between the partition functions of the normal and deuterated molecules in the initial and transition states

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

(equation [2]). The partition function Q may be factorized into $Q_{trans} \times Q_{rot} \times Q_{vib} \times Q_{int\ rot}$.

$$[2] \qquad (k_H/k_D)_{int} = \frac{Q_H^{\ddagger}}{Q_H} \cdot \frac{Q_D}{Q_D^{\ddagger}}.$$

The maximum rate ratios which could arise from the translational and rotational partition function differences would occur if the initial state were unsolvated and the transition state highly solvated (11). For this extreme case the rate ratios are given by the equations

$$[3] \qquad (k_H/k_D)_{trans} = \left(\frac{M_D}{M_H}\right)^{3/2},$$

$$[4] \qquad (k_H/k_D)_{rot} = \left(\frac{\Pi I_D}{\Pi I_H}\right)^{1/2}.$$

In practice neither of these contributions to the isotope effect can be expected to exceed a few per cent. The contribution from the vibrational partition function is also small at the ordinary temperatures used in this study (18, 19).

The theory regarding internal rotation in molecules has remained less than adequate despite the considerable amount of research into the subject (20). Nevertheless, it has been recognized that changes in barriers to internal rotation during chemical reactions must be important in determining the thermodynamic reaction parameters (20). The isotope effects observed during this study can be accounted for semiquantitatively on the basis of the following two postulates concerning the barriers to internal rotation of the methyl groups in isopropyl compounds for the water solvolysis reaction. It is postulated: (*a*) that there is a considerable decrease in the barrier to rotation of the CH_3 (or CD_3) groups on going from the initial to the transition state and (*b*) that the barrier to rotation of the methyl groups is higher in the protium compound than in the deuterium compound in the initial state.

The justification of the first postulate is the empirical rule that sixfold barriers to rotation are considerably smaller than threefold barriers (20, 21). Examples can be found in methyl derivatives of benzene where the barriers to rotation of the methyl groups are about 0.5 kcal per mole (21). If it is accepted that the transition state in the water solvolysis of isopropyl sulphonates and halides approximates a planar carbonium ion, then the barrier will become sixfold during the activation process and hence will be greatly reduced in the transition state. The entropy of activation for the water solvolysis reaction becomes increasingly more positive along the series ethyl halide, isopropyl halide, tertiary butyl halide (16), a variation which is also in qualitative agreement with postulate (*a*).

Postulate (*b*) is based on a limited number of microwave spectroscopic measurements. Swalen and Costain (22) found that the barrier to internal rotation for the CH_3 group in acetone is approximately 6% higher than that for the CD_3 groups in acetone-d_6. In nitromethane, the barrier to internal rotation of the methyl group is 16% greater in the normal compound that in the deuterated compound (23). On the other hand, recent work on the barrier in deuterated ethanes, using infrared data, gives no clear indication that CH_3 groups have a higher barrier than CD_3 groups (24). Theoretical support for postulate (*b*) is not easily found since barriers to internal rotation are not well understood. Bartell (25) has recently drawn attention to the size effects among isotopic molecules as a possible explanation for secondary deuterium isotope effects. Since

For personal use only.

hydrogen–carbon bonds are slightly longer and have slightly larger amplitudes of vibration than deuterium–carbon bonds, it might be expected that normal methyl groups will have higher barriers to rotation than deuteromethyl groups, in consideration of the calculations made by Kreevoy and Mason (26) on steric effects and barriers to rotation. Libby suggests (27) "that a further investigation of the dependence of barrier height on isotopic substitution might settle the question as to whether repulsion between hydrogen atoms is the cause of the barrier in ethane". While it is admitted that steric considerations alone certainly grossly oversimplify the problem of barriers to internal rotation, further experimental measurements may well prove postulate (*b*) correct.

On the basis of the two postulates, approximate calculations have been made for a molecule $(CH_3)_2CHX$, where X is a heavy group. For several assumed barrier heights, the contributions to the enthalpy and entropy of activation from the restricted rotation of methyl groups were determined using Pitzer's Tables (28). The use of these tables introduces the additional assumption that the two methyl groups in the isopropyl radical are non-interacting, an assumption which is probably incorrect. However, since the values of the moments of inertia and barrier heights used in the calculation are only approximate, the results contain inherent uncertainties large enough to justify the neglect of any methyl–methyl interaction.

Some results of these calculations are shown in Table III. The top half of this table

TABLE III

Contributions to the secondary β-deuterium isotope effects for the solvolysis of isopropyl compounds in water from internal rotation effects

Barrier to methyl rotation (cal mole^{-1})				
Initial state		Transition state	$(\Delta H_D^{\neq} - \Delta H_H^{\neq})_{int\ rot}$ per methyl group (cal mole^{-1})	$(\Delta S_D^{\neq} - \Delta S_H^{\neq})_{int\ rot}$ per methyl group (cal mole^{-1} deg^{-1})
H cpd.	D cpd.	Both cpds.		
3000	3000	0	−65	0.06
3000	3000	600	−29	0.05
3000	3000	1200	−15	0.04
3000	2400	0	−93	−0.26
3000	2400	600	−31	−0.26
3000	2400	1200	−44	−0.26

shows results obtained by the application of postulate (*a*) alone. The entropy of activation difference here is due to the difference in mass between hydrogen and deuterium and is seen to be small and in the direction opposite to that observed in Table II. The bottom half of Table III shows the results obtained by application of both postulates, assuming a 20% difference between the barriers to internal rotation of the normal methyl and deuteromethyl groups. When the figures in the right-hand column, for the entropy of activation difference per methyl group, are multiplied by 2, quite a large part of the observed entropy difference can be explained. At the same time an enthalpy of activation difference is obtained opposite in sign to that springing from a zero-point energy effect.

It is therefore suggested that the major part of the observed isotope effect for the water solvolysis of isopropyl compounds is due to internal rotational effects, and that the most probable cause of the lack of an isotope effect on the enthalpy of activation is a fortuitous cancellation between enthalpy effects arising from zero-point energy sources and internal rotational effects.

EXPERIMENTAL

Isopropyl-β-d_6 alcohol was obtained by the reduction of acetone-d_6 with lithium aluminum hydride using the procedure described by Shiner (29). The crude product was redistilled, boiling point range 83.5–84.5° C. Yields up to 99% were obtained using this procedure. The N.M.R. spectrum of this compound showed that the β-carbon atom was fully deuterated. Treatment of the alcohol with "constant boiling" hydrobromic acid yielded the bromide, boiling point range 60–61° C, in 55% yield after purification.

Isopropyl-β-d_6 methanesulphonate and p-toluenesulphonate were prepared by reaction of the bromide with the appropriate silver sulphonate as previously described for ethyl compounds (30). The sulphonates were purified by distillation under a vacuum.

The protium analogues of the above compounds were prepared by parallel reactions and were used to check the rate constants which had been previously determined in this laboratory (14).

The rate measurements were made conductometrically as described in detail in Part III of this series (31).

ACKNOWLEDGMENTS

Among those with whom we have discussed the above results, we would like to mention, in particular, Professor E. S. Lewis and Dr. J. M. W. Scott.

THE CONSTITUTION OF THE HEMICELLULOSE OF APPLE WOOD (MALUS PUMILA L. VAR. GOLDEN TRANSPARENT)[1]

G. G. S. DUTTON AND T. G. MURATA

ABSTRACT

The hemicellulose isolated by direct alkaline extraction of the wood has been shown to be a 4-*O*-methylglucuronoxylan. Methylation data indicate a backbone of approximately 120 D-xylopyranose units linked by β, 1—4 bonds with single units of 4-*O*-methyl-D-glucuronic acid linked by α, 1—2 bonds. The proportion of acid units to xylose is approximately 1:6. Two artifacts were isolated from the hydrolysis products of the methylated polysaccharide: 4-*O*-(2,3-di-*O*-methyl-α-D-xylopyranosyl)-2,3-di-*O*-methyl-D-xylose and 2,3-di-*O*-methyl-D-lyxose.

Hemicelluloses from many deciduous and coniferous trees have been isolated and studied, and these results have been reviewed (1). The majority of the trees so far investigated have been those of commercial importance for pulping, such as birch, beech, hemlock, and spruce, etc. Certain generalizations on the structure of hemicelluloses have emerged as a result of these studies, the most notable being that the hemicelluloses from coniferous trees have a high mannose content whereas those from deciduous trees are very low in this sugar (1). It was of interest to include other species in these structural investigations and accordingly the hemicelluloses from two members of the Rosaceae family have been studied. The present paper reports the results on *Malus pumila* Mill. (var. Golden Transparent), and the results on *Prunus avium* L. (var. Bing) will be reported later (2).

Finely ground apple wood was extracted with hot alcohol:benzene (1:2) and the air-dried residue was shaken with 0.1 *N* sodium hydroxide. The highly colored extract was discarded and the residue re-extracted with 1 *N* sodium hydroxide according to the method of McDonald (3). The hemicellulose was isolated by pouring the alkaline extract into acidified ethanol and, after being dried by solvent exchange, amounted to 8–12% of the dry wood.

The hydrolysis products of the hemicellulose were resolved on ion exchange resins into a neutral and an acidic fraction. Chromatographic analysis of the former showed it to contain predominantly D-xylose which was characterized as the crystalline sugar. There were also trace amounts of arabinose, galactose, and rhamnose, together with two components having a greater mobility than rhamnose. The identities of these two sugars have not yet been determined. The acidic fraction contained appreciable amounts of an aldobiouronic acid, characterized by conversion to the crystalline methyl 2-*O*-(2,3-di-*O*-acetyl-4-*O*-methyl-α-D-glucopyranosyl)uronate 3,4-di-*O*-acetyl-D-xylopyranoside (4), together with smaller amounts of materials assumed to be free uronic acid and an aldotriouronic acid.

The hemicellulose was methylated, fractionated, and cleaved by methanolysis. After the methyl esters of the acidic components had been saponified with barium hydroxide the mixture of glycosides was resolved into neutral and acidic portions. The acidic fraction was re-esterified with diazomethane and reduced with lithium aluminum hydride with the expectation that the crystalline methyl 2-*O*-(2,3,4-tri-*O*-methyl-D-glucopyranosyl)-3-*O*-methyl-D-xyloside would be obtained. The sirup did not crystallize, even on

[1]*Manuscript received July 10, 1961.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver, B.C. Presented at the 43rd C.I.C. Conference, Ottawa, June 1960.

seeding, although on hydrolysis, 3-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-glucose were obtained and characterized as their crystalline anilides. Later work (5) has suggested that not all the uronic acid units are terminal and hence the aldobiouronic acid fraction, and thus the derived disaccharide fraction, would not be a single component. This was not apparent in the methylation study reported here.

