These variations in the bands just considered, at first sight seem to support the view that deformation frequencies rise as hydrogen bonds get stronger. However, because of the large deviations from a linear relationship between the stretching frequency, ν_{7a}, and the deformation frequency, this view must be taken as tentative at this stage. The near constancy of ν_{9b} and ν_{11} also does not support this view. There may be mechanical factors involved, too, which could complicate the matter.

ACKNOWLEDGMENTS

I am greatly indebted to Dr. J. C. Evans for his measurements of the Raman shifts in pyridine hydrochloride and for helpful discussion, and to Dr. C. Rérat for information on the structure of pyridine hydrochloride, before publication. The assistance of Miss C. D. Anderson in preparing some of the compounds and recording their spectra, and of Mr. D. G. Barnes for some of the analyses, is gratefully acknowledged.

SOME FACTORS AFFECTING THE KÖNIGS–KNORR SYNTHESIS OF GLYCOSIDES[1]

H. R. GOLDSCHMID[2] AND A. S. PERLIN

ABSTRACT

Glycosyl halides decompose readily in the presence of silver oxide under conditions generally used for the Königs–Knorr synthesis of glycosides. This "side reaction" probably accounts for the low yields commonly obtained in the synthesis of oligosaccharides, particularly those involving the formation of a glycosidic union through an unreactive secondary position. The rate of the side reaction, as well as that of the normal condensation reaction, is dependent on the condition of the silver oxide, and is retarded markedly by elemental iodine. This latter effect appears to be related to the improved yield obtained in Königs–Knorr syntheses when iodine is used. Among the products formed in the decomposition of 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide are 2,3,4,6-tetra-*O*-acetyl-D-mannose, a heptaacetyl 1,2,1′-linked dimeric orthoacetate, and a second high-molecular-weight compound that also shows ortho ester properties.

The Königs–Knorr reaction (1)—the condensation of a glycosyl halide with a hydroxylic compound in the presence of a catalyst or acid acceptor—constitutes a method of high stereochemical selectivity for the synthesis of glycosides. Several detailed reviews and articles deal with the mechanism of this reaction and its many applications (2–9). Although glycosides of simple alcohols and phenols may usually be prepared in high yield, the method is less generally effective for oligosaccharides. This is true particularly when the hydroxylic component is relatively unreactive. Yields of disaccharides thus are optimal (60–75%) when the glycosyl unit is coupled with a primary hydroxyl group (5, 10, 11), and much lower (frequently less than 10%) when the condensation involves an anomeric or a secondary hydroxyl group (5, 12, 13).

Generally, the synthesis of oligosaccharides involves the use of an "inert" solvent (e.g., chloroform or benzene), a desiccant to minimize hydrolysis of the glycosyl halide, and a condensing agent. Most commonly, the condensing agent is silver oxide or carbonate. Using these normal Königs–Knorr conditions for preparing certain disaccharides we have found that a reaction occurs readily between the acetohalogen sugar and the condensing agent *even in the absence of an added hydroxylic component.* Thus, addition of silver oxide to a solution of tetra-*O*-acetyl- (or *O*-benzoyl-) α-D-mannopyranosyl or D-glucopyranosyl bromide in dry benzene or chloroform resulted in a rapid drop in the optical rotation of the solution (Table I). Chromatographic examination of the reaction mixture at intervals (after prior treatment with sodium methoxide) showed that this drop was caused by decomposition of the halide and that derivatives of the parent hexose (i.e., D-mannose or D-glucose) were being formed.* The amount of rotatory change, to a maximum value, depended on the proportion of silver oxide used (Table I), and when this maximum change had occurred, little, or none, of the glycosyl halide remained intact. However, there was a wide variation in the activity of oxide samples from different

**The glycosyl halides themselves are converted by excess sodium methoxide to the methyl glycosides. Hence, both the parent sugar and glycoside were detected in varying proportions at intermediate stages of the reaction between the halides and silver oxide (see footnotes, Table I).*

sources, as shown by the varied amount of rotatory change produced* (Table II). The glycosyl halides were vigorously decomposed also with silver carbonate as well as in other solvents (e.g., tetrahydrofuran), but were much more stable in the presence of a soluble base, pyridine. These effects suggested that the metallic oxides serve as catalysts of the observed "side reaction", possibly as in the solvolysis of alkyl halides (16, 17).

TABLE II

Variation in activity of silver oxide (tetra-*O*-acetyl-α-D-mannosyl bromide (50 mg) in benzene (2 ml) containing Drierite (0.7 g) and silver oxide (25 mg); initial α_D 1.95° (0.5 dm))

*At 18 hours the rotational values were virtually unchanged.
†Paper chromatographic examination of the deacetylated (with sodium methoxide) material showed mannose, no methyl mannoside.
‡Paper chromatographic examination of the deacetylated (with sodium methoxide) material showed mannose *plus* methyl mannoside.

The reaction products isolated after treatment of the acetylated glycosyl halides with silver oxide in benzene were amorphous solids essentially free from halogen. They did

**Helferich and Klein (14) have noted that the effectiveness of silver oxide in disaccharide syntheses varies with the method of preparation of the oxide. The age of the oxide may also be important, and hence the literature contains frequent references to the use of a "freshly-prepared" sample. Two of the samples tested in the current study were found to be stable over a period of 1 year whereas the activity of a third sample decreased slowly. The importance of using properly prepared silver chloride for converting an α-D-glycosyl bromide to the β-D-chloride (15) is perhaps a related example of how the condition of a silver salt may affect the reactions of glycosyl halides.*

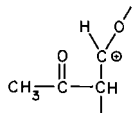
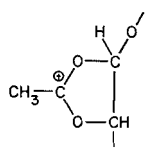
not exhibit unsaturated properties and absorbed weakly in the infrared region characteristic of hydroxyl groups. Elemental analysis data suggested that formation of these products involved the introduction of one oxygen atom per two tetraacetyl hexosyl residues (R), as represented by the reaction

$$2RBr + Ag_2O \rightarrow ROR + 2AgBr.$$



Consistent with this possibility was the finding that the reaction products contained a high proportion of dimeric (and possibly trimeric) components. These components were readily detected chromatographically, after deacetylation with sodium or barium methoxide, as material travelling at the rate of disaccharides and higher oligosaccharides. However, the free hexose was the major product found on the chromatograms.

By column chromatography on silicic acid, several fractions were obtained from each reaction product. Those fractions derived from the D-glucosyl bromide were syrups, but in the D-mannose series three crystalline compounds were isolated. Of these, the major identifiable product was 2,3,4,6-tetra-*O*-acetyl-D-mannose (I) (isolated as the α-anomer), accounting for about 25% of the total. The two other products (II and V) each amounted to about 10% of the mixture and, on deacetylation, were found to correspond chromatographically to two of the slow-moving materials referred to in the preceding paragraph.



The total acetyl content (C-methyl groups) of compound II was greater than the *O*-acetyl content, the ratio of the two values being 8 to 7. When deacetylated with sodium methoxide, II afforded a crystalline material (III) which was reconverted to II by acetylation. Compound III was easily hydrolyzed by cold dilute acid to mannose and a syrupy product (IV) which, chromatographically and from a comparison of infrared absorption spectra, was indistinguishable from 2-*O*-acetyl-D-mannose (18, 19). These properties, together with the C-methyl content of III, suggested that III is composed of two D-mannose units linked by an orthoacetate structure, and that II is the corresponding heptaacetate. Further evidence for the presence of an ortho ester grouping in II was the rapid rotatory change produced by treatment with dilute methanolic hydrogen chloride, which closely paralleled that observed for other *O*-acetyl orthoacetates of D-mannose (19, 20, 21). As with tri-*O*-acetyl-D-mannose methyl 1,2-orthoacetate, the methanolysis yielded a product which appears to be 3,4,6-tri-*O*-acetyl-D-mannose (20, 22). Methylation of III via the liquid-ammonia procedure (23) afforded a crystalline ether which on hydrolysis yielded a tri- and a tetra-methyl derivative. From these data the structure of II is tentatively assigned a 1,2,1′-orthoacetyl linkage, as in formula II (Ac = CH_3CO).

II

VII

VIII

The molecular weight of V suggested that this product also is dimeric, and with methanolic hydrogen chloride the compound showed properties closely similar to those observed with II. On deacetylation with sodium methoxide, V yielded the crystalline

compound VI, which on a paper chromatogram was much slower than III and contained slightly less than one C-methyl group per two hexose units. Gentle acid hydrolysis of VI afforded mannose and a syrupy reducing ester which, however, was not 2-*O*-acetyl-D-mannose. This ester, on deacetylation with sodium methoxide, yielded non-reducing components as well as mannose. Hence V is not an isomer of II, although it also shows ortho ester properties. A more complete characterization of these new ortho esters and their various degradation products is being carried out. For the present purposes, however, it is clear that at least two types of high-molecular-weight ortho esters are produced during the decomposition of tetra-*O*-acetyl-α-D-mannosyl bromide in the presence of silver oxide.

The high-molecular-weight products formed in the decomposition of the D-glucosyl bromide also appear to be ortho esters since, as noted earlier, they are stable to methoxide ion, but were found to be hydrolyzed easily by acid. It is presumed, therefore, that the compounds are structurally akin to the D-mannose derivatives II and V.

Water appears to play a role in the formation of these products. Thus, tetra-*O*-acetyl-D-mannose may be derived from the bromide by hydrolysis. In the presence of silver ion this would be expected to involve dissociation of the bromide to yield a carbonium ion (e.g., partial structures VII and/or VIII) (6, 7, 8). Reaction, in turn, of the tetraacetate with VIII could yield an orthoacetate, such as II, but the formation of V appears to involve additional pathways. The practical difficulty of achieving completely anhydrous conditions (24),* together with the high efficiency of water in solvating carbonium ions, makes it possible that the water required for such reactions could be derived from sources such as the solvent, silver oxide,† or atmosphere. Since much of the reaction product is unaccounted for, there is the possibility also that water is produced by reaction of the silver oxide with hydrogen bromide, the elements of which come from the glycosyl halide. Alternatively, in view of the catalytic aspects of the reaction, it is not inconceivable that compounds such as II and V are produced on the surface of the silver oxide without the involvement of D-mannose tetraacetate, and that the latter is formed, at least partially, by hydrolysis of labile intermediates during processing of the reaction products. In any event, all attempts made in the present study to exclude and remove moisture from the reaction mixtures, including the precautions generally employed in Königs–Knorr syntheses (5), were ineffective in preventing the side reactions.

That side reactions of the same type occur during Königs–Knorr syntheses was shown by condensing the aforementioned glycosyl halides with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose under conditions similar to those recommended by Reynolds and Evans (11). When the reaction mixtures were examined chromatographically at intervals, after prior treatment with sodium methoxide, it was found that a high proportion of the acetohalogen sugar present initially could not be accounted for either as synthesized gentiobiose or as unchanged material (i.e., as the methyl glycoside). With the D-mannosyl bromides the effect was more clearly evident from the appearance of an increasing proportion of free mannose.

Since water is a by-product of these syntheses, i.e.,

$$2RX + 2R'OH + Ag_2O \rightarrow 2ROR' + 2AgX + H_2O,$$

side reactions may be expected to occur even more readily when the hydroxylic component

*It is possible that the reaction of these glycosyl halides with silver oxide is related to the rotational changes exhibited by solutions of glycosyl chlorides of the "unstable" series, i.e., by 1,2-trans-(e,e)-chloride-acetates (see ref. 6). Recent evidence (24) shows that these changes are due not to anomerization but to hydrolysis by traces of moisture present in nominally "dry" solvents. Hydrolysis of the more stable halides used in the current study may occur in the same media only when catalytic agents, such as silver oxide, are present.

†Silver oxide is reported to adsorb hydroxyl ions strongly during preparation (25).

is present than when it is absent. To keep the concentration of liberated water to a minimum, Reynolds and Evans' procedure calls for slow addition of the glycosyl halide to the alcohol component in the presence of the condensing agent and a highly efficient desiccant. In this way the alcohol component is present in large excess (particularly at the outset) as for the preparation of simpler glycosides. Isbell and Frush (3) showed that when the method of addition is reversed, the yield of the normal condensation product is lowered, and suggested that interference by water then becomes marked. Thus, when methanol was added slowly to a solution of acetobromo-α-D-mannose or -glucose in the presence of silver carbonate (but not a desiccant) a high yield of the respective hexose tetraacetate was obtained (3). However, since the glycosyl halide and condensing agent were brought together in the absence of a large proportion of the hydroxylic component, the observed effects were probably caused, partly at least, by side reactions such as described above. *Hence, the practice of adding the glycosyl halide slowly to excess of the alcohol appears to be advantageous for minimizing side reactions having different origins.* The situation should be more difficult when the hydroxylic component is unreactive. Side reactions then may occur preferentially irrespective of whether or not water has been formed through glycoside synthesis, leaving little glycosyl halide for the desired condensation. This effect probably accounts for the poor yields of disaccharides obtained, as noted earlier, particularly in attempts to form a glycosidic union through a hindered secondary position.*

A preparation of silver oxide that promotes rapid decomposition of a glycosyl halide is also a vigorous Königs–Knorr condensing agent. Thus, by using one silver oxide sample (commercial sample 1, Table II) for the above synthesis of gentiobiose a reaction period of 2 hours was sufficient, as shown by the fact that only a trace of the D-glucosyl halide remained after that time, whereas the reaction period had to be extended to 70 hours for a less active silver oxide (sample 3). Therefore, the optimum duration of a Königs–Knorr reaction, or the optimum proportion of oxide to be used, may vary greatly, and experimental details of various recorded syntheses should not be regarded as universally applicable. According to the present data (Table II), however, the effectiveness of a given sample of silver oxide may be appraised in advance by polarimetric measurement of its reaction with the glycosyl halide to be used.

The use, as described by Helferich, Bohm, and Winkler (27), of elemental iodine as a catalyst in Königs–Knorr reaction mixtures is often followed, and makes for substantially increased yields (5, 11, 12, 21, 27). Since glycosyl halides may well react in these syntheses by an S_N1 mechanism (7, 8, 19), it has been suggested (7) that the effect of iodine is to increase the polarity of the solvent and hence the reaction rate. Although iodine is highly beneficial in the synthesis of gentiobiose (11), it was found during the experiments reported above that the disaccharide actually is formed more *slowly* in the presence of iodine than in its absence. However, iodine also suppresses the side reaction between glycosyl halides and silver oxide (Table III), a highly active sample of the oxide decolorizing the iodine solution more rapidly than a less active sample. Possibly, the side reaction is hindered more effectively in this way than is the condensation step, thereby leading to an enhanced yield of the desired product. When the proportion of iodine is low, the side reaction should be prominent (Table III), but there may be insufficient silver oxide for complete condensation if the ratio is too high. It follows that there should be an optimum proportion of iodine for Königs–Knorr syntheses, which may

**As shown by Curtis and Jones (26), it may be advantageous to use as the hydroxylic components, acyclic derivatives, the secondary hydroxyl groups of which are usually more reactive than those of related cyclic derivatives.*

TABLE III

Effect of iodine on the decomposition of tetra-*O*-acetyl-α-D-glycosyl halides in the presence of silver oxide*

not coincide with the proportion generally used on the assumption that the iodine functions as a catalyst. Further, if iodine does in fact competitively inhibit the side reaction, there remains the possibility that more efficient inhibitors will be found.

EXPERIMENTAL

Solvents were purified and dried by standard methods. Silver oxide was prepared according to Young (28) and Helferich and Klein (14), or obtained commercially, and was dried in a high vacuum at 80° C. 2,3,4,6-Tetra-*O*-acetyl-α-D-mannopyranosyl bromide was prepared by the procedure of Talley, Reynolds, and Evans (21), and the corresponding benzoyl derivative according to Ness, Fletcher, and Hudson (29).

Paper chromatography was carried out with Whatman No. 1 paper using (A) butanol–ethanol–water (40:11:19) and (B) ethyl acetate – pyridine – water (10:4:3) as solvents, and *p*-anisidine hydrochloride (30) or ammoniacal silver nitrate (31) as spray reagents.

Silicic acid used for column chromatography was washed with water, then acetone, and dried at 110° C.

O-Acetyl was determined by a semimicro adaptation of the procedure of Kunz (32).

Optical rotations were measured at 25°±2°. Melting points are corrected.

Evaporations were carried out *in vacuo* at 40° C.

Treatment of 2,3,4,6-Tetra-O-acetyl-α-D-mannopyranosyl Bromide with Silver Oxide

A suspension of silver oxide (4.0 g) and Drierite (6.0 g) in benzene (15 ml) was shaken for 2 hours, the D-mannosyl bromide (1.5 g) was added, and the mixture was shaken for 18 hours; α_D −0.97° (0.5 dm). The solids were filtered off and washed well with benzene and the filtrate was concentrated. An amorphous solid was obtained and dried *in vacuo*, first at 80° for 2 hours and then at room temperature for 18 hours. Yield, 1.0 g. Calculated for $(C_{14}H_{19}O_9)_2O$: C, 49.56%; H, 5.65%. Found: C, 49.72%; H, 5.66%; bromine, 0.30%.

Chromatographic examination of the material after deacetylation with sodium methoxide showed (*p*-anisidine spray) the presence of mannose, two lesser components at $R_{mannose}$ 0.72 and 0.42, and a trace component at $R_{mannose}$ 0.79. No other products were detected with the silver nitrate spray.

Ortho Ester Acetate II

The amorphous product (19.7 g) obtained by treating the D-mannosyl bromide (24.0 g) with silver oxide in benzene,* as above, was dissolved in chloroform (25 ml) and trans-

**Compound II was also obtained (6% yield) when chloroform was used as the solvent.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ferred to a silicic acid column (6×50 cm), and the column was washed with chloroform. The first major fraction eluted (1.5 g) crystallized from alcohol and after recrystallization had m.p. 152–154°; $[\alpha]_D$ −23.6° (*c*, 1.2, $CHCl_3$). Calculated for $C_{28}H_{38}O_{19}$: C, 49.56%; H, 5.65%; C-methyl (8 groups), 31.7%; *O*-acetyl (7 groups), 44.4%. Found: C, 49.53%; H, 5.78%; C-methyl, 30.52%; *O*-acetyl, 44.78%.

Methanolysis of II

The ortho ester acetate (16.7 mg) was dissolved in chloroform–methanol (0.8 ml, 1:1); α_D −0.16° (1 dm). Methanolic hydrogen chloride (0.1 ml, 1.5%) was added and the rotation of the solution was then α_D 0.28° (3 min), 0.33° (5 min), 0.34° (15 min). Excess of ethereal diazomethane was added and the solution was found chromatographically (solvent A) to contain a major component corresponding to 3,4,6-tri-*O*-acetyl-D-mannose (20, 22). Evaporation of the solution and treatment of the residual syrup with excess lead tetraacetate in acetic acid showed this component to be oxidized readily to yield a product which travelled more rapidly on a paper chromatogram and gave a typical pentose color with the *p*-anisidine spray, showing that the cleavage had occurred between carbons-1 and -2.

Ortho Ester III

Compound II (370 mg) was suspended in methanol (3 ml) and treated under reflux for 10 minutes with a slight excess of sodium methoxide. During this period the compound dissolved, and when the solution was cooled, a precipitate (170 mg) was obtained, which was crystallized from water–methanol; m.p. 120°; $R_{mannose}$ 0.72. Calculated for $C_{14}H_{24}O_{12}.CH_3OH$: C, 43.27%; H, 6.78%; C-methyl (1 group), 6.5%; methoxyl, 7.5%. Found: C, 43.43%; H, 6.73%; C-methyl, 7.34%; methoxyl, 8.23%.

Ortho ester III (138 mg) in pyridine (5 ml) was treated with acetic anhydride (3 ml) for 5 hours, the reaction mixture was decomposed with ice water, and the solid product was collected. Yield, 159 mg. After recrystallization from ethanol, the product had m.p. 152–154° C, $[\alpha]_D$ −25.9° (*c*, 1.1, $CHCl_3$).

Hydrolysis of III

The ortho ester (III) (200 mg) was dissolved in 0.1 *N* sulphuric acid (4 ml), and after 2 hours the solution was neutralized with Dowex-1 resin (bicarbonate form) and concentrated. The residual syrup was found to contain approximately equal proportions of mannose and a second component which travelled at the rate of 2-*O*-acetyl-D-mannose. By chromatography on sheets of Whatman 3 MM paper, using solvent A, the mixture was separated, and the unknown syrupy component was found by infrared spectroscopy (potassium bromide disk) to be indistinguishable from the known syrupy D-mannose monoacetate. The latter was prepared from 3,4,6-tri-*O*-acetyl-D-mannose-1,2-orthoacetate by the procedure used for conversion of the corresponding L-rhamnose ortho ester to 2-*O*-acetyl-L-rhamnose (18).

Methylation of III

The deacetylated ortho ester (III) (342 mg) in liquid ammonia (15 ml) was treated with a slight excess of potassium (23), the ammonia was evaporated off, and the residue was heated under reflux in methyl iodide (5 ml) for 3 hours. After evaporation of the methyl iodide, the methylation procedure was repeated twice. The final product (348 mg) was crystallized from *n*-hexane; m.p. 142–144° C, $[\alpha]_D$ −36.5° (*c*, 1.0, $CHCl_3$). Calculated for $C_{21}H_{38}O_{12}$: C, 52.27%; H, 7.94%; methoxyl, 45.0%. Found: C, 52.21%; H, 7.93%; methoxyl, 44.1%.

The methylation product (4.8 mg) in methanol (0.5 ml) (α_D −0.10°, 0.5 dm) was treated with methanolic hydrogen chloride (0.05 ml, 6%), which caused a change in rotation to α_D 0.35° (2 min), 0.40° (5 min). After neutralization with ethereal diazomethane, the solution was found by paper chromatography to contain two components corresponding to 3,4,6-tri- and 2,3,4,6-tetra-*O*-methyl-D-mannose, respectively. Assignment of a 3,4,6-structure to the former was supported by the fact that this component was readily oxidized by lead tetraacetate in acetic acid, yielding a faster-moving product (presumably trimethyl arabinose); the tetramethyl derivative was unaffected by this treatment. When the methylation product was treated under reflux with 1% methanolic hydrogen chloride, the two products formed corresponded, as indicated by gas–liquid chromatography, to a tri- and a tetra-*O*-methyl methyl glycoside, respectively.

2,3,4,6-Tetra-O-acetyl-α-D-mannose (I)

By continued washing of the silicic acid column (above) with chloroform, a second major fraction was obtained (5.4 g), which was crystallized from a highly concentrated solution in ether; m.p. 91–92° C, $[\alpha]_D$ 25.2° (*c*, 1.4, $CHCl_3$) (lit. (33) m.p. 93°, $[\alpha]_D$ 26.3°). Calculated for $C_{14}H_{20}O_{10}$: C, 48.27%; H, 4.79%; acetyl, 49.5%. Found: C, 48.53%; H, 5.83%; acetyl, 49.23%.

On acetylation with acetic anhydride – sodium acetate the compound afforded 1,2,3,4,6-penta-*O*-acetyl-β-D-mannose; m.p. 116–118°, $[\alpha]_D$ −24.5° (*c*, 1.2, $CHCl_3$).

Ortho Ester Acetate V

When the silicic acid column was washed with chloroform–ether (3:1) a fraction (2.1 g) was eluted, which crystallized, and was recrystallized from ethanol; m.p. 216–219°, $[\alpha]_D$ −26.5° (*c*, 1.1, $CHCl_3$). Found: C, 50.00%; H, 5.66%; acetyl, 42.77%; molecular weight (Rast), 753.

In another experiment, this ortho ester also was isolated directly from the reaction mixture. Silver oxide (20 g) in benzene (100 ml) was heated under reflux for 1 hour and then approximately 50 ml of the benzene was distilled off. Drierite (30 g) was added to the cooled suspension, followed by acetobromo-α-D-mannose (7.5 g) in benzene (50 ml). After being shaken for 10 hours, the reaction mixture (α_D −0.30°) was filtered, and the solution concentrated, affording an amorphous solid (5.0 g). The latter, on being dissolved in warm ethanol, yielded crystalline material (0.58 g), m.p. 206–208° C. Recrystallization from ethanol gave a melting point of 208–211°, undepressed by admixture with the ortho ester described in the preceding paragraph. Found: C, 50.11%; H, 5.69%; C-methyl, 27.51%; molecular weight (Rast), 705; (isothermal distillation (34), acetone), 690.

The ortho ester (22.6 mg) was dissolved in chloroform–methanol (1.0 ml, 1:1); α_D −0.51° (1 dm). On addition of methanolic hydrogen chloride (0.5 ml, 1%) to the solution, the observed rotation was α_D 0.20 (2 min), 0.38 (5 min), 0.43 (25 min). Neutralization of the solution with silver carbonate, followed by paper chromatographic examination, showed the presence of a major component corresponding to 3,4,6-tri-*O*-acetyl-D-mannose, this component being readily oxidized by lead tetraacetate in acetic acid.

Ortho Ester VI

Ortho ester acetate V (500 mg) was suspended in methanol (8 ml) and treated under reflux for 10 minutes with a slight excess of sodium methoxide. The clear solution, on being cooled, deposited a precipitate which was crystallized from water–ethanol; m.p.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

156–157° C, $R_{mannose}$ 0.41, $[\alpha]_D$ −5.4° (*c*, 1.1, H_2O). Found: C, 45.15%; H, 6.42%; C-methyl, 5.85%.*

The deacetylation product (V) (194 mg) was treated with 0.1 *N* sulphuric acid (4 ml) for 3 hours at room temperature, and the solution was neutralized with Dowex-1 (bicarbonate form) and evaporated. Paper chromatographic examination of the product showed the presence of mannose and an equally prominent second component, $R_{mannose}$ 0.7 (solvent A) or $R_{mannose}$ 1.2 (solvent B). This mixture was separated on Whatman 3 MM paper affording the unknown component as a syrup (86 mg). The latter absorbed strongly in the infrared regions characteristic of acyl groups and, on treatment with excess sodium methoxide, yielded mannose and two non-reducing products having $R_{mannose}$ 2.5 and 2.8, respectively (solvent A).

Treatment of 2,3,4,6-Tetra-O-acetyl-α-D-glucopyranosyl Bromide with Silver Oxide

To a solution of the bromide (0.6 g) in benzene (7 ml) was added Drierite (3.0 g) and silver oxide (2.0 g), and the mixture was shaken for 16 hours; during this period the observed rotation changed from α_D 20.2° to 1.75° (1 dm). The solids were filtered off and washed with benzene, the filtrate was evaporated, and the amorphous solid obtained was dried in a high vacuum. Yield, 0.4 g. Calculated for $(C_{14}H_{19}O_9)_2O$: C, 49.56%; H, 5.65%. Found: C, 50.15%; H, 5.67%; bromine, 0.28%. On deacetylation with barium methoxide the product yielded glucose and two lesser-reducing components (*p*-anisidine spray) having $R_{glucose}$ 0.7 and 0.1, respectively. The latter two were hydrolyzed when the deacetylation mixture, acidified with acetic acid, was heated briefly.

The product was chromatographed on a column of silicic acid, using chloroform and chloroform–ether (varying proportions) as the eluting solvents. Several syrupy fractions were obtained, none of which, however, afforded crystalline material.

ACKNOWLEDGMENTS

The authors thank Dr. G. L. Mattock for helpful discussion, and Mr. J. W. L. C. Christ and Mrs. J. Nuttall for technical assistance. Microanalyses were performed by Mr. M. Mazurek, and infrared absorption spectra were prepared by Miss Inez Gaffney.

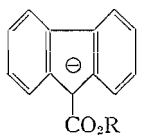
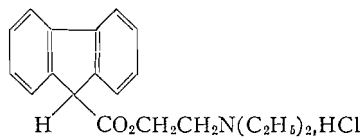
ALIPHATIC CHEMISTRY OF FLUORENE



PART VII. SPIROLACTONES[1]

P. M. G. BAVIN[2]



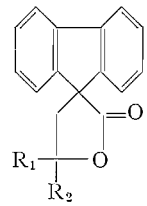
ABSTRACT

A number of spirolactones have been prepared from fluorene-9-carboxylic acid, either by the halolactonization reaction or by alkylation of the methyl ester with hydroxyalkyl halides.

The ease with which methyl fluorene-9-carboxylate anion (I*a*) reacts with a wide range of alkyl halides (1, 2, 3) prompted attempts to prepare 9-alkyl derivatives of the ester-hydrochloride (II), which has found use as an anti-spasmolytic agent (4) under the name Pavatrine (5, pp. 259–261). Attempts to alkylate the anion I*b* or to effect trans esterification of methyl 9-alkylfluorene-9-carboxylates with sodium 2-diethylaminoethoxide gave only traces of the desired products, but led indirectly to the preparation of some spirolactones.

I*a*, R = CH_3
I*b*, R = $CH_2CH_2N(C_2H_5)_2$

II



The reaction between 2,3-dihydroxypropyl chloride and either of the anions I*a* or *b* gave the hydroxy-γ-lactone III*b* in good yield. The unsubstituted γ (III*a*) and δ (IV*a*) lactones were prepared similarly, by alkylating I*a* with 2-bromoethanol and 3-chloropropanol,* respectively. The phenyl γ-lactone (III*c*) was obtained by reducing methyl 9-ω-phenacylfluorene-9-carboxylate (6) with sodium borohydride. The carbonyl stretching frequencies of chloroform solutions of these lactones and the related compound V*a* (7), isomeric with III*a*, agree well with the generally accepted values (8, pp. 159–160).

The hydroxylactone (III*b*) was first reported (3) as having the isomeric δ-structure (IV*b*), on the basis of the carbonyl stretching frequency of a sample prepared as a pressed potassium bromide disk. However, the infrared spectrum of a chloroform solution indicated the γ-lactone structure (III*b*), and this has been confirmed by reaction with thionyl chloride to give the chloro-γ-lactone (III*d*) (cf. reactions of the hydroxylactones derived from stilbene-2-carboxylic acids (9)). The chlorolactone has also been prepared from 9-allylfluorene-9-carboxylic acid (below). Structure III*b* for the hydroxylactone is in accord with the preferred formation of γ- over δ-lactones in the sugar series (10, pp. 33–34) and the hydroxylactones of stilbene-2-carboxylic acids (11).

The abnormal differences in the carbonyl stretching frequencies of samples of III*b* prepared as a potassium bromide disk and as a solution in chloroform may be due to

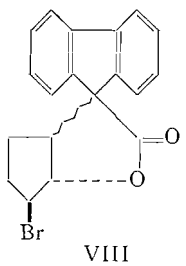
isomerization brought about by the high pressures required for disk formation (12, pp. 297–298; for another example of an abnormally low carbonyl frequency in a KBr disk, see ref. 13). Consequently, the infrared data discussed later in this paper refer to solutions in chloroform.

Reaction of the anion I*a* with *trans*-2-bromocyclohexanol, *cis*-2-chlorocyclohexanol, or cyclohexene oxide gave the same lactone (VI). Since cyclohexene oxide is known to react with nucleophiles with inversion at one carbon atom (14, 15), the lactone must have the trans structure. The lactone is formed from *trans*-2-bromocyclohexanol by prior formation of cyclohexene oxide (15) and from *cis*-2-chlorocyclohexanol by displacement with inversion (cf. the acetates of the 2-chlorocyclohexanols (16)). The reaction between I*a* and 2-chlorocyclohexanone failed, thwarting attempts to prepare the cis isomer of VI. Notwithstanding Westheimer's successful preparation of a hydroxy diester from cyclopentene oxide and diethyl malonate (14), the reaction between I*a* and *trans*-2-bromocyclopentanol failed to give the desired product.

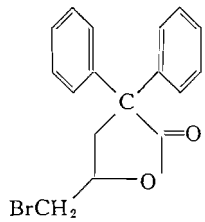


The halolactonization and related reactions have recently aroused considerable interest. Van Tamelen and Shamma (17) have suggested that the formation of iodolactones is of diagnostic value in determining the position of unsaturation in olefinic acids, and this technique has been found to be of some use (18, 19). The formation of halolactones has proved particularly useful in the bicyclo[221]heptene series (e.g. ref. 20). The mechanism has been examined by Bartlett (21), Craig (22, 23), Arnold and co-workers (24, 25, 26, 27), and, in some detail, by Berti (9, 11, 28, 29, 30, 31). It has been shown to be stereospecific (9) and much evidence suggests that a carbonium ion or related species is the essential intermediate. Since α,α-disubstituted allylacetic acids form halolactones particularly readily (9), the opportunity has been taken to examine some 9-alkenylfluorene-9-carboxylic acids. (For the method of preparation of the acids, see ref. 3.)

9-Allylfluorene-9-carboxylic acid has now been shown to form a chloro-γ-lactone (III*d*) as well as the corresponding bromo (25) and iodo (24) compounds (III*e* and *f*, respectively). 9-Crotylfluorene-9-carboxylic acid* has been found to yield mainly the bromo-γ-lactone (III*g*) together with a trace of the isomeric δ-lactone (IV*c*), not obtained pure. 9-Cinnamylfluorene-9-carboxylic acid gave only the bromo-δ-lactone (IV*d*), which decomposed surprisingly readily to 9-cinnamylidenefluorene. The reactions of the crotyl and cinnamyl acids, like those of *cis*- and *trans*-stilbene-2-carboxylic acids (9), are best interpreted as proceeding by way of the more stable carbonium ion. It had been the intention to test this conclusion by examining the reactions of para-substituted cinnamyl derivatives but insufficient time has curtailed the project. 9-Propargylfluorene-9-carboxylic acid gave the heavily substituted tribromo-γ-lactone (III*h*), which decomposed at its melting point with evolution of bromine.

VII

$\nu_{C=O}$ ($CHCl_3$) = 1777 cm^{-1}



VIII

$\nu_{C=O}$ ($CHCl_3$) = 1777 cm^{-1}

**The structure of this acid was proved by hydrogenation of the methyl ester to the known (2) methyl 9-butylfluorene-9-carboxylate. This confirmation was necessary since crotyl bromide exists as an equilibrium mixture under normal conditions (32) and can give rise to 'abnormal products' by the S_N2 mechanism (33).*

9-3′-Cyclohexenylfluorene-9-carboxylic acid gave a good yield of the bromo-γ-lactone (VII). The homologous 3′-cyclopentenyl acid gave only a moderate yield of the lactone (VIII) but, nevertheless, afforded an example of the formation of a derivative of bicyclo-[330]octane under mild conditions. By analogy with Berti's studies (9), the lactones must have the partial stereochemistry shown. The preparation of VIII can be compared with the formation of the highly strained halo-β-lactones from dimethylmaleic and fumaric acids (21).

The carbonyl stretching frequency of the bromolactone prepared from allyldiphenylacetic acid (22) is 1783 cm^{-1}, showing it to be the γ-lactone IX.

IX

The infrared data in this paper show that introduction of halogen γ or δ to the carbonyl group of δ- and γ-lactones results in a shift of the carbonyl stretching frequency to higher frequencies, by 15–20 cm^{-1}. Similar results have only been reported previously for α-halo esters and α-halo ketones (12, pp. 443–509). The shift is shown by α-halo alicyclic ketones only when the halogen is equatorial and approximately coplanar with the carbonyl group. The larger shift of 32 cm^{-1} shown by the tribromolactone (III*h*) may be compared with the very exceptional shifts shown by esters of perfluoroalkyl carboxylic acids (34).

EXPERIMENTAL

Methyl fluorene-9-carboxylate was prepared and alkylated as described elsewhere (2, 3).

Lactone of 9-(2′-Hydroxyethyl)-fluorene-9-carboxylic acid (IIIa)

Methyl fluorene-9-carboxylate (0.7 g) and 2-bromoethanol gave the lactone, which crystallized from benzene as long white needles (0.5 g), m.p. 184–185°. Found: C, 82.56; H, 5.47%. Calculated for $C_{16}H_{12}O_2$: C, 82.73; H, 5.21%.

Reduction with ethereal lithium aluminum hydride gave an almost quantitative yield of 9-(2′-hydroxyethyl)-9-fluorenylmethanol, crystallizing from benzene–hexane as small colorless needles, m.p. 94–95°. Found: C, 80.0; H, 6.59%. Calculated for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

Methyl fluorene-9-carboxylate and methyl bromoacetate gave methyl 9-carbomethoxymethylfluorene-9-carboxylate (88%), which formed colorless prisms from methanol, m.p. 91–92°. Found: C, 72.84; H, 5.60%. Calculated for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44%. Reduction with ethereal lithium aluminum hydride gave the diol described above, identity being established by mixed melting point determination and by comparison of infrared spectra.

Lactone of 9-(3′-Hydroxypropyl)-fluorene-9-carboxylic acid (IVa)

Methyl fluorene-9-carboxylate (0.7 g) and pure 3-chloropropanol (b.p. 69.5–70.0° at 19 mm; n_D^{24} 1.4487) gave the lactone, which formed colorless, well-defined prisms

(0.64 g) from benzene–hexane, m.p. 232–234°. Found: C, 81.69; H, 5.62%. Calculated for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%.

γ-Lactone of 9-(2′,3′-Dihydroxypropyl)-fluorene-9-carboxylic acid (IIIb)

Methyl fluorene-9-carboxylate and pure 2,3-dihydroxypropyl chloride gave the γ-lactone, which crystallized from chloroform–hexane as small colorless prisms (65–78%), m.p. 180–181°. Found: C, 76.85; H, 5.54%. Calculated for $C_{17}H_{14}O_3$: C, 76.67; H, 5.30%.

The infrared spectrum of a chloroform solution of the material retained in the mother liquors suggested the presence of methyl fluorene-9-carboxylate ($\nu_{C=O}$ 1760 cm^{-1}), further amounts of the γ-lactone (1770 cm^{-1}), and traces of the isomeric δ-lactone (1730 cm^{-1}).

Lactone of 9-(2′-Hydroxy-2′-phenylethyl)-fluorene-9-carboxylic acid (IIIc)

Methyl 9-ω-phenacylfluorene-9-carboxylate (6) (0.8 g) was reduced with a solution of sodium borohydride (0.5 g) in methanol (20 ml). The lactone separated from benzene–hexane as radiating clusters of elongated prisms (0.65 g), m.p. 180–181°, depressed to 165–171° by addition of the starting keto ester (m.p. 184–185°). Found: C, 84.49; H, 5.05%. Calculated for $C_{22}H_{16}O_2$: C, 84.59; H, 5.16%.

Trans Lactone of 9-(2′-Hydroxycyclohexyl)-fluorene-9-carboxylic acid (VI)

Methyl fluorene-9-carboxylate and cyclohexene oxide gave the lactone, which separated from benzene–hexane as small, well-defined rhombs (88%), m.p. 272–273°. Found: C, 82.74; H, 6.21%. Calculated for $C_{20}H_{18}O_2$: C, 82.73; H, 6.28%.

Alkylation with *cis*-2-chlorocyclohexanol (15) or *trans*-2-bromocyclohexanol (prepared by a general method (35)) gave the same lactone, identified by mixed melting point determinations and by careful comparison of the infrared spectra of chloroform solutions. To obtain good yields of lactone from the bromohydrin it was found necessary to employ 2 moles of methoxide, indicating that the reaction proceeded by prior formation of cyclohexene oxide.

Several attempts to alkylate methyl fluorene-9-carboxylate with *trans*-2-bromocyclopentanol (prepared as for the cyclohexane homologue (35)) were unsuccessful. Occasionally traces of methyl 9-hydroxyfluorene-9-carboxylate were obtained as long white needles from cyclohexane, m.p. 160–161°, identified by comparison with an authentic specimen ((36), m.p. 158–159°).

Halolactones

The 9-alkenylfluorene-9-carboxylic acids were prepared by a general method (3). Methyl esters were characterized only when obtained crystalline. Bromolactones were prepared by adding a slight excess of a solution of bromine in chloroform to the appropriate acid.

9-Allylfluorene-9-carboxylic acid (37), most easily prepared according to reference 2, and the lactone of 9-(3′-bromo-2′-hydroxypropyl)-fluorene-9-carboxylic acid (25) have been described elsewhere. The lactone of 9-(3′-iodo-2′-hydroxypropyl)-fluorene-9-carboxylic acid (24) was more conveniently prepared by Van Tamelen's procedure (17).

The lactone of 9-(3′-chloro-2′-hydroxypropyl)-fluorene-9-carboxylic acid (III*d*), prepared by reaction of the acid with a solution of chlorine in chloroform (9), crystallized as needles from heptane (76%), m.p. 166–167°. Found: C, 71.76; H, 4.65%. Calculated for $C_{17}H_{13}O_2Cl$: C, 71.71; H, 4.60%. The same lactone was obtained in 64% yield from the reaction between thionyl chloride and the hydroxylactone (III*b*), using the conditions described by Berti (9).

The Lactone of 9-(3′-Bromo-2′-hydroxybutyl)-fluorene-9-carboxylic acid (IIIg)

9-Crotylfluorene-9-carboxylic acid was obtained as small colorless prisms (65%), m.p. 120–122°, after three crystallizations from benzene–hexane. Found: C, 81.99; H, 6.04%. Calculated for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10%. Esterification of the pure acid with diazomethane and hydrogenation of the oily methyl ester in methanol over 5% palladized charcoal gave methyl 9-butylfluorene-9-carboxylate, identical with an authentic specimen ((2), m.p. 34.0–34.5°). Saponification gave 9-butylfluorene-9-carboxylic acid, which crystallized as irregular rhombs from benzene, m.p. 115–116°. Found: C, 81.17; H, 6.81%. The identical acid was obtained by saponification of the authentic ester. The alternative product of hydrogenation, methyl 9-*s*-butylfluorene-9-carboxylate, has m.p. 70–71° (2).

The bromolactone separated from benzene–hexane as colorless needles (86%), m.p. 149–150°. Found: C, 63.06; H, 4.41%. Calculated for $C_{18}H_{15}O_2Br$: C, 63.00; H, 4.41%. Fractional crystallization of the mother liquors, using infrared spectra as a guide, gave a few milligrams of white needles, m.p. 112–116°, strongly depressed by the above lactone. The infrared spectra suggested that the minor product was the δ-lactone (IV*c*), originally present in approximately 1–4%.

The Lactone of 9-(2′,3′,3′-Tribromo-2′-hydroxypropyl)-fluorene-9-carboxylic acid (IIIh)

9-Propargylfluorene-9-carboxylic acid separated from benzene–hexane as colorless needles or prisms (72% based on methyl fluorene-9-carboxylate), m.p. 182–184° with decomposition. Found: C, 82.17; H, 4.85%. Calculated for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87%. The methyl ester crystallized as colorless prisms from methanol, m.p. 117–119° (not analyzed). The infrared spectra of solutions of the acid and ester in chloroform showed the characteristic acetylenic C—H stretching band at 3300 cm^{-1} (8, p. 49).

The tribromolactone formed clusters of prisms (77%) from benzene–hexane, m.p. 155–156° with decomposition and evolution of bromine. Found: C, 42.05; H, 2.56%. Calculated for $C_{17}H_{11}O_2Br_3$: C, 41.92; H, 2.28%.

The Lactone of 9-(2′-Bromo-3′-hydroxy-3′-phenylpropyl)-fluorene-9-carboxylic acid (IVd)

9-Cinnamylfluorene-9-carboxylic acid crystallized from chloroform as well-defined prisms (71%), m.p. 162–163°. Found: C, 84.81; H, 5.72%. Calculated for $C_{23}H_{18}O_2$: C, 84.64; H, 5.56%. Hydrogenation in acetic acid over 10% palladium-on-charcoal gave 9-(3′-phenylpropyl)-fluorene-9-carboxylic acid, m.p. 124–126°, identical with an authentic specimen (38).

The crude bromolactone (1 g) was dissolved in cold chloroform (5 ml) and diluted with hot heptane (10 ml); pure lactone separated as small colorless prisms (0.6 g), m.p. 195–197° with decomposition to 9-cinnamylidenefluorene (below). Found: C, 68.24; H, 4.44; Br, 19.94%. Calculated for $C_{23}H_{17}O_2Br$: C, 68.16; H, 4.23; Br, 19.72%. The crude lactone was very unstable but samples of the pure substance have remained unchanged for 2 years.

The lactone (0.1 g) was boiled for 10 minutes with glacial acetic acid (2 ml). When the solution was cooled, 9-cinnamylidenefluorene separated as bright yellow needles (45 mg), m.p. 152–153° (lit. m.p. 150.5–151.0° for the all-trans isomer (39)).

The Lactone of 9-(3′-Bromo-2′-hydroxycyclohexyl)-fluorene-9-carboxylic acid (VII)

9-(3′-Cyclohexenyl)-fluorene-9-carboxylic acid, prepared from 3-bromocyclohexene (40), formed large, colorless prisms (73%) from benzene–hexane, m.p. 168–170° with decomposition. Found for a sample dried 12 hours at 80° and 1 mm; C, 82.52; H, 6.35%. Calculated for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%.

The bromolactone crystallized from benzene–hexane as colorless needles (89%), m.p. 186–187°. Found: C, 64.92; H, 4.70%. Calculated for $C_{20}H_{17}O_2Br$: C, 65.05; H, 4.64%.

The Lactone of 9-(3′-Bromo-2′-hydroxycyclopentyl)-fluorene-9-carboxylic acid (VIII)

Methyl 9-(3′-Cyclopentenyl)-fluorene-9-carboxylate

Alkylation of methyl fluorene-9-carboxylate with 3-chlorocyclopentene (41) gave a brown resin. Extraction with boiling heptane and passage of the resulting solution through a short column of activated alumina gave the pure ester, crystallizing from heptane as small colorless needles (67%), m.p. 93–94°. Found: C, 82.56; H, 6.32%. Calculated for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%. Hydrogenation in methanol over 5% palladized charcoal gave methyl 9-cyclopentylfluorene-9-carboxylate as elongated prisms from methanol or hexane, m.p. 83.0–84.5°. Found: C, 82.06; H, 6.78%. Calculated for $C_{20}H_{20}O_2$: C, 82.15; H, 6.89%. The same ester was obtained by alkylating fluorene ester with cyclopentyl bromide.

9-(3′-Cyclopentenyl)-fluorene-9-carboxylic acid separated from benzene–hexane as prismatic needles, m.p. 184–186°, after a change of crystalline form at 160–161°. Found: C, 83.12; H, 5.30%. Calculated for $C_{19}H_{16}O_2$: C, 82.78; H, 5.54%.

The bromolactone formed small prisms (45%) from benzene–hexane, m.p. 208–210°. Found: C, 64.17; H, 4.10%. Calculated for $C_{19}H_{15}O_2Br$: C, 64.24; H, 4.26%.

The Lactone of 5-Bromo-4-hydroxy-2,2-diphenylpentanoic acid (IX)

Allyldiphenylacetic acid was prepared as described (42) for methyldiphenylacetic acid. It formed rosettes of prisms (77%) from benzene–hexane, m.p. 143–144° (lit. m.p. 142–143° (43)). The lactone of 5-bromo-4-hydroxy-2,2-diphenylpentanoic acid (IX) crystallized as large prisms from benzene–hexane, m.p. 88–89° (lit. m.p. 87–88° (22)). Found: C, 62.03; H, 4.39%. Calculated for $C_{17}H_{15}O_2Br$: C, 61.64; H, 4.57%.

ACKNOWLEDGMENTS

The author is particularly indebted to Dr. G. W. Gray and Miss A. Stephenson for carefully recording the infrared spectra with a Unicam S.P.100 double beam instrument equipped with rock salt optics.

A gift of chemicals by G. D. Searle and Company is gratefully acknowledged.

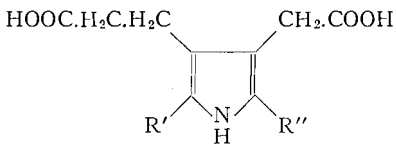
PYRROLES RELATED TO PORPHOBILINOGEN[1]

G. P. ARSENAULT[2] AND S. F. MACDONALD

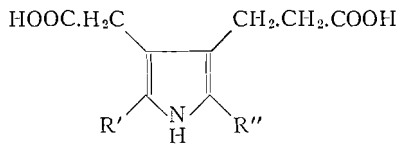
ABSTRACT

A study of the decarboxylation of pyrroles related to 5-carboxyporphobilinogen has led to an improved synthesis of porphobilinogen, to isoporphobilinogen, and to other pyrroles required for the preparation of possible intermediates in the biosynthesis of porphyrins.



Among the porphobilinogen derivatives which have been considered as possible intermediates in the biosynthesis of uroporphinogens from porphobilinogen are isoporphobilinogen, 5-aminomethylporphobilinogen (2), the carbinols analogous to these and to porphobilinogen, and polypyrranes. The behavior of synthetic specimens of these with enzymes is pertinent to the biogenetic problem. Also, a study of isoporphobilinogen under conditions which convert porphobilinogen to uroporphinogens might clarify ill-defined assumptions relating the mechanisms of the enzymic and non-enzymic conversions of porphobilinogen.

Many projected syntheses of these postulated intermediates required pyrroles with one α-position free and the other bearing a potential aminomethyl group, carbinol group, or bridge. We had found only one route to such intermediates in the decarboxylation of 5-carboxyporphobilinogen lactam in boiling water, a method too dependent on structure for its applicability in analogous cases to be assessed other than empirically. Consequently, other methods were studied for decarboxylating 5-carboxypyrroles with appropriate substituents in the remaining positions.



The triethyl ester of I*a* had been converted into the ester of I*c* and thence into I*c* itself (3). This last was treated with iodine in bicarbonate to yield the iodo-aldehyde I*f*. Although this product was obtained only once analytically pure, the other specimens were otherwise undistinguished and were quite satisfactory as intermediates. The analytical difficulties could not be ascribed to an iodine–pyrrole complex (4). The iodo-aldehyde I*f* was reduced catalytically to the α-free aldehyde I*h*. The carbinol (I, R′ = H, R″ = CH_2OH) would be expected to be very unstable (5) and has not yet been isolated as a reduction product of I*h*. The oxime, I*i*, was obtained from I*h* but more conveniently by two unexpected routes. An attempt to prepare the oxime of I*f* led directly to I*i*, iodine being lost; the ready dehalogenation of some iodopyrroles has been reported (4). This dehalogenation with hydroxylamine is of limited applicability as the triethyl ester of I*g* survived the same treatment unchanged. An attempt to improve the conversion of the aldehyde I*c* into its oxime I*d* (3) led to the third and best preparation of I*i*: longer heating resulted in the expected oxime I*d* being decarboxylated to I*i*. The ease of this decarboxylation may be unrelated to that of 5-carboxy-alkylpyrroles and of 5-carboxy-porphobilinogen lactam; some 5-carboxypyrromethenes also decarboxylate readily (6).

Under carefully chosen conditions (see below and Experimental) the catalytic reduction of I*i* gave as the sole product porphobilinogen I*j*, identified by comparison with natural material as such, as the hydrochloride, and as the lactam. The yield of porphobilinogen from the triethyl ester of I*a* in four steps was 29%. On a much smaller scale our previous synthesis (7) had given 5% in seven steps after extensive purification.

The carbinol (I, R′ = H, R″ = CH_2OH) was mentioned above, and routes to aminomethyl-porphobilinogen (I, R′ = R″ = CH_2NH_2) are also being explored. When the aldehyde group of I*h* was protected by condensation with cyanoacetic ester (8), the product, I*m*, could not be esterified. However, the aldehyde group of the ethyl ester of I*h* was similarly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

protected and the resulting ester of I*m* was formylated to the ethyl ester of I*o* using dimethyl formamide and phosphorus oxychloride. The methyl ester of the oxime I*i*, which formed a stable hydrochloride, was converted into the methyl ester of the nitrile I*k* by dimethyl formamide and phosphorus oxychloride under mild conditions. Under more vigorous conditions the same reagents formylated the nitrile ester I*k* to the ester of the aldehyde-nitrile I*n*.

The structures of I*k* and I*n* were confirmed by conversion into known derivatives of II*a*: I*k* into II*l* and its ethyl ester, I*n* into II*c*. The sequence implies a formally general solution to the problem of interconverting isomeric 3,4-dialkylpyrroles such as I*a* and II*a*. Only particular solutions had been found to this problem which was once of some practical significance (9).

Both porphobilinogen and isoporphobilinogen (I*j* and II*j*) had been identified by paper chromatography among the products obtained by heating their 5-carboxy derivatives (I*e* and II*e*) with copper acetate in aqueous pyridine (10). However, neither had been isolated and in the case of porphobilinogen, our own experience with this synthesis had been discouraging (7). Accordingly, the synthesis of isoporphobilinogen originally projected depended on the decarboxylation of II*e* after acylating the primary amino group, a closer analogue of the easily decarboxylated 5-carboxyporphobilinogen lactam being hardly to be expected. To this end the ethyl ester of the aldehyde II*c*, obtained from II*a*, was converted to the ester of the oxime II*d* and thence to the ethyl ester hydrochloride of II*e*. We then turned to the following more attractive route analogous to the new synthesis of porphobilinogen. The aldehyde II*c*, obtained from its ester, was converted into isoporphobilinogen through II*f* and II*i*. We also converted II*f* into the α'-free aldehyde II*h*.

The reduction of the oxime I*i* to porphobilinogen, I*j*, had been carried out in relatively dilute solution to completely suppress the formation of a by-product of unknown structure and higher R_f (see Experimental). Although both products showed some reactions expected of porphobilinogen and gave similar analytical figures, the required product was identified through derivatives as a monohydrate corresponding to the structure I*j*, and through comparison with natural material, as porphobilinogen.

The reduction of the oxime II*i* to isoporphobilinogen, II*j*, had to be carried out at greater dilution than was that of I*i*, to completely suppress the formation of small amounts of an analogous by-product which again had a higher R_f. Isoporphobilinogen could be identified because it analyzed for anhydrous II*j*, had an R_f identical with that of porphobilinogen, and gave a well-characterized diethyl ester hydrochloride.

Of the pyrromethanes related to porphobilinogen, only the 5,5′-free compounds are known (11). In two approaches to others, the ethyl ester of porphobilinogen lactam, III, was condensed with the ester of I*b*, and 5-carboxyporphobilinogen, I*e*, was condensed with formic acid and hydrogen bromide to give compounds which may be provisionally formulated as IV and V, although we have not yet developed methods for checking the homogeneity of such pyrromethanes and pyrromethenes by paper chromatography. The methene V was reduced to a colorless substance which did not analyze well for the corresponding pyrromethane and which was not converted into uroporphyrins enzymically (12).

EXPERIMENTAL

The melting points are uncorrected as taken in capillaries. The infrared spectra in Nujol mull and X-ray powder photographs are by Dr. R. N. Jones and Mr. R. Lauzon,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and by Dr. Maria Przybylska. Paper chromatograms were ascending overnight runs in ethanol – concentrated ammonia – water (7:1:2), using an acidic permanganate spray (13) or, in the upper layer of *n*-butanol – glacial acetic acid – water (4:1:5), using an Ehrlich's spray. Such runs determining R_f's designated by "in ammonia" and "in acetic acid" respectively showed one spot only. Darco refers to Darco G-60 charcoal and ether, to anhydrous ether. The analyses on specimens dried to constant weight were by Mr. J. R. H. Séguin.

2-Formyl-5-carboxy-pyrrole-3-acetic acid-4-propionic acid (Ic)

The following method has given more consistent yields than did the earlier method (3). The triethyl ester of I*c* (16 g) (3) and 360 ml of absolute ethanol were added to 24 g of sodium hydroxide in 600 ml of water. Nitrogen was passed through while the mixture was warmed to solution and then kept at 50° for 1 hour. The orange solution was then concentrated to 100 ml in a rotary evaporator at <40°. The red concentrate was maintained below 10° while it was acidified to Congo red with 52 ml of concentrated hydrochloric acid. The temperature was then raised to 25°. The product crystallized as brownish-pink microneedles (12 g) which were filtered off after ¼ hour and washed with water, then with ether. It was purified by extracting into 800 ml of acetone (Soxhlet, 5 hours, 200 mg insoluble). The cooled acetone solution was forced by air pressure through a column (35 mm diam. × 60 mm of Darco/Celite 535 (1:1 by vol.) supported on a 15-mm bed of Celite 535) which was then thoroughly washed with acetone. When the pale yellow eluate was concentrated to 75 ml and cooled to 0°, 9.9 g (81%) of colorless needles separated; m.p. 241–243° (decomp., inserting at 235°), Ehrlich test dark red on heating; R_f "in ammonia": 0.19.

For analysis the product was recrystallized from acetone (Soxhlet) and dried at 56° and 5×10^{-2} mm. Calc. for $C_{11}H_{11}O_7N$: C, 49.07; H, 4.12; N, 5.20. Found: C, 49.33; H, 4.24; N, 5.32.

2-Formyl-5-iodopyrrole-3-acetic acid-4-propionic acid (If)

A suspension of 4.0 g of I*c* in 60 ml of water and 3.0 g of $KHCO_3$ was added to a solution of 9.0 g KI and 3.8 g of iodine in 60 ml of water. After the mixture was shaken to solution on the steam bath, heating was continued for 1 hour while carbon dioxide was evolved and the color lightened considerably. A cold finger, occasionally washed down with a few drops of absolute ethanol, prevented the loss of iodine. The solution was cooled to 20° and scratched. After ¼ hour the crude product (2.9 g, m.p. 196–197° decomp.) was filtered off and washed with water. After two recrystallizations from 65 ml of water, flesh-colored needles resulted (2.6 g, 50%); m.p. 199–200° (decomp., iodine evolved, inserted at 185°); Ehrlich test slowly positive cold; R_f "in ammonia": 0.40.

For analysis it was dried (60°, 1×10^{-4} mm). Calc. for $C_{10}H_{10}O_5NI$: C, 34.21; H, 2.87; N, 3.99; I, 36.15. Found: C, 34.28; H, 2.94; N, 4.17; I, 36.47, 36.04 (Schöniger), 35.97 (Carius).

2-Formylpyrrole-3-acetic acid-4-propionic acid (Ih)

The iodopyrrole I*f* (2.0 g) in 60 ml of absolute ethanol was added to 25 ml of water containing 776 mg of sodium acetate trihydrate and 250 mg of palladium black. The mixture was shaken under hydrogen (20°, 1 atm) until absorption ceased after the uptake of 1 mole during 1 hour. The filtrate and aqueous washings were taken to dryness in a rotary evaporator (bath at 50°) and 20 ml of water was twice added and removed in the same way. The residue was extracted with 5 ml of water and the insoluble product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

filtered off and then washed (2×1 ml). This product was dried and then extracted into 200 ml of ether (Soxhlet, 6 hours). After the ether solution had been concentrated to 50 ml, yellow needles separated (970 mg, 76%); m.p. 176–180° (decomp., inserting at 160°); Beilstein test for halogen negative; Ehrlich test (magenta) fast in the cold; R_f "in ammonia": 0.33; in ethanol, λ_{max} 302 mμ ($\epsilon = 16\times10^3$). The aldehyde CH and the pyrrole ring CH were both confirmed by the N.M.R. spectrum.*

For analysis the product in acetone was decolorized by passage through a small column of Darco. The precipitate obtained from the eluate by adding ether was recrystallized three times from acetone–ether: colorless, flat needles, m.p. unchanged. Calc. for $C_{10}H_{11}O_5N$: C, 53.33; H, 4.92; N, 6.22. Found: C, 53.61; H, 4.94; N, 6.12.

2-Formylpyrrole-3-acetic acid-4-propionic acid Diethyl Ester

The aldehyde I*h* (351 mg) was warmed to solution in 5 ml of absolute ethanol, and diazoethane (from 3 g of nitrosoethylurea) in 75 ml of ether was added to the cooled solution. Evaporation left an oil which was dried *in vacuo* overnight and then crystallized by rubbing with ether. After sublimation (135°, 5×10^{-4} mm) it was obtained as pale yellow crystals (353 mg, 79%); m.p. 47–52°, softening from 37°; Ehrlich test red in the cold. The product of only one run crystallized and was not analyzed.

2-Formylpyrrole-3-acetic acid-4-propionic acid Oxime (Ii)

Method (a)

Hydroxylamine hydrochloride (500 mg) was dissolved in 3 ml of water, and 2 ml of 10% sodium hydroxide was added. The aldehyde I*h* (128 mg) and 1.4 ml of this solution were heated on the steam bath for ½ hour. The cooled solution was acidified to Congo red with 2 drops of concentrated hydrochloric acid and cooled at 0° for ½ hour; then the product (128 mg, 94%) was separated and washed successively with water, ethanol, and ether. It formed colorless microcrystals; m.p. 210–212° (decomp., inserted at 200°); Ehrlich test slowly violet cold. The R_f "in ammonia" (0.29) and the X-ray powder photograph were identical with those of the products of methods (*b*) and (*c*) below.

For analysis it was recrystallized four times (70% recovery) from 0.01 *N* NaOH/0.01 *N* HCl and dried at 60°, 0.02 mm. Calc. for $C_{10}H_{12}O_5N_2$: C, 50.00; H, 5.04; N, 11.66. Found: C, 49.82; H, 5.11; N, 11.55.

Method (b)

The iodopyrrole I*f* (3 g), 6 g of hydroxylamine hydrochloride, 36 ml of water, and 24 ml of 10% sodium hydroxide were heated for 1 hour on the steam bath (gases evolved). The cooled solution was passed through a column of Darco (22 mm diam.×10 mm), the column being washed with 15 ml of water. The yellow filtrate and washings were made acid to Congo red with ca. 18 ml of 2 *N* HCl, then cooled to 0° for 1 hour. The product (1.7 g, 81%) was separated and washed successively with water, ethanol, and ether to give cream-colored crystals; m.p. 212–213.5° (decomp., inserted at 200°); Beilstein halogen test negative, Ehrlich test slowly violet cold; in ethanol, λ_{max} 287 mμ ($\epsilon = 19\times10^3$).

For analysis it was recrystallized from acetone (Soxhlet) and dried (60°, 0.1 mm), giving cream-colored needles, m.p. 211–212° (decomp., inserted at 200°). Found: C, 49.89; H, 5.05; N, 11.51.

Preparative Method (c)

Hydroxylamine hydrochloride (24 g) in 144 ml of water was brought to pH 6–7 with

*We are grateful to Dr. H. J. Bernstein for this interpretation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

96 ml of 10% NaOH. The 5-carboxylpyrrole I*c* (9 g) was added and the solution was refluxed (mantle) under nitrogen for 7 hours in the dark. After being left at 20° in the dark overnight (important), the solution was filtered through a column of Darco (18 mm diam. × 40 mm, prewashed with water) and the column washed with water until the eluate was colorless. The purple eluate was acidified to Congo red with ca. 95 ml of 2 *N* HCl, scratched, and left at 0° for 1½ hours. The nearly colorless diamond-shaped crystals (6.02 g) were separated and washed successively with water, ethanol, and ether. A colorless product (5.29 g, 66%) was obtained after two recrystallizations from 0.1 *N* NaOH/2 *N* HCl (to pH 3); m.p. 210–211° (decomp., inserted at 200°); R_f "in acetic acid": 0.67.

For analysis it was recrystallized twice more in the same way and dried (60°, 0.01 mm). Found: C, 49.85; H, 5.33; N, 11.80.

2-Formylpyrrole-3-acetic acid-4-propionic acid Dimethyl Ester Oxime

A solution of 2 g of the oxime I*i* in 60 ml of 5% hydrogen chloride in methanol was kept at 0° overnight and then taken to dryness *in vacuo* below 20° in a rotary evaporator. To the residue dissolved in 100 ml of water, 4 ml of 2 *N* NaOH was added. After ½ hour the red-brown precipitate was separated, washed with water, dried (weight: 2 g), and extracted into 750 ml of ether (Soxhlet, 2 hours). The light brown extract was filtered through a column of Darco (18 mm diam. × 16 mm). The colorless eluate and ether wash were concentrated to 15 ml, and 50 ml of *n*-pentane was added with scratching. The colorless needles which separated (1.86 g, 83%) were washed with pentane; m.p. 130–133°; Beilstein halogen test negative; Ehrlich test slowly red cold; in ethanol, λ_{max} 285 mμ ($\epsilon = 20\times10^3$).

For analysis it was recrystallized twice from methanol–water (65% recovery) and dried (20°, 0.01 mm), m.p. 131–135°. Calc. for $C_{12}H_{16}O_5N_2$: C, 53.72; H, 6.01; N, 10.44; OMe, 23.14. Found: C, 53.86; H, 5.84; N, 10.53; OMe, 22.88.

2-Formylpyrrole-3-acetic acid-4-propionic acid Dimethyl Ester Oxime Hydrochloride

A solution of 201 mg of the oxime I*i* in 6 ml of 5% hydrogen chloride in methanol was kept at 0° for 3 hours and then taken to dryness at 20°; 6 ml of methanol was thrice added and removed in the same way. The residue was slurried with 10 ml of chloroform and the pink crystals (181 mg, 71%) filtered off, m.p. 160–164° (decomp., inserted at 150°); Beilstein halogen test positive; Ehrlich test very slowly violet cold.

For analysis it was twice precipitated from methanol by ether at 20° and dried (25°, 1×10^{-4} mm), giving colorless needles (35% recovery), m.p. 162–164° (decomp., inserted at 150°). Calc. for $C_{12}H_{16}O_5N_2.HCl$: C, 47.29; H, 5.62; N, 9.19; Cl, 11.64; OMe, 20.37. Found: C, 47.43; H, 5.65; N, 9.05; Cl, 11.44; OMe, 20.22.

2-Aminomethylpyrrole-3-acetic acid-4-propionic acid (Porphobilinogen, Ij)

A suspension of 5 g of the oxime I*i* and 2 g of palladium black in 100 ml of water was shaken under hydrogen at room temperature and pressure until absorption ceased after the uptake of 2 moles in about 2 hours. After the addition of 5 ml of concentrated ammonia to dissolve the product, filtration through paper (Whatman No. 5) gave a yellow solution. After bringing its pH to 7 with glacial acetic acid this solution was filtered through a column of alumina (Woelm, neutral, prewashed with water, 18 mm diam. × 50 mm) and the column washed with water until the Ehrlich reaction of the eluate was faint. The eluate (400 ml) was concentrated to 100 ml in a rotary evaporator (oil pump, baths 25–30° and ice–salt). The concentrate was acidified to pH 4.5 with glacial acetic acid with scratching, quickly cooled, and kept at 0° for 4 hours. The product, after being washed successively with water, ethanol, and ether, formed buff-colored, barrel-shaped

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

plates (3.2 g, 63% as the monohydrate); m.p. 174–177° (decomp., inserting at 167°); Ehrlich reaction rapidly positive cold. Its R_f "in acetic acid" (0.49) and its infrared mull spectrum were identical with those of natural porphobilinogen.

The X-ray powder photograph was identical with that of porphobilinogen synthesized over the lactam (7). Between these photographs and that of natural material there were differences in the relative intensities of 3 lines among 30. These differences are not considered significant because the natural porphobilinogen was photographed only as received, when its infrared mull spectrum showed a gross anomaly, unlike the spectrum of the same material after recrystallization as the hydrochloride and then as the base.

The synthetic porphobilinogen also agreed with natural material in the following respects:* (1) the quantitative Ehrlich reaction; (2) paper electrophoresis at pH 2.4, 4.4, 6.6, and 10.4; (3) the uroporphyrin mixtures (examined by paper chromatography after conversion to coproporphyrins) formed by the self-condensation of the porphobilinogen at various pH's; (4) the enzymic conversion to uroporphyrin.

For analysis it was recrystallized from 0.7 *N* ammonia – glacial acetic acid and dried (20°, 0.01 mm). Calc. for $C_{10}H_{14}O_4N_2.H_2O$: C, 49.17; H, 6.60; N, 11.47. Found: C, 48.88; H, 6.87; N, 11.41.

Porphobilinogen Lactam

This synthetic porphobilinogen was converted into the lactam (52%) by the method of Cookson and Rimington (14) as colorless hexagonal plates, Ehrlich test fast cold.

For analysis it was recrystallized from water (Soxhlet) and dried (20°, 0.01 mm), m.p. 281–283° (decomp., inserted at 270°). It was identical with the lactam from natural porphobilinogen by the following criteria: infrared mull spectrum, X-ray powder photograph, and R_f (0.63 "in acetic acid"). Calc. for $C_{10}H_{12}O_3N_2$: C, 57.68; H, 5.81; N, 13.46. Found: C, 57.43; H, 5.77; N, 13.35.

Porphobilinogen Hydrochloride

This synthetic porphobilinogen was converted into the monohydrate of the hydrochloride (59%) by the method of Cookson and Rimington (14).

For analysis it was recrystallized from 2 *N* hydrochloric acid, dried (2 hours, 20°, 0.01 mm), and then exposed to air overnight to give faintly pink microneedles giving an I.R. mull spectrum and X-ray powder photograph identical with those of the natural hydrochloride. Calc. for $C_{10}H_{14}O_4N_2.HCl.H_2O$: C, 42.78; H, 6.10; N, 9.98; Cl, 12.63. Found: C, 43.01; H, 5.98; N, 9.89; Cl, 12.44.

A *by-product* of the reduction of the oxime Ii to porphobilinogen was initially very troublesome. The formation of this by-product, like that of porphobilinogen, was accompanied by the uptake of 2 moles of hydrogen. The ratio of the two products was independent of the hydrogen pressure but the by-product was favored by higher oxime concentrations and by reduction in dilute ammonia rather than in water. For example, 100 mg of the oxime with the catalyst in 1 ml of 1.5 *N* ammonia (1 atm of hydrogen) gave the by-product and a trace of porphobilinogen; in 25 ml of 0.7 *N* ammonia (1 atm or 120 atm of hydrogen) or in 1 ml of 0.7 *N* acetic acid (1 atm of hydrogen), porphobilinogen and a trace of by-product resulted.

The by-product analyzed much like the porphobilinogen monohydrate, gave a positive Ehrlich test cold, gave uroporphyrins with hot 2 *N* hydrochloric acid, and formed a hydrochloride. However, it gave no lactam by the method of Cookson and Rimington (14)

*We are indebted to Dr. J. J. Scott and to Professor L. Bogorad for the tests with enzymes, and to Dr. D. Mauzerall for the other tests.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and it differed from porphobilinogen in its R_f (0.66 "in acetic acid"), in its X-ray powder photograph, and in the infrared mull spectra of both the base and hydrochloride.

For analysis it was recrystallized from 1.5 *N* ammonia – acetic acid and dried (20°, 1×10^{-4} mm) to give colorless hair-like microcrystals, m.p. 178–181° (decomp., inserted at 166°). Calc. for $C_{10}H_{14}O_5N_2$: C, 49.58; H, 5.83; N, 11.57. Found: C, 49.68; H. 6.31; N, 11.05.

2-(ω-Cyano-ω-carbethoxy-vinyl)-pyrrole-3-acetic acid-4-propionic acid Diethyl Ester (Ethyl Ester of Im)

The ethyl ester of the aldehyde I*h* (the crude oily product from 351 mg of I*h* and ethereal diazoethane) was heated for ½ hour on the steam bath with 200 mg of ethyl cyanoacetate, 5 ml of absolute ethanol, and 2 drops of 25% aqueous methylamine. The crude product, which separated on cooling and scratching, was recrystallized from ethanol, giving 297 mg (51%), m.p. 108–110°.

For analysis it was recrystallized four times from ethanol (80% recovery) and dried (60°, 0.01 mm), giving yellow microneedles; m.p. 111–112° (softening from 105°); Ehrlich's test blue hot; insoluble in cold ethanol. Calc. for $C_{19}H_{24}O_6N_2$: C, 60.62; H, 6.43; N, 7.44. Found: C, 60.91; H, 6.50; N, 7.34.

The acid I*m* was prepared analogously from I*h* using aniline as the catalyst. It formed yellow crystals from ethanol; m.p. 191–194° (decomp., inserted at 180°); soluble in hot acetone; insoluble in refluxing ether. Attempts to esterify it with 5% ethanolic hydrogen chloride and with ethereal diazoethane failed.

2-(ω-Cyano-ω-carbethoxy-vinyl)-5-formylpyrrole-3-acetic acid-4-propionic acid Diethyl Ester (Ethyl Ester of Io)

The ethyl ester of I*m* (247 mg), suspended in 0.428 ml of dimethyl formamide, was treated with 0.070 ml of phosphorous oxychloride (10% excess) and heated to solution on the steam bath, then for 10 minutes longer. Water (15 ml) containing 573 mg of sodium acetate trihydrate was added to the cooled solution. After the mixture was scratched and allowed to stand ½ hour, the brownish-yellow product separated. Its solution in 10 ml of chloroform was filtered through a column of alumina (Woelm neutral grade IV, 8 mm diam. × 20 mm). The residue left on evaporating the eluate was recrystallized from ether – *n*-pentane and then from ethanol–water, giving yellow needles (137 mg, 52%), m.p. 107–109°.

For analysis it was twice recrystallized from ethanol–water (65% recovery) and dried (56°, 5×10^{-4} mm), m.p. 110–111°. Calc. for $C_{20}H_{24}O_7N_2$: C, 59.40; H, 5.98; N, 6.93. Found: C, 59.35; H, 5.79; N, 6.99.

2-Cyanopyrrole-3-acetic acid-4-propionic acid Dimethyl Ester (Methyl Ester of Ik)

The dimethyl ester of I*i* (500 mg, 1.87 mmoles) was warmed to solution in 0.67 ml of dimethyl formamide (previously distilled over phosphorus pentoxide). This solution was shaken vigorously at −15° while 0.19 ml (2.06 mmoles) of phosphorus oxychloride was added slowly, then left at 20° for ¼ hour. The mixture was treated with 1.125 g (8.3 mmoles) of sodium acetate trihydrate in 5 ml of water, diluted to 25 ml with water, and scratched; light brown crystals (394 mg) then separated. These were extracted into 200 ml of ether (Soxhlet, 1 hour), the solution was filtered through a column of Darco (8 mm diam. × 15 mm), and the column was washed with ether. The colorless eluate was concentrated to 10 ml. Crystallization was induced by scratching and completed by evaporating more ether while adding *n*-pentane. The product (344 mg, 74%) formed colorless

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

glittering crystals, Ehrlich test faintly rose hot. It exists in two forms, m.p. 81–83° and 103–106°, either of which might separate from solution or melt and which gave identical infrared mull spectra (nitrile band at 2240 cm^{-1}). The U.V. spectrum in ethanol, λ_{max} at 256 mμ ($\epsilon = 12\times10^3$) and 235 mμ ($\epsilon = 8\times10^3$), with no absorption at 280–290 mμ, showed that the oxime was absent.

For analysis it was twice recrystallized from ether – *n*-pentane (74% recovery) and dried (20°, 0.01 mm), m.p. 80–82° (softening from 75°). Calc. for $C_{12}H_{14}O_4N_2$: C, 57.59; H, 5.64; N, 11.20; OMe, 24.80. Found: C, 57.40; H, 5.62; N, 11.35; OMe, 24.64.

2-Carboxypyrrole-3-acetic acid-4-propionic acid (IIl)

The dimethyl ester of the nitrile I*k* (102 mg) in 4 ml of 10% sodium hydroxide and enough ethanol (about 2 ml) to effect solution was heated on the steam bath for 6 hours while nitrogen was bubbled through it and its volume maintained at 4 ml by the occasional addition of water. The cooled solution was passed through a column of Amberlite IR-120 (wet hydrogen form, 16 g) and the column was washed with water until the eluate gave a negative Ehrlich test cold. The residue left on taking the eluate to dryness in a rotary evaporator (bath at 45°) was extracted by 5×15-ml portions of boiling acetone. The extract was filtered and concentrated to 5 ml, 20 ml of ether was added, and amorphous mauve-colored impurities were filtered off at once. When the filtrate was scratched, the product (55 mg, 56%) crystallized as nearly colorless rectangular plates; m.p. 183–184° (decomp., inserted at 165°), undepressed by authentic material derived from the ester of II*a* (lit. 178° (3)); Ehrlich test quickly bluish-red cold. The R_f "in ammonia" (0.16) was identical with that of authentic material.

2-Carboxypyrrole-3-acetic acid-4-propionic acid Triethyl Ester

The acid (from the ester of I*k*) with diazoethane in ether gave the product as colorless needles; Ehrlich test slowly bluish-red cold; m.p. 51–52.5°, undepressed by authentic material (lit. 51–52° (3)). The two specimens also gave identical infrared mull spectra and X-ray powder photographs.

2-Cyano-5-formylpyrrole-3-acetic acid-4-propionic acid Dimethyl Ester (Ester of In)

The ester of the nitrile I*k* (200 mg, 0.8 mmole) was dissolved in 0.4 ml of dimethyl formamide (previously distilled over phosphorus pentoxide), and 0.1 ml (1.1 mmole) of phosphorus oxychloride was added. The solution was heated for 25 minutes on the steam bath in an open vessel and cooled to 20°, and 592 mg (4.4 mmoles) of sodium acetate trihydrate in 2.5 ml of water was added. The suspended oil crystallized after the solution was scratched. After the volume of the mixture was made up to 8 ml with water, the buff-colored precipitate was filtered off and washed with water. The dried precipitate (134 mg) was dissolved in 125 ml of boiling ether and the cooled solution filtered through a column of Darco (8 mm diam. × 10 mm). The colorless eluate was concentrated to 2 ml, crystallization was induced by scratching, and the product (112 mg, 50%) was filtered off and washed with 1 ml of ether and then with *n*-pentane. It formed colorless plates; m.p. 113–116° (softening from 90°); Ehrlich test slowly brown hot; infrared band at 2255 cm^{-1} in Nujol mull; in ethanol, λ_{max} 294 mμ ($\epsilon = 19\times10^3$). It can be distilled at 160°, 1×10^{-5} mm.