The neutral sugar glycosides were hydrolyzed and resolved on a cellulose–hydrocellulose column (6). The principal component was 2,3-di-*O*-methyl-D-xylose, with small amounts of 2,3,4-tri-*O*-methyl-D-xylose and 2-*O*- and 3-*O*-methyl-D-xylose. There was also a very small amount of a material judged to be a tri-*O*-methylrhamnose from its chromatographic behavior. Other components isolated were 4-*O*-(2,3-di-*O*-methyl-α-D-xylopyranosyl)-2,3-di-*O*-methyl-D-xylose, i.e. a methylated xylobiose, and 2,3-di-*O*-methyl-D-lyxose. The former compound has an R_F value of about 0.70 (butanone–water), $[\alpha]_D$ 112° (*c*, 3 in methanol) and a melting point of 83.0–83.5° C. It appears to be identical with the sirupy compound isolated by Geerdes and Smith from methylated flax hemicellulose (7). Since the disaccharide D-xylose-$\beta(1 \rightarrow 4)$-D-xylose is well known and has a negative rotation (8) it may be assumed that its methylated derivative would also be negative. For this reason and also because it has been shown that the acid reversion of D-xylose produces α-linked disaccharides (9) it is assumed that the methylated disaccharide isolated in the present case has the alpha configuration and that it arises by acid reversion from 2,3-di-*O*-methyl-D-xylose. There is, however, the possibility that the native xylan contains a few alpha linkages and that these disaccharides accumulate in the hydrolysis products by analogy with the known greater stability of methyl α-D-glycopyranosides (10). On the other hand, maltose is known to be hydrolyzed faster than cellobiose (10). Until such time as mild hydrolysis of a xylan demonstrates the existence, in nature, of xylose units joined by alpha linkages the reversion theory seems more acceptable. The acid reversion of 2,3-di-*O*-methyl-D-xylose is now being studied.

The second artifact, 2,3-di-*O*-methyl-D-lyxose, caused some trouble. In the column separation of the methylated sugars there was isolated a small amount of a component having an R_F value of 0.40 (butanone–water) and $[\alpha]_D$ −26° in methanol. A compound which was chromatographically identical was also isolated in larger amounts from methylated cherry wood hemicellulose (2). A negative rotation is not recorded for any methyl ethers of D-xylose and two attempts to carry out a hydrobromic acid demethylation (11) led to complete disintegration of the compound. Fortunately the elegant boron trichloride method of demethylation (12) yielded a clean product which was readily identified by chromatography as D-lyxose. The compound 2,3-di-*O*-methyl-D-lyxose has been reported crystalline (13) and has been so obtained by us in another instance (2) but the material isolated here did not crystallize and was too small in amount to convert into a crystalline derivative. The presence of the 2,3-di-*O*-methyl-D-lyxose must be due to a facile epimerization of the D-xylose derivative caused by the alkali present in the barium carbonate used for neutralizing sulphuric acid hydrolyzates. Further work has shown that 2,3-di-*O*-methyl-D-xylose is very readily epimerized by base and these results will be reported later. A recheck of the hydrolyzate of the original polysaccharide failed to show the presence of any lyxose. Epimerization of methylated sugars from polysaccharides has not previously been recorded, although it is well known in the case of monosaccharides and has also been described in the case of aldobiouronic acids (14, 15).

A sample of the neutral methylated sugars was chromatographed, and their ratio estimated by the phenol – sulphuric acid method (16). These values together with that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

obtained gravimetrically for the aldobiouronic acid gave a mole ratio of 1:97:21:19 for tri-, di-, mono-*O*-methyl pentoses, and uronic acid respectively. The slight excess of mono-*O*-methyl pentose over that required by the uronic acid might indicate a small degree of branching, but in view of the observations of Croon and Timell this seems unlikely (17). These results therefore indicate that apple wood hemicellulose has a chain length of approximately 120 D-xylose units and a xylose:uronic acid ratio of 6:1. It would thus appear that this hemicellulose is similar in structure to other wood hemicelluloses except that the proportion of uronic acid is higher than has been found for the majority of deciduous trees so far examined. This ratio is usually about 10 or 11 to 1 (1) although white elm has been found to have a ratio of 7:1 (18). In general it is characteristic of coniferous woods to have a high uronic acid content, i.e. 5 or 6 to 1.

EXPERIMENTAL

The following solvent systems (v/v) were used: (A) ethyl acetate:acetic acid:formic acid:water, 18:3:1:4; (B) 1-butanol:ethanol:water:ammonia, 40:11:19:1; (C) butanone–water azeotrope; (D) 1-butanol:acetone:water, 5:4:1. With solvent system D, phosphate-impregnated papers, which were prepared by dipping papers into a disodium hydrogen phosphate and potassium dihydrogen phosphate buffer (pH 5), were used (19). Electrophoresis was carried out using 0.05 *M* sodium borate (20). Evaporations were carried out *in vacuo* at 40° C and rotations were recorded at 22±2° C.

Isolation of Apple Wood Hemicellulose

Sawdust (200 g) was extracted with hot alcohol–benzene (1:2) for 4 hours and air dried. The sawdust was suspended in sodium hydroxide (0.1 *N*, 1.8 l.) for 24 hours at room temperature, after which the mixture was filtered and the filtrate discarded. The residue was washed with water and then extracted with sodium hydroxide (1 *N*, 1.8 l.) with shaking, for 48 hours, at room temperature. The suspension was filtered and the residue washed with water to give a total volume of 2 l. The hemicellulose was isolated by pouring the extract into cold ethanol containing acetic acid. The material thus obtained was dried by solvent exchange and a typical preparation had $[\alpha]_D$ −62° (*c*, 1.2 in 8% NaOH) and an ash content of 4.7%. The yield was 10–12 g of hemicellulose per 100 g of sawdust.

Hydrolysis of the Hemicellulose

Hemicellulose (214 mg) in sulphuric acid (1 *N*) was heated on a steam bath for 9 hours during which time the rotation changed from $[\alpha]_D$ −62° to +41°. Sulphuric acid was neutralized with barium carbonate and the solution was passed through Amberlite IR 120 and Duolite A4 resins. Evaporation of the neutral eluate yielded a sirup (144 mg), which was examined in solvents A, B, C, and D. In each system a large spot corresponding to xylose was observed, in solvent D traces of arabinose, rhamnose, and galactose were observed, and in solvent C two additional components with R_F 0.17 and 0.30 were detected.

The acidic components were eluted from the anion resin with sodium hydroxide (2 *N*, 5 ml), and the free acids were liberated by passage through fresh cation resin. Evaporation yielded a sirup (24.5 mg) which, in solvent A, showed three components having R_{xylose} 1.2, 1.0, and 0.69. These correspond to uronic acid, aldobiouronic acid, and aldotriouronic acid (21).

In a similar way, approximately 30 g of hemicellulose was hydrolyzed to yield 22.14 g of neutral sugars and 5.84 g of acids. The sirup containing the neutral sugars crystallized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

spontaneously, and the D-xylose after recrystallization from methanol–water had m.p. and mixed m.p. 143–145° C and $[\alpha]_D$ 17.7° (*c*, 1.69 in water, equil.). The mother liquor contained a component chromatographically and electrophoretically indistinguishable from rhamnose and also two compounds with R_F values 0.17 and 0.30 in solvent C.

A portion of the acid sirup was streaked on Whatman 3MM paper and irrigated with solvent A for 16 hours. The section containing the component with R_x 1.0 was eluted with methanol and this component was characterized as methyl 2-*O*-methyl(2,3-di-*O*-acetyl-4-*O*-methyl-α-D-glucopyranosyl)uronate 3,4-di-*O*-acetyl-D-xylopyranoside according to the method of Timell (4); m.p. 191–193° C, undepressed by an authentic sample.

Methylation and Methanolysis of the Hemicellulose

The hemicellulose was methylated with methyl sulphate and sodium hydroxide five times and then three times with methyl iodide and silver oxide. After these treatments there was no hydroxyl band in the I.R. spectrum and the methoxyl content was 38.7%. Fractional precipitation of a chloroform solution with petroleum ether (30–60°) gave a fraction having $[\alpha]_D$ −57.8° (chloroform) and methoxyl 39.1%. A portion of this material (2.02 g) was refluxed for 7 hours in 3% methanolic hydrogen chloride, and after neutralization (Ag_2CO_3) and evaporation there was obtained a dark sirup of the methyl glycosides (2.13 g). This sirup was dissolved in saturated barium hydroxide (25 ml) and heated at 60° for 2 hours. The aqueous solution was continuously extracted with petroleum ether (30–60°) for 20 hours and was then resolved into neutral and acidic fractions by Amberlite IR 120 and Duolite A4 resins in the usual way. The petroleum ether extract was added to the sirup from the neutral eluate and re-evaporation gave the methyl glycosides (1.52 g). The acidic component amounted to 475 mg.

Identification of the Acidic Component

The acidic component was dissolved in methanol and treated with diazomethane. The resulting ester was dissolved in dry tetrahydrofuran (75 ml), and a solution of lithium aluminum hydride (500 mg) in the same solvent (20 ml) was slowly added, with stirring, at room temperature. Reduction was completed by refluxing for 1 hour, and the product was isolated by acetylation as previously described (22). The colorless sirup (344 mg) failed to crystallize even on seeding. Accordingly a portion of the disaccharide (186 mg) was dissolved in methanol (10 ml) containing acetyl chloride (0.5 ml) and refluxed for 5 hours. The mixture was neutralized (Ag_2CO_3), filtered, and evaporated to give a mixture of glycosides (202 mg) which were then hydrolyzed by sulphuric acid (1 *N*, 5 ml) on the steam bath for 7 hours. The solution was deionized with Duolite A4 and after concentration, chromatographic and electrophoretic examination revealed components identical with 2,3,4,-tri-*O*-methyl-D-glucose, 3-*O*-methyl-D-xylose, and a trace of what was assumed to be incompletely hydrolyzed material.

The mixture of sugars (126 mg) was separated on a cellulose–hydrocellulose column (6) using butanone–water azeotrope (36 ml per hour) and fractions were collected at 20-minute intervals. Concentration of the contents of tubes 11–17 gave a sirup (37 mg), $[\alpha]_D$ 73° (*c*, 0.7 in ethyl acetate), chromatographically identical with 2,3,4-tri-*O*-methyl-D-glucose. This was confirmed by the preparation of 2,3,4-tri-*O*-methyl-*N*-phenyl-D-glucosylamine, which had m.p. 141–143° C on recrystallization from ethyl acetate – petroleum ether (lit. value 145–146° C (23)).

Concentration of the contents of tubes 60–80 gave a sirup (24 mg) electrophoretically identical with 3-*O*-methyl-D-xylose. The derived 3-*O*-methyl-*N*-phenyl-D-xylosylamine had m.p. 133–134° C (lit. value m.p. 137° C (24)).

Identification of the Neutral Sugars

The methyl glycosides (1.36 g) were hydrolyzed with sulphuric acid (1 *N*, 60 ml) by heating the mixture on the steam bath for 8 hours. Neutralization ($BaCO_3$) and evaporation yielded a sirup (1.16 g), part of which (1.04 g) was separated on a cellulose–hydrocellulose column as before. One hundred fractions were collected at 10-minute intervals and a further 100 fractions at 30-minute intervals. The results are shown in Table I.

TABLE I

Separation of methylated sugars of apple wood hemicellulose

Component	Tube number	Weight, mg	Identity
1	6–9	17.0	Tri-*O*-methylrhamnose
	10		1+2
2	11–13	21.9	2,3,4-Tri-*O*-methyl-D-xylose
	14–15	14.7	2+3
3	16–22	56.0	Methylated xylobiose

7	160–185	8.6	D-Xylose
		849	

NOTE: Recovery 82%.

Component 1.—This had R_F 0.86 and gave a characteristic pale yellow color with the *p*-anisidine spray. It was thus tentatively identified as a tri-*O*-methylrhamnose.

Component 2.—This was chromatographically identical with 2,3,4-tri-*O*-methyl-D-xylose. The rotation of the sirup, $[\alpha]_D$ ca. 6° (*c*, 0.4 in methanol), indicated that it was not pure and attempts to crystallize the sirup and prepare the crystalline *N*-phenylglycosylamine both failed.

Component 3.—This fraction had R_F 0.71 and $[\alpha]_D$ 112° (*c*, 3 in methanol). On evaporation of the solvent it readily crystallized to long, feathery needles. All attempts to recrystallize the solid failed but it was readily recovered in crystalline form by allowing the solvent to evaporate; m.p. 83.0–83.5° C. Hydrolysis with hot sulphuric acid (1 *N*) gave a compound chromatographically identical with 2,3-di-*O*-methyl-D-xylose.

Component 4.—This material had R_F 0.50 and was the major component. It was identified as 2,3-di-*O*-methyl-*N*-phenyl-D-xylosylamine, m.p. 122–123° C, on recrystallization from ethyl acetate – petroleum ether (lit. m.p. 121–123° C (25)).

Component 5.—This fraction had R_F 0.40 and was present in only small amount. It had $[\alpha]_D$ ca. −26° in methanol and was chromatographically identical with the material characterized as 2,3-di-*O*-methyl-D-lyxose isolated from cherry wood hemicellulose (2). This was confirmed as follows. A portion of the unknown sugar (10 mg) was dissolved in dry dichloromethane (3 ml) and the solution cooled to −78°. Boron trichloride (1–2 g) was distilled into this solution and the temperature maintained at −78° for 30 minutes. The solution was allowed to come to room temperature and to evaporate overnight. Electrophoresis and chromatography (solvent D) of the residue dissolved in aqueous methanol indicated the presence of lyxose.

Component 6.—This was readily shown by electrophoresis to be a mixture of 2-*O*- and 3-*O*-methyl-D-xylose.

Component 7.—This was chromatographically identical with xylose.

Quantitative Analysis of Neutral Sugars

A portion of the neutral sugars was separated on Whatman No. 1 paper using butanone–water azeotrope. The zones corresponding to tri-, di-, and mono-*O*-methylpentoses were separately eluted with water and the concentration of the sugars determined by the phenol – sulphuric acid method (16). The ratios thus determined were 1:97:2. Standard curves were prepared from 2,3,4-tri-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, and 2-*O*-methyl-D-xylose.

ACKNOWLEDGMENTS

We are grateful to Dr. T. E. Timell for the gift of authentic samples, and to the National Research Council for generous financial support.

We are also indebted to Dr. C. T. Bishop for kindly presenting this material at the 43rd Conference of the Chemical Institute of Canada.

THE CHEMISTRY OF ALUMINUM–NITROGEN COMPOUNDS

I. REACTIONS OF TRIMETHYLALUMINUM AND TRIMETHYLALUMINUM TRIMETHYLAMINE WITH SEVERAL METHYLHYDRAZINES[1]

NEIL R. FETTER AND BODO BARTOCHA

ABSTRACT

The reactions of trimethylaluminum and trimethylaluminum trimethylamine with various methylhydrazines have produced a number of complexes and polymers: with methylhydrazine, both Me_3Al and $Me_3Al{:}NMe_3$ produce the polymer $[—MeAlNHNMe—]_n$; with 1,2-dimethylhydrazine, both produce the polymer $[—Al(MeNNMe)_{1.5}—]_n$; with 1,1-dimethylhydrazine, Me_3Al produces $[Me_2Al—NHNMe_2]_2$ and $Me_3Al{:}NMe_3$ produces the unusual complex $Me_2Al(NHNMe_2)(NH_2NMe_2)$; with trimethylhydrazine, Me_3Al produces $[Me_2Al—NMeNMe_2]_2$ and $Me_3Al{:}NMe_3$ produces an isomer with the same formula but an as-yet-uncharacterized structure. In addition, the intermediate $Me_3Al{:}NHMeNMe_2$ has been isolated from the reaction of either Me_3Al or $Me_3Al{:}NMe_3$ with trimethylhydrazine. With tetramethylhydrazine, Me_3Al produces $Me_3Al{:}NMe_2NMe_2$. The formation of the complexes with covalent aluminum–nitrogen bonds is specific and methane is the only gas eliminated during these reactions.

INTRODUCTION

Until recently, only a few molecular addition compounds of aluminum with ligands of group V had been reported (1). In some of the earliest work, Brown and Davidson (2) described methylaluminum–methylamine complexes. Later, Wiberg and May (3) reported some reactions of aluminum hydride with amines and ammonia, an area of interest recently extended by studies of Ruff and Hawthorne (4, 5). Bonitz (6) isolated a triethylaluminum isoquinoline complex, and Ziegler, Gellert, and Neumann (7) base some analytical procedures on the reaction of alkylaluminum hydrides with amines. The compound $Et_2Al—NMe_2$ was reported in the patent literature (8), and a note on a new aluminum hydride adduct appeared in print (9).

Most of the compounds described in these previous publications contain a covalent aluminum–nitrogen bond which is formed by one of two general reactions:

(1) elimination of a hydrocarbon when an aluminum trialkyl reacts with a secondary or primary amine:

$$R_3Al + NHR_2' \rightarrow [R_3Al{:}NHR_2'] \rightarrow R_2Al—NR_2' + RH;$$

(2) elimination of hydrogen when an alkylaluminum hydride or aluminum hydride reacts with ammonia or a primary or secondary amine:

$$R_2AlH + NH_3 \rightarrow [R_2AlH{:}NH_3] \overset{\Delta}{\rightarrow} R_2Al—NH_2 + H_2,$$

$$R_2AlH + NHR_2' \rightarrow [R_2AlH{:}NHR_2'] \overset{\Delta}{\rightarrow} R_2Al—NR_2' + H_2.$$

In both cases a stable covalent bond is formed via an intermediate with a dative bond, and in several instances the materials seem to react further to form polymeric substances (10).

We were interested in the interactions of hydrazines with aluminum alkyls or aluminum hydride, and, in particular, of those hydrazines which carry both functional groups, namely, the N—H and N—C bonds. In this paper we report the reactions of trimethylaluminum and trimethylaluminum trimethylamine with methylhydrazines. Several new compounds with covalent or dative Al—N bonds were synthesized, and their physical constants determined.

EXPERIMENTAL

Apparatus

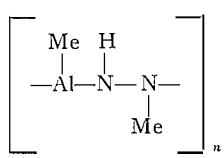
Most of the reactions were carried out in a conventional high-vacuum system. The hydrazine was transferred *in vacuo* to a cold trap (−196° C) containing the Me_3Al or $Me_3Al{:}NMe_3$ and any necessary solvent, such as pentane. After the mixtures had reached room temperature or had been heated so that the reaction would be completed, the solvent was pumped off and, if possible, the product was purified by sublimation.

In a few cases, use of the vacuum technique resulted in explosions, and the reactions were therefore carried out at atmospheric pressure under a nitrogen atmosphere. The hydrazine was added slowly to a cooled (−10° C) pentane solution of Me_3Al or $Me_3Al{:}NMe_3$. After the addition had been completed and the reaction mixture had reached room temperature, the solvent was removed in vacuum.

Molecular Weights

Molecular-weight determinations were conducted in a conventional freezing-point apparatus with cyclohexane as the solvent. The inner vessel was designed so that samples and solvent could be weighed in a dry box.

Reagents



Methylhydrazine (Commercial Solvents Corporation), 1,1-dimethylhydrazine (Olin Mathieson Corporation), 1,2-dimethylhydrazine (Metalectro Corporation), and tetramethylhydrazine (Metalectro Corporation) were distilled over calcium hydride before use. The trimethylhydrazine was prepared by the method of Class, Aston, and Oakwood (11). Trimethylaluminum was purchased from the Ethyl Corporation of Baton Rouge, Louisiana, and vacuum-distilled before use. The preparation of trimethylaluminum trimethylamine was based on a procedure described by Brown and Davidson (2). All solvents were reagent grade, and all were distilled over calcium hydride before use.

Analysis

The evolved gases were measured by fractionating the mixtures through a series of traps into a calibrated volume and removing the uncondensable material with a Toepler pump. Aluminum was determined as Al_2O_3 after the sample had been decomposed with methanol and ashed. Elemental analyses were performed by the Schwarzkopf Microanalytical Laboratory, Woodside 77, New York.