For analysis it was recrystallized from ether and twice dried (20° and 1×10^{-2} mm, then 100° and 1×10^{-3} mm), giving colorless plates, m.p. 113–115°. Calc. for $C_{13}H_{14}O_5N_2$: C, 56.11; H, 5.07; N, 10.07. Found: C, 55.87; H, 4.98; N, 9.99. Specimens dried at 20°, softened from about 100°, and analyzed as a hydrate containing $\frac{1}{3}H_2O$.

2-Carboxy-5-formylpyrrole-3-acetic acid-4-propionic acid (IIc)

(a) From the Triethyl Ester of Ia via the Dimethyl Ester of In

This was carried out before the ester of I*n* had been obtained crystalline. The crude oily ester of I*n* (obtained as above by adding aqueous sodium acetate after reacting the ester of I*k* with dimethyl formamide and phosphorus oxychloride) was hydrolyzed for 6 hours on the steam bath in 10% sodium hydroxide. After passage through Amberlite IR-120 (hydrogen form), the solution was evaporated to dryness. The solution of the residue in acetone was decolorized by filtration through a column of Darco and was then taken to dryness. Adding ether to the residue induced the product to crystallize. This showed a single spot on paper chromatography and gave an infrared mull spectrum, X-ray powder photograph, and R_f ("in ammonia" but descending for 70 hours to ensure the absence of II*l*) identical with those of authentic material obtained ultimately from the ester of II*a* by method (*b*) below.

(b) Preparative Method (from the Triethyl Ester of IIa via the Triethyl Ester of IIc)

The triethyl ester of II*c* (3) (16 g) was hydrolyzed to II*c* just as the ester of I*c* was to I*c*. The crude product (red crystals, 9.36 g) was extracted into acetone and passed through Darco to give 7.34 g (60%) of cream-colored crystals; m.p. 234–238° (decomp., inserted at 225°); Ehrlich test slowly brownish-red cold; R_f "in ammonia" identical with that of I*c*.

For analysis it was recrystallized from acetone (Soxhlet) and then at <50° from water and then dried at 25° and 1×10^{-2} mm to give pink radiating needles. Calc. for $C_{11}H_{11}O_7N$: C, 49.07; H, 4.12; N, 5.20. Found: C, 48.97; H, 4.38; N, 5.14.

2-Formyl-5-iodopyrrole-3-propionic acid-4-acetic acid (IIf)

The preparation of II*f* from 4 g of II*c* followed that of I*f* from I*c*. The buff-colored crystalline crude product (1.89 g), m.p. 221–222° (decomp., introduced at 200°), was twice recrystallized from 110 ml of water. The product (1.46 g, 28%) formed yellow needles; m.p. 221–224° (decomp., iodine evolved, introduced at 200°); Ehrlich test slowly positive cold; R_f "in ammonia" identical with that of I*f*.

For analysis an acetone solution was decolorized by filtration through a small column of Darco. The precipitate, obtained from the eluate by adding hexane, was recrystallized four times from water and dried (56°, 1×10^{-4} mm), giving colorless needles, m.p. 215–220° (decomp., iodine evolved, introduced at 200°). Calc. for $C_{10}H_{10}O_5NI$: C, 34.21; H, 2.87; N, 3.99; I, 36.15. Found: C, 34.35; H, 3.12; N, 3.99; I, 36.24.

2-Formylpyrrole-3-propionic acid-4-acetic acid (IIh)

The iodopyrrole II*f* (500 mg) in 24 ml absolute ethanol was added to 194 mg sodium acetate trihydrate in 16 ml of water, and the solution was shaken for 1 hour under hydrogen (20°, 1 atm) with 125 mg of palladium black. The filtrate and aqueous washings from the catalyst were taken to dryness in a rotary evaporator (bath temp. 45°), then 5 ml of water was twice added and removed in the same way. The residue was extracted into 75 ml of ether (Soxhlet, 6 hours). The residue left on evaporating the ether was dissolved in 15 ml of boiling acetone. This solution was filtered through a column of Darco, the eluate concentrated to 5 ml, and the colorless product (175 mg, 55%) precipitated by the addition of 20 ml of ether.

For analysis it was recrystallized twice from water (56% recovery) and dried (56°, 1×10^{-4} mm) to give colorless needles; m.p. 178–182° (decomp., inserted at 160°); Beilstein test for halogen negative, Ehrlich test rapidly red cold; R_f "in ammonia" identical with that of its isomer I*h*. Calc. for $C_{10}H_{11}O_5N$: C, 53.33; H, 4.92; N, 6.22. Found: C, 53.50; H, 4.82; N, 6.25.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

This preparation could presumably be improved by using the method later developed for I*h*, that is, by washing the crude product with water before extracting into ether.

*2-Formylpyrrole-3-propionic acid-4-acetic acid Oxime (II*i*)*

Hydroxylamine hydrochloride (2 g) was dissolved in 12 ml of water and 8 ml of 10% NaOH added (pH 6–7), then 1 g of the iodopyrrole II*f*. The solution was heated on the steam bath for $1\frac{1}{2}$ hours (gas evolved), cooled to 20°, brought to pH 3 with concentrated hydrochloric acid, and then left overnight at 0°. The precipitate (403 mg) was separated, washed with a little water, then pentane, and dissolved in 4 ml of boiling water. Left at 20° overnight, the solution deposited buff-colored crystals (366 mg, 54%); m.p. 178–180° (decomp., inserted at 160°); Ehrlich test very slowly blue cold; Beilstein halogen test negative. The R_f "in ammonia" (0.33) was exceptional in that it differed from that of the isomeric I*i* (0.29).

For analysis it was recrystallized from water and dried, giving buff-colored crystals, m.p. unchanged. Calc. for $C_{10}H_{12}O_5N_2$: C, 50.00; H, 5.04; N, 11.66. Found: C, 49.76; H, 4.89; N, 11.56.

This product appears to remain in supersaturated aqueous solutions more than does its isomer I*i* and to be more strongly retained on Darco. Paper chromatography indicated that it was the sole product when II*c* was treated as in the conversion of I*c* to I*i* by method (*c*), but the isolation of the II*i* resulting by this method has not been worked out.

*2-Aminomethylpyrrole-3-propionic acid-4-acetic acid (isoporphobilinogen, II*j*)*

The oxime II*i* (125 mg) and 250 mg of palladium black were shaken under hydrogen (20°, 1 atm) with 250 ml of redistilled water until absorption ceased after the uptake of 2 moles in 2 hours. The catalyst was filtered off (Whatman No. 1 paper) and the filtrate concentrated to 20 ml in a rotary evaporator (baths at 30° and 0°). The pink solution, after the pH was brought to 7, was filtered through an alumina column (Woelm, neutral, 8 mm diam. × 20 mm, prewashed with water), which was then washed with water until the eluate gave a very faint Ehrlich test in the cold. The eluate (50 ml) was concentrated in a rotary evaporator (baths at 30° and 0°) to about 0.5 ml. After the addition of 0.7 *N* ammonia, the pH was brought to 4–5 with glacial acetic acid (volume of solution now <2 ml). After the solution was scratched, it was left at 0° for 3 hours. The product (83 mg, 70%) was separated and washed with a little water to give colorless needles; m.p. 192–195° (decomp., inserted at 180°); Ehrlich test rapidly red cold; R_f "in acetic acid" identical with that of porphobilinogen. It was also characterized by its X-ray powder photograph and infrared mull spectrum.

For analysis it was recrystallized from 0.7 *N* ammonia – glacial acetic acid and dried (20°, 0.01 mm). Calc. for $C_{10}H_{14}O_4N_2$: C, 53.09; H, 6.24; N, 12.38. Found: C, 52.92; H, 6.29; N, 11.96.

Isoporphobilinogen Diethyl Ester Hydrochloride

A solution of 51 mg of isoporphobilinogen, II*j*, in 2 ml of 5% hydrogen chloride in ethanol was left at 0° overnight. The colorless solution was taken to dryness *in vacuo* below 20° and 1 ml of ethanol was three times added and removed as above. The product crystallized on adding ether and seeding, giving 66 mg (92%) of colorless needles; m.p. 97–98.5°; Ehrlich test rapidly red cold; soluble in water and in ethanol. It was also characterized by its X-ray powder photograph and infrared mull spectrum.

For analysis it was recrystallized from ethanol–ether (recovery 88%) and dried (20°, 0.01 mm), m.p. 99–100°. Calc. for $C_{14}H_{23}O_4N_2Cl$: C, 52.74; H, 7.27; N, 8.79; Cl, 11.12. Found: C, 52.68; H, 7.24; N, 8.63; Cl, 11.03.

2-Formyl-5-carboxypyrrole-3-propionic acid-4-acetic acid Triethyl Ester Oxime (Ethyl Ester of IId)

Hydroxylamine hydrochloride (122 mg) in 0.6 ml of water was added to 42 mg of sodium in 10 ml of ethanol and the precipitate was filtered off and washed with ethanol. The filtrate and 500 mg of the ester of II*c* (3) were refluxed for $\frac{3}{4}$ hour. The cooled solution was poured into 175 ml of ice water. After being left overnight at 0°, the product (435 mg, 83%) was filtered off and washed with water, leaving colorless needles, m.p. 104–109°.

For analysis it was twice recrystallized from aqueous ethanol (65% recovery) and dried (57°, 1×10^{-4} mm), m.p. 107–112° softening from 103° (lit. (10), 88°). Calc. for $C_{17}H_{24}O_7N_2$: C, 55.43; H, 6.56; N, 7.61. Found: C, 55.31; H, 6.38; N, 7.79.

2-Aminomethyl-5-carboxypyrrole-3-propionic acid-4-acetic acid Triethyl Ester Hydrochloride (Ester Hydrochloride of IIe)

The ethyl ester of II*d* (476 mg) was shaken under hydrogen (20°, 1 atm) with 100 mg of palladium black, 50 ml of absolute ethanol, and 0.25 ml of concentrated hydrochloric acid until the uptake of hydrogen ceased ($3\frac{1}{2}$ hours, 2 moles taken up). The filtered solution was concentrated to 5 ml *in vacuo*, and 50 ml of ether was added. Scratching induced the separation of the product (386 mg, 76%) as colorless crystals; m.p. 147.5–149°; soluble in 2 *N* HCl; Ehrlich reaction positive hot.

For analysis it was recrystallized from ethanol–ether (recovery 93%) and dried *in vacuo* at 90°, m.p. 147.5–149.5°. Calc. for $C_{17}H_{27}O_6N_2Cl$: C, 52.33; H, 6.96; N, 7.17; Cl, 9.07. Found: C, 52.44; H, 6.93; N, 6.99; Cl, 8.73. The m.p. of the free ester has been reported as 185° (10).

Porphobilinogen Lactam Ethyl Ester (III)

Porphobilinogen lactam (100 mg) (7) was left for 5 hours in 8% ethanolic hydrogen chloride at 20°. The solvent was removed *in vacuo*, then more ethanol was added and removed in the same way. When the residue was crystallized from 3 ml of hot ethanol, two crops of the product were obtained as tan irregular plates (66 mg, 58%), m.p. 239–244° (decomp., inserting at 230°). Calc. for $C_{12}H_{16}N_2O_3$: C, 61.00; H, 6.83; N, 11.86. Found: C, 60.99; H, 7.23; N, 12.01. The ester was also prepared from the lactam with diazoethane in ether–ethanol.

5-Aminomethyl-5′-carboxypyrromethane-4,3′-diacetic acid-3,4′-dipropionic acid Lactam Tetraethyl Ester (IV)

The ethyl ester of porphobilinogen lactam (III, 47.6 mg) and the ethyl ester of I*b* (83.7 mg) (15) were heated for 40 minutes on the steam bath with 1.7 ml of anhydrous sodium acetate in acetic acid (100 mg in 10 ml). Water (4 ml) was added slowly and the mixture heated nearly to a clear solution, then cooled slowly. When a few crystals had separated, the volume was brought to 20 ml with hot water. The nearly colorless amorphous product (81 mg, 70%) was separated from the cooled solution. At about 170° it either melted or changed to crystals, m.p. 181–186°.

For analysis it was extracted by ether (thimble) in which it is very slightly soluble, giving colorless microprisms which at 170° sintered and changed to needles, m.p. 185–189° (hot stage). Calc. for $C_{29}H_{39}N_3O_9$: C, 60.72; H, 6.85; N, 7.33; Found: C, 60.93; H, 6.85; N, 7.21.

The assigned structure is consistent with its U.V. spectrum in ethanol: minimum at 254 mμ and $\epsilon = 15.5\times10^3$ at the 281 mμ maximum. Compare the spectrum of the hexaethyl ester of 5,5′-dicarboxypyrromethane-3,3′-diacetic acid-4,4′-dipropionic acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

($\epsilon = 30.8 \times 10^3$ at 283 mμ (maximum); no minimum) and of the ethyl ester of porphobilinogen lactam (no maximum but a rise toward 210 mμ).

Condensation of 5-Carboxyporphobilinogen with Formic Acid

5-Carboxyporphobilinogen (7) (500 mg), Ie, was heated on the steam bath for $\frac{1}{2}$ hour with 5 ml of 98% formic acid and 2.5 ml of hydrogen bromide (30% in acetic acid). The cooled solution was scratched after the addition of 10 ml of acetic acid then kept at 0° for 1 hour. The crystalline product, formulated as V (472 mg, 72%), was washed with acetic acid, then ether, and twice recrystallized from formic acid – acetic acid (1:4). After being dried overnight at 20° *in vacuo* over sodium hydroxide, the product (57% recovery) formed orange microneedles, decomposing on heating. Calc. for $C_{21}H_{29}O_8N_4Br_3$: C, 35.76; H, 4.14; N, 7.95; Br, 34.00. Found: C, 36.07; H, 3.94; N, 7.49; Br, 33.08.

Adding three equivalents of sodium hydroxide to a solution of the hydrobromide in water precipitated yellow plates, which did not analyze for the free base of the pyrromethene; m.p. about 275° (decomp.); Beilstein halogen test negative. Calc. for $C_{21}H_{26}O_8N_4$: C, 54.54; H, 5.67; N, 12.12. Found: C, 52.08; H, 6.26; N, 14.68.

After the hydrobromide was reduced in dilute sodium hydroxide with sodium amalgam, acetic acid precipitated initially colorless crystals which, after recrystallization, did not analyze well for the pyrromethane. Calc. for $C_{21}H_{28}O_8N_4$: C, 54.30; H, 6.08; N, 12.06. For $C_{21}H_{28}O_8N_4.C_2H_4O_2$: C, 52.67; H, 6.15; N, 10.68. Found: C, 52.84; H, 6.30; N, 10.33.

PHOTOLYSIS OF POLYACRYLONITRILE[1]

H. H. G. Jellinek and I. J. Bastien[2]

ABSTRACT

The photolysis of polyacrylonitrile has been investigated in solution (80:20 by weight of ethylene carbonate to propylene carbonate), in powder form, and as a film. Experiments have been carried out in vacuum and in the presence of oxygen. All polymer samples were exposed to ultraviolet light of wavelength 2537 Å. In solution a random chain-scission reaction with a small quantum yield (ca. 10^{-4} main chain bonds broken/quantum absorbed) takes place; at the same time, photochemical reactions occur involving side groups of the polymer chains, as evidenced by the change in the ultraviolet spectra of the polymer solutions. It seems likely that double-bond formation, both conjugated and isolated, and cyclization are responsible for the change in spectra. Infrared spectra do not show any change. Exposed polymer films become cross-linked and exposed powder also cross-links and evolves small molecules, such as nitriles, particularly HCN. Degradation in oxygen suppresses what is believed to be double-bond formation as evidenced by ultraviolet absorption spectra. The photolysis of glutaronitrile as a model substance has also been studied.

INTRODUCTION

Experiments on the photodegradation *in vacuo* of polyacrylonitrile dissolved in a mixture of ethylene carbonate and propylene carbonate (88:20 by weight) and exposed to light of wavelength 2537 Å were presented by Jellinek and Schlueter in a previous paper (1). It was shown that the experimental data could be represented with fair approximation by a random chain-scission process. The small quantum yield which was obtained for the photodegradation is in accord with such a random breakdown process. The rate constants derived on the basis of random degradation were found to be linearly dependent on the incident light intensity.

The present work deals with an extension of the investigation to the photodegradation as a function of polymer concentration, chain length, and history of the polymer samples. In addition, ultraviolet and infrared absorption spectra at various stages of the degradation process have been investigated in detail. The previous results of Jellinek and Schlueter (1) have been re-evaluated by the use of a more appropriate intrinsic viscosity – number-average molecular weight relationship. Further, experiments on the photodegradation of polyacrylonitrile in the form of films and powder and on the production of small molecules during degradation are presented. A model substance, glutaronitrile, has also been investigated.

EXPERIMENTAL

(a) Apparatus

The apparatus was similar to that used previously (1) with only some minor modifications. The irradiations were carried out with a stronger mercury lamp of the same type as employed before. It operated at not more than 600 R.M.S. volts and carried 60 ma instead of 30 ma. Not less than 95% of its light output occurred at 2537 Å. The light source was placed near the reaction vessel, which was located in a thermostat at $25\pm0.05°$ C. The light intensities were appreciably greater than those in the previous experiments and a higher experimental accuracy resulted. The lamp was stabilized by a

[1]*Manuscript received June 7, 1961.*
Contribution from the Department of Chemistry, Essex College, Assumption University of Windsor, Windsor, Ontario.
[2]*National Research Council of Canada Scholarship.*

constant-voltage transformer. The 30-ma lamp used previously was also employed for rate measurements as a function of light intensity.

Ultraviolet absorption spectra were measured on a Beckman spectrophotometer (Model DU) and on a Bausch and Lomb Spectronic 505. Infrared spectra were obtained with a Beckman IR-5.

All polymer solutions were irradiated in cylindrical Ultrasil quartz cells with plane, parallel, polished windows. The solutions were evacuated to 10^{-5} mm Hg or better and sealed off before exposure.

Intrinsic viscosities of the polymer samples were determined in Ostwald–Fenske viscometers. The measurements were carried out at 25±0.05° C. All intrinsic viscosities are expressed in $(g/100\ ml)^{-1}$.

(b) Materials

Polyacrylonitrile samples of number-average molecular weights 99,100, 54,590, and 26,320 were obtained from the Chemstrand Corporation. Their intrinsic viscosities in dimethylformamide and ethylene carbonate – propylene carbonate (80:20 by weight) respectively were $[\eta]_{DMF}$: 2.19, 1.40, 0.81, and $[\eta]_{EPC}$: 1.65, 1.21, 0.78.

The number-average molecular weights were derived from an equation by Cleland and Stockmayer (2) for dimethylformamide solutions: $[\eta]_{DMF} = 0.392\times10^{-3}\ M_n^{0.75}$.

A polymer sample was also prepared in the authors' laboratory. The procedure was as follows.* Acrylonitrile supplied by Eastman Kodak was washed successively with 3 *N* sulphuric acid, 3 *N* sodium carbonate, and water. It was dried with calcium chloride and distilled twice under atmospheric pressure. Ethylene carbonate was used as a solvent for the polymerization and Eastman Kodak azobisisobutyronitrile served as a catalyst. The solution was 0.058 *M* and 0.0135 *M* with respect to monomer and catalyst respectively. The polymerization was carried out under vacuum at a temperature of 60 to 65° C. After 45 minutes, the reaction mixture was poured into well-stirred methanol; the precipitated polymer was filtered off and washed thoroughly with methanol. Subsequently, it was first refluxed with ether (BDH Analar) for about 1 hour and then refluxed, filtered, and washed with methanol. The refluxing with methanol was repeated to ensure that the polymer was properly purified. The polymer sample was then dried to constant weight in a vacuum oven at 40° C. Its intrinsic viscosity in dimethylformamide and the solvent mixture was respectively 0.50 and 0.54, corresponding to a number-average molecular weight of 13,800.

The solvent mixture for the irradiation experiments was the same as that used previously (1): 80:20 by weight of ethylene carbonate to propanediol cyclic carbonate. The purification methods for these compounds were similar to those employed before.

Ethylene carbonate was accepted to be of sufficient purity when an 80:20 mixture by weight of the carbonate with optically pure methanol gave an optical density (1 cm) of less than 0.06 at 2537 Å, measured against distilled water. The melting point of the carbonate after purification was 34–35° C.

The 1,2 propanediol cyclic carbonate was purified by passage through columns of activated charcoal (BDH Norit) mixed with small amounts of adsorption alumina (Fisher).

The resultant 80:20 mixture by weight of the carbonates was dried in vacuum and had an optical density (1 cm) of 0.05 at 2537 Å.

All other materials used in this work were of Analar grade.

**The procedure was supplied by L. H. Peebles, Jr., of the Chemstrand Corporation.*

(c) Re-evaluation of Previous Experimental Results (1)

In the previous work all number-average chain lengths were evaluated by means of an equation obtained by Onyon (4) for dimethylformamide solutions:

$$[\eta]_{DMF} = 1.97\times10^{-3}\, M_n^{0.625}.$$

By measuring also intrinsic viscosities in the ethylene carbonate – propylene carbonate mixture, the following equation could be derived:

$$[\eta]_{EPC} = 8.9\times10^{-3}\, M_n^{0.47}.$$

All number-average chain lengths of the previous work were recalculated using the Cleland–Stockmayer (2) equation:

$$[\eta]_{DMF} = 0.392\times10^{-3}\, M_n^{0.75}.$$

Here again an equation was derived for the solvent mixture based on the above equation:

[1] $$[\eta]_{EPC} = 2.65\times10^{-3}\, M_n^{0.56}.$$

This equation was used for the recalculation of all the chain lengths. This resulted in different degradation rate constants k_{exp} derived from the equation

[2] $$\frac{1}{P_t} - \frac{1}{P_0} = k_{exp}t,$$

which is valid for a random chain-scission (3) process. P_0 and P_t are the number-average chain lengths at the beginning and at time t of the irradiation process, respectively. All subsequent calculations in this work were carried out using equation [1].

The new rate constants, derived from Jellinek and Schlueter's work, plotted against the relative light intensities give now a straight line passing through the origin of the co-ordinate system, as Fig. 1 shows. Previously, the straight line did not pass through the origin of the co-ordinate system. This could not be explained at the time.

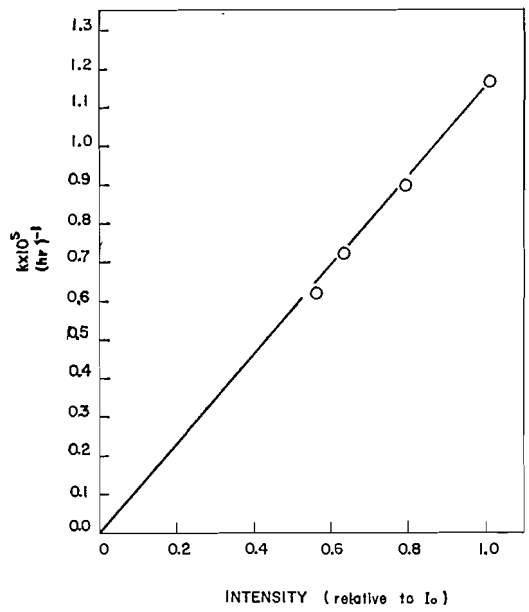

FIG. 1. Experimental rate constants as a function of relative light intensity (re-evaluated data from Jellinek and Schlueter (1)).

(d) Photodegradation as a Function of Polymer Concentration

Figure 2 shows intrinsic viscosities plotted as a function of time of irradiation for all

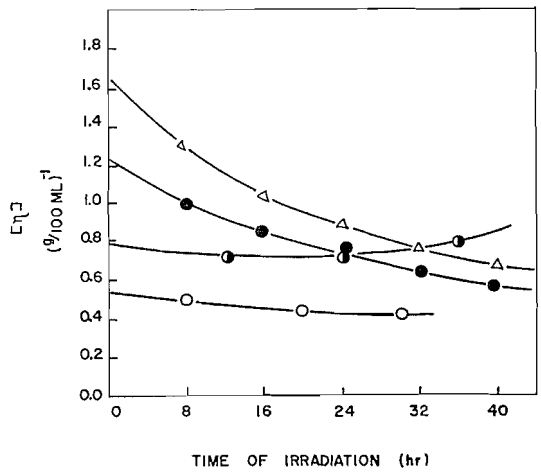

FIG. 2. Intrinsic viscosity as a function of irradiation time. Solutions (0.1% w/v) of PAN in ethylene carbonate – propylene carbonate (80:20 by weight): △ $[\eta]_{EPC,\,0} = 1.65$; ● $[\eta]_{EPC,\,0} = 1.21$; ◑ $[\eta]_{EPC,\,0} = 0.78$; ○ $[\eta]_{EPC,\,0} = 0.54$, homemade sample.

the samples. One sample of intrinsic viscosity $[\eta]_{EPC} = 0.78$ is quite abnormal. Its ultraviolet spectrum also does not agree with those of the other samples. In contrast to the other solutions, solutions of this sample turned distinctly yellow during degradation and showed appreciable fluorescence. This sample apparently cross-links, probably due to impurities. This was not further investigated.

The effect of polymer concentration on degradation was studied with the sample of $[\eta]_{EPC} = 1.21$ over a range of concentrations (0.1%, 0.2%, and 0.4%, w/v). The results are shown in Figs. 3 and 4, where $1/[\eta]_{EPC}$ and $1/P_t - 1/P_0$ respectively are plotted against the time of irradiation. Apparently, the rate is independent of the polymer concentration. The rate constant k_{exp} for equation [2], derived by the least-squares method, is 6.57×10^{-5} hr^{-1}. The number of quanta incident on the reaction vessel for these experiments was 2.58×10^{17} quanta/sec. The reaction vessel had a cross section of 11 cm^2.

(e) Photodegradation as a Function of Initial Polymer Chain Length

Figures 5 and 6 show plots of $1/[\eta]$ and $1/P_t - 1/P_0$ against irradiation time for 0.1% w/v polymer solutions. The rate constants for the two Chemstrand samples, which have similar histories, are quite close, whereas the homemade sample has an appreciably greater rate constant. It is also noteworthy that the $1/[\eta]$ versus t plots are straight lines with identical slopes for all samples. This is not the case when plotting $1/P_t - 1/P_0$ against time. The rate constants are given below.

P_0	$[\eta]_{EPC,\,0}$ ((g/100 ml)$^{-1}$)	$k_{exp} \times 10^5$ (hr^{-1})	$k' \times 10^2$ (100 ml hr^{-1} g^{-1})
1886	1.65	6.05	2.25
1030	1.21	6.57	2.25
252	0.54	9.60	2.25

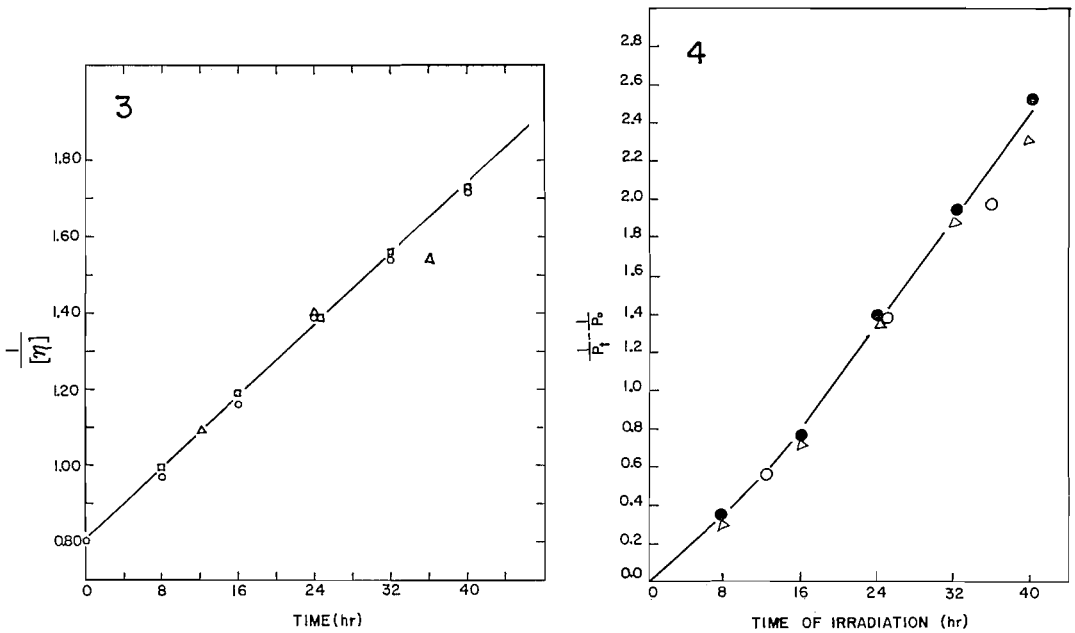

FIG. 3. $1/[\eta]$ as a function of irradiation time for different polymer concentrations (sample of $[\eta]_{EPC,\,0} = 1.21$): ○ 0.1% w/v; □ 0.2% w/v; △ 0.4% w/v in ethylene carbonate – propylene carbonate.

FIG. 4. $1/P_t - 1/P_0$ as a function of polymer concentration (sample of $[\eta]_{EPC,\,0} = 1.21$): △ 0.1% w/v; ● 0.2% w/v; ○ 0.4% w/v in ethylene carbonate – propylene carbonate.

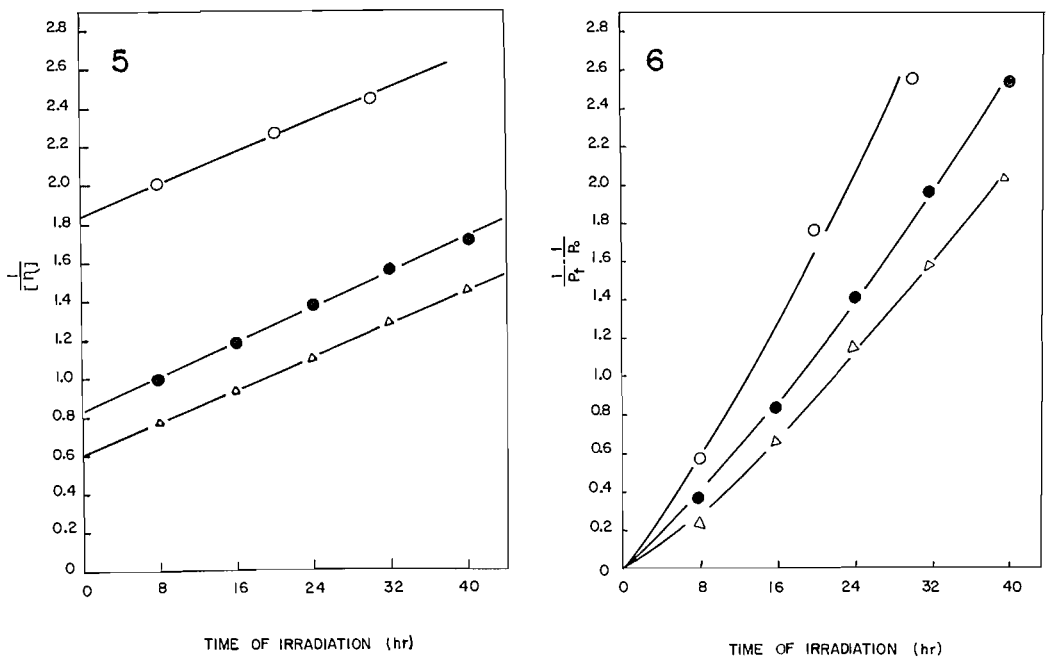

FIG. 5. $1/[\eta]$ as a function of irradiation time for different initial polymer chain lengths (0.1% w/v in ethylene carbonate – propylene carbonate): ○ $[\eta]_{EPC,\,0} = 0.54$, homemade sample; ● $[\eta]_{EPC,0} = 1.21$; △ $[\eta]_{EPC,\,0} = 1.65$.

FIG. 6. $1/P_t - 1/P_0$ as a function of irradiation time for different initial chain lengths (0.1% w/v in ethylene carbonate – propylene carbonate): ○ $[\eta]_{EPC,\,0} = 0.54$, homemade sample; ● $[\eta]_{EPC,\,0} = 1.21$; △ $[\eta]_{EPC,\,0} = 1.65$.

(f) Photodegradation as a Function of Incident Light Intensity

Irradiations were carried out at three incident light intensities on 0.1% w/v solutions of the sample of $[\eta]_{EPC} = 1.21$ (g/100 ml)$^{-1}$. The light intensities were obtained by different positions of the 60-ma lamp and also by employing the 30-ma lamp. The incident intensities were determined in terms of quanta by means of the uranyl actinometer (5). The rate constants obtained at the various intensities were as given below.

Light intensity incident on the 11-cm^2 reaction cell window $\times 10^{-17}$ (quanta/second)	$k_{exp} \times 10^5$ (hr^{-1})
2.58	6.57
1.67	3.92
0.61	1.52

Figure 7 shows that the rate constants are proportional to the first power of the light intensity.

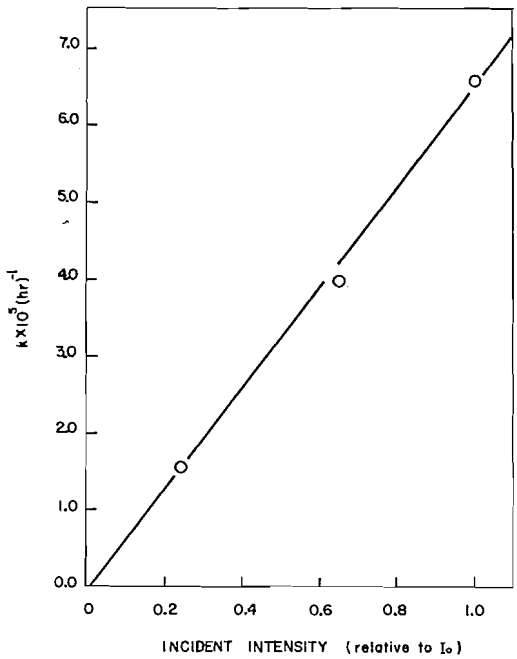

FIG. 7. Experimental rate constants as a function of relative light intensity (0.1% w/v of $[\eta]_{EPC, 0} = 1.21$).

(g) Ultraviolet Absorption Spectra

Figure 8 shows the ultraviolet absorption spectra of the polyacrylonitrile (PAN) sample of $[\eta]_{EPC} = 1.21$ exposed in 0.1% w/v solutions at different stages of the degradation. A pronounced absorption maximum develops at 2950 Å during the irradiation. In Figs. 9 and 10, optical densities at 2537 Å and 2950 Å respectively are given as a function of irradiation time.

Subsequently it was found, using the Bausch and Lomb Spectronic 505, that PAN also has an adsorption maximum at 2160 Å which changes during irradiation. This is shown in Fig. 11.

The homemade sample follows similar changes in its ultraviolet spectra as is the case with the two other samples, as Fig. 12 shows.

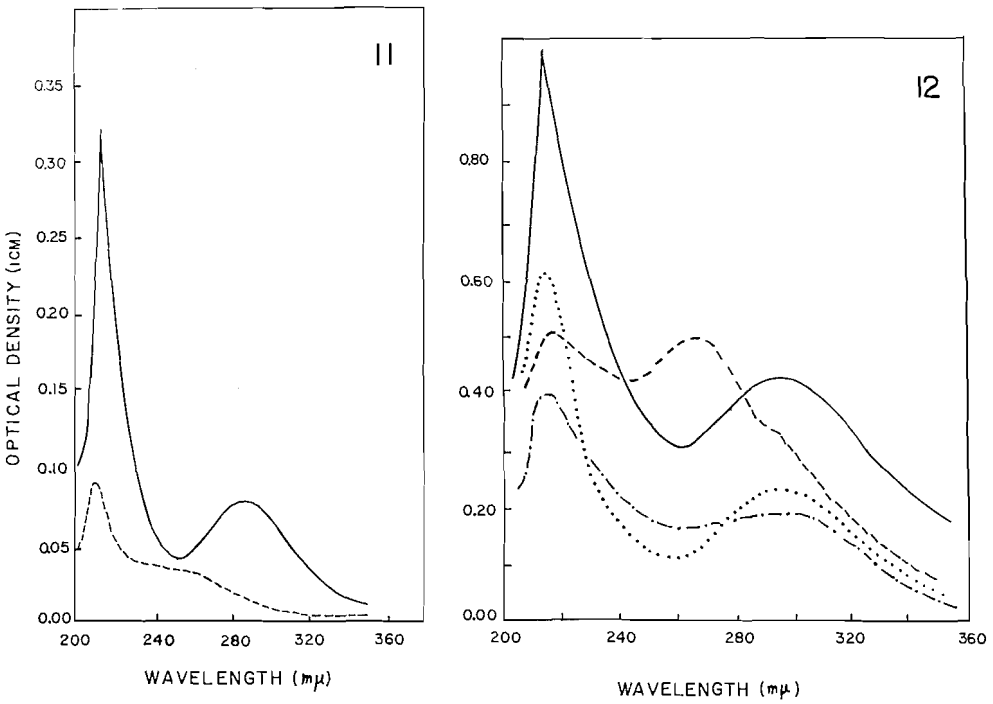

FIG. 11. Optical density (1 cm) of unexposed (– – –) and exposed for 4 hours (——) PAN, $[\eta]_{EPC,\,0} = 1.21$, 0.1% w/v, showing change in absorption at 2160 Å.

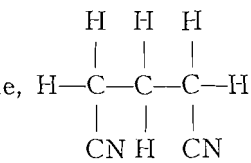
FIG. 12. Absorption spectra of 'homemade' PAN, $[\eta]_{EPC,\,0} = 0.54$, 0.1% w/v, as a function of irradiation time: – – – unexposed; –·– 8 hours; ... 20 hours; —— 30 hours.

(h) Infrared Absorption Spectra

One per cent w/v solutions of PAN of $[\eta]_{EPC} = 1.21$ (g/100 ml)$^{-1}$ were exposed under vacuum for 40 hours. Samples of unexposed and exposed polymer were precipitated from solution by distilled water; the precipitate was washed with water and dried under vacuum. A doublet appeared at 1770 to 1780 cm^{-1}, which could be shown to be due to residual solvent. No other significant changes could be detected.



(i) Oxidative Photodegradation

A 1% w/v solution of PAN ($[\eta]_{EPC} = 1.21$ (g/100 ml)$^{-1}$) was irradiated under vacuum for 16 hours. The solution was diluted to 0.5% w/v, and its ultraviolet absorption spectrum determined. The solution was then saturated with oxygen and exposed again. The absorption spectra at various stages of the irradiation process are shown in Fig. 13.

It is apparent that on irradiation in the presence of oxygen, the maximum at 2950 Å is gradually eliminated, indicating that the group responsible for this maximum is subject to photooxidation.

(j) Photolysis of Glutaronitrile as a Model Substance

One per cent w/v solutions of glutaronitrile,

ture were exposed under vacuum to the ultraviolet light source. Ultraviolet absorption

irradiation. This indicates that changes in the absorption spectra in PAN do not need to be directly related to the chain-scission reaction in the polymer.

(k) Photodegradation of PAN in Bulk and Production of Small Molecules During Irradiation

PAN ($[\eta]_{EPC} = 1.21$ (g/100 ml)$^{-1}$) was degraded in powder form and in the form of films. The powder was irradiated for 4 hours under vacuum; volatile products were collected in a trap cooled by liquid air. On removal of the liquid-air bath and addition of an alcoholic tincture of gum guaiac and 1:1000 $CuSO_4$ solution (6), a dark blue color appeared, indicating the presence of small molecules such as nitriles and ammonia. The product had a distinct smell of HCN. The exposed powder showed a light brown color and was insoluble in dimethylformamide; apparently cross linking had taken place.

PAN films ($[\eta]_{EPC} = 1.21$ (g/100 ml)$^{-1}$) were prepared by evaporating, under vacuum, dilute solutions of PAN in dimethylformamide. The films were dried under vacuum for at least 24 hours. Their thickness was approximately 30 μ. They were exposed to the ultraviolet light source both under vacuum and in the presence of air for about 6 hours. Loss of weight, either by weighing or with a quartz spring, could not be detected. However, for the same time of exposure, the films turned to a yellow color when exposed in air and to a dark brown color in vacuum. The exposed films were insoluble in dimethylformamide. Upon being heated on a steam bath, part of the films dissolved, leaving colored material in suspension.

One per cent w/v solutions exposed under vacuum gave positive tests for small molecules collected in a trap cooled by liquid air.

DISCUSSION

The experimental results agree quite satisfactorily with a random chain-scission process, although the rate constants depend to a certain extent on the history of the polymer. Also reactions other than chain scission take place simultaneously. In a recent note (7), the kinetics for a photodegradation process in solution leading to random chain scission was derived. The theory for films is considered in a different paper (8). It was assumed that the rate of breaking links is directly proportional to the absorbed light intensity, all main chain links being of equal strength. It is further required for a random chain-scission process that an appreciable decrease in the number-average chain length should take place and that the amounts of monomer produced should be negligible (3). Other assumptions made are as follows: (*a*) the absorbed light intensity remains constant during the degradation process, (*b*) Beer–Lambert's law is obeyed and, (*c*) the number of main chain scissions remains small. It was experimentally shown that the polymer solutions obey Beer–Lambert's law; also the number of chain scissions is small in all present experiments. Assumption (*a*) is not fulfilled; the absorption at 2537 Å first decreases and then increases linearly with the extent of degradation. However, this does not necessarily mean that the light absorption with respect to the main chain-scission process does not remain constant. According to the above assumption, the rate of breaking links is given by

$$-\frac{dn}{dt} = k_1 I_{abs}, \qquad [3]$$

where n is the concentration of C—C links in the chain of the polymer (number of links per unit volume) at time t of the irradiation process; k_1, a rate constant; and I_{abs}, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

absorbed light intensity (I_{abs} is the light absorbed per second over the length and 1 cm² of the cross section of the reaction cell). Equation [3] can also be written as

$$-\frac{dn}{dt} = \phi I'_{abs},$$

where ϕ is the quantum yield and I'_{abs} is the average number of quanta absorbed per cm³ per second. Equation [3] leads to (7)

$$[4] \qquad \frac{s}{P_0} = \frac{1}{P_t} - \frac{1}{P_0} = \frac{k_1(1-e^{-k_2 0 n l})I_0 t}{n_0},$$

where P_t and P_0 are the number-average chain lengths at time t and $t = 0$ respectively; I_0, the incident light intensity for each cm²; n_0, the concentration of main chain links at the beginning of the degradation process (as only a small number of links are broken during the degradation process, n_0 is practically constant); s, the average number of links broken in each original chain at time t; k_2, a constant; and l, the length of the reaction vessel. Further, $k_2 = 2.303E/(n_0 l)$, where $E = \log (I_0/I_t)$ is the optical density of the solution and I_t is the transmitted light intensity. For small light absorption, equation [4] reduces to

$$[5] \qquad \frac{s}{P_0} = \frac{1}{P_t} - \frac{1}{P_0} = k_1 k_2 l I_0 t = \phi k_2 I_0 t = \phi \frac{2.303E}{n_0 l} I_0 t,$$

where $\phi = k_1 l$ is the quantum yield given by

$$\phi = \frac{\text{number of main chain links broken in the system}}{\text{number of quanta absorbed by the system}}.$$

Equation [5] shows that for small light absorption, s/P_0 should be independent of initial chain length and polymer concentration and directly proportional to the incident light intensity. Hence $1/P_t$ plotted against time of irradiation should give straight lines, which is approximately the case (see Figs. 4 and 6). The rate constants $k_{exp} = k_1 k_2 l I_0$ should be independent of polymer concentration and initial chain length. This is true as far as the dependence on concentration is concerned (see Fig. 4); however, k_{exp} with respect to the initial polymer chain length seems also to be dependent on the history of the polymer. The condition that k_{exp} is directly proportional to the light intensity is very well fulfilled (see Fig. 7).

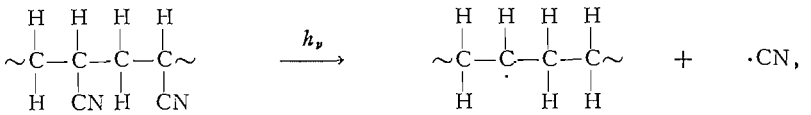
In the previous work (1), the quantum yield was found to be $\phi = 7.7 \times 10^{-4}$ main chain bonds broken for each quantum absorbed. In the present work, the quantum yield was calculated from equation [5] for one of the experiments (0.1% w/v of polymer of $[\eta]_{EPC} = 1.21$, $k_{exp} = 6.57 \times 10^{-5}$ hr^{-1}). The optical density was averaged for a 40-hour period of irradiation, assuming a straight-line relationship between the optical density at 2537 Å and the time of irradiation. The quantum yield in this case is 0.84×10^{-4} main chain bonds broken per quantum absorbed. This value is of the same magnitude as that obtained previously and is in accord with a random chain-scission process. Quantum yields for other polymers (9) are of similar magnitude except for polymethylmethacrylate which is known to follow a depolymerization process (10).

The small curvature in the $1/P_t$ versus time curves may be due to a number of reasons:

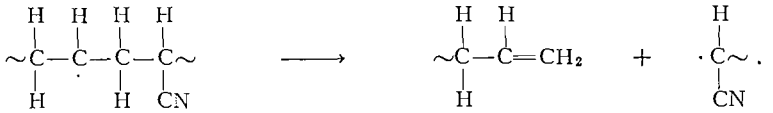
(*a*) The intrinsic viscosity – number-average molecular weight relationship may not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

be quite correct; an increase in the exponent of M_n in the relationship would straighten the curves. This is indicated by the fact that straight lines are obtained when $1/[\eta]_{EPC}$ is plotted against the time of irradiation (see Figs. 3 and 5).

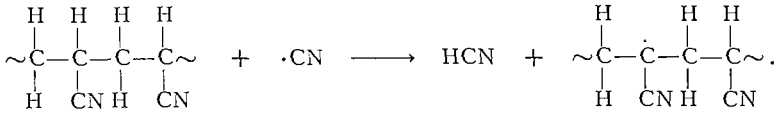


(*b*) The molecular-size distributions change during degradation, which may affect the parameters in the intrinsic viscosity – number-average molecular weight relationship.



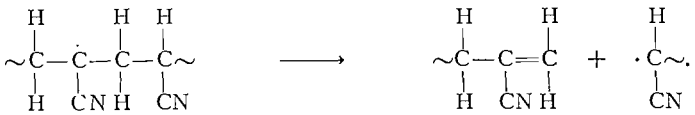
(*c*) The absorbed light intensity does not remain constant during irradiation.

It seems unlikely that the change in absorbed light intensity is the cause of the curvature in the $1/P_t$ versus time curves. Especially during the first 8 hours, a very pronounced change in absorption takes place at 2537 Å, which is not reflected in these curves (see Figs. 4 and 6). It is likely that the change in absorption spectra has nothing or very little to do with the chain-scission reaction. This is supported by the fact that the absorption spectrum for glutaronitrile changes in a way similar to that of the polymer during irradiation. Thus it is probable that this change in the spectra is mainly due to reactions at the nitrile groups leading to formation of other groups, which then cause the change in the absorption spectra. It appears, therefore, that the light absorption related to the chain-scission process remains reasonably constant, while absorption connected with other photochemical reactions changes appreciably. The most likely explanation for the curvature in the $1/P_t$ versus t curves seems, therefore, to be that the intrinsic viscosity – number-average molecular weight relationship is not quite appropriate for the samples employed in this work.



Tentative suggestions as to the reactions involved in the chain-scission process were presented in the previous paper. These reactions can now be elaborated in more detail on the basis of the additional information gained in this work. However, it must be kept in mind that any of the proposed reactions are speculative.

Chain scission may be brought about by the following reactions:

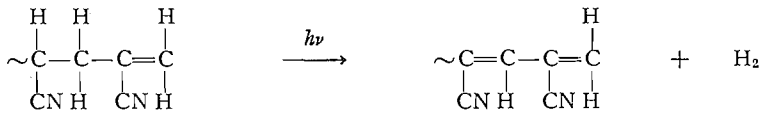


[1] 

[2] 

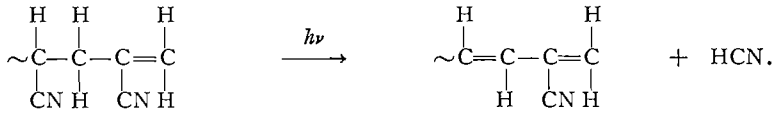
The ·CN radical could react with an α-hydrogen atom,

[3] 



Reaction [3] may be followed by another chain scission,

[4] 

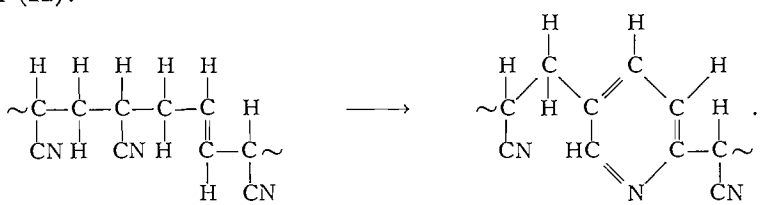


The terminal double bond may give rise to the increase of the absorption maximum at 2160 Å.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Two other reactions may take place, not leading to chain scission but producing small molecules:

[5] 



and

[6] 

Such conjugated systems may give rise to the absorption at 2950 Å.

A reaction in which HCN was produced was postulated by Straus and Madorsky (11) for the thermal degradation.

After removal of HCN, cyclization may also occur. This has been formulated by Kobayashi (12):

[7] 

Such substituted pyridines absorb in the 3000-Å region.

In summary, it may be stated that photodegradation of polyacrylonitrile in solution follows a random chain-scission process, although other photochemical reactions also occur at the same time. As a matter of fact, these side reactions are really more extensive than the chain-scission reaction from a chemical point of view, but the scission reaction is more prominent as it affects the molecular weight of the polymer so drastically. Exposure in bulk leads to cross linking and production of small molecules such as HCN.

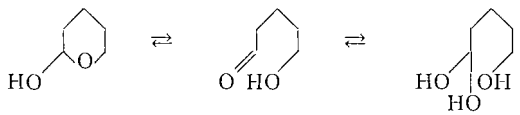
STEREOCHEMICAL STUDIES



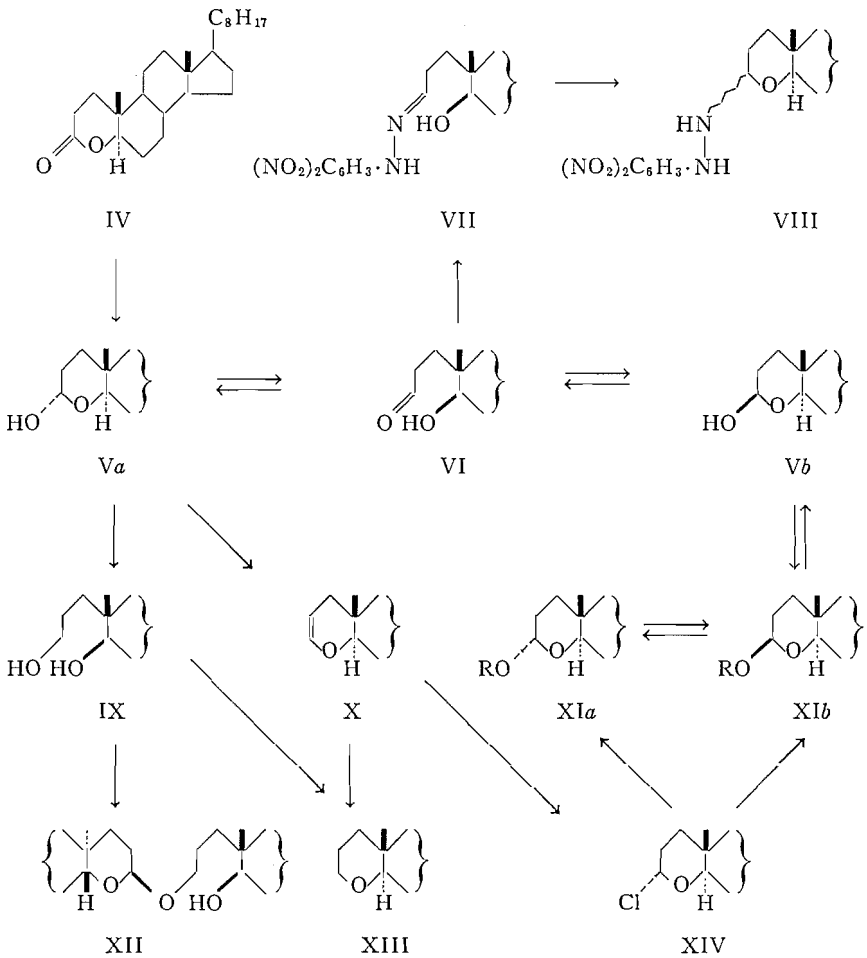
III. REACTIONS OF 4-OXA-5α-CHOLESTAN-3α-OL, A CARBOHYDRATE MODEL[1]

J. T. EDWARD, P. F. MORAND,[2] AND I. PUSKAS[2]

ABSTRACT

4-Oxa-5α-cholestan-3α-ol was prepared by reduction of 4-oxa-5α-cholestan-3-one with lithium aluminum hydride. It showed several typical carbohydrate reactions, such as mutarotation in aqueous tetrahydrofuran and condensation with alcohols in the presence of hydrogen chloride to give 3-alkoxy-4-oxa-5α-cholestanes. These compounds were also prepared by the reaction of alcohols with 3α-chloro-4-oxa-5α-cholestane in the presence of base. Factors governing the proportions of 3α and 3β isomers formed in these reactions are discussed.

The study of the pyranose ring system in simple compounds (e.g. I), devoid of the many hydroxyl groups and asymmetric carbon atoms of the common sugars, has attracted some interest (1, 2, 3, 4). Hurd and Saunders (5) showed that tetrahydropyran-2-ol (I) (6) in 75% aqueous dioxan had an ultraviolet absorption peak at 287 mμ, indicating the presence of the open-chain tautomer, 5-hydroxypentanal (II). From a comparison of the intensity of this peak with that of 5-methoxypentanal, they estimated that 5-hydroxypentanal made up 6% of the equilibrium mixture. They assumed the remaining 94% to be entirely in the lactol form I, but it is likely that about 2–3% is present as the hydrated aldehyde III (7, 8).



I II III

Substitution of the lactol stabilizes it with respect to the open-chain tautomer, which at equilibrium is present to only a very minor extent in solutions of the common pentoses and hexoses (9), perhaps because of conformational effects (10).

There appear to be advantages in studying the reactions of the lactol fused to a rigid polycyclic system, as in V. The use of optically active compounds makes it possible to determine the stereochemical course of reactions from the optical rotations of products, while the interpretation of results is simplified by the fact that the pyranose ring is locked into the C-1 conformation, the more stable conformation of glucose and many other pyranoses (11).

To obtain the desired lactol (V), 4-oxa-5α-cholestan-3-one (IV) (12, 13) in tetrahydrofuran was reduced with one-quarter of a mole of lithium aluminum hydride (14). A crystalline product, $C_{26}H_{46}O_2$, was obtained which possessed a potential carbonyl group, as shown by its reaction with 2,4-dinitrophenylhydrazine to form a derivative, $C_{32}H_{50}O_6N_4$. The infrared spectrum of this derivative had no hydroxyl peak, indicating that it had the cyclic structure VIII rather than the structure VII. Such cyclic structures have been postulated for the phenylhydrazones of some pyranoses, although the evidence for them is equivocal (15).

[1]*Manuscript received June 5, 1961.*
Contribution from the Department of Chemistry, McGill University, Montreal, Que.
[2]*Holders of N.R.C. Studentships, 1957–59 (P. F. M.), and 1959–61 (I. P.).*

The reduction product itself is also in a cyclic form (V), since no carbonyl peak characteristic of the hydroxyaldehyde VI could be detected in the ultraviolet absorption spectrum of the compound in 90% aqueous dioxan or 85–90% aqueous tetrahydrofuran, or in the infrared absorption spectrum of the compound as a solid or in solution in chloroform, carbon tetrachloride, or tetrahydrofuran. Evidently fusing the lactol I to the rigid BCD ring system of cholesterol stabilizes the cyclic form.

The α-configuration (V*a*) of the 3-hydroxyl group of the crystalline lactone V is shown by the molecular rotation of the lactol, given in Table I along with the values calculated for the 3α (V*a*) and 3β (V*b*) compounds (using the known value for the parent compound (XIII)) by the elegant and powerful method of Brewster (16). Calculation by Whiffen's method (17) gives almost the same values; however, Whiffen's parameters are considered to be slightly less reliable in the present application, since for the most part they are derived from rotations of compounds dissolved in water rather than in organic solvents. The effect of solvent on rotation, not taken in account in Whiffen's or Brewster's treatments, is appreciable for our compounds (cf. Table I), but not so large as to invalidate the use of these treatments for assigning configurations.

‡Calculated from the average increment in molecular rotation (+191° and −191°) in forming α- and β-benzyl-D-glycosides from the respective anomers (19).

While the optical rotation of the lactol V*a* dissolved in chloroform, carbon tetrachloride, or tetrahydrofuran showed no change on standing, it dropped rapidly for solutions in 85–90% aqueous tetrahydrofuran (Fig. 1), and with 1% hydrochloric acid

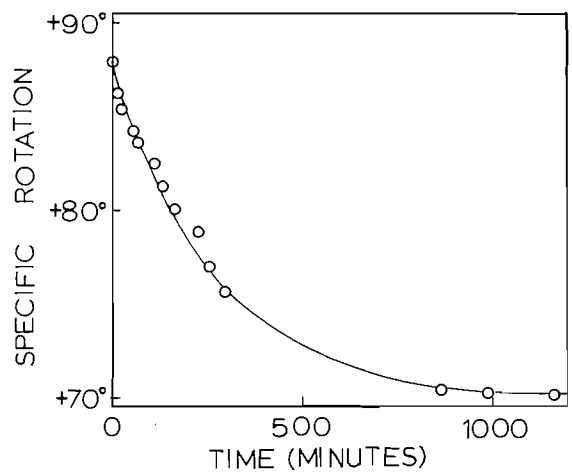

FIG. 1. Change in specific rotation of 4-oxa-5α-cholestan-3α-ol in 90% aqueous tetrahydrofuran (v/v) at 21° C. Theoretical curve for a first-order reaction having a rate constant of 0.0038 min^{-1} (natural logarithms).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

in this solvent it had dropped to a steady value in less than 5 minutes. This change in rotation indicated the formation of the β isomer V*b*; such mutarotation is known to be catalyzed by acid (20). Assuming for the 3β isomer V*b* the molecular rotation shown in Table I, the lactol in 90% aqueous tetrahydrofuran is made up of 55% of the α isomer and 45% of the β isomer. However, all attempts to isolate the β isomer by crystallization from different solvents failed, only the α isomer being obtained.

Treatment of the lactol V*a* with hot acetic anhydride – sodium acetate gave 4-oxa-5α-cholest-2-ene (X), more conveniently prepared by the action of phosphorus oxychloride in pyridine. The acetate (XI, R = CH_3CO) could be prepared by the action of acetic anhydride in pyridine at 20° C, but proved reactive and difficult to purify; attempts to crystallize it from methanol afforded 3α-methoxy-4-oxa-5α-cholestane (XI*a*, R = Me), described below. Hydrogenation of the unsaturated ether X gave 4-oxa-5α-cholestane (XIII), previously obtained by dehydration of the diol IX (13).

Like dihydropyran (21), 4-oxa-5α-cholest-2-ene (X) in ether added hydrogen chloride to give a reactive chloro ether, which in the present instance must be 3α-chloro-4-oxa-5α-cholestane (XIV). This addition reaction may be reversible, like that of dihydropyran (21), because infrared studies showed the chloro ether always to be contaminated with small amounts of the unsaturated ether X, and attempts to purify it by crystallization from inert solvents always led to a drop in melting point. However, when a solution of the chloro ether in carbon tetrachloride ($[\alpha]_D$ +153°), shown by quantitative infrared measurements to contain 4% of the unsaturated ether, was saturated with hydrogen chloride, the specific rotation rose to +163° and the infrared peaks due to the unsaturated ether disappeared. The molecular rotations recorded in Table I for this compound are all for solutions saturated with hydrogen chloride.

The α-configuration at the 3-position of the chloro ether is probable from its molecular rotation (Table I). The molecular rotation of 3β-chloro-4-oxa-5α-cholestane should, according to the treatments of Whiffen and Brewster, be about the same as that of the parent compound (XIII); the molecular rotation of the 3α-chloro compound should be different, but the parameters which enable one to calculate it are not available. However, it is evident from Table II that the introduction of an α-chlorine atom at the 1-position

TABLE II

Molecular rotation values $[M]_D$ (deg) of sugar derivatives

of a pyranose ring in the C-1 conformation (11) causes a shift in molecular rotation of about +500°, the nature and configuration of the adjoining asymmetric center having a comparatively minor effect, so that the molecular rotation of 3α-chloro-4-oxa-5α-cholestane (XIV) should be about +686°, in good agreement with the values found for our chloro ether.

This argument by itself cannot be considered completely conclusive because the

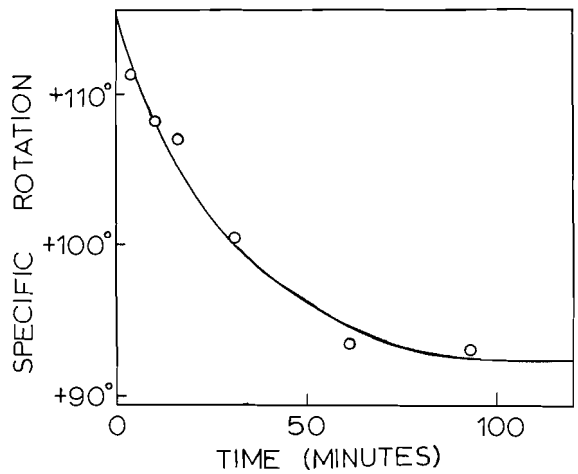
evidence for the configurations assigned to the glycosyl halides is generally indirect and dependent on an interpretation of the stereochemical course of reactions (30). However, the configurations assigned to the stable glycosyl halides (30) and to 3α-chloro-4-oxa-5α-cholestane are those to be expected from the "anomeric effect" (31, 32, 33), discussed further below, which predicts that in dihydropyran rings a halogen atom on the carbon atom adjacent to the ring oxygen will be more stable in the axial orientation.

The lactol V*a* in methanol containing 3% hydrogen chloride gave an 88% yield of a crystalline methoxy derivative, shown by its rotation (Table I) to be 3α-methoxy-4-oxa-5α-cholestane (XI*a*, R = Me). This compound was stable in alkaline solution, but in aqueous acid was readily hydrolyzed to the lactol. Second crops from the preparation of the ether (XI*a*, R = Me), when obtained by rapid evaporation of the solvent at a low temperature (i.e. under non-equilibrating conditions (see below)), had a shoulder at 1068 cm^{-1}, absent in the infrared spectrum of the pure 3α isomer, which is probably due to the 3β isomer (XI*b*, R = Me). However, the latter could not be isolated in a pure state.

A solution of 3α-methoxy-4-oxa-5α-cholestane in methanol–tetrahydrofuran (1:1, v/v) having a low concentration (0.018 *M*) of hydrogen chloride showed a rapid drop in rotation (Fig. 2); with a 0.06 *M* concentration of hydrogen chloride the rotational drop



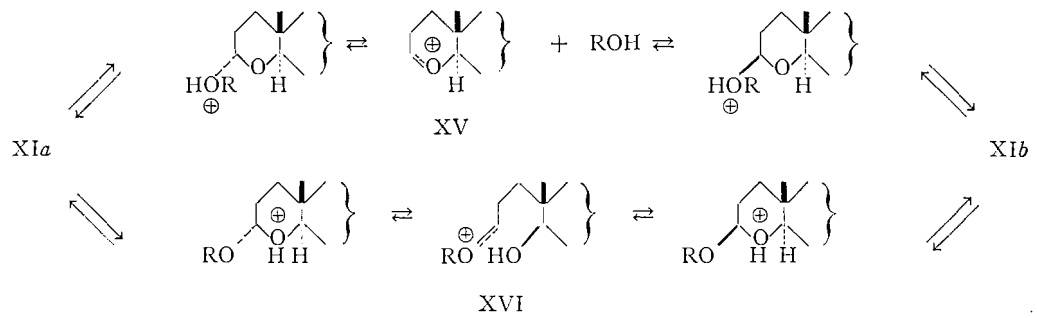


FIG. 2. Change in specific rotation of 3α-methoxy-4-oxa-5α-cholestane in tetrahydrofuran–methanol (1:1, v/v), 0.018 *M* with respect to hydrochloric acid, at 23° C. Theoretical curve for a first-order reaction having a rate constant of 0.040 min^{-1}.

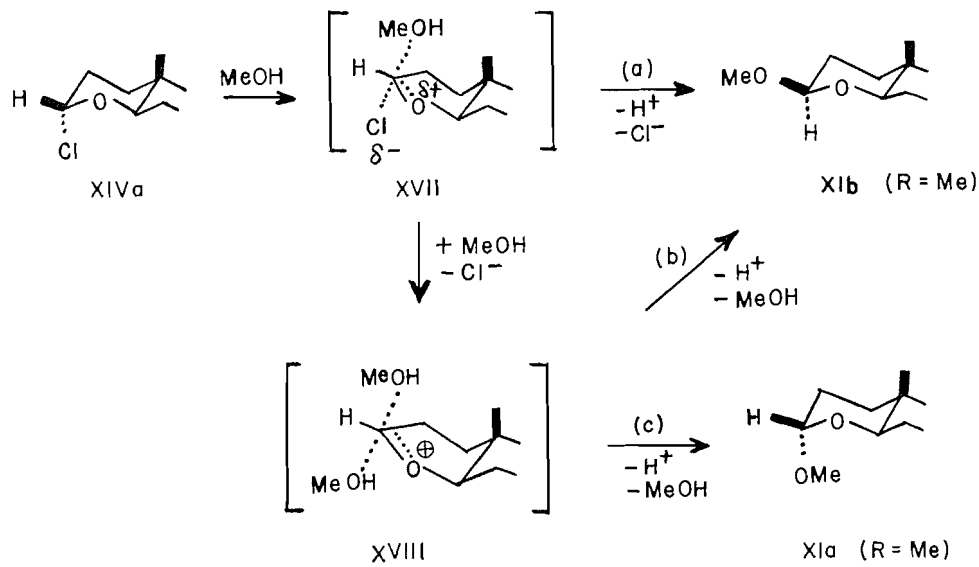
was too fast to be measured. The solid recovered from the neutralized solution after equilibrium had been reached showed again a shoulder at 1068 cm^{-1}. These changes can be due only to the partial isomerization of the 3α (XI*a*, R = Me) to 3β (XI*b*, R = Me) compound. In methanol containing an acid these compounds would be expected to be in equilibrium via the intermediate cyclic (XV) (31) or acyclic carboxonium ion (XVI) (34).



Accepting the calculated value (Table I) for the optical rotation of the 3β isomer, the change in rotation indicates a 24% conversion of the 3α to the 3β isomer.

The rate of this isomerization is considerably faster than that of α-methyl-2-deoxy-D-galactopyranoside (35), which in turn is faster than that of α-methyl-D-galactopyranoside (36). A progressive decrease in rate with the introduction of electron-attracting

groups is expected because of their effect in decreasing the basicity of the acetal oxygen, and hence the concentration of protonated intermediate, and also because of their effect in decreasing the stability, and hence probably the rate of formation, of the intermediate carboxonium ion (37, 38).

In an attempt to obtain a mixture rich in 3β-methoxy-4-oxa-5α-cholestane (XI*b*, R = Me), from which it might be isolated, the chloro ether XIV was solvolyzed in methanol containing methoxide ion or pyridine to neutralize the acid formed. With pyranosyl chlorides derived from methylated or acetylated sugars, such reactions take place with predominant inversion (30, 39, 40), provided that neighboring groups do not participate (41), and provided that steric hindrance to the entering group is not excessive (40). However, in the present instance the 3α-methoxy compound was the chief product, and no 3β-methoxy compound could be isolated, although its presence was indicated by a strong peak at 1068 cm^{-1}. The displacement of chlorine consequently takes place mainly with retention of configuration at the 3-position. The solvolysis of such a chloride in methanol is known to take place by an S_N1 mechanism (39, 40, 42, 43) and probably gives the solvated ion pair XVII (44). This ion pair would be more stable than the ion pairs formed from the chlorides of pyranose sugar derivatives because of the inductive effects of the many oxygen functions of the latter. Consequently, it would be relatively long lived, and not constrained to give an inverted product (XI*b*,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

R = Me) by reacting with methanol before the chloride ion had diffused away (route (*a*)). The reaction of the symmetrically solvated carboxonium ion XVIII might seem equally likely to give the 3β (route (*b*)) and 3α product (route (*c*)); the preference for the latter probably arises from the steric effect of the angular methyl group at the 10-position, which generally favors the formation of α-substituted products in rings A and B of steroids (45). Very recently, Rhind-Tutt and Vernon (40) have observed a similar effect in the solvolysis of 2,3,4,6-tetra-*O*-methyl-α-D-mannopyranosyl chloride in methanol, which proceeded with 41–43% retention of configuration, while the corresponding glucose derivative gave almost complete inversion. This was attributed to steric hindrance in the mannopyranosyl chloride by the axial methoxyl group on the carbon adjacent to the reacting center, a far more severe hindrance than that offered by the angular methyl group of the chloro ether XIV. The fact that, even so, 57–59% inversion occurs in solvolysis of the mannopyranosyl chloride may be explained by the inductive effect mentioned above.*

Reaction of 3α-chloro-4-oxa-5α-cholestane with methanol in the presence of silver carbonate again gave mainly the 3α-methoxy compound, although under these conditions glycosyl halides generally give β-methoxy derivatives (46).

The reaction of 4-oxa-5α-cholestan-3α-ol with benzyl alcohol containing 3% hydrogen chloride gave a syrup from which was obtained, by chromatography on basic alumina (activity grade III), two compounds having the analysis and ultraviolet absorption spectra expected for the benzyl ethers (XI*a* and XI*b*, R = CH_2Ph). Their optical rotations (Table I) indicated one to be the 3α isomer (XI*a*, R = CH_2Ph) and the second to be the 3β isomer (XI*b*, R = CH_2Ph).

In a 0.005 *M* solution of hydrogen chloride in tetrahydrofuran – benzyl alcohol (2:3, v/v) both the 3α ($[\alpha]_D$ +91°) and 3β ($[\alpha]_D$ −4°) isomer underwent mutarotation to give a solution having $[\alpha]_D$ +66° (Fig. 3), and hence containing about 73% of the α and

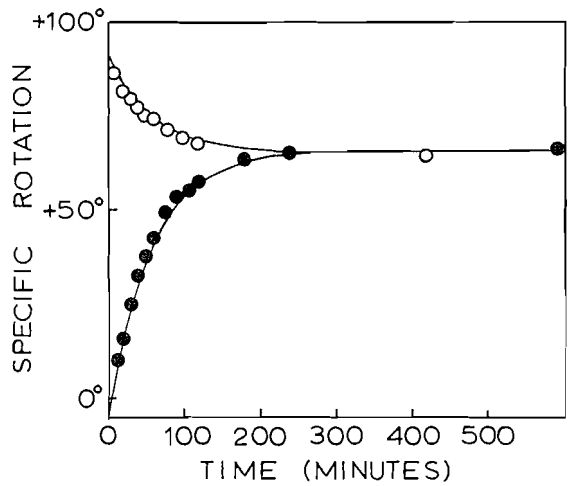

FIG. 3. Change in specific rotation of 3α- (○) and 3β-benzyloxy-4-oxa-5α-cholestane (●) in a 0.0032 *M* solution of hydrogen chloride in absolute tetrahydrofuran – benzyl alcohol (2:3, v/v) at 22.5° ± 0.5°C. Theoretical curves for first-order reactions having a rate constant of 0.0018 min^{-1}.

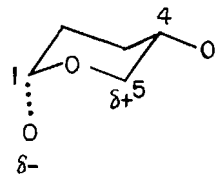
**Rhind-Tutt and Vernon (40) have claimed that the comparative unreactivity of pyranosyl chlorides derived from hexoses, as compared with simple α-chloro ethers, argues against a half-chair form of the carboxonium ion (31) being generated in solvolysis, with the positive charge localized chiefly on the oxygen. Such an argument ignores the inductive effects operating in derivatives of sugars.*

27% of the β isomer. This interpretation of the rotational changes was confirmed by starting with the pure 3α ether and isolating, after equilibration, 68% of the α and 12% of the β isomer. An attempt was made to catalyze this isomerization also by titanium tetrachloride in carbon tetrachloride, under conditions found successful for some carbohydrate derivatives (29). However, the only crystalline product to be isolated was 4-oxa-5α-cholestan-3α-ol (V*a*), probably formed from 3α-chloro-4-oxa-5α-cholestane when the mixture was treated with water at the end of the reaction.

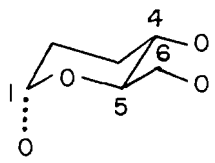
Reaction of 3α-chloro-4-oxa-5α-cholestane (XIV) with benzyl alcohol in the presence of sodium acetate afforded the 3α and 3β benzyl ethers, isolated in 68% and 9% yields respectively. This is a further example of the solvolysis of the chloro ether proceeding mainly with retention of configuration at the 3-position.

While the benzyl ethers (XI*a* and XI*b*, R = CH_2Ph) would be expected to be fairly stable; in fact, on neutral and basic alumina of activity grade I, decomposition to 4-oxa-5α-cholest-2-ene (X) and 4-oxa-5α-cholestan-3α-ol (V*a*) took place. Consequently, all chromatographic separations were carried out with basic alumina, activity grade III, and even with this adsorbent there was evidence of slight decomposition.



In Table III are summarized the results of the equilibrations of the 3-substituted

TABLE III



Thermodynamic constants for equilibrations of 3-substituted 4-oxa-5α-cholestanes at 22°±1° C

3-Substituent	Solvent	K	$-\Delta F_{obs}$ (cal/mole)	$-\Delta F_{calc}$ (cal/mole)
OH	Tetrahydrofuran–water (9:1, v/v)	1.2	110	170
OMe	Tetrahydrofuran–methanol (1:1, v/v)	3.1	670	710
OCH_2Ph	Tetrahydrofuran – benzyl alcohol (3:2, v/v)	2.7	590	710

4-oxa-5α-cholestanes expressed as equilibrium constants K (concentration of 3α isomer/concentration of 3β isomer). It is evident that in all cases the axial α isomer is more stable than the equatorial β isomer. This reversal of the usual order of stabilities found in cyclohexane derivatives is undoubtedly due to the ring oxygen, and has been variously explained (31, 32, 33). The most convincing explanation is due to Lemieux and Chu (32, 33), who showed that a consideration of bond lengths, bond angles, and dipoles in the structures XIX and XX indicated an attraction between C-5 and the anomeric oxygen (termed the "anomeric effect") large enough to overcome the steric repulsions from axial hydrogen atoms and hence to favor an axial orientation for the anomeric oxygen atom.

XIX

XX

Also shown in Table III are the free energy differences (ΔF_{obs}) between the 3α and 3β isomers given by the relation $\Delta F = -RT \ln K$. With some isomerizations and conformational changes such free energy differences have been successfully calculated by

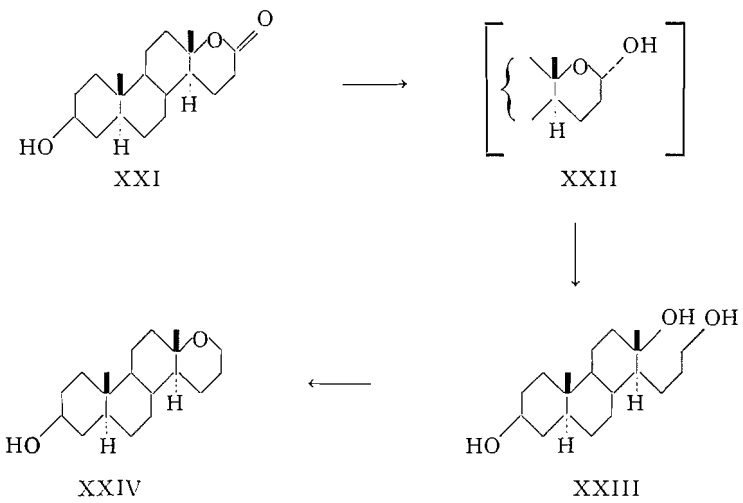
additions of terms due to differences in non-bonded interactions in the two isomers (32, 33, 47) or conformers (48). In fact, the repulsion energies giving rise to these non-bonded interaction terms should affect only the enthalpy and not the entropy component of the free energy (49). However, Lemieux and Chu (32, 33) give reasons for believing that the entropy difference is negligible for the anomers of aldopentopyranose tetra-acetates and aldohexopyranose pentaacetates, and this may be true also for the isomeric forms of the ethers (XI, R = Me and CH_2Ph). It is less obviously true for the isomeric forms of the lactol V, as shown by the work of Kabayama, Patterson, and Piche (50) on the entropy differences between α and β forms of pyranose sugars in aqueous solution; however, their interpretation of these differences stresses the importance of the quasi-crystalline structure of water, and it is possible that the differences become less in organic solvents.