Reaction of Trimethylaluminum Trimethylamine with Methylhydrazine

The atmospheric method was used for the reaction of $Me_3Al{:}NMe_3$ with H_2NNHMe. After 1.53 g (11.7 mmoles) of $Me_3Al{:}NMe_3$ and 0.602 g (13.1 mmoles) of H_2NNHMe had reacted and the solvent had been removed, a powdery white solid remained. This material could not be sublimed and was insoluble in hydrocarbons. It did not have a sharp melting point but decomposed slowly when heated to 200° C. Elemental analysis gave results which agree with the empirical formula $C_2H_7N_2Al$. Calc.: Al, 31.34%; C, 27.90%; H, 8.20%; N, 32.55%. Found: Al, 30.40%; C, 28.18%; H, 8.05%; N, 30.37%. From this formula, the following structure may be written:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The equation for the reaction is

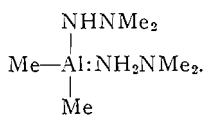
$$n\mathrm{Me_3Al{:}NMe_3} + n\mathrm{H_2NNHMe} \rightarrow [\text{—MeAlNHNMe—}]_n + 2n\mathrm{CH_4} + n\mathrm{NMe_3}.$$

Hydrolysis of 0.243 g (2.83 mmoles) of the product yielded 0.0338 g (2.11 mmoles) of methane. The molar ratio of CH_4 to $[\text{—MeAlNHNMe—}]_n$ is 0.775.

Reaction of Trimethylaluminum with Methylhydrazine

By the procedure described above, the reaction of Me_3Al with methylhydrazine produces a material whose physical properties are the same as those of the $Me_3Al{:}NMe_3$–methylhydrazine polymer. An aluminum assay gave 30.55% Al (calc.: 31.34%), and the infrared spectra of the two materials were identical. The reaction may thus be written:

$$n\mathrm{Me_3Al} + n\mathrm{H_2NNHMe} \rightarrow [\text{—MeAlNHNMe—}]_n + 2n\mathrm{CH_4}.$$



Reaction of Trimethylaluminum with 1,1-Dimethylhydrazine

By the vacuum method, the direct reaction of 0.680 g (9.45 mmoles) of Me_3Al with 0.632 g (10.5 mmoles) of H_2NNMe_2 gave a crystalline solid (m.p. 77–78.5° C)* and 0.143 g (8.45 mmoles) of methane. The molar ratio of CH_4 to Me_3Al is 0.945. Sublimed once, at 60° and 0.005 mm Hg, the reaction product was analyzed, and the results were found to agree with the empirical formula $C_4H_{13}N_2Al$. Calc.: Al, 23.23%; C, 41.36%; H, 11.28%; N, 24.13%. Found: Al, 23.82%; C, 41.12%; H, 11.04%; N, 24.21%. Two molecular-weight values of 238 and 240 indicate that this compound is dimeric (calc.: 230.2). The equation for the reaction is

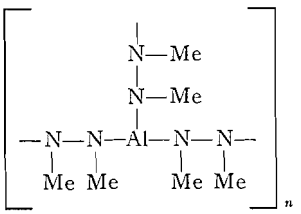
$$2\mathrm{Me_3Al} + 2\mathrm{H_2NNMe_2} \rightarrow [\mathrm{Me_2Al—NHNMe_2}]_2 + 2\mathrm{CH_4}.$$

Reaction of Trimethylaluminum Trimethylamine with 1,1-Dimethylhydrazine

Again by the vacuum method, direct reaction of 1.63 g (10.4 mmoles) of $Me_3Al{:}NMe_3$ with 1.62 g (27.1 mmoles) of H_2NNMe_2 yielded a white crystalline solid (m.p. 81–82.0° C), 0.141 g (8.86 mmoles) of methane, and 0.451 g (7.65 mmoles) of trimethylamine. The molar ratio of CH_4 to $Me_3Al{:}NMe_3$ is 0.852, and the molar ratio of NMe_3 to $Me_3Al{:}NMe_3$ is 0.746. Elemental analysis of the product, which had been purified by sublimation at 30° C and 0.005 mm Hg, gave results which correspond to the percentages calculated for the empirical formula $C_6H_{21}N_4Al$. Calc.: Al, 15.30%; C, 40.89%; H, 12.01%; N, 31.78%. Found: Al, 15.95%; C, 40.60%; H, 11.77%; N, 31.58%. These data and a molecular-weight determination of 179 (calc.: 176.1) suggest the structural formula

Hydrolysis of 0.275 g (2.08 mmoles) of the complex produced 0.0685 g (4.28 mmoles) of methane; thus, the expected 2:1 molar ratio of methane to complex was obtained. The reactions of Me_3Al and $Me_3Al{:}NMe_3$ with 1,1-dimethylhydrazine are not influenced by the ratios of starting materials. An experiment with a molar ratio of 1:1 for H_2NNMe_2 and $Me_3Al{:}NMe_3$ yielded only $Me_2Al(NHNMe_2)(H_2NNMe_2)$ and an experiment with a starting molar ratio of 1.5:1 for H_2NNMe_2 and Me_3Al produced only $[Me_2Al—NHNMe_2]_2$.

Reaction of Trimethylaluminum Trimethylamine with 1,2-Dimethylhydrazine



By the vacuum method, 0.812 g (6.20 mmoles) of $Me_3Al{:}NMe_3$ was treated with 0.530 g (8.83 mmoles) of NHMeNHMe at room temperature for 18 hours. At the end of this

**All melting points reported are uncorrected.*

period a white precipitate had formed, and 0.293 g (18.3 mmoles) of methane and 0.427 g (5.77 mmoles) of NMe_3 had been recovered. The molar ratio of recovered CH_4 to starting $Me_3Al{:}NMe_3$ is 2.96, and the molar ratio of NMe_3 to $Me_3Al{:}NMe_3$ is 0.932. The product was insoluble in hydrocarbons, did not have a sharp melting point, and could not be sublimed; however, on elemental analysis, the crude product gave results which agree with the formula $C_3H_9N_3Al$. Calc.: Al, 23.65%; C, 31.58%; H, 7.94%. Found: Al, 24.09%; C, 30.34%; H, 7.94%. From these data, the following reaction may be formulated:

$$n\text{Me}_3\text{Al:NMe}_3 + 1.5n\text{NHMeNHMe} \rightarrow [\text{—Al(MeNNMe)}_{1.5}\text{—}]_n + 3n\text{CH}_4 + n\text{NMe}_3.$$

The reaction product probably is a completely cross-linked polymer, with each aluminum atom incorporating one half of three [—MeNNMe—] units; hence the structural formula may be written as follows:

Hydrolysis of this material produces no methane, as expected, and the infrared spectrum shows no N—H bond in the 3.05-μ region.

Trimethylaluminum reacts with 1,2-dimethylhydrazine to produce the same polymer.

Reaction of Trimethylaluminum with Trimethylhydrazine

In all the reactions discussed above, the elimination of methane accompanied the complex formation. However, in the reaction of Me_3Al with $HNMeNMe_2$, the adduct intermediate was isolated and then converted into the covalent structure with elimination of methane. The intermediate was fairly stable; in fact, heating the reaction mixture for 20 hours at 60° C was required to effect the conversion.

By the vacuum procedure, 3.53 g (49.1 mmoles) of Me_3Al was treated with 9.61 g (130 mmoles) of $HNMeNMe_2$ at room temperature. From the liquid residue remaining after removal of the excess trimethylamine, a volatile, white crystalline solid (m.p. 80.0–83.0° C) was isolated by evaporation at 25° C onto a cold finger maintained at −15° C. The elemental analysis corresponds to the values for the formula $C_6H_{19}N_2Al$. Calc.: Al, 18.45%; C, 49.29%; H, 13.10%; N, 19.16%. Found: Al, 18.58%; C, 50.14%; H, 12.60%; N, 18.92%. A molecular-weight measurement gave the value 142.0 (calc.: 146.2). The initial reaction may thus be written:

$$\text{Me}_3\text{Al} + \text{HNMeNMe}_2 \rightarrow \text{Me}_3\text{Al:NHMeNMe}_2.$$

I

Compound I was then heated for 20 hours at 60° C and resublimed. A white crystalline solid (m.p. 125.0–126.5° C) was obtained and analyzed. Calc. for $C_5H_{15}N_2Al$: Al, 20.73%; C, 46.13%; H, 11.61%; N, 21.52%. Found: Al, 20.34%; C, 44.82%; H, 11.77%; N, 22.82%. A molecular-weight determination gave the value 258.0 (calc.: 260.4). The elimination reaction may then be written as follows:

$$2\text{Me}_3\text{Al:NHMeNMe}_2 \xrightarrow{60^\circ\text{ C}} [\text{Me}_2\text{Al—NMeNMe}_2]_2 + 2\text{CH}_4.$$

II

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Compound II was also synthesized directly from Me_3Al and trimethylhydrazine by heating together 1.24 g (17.3 mmoles) of Me_3Al and 1.26 g (17.1 mmoles) of $HNMeNMe_2$ to 55° C for 20 hours. A crystalline solid (m.p. 125.0–126.5° C) and 0.270 g (16.8 mmoles) of methane were produced. Calc.: Al, 20.73%; C, 46.13%; H, 11.61%; N, 21.52%. Found: Al, 20.42%; C, 45.59%; H, 11.52%; N, 23.49%.

Reaction of Trimethylaluminum Trimethylamine with Trimethylhydrazine

In its initial step, this reaction is similar to that between Me_3Al and $HNMeNMe_2$ except that NMe_3 is displaced during the formation of the intermediate:

$$Me_3Al{:}NMe_3 + HNMeNMe_2 \rightarrow Me_3Al{:}NHMeNMe_2 + NMe_3.$$

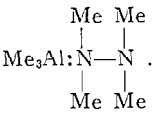
In vacuo, 1.34 g (10.2 mmoles) of $Me_3Al{:}NMe_3$ was heated at 60° C with 0.813 g (11.0 mmoles) $HNMeNMe_2$ until NMe_3 evolution ceased (20 hours). Elemental analysis of this sublimed complex (m.p. 80.0–83.0° C) agreed with the formula for I. Calc.: Al, 18.45%; C, 49.29%; H, 13.10%; N, 19.16%. Found: Al, 18.27%; C, 50.99%; H, 13.33%; N, 18.57%.

However, in another experiment 1.96 g (14.9 mmoles) of $Me_3Al{:}NMe_3$ and 2.31 g (31.1 mmoles) of $HNMeNMe_2$ were heated at 75° C for 2 days. When gas evolution ceased, a clear liquid remained, and 0.192 g (12.0 mmoles) of CH_4 and 0.576 g (9.77 mmoles) of NMe_3 had been recovered. The liquid was vacuum-distilled at 25° C into a −30° C trap, and elemental analysis of the distillate (m.p. 13.5–15.0° C) gave results that correspond to the values for II. Calc.: Al, 20.73%; C, 46.13%; H, 11.61%; N, 21.52%. Found: Al, 21.94%; C, 44.09%; H, 11.63%; N, 23.11%. The reaction may be written as follows:

$$Me_3Al{:}NMe_3 + HNMeNMe_2 \xrightarrow[\text{excess } HNMeNMe_2]{75^\circ\ C} C_5H_{15}N_2Al + CH_4 + NMe_3.$$

Two molecular-weight measurements gave the values 189 and 195 (calc. for the monomer: 130.2; for the dimer: 260.4). Hydrolysis of 0.229 g (17.6 mmoles) produced 0.0483 g (30.2 mmoles) of methane; hence, the molar ratio of CH_4 to $C_5H_{15}N_2Al$ is 1.72. These data indicate that this complex is not compound II, but that it does contain an Me_2Al group and its empirical formula is the same as that for II. The molcular-weight data suggest a complex which is only partially associated in cyclohexane; however, the data are insufficient to indicate structural formula at this time.

Two attempts were made to convert compound II to the liquid complex described above. In the first attempt, 0.5 g of compound II was heated at 75° C for 48 hours followed by 120° C for 2 hours. The material remained unchanged. In the second attempt, 0.5 g of II was heated at 75° C for 48 hours with 1.0 g of trimethylhydrazine. After removal of the trimethylhydrazine an attempt to vacuum-distill the liquid residue at 90° C under 0.001 mm Hg pressure failed. The compound would not distill. The infrared spectrum of the liquid indicated it was neither II nor the material obtained above.



It should be noted that the temperature employed to prepare $Me_3Al{:}HNMeNMe_2$ from $Me_3Al{:}NMe_3$ and trimethylhydrazine (60° C) is also that used to convert $Me_3Al{:}HNMeNMe_2$ into $Me_2Al—NMeNMe_2$ when the former complex is prepared from Me_3Al and trimethylhydrazine. The authors have no explanation for this anomaly, but it must be presented as the condition under which these reactions occurred.

Reaction of Trimethylaluminum with Tetramethylhydrazine

By the vacuum method, 1.10 g (15.3 mmoles) of Me_3Al was treated with 1.50 g (17.0 mmoles) of Me_2NNMe_2 for 2 hours at room temperature. No gas evolution was observed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

during this period, and a white crystalline solid formed in the reaction vessel. The material was sublimed at 60° C (m.p. 65.5–66.0° C), and elemental analysis of the sublimate agreed with the values calculated for the 1:1 complex:

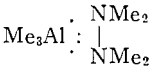
Calc.: Al, 16.84%; C, 52.47%; H, 13.21%; N, 17.48%. Found: Al, 16.87%; C, 52.48%; H, 13.03%; N, 17.04%. A molecular-weight measurement gave the value 164 (calc.: 160.3); hence, the following reaction may be written:

$$Me_3Al + Me_2NNMe_2 \xrightarrow{25^\circ C} Me_3Al{:}NMe_2NMe_2.$$

All of the compounds described above hydrolyze rapidly in methanol, ethanol, and 1,4-dioxane and react vigorously with water. They decompose in air without inflaming and they react slowly with dry air. The polymeric compounds are somewhat less sensitive to moisture and oxygen. Yields of purified products were approximately 65–70 mole% of the initial quantity of Me_3Al or $Me_3Al{:}NMe_3$.

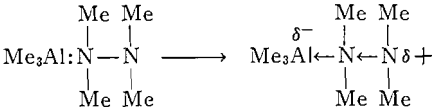
DISCUSSION

The reactions described above occur by two sequential steps. The first is the formation of a dative-bonded complex of trimethylaluminum and the hydrazine:



$$Me_3Al + R_2NNR_2 \rightarrow Me_3Al{:}R_2NNR_2. \qquad [1]$$

The second is the elimination of methane to form a complex with a covalent aluminum–nitrogen bond:



$$Me_3Al{:}RHNNR_2 \rightarrow Me_2Al{-}NRNR_2 + CH_4. \qquad [2]$$

The structure of the dative-bonded complexes cannot be determined from the data available, but it should be noted that in the two cases wherein the complexes could be isolated, i.e., the reactions of trimethylhydrazine and tetramethylhydrazine with trimethylaluminum, only 1:1 adducts are formed. This fact suggests a structure which prohibits further complexing of another Me_3Al molecule to the other nitrogen atom of the hydrazine.

A complex involving a pentaco-ordinated aluminum atom:

or the charge distribution on the structure with a tetraco-ordinated aluminum atom:

would inhibit further addition; hence one of these two formulas may represent the configuration of the dative-bonded adducts.

The elimination of methane during the formation of the covalent-bonded complexes

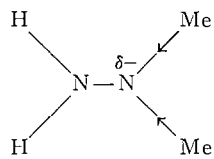
is a striking feature of *all* the reactions in which such elimination occurs. The absence of ethane which would be liberated if the following mechanism:

$$Me_3Al + H_2NNMe_2 \rightarrow Me_2AlNMeNH_2 + C_2H_6, \qquad [3]$$

was followed indicates that in unsymmetrical hydrazines, the nitrogen atom with the largest number of N—H bonds forms the covalent bond with aluminum:



$$Me_3Al{:}MeHNNMe_2 \rightarrow Me_2Al{-}NMeNMe_2 + CH_4.$$

The specificity of this reaction may be the combined effect of steric and electronic factors. For example, with unsymmetrical hydrazines, if one assumes the formation of a tetraco-ordinated intermediate, the Me_3Al may bond with the least sterically hindered nitrogen atom, namely, the one with the greatest number of N—H bonds and the subsequent methane elimination occurs from these adjacent aluminum and nitrogen atoms. If one postulates the pentaco-ordinated aluminum complex:

$$Me_3Al{:}\begin{array}{l}NHMe\\|\\NMe_2\end{array},$$

the aluminum atom may be forced into closer proximity to the nitrogen atom with N—H bonds, and covalent bonding with aluminum would tend to occur here.

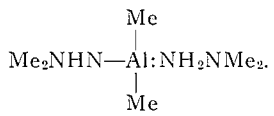
The classical theory of inductive effect would assign to the nitrogen atom of an unsymmetrical hydrazine with the greatest number of methyl groups the greater negative charge:

One would thus expect a Lewis acid such as Me_3Al to form a dative bond with this nitrogen atom. The formation of the covalent bond should produce ethane, however (eq. [3]). Since none is observed, this hypothesis is not tenable. If electronic effects influence the formation of the covalent Al—N bond, then they are of an order that cannot be inferred from the available data.

Analysis of the reaction products obtained from trimethylaluminum and either methylhydrazine (eq. [4]) or 1,2-dimethylhydrazine (eq. [5]) shows that both nitrogen atoms react with equal probability. It has been observed from the evidence available (7, 8)

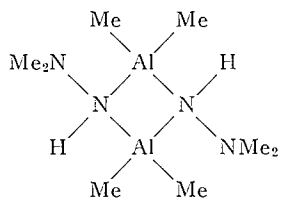
$$Me_3Al + NHMeNHMe \longrightarrow \left[\begin{array}{l}\quad\quad Me\ Me\\|\quad\ |\quad\ |\\-Al-N-N-\end{array}\right]_n \qquad [4]$$

$$Me_3Al + H_2NNHMe \longrightarrow \left[\begin{array}{l}\quad Me\ H\ \ Me\\|\quad\ |\ \ |\\-Al-N-N-\end{array}\right]_n \qquad [5]$$



that no more than one aluminum trialkyl molecule will add to the nitrogen atom of H_2NMe; hence, the alternative structural formula:

$$\left[\begin{array}{l}Me\\|\\-Al-N-\\\quad\ |\\Me-N-H\end{array}\right]_n$$



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

for the product of reaction [4] seems unlikely. Even when a large excess of trimethylaluminum is present and even under vigorous reaction conditions (i.e., heating for a prolonged period of time), we also found no indication that an $—NH_2$ group would react more than once with the trimethylaluminum.

A very interesting compound is formed in the reaction between 1,1-dimethylhydrazine with trimethylaluminum trimethylamine. Brown and Davidson (2) report that $Me_2Al—NMe_2$ does not react further with diethyl ether or trimethylamine to form a dative-bonded complex; however, in the case of the hydrazine reaction, a compound was isolated which appeared to contain both covalent and dative Al—N bonds:

Our molecular-weight determinations have shown that at least two of the compounds are dimeric: $[Me_2Al—NHNMe_2]_2$ and $[Me_2Al—NMeNMe_2]_2$. It has been shown (12, 13) that similar boron compounds associate through nitrogen bridges; hence, it is reasonable to assume that the dimeric compounds which we prepared also associate through Al—N bridges:

In conclusion, it can be said that, in general, hydrazines react with trimethylaluminum in the same manner as do primary or secondary amines, but the reactions of methylhydrazines and trimethylaluminum trimethylamine have produced, in some cases, compounds of unusual character. We believe that additional insight into the nature of these and similar reactions will be provided by work currently in progress at this laboratory.

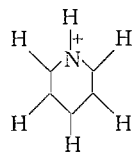
VIBRATIONAL SPECTRA OF PYRIDINIUM SALTS[1]



DENYS COOK

ABSTRACT

The vibrational spectrum of the pyridinium ion, $C_5H_5NH^+$, and the N-deuterated species has been studied in several pyridinium salts. By comparison with benzene and deuterobenzene (with which the pyridinium ion is isoelectronic) a fairly complete assignment has been made. The N—H bonds, which are hydrogen bonded to the anions, have stretching vibrations which show systematic variations depending on the nature of the anion. The N—H in-plane deformation vibrations show little variation while the out-of-plane deformation vibrations, some of which do vary, are probably affected, in addition, by other factors.

INTRODUCTION

Pyridine forms salts with many strong mineral and organic acids. In these salts it is assumed that complete proton transfer takes place between the acid and the pyridine molecule, giving the pyridinium ion I and an anion.

I

Little spectroscopic data on such salts is available in the published literature.* Greenwood and Wade (1) assigned a few bands from their published spectra of $C_5H_5NH^+Cl^-$ and $C_5H_5NH^+BCl_4^-$, while Kynaston and co-workers (2) listed all the bands in the latter salt. Spinner published a list of frequencies in the infrared and Raman spectrum (aqueous solution) of $C_5H_5NH^+Cl^-$ (3) and made a few assignments.