Lemieux and Chu (32, 33) found the free energies of sugar acetates to be additive functions of the following terms (among others): steric repulsion between axial hydrogen and axial oxygen, 180 cal/mole; anomeric effect for pentopyranose derivatives (XIX), 1290 cal/mole; anomeric effect for hexopyranose derivatives (XX), 1510 cal/mole. The first value seemed to be reasonably independent of the nature of the non-aqueous solvent (33), and is adopted here for the methyl and benzyl ethers (XI, R = Me and CH_2Ph), together with a value of 1070 cal/mole for the anomeric effect in these compounds. This latter value is derived on the assumption that the effect is due to the positive charge at C-5 caused by the ring oxygen atom. Addition of another oxygen atom at C-4 should increase the positive charge in the pentose derivatives XIX and give an anomeric effect of $1070+220 = 1290$ cal/mole, while addition of two oxygen atoms, at C-4 and C-6, should give an anomeric effect of $1070+2\times220 = 1510$ cal/mole in the hexose derivatives XX, on the assumption that the inductive effects of the C-4 and C-6 oxygens are the same, and that those of the C-2 and C-3 oxygens may be ignored. The free energy differences between α and β ethers (XI, R = Me and CH_2Ph) calculated using these terms are in reasonable agreement with the values found (Table III).

Chiurdoglu and Masschelein (51) have recently shown that the free energy of the axial hydroxyl – axial hydrogen interaction in cyclohexanol is 150–180 cal/mole, about the same as Lemieux and Chu's value for the axial acetoxyl – axial hydrogen interaction, and independent of the nature of the solvent. However, the most powerful hydrogen-donor solvent investigated by Chiurdoglu and Masschelein was chloroform. There is some evidence that the free energy of the axial hydroxyl – axial hydrogen interaction becomes considerably greater in aqueous or alcoholic solvents (33, 47), and Angyal and McHugh (48) calculated for it a value of 450 cal/mole from studies of the equilibria between cyclitols and their borate complexes in aqueous solution. The free energy difference between α and β forms of the lactol V calculated with this value and a value of 1070 cal/mole for the anomeric effect is again in reasonable agreement with the observed value (Table III), although this agreement may be fortuitous because of neglect of the entropy change.

While the reduction of the lactone IV with 0.25 mole of lithium aluminum hydride gave the lactol V*a*, with 1.2 mole of hydride it gave the diol IX (13), also obtained from the lactol V*a* by hydride reduction. In one experiment in which the lactone was reduced with 0.4 mole of hydride, a syrupy product was isolated, which, by chromatography on alumina, yielded 4-oxa-5α-cholest-2-ene, 4-oxa-5α-cholestan-3α-ol, a solid (product A), and 3,5-seco-A-norcholestan-3,5β-diol (IX). Product A was indicated by analysis to be composed of one molecule of 4-oxa-5α-cholestan-3α-ol and two molecules

of 3,5-seco-A-norcholestan-3,5β-diol, less one molecule of water; in agreement with this formulation, it gave, on treatment with methanolic hydrogen chloride, 3α-methoxy-4-oxa-5α-cholestane and the diol in about the expected proportions. It seems likely that it is a stable complex of one molecule of the structure XII with one molecule of diol, possibly formed when the eluent from the chromatogram containing the lactol V and diol was concentrated. The molecular rotation (+654°) supports this structure, being close to the value (+641°) calculated from the sum of the rotations of two molecules of diol and one molecule of 3α-alkoxy-4-oxa-5α-cholestane (assumed to have the same molecular rotation as the 3α-methoxy derivative). In camphor the complex is dissociated, a Rast determination of molecular weight indicating about half the theoretical value.

Attempts were made to prepare the lactol XXII, in which the steric repulsion of the angular methyl group would be expected to outweigh the anomeric effect, and which in consequence should have an equatorial hydroxyl group. However, reduction of the lactone XXI (52) with varying quantities of lithium aluminum hydride gave only starting material or the completely reduced diol XXIII. The latter was cyclized to 17α-oxa-D-homo-5α-androstan-3β-ol (XXIV) with benzenesulphonyl chloride in lutidine (cf. ref. 13).

EXPERIMENTAL

Where concentrations are not given, specific rotations are averages of 2–3 determinations using concentrations of 1.5–2.3 g/100 ml. Intensities of infrared absorption are indicated in parentheses after the frequencies either by the semiquantitative notation used previously (13), or as molecular extinction coefficients. Chromatography was on Woelm alumina; Brockmann activity grades shown.

4-Oxa-5α-cholestan-3α-ol (Va)

Lithium aluminum hydride (215 mg, 5.41 mmoles) in anhydrous, peroxide-free tetrahydrofuran (70 ml) was added under nitrogen to a stirred solution of 4-oxa-5α-cholestan-3-one (7.50 g, 19.33 mmoles) in the same solvent (75 ml), over a period of 10 minutes. During the addition, the reaction flask was cooled in an ice–salt bath; it was then allowed to warm up to room temperature while the stirring was continued for 1 hour. The reaction mixture was poured into cold 1 *N* sulphuric acid (150 ml). The white solid which precipitated was removed by filtration, washed with water, and dried. It was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

taken up in anhydrous ethyl acetate and filtered through infusorial earth. Addition of petroleum ether to the filtrate resulted in the separation of colorless crystals (6.32 g, 84% yield), m.p. 184°–186° C. The melting point was raised, by recrystallization, to 188°–190° C (bath preheated to 180°, temperature rise 2° C per minute), but was dependent on the rate of heating. $[\alpha]_D^{25}$ +64° (in chloroform); $[\alpha]_D^{26}$ +88° (in tetrahydrofuran); $\nu_{max}^{CCl_4}$ in cm^{-1}: 3620 (55), 3385 (60), 2928 (495), 2853 (290), 1469 (152), 1449 (135), 1385 (115), 1368 (110), 1083 (285), 1045 (220), 947 (118). Calc. for $C_{26}H_{46}O_2$: C, 79.94; H, 11.87%. Found: C, 79.95; H, 12.02%.

3ξ-2′,4′-Dinitrophenylhydrazo-4-oxa-5α-cholestane (VIII)

A solution of 4-oxa-5α-cholestan-3α-ol (78 mg) in 96% ethanol (6 ml) was added to a solution of 2,4-dinitrophenylhydrazine (39.6 mg) in 96% ethanol (2 ml) containing concentrated hydrochloric acid (0.8 ml). The mixture was boiled for 10 minutes. When the solution was cooled, yellow crystals (71 mg) separated, which after two recrystallizations from ethanol–benzene (9:1, v/v) melted at 154.5°–155.5° C. $[\alpha]_D^{25}$ +3.2° (*c*, 2.36 in chloroform); $[\alpha]_D^{23}$ +7.6° (*c*, 1.58 in pyridine–methanol (1:1, v/v); $\lambda\lambda_{max}$ 262, 347 mμ, $\epsilon\epsilon_{max}$ 11,900, 22,800 (in chloroform); $\lambda\lambda_{max}$ 248–255 (flat peak), 328 mμ (shoulder at 367 mμ), $\epsilon\epsilon_{max}$ 10,900, 18,500 (in cyclohexane); $\nu_{max}^{CCl_4}$ in cm^{-1}: 3350 (95), 3092 (39), 2930 (370), 2850 (200), 1620 (510), 1470 (140), 1430 (195), 1338 (610), 1313 (340), 1280 (160), 1137 (180), 1072 (235), 1062 (220), 1050 (187), 926 (130). Calc. for $C_{32}H_{50}O_5N_4$: C, 67.34; H, 8.83; N, 9.82%. Found: C, 67.45; H, 8.75; N, 10.04%.

3,5-Seco-A-norcholestan-3,5β-diol (IX)

A solution of 4-oxa-5α-cholestan-3α-ol (200 mg) in tetrahydrofuran (5 ml) was added dropwise, with stirring, under nitrogen, to a solution of lithium aluminum hydride (13 mg) in tetrahydrofuran (3 ml). The mixture was stirred a further 1.5 hours, and then the excess hydride decomposed by slowly adding aqueous tetrahydrofuran. The reaction mixture was added to ice-cold 1 *N* sulphuric acid solution. An oil separated which soon solidified (176 mg, 86%), and was identified as 3,5-seco-A-norcholestan-3,5β-diol (IX) (13) by melting point, mixed melting point, and infrared spectrum.

Reduction Product A

4-Oxa–5α-cholestan-3-one (4.33 g) in diethyl ether (75 ml) was reduced with a slurry of lithium aluminum hydride (175 mg) in diethyl ether (30 ml), following the procedure described above for 4-oxa-5α-cholestan-3α-ol. Instead of a white solid, a syrup was obtained, which was chromatographed on alumina (Merck). Elution with the solvents indicated gave the following fractions: (1) a syrup (2.22 g), shown by infrared analysis to contain no hydroxyl group (ligroin); (2) 4-oxa-5α-cholest-2-ene (23 mg), identified by infrared spectrum (ligroin); (3) 4-oxa-5α-cholestan-3α-ol, isolated after several recrystallizations from ethyl acetate as needles (280 mg), m.p. 184–186°, and identified by mixed melting point and infrared spectrum (benzene–ether (1:1, v/v)); (4) product A (ether); (5) 3,5-seco-A-norcholestan-3,5β-diol, isolated after several recrystallizations from ethyl acetate as needles (65 mg), m.p. 133–134°, and identified by mixed melting point and infrared spectrum (ether–ethanol (1:1, v/v)).

Product A crystallized from anhydrous ethyl acetate as colorless needles (309 mg), m.p. 139.5°–140.5° C. $[\alpha]_D^{26}$ +56.5 (*c*, 2.66 in chloroform); $[\alpha]_D^{27}$ +54.9 (*c*, 1.98 in tetrahydrofuran); $\nu_{max}^{CCl_4}$ in cm^{-1}: 3580 (m), 3470 (m), 2960 (s), 2885 (s), 1473 (s), 1452 (s), 1387 (s), 1371 (m), 1347 (w), 1127 (m), 1036 (s), 933 (w). Calc. for $C_{78}H_{140}O_5$: C, 80.90; H, 12.18%; molecular weight, 1158. Found: C, 80.75; H, 12.17%; molecular weight (Rast, camphor), 590.

Reaction of Product A with Methanolic Hydrogen Chloride

Acetyl chloride (0.6 ml) was added to absolute methanol (15 ml) to give an approximately 3% solution of hydrogen chloride. Product A (150 mg) was dissolved in this solution, and the mixture refluxed for 1 hour and then concentrated by distillation to 7 ml. The solution, on cooling, deposited plates (44 mg), m.p. 86°–88° C, raised to 98°–99.5° by recrystallization from methanol, which were identified as 3α-methoxy-4-oxa-5α-cholestane (see below) by mixed melting point, specific rotation, and infrared spectrum.

The mother liquors from the first crystallization were taken to dryness *in vacuo*, and the solid thus obtained was washed with water and dried. The crude solid (97 mg, m.p. 115°–121° C), after recrystallization from ligroin, melted at 134°–134.5° C, and was identified as 3,5-seco-A-norcholestan-3,5β-diol (IX) (13) by mixed melting point and infrared spectrum.

4-Oxa-5α-cholest-2-ene (X)

(*a*) A solution of 4-oxa-5α-cholestan-3α-ol (900 mg) and phosphorus oxychloride (2.3 ml) in pyridine (7 ml) was refluxed for 1 hour. The cooled solution was diluted with water and extracted with ether. The ether solution was washed with aqueous bicarbonate, dried (sodium sulphate), concentrated, and diluted with methanol (10 ml). On standing, the solution deposited colorless prisms of 4-oxa-5α-cholest-2-ene (686 mg, 80% yield), m.p. 68–70° C, raised by recrystallization from ethanol to 70°–72° C. $[\alpha]_D^{25}$ +88.8° (chloroform); ϵ_{210} 5500 (in cyclohexane, end absorption only); $\nu_{max}^{CCl_4}$ in cm^{-1}: 3050 (40), 2930 (510), 1647 (133), 1470 (150), 1448 (120), 1386 (110), 1370 (79), 1243 (95), 1204 (82), 1080 (420), 945 (82), 914 (40). Calc. for $C_{26}H_{44}O$: C, 83.82; H, 11.91%. Found: C, 83.83; H, 12.00%.

(*b*) A solution of 4-oxa-5α-cholestan-3α-ol (300 mg) and fused sodium acetate (150 mg) in acetic anhydride (2.0 ml) was refluxed for 5 hours, and then poured into ice water. The brown oil separating slowly solidified, and was purified by several crystallizations from methanol, giving white plates, m.p. 67–68°, and shown by mixed melting point and infrared spectrum to be identical with 4-oxa-5α-cholest-2-ene obtained above.

4-Oxa-5α-cholestane (XIII)

4-Oxa-5α-cholest-2-ene (510 mg) in glacial acetic acid (20 ml) was hydrogenated over platinum oxide (140 mg). After 3 hours, 95% of the theoretical volume of hydrogen had been absorbed. The catalyst was removed by filtration, the solution diluted with ether and washed with water, aqueous bicarbonate, and water, and dried (sodium sulphate). Evaporation of the ether left a white solid (0.48 g), which after one crystallization from methanol had m.p. 89°–90° C, undepressed by admixture with 4-oxa-5α-cholestane prepared from 3,5-seco-A-norcholestan-3,5β-diol (13), and having the same infrared spectrum. Fieser *et al.* (18) have reported a melting point of 93°–94° C for this compound prepared by a different route.

3-Acetoxy-4-oxa-5α-cholestane (XI, R = MeCO)

4-Oxa-5α-cholestan-3α-ol (204 mg) was dissolved in pyridine (3 ml) with gentle warming, and acetic anhydride (0.3 ml) was added to the cooled solution. After 2 days, the solution was poured into ice water to give a solid which was washed free from acid with water and dried. The crude product (203 mg), m.p. 90°–101° C, was probably a mixture of the isomeric 3-acetoxy compounds (XI*a* and XI*b*, R = MeCO); $\nu_{max}^{CCl_4}$ in cm^{-1}: 2940 (s), 2860 (s), 1755 (s), 1473 (m), 1463 (sh), 1450 (m), 1385 (m), 1374 (m), 1222 (s), 1158 (m),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

1142 (m), 1046 (s), 939 (m), 891 (m). Recrystallization from methanol afforded a mixture (164 mg), m.p. 65–80° C, as shown by chromatography on neutral alumina (5 g, grade III). The following fractions were eluted: (*a*) with hexane (30 ml), 3α-methoxy-4-oxa-5α-cholestane (72 mg), m.p. and mixed m.p. 93°–94° and 94°–95°; (*b*) with hexane–benzene, 1:1 (30 ml), a fraction (62 mg), m.p. 74°–85° C, having the same infrared spectrum as the crude acetate described above; (*c*) with ether (50 ml), 4-oxa-5α-cholestan-3α-ol (20 mg) identified by infrared spectrum. Attempts to recrystallize the acetate from anhydrous ether, tetrahydrofuran, benzene, or petroleum ether failed.

3α-Chloro-4-oxa-5α-cholestane (XIV)

A solution of 4-oxa-5α-cholest-2-ene (140 mg) in anhydrous ether (10 ml) saturated with hydrogen chloride was kept under nitrogen for 2 hours. Evaporation of the ether by a jet of dry nitrogen left crystals which sintered at 95° C, m.p. 104°–107° C. $[\alpha]_D^{20}$ +156° (*c*, 1.56 in absolute chloroform); $\nu_{max}^{CCl_4}$ in cm^{-1}: 2925 (585), 2855 (330), 1469 (150), 1448 (135), 1384 (110), 1367 (92), 1330 (47), 1155 (272), 1130 (292), 1119 (sh, 197), 1033 (258), 928 (82), 908 (56). Calc. for $C_{26}H_{45}OCl$: C, 76.34; H, 11.09%. Found: C, 76.16; H, 10.89%. Quantitative infrared measurements showed that this material, in different preparations, contained 3–6% of starting material; however, all attempts at recrystallization led to a lowering of the melting point.

3α-Methoxy-4-oxa-5α-cholestane (XI, R = Me)

(a) From 4-Oxa-5α-cholestan-3α-ol

Acetyl chloride (1.2 ml) was added to absolute methanol (30 ml) to give an approximately 3% solution of hydrogen chloride. A solution of 4-oxa-5α-cholestan-3α-ol (333 mg) in this solvent was refluxed for 30 minutes. When concentrated to 10 ml, the solution deposited glistening white plates (302 mg), m.p. 91–93° C. These were washed with water to remove traces of acid, dried, and recrystallized from methanol, giving crystals melting at 98°–99.5° C. $[\alpha]_D^{26}$ +109° (*c*, 1.43 in chloroform); $[\alpha]_D^{22}$ +113.5° (*c*, 1.49 in methanol–tetrahydrofuran (1:1, v/v)); $\nu_{max}^{CCl_4}$ in cm^{-1}: 2930 (580), 2860 (340), 1470 (170), 1457 (138), 1448 (148), 1382 (124), 1368 (134), 1132 (360), 1058 (360), 1039 (412), 934 (105), 893 (178). Calc. for $C_{27}H_{48}O_2$: C, 80.20; H, 11.95; OMe, 7.68%. Found: C, 80.25; H, 12.00; OMe, 7.92%.

Fieser *et al.* (18) have recently reported preparing, by a different route, a compound, m.p. 89°–92° C, having the structure of our compound but undefined stereochemistry; it is probably identical with our compound.

(b) From 3α-Chloro-4-oxa-5α-cholestane

Sodium (60 mg) was dissolved in absolute methanol (12 ml), followed by 3α-chloro-4-oxa-5α-cholestane (153 mg), dissolution of the latter requiring that the solution be warmed. The solution was refluxed for 40 minutes, and the solvent then removed under reduced pressure. The residue was treated with water (12 ml) and ether (12 ml), and the ether layer was washed, dried, and diluted with methanol (8 ml). On standing for 2 days, with partial evaporation of the ether, the solution deposited long plates of 3α-methoxy-4-oxa-5α-cholestane (110 mg), m.p. 98.5–99.5, undepressed by admixture with authentic material. Further concentration of the solution gave a brownish semisolid mass (48 mg), which in carbon tetrachloride solution had an infrared spectrum similar to that of pure 3α-methoxy-4-oxa-5α-cholestane, with the addition of a peak at 1068 cm^{-1} and a shoulder at 1126 cm^{-1}. This material resisted all attempts at purification.

(c) From 3α-Chloro-4-oxa-5α-cholestane in the Presence of Silver Carbonate

To a suspension of powdered calcium chloride (500 mg) and freshly prepared silver carbonate (53) (230 mg) in absolute chloroform (15 ml) was added a solution of 3α-chloro-4-oxa-5α-cholestane (287 mg) in absolute chloroform (15 ml), followed by the slow addition, with vigorous stirring, of methanol (0.12 ml) in absolute chloroform (3 ml). The mixture was stirred for 30 minutes at room temperature and 30 minutes at 50° C. Then water was added, the mixture was filtered through infusorial earth, and the organic layer was separated, washed with water, and dried. Concentration of this solution afforded a syrup which in contact with a little methanol solidified. The solid, crystallized from ether–methanol, gave a first crop (226 mg), m.p. 86°–94° C, $[\alpha]_D^{20}$ +110° (*c*, 1.15 in chloroform); second crop (15 mg), m.p. 79°–85° C, $[\alpha]_D^{20}$ +98.5° (*c*, 1.16 in chloroform); third crop (7 mg), m.p. 62°–68° C; and a brownish semisolid residue (28 mg). Infrared examination showed the first crop to be 3α-methoxy-4-oxa-5α-cholestane contaminated with a small amount of 4-oxa-5α-cholest-2-ene, and the third crop to have the spectrum of 3α-methoxy-4-oxa-5α-cholestane, with the addition of a weak shoulder at 1068 cm^{-1}.

Hydrolysis of 3α-Methoxy-4-oxa-5α-cholestane

A solution of 3α-methoxy-4-oxa-5α-cholestane (150 mg) in tetrahydrofuran (10 ml) – 15% aqueous hydrochloric acid (3.5 ml) was refluxed for 10 minutes, then poured into ice water. A solid was removed by filtration, washed with water, and dried; this crude product (125 mg), m.p. 154°–158° C, was recrystallized from methanol and identified as 4-oxa-5α-cholestan-3α-ol by melting point, mixed melting point, and infrared spectrum.

3α- and 3β-Benzyloxy-4-oxa-5α-cholestane (XIa and XIb, R = CH_2Ph)

(a) From 4-Oxa-5α-cholestan-3α-ol

Acetyl chloride (0.4 ml) was added to benzyl alcohol (10 ml), then 4-oxa-5α-cholestan-3α-ol (100 mg) was dissolved in this solution. The solution, after 24 hours at room temperature, was concentrated at 0.5 mm; removal of the dibenzyl ether formed in this reaction required that the flask be heated to 100°. The residual syrup, which partially crystallized, was chromatographed on basic alumina (25 g, grade III), and the fractions eluted from the column were examined by infrared spectroscopy. The fractions fell into the following groups: (*a*) with ligroin (b.p. 65–75°; 60 ml), 4-oxa-5α-cholest-2-ene, obtained as crystals (10 mg), m.p. 63–66°, having the characteristic infrared spectrum; (*b*) with more ligroin (110 ml), a syrup (65 mg) identified as 3α-benzyloxy-4-oxa-5α-cholestane (see below); (*c*) with ligroin–benzene (4:1, v/v) (30 ml), a syrup (25 mg) shown by infrared spectroscopy to be a slightly impure mixture of 3α- and 3β-benzyloxy-4-oxa-5α-cholestane; (*d*) with more ligroin–benzene (4:1, v/v) (50 ml), impure crystals of 3β-benzyloxy-4-oxa-5α-cholestane.

Fractions (*b*) were dissolved in hot methanol and filtered through charcoal–celite. The syrup (62 mg) which separated on being cooled was dried at 100° C at 0.5 mm. The syrup from some runs crystallized to a solid, m.p. 42–51° C, when cooled to 15° and rubbed; the syrup from other runs could not be crystallized, but was indistinguishable with respect to specific rotation and infrared spectrum. Attempts to recrystallize the solid at low temperatures with seeding afforded always a syrup without change in specific rotation or infrared spectrum: $[\alpha]_D^{26}$ +99° (*c*, 2.23 in chloroform); $[\alpha]_D^{22}$ +91° (*c*, 1.46 in 3:2 benzyl alcohol – tetrahydrofuran, v/v); $\lambda\lambda_{max}^{EtOH}$ 248, 252.5, 258, 264, 268 mμ; $\epsilon\epsilon_{max}$ 165, 234, 272, 217, 148; $\nu_{max}^{CCl_4}$ in cm^{-1}: 3060 (40), 3020 (55), 2920 (540), 2855 (355),

1470 (175), 1457 (175), 1382 (128), 1342 (88), 1164 (100), 1130 (250), 1052 (215), 1037 (380), 1027 (360), 945 (110), 935 (125), 889 (90), 696 (81). Calc. for $C_{33}H_{52}O_2$: C, 82.45; H, 10.91%. Found: C, 82.37; H, 10.84%.

Chromatographic fractions (*d*) were dissolved in ligroin and treated with charcoal. Evaporation of the solvent afforded well-formed prisms, which were washed on the filter with ligroin (cooled to −10° C) and then recrystallized from ligroin or methanol to give pure 3β-benzyloxy-4-oxa-5α-cholestane (12 mg), melting at 131°–132° C. $[\alpha]_D^{22}$ −22° (*c*, 2.02 in chloroform; $[\alpha]_D^{22}$ −3.8 (*c*, 1.46 in tetrahydrofuran – benzyl alcohol (2:3, v/v)); $\lambda\lambda_{max}$ 248, 252.5, 258.5, 264.5, 268 mμ; $\epsilon\epsilon_{max}$ 171, 218, 252, 210, 151 (in cyclohexane); $\nu_{max}^{CCl_4}$ in cm^{-1}: 3060 (40), 3028 (57), 2930 (575), 2850 (340), 1497 (40), 1469 (174), 1457 (180), 1450 (155), 1387 (134), 1370 (126), 1344 (102), 1166 (224), 1141 (210), 1120 (215), 1094 (190), 1070 (510), 1047 (335), 935 (122), 902 (66), 695 (88). Calc. for $C_{33}H_{52}O_2$: C, 82.45; H, 10.91%. Found: C, 82.38, H, 10.98%.

(b) From 3α-Chloro-4-oxa-5α-cholestane

A suspension of 3α-chloro-4-oxa-5α-cholestane (265 mg) and finely powdered anhydrous sodium acetate (150 mg) in anhydrous benzyl alcohol (5 ml) was heated on a steam bath for 1 hour. The solvent was then removed at reduced pressure, the residue dissolved in ether and water, and the ether layer dried and then taken to dryness. The residue was dissolved in hexane and chromatographed on basic alumina (grade III), as described above, to give slightly impure 3α-benzyloxy-4-oxa-5α-cholestane (239 mg, 76%) and 3β-benzyloxy-4-oxa-5α-cholestane (70 mg, 22%), identified by melting point and infrared spectra.

Isomerization of 3α-Benzyloxy-4-oxa-5α-cholestane (XIa, R = CH_2Ph)

Acetyl chloride (4 drops) was added to benzyl alcohol (0.4 ml) to generate hydrogen chloride, and the solution was diluted with anhydrous ether (3 ml). 3α-Benzyloxy-4-oxa-5α-cholestane (110 mg) was dissolved in this solution. After 4 hours at room temperature, the solvents were removed at reduced pressure (0.5 mm at 80° C) and the residual syrup was chromatographed on basic alumina (grade III) as described above to give starting material (71 mg) and 3β-benzyloxy-4-oxa-5α-cholestane (13 mg), identified by melting point, mixed melting point, and infrared spectrum.

For preparative purposes, the yield of β isomer was increased by allowing a syrupy mixture of isomers containing a trace of acid to stand for several weeks, after which time a certain amount of the β isomer had crystallized out. The whole mixture was then neutralized and chromatographed to give a 25% yield of β isomer.

Action of Titanium Tetrachloride on 3α-Benzyloxy-4-oxa-5α-cholestane

Titanium tetrachloride was purified by standard vacuum-line techniques, and an estimated 100–150 mg was distilled into a frozen solution of 3α-benzyloxy-4-oxa-5α-cholestane (120 mg) in carbon tetrachloride (5 ml). The mixture was allowed to melt under vacuum, refluxed for 5 hours with rigid exclusion of moisture, and then poured into ice water. More carbon tetrachloride was added and the organic layer was separated, washed with bicarbonate and water, and dried over magnesium sulphate. Removal of the solvent at reduced pressure left a yellowish solid (125 mg) which was treated with cold ligroin. The undissolved fraction (35 mg) proved by melting point and mixed melting point to be slightly impure 4-oxa-5α-cholestan-3α-ol. The ligroin solution, on chromatography on basic alumina (grade III), gave only glassy, unidentifiable materials, followed by a small quantity of impure 4-oxa-5α-cholestan-3α-ol (18 mg).

*17α-Oxa-*D*-homo-5α-androstan-3β-ol (XXIV) (40)*

13,17-Seco-5α-androstan-3β,13α-17-triol (54) (510 mg) was treated with benzenesulphonyl chloride in lutidine under conditions already described (13). The product, isolated in the usual way, was an oil (427 mg) which was chromatographed on alumina (activity II–III). Elution with ether–acetone, 9:1, gave 17α-oxa-D-homo-5α-androstan-3β-ol (114 mg), m.p. 171°–174° C, raised by one crystallization from methanol to 174°–175° C. $\nu_{max}^{CCl_4}$ in cm^{-1}: 3635 (m), 2940 (s), 2860 (sh), 2708 (w), 1462 (sh), 1451 (s), 1440 (sh), 1375 (s), 1282 (m), 1212 (w), 1155 (m), 1132 (sh), 1120 (s), 1080 (s), 1075 (sh), 1064 (sh), 1044 (s), 1032 (s), 973 (w), 955 (w), 945 (w), 935 (m), 923 (w), 895 (w), 877 (w), 848 (w), 840 (w). Calc. for $C_{19}H_{32}O_2$: C, 78.02; H, 11.03%. Found: C, 77.84; H, 10.79%.

ACKNOWLEDGMENTS

We are grateful to the National Research Council for generous financial support, Ayerst, McKenna and Harrison, Ltd., Montreal, for a gift of androsterone, Professor A. Taurins for help in obtaining infrared spectra, Professor M. Onyszchuk for collaboration in carrying out the experiment with titanium tetrachloride, and Professor R. U. Lemieux for helpful discussion.

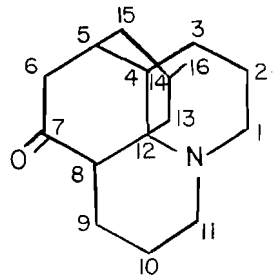
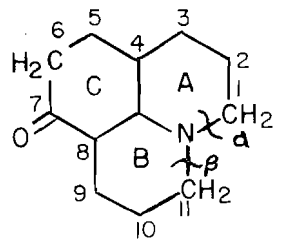
LYCOPODIUM ALKALOIDS



X. THE STRUCTURE OF LYCOPODINE[1]

W. A. HARRISON,[2] M. CURCUMELLI-RODOSTAMO, D. F. CARSON,[3]
L. R. C. BARCLAY, AND D. B. MACLEAN

ABSTRACT



The reactions leading to the establishment of structure I for lycopodine are discussed. Structures are proposed for three cyclization products derived from lycopodine.

In a short communication (1) we proposed structure I for lycopodine. This structure has been confirmed by the work of Anet (2), who succeeded in interconverting several *Lycopodium* alkaloids, among which was lycopodine. In this paper we wish to give a full account of our work on the elucidation of the structure of the alkaloid and to discuss the structures of the tetracylic compounds obtained on elimination of hydrogen halide from lycopodine methiodide and α- and β-cyanobromolycopodine.

I

Partial structure A proposed in 1959 (3) is a convenient starting point for the ensuing discussion.

A

In structure A the carbon atoms known with certainty at that time are designated, as are the bonds cleaved in the formation of α- and β-cyanobromolycopodine, II and III respectively (4, 5). The reasons for proposing structure A are reviewed briefly below. Entry had been gained to rings A and B by reaction with cyanogen bromide. The α-bromide II had been converted to the corresponding acid and thence to the ring-A lactam IV. The infrared spectrum of the latter indicated that ring A was six-membered or larger (3). The β-bromide III had been converted to the corresponding acid which, on reduction with sodium borohydride, readily formed a lactone (V). The infrared spectrum of the lactone indicated that it was either five- or six-membered (3). The carbonyl ring, C, was considered to be six-membered or larger because of the infrared absorption of the carbonyl group near 1700 cm^{-1} (4). The presence of the methylene group adjacent to the carbonyl had been established by conversion of α-cyanolycopodine (VI) to a benzylidene derivative (VII) and to an enolic α-diketone (VIII) (5). Finally, the hexahydrojulolidine system had been found in the alkaloid annotinine, then the only alkaloid of the *Lycopodium* group of known structure (6). No attempt was made at that time to locate the fourth ring of lycopodine.

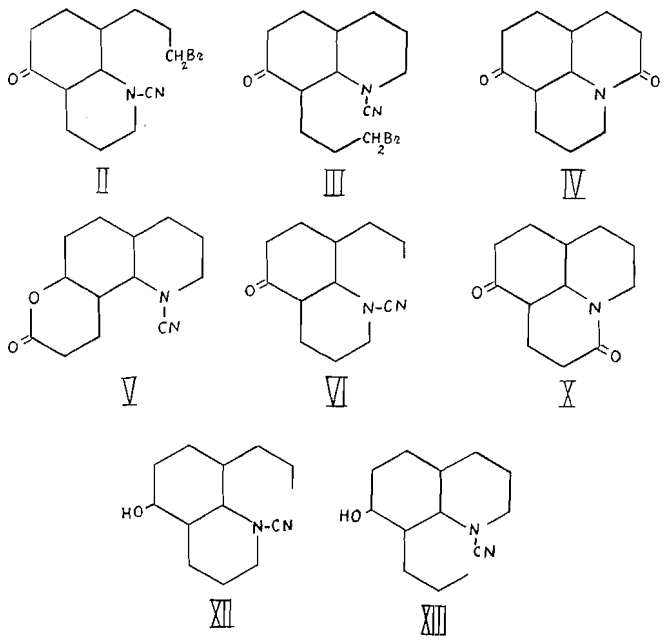
Support for the proposal that ring B was six-membered came from the following sequence. The methyl ester, IX, of β-cyanolycopodine carboxylic acid (3) was converted by hydrolysis and subsequent treatment with diazomethane to the methyl ester of the corresponding amino acid. When the ester was heated under reflux in xylene it yielded the lactam X, $C_{16}H_{23}O_2N$, which showed absorption in the infrared at 1626 cm^{-1} indicative of a six-membered or larger lactam. Reduction of X with lithium aluminum hydride gave dihydrolycopodine XI (4). Thus no skeletal rearrangement had occurred in the reactions outlined.

The nature of four more carbon atoms in rings A and B was established by modified Kuhn–Roth oxidation of α- and β-cyanodihydrolycopodine, XII and XIII respectively (5, 7). The oxidations were performed according to the procedure of Lemieux and Purves (8). The volatile acids were recovered from the aqueous distillate as their sodium salts. The free acids were liberated with dry hydrogen chloride, distilled, and converted to their methyl esters with diazomethane. The esters were separated by liquid–vapor partition chromatography and identified by comparison of their retention times with values determined by running known mixtures under the same conditions.

Both XII and XIII yielded mixtures of acetic, propionic, and *n*-butyric acids, and it can be concluded that both compounds contain *n*-propyl groups attached to carbon. Oxidation of lycopodine under the same conditions yielded only acetic acid. Therefore, methylene groups can be written at C_2, C_3, C_9, and C_{10} in structure A. The relatively high proportion (24%) of butyric acid in the acid mixture derived from the oxidation of XII suggests that C_4 is not quaternary which implies that the carbon skeleton of lycopodine must differ from that of annotinine. These results establish the sequence $-(CH_2)_3-N-(CH_2)_3-$ in the lycopodine molecule and are consistent with structure A, but do not verify the proposed relationship between the carbonyl function and the nitrogen atom. However, the reactions of the carbonyl ring reported below have established that the proposed relationship is the correct one.

Partial structures for some of the above compounds are given in Chart I.

The benzylidene derivative, VII, of α-cyanolycopodine was the key compound in the investigation of ring C. Upon ozonolysis it yielded the enolic diketone VIII, which had been prepared previously by Barclay and MacLean (5) by bromination and hydrolysis



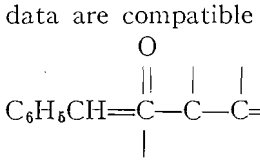


CHART I

of α-cyanolycopodine (VI). The enolic character of this α-diketone established that at least one enolizable hydrogen must be present on a carbon adjacent to one of its two carbonyl groups. The alternatives are represented in partial formulas VIII(*a*) and VIII(*b*).

Oxidation of VII with selenium dioxide yielded two products. One of these products was a compound (XIV), $C_{24}H_{30}O_2N_2$, which had hydroxyl absorption in its infrared spectrum at 3560 cm^{-1} and carbonyl absorption at 1692 cm^{-1} in chloroform solution. The carbonyl absorption of the starting material VII appeared at 1685 cm^{-1} in the same solvent. This shift in the carbonyl frequency implied that the hydroxyl group had entered alpha and axial to the carbonyl function. The second oxidation product (XV), $C_{24}H_{28}ON_2$, was a yellow compound formed from the starting material by loss of two hydrogens. The ultraviolet spectrum of XV differed markedly from that of both VII and XIV, in each of which a maximum occurred near 280 mμ. In XV the 280-mμ band of the starting material had shifted to 310 mμ. The infrared spectrum of XV was also very different from that of VII. There were three very sharp bands at 1677 cm^{-1}, 1626 cm^{-1}, and 1590 cm^{-1} when the spectrum was run in chloroform. The shift in the frequency of the carbonyl band from 1685 in VII to 1677 cm^{-1} in XV indicated that reaction had occurred adjacent to the carbonyl group. The band at 1626 cm^{-1} is assigned to olefin absorption and that at 1590 cm^{-1} to the conjugated phenyl group. The analysis and the spectral data are compatible with the presence, in the molecule, of the chromophoric system

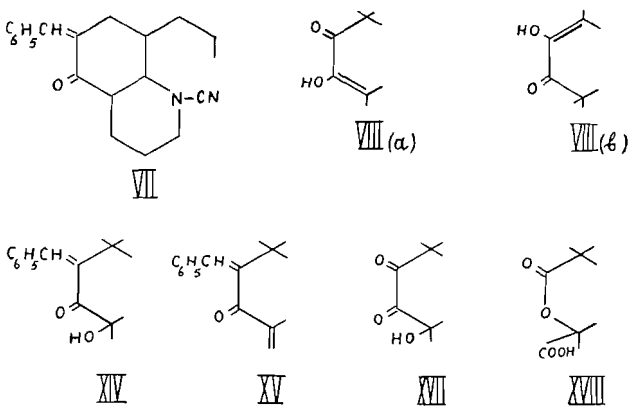
. The spectrum of an analogous system has been studied in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the infrared (9) and in the ultraviolet region (10) and the results are similar to, although not identical with, the above. The formation of XV from VII occurred without alteration of the carbon skeleton since both VII and XV yielded the same product (XVI), $C_{24}H_{32}ON_2$, on treatment with hydrogen over a platinum catalyst.

Ozonolysis of XIV gave two products, a diketo alcohol (XVII), $C_{17}H_{24}O_3N_2$, and a lactone carboxylic acid (XVIII), $C_{17}H_{24}O_4N_2$. The former was a yellow compound with weak absorption in the ultraviolet at 420 mμ characteristic of an α-diketone. Treatment of XVII with H_2 and platinum yielded the enol VIII. However, unlike VIII, compound XVII had no enolic properties. One must therefore conclude that the hydroxyl group in XVII has replaced the only enolizable hydrogen in VIII and that the carbon adjacent to one of the two carbonyl groups is quaternary or at a bridgehead where enolization would be in violation of Bredt's rule.

Deuterium exchange of lycopodine (I) and α-cyanolycopodine (VI) established the presence of three enolizable hydrogens in each. Therefore, partial structure VIII(a) must represent enol VIII and partial structures XIV, XV, XVII, and XVIII, the hydroxybenzal compound, the olefinic benzal compound, the diketo alcohol, and the lactone carboxylic acid, respectively. Therefore, position 5 in partial structure A, must be quaternary or at a bridgehead. This represents again a departure from the annotinine skeleton. Partial structures for the compounds above are given in Chart II.



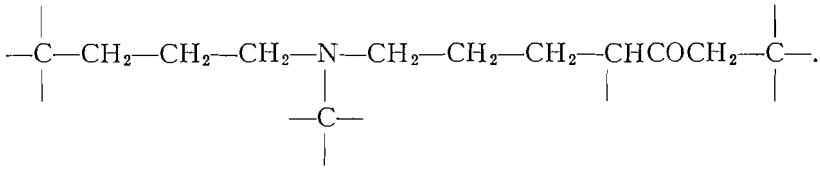


CHART II

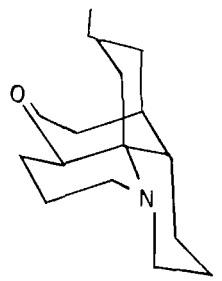
The peripheral structure of the molecule can now be extended to

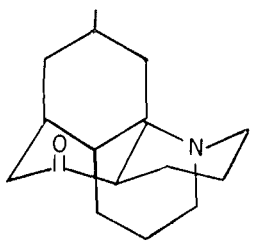
This is the only structure compatible with the formation of lactone V on borohydride reduction of the acid derived from ester IX, and with the above results.

This structure is in complete accord with partial structure A but, although the evidence



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

for structure A is substantial, it is not unequivocal. Rings A and B must make up a reduced quinolizine system if these rings are six-membered, as lactams IV and X suggest. There is evidence that rings B and C make up a reduced quinoline system, because dehydrogenation of XIX (a product formed by dehydration and hydride reduction of XII) yielded a base (XX), in small yield, with the properties of a quinoline. Although the structure of this base has not been proved, it may be 8-*n*-propyl-7-isobutylquinoline.

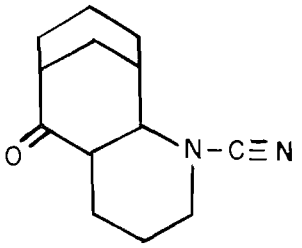


In partial structure A there are only three positions, C_4, C_5, and C_{12}, to which the fourth ring of the alkaloid, ring D, can be attached. Since it has been shown that C_5 is either quaternary or at a bridgehead and since there is evidence from chromic acid oxidation that C_4 is not quaternary, it appears that ring D is closed by a bridge between C_5 and C_{12}.

The structure of this bridge may be deduced from the dehydrogenation experiments of Marion and Manske (11). They found that lycopodine yielded five basic products on dehydrogenation, of which they were able to identify two: 7-methylquinoline and 5,7-dimethylquinoline. The tendency to form 7-methylquinoline was particularly strong. By bridging C_5 and C_{12} in structure A with the unit $-CH_2-\underset{\displaystyle CH_3}{\underset{|}{CH}}-CH_2-$, there is obtained structure I. This structure is completely consistent with the dehydrogenation results and is compatible with the rest of the chemical evidence. It is also in accord with the N.M.R. spectrum of lycopodine, which shows a single C-methyl group attached to a tertiary carbon.

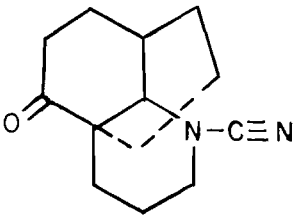
The relative configuration of the asymmetric centers in lycopodine has been discussed by Anet (2). Except for the configuration at C_{14}, for which we had no experimental evidence, we had arrived at the same conclusion (12). The perspective formulas B and C give an idea of the spatial relationships which exist.

B



C

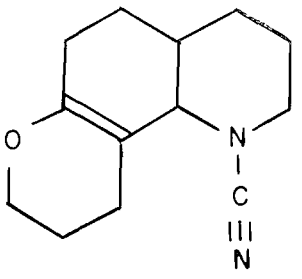
The elucidation of the structure of lycopodine has at the same time provided the structures of alkaloids L 2 and L 14. Douglas, Lewis, and Marion (13) have shown that L 2 is the acetyl derivative of dihydrolycopodine and that L 14 is anhydrodihydrolycopodine. The double bond in L 14 occupies the C_7—C_8 position, for Anet has shown, and we have confirmed, that its N.M.R. spectrum shows the presence of a single olefinic proton. We have also shown that alkaloid L 1, complanatine (14), is identical with dihydrolycopodine; its formula should be revised to $C_{16}H_{27}ON$. The formation of dihydrolycopodine from lycopodine by hydride reduction implies that the OH group



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

is axial in the chair conformation and cis to the C_5—C_{12} bridge since hydride reduction will occur from the less-hindered side of the system.

The structure of the cyclized product XXI, $C_{17}H_{24}ON_2$, formed from α-cyanobromolycopodine by treatment with alkali (4), has now been clarified. Recently (7) we proposed the alternative partial structures D and E for this compound. Deuterium exchange



D

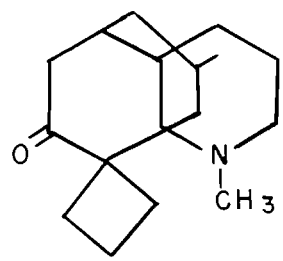
E

studies and infrared spectroscopy have allowed us to differentiate between the alternatives. It was found that XXI exchanged two hydrogens for deuterium and this is consistent with partial structure E. Such a result is possible but unlikely for the bicyclo-(3.3.1)nonane system present in D. In the infrared spectrum of XXI there is a band at 1413 cm^{-1} which is absent in deuterated XXI. This behavior is in keeping with ketones containing an α-methylene group (15, 16). Therefore partial structure E must pertain. It is the study of this cyclization reaction which has allowed an assignment of configuration to C_4 of the lycopodine molecule and the other alkaloids which Anet (2) has related to lycopodine.

An isomeric cyclized compound (XXII), $C_{17}H_{24}ON_2$, is obtained from the β-bromide III by treatment with base (4), and for this compound we proposed partial structure F (7).

F

This compound does not exchange hydrogen for deuterium, in keeping with the proposed structure. Its N.M.R. spectrum showed two groups of peaks which were distinctly separate from the bulk of the absorption. The areas under the curves corresponded in both cases to two protons. One group of peaks (δ = 2.36) was in the region characteristic of



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

protons in a $—CH_2—O—$ group while the other (δ = 4.14) was probably associated with the hydrogens of C_1, which is adjacent to the cyanamide function. No band was observed which could be assigned to a $\diagdown C{=}C—H \diagup\diagdown$ group.* The N.M.R. spectrum of XXI was run for comparison, and it showed one unresolved band (δ = 4.09; area = two protons) slightly displaced from the rest of the spectrum. This band was attributed to the protons of C_{11}.

The reasons for the unusual stability of the enol ether function of XXII become clear when an examination is made of a molecular model. As can be seen from the perspective formulas of lycopodine, B and C, C_8 is particularly subject to steric hindrance. The approach of bulky reagents to the vicinity of C_8 will, therefore, be opposed. This will be generally true, not only of the alkaloid, but also of all the known derivatives. In addition, the nature of the structure is such that the $C_7—C_8$ position is a particularly favorable one for a double bond. The introduction of unsaturation at $C_7—C_8$ (or $C_8—C_9$) will relieve steric hindrance by eliminating the interaction of the C_8 hydrogen with the axial hydrogens of C_1 and C_3 as well as the interaction between the hydrogens of C_9 and C_{13}. It is to be expected that any attempt to destroy the planarity of C_8 by attack on the double bond will be resisted. Cyclized compound XXII is not the only known example of a lycopodine derivative with a very stable $C_7—C_8$ double bond. We have found that anhydrodihydrolycopodine is resistant to hydrogenation and ozonolysis.

A third cyclized compound (XXIII), $C_{17}H_{27}ON$, which has not been previously reported, has been derived from lycopodine methiodide by the action of potassium tertiary butoxide in tertiary butanol. This compound showed no double-bond absorption in its infrared and was inert to the action of ozone and hydrogen. Its N.M.R. spectrum was devoid of peaks in the region of olefinic protons. On treatment with cyanogen bromide it yielded a cyanamide (XXIV), $C_{17}H_{24}ON_2$, which was isomeric but not identical with either of the two cyclized compounds, XXI and XXII, discussed above. The oxygen function in XXIII was not affected by sodium borohydride in ethanol or by lithium aluminum hydride in ether or tetrahydrofuran. However, the infrared spectrum of XXIII showed a strong peak in the carbonyl region at 1695 cm^{-1} and there was also a peak at 1410 cm^{-1} characteristic of a $—CH_2—$ adjacent to a carbonyl function.

Deuterium exchange was carried out on this compound and it was found that two enolizable hydrogens were present. Furthermore, the absorption in the infrared at 1410 cm^{-1} was absent in the deuterated compound. The only structure consistent with these data is structure XXIII below.

XXIII

Displacements are recorded in parts per million from chloroform.

EXPERIMENTAL

Lycopodine

The alkaloid was isolated from *Lycopodium flabelliforme* by the procedure described by Barclay and MacLean (5). It melted at 116° after recrystallization from petroleum ether.

The nuclear magnetic resonance spectrum of the alkaloid showed a strong doublet, $\delta = 6.6$, whose area corresponded to three protons. This was attributed to the presence of a methyl group attached to a tertiary carbon.

Dihydrolycopodine

Dihydrolycopodine was prepared by the method of MacLean, Manske, and Marion (4). We have also isolated from *L. flabelliforme* an alkaloid identical with dihydrolycopodine. This alkaloid follows lycopodine in the chromatographic separation of the crude alkaloids (5), and appears to be the second most abundant alkaloid. We have also established (14) that complanatine, alkaloid L 1, is identical with dihydrolycopodine. Identity was established by a comparison of their infrared spectra and a mixed melting point determination. We are grateful to Dr. R. H. F. Manske for a sample of complanatine.

Reaction of Lycopodine with Cyanogen Bromide

The reaction was carried out and the bromocyanamides II and III isolated by the procedure described previously (4, 5).

Preparation of the β-Lactam

To a solution of 216 mg of ester IX* (m.p. 160–162°) (3) in *n*-propyl alcohol (2.5 ml) was added 15 ml of 2 *M* hydrochloric acid. After the mixture had been heated for 15 hours on a steam bath it was evaporated to dryness, and the residue was washed with ether to remove unhydrolyzed material. The residual crude amino acid hydrochloride was dissolved in methanol and the ice-cooled solution was treated with an excess of freshly prepared diazomethane solution. After 20 minutes the solution was evaporated and the residue worked up to give the basic product (150 mg). The infrared spectrum of the crude product showed strong ketone and ester carbonyl bands and weak absorption in the N—H region.

A solution of the crude amino ester (150 mg) in xylene (30 ml) was distilled very slowly at atmospheric pressure. After 10 hours, when the solution had been reduced to about one third of its original volume, the rest of the solvent was removed under reduced pressure. The infrared spectrum of the residual oil showed a strong band at 1625 cm^{-1} and weakened ester absorption. The oil was worked up to give basic and neutral fractions. Further purification of the neutral fraction was effected by chromatography on alumina with benzene–methanol as the eluant. A band, which passed down the column, yielded 58 mg of crystalline material. Recrystallization from ether – petroleum ether gave long, colorless needles which melted at 177–179°. Calc. for $C_{16}H_{23}O_2N$: C, 73.5; H, 8.87; N, 5.4%. Found: C, 73.5; H, 8.78; N, 5.5%.

The infrared spectrum of this compound, X, in nujol had strong maxima at 1700 cm^{-1} (ketone) and 1626 cm^{-1} (lactam carbonyl). When the spectrum was determined in chloroform solution, the bands appeared at 1709 and 1622 cm^{-1}. There was no absorption in the cyanamide and ester carbonyl regions.

A mixed melting point determination showed that lactams X and IV were not the same.

**This ester exists in two crystalline forms melting at 127–129° and 160–162°.*

Reduction of the β-Lactam with Lithium Aluminum Hydride

About 30 mg of lactam X was reduced for 20 hours with lithium aluminum hydride (0.1 g) in boiling tetrahydrofuran. The excess hydride was destroyed by the addition of wet tetrahydrofuran and the mixture evaporated. Sodium hydroxide solution was added to the residue and the organic material extracted with chloroform. Evaporation of the chloroform solution yielded an oil which partially crystallized, but attempts to obtain a sharp-melting product by recrystallization were unsuccessful. The crude product, was, therefore, dissolved in acetone and treated with methyl iodide. The crystalline methiodide which formed melted with decomposition at 287–289°. Its melting point was not depressed by the addition of dihydrolycopodine methiodide, m.p. 293–295° (decomp.). The infrared spectra of the methiodides were identical.

α-Cyanodihydrolycopodine XII

This compound was prepared by the method of Barclay and MacLean (5).

β-Cyanodihydrolycopodine XIII

This compound was prepared by the method of MacLean, Song, and Harrison (7).

Chromic Acid Oxidation of I, XII, and XIII

The oxidation procedure which was used was originally developed by Lemieux and Purves (8) for the quantitative estimation of acetyl, ethylidene, ethoxy, and α-hydroxyethyl groups. The distillate from the oxidation, which was pale yellow, was redistilled, and the colorless second distillate was titrated (pH meter) with 0.1 *N* sodium hydroxide. A small excess of alkali was added and the solution was evaporated to dryness.

Recovery of the acids was carried out by treating the residue of sodium salts with liquid hydrogen chloride. The excess hydrogen chloride was removed and the liberated acids distilled under high vacuum. The acids were recovered from their salts in about 90–95% yield by this procedure. The liberated acids contained a considerable amount of hydrogen chloride.

The recovered acids were treated with a slight excess of a freshly prepared solution of diazomethane in ether and the resulting solution of methyl esters was dried with a few crystals of anhydrous sodium sulphate. The solution was then separated into its components by gas chromatography. The methyl esters were identified by comparing the retention times of the bands with values obtained for known mixtures. The separation was carried out on a Perkin–Elmer column 'A' (didecyl phthalate on Celite) at 75° and at a flow rate of 150 ml/min. Under these conditions the following retention times (in minutes) were obtained:

Ether (used as reference)	0.00	Methyl butyrate	10.7
Methyl acetate	1.2	Methyl isovalerate	17.2
Methyl propionate	4.3	Methyl valerate	27
Methyl isobutyrate	6.8		

The actual retention time for ether was about 2 minutes. The relative yields of the acids formed in the oxidation were estimated by comparing the areas under the recorded ester peaks. The factors needed to correct the measured band areas for differences in the thermal conductivities of the esters were calculated from graphs obtained on chromatography of solutions of known composition. The over-all yield of acid was estimated from the amount of standard alkali which was required to neutralize the distillate from the oxidation. Since no titration blanks were run, however, the figures obtained for the over-all yields are not considered to be very reliable.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

When oxidized by this procedure, both α- and β-cyanodihydrolycopodine, XII and XIII, gave a mixture of acetic, propionic, and butyric acid. Lycopodine gave only acetic acid. The yields of the acids were as follows:

	Relative yields (%)			Total yield of acid (%)
	Acetic	Propionic	Butyric	
I	100	—	—	(50)
XII	62	14	24	(50)
XIII	69	23	8	(70)

The yields listed in the table for I and XII were obtained by the oxidation of 100-mg samples with 10 ml of 30% aqueous chromium trioxide. Oxidation of this much material was found to be unnecessary and a sample size of 10–25 mg is now recommended.

Preparation of the Benzylidene Derivative VII

The benzylidene derivative was prepared by the procedure of Barclay and MacLean (5). The ultraviolet spectrum of this compound had two maxima, at 240 mμ, log ε = 4.3, and at 280 mμ, log ε = 4.14.

Preparation of the Enol VIII

A solution of VII (0.40 g) in 15 ml of glacial acetic acid and 15 ml of methanol was cooled to −40° in a dry ice – acetone bath. A stream of oxygen containing 5% ozone was passed through the solution for 15 minutes at a rate of 50 ml/min. The solution was then transferred to a hydrogenation bottle, platinum oxide catalyst was added, and the mixture was shaken for about 2 hours under hydrogen at a pressure of 30 p.s.i. The solution was then filtered and evaporated, dilute aqueous bicarbonate and ether were added to the residue, and the ether layer was separated. The ether solution was washed successively with dilute hydrochloric acid, sodium bicarbonate solution, and water, and then extracted with a solution of sodium hydroxide. The alkaline extract was acidified with hydrochloric acid and extracted with chloroform. Evaporation of the chloroform solution gave a crystalline product (0.25 g) which melted at 157–158° after recrystallization from ether – petroleum ether. The melting point is the same as that reported by Barclay and MacLean (4), and the melting point of a mixture of the two compounds was not depressed.

Treatment of the Benzylidene Compound VII with Selenium Dioxide

The benzylidene derivative VII (2.86 g) and selenium dioxide (1.09 g) were dissolved in 100 ml of dioxane and heated under reflux for 3 hours. The mixture was evaporated to dryness and the residue exhaustively extracted with ether. The ether extract was washed with water to remove excess selenium dioxide, dried, and concentrated. From the concentrated solution, 1.78 g of the hydroxy derivative XIV separated. This material, after recrystallization from ether, melted at 212–217° C. Calc. for $C_{24}H_{30}O_2N_2$: C, 76.1; H, 7.99; N, 7.4%. Found: C, 76.1; H, 7.90; N, 7.4%.

The infrared spectrum of this compound showed hydroxyl absorption at 3560 cm^{-1}, cyanamide absorption at 2210 cm^{-1}, and carbonyl absorption at 1692 cm^{-1}, in solution in chloroform. The ultraviolet spectrum showed a maximum at 285 mμ, log ε = 4.2.

The mother liquor from the separation of XIV above was treated with methanol. From the ether–methanol solution, 0.46 g of compound XV separated. After recrystallization from ether–methanol it melted at 199–202°. Calc. for $C_{24}H_{28}ON_2$: C, 79.9; H, 7.84; N, 7.8%. Found: C, 79.6; H, 7.84; N, 7.7%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The infrared spectrum of this compound showed the usual cyanamide absorption at 2220 cm^{-1}, carbonyl absorption at 1677 cm^{-1}, a strong, sharp band at 1626 cm^{-1} attributed to double-bond absorption, and a band at 1590 cm^{-1} in the region of phenyl absorption.

The ultraviolet spectrum showed two maxima, at 310 mμ, log $\epsilon = 4.2$, and at 228 mμ, log $\epsilon = 3.0$.

Treatment of XIV with Ozone

Compound XIV (0.36 g) was dissolved in a mixture of 20 ml of methanol and 15 ml of glacial acetic acid. The solution was cooled to $-20°$ C and treated with a stream of 5% ozone in oxygen for a period of $\frac{1}{2}$ hour. The reaction mixture was then transferred to a flask fitted for steam distillation, and steam was passed through for 5–10 minutes. A yellow crystalline solid separated when the aqueous acetic acid mixture was cooled. The solid was collected and recrystallized from ether, and melted at 223–225° with decomposition. Calc. for $C_{17}H_{24}O_3N_2$: C, 67.1; H, 7.95; N, 9.2%. Found: C, 67.1; H, 7.99; N, 8.8%.

The infrared spectrum showed the usual cyanamide absorption at 2200 cm^{-1}, broad hydroxyl absorption and carbonyl absorption at 1724 cm^{-1}. The ultraviolet spectrum had a maximum at 420 mμ, log $\epsilon = 25$. There was no change in the ultraviolet spectrum when the solution was made alkaline.

The mother liquor from the separation of XVII above was extracted with chloroform. The chloroform extract was extracted with aqueous bicarbonate, and the bicarbonate extract was acidified and extracted again with chloroform. The latter chloroform extract was dried over sodium sulphate and evaporated to dryness. The residue was dissolved in a small volume of acetone from which it crystallized. After recrystallization from ether–acetone, compound XVIII melted at 206–208°. Calc. for $C_{17}H_{24}O_4N_2$: C, 63.7; H, 7.55; N, 8.7%. Found: C, 63.7; H, 7.71; N, 8.4%.

The infrared spectrum of this compound showed cyanamide absorption at 2210 cm^{-1}, a peak of 1735 cm^{-1} attributed to a six-membered lactone, and a peak at 1680 cm^{-1} attributed to a carboxyl group.

Conversion of XVII to VIII

The hydroxydione XVII (0.1 g) was dissolved in methanol and shaken with hydrogen at 35 p.s.i. over a platinum catalyst for 4 hours. The solution was filtered free of catalyst and evaporated to dryness, and the residue was crystallized from ether. The product melted at 157–158°, either alone or in admixture with the enol VIII.

Treatment of XV and VII with Hydrogen

Compound XV (0.15 g) was dissolved in methanol and shaken with hydrogen at 30 p.s.i. over a platinum catalyst for 11 hours. The solution was filtered free of catalyst and evaporated to dryness. Addition of ether gave a crystalline product which, after recrystallization from ether, melted at 206–208°. Calc. for $C_{24}H_{32}ON_2$: C, 79.1; H, 8.85; N, 7.7%. Found: C, 79.2; H, 8.85; N, 7.8%.

The infrared spectrum of XVI showed absorption in the carbonyl region in carbon tetrachloride solution at 1708 cm^{-1}. Its ultraviolet spectrum showed only non-conjugated phenyl absorption.

The same product was obtained on similar treatment of VII.

Deuterium Exchange and Deuterium Analysis

The compound (50 mg) was dissolved in deuteromethanol (CH_3OD), and 0.05 ml of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

20% sodium deuteroxide was added. The reaction mixture was heated under reflux for ½ hour under an atmosphere of nitrogen and then taken to dryness. A total of four such exchanges was carried out on each sample. To the residue remaining after the last exchange there was added 0.5 ml of deuterium oxide, and the reaction mixture was extracted with ether. The ether extract was dried over anhydrous magnesium sulphate, and the ether was evaporated, leaving a residue, which was purified by sublimation or crystallization from a non-hydroxylic solvent.

The deuterated samples were analyzed for their deuterium content by the method of Jones and MacKenzie (17). Deuterobiphenyl, $C_{12}D_{10}$, was used as a standard to check the analytical method. The results are tabulated below.

Compound	Number of deuterium atoms per molecule
Biphenyl	10.1, 10.0, 10.3
Lycopodine	2.74, 2.78, 2.74
α-Cyanolycopodine, VI	2.51, 2.61
α-Cyclized compound, XXI	1.95, 1.93, 1.95
β-Cyclized compound, XXII	0.00, 0.00
Hofmann product, XXIII*	1.92, 1.89, 1.92

*In this case each exchange was carried out for a 12-hour period. Under the conditions stated above the following results were obtained: 1.69, 1.65, 1.69.

Cyclized Compound XXI

The compound was prepared by the method reported previously (4, 7).

Cyclized Compound XXII

The compound was prepared by the method reported previously (4, 7).

Preparation of XIX by Dehydration and Hydride Reduction of XII

Compound XII (1.0 g) was dissolved in xylene containing *p*-toluenesulphonic acid (0.15 g), and the mixture was refluxed for 4 hours. The reaction mixture was cooled, washed with dilute acid, dilute sodium bicarbonate, and water. On removal of the xylene under reduced pressure on the steam bath, there remained a mobile oil (0.75 g) which failed to crystallize even after chromatography on alumina.

The infrared absorption spectrum of a film of this compound showed weak absorption in the unsaturation region near 1650 cm^{-1} and lacked hydroxyl absorption. The cyanamide absorption appeared at 2210 cm^{-1}.

The anhydro compound (1.6 g), prepared as described above, was added to a solution of 1.0 g of lithium aluminum hydride in boiling ethyl ether. The mixture was refluxed in a nitrogen atmosphere overnight. The excess lithium aluminum hydride was decomposed with moist ether; water was added and the mixture extracted with chloroform. On distillation of the chloroform there remained 1.2 g of an oil. This crude material was dissolved in ether and the basic fraction extracted with dilute hydrochloric acid. The acid extract was made alkaline with ammonia and the free base removed by ether extraction. A sample of this amorphous base was dissolved in a small volume of acetone. Concentrated hydrochloric acid was added and crystals of the hydrochloride formed. Recrystallization from acetone produced colorless needles, m.p. 245–247° C. Calc. for $C_{16}H_{27}N.HCl$: C, 71.2; H, 10.10; N, 5.2%. Found: C, 71.5; H, 10.20; N, 5.0%.

In carbon tetrachloride, the free base XIX showed infrared absorption in the unsaturation region at 1655 cm^{-1} and lacked cyanamide absorption. The hydrochloride showed a strong band at 1585 cm^{-1} in nujol or in chloroform, attributed to the ionized salt of the secondary amine.

Dehydrogenation of XIX

The dehydrogenation was carried out in a 15-ml, round-bottomed flask sealed to a 15-cm tube which served as an air condenser for the refluxing mixture. The apparatus was constructed so that it could be evacuated, flushed with nitrogen, and the reaction carried out in a slow stream of purified nitrogen. A small thermometer was inserted into the reaction flask to permit direct reading of the temperature of the mixture.

Compound XIX (0.80 g) was mixed with 0.80 g of selenium powder in the dehydrogenation apparatus. The apparatus was flushed with nitrogen several times and then inserted into an electrically heated salt bath maintained initially at 250°. The temperature of the reaction mixture was raised to 295° in $\frac{1}{2}$ hour, at which time the decomposition appeared to be rapid. The dehydrogenation was allowed to continue overnight in a slow stream of nitrogen and at a temperature up to 300°. The residue was removed from the apparatus with boiling chloroform. The chloroform extract was evaporated to dryness and the residue treated with boiling ethyl ether. The ether-soluble material was extracted repeatedly with dilute hydrochloric acid, and the combined acid extract was basified and then extracted repeatedly with ether. The crude base isolated in this manner amounted to 0.37 g. This material was dissolved in a small volume of cyclohexane and chromatographed on alumina. The progress of the fractionation was followed by recording the ultraviolet spectra of the eluates. The first eluates showed identical spectra. These were combined, and the solvent was evaporated to yield 0.07 g of a clear oil. This material was dissolved in a small volume of ether and added to a solution of an equal weight of picric acid dissolved in refluxing ether. There was immediate separation of glistening, yellow plates which, after recrystallization from ether, melted at 160–162°. Calc. for $C_{22}H_{24}N_4O_7$: C, 58.0; H, 5.26; N, 12.3%. Found: C, 58.3; H, 5.27; N, 12.2%.

The free base recovered from the picrate was analyzed on a high-temperature mass spectrometer and found to have a parent mass of 227, corresponding to $C_{16}H_{21}N$. The ultraviolet spectrum of this compound was typical of alkyl quinolines and was remarkably similar to that of 7,8-dimethylquinoline.

Preparation of Cyclized Product XXIII

Lycopodine was dissolved in acetone, and methyl iodide added. The methiodide separated immediately and virtually quantitatively and was recrystallized from methanol–acetone.

Lycopodine methiodide (3.3 g) was added to a solution of potassium (1.5 g) in *t*-butyl alcohol (100 ml). The mixture was heated under reflux for 12 hours and then evaporated to dryness. Water was added to the residue and the aqueous mixture extracted with ether. The dried ether extract was evaporated to dryness and dissolved in acetone, and the base was precipitated as its hydrochloride by addition of concentrated hydrochloric acid. The hydrochloride was dissolved in water, and the solution was made basic with ammonia and then extracted with ether. Evaporation of the ether gave a crystalline residue which was recrystallized from petroleum ether to yield compound XXIII which melted at 82°. The crude yield was 86%. Calc. for $C_{17}H_{27}ON$: C, 78.2; H, 10.34; N, 5.4%. Found: C, 78.1; H, 10.21; N, 5.3%.

The compound showed a strong band at 1695 cm^{-1} in its infrared spectrum. There were no bands which might be attributed to an olefin or olefinic hydrogens. The N.M.R. spectrum showed the presence of $\diagdown\!\!\diagup N—CH_3$ and $\diagdown\!\!\diagup CHCH_3$ groups.

Treatment of XXIII with Cyanogen Bromide

A small sample of XXIII was dissolved in dry benzene and treated with an excess of cyanogen bromide in dry benzene, and the mixture was allowed to stand overnight in the refrigerator. The cyanogen bromide and benzene were removed under reduced pressure, and the residue was taken up in chloroform, washed with acid, alkali, and water, dried, and taken to dryness. The residue formed a crystalline solid which was recrystallized from ether and melted at 162° C. Calc. for $C_{17}H_{24}ON_2$: C, 75.0; H, 8.82; N, 10.3%. Found: C, 74.9; H, 8.71; N, 10.3%.

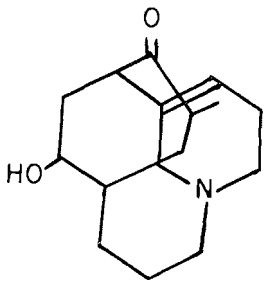
LYCOPODIUM ALKALOIDS



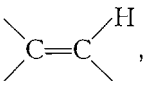
XI. THE STRUCTURE AND REACTIONS OF ACRIFOLINE[1]

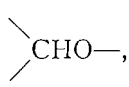
W. N. FRENCH[2] AND D. B. MACLEAN

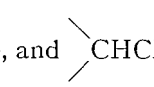
ABSTRACT

Structure A for acrifoline is proposed from a study of the products formed in the Hofmann degradation, von Braun degradation, and several oxidative degradations of the alkaloid. Structure C is proposed for a compound formed on treatment of dihydroacrifoline with copper sulphate in pyridine or with peroxytrifluoroacetic acid.

In a preliminary communication (1) we reported that acrifoline, $C_{16}H_{23}O_2N$, a minor alkaloid of *Lycopodium annotinum*, (2) had structure A. This structure has received support from the work of Anet (3), who has succeeded in interrelating acrifoline and several other *Lycopodium* alkaloids.



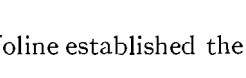




A

We now wish to report in greater detail the evidence in favor of this structure. Previously, Perry and MacLean (4) had established that acrifoline had a double bond, a hydroxyl group, a carbonyl group, and a tertiary nitrogen atom, and therefore was tetracyclic. The application of nuclear magnetic resonance spectroscopy has provided further information on the nature of these functional groups.

The N.M.R. spectrum of acrifoline showed absorptions of area 1 at displacements of 3.35 and 2.04 p.p.m.* attributed to $\diagdown$CHO— and $\diagdown$C=C$\diagup^{H}$ groups respectively. A doublet of area 3, occurring at a displacement of 6.20 p.p.m., established the presence of a $\diagdown$CHCH$_3$ group. The presence of one C-methyl group was also shown by Kuhn–Roth analysis of acrifoline (as its hydrobromide salt). An examination of the N.M.R. spectrum of acetylacrifoline (4) confirmed the above results. Its N.M.R. spectrum



[1]*Manuscript received June 30, 1961.*

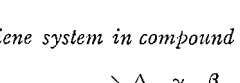
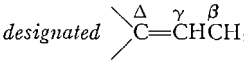
[2]*Holder of a National Research Council Studentship, 1958–60.*
**Chemical shifts are given in parts per million (p.p.m.) from chloroform.*

showed absorptions attributed to  ,  , and  at displacements

of 1.97, 2.64, and 6.30 p.p.m. respectively. A sharp peak at a displacement of 5.50 p.p.m. was assigned to the $-COCH_3$ group. The absence of absorption at low field in both of the above N.M.R. spectra rules out the presence of an aldehyde group and therefore, the carbonyl group of acrifoline must be ketonic. The hydroxyl group is secondary since the signal area of the CHO group corresponded to one proton.





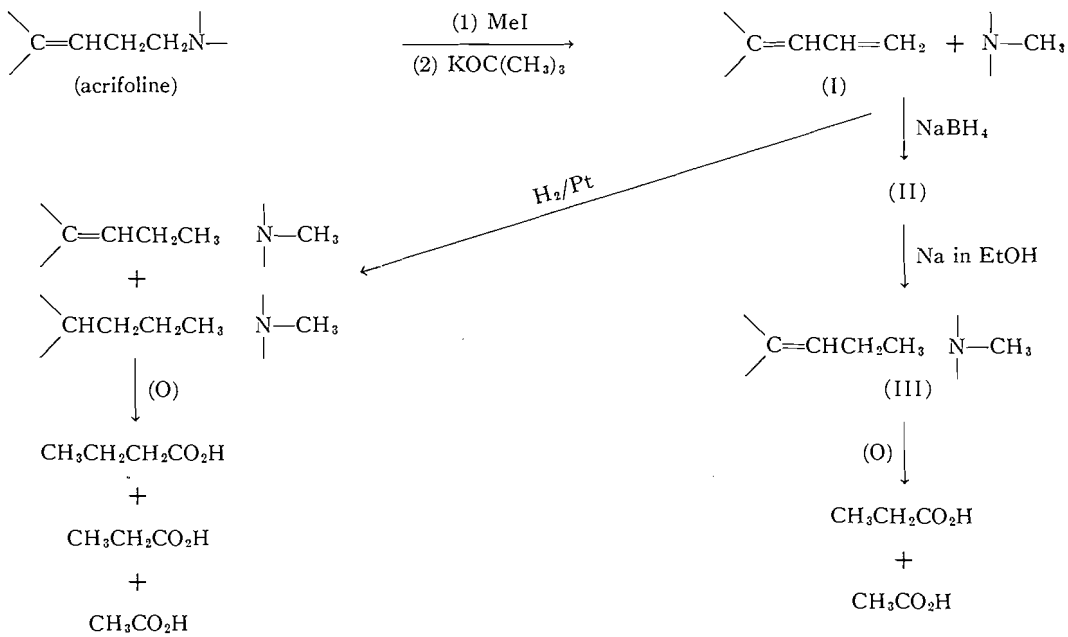
A clue to the spatial relationship of the carbonyl and hydroxyl groups came from infrared spectroscopy. The infrared spectrum of acrifoline in nujol showed hydroxyl absorption at 3310 cm^{-1}, but no carbonyl absorption, while in solution it exhibited strong carbonyl absorption at 1700 cm^{-1}, as well as the usual hydroxyl absorption. Both spectra showed ether absorption near 1100 cm^{-1}. The absence of carbonyl absorption in the solid state implies that acrifoline crystallizes as a hemiketal, whereas the presence of carbonyl absorption in solution indicates that an equilibrium exists between the hemiketal and the hydroxy-ketone forms. Since only five- and six-membered cyclic hemiketals form spontaneously, the carbonyl group and the carbon atom bearing the hydroxyl group must be separated by two or three atoms. The same phenomenon was also observed in many derivatives of acrifoline which contained the original carbonyl and hydroxyl groups.

A study of the products formed in the Hofmann degradation, in the von Braun degradation, and in several oxidative degradations led to the proposal of structure A for acrifoline. Each of these degradative approaches will be discussed in detail below.

The Hofmann degradation of acrifoline established the sequence  in

the molecule. Acrifoline readily formed a methiodide which, on treatment with potassium tertiary butoxide in boiling tertiary butanol, underwent Hofmann elimination to give a crystalline base (I), $C_{17}H_{25}O_2N$, in 70% yield. The infrared spectrum of I showed strong absorption at 900 cm^{-1} with an overtone at 1800 cm^{-1}, characteristic of a terminal methylene group. Strong absorption in the ultraviolet spectrum with a maximum at 2400 Å (ϵ = 24,000), along with an enhanced double-bond absorption in the infrared at 1625 cm^{-1}, showed that a conjugated diene system was present in compound I, and that the double bond introduced during the Hofmann reaction was in conjugation with the original double bond of acrifoline. Barring rearrangement, the original double bond in acrifoline must have occupied a γ,Δ position* relative to nitrogen. Ozonolysis of compound I, and subsequent isolation and identification of formaldehyde, confirmed the presence of a $=CH_2$ group. No other volatile carbonyl compound was isolated from the ozonolysis, nor were any non-volatile fragments characterized.

Catalytic reduction of the diene system in compound I led to the formation of a non-crystalline product which was probably a mixture of partially reduced and fully reduced compounds. A quantitative microhydrogenation of compound I showed the rapid uptake of one mole of hydrogen while the second mole was only partially consumed after several hours. However, chemical reduction of the diene system resulted in the formation of a



*The four carbon atoms in the conjugated diene system in compound I are designated  to facilitate the present discussion. Acrifoline is designated  .

For personal use only.

1,2-reduced product. The carbonyl group in compound I was first reduced with sodium borohydride to give a diol (II), $C_{17}H_{27}O_2N$. Treatment of II with sodium in alcohol gave III, $C_{17}H_{29}O_2N$. Compound III was oxidized by a modified Kuhn–Roth method (5) and yielded acetic acid and propionic acid. The acids were identified by vapor-phase chromatography of their methyl esters. The isolation of propionic acid established the presence of an ethyl group in III and proved that a 1,2-reduction had occurred with sodium in alcohol. Acrifoline was subjected to the same treatment and yielded only acetic acid, as expected.

Modified Kuhn–Roth oxidation of the crude material obtained by hydrogenation of the Hofmann product, I, yielded butyric acid as well as propionic and acetic acids. Therefore, a *n*-propyl group was present in the product of complete hydrogenation of compound I.