In these papers emphasis was placed on similarities between these salts and C_5H_5N. It is believed that a more pertinent and helpful comparison is between the pyridinium ion and C_6H_6. These molecules contain the same number of atoms, are isoelectronic, and, apart from the mass and electronegativity of the nitrogen atom, would be identical. This physical similarity breaks down, however, when the symmetry of the two molecules is compared. C_6H_6 has D_{6h}, and $C_5H_5NH^+$ is expected to have C_{2v} symmetry. Thus C_6H_6 has only four (strictly) infrared-active fundamentals and seven Raman fundamentals. $C_5H_5NH^+$ will have 30 Raman-active fundamentals and 27 infrared-active fundamentals. (The selection rules are shown in Table I.) The comparison between C_6H_5D and $C_5H_5ND^+$, however, reveals a much closer similarity, since both molecules now have C_{2v} symmetry, with identical selection rules.

[1]*Manuscript received May 26, 1961.*
Contribution No. 39 from the Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario. This work was presented, in part, at the Seventh Ottawa Symposium on Applied Spectroscopy, October 5, 1960.

**As this paper was being prepared, a partial listing of the frequencies in some pyridinium salts was published (R. H. Nuttall, D. W. A. Sharpe, and T. C. Waddington. J. Chem. Soc. 4965 (1960)), but not in a complete enough state to warrant comparison at this time.*

TABLE I

Selection rules for the pyridinium ion (symmetry C_{2v})

Class	Symmetry elements			Raman	I.R.	Vibrations		
	C_2 (z)	σ_v (xz)	σ_v (yz)			Ring	H	Total
A_1	*s*	*s*	*s*	*p*	*a*	5	6	11
A_2	*s*	*as*	*as*	*dp*	*ia*	1	2	3
B_1	*as*	*s*	*as*	*dp*	*a*	4	6	10
B_2	*as*	*as*	*s*	*dp*	*a*	2	4	6

Accordingly, many pyridinium salts have been prepared, together with their N-deuterated analogues,* and their infrared spectra in the solid state have been recorded with the high precision of a prism-grating spectrophotometer. The Raman shifts (of the HCl salt in aqueous solution), together with polarization measurements, were obtained through the courtesy of Dr. J. C. Evans, Chemical Physics Research Laboratory, the Dow Chemical Company, Midland, Michigan, U.S.A. (4). The spectra have been compared with those of C_6H_6 and C_6H_5D for which the assignments are known with precision and confidence (5–11).

EXPERIMENTAL

The Spectra

The spectra were recorded on a Perkin–Elmer model 221 spectrometer equipped with a sodium chloride prism-grating combination.

All the spectra were of the solid state as emulsions in nujol or fluorolube. Some of the salts which were hygroscopic, and all the deuterium salts, were handled in a dry box.

Preparation of the Compounds

$C_5H_5NH^+Cl^-$.—Anhydrous HCl was passed through an ethereal solution of pyridine. The resulting precipitate was recrystallized from a methanol–acetone mixture. M.p. 140–142° C; HCl: found: 31.5%, calc.: 31.6%.

$C_5H_5NH^+Br^-$.—An ether solution of pyridine was treated with anhydrous HBr to give a white solid which was recrystallized from a methanol–acetone mixture. M.p. 213–214° C; HBr: found: 51.7%, calc.: 50.5%.

$C_5H_5NH^+I^-$.—Aqueous HI was added to an ethereal solution of pyridine. The white precipitate so formed was recrystallized from methanol. M.p. 214° C (decomp.); HI: found: 63.0%, calc.: 61.8%.

$(C_5H_5NH^+)_2ZnCl_4^=$.—Acetone solutions of $C_5H_5NH^+Cl^-$ and $ZnCl_2$ were mixed and poured into ether; a white solid separated. This was identical with that formed when the pyridine:$ZnCl_2$ complex in warm acetone was treated with HCl. M.p. 179–182° C.

$(C_5H_5NH^+)_2SnBr_6^=$.—Chloroform solutions of $C_5H_5NH^+Br^-$ and $SnBr_4$ were mixed, and the resulting pale yellow precipitate was recrystallized from water. M.p. 280° C; Sn: found: 13.8%, calc.: 15.7%.

$(C_5H_5NH^+)_2SnCl_6^=$.—Chloroform solutions of $C_5H_5NH^+Cl^-$ and $SnCl_4$ were mixed, and the resulting white precipitate was recrystallized from water. M.p. 280° C; Sn: found: 26.0%, calc.: 24.0%; Cl: found: 45.0%, calc.: 43.7%.

$C_5H_5NH^+ClO_4^-$.—Perchloric acid (70%) was added slowly to liquid pyridine. The

**For the sake of brevity, the terms* H *salt and* D *salt may be employed in what follows. It is to be understood that* D *salt means* D *substitution for* H *only at the nitrogen atom.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

white precipitate so formed was recrystallized from 95% ethanol. M.p. 280–283° C; $HClO_4$: found: 56.9%, calc.: 56.0%.

$C_5H_5NH^+BF_4^-$.—Aqueous 50% HBF_4 added to pyridine gave a white solid, which was taken up in acetone and recrystallized by the addition of ether. M.p. 208–210° C.

$C_5H_5NH^+SbCl_6^-$.—Chloroform solutions of $C_5H_5NH^+Cl^-$ and $SbCl_5$, on being mixed, gave a white precipitate which was used without further treatment after washing with ether. M.p. 215–218° C; Sb: found: 29.1%, calc.: 29.5%; Cl: found: 53.0%, calc.: 51.3%.

Pyridinium reineckate.—Aqueous solutions of $C_5H_5NH^+Cl^-$ and reinecke salt were mixed. Removal of solvent gave a purple solid, which was recrystallized from ethanol. M.p. 205–209° C.

Deuterated salts.—Deuterated salts were prepared by twice exchanging with D_2O, the excess being pumped off *in vacuo* with a mercury diffusion pump.

RESULTS

The spectrum of one of the salts is shown in Fig. 1. It is actually as recorded on blank paper, after first recording on grid paper. The broken lines are drawn in by hand from the recorded spectrum of the deuterated compound, occasionally with slight alteration of background for the sake of clarity. Table II shows the bands in these spectra, while Table III shows a comparison of the assigned fundamentals with those of C_6H_6 and C_6H_5D. Bands due to polyatomic anions have been omitted since their locations are known and no new factors are involved.

DISCUSSION

It will be convenient to accept I as a model for the assignments of the cation. This has C_{2v} symmetry, requiring 30 fundamentals of which 3 would be inactive in the infrared; all of them would be Raman active. Table I shows the selection rules for the various vibrations, and Table IV describes their approximate character. The notation is that of Wilson (5), which has been followed by many authors. The use, in parentheses, of a capital *A* or *B* with subscript 1 or 2 obviously refers to the species of a vibration. When confusion would otherwise result, the frequency designation may be followed by H or D, in parentheses, to distinguish between the H salt and the D salt.

For the purpose of discussion, the frequencies of the salt $(C_5H_5NH^+)_2SnBr_6^=$ and its deuterated analogue will be used. Certain bands show trends depending on the anion. The $SnBr_6^=$ salt is approximately median with respect to these trends. It will be convenient to divide the spectra into four regions.

The 3500 to 1650 cm^{-1} Region

All the C—H and N—H stretching bands will occur in this region. The various spectra are characterized by large variations in frequency and intensity. Certain medium-intensity bands do show a consistent pattern and are to be identified as the C—H stretching modes above 3000 cm^{-1}. Of greater interest is the band which can be described as a N—H stretching vibration: this is ν_{7a}. It shows a large variation in intensity, band width, and frequency—from a very broad, intense band at 2439 cm^{-1} in $C_5H_5NH^+Cl^-$ to a sharp, medium intensity band at 3300 cm^{-1} in $C_5H_5NH^+SbCl_6^-$. In the median compound chosen, it is at 3236 cm^{-1} (with two submaxima) and in the deuterated salt it is at 2392 cm^{-1}, a ratio of 1.35. This band could then be properly designated as due mainly

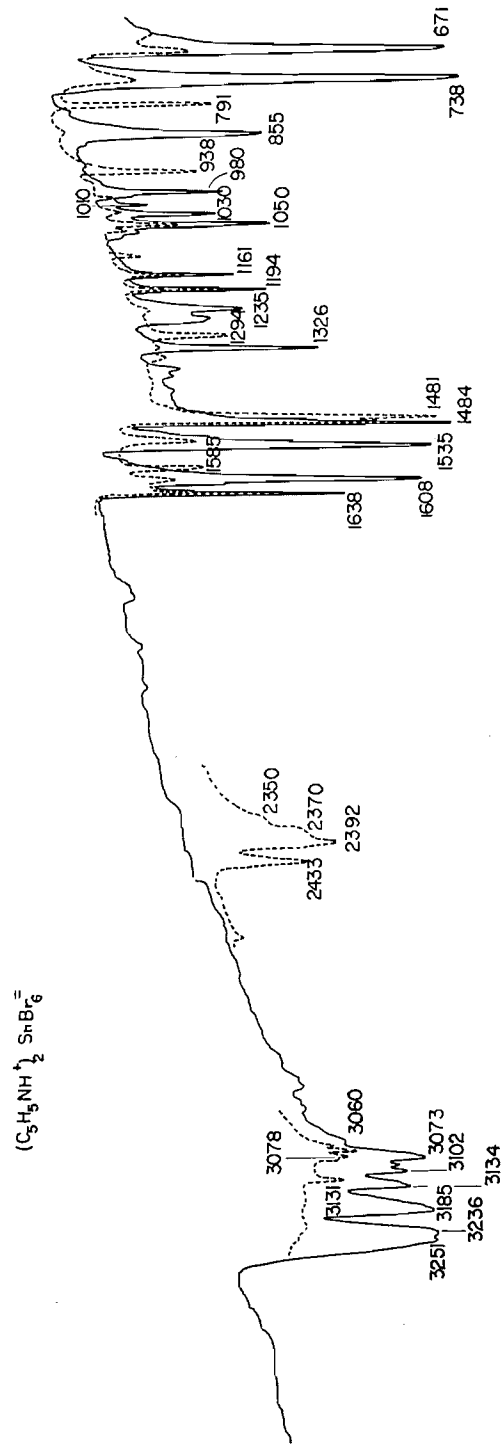

FIG. 1. Spectrum of $(C_5H_5NH^+)_2SnBr_6^=$.

to the hydrogen motion. Further discussion on the shape, intensity, and position of this band will be reserved for a later section.