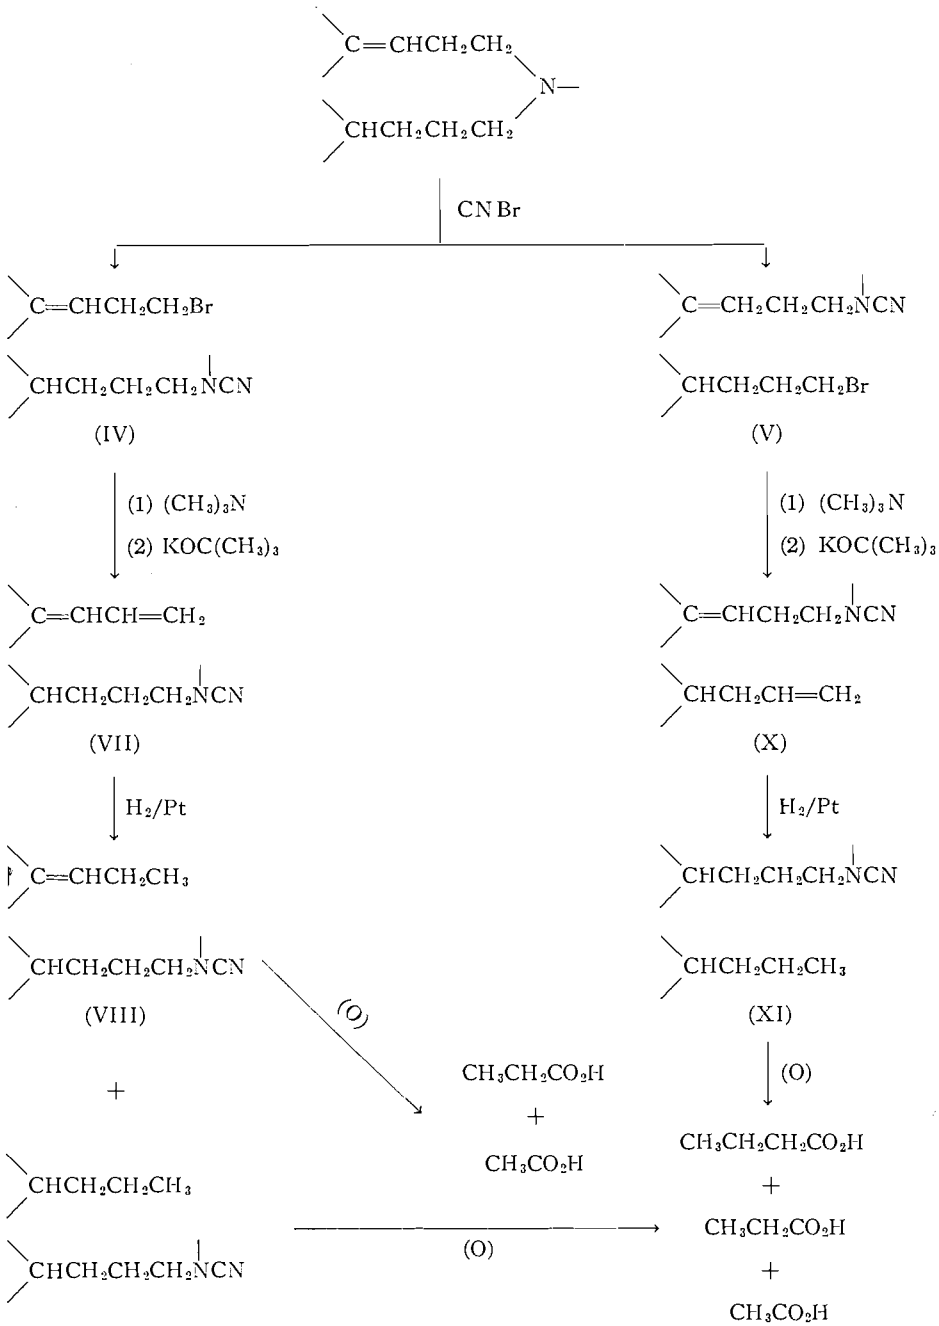
The N.M.R. spectrum of acrifoline established that the double bond was trialkylated. The oxidation studies show that the double bond must occupy a γ,Δ-position relative to nitrogen with the Δ C-atom dialkylated. The preceding series of reactions is summarized in the chart below.

Products from Hofmann degradation

A study of the products of the von Braun reaction of acrifoline confirmed the results of the Hofmann degradation and, in addition, allowed an extension of the peripheral structure to $-CH_2CH_2CH_2-\underset{|}{N}-CH_2CH_2CH=C\diagup\diagdown$. Reaction of acrifoline with cyanogen bromide yielded two isomeric cleavage products, α- and β-cyanobromoacrifoline, IV and V, respectively. β-Cyanobromoacrifoline (V), $C_{17}H_{23}O_2N_2Br$, was isolated in 30% yield as a crystalline product and α-cyanobromoacrifoline (IV) was obtained in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

22% yield as a crystalline quaternary ammonium bromide (VI), $C_{20}H_{32}O_2N_3Br$, on treatment of the mother liquor from the isolation of β-cyanobromoacrifoline (V) with trimethylamine. The quaternary ammonium bromide VI readily eliminated trimethylamine on treatment with potassium tertiary butoxide and formed a neutral product (VII), $C_{17}H_{22}O_2N_2$. The presence of a diene system in VII similar to that in I was established by an examination of its infrared and ultraviolet spectrum. One can conclude that the same ring cleavage occurred in the formation of both Hofmann product I, and α-cyanobromoacrifoline (IV).



Treatment of compound VII with hydrogen and platinum resulted mainly in a 1,2-reduction of the conjugated diene system. The crystalline product VIII, $C_{17}H_{24}O_2N_2$, was isolated in 50% yield, and gave propionic and acetic acids on oxidation by the modified Kuhn–Roth procedure. Some fully saturated material containing a *n*-propyl side chain was also formed along with compound VIII since oxidation of the material in the mother liquor from the isolation of VIII yielded a small amount of butyric acid in addition to propionic and acetic acids. These results substantiate the presence of the sequence $\diagdown C{=}CHCH_2CH_2N \diagup\diagdown$, in acrifoline.

The reaction of crystalline β-cyanobromoacrifoline (V) with trimethylamine gave a non-crystalline, ether-insoluble quaternary ammonium bromide (IX). Other reactions carried out on compound V, including reduction of the carbonyl group with sodium borohydride and removal of the bromine atom with hydrogen and palladium at room temperature or dry-ice temperature, also gave non-crystalline products. Treatment of the quaternary bromide IX with potassium tertiary butoxide gave an oil (X) which contained a terminal methylene group, as indicated by its infrared spectrum, and confirmed by the formation of formaldehyde upon ozonolysis. The terminal double bond was not in conjugation with the original double bond since there was no intense absorption in the ultraviolet region. Hydrogenation of the diolefin X gave an oil that partially crystallized from ether. This crystalline product (XI), $C_{17}H_{26}O_2N_2$, gave butyric, propionic, and acetic acids in an over-all yield of 68%, in a molar ratio of approximately 44:14:42, on modified Kuhn–Roth oxidation. The presence of butyric acid among the oxidation products proved that compound XI had a *n*-propyl side chain, and therefore, that the sequence $-\overset{|}{\underset{|}{C}}CH_2CH_2CH_2N\diagup\diagdown$ was present in acrifoline. The relatively high yield of butyric acid indicated that the *n*-propyl group in compound XI was not joined to a quaternary center. The reactions are summarized in the chart below.

The sequence $-COCH(CH_3)CH_2-$ in acrifoline, as well as the relationship of this sequence to the $\diagdown CHOH \diagup$ function, was established by a study of the products of selenium dioxide oxidation of acrifoline. The major product XII, $C_{16}H_{21}O_2N$, of this reaction proved to be an α,β-unsaturated ketone. The infrared spectrum of its perchlorate showed carbonyl absorption at 1690 cm^{-1} and enhanced double-bond absorption at 1627 cm^{-1}, and the ultraviolet spectrum of its perchlorate exhibited a maximum at 2430 Å ($\epsilon = 5330$). The possibility of skeletal rearrangement during the formation of compound XII was excluded by hydrogenation of compound XII to dihydroacrifoline.

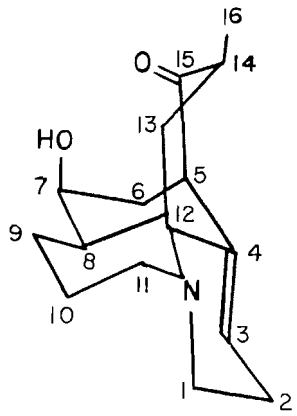
Products from von Braun degradation

The N.M.R. spectrum of compound XII had two peaks of area 1 at displacements of 1.96 and 3.37 p.p.m. representing the isolated double-bond proton and the $\diagdown$CHO

group respectively. A single, sharp peak at a displacement of 5.50 p.p.m. indicated that the methyl group was located on the double bond α,β to the carbonyl group. A single peak of area 1 occurring at a displacement of 0.23 p.p.m. was attributed to a proton on the β-carbon of the α,β-unsaturated ketone.

The minor product, XIII, isolated from the reaction of acrifoline with selenium dioxide had the same molecular formula, $C_{16}H_{21}O_2N$, as the major product XII. However, the ultraviolet spectrum of this material (as the perchlorate) showed no strong absorption while its infrared spectrum showed carbonyl absorption at 1725 cm^{-1}, but no hydroxyl absorption. Conversion of XII to XIII by treatment with base indicated that XIII was formed in the reaction medium by intramolecular addition of the hydroxyl group to the conjugated double-bond system. The ease of this addition implies that a five- or six-membered cyclic ether is formed, and that the carbon atom β to the carbonyl group and the carbon atom carrying the hydroxyl group are separated by two or three atoms. The N.M.R. spectrum of compound XIII had a doublet at a displacement of 6.22 p.p.m. representing the $\diagdown\!\!\diagup CHCH_3$ group, and a peak of area 1 at a displacement of 1.99 p.p.m. representing the single proton on the double bond. Two peaks, each of area 1, occurring at displacements of 3.19 and 3.54 p.p.m., were attributed to absorption by the two CHO groups, one group at either end of the ether linkage. The N.M.R. results on XII and XIII can only be explained if the sequence $-COC(CH_3)=CH-$ is present in the former and the sequence $-COCH(O\diagdown\!\!\diagup)CH-$ in the latter.

Oppenauer oxidation of dihydroacrifolinol* with aluminum tertiary butoxide and cyclohexanone in boiling toluene gave a crude product that showed two strong absorptions of equal magnitude at 1705 and 1735 cm^{-1} in the carbonyl region of the infrared spectrum, and hydroxyl absorption at 3500 cm^{-1}. Chromatography of the crude product led to the isolation of only one compound (XIV), $C_{16}H_{23}O_2N$, in 45% yield. The infrared spectrum of XIV showed a single, strong carbonyl absorption at 1705 cm^{-1} and no hydroxyl absorption. Compound XIV is probably a diketone with both carbonyl groups located in rings that are six-membered or larger. Absorption at 1420 cm^{-1} in the spectra of both the base XIV and its hydrobromide and none in this region in the spectrum of acrifoline (nujol, chloroform, or carbon tetrachloride) implies that a $-CH_2CO-$ group is present in compound XIV but is absent in acrifoline (6). Thus the $-CH_2CO-$ group in the diketone XIV must have arisen from a $-CH_2CHOH-$ group in acrifoline.



The occurrence of peaks at 1735 cm^{-1} and 3500 cm^{-1} in the infrared spectrum of crude compound XIV may be due to the presence of an aldol impurity containing a five-membered ketone ring.

**Previously, two dihydroacrifolinols were reported (4). α-Dihydroacrifolinol was reported to form by hydrogenation of acrifoline to dihydroacrifoline followed by reduction of the carbonyl group with lithium aluminum hydride. β-Dihydroacrifolinol was formed by initial reduction of the carbonyl group in acrifoline to give acrifolinol followed by hydrogenation. In the present investigation, the same product, melting at 192.5–193.0° and identical with α-dihydroacrifolinol, was formed by either of the above procedures.*

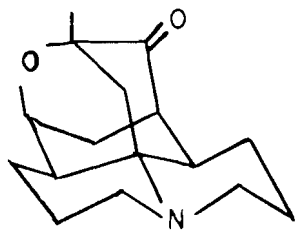
Structure A, which has been formulated for acrifoline, is in accord with the data presented above. It explains the existence of the hemiketal formed by interaction between the carbonyl and the hydroxyl functions. The facile conversion of the unsaturated compound XII to its saturated isomer XIII is readily accommodated by this structure. The separation of the double bond and the carbonyl group by a bridgehead carbon explains why an interaction between these two groups was never observed in acrifoline or its degradation products. The structure is biogenetically feasible and is compatible with the proposal recently put forward by Conroy (7). Furthermore, this structure is corroborated by the work, on annofoline, of Anet (8), who has also shown that annofoline is the C_4 epimer of dihydroacrifoline (4).

The stereochemistry of acrifoline has been discussed by Anet (3), who has proposed that it has the configuration shown in the perspective formula B below.

B



The only center where configuration might be in doubt is C_8, and the assignment shown is supported by the following experiments. Acrifoline underwent Wolff–Kishner reduction to XV, $C_{16}H_{25}ON$. The latter was converted by chromic acid oxidation to the ketone (XVI), $C_{16}H_{23}ON$, which was stable to the action of alkali.

Treatment of dihydroacrifoline, with copper sulphate in pyridine or with peroxytrifluoroacetic acid, resulted in the formation of a new compound (XVII), $C_{16}H_{23}O_2N$. The structure of this compound has been established and its formation involved an unexpected ether-bridging reaction.

Product XVII was formed in 78% yield on treatment of dihydroacrifoline with copper sulphate in pyridine. In its infrared spectrum there was a peak at 1725 cm^{-1} attributed to a carbonyl group, but no absorption which could be attributed to a hydroxyl group. The carbonyl peak was shifted by 25 cm^{-1} from its position in the starting material. The N.M.R. spectrum of XVII had absorption of area 1 at a displacement of 3.55 p.p.m. due to a $\diagdown\!\!\diagup$CHO— group, and a sharp, single peak at a displacement of 6.16 p.p.m. due to the methyl group on a carbon atom not carrying a proton. Compound XVII underwent reduction to a secondary alcohol (XVIII) with sodium borohydride and reacted with phenyllithium to form a phenylcarbinol (XIX). The alcohol XVIII yielded a monoacetate (XX) on treatment with a mixture of acetic acid and trifluoroacetic anhydride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and was converted with chromic acid to the ketone XVII. Compound XVII was, therefore, assigned structure C.

C

The over-all reaction closely resembles the oxidation of other aldehydes and ketones by various reagents (9, 10), in which oxidation occurs by a free radical process at the α-carbon atom after enolization has occurred.

The same product was obtained on attempted Baeyer–Villiger oxidation of dihydroacrifoline. The reaction was carried out under standard conditions (11, 12) using peroxytrifluoroacetic acid in methylene chloride in the presence of disodium phosphate.

EXPERIMENTAL

Acrifoline

Acrifoline was obtained from annotoxine according to the procedure of Perry and MacLean (4). Calc. for $C_{16}H_{23}O_2N.HBr$: one C-methyl, 4.39%. Found: C-methyl, 4.15%.

Acetyl Acrifoline

Acetyl acrifoline was prepared from acrifoline by the procedure of Perry and MacLean (4).

Preparation of Acrifoline Methiodide

A solution of acrifoline (1.0 g) in 15 ml of acetone and 3 ml of methyl iodide was heated under reflux and, within 2 minutes, a crystalline methiodide began to separate. The mixture was heated for 15 minutes longer, cooled, and allowed to stand at room temperature for 1 hour. Filtration gave 1.23 g (80%) of product melting at 278–279° (with decomposition). An additional 0.260 g (17%) of product was obtained from the filtrate on further treatment with methyl iodide in acetone. Recrystallization of the methiodide from methanol–acetone gave colorless needles melting at 280–281° (with darkening). Bertho and Stoll (13) report a melting point of 249–250°, and Achmatowicz and Rodewald (14), a melting point of 267–268° for this compound. Calc. for $C_{16}H_{23}O_2N.CH_3I$: C, 50.6; H, 6.49; N, 3.47%. Found: C, 50.5; H, 6.47; N, 3.12%.

Treatment of Acrifoline Methiodide with Potassium Tertiary Butoxide

A mixture of acrifoline methiodide (1.10 g) and potassium tertiary butoxide (1.50 g) in 60 ml of tertiary butanol and 2 ml of benzene was heated under reflux for 4 hours. The mixture was cooled, water was added, and the organic solvents were removed under reduced pressure. The resulting alkaline aqueous mixture was extracted several times

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure. The residual oil was crystallized from petroleum ether to give 0.53 g (70%) of colorless needles melting at 158–159°. Recrystallization from petroleum ether gave compound I which melted sharply at 161°. Calc. for $C_{17}H_{25}O_2N$: C, 74.1; H, 9.15%. Found: C, 73.7; H, 9.02%.

The infrared spectrum of this material had hydroxyl absorption at 3500 cm^{-1}, carbonyl absorption at 1700 cm^{-1}, double-bond absorption at 1650 cm^{-1} (weak) and 1625 cm^{-1} (strong), and $=CH_2$ absorption at 900 cm^{-1} with an overtone at 1800 cm^{-1}. The ultraviolet spectrum had $\lambda_{max}^{C_2H_5OH}$ at 2400 Å, ϵ = 24,000.

Ozonolysis of the Hofmann Product I

A stream of ozone-enriched oxygen was passed through a solution of the Hofmann product (0.10 g) in 15 ml of glacial acetic acid until the uptake of ozone was complete (about 20 minutes), then zinc dust (0.50 g) was added and the mixture steam distilled.

Formaldehyde was isolated from the steam distillate as its 2,4-dinitrophenylhydrazone and as its dimedone derivative. The melting points of both derivatives agreed with recorded values, and showed no depression on admixture with authentic samples.

Reduction of I with Sodium Borohydride

A solution of compound I (0.20 g) and $NaBH_4$ (0.2 g) in 15 ml of absolute ethanol was allowed to stand at room temperature for 6 hours. The excess borohydride was destroyed with formaldehyde, water was added, and the organic solvent was removed under reduced pressure. The product was isolated by extraction of the aqueous alkaline mixture with chloroform, extraction of this chloroform solution with dilute aqueous acid, and extraction of the basified aqueous solution with chloroform. The latter chloroform solution was dried over anhydrous sodium sulphate and evaporated under reduced pressure, yielding 0.20 g of crystalline solid melting at 249–251°. An analytical sample of compound II, m.p. 251.5–252.0°, was obtained after two recrystallizations from methanol–acetone. Calc. for $C_{17}H_{27}O_2N$: C, 73.6; H, 9.81; N, 5.05; NCH_3, 10.5%. Found: C, 73.4; H, 9.83; N, 5.07; NCH_3, 10.8%.

The infrared spectrum had hydroxyl absorption in the 3000–3200 cm^{-1} region, no carbonyl absorption, double-bond absorption at 1625 and 1590 cm^{-1}, and $=CH_2$ absorption at 900 cm^{-1} with an overtone at 1800 cm^{-1}. The ultraviolet spectrum had $\lambda_{max}^{C_2H_5OH}$ at 2400 Å, ϵ = 28,000.

Sodium in Alcohol Reduction of the Diol II

A solution of compound II (0.30 g) in 75 ml of absolute ethanol was heated to boiling, and sodium was added in small pieces over a period of $3\frac{1}{2}$ hours at such a rate that metallic sodium was always present in the medium. The solution was cooled, ethanol and water were added, and the organic solvent was removed under reduced pressure. The resulting aqueous mixture was extracted several times with chloroform. The combined, pale yellow chloroform solution was extracted with dilute aqueous acid and the acid extract made alkaline with ammonia and extracted with chloroform. The latter chloroform solution was dried over anhydrous sodium sulphate and evaporated under reduced pressure. The residual colorless oil was crystallized from acetone–ether, yielding 0.264 g (88%) of compound III which melted at 191.5–192.5°. Recrystallization from acetone–ether raised the melting point to 194.5–195.0°. Calc. for $C_{17}H_{29}O_2N$: C, 73.0; H, 10.5%. Found: C, 72.8; H, 10.5%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Neither the infrared nor ultraviolet spectrum of this compound showed absorption characteristic of a conjugated diene system.

Oxidative Determination of Alkyl Side Chains

The oxidations were carried out and the acids analyzed by the method described by Harrison (5).

Modified Kuhn–Roth Oxidation of Acrifoline

Oxidation of 0.025 g (0.096 millimole) of acrifoline yielded 0.082 milliequivalent (86%) of volatile carboxylic acid. Vapor-phase chromatography of its methyl ester indicated only the presence of methyl acetate.

Modified Kuhn–Roth Oxidation of the 1,2-Reduced Hofmann Product III

Oxidation of 0.030 g (0.108 millimole) of compound III yielded 0.183 milliequivalent (85%) of volatile carboxylic acids. Vapor-phase chromatography of their methyl esters revealed the presence of methyl acetate and methyl propionate in the molar ratio of 67:33 respectively.

Modified Kuhn–Roth Oxidation of Crude Hydrogenated Hofmann Product

The Hofmann product I (0.030 g, 0.109 millimole) was dissolved in methanol and treated with hydrogen (50 p.s.i.g.) and platinum (0.025 g PtO_2) for 15 hours. The catalyst was removed by filtration, and the solvent was evaporated under reduced pressure, leaving a colorless oil. Chromic acid oxidation of this crude product yielded 0.218 milliequivalent of volatile carboxylic acids. Vapor-phase chromatography of their methyl esters revealed the presence of methyl acetate, methyl propionate, and methyl butyrate in the molar ratio of 77:19:4 respectively.

Reaction of Acrifoline with Cyanogen Bromide

(a) Isolation of β-Cyanobromoacrifoline V

A solution of acrifoline (1.0 g) and cyanogen bromide (1.0 g) in 15 ml of anhydrous benzene was allowed to stand at room temperature for 40 hours. The solvent and excess cyanogen bromide were removed under reduced pressure and the residue taken up in chloroform, washed with dilute acid, water, and aqueous sodium bicarbonate. Acrifoline (0.13 g) was recovered from the acid extract. The chloroform solution was dried over anhydrous sodium sulphate and evaporated under reduced pressure leaving 1.0 g of a pale yellow oil, which was taken up in acetone–ether and placed in the refrigerator. After several hours, 0.41 g (30%) of colorless crystals, melting at 153–154°, were removed by filtration. Recrystallization from acetone–ether raised the melting point to 154.5°. Calc. for $C_{17}H_{23}O_2N_2Br$: C, 55.6; H, 6.31; N, 7.63%. Found: C, 56.0; H, 6.67; N, 7.92%.

The infrared spectrum of this material in nujol showed cyanamide absorption at 2200 cm^{-1} and hydroxyl absorption at 3300 cm^{-1}, but no absorption in the carbonyl region. The infrared spectrum in chloroform showed hydroxyl absorption at 3580 cm^{-1}, cyanamide absorption at 2205 cm^{-1}, weak carbonyl absorption at 1710 cm^{-1}, and double-bond absorption at 1670 cm^{-1}.

(b) Isolation of α-Cyanobromoacrifoline IV as its Quaternary Trimethylammonium Bromide VI

The filtrate from the separation of the crystalline bromide V was evaporated to dryness, yielding an oil, which was dissolved in 5 ml of absolute ethanol containing trimethylamine (0.00075 equiv. per ml). After the solution had remained for 24 hours at room temperature, the solvent and excess trimethylamine were removed under reduced pressure. The residue

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

partially crystallized on addition of acetone, and on filtration yielded 0.364 g (22%, based on the weight of acrifoline used) of colorless crystals melting at 276.0–276.5°. Recrystallization from methanol–acetone raised the melting point to 276.5–277.0°. Calc. for $C_{20}H_{32}O_2N_3Br$: C, 56.3; H, 7.57; N, 9.86%. Found: C, 56.5; H, 7.57; N, 9.66%.

The infrared spectrum showed hydroxyl absorption at 3300 cm^{-1}, cyanamide absorption at 2210 cm^{-1}, double-bond absorption at 1655 cm^{-1}, and weak carbonyl absorption at 1700 cm^{-1}.

Treatment of VI with Potassium Tertiary Butoxide

A mixture of the quaternary ammonium bromide VI (0.250 g) and potassium tertiary butoxide (0.50 g) in 25 ml of tertiary butanol and 1 ml of benzene was heated under reflux for 2 hours. The mixture was cooled, water was added, and the organic solvent was removed under reduced pressure. The resulting alkaline aqueous mixture was extracted several times with chloroform. The combined chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure, yielding a colorless oil which crystallized from petroleum ether. The first crop of compound VII weighed 0.135 g (80%) and melted at 183.0–183.5°. Recrystallization from ether – petroleum ether did not raise the melting point. Calc. for $C_{17}H_{22}O_2N_2$: C, 71.3; H, 7.75; N, 9.78%. Found: C, 71.4; H, 7.67; N, 9.86%.

The infrared spectrum in nujol showed terminal methylene absorption at 900 cm^{-1} with an overtone at 1800 cm^{-1}, double bond absorption at 1640 cm^{-1} and 1590 cm^{-1}, cyanamide absorption at 2210 cm^{-1}, and hydroxyl absorption at 3300 cm^{-1}. The infrared spectrum in chloroform showed carbonyl absorption at 1705 cm^{-1} and hydroxyl absorption at 3480 cm^{-1} as well as the absorptions due to unsaturation and the cyanamide group. The ultraviolet spectrum had $\lambda_{max}^{95\%\ EtOH}$ at 2400 Å, $\epsilon = 24{,}800$.

Hydrogenation of VII

Compound VII (0.087 g) was dissolved in 20 ml of methanol and treated with hydrogen (50 p.s.i.g.) and platinum (0.050 g PtO_2) for 15 hours. The catalyst was removed by filtration, and the solvent was evaporated under reduced pressure. The colorless residue was dissolved in chloroform, and the chloroform solution was washed first with dilute hydrochloric acid and then with aqueous sodium bicarbonate, and dried over anhydrous sodium sulphate. Evaporation of the chloroform under reduced pressure left a colorless oil which partially crystallized from ether. A total of 0.045 g (50%) of crystalline product VIII, melting at 154–155°, was obtained. This material was sublimed at 0.001 mm and 140° for analysis. Calc. for $C_{17}H_{24}O_2N_2$: C, 70.8; H, 8.39%. Found: C, 70.3; H, 8.37%.

The infrared spectrum of this compound had broad hydroxyl absorption in the 3400 cm^{-1} region, weak carbonyl absorption at 1710 cm^{-1}, and cyanamide absorption at 2240 cm^{-1}. In chloroform solution, the infrared spectrum of VIII showed hydroxyl absorption at 3650 cm^{-1}, weak carbonyl absorption at 1710 cm^{-1}, cyanamide absorption at 2240 cm^{-1}, and strong ether absorption at 1100 cm^{-1}.

Modified Kuhn–Roth Oxidation of VIII

Oxidation of 0.0134 g (0.047 millimole) of VIII yielded 0.068 milliequivalent (73%) of volatile carboxylic acids. Vapor-phase chromatography of their methyl esters indicated the presence of methyl acetate and methyl propionate in the molar ratio of 69:31 respectively.

Modified Kuhn–Roth Oxidation of Crude Hydrogenated α-Cyano Compound VII

The filtrate obtained from the isolation of crystalline VIII was taken to dryness and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the residual oil distilled at 0.001 mm and 130–140°. Chromic acid oxidation of a portion of this material (0.012 g, 0.045 millimole) yielded 0.061 milliequivalent (68%) of volatile carboxylic acids. Vapor-phase chromatography of their methyl esters indicated the presence of methyl acetate, methyl propionate, and methyl butyrate in the molar ratios of 77:21:2 respectively.

Removal of Hydrogen Bromide from β-Cyanobromoacrifoline V

A solution of β-cyanobromoacrifoline (V) (0.20 g) in 7 ml of absolute ethanol containing trimethylamine (0.00075 equiv. per ml) was allowed to stand for 40 hours at room temperature. The solvent and excess trimethylamine were removed under reduced pressure, leaving an oil (IX) which could not be induced to crystallize.

A solution of the non-crystalline quaternary ammonium bromide IX in 20 ml of tertiary butanol and 1 ml of benzene was heated under reflux with potassium tertiary butoxide (0.60 g) for 3 hours. The mixture was cooled, water was added, and the organic solvents were removed under reduced pressure. The resulting aqueous mixture was extracted several times with chloroform. The combined chloroform extract was washed with dilute aqueous acid and aqueous sodium bicarbonate, dried over anhydrous sodium sulphate, and evaporated under reduced pressure. The residual colorless oil (X) (0.090 g, 58%) could not be induced to crystallize, even after purification by chromatography on alumina or by distillation *in vacuo*.

The infrared spectrum (film) of the oil X showed carbonyl absorption at 1705 cm^{-1}, double-bond absorption at 1635 cm^{-1}, terminal double-bond absorption at 910 cm^{-1} with an overtone at 1820 cm^{-1}, hydroxyl absorption at 3490 cm^{-1}, and cyanamide absorption at 2200 cm^{-1}. The crude oil showed no absorption in the ultraviolet region of the spectrum other than weak absorption owing to the carbonyl group.

Ozonolysis of Compound X

A solution of compound X (0.048 g) in 10 ml of glacial acetic acid was treated with an excess of ozone. Zinc dust (0.30 g) was added to the solution and the mixture steam distilled. The steam distillate (30 ml) was neutralized with sodium hydroxide, made slightly acid with acetic acid, and treated with 5 ml of dimedone solution. Five hours later, 0.044 g of needles, melting at 165–175°, was removed by filtration. Recrystallization gave 0.025 g of dimedone derivative with a sharp melting point of 190°. A mixture melting point with authentic formaldehyde dimedone derivative showed no depression.

Hydrogenation of X

Compound X, prepared as above from 0.205 g of V, was dissolved in methanol and treated with hydrogen (50 p.s.i.g.) and platinum (0.050 g of PtO_2) for 10 hours. The catalyst was removed by filtration and the solvent by evaporation under reduced pressure. The residual colorless oil was taken up in ether from which colorless crystals separated after several hours. The crystalline product XI amounted to 0.039 g (24%, based on the weight of β-cyanobromoacrifoline (V) used), and melted at 155.5–157.5°. This material was sublimed at 100–130° and 0.001 mm for analysis. Calc. for $C_{17}H_{26}O_2N_2$: C, 70.3; H, 9.03; N, 9.65%. Found: C, 70.4; H, 8.91; N, 9.43%.

The infrared spectrum of XI had a sharp absorption at 3370 cm^{-1} due to hydroxyl, strong absorption at 2200 cm^{-1} due to the cyanamide group, but no absorption in the 1600–1800 cm^{-1} region.

Modified Kuhn–Roth Oxidation of XI

Oxidation of 0.019 g (0.067 millimole) of dihydro-β-cyanoacrifoline (XI) yielded

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

0.086 milliequivalent (66%) of volatile carboxylic acids. Vapor-phase chromatography of their methyl esters revealed the presence of methyl acetate, methyl propionate, and methyl butyrate in the molar ratios of 42:14:44 respectively.

Selenium Dioxide Oxidation of Acrifoline

A stirred solution of 0.50 g of selenium dioxide and 0.50 g of acrifoline in 25 ml of aqueous dioxane (10% water) was heated under reflux under an atmosphere of nitrogen for 8 hours. During this period, black selenium metal precipitated and the solution became deep yellow in color. The solution was cooled, diluted with 50 ml of water, and excess selenium dioxide destroyed by reduction with sulphur dioxide. The precipitated metallic selenium was removed by filtration through a sintered glass funnel and the clear, yellow acidic filtrate was washed with chloroform, made alkaline with ammonia and extracted several times with chloroform. The latter chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure. The residual yellow oil (0.415 g) was chromatographed on alumina with benzene. The first band, eluted with benzene, was a colorless oil (XIII) which formed 0.045 g (6.5%) of a crystalline perchlorate melting at 270–271° (with decomposition). Calc. for $C_{16}H_{21}O_2N.HClO_4$: C, 53.4; H, 6.16; N, 3.89%. Found: C, 53.4; H, 6.12; N, 4.05%.

The infrared spectrum of this compound had carbonyl absorption at 1725 cm^{-1}, double-bond absorption at 1680 cm^{-1}, but had no absorption in the hydroxyl region. The ultraviolet absorption spectrum showed only weak absorption at 2900 Å corresponding to a carbonyl group.

A second band was eluted from the column with chloroform. Evaporation of the solvent left a light yellow oil that partially formed a crystalline perchlorate from acetone–ether. The perchlorate (0.20 g) (30%) (m.p. 267–269°) was purified for analysis by two recrystallizations from methanol–acetone. It finally melted at 273.5–274.0°. Calc. for $C_{16}H_{21}O_2N.HClO_4$: C, 53.4; H, 6.16; N, 3.89%. Found: C, 53.6; H, 6.17; N, 3.97%.

The infrared spectrum of the perchlorate had hydroxyl absorption at 3530 cm^{-1}, carbonyl absorption at 1690 cm^{-1}, and conjugated double-bond absorption at 1627 cm^{-1}. The ultraviolet absorption spectrum had $\lambda_{max}^{C_2H_5OH}$ at 2430 Å, $\epsilon = 5330$.

The base recovered from the filtrate of the above perchlorate preparation weighed 0.150 g but was not characterized.

Conversion of the Unsaturated Compound XII to the Saturated Compound XIII

A solution of the perchlorate of the unsaturated carbonyl compound (0.020 g) in 6 ml of 95% ethanol containing sodium hydroxide (0.05 g) was allowed to stand at room temperature for 24 hours. The solution was diluted with water and extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated to dryness leaving a colorless oil which formed 0.015 g (75%) of crystalline perchlorate. The infrared spectrum of this salt was identical with that of the perchlorate of the saturated carbonyl compound XIII obtained from the selenium dioxide reaction.

Oppenauer Oxidation of Dihydroacrifolinol

A solution of 0.170 g of dihydroacrifolinol (4) and aluminum tertiary butoxide (0.50 g) in 2 ml of cyclohexanone and 25 ml of toluene was heated under reflux for 7 hours, then poured into cold dilute hydrochloric acid, and the organic layer extracted several times with dilute acid. The aqueous extract was made alkaline with sodium hydroxide solution and extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure, leaving a pale yellow oil whose infrared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

spectrum (film) showed two intense absorptions of equal magnitude at 1705 cm^{-1} and 1735 cm^{-1} in the carbonyl region, and absorption at 3500 cm^{-1} in the hydroxyl region.

The crude base obtained above was chromatographed on alumina with 25% chloroform in benzene, and yielded a colorless oil which crystallized in poor yield from ether – petroleum ether, giving 0.016 g of solid XIV which melted at 128–129°. The infrared spectrum of this solid XIV showed a single strong carbonyl absorption at 1705 cm^{-1} and no hydroxyl absorption. A sharp peak at 1420 cm^{-1} was indicative of a —CH_2— group adjacent to a carbonyl. The entire pure product obtained by chromatography was converted to the hydrobromide salt which was recrystallized twice from methanol–acetone for analysis. The total yield of salt (which melted above 315°) was 0.10 g (45%). Calc. for $C_{16}H_{23}O_2N$.HBr: C, 56.1; H, 7.07; N, 4.09%. Found: C, 56.2; H, 7.12; N, 4.11%.

The infrared spectrum of the hydrobromide showed a single, strong carbonyl absorption at 1700 cm^{-1}, but no hydroxyl absorption. A sharp peak at 1420 cm^{-1} was again indicative of a —CH_2— group adjacent to a carbonyl. There was no strong absorption in the ultraviolet spectrum.

A second product of the Oppenauer oxidation containing carbonyl absorption at 1735 cm^{-1} in the infrared spectrum was not isolated.

Wolff–Kishner Reduction of Acrifoline

A solution of acrifoline (0.75 g), potassium hydroxide (2.5 g), and 95% hydrazine hydrate (2 ml) in 25 ml of ethylene glycol was heated in a flask provided with a reflux condenser and a thermometer dipping into the liquid. The solution was heated under reflux for 4 hours (reaction medium at 155°), then the apparatus was arranged for distillation. Distillation was carried out until the flask contents reached a temperature of 185°. The solution was heated under reflux for 7 hours at this temperature, then cooled, diluted with water, and extracted with chloroform. The chloroform extract was washed with water, dried over anhydrous sodium sulphate, and evaporated to dryness under reduced pressure. The colorless residual oil readily crystallized and yielded 0.60 g (85%) of product which melted 122–123° on recrystallization from petroleum–ether. Calc. for $C_{16}H_{25}ON$: C, 77.7; H, 10.1; N, 5.7%. Found: C, 77.6; H, 10.3; N, 5.7%.

The infrared spectrum of this compound showed hydroxyl absorption at 3120 cm^{-1} and no carbonyl absorption. Carbonyl absorption was also absent when the spectrum was measured in chloroform.

Chromic Acid Oxidation of the Wolff–Kishner Product

A solution of 0.55 g of the Wolff–Kishner product in 20 ml of aqueous acetic acid (15% water) was cooled to −10° and treated with 1.0 g of chromic anhydride. The solution was stirred at this temperature for 1 hour, allowed to stand at 0° for 10 hours, and stirred at 0° for 4 hours. Ethanol was added to destroy excess oxidant, then water was added, and most of the acetic acid was removed by evaporation under reduced pressure. The resulting aqueous solution was made alkaline with ammonia and extracted with chloroform. The dried chloroform extract, on evaporation, yielded a colorless oil which readily crystallized without addition of solvent. Purification by sublimation at 80° and 0.001 mm gave 0.415 g (76%) of product melting at 73.5–75.0°.

The infrared spectrum showed strong carbonyl absorption at 1710 cm^{-1} and no hydroxyl absorption.

The perchlorate of this base melted at 246–247° and had strong carbonyl absorption at 1710 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Ketone XVI was recovered unchanged after treatment with sodium methoxide in methanol or potassium tertiary butoxide in tertiary butanol.

Oxidation of Dihydroacrifoline with Copper Sulphate

A solution of dihydroacrifoline (0.5 g), prepared by the method of Perry and MacLean (4), and $CuSO_4.5H_2O$ (1.2 g) in 12 ml of pyridine and 4 ml of water was heated on the steam bath for 24 hours. The deep blue solution was cooled, poured into water, and extracted several times with chloroform. The combined chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure, leaving a yellow oil. Chromatography of this oil with chloroform on alumina yielded a colorless oil that readily formed 0.51 g (78%) of a crystalline hydrobromide (m.p. above 315°) from acetone. Calc. for $C_{16}H_{23}O_2N.HBr$: C, 56.1; H, 7.07; N, 4.09%. Found: C, 55.8; H, 6.87; N, 4.11%.

The infrared spectrum showed strong carbonyl absorption at 1720 cm^{-1} but no absorption in the hydroxyl region.

A sample of the hydrobromide of compound XVII was converted to the perchlorate salt which melted above 315°. Calc. for $C_{16}H_{23}O_2N.HClO_4$: C, 53.1; H, 6.68; N, 3.87%. Found: C, 53.4; H, 6.83; N, 3.99%.

The perchlorate showed strong absorption at 1720 cm^{-1} in the carbonyl region of the infrared spectrum, but no absorption in the hydroxyl region. Likewise, the infrared spectrum of the free base XXIV showed only carbonyl absorption and no hydroxyl absorption when measured either as a film or in chloroform solution.

Oxidation of Dihydroacrifoline with Peroxytrifluoroacetic Acid

A stock solution of peroxytrifluoroacetic acid in methylene chloride was prepared in the following manner. A solution of trifluoroacetic anhydride (6.3 ml) in 10 ml of methylene chloride was added to a cold, stirred suspension of 1 ml of 90% hydrogen peroxide in 10 ml of methylene chloride and the mixture was stirred until homogeneous and then diluted to 100 ml with methylene chloride. To 35 ml of this solution was added 0.10 g of dihydroacrifoline and 3.0 g of Na_2HPO_4. The mixture was heated under reflux for 16 hours, cooled, and poured into an aqueous solution of sulphur dioxide. After 30 minutes, the aqueous phase was made alkaline with ammonia and extracted several times with chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure, leaving 0.050 g of colorless oil. This oil formed hydrobromide and perchlorate salts whose infrared spectra were identical with those of the corresponding salts of the product XVII isolated from the oxidation of dihydroacrifoline with copper sulphate.

Reduction of Compound XVII

A solution of the hydrobromide of XVII (0.20 g) and sodium borohydride (0.20 g) in 25 ml of absolute ethanol was heated under reflux for 1 hour. The mixture was cooled and acetone was added to destroy excess sodium borohydride. Water was then added, and the organic solvents removed under reduced pressure. The resulting aqueous mixture was extracted with chloroform, and the dried chloroform extract evaporated under reduced pressure. Crystallization of the residual oil from ether–petroleum ether gave 0.115 g (75%) of product XVIII which melted at 182–183°. This material was sublimed at 0.001 mm and 110° for analysis. It melted at 182–183°. Calc. for $C_{16}H_{25}O_2N$: C, 73.0; H, 9.56; N, 5.32%. Found: C, 73.1; H, 9.75; N, 4.65%.

The infrared spectrum of compound XVIII showed hydroxyl absorption at 3380 cm^{-1},

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

no carbonyl absorption, and peaks at 1070 cm^{-1} and 1100 cm^{-1} attributed to ether absorption.

The mother liquor from the separation of the crystalline base was acidified with hydrobromic acid, and yielded 0.040 g (20%) of hydrobromide salt of compound XVIII. The hydrobromide was crystallized twice from methanol–acetone for analysis. It melted above 310°. Calc. for $C_{16}H_{25}O_2N.HBr$: C, 55.8; H, 7.61; N, 4.07%. Found: C, 56.1; H, 7.45; N, 4.45%.

The infrared spectrum showed hydroxyl absorption at 3300 cm^{-1} and ether absorption at 1075 cm^{-1} and 1105 cm^{-1}.

Preparation of the Acetate of XVIII

A solution of 0.030 g of XVIII in the mixed anhydride of trifluoroacetic acid and acetic acid (prepared by mixing 0.10 ml of glacial acetic acid and 0.16 ml of trifluoroacetic anhydride) was allowed to stand overnight at room temperature. The solution was poured into a dilute aqueous ammonia solution, and then extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure, leaving a colorless oil which slowly solidified. The solid, compound XX, was sublimed at 75° and 0.001 mm for analysis, and melted at 148–149°. Calc. for $C_{18}H_{27}O_3N$: C, 70.8; H, 8.91; N, 4.59%. Found: C, 71.1; H, 8.75; N, 4.88%.

The infrared spectrum of XX had no hydroxyl absorption but had strong acetate absorption at 1730 cm^{-1} and 1235 cm^{-1}. A strong peak at 1042 cm^{-1} was attributed to ether absorption.

Oxidation of Compound XVIII to XVII with Chromic Acid

A solution of 0.025 g of XVIII in 25 ml of 85% acetic acid–water was cooled to −15°, and treated with 0.10 g of chromic anhydride. The mixture was stirred at −15° for 2 hours, and then for 4 hours at −5°. Methanol was added to destroy excess chromic acid, and the solution allowed to stand overnight in the refrigerator. Water was added and the organic solvents removed under reduced pressure. The resulting aqueous solution was acidified with hydrochloric acid, extracted with ether, made alkaline with ammonia, and extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure, leaving a colorless oil. The infrared spectrum of this oil (film) was identical with that of the XVII. The oil yielded 0.028 g (86%) of hydrobromide salt whose infrared spectrum was identical with that of the hydrobromide of the XVII.

Reaction of Compound XVII with Phenyllithium

To a solution of phenyllithium in ether (prepared from 0.10 g of lithium and 1.14 g of bromobenzene in 20 ml of ether) was added 0.202 g of the copper sulphate product XVII in 15 ml of ether. The solution was heated under reflux for 2 hours, allowed to stand overnight, and poured into cold dilute hydrochloric acid. The aqueous solution was extracted several times with ether, made alkaline with ammonia, and extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure. The residual pale yellow oil partially solidified but a crystalline product was not obtained in good yield. The base was dissolved in acetone and treated with hydrobromic acid, yielding 0.289 g (89%) of colorless crystals melting above 315°. The salt was crystallized twice from methanol–acetone for analysis. Calc. for $C_{22}H_{29}O_2N.HBr$: C, 62.9; H, 7.19; N, 3.33%. Found: C, 62.9; H, 7.26; N, 3.32%.

The infrared spectrum of this compound had hydroxyl absorption at 3330 cm^{-1}, no

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

carbonyl absorption, and weak phenyl absorption at 1600 cm^{-1} and 1500 cm^{-1}. The ultraviolet spectrum showed benzenoid absorption with $\lambda_{max}^{95\%\ EtOH}$ at 2580 Å, $\epsilon = 237$.

PARALYTIC SHELLFISH POISON

VIII. SOME CHEMICAL AND PHYSICAL PROPERTIES OF PURIFIED CLAM AND MUSSEL POISONS[1]

EDWARD J. SCHANTZ, JAMES D. MOLD,[2] WILLIAM L. HOWARD,[3] JOHN P. BOWDEN, D. WARREN STANGER, JOSEPH M. LYNCH, OSKAR P. WINTERSTEINER, JAMES D. DUTCHER, DAVID R. WALTERS, AND BYRON RIEGEL[4]

ABSTRACT

Mild reduction of purified clam and mussel poisons with hydrogen yielded a nontoxic dihydro derivative. The poisons and the dihydro derivative showed no absorption in the ultraviolet but all absorbed in the infrared at 3, 6, and 9 μ. Mild oxidation of the poisons in alkaline solution produced nontoxic products with strong absorption in the ultraviolet. Preliminary studies on oxidation with permanganate or periodate and on hydrolysis with acid yielded only small fragments such as guanidopropionic acid, urea, guanidine, ammonia, and carbon dioxide. Titration of the poisons and the dihydro derivatives showed pK_a values at 8.1 and 11.5. The two poisons appear to be similar in their chemical and physical properties.

The purification of the paralytic poison found in toxic Alaska butter clams (*Saxidomus giganteus*) and in toxic mussels (*Mytilus californianus*), and some properties of these poisons, have been described in previous papers (1, 2, 3). The purified poisons[5] are white hygroscopic solids, very soluble in water and methanol, somewhat soluble in ethanol and glacial acetic acid, and insoluble in lipid solvents. They have a specific rotation of +130° and show no absorption in the ultraviolet above 220 mμ. The toxicity in white mice (Webster strain) is about 5.5×10^6 lethal doses per gram (4). The molecular formula is $C_{10}H_{17}N_7O_4.2HCl$ (molecular weight 372), and the molecule appears to exist in two tautomeric forms. A positive color test is given by both purified poisons with the Jaffe, Benedict–Behre, and Weber reagents, but the Sakaguchi test was negative. Additional physical and chemical properties are presented here to aid in the future elucidation of the structure of the poisons.

Both clam and mussel poisons were easily reduced with hydrogen to produce dihydro derivatives which were nontoxic (2). This reduction proceeded in aqueous neutral, acid, or alkaline solutions in the presence of a platinum catalyst, and under an atmosphere of hydrogen to a maximum uptake of 1 mole of hydrogen for each mole of poison. The loss of toxicity paralleled the hydrogen uptake and when 1 mole of hydrogen was consumed, 98% of the toxicity had disappeared. This relatively simple change in chemical structure resulting in almost complete loss of toxicity has been of considerable interest in studying many properties of the poison relating to structure and toxicity. The Benedict–Behre and Jaffe tests became negative upon reduction of the poisons whereas the Sakaguchi test remained negative and the Weber test remained positive. The application of these tests to the poison and the various derivatives has been described previously (2).

The infrared spectra of the poisons and the dihydro derivative are given in Fig. 1.

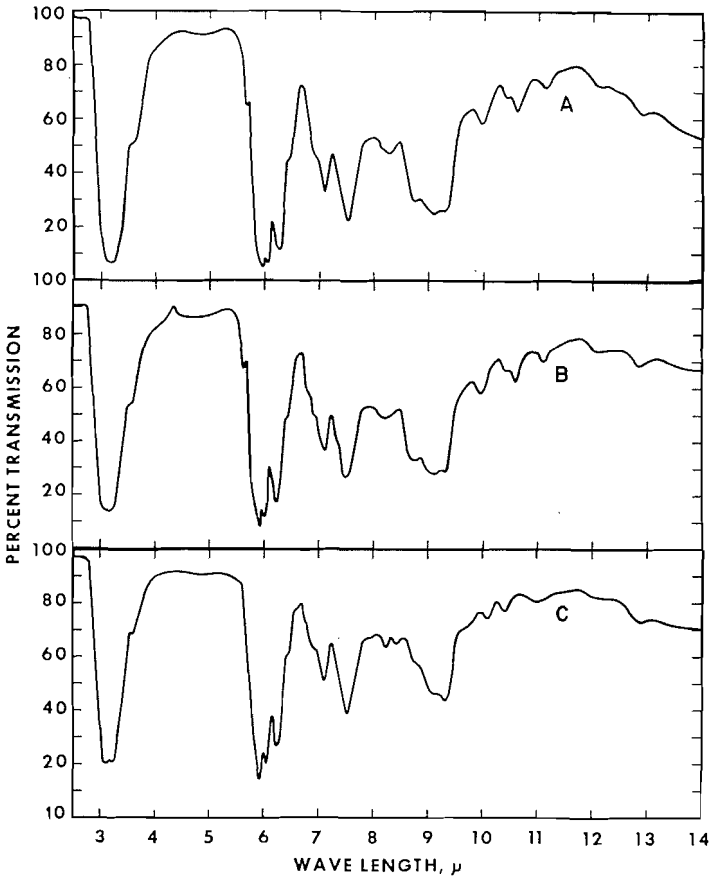

FIG. 1. Infrared spectra of (A) clam poison dihydrochloride, (B) mussel poison dihydrochloride, and (C) dihydro clam poison dihydrochloride.

The spectra for the two poisons are very similar and agree well with spectra obtained recently by Casselman *et al.* (3). The dihydro derivative showed some loss of absorption at 5.65 and 8.75 mμ.

No ultraviolet absorption above 220 mμ was observed for the poisons or for the dihydro derivatives. However, in alkaline solutions exposed to air, the poisons developed absorption maxima at 235 and 333 which reached maximum molecular extinctions of about 7000 at 235 mμ and about 5200 at 333 mμ. Under anaerobic conditions no maxima developed, which indicated that the absorption was brought about by an alkaline oxidation. Maximum extinction was reached and all toxicity disappeared when approximately 1 mole of oxygen was taken up per mole of poison (Fig. 2). The dihydro derivative did not take up oxygen in alkaline solution.

The specific rotation of both poisons (+130°) was affected by the presence of alkali, and under aerobic conditions there was a gradual decrease in the specific rotation to zero as the maximum extinctions at 235 and 333 were reached. Reduction of the poison with hydrogen did not change the rotation but eliminated the tautomeric forms.

Titration of the poisons in glacial acetic acid solution with perchloric acid and titration in aqueous solution with acid and alkali established that two base functions are present

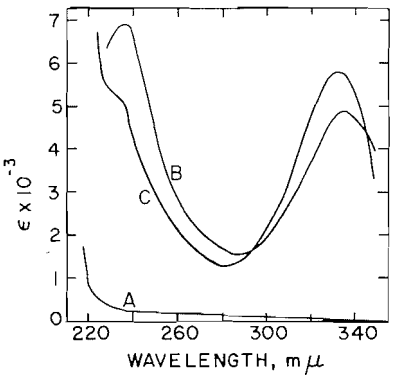

FIG. 2. Ultraviolet absorption spectra of (A) clam poison dihydrochloride, (B) alkaline oxidation product of clam poison in 0.25 *N* barium hydroxide, and (C) alkaline oxidation product of clam poison in acid solution, pH 1.

in equivalent amounts, pK_a 8.1 and ca. 11.5 (Fig. 3). No strong acidic group was found. Aqueous titration of the dihydro compounds from clam and mussel poisons gave results similar to those described for the poisons (pK_a 8.3 and ca. 11.5).

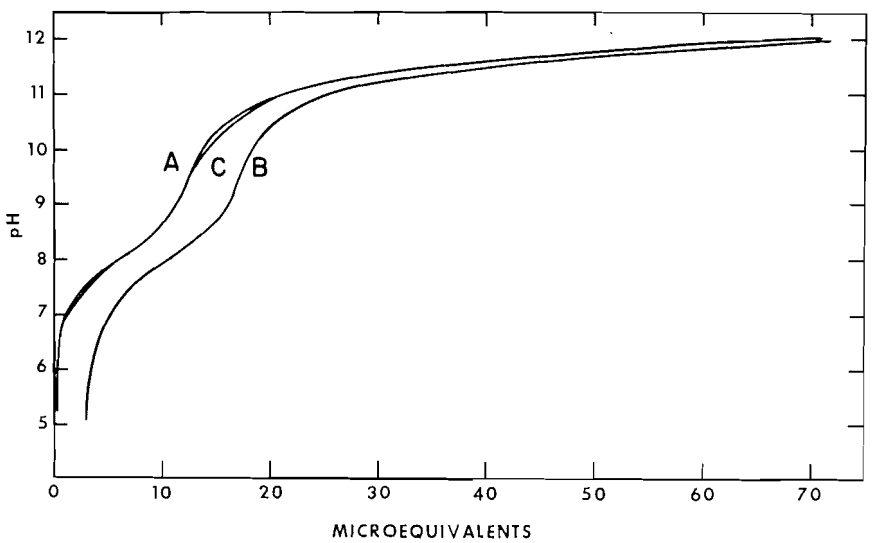

FIG. 3. Titration of clam poison dihydrochloride: (A) initial titration with 0.427 *N* barium hydroxide; (B) back-titration of (A) with 0.479 *N* sulphuric acid following aging at high pH; (C) second titration of (B) with 0.427 *N* barium hydroxide after evaporation from acid.

Preliminary studies on more drastic oxidation of the poisons with periodic acid or potassium permanganate have resulted in the isolation of guanidopropionic acid, urea, carbon dioxide, and ammonia, along with some unidentified products. No success was attained in isolating degradation products, from either the mild or strong oxidations, which represented a sufficiently large portion of the molecule to be of value in determining the chemical structure. Two moles of periodate were consumed very rapidly when the reaction was carried out at pH values between 5 and 13; a third mole was consumed within 24 hours and a fourth after 23 days. Each micromole of poison reduced

For personal use only.

17 equivalents of permanganate in 5 minutes at 75° C. Hydrolysis of the dihydro poisons in 12 *N* hydrochloric acid yielded guanidine. Sakaguchi-positive substances were found among the products of oxidation and hydrolysis. The Benedict–Behre and Jaffe tests became negative.

In summary, it is apparent that both reduction with hydrogen or oxidation under aerobic conditions in alkaline solution resulted in the loss of an unsaturated bond essential for toxicity. In the first case it has been demonstrated by countercurrent studies (2) and by studies reported herein that a dihydro derivative of the poison was formed upon reduction. Secondly, no oxygen uptake was apparent for the dihydro derivative, under the conditions described for the mild oxidation of the poison. In addition, the Benedict–Behre and Jaffe tests, which are positive for the poison and negative for the dihydro derivative, were found to be negative for the oxidized poison. Both reduction and oxidation destroyed toxicity. Theoretically only $\frac{1}{2}$ mole of oxygen would be required to bridge a double bond. Because the complete destruction of toxicity required the uptake of 1 mole of oxygen per mole of poison and because the reduced poison took up no oxygen, it is assumed that the oxidation is initiated at the unsaturated bond and that other reactions concurrent with the loss of this bond are taking place. The fact that changes occurred in the ultraviolet absorption and in the optical rotation upon mild oxidation of the poison supports this assumption.

Because reduction of the poison did not change the optical rotation, it appears likely that this unsaturated bond, which is essential to the toxic structure, is not involved in the structure at the optical center.

The strongly basic group would indicate the possibility of an amine or a quaternary ammonium base. However, studies on the alkylation of the poisons gave no evidence for such structures. The absence of an acidic group precludes the existence of a betaine-type base.

The ultraviolet and infrared spectra indicate no aromatic structures, conjugate unsaturation, or isolated carbonyl groups but the elemental ratios require that ring structures be present. Analysis of mussel poison for alkoxyl, alkimide, and C-methyl groups showed the groups to be absent. The Kjeldahl procedure converts all nitrogen to ammonia, which indicates no nitrogen-to-nitrogen bonds. Some of the nitrogen atoms, therefore, must be in heterocyclic structures involving a guanidine group in the cycle to account for the strong basicity of the poison in conjunction with the negative Sakaguchi test. The fact that Sakaguchi-positive compounds are formed upon oxidation or hydrolysis of the poison supports the above indications.

EXPERIMENTAL

Catalytic Hydrogenation of Clam and Mussel Poisons

The catalytic hydrogenation of clam and mussel poisons was carried out in a Warburg respirometer by a procedure similar to that described by Umbreit (5). Platinum black, prepared from platinum dioxide, and platinum black absorbed on charcoal were both effective in catalyzing this reduction in neutral, acid, or alkaline aqueous solutions.

In a typical experiment, platinum black was suspended in 2.0 ml of 0.1 *M* hydrochloric acid in the annulus of a Warburg flask, and 0.40 ml of clam poison dihydrochloride solution (2.50 mg/ml) was placed in the side arm. After the apparatus was gassed with purified hydrogen, the flask was equilibrated at 30°, and the poison solution was tipped into the catalyst. After 440 minutes, the uptake of hydrogen had ceased at 2.65 μmoles, equivalent to 0.95 moles of hydrogen per mole of poison. Four samples of clam poison

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

had an average uptake of 1.03 moles of hydrogen per mole of poison (range, 0.95–1.16), and eleven samples of mussel poison gave an average of 1.02 moles (range, 0.88–1.25).

An aliquot of a solution of the reduction products from clam poison dihydrochloride (240 μg) was tested for ammonia with the Nessler reagent. A negative reaction was obtained, indicating less than 5 μg of ammonia nitrogen. Countercurrent distribution studies on the reduced poison showed that only one component was produced during the reduction (2). The diffusion coefficient determined in the Northrup diffusion cell was 4.6×10^{-6} cm^2 sec^{-1}, which is similar to that of the poison and therefore indicates a similar molecular weight. The neutralization equivalent was 188, and two titratable groups indicate a molecular weight of 376. Anal. Calc. for $C_{10}H_{21}N_7O_4Cl_2$: C, 32.06; H, 5.66; N, 26.2; O, 17.1; Cl, 18.95%. Found: C, 32.3; H, 5.4; N, 26.3; O (direct), 16.97%.

Infrared Absorption Spectra[6]

The infrared absorption spectra were determined for films, dried from aqueous solutions on polished plates of silver chloride, of the test substance. In order to obtain spectra with a minimum amount of material, the plates were masked with Parafilm (Menasha Products Co., Menasha, Wis.) to reduce the area over which the solution was deposited. Spectra were observed with a Perkin–Elmer Model 12 C spectrophotometer and the results are illustrated in Fig. 1. Comparable spectra were obtained for films of the poison on KRS-5 (potassium thallium bromide), for films deposited from ethyl alcohol solution on sodium chloride,[7] and for pellets with potassium bromide.[8]

Ultraviolet Absorption

All measurements of the ultraviolet spectrum were made in aqueous acid solution (pH 3 to 5) of the poisons in a Model DU Beckman spectrophotometer or a Cary Model 14 spectrophotometer. In special cases when the absorption spectra were measured during the process of alkaline oxidation, small samples were withdrawn from the alkaline reaction flask and measured at the pH of the reaction mixture. The spectra of the poison under various conditions are shown in Fig. 2.

Optical Rotation

Measurements of the optical rotation were made with a Rudolph and Sons No. 80 polarimeter and a sodium-vapor lamp. Normally the measurements were made on aqueous acid (pH 3 to 5) solutions of the poisons in 2-dm tubes. In cases where the rotation was measured during the process of alkaline oxidation, samples were withdrawn from the alkaline reaction flask for each measurement. Where measurements were made under anaerobic conditions the poison solution was kept in the tightly sealed polarimeter tube during the entire period of observation.

Alkaline Oxidation of the Clam Poison

A mixture of 0.5 ml of clam poison solution (4.31 mg/ml; 0.0132 *M*; pH 1.5) and 9.5 ml of 1 *N* sodium hydroxide was allowed to stand in a stoppered flask (no attempt was made initially to exclude oxygen) at room temperature. The solution slowly took on a yellow color, and the formation of the alkaline oxidation product was conveniently

[6]*The spectra were observed by Mr. Edward Weneck except where noted.*

[7]*These spectra were determined by Dr. Robert C. Gore, Stamford Research Laboratories, American Cyanamid Co.*

[8]*The spectra were observed with a Beckman IR2T recording spectrophotometer. U. Schiedt and H. Reinwein. Z. Naturforsch. Part b,* **7b**, *270 (1952); M. M. Stimson and M. J. O'Donnell. J. Am. Chem. Soc.* **74**, *1805 (1952); Perkin–Elmer Instrumental News,* **4**, *No. 3 (1953).*

For personal use only.

followed by periodically determining the intensity of ultraviolet absorption at 333 mμ. Maximum absorption ($\epsilon = 5210$) was observed after 4 days. In 0.5 *N* or 0.25 *N* solutions of either sodium or barium hydroxide, 6 days were required for complete reaction, while in 7.5 *N* ammonium hydroxide, the molecular extinction at 333 mμ was only 1500 (30% of maximum) after the same period of time.

When carbon-dioxide-free air was bubbled through 4.0 ml of barium hydroxide solution containing 3.78 mg of clam poison the maximum extinction ($\epsilon = 5090$) was reached in only 9 hours.

The quantitative oxygen uptake involved in the alkaline oxidation reaction was determined by use of the Warburg apparatus. In the bottom of each Warburg flask was placed 0.8 ml of poison solution (4.85 mg/ml), and the side arm contained 0.8 ml of 0.5 *N* barium hydroxide. The center cup contained 0.2 ml of 0.2 *N* sulphuric acid to absorb any ammonia evolved during the reaction. After the flasks had been attached to the individual manometers, they were placed in a water bath maintained at 21°. When the flasks were fully equilibrated, the reaction was started by spilling the contents of the side arm into the bottom of each flask. As the flask was shaken the change in pressure was recorded periodically until the manometric readings remained constant. The results of 12 such determinations showed an average of 0.96 mole of oxygen consumed per mole of poison.

Potentiometric Titrations

Titrations of the poisons and their dihydro derivatives were performed with distilled-water solutions in a 10-ml beaker fitted with a cover provided with holes for the insertion of the glass electrode (No. 290) and calomel electrode (No. 270) of a Beckman pH meter (Model G), a microburette (Gilmont Combination Micro Pipet-Buret, Emil Greiner Co., New York, N.Y.), and a gas delivery tube. Dissolved carbon dioxide was removed from the titration solutions by thoroughly flushing with nitrogen prior to the insertion of the burette. The nitrogen was freed from acidic or basic contaminants by scrubbing with dilute alkali and acid. During the titration, the solution was magnetically stirred and maintained under a stream of the purified nitrogen. Increments of 0.4–0.5 *N* acid or base were added to produce changes in pH of about 0.1–0.2 units. No electrode corrections were applied to the readings taken at high pH because sodium and potassium ions were absent. The temperature of the room varied from 24–25° during the titrations, and no other temperature control was attempted. Values of pK_a were estimated from the data obtained after applying corrections for a distilled water blank.

Titration of Clam Poison Dihydrochloride

A 3.36-ml sample of an aqueous solution containing 4.79 mg of clam poison dihydrochloride was measured into the titration cell. Titration of the sample to pH 12.02 was completed in 24 minutes and required 0.170 ml of 0.427 *N* barium hydroxide. The burette was removed, and the solution was allowed to stand under nitrogen, without stirring, for 2 hours. There was no evidence of a precipitate, indicating that the exclusion of carbon dioxide was complete. A second burette was inserted and the solution was back-titrated with 0.479 *N* sulphuric acid. The final pH of 5.05 was attained in 26 minutes and required 0.145 ml of the reagent. After filtration and lyophilization, the product was dissolved in 5 ml of 0.01 *N* hydrochloric acid and slowly evaporated to dryness (24–48 hours) at room temperature in a vacuum desiccator over potassium hydroxide and phosphoric anhydride. This residue was redissolved in 3.36 ml of water and titrated with 0.168 ml of the standard barium hydroxide to pH 12.02 as described

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

above. The titration curves are shown in Fig. 3. After again being aged for $2\frac{1}{2}$ hours, the solution was back-titrated with 0.147 ml of the standard acid to pH 4.3. Bioassay of the final solution indicated that 74% of the original toxicity was still present.

Titration of Mussel Poison Dihydrochloride

A 3.27-ml sample of an aqueous solution containing 5.04 mg of mussel poison dihydrochloride was weighed into the titration cell and titrated in the same manner as above. The results were similar to those obtained for clam poison and are illustrated in Fig. 3.

Titration of Dihydro Mussel Poison Dihydrochloride

A sample of dihydro mussel poison dihydrochloride (5.1 mg) was dissolved in 2.0 ml of water and titrated as described above with 0.200 ml of 0.427 *N* barium hydroxide to pH 12.01. The results were similar to those for clam and mussel poisons.

Nonaqueous Titrations

These titrations were carried out with 5-mg samples of clam and mussel poisons according to the procedure given by Seaman and Allen (6) and by Pifer and Wollish (7).

NOTES

THE MOLECULAR STRUCTURE OF (−)-N-METHYL-GELSEMICINE HYDRIODIDE, $C_{21}H_{29}O_4N_2I$*

MARIA PRZYBYLSKA AND LÉO MARION

Gelsemicine ($C_{20}H_{26}O_4N_2$), one of the minor alkaloids of *Gelsemium sempervirens* Ait., was discovered by Chou in 1931 (1). It is a monoacidic base which forms a non-basic monobenzoyl derivative so that its basic nitrogen is secondary, a conclusion confirmed by treatment of the base with methyl iodide which gives rise to N-methyl-gelsemicine hydriodide. On hydrogenation over Adams' catalyst, the alkaloid absorbs 3 moles of hydrogen (2) and a comparison of its infrared absorption spectrum with that of its reduction product shows that it must contain a benzene ring since the absorption bands characteristic of that group are no longer present in the spectrum of the reduction product (3). Furthermore, gelsemicine contains two methoxyl groups, and its infrared absorption spectrum contains an absorption band indicative of a carbonyl group (3). It carries a substituent on one of the nitrogens which has been assumed previously to be a methyl group. This sums up the chemical knowledge concerning the alkaloid.

There are two monoclinic forms of N-methyl-gelsemicine hydriodide, one of space group $P2_1$ with two molecules per asymmetric unit and another which crystallizes in space group $C2$ with one molecule per asymmetric unit. The latter compound was chosen for a detailed X-ray analysis. Its unit-cell dimensions are: $a = 16.75$, $b = 9.52$, $c = 14.06$ Å; $\beta = 90°13'$; and $z = 4$.

A total of 2800 reflections were measured and they amounted to 67% of those theoretically available with Cu radiation. The x and z co-ordinates of the iodine atom were derived from two-dimensional Patterson syntheses. After an assumption that the iodine atom lies at $y = \frac{1}{2}$ was made, a three-dimensional Fourier synthesis was evaluated using the phases based only on the iodine atom contributions. The electron-density maps had the symmetry of space group $C2/m$ and the real peaks of the structure were accompanied by mirror-image peaks related to them by planes of symmetry at $y = 0$ and $\frac{1}{2}$. In spite of this difficulty it was possible to locate 22 light atoms of the molecule. Several cycles of refinement using three-dimensional data led gradually to complete solution of the structure. Making use of the anomalous dispersion effects of Cu Kα radiation caused by the iodine atom, it was possible to determine the absolute configuration of this laevorotatory isomer. It is represented by the schematic drawing and the photograph of the molecular model (Fig. 1). The two nitrogen atoms were identified indirectly: that the methyl group is attached to one of them was taken into account, and the position of the second one was considered as established as soon as the oxindole nucleus was recognized (3).

The oxygen atoms were indicated by ρ_o and $(\rho_o - \rho_c)$ maps. Their location was further substantiated by the values of bond lengths, which are in good agreement with the nominal bond lengths.

The reliability factor, R, for all three-dimensional data is 0.16, whereas for the two zones ($h0l$) and ($0kl$), it is 0.16 and 0.10 respectively. The R factor for the centrosymmetric ($h0l$) zone is expected to be higher than for the non-centrosymmetric ($0kl$) data (4).

*Issued as N.R.C. No. 6470.

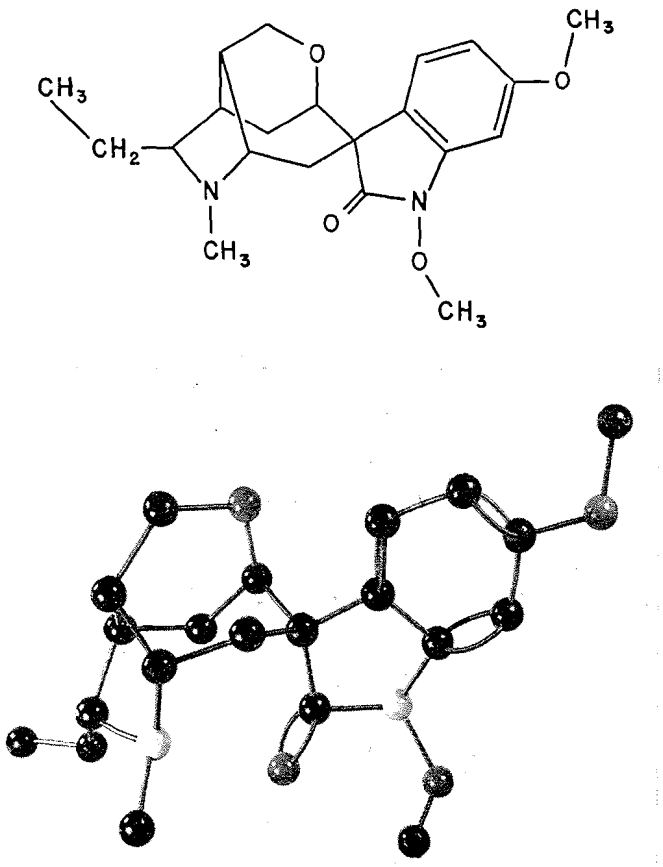

FIG. 1. Molecular model of (−)-N-methyl-gelsemicine.

A full account of this work will be published at a later date.

On comparison of the skeleton of N-methyl-gelsemicine and gelsemine (5) we find that they are very similar, but the skeleton of N-methyl-gelsemicine has one carbon atom less which leads to a somewhat simplified structure.

One unusual feature that deserves comment is the presence of a methoxyl group linked to the oxindole nitrogen. It has been shown chemically that the molecule of gelsemicine contains two methoxyl groups. The base forms salts which are normal and not of the anhydronium type as shown by their infrared spectra and by the recovery from these salts of the intact base still containing two methoxyl groups. Hence, the two-atom group attached to the carbon next to the basic nitrogen cannot be a methoxyl group.

The distance between the nitrogen ion $\begin{array}{l}\diagdown\\ \diagup\end{array}\!\!\overset{+}{\underset{|}{\text{N}}}\!\!-\text{H}$ (with CH_3 on the nitrogen) and the oxygen of the carbonyl group in N-methyl-gelsemicine hydriodide is 2.77 Å. Since the hydrogen atom attached to the nitrogen is directed towards the oxygen atom, an intramolecular hydrogen-bond formation is indicated. Additional evidence is supplied by the infrared absorption spectrum, Fig. 2,

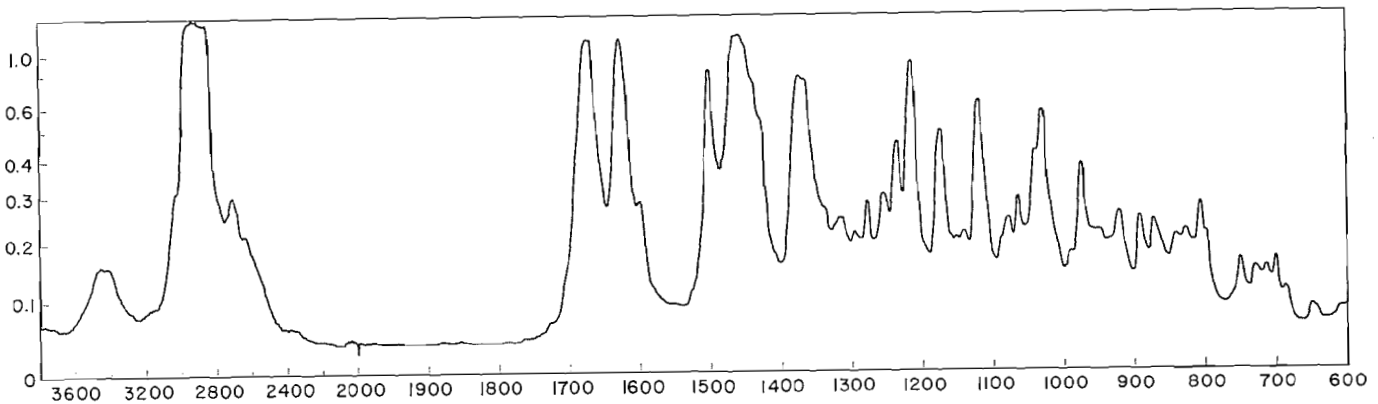

FIG. 2. Infrared absorption spectrum of N-methyl-gelsemicine hydriodide in Nujol mull.

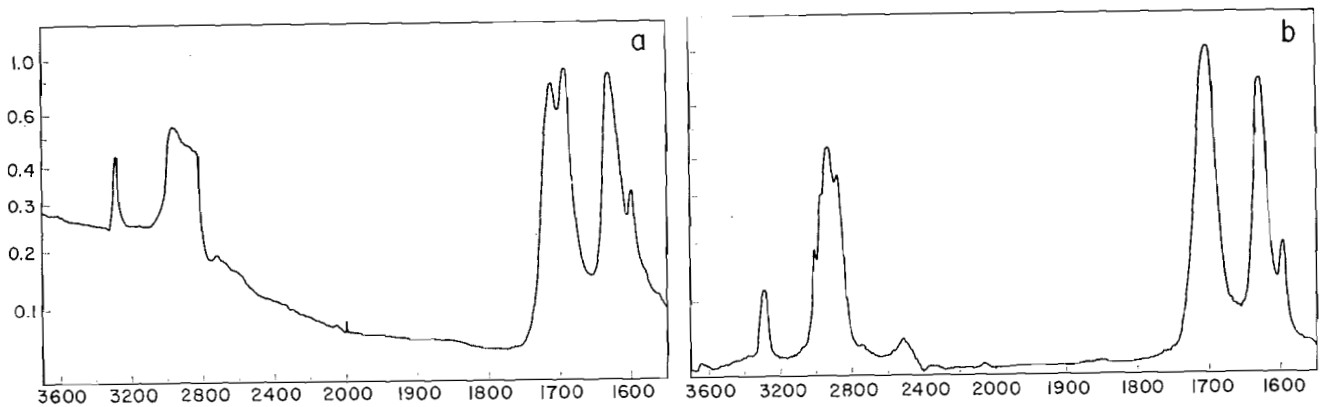

FIG. 3. Infrared spectra of gelsemicine: (*a*) in Nujol mull; (*b*) in chloroform solution.

which shows a markedly broadened band at ~3340 cm^{-1} and a considerable shift in the absorption of the carbonyl band, with a maximum at 1674 cm^{-1}.

It is of interest that the infrared spectrum of gelsemicine itself in Nujol mull shows a double peak in the carbonyl region, whereas a single maximum is obtained in chloroform solution (Fig. 3). It seems that the C=O group, only in some, but not all molecules of the crystalline gelsemicine, is involved in the hydrogen-bond formation. The C=O bond in the spectrum in chloroform solution lies between the position of the two peaks of the Nujol mull spectrum and this indicates that the C=O groups of all the molecules may be involved in H bonding with the C—H group of chloroform. Although crystalline gelsemicine itself has not been X-ray analyzed, some support to this explanation is given by the fact that in gelsemicine hydrobromide hemihydrate, N-methyl-gelsemicine hydrobromide tetrahydrate (6), and also in N-methyl-gelsemicine hydriodide of space group $P2_1$, the asymmetric unit was found to consist of two molecules which are, therefore, crystallographically not equivalent. This tendency of the compound to crystallize in pairs of molecules may well be due to the shape of its skeleton which contains a large planar oxindole group. In this connection, it is noteworthy that the infrared spectrum of dihydrogelsemine in chloroform also shows a single peak in the carbonyl region, although in a mull, a double peak is obtained.

ACKNOWLEDGMENTS

Grateful acknowledgment is made to Dr. F. R. Ahmed for computational assistance and invaluable discussions, and to Dr. S. McLean for the preparation of authenticated, pure crystals of the salt. Thanks are also due to Mrs. C. Mackey for her help in computing and preparing the X-ray data, and to Mr. R. Lauzon for the infrared absorption spectra.

hours at 36°, instead of in 15 to 18 hours at 180–200°. No scission of methyl phenyl and ethyl phenyl ethers was observed. *n*-Butylmagnesium bromide was effective (1, 2), but Tomita and Watanabe (3) found that the yield of cleavage products was somewhat greater when the tertiary isomer was used; the replacement of diethyl ether by tetrahydrofuran as the solvent increased the yield threefold.

On the present occasion, eight experiments with 2-methoxydiphenyl ether were carried out, the Grignard reagent being made from either *n*-butyl or *t*-butyl bromide, and the solvent being ether or tetrahydrofuran. The best result was obtained with *t*-butylmagnesium bromide in tetrahydrofuran. With a 30-fold molar excess, 36% of the original substance was recovered unchanged together with 35% of phenols, corresponding to a degree of cleavage of about 60%. This yield corresponded closely to the value of 62% obtained by Tomita and Watanabe (3) for the same compound. Both guaiacol and phenol were isolated as the pure, crystalline benzoates, and cleavage therefore occurred on both sides of the diphenyl ether oxygen atom, in agreement with the work of Kharasch and Huang (1). Tomita and Watanabe (3) thought that this ether oxygen atom was completely retained by the guaiacol (benzene presumably was the only other product), but an attempt to repeat their isolation of the guaiacol as the *p*-nitrobenzoate gave a crystalline product which probably contained some of the phenol derivative. Fruitless attempts were also made to detect catechol, by paper chromatography, among the products, and this negative result agreed with the claim that methyl phenyl ether groups were not affected by the reagent.

t-Butylmagnesium bromide – cobaltous chloride, when warmed with a suspension of fully methylated spruce formaldehyde periodate lignin (4) in tetrahydrofuran, produced 2% of phenolic material which resinified too rapidly to be examined in detail, together with a little neutral, high-boiling oil. There was no clear evidence that any cleavage of ether groups occurred in this lignin. When the experiment was repeated with fully methylated spruce periodate lignin, the resulting 4% of ether-soluble material probably contained guaiacol, and the 90% of residual lignin increased in methoxyl content from 17.2 to 18.5% on remethylation with diazomethane. In this case, about 0.7% of phenolic groups might have been liberated by cleavage.