The 1650 to 1400 cm^{-1} Region

All the spectra show a striking similarity in this region for all the compounds studied. Four bands of a remarkable constancy in frequency and intensity ratio are located near 1635, 1610, 1535, and 1485 cm^{-1}. This constancy in position and intensity indicates that they arise from motions unlikely to be affected by peripheral interaction, and suggests that they are due to nuclear vibrations. They have been assigned to the following vibrations respectively: ν_{8a} (A_1), ν_{8b} (B_1), ν_{19b} (B_1), ν_{19a} (A_1). The motions involved in these vibrations are visualized approximately in Fig. 2, which shows a set of normal co-ordinate

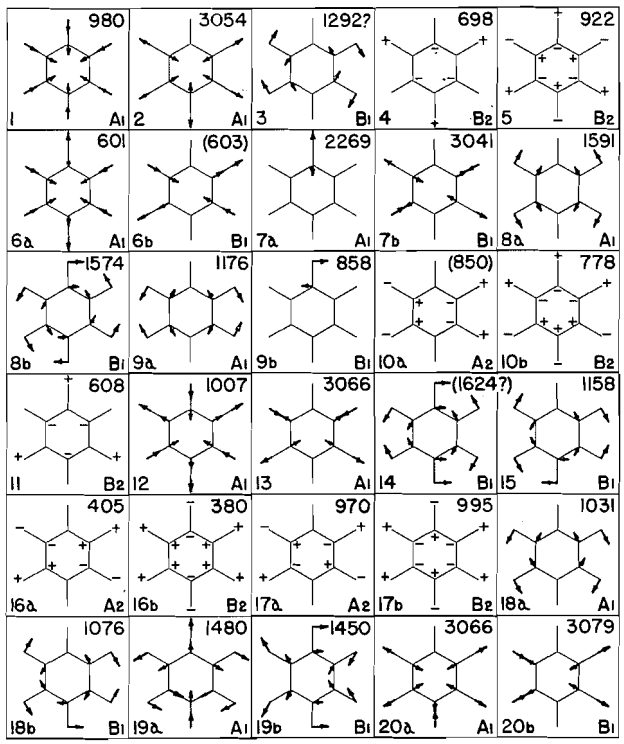

FIG. 2. Normal co-ordinate displacements for C_6H_5D.

displacements for C_6H_5D, collected from several of Ingold's papers (7). The displacements are not intended to be strictly accurate.

The Raman spectrum shows the 1635 and 1610 cm^{-1} bands to be depolarized and the 1485 cm^{-1} band probably polarized. The 1635 cm^{-1} band would be expected to be polarized completely, but even a slight polarization is consistent with a vibration of A_1 species.

The changes noticed in the N-deuterated analogue are those expected for vibrations having little or no movement of the H or D atom. The 1610 and 1535 cm^{-1} bands disappear, to be replaced by two bands at 1585 and 1475 cm^{-1}, the latter being often very close to ν_{9a} at 1485 cm^{-1}. The ratios ν_H/ν_D for ν_{8b} and ν_{19b} are 1.02 and 1.04, respectively, which are very close to those of C_6H_6 and C_6H_5D as shown in Table III.

Although the frequency ratios between the H and D salts just mentioned seem satisfactory, the intensity changes on deuteration are not as clear. The 1610 cm^{-1} band, a strong band in the H salt, seems on occasion to be quite weak in some of the D salts. While changes like this are often real, it may be that the situation is complicated further by Fermi resonance between some overtone, or combination tone, and ν_{8b}. This would have an effect on the intensity of the band in the H salt but not in the D salt because of its new position. In the D salts some bands are seen near 1615 and 1610 cm^{-1}, which are thought to be real overtones or combination bands, not simply residual bands.

The 1400 to 1020 cm^{-1} Region

In this region there should be six in-plane hydrogen-deformation frequencies. In C_6H_6 and C_6H_5D, they are weak in the infrared. The same is true of the pyridinium ion. They have been identified and assigned as ν_3, 1320 cm^{-1}; ν_{9a}, 1194 cm^{-1}; ν_{9b}, 1235 cm^{-1}; ν_{15}, 1161 cm^{-1}; ν_{18a}, 1030 cm^{-1}; ν_{18b}, 1050 cm^{-1}. The changes that occur on deuteration are a shift of the 1320 cm^{-1} band to 1294 cm^{-1}, and a more pronounced shift of ν_{9b} from 1235 to 938 cm^{-1}. The ratio of these last two frequencies is 1.32, again identifying this vibration as predominantly an in-plane deformation of the hydrogen attached to the nitrogen atom. In C_6H_6 this band is at 1178 cm^{-1}, shifting to 859 cm^{-1} in C_6H_5D, a ratio of 1.37. The vibration ν_{9b} occurs at a very constant frequency in a large number of compounds. The corresponding band in pyrrole is at 1146 cm^{-1}, moving to 915 cm^{-1} in pyrrole-N-*d* (12). Here the ratio is 1.25, indicating the vibration to be a slightly mixed one.

The marked similarity in frequency of the in-plane hydrogen-deformation bands between C_6H_6 and $C_5H_5NH^+$ and their deuterated analogues is noteworthy. With the exception of ν_{9b}, the largest difference is 28 cm^{-1}, and the next largest is 16 cm^{-1}. This is to be expected if the proposed similarity between the two compounds exists. The largest difference between them is at the nitrogen atom. Thus the N—H motions would be expected to show the largest difference, with the other four C—H bonds being little different from C_6H_6.

There should also be in this region an in-plane carbon–carbon bending mode, ν_{12} (A_1). This is doubtless the Raman shift at 1050 cm^{-1} which is polarized and, therefore, belongs to the A_1 species. This band is unlikely to be strong in the infrared (it was not listed in the infrared spectrum of C_6H_5D vapor by Ingold); therefore, it seems preferable to retain the 1050 cm^{-1} band for ν_{18b} and regard ν_{12} as unidentified.

The 1020 to 640 cm^{-1} Region

This region will contain the ring-breathing and -bending modes as well as the characteristic out-of-plane hydrogen-deformation vibrations. The higher-frequency area in this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

region is, unfortunately, not too well defined. The bands are weak, and their intensity ratios are variable in different salts. Neither is there any well-defined consistency in frequency such as that shown by the bands in the first two regions. These variations, however, though making the assignments a little more time consuming, eventually reveal trends which are important in determining intermolecular effects, which will be treated later.

A weak band in the infrared spectrum at 1010 cm^{-1} (998 cm^{-1} in the deuterium analogue) and at 1009 cm^{-1} in the Raman spectrum (the strongest band in the spectrum) can be confidently assigned to ν_1 (A_1), the totally symmetric ring-breathing mode.

Of the six out-of-plane hydrogen-bending frequencies, two belonging to the A_2 species are inactive in the infrared; these are ν_{17a} and ν_{10a}. A band at 980 cm^{-1} in $C_5H_5NH^+$, moving to 791 cm^{-1} (a ratio of 1.24) in $C_5H_5ND^+$, has been assigned to ν_5, by analogy with the 985 and 922 cm^{-1} bands in C_6H_6 and C_6H_5D. This band shows certain trends in different compounds, which will be discussed later, as does a band at 855 cm^{-1}, which has been assigned to ν_{10b}. This band disappears in the deuterated compound but a band at 680 cm^{-1} has been tentatively assigned to this vibration. Its precise identification hinges on the location of ν_4. The 738 cm^{-1} band fits this assignment reasonably well but it disappears on deuteration. The corresponding bands in C_6H_6 and C_6H_5D at 703 (forbidden) and 698 cm^{-1}, respectively, show virtually no shift on deuteration. The assignments in this region are hampered by the lack of knowledge of data below 640 cm^{-1}.

The ratios for the H and D species of ν_5 and ν_{10b} are 1.24 and 1.26 respectively, for the pyridinium ion; for C_6H_6 and C_6H_5D, they are 1.07 and 1.09. These are rather large differences but seem to be the most plausible assignments, though possible alternative ones are discussed in the next section.

This completes the assignments as far as possible at this stage. The assignments of the C—C (C—N) stretching modes and the C—H and N—H stretching modes, as well as the in-plane bending modes seem reasonably satisfactory, although the out-of-plane hydrogen-deformation vibrations and C—C (C—N) bending modes are rather more difficult to assign. One factor contributing is the absence of band shapes to assist vapor-phase assignments. This situation may be insuperable since experimental difficulties involved in recording a vapor-state spectrum seem formidable.

Alternative Assignments

Although the assignments in Table III seem satisfactory, some of the H/D ratios are a little different from the C_6H_6/C_6H_5D ratios, so that alternative assignments were considered in order to see if a more consistent set of values could be achieved. These are shown in Table V for the bands involving a shift on deuteration.

TABLE V

Alternative assignments of fundamentals

	C_6H_6	C_6H_5D	Ratio	$C_5H_5NH^+$	$C_5H_5ND^+$	Ratio
ν_{8b} (B_1)	1596	1574	1.02	1608	1585	1.02
ν_{19b} (B_1)	1485	1449	1.02	1535	1481	1.04
ν_{9b} (B_1)	1178	857	1.37	1235	(953)	(1.37)
ν_5 (B_2)				980	938	1.04
ν_{10b} (B_2)	849	775	1.09	855	791	1.08
ν_{11} (B_2)	671	608	1.10	671	(608)	(1.10)

The assignments of the 1610 and 1535 cm^{-1} bands to ν_{8b} and ν_{19b} seem unquestionably

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

correct. However, by displacing the other bands progressively to the next lower assignment, such that the 938 cm^{-1} band is allotted to ν_5, etc., an impressive agreement between the ratios is noticed. The figures in parentheses in Table V are calculated assuming the same ratio for the pyridinium series as for the benzene series.

The test of this set of assignments seems to be in the fate of the vibration ν_{9b} (D). If the 938 cm^{-1} band is allocated to ν_5 (D), then it is difficult to find a suitable band for ν_{9b} (D). Its calculated value would be about 953 cm^{-1}. No band near this frequency has been seen, unless it is obscured by the band at 938 cm^{-1}. (It will be recalled that ν_5 is a band which shows a trend depending on the anion.) This is unlikely since ν_5 is generally weak, and no structure can be observed in it. Moreover, it becomes even more unlikely to have to assume that ν_{9b} (D) is always hidden by ν_5 (D).