EXPERIMENTAL

Materials

Tetrahydrofuran, boiling correctly at 76°, was used not more than 2 days after purification by distillation in succession from solid sodium hydroxide, metallic sodium, and lithium aluminum hydride. The Grignard reagent was made from pure *t*-butyl bromide and dry, polished magnesium ribbon (5, 6); the use of powdered crystals of sublimed magnesium, obtained through the courtesy of Dow Chemical Company of Canada, yielded a particularly clear, colorless reagent (7). Dilution of an aliquot with a known volume of standard acid, and a back titration with standard alkali to a phenolphthalein end point (8), established the molarity of the reagent. The yield amounted to 50% of the magnesium when tetrahydrofuran was the solvent, whereas the reported yield was 33% (6).

A published method (9) of preparing anhydrous cobaltous chloride was modified by heating the pure hexahydrate for 2 days at 45° and 20 mm pressure, and then gradually raising the temperature to 220° (1 mm). The light pink of the partly dehydrated product changed through dark blue to the pale blue color of the anhydrous salt, which was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

extremely finely divided. Ullmann and Stein's method (10) was used to synthesize 2-methoxydiphenyl ether, which was recrystallized from hexane and redistilled under diminished pressure; m.p. 76°, the recorded value being 78°.

Cleavage of 2-Methoxydiphenyl Ether

The apparatus consisted of a three-necked flask equipped with ground-glass joints, a magnetic stirrer, a reflux condenser, leads for dry nitrogen gas, and an L-shaped tube, revolving in a ground-glass joint, for the addition of the anhydrous cobaltous chloride. This tube could be warmed externally to prevent the condensation of solvent, which made the finely divided chloride sticky. A solution of 0.098 mole of *t*-butylmagnesium bromide in tetrahydrofuran was filtered through dry glass wool into the flask, the volume plus rinsings being 80 ml. After 1.3 g (6.5 mmoles) of 2-methoxydiphenyl ether had been added, the apparatus was flushed with nitrogen, and solution was completed by gentle heating and stirring. The cobaltous chloride, 4.68 g (36 mmoles), was then added from the L tube in 12 successive portions at 15-minute intervals, after which the mixture was heated for 3 hours under reflux.

The mixture was acidified near 0° with 4 *N* hydrochloric acid and thoroughly extracted with ether, and the extract was re-extracted with 5% aqueous sodium hydroxide (1). A neutral fraction, 0.50 g, isolated from the ether, yielded 0.375 g (29%) of twice-recrystallized 2-methoxydiphenyl ether with the correct melting point and mixed melting point. Benzoylation (5) of the product extracted by the alkali, 0.50 g, yielded 0.72 g of crystals, m.p. 51–56°, which on recrystallization from ethanol produced 0.45 g of guaiacol benzoate, m.p. 57–58°, and mixed m.p. 56–58°. Evaporation of the ethanol mother liquors left a gum which on standing deposited 0.07 g (0.35 mmole) or 5% of crystals melting at 63–66°, increased to m.p. 69° by recrystallization. Authentic phenyl benzoate had this melting point, and a mixed melting point with the crystals was not depressed. A further 0.08 g of pure guaiacol benzoate, isolated from the final mother liquors, brought the total yield of this product to 2.3 mmoles or to 35% of theory. Since a control benzoylation of pure guaiacol gave only a 50% yield of the pure, recrystallized benzoate, the yield of guaiacol actually produced in the cleavage was probably near 70%.

In another experiment, a small portion of the alkali-soluble product from the scission of 1.04 g (5.2 mmoles) of 2-methoxydiphenyl ether was chromatographed on paper for 20 hours with butanol – 2% aqueous ammonia as the solvent and a ferric chloride mixture (4) as the spray. Only the spot characteristic of guaiacol, R_f 0.95, was present, and there was no spot in the catechol position, R_f 0.87. The remainder of the product, when esterified with *p*-nitrobenzoyl chloride in pyridine (5), yielded 0.47 g of material which was recrystallized once from ethanol. Although the crystals, 0.26 g, melted rather sharply at 96–97°, many recrystallizations from ethanol and methanol separated them into 0.15 g melting at 86–92°, and 0.03 g melting at 98–100°. Since the melting points of the *p*-nitrobenzoates of guaiacol and phenol were 97° and 102°, respectively, the above product was probably an incompletely resolved mixture of these two compounds.

Attempted Scission of Fully Methylated Lignins

A 1.4-g sample of dry, finely divided spruce formaldehyde periodate lignin, fully methylated to OCH_3, 15.0% (4), was suspended in 90 ml of tetrahydrofuran containing 80 mmoles of *t*-butylmagnesium chloride. Six grams of anhydrous cobaltous chloride was added in 12 portions during 3 hours, and the subsequent heating under reflux was for 3 hours. The cold, acidified suspension was then extracted with ether, and the aqueous

For personal use only.

residue was dialyzed against distilled water. The non-dialyzed portion yielded 1.20 g of a precipitate. Found: ash, 0.7%; OCH_3, 12.5%, not altered by methylation with diazomethane. The ether extract contained 0.2 g of a neutral, high-boiling oil, and 0.03 g of alkali-soluble material with R_f 0.21 on paper chromatograms.

The experiment was repeated with 1.42 g of spruce periodate lignin fully methylated to OCH_3, 17.6; ash, 1.2% (4). Dialysis of the aqueous portion of the reaction mixture yielded 1.29 g of insoluble material. Found: ash, 0.2%; OCH_3, 17.2%, increased to 18.6% by remethylation with diazomethane. The neutral ether-soluble oil, 0.085 g, was volatile enough to leave only 0.02 g of residue when heated at 100° *in vacuo*. When the ether-soluble phenols, 0.06 g, were chromatographed on paper only the spot of R_f 0.95 pertaining to guaiacol was observed.

THE DECOMPOSITION OF HYDROGEN PEROXIDE IN THE PRESENCE OF HYDROGEN

R. R. BALDWIN, D. BOOTH,* AND D. BRATTAN†

In a paper (1) presented at the Eighth International Combustion Symposium at Pasadena in September 1960, we reported a marked acceleration of the decomposition of H_2O_2 in the presence of H_2. The studies were carried out using a flow system at atmospheric pressure, the partial pressure of H_2O_2 varying from 0.2–1.0 mm Hg, and the partial pressure of H_2 varying from 10–760 mm Hg. In such a system, where the H_2/H_2O_2 ratios were relatively high, the experimental results are interpreted precisely by the following simple scheme:‡

$$H_2O_2 + M' = 2OH + M' \quad [7]$$

$$OH + H_2 = H_2O + H \quad [1]$$

$$H + H_2O_2 = H_2O + OH \quad [14]$$

$$H + H_2O_2 = H_2 + HO_2 \quad [14a]$$

$$OH + H_2O_2 = H_2O + HO_2 \quad [15]$$

$$2HO_2 = H_2O_2 + O_2. \quad [10]$$

Reactions [15] and [14*a*] represent the termination reactions dominant at low and high H_2/H_2O_2 ratios respectively, and from the results, values for k_{15}/k_1 of 6.0 ± 0.5 and for k_{14a}/k_{14} of approximately 0.1 are obtained. In the presence of O_2, the termination reaction [4] also becomes important.

$$H + O_2 + M = HO_2 + M \qquad [4]$$

The results and discussion given by Forst (2) in a recent paper in this journal seem, at first sight, to be at variance with the simple mechanism given above, and we wish to show that Forst's results are, in fact, consistent with the above mechanism. Forst's results, all obtained at 431.5° C, fall into three sections, which are given below as points (*a*), (*b*), and (*c*).

(*a*) His Fig. 1 gives the pressure–time curve for the decomposition of H_2O_2 alone (9.6 mm Hg pressure) and in the presence of 19.2 and 96.2 mm Hg of H_2. With pure H_2O_2, the limiting pressure rise of 4.5 mm is close to the theoretical value (4.8 mm Hg), but the pressure rise decreases to 2.6 and 1.5 mm Hg respectively in the presence of H_2.

(*b*) Figure 2 gives the initial rate (mm Hg of O_2 per sec) of decomposition of 9.6 mm of H_2O_2 in the presence of 10–77.5 mm Hg of H_2.

(*c*) Figure 3 gives the initial rate of decomposition as a function of H_2O_2 concentration over the range 3–16 mm Hg, the pressure of H_2 being 57.9 mm Hg.

To allow for the different coefficients of H_2 and H_2O_2 in reaction [7], the rate of [7] may be written

$$R = k_{7P}[P]^2 + k_{7H_2}[H_2][P], \qquad [i]$$

where [P] is the concentration of H_2O_2. Forst* evaluated the ratio k_{7H_2}/k_{7P} as 0.18 by assuming that the ratio k_{7H_2}/k_{7He} is the ratio of the calculated collision frequencies (1.64), the ratio k_{7He}/k_{7P} having been determined as 0.11 (3). Use of this value for k_{7H_2}/k_{7P} gives the linear increase in rate with added H_2, as found experimentally, but the calculated rate increases slower than the experimental rate as H_2 is added. The same is found with the data of Fig. 3, and Forst concludes that some chemical effect of H_2 is also present. Since reactions [1], [14], and [14*a*] only increase the rate of H_2O_2 decomposition and do not affect the rate of O_2 formation, he concludes that other reactions must occur.

Studies of the H_2–O_2 reaction, however, indicate that the ratio k_{4H_2}/k_{4He} is almost twice the calculated collision frequency ratio and that the ratio of the values of k_4 is only equal to the collision frequency ratio if both gases are monatomic or if both gases are diatomic (4). A more likely estimate of the ratio of k_{7H_2}/k_{7P}, therefore, is obtained by assuming that the relative coefficients of H_2 and N_2 are the same in reactions [4] and [7]. Since $k_{4N_2}/k_{4H_2} = 0.43$ (4), and $k_{7P}/k_{7N_2} = 6$–7 (1, 5), k_{7H_2}/k_{7P} should be approximately 0.33–0.38.

A value in agreement with this estimate can be obtained from Forst's results if they are interpreted by the Baldwin–Brattan mechanism. This mechanism, which is also consistent with independent studies of the hydrogen–oxygen reaction (6, 7), gives the rate expressions

$$-\frac{d[P]}{dt} = \frac{2k_7[P][M']\{k_1[H_2]+k_{15}[P]\}}{\alpha k_1[H_2]+k_{15}[P]}, \qquad [ii]$$

$$\frac{d[O_2]}{dt} = k_7[P][M'], \qquad [iii]$$

**The authors are grateful to Dr. Forst for explaining the basis of this calculation.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where $\alpha = k_{14a}/(k_{14}+k_{14a})$. Since Forst followed the decomposition by measurement of pressure change, his rate measurements are represented by [iii], which can be written in a similar manner to [i] and predicts the linear increase in rate with H_2 concentration shown in Fig. 2 of Forst's paper. From the gradient and intercept of this line, experimental values of k_{7H_2} and k_{7P} can be obtained, the ratio being 0.30. These experimental values can now be used to predict the variation of initial rate with H_2O_2 concentration at constant H_2 concentration. Figure 1 shows the experimental points taken from Forst's

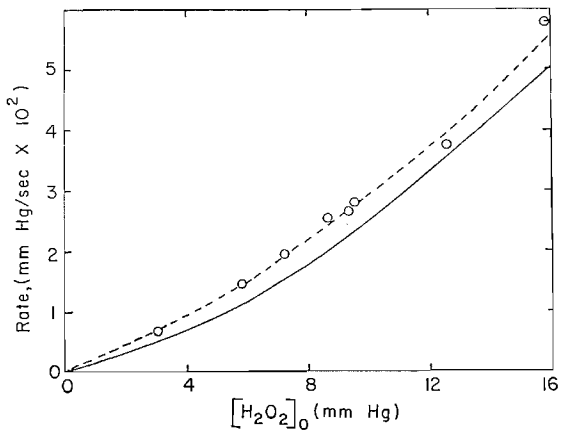

FIG. 1. Decomposition of H_2O_2 in the presence of hydrogen at 431.5° C (initial concentration H_2 = 57.9 mm Hg): O experimental points (Forst (2), Fig. 3); —— calculated curve (Forst (2), Fig. 3); – – – calculated curve (Baldwin–Brattan mechanism).

paper (Fig. 3), the calculated curve using Forst's ratio of 0.18, and the corresponding curve using a ratio of 0.30. This latter ratio thus accounts for both sets of experimental results obtained by Forst, and is in sufficiently close agreement with the estimate of 0.33–0.38 above, particularly since allowance for surface decomposition, admitted by Forst to be significant at this temperature, would increase the value of k_{7H_2}/k_{7P}.

From [ii] and [iii],

$$\frac{-d[P]}{d[O_2]} = \frac{2(k_1[H_2]+k_{15}[P])}{\alpha k_1[H_2]+k_{15}[P]}.$$

Integration* between the initial peroxide concentration $[P_0]$ and zero gives the total amount of O_2 formed as

$$2[O_2]_t = [P_0]-(1-\alpha)R[H_2]\log_e\frac{[P_0]+R[H_2]}{R[H_2]},$$

where $R = k_1/k_{15} = 1/6$ (1). Insertion of the values used in Fig. 1 of Forst's paper, $[H_2O_2]$ = 9.6 mm Hg, $[H_2]$ = 19.2 and 96.2 mm Hg, gives $[O_2]_t$ as 2.8 and 1.4 mm Hg, in close agreement with the experimental values of 2.6 and 1.5 mm Hg respectively.

It may thus be concluded that the Baldwin–Brattan mechanism gives a completely satisfactory account of Forst's observations without the necessity of postulating further reactions.

**This integration assumes that reaction [4] may be neglected and that* $[H_2]$ *is constant. From the known (1) values of* k_2/k_4 *and* k_{14}/k_2*, it can be shown that, under Forst's experimental conditions, reaction [4] will not compete with [14] until* $[H_2O_2] \approx 0.1$ *mm Hg. The error resulting from the assumption that* $[H_2]$ *is constant can also be neglected.*

CRYSTALLOGRAPHIC DATA FOR ETHYL 3,5-DINITROBENZOATE

N. CAMERMAN AND J. TROTTER

An analysis of the crystal structure of ethyl 3,5-dinitrobenzoate was undertaken to investigate any deviations of the nitro groups from coplanarity with the aromatic ring. However, the structure has proved too complex for a complete determination of the molecular parameters, and since the crystallographic data might be useful, they are outlined in this note.

Crystals of ethyl 3,5-dinitrobenzoate, prepared by reaction of 3,5-dinitrobenzoyl chloride with ethanol, and recrystallized from ethanol, are pale yellow needles elongated along the *b*-axis, with the (001) plane developed and a smaller (100) face. The density was measured by flotation in aqueous potassium iodide solution, and the unit-cell dimensions and space group were determined from rotation and oscillation photographs of a crystal rotating about the *b*-axis, *h*0*l* and *h*1*l* Weissenberg films, and *hk*0 and 0*kl* precession films.

Crystal Data

Ethyl 3,5-dinitrobenzoate: $C_9H_8N_2O_6$; molecular weight = 240.2; melting point = 92–94° C.

Monoclinic; $a = 18.36 \pm 0.05$, $b = 4.78 \pm 0.01$, $c = 13.82 \pm 0.03$ Å; $\beta = 119.7° \pm 0.5°$.

Volume of the unit cell = 1054 Å^3.

Density: calculated (with $Z = 4$) = 1.505, measured = 1.511 g cm^{-3}.

Absorption coefficient for X rays, $\lambda = 1.542$ Å, $\mu = 12.9$ cm^{-1}.

Total number of electrons per unit cell = $F(000) = 496$.

Examination of the films revealed that *h*0*l* reflections are systematically absent when *h* is odd. Of the 0*k*0 reflections only 040 was observed, so that a screw axis parallel to *b* was indicated. Since only one 0*k*0 reflection was observable the presence of the 2_1 axis was not definitely established, but the $N(z)$ intensity distribution (1) for the *h*0*l* zone corresponded to a centrosymmetric projection. These facts, taken together, suggested that the space group was probably $P2_1/a$.

The intensities of the *h*0*l* reflections were measured by the Weissenberg multiple-film technique (2), with Cu $K\alpha$ radiation, and the values of the structure amplitudes were

Monoclinic; $a = 18.36 \pm 0.05$, $b = 4.78 \pm 0.01$, $c = 13.82 \pm 0.03$ Å; $\beta = 119.7° \pm 0.5°$.

Volume of the unit cell = 1054 Å^3.

Density: calculated (with $Z = 4$) = 1.505, measured = 1.511 g cm^{-3}.

Absorption coefficient for X rays, $\lambda = 1.542$ Å, $\mu = 12.9$ cm^{-1}.

Total number of electrons per unit cell = $F(000) = 496$.

Examination of the films revealed that *h*0*l* reflections are systematically absent when *h* is odd. Of the 0*k*0 reflections only 040 was observed, so that a screw axis parallel to *b* was indicated. Since only one 0*k*0 reflection was observable the presence of the 2_1 axis was not definitely established, but the $N(z)$ intensity distribution (1) for the *h*0*l* zone corresponded to a centrosymmetric projection. These facts, taken together, suggested that the space group was probably $P2_1/a$.

The intensities of the *h*0*l* reflections were measured by the Weissenberg multiple-film technique (2), with Cu $K\alpha$ radiation, and the values of the structure amplitudes were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

derived by the usual formulae. One hundred and three reflections were recorded. In space group $P2_1/a$ there is one molecule in the asymmetric crystal unit, and the orientation of this molecule in the unit cell was deduced by Fourier-transform methods and from the intramolecular peaks in the Patterson projection. However, it was impossible to pack molecules in this orientation into the unit cell in space group $P2_1/a$, so that it seemed that there might be two molecules in the asymmetric unit arranged in space group Pa, the 010 and 030 reflections being by chance too weak to be observed, and the $N(z)$ test being misleading (a not uncommon occurrence). Alternatively there might be some type of disordered arrangement of molecules. The problem, therefore, seemed too complex for solution by the usual trial and error methods, and no further detailed structural analysis is proposed. The structure-factor data have been recorded (3).

A NEW METHOD FOR THE DEOXYGENATION OF AROMATIC *N*-OXIDES

R. A. ABRAMOVITCH AND K. A. H. ADAMS

In the course of a study of the cyclization of some nitrophenylpyridine derivatives with ferrous oxalate it was observed that when 2-*o*-nitrophenylpyridine-*N*-oxide was heated with this reagent the only product isolated was pyrido[1,2-*b*]indazole (1). It was also shown that the first stage in this reaction was probably the elimination of the *N*-oxide grouping; 2-phenylpyridine-*N*-oxide itself was deoxygenated under these conditions but was unaffected in the absence of the ferrous oxalate.

The scope of this deoxygenation has now been extended to a number of other pyridine-*N*-oxide derivatives and to *N*,*N*-dimethylaniline-*N*-oxide. The results are summarized in the table.

N-Oxide	Yield of tertiary amine, %
Pyridine-*N*-oxide	64
2-Picoline-*N*-oxide	62
3-Picoline-*N*-oxide	72
2-Aminopyridine-*N*-oxide	45
2-Phenylpyridine-*N*-oxide	63
N,*N*-Dimethylaniline-*N*-oxide	55 (crude)

This new procedure may well be of value, particularly in cases (e.g. when an amino group is present) where other methods currently in use (such as that involving phosphorus trichloride) may not be employed. Its limitations include applications to (*a*) those substances containing groupings, e.g. nitro, which are attacked by ferrous oxalate; and (*b*)

3-Picoline-*N*-oxide	72
2-Aminopyridine-*N*-oxide	45
2-Phenylpyridine-*N*-oxide	63
N,*N*-Dimethylaniline-*N*-oxide	55 (crude)

This new procedure may well be of value, particularly in cases (e.g. when an amino group is present) where other methods currently in use (such as that involving phosphorus trichloride) may not be employed. Its limitations include applications to (*a*) those substances containing groupings, e.g. nitro, which are attacked by ferrous oxalate; and (*b*)

probably aliphatic tertiary amine *N*-oxides, which are known (see ref. 2) to undergo elimination of the amine group by the action of heat and to give an olefin.

EXPERIMENTAL

The *N*-oxide was mixed with 4 molar equivalents of ferrous oxalate dihydrate and granulated lead (ca. 6 g/g of *N*-oxide), and the mixture ((*a*) in a flask arranged for distillation for *N*-oxides of liquid amines, or (*b*) in a flask fitted with a condenser for *N*-oxides of solid amines) was heated in a metal bath at 300° (bath temperature) for 30 minutes. The product isolated by distillation (in case (*a*)), or by ether extraction of the reaction mixture (in case (*b*)), was dried overnight over potassium hydroxide pellets. The identity of the products was established by comparison of their infrared spectra with those of authentic samples of the bases. The picrates of the products were prepared in the cases of pyridine-, 2-picoline-, 3-picoline-, and 2-phenylpyridine-*N*-oxides, and their identity confirmed by melting point and mixed melting point determinations. 2-Aminopyridine, as isolated from this reaction, was recrystallized from light petroleum (40–60°) and had m.p. 57–59°, which was not depressed on admixture with an authentic sample.

THE IRRADIATION OF β-IONONE

P. de Mayo, J. B. Stothers, and R. W. Yip

Study of the literature suggests that the irradiation of substances containing the system (I) where Y is carbon and (or) a hetero atom(s) leads to (reversible) hydrogen transfer and the formation of (II) which may then be further transformed. In those cases noted there is the possibility of $n \rightarrow \pi^*$ excitation, though this may not be a requirement. The irradiation of α,β-unsaturated ketones ((I), Y = C·CH_3) gives, for example, the β,γ-unsaturated isomer (1). All the requirements of the *o*-nitrobenzaldehyde ((I), Y = NO) – *o*-nitrosobenzoic acid conversion and related changes are met by the postulation of an intermediate ketene formed by hydrogen transfer (2). Recently it has been shown that substituted benzophenones ((I), Y = C·Ph) are enolized by irradiation (3).

β-Ionone (III) on irradiation has been shown (4) to give (reversibly) the pyran (IV) as main product, together with a by-product which was tentatively attributed the structure (V). The alternative (VI) was considered and rejected on reasonable but negative evidence. Since β-ionone falls into the class of substance under present consideration, by vinylogous extension, (VI) seemed mechanistically much more favored. We have repeated the preparation and determined the n.m.r. spectrum (Fig. 1), which was not available at the time of the earlier work.

DIELECTRIC RELAXATION IN LIQUIDS

II. ISOMERIC PENTANEDIOLS[1]

D. W. DAVIDSON

ABSTRACT

For five pentanediols the infrared spectra, the dipole moments, and the static dielectric constants show an increasing degree of internal hydrogen bonding with increasing proximity of the OH groups. The dielectric dispersion loci at low temperatures are skewed arcs over most of the dispersion range. Values of the parameter β decrease from ca. 1 to 0.55 in the series 1,5-, 1,4-, 1,2-, 2,4-, and 2,3-pentanediol, which is also the order of increasing relaxation time τ_0 at low temperatures. Increased τ_0 is associated with increased irregularity of intermolecular hydrogen bonding, an effect which supports the view that relaxation proceeds by a co-operative mechanism which is facilitated by regularity in the liquid structure. At temperatures of "structural relaxation", values of log τ_0 are linear in $(T-T_\infty)^{-1}$; the proportionality constants, but not the T_∞'s, are the same for all five diols.

The experimental behavior at relatively high frequencies departs from both the skewed-arc and Glarum equations, although less from the latter. These departures are compared with the high frequency dispersion regions in *n*-propanol.

In a previous paper (1) the ability of the skewed-arc expression to represent the results of dielectric relaxation measurements of liquids has been discussed. Most monohydroxyl alcohols exhibit a principal dispersion region which is, within the experimental errors, of the classical Debye type ($\beta = 1$ in the skewed-arc representation). This is in contrast to the relaxation behavior of such polyhydroxyl alcohols as have been studied, for which values of β considerably smaller than unity must be invoked. It is natural to attempt to relate this qualitative difference in the relaxation behavior to the absence in the polyhydroxyl liquids of the same degree of regularity in *inter*molecular hydrogen bonding that exists in the simple alcohols. In order to examine the role played by *intra*molecular hydrogen bonding and steric factors in the extent and regularity of the hydrogen bonding between polyhydroxyl molecules, we have studied the relaxation behavior of five isomeric pentanediols. With one exception, the pentanediols may be cooled sufficiently to bring the dispersion regions within the frequency range required for bridge measurements.

Information about the extent of *intra*molecular hydrogen bonding was provided by an examination of the hydroxyl-group stretching bands in the infrared spectra of dilute solutions of the pentanediols in carbon tetrachloride and by measurement of the dipole moments of the pentanediols in dioxane solution.

EXPERIMENTAL METHODS

1,2-Pentanediol was prepared by bromohydrination of pentene-1 with N-bromosuccinimide, conversion to the epoxide (b.p. 76–78°), and hydrolysis to the diol with Dowex 50 resin.

[1]*Manuscript received May 25, 1961.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 6503.

The infrared spectrum of a commercial sample of 2,3-pentanediol showed a strong spurious band at 1733 cm^{-1}, which disappeared after saponification with sodium hydroxide. An authentic sample of the 2,3-diol was prepared from pentene-2 (which gas-chromatographic analysis showed to consist of roughly equal proportions of the trans and cis forms) by performic acid oxidation and hydrolysis. The product (*B*) consisted of approximately equal amounts of *threo* and *erythro* isomers. Its infrared spectrum was almost identical with that of the saponified commercial product (*A*).

The other pentanediols were commercial products.

All the pentanediols were fractionated in a Todd still. The boiling ranges and refractive indices are given in Table I.

TABLE I

Pentanediol		Boiling range (p, mm)	n_D
1,2		83–84° (3)	1.4387 (23°)
2,3	*A*	70–71° (3.5)	1.4404 (20°)
	B		1.4405 (20°)
1,4		221–222° (748)	
		103° (4)	1.4451 (25°)
2,4	*A*	199–200° (757)	1.4329 (25°)
	B	83° (5)	1.4329 (25°)
1,5		239° (759)	
		121° (6)	1.4495 (25°)

1,4-Dioxane was refluxed for several hours over calcium hydride and distilled.

The dielectric constant and loss measurements at frequencies up to 500 kc/sec and the temperature measurement and control were essentially as outlined previously (2). Less accurate measurements at higher frequencies were made in the case of 1,5-pentanediol with (*a*) a Model 260A Boonton Q-Meter and a cell consisting of two parallel-plate platinum electrodes mounted in a glass vessel, and (*b*) a Model 250A Boonton RX-Meter and a cell constructed of two coaxial stainless steel electrodes with Teflon insulation.

Measurements of the dipole moments of the pentanediols in dioxane were made by the method previously described (3). Infrared spectra of the carbon tetrachloride solutions were obtained with a Perkin–Elmer Model 112 infrared spectrometer equipped with sodium chloride and calcium fluoride optics.

RESULTS AND DISCUSSION

Intramolecular Hydrogen Bonding

(a) OH Stretching Vibrations

The fundamental OH stretching vibration region of the infrared spectra of solutions of the pentanediols in carbon tetrachloride is shown in Fig. 1. Following Kuhn (4) and others, one may associate the presence in this region of two bands of concentration-independent relative intensity at low concentrations (less than 0.1% or 0.015 molar) with the presence of both free and *intra*molecularly hydrogen-bonded OH groups. The frequencies of free OH groups and of those taking part in *intra*molecular and, at higher concentrations, in *inter*molecular hydrogen bonds are given in Table II. The latter are somewhat concentration dependent; the values given are for concentrations in the range 0.2 to 0.6%.

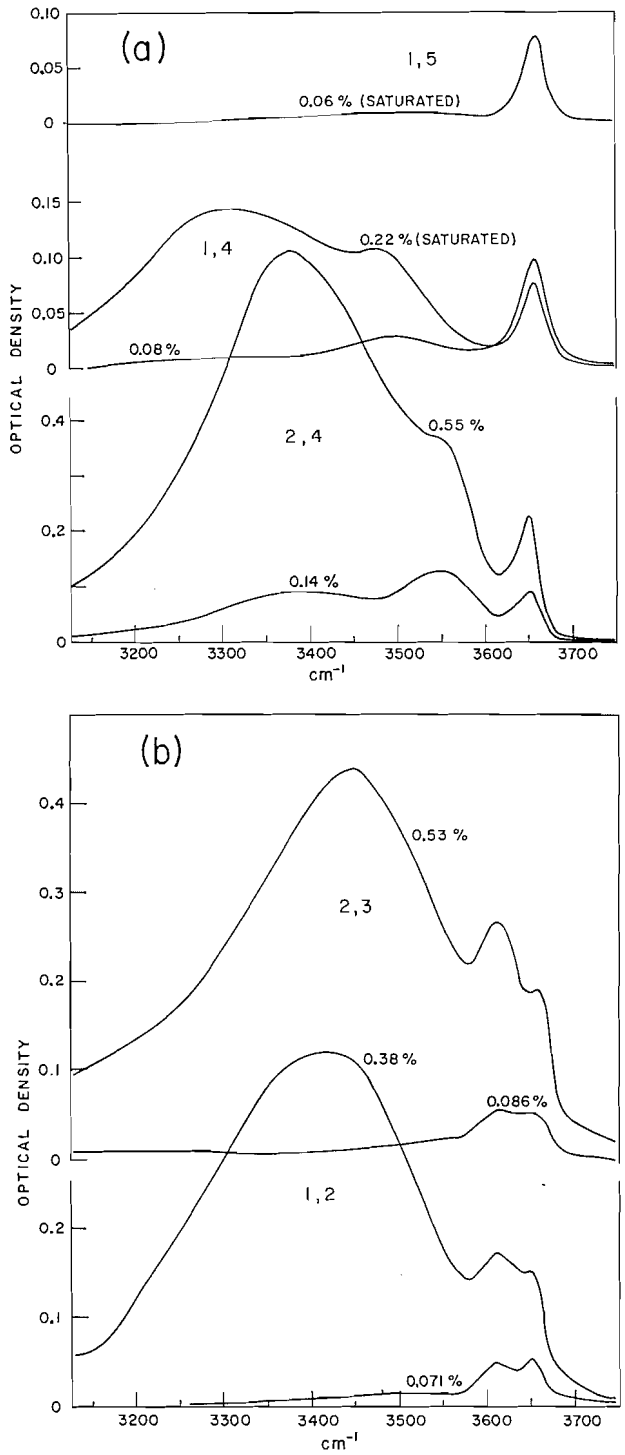

FIG. 1(*a*) and (*b*). OH stretching vibration region of the infrared spectra of the pentanediols in CCl_4.

TABLE II

OH stretching vibration bands of pentanediols in CCl_4

Diol	Frequencies (cm^{-1})			Approx. fraction of free OH groups*
	Free OH	*Intra*bonded OH	*Inter*bonded OH	
1,5	3639			1
1,4	3638	3464	3292	0.85
2,4	3639	3538	3369	0.65
1,2	3646	3604	3407	0.55
2,3	3646	3600	3437	0.50

*At low concentrations.

Like 1,6-hexanediol (4), 1,5-pentanediol shows no evidence of internal hydrogen bonding. A small degree of internal bonding takes place in 1,4-pentanediol, as shown by the presence of a weak band whose frequency shift from the free OH band ($\Delta\tilde{\nu} = 174$ cm^{-1}) is similar to that shown by 1,4-butanediol (156 cm^{-1} (4); 170 cm^{-1} (5)). More extensive *intra*molecular hydrogen bonding takes place in 2,4-pentanediol; the frequency difference (101 cm^{-1}) is somewhat larger than for 1,3-propanediol (78 cm^{-1} (4)) or 1,3-butanediol (80 cm^{-1} (5)). The bands arising from internally bonded OH groups in the vicinal pentanediols are about as strong as those arising from the free OH groups. The frequency shifts are similar to those found in other *vic*-diols.

In view of the well-known correlation between $\Delta\tilde{\nu}$ and hydrogen bond "strength", it is a fair inference that, although the number of molecules which are *intra*molecularly bonded *increases*, the strength of the bonds *decreases* in the sequence 1,4- to *vic*-diol. The frequencies associated with the broad bands due to *inter*molecular hydrogen bonding (Table II, column 4) likewise suggest that the bonds between molecules become somewhat weaker in the same sequence.

The estimates of the fraction of free OH groups given in the last column of Table II are based on the approximation that the extinction coefficient is the same for the free OH stretching band in all five pentanediols.

With increasing concentration the *intra*molecular hydrogen-bonding bands become obscured by the strong *inter*molecular ones. Solutions of the pentanediols in dioxane all show strong bands with peaks near 3480 cm^{-1} arising from association with the solvent.

(b) Dipole Moments

Because of the limited solubility of some of the pentanediols in CCl_4 and other inert solvents and the tendency of diol molecules in such solvents to associate even at low concentrations, the dipole moments were measured for solutions in dioxane. The results, based on measurements of 6 to 8 solutions in the weight fraction range between 0.005 and 0.08, are given in Table III. The dipole moments of some other diols are included for comparison.

Two primary solvent effects are to be expected: an enhanced moment for each OH group which is hydrogen bonded to the solvent, and a change (usually a reduction) in the molecular moment arising from the effect on the extent of *intra*molecular hydrogen bonding of the competition provided by bonding to dioxane. To get an indication of the magnitude of the first effect, the dipole moment of water in dioxane was measured with the same technique as was employed with the pentanediols. The resulting value of 1.91 debyes, like several earlier values (10), was only slightly greater than the vapor value of 1.85 debyes (11). The second effect is more difficult to gauge. The agreement

between the moment of 1,2-ethanediol in dioxane (2.29 debyes) and in the vapor (2.25 debyes) (12*a*) suggests that it is not great for the vicinal diols. The effect may well be greater for diols less completely internally hydrogen bonded than the vicinal ones.

The dipole moment of 1,5-pentanediol is very nearly $\sqrt{2}$ times as large as that typical of monohydroxyl alcohols (1.66 debyes). This suggests that there is, on the average, no net correlation between the directions of the two COH dipoles and that no appreciable internal hydrogen bonding exists. With increasing proximity of the OH groups in the pentanediols the moments increase, until, for the vicinal diols, they fall to their lowest values. As shown by the other moments in Table III, this trend is general for diols.

Calculation of the resultant moment of the internally hydrogen-bonded molecules is in general prevented by a lack of knowledge of the geometry of the rings formed. The presence of a linear hydrogen bond between two OH groups generally results in a higher moment than that to be expected for unbonded configurations, but the constraints imposed by the comparably inflexible valence-bond angles are likely to lead to considerable bending of the O—H- -O bond in small rings. A certain amount of bending increases the moment beyond its value for a linear bond and values of about 3 debyes are to be expected for angles of the order of 135°. This is consistent with the observed moments of 1,4- and 2,4-pentanediol if the extent of *intra*molecular hydrogen bonding is not greatly less in dioxane than in carbon tetrachloride (compare Table II).

For much larger angles of bend of the hydrogen bond a fall in the resultant moment is predicted. This is the case for the *vic*-diols, which, as considered in more detail in the Appendix, appear to consist substantially of internally hydrogen-bonded forms in which the two CO bonds are not far from gauche in their relative orientation about the connecting C—C bond. Part, at least, of the reduction in "strength" of the hydrogen bonds with decreasing separation of the OH groups in the molecule may be attributed to their increasing departure from linearity.

There is some evidence that the extent of internal hydrogen bonding increases with alkyl-group substitution on the carbon atoms bearing the OH groups, as is to be expected from steric considerations. Thus there is a pronounced increase of moment in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

series 1,3-propanediol, 2,4-pentanediol, 2-methyl-2,4-pentanediol (Table III). It appears possible for a highly substituted 1,5-pentanediol to be appreciably internally hydrogen bonded (13).

Static Dielectric Constants

Values of ϵ_0 for the pentanediols in the liquid state are plotted versus $1/T$ in Fig. 2.

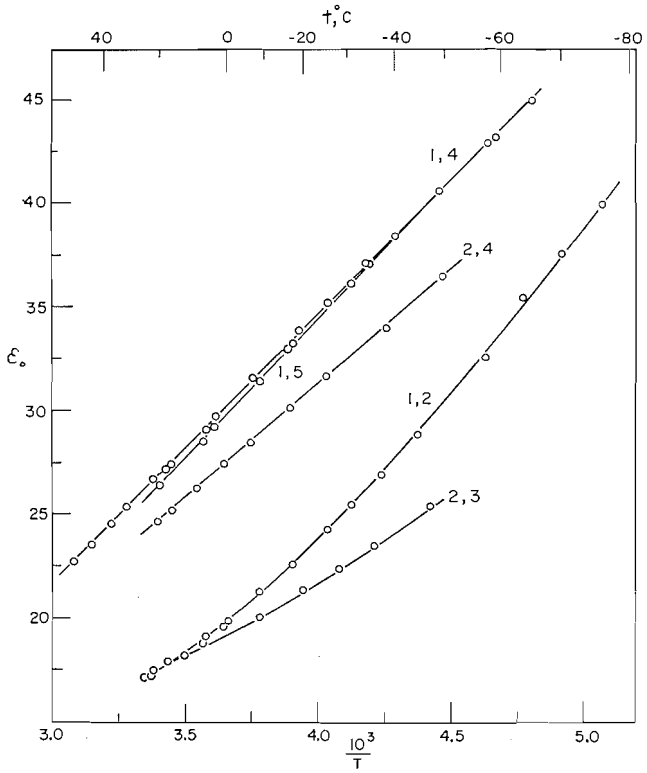

FIG. 2. Temperature dependence of the static dielectric constants of liquid pentanediols.

For three of the diols these values may be represented by a linear function of $1/T$ over the experimental temperature range. The static dielectric constants of the vicinal diols increase more rapidly at low temperatures and are given by

$$\epsilon_0 = a+b/(T-T_c)$$

for which the empirical constants have the values listed in Table IV.*

TABLE IV

Parameters for temperature dependence of ϵ_0

Pentanediol	Temp. range	a	$b\times10^{-3}$	T_c	Av. deviation (%)
1,5	−35 to 25°	−19.54	13.50	0	±0.2
1,4	−65 to 52°	−16.88$_5$	12.89	0	0.3
2,4	−50 to 25°	−12.51	10.96	0	0.2
1,2	−70 to 25°	− 1.13	3.244	120	0.6
2,3	−50 to 25°	+ 4.04	2.487	110	0.2

**Other reported dielectric constants of 1,5-pentanediol (with the values computed from the equation in parentheses) are: −20°, 33.5 (33.8); 0°, 30.0 (29.9); 25°, 26.3 (25.7) (14); and 20°, 26.2 (26.5) (7).*

The dielectric constants of 1,5- and 1,4-pentanediol suggest that the individual OH groups have almost as much freedom to associate with other molecules as has the single OH group in simple alcohols. Thus, each of these diols at 20° has a dielectric constant of which the part arising from the orientation of dipoles (ca. 27–3) is twice that of *n*-pentanol (15–3), a liquid with about half as many OH groups per unit volume. In the case of 1,4-pentanediol, it is likely that a reduced extent of *inter*molecular association is offset by the increased average moment resulting from some *intra*molecular hydrogen bonding. In 2,4-pentanediol the former effect predominates.

The lower dielectric constants of the vicinal diols reflect a high degree of internal hydrogen bonding. Formal calculation of the Kirkwood correlation factors from the observed dielectric constants give values somewhat greater than 2 at room temperature and progressively increasing values at lower temperatures. Although such values cannot be directly compared with those of simple alcohols, for which similar values are obtained (15), they are sufficiently high to suggest the presence of extensive hydrogen-bonded chains. The structure is complicated by the possibility of cross-linking of the chains of hydrogen bonds at some molecules which are not internally hydrogen bonded, a process which should result in higher dielectric constants and which may be responsible for the high values found, particularly for the 1,2-diol, at low temperatures.

Most of the pentanediols remained liquid at temperatures lower than those at which the dielectric dispersion–absorption effects (next section) occurred at audio frequencies.* However, the 1,5-diol froze rapidly when cooled below −30°, even when as much as 5% water was added. Examination of its dielectric constant in the solid revealed no anomalies at temperatures down to −190°. The dielectric constant remained almost invariant at about 2.7 as the sample was heated from this temperature until it started to rise a few degrees below the melting point (−16°).

Dielectric Relaxation

A typical absorption–dispersion locus for each pentanediol is illustrated in Fig. 3.

Since 1,5-pentanediol could not be sufficiently supercooled to bring the dispersion effects into the frequency range of bridge measurements, Q-meter and RX-meter measurements were made at higher frequencies. As shown in the plot of Fig. 3 for the 1,5-diol at −30°, the Q-meter results show considerable scatter, a large part of which may be attributed to changes in lead capacitance brought about by connecting and disconnecting the low potential lead to the cell. In the hope that these effects would show a random scatter, a large number of measurements were made. The RX-meter measurements, for which the height of the liquid between the coaxial electrodes was varied to eliminate fixed capacitance, were more reproducible, but were complicated by inductance effects at high frequencies. The data were not sufficiently accurate to distinguish between a semicircular locus with additional high-frequency dispersion regions, as in the simple alcohols, and a slightly skewed locus (with β of the order of 0.9). From measurements over a very extensive frequency range, Mme. Moriamez-Boullet reported (14) the presence of at least two distinct dispersion regions, of which the principal (low-frequency) one was semicircular. In view of the evidence already given for the ability of each OH group in 1,5-pentanediol to freely associate with other molecules, relaxation behavior similar to that of the simple monohydroxyl alcohols might well be expected.

For the other four pentanediols studied, as is evident from the extent of the agreement between the experimental and calculated points (Fig. 3), the skewed-arc locus provides

**One sample of 2,4-diol slowly froze after being maintained for several days at −45°.*

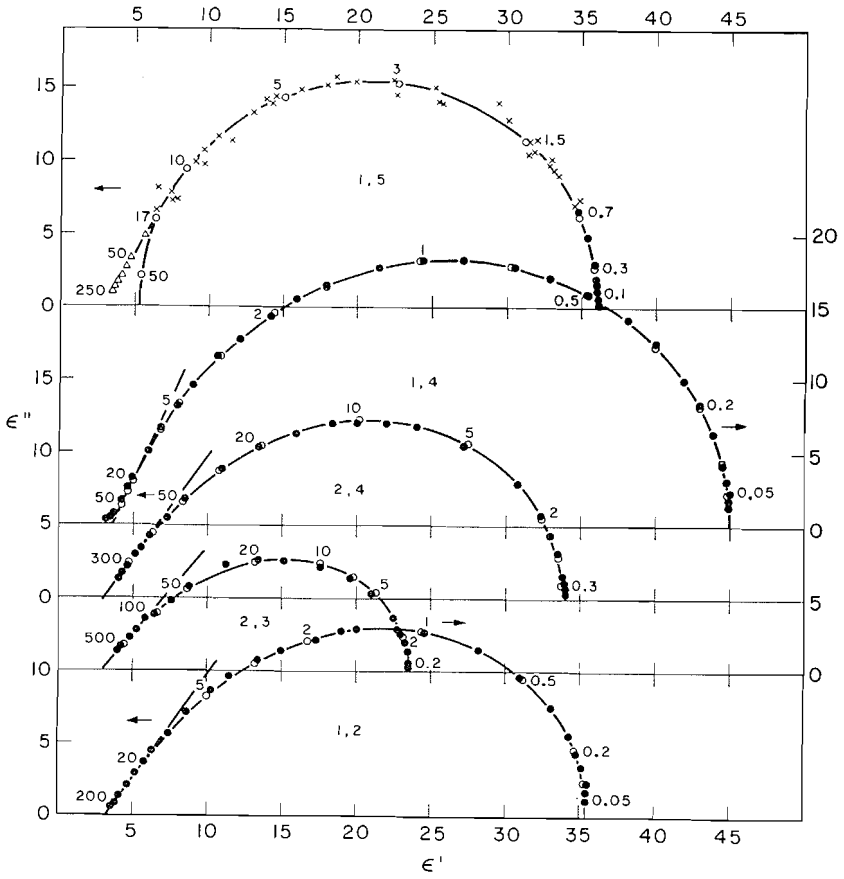

FIG. 3. Complex dielectric constant loci of the pentanediols: ● bridge, × Q-meter, and △ RX-meter measurements; O values calculated from the parameters starred in Table V. Numbers on loci are frequencies in Mc/sec for 1,5-pentanediol, in kc/sec for the others.

an accurate description of the dispersion effects (except at relatively high frequencies). Values of β tend to become smaller with the approach of the two OH groups to one another.

Values of the parameters used in the calculation of the absorption–dispersion loci of Fig. 3 are given in Table V, together with the corresponding skewed-arc parameters at several other temperatures.

Relaxation Times

The variation of the relaxation times with temperature is shown in Fig. 4.

The τ_0 values for 1,5-pentanediol are based on three types of measurement, as indicated in the caption of the figure. Debye behavior has been assumed. Bridge measurements of ϵ'' were made at frequencies on the low-frequency side of the absorption region and the relaxation times were calculated from the slope of a plot of ϵ'' vs. frequency, according to

$$\epsilon'' = 2\pi(\epsilon_0 - \epsilon_1)\beta\tau_0 f, \qquad [1]$$

with, in this case, $\beta = 1$. The experimental ϵ'' values were corrected for the contributions

†Values in parentheses are values assumed in order to calculate τ_0.

from d-c. conductance. Relaxation times by this method were considered less accurate than those derived from the frequencies of maximum loss given by the Q-meter and RX-meter measurements, and were assigned half the weight in fitting the temperature dependence of the relaxation times by least squares.

Values of τ_0 of the other pentanediols were obtained from bridge measurements alone. Relaxation times of less than 3×10^{-7} second made use of values of β estimated by extrapolation from lower temperatures, and at the high end of the temperature range equation [1] was employed.

From Fig. 4 it is apparent that, with the possible exception of the 1,5-diol, the relaxation times do not follow an equation of the form

$$[2] \qquad \log_{10}\tau_0 = A'+B'/T.$$

They may, however, be represented over most of the temperature range of the measurements by

$$[3] \qquad \log_{10}\tau_0 = A+B/(T-T_\infty),$$

as in the case of a number of other alcohols (15, 16, 17) and alkyl halides (18). It was found that the values of B, as determined by least-squares best fit of equation [3] to the data, were very nearly the same for the four pentanediols. In fact, for the values of A and T_∞ of Table VI, a plot of the product $(\log_{10}\tau_0-A)(T-T_\infty) = B$ yields values of B which are, within experimental error, equal to 985 over most of the temperature range. (See inset of Fig. 5.) Moreover, the less accurate and extensive data for 1,5-pentanediol can be represented by the same B, with A and T_∞ given in Table VI, slightly better (average deviation between experimental and computed relaxation times of 6.7%) than by equation [2] with A' and B' evaluated by least squares (average deviation 7.7%). It is to be noted (Fig. 5) that, although the data for the 1,5- and 1,4-diols show no departures from equation [3] with $B = 985$ up to room temperature, those for the

1,2	118.5	−14.595	−75, −15*	10	2.5
2,3	144	−15.279	−73, −10*	7	4.0

*Departures from equation [3] occur at higher temperatures.

2,4- and particularly for the vicinal diols show consistent departures at the high temperature end (Fig. 4) in the sense of greater relaxation times than predicted by equation [3]. It may be significant that the greater the degree of *inter*molecular hydrogen bonding the higher the upper temperature limit of validity of the equation.

Published values of the constant B of equation [3] as it has been applied to other

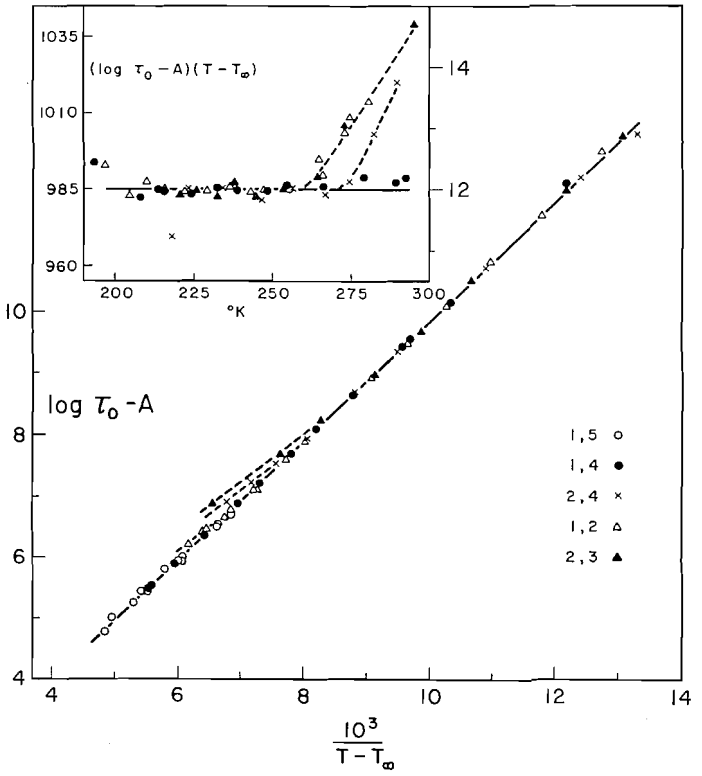

FIG. 5. Dependence of log $\tau_0 - A$ on $1/(T-T_\infty)$ for the values of A and T_∞ listed in Table VI. Inset: temperature variation of (log $\tau_0 - A)(T-T_\infty)$.

hydroxyl-containing liquids (16) are considerably smaller than 985, but this value is approached in the case of highly associated glycerol, for which $B = 957$ has been reported. It is now believed that the available data indicate a common value of B ($\simeq 985$) for liquids at low temperatures. The lower values of B that have been reported probably arise from the inclusion in the data treated of relaxation times obtained at temperatures beyond the range of the common low-temperature behavior.

The case of *n*-propanol may be particularly mentioned. By a combination of bridge and transient techniques, relaxation times between 10^{-8} and 10^{3} seconds have been measured for this liquid. Published (19) parameters for equation [3] (including $B = 477$) describe the experimental relaxation times between 210 and 130° K (that is, up to ca. 10^{-4} second) but not those obtained at lower temperatures. With $B = 985$, together with $A = -14.354$ and $T_\infty = 44°$, on the other hand, the relaxation times in the range 10^{-5} to 10^{3} seconds may be accurately described. Deviations similar to those shown by the vicinal pentanediols become evident at temperatures above 150° K.

The similarity between the temperature dependence of dielectric relaxation times, viscosities, and d-c. conductivities at low temperatures is a matter of common observation, as is also their tendency to depart from such common behavior as the temperature is raised (16, 20, 2). In the case of the pentanediols the conductivities (Fig. 6) vary with temperature very much as do the relaxation times. It was not possible to follow the temperature dependence of conductivity with the same accuracy as for the relaxation

For personal use only.

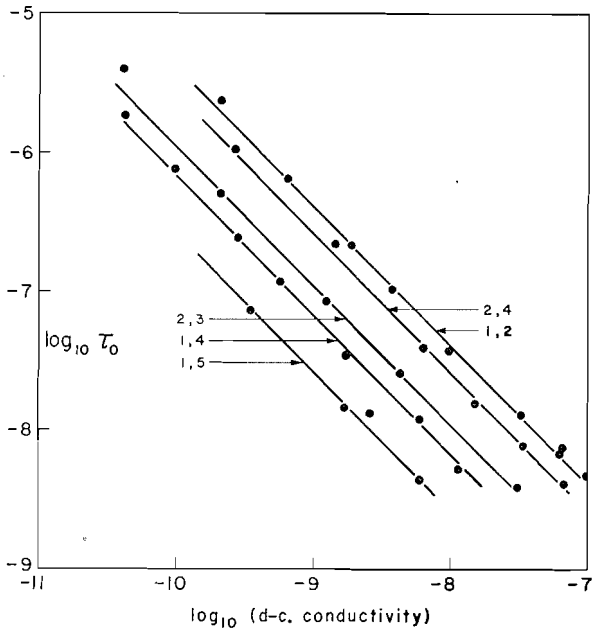

FIG. 6. Plot showing the proportionality between the relaxation times and d-c. conductivities of the pentanediols.

times, since it changed not only from sample to sample, but also slowly with time after the cell had been filled.

The evidence suggests that physical rate processes of many liquids at low temperatures may be represented by equation [3] with a common value of B and a value of T_∞ characteristic of the liquid. For a given liquid only A changes with the rate process being measured. It is planned to examine elsewhere the question of the general validity of equation [3] as a characteristic feature of what may be called "structural relaxation" of liquids.

It is apparent that the present representation of structural relaxation has much in common with Ferry's method of expressing mechanical relaxation times of polymers in terms of their values at an arbitrary standard temperature (21). When put into the form of equation [3], his expression corresponds to a value of B some 10% lower than the one employed here.

Dispersion at High Frequencies

If the principal dispersion region in 1,5-pentanediol is taken to be of the simple Debye type, our data (cf. Fig. 3) show the presence of an additional dispersion region at relatively high frequencies. They are consistent with the results of Mme Moriamez-Boullet (14), who reports at $-20°$ a second dispersion region which is a circular arc defined by $\epsilon_1 = 5.4 \pm 0.2$, $\epsilon_2 = 2.9 \pm 0.2$, $\alpha = 0.11 \pm 0.02$, and a most probable relaxation time some 80 times smaller than the single relaxation time of the primary dispersion.

The other pentanediols, like other liquids exhibiting skewed-arc behavior (1), show additional dispersion–absorption effects at frequencies of the order of several hundred times as great as that which corresponds to τ_0. The nature of these departures from the limiting straight line predicted by the skewed-arc locus for high frequencies is illustrated in the ϵ'' vs. ϵ' plots of Fig. 7.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

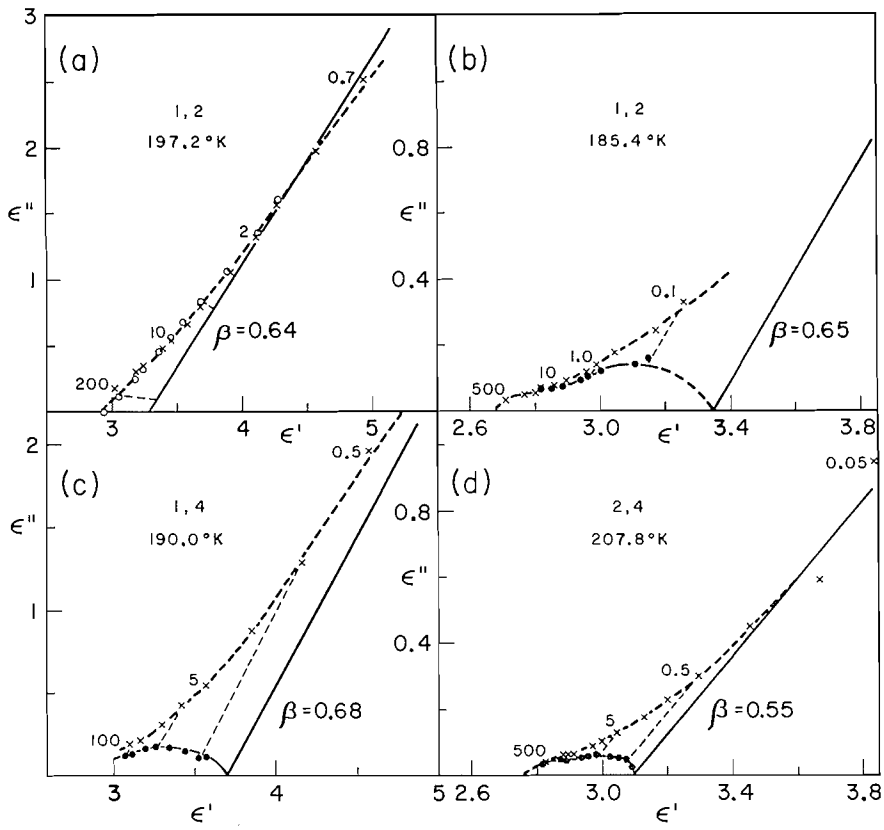

FIG. 7. Departures at relatively high frequencies of pentanediols from skewed-arc behavior: × experimental points; ○ Glarum locus with $a_0 = 4$, $\tau_0 = 1.07\times10^{-2}$ sec; ● points obtained by subtraction from experimental points of skewed-arc loci with values of τ_0 of (*b*) 6.4, (*c*) 3.2×10^{-2}, (*d*) 1.6 sec.

In order to explore the possibility that these effects may arise from the superposition of the skewed-arc locus and some physically distinct relaxation mechanism occurring at relatively high frequencies, attempts have been made to subtract the contribution of the skewed-arc locus to the experimental results. This procedure is more approximate than was the case of, for example, *n*-propanol (16, 19) since the skewed-arc locus makes much larger contributions at high frequencies and requires one more parameter (β) for its representation than does the Debye semicircle. As shown in Fig. 6(*b*, *c*, *d*), it is possible to obtain, by this somewhat laborious procedure, a residual absorption which resembles two overlapping circular arcs, much like those reported for *n*-propanol. It should be pointed out that the only justification for this arbitrary method of treating the data lies in the similarity between the resulting residues and those obtained for simple alcohols. Moreover, slight changes in the skewed-arc parameters lead to either overlap of the residual locus with the high-frequency end of the skewed-arc locus or to negative residual absorption at some frequencies. To get residues of the type shown, it is necessary to assign values of τ_0 which are somewhat larger than predicted by the linear relationship (see above) between $\log \tau_0$ and $1/(T-T_\infty)$.

The Glarum model (22) of relaxation leads to an expression which differs appreciably from that of the skewed arc only at high frequencies. The Glarum equation is capable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of representing the experimental results for the pentanediols to considerably higher frequencies than is the skewed-arc equation. This is illustrated for 1,2-pentanediol in Fig. 6(*a*). At still higher frequencies (or lower temperatures, Fig. 6(*b*)) the experimental absorption exceeds that of the Glarum locus which, in the limit of high frequencies, becomes a straight line which approaches the ϵ' axis at 45°. It is interesting to note that subtraction of the Glarum locus from the experimental one now leaves a single arc, which approximately corresponds to the higher-frequency arc of the pair that resulted from subtraction of the skewed arc.

In all events, there is an extremely broad loss spectrum at very high frequencies, which, if not completely accounted for by the diffusion-controlled relaxation process of Glarum, does appear to arise from a mechanism different from the co-operative orientation of locally ordered molecules responsible (1) for the behavior at lower frequencies.

The values of ϵ_1, whether determined by the high-frequency intercept of the skewed-arc or of the Glarum locus, decrease in the order 1,5-, 1,4-, 1,2-, 2,4-, and 2,3-pentanediol (see Table VII). This is roughly the order in which the relative number of weak and

TABLE VII

Variation of ϵ_1 and β with temperature (based on data between ca. −80 and −20° C)

	Skewed arc				Glarum,
Pentanediol	$\epsilon_1(-60°\text{ C})$	$d\epsilon_1/d(10^3/T)$	$\beta(-60°\text{ C})$	$d\beta/d(10^3/T)$	$\epsilon_1(-60°\text{ C})$
1,5	(5.2_5) (−30° C)		(1)		(5.2_5) (−30° C)
1,4	3.61	+0.020	0.73	−0.10	3.2_1
1,2	3.29	0.014	0.64	−0.03	2.9_8
2,4	3.17	0.012	0.55_5	−0.15	2.8_4
2,3	2.92	0.004	0.52_5	−0.03	2.6_9

broken hydrogen bonds increases, so that the magnitude of ϵ_1 cannot be directly related to the orientation of free or weakly hydrogen-bonded OH groups. At very high frequencies the absorption approaches zero at values of ϵ' of the order of 2.6 to 2.7, somewhat in excess of likely values of the square of the refractive indices, but similar to the dielectric constant observed for solid 1,5-pentanediol at comparable temperatures.

Temperature Dependence of the Dispersion

As may be seen from Table VII, the value of β in the skewed-arc representation tends to decrease with decreasing temperature. Although the values of $d\beta/d(1/T)$ tabulated are only approximate, they seem to show no systematic dependence on β. Moreover, the variation of β with temperature cannot be related to a model which assumes that the distribution of relaxation times arises from the presence of a temperature-independent distribution of barrier heights to rotation, such as may approximately account for the broadening of the dispersion exhibited by some solids with decreasing temperature (23).

In the Glarum representation (22), the shape of the dispersion–absorption locus depends on a_0 alone. As the temperature gets lower, the value of a_0 decreases, that is, the contribution of the diffusion-controlled relaxation becomes greater. Since $a_0 = l^2/D\tau_0$, this may be naively accounted for if the average defect diffusion relaxation time (l^2/D) increases less with decreasing temperature than does relaxation time for co-operative molecular rotation (τ_0) and the values of the two "relaxation times" therefore approach one another.

No extensive results are yet available for liquids at temperatures corresponding to β

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

less than 0.5 ($a_0 < 1$) where the Glarum theory makes the interesting prediction of behavior intermediate between that of the skewed arc and circular arc.

CONCLUSIONS

It may be concluded that departures of this type of asymmetric locus from the Debye semicircle arise from the presence of disordered regions in the liquid.

The increased asymmetry of the loss spectrum which results from increased interference with *inter*molecular hydrogen bonding as the OH groups move in from the ends of the pentane chain, in the sequence 1,5-, 1,4-, 1,2-, 2,4-, and 2,3-pentanediol, is accompanied at low temperatures by a large increase in the most probable relaxation time τ_0.* This type of relaxation is therefore not made easier by structural irregularity, within the present limits, but rather takes place most readily for liquids with the highest degree of local order. It is apparent that regularity of structure is somehow important in the activation process. This co-operative relaxation process may involve the sharing among many molecules of an accumulation of energy obtained at the expense of the vibrational energy of the quasi-crystalline lattice. The common nature of the variation of τ_0 with temperature is consistent with this picture.

APPENDIX

Calculation of the Dipole Moment of Vicinal Diols

In Table VIII are listed values of dipole moments for assumed models of vicinal diols. The OH and OC bond moments have been taken to be 1.51 (12*b*) and 1.10 debyes, respectively, with all angles assumed, for simplicity, to be tetrahedral. Since the small CH moments have not been taken explicitly into account, their effects are approximately included in the value taken for the OC moment.

Forms (*c*) to (*g*) are internally hydrogen bonded. In (*d*) the free OH group is rotated

**A similar steric effect is noticed in the recent results of Bennett (24), who finds that 1-phenyl-propanol ($\beta = 0.7$) exhibits much higher relaxation times at low temperatures than do 3-phenyl-propanol and 2-phenyl-ethanol ($\beta = 1$).*

TABLE VIII

Calculated dipole moments of vicinal diols

Model	Dipole moment (debyes)
(*a*) Free rot. about all bonds	2.07
(*b*) Free rot. about trans CO bonds	2.01
(*c*) CO bonds cis, all atoms coplanar	2.91
(*d*) CO bonds cis, e.o. in plane	2.52
(*e*) CO bonds gauche, $r_{O\cdots H}$ min, $r_{H\cdots H}$ max	2.64
(*f*) CO bonds gauche, first e.o. in plane of CO, O- - -H	2.48
(*g*) CO bonds gauche, second e.o. in plane of CO, O- - -H	2.10

about its CO bond through 120° from the planar case (*c*) so as to bring the direction of maximum electron density of either of the lone pair electron orbitals (e.o.) into the plane of the rest of the molecule.

In the three gauche forms, (*e*) to (*g*), the length of the hydrogen bond is made a minimum by rotation of the bonded OH group about its CO bond. Form (*e*) results from rotation of the free OH group about the CO bond until its H atom is as far as possible from the H atom in the bond. In (*f*) and (*g*) one or the other of the e.o.'s on the O atom is brought by this rotation as near as possible to the H atom in the bond.

The O- - -H and O- - -O distances are 1.84 and 2.49 Å, respectively, for the cis forms, and 2.33 and 2.82 Å for the gauche forms, with the following bond lengths assumed: OH 0.97, OC 1.42, C—C 1.54 Å. The O—H- - -O angles, measured within the ring, are 122° (cis) and 111° (gauche).

Most of the calculated dipole moments of the internally hydrogen-bonded forms are higher than the experimental moments of Table III. Form (*g*) fits the data best, but, since there is no good reason for preferring it to (*f*), the r.m.s. value of the moments of these two forms should be taken. This value (2.31 debyes) is sufficiently close to the experimental moments to suggest that the predominant hydrogen-bonded species are approximately gauche forms in which the orbitals of the lone pair electrons of the O atom in the hydrogen bond tend to be oriented toward the H atom. It is likely that the energy of the hydrogen bond is too small to produce much of a rotation from the normal gauche toward the cis configuration. Although there is no evidence for an appreciable population of trans forms in CCl_4 (compare Table II), it is possible that such forms may be promoted in dioxane by hydrogen bonding to the solvent.

The approximate nature of the calculations should be borne in mind. Thus, the values of the OH and OC bond moments (1.55 and 1.30 debyes) required to give agreement with the experimental moment of 1.66 debyes for monohydroxyl alcohols are considerably larger than the ones assumed here, and result in calculated moments which are larger by some 0.2 debyes than those given in Table VIII. If the O angle is taken to be 105° instead of tetrahedral, the bond moments and the resultant moments are somewhat reduced.

SOLVOLYSIS IN HYDROGEN AND DEUTERIUM OXIDE

IV. HALIDES WITH NEIGHBORING GROUPS[1]

P. M. LAUGHTON[2] AND R. E. ROBERTSON

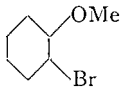
ABSTRACT

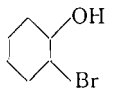
Rate data for the hydrolysis of a series of halohydrins and related compounds in light and heavy water are reported. The solvent isotope effects (k_{D_2O}/k_{H_2O}) from these measurements fall into three groups compared with those of simple halides. Thus the presence of a hydroxyl group in proximity to the seat of reaction may lead to increased, decreased, or normal solvent isotope ratios. The abnormal ratios can be interpreted in terms of the effect of anchimeric assistance on the solvation shell in the activation process.

In previous papers of this series, the solvent isotope effect (k_{D_2O}/k_{H_2O}) was shown to be remarkably insensitive to the structure of the alkyl group (1, 2, 3). This insensitivity appeared to rule out significant changing contributions from secondary isotope effects arising from variation in nucleophilic interaction (4, 5) and led to an explanation of the observed solvent isotope effect in terms of the relative stability of the initial state solvation shell. In the present paper we extend this hypothesis to include a series of compounds where apparent exceptions to the above generalization are found, and we are led to re-examine the hypothesis that transition state differences such as varying nucleophilic interaction may be neglected.

Specifically, we examine the solvent isotope effect for a series of halohydrins and analogous compounds substituted with alkoxyl or halide in positions where in certain cases other evidence leads to the expectation of anchimeric assistance in hydrolysis.

Rate data for the compounds studied in H_2O and D_2O were determined by a conductance method described in an earlier paper (6). It is generally recognized that this method gives the most accurate rate measurements available for this type of reaction, a fact of particular importance where questions relating to differences in rate ratios are involved. Since in this work we report a large number of kinetic data for a series of interesting compounds which, with few exceptions, had not previously been studied in water, it was considered desirable to publish now, even though only a qualitative interpretation is warranted at this time. Rate data for hydrolysis in D_2O and H_2O with corresponding temperatures are given in Table I. The sources of the compounds studied are included in the section on experimental detail, following the discussion.





CORRELATION OF SOLVENT ISOTOPE EFFECTS

In earlier papers we showed that whereas there was a marked difference between the solvent isotope effect for sulphonates and halides, the differences between corresponding halides—chlorides, bromides, and iodides—were much smaller, and these could be further reduced if due allowance was made for the effect of temperature on this ratio (3). We

*Rates for these compounds were determined by L. E. Hakka, summer research assistant, 1961.

have recently shown (5) that the temperature dependence of the solvent isotope effect for isopropyl bromide can be expressed by the equation

$$[1] \qquad \log_{10} k_{D_2O}/k_{H_2O} = (-693.7073/T) - 4.4867 \log_{10} T + 13.2935$$

and from this we may determine average values of k_{D_2O}/k_{H_2O} to be expected for halides* over the experimental range.

The solid curve in Fig. 1 is a plot of log k_{D_2O}/k_{H_2O} versus $1/T$ for isopropyl bromide. This is shown to parallel the individual values for the k_{D_2O}/k_{H_2O} ratio for a wide range of halides supporting the above generalization.

It will be apparent from this plot that the ratios given in Table I for compounds having a hydroxyl or methoxyl so placed as to provide for a possibility of anchimeric assistance, may be divided with respect to this chosen norm into three groups. A number coincide within a few per cent with the reference curve based on equation [1]. These include the three ethylene halohydrins (I, V, and IX), pinacol chlorohydrin (XVII), and the strongly anchimeric tertiary chloride (XVIII) with a rate enhancement (in 80% ethanol) of 740 (7). Several other values of k_{D_2O}/k_{H_2O} from our earlier work are included in the plot as further evidence of the common trend with temperature in the value of the k_{D_2O}/k_{H_2O} ratio for the halides.

**Actually, because the value of k_{D_2O}/k_{H_2O} for isopropyl bromide is lower than for many halides, the true average would probably lie 1 to 2 per cent higher than given by equation [1].*

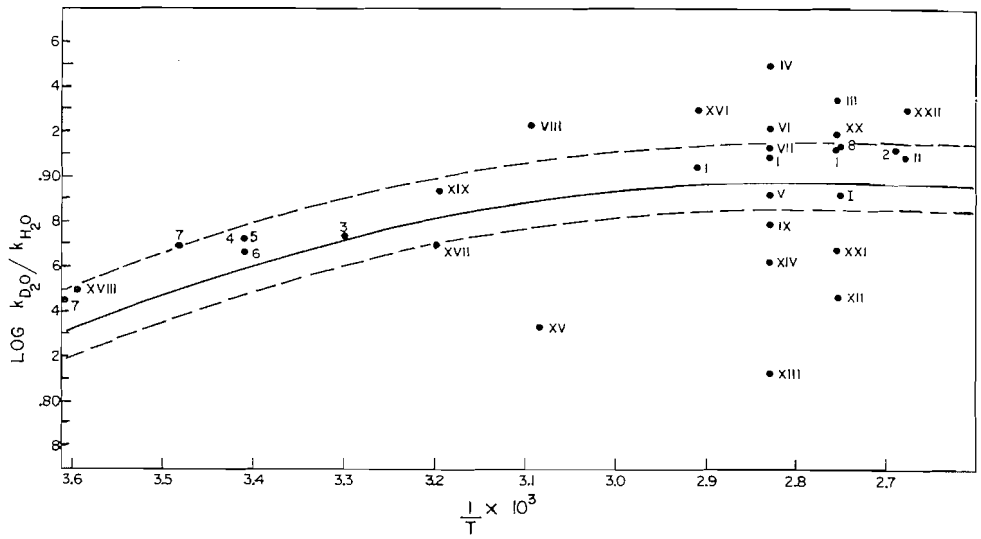

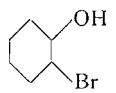

FIG. 1. The temperature dependence of solvent isotope effect for a series of halides, illustrating exceptional cases. Compounds from Table I are identified by Roman numerals. The remaining ratios are taken from paper III in this series (ref. 3): 1, MeBr; 2, EtBr; 3, *p*-$MeC_6H_4CH_2Cl$; 4, *p*-$MeC_6H_4CH_2Br$; 5, *o*-$MeC_6H_4CH_2Br$; 6, $PhCH_2Br$; 7, *t*-BuCl; 8, *t*-BuF. The solid line represents the data for *i*-PrBr from ref. 5.

The five compounds in the second group have ratios which lie below this arbitrary norm (Table II). These are the isobutylene and trimethylethylene halohydrins (XII, XIII, XIV, and XV) and the *trans*-cyclohexene bromohydrin (XXI). In the first four cases there appears to be anchimeric assistance, judging from the higher rates observed compared with the hydroxyl-free analogues and taking into consideration the fact that the normal inductive effect of β-hydroxyl would be reduction of the rate by a factor of 20 to 100 (8).

TABLE II

Rate ratios k_{D_2O}/k_{H_2O} for neighboring group halides showing lower than normal ratios

Code	Halide	k_{D_2O}/k_{H_2O} obs.	k_{D_2O}/k_{H_2O} normal*
XII	$HOCMe_2CH_2Cl$	0.70	0.789
XIII	$HOCMe_2CH_2Br$	0.65	0.788
XIV	$HOCMe_2CHMeCl$	0.73	0.788
XV	$HOCMe_2CHMeBr$	0.68	0.774
XXI	*trans* 	0.74	0.789

*Value calculated for *i*-PrBr at the same temperature.

The third group (Table III) displays somewhat higher values of the k_{D_2O}/k_{H_2O} ratio than normal and includes the three fast-reacting tetramethylene derivatives (III, IV, and VIII) and the isobutylene and trimethylethylene methoxybromides (XXII and XVI).

XXII	$MeOCMe_2CH_2Br$	0.86	0.786

*Value calculated for *i*-PrBr at the same temperature.

Thus it is apparent that an oxygen-containing β-substituent may raise, lower, or leave unchanged the solvent isotope effect. We now propose to show how these varying results can be fitted into the general explanation, based on the relative stability of the initial state solvation shell combined in certain cases (group 2, 3) with the influence of unusual reorganization arising in consequence of anchimeric assistance. It will be obvious that in the case of the halohydrins in D_2O, the OH will rapidly exchange with the medium to give OD, but it does not appear that secondary deuterium isotope effects from this source can provide a sufficient basis for the observed differences between the three groups. At any rate, another effect must dominate since this secondary isotope effect should result in shifting the ratios of all of the anchimerically assisted halohydrins in the same direction.

Evidence for Anchimeric Assistance in Hydrolysis

Because water is a fair nucleophile as well as a good ionizing medium, the probability of anchimeric interaction assisting solvolysis is less here than in the case with acetic acid as solvent (8), but it is not eliminated. With this reservation, evidence of such assistance follows the structural conditions noted in the less nucleophilic solvent. Thus ethylene halohydrins of Cl (I), Br (V), and I (IX) react at .043, .04, and .028 of the rate of the corresponding unsubstituted compounds, and a β-methoxyl introduces a rate reduction of 0.033 in the primary ethyl bromide (est. 5.1×10^{-5} sec^{-1} at 100°) (9), pointing to an absence of anchimeric effects. Methylation of the β- or hydroxyl-carbon leads to increased evidence for anchimeric assistance. For example, isobutylene chlorohydrin (XII) and bromohydrin (XIII) solvolyse more rapidly than ethylene chlorohydrin (I) and bromohydrin (V), as noted earlier by Nilsson and Smith (10) for reaction with alkali, thus differing sharply from the unsubstituted ethyl and isobutyl halides. Although the data are not available to calculate σ^* in the Taft equation ($\log k/k_0 = \rho\sigma^*$ (11)), for substrates isobutylene chlorohydrin (XII) and bromohydrin (XIII), it is plain that there must be substantial anchimeric assistance in these cases. Reasons for this substitution effect have been given by Thorpe *et al.* (12) and Schleyer (13). Tetramethylene chlorohydrin (III) reacts some 60 times more rapidly than *n*-propyl chloride, while trimethylene (II) and ethylene chlorohydrin (I) react successively more slowly. The difference in rate of hydrolysis between the tetramethylene methoxychloride (IV) and III is small. A similar trend is evident in the related bromides V, VI, VII, and VIII in Table I, the tetramethylene bromohydrin proving too reactive to obtain in a pure state. These data confirm the activating influence of a hydroxyl or other basic substituent in a 5-member ring-forming position, as noted by many workers, for example, Heine (14), and recently studied by Winstein *et al.* for solvolysis of methoxyalkyl brosylates (15).

Group 1. Normal k_{D_2O}/k_{H_2O} Values

These compounds in Table I which have normal values of k_{D_2O}/k_{H_2O} include without exception the halohydrins and corresponding methoxyhalides which give no evidence of anchimeric assistance. It would appear that the dihalides give "normal" values of k_{D_2O}/k_{H_2O} whether involving anchimeric assistance, XVIII, or not, XXIII. Tetramethylene dibromide (VII) is apparently a borderline case with the slightly higher than normal ratio of 0.818.

From our study of the temperature dependence of the solvent isotope effect for isopropyl bromide we concluded that the presence of the alkyl halide increased the structural stability of the initial state solvation shell relative to bulk water by about 20%. The very similar values of k_{D_2O}/k_{H_2O} found for the "normal" substrates in Table I suggest that the neighboring OH or MeO have not changed the degree of solvent reorganization about the anionic portion of the molecules in going from the initial to the transition state. Now it is very probable that the hydroxyl group is hydrogen bonded to the adjacent water structure, as is indicated by the large increase in solubility caused by its presence. In the absence of anchimeric assistance there is no reason to believe that this interaction is disturbed in the activation process, and hence there is no significant change in the energy required to reorganize the solvent in the activation process, from that required for the unsubstituted halide. It follows that normal k_{D_2O}/k_{H_2O} ratios are observed.

Group 2. Low k_{D_2O}/k_{H_2O} Values (Table II)

All of the compounds in this group are halohydrins; it is noteworthy that the corresponding methoxy compounds fall in group 3.

Following our earlier explanation of the solvent isotope effect, either the substrates with unusually low k_{D_2O}/k_{H_2O} ratios have a more stable solvent structure in the initial state or a more drastic reorganization occurs in the activation process. The first alternative is ruled out by the results of group 1 halohydrins, and since group 2 compounds all show anchimeric assistance, the second suggestion would seem more plausible. However, a further assumption is necessary since the third group with k_{D_2O}/k_{H_2O} values higher than "normal" also gives evidence of anchimeric assistance.

Judging from enhanced solubility compared with that of unsubstituted halides it may be inferred that the OH groups of those compounds giving abnormal k_{D_2O}/k_{H_2O} values must, like the normal compounds, interact, through hydrogen bonding, with the water in the initial state. It is noteworthy that the corresponding methoxy compounds fall into group 3.

Evidence of anchimeric assistance implies that, in contrast to group 1 compounds, this hydrogen bonding is more or less disrupted in the activation process. The phrase "more or less" is purposely vague for we do not yet possess sufficiently detailed knowledge to correlate the variation from the "normal" values of k_{D_2O}/k_{H_2O} with the degree of anchimeric assistance. To account for the abnormal k_{D_2O}/k_{H_2O} values it is sufficient to assume that the hydroxyl group will be pulled out of its initial state position in the water structure and bent laterally to form the transitory ethyleneoxonium ions. This more extensive rearrangement will, of course, accentuate the effects of structural differences between D_2O and H_2O as observed.

It is notable that as the seat of reaction changes successively from primary (XII, XIII) to secondary (XIV, XV) to tertiary (XVII) there is a trend toward more normal k_{D_2O}/k_{H_2O} ratios. This trend parallels the expected decrease in the importance of anchimeric assistance in these compounds.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

While this rationalization is admittedly *ad hoc*, our proposed explanation has certain implications concerning accompanying changes in entropy, enthalpy, and heat capacity which are open to experimental verification and these are currently under investigation.

Group 3. High k_{D_2O}/k_{H_2O} Values (Table III)

There are a number of hydroxyl- and methoxyl-substituted halides which show varying degrees of anchimeric assistance and yet have solvent isotope ratios (k_{D_2O}/k_{H_2O}) closer to unity than "normal". These include the tetramethylene chlorohydrin (III), methoxychloride (IV), and methoxybromide (VIII); trimethylene bromohydrin (VI); and isobutylene (XXII), trimethylethylene (XVI), and *trans*-cyclohexene methoxybromides (XX), which are to be contrasted with the corresponding bromohydrins (XIII, XV, and XXI). To these may be added isobutyl and neopentyl bromide, which gave indications of "higher" than normal solvent isotope ratios (3). The solvent isotope effects here deviate less from the normal than those found for group 2, and it is by no means certain that these deviations arise from the same cause in every case.

In an earlier paper (1) we discounted the isotope effect arising from varying nucleophilic interaction, yet it was difficult to imagine that the degree of reorganization which occurs about the cation would have no solvent isotope effect at all. It was more reasonable to equate at least part of the scatter apparent among the unsubstituted halides (normal solvent isotope effect) to this source. Both when the substituent group in the initial state blocks the rear side of the carbon undergoing displacement, and particularly when, as in the anchimerically assisted cases, it also serves as the displacing nucleophile, a lesser degree than normal of solvent reorganization will take place. This should lead to ratios nearer unity.

While the differentiation between groups 2 and 3 has a strong *ad hoc* flavor, it does have the advantage of explaining the quite different behavior of the tetramethylene chlorides (III) and (IV), both of which are group 3 compounds, while the pairs of compounds (XIII) and (XXII), (XV) and (XVI), and (XX) and (XXI) split between groups 2 and 3. In the latter cases the lateral displacements of the intramolecular nucleophiles require, for (XIII), (XV), and (XXI), the removal of the hydroxyl group *from* the water shell, and for (XIII), (XVI), and (XX), the movement of methoxyl *within* the solvent shell. The former leads to extensive reorganization and lower isotopic ratios; the latter leads to higher ratios because the displacement leads to relatively less reorganization than the abstraction of one water molecule from the solvent shell to serve as nucleophilic reagent. In the case of (III) and (IV), on the other hand, the intramolecular nucleophile must lie properly oriented behind the carbon–halogen bond early in the activation process, hence little reorganization is required.

At first we found it troublesome to understand why the iodochloride (XVIII) did not have as high a ratio as the isobutylene methoxybromide (XXII). Inspection of models shows that the iodine atom is so large that it is already almost touching the backside of the tertiary carbon undergoing displacement in XVIII, while the methoxyl group in XXII has to move an appreciable distance. However, the iodine is not hydrogen bonded to water in the initial state but presumably interacts as an exposed iodonium ion in the transition state. The methoxyl oxygen, on the other hand, is protected from solvation in the transition state by the alkyl group.

The case of compounds (XX) and (XXI) is being further investigated because their thermodynamic parameters of activation (24) indicate no noticeable anchimeric rate enhancement, although they clearly split between groups 2 and 3. A more detailed

analysis may show whether an anchimeric reaction may be proceeding through an unfavorable diaxial conformation, thus offsetting the rate enhancement.

EXPERIMENTAL DETAIL

The sources of the compounds and the available physical constants are summarized in Table IV. Commercially available compounds were either recrystallized or fractionally distilled under reduced pressure. In all cases linear pseudo first-order plots were obtained and this was considered to be the best critique of purity for the present purpose. Those compounds not otherwise available were synthesized* by the methods referenced in Table IV.

TABLE IV

Summary of sources and characteristics of halides solvolysed

RADIATION CHEMISTRY OF CYCLOHEXANE

III. EFFECT OF BENZENE AND IODINE ON THE ISOTOPIC COMPOSITION OF RADIOLYTIC HYDROGEN FROM C_6D_{12}–C_6H_{12} MIXTURES[1]

P. J. Dyne and W. M. Jenkinson

ABSTRACT

The isotopic composition of hydrogen evolved in the radiolysis of C_6D_{12}–C_6H_{12} mixtures has been measured in the presence of various amounts of benzene and iodine. The yield of the unimolecular decomposition and the specific yield of the bimolecular reaction are reduced in approximately the same proportion as the yield of total hydrogen. It is concluded that (i) iodine and benzene interact to a comparable extent with both unimolecular and bimolecular decomposition modes, (ii) it is probable that neither of these additives act by scavenging, and (iii) it is probable that they act by quenching a common precursor of the two decomposition modes.

INTRODUCTION

We have shown from measurements of the isotopic composition of hydrogen produced in the radiolysis of C_6D_{12}–C_6H_{12} mixtures (1) that part of the hydrogen is formed in a bimolecular process

$$C_6H_{12} \text{ —}\sim\sim\rightarrow X_H + P \qquad \text{yield } G_2(H) \qquad [1]$$

$$X_H + C_6H_{12} \rightarrow H_2 + P \qquad [2]$$

where the atoms in the H_2 molecule come from two different cyclohexane molecules, and part is formed in a unimolecular process

$$C_6H_{12} \text{ —}\sim\sim\rightarrow H_2 + P \qquad \text{yield } G_1(H) \qquad [3]$$

where both hydrogen atoms come from the same cyclohexane molecule. The symbol P represents any product or residue and X_H is the reactive intermediate in the bimolecular process.

The specific yield of the decomposition

$$C_6D_{12} \text{ —}\sim\sim\rightarrow D_2 + P \qquad \text{yield } G_1(D) \qquad [4]$$

in a large excess of C_6H_{12} was shown to be 0.25 molecules/100 ev absorbed in the C_6D_{12}. However, the yield of reaction [3] in pure C_6H_{12} may amount to between 25% (2) and nearly 50% (3) of the total yield. It is conceivable that this large "isotope effect" expresses variations in $G_1(D)$ and $G_1(H)$ with the isotopic composition of the solvent due to some type of energy transfer or charge transfer effect. In the experiments described in this paper we used the yield of D_2 from C_6D_{12} as an "indicator" of the efficiency of unimolecular processes in benzene and iodine solutions in cyclohexane.

We also showed (1) that $G_1(D)$, the yield of reaction [4], was reduced by biphenyl, and slightly reduced by iodine. We concluded that biphenyl could act as a quenching agent[2] on the excited precursors involved in the unimolecular decomposition.

In this paper we describe a series of measurements of the isotopic composition of hydrogen evolved in the radiolysis of C_6D_{12}–C_6H_{12} mixtures in the presence of varying amounts of benzene and iodine. We find that, for both these substances, $G_1(D)$ is reduced in approximately the same proportion as the total hydrogen yield, and we infer that the unimolecular and bimolecular decompositions are quenched to approximately the same extent by these substances. Burton and Chang (4) have studied the change in isotopic

[1]*Manuscript received June 22, 1961.*
Contribution from the Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 1340.

[2]*In this paper 'quenching' refers to any process (energy transfer, charge transfer), other than radical scavenging, which inhibits decomposition or reduces a yield.*

composition of hydrogen evolved from mixtures containing roughly equimolar amounts of C_6H_{12} and C_6D_{12} and have discussed their results in terms of the function

$$f = \frac{[HD]^2}{[H_2][D_2]}.$$

The addition of benzene, iodine, methyl iodide, and cyclohexene to a given mixture of C_6D_{12} and C_6H_{12} changes f very little, even though G(hydrogen) may be reduced by as much as 80%.

Our work is, in the main, in agreement with their results and conclusions.[3] It differs in the following respects: we studied solutions containing less than 10 mole% C_6D_{12}, and discuss our results in terms of changes in G_1(D) and G(HD) rather than in f. At these concentrations of C_6D_{12} we observed small changes in f on the addition of benzene and iodine to a C_6D_{12}–C_6H_{12} mixture.

EXPERIMENTAL

The salient experimental details have been given in ref. 1. In the present experiments, however, the 2-ml samples were irradiated for 2 hours at a dose rate of $\sim 2.2\times10^{22}$ ev/lt hr. The total dose is about one-third that given in the earlier experiments and the experimental values of G(hydrogen) are, consequently, higher.

Solutions of four concentrations of C_6D_{12}, viz. 2.43, 4.78, 6.98, and 9.09 mole% were studied at four concentrations of benzene and three of iodine. These results are shown in Table I.

Values of $G_1(D)$, the unimolecular yield, were obtained using the graphical extrapolation described in (1). Values of $g(HD)$,[4] the yield of HD per unit mole fraction of C_6D_{12}, were obtained from the slope of the linear plot of $G(HD)$ vs. mole fraction C_6D_{12}. These derived values, together with values normalized to the mixture containing neither benzene nor iodine, are given in Table II.

TABLE II
Values of absolute and normalized yields

Concn. of additive	G(hyd) ±0.08	Norm.	G_1(D) ±0.02	Norm.	g(HD) ±0.1	Norm.
None	5.34	1.00	0.32_2	1.00	3.59	1.00

5×10^{-2} M I_2	3.31	0.61_8	0.23	0.71_5	2.60	0.72_2

The error given in the value of G(hyd) in Table II covers the range of the experimental values. The errors in $G_1(D)$ and $g(HD)$ were obtained from the extreme values of the intercepts and slopes which could be derived from the experimental points and contain errors from both G(hydrogen) and from the isotopic analysis. Uncertainties in % D_2 at the lowest concentration of C_6D_{12} amount to ±10% and to ±2% at the highest.

The value of $G_1(D)$ in the absence of additives, 0.32±0.02, is greater than the value of 0.25 previously reported. This is because the present experiments were carried out at lower total doses. The newer value is more precise and compares well with the value of 0.35 obtained by Burton and Chang in similar experiments.

THE KINETIC ANALYSIS

The complete mechanism used for the interpretation of these results is:

$C_H \longrightarrow C_H^*$	yield $G_1(H)$
$C_H^* \rightarrow H_2 + P$	
$C_D \longrightarrow C_D^*$	yield $G_1(D)$
$C_D^* \rightarrow D_2 + P$	
$C_H \longrightarrow C_H^{**}$	yield $G_2(H)$
$C_H^{**} \rightarrow X_H + P$	
$C_D \longrightarrow C_D^{**}$	yield $G_2(D)$
$C_D^{**} \rightarrow X_D + P$	
$X_H + C_H \rightarrow H_2 + P$	rate constant k_1
$X_D + C_H \rightarrow HD + P$	k_2
$X_H + C_D \rightarrow HD + P$	k_3
$X_D + C_D \rightarrow D_2 + P$	k_4

where $C_H = C_6H_{12}$, $C_D = C_6D_{12}$. P and X_H have been defined in the introduction.

We have shown (1) that, in mixtures containing C_D moles of C_6D_{12} and C_H moles of C_6H_{12},

$$G(D_2) = G_2(D)\times k_4/k_2\times(C_D/C_H)^2+G_1(D)\times C_D/C_H \qquad [1]$$

when $CH \gg C_D$.

[4] *g*(HD) *is precisely defined in the discussion.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

A similar steady state argument gives

$$G(\mathrm{HD}) = \mathrm{C_D}/\mathrm{C_H}\,[(k_3/k_1)\times G_2(\mathrm{H})+G_2(\mathrm{D})] \qquad [2]$$

when $\mathrm{C_H} \gg \mathrm{C_D}$. We define $g(\mathrm{HD}) = (k_3/k_1)\times G_2(\mathrm{H})+G_2(\mathrm{D})$.

The above analysis identifies the unimolecular yield $G_1(\mathrm{D})$ as that fraction of the yield of $\mathrm{D_2}$ which is first order with respect to $\mathrm{C_D}$ and resolves the term $g(\mathrm{HD})$ into the sum of two terms, the weighted yields of the intermediates $\mathrm{X_H}$ and $\mathrm{X_D}$ in the bimolecular reactions. The terms $G_1(\mathrm{D})$, $G_2(\mathrm{D})$ and $G_1(\mathrm{H})$, $G_2(\mathrm{H})$ contribute to the total yields in proportion to the mole fractions of $\mathrm{C_6D_{12}}$ and $\mathrm{C_6H_{12}}$.

DISCUSSION: IMMEDIATE CONCLUSIONS

An additive may interfere with and reduce either or both of the two decomposition mechanisms. Consider an additive which quenches the unimolecular mechanism and leaves the bimolecular mechanism unchanged. The yield $G_1(\mathrm{D})$, measured in these experiments, will decrease, and should decrease more rapidly than the total yield of hydrogen if the effects on $G_1(\mathrm{D})$ and $G_1(\mathrm{H})$ are comparable. Further, in experiments where essentially all the observed $\mathrm{D_2}$ comes from the unimolecular decomposition (as in the present case), the percentage of $\mathrm{D_2}$ must decrease. Since, by hypothesis, $g(\mathrm{HD})$ is unchanged and $G(\mathrm{hydrogen})$ is reduced, then the % HD must increase.

The changes in % $\mathrm{D_2}$ and % HD will depend on the relative contributions of the unimolecular and bimolecular yields. If, for instance, the bimolecular yield is a large fraction of the total, then the change in % $\mathrm{D_2}$ will be of the same order as the percentage change in total hydrogen. If the bimolecular yield is small the change in % $\mathrm{D_2}$ will be large compared with the change in total hydrogen.

The possible changes in $G_1(\mathrm{D})$, $g(\mathrm{HD})$, and percentage composition are summarized below:

	$G_1(\mathrm{D})$	$g(\mathrm{HD})$	% $\mathrm{D_2}$	% HD
Unimolecular mechanism quenched	Decreased more rapidly than total hydrogen	Unchanged	Decreased	Increased
Bimolecular mechanism quenched or scavenged	Unchanged	Decreased more rapidly than total hydrogen	Increased	Decreased
Both mechanisms quenched/ scavenged	Decreased	Decreased	Small changes +ve or −ve	Small changes +ve or −ve

In the case where both mechanisms are quenched the magnitude of the decreases in $G_1(\mathrm{D})$ and $g(\mathrm{HD})$ relative to the decrease in $G(\mathrm{hydrogen})$ will depend on several factors: the relative yields of the two mechanisms, the sensitivity of the precursors $\mathrm{C_H}^*$, $\mathrm{C_H}^{**}$, or $\mathrm{X_H}$ to the additive, and isotope effects in the reactivity of $\mathrm{C_H}^*$ and $\mathrm{C_D}^*$ or $\mathrm{X_H}$ and $\mathrm{X_D}$ with the additive.

Qualitatively the results in Tables I and II and Fig. 1 fall into the third category, and it follows that both the unimolecular and bimolecular yields of hydrogen are quenched/ scavenged by benzene and by iodine to a comparable extent.

It can be argued, from these results, firstly, that the action of these additives is the quenching of both mechanisms, and secondly, that both mechanisms have a common precursor, i.e. $\mathrm{C_H}^* \equiv \mathrm{C_H}^{**}$. These arguments proceed as follows. If the bimolecular mechanism is reduced by scavenging then the scavenging reaction,

$$\mathrm{M} + \mathrm{X_H} \rightarrow \text{products}, \qquad [a]$$

has a comparable efficiency to the quenching of the unimolecular mechanism,

$$\mathrm{C_H}^* + \mathrm{M} \rightarrow \mathrm{C_H} + \mathrm{M}^*. \qquad [b]$$

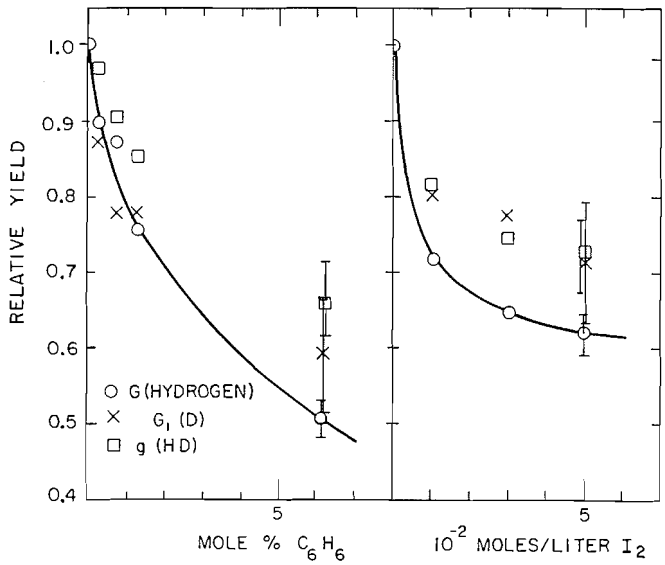

FIG. 1. Relative values of G(hydrogen), G_1(D), and g(HD) as a function of (*a*) benzene and (*b*) iodine concentrations. The precise numerical data may be found in Table II. The bars at the highest concentrations give the limits of error on the values.

These are different physical processes; one involves the rearrangement of chemical bonds, the other does not. It is consequently improbable that they would have rate constants which are within about 30% of one another, as implied by our data, and even more improbable that this would be so for both benzene and iodine. The mode of interaction is therefore *quenching* of both mechanisms, i.e. by [*b*] and

$$C_H^{**} + M \rightarrow C_H + M^*. \qquad [c]$$

It can also be argued that it is improbable that there are two quenching reactions [*b*] and [*c*] having comparable rates for both additives. The simplest explanation is that the precursors C_H^* and C_H^{**} are identical. The reaction scheme is therefore

$$C_H \rightsquigarrow C_H^*$$

$$C_H^* \begin{cases} \nearrow X_H + P \\ \searrow H_2 + P \end{cases}$$

$$C_H^* + M \rightarrow C_H + M^*.$$

This last conclusion would be inescapable if the isotopic composition were precisely unaltered by the addition of benzene or iodine.

However, as can be seen from an inspection of Table I, some changes in isotopic composition are observed. Further significant differences can be observed from the behavior of the function

$$f = [HD]^2/[H_2]\,[D_2].$$

If hydrogen were produced exclusively by a bimolecular mechanism which proceeded statistically with no isotopic discrimination, then $f = 4$.

From the kinetic scheme given above it can be shown that

$$f = 4\,\frac{k_2\,k_3}{k_1\,k_4}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and a consideration of the isotope effects in hydrogen and deuterium abstraction reactions shows that f will be always greater than 4.

As, experimentally, f is always less than 4 it follows that other processes forming H_2 and D_2 are operative: this is prima facie evidence that the contribution of the unimolecular processes is appreciable (2, 3) (or that the species X_H are not hydrogen atoms and the ratios k_1/k_2, k_3/k_4 are quite different from the estimates). In Fig. 2 we present a plot of f vs. mole% C_6D_{12}. The addition of benzene raises the value of f significantly; iodine lowers it slightly.

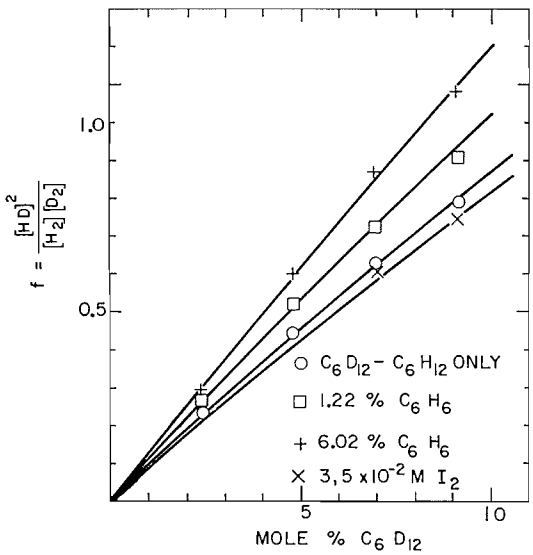

FIG. 2. Variation of f as a function of the concentrations of C_6D_{12} in the presence of varying amounts of benzene and iodine. The precise numerical data may be found in Table I.

These effects of benzene and iodine on f make it appear that, in effect, benzene quenches the unimolecular processes (giving H_2 and D_2) slightly more efficiently than the bimolecular processes. Iodine reacts conversely. The same conclusion can be reached from Fig. 1. For benzene, for instance, the curve for $G_1(D)$ lies below the curve for $g(HD)$. Such an effect could be produced by an isotopic effect in the efficiency of quenching C_H^* and C_D^*. If C_D^* were more efficiently quenched than C_H^*, then $G_1(D)$ would fall more rapidly than $g(HD)$, which is, in effect, the sum of the net yields of C_H^{**} and C_D^{**}.

In summary we conclude that (i) iodine and benzene interact to a comparable extent with both unimolecular and bimolecular decomposition modes, and (ii) it is probable that neither of these additives act by scavenging, and (iii) it is probable that they act by quenching a common precursor of the two decomposition modes. The first conclusion is clear; the second and third are debatable.

FURTHER IMPLICATIONS

The effects of benzene, iodine, and other additives on $G(H_2)$ from cyclohexane have been studied by many workers. (See, for instance, refs. 5–8.) In general the curve of $G(H_2)$ vs. additive concentration consists of two segments: an initial rapid decrease in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the concentration range 0–5% and a much slower decrease at higher concentrations. The yield curve cannot be described by simple kinetic schemes involving the quenching or scavenging of one precursor. The existence of two precursors is frequently postulated; one of these is readily quenched (or scavenged) at low concentrations, the other is only quenched (or scavenged) at high concentrations. As the additives are often supposed to be very reactive radical scavengers, the efficient reaction may be identified as radical scavenging and the less efficient reaction identified as the quenching of a non-scavengeable reaction, e.g. the unimolecular decomposition.

In this paper we have shown that benzene and iodine reduce the bimolecular (scavengeable) and unimolecular (unscavengeable) yields concurrently in the low concentration region, and it follows that the interpretations of the type outlined above are, at best, only partially true.

In the absence of chemical identification of the products of scavenging this discrepancy turns on two points, the validity of the kinetic analysis which distinguishes between the two processes and the assumption that the additive acts as a scavenger.

The kinetic analysis is generally performed on transformed versions of the yield curve involving functions of the reciprocal of the yield: these versions give linear plots. It should be noted that a reciprocal of a smooth curve (such as the yield curve) will always give an approximate straight line.[5] Consequently the linearity of these plots, if based on a limited region of the yield curve, is as significant or trivial as, for instance, the linearity of a logarithmic plot. (See for instance ref. 11.) A kinetic analysis which leads to the conclusion that two processes are occurring only demonstrates rigorously that one process in a simple scheme *cannot* account for the data.

It is well known that many reactive radical scavengers are potentially efficient energy sinks or charge acceptors. Our ignorance of the mechanism of energy and charge transfer in irradiated liquid systems is so profound that it is unwise to identify a substance, *a priori*, as a radical scavenger and assume that it cannot react otherwise.

For benzene there is chemical evidence that it does not act as a conventional scavenger, since G(-benzene) is small at these concentrations (9). This does not preclude the possibility (7, 10), that benzene acts as a "catalyst" by a series of reactions such as

$$C_6H_6 + H \rightarrow C_6H_7$$

$$C_6H_7 + C_6H_{11} \rightarrow C_6H_6 + C_6H_{12}.$$

For iodine it is known that HI is found in the initial stage of the radiolysis in an amount which is equivalent to the concurrent reduction in hydrogen yield, and which is also consistent with the 'hydrogen atom yield' derived from kinetic analysis. If the unimolecular decomposition of cyclohexane is a significant fraction of the total, then we would be forced to conclude, in spite of the strong arguments to the contrary advanced by Forrestal and Hamill (11), that HI is formed by some reaction other than hydrogen atom scavenging by molecular iodine.

ACKNOWLEDGMENTS

It is a pleasure to acknowledge both the detailed correspondence we have had with Professor Milton Burton and the helpful discussions we had with Dr. R. H. Betts.

[5]*The sceptical reader might test this with synthetic, freehand yield curves. We are obliged to Dr. J. W. Otvos for pointing out to us this property of numbers.*

THE VIBRATIONAL SPECTRA OF SULPHURYL AND THIONYL HALIDES[1]

R. J. GILLESPIE AND E. A. ROBINSON[2]

ABSTRACT

New assignments are proposed for the fundamental frequencies of SOF_2, $SOCl_2$, SO_2Cl_2, SO_2F_2, and SO_2FBr, based on new measurements of the Raman spectrum of SO_2Cl_2 and previous measurements of the infrared and Raman spectra of these molecules. The fundamental frequencies of these molecules are found to be related to each other and to those of similar molecules when the normal modes are described in terms of characteristic vibrations of the SO, SO_2, S(Hal), and $S(Hal)_2$ groups.

INTRODUCTION

The purpose of this paper is to give a consistent assignment of the observed vibrational frequencies of the thionyl and sulphuryl halides to the various modes of vibration of these molecules. This work was undertaken as a necessary preliminary to the interpretation of the vibrational spectra of a number of more complicated polysulphuryl compounds (1). Although both the infrared and Raman spectra of several of these molecules have each been examined a number of times, no complete agreement has been reached concerning the assignments of the observed frequencies (e.g. references 2, 3, and 4). We have found, by comparing the spectra of these molecules and certain others containing SO, SO_2, S(Hal), and $S(Hal)_2$ groups, that a consistent and satisfactory set of assignments can be given for all the sulphuryl and thionyl halides that have been studied.

Of the spectra discussed, only the Raman spectrum of SO_2Cl_2 has been re-examined in the present work. The spectrum is shown in Fig. 1. The vibrational frequencies for

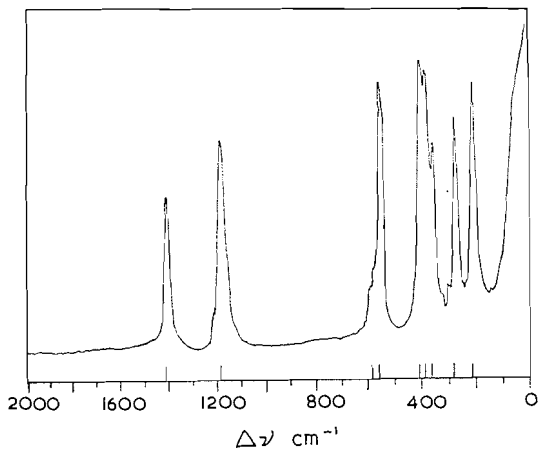

FIG. 1. The Raman spectrum of sulphuryl chloride.

sulphuryl chloride and for the other sulphuryl and thionyl halides obtained in the present and previous work are given in Tables I–V.

The sulphuryl halides, SO_2X_2, have C_{2v} symmetry and they therefore have nine fundamental vibrations, four of which are totally symmetric. To a first approximation, at least, three of the vibrations can be associated with valency deformations of the SO_2 group (symmetric and asymmetric stretches and a bend) and three similar vibrations with the SX_2 group. The remaining normal modes can be described as a torsion (inactive in the infrared) and as SO_2 and SX_2 rocking modes.

The thionyl halides, SOX_2, have pyramidal structures with C_s symmetry and six fundamental vibrations which may be approximately described as an SX_2 symmetric and asymmetric stretch, an SX_2 rock, an SO stretch, and an SO wag (or OSX_2 deformation).

DISCUSSION

Thionyl Fluoride and Thionyl Chloride

All six normal vibrations have been observed for thionyl chloride, and, as expected, four of the lines in the Raman spectrum are polarized (Table IV). Only five fundamentals, three of which are polarized, have been observed with certainty for thionyl fluoride, although Yost (5) has claimed a line in the Raman spectrum at 326 cm^{-1}, in addition to the five lines reported by other workers.

Frequencies can readily be assigned to the SO stretch, the SX_2 stretches, and the SX_2 bend in both SOF_2 and $SOCl_2$ by comparison with the frequencies of these vibrations in similar molecules, as shown in Table VI. The polarized line at 344 cm^{-1} in the spectrum of $SOCl_2$ must then be assigned to the totally symmetric SO wag and the remaining line at 284 cm^{-1} (depolarized) to the SCl_2 rocking mode. Similarly in the spectrum of SO_2F_2 the depolarized line at 393 cm^{-1} must be assigned to the SF_2 rocking mode and the remaining line at 326 cm^{-1} to the SO wag. Although the degree of polarization of this line is not known, it seems reasonable to suppose that it is polarized, since only three of the other lines have been found to be polarized. Our assignment for $SOCl_2$ agrees with that given by Martz and Lagemann (18). Assignments for the spectra of selenium oxychloride (17) and selenium oxyfluoride (16) can readily be made by comparison with the

spectra of the corresponding thionyl compounds. Our assignments for these molecules are given in Table VI.

Sulphuryl Chloride and Sulphuryl Fluoride

In the Raman spectrum of sulphuryl chloride eight of the expected nine lines are observed as distinctly resolved peaks. The ninth appears as a shoulder at approximately 580 cm^{-1} on the 560 cm^{-1} peak. Vogel-Högler (19) reported three lines at 556, 563, and 578 cm^{-1} in the infrared in this region. Martz and Lagemann (18) also reported three lines in the infrared, but at frequencies of 577, 586, and 595 cm^{-1}, of which the first two were intense and assigned as fundamentals while the third was rather weak and assigned as a combination band. We will assume that there are only two fundamentals in this region of the spectrum with frequencies of approximately 560 cm^{-1} and 580 cm^{-1}. Raman frequencies for the liquid appear to be consistently lower than the corresponding infrared frequencies for the gas. To facilitate comparison with the Raman data, infrared frequencies that have been reduced by 20 cm^{-1} are listed in addition to the observed values.

In the case of sulphuryl fluoride, three lines at 539, 544, and 553 cm^{-1} have been reported (2, 20) in the infrared spectrum but only one at 547 cm^{-1} in the Raman spectrum (4, 21). It seems likely that there are indeed three lines that are not resolved from each other in the Raman spectrum; accordingly three vibrations are each assigned a frequency of 545 cm^{-1}.

Frequencies can readily be assigned to the SO_2 stretches, the SO_2 bend, the SX_2 stretches, the SX_2 bends, and the SX_2 rocking mode by comparison with the frequencies of these vibrations in the thionyl halides or other similar molecules, as shown in Table VI. The only vibrations to which frequencies cannot be easily assigned in this way are the SO_2 rocking mode and the torsion, which is inactive in the infrared. In the spectrum of sulphuryl chloride we have unassigned lines at 388 cm^{-1} (R) and at 580 cm^{-1} (R and I.R.) and in the spectrum of sulphuryl fluoride at 274 cm^{-1} and at 545 cm^{-1} (the third of three lines with approximately this frequency). The torsion must therefore be assigned at 388 cm^{-1} in SO_2Cl_2. It is reasonable that no line of approximately this frequency is observed in the Raman spectrum of SO_2F_2, as it would probably not be resolved from the rather broad band at 388 cm^{-1}, which has been assigned as the SF_2 rocking mode. Hunt and Wilson (2) have indeed assigned this vibration at a frequency of 360 cm^{-1} in sulphuryl fluoride on the ground of the observation of a line at 720 cm^{-1} in the infrared, which they interpret as the first overtone of 360 cm^{-1}. This leaves a line at approximately 545 cm^{-1} in SO_2F_2 and the line at 580 cm^{-1} in SO_2Cl_2 to be attributed to the SO_2 rock in these molecules.

Hunt and Wilson (2) have assigned a frequency of 274 cm^{-1}, which they observed in the infrared spectrum of SO_2F_2, to the SF_2 bending mode by comparison with a frequency of 235 cm^{-1} in the spectrum of sulphur tetrafluoride, which has been assigned as an SF bending mode (9). It seems to us more probable that this low frequency of 235 cm^{-1} in the Raman spectrum of liquid SF_4 is due to some polymeric species formed by fluorine bridging between SF_4 molecules in the same way that antimony pentafluoride is associated by fluorine-bridge bonds (28). The line at 274 cm^{-1} reported by these authors is difficult to understand as its frequency seems to be too low for it to be due to any vibration of SO_2F_2. A possible explanation is that it is due to either SO_2Br_2 or SO_2FBr formed by attack on the bromide windows of the cell and, indeed, a frequency of 270 cm^{-1} has been observed in the spectrum of SO_2FBr (29). All the overtone bands that have been observed in the infrared spectra of SO_2F_2, SO_2Cl_2, $SOCl_2$, and SOF_2 can be satisfactorily accounted for as allowed combinations of the fundamentals, as shown in Tables I–IV.

Sulphuryl Bromofluoride

The infrared spectrum of sulphuryl bromofluoride, SO_2BrF, has been reported by Crow and Lagemann (29), who have given an assignment of the observed frequencies in terms of characteristic vibrations of the SO_2 and SFBr groups. We prefer, however, to treat the vibrations of the S—F and S—Br bonds separately and to describe the nine fundamental vibrations as an SO_2 symmetric and asymmetric stretch, an SO_2 bend and an SO_2 rock, an SF stretch and an SF wag, an SBr stretch and an SBr wag, and a torsion. On this basis we have been able to assign frequencies to all except one of the fundamental vibrations in a manner which is quite consistent with the assignments which have been proposed above for SO_2Cl_2 and SO_2F_2, as shown in Table VI. The justification for the majority of these assignments is obvious from the data given in this table. The frequency of the S—Br stretch would be expected to fall in the range 250–320 cm^{-1} from the following data for the P—Hal symmetric stretches: POF_3, 873 cm^{-1}; $POCl_3$, 486 cm^{-1}; $POBr_3$, 340 cm^{-1} (30, 31); and for the S—Hal stretches: SO_2F_2, 848 cm^{-1}; SO_2Cl_2, 405 cm^{-1}. Therefore, one of the frequencies 320 cm^{-1} or 270 cm^{-1} must be assigned to this vibration. The S—F wag might be expected to have a frequency somewhere near that of the S=O wag in SOF_2 (326 cm^{-1}), since the SF_2 bend and the SO_2 bend in SO_2F_2 have similar frequencies of approximately 545 cm^{-1}. Thus it seems reasonable to assign 320 cm^{-1} to this vibration, which leaves 270 cm^{-1} as the S—Br stretch. The S—Br wag would be expected to have a very low frequency, certainly lower than the S—Br stretch. P—Br bending modes have been assigned frequencies of 162 and 173 cm^{-1} in PBr_3 (32) and 173 cm^{-1} in $POBr_3$ (31), for which the stretching modes have been assigned at 380 and 340 cm^{-1}, respectively. We conclude therefore that the S—Br wag has a frequency less than 200 cm^{-1} and has not been observed. A detailed examination of the infrared spectrum leads to the conclusion that the infrared band at 353 cm^{-1} is best interpreted as the first overtone of the S—Br wag so that a frequency of 176 cm^{-1} can be assigned to this vibration. This assignment enables certain other overtone bands in the infrared to be assigned in a satisfactory manner (Table V). The remaining frequency of 461 cm^{-1} is assigned to the torsion. The complete infrared spectrum of SO_2BrF can be satisfactorily accounted for on the basis of the present assignment of the fundamental vibrations (Table V).

EXPERIMENTAL

Sulphuryl chloride was purified by double distillation of the commercial product, which had been dried over phosphoric oxide. The fraction boiling at 69° was collected. The Raman apparatus and the method used for obtaining depolarization factors are described in the following paper (1).

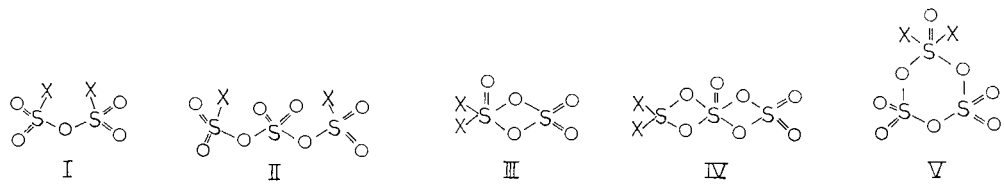
THE RAMAN SPECTRA OF SOME POLYSULPHURYL CHLORIDES AND FLUORIDES[1]



R. J. GILLESPIE AND E. A. ROBINSON[2]

ABSTRACT

The Raman spectrum of disulphuryl chloride, $S_2O_5Cl_2$, has been reinvestigated and the Raman spectra of $S_2O_5F_2$, S_2O_5ClF, $S_3O_8Cl_2$, $S_3O_8F_2$, and the new compound S_3O_8ClF are reported for the first time. The vibrational spectra of these polysulphuryl halides are interpreted in terms of characteristic group frequencies by comparison with the vibrational spectra of simple sulphuryl compounds. The spectra are consistent with acyclic structures for the polysulphuryl halides.

The Raman spectrum of disulphuryl chloride, $S_2O_5Cl_2$, has been investigated previously by Gerding and Linden (1), and the infrared spectrum of disulphuryl fluoride, $S_2O_5F_2$, has been obtained over a limited frequency range (2). We have measured the Raman spectra of both of these compounds and also of disulphuryl chlorofluoride, S_2O_5ClF; trisulphuryl chloride, $S_3O_8Cl_2$; trisulphuryl fluoride, $S_3O_8F_2$; and the new compound trisulphuryl chlorofluoride, S_3O_8ClF. The spectra are given in Tables I, II, and III and Fig. 1.

It has generally been assumed that these substances have the acyclic configurations I and II, although no direct experimental evidence for these structures has been obtained. The fluorine n.m.r. spectrum of $S_2O_5F_2$ has been found to consist of a single line (3), and in the present work we have found that the n.m.r. spectrum of $S_3O_8F_2$ also consists of

I II III IV V

a single line, showing that the fluorine atoms are structurally equivalent; this is consistent with structures I and II. Other formally possible formulations such as III, IV, and V contain improbable four-membered rings and five-co-ordinated sulphur. It has been shown, moreover, that $S_2O_5Cl_2$ is not just a molecular "addition compound" of SO_2Cl_2 and SO_3 since it is not formed in mixtures of these substances at room temperature or on being refluxed at 60°. Similarly $S_3O_8F_2$ is not formed from $S_2O_5F_2$ and SO_3 (4). Hydrolysis of $S_2O_5Cl_2$ and $S_2O_5F_2$ gives 2 moles of the corresponding halogenosulphuric acid and not sulphuric acid and the sulphuryl halide, as would be expected for structure III. Thus the acyclic structures I and II seem very probable, and it is shown in this paper that the Raman spectra are also consistent with these structures.

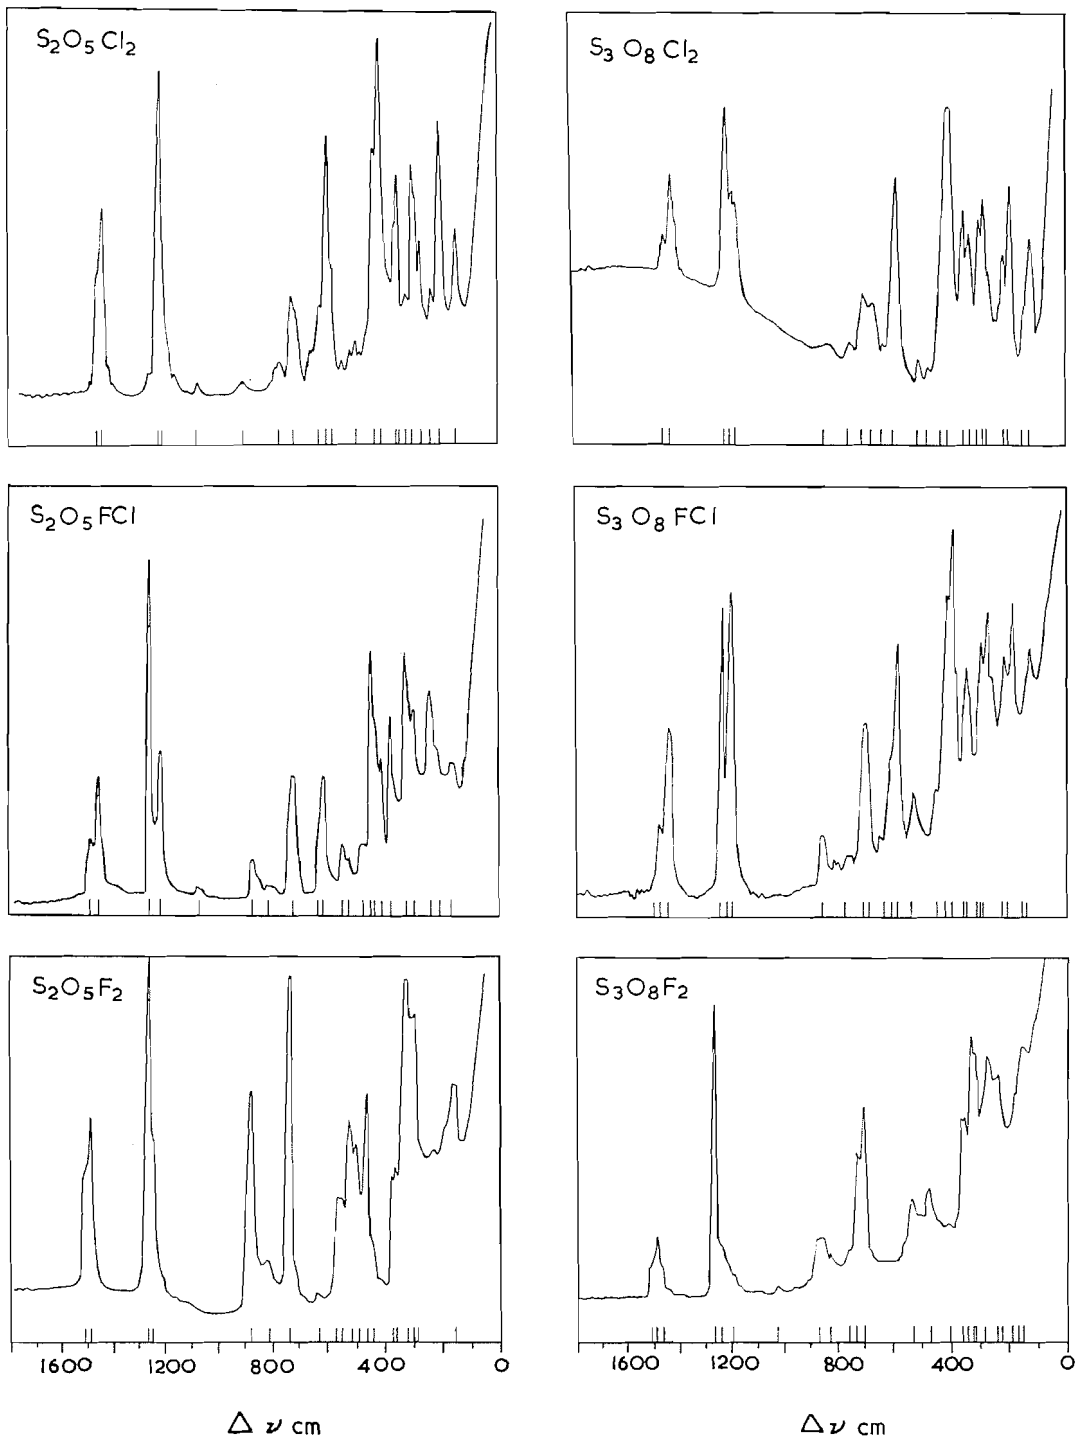

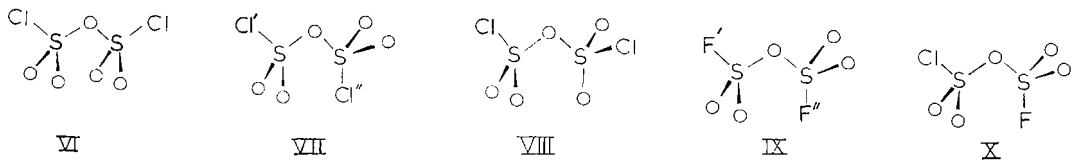

FIG. 1. Raman spectra.

DISULPHURYL HALIDES

If the disulphuryl halides have the acyclic structure I they should have 21 normal modes of vibration. Gerding and Linden (1) assumed that $S_2O_5Cl_2$ had the conformation VI and C_{2v} symmetry. In this case all 21 normal modes are active in the Raman effect

VI VII VIII IX X

and 7 of the Raman lines should be polarized. It seems more likely, however, that the molecule will have a staggered conformation, either VII, in which the halogen atoms are trans to each other (C_s symmetry), or VIII, in which the halogen atoms are in the "*gauche*" position and which has no symmetry elements. For VII, 13 of the 21 Raman lines should be polarized. We find at least nine of the Raman lines of $S_2O_5Cl_2$ to be polarized, which supports a staggered configuration such as VII or VIII rather than the cis conformation VI. Similarly $S_2O_5F_2$ and S_2O_5ClF would be expected to have the conformations IX and X respectively.

It is convenient to describe the normal modes of vibration in terms of the group frequencies that have been used previously for the simple sulphuryl compounds (5). This description can only be a rather crude approximation, but, as we shall show, it does enable a very reasonable assignment to be made for the majority of the Raman shifts of the polysulphuryl halides.

Seven vibrations may be ascribed to the SO_2X group: SO_2 symmetric and asymmetric stretches, an SO_2 bend, an SO_2 rock, an S—X stretch, an S—X wag, and a torsion. Each of these gives rise to two lines in the spectrum. These may be regarded as arising from coupling between the two halves of the molecule, and they may be conveniently described as in-phase and out-of-phase motions of the two SO_2X groups. In the staggered conformations VII and VIII the two SO_2X groups are not equivalent to each other, so slightly different frequencies for each group would be expected even if there were no coupling between them. In addition, the SO_2 rocking vibrations and the S—X wags can each occur parallel to, or perpendicular to, the plane containing the SOS group. Finally, three vibrations may be assigned to the SOS bridging group: a symmetric stretch, an asymmetric stretch, and a bend.

Frequencies can be readily assigned to the SO_2 stretches, the SO_2 bends, and the SF and SCl stretching modes, as shown in Tables I and II, by comparison with the frequencies observed for these vibrations in the simple sulphuryl halides (5). The SO_2 stretching frequencies are consistent with the linear relationship that has been shown to hold between the frequencies of the symmetric and asymmetric SO_2 stretches (6). The mean SO_2 symmetric and asymmetric frequencies in $S_2O_5F_2$ are both slightly lower than the corresponding frequencies in SO_2F_2, which is consistent with the replacement of fluorine by the slightly less electronegative SO_3F group. On the other hand, in $S_2O_5Cl_2$ these frequencies are both slightly higher than the corresponding frequencies in SO_2Cl_2; this is consistent with the replacement of chlorine by the more electronegative SO_3Cl group (6). In S_2O_5ClF, one of the SO_2 symmetric stretches, one of the asymmetric

stretches, and one of the SO_2 bends have frequencies close to those in $S_2O_5F_2$, while the other frequencies for these vibrations are close to those in $S_2O_5Cl_2$.

SOS Skeletal Vibrations

An important feature of the spectra of $S_2O_5F_2$, S_2O_5ClF, and $S_2O_5Cl_2$ is the occurrence of rather broad, moderately strong, polarized lines at 157, 154, and 147 cm^{-1}, respectively. No lines at such a low frequency are observed in the spectra of the simple sulphuryl halides and they can therefore only be reasonably attributed to an SOS skeletal vibration; since the SOS bending mode would be expected to have the lowest frequency of the three skeletal vibrations, they are assigned to this vibration. The similar frequencies of this vibration in the three molecules suggest that the corresponding SOS symmetric stretches might also have rather similar frequencies. An examination of the frequency of the symmetric stretch in a number of simple nonlinear triatomic molecules shows that this is generally approximately twice that of the bend (7). Thus the relatively strong polarized lines at 323, 313, and 298 cm^{-1}, are assigned as the SOS symmetric stretch in $S_2O_5F_2$, S_2O_5ClF, and $S_2O_5Cl_2$, respectively. The asymmetric SOS stretch is more difficult to assign. It is expected to have a considerably higher frequency than the symmetric stretch since it is largely the vibration of an oxygen atom between the two relatively heavy SO_2X groups. A weak depolarized line, which cannot be attributed to any of the group vibrations which are observed in the simple sulphuryl halides, occurs in all three spectra at approximately 800 cm^{-1}. Therefore the lines at 814, 802, and 760 cm^{-1} in the spectra of $S_2O_5F_2$, S_2O_5ClF, and $S_2O_5Cl_2$, respectively, are assigned to the asymmetric SOS stretch.

Our assignment for these skeletal vibrations is consistent with the assignment recently given by Kriegsmann (8) for the Si—O—Si vibrations in some siloxanes. For example, for hexamethyldisiloxane he gives the Si—O—Si bend at 180 cm^{-1}, the symmetric Si—O—Si stretch at 519 cm^{-1}, and the asymmetric stretch at 1055 cm^{-1}.

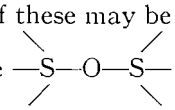
SO_2 Rocking Modes

The SO_2 rock has been assigned frequencies of 580 and 545 cm^{-1} in SO_2Cl_2 and SO_2F_2 respectively (5). It is apparent from a model that for structure VII there is considerable interaction between one SO_2 group and the halogen atom on the other sulphur atom. This would be expected to lead to a considerable difference in the frequencies of the two SO_2 parallel rocking modes. The out-of-phase mode, in which the two SO_2 groups move towards each other, would be expected to have the higher frequency. A rather strong, polarized line is observed at 733, 715, and 716 cm^{-1} in the spectra of $S_2O_5F_2$, S_2O_5ClF, and $S_2O_5Cl_2$, respectively, and this is assigned to the out-of-phase SO_2 parallel rock. In the spectrum of $S_2O_5Cl_2$ there are three lines between 716 cm^{-1} and the lines due to the S—Cl stretching modes at 427 and 412 cm^{-1}. These lines, at 621, 560, and 490 cm^{-1}, are tentatively assigned to the three remaining SO_2 rocking modes, possibly the perpendicular out-of-phase, the perpendicular in-phase, and the parallel in-phase, respectively. Similarly in $S_2O_5F_2$ and in S_2O_5ClF these vibrations are assigned frequencies of 630, 560, and 487 cm^{-1} and of 616, 535, and 458 cm^{-1} respectively.

SX Wagging Modes

The SCl wag has been assigned a frequency of 200 cm^{-1} in chlorosulphuric acid and 220 cm^{-1} in the chlorosulphate ion (9), and it is a rather similar vibration to the SCl_2 bend, which is at 218 cm^{-1} in SO_2Cl_2 and 194 cm^{-1} in $SOCl_2$. Therefore the pair of frequencies at 200 and 235 cm^{-1} in the spectrum of $S_2O_5Cl_2$ can be reasonably assigned as the SCl′ wags. The higher frequencies of 326 and 353 cm^{-1} are assigned to the SCl″ wags,

as the motions of the Cl″ atom are restricted by the proximity of the SO_2 group to which it is not directly bonded. This assignment receives some confirmation from the fact that lines at 204 and 231 cm^{-1}, which must also presumably be assigned as SCl wags, are found in the spectrum of S_2O_5ClF.



In SO_2FBr and CH_3SO_2F the SF wag has been assigned frequencies of 320 and 326 cm^{-1} respectively (5, 10); thus the two lines at 301 and 350 cm^{-1} in the spectrum of $S_2O_5F_2$ may be reasonably assigned as SF′ wagging modes and the pair of lines at 435 and 455 cm^{-1}, which are analogous to the pair at 326 and 353 cm^{-1} in the spectrum of $S_2O_5Cl_2$, are assigned to the SF″ wagging modes. The conformation of S_2O_5ClF is expected to be X in which the chlorine atom resembles the Cl′ in $S_2O_5Cl_2$ and the F atom resembles the F″ in $S_2O_5F_2$. Thus the S—Cl wags should correspond to the low-frequency pair in $S_2O_5Cl_2$ and the SF wags should correspond to the high-frequency pair in $S_2O_5F_2$. The latter may therefore be assigned to the pair of lines at 397 and 419 cm^{-1}.

Torsional Modes

In sulphuryl chloride and sulphuryl fluoride the torsional mode has a frequency of approximately 360 cm^{-1} (5). It seems reasonable, therefore, to attribute the as-yet-unassigned lines at 366 cm^{-1} for $S_2O_5F_2$, 370 cm^{-1} for $S_2O_5Cl_2$, and 360 cm^{-1} for S_2O_5ClF to one of the torsional modes in these molecules.

There is another moderately strong line, as yet unassigned, which occurs at a very similar frequency for each of the species, i.e. $S_2O_5F_2$, 290 cm^{-1}; S_2O_5ClF, 284 cm^{-1}; $S_2O_5Cl_2$, 273 cm^{-1}, in the spectrum of each of the disulphuryl halides. This line we also assign to a torsion on the grounds that the frequency is relatively independent of the nature of the halogen atoms involved, as is the case for the torsional modes in SO_2Cl_2 and SO_2F_2.

Although a number of the assignments made above are somewhat tentative, it is clear that others are quite certain, e.g. the SO_2 and S(Hal) stretching modes, and the SOS bend and symmetric stretch, which are characteristic of the disulphuryl group. The strong polarized line at approximately 700 cm^{-1}, which is very probably the SO_2 parallel rocking vibration, and the vibration in the region of 270 to 290 cm^{-1}, which we have assigned as a torsion, also appear to be diagnostic of the disulphuryl group. Use is made of these assignments in identifying disulphuryl compounds in other systems, e.g. disulphuric acid and fluoro- and chloro-disulphuric acids, as will be discussed in following papers.

A number of rather weak or ill-defined shoulders on various peaks in the spectra have not been assigned. It seems probable that at least some of these may be due to conformational isomers arising from hindered rotation around the  bonds.

Comparison with Previous Work

A number of our assignments for $S_2O_5Cl_2$ differ from those given previously by Gerding and Linden (1). For example, these authors assign the polarized line at 147 cm^{-1} as an S—Cl wag whereas we have assigned it as the SOS bend. The earlier assignment is not consistent with the fact that an obviously similar line is found at 157 cm^{-1} in the spectrum of $S_2O_5F_2$ since S—F wags are expected, and are generally found, to have appreciably higher frequencies than the corresponding S—Cl vibrations. Gerding and Linden assign to the SOS bend a frequency of 486 cm^{-1}: this is presumably the line we find at 490 cm^{-1}, which does not appear to be polarized and which we have assigned as an SO_2 rock. These authors assign to the SOS symmetric stretch the frequency of 716 cm^{-1}, which seems very

high in view of the total mass of the atoms attached to each sulphur atom, and which is, moreover, not consistent with our assignment for the SOS bend. For both of these reasons our assignment of the polarized line at 298 cm^{-1} to the SOS symmetric stretch seems more reasonable.

TRISULPHURYL HALIDES

The trisulphuryl halides presumably have one of several possible staggered conformations with C_s symmetry such as II. They have 33 normal modes of vibration, all of which should be active in the Raman effect. In terms of the description we have used for the disulphuryl halides there will be three symmetric and three asymmetric SO_2 stretching modes, three parallel and three perpendicular SO_2 rocking modes, three SO_2 bending

modes, and three torsions. In addition there will be two SX stretches and four SX wags for $S_2O_5X_2$ molecules, or an SX stretch, an SY stretch, two SX wags, and two SY wags for S_3O_8XY molecules, and nine skeletal, or SOSOS, vibrations.

By comparing the spectra of the trisulphuryl halides with each other and with the spectra of the disulphuryl halides it was possible to make reasonable assignments for all the observed lines, as shown in Table III. There are several features that distinguish the spectra of trisulphuryl compounds from those of disulphuryl compounds. An important characteristic of the spectra of the trisulphuryl halides is the occurrence of two high-frequency SO_2 rocks in the region of 700 cm^{-1}, as compared to the occurrence of a single line in this region in the spectra of disulphuryl compounds. A similar "splitting" of a frequency in this region of the spectra has been previously claimed as diagnostic of the change in structure in going from a diphosphate to a triphosphate (11). In the infrared spectra of diphosphates an absorption band near 730 cm^{-1} is replaced by two bands near 680 and 730 cm^{-1} in triphosphates. Another distinct difference between the spectra of disulphuryl and trisulphuryl compounds is that the symmetric stretch near 300 cm^{-1} in disulphuryl compounds is replaced by two skeletal stretches in the same region of the spectrum in trisulphuryl compounds and that the SOS asymmetric stretch, which occurs near 800 cm^{-1} in the spectrum of disulphuryl halides, is replaced by two skeletal stretches of similar frequencies in trisulphuryl compounds.

In addition to the four stretching modes the SOSOS skeleton also has five bending modes. These are thought to give rise to the low-frequency lines at 145, 165, 195, 226, and 241 cm^{-1} in the spectrum of $S_3O_8F_2$. Fewer than five lines that can be attributed to these bending modes are observed in the spectra of $S_3O_8Cl_2$ and S_3O_8ClF; this is probably because they coincide with the very strong lines due to the SCl wags which also occur in this region of the spectrum.

EXPERIMENTAL

Disulphuryl Fluoride

This compound was prepared by the reaction between antimony pentafluoride and liquid sulphur trioxide, according to the method of Hayek and Koller (12). The components were heated under gentle reflux for 2 hours and the resulting $S_2O_5F_2$ was distilled off. The product was washed with 100% sulphuric acid to remove sulphur trioxide and redistilled, b.p. 51–52°.

Disulphuryl Chloride

This compound was made by the reaction of 2 moles of sulphur trioxide and 1 mole of carbon tetrachloride at 40 to 45° for several hours. The mixture was then distilled and the fraction boiling above 140° collected. It was washed with 100% sulphuric acid and redistilled. The fraction boiling at 151 to 153° at atmospheric pressure was collected. Redetermination of the boiling point gave 152°.

Disulphuryl Chlorofluoride

This compound was prepared by fluorinating $S_2O_5Cl_2$ with AgF_2. Contrary to a previous report (13) this was found to be a satisfactory method. Disulphuryl chloride was added slowly from a dropping funnel to AgF_2 in a flask equipped with a reflux condenser. Two moles of $S_2O_5Cl_2$ were used per mole of AgF_2. After the vigorous reaction had subsided the product was distilled and the fraction boiling above 95° collected. Redistillation through an efficient column gave a fraction of b.p. 100–101°. The material had a fluorine n.m.r. spectrum consisting of a single peak. The % F was determined by comparing the

areas of the fluorine n.m.r. peaks in a mixture of the compound with $S_2O_5F_2$ (found, 9.5%; calculated for S_2O_5ClF, 9.57%).

Trisulphuryl Fluoride

This compound was prepared by the method of Lehmann and Kolditz (14) by bubbling BF_3 gas through liquid sulphur trioxide until a dense, solid white mass resulted. Sulphuric acid, previously cooled in ice, was then added to the mixture, and two liquid layers were obtained, a lower layer of sulphuric acid and an upper layer containing $S_3O_8F_2$. (It made little difference whether the decomposition was carried out with 70% sulphuric acid, as recommended by Lehmann, or with 100% acid.) The trisulphuryl fluoride layer was separated and washed several times with sulphuric acid to remove sulphur trioxide. It was then washed with water and dried over phosphoric oxide. The fraction of b.p. 29–31° at a pressure of 2 to 4 mm Hg was collected. Redetermination of the boiling point at atmospheric pressure gave a value of 121.5° (Lehmann and Kolditz reported a value of 120°), but slow decomposition takes place under these conditions. The material had a fluorine n.m.r. spectrum consisting of a single peak. The % F was determined by comparing the areas of the two fluorine n.m.r. peaks in a mixture of the compound with $S_2O_5F_2$ (found, 15.0%; calculated for $S_3O_8F_2$, 14.87%).

Trisulphuryl Chloride

This compound was prepared by the method of Lehmann and Ladwig (15) by heating 4 moles of sulphur trioxide and 1 mole of carbon tetrachloride under reflux for 4 hours during which time the temperature was raised to 85°:

$$CCl_4 + 3SO_3 = S_3O_8Cl_2 + COCl_2.$$

The mixture was distilled under reduced pressure and gave $S_3O_8Cl_2$, b.p. 55–65° at 2 to 3 mm Hg pressure, and a small amount of $S_2O_5Cl_2$. The product was washed with sulphuric acid and redistilled. The fraction b.p. 60–65° at 2.5 to 3 mm Hg was collected.

Trisulphuryl Chlorofluoride

This compound was prepared by fluorination of $S_3O_8Cl_2$ with AgF_2, using 2 moles of $S_3O_8Cl_2$ to 1 mole of AgF_2. In contrast to the violent reaction of $S_2O_5Cl_2$ with AgF_2 the reaction was slow, as indicated by the conversion of the fluoride to silver chloride, and it was necessary to heat the reaction mixture to 100° for 12 hours. The product was separated from silver chloride and distilled under reduced pressure. Redistillation at 15 to 20 mm of Hg pressure gave S_3O_8ClF, b.p. 40–45°. At atmospheric pressure the substance boils with decomposition at approximately 145°. The material had a fluorine n.m.r. spectrum consisting of a single peak. The % F was determined by comparing the areas of the two fluorine n.m.r. peaks in a mixture of the compound with $S_3O_8F_2$ (found, 6.8%; calculated for 6.82%).

Apparatus

The apparatus consisted of a Hilger E612 Raman spectrometer with glass prisms, used in conjunction with a water-cooled mercury-arc lamp. After the spiral of the lamp had been preheated with infrared lamps, and the mercury pool electrodes with nichrome heaters, the arc was easily struck by using the discharge from a "tesla" coil. The power supply was 250 volts d-c. and an operating current of 12 amp was used.

Liquid samples from 5 to 40 ml were contained in Pyrex glass cells mounted vertically and surrounded by a jacket containing saturated sodium nitrite solution as an optical filter. The filter solution was cooled and circulated through the jacket.

A prism was used to reflect the Raman radiation through 90° and a two-lens system ensured that most of the light scattered from the sample was collected. Spectra were recorded on Kodak 103*a*O, 2*a*O, or 3*a*O spectroscopic plates and the positions of the lines were measured by means of a Leeds and Northrup microphotometer, using an iron arc for calibration. Raman shifts could be measured to ± 3 cm^{-1} directly from the chart paper. When a qualitative comparison of the intensities of lines from different samples was required the spectra were compared on the same photographic plate. When fast plates (103*a*O or 2*a*O) were used, exposures of a few minutes gave excellent spectra with little background and tolerable broadening of the 4358 Å exciting line, so that Raman shifts as small as 150 cm^{-1} were easily resolved from the exciting line.

Polarization measurements were carried out using polaroid cylinders polarized parallel to and perpendicular to the plane of the incident light. A system of baffles was used to ensure that the incident light was perpendicular to the plane of the polaroid, which was situated inside the filter jacket surrounding the sample tube. Such polarization measurements are only qualitative.

CONCLUSIONS

Our Raman spectra provide strong support for the acyclic structures I and II for the di- and tri-sulphuryl halides.

The general consistency of the assignments of group vibrational frequencies for all the molecules we have discussed show that our approximate description of the normal modes is useful for at least some of the vibrations, and that characteristic spectral features due to —SO_2—, —S_2O_5—, and S_3O_8— groups can be recognized. Use is made of these conclusions in following papers to obtain structural information on some related compounds.

The close similarities between the spectra of S_3O_8ClF and those of $S_3O_8F_2$ and $S_3O_8Cl_2$, and also the expected relationship to the spectrum of S_2O_5ClF, appear to adequately establish its structure; additional evidence will be presented in a following paper.

ACKNOWLEDGMENTS

Mr. A. W. Richardson and Mr. R. C. Dixon are thanked for the preparation of disulphuryl chlorofluoride and for help with the measurement of its Raman spectrum.

Our thanks are also due to Professor H. L. Welsh of the Department of Physics, University of Toronto, for assistance with the construction of the "Toronto" mercury-arc lamp.

The National Research Council, the Defence Research Board, and the Allied Chemical Company are thanked for financial assistance.

THE RAMAN SPECTRA OF LIQUID SULPHUR TRIOXIDE AND SOLUTIONS OF SULPHUR TRIOXIDE IN INERT SOLVENTS[1]

R. J. GILLESPIE AND E. A. ROBINSON[2]

ABSTRACT

The Raman spectra of liquid sulphur trioxide and of sulphur trioxide dissolved in a number of "inert" solvents have been investigated. A detailed analysis of the spectrum of liquid sulphur trioxide supports the earlier suggestion of Gerding and Nijveld that the main polymeric species in liquid sulphur trioxide is the cyclic trimer. Frequencies are assigned for all the Raman active vibrations of the cyclic trimer. These assignments differ substantially from those given previously by Gerding and Nijveld.

The spectra of dilute solutions of sulphur trioxide in sulphur dioxide, sulphuryl chloride, carbon tetrachloride, tetrachlorethylene, and trichlorfluormethane (Freon 11) show that the sulphur trioxide is present mainly in the monomeric form at low concentrations while at higher concentrations a polymeric form, which is very probably the trimer, is also present.

The chemistry of sulphur trioxide is complex due to the ease with which it polymerizes. In the solid state, three principal forms are recognized: the γ or ice-like form, the β or low-melting asbestos form, and the α or high-melting asbestos form. Liquid sulphur trioxide is stable under anhydrous conditions but in the presence of a trace of water, high-molecular-weight polymers are formed and a solid phase separates. The structures of the solid forms and of liquid sulphur trioxide have been examined previously by Raman spectroscopy and by X-ray diffraction (1, p. 351; 2–9).

Only one strong line at 1069 cm^{-1} has been found in the Raman spectrum of sulphur trioxide gas at a pressure of 11 atm (2). Vapor pressure measurements have shown (5) that sulphur trioxide is monomeric in the gas phase, so this line can be assigned to the monomer. Other vibration frequencies for the monomer have been obtained from the spectra of mixtures of sulphur trioxide and sulphur dioxide at 60° (7, 8). The SO_3 molecule is planar (10) and therefore has four fundamental vibrations one of which is inactive in the Raman and one inactive in the infrared (Table I). The present measurements on

liquid sulphur trioxide and on solutions of sulphur trioxide dissolved in various solvents support these assignments. The Raman spectrum of sulphur trioxide monomer is therefore well established and the strong, sharp line at 1069 cm^{-1} is diagnostic of this species.

LIQUID SULPHUR TRIOXIDE

The most extensive previous study of the Raman spectrum of liquid sulphur trioxide is due to Gerding and Nijveld (9), who also summarized the earlier work of Bhavagantam

(3) and Venkateswaren (4). Gerding and Nijveld found 17 Raman lines, 5 of which were definitely polarized, in addition to those of the monomer. In the present work, 25 Raman shifts were observed, 5 of which were found to be definitely polarized and 1 possibly weakly polarized (Table II and Figs. 1 and 2). Liquid sulphur trioxide, obtained by

distillation from 65% oleum, and "Sulfan B" (stabilized liquid sulphur trioxide) gave exactly the same Raman lines although the relative intensity of the monomer lines was slightly greater in the "Sulfan B" than in the freshly distilled material.

Sulphur trioxide can presumably polymerize to give either rings or long chains, e.g. structures I, II, III, and IV. The dimer I, which involves a four-membered ring, and other possible higher polymers involving the same ring are rather improbable because of the high degree of strain that would be present, particularly at the oxygen atoms. The corresponding dimetaphosphate ion V, for example, is not known (11). In the trimer II, tetramer III, similar larger cyclic polymers, and long chains such as IV, the configuration around sulphur is tetrahedral and the structures are expected to be non-planar. Gerding and Nijveld (9) have calculated the number of fundamental vibrations of both the planar and the more probable non-planar forms of the dimer, trimer, and tetramer (Table III). Although their evidence was by no means conclusive these authors suggested that liquid sulphur trioxide consists mainly of a mixture of the cyclic trimer II and the monomer. When the temperature is raised extensive depolymerization apparently takes

place, as the Raman spectrum of the liquid at 100° (7) shows only those vibration frequencies which have been assigned to the monomer. Open chains IV, of varying lengths, may also be present in the liquid at room temperature but presumably only in small amounts as they require end groups Y, which would have to originate from impurities.

I II III

IV V

Further support for the suggestion that liquid sulphur trioxide consists of the trimer in equilibrium with the monomer can be obtained by a comparison of the spectrum of the liquid with the spectra of the solid α, β, and γ forms. The lines of the γ form all occur quite strongly in the spectrum of the liquid, and this form has been shown by X-ray crystallography to have a structure consisting of trimeric rings (III) in the "chair" form with C_{3v} symmetry. The solid β form on the other hand consists of SO_4 tetrahedra linked together to form long spiral chains (12, 13).

If it is assumed that the trimer is the main species present in the liquid and that the trimer is, at least mainly, in the chair form, frequencies can be assigned to this molecule as shown in Table IV. There are 20 normal vibrations of which the three A_2 vibrations are inactive in the Raman. Seven of the vibrations, 3 of which are polarized, can be assigned to the ring and the other 10, 4 of which should be polarized, involve the atoms of the SO_2 groups (9) (Fig. 3).

Sulphuryl Group Vibrations

Sulphuryl group vibrations would be expected to have frequencies close to those observed in simple molecules such as sulphuric acid and sulphuryl fluoride and would be expected therefore to occur at approximately the following frequencies: symmetric

*Coincident with the analogous vibration of the monomer.

stretches, 1100–1300 cm^{-1}; asymmetric stretches, 1300–1500 cm^{-1}; symmetric deformations, 500–600 cm^{-1}; rocking and torsional vibrations, 300–600 cm^{-1} (14).

The five lines observed at frequencies greater than 1200 cm^{-1} can only be reasonably assigned as SO_2 stretching vibrations. One of these, at 1390 cm^{-1}, is due to the monomer and the other four may be assigned in pairs as the in-phase symmetric and asymmetric stretch ν_1 and ν_5 at 1270 cm^{-1} and 1515 cm^{-1}, respectively, and the out-of-phase symmetric and asymmetric stretch ν_{11} and ν_{17} at 1231 and 1489 cm^{-1}, respectively (Table II). The in-phase vibrations are of species A_1 and should therefore be polarized. The vibration at 1270 cm^{-1} is definitely polarized and that at 1515 cm^{-1} was reported to be weakly so by Venkateswaren (4). The frequencies of both pairs of lines are consistent with the linear relationship that has been found between the SO_2 symmetric and asymmetric stretching frequencies (15, 16). The relatively high values of the SO_2 vibrational frequencies imply that the S—O bonds exterior to the ring have substantial double-bond character. This is consistent with the bond length of 1.4 Å and the large OSO angle of 122° (17). It appears reasonable to assign the in-phase vibrations at higher frequencies than the out-of-phase vibrations since in the former, but not in the latter, distortion of the ring occurs. Gerding and Nijveld (9) assumed that coupling between the SO_2 groups is very weak and that the in-phase and out-of-phase vibrations of the SO_2 group are degenerate. They assigned the line at 1270 cm^{-1} to the symmetric stretch and the line at 1489 cm^{-1} to the asymmetric stretch. These authors attributed the 1515 cm^{-1} frequency to the forbidden ring vibration ν_{10} and the line at 1230 cm^{-1} to the ring vibration ν_{15}.

In simple sulphuryl compounds such as sulphuric acid, the SO_2 bend is in the range 500–600 cm^{-1}, and in the sulphur trioxide monomer the similar vibration is at 532 cm^{-1}. In liquid sulphur trioxide there is a line at 534 cm^{-1} which is relatively strong and is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

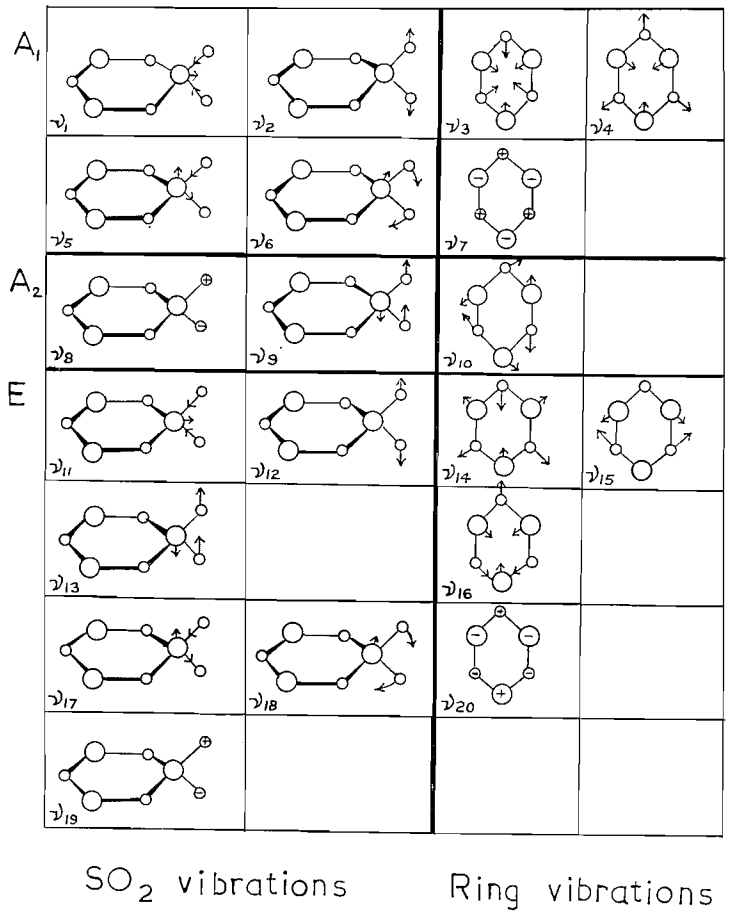

FIG. 3. Approximate atomic motions in the normal modes of S_3O_9. In the A_1 and A_2 vibrations the motions of the three SO_2 groups are in-phase while in the E vibrations the motions of the SO_2 groups are out-of-phase.

probably polarized and this we assign to the in-phase bend of the trimer ν_2, as well as to the monomer, since it is much stronger in the liquid than would be expected for the amount of monomer implied by the intensity of the 1070 cm^{-1} Raman shift in the liquid.

The out-of-phase SO_2 bend, ν_{12}, may be tentatively assigned as the rather weak line at 480 cm^{-1}. Gerding and Nijveld assigned the polarized line at 651 cm^{-1} to the SO_2 bend, but although a large number of compounds have been investigated the SO_2 bend has never been found at such a high frequency and it very rarely occurs at a frequency higher than 600 cm^{-1} (14).

Rocking and torsional modes of the sulphuryl group have frequencies in the range 300–600 cm^{-1} in simple sulphuryl compounds (14). In trimeric sulphur trioxide there is a total of six vibrations of these types: four rocking modes ν_6, ν_9, ν_{13}, and ν_{18} and two torsional modes ν_8 and ν_{19}, of which ν_8 and ν_9 are forbidden in the spectrum for a molecule with C_{3v} symmetry. Vibration ν_6 is of species A_1 and should therefore be polarized. There are four polarized lines as yet unassigned at 368, 657, 665, and 698 cm^{-1}. A model of the chair form of sulphur trioxide trimer shows that the axial oxygens of the SO_2 groups are close together and there will be considerable interaction between these oxygen atoms

in vibration ν_6; this would be expected to increase its frequency above the range of 500–600 cm^{-1} found for simple sulphuryl compounds, and therefore one of the lines at 657, 665, or 698 cm^{-1} must be assigned to this vibration. Tentatively we choose the 698 cm^{-1} line as it has been found in the di- and tri-sulphuryl halides, where similar interaction between an SO_2 group and a halogen occurs in an SO_2 rocking mode, that the frequency can be raised as high as 730 cm^{-1} (18). The frequency of ν_{18} would be expected to be fairly close to that of ν_6. There is no obvious depolarized line in this region of the spectrum and it must be assumed that it is of low intensity and is hidden under the broad, incompletely resolved band between 657 and 698 cm^{-1}. The remaining SO_2 rocking mode, ν_{13}, would be expected to be of lower frequency and the only possibility seems to be to assign it to the shoulder of the 534 cm^{-1} line at approximately 560 cm^{-1}. As ν_{13} would give a depolarized line, this provides an explanation for the difficulty of observing the expected polarization of the 534 cm^{-1} line. Torsional modes have frequencies in the range 270–370 cm^{-1} in mono-, di-, and tri-sulphuryl chlorides and fluorides (14, 18) and therefore it seems reasonable to assign the line observed at 322 cm^{-1} to ν_{19}. Gerding and Nijveld assigned the very weak line at 600 cm^{-1} to this vibration, but in none of the simple sulphuryl, or polysulphuryl, compounds has a torsional mode been found to have such a high frequency.

Ring Vibrations

The three vibrations ν_3, ν_4, and ν_7 should give rise to polarized lines; they must therefore be assigned to the three lines at 368, 657, and 665 cm^{-1}. The symmetric breathing vibration would be expected to have the lowest frequency and can therefore be assigned to the 368 cm^{-1} line. This vibration is, moreover, rather similar to the symmetric SOS skeletal stretch of the disulphuryl halides which have been assigned at 298, 313, and 323 cm^{-1} for $S_2O_5Cl_2$, S_2O_5ClF, and $S_2O_5F_2$ respectively.