Another assumption, which begs the question, and is equally unpalatable, is that ν_{9b} (D) is so weak that it is unobservable even in thick films (or with electronic ordinate expansion). ν_{9b} for C_6H_5D is actually a medium strong band and is easily observable. It seems, therefore, that this assumption is unlikely to be valid for the pyridinium ion.

The alternative assignments quoted in Table V seem to require too many coincidences to appear plausible. They are considered simply because the other assignments seem to give H/D ratios which are not consistent between the benzene and pyridinium series. There may be good reasons why these ratios should not be so similar in the two compounds. The vibrations considered involve the nitrogen atom and the hydrogen atom attached to it. There is no doubt that this is a highly polar link, much more so than the C—H link in C_6H_6. It is, perhaps, therefore, not too unreasonable to expect different H/D ratios between the two compounds.

Comparison with Other Studies

Two previous papers have considered assignments of the pyridinium ion. Greenwood and Wade (1) made assignments after studying the hydrochloride and the tetrachloroborate; Spinner (3) published the Raman spectrum of an aqueous solution of the hydrochloride. Their results are shown in Table VI and compared with the present infrared data, and the Raman shifts measured by Evans (4).

All authors agree on the assignment of the 1634 and 1610 cm^{-1} bands to ν_{8a} and ν_{8b}. Greenwood and Wade reverse ν_{19a} and ν_{19b}, while Spinner does not record the 1535 cm^{-1} band. The presence of the almost certainly polarized band at 1490 cm^{-1}, although weak, justifies designation of this band as ν_{19a} of A_1 species rather than ν_{19b} of B_1 species. The absence of the 1532 cm^{-1} band in both Raman spectra can be taken as strong evidence that it is extraordinarily weak and, therefore, not an A_1 band.

Of the two bands at 1200 and 1244 cm^{-1}, the latter, because of its disappearance on N-deuteration, must be associated with the nitrogen—hydrogen atom. The analogy with the benzene spectrum, and the lower intensity of the Raman shift compared with the 1200 cm^{-1} band, establish the 1244 cm^{-1} band as ν_{9b} (B_1). The 1200 cm^{-1} band must then be ν_{9a} (A_1), though it is not polarized.

The Raman studies show the 1162 cm^{-1} band as depolarized and quite weak. This is in keeping with the species and assignment of ν_{15} (B_1).

The assignment of the 1030 and 1060 cm^{-1} infrared bands to ν_{18a} (A_1) and ν_{18b} (B_1) is firmly supported by the Raman shift at 1025 cm^{-1}, which is polarized and intense. The 1060 cm^{-1} band has been assigned to ν_{18b}, more by analogy with benzene than by regard to the Raman data. ν_{18b} in benzene was at 1075 cm^{-1}, but ν_{12} was not observed in the infrared vapor spectrum. It is, therefore, not inconsistent to assign the infrared 1060 cm^{-1}

band to ν_{18b} while assigning the polarized 1060 cm^{-1} Raman shift to ν_{12} (A_1). Greenwood and Wade have ν_{12} (A_1) at 1059 cm^{-1} and this may indeed be so.

No exception is taken to the universal assignment of the band near 995 cm^{-1} to the totally symmetric ring-breathing mode, ν_1. It is the strongest band in the Raman spectrum and is polarized although it is weak in the infrared.

The out-of-plane hydrogen deformations ν_5 and ν_{10b} are assigned chiefly on their movement upon N-deuteration. No help can be gleaned from the Raman data since no bands were observed in this region. The 952 cm^{-1} band quoted by Spinner is said by Evans to be the 1009 cm^{-1} band excited by the 4348-Å Hg line.

The intense bands at 754 and 682 cm^{-1} are unequivocally assigned to ν_4, the ring-bending mode, and ν_{11}, the out-of-plane hydrogen deformation, respectively. Although these bands are not visible in the Raman shifts, their characteristic intensity and position in the infrared spectrum are unmistakable.

The assignments of the bands having been considered, it is now convenient to examine the variations or trends in certain bands that have been briefly noted previously.

Variation of ν_{7a}

Table VII shows the variation in frequency of ν_{7a}. Some of these bands are not single bands, but have two, three, or occasionally four components. The second column in the table is the one of strongest intensity.

This band varies in frequency from 2439 cm^{-1} in $C_5H_5NH^+Cl^-$ to 3302 cm^{-1} in pyridinium reineckate. As noted earlier, it is broad and strong at low frequencies, but becomes sharper and less intense as it moves towards higher frequencies. Half widths for some of the bands at higher frequency are: $SnBr_6^=$, 68 cm^{-1}; $SnCl_6^=$, 76; ClO_4^-, 93; BF_4^-, 95; $SbCl_6^-$, 76. Undoubtedly the breadth, intensity, and low frequency are due to a strong

interaction between the nitrogen hydrogen and a small anion associated with an intense force field. In the series Cl^-, Br^-, I^-, as the anion gets larger and the force field weakens as the effect of the anionic charge is diminished by more and more completed electron shells, the band is found at 2439, 2591, and 2833 cm^{-1}, respectively. For the compounds containing polyatomic anions associated with weak peripheral force fields, the frequency rises to higher values, till, with anions such as the hexachloroantimonate, it is questionable whether there is any significant interaction, and the N—H stretching frequency might be termed free.

This behavior has been noted and discussed by Chenon and Sandorfy (various amine salts) (13), Ebsworth and Sheppard (trimethylamine salts) (14), Nakanishi, Goto, and Ohashi (various amine salts) (15), and, most recently, by Mathieu and Poulet (ammonium salts) (16), who also have the most extensive list of anions. Nakanishi *et al.* were of the opinion that the tetraphenyl boron anion represented a case of a free N—H stretching frequency. Mathieu and Poulet question this, however, and quote higher frequencies than that in the $B(C_6H_5)_4^-$ salt, and consider that there may be some interaction between the nitrogen hydrogen and the π electrons of the aromatic rings. Such phenomena have been considered previously by several authors (17–19). Be this as it may, $C_5H_5NH^+B(C_6H_5)_4^-$ certainly does have a lower frequency than pyridinium reineckate, or $C_5H_5NH^+SbCl_6^-$: it absorbs at 3215 cm^{-1}.

The presence of multiple N—H stretching bands is an interesting and controversial aspect of hydrogen bonding in amine salts. It has been suggested (20) that they are due to a double minimum in the potential surface of the vibrating species, though this is unlikely to be so in the present cases. One consideration to be borne in mind is that there may be different N—H---X distances within the structure, giving rise to different frequencies. This is certainly so in the one structure that is known. In pyridinium reineckate, $C_5H_5NH^+[Cr(NCS)_4(NH_3)_2]^-$, the organic ion is surrounded by 12 sulphur atoms belonging to N≡C—S^- groups (21). Nearest to the nitrogen—hydrogen atom, are two sulphur atoms at 3.36 Å and two at 3.60 Å. These are large distances but may be construed as very weak hydrogen bonds, giving rise to the two bands at 3238 and 3302 cm^{-1}. Preliminary data, supplied through the courtesy of Dr. C. Rérat, Bellevue, Paris, indicate a short hydrogen bond of 2.95 Å for the N—H---Cl bond in pyridine hydrochloride (22). At present it is not known whether there are other hydrogen bonds of different length in the structure.

Associated with this possibility, however, is the view that the satellites to the intense N—H stretching vibration are due to combination and difference bands between the

main fundamental and a low-frequency vibration associated with the N---X vibration in a hydrogen bond N—H---X (20).

Variation of ν_{9b}

It is rather surprising to find very little variation throughout the salts studied in the value of ν_{9b}, since it has been suggested that as a hydrogen bond is formed the stretching-vibration frequency is lowered, but the bending-vibration frequency is raised (23). The largest and smallest values are 1255 and 1230 cm^{-1}, and in the deuterated salt, 946 and 927 cm^{-1}. There is no smooth relation between ν_{9b} and ν_{7a} as the values in Tables VII and VIII show.

$Rein^-$	1245 (1.34)	930	968 (1.24)	780	840 (1.24)	680	662

A study of the hydrogen-bending mode in trimethylamine-N-oxide salts has revealed (24) a difference of 15 cm^{-1} between the hydrochloride (1525 cm^{-1}) and the hydrobromide (1510 cm^{-1}), though four other salts ($B(C_6H_5)_4^-$, BF_4^-, ClO_4^-, and I^-) were reasonably constant around ~1500 cm^{-1}. There is a difference of ~700 cm^{-1} in the stretching vibration. Again it should be noted that the hydrofluoride has not been studied yet, and there may be a large difference between this and other salts. The situation is very similar in the trimethylamine salts as Table IX shows. The ammonium salts show

TABLE IX

Hydrogen-bending frequencies in some amine salts

	Me_3NOH^+	Me_3NH^+	NH_4^+	$C_5H_5NH^+$

quite clearly a large difference between the fluoride and the other halides, which has been discussed by Plumb and Hornig (25).

Thus is would seem that while the hydrofluorides and hydrochlorides of these bases may have higher bending frequencies, salts with other anions show no systematic variations but minor differences due to coupling or mechanical interaction. Not enough types of

salts have been studied to see whether this behavior is the exception rather than the rule. Mathieu and Poulet's paper unfortunately gave no data on the bending modes. Miller and Wilkins (26), however, showed that for about 15 ammonium salts there was only a small variation of about ± 15 cm^{-1} in the bending frequency.

Variation of ν_5, ν_{10b}, and ν_{11}

ν_5, ν_{10b}, and ν_{11} are out-of-plane hydrogen-deformation vibrations (see Table VIII). They all show variations with the nature of the anion, that of ν_5 being the most convincing. A smooth relation between ν_5 and ν_{7a} suggests a connection between them. This is in line with the expectation that deformation frequencies get smaller, as stretching frequencies get larger, as hydrogen bonds get weaker. The total variation in ν_5 is really quite small, about 35 cm^{-1}, though most of this occurs in the last two salts, the hexachloroantimonate and the reineckate.

The case of ν_{10b} is a little more difficult. A total variation of about 105 cm^{-1} is observed, but much of the variation is random, without the fairly smooth relation that ν_5 exhibits. ν_{11} shows quite a small variation, only 20 cm^{-1}, again mostly to be seen in the last two compounds in the list, the hexachloroantimonate and the reineckate. Neglecting these two, the variation is 11 cm^{-1}, which cannot be called significant.