The remaining unassigned lines, other than very weak lines and some very low frequency lines, are at 860, 840, 407, and 290 cm^{-1}. If we assume that the order of the frequencies of the ring vibrations of species E will be the same as for the analogous vibrations of the benzene ring, then these may be assigned as ν_{15}, ν_{16}, ν_{14}, and ν_{20} respectively. The analogous vibrations of the benzene molecule have frequencies of 1585, 1478, 606, and 404 cm^{-1} respectively (19). The assignment of these ring vibrations agrees with that given by Gerding and Nijveld except that they assigned ν_{15} to the 1231 cm^{-1} line which we have assigned as ν_{11}. Gerding and Nijveld did not assign the 860 cm^{-1} line and they assumed that ν_{11} had the same frequency as ν_1, i.e. 1270 cm^{-1}.

Weak Lines

Of the 25 lines observed with certainty in the Raman spectrum of liquid sulphur trioxide, 18 have been assigned to the chair form of the trimer together with the monomer, 16 to the trimer, and 3 to the monomer with one coincidence. This assignment accounts for all except seven very weak lines at 150, 243, 327, 600, 773, 1018, and 1162 cm^{-1} and some very indefinite shoulders on the side of the exciting line at frequencies of less than 150 cm^{-1}. Some of these lines could be overtone or combination bands but perhaps the most likely explanation for most of them is the presence of small amounts of the "boat" form of the trimer. Other possible species that may be present in small quantities are the tetramer and higher cyclic polymers, together with acyclic polymers, presumably of fairly high molecular weight. The line at 150 cm^{-1} could be due to acyclic polymers since the SOS skeletal bending mode has been assigned frequencies of approximately 150 cm^{-1} in the di- and tri-sulphuryl halides (18).

Conclusion

The Raman spectrum of liquid sulphur trioxide can be reasonably satisfactorily accounted for in terms of an equilibrium between the monomer and the "chair" form of the cyclic trimer. All except the very weakest lines in the spectrum can be accounted for in this way. The additional lines are probably due to small concentrations of the "boat" form of the trimer and higher cyclic or acyclic polymers.

SOLUTIONS OF SULPHUR TRIOXIDE

Solutions of sulphur trioxide in sulphur dioxide, sulphuryl chloride, disulphuryl chloride, disulphuryl fluoride, carbon tetrachloride, tetrachlorethylene, and trichlorfluormethane (Freon 11) were investigated. In most cases, the spectra show only lines due to sulphur trioxide and the solvent, although in a few cases there are additional lines which can be attributed to small amounts of polysulphuryl halides. An estimate of the proportions of monomeric and trimeric sulphur trioxide can be made from the relative intensities of the line at approximately 1069 cm^{-1}, characteristic of the monomer, and the strongest line of the trimer at 1270 cm^{-1}.

Solutions in Sulphur Dioxide

The spectra of three solutions of composition approximately 10, 20, and 40% sulphur trioxide by weight were investigated at approximately −10°. All the spectra (Fig. 3 and Table V) clearly show that sulphur trioxide in sulphur dioxide is present mainly

as the monomer. Only in the 40% solution did the 1270 cm^{-1} line characteristic of S_3O_9 appear. The spectra of the solutions are just a superposition of the components and no new substances appear to be formed. Previous workers (1, p. 358) have claimed the occurrence of an unstable volatile liquid with the composition $2SO_3.SO_2$ but no evidence for such a compound is given by our Raman spectra.

Solutions in Sulphuryl Halides

The Raman spectra of these solutions show that there is no reaction between sulphur trioxide and sulphuryl chloride (Fig. 2) at room temperature, although higher polysulphuryl halides could, in principle, have been formed, e.g. $S_2O_5Cl_2 + SO_3 = S_3O_8Cl_2$. For solutions of sulphur trioxide in disulphuryl chloride and in disulphuryl fluoride similar results were obtained. In the case of sulphuryl chloride this conclusion has also been reached by other workers (20, 21), who refluxed sulphur trioxide with various proportions of sulphuryl chloride for periods up to 24 hours and obtained only the pure components on distillation. The compound $2SO_2Cl_2.SO_3$ has been claimed at low temperatures but is reported as being unstable above the melting point (22).

The Raman spectra show that at low concentrations, sulphur trioxide is almost entirely in the form of the monomer while solutions containing more sulphur trioxide than 0.2 mole fraction contain increasing concentrations of the trimer (Table VI).

†Coincidence with SO_3 line.

carbon tetrachloride solutions the observed lines can be attributed to the solvent or to SO_3 monomer or trimer.

Sulphur trioxide is known to react with carbon tetrachloride under reflux (22) to give polysulphuryl halides according to the equation

$$CCl_4 + nSO_3 = SO_2(SO_3)_{n-1}Cl_2 + COCl_2.$$

The Raman spectra show that this reaction appears to proceed slowly even at room temperature, as additional lines, which can reasonably be attributed to $S_2O_5Cl_2$, appear

in the spectra of the carbon tetrachloride solutions. The amounts of polysulphuryl halides formed in a few hours are however quite small and carbon tetrachloride is for many purposes a useful solvent for sulphur trioxide.

In all the solutions studied, monomer and trimer are in equilibrium. At low concentrations the equilibrium favors the monomer but the actual position of the equilibrium for a given concentration of sulphur trioxide depends on the solvent. Thus in solutions of a given concentration in the following solvents, the monomer–trimer equilibrium shifts progressively in favor of the trimer in the order sulphur dioxide, sulphuryl chloride, halogenated hydrocarbons.

EXPERIMENTAL

The Raman spectrometer has been described previously (18). When necessary, for example for sulphur dioxide solutions, an additional jacket was provided between the sample tube and the filter jacket through which cold alcohol could be passed to cool the sample.

Sulphur trioxide was obtained by distillation from 65% oleum from which sulphur dioxide had been removed by oxidation with potassium persulphate. "Sulfan B" was obtained from the Allied Chemical Company. The solvents used were dried over phosphoric oxide and purified by distillation except for sulphur dioxide, which was obtained from a cylinder and purified by trap-to-trap distillation. Sulphuryl chloride was stored in the absence of light. The preparation of disulphuryl chloride and disulphuryl fluoride has been described previously (18, 23).

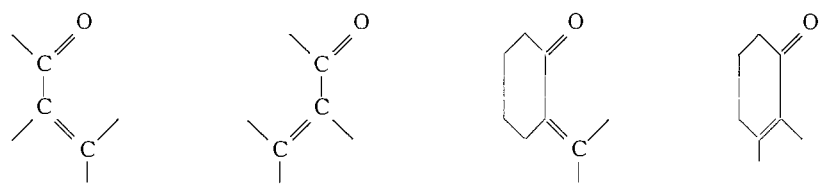
SOME STEREOCHEMICAL STUDIES ON α,β-UNSATURATED KETONES USING RAMAN SPECTROPHOTOMETRY[1]

K. NOACK[2] AND R. NORMAN JONES



ABSTRACT

The Raman spectra of 12 α,β-unsaturated open-chain and cyclic ketones have been measured in the region of the C=O and C=C stretching vibrations, and the band positions and intensities have been compared with the corresponding bands in the infrared spectra. If due allowance is made for solvent effects, the infrared and Raman bands are observed at the same positions, but the relative intensities of the C=O and C=C bands are different; in particular, the Raman C=O stretching bands of the ketones in the *s*-trans configuration are from 5 to 10 times more intense than the Raman bands for the *s*-cis isomers. The cyclic *s*-trans ketones with a hydrogen atom on the α-carbon atom exhibit a solvent-sensitive doubling of the carbonyl maximum similar to that noted previously for certain α,β-unsaturated lactones, unsaturated acid anhydrides, and Δ^2-cyclopentenone derivatives. These doublet carbonyl maxima are observed also in the infrared spectra. The C=C frequency is not similarly perturbed and the effect is distinct from the doubling of both the C=O and the C=C bands exhibited by some open-chain α,β-unsaturated ketones that exist in the liquid phase as equilibrium mixtures of *s*-cis and *s*-trans isomers.

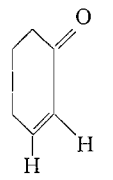
INTRODUCTION

The use of Raman spectroscopy by organic chemists for the characterization of natural products has been limited by the intrinsic weakness of the Raman effect and the need to employ large samples of material. Recent instrumental developments make it practical to record Raman spectra photoelectrically, using liquid samples excited in capillary tubes. Complete spectra can be measured over the range 150–4000 cm^{-1} using 25- to 200-mg samples, and the more intense bands, such as those associated with C=C and C≡C stretching modes, can be recorded with 10-mg samples in carbon disulphide solution.

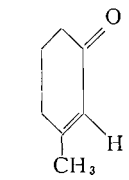
In the absence of steric hindrance, a system of two conjugated double bonds will favor a planar conformation, for which *s*-cis (I) and *s*-trans (II) structures are possible. In cyclic ketones (III, IV) these configurations are fixed. In open-chain structures one

I II III IV

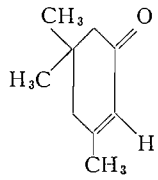
of the conformations will commonly be preferred to the virtual exclusion of the other; occasions do arise, however, where the energy differences are small and both forms are present in significant concentration in the liquid or vapor phase.



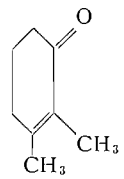
Mecke and Noack (1, 2) have shown that, for α,β-unsaturated ketones, such conformational isomers can be distinguished by the positions and intensities of the C=O and C=C stretching bands in the infrared spectrum, and additional examples have been cited by Erskine and Waight (3) and by Timmons (4). The Raman spectra of some of



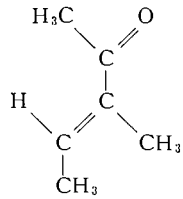
[1]*Manuscript received June 21, 1961.*
Contribution from the Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada. Issued as N.R.C. No. 6513.
[2]*National Research Council of Canada Postdoctorate Fellow.*



these compounds have now been measured. The Raman frequencies of the C=O and C=C stretching bands agree with the infrared frequencies if allowances are made for solvent effects; these effects are particularly significant for the C=O stretching band of the *s*-trans isomers. The relative intensities of the C=O and the C=C Raman and infrared bands differ, but the Raman spectra confirm the conformational assignments proposed by Noack and Mecke for the open-chain compounds on the basis of infrared measurements. Some of the cyclic *s*-trans ketones exhibit solvent-sensitive doublet carbonyl peaks in the Raman spectra, and on reinvestigation the same effects are noted in the infrared spectra. Doublet C=O and C=C bands also occur in some open-chain ketones, but, in these cases, conformational equilibria are involved. Ketones exhibiting conformational equilibria of this type are dealt with in a separate paper in which effects of temperature change are also examined (5).



EXPERIMENTAL



The ketones employed in this investigation (V–XVI) were obtained from a collection prepared by Mecke and Noack for the infrared studies, and their chemical characterization

has already been described (2). The Raman spectra were measured on a Cary Model 81 spectrophotometer using a micro sample tube of 2-mm external diameter and 200-microliter volume. After quantitative dilution with carbon tetrachloride, as described below, the freshly distilled ketone was introduced into the Raman tube by means of a narrow, flexible metal capillary tube attached to a hypodermic syringe mounted vertically on a stand. Ketone mole ratios of approximately 0.4 were normally employed, and 120–150 mg of the ketone was needed to fill the cell. The spectra were measured at a spectral slit width of 5 cm^{-1} and the estimated uncertainty in the positions of the band maxima is ± 2 cm^{-1}. A scanning rate of 15 cm^{-1} per minute was normally used.

The Toronto-type arc lamp was constructed of Corning 1720 glass, and the Hg 4358 Å exciting line was isolated with aqueous potassium nitrite and aqueous Rhodamine GDN extra filter solutions in separate annular jackets with a common dividing wall. The potassium nitrite solution in the outer jacket was circulated through a cooling system; the Rhodamine solution was not circulated and was stabilized by the addition of hydrochloric acid. A cylindrical Polaroid polarizer with the direction of polarization perpendicular to the axis of the Raman tube was inserted between the filter system and the Raman tube to eliminate effects of oblique illumination.

Intensity Measurements

The peak heights of the Raman bands were measured relative to the 459 cm^{-1} band of carbon tetrachloride, which was taken as 100 units. The accurate evaluation of this intensity involves several instrumental and theoretical factors (6–9). The unit employed here, and in other contemporary papers from this laboratory, does not take into account all the variables that may affect the accuracy of the measurements; it has been devised to meet immediate needs, and to cope with technical problems associated with the use of the capillary sample tube.

The determination of the Raman band intensities involves comparison with an internal or external standard (8). If an external standard is used the emission intensity of the measured Raman band is compared with the standard band as observed with a matched sample tube under the same experimental conditions. This assumes that the illumination of the Raman tube, and its alignment with respect to the spectrometer optics, are reproducible. These conditions are usually not critical, but the external-standard method also suffers from the serious defect that the sample spectrum and the standard spectrum are usually obtained from media of different refractive index. The refractive index influences the intrinsic intensity of the Raman radiation through a solvent field effect and it also determines the fraction of the total Raman radiation that enters the spectrometer. Using wide tubes, where wall effects can be neglected, Woodward and George (9) have shown that the instrumental effect is inversely proportional to the square of the refractive index of the medium. Rea (7) has analyzed the problem for narrower tubes where wall effects become significant, though his initial treatment was not complete, and the application of an additional empirical correction was later required (10). When the Raman radiation is generated within a capillary tube, the energy entering the spectrometer from a Pyrex capillary is found to increase by a factor of five with increase in the refractive index from 1.35 to 1.65. It would appear that under these conditions, the wall effect becomes dominant, the radiation probably suffering multiple reflection before reaching the entrance slit; a considerable proportion is accordingly lost through the walls of the tube en route.

The difficulties associated with the intensity measurement can be largely circumvented

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

by the addition of the standard calibrating liquid to the sample in known proportion. The standard band is then measured in a medium of the same refractive index as the sample band. The internal-standard technique can only be used where the overlap of the two spectra is not significant, but using the 459 cm^{-1} carbon tetrachloride band as standard, this problem caused no difficulty for the ketones considered in this paper. The use of the internal standard also avoids the need to determine the density of the liquid, which is otherwise required if the intensities are to be expressed on a molar basis. The intrinsic intensity of the standard may be modified by intermolecular interactions but this can be checked to some extent by use of a series of measurements at different concentrations, or by cross checking with different secondary standard bands; significant variations may be involved here (11) but more extensive experimental and theoretical study is needed if these effects are to be properly interpreted. In our investigations the concentrations were so adjusted that the peak height of the 459 cm^{-1} carbon tetrachloride band was comparable with the C=O and C=C bands, and, for this, mole fractions of about 0.4 ketone and 0.6 carbon tetrachloride were required.

On the basis of these considerations, the Raman intensity coefficient was expressed as

$$[1] \qquad k_A^{\nu} = \frac{I_A^{\nu}}{I_{CCl_4}^{459}} \cdot \frac{N_{CCl_4}}{N_A} \cdot 100,$$

where k_A^{ν} = the Raman intensity coefficient at ν cm^{-1} displacement from the exciting line for substance A;

I_A^{ν} = the emission intensity at ν cm^{-1} displacement from the exciting line, measured in arbitrary units;

$I_{CCl_4}^{459}$ = the emission intensity at the 459 cm^{-1} peak of carbon tetrachloride measured in the same units as I_A^{ν};

N_A = the mole fraction of A;

N_{CCl_4} = the mole fraction of carbon tetrachloride.

No correction was applied for the change in the spectral sensitivity of the spectrophotometer since this did not vary by more than 3% over the measured wavenumber range.

The insertion of the cyclindrical polarizer influences the intensity considerably, as the 459 cm^{-1} carbon tetrachloride band is highly polarized, and the convergence errors are large if the measured band has a different depolarization ratio from the standard band. Comparisons made with and without the Polaroid filter (oriented to transmit radiation with the electric vector perpendicular to the tube axis) consistently gave values for these ketones that were 30% lower when the polarizer was in place. The Raman C=O bands of compounds VII and XIV have also been measured by Michel and Duyckaerts (8) with no polarizer in their spectrometer. Their measurements were some 30% greater than the values we obtain when the polarizer is used. The constancy of this systematic intensity difference is attributed to the fact that all the C=O bands in these ketones have similar depolarization ratios close to 0.4.

The measurement of band height against a sloping background invariably introduces uncertainty in the location of the baseline. Where feasible, the line was drawn tangentially to the curve, usually at about three half band widths on either side of the band center. In some cases the location of the line was rather arbitrary; this accounts for the major uncertainty in the measured intensity coefficients and largely invalidates any attempts to apply corrections for smaller physical variables affecting the accuracy of the measurements.

Band Area Measurements

The area beneath the Raman band was not measured directly, but a quantity approximately proportional to it was calculated. This quantity, which we call the *band area coefficient* (L), is defined as

$$[2] \qquad L_A^{\nu_{max}} = k_A^{\nu_{max}} \cdot \frac{\Delta\nu_{\frac{1}{2}}^{A}}{\Delta\nu_{\frac{1}{2}}^{CCl_4}},$$

where $L_A^{\nu_{max}}$ = the band area coefficient for the band of substance A;
$\Delta\nu_{\frac{1}{2}}^{A}$ = the band width at half maximal intensity, measured on the spectral chart in arbitrary units;
$\Delta\nu_{\frac{1}{2}}^{CCl_4}$ = the band width at half maximal intensity of the 459 cm^{-1} band of carbon tetrachloride measured under the same conditions as $\Delta\nu_{\frac{1}{2}}^{A}$.

The band area coefficient is, therefore, equal to 100 times the ratio of the sample band area to that of the (internal) standard band. The ratio L can be derived directly from the measured spectrum without resort to arithmetical integration, and it is adequate for the comparison of gross differences between Raman bands of varying types. More refined measurements are not justified in view of the large errors associated with contemporary microtechniques.

RESULTS

The positions and intensities of the C=O and C=C stretching bands in the Raman and infrared spectra of ketones V–XVI are listed in Table I.

Band Positions

Though the two fundamental absorption bands of α,β-unsaturated ketones in the 1750–1600 cm^{-1} range are coupled, it is customary (and convenient) to identify the band at higher wavenumber with a localized "C=O stretching" vibration and the band at lower wavenumber with a "C=C stretching" mode.*

Comparison of ν_{max} for the infrared and Raman bands listed in Table I indicates that the bands fall into the same frequency ranges in both the infrared and the Raman spectra. The *s*-cis and *s*-trans structures can therefore be distinguished from the Raman band positions as well as from the infrared, and the conformational assignments for the open-chain ketones made by Mecke and Noack from the infrared data are confirmed by the Raman measurements. For both the cyclic and open-chain *s*-cis compounds the Raman and infrared C=O and C=C band frequencies agree within the precision of the experimental data (±3 cm^{-1}) and this holds also for the C=C bands of the cyclic and open-chain *s*-trans ketones. For the cyclic and open-chain *s*-trans ketones, however, the Raman C=O frequencies given in Table I are uniformly 4–8 cm^{-1} lower than the corresponding infrared values. Whereas the Raman spectra were measured at high concentrations in carbon tetrachloride, the infrared spectra were initially obtained at much lower concentrations in tetrachloroethylene. When the infrared spectra were remeasured on capillary films in carbon tetrachloride at the same concentrations as were used for the Raman spectra, the band positions listed in Table II were obtained. This table demonstrates clearly that the significant differences between the infrared and Raman C=O peak positions are due to solvent effects. The infrared band positions in dilute solutions of

**The tacit assumption that the "C=O" band invariably lies above the "C=C" band may not be justified, and Cook has recently suggested that the sequence may be inverted for 2,6-dimethyl-4-pyrone (12).*

§The infrared band intensities are recorded in the "practical unit" defined by the Commission on Molecular Structure and Spectroscopy of IUPAC (19). This unit is given by $E_{\nu_1}^{\nu_2} = \int_{\nu_1}^{\nu_2} \epsilon_\nu d\nu$, where $\epsilon_\nu = 1/bc \log_{10} (I_0/I)_\nu$ in which b is the cell length in cm, c is the concentration in moles per liter, and $\log_{10}(I_0/I)$ is the absorbance.

Mecke and Noack employed an intensity unit based on a wavelength abscissa, and their values ($A_{(M)}$) are given in parentheses in the infrared band intensity columns of the table. The IUPAC "practical unit" E and the Mecke unit $A_{(M)}$ are related, in close approximation, by the equation $E = 0.434 A_{(M)} \nu_{max}^2 .10^{-2}$.

carbon tetrachloride agree with the measurements on dilute solutions in tetrachloroethylene and the considerable displacements between the infrared and Raman C=O frequencies of the *s*-trans ketones are due more to the concentration difference than to the specific nature of the solvent.

The open-chain *s*-trans ketones IX and X, and 2,3-dimethyl-Δ^2-cyclohexen-1-one (VIII) give Raman C=O bands of normal contour. The C=O bands of the cyclic *s*-trans compounds V–VII, however, exhibit asymmetry of varying degree (Figs. 1–3). This is most apparent for the Raman spectrum of cyclohexenone (Fig. 1), which exhibits a main peak at 1686 cm^{-1} and a shoulder at 1677 cm^{-1} in carbon tetrachloride solution. In chloroform, the relative intensities of these peaks are reversed. On re-examination, the

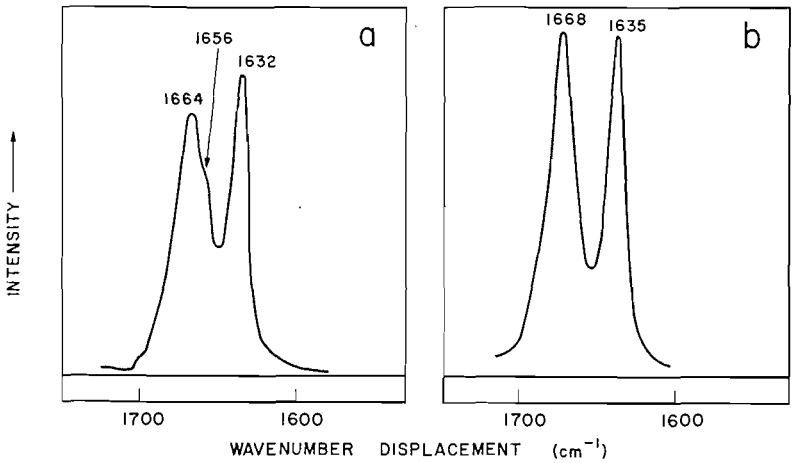

FIG. 3. Raman spectrum of 3,5,5-trimethyl-Δ^2-cyclohexen-1-one (VII): *a*, in chloroform; *b*, in carbon tetrachloride.

infrared spectra of the cyclic *s*-trans ketones demonstrated similar C=O band asymmetry in an enhanced degree (Figs. 4–6). These infrared spectra were measured on a Perkin–Elmer Model 112 spectrometer at a spectral slit width of 1.5 cm^{-1} and were subsequently checked on a nitrogen-purged Model 221 Perkin–Elmer spectrometer at a spectral slit width of 1 cm^{-1}. The purity of the ketones used for these measurements was established by vapor phase chromatography, and, for all four samples, over 99% of the material passed through the column in a single symmetrical peak. In both the Raman and infrared spectra of cyclohexenone the band component of higher frequency augments in intensity in carbon tetrachloride and the lower frequency band intensifies in chloroform solution. (Figs. 1 and 4). This resembles the behavior noted by Yates and collaborators (13, 14) for derivatives of Δ^2-cyclopentenone and by Jones and collaborators (15) for α,β-unsaturated lactones and cyclic unsaturated acid anhydrides. The asymmetry of VI follows

the same pattern as V, though the high-frequency component is weaker. The spectra of VII differ in that the asymmetry is more pronounced in chloroform than in carbon tetrachloride.

The failure to observe any C=O band asymmetry for VIII supports the view that the partial structure XVII, with a free α-hydrogen atom, is required for this effect, and it is commonly presumed that this solvent-sensitive C=O band splitting is caused by a Fermi resonance with the overtone of the α-C—H out-of-plane deformation vibration.

Band Intensities

The relationships between band intensity and steric configuration are different for the Raman and the infrared spectra. The intensities of the infrared C=O bands of all the conjugated ketones lie in a comparatively narrow range. The *s*-cis compounds have weaker infrared C=O bands than the *s*-trans compounds, but no significant differences are noted between cyclic *s*-cis and open-chain *s*-cis compounds. The cyclic *s*-trans ketones have more intense infrared C=O bands than the open-chain *s*-trans ketones but this may be associated with the doublet character of the bands of the cyclic compounds.

The intensities of the infrared C=C stretching bands are more variable and the bands for the *s*-cis compounds are significantly stronger than for the *s*-trans. The extreme weakness of the infrared C=C band in Δ^2-cyclohexenone is particularly remarkable.

In the Raman spectra the band area coefficients of the C=C bands vary from 51 units for V to 290 units for IX but the variations do not fall into any distinguishable classes in terms of conformation or cyclization. The Raman C=O band intensities, on the contrary, show marked stereochemical specificity, and the *s*-trans C=O bands (135–263 units) are from 5 to 10 times more intense than the *s*-cis bands (17.5–46 units). In terms of peak heights, the relationships are similar, though the band area measurements for the doublet carbonyl bands of V–VII group more closely with VIII–X than do the peak height measurements.

These Raman band intensities can be compared with data in the literature for C=O and C=C groups in non-conjugated systems. An extensive study of the Raman C=C stretching bands of mono-olefins by Rea (10) has shown that alkyl substitution has little effect and the integrated intensities fall in the range 30–50 when converted to units that are comparable with ours.* Conjugation with the ketone therefore raises the Raman C=C stretching band intensity by a factor of 5 to 10. According to Michel and Duyckaerts (8) the peak heights of the Raman C=O bands for saturated ketones fall in the range 10–13 in our units, reducing to approximately 8–10 units when corrected for polarization convergence effects. In the *s*-cis configuration, conjugation with the ethylene bond enhances the C=O band intensity slightly, and in the *s*-trans configuration it is raised by a factor of about 10. Mecke and Noack (2) have pointed out previously that for the infrared spectra the C=O intensity for *s*-cis ketones may actually be weaker than for comparable non-conjugated systems.

DISCUSSION

The four distinguishing features of the *s*-cis configuration are (*a*) greater frequency separation between the C=O and the C=C stretching bands in comparison with the *s*-trans; (*b*) the greatly diminished intensity of the Raman C=O band; (*c*) the lesser, but still significant diminution in the infrared C=O band intensity; (*d*) the increase in the infrared C=C band intensity. It is difficult to account for all these effects by any simple and self-consistent mechanism.

In both the *s*-cis and the *s*-trans configurations, the C=O and the C=C band frequencies are displaced downwards from their positions in non-conjugated systems carrying comparable substituents. Assuming, for the time being, that the two frequencies are not vibrationally coupled, it follows that both the C=O and the C=C bonds have reduced force constants in the conjugated system, presumably because of the mesomeric effect. This in turn must lead to charge displacements on the terminal atoms, and the polarized *s*-cis structure XIX will then be further stabilized by a direct field interaction between the ends of the conjugated system. This could lead to an additional lowering of both the C=O and the C=C frequencies in comparison with the *s*-trans frequencies. If it is assumed that change in bond polarization with bond length increases in systems where the bond is more highly polarized in the equilibrium position, both the *s*-cis C=O and the *s*-cis C=C infrared bands should be intensified by this field effect. This is consistent with the observed changes for the C=C band, but not for the C=O band.

XIX XX XXI

The closer proximity of the terminal charges for XIX in comparison with XX may also induce mutual perturbations of the C=O and C=C bond polarizations of a more direct type, and these are considered by Erskine and Waight (3) to have the major effect

**Rea's intensities are based on the use of an external standard and a wider Raman tube. One of his intensity units is approximately equivalent to one hundred of ours (10).*

in influencing the C=O and C=C band intensities. Such direct field effects can be quite large, as is well recognized in systems such as XXI where the C—Br dipole induces an upward displacement of 20 cm^{-1} in the C=O frequency, and also diminishes the intensity (17). Regarded from this point of view, the dipole interaction in XIX should produce an opposite effect on the C=O band than does the C—Br group, since the direction of the dipole is reversed. On this basis we would also expect both the C=O and the C=C infrared bands to be intensified and displaced to lower frequency in the *s*-cis configuration. It is therefore difficult in these terms to account for the diminished intensity and upward frequency displacement of the *s*-cis C=O infrared band.

The Raman band intensities, being dependent on the change in the bond polarizability during the vibration, might be expected to vary with the electron density in the bond and should, therefore, be increased by factors that increase the degree of double-bond character. The very low intensity of the Raman C=O band in the *s*-cis configuration would then indicate a high charge displacement at the equilibrium bond length. However, Michel and Duyckaerts (8) have shown that in general the Raman and infrared C=O band intensities vary in the same sense, and not inversely, and more extensive investigations are obviously needed to clarify the relationships between bond polarization and bond polarizability in conjugated systems.

These difficulties may in part be due to the fact that the C=O and C=C stretching bands should not be regarded as localized vibrations. Since the separation between the two bands is less in the *s*-trans than the *s*-cis form, the vibrational coupling will be greater for *s*-trans isomers. As the unperturbed C=O and C=C frequencies approach the same value, the character of the vibrations will change from localized double-bond stretching modes to in-phase and out-of-phase coupled modes extending through the conjugated system. In the limit the bands will become analogues of the doublet C=O band systems of acid anhydrides and peroxides. The over-all pseudosymmetry of the conjugated system may then become an important factor in determining the relative intensity of the two bands, as Bellamy and collaborators have suggested for the anhydride and peroxide systems (18). There may be a minimum separation distance between the observed "C=O" and "C=C" frequencies below which the coupling becomes strong enough to force the frequencies apart again. It is not suggested that these are the *dominant* factors in the conjugated systems considered here, and the fact that the band at higher frequency is much more sensitive to solvent effects (particularly in the trans configuration) is a good indication that this band is predominantly carbonylic while the band at lower frequency is predominantly ethylenic (Table II). Nevertheless, considerations of this kind must be kept in mind when one is dealing with vibrational modes of conjugated systems. Analogies with substitutional effects in non-conjugated carbonylic and olefinic systems, must be made with caution, particularly when attempts are made to consider the substitution effects quantitatively, as, for example, by correlating them with Taft or Hammett sigma parameters.

ACKNOWLEDGMENTS

We wish to thank the Cyanamid European Research Institute for providing facilities for vapor phase chromatography and for the use of the Model 221 spectrophotometer. We are also grateful to Mrs. M. A. MacKenzie and Dr. J. W. Elliott for measuring four Raman and infrared spectra at Ottawa.

CONFORMATIONAL EQUILIBRIA IN DIETHYL KETONE[1]

R. NORMAN JONES AND K. NOACK[2]

ABSTRACT

A variable-thickness, variable-temperature absorption cell, modified from the design of Holden, Taylor, and Johnston, has been used to compare the infrared spectrum of diethyl ketone at −75° and +25° C. The Raman spectrum of diethyl ketone has also been measured at +6°, +25°, and +85° C, and the proton magnetic resonance spectrum over the range −61° to 104° C.

Both the infrared and Raman spectra exhibit pronounced temperature sensitivity, which is attributed to the presence of at least two conformational isomers in the liquid phase. Possible structures for these isomers are considered. Small but significant chemical shifts are noted in the proton magnetic resonance spectrum.

The vibrational spectra of large molecules are particularly difficult to interpret when the substance exists as a mixture of conformational isomers in the liquid state; to analyze such spectra it is first necessary to recognize the presence of the equilibria and to sort out the bands belonging to the different forms. This may sometimes be done by comparison with the spectrum of the crystalline solid, since only one conformational form will normally be present in the crystal lattice. The solid phase spectra, however, may be perturbed by intermolecular force fields and hydrogen bonding. In the liquid phase the equilibrium between the conformational isomers is usually temperature sensitive and the spectra of the isomers can be differentiated by noting the relative changes in the band intensities with temperature.

Cells suitable for such measurements tend to become complicated, particularly if it is desired to control the temperature with some accuracy, and to make measurements at temperatures that depart appreciably from those obtainable with simple cryostatic systems. In this paper we describe a cell suitable for the measurement of infrared spectra over a wide range of temperature, and discuss its use to investigate conformational equilibria in diethyl ketone.

EXPERIMENTAL

The variable-temperature infrared absorption cell is illustrated in Figs. 1 and 2. It is based on the excellent design of Holden, Taylor, and Johnston (1), but is intended only for use above −190°; this permits a simplification of the cell proper and of the gear mechanism and controls for varying the sample thickness without breaking the vacuum. The apparatus is portable and the cell fits conveniently into the 14-cm working space of the Perkin–Elmer Model 21 and Model 112 spectrometers.

The cell proper consists of a pair of silver chloride windows (2.5-cm diameter) sealed by Teflon washers and separated by one convolution of a soft bronze bellows, which is soldered to fixed and moveable units of the cell body. Motion is provided by means of a worm drive attached through a universal joint to the control shaft, which passes out through the top of the vacuum chamber through a vacuum seal. The maximum cell window separation is about 1 mm. The cell assembly is held vacuum tight by a steel spring and three set screws, as shown in the exploded section of the diagram in Fig. 2. A copper–constantan thermocouple is inserted in a hole in one of the silver chloride

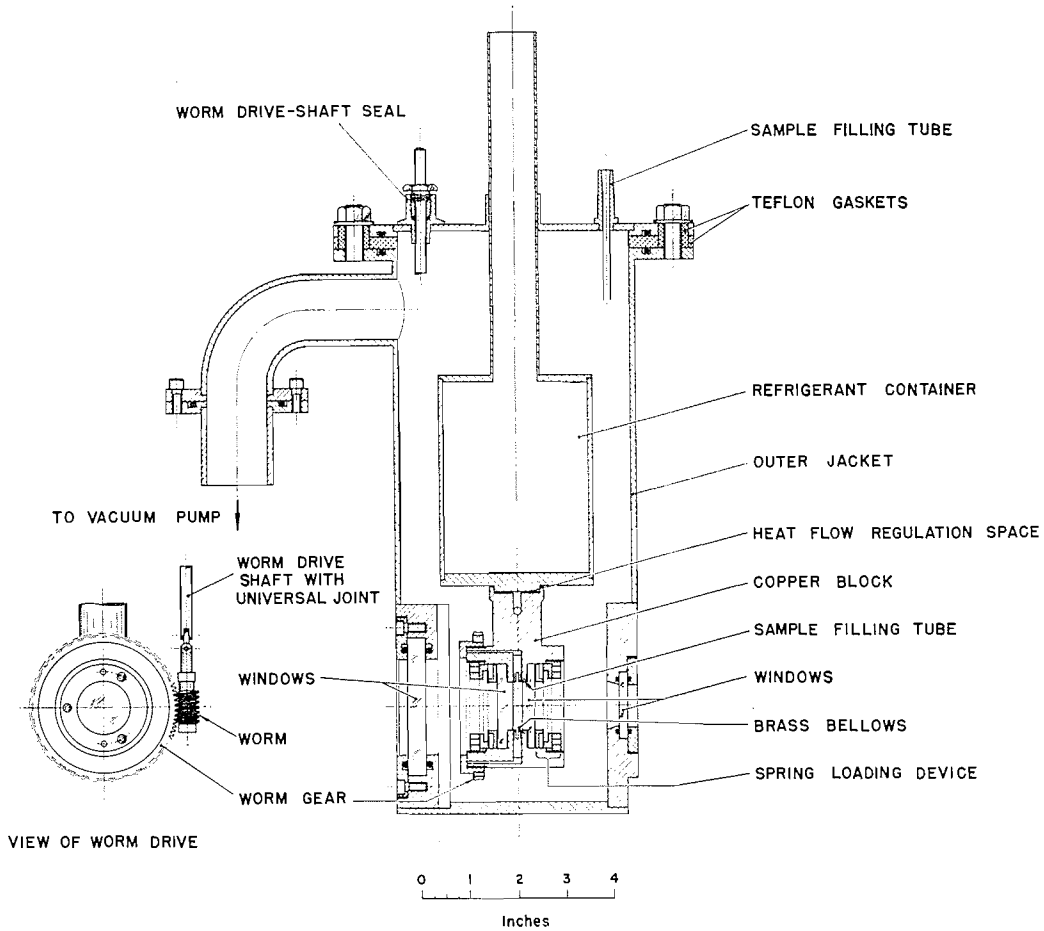

FIG. 1. Variable-temperature infrared cell. General diagram.

windows, with the leads passing out through the top of the cell. The cell unit is attached by a heavy copper bar to the coolant chamber. As in the design of Holden, Taylor, and Johnston, a transverse slot is milled into the neck of the copper bar, and provision is made for the slot to be filled with hydrogen to raise the heat conduction; alternatively the slot cavity can be evacuated for maximal thermal insulation of the cell unit. A 100-watt heating coil is wrapped around the cell proper so that temperatures above the cryostatic control temperature can be maintained.

The cell unit is mounted in an outer container which can be evacuated with an oil diffusion pump. This pump, not shown in the diagram, is welded directly to the wide vacuum connection tube of the lower component of the outer jacket. The apparatus is demountable, the inner cell unit being attached to the upper portion of the outer container through which pass all access tubes and controls except the evacuation outlet. The upper unit is bolted to the lower unit by a flange. The two sections of this flange are separated by a Teflon ring to improve the thermal insulation. The inner cell unit is constructed of copper and the outer vessel of brass, while stainless steel is used for all metal sections in which heat transfer is to be avoided. A mechanical backing pump, a

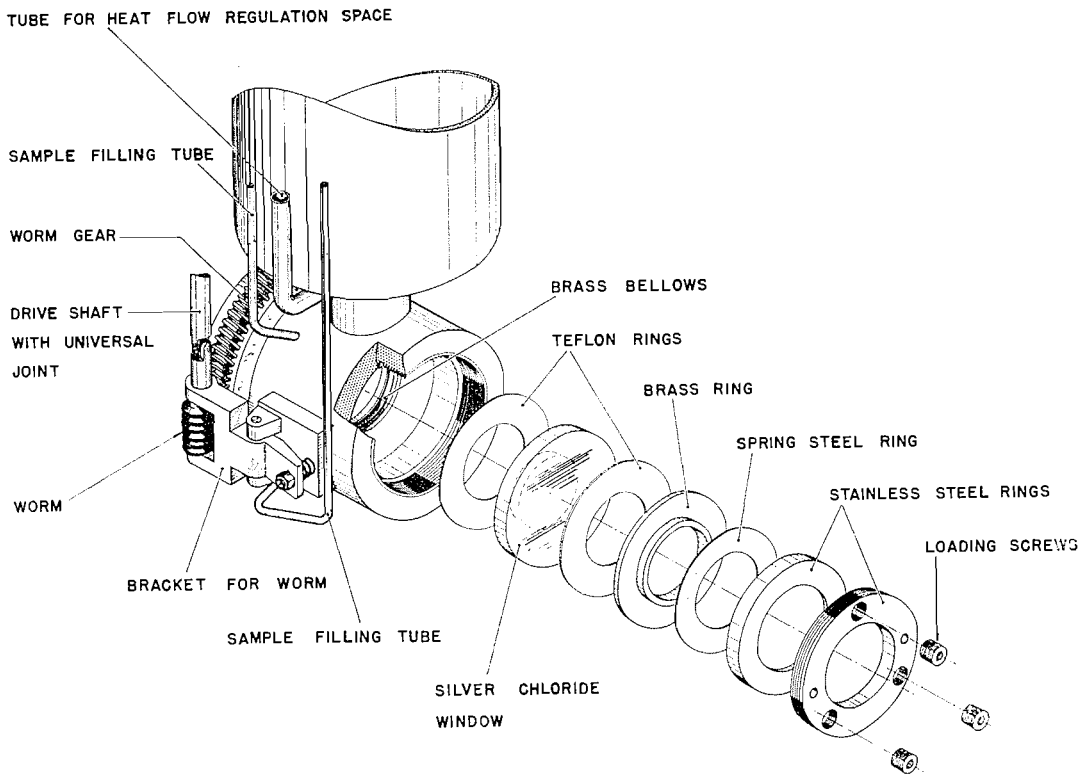

FIG. 2. Variable-temperature infrared cell. Details of inner cell structure.

Phillips vacuum gauge, a potentiometer, and a control Variac for adjusting and monitoring the temperature and pressure in the cell are mounted separately on a portable carriage which permits the cell to be used conveniently with different spectrometers.

For low-temperature measurements in solution, carbon disulphide can be used to $-100°$. For the range 1500–1300 cm^{-1}, where carbon disulphide is opaque, a ternary mixture of carbon tetrachloride, chloroform, and tetrachloroethylene in proportions of 58:36:6 by volume can be used to $-80°$, and a binary mixture of carbon tetrachloride and tetrachloroethylene (70:30), to $-58°$. The latter solvent mixture has superior transparency, particularly near 1450 cm^{-1}.

In precision low-temperature infrared spectrophotometry there are several sources of systematic error that need to be considered. Allowance must be made for the change in concentration due to the increase in the density of the cooled solution, and a small additional error, of opposite sign, may be introduced by the linear contraction of the cell thickness. In these investigations the density of the solvent was measured at $-75°$ and the extinction coefficients were adjusted proportionately; it was assumed that the densities of the solutions and the solvent did not differ significantly. No correction was applied for the cell-length contraction.

In the Perkin–Elmer Model 112 spectrometer, the beam chopper is located between the cell and the detector. Under these conditions rotation of the chopper may induce a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

pulsed temperature change at the tuned amplifier frequency due to the fact that when the chopper interrupts the beam, the thermocouple "sees" black-body radiation at a temperature different from that radiated by the cooled cell. This would manifest itself as a displacement of the zero-transmission line. For the region between 1500 and 1350 cm^{-1} this source of error has been checked by observing the apparent transmission through a 1-mm path length of carbon disulphide at $+25°$ and $-75°$ C. In this wavenumber range carbon disulphide is almost totally absorbing and can be used as a temperature-variable shutter. The displacement of the zero-transmission curve with cooling did not exceed 2%, and the photometric errors due to this cause were considered negligible though they could become appreciable in other regions of the spectrum and at lower temperatures. It was also observed that with 1-mm path length of cooled carbon disulphide in the cell the zero-transmission line was not significantly displaced when an opaque shutter, at room temperature, was placed either between the cell and the entrance slit of the spectrometer, or between the source and the cell.* In the discussion of the infrared spectrum of diethyl ketone which follows we are concerned only with relative changes in the intensities of neighboring bands, but the factors considered above will have to be investigated more thoroughly before attempts are made to evaluate absolute infrared band intensities at depressed or elevated temperatures.

The Raman spectra were measured on a Cary Model 81 spectrophotometer. Room-temperature spectra were obtained with an internal carbon tetrachloride standard, using the technique described previously (2) except that a 5-ml Raman tube was used in place of the capillary tube and the convergent errors were not corrected with a polarizer. Depolarization ratios were measured by the method of Edsall and Wilson (3) and are also uncorrected for convergence. Raman spectra at $+6°$ and $+85°$ were obtained by surrounding the Raman tube with a jacket through which cooled or heated water was circulated.

RESULTS

The positions and intensities of both the infrared and Raman spectra, measured at room temperature, are summarized in Table I.

At room temperature, diethyl ketone exhibits a series of six infrared bands at 1461, 1454, 1414, 1379, 1355, and 1327 cm^{-1} (bands A–F of Fig. 3). These were investigated in carbon tetrachloride solution by Nolin and Jones (4), and from a comparative study of the spectra of selectively deuterated derivatives it was established that bands A, B, and D involve methyl group vibrations while C and E are associated with methylene groups. These investigators did not discuss the weak band F at 1320 cm^{-1} but it is evident from their published spectra that this also is a methylene band. The infrared spectrum of diethyl ketone in the ternary solvent mixture at $+25°$ and $-70°$ is shown in Fig. 3. The spectra of the pure liquid at room temperature and of the solid at $-75°$, measured under slightly lower resolution, are compared in Fig. 4, and the Raman spectrum in the presence of 9% by weight of carbon tetrachloride, measured at $+25°$, is shown in Fig. 5.

With falling temperature, most of the bands sharpen because of thermal solvent effects, and caution is necessary to distinguish this from the more fundamental effects of temperature on the molecular structure of the solute. Band C at 1414 cm^{-1} splits into a doublet in the cooled solution (Fig. 3) and it is clear from the shape of the band envelope that this is a real change and not merely a consequence of the band sharpening. The other

†See experimental section.

pair of methylene bands also shows significant changes. The peak at 1355 cm^{-1} shifts to 1362 cm^{-1} with a shoulder remaining at 1355 cm^{-1}, and the absorption at 1325 cm^{-1} intensifies. Comparison with the changes in the solid phase spectrum (Fig. 4) also suggests that real structural changes in the molecule are involved. The changes in the methyl bands are more difficult to assess. The intensification of band D without frequency displacement is probably only a thermal effect. Bands A and B are both more clearly resolved in the low-temperature spectrum, but the ratio of the peak intensities is not significantly altered. In the spectrum of the solid the most notable change is the complete disappearance of the 1355 cm^{-1} band, the development of the 1333 cm^{-1} maximum, and the profound change in the methyl absorption between 1475 and 1440 cm^{-1}.

The Raman spectrum, shown in Fig. 5, is less informative in the 1500–1300 cm^{-1} region, as the bands are less well resolved. The absence of the 1375 cm^{-1} band is in accord with the well-established fact that the symmetrical C—H bending mode of the methyl group is Raman inactive in aliphatic hydrocarbons.

Spectra in Other Regions

Apart from noting their complexity, Nolin and Jones did not discuss the spectra of the

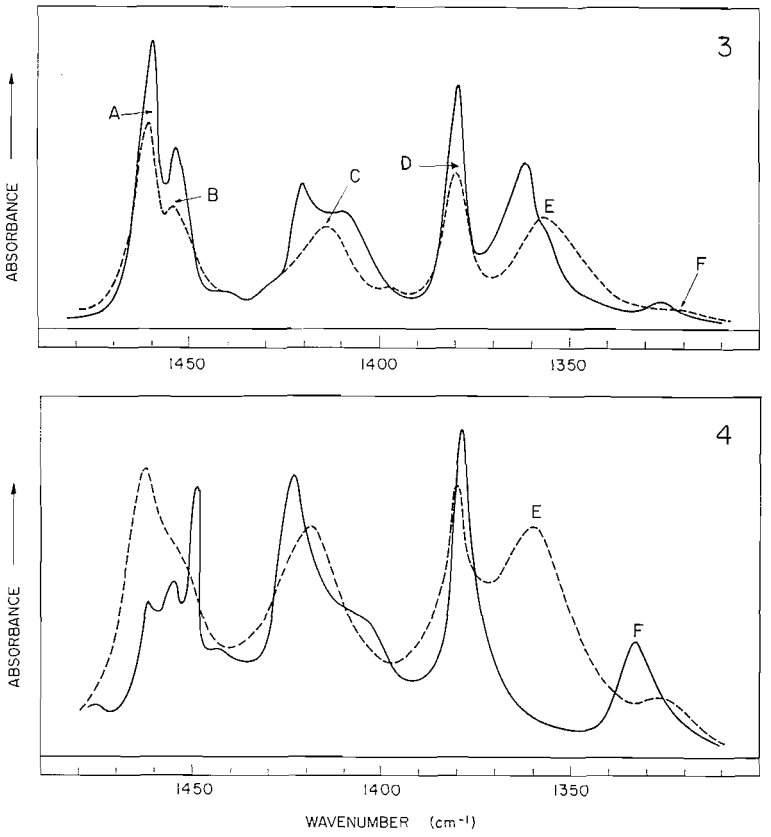

FIG. 3. Infrared spectrum of diethyl ketone. The effect of temperature on 1500–1300 cm^{-1} region in $CCl_4/C_2Cl_4/CHCl_3$ solution at 0.3 *M* concentration. —— −70° C; – – – +25° C.

FIG. 4. Infrared spectrum of diethyl ketone. Comparison of spectra in liquid and solid phases over the range 1500–1300 cm^{-1}. —— solid at −75° C; – – – liquid at +25° C.

deuterated diethyl ketones below 1300 cm^{-1}. The infrared and Raman spectra shown in Figs. 5–7 exhibit a number of temperature-sensitive bands; particularly notable is the highly polarized pair of Raman bands at 784 and 748 cm^{-1}, which reverse in relative intensity at +85°. The most significant temperature effect in the infrared spectrum is the weakening of the 1167 cm^{-1} and the 939 cm^{-1} bands in the cooled solution, and the disappearance of these bands from the spectrum of the solid.

The carbonyl stretching band, measured in the ternary solvent mixture at 0.3 *M* concentration, is symmetrical, with a maximum at 1761 cm^{-1} at 25° C. When the solution is cooled to −75° the maximum shifts to 1710 cm^{-1} with no significant change in the band shape. Such a solvent–temperature shift is normal to a monomolecular species and discounts dimolecular association as an explanation for the behavior of the other temperature-sensitive bands. The band is at 1710 cm^{-1} for the solid at room temperature. In the C—H stretching region both the infrared and the Raman spectra exhibit the four bands that have been discussed previously and none show significant temperature sensitivity.

DISCUSSION

The flexibility of the diethyl ketone molecule permits great freedom for conformational variation, and any attempt to relate these spectral changes to the molecular structure must, of necessity, be speculative. Assuming restricted rotation about the CO—CH_2 bonds, but free rotation about the C—CH_3 bonds, the four conformational structures I–IV can be written for diethyl ketone. They all possess either a plane of symmetry, a twofold axis of symmetry, or both. There are, in addition, innumerable forms with C_s symmetry which may be visualized as derived from I by the synchronous rotation of the C—Et bonds in the same direction; after rotation through 180°, structure IV is

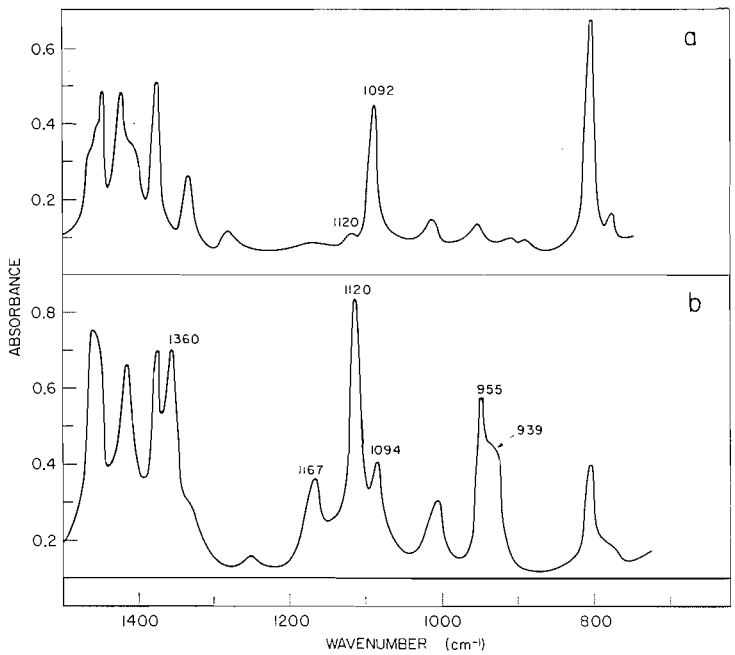

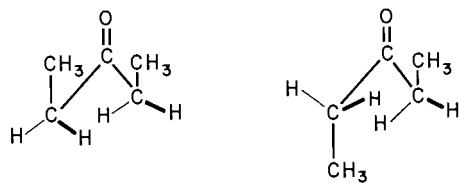

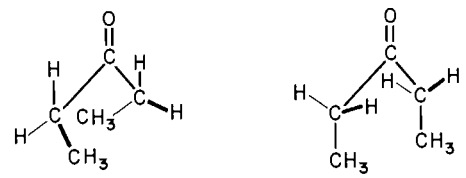

FIG. 7. Infrared spectrum of diethyl ketone. Comparison of the spectra in the solid (*a*, −75° C) and liquid (*b*, +25° C) phases over the range 1500–700 cm^{-1}.

I (C_{2V}) II (C_S)

III (C_2) IV (C_{2V})

reached. If the C—Et bonds of I are synchronously rotated in opposite directions an infinite set of C_2 structures is obtained; a 120° rotation corresponding to III while an 180° rotation again produces IV. Unequal rotation of the C—Et bonds in either direction will produce skew structures with no symmetry elements save identity.

Sirkar and Bishui (5) consider that the presence of a totally depolarized Raman

band with a depolarization ratio close to the theoretical maximum of 0.857 is acceptable as evidence for a plane or twofold axis of symmetry in a molecule. They noted such bands in the spectra of liquid acetone, methyl ethyl ketone, and di-*n*-propyl ketone, but not in diethyl ketone. We observed bands in the Raman spectrum of diethyl ketone at 1463, 1238, 960, and 944 cm^{-1} with measured depolarization ratios of 0.90, 0.86, 0.90, and 0.87 respectively, but the significance to be attached to these figures depends very critically on the magnitude of the convergence error. When this was evaluated by the method of Rank and Kagarise (6), our correction curve was found to slope much less steeply than that reported by the original authors, who used a lamp of different geometrical form. In particular, our correction was negligibly small for measured depolarization ratios above 0.8 and large (>0.2) for strongly polarized bands. Our measurements, therefore, lead us to conclude that at least four bands in the Raman spectrum of diethyl ketone are totally depolarized. Furthermore, it is difficult to believe that diethyl ketone would exist exclusively in skew conformations while such closely related molecules as methyl ethyl ketone and di-*n*-propyl ketone possess a plane of symmetry, or a twofold axis of symmetry, or both.

In the present state of our knowledge, caution must be exercised in attaching structural significance to "totally depolarized" bands. More accurate techniques for the absolute measurement of depolarization ratios are needed, and experience must be acquired in interpreting their significance in connection with the normal vibrations of large molecules.

This discussion will be developed in terms of the four structures illustrated above which, from symmetry considerations, must approximate closely to conformations of minimum or maximum energy. Displacements may occur to minimize the non-bonded hydrogen–hydrogen and hydrogen–oxygen interactions but unless the molecule is thermally excited these should be small; they are more likely to be symmetrical than skew.

The spectrographic data do not distinguish unequivocally among the structures I–IV, but there are no features of the liquid phase spectra that are inconsistent with a simple equilibrium between two of these species. Structure IV can be rejected on thermodynamic grounds, because of the close packing of the hydrogen atoms of the methyl groups. The non-bonded interaction energies will undoubtedly be minimal for III, in which the methyl groups project forward and backward from the plane of the C—CO—C skeletal unit. Structure III would accordingly seem strongly preferred in the liquid phase. Structural significance is undoubtedly associated with the splitting of the 1415 cm^{-1} band into the 1420, 1410 cm^{-1} doublet on cooling. The displacement of this α-methylene scissoring band from its unperturbed position near 1467 cm^{-1} in aliphatic hydrocarbons depends on its steric relation to the carbonyl group. The appearance of the two peaks at low temperature favors II for the form stabilized at low temperature in the liquid phase, as this is the only structure in which the steric environment of the two methylene groups differs. The 1410 cm^{-1} frequency approaches closely to the low α-methylene scissoring frequency of 1406 cm^{-1} in cyclopentanone, with which one of the α-methylene groups of II has configurational similarity. The increased complexity of the methylene wagging absorption at 1362, 1355, and 1327 cm^{-1} in the cooled solution is also consistent with this structure. Splitting of the α-methylene scissoring band could come about through an in-phase and out-of-phase coupling between the scissoring modes of the two methylene groups provided they are suitably located relative to one another. This might be realized in I, but this structure is not preferred in the liquid phase because there will be appreciable non-bonded repulsion between the eclipsed hydrogens of the two methylene groups which occupy

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

1,3 positions (7); there will also be repulsion between the methyl groups and the oxygen atom.

In so far as the solid is concerned, it is unfortunate that no X-ray diffraction measurements have yet been made, and recent attempts to prepare single crystals suitable for such analysis have been unsuccessful (8). The planar zig-zag structure (I) would pack more conveniently into a lattice and this entropy factor could favor I for the crystal in spite of the objections in the preceding paragraph. Its higher C_{2v} symmetry is also in accord with the much simpler infrared spectrum of the solid in comparison with the cooled liquid (Fig. 5).*

In summary, these spectrographic measurements indicate that diethyl ketone exists as an equilibrium mixture of at least two conformational forms in the liquid state. It is not possible to identify the particular structures involved, and the flexibility of the molecule would permit innumerable skew structures of low symmetry. Certain aspects of the spectra are most simply reconciled with the requirements of conformational stability by an equilibrium between structures II and III in which II predominates at low temperatures. The ketone may crystallize as II or possibly as I.

Proton Magnetic Resonance Spectrum

The n.m.r. spectrum of diethyl ketone has also been measured at a concentration of 5 mole% in cyclopentane over a temperature range from −61° to 104° C, using tetramethylsilane as an internal frequency standard. The spectrum exhibits the quartet and triplet band systems characteristic of the methylene and methyl groups. The band contours exhibit no significant changes with temperature but the centers of the band systems are displaced, the methylene signals moving to higher field and the methyl signals to lower field with increasing temperature (Table II). Though the shifts are not directly

TABLE II

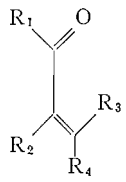
CONFORMATIONAL EQUILIBRIA IN OPEN-CHAIN α,β-UNSATURATED KETONES[1]

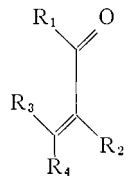
K. NOACK[2] AND R. NORMAN JONES

ABSTRACT



The infrared and Raman spectra of *trans*-Δ^3-penten-2-one have been measured over the temperature range +30° to −75° and +85° to +5° respectively. The temperature-dependent changes observed in the spectra indicate that this ketone exists as an equilibrium mixture of *s*-cis and *s*-trans conformational isomers in the liquid state. The *s*-trans form is the more stable and is present exclusively in the crystalline solid.

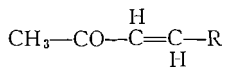
Similar measurements have been carried out on Δ^3-buten-2-one. The infrared and Raman spectra of this ketone also exhibit temperature effects that can be explained by a similar equilibrium, though the evidence is not as conclusive as for *trans*-Δ^3-penten-2-one.



The influence of alkyl substitution at the α- and β-carbon atoms on the relative stability of the *s*-cis and *s*-trans forms of α,β-unsaturated ketones is discussed.

INTRODUCTION

The *s*-cis (I) and *s*-trans (II) conformations of open-chain α,β-unsaturated ketones can be distinguished from the positions and intensities of the C=O and C=C stretching



I

II

bands in the infrared (1–4) and Raman (5) spectra. In the liquid state most conjugated ketones exist predominantly or perhaps exclusively in one or other of the two conformations, but Mecke and Noack (2) have observed that the infrared spectrum of *trans*-Δ^3-penten-2-one (III*a*) and related compounds (III*b*–III*d*) exhibit two carbonyl bands near 1700 cm^{-1} and 1680 cm^{-1} in tetrachloroethylene solution. The positions of these bands

IV

(*a*) R = —CH_3
(*b*) R = —CH_2—CH_3

suggested an equilibrium between the *s*-cis and *s*-trans isomers. Similar doublet carbonyl bands were noted by Mecke and Noack for ketones of structure IV*a*–IV*b*. Timmons and collaborators (4) have commented similarly on the spectrum of *trans*-Δ^3-penten-2-one, and other examples of this behavior have been cited by Erskine and Waight (3).

In the present investigation the effects of temperature on the infrared and Raman spectra of *trans*-Δ^3-penten-2-one and Δ^3-buten-2-one have been examined in an attempt to confirm the existence of these equilibrium systems.

EXPERIMENTAL METHODS AND RESULTS

The preparation and purification of the ketones have been described by Mecke and Noack (2). The infrared spectra were measured on Perkin–Elmer Model 21 and Model 112 spectrometers using the low-temperature technique described previously (6). The Raman spectra were obtained with a Cary Model 81 spectrometer (5). The spectra are illustrated in Figs. 1–8 and the numerical data are summarized in Tables I–III.

Spectra of trans-Δ^3-Penten-2-one

The infrared spectrum of *trans*-Δ^3-penten-2-one, measured in a eutectic mixture of carbon tetrachloride, tetrachloroethylene, and chloroform (6) in the region of the C=O and C=C stretching bands is shown in Fig. 1. At room temperature, four well-resolved bands (A–D) are observed at 1693, 1674, 1645, and 1630 cm^{-1} with a weaker shoulder (E) at 1615 cm^{-1}. In the Raman spectrum, measured at +5° in the presence of 9% by weight of carbon tetrachloride, the bands occur near the same positions (Fig. 2), but the relative intensities are different; band A, in particular, is reduced to a weak inflection. From comparison with the spectra of other α,β-unsaturated ketones (2, 5), bands A and D can be assigned to the *s*-cis isomer and bands B and C to the *s*-trans form. The weak

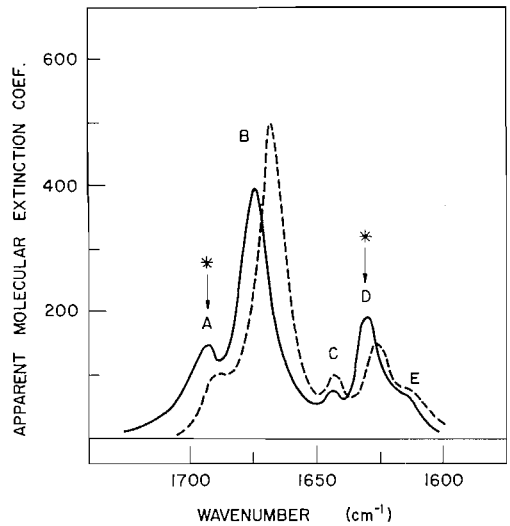

FIG. 1. Infrared spectrum of *trans*-Δ^3-penten-2-one in $CHCl_3/CCl_4/C_2Cl_4$ solvent. Bands indicated by arrows and asterisks weaken in the cooled solution and are absent from the spectrum of the solid. —— +30° C; - - - −75° C.

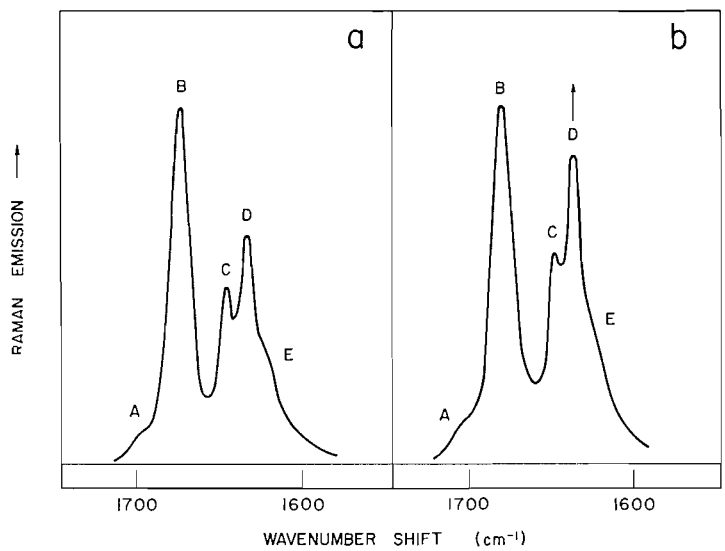

FIG. 2. Raman spectrum of *trans*-Δ^3-penten-2-one measured in the presence of 9% by weight of carbon tetrachloride: *a*, +6° C; *b*, +85° C. The intensity scale is arbitrarily adjusted so that band B is of equal height in both spectra.

band E is probably an overtone or combination band; its weakness in the Raman spectrum is an argument against attributing it to a C=C vibration of an impurity.

In the infrared spectrum at −75° (Fig. 1) bands B and C are more intense than at room temperature while bands A and D are weaker, indicating the greater thermodynamic stability of the *s*-trans form. Bands A and D are absent from the spectrum of the solid

For personal use only.

at $-100°$, suggesting that the ketone crystallizes exclusively in the *s*-trans form. The Raman spectrum at $+85°$ shows a relative intensification of the *s*-cis bands. The intensity ratio k_B/k_D is 1.38 at $+5°$ and 1.17 at $+85°$ and the ratio k_D/k_C is 1.28 and 1.47 respectively at the lower and higher temperatures. While these figures indicate an intensification of the *s*-cis band relative to the *s*-trans with rising temperature, they are not necessarily proportional to the concentration changes, since the bands broaden with rising temperature. Unfortunately the band overlap is too great to permit evaluation of the areas beneath the component peaks from which the relative concentrations of the isomers might be derived.

The fact that both the C=O and the C=C bands are temperature sensitive indicates that the band splitting is not due to a Fermi resonance of the type associated with C=O band splitting in cyclic *s*-trans ketones (5). It is also significant in this connection that the room-temperature spectra for dilute solutions in carbon tetrachloride, chloroform, and tetrachloroethylene closely resemble the spectrum of the liquid ketone; only minor changes in band position and intensity are noted, such as would be expected from normal solvent effects.

Other regions of the infrared and Raman spectra of *trans*-Δ^3-penten-2-one are shown in Figs. 3 and 4. Infrared bands of liquids and solutions usually become narrower and sharper with diminishing temperature, and it is difficult to distinguish an increase in band height due to this solvent–solute effect from band intensification due to an increase in the relative concentration of a conformational isomer. The inverse effect, viz. the weakening of a band at lower temperature due to the fall in concentration of a less-stable isomer is more convincing as evidence for a change in isomer equilibrium, and in the infrared spectrum of *trans*-Δ^3-penten-2-one in carbon disulphide at $-65°$ the bands at 1289, 1177, and 860 cm^{-1} weaken in this fashion. Furthermore the bands at 1289 cm^{-1} and 860 cm^{-1} are absent from the spectrum of the solid ketone at $-100°$, while the band at 1177 cm^{-1} persists only as a broad residuum. These bands can all be attributed to the *s*-cis form. For the spectra at elevated temperatures, the converse argument applies, and the bands that intensify on heating are most plausibly indentified with a change in the equilibrium in favor of the *s*-cis form. In the Raman spectrum at $+85°$ this is observed for the bands at 1291, 620, 603, and 377 cm^{-1}.

Spectra of Δ^3-Buten-2-one

The infrared spectrum of Δ^3-buten-2-one, measured on a capillary film of the undiluted ketone, exhibits two bands in the C=O stretching region at 1701 and 1683 cm^{-1} (bands A and B of Fig. 5). Cooling the film to $-65°$ changes the relative intensities; the ratios of the maximal absorbances (B/A) are 1.64 at $+30°$ and 2.08 at $-65°$. The positions are consistent with the assignment of band A to the *s*-cis isomer and band B to the *s*-trans form. In the infrared spectrum of the solid at $-100°$ there is no band near 1700 cm^{-1} but there is a doublet at 1680 and 1673 cm^{-1} (Fig. 5). It seems reasonable to interpret this as a splitting of band B, and the disappearance of band A. The splitting introduces a complication in the interpretation of the structure of the solid; it could be due to combination with a lattice vibration or to the packing of two molecules in a slightly different environment in the unit cell. The latter explanation is supported by the similar close splitting of the C=C band, also shown in Fig. 5. In the Raman spectrum at $+5°$ the 1700 cm^{-1} component appears only as a weak inflection on the high-frequency side of the strong band at 1677 cm^{-1} and there is no measurable change at higher temperature. The weakness of this Raman band is consistent with the *s*-cis assignment (5).

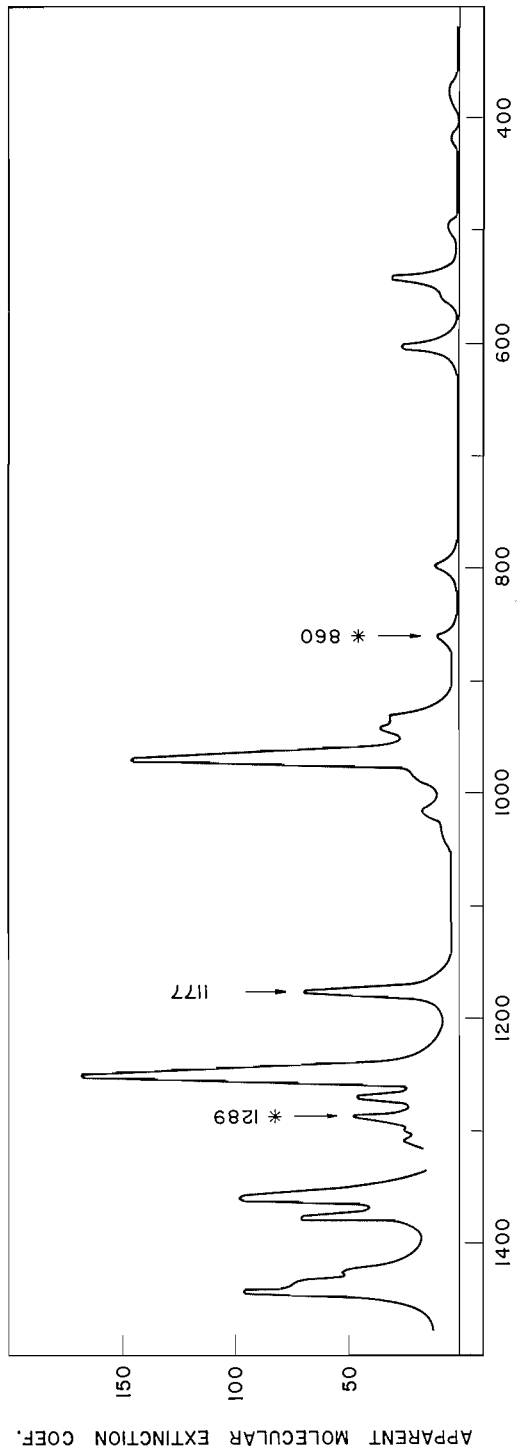

FIG. 3. Infrared spectrum of *trans*-Δ^3-penten-2-one. For conditions see footnote † of Table I and footnote to Fig. 1.

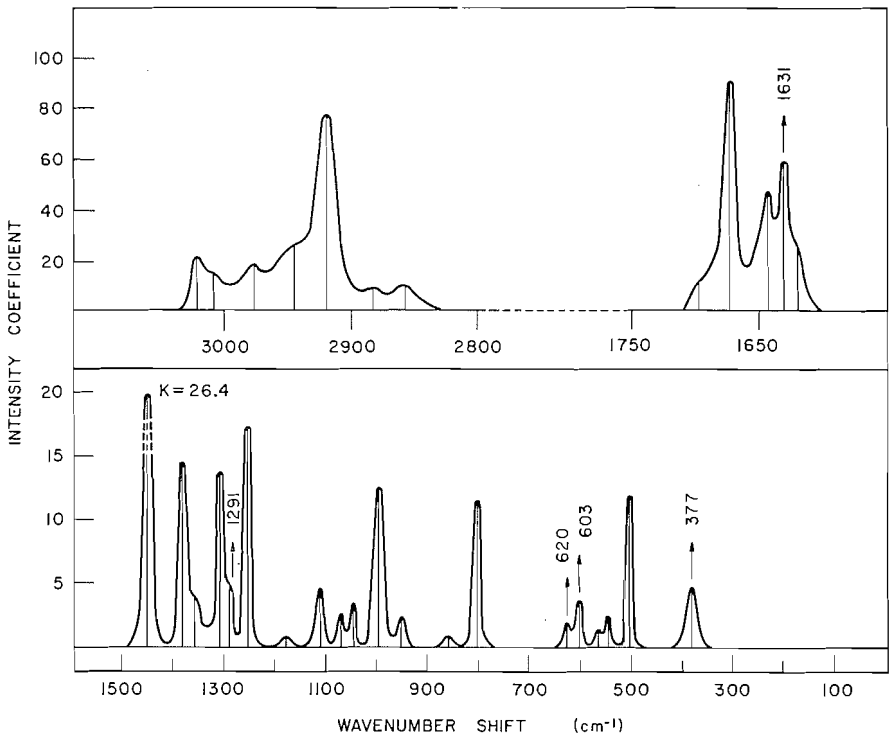

FIG. 4. Raman spectrum of *trans*-Δ^3-penten-2-one measured in the presence of 9% by weight of carbon tetrachloride. The carbon tetrachloride bands at 459, 314, and 218 cm^{-1} are omitted. The band contours are diagrammatic only. Upward pointing arrows designate bands that intensify on heating.

Δ^3-Buten-2-one exhibits only one C=C stretching maximum in both the infrared and the Raman spectra, and if the two carbonyl bands are to be attributed to a conformational equilibrium it is necessary to assume that the C=C stretching bands for both the *s*-cis and the *s*-trans forms overlap each other and are not resolved. In the case of *trans*-Δ^3-penten-2-one the parallel changes in the A/D and B/C band pairs are a strong argument in support of the equilibrium system, and the failure to observe similar behavior for Δ^3-buten-2-one adds considerably to the difficulty in interpreting the other temperature changes in this spectrum. In Table III the positions and intensities of the C=O and C=C bands of Δ^3-buten-2-one in carbon tetrachloride and chloroform are compared. The ratios of the C=O band intensities in the two solvents are not very different and do not suggest that we are dealing with a Fermi resonance type of carbonyl band splitting (5, 7). The change in the relative heights of several bands distributed through the 1400–900 cm^{-1} region of the spectrum are described below, and these also are inconsistent with the Fermi resonance explanation.

The infrared spectrum of Δ^3-buten-2-one from 1750 to 280 cm^{-1} is shown in Fig. 6, and the temperature-sensitive bands are illustrated in the three infrared spectra shown in Fig. 7, covering the 1400–900 cm^{-1} range at temperatures extending from -65 to $+85°$. Changes are particularly notable for the bands at 1360, 1248, 991, and 954 cm^{-1}, which intensify on cooling, and for the band at 1180 cm^{-1}, which weakens on cooling and is absent from the spectrum of the solid. These changes are most readily reconciled with

the *s*-cis ⇌ *s*-trans equilibrium though they mainly involve intensification on cooling. It may be significant that a band near 1180 cm^{-1} appears to be associated with the *s*-cis forms of both Δ^3-buten-2-one and *trans*-Δ^3-penten-2-one. The Raman spectrum of Δ^3-buten-2-one measured at +5° is shown in Fig. 8; raising of the temperature to +70° causes the bands at 1247, 1054, 686, and 527 cm^{-1} to diminish in peak height by about 30% while the remaining bands retain 90–100% of their intensity at +5°.

In summary we infer from these experiments that *trans*-Δ^3-penten-2-one exists as a mixture of *s*-cis and *s*-trans isomers. For Δ^3-buten-2-one, the failure to observe two C=C

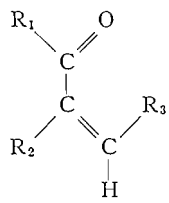
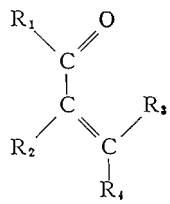
stretching bands makes it unwise to draw definite conclusions, though the temperature changes through the remainder of the spectrum are consistent with the presence of the equilibrium system.



CONCLUDING REMARKS

The α,β-unsaturated ketones for which equilibria between *s*-cis and *s*-trans forms have been observed or postulated possess common structural features. It appears necessary that (*a*) the α-carbon atom carry a hydrogen atom, (*b*) the *s*-trans form be sterically unhindered (viz. R_2 and R_3 = H in I and II).



If the hydrogen at R_2 is replaced by alkyl, only the *s*-trans form is obtained, presumably because the *s*-cis structure is destabilized by repulsion between the non-bonded hydrogen atoms on R_1 and R_2.* If R_3 is alkyl there will be strong repulsion in the *s*-trans form between the hydrogen atoms on R_1 and R_3; ketones of structure V therefore exist exclusively in the *s*-cis form. This remains the preferred configuration even when alkyl groups are present at R_2 and R_4 (VI, VII), although, as noted above, there is some steric

V

VI

VII

strain between R_1 and R_2 in these structures. In VI and VII the conditions are favorable for non-planar forms, but the three ketones of these types included in these investigations show no abnormal displacements of the C=O and C=C frequencies. These would be expected if the molecules were significantly non-planar. It is notable that the infrared C=C stretching bands of ketones of structure VI and VII are very broad, their half band widths are 20.5, 36, and 17.5 cm^{-1} respectively in tetrachloroethylene solution, compared with normal values in the range 8.5–16.5 cm^{-1} for other types of open-chain α,β-unsaturated ketones;† the Raman spectra show similar behavior.‡ This band broadening is probably attributable to the destabilization of the planar structure, resulting in a shallow potential-energy well for rotation about the center C—C bond of the conjugated system. As a result, the torsionally excited energy levels will be more highly populated and these will be associated with decreased C=C stretching frequencies.

It is also to be noted that the ketones that exist predominantly or exclusively in the *s*-cis conformation readily undergo a partial isomerization to the β,γ-unsaturated ketones in the presence of iodine or other catalysts. Ketones with unhindered *s*-trans structures are much less reactive under these conditions and isomerize only to the (*s*-cis) cis α,β-unsaturated ketones without migration of the double bond.

**Equilibrium systems containing the s-cis isomer might be expected for the converse structure where* R_1 = H *and* R_2 = *alkyl, i.e. α-methylacrolein. The infrared spectrum of this aldehyde, measured on the pure liquid, shows no significant change on cooling from +30 to −65° (8); it has normal singlet* C=O *and* C=C *bands (2, 7) and is presumably entirely in the s-trans form.*

†See compounds 43–45 in the table in reference 2.

‡See compounds XV and XVI in Table I of reference 5. The half band widths are not reported in this paper but they are proportional to L/k.

POLAROGRAPHIC DETERMINATION OF THE DISSOCIATION CONSTANT OF THE SULPHYDRYL GROUP AND DIFFUSION COEFFICIENT MEASUREMENTS OF THIOMALIC ACID[1]

R. C. KAPOOR, O. P. AGRAWAL, AND T. D. SETH

ABSTRACT

Polarographic study of thiomalic acid has been made in the pH range 1–12.5 using Britton–Robinson buffer at 30°. The half-wave potential ($E_{\frac{1}{2}}$) values have been used to determine the pK_3 (SH) value of the acid (pK_3 = 10.55).

The diffusion current obtained in these experiments has been utilized to calculate the diffusion coefficients of the different charged species of thiomalic acid. The values thus obtained for the respective species are $H_3A = 1.20\times10^{-6}$ cm²/sec; $H_2A^- = 1.16\times10^{-5}$ cm²/sec; $HA^{--} = 1.08\times10^{-5}$ cm²/sec; and $A^{---} = 7.67\times10^{-6}$ cm²/sec.

The standard potential of the reaction

$$TSH + Hg = TSHg + H^+ + e^-$$

has been calculated as +0.266 volt vs. N.H.E.

Thiomalic acid or mercaptosuccinic acid has been recently used in a number of studies with metal complexes such as copper (1), zinc, cobalt, and nickel (2), and some other metals (3). Polarographic behavior of this compound has been systematically investigated (4, 5, 6) in these laboratories.

Cheney, Fernando, and Freiser (2) have reported the acid dissociation constants of thiomalic acid as calculated from potentiometric titration data.

Thiomalic acid has three replaceable hydrogen ions as indicated in the formula below.

$$\begin{array}{l} {}^{III}HSCHCOOH^{I} \\ \quad\quad\quad\quad | \\ \quad\quad\quad CH_2COOH^{II} \end{array}$$

If we represent the acid as H_3A the equilibria involved are

$$H_3A \rightleftharpoons H_2A^- + H^+, \quad [1]$$

$$H_2A^- \rightleftharpoons HA^{--} + H^+, \quad [2]$$

$$HA^{--} \rightleftharpoons A^{---} + H^+, \quad [3]$$

which correspond to the three dissociation constants K_1, K_2, and K_3. K_1 and K_2 correspond to the two carboxylic hydrogen atoms while K_3 corresponds to the hydrogen atom linked to the sulphur atom. The three values reported by Cheney *et al.* (2) at 25° are pK_1 = 3.30; pK_2 = 4.94; pK_3 (SH) = 10.64.

The authors have used polarographic data in calculating the pK_3 value of thiomalic acid. The different charged species of thiomalic acid have been shown to have different diffusion properties. The diffusion coefficient values of these species have also been calculated.

MATERIAL

Thiomalic acid was obtained as a gift from Evans Chemetics Incorporated, New York. The material was 99% pure and was used as such. Stock solutions were prepared in doubly distilled water, and only freshly prepared solutions were used. All other chemicals used were of AnalaR or chemically pure grade. The mercury used in the dropping mercury

[1]*Manuscript received June 19, 1961.*
Contribution from the Chemistry Department, University of Allahabad, Allahabad, Uttar Pradesh, India.

electrode was first purified chemically by treatment with nitric acid and subsequently distilled twice.

EXPERIMENTAL

Automatic polarograms were taken with a Leeds and Northrup Electro-Chemograph, Type E. Current–voltage curves in all cases were also taken manually with a circuit described by Lingane and Kolthoff (7).

Current–voltage curves were taken at 30°. All potentials were measured against the saturated calomel electrode (S.C.E.). An atmosphere of purified nitrogen was maintained throughout all investigations.

The characteristics of the capillary used are $m = 1.357$ mg/sec; $t = 3.37$ sec; $m^{2/3}/t^{1/6} = 1.501$ $mg^{2/3}sec^{-1/2}$.

The pH measurements were made with a Leeds and Northrup pH meter (Cat. 7666).

RESULTS AND DISCUSSION

Dissociation Constant of the Sulphydryl Group

Polarograms of 5×10^{-4} M thiomalic acid were taken at different pH values using Britton–Robinson buffer. Fig. 1 shows the current–voltage curves of 5×10^{-4} M thiomalic acid at different pH values.

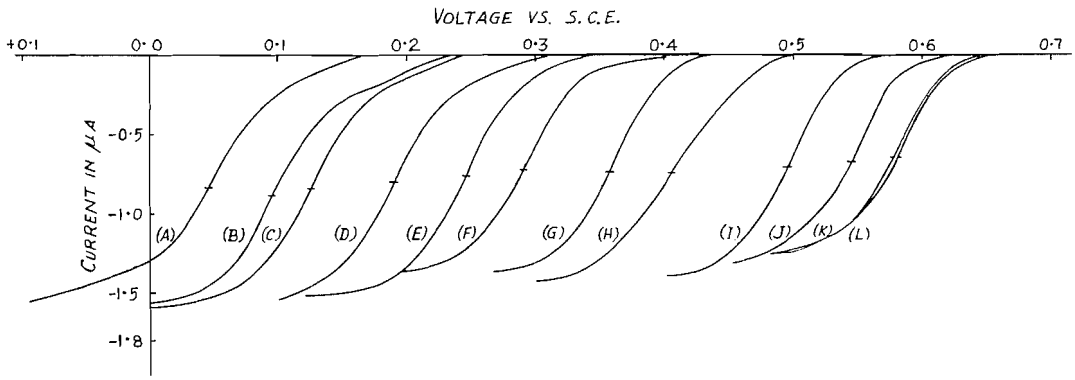

FIG. 1. Anodic waves of 5×10^{-4} M thiomalic acid in B-R buffer at different pH values. The pH and $E_{\frac{1}{2}}$ values are given respectively as (A) 1.15, −0.045 v; (B) 2.0, −0.095 v; (C) 2.5, 0.125 v; (D) 3.7, −0.190 v; (E) 4.6, −0.246 v; (F) 5.6, −0.291 v; (G) 6.6, -0.357_5 v; (H) 7.7, −0.405 v; (I) 9.0, −0.495 v; (J) 10.0, −0.545 v; (K) 11.35, -0.577_5 v; (L) 11.7, -0.582_5 v.

Thiomalic acid gives a prewave at low pH values up to 3.7. Such prewaves are often given by sulphur compounds such as glutathione, thioglycollic acid, and 2,3-dimercaptopropanol (8, p. 470). These prewaves have adsorption character and occur at more negative potential than the main anodic wave. The half-wave potentials of the main waves have been marked after separation of the prewaves. However, the total current is diffusion-controlled and corresponds to a one-electron change in all the polarograms.

The characteristics of the anodic wave of thiomalic acid have already been established (4, 5, 6). It has been shown that the anodic wave is not due to formation of a dimer but due to the formation of a mercury compound as indicated below:

$$TSH + Hg = TSHg + H^+ + e^-.$$

A plot of $E_{\frac{1}{2}}$ values against pH is given in Fig. 2. It can be easily seen that there are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

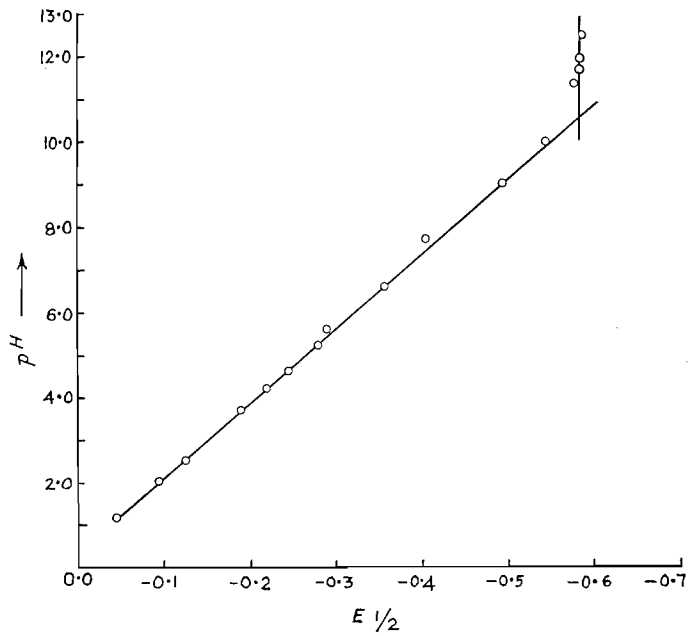

FIG. 2. Plot of $E_{\frac{1}{2}}$ and pH values.

two linear portions in the plot, whose intersection corresponds to the pH of 10.55. This indicates that under the conditions of the experiment the H^+ ion of the sulphydryl group has a pK of 10.55 (8, p. 472). This value agrees fairly well with that obtained by Cheney, Fernando, and Freiser (2) at 25°.

The change of $E_{\frac{1}{2}}$ per unit change of pH in the pH range 1–10 is 0.057 volt, which is sufficiently near the theoretical value of 0.060 volt at 30°.

The value of $E_{\frac{1}{2}}$, extrapolated to zero pH (hydrogen ion concentration = 1), is +0.02 volt, which corresponds to the standard potential of the reaction taking place at the electrode:

$$TSH + Hg = TSHg + H^+ + e^-.$$

The value thus calculated is +0.266 volt vs. N.H.E.

Diffusion Coefficients of Different Charged Species of Thiomalic Acid

Measurements of diffusion currents of thiomalic acid have been made in the pH range 1.15 to 12.50. Table I includes the values of the diffusion coefficient constants calculated according to the Ilkovič equation. The value of the diffusion current decreases on increasing the pH.

Thiomalic acid, as indicated earlier, exists in solution in four different species. The percentage of the different species can be calculated by the three pK values of this acid. The variation of the acid constants with temperature can be estimated from the apparent heats of ionization ($\Delta H'$) for the two carboxyl groups by applying the van't Hoff's equation and assuming that $\Delta H'$ is independent of temperature over the range of measurement.

The $\Delta H'$ for the two acid dissociation constants, K_1 and K_2, of succinic acid have been reported as +710 cal/mole and −340 cal/mole respectively (9). These same values of

11.95	−1.29	0.801	-0.582_5
12.5	−1.26	0.767	-0.587_5

$\Delta H'$ were used for the two carboxyl groups of thiomalic acid to give calculated pK values at 30° of $pK_1 = 3.29$ and $pK_2 = 4.94$.

pK_3 as determined by our experiments from the $E_{\frac{1}{2}}$ values is 10.55 at 30°.

The percentage of different species of thiomalic acid can be calculated on the basis of the above pK values.

The concentration of different species have been calculated on such a basis that we see that at pH 1.15 practically all the acid exists in the form of uncharged H_3A species. At pH 7.7 almost all the acid is in the form of HA^{--}, while at pH 12.5 the only species present in the solution is the completely ionized form A^{---}.

Thus the diffusion currents at these three pH values can be used to calculate the diffusion coefficients of the above-mentioned three species. The diffusion coefficient of the remaining species, H_2A^-, can be calculated from the intermediate measurements in the pH range 3.70–5.60 using the already calculated D values of H_3A and HA^{--} species.

TABLE II
Diffusion coefficient values of different species of thiomalic acid at 30°

Species	$D\times10^5$ (cm²/sec)	pH
H_3A	1.20	1.15
HA^{--}	1.08	7.7
A^{---}	0.767	12.5
H_2A^-	1.16	4.2
H_2A^-	1.19	4.6
H_2A^-	1.14	5.2

The average value of the species H_2A has been taken as 1.16×10^{-5} cm²/sec.

ASSOCIATION IN THE BINARY LIQUID SYSTEM DIMETHYL SULPHOXIDE – WATER[1]

J. M. G. Cowie and P. M. Toporowski

ABSTRACT

The viscosities and densities of several mixtures of dimethyl sulphoxide and water have been measured at 25°, 45°, and 65° C. Heats of mixing and refractive indices at 25° C are also reported. The results indicate there is strong association of the two liquids which may be attributed to hydrogen bonding.

INTRODUCTION

The widespread application of dimethyl sulphoxide (DMSO) as a solvent, plasticizer, and chemical intermediate has led to its large-scale production in recent years. In spite of the increased use of this compound its physical properties do not appear to have been studied extensively.

DMSO is a colorless, non-toxic liquid which boils at 189° C and freezes at 18.5° C. It is completely miscible with water and is strongly hygroscopic, but little has been reported about the behavior of DMSO–H_2O mixtures (1). During the course of a recent investigation on the solution properties of amylose dissolved in DMSO, it was found that water alters the viscosity of amylose–DMSO solutions in such a manner as to suggest a strong interaction between DMSO and H_2O.

Many binary liquid systems exhibit non-linear viscosity isotherms which pass through a minimum. However, a smaller group possess a maximum, indicating some form of liquid–liquid interaction, and the DMSO–H_2O system was found to belong to this latter class.

Viscosities and densities of 14 mixtures have been measured at 25°, 45°, and 65° C while refractive indices and heats of mixing have been determined at 25° C.

EXPERIMENTAL

Solvents

DMSO, supplied by Crown Zellerbach Corporation, was carefully dried by refluxing for 24 hours over CaO. It was left in contact with this drying agent for about 10 days with occasional shaking and then fractionally distilled under reduced pressure. The middle fraction, with boiling point approximately 68° C at 6–7 mm pressure, was collected and used in all physical measurements. The purity of this fraction was determined by analysis for water using two independent methods.

LeBel and Goring (1) have suggested a method using infrared spectroscopy in which the height of the OH absorption peak at 3500 cm^{-1} is measured and can be related to the water concentration in the sample. The method was calibrated using mixtures up to 0.5% water but no peak was detected in the distilled DMSO used in this investigation.

Analysis for water by the Karl Fischer (2) technique indicated that there was less than 0.01% water present in the DMSO.

Viscosity

The viscometer used was a Cannon-Ubbelohde model designed to have negligible

[1]*Manuscript received July 10, 1961.*

Issued as N.R.C. No. 6510.

kinetic energy correction (3). Absolute viscosities, measured in centipoise, could be obtained from the flow time of the liquid, its density, and a calibration constant supplied by the manufacturer. The viscometer was reproducibly positioned in the thermostat baths by a three-point suspension system. Thermostat temperatures were maintained at 25°, 45°, and 65°±0.01° C.

Density

The liquid densities were determined at 25°, 45°, and 65° C using a Sprengel Ostwald pycnometer with a capacity of about 21 ml.

Refractive Index

Refractive indices were measured on an Abbé refractometer at 25° C using the sodium D line (λ = 5893 Å).

Calorimetry

The heats of mixing of several mixtures of water and DMSO were measured in a Dewar calorimeter similar to the one described by Vold (4). The liquids were kept separate in the calorimeter before being mixed by means of a hollow glass cylinder resting on a pool of mercury. Rapid mixing was obtained by raising the cylinder and stirring one liquid into the other. The final liquid volume was always about 150 ml, which kept the vapor space above the mixtures at a minimum. Recorded temperature rises varied from 7° to 25° C. The heat capacity of the calorimeter and its contents was determined after each measurement by passing a specific amount of electric current through the heater and measuring the temperature rise produced.

RESULTS

Table I lists the viscosities, densities, and refractive indices of several DMSO–H_2O mixtures. The results all show a positive deviation from ideality, which strongly suggests

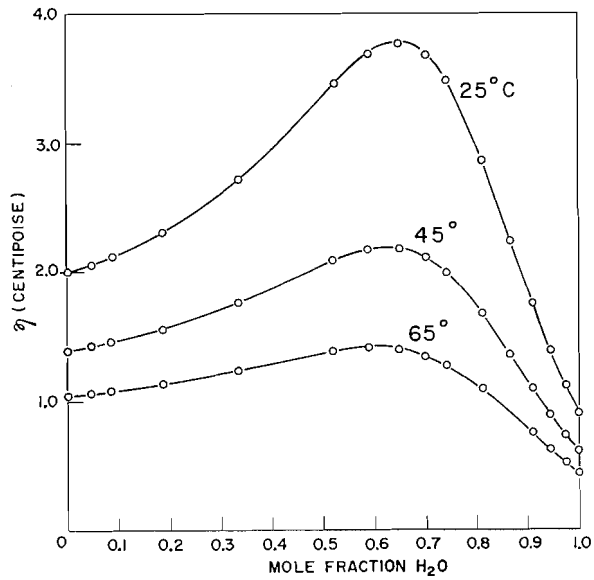

FIG. 1. The viscosities of DMSO–H_2O mixtures at 25°, 45°, and 65° C as a function of mole fraction of water.

region of 0.65 mole fraction of water, each isotherm exhibits a maximum which decreases with increase in temperature, and shifts slightly towards a lower water concentration. A maximum is also observed in the density measurements at 0.40 mole fraction of water which shifts towards higher water concentration with increase in temperature.

It has been suggested by Geddes (5) that such maxima have no real meaning and that it is the point of greatest deviation from linearity which is related to the composition of any complex formed on mixing. On this basis both viscosiy and density measurements have maximum deviations at a ratio of 2 moles water to 1 mole DMSO.

Heats of mixing are listed in Table II. These are negative over the whole range of compositions examined, which is again indicative of a strong interaction between the

DISCUSSION

Aqueous solutions of non-electrolytes are the most difficult class of binary liquid systems to understand, and as a result no theory has been developed which can describe their thermodynamic properties adequately. An attempt has been made by Rowlinson (6) to classify these systems in terms of increasing numbers of solute–water hydrogen bonds, ranging from weakly interacting substances such as ketones to the strongly bonded hydrogen peroxide – water system.

The results obtained here indicate that there is a greater degree of association in water–DMSO mixtures than in water alone, which may be explained in terms of the polar sulphoxide group. The DMSO molecule can be represented (7) by the forms I and II,

I II

in which the negatively charged oxygen should form hydrogen bonds with the water molecules. This hypothesis is substantiated by the considerable volume contraction on mixing, the large negative heat of mixing, and the positive maxima in the viscosity isotherms.

Thus it is probable that a DMSO hydrate is formed, although it cannot be stated definitely from the above data that a stable compound exists at the temperatures investigated. The fact that the maximum in the viscosity isotherm decreases with increasing temperature suggests that any association complex formed is thermally labile and could only be expected to exist in a completely undissociated state at low temperatures. Further investigation would be necessary to establish its existence and composition.

CONCLUSIONS

The system DMSO–H_2O belongs to the class of solutions possessing numerous solute–water bonds which are stronger than the hydrogen bonds between water molecules. Evidence is presented for the existence of a 2:1 association complex between water and DMSO, but this cannot be proved on the basis of the data presented. Finally it should be stressed that DMSO must be carefully dried before being used as a solvent in physical measurements, especially viscosity determinations, if meaningful results are to be obtained.

ACKNOWLEDGMENTS

The authors wish to thank Dr. D. A. I. Goring for allowing them access to his manuscript prior to publication, Mr. R. Ironside for carrying out the water analyses, and Dr. S. Bywater for his interest in the work.

THE DECOMPOSITION OF CARBON DIOXIDE BY Hg $6(^3P_1)$ AND Hg $6(^3P_0)$ ATOMS[1]

OTTO P. STRAUSZ AND HARRY E. GUNNING

ABSTRACT

Carbon dioxide has been shown to decompose into carbon monoxide and oxygen atoms, when exposed to radiation at 2537 Å, in the presence of mercury vapor. The rate rises steeply with decreasing substrate pressure, and varies directly with the 1.8 ± 0.1 power of the light intensity. The proposed mechanism attributes reaction to the collision of electronically excited CO_2 molecules with Hg $6(^3P_1)$ atoms. The suppression of reaction at higher substrate pressures is readily explained in terms of collisional deactivation of the excited CO_2 species. Nitrogen was found to increase the rate of CO formation; the maximum effect was obtained for a mixture of 7.4 mm nitrogen and 3.74 mm carbon dioxide, in which case the rate was 1.58 times that for pure substrate. It is shown that nitrogen serves to generate metastable Hg $6(^3P_0)$ atoms, which can sensitize the decomposition. The reaction might serve as a chemical method for monitoring Hg $6(^3P_0)$ atoms. For CO_2–N_2 mixtures, the rate was found to rise when the reacting system was exposed to radiation at 4047 Å. This is taken as direct evidence of sensitization by higher states of mercury, generated by stepwise excitation, since radiation at 4047 Å converts Hg $6(^3P_0)$ to Hg $7(^3S_1)$.

INTRODUCTION

Several studies (1–4) have been made of the photolysis of carbon dioxide in the vacuum ultraviolet. With a xenon source, Groth (2) found the quantum yield of CO formation, Φ_{CO}, to be 0.96, and he suggested that atomic oxygen is formed in the primary process. However, Jucker and Rideal (3), for the 1470-Å line of xenon, obtained 1.9 ± 0.2 for Φ_{CO}. They proposed a mechanism involving the initial formation of an excited molecule which, upon collision with the substrate, formed $2CO + O_2$. Recently Mahan (4) has studied the photolysis, at both 1236 Å and 1470 Å. In agreement with Groth (2), he found Φ_{CO} to have values near unity at both wavelengths and he presented convincing arguments for a primary process leading to the formation of excited (^1D) oxygen atoms.

The first mercury-photosensitized decomposition of carbon dioxide was carried out by Herschfinkel (5), although the role of mercury was not recognized until later by Coehn and May (6). In a more detailed study, Cline and Forbes (7) showed that the decomposition was specifically initiated by Hg $6(^1P_1)$ atoms, arising by absorption by mercury of its resonance radiation at 1849 Å; they found no evidence for a reaction of carbon dioxide with Hg $6(^3P_1)$ atoms.

The present study arose from the observation that carbon dioxide, in the presence of mercury vapor, undergoes a slow decomposition when exposed to 2537-Å radiation, contrary to previous findings (7). The dissociation of CO_2 into $CO + O$ requires at least 126.7 kcal/mole, whereas only 112.2 kcal/mole are available from a simple collision of the second kind with Hg $6(^3P_1)$ atoms. The additional energy needed for the reaction to proceed could be supplied either from the primary formation of HgO, or from reactions involving energy accumulation, such as the formation of excited carbon dioxide molecules. In the present study, emphasis has been placed on the nature of the primary reactions involved in the decomposition. The investigation forms part of a general program on primary processes in mercury photosensitization.

EXPERIMENTAL

The reaction was studied under static conditions. For the reaction cell, a cylindrical tube of Vycor 7900 glass was used, 120 mm in length and 26 mm in diameter, with flat windows of Vycor 7910 glass at each end. The side arm connecting the cell to the high-vacuum system was placed near one window, in order that the cell could be inserted axially into the coils of a spiral Hanovia SC-2537 mercury resonance source. The lamp-cell assembly was positioned in a water thermostat, maintained at 30°, in such a fashion that the end windows were opposite ports of window glass in the sides of the thermostat. Thus, in addition to the radiation from the spiral lamp, the cell could be independently irradiated at both ends by sources external to the thermostat. For these external sources, Hanovia Biosteritron resonance lamps were employed.

After each exposure, gases non-condensable in liquid nitrogen were transferred to a gas burette, and subsequently analyzed by gas–liquid partition chromatography (G.L.P.C.). Between experiments the cell was cleaned in hot nitric acid, rinsed with distilled water and ethanol, and dried at 200°. A reaction was also performed by using a ^{202}Hg electrodeless discharge source. A Vycor 7910 glass cell attached to a small mercury pump and to a 1-liter bulb was filled with CO_2, sealed off, and irradiated with the above lamp. After the reaction was completed the cell containing the HgO was pumped for 12 hours. Then the HgO was dissolved in very dilute HCl, plated out on copper wire, distilled, and collected *in vacuo* into a small break-seal. Finally the isotopic composition of the recovered mercury was determined by mass spectrometry.

The carbon dioxide used was Matheson 'Bone-Dry' grade, with stated purity of 99.8%. It was subjected, before use, to several low-temperature distillations, after which no impurities could be detected by G.L.P.C. The nitrogen (Canadian Liquid Air 'Purified Grade', with minimum purity of 99.9%) was passed through a quartz furnace containing copper filings at 500°, and several liquid nitrogen traps, before use.

RESULTS

The products of the reaction were carbon monoxide and mercuric oxide. Molecular oxygen was not detected in any of the runs. In Fig. 1, the micromoles of CO formed, as a function of CO_2 pressure, are given for runs of 150 minutes in duration. The percentage conversion at the lowest pressure, 0.6 mm, was 28.7%. At 13.3 mm, only 0.5% of the CO_2 was decomposed.

The absorbed light intensity at 2537 Å, as determined with propane as actinometer (8), was 3.34×10^{-5} einstein/minute. The maximum rate of CO formation occurred at a CO_2 pressure of 0.6 mm; 2.87 μmoles of CO were formed in 150 minutes of exposure. This rate would correspond to a quantum yield of 5.7×10^{-4} moles/einstein. Of course, at a pressure of 0.6 mm, only a small fraction of the excited mercury atoms are quenched. It is estimated that the actual quantum yield of CO formation under these conditions is at least 0.01.

The addition of nitrogen was found to influence markedly the rate of CO formation. The effect is shown in Table I. The runs with and without added nitrogen were carried out under identical conditions. The highest rate increase observed was 58%, in the case of a mixture of 3.74 mm CO_2 and 7.4 mm N_2.

The fact that the rate of CO formation rapidly decreases with increasing substrate pressure, as shown in Fig. 1, would suggest that excited CO_2 molecules are involved in

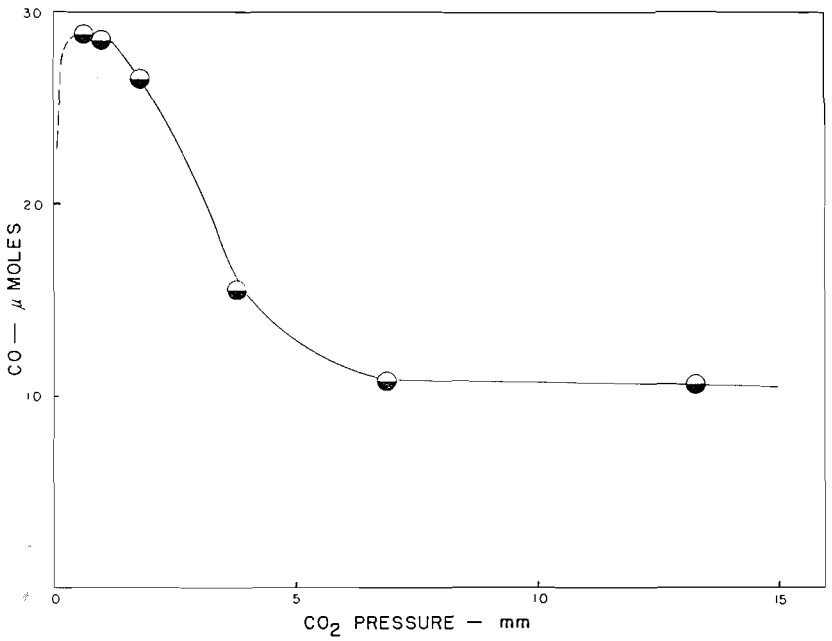

FIG. 1. Micromoles of CO formed for runs of 150 minutes in duration, as a function of substrate pressure.

TABLE I

The effect of nitrogen on the rate of CO formation in the reaction of CO_2 with Hg $6(^3P)$ atoms

the reaction, and that these are suffering progressive collisional deactivation with increasing CO_2 pressure. From Table I, which exhibits the marked effect of nitrogen on the rate of CO formation, the participation of metastable Hg $6(^3P_0)$ atoms is suggested. If the CO product is formed by collisions between excited CO_2 molecules and Hg $6(^3P_1)$ atoms and/or Hg $6(^3P_0)$ atoms, one would expect the rate to depend upon the square of the absorbed light intensity. An alternative or additional process which could be operative is that of stepwise excitation. Mercury resonance lamps are good sources of the 4047-Å line, which is absorbed by Hg $6(^3P_0)$ atoms to form the $7(^3S_1)$ state. Direct collisional deactivation of $7(^3S_1)$ atoms to the ground, $6(^1S_0)$, state would release 7.95 ev, or ca. 183 kcal/mole. For the afore-mentioned reasons, it appeared particularly instructive to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

examine the effect of light intensity and 4047-Å radiation on the rate of CO formation.

The dependence of the rate upon light intensity was determined by the use of two bromine filters of different transmission characteristics. Both filters were doughnut types, 110 mm in length, 35 mm I.D., and 60 mm O.D. They were designed to fit axially over the reaction cell and within the coils of the spiral resonance lamp. Both filters were filled with bromine vapor at 170 mm. Their transmission characteristics were determined both spectrophotometrically and by propane actinometry (8). Filter I was made of Vycor 7910 and filter II of Vycor 7900. Their characteristics were as follows: filter I, transmitted 55.7% at 2537 Å, and less than 1% at 4047 Å; filter II, transmitted 17.5% at 2537 Å, and less than 1% at 4047 Å.

In Table II the results are given for six experiments performed with decreased light

TABLE II

The relation between μmoles of CO formed and incident intensity at 2537 Å, for runs of 150 minutes in duration

				Mean = 1.8±0.1

intensities, achieved by inserting the filters as indicated. In each case, the results are compared with those without filter. In the last column is given the order of dependence of the rate on the intensity of the 2537-Å radiation. The mean value of the exponent is 1.8±0.1. It should also be noted from Table II that the near second-order dependence of the rate upon the light intensity also obtains in the presence of added nitrogen.

The effect of 4047-Å radiation on the reaction was studied by placing Biosteritron sources at the ports of the thermostat. By this means the cell could be exposed at both ends to the radiation transmitted through the window glass in the thermostat ports. Only radiation exceeding ca. 3800 Å in wavelength could thereby enter the cell.

In Table III is shown the effect, on the rate of CO formation, of dosing the reaction cell at each end with 4047-Å radiation, while the normal reaction is in progress. It can be seen that the 4047-Å radiation increases the rate by ca. 22% for the optimum CO_2–N_2 mixture, for an incident intensity at 2537 Å of 3.3×10^{-5} einstein/minute. The effect appears to be much larger at lower intensities of the resonance radiation, as shown in the last run listed in the table, where a 53% increase in rate is achieved.

In order to confirm that the reaction was indeed mercury sensitized, one experiment was performed at 5°. Under these conditions there was a drastic decrease in reaction rate, indicating the dependence of the reaction on the presence of mercury vapor.

†For runs of 150 minutes in duration.

Finally, one 30-hour run was made with $P_{CO_2} = 1.82$ mm, using a ^{202}Hg electrodeless discharge source. Mass spectrometric analysis showed that the ^{202}Hg content of the HgO product was 31.6%, compared to the normal abundance of 29.8%.

DISCUSSION

From Fig. 1, it is apparent that the reaction of carbon dioxide with Hg $6(^3P)$ atoms is a remarkable example of collisional deactivation. In the pressure region studied, i.e. 0–15 mm, the rate of CO formation, R_{CO}, falls off rapidly with increasing substrate pressure, despite the fact that the fraction of the incident light energy transferred to the substrate by quenching is simultaneously rising. Combining the foregoing with the near-second-order dependence of R_{CO} on light intensity, as shown in Table II, would suggest strongly a mechanism involving the reaction of excited CO_2 molecules with Hg $6(^3P)$ atoms:

$$Hg + h\nu \rightarrow Hg^* \quad [1]$$

$$Hg^* \rightarrow Hg + h\nu \quad [2]$$

$$Hg^* + CO_2 \rightarrow CO_2^* + Hg \quad [3]$$

$$CO_2^* + CO_2 \rightarrow 2CO_2 \quad [4]$$

$$CO_2^* + Hg^* \rightarrow CO + Hg + O, \quad [5]$$

where $Hg^* = Hg\ 6(^3P_1)$ and CO_2^* represents an energy-rich CO_2 molecule. It is assumed that the CO_2^* which reacts in [5] possesses at least (126.7−112.2) kcal/mole of excess energy.

Since the quantum yield, Φ_{CO}, is very small for the reaction, i.e. less than 0.01, we may reasonably assume that step [5] does not appreciably alter the steady-state concentrations of Hg^*. With this approximation we obtain the following expression for the rate of CO formation:

$$R_{CO} = K\frac{(CO_2)}{A+B(CO_2)+C(CO_2)^2+D(CO_2)^3}, \quad [a]$$

where $K = K_3K_5I_a^2$, $A = K_2K_5I_a$, $B = K_2^2K_4 + K_3K_5I_a$, $C = 2K_2K_3K_4$, $D = K_3^2K_4$, and I_a is the absorbed light intensity at 2537 Å. The mechanism therefore predicts that R_{CO} will (*a*) decrease rapidly with increasing substrate pressure and (*b*) vary nearly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

directly with I_a^2, in qualitative accordance with our findings. Alternately step [5] may be replaced by

$$CO_2^* + CO_2^* \rightarrow CO_2 + CO + O. \qquad [5']$$

An approximate solution of the steady-state equations with [5'] replacing [5] yields an expression similar to [*a*]. Thus both steps [5] and [5'] are qualitatively consistent with the observed kinetics for pure carbon dioxide. In this connection, it should be noted that the absence of molecular oxygen precludes the possibility of O_2 formation in [5'].

At low substrate pressure other processes such as radiative transition and(or) deactivation at the wall may also occur.

The low isotopic enrichment of the HgO formed in the reaction gives additional evidence that the process

$$CO_2 + Hg^* \rightarrow CO + HgO$$

does not occur to an appreciable extent.

The electronic state of the excited carbon dioxide is probably a metastable triplet. Indeed the first known electronic state above the ground state is triplet π, with an excitation energy estimated not to exceed 130 kcal/mole (9, 10). Now for reaction [5] to be energetically possible, CO_2^* must possess 14.5 kcal/mole of excess energy. It is pertinent here to note that Walsh (11, 12) has assigned to CO_2 a $^3B_2$ state at 30–40 kcal/mole above the ground state. For this state to participate in the present reaction, CO would have to be formed by [5] rather than [5'].

The effect of added nitrogen on R_{CO} can readily be explained by the production of metastable Hg $6(^3P_0)$ atoms (Hg^0) and by their subsequent reactions with CO_2:

$$CO_2 + Hg^0 \rightarrow CO_2^* + Hg \qquad [6]$$

$$CO_2^* + Hg^0 \rightarrow CO + Hg + O. \qquad [7]$$

Klumb and Pringsheim (13, 14) have shown that the concentration of Hg^0, in the presence of nitrogen, may be expressed by the relation

$$(Hg^0) = AP/[1+BP+CP^2],$$

where A, B, and C are constants, and P is the nitrogen pressure. The maximum value of (Hg^0) was reported to occur at a nitrogen pressure of 6 mm. We observed a maximum 1.58-fold increase in R_{CO} (Table I) when 7.4 mm N_2 was added to 3.74 mm CO_2, which would correspond to a 2.4-fold increase if we compare it to R_{CO} at a CO_2 pressure equal to the total pressure of CO_2 and N_2 (approx. 11 mm).

Owing to the higher lifetime for the metastable state, the concentration of Hg $6(^3P_0)$ atoms should be about 1 or 2 orders of magnitude higher than the concentration of Hg $6(^3P_1)$ atoms. We may therefore infer that the metastable species show much lower reactivity in the present system than do Hg $6(^3P_1)$ atoms.

In Table III, evidence is presented for a positive contribution of 4047-Å radiation to the rate of decomposition of CO_2–N_2 mixtures. The results with filter I in position are especially interesting. Here the 4047-Å radiation from the spiral source has been reduced to ca. 1% of its original value by the filter. When 4047-Å radiation is then introduced at the ends of the cell, the value of R_{CO} increases by 53%. It would appear unwise at this time to attempt to write a mechanism for this effect. We may note that quenching by CO_2 of Hg $7(^3S_1)$ atoms could result in the mercury being converted to any of the three triplet states, or to the ground state. Certainly the phenomenon merits more detailed study.

CONCLUSIONS

As a result of the present investigation, it may be concluded that carbon dioxide undergoes a slow decomposition when sensitized by either Hg $6(^3P_1)$ or Hg $6(^3P_0)$ atoms. The observed kinetics dictate the participation in the reaction of excited CO_2 molecules, presumably in metastable triplet states. Apart from its inherent interest as an example of a mercury-photosensitized reaction which is second order in the light intensity, the system might serve as a chemical method for monitoring Hg $6(^3P_0)$ atoms. Finally, the present study has provided evidence of reaction associated with higher states of mercury which have been generated *in situ* by stepwise excitation.

PRIMARY QUANTUM YIELD DETERMINATION BY INTERMITTENT ILLUMINATION IN THE REACTION OF METHANOL VAPOR WITH Hg 6($^3P_1$) ATOMS[1]

ARTHUR R. KNIGHT AND HARRY E. GUNNING

ABSTRACT

The decomposition of methanol vapor by Hg 6($^3P_1$) atoms has been studied under intermittent illumination conditions, in a static system at 25° C. The behavior of the NO-inhibited reaction under intermittent illumination has also been examined.

For the pure substrate at a pressure of 50 mm, the quantum yield of hydrogen formation, $\Phi(H_2)$, was found to rise steadily toward unity with decreasing light period (t_L). The maximum value of $\Phi(H_2)$ at a given t_L could only be obtained if the dark period (t_D) exceeded 100 mseconds. At the shortest t_L studied, 0.156 msecond, $\Phi(H_2)$ was 0.89 compared with the steady illumination value, at zero extent of reaction, of 0.46. A linear relation was found to obtain between $\Phi(H_2)$ and log (t_L) at a given t_D. Extrapolation showed that $\Phi(H_2)$ would be unity at t_L = 0.040 msecond.

For a mixture of 4.8 mm of NO and 50 mm of CH_3OH, $\Phi(CH_3ONO)$ was found to rise from its steady illumination value of 0.14 to 0.27 at a sector speed of 300 r.p.m., with a dark/light ratio of 20. At higher speeds the quantum yield decreased again.

From the study it is concluded that the primary process of H atom detachment is at least 89% efficient, and that the primary quantum yield is likely unity. The fact that the quantum yield under steady illumination is only 0.46 is attributed to the consumption of H atoms by radical addition processes of which the most probable is the addition of H to CH_2OH. For the inhibited reaction the low value of $\Phi(CH_3ONO)$ under steady illumination is ascribed to the abstractive attack of CH_3O on NOH.

The kinetic effects of intermittent illumination are discussed, in the light of the results. It is concluded that the technique should be of considerable value in primary process studies in mercury photosensitization.

INTRODUCTION

In a previous study (1) of the reaction of methanol vapor with Hg 6($^3P_1$) atoms, it was shown that the quantum yield of hydrogen formation, extrapolated to zero exposure duration, $\Phi(H_2)$, was 0.46. The fact that this value is not unity could be due to the reactions:

$$H + H \xrightarrow{M} H_2, \qquad [1]$$

$$H + CH_2OH \rightarrow CH_3OH, \qquad [2]$$

$$H + CH_3O \rightarrow CH_3OH. \qquad [3]$$

Since, at the substrate pressure used (50 mm) in the previous study (1), CH_3O was shown to react almost exclusively with the substrate to form CH_2OH, it is likely that [2] is the most important of the above three steps competing for H atoms with the abstraction reaction:

$$H + CH_3OH \rightarrow H_2 + CH_2OH. \qquad [4]$$

For the reaction inhibited by NO, the steps

$$CH_3O + NOH \rightarrow CH_3OH + NO \qquad [5]$$

and

$$CH_3O + CH_3ONO \rightarrow CH_3OH + CH_2O + NO \qquad [6]$$

have been suggested (1) to explain the fact that $\Phi°(CH_3ONO)$ was found to be less than unity. The rates for reactions [1]–[3] will be proportional to the products of the con-

[1]*Manuscript received July 21, 1961.*
Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta.

centrations of the radicals involved. Similarly, for the inhibited reaction, (NOH) will vary with (H), and therefore the rate of step [5] will also depend upon a product of radical concentrations.

Under intermittent illumination, with progressive shortening of the light period (t_L), it should be possible to interrupt the light beam before the radical concentrations have reached their steady-state values. In this region, $\Phi(H_2)$ should rise sharply with decreasing t_L, provided that the radical concentrations are allowed to decay to zero during the dark period (t_D). Hence it is also necessary to study the effect of t_D on $\Phi(H_2)$. With decreasing t_L, $\Phi(H_2)$ should approach unity, if (*a*) the primary reaction between Hg $6(^3P_1)$ and CH_3OH shows perfect efficiency for detachment of H atoms, and (*b*) steps [1]–[3] include the processes responsible for the disappearance of H atoms without concomitant H_2 formation.

In the present communication are reported the results of varying t_L and t_D, on $\Phi(H_2)$ for the decomposition of pure CH_3OH, and on $\Phi(CH_3ONO)$ for the reaction in the presence of NO.

EXPERIMENTAL

The purification and storage of the methanol, the all-quartz high-vacuum system employed, and the analytical techniques have been previously described (1). After the reaction cell had been filled, it was placed in one of the two devices detailed below.

For the runs with pure substrate with t_D = 103 and 67 milliseconds (msec), and for the studies on the inhibited reaction, the sector apparatus consisted of a Hanovia, 87A45, mercury-in-quartz resonance tube, in a cylindrical housing, with a 5-cm diameter window covered with a Vycor 7910 filter. A rotating metal disk with an adjustable sector aperture was interposed between the light source and a shield with a 5-cm diameter opening, directly behind which the cell was placed. The disk was mounted on the shaft of a variable speed motor, of which the speed of rotation could be controlled to $\pm 4\%$. The r.p.m. of the sector was checked during each run by a stroboscope. The disk consisted of two metal plates from which two 90° sectors had been cut. The sector angle was determined by closing the plates on a steel rod of accurately known diameter, placed at a known distance from the center. One of the two resulting apertures was closed for all runs except those at long t_L.

For the runs with t_D = 80 and 160 msec, the lamp (Engelhard 11639) was placed in a rectangular housing with a 6-cm^2 opening covered by a Vycor 7910 filter. The light beam was chopped by two overlapping disks mounted between two $\frac{3}{8}$-in. plates, connected by a gear chain, and driven by a constant speed motor. One disk, rotating at 3000 r.p.m., had one sector aperture set accurately as described above. The other sector disk revolved at 375 r.p.m. and had two approximately 30° apertures. The beam was partially collimated by a 6-cm diameter opening, placed between the disks and the cell. The cell was located behind the shield already described. The rotations of the disks were so synchronized that the more slowly rotating sector uncovered the entire cell face as the high speed disk made each exposure. With both 30° sector apertures operative, t_D was 80 msec; by blocking one of the apertures, t_D = 160 msec was obtained.

Light intensities were determined with propane as actinometer (2), using the differential method of Back (3) for obtaining the steady-state value for dH_2/dt.

At the end of each run, the products non-condensable in liquid nitrogen were analyzed by G.L.P.C. on a molecular sieves column. The hydrogen content of this gas was never less than 96 mole%, with the remainder consisting of CO and CH_4. For the runs with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$t_L < 0.5$ msec, the $(CO+CH_4)$ content was less than 0.5 mole%. The analysis for methyl nitrite has been previously described (1).

RESULTS

During the course of the investigation various minor modifications were made in the sector system which resulted in changes in the absorbed light intensity at 2537 Å. For the range of values of the sector parameters reported here, it was found that $\Phi(H_2)$ was independent of exposure duration at least to a total quantum input of 5 microeinsteins. In Fig. 1, $\Phi(H_2)$ is shown as a function of log (t_L) for four series of runs at dark periods of 67, 80, 103, and 160 mseconds. In all cases, the cell was filled with pure CH_3OH at a pressure of 50 mm. For the runs with $t_D = 67$ and 103 mseconds, the single sector was used, with absorbed light intensities of both 0.91 and 1.06 microeinsteins/minute, and net exposure durations of 4.3–5.0 minutes. The series with $t_D = 80$ and 160 msec were performed with the double sector apparatus. Here, absorbed light intensities of 1.25, 2.19, and 3.25 microeinsteins/minute were used, and net exposure durations of 0.43–1.0 minutes.

From the plot of $\Phi(H_2)$ vs. log (t_L) in Fig. 1, it is apparent that $\Phi(H_2)$ rises steadily

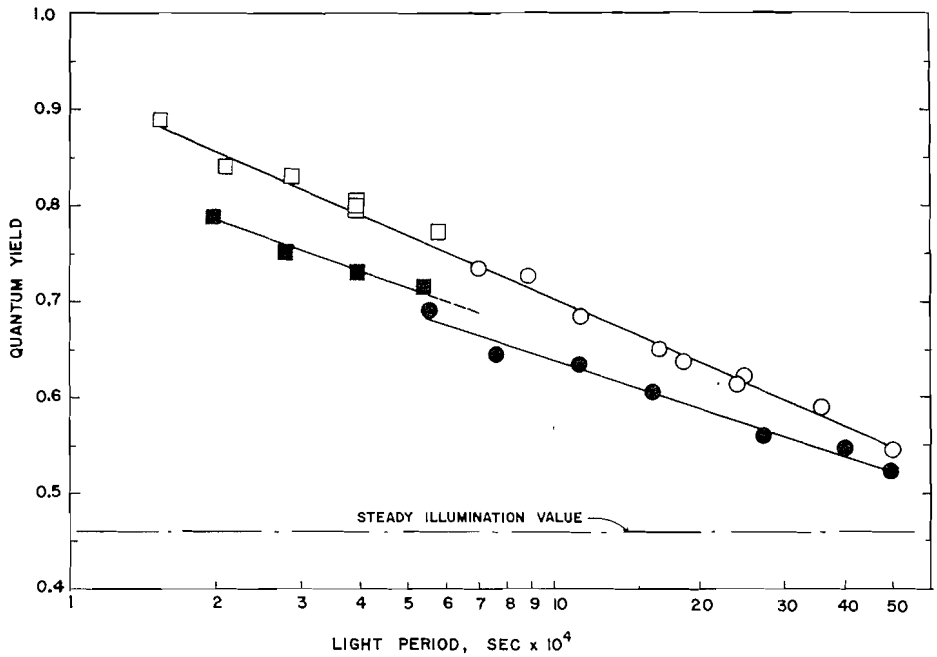

FIG. 1. The quantum yield of hydrogen formation at a methanol pressure of 50 mm, as a function of the logarithm of the light period for dark periods of □ 160, ■ 80, ○ 103, and ● 67 milliseconds.

above its steady illumination value of 0.46 with decreasing t_L, at least for t_L values less than 5 mseconds. Furthermore, from Fig. 1, the effect of t_D on $\Phi(H_2)$ is to be noted. For maximum values of $\Phi(H_2)$ at a given t_L, it is necessary that t_D be at least ca. 100 mseconds. In these runs the maximum value obtained for $\Phi(H_2)$ was 0.89, with $t_L = 0.156$ msecond and $t_D = 160$ mseconds. The absorbed light intensity was 1.25 microeinsteins/minute, and the net exposure duration was 1.00 minute. The t_L value of 0.156 msecond was the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

shortest light pulse which could be obtained with the sector equipment used. Since $\Phi(H_2)$ seems to be a linear function of log (t_L), the upper curve in Fig. 1 was linearly extrapolated to $\Phi = 1.00$. The corresponding t_L value was 0.040 msecond.

For the inhibited reaction, a short series of runs was performed with a constant t_D/t_L ratio of 20, in which t_L was varied from 6.50 to 2.79 mseconds. The reaction mixture consisted of 4.8 mm of NO and 50 mm of CH_3OH. The net exposure duration was 4.75 minutes. In Fig. 2, $\Phi(CH_3ONO)$ is shown as a function of the r.p.m. of the sector. The

maximum value obtained for $\Phi(CH_3ONO)$ was 0.272, with $t_L = 4.61$ mseconds. The steady illumination value for $\Phi(CH_3ONO)$ was 0.140.

DISCUSSION

For the decomposition of pure CH_3OH, the present study has shown that the primary process is of considerably higher efficiency than would be indicated by the $\Phi^\circ(H_2)$ value of 0.46. Since the highest value obtained for $\Phi(H_2)$ was 0.89, the primary process must have an efficiency of at least 89%. Furthermore, assuming the validity of a short linear extrapolation of the upper $\Phi(H_2)$ vs. log (t_L) line in Fig. 1, we may conclude that $\Phi(H_2)$ would be unity for a t_L of 0.040 msecond.

The observed increase toward unity of $\Phi(H_2)$ with decreasing t_L supports the hypothesis that radical addition reactions involving H atoms, such as steps [1]–[3], are responsible for the fact that $\Phi^\circ(H_2)$, under steady illumination, is considerably less than unity.

One surprising result of this study was the relatively long dark period required to achieve the maximum value of $\Phi(H_2)$ at a constant t_L. The data, however, clearly indicate that there must be at least 100 mseconds between light pulses for optimum $\Phi(H_2)$ values to be obtained. If the 100-msecond dark interval does not represent the actual time required for the radical concentrations to decay to negligible values, then an alternate explanation might be that radiation partitioning to reaction products is occurring in the light period, and the dark period serves to allow these products to diffuse away from the reaction zone. From the previous study (1), formaldehyde would be the most reactive primary product present in the reaction zone. The presence of CO would be evidence of the secondary decomposition of this material. However, our analyses show that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

total yields of ($CO+CH_4$) do not exceed 0.5 mole% of the non-condensable gas runs with t_L less than 0.5 msecond. It therefore seems unlikely that product diffusion is a significant factor in determining the magnitude of the optimum dark period. Now at the onset of the dark period, the radicals present in greatest abundance would likely be H and CH_2OH. The H atoms would diffuse much more rapidly than the CH_2OH radicals from the reaction zone, and this diffusive separation would favor reaction [4] over [2], with a resulting increase in $\Phi(H_2)$.

The behavior of $\Phi(CH_3ONO)$ as a function of sector disk speed, as shown in Fig. 2, again illustrates the effects of both t_L and t_D on the radical concentrations. With decreasing t_L, the concentrations of both CH_3O and NOH would be reduced, rendering step [5] less probable, and thus favoring the formation of CH_3ONO. This accounts for the increasing $\Phi(CH_3ONO)$ with r.p.m. of the sector, as shown in Fig. 2. The decline in nitrite yield at high sector speeds is attributable to the decreasing t_D, resulting in a finite radical concentration being present at the beginning of the next light pulse.

CONCLUSIONS

As a result of the present study it can be concluded that the primary process of H atom detachment in the reaction of methanol vapor with Hg $6(^3P_1)$ atoms is at least 89% efficient, and that it is likely that the primary quantum yield is in fact unity. The fact that $\Phi^\circ(H_2)$ is only 0.46 under steady illumination conditions would appear to be due to radical addition reactions involving H atoms, of which the most probable is the addition of H atoms to CH_2OH radicals.

For the NO-inhibited reaction, it is concluded that the low value for $\Phi(CH_3ONO)$ under steady illumination is due mainly to the abstractive attack of CH_3O on NOH.

As a general conclusion from the present study, the rotating sector method should prove of considerable value in primary process studies in mercury photosensitization. Similar studies on the reactions of Hg $6(^3P_1)$ atoms with ethanol and isopropanol will be published shortly.

ACKNOWLEDGMENTS

The authors would like to express their appreciation to Dr. W. F. Allen of this laboratory for valuable assistance and advice. Our program was supported in part by the National Research Council under Term Grant No. NRC T-162 (Gunning). This support is very gratefully acknowledged.

THEORETICAL STUDIES ON THE ELECTRONIC SPECTRA OF SUBSTITUTED AROMATIC MOLECULES

PART I. THE INTRAMOLECULAR ELECTRON TRANSFER MODEL[1]

J. E. Bloor

ABSTRACT

A simple empirical model, based on molecular orbital theory without configuration interaction, is used to interpret the K band transitions of substituted aromatic molecules as involving intramolecular electron transfer between substituent and hydrocarbon. For electron-donating substituents, such as amino, methoxyl, chloro, bromo, and iodo, the transfer is from substituent to hydrocarbon, while for electron-attracting substituents, such as nitro, formyl, acetyl, and cyano, the charge transfer is from hydrocarbon to substituent. Such a treatment is successful for "long field molecules" (benzene, diphenyl, terphenyl, styrene, and stilbene), but for "round field" molecules agreement between experiment and theory was achieved only for electron-donating substituents. The theory, like less empirical theories, overestimates the relative effect of a substituent in the 2-position compared with substitution in the 1-position.

In molecular orbital (MO) calculations of the electronic transitions in conjugated molecules the importance of configuration interaction is well recognized (1–4). However, for all but the simplest molecules it has been the custom to restrict, quite arbitrarily (4), the configuration interaction to singly excited configurations and to introduce empirically the values of certain interaction integrals by recourse to experiment (5, 6). Because of this empirical element in self-consistent field calculations and the rather large amount of labor necessary for the carrying out of such calculations it is still of interest to see whether it is possible to interpret the electronic spectra of aromatic molecules containing polar substituents by some simple model without configuration interaction (CI), in which the neglect of CI might be compensated for by empirical adjustment of the parameters of the adopted model. Such a model is that used previously (7–10) to calculate the transition energy of the K bands of substituted benzenes as being due to an electron transfer between substituent and benzene. We have found it possible to extend this interpretation to the K band spectra of long field molecules (11), substituted in the 4-position by the nitro, the cyano, the acetyl, and the formyl groups and for both long field and round field molecules substituted by the electron-donating amino, methoxyl, bromo, chloro, and iodo groups. Such an interpretation of the K band spectra is similar to the qualitative theory of Burawoy (12–14), which, however, assumes that electron transfer in the ground state occurs only by an inductive mechanism.

METHODS AND RESULTS

The details of the method have been described elsewhere (7–10). The substituted hydrocarbon is regarded as being built up from two sets of energy levels, those of the parent hydrocarbon (R—H) and those of the substituent (S—H). The difference between the energy levels of the isolated systems R—H and S—H and the system R—S are calculated by a perturbation method. The energy of the intramolecular charge transfer band (E_1) is then given, for electron-attracting substituents, by the difference in energy between the highest occupied perturbed level of fragment R− and the lowest unoccupied perturbed level of fragment S, eq. [1]. For electron-donating substituents the energy

[1]*Manuscript received July 7, 1961.*
Contribution from the Chemistry Division, British Columbia Research Council, Vancouver 8, B.C.

of the intramolecular charge transfer band is given by the difference (E_2) between the energy of the highest perturbed occupied level of fragment $-$S and the energy of the lowest unoccupied perturbed level of fragment R$-$, eq. [2].

$$[1] \qquad E_1 = [(V_S - H_R)^2 + 4C_{V_S}^2 C_{H_R}^2 \beta_{R-S}^2]^{\frac{1}{2}},$$

$$[2] \qquad E_2 = [(V_R - H_S)^2 + 4C_{V_R}^2 C_{H_S}^2 \beta_{R-S}^2]^{\frac{1}{2}}.$$

H_R and H_S are the energies of the highest unperturbed occupied molecular orbitals (MO's) of R—H and S—H respectively. V_R and V_S are the energies of the unperturbed unoccupied MO's of R—H and S—H respectively. The atomic orbital (AO) coefficients C_{H_R}, C_{H_S}, C_{V_R}, C_{V_S}, are the values in the MO's of energies H_R, H_S, V_R, V_S at the atoms at which the connecting link between R—S is formed. H_S has previously (7–10) been taken as the ionization potential of either the corresponding methyl derivative (Me—S) or hydrogen derivative (H—S). However, in the hydrocarbon H—S the substituent S is attached to a trigonally hybridized carbon atom which is more electron attracting than either a tetrahedrally hybridized carbon atom or a hydrogen atom, so values of H_S were obtained by fitting eq. [1] to the experimental results for the K bands of benzene derivatives. The values so obtained are given in Table II.

V_S has previously been taken as the difference between the ionization potential and the energy of the R band transition of the corresponding methyl derivative (Me—S) (7). This assumption is open to the objection that both the repulsion forces and the changes in the Hamiltonian on going from the ground state to the excited state are different for R bands than for K bands, since the charge distribution in the excited state is different for the two transitions. Therefore empirical values for V_S were obtained by adjusting its value so that eq. [1] reproduced the experimental values of the K band of benzene derivatives. These values are given in Table II. For the nitro group the value which fitted nitrobenzene ($V_S = -4.4$ ev) gave poor results for the other derivatives so $V_S = -5.1$ ev was adopted as giving the best over-all results.

V_R has previously (7) been taken as the difference between the observed energy of the K band transition of R—H and its ionization potential (H_R), i.e. the K band of the hydrocarbon R—H is assumed to arise from a configuration in which an electron is excited from the highest filled MO to the lowest unoccupied MO. Such an assumption, however, always results in an electron transfer (ET) configuration of higher energy than the parent hydrocarbon K band for all values of H_S consistent with the limitation (necessary to explain the reduction of the ionization potential of R—H on substitution by an electron-donating S) that H_S should be less than H_R. V_R was therefore regarded as an empirical parameter and was obtained by equating E_2, calculated by eq. [2], to the observed K band spectra. The results of Table IV are those obtained by using such average values given in Table I. Such an adjustment of parameters is made very simple by the fact that eq. [2] is a hyperbola of the type $x^2 - b^2 = y^2$ where x is E_2 and y is $(H_S - V_R)$ and the range of values of x in which the transitions under discussion lie are such that a plot of E_2^2 against $(H_S - V_R)^2$ is linear for a given series of substituents with the same value of C_{H_S}. The empirical values of V_R so obtained are in the same relative order as those obtained by using ionization potential and ultraviolet data (Table I).

The AO coefficients C_{H_R} and C_{V_R} were obtained by LCAO calculations. C_{H_S} and C_{V_S} were given values between 0.5 and 1.0 consistent with giving the best fit between experiments and theory, Nagakura's (7–10) values being adopted wherever possible. The values used are given in Tables I and II. The values of E_1 and E_2 calculated by inserting

†Values used by Nagakura.

the parameters of Tables I and II in eq. [1] and [2] are compared with the available experimental data in Tables III and IV. Table V compares results for nitro compounds with $V_S = -5.5$ ev with those of Nagakura (8) with $V_S = -5.1$ ev. β_{R-S} is given the value 3 ev for all substituents (7–10).

DISCUSSION

The calculated values obtained by using the parameters of Tables I and II in eq. [1] and [2] are compared with experimental data for K band absorption in Tables III, IV, and V. In general, the calculated values are in fairly good agreement with the experimental ones.

For the electron-attracting groups the experimental data are not at the moment extensive enough to carry out a satisfactory statistical test of the validity of the simple charge transfer model. However, it can be seen from Table III that once the appropriate choice of H_R and V_S has been made the difference in K band transition energy of the nitro, acetyl, formyl, and cyano derivatives of benzene and diphenyl is predicted correctly within 0.03 ev (i.e. within 30° A at 3100° A). Using $V_{NO_2} = -5.1$ ev the K band positions of seven nitro compounds have been calculated (Tables IV and V) and these give a correlation coefficient of 0.850 on comparison with the observed values. The agreement would be even better if the experimental results (Table V) for 1-nitro-2-methyl-ethylene and 1-nitro-4-methyl-butadiene were corrected for the bathochromic effect of the methyl group (0.1 ev) and the solvent effect of the ethanol, the results being taken from (8).

The use of $V_{NO_2} = -5.1$ ev can be seen to give better agreement with experiment than the original value of $V_{NO_2} = -5.5$ ev used by Nagakura (8). The theory predicts well the effect of increasing the size of the conjugated system attached to the nitro group. This is shown in Fig. 1 where the experimental and predicted values are plotted against the size of the conjugated system. The results of Table V also give a theoretical basis to the empirical rule of Burawoy (14) that the larger the conjugated system (a good measure of the length of the conjugation is the K band transition energy of the hydrocarbon) the

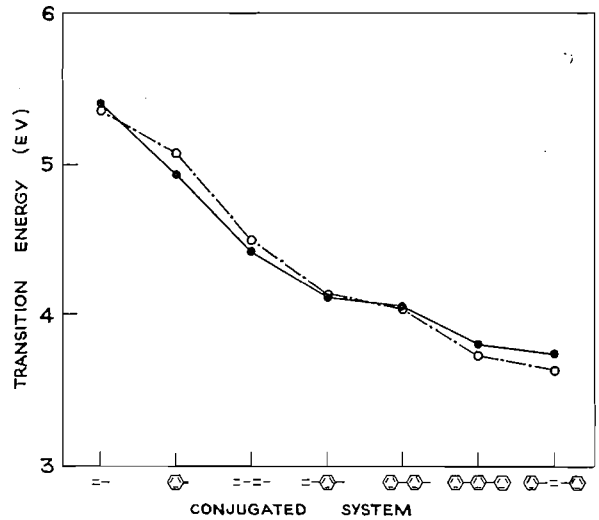

FIG. 1. Comparison between calculated (-·-o-·-) and observed (-●-) K band transition energies of conjugated nitro compounds.

smaller the effect of a given substituent. Thus the magnitude of the transition energy change brought about by the nitro group grows smaller as we descend Table V from ethylene (where the change on substitution is 2.03 ev) to stilbene (where it is only 0.52 ev).

The free valence (15) has often been taken as a measure of the conjugating power of a hydrocarbon with a substituent and either this or the proportional quantity, the self-polarizability (18), is related to the K band transition energy change on substitution. The values of the free valence and the observed transition energy change recorded in Table V show that this is only a very rough approximation. In particular the free valence predicts that the conjugating power of diphenyl and terphenyl in the para position should be the same and that stilbene should have a conjugating power greater than benzene when in fact the nitro group has the least effect on the K band transition energy of stilbene as is predicted on the "charge transfer" model.

In the case of the round field molecules, naphthalene and anthracene, it can be seen from Table III that agreement between experiment and theory is poor. Whereas it is always found experimentally that substitution in the 1-position of naphthalene produces a bigger bathochromic shift of the K band than substitution in the 2-position, the simple charge transfer theory predicts the opposite for both electron-attracting and electron-donating substituents. No explanation for this breakdown can be offered but it should be pointed out that even the most sophisticated calculations carried out to date (19), which include limited configuration interaction, overestimate the effect of the effect of the substituent in the 2-position of naphthalene. It is possible that calculations using self-consistent field ground state orbitals may remove this deficiency.

For electron-donating substituents which may be regarded as monatomic substituents the available experimental data is much more plentiful than for electron-attracting substituents. For the K bands of long field molecules the band maxima of both the parent hydrocarbon and the substituted compound are quite sharp and the band envelopes are, with the exception of benzene and halogeno-benzenes, fairly symmetrical. This means

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

that the changes in transition energy can be measured to within 50–100 cm^{-1} (i.e. to within less than 0.1 ev) whereas for round field molecules the K band is much broader and often contains fine structure which is altered on substitution (19, 20).

In Table III are recorded 29 comparisons between experimental and theoretical transition energies. The relationship between calculated and observed transition energies gives a correlation coefficient of 0.951 (this includes the particularly bad result for 4-methoxy-stilbene but omits the results for 2-substituted naphthalenes since, as has been discussed above, it is known the theory is incorrect in its predictions for these latter compounds).

This high correlation coefficient is most unexpected for such a crude theory which neglects completely the interaction between the highest occupied level of the parent hydrocarbon and the corresponding level in the substituent. This interaction on the LCAO model is regarded as the main effect of the substituent (21). It seems likely that the empirical element introduced into the theory by the adjustment of the parameters to fit experimental data and the neglect of configuration interaction may compensate for this neglect.

Both the charge transfer and the LCAO methods involve a transfer of electrons from the electron-donating substituent to the parent hydrocarbon; however, comparison of similar calculations show that the LCAO method consistently predicts a greater charge transfer in the ground state than the charge transfer method when the parameters are chosen to give agreement with experiment. It may therefore be possible to decide which is the better model by comparison between theoretical calculations and experiments on ground state properties (heats of combustion, n.m.r. chemical shifts, and infrared stretching frequencies and intensities). It has recently been reported (22) that the charge transfer method gives a satisfactory model for the interpretation of the infrared intensities of substituted benzonitriles; similar calculations using the LCAO method are not yet available.

SOME ASPECTS OF THE NUCLEAR MAGNETIC RESONANCE SPECTRA OF COMPOUNDS CONTAINING C-METHYL GROUPS[1]

F. A. L. ANET

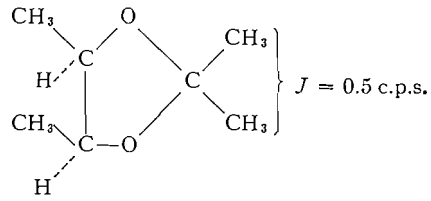
ABSTRACT

The N.M.R. spectra of compounds containing various types of C-methyl groups are discussed with special reference to the effects of spin coupling. Particular attention is given to compounds containing the $CHCH_3$ group in saturated systems. It is pointed out that the observed splitting of the methyl band is not always equal to the coupling constant between the methyl protons and the adjacent proton, even when the chemical shift between the two groups of protons is large.

The detection and differentiation of C-methyl groups in organic compounds is of importance, particularly in natural product chemistry. The standard (Kuhn–Roth) method of estimating C-methyl groups consists of oxidizing the compound with chromic acid and determining the acetic acid (and(or) higher homologue(s)) produced. By suitable modifications (1) it is possible to analyze for each acid separately and so to find out whether the group is a simple C-methyl group, or a C-ethyl group, etc. Infrared spectroscopy (2) has been used to detect and to determine C-methyl groups, and also to differentiate between isopropyl, *tert*-butyl, and other C-methyl groups.

Both of the above methods have limitations for the differentiation of C-methyl groups. Proton nuclear magnetic resonance (N.M.R.) has already been applied to the problem (3) but little discussion of the scope and limitations of the method has been published. In the present paper the effect of coupling of a methyl group to other protons in a molecule is considered in detail.

The detection of C-methyl groups by means of N.M.R. spectroscopy is especially favorable for two reasons. In the first place, a strong signal is usually obtained because of the complete magnetic equivalence of the three protons as a result of the rapid internal rotation of the methyl group. Secondly, when the methyl group is attached to a saturated carbon atom, the chemical shift of the methyl group, which is about 1 p.p.m. downfield from tetramethylsilane, is usually different from that of other protons in the molecule. Exceptions occur in compounds containing certain structural features such as cyclopropane rings. *trans*-1,1-Dichloro-2,3-dimethylcyclopropane (4), for example, has an N.M.R. spectrum which is essentially a single line at 8.78 τ.



The N.M.R. spectra of compounds containing C-methyl groups attached to unsaturated carbon atoms have been discussed in some detail by several authors (5, 6, 7, 8, 9, 10) and will not be considered here.

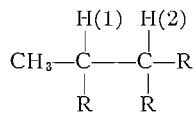
When the methyl group is attached to a saturated carbon atom we may consider three separate cases, depending on whether the saturated carbon atom also carries (*a*) no hydrogen atom, (*b*) one hydrogen atom, or (*c*) two hydrogen atoms.

In class (*a*), when there is no hydrogen atom on the adjacent carbon atom, the methyl group generally gives rise to a single sharp line. Since all the intensity is concentrated in one line there is no difficulty in observing such a signal in a spectrum. Typical examples are the 18- and 19-methyl groups of steroids (11) and the methyl groups in camphane derivatives (12). In exceptional cases, the methyl group may show very weak coupling to

[1]*Manuscript received June 20, 1961.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa 2, Ontario.

other protons in the molecule, thus (4) the two non-equivalent *gem*-methyl groups of (I) are coupled together to the extent of 0.5 c.p.s. Roberts (13) has reported a value of 0.75 c.p.s. for the coupling constant of the C-methyl group to one of the protons of the methylene group in methyl 2-bromo-2-methylpropionate. In general, it may be anticipated that this type of coupling will be very small (<1 c.p.s.) and can be neglected for practical purposes.

(I)



The second class is that of compounds containing the $CHCH_3$ group. The spectrum to be expected from such a system, in the absence of other magnetically active nuclei, has been dealt with in several places (cf. ref. 14). The simplest case, usually designated (15) by the symbols AX_3, occurs when the chemical shift of the two groups of protons is large compared with the coupling constant between them. The methyl group then gives rise to a doublet, and the separation is equal to the coupling constant. It may be mentioned here that the coupling constants of methyl groups to adjacent protons generally lie in the range of 6–8 c.p.s.

We may also place in this class the isopropyl group. If the two methyl groups are chemically identical and are well shifted from the CH proton, the situation is analogous to that just described. If the two methyl groups are not chemically identical, usually (but not necessarily) because of the presence of an asymmetric center in the molecule, two different methyl doublets, which may overlap, are obtained (16, 17). The non-equivalence of methyl groups in such systems is similar to that of two protons of a methylene group in certain molecules (18, 19).

When the chemical shift in the $CHCH_3$ group is not very large, the spectrum becomes an AB_3 type (15) and contains more lines. However, when the ratio of coupling constant to chemical shift is not more than about 0.25, the spectrum of the methyl group is still approximately a doublet. More exactly, each "line" of the doublet is now split into a number of lines, and the high-field component is split more and also is of lower intensity than the low-field component (assuming the CH group to be at low field of the methyl group). When the chemical shift is much less, a doublet is no longer recognizable. Jackman (3) has tried to rationalize the spectra of certain compounds (e.g. methylcyclohexane) containing $CHCH_3$ groups simply in terms of AB_3 systems. However, closer inspection shows that the observed and calculated spectra of the methyl groups cannot be made to agree completely, no matter what combination of chemical shifts and coupling constants are used. In each case there are other protons in the molecule which are appreciably coupled to, but only slightly chemically shifted from, the tertiary proton of the $CHCH_3$ group. These protons *must* be included in the analysis in order to obtain correct results. This is so even if, as is generally true, the methyl group is coupled only to the tertiary proton and not to the other protons of the molecule.

For personal use only.

We shall first examine the spectrum to be expected for the methyl group in a molecule such as (II), where the R's are not involved in coupling with the system under consideration. We will assume that the methyl group is well chemically shifted from H(1) and

(II)

H(2) and that $J_{CH_3,H(2)}$ is zero. This is actually a special case of the X_3AB system, which has been treated by Fessenden and Waugh (9). Figure 1 shows the calculated spectra due

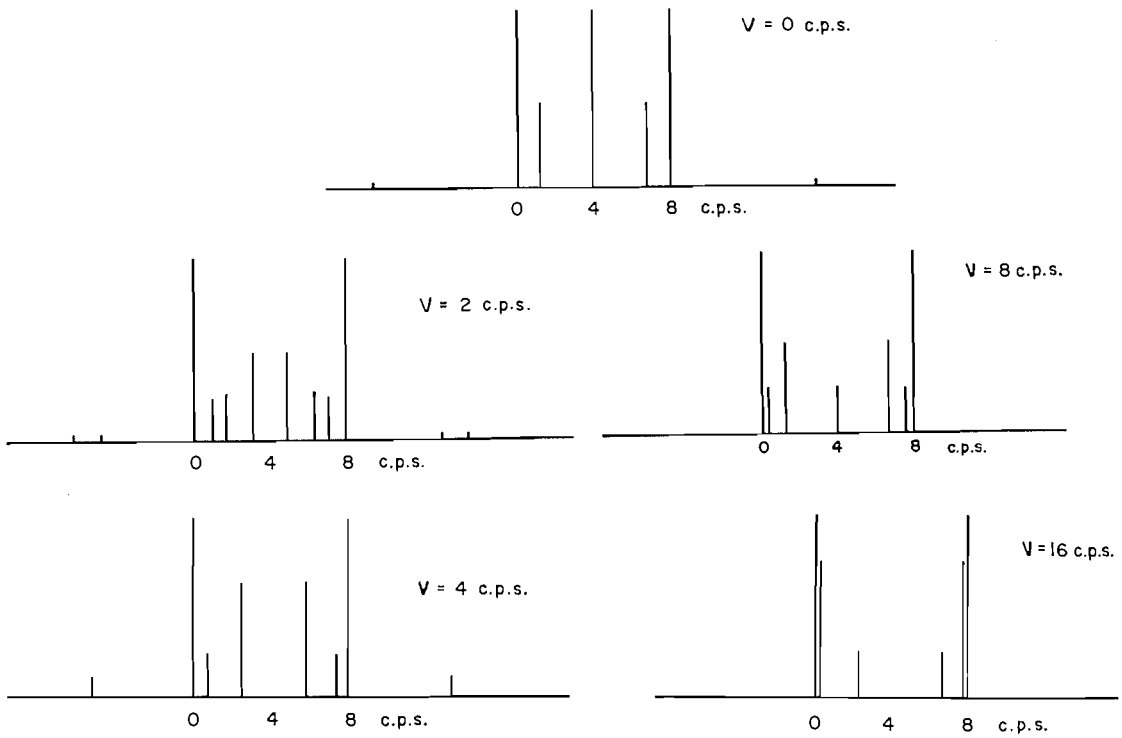

FIG. 1. Calculated spectra for compounds of type (II) for various values of the chemical shift (ν) between H(1) and H(2) and with $J_{CH_3,H(1)} = J_{H(1),H(2)} = 8$ c.p.s. and $J_{CH_3,H(2)} = 0$.

to the CH_3 group for various values of the chemical shift ($\nu_{H(1),H(2)}$) between H(1) and H(2), and, for simplicity, with $J_{CH_3,H(1)} = J_{H(1),H(2)} = 8.0$ c.p.s. Although the coupling constants are not generally equal, this does not affect the general conclusions drawn from the calculations.

When the chemical shift, $\nu_{H(1),H(2)}$, is very large the spectrum of the methyl group is a doublet, the lines being at $+1/2J_{CH_3,H(1)}$ and $-1/2J_{CH_3,H(1)}$ from the position of the methyl band in the absence of coupling. This is, of course, just the result expected from a first-order treatment. When the chemical shift is *not* large, only half of the intensity of the methyl band resides in the two lines at positions mentioned above. Most of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

remaining intensity is situated *between* these two lines, the exact distribution depending very markedly on the value of $\nu_{H(1),H(2)}$ (Fig. 1). The effect of H(2) is most pronounced when $\nu_{H(1),H(2)}$ is no greater than $J_{H(1),H(2)}$ and is negligible when $\nu_{H(1),H(2)} > 2J_{H(1),H(2)}$.

It can easily be understood why half of the intensity is in the lines at $\pm 1/2J_{CH_3,H(1)}$. There are four spin states for the protons H(1) and H(2), and the wave functions of the states with both protons having a spin of $+1/2$ or with both protons having a spin of $-1/2$ will not mix with any other functions, whereas the pairs of wave functions associated with one proton having a spin of $+1/2$ and the other a spin of $-1/2$ and vice versa do mix as they have the same total spin (15). From similar considerations it can be seen that if there are two protons similar to H(2), then only one quarter of the intensity of the methyl group lies in the "unperturbed" lines at $\pm 1/2J_{CH_3,H(1)}$. For three and four protons these fractions fall to 1/8 and 1/16 respectively. Complete solutions in these cases would be very laborious but it can be surmised that most of the remaining intensity, in the form of many lines, will be situated, as before, between the pair of unperturbed lines.

Therefore, the $CHCH_3$ group in a complex molecule may be expected to be a doublet or a doublet showing some additional lines, or in extreme cases, just a wide band with little resolved structure. This is the situation where the chemical shift between the CH_3 group and the adjacent proton is large compared with the coupling constant. When the chemical shift is not large, a similar effect is to be expected. The spectrum of the methyl group will correspond to the B_3 part of an AB_3 system only when A is not coupled to any protons other than the B protons. If the effects described above for the AX_3 system are important, a much more complex spectrum may be expected, which in extreme cases may reduce to a structureless wide band.

It should be noted that the observed splitting of the methyl band will not always be equal to the coupling constant. The splitting will usually be less because most of the intensity of the extra lines lies inside the two unperturbed lines whose separation gives the true coupling constant. This is probably the explanation for the wide variation in the "coupling constants"* of the methyl groups of 6α- and 6β-methyl steroids found by Slomp and McGarvey (20). In particular, for certain compounds some quite small splittings were found for which no explanation was presented. It would be expected that the coupling constant of the methyl group to the adjacent proton would not vary greatly in such a series of compounds. In agreement with the arguments presented in this paper is the fact that small splittings were not observed whenever the tertiary proton on C6 was likely to be chemically shifted (generally to low field) from the protons on C7, such as by the presence of a $\Delta^{4,5}$ double bond, or by the C6 proton being equatorial rather than axial (21). Unfortunately, the chemical shifts of the significant protons in such complex molecules cannot be observed directly, because the bands of a large number of other protons interfere.

Similar effects are found in the dimethylcyclohexanes examined recently by Musher (22). From the 40 Mc/sec N.M.R. spectra of the cis and trans isomers of 1,2-, 1,3-, and 1,4-dimethylcyclohexanes, Musher concluded that the coupling constants of equatorial methyl groups to the adjacent axial protons were zero or small (2.7 c.p.s.). In the alternative case of axial methyl groups and adjacent equatorial protons, appreciable (ca. 5 c.p.s.) coupling constants were observed. However, these "coupling constants" were merely the observed splittings of the methyl bands. Since the compounds used should be particularly liable to the effects discussed in this paper, the conclusions of Musher

*In cases of this type the term "splitting" would seem to be preferable to the term "coupling constant".

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

regarding coupling constants cannot be regarded as correct. The correct constants could no doubt be obtained by preparing suitably deuterated derivatives, which is, unfortunately, not an easy task, but which has been achieved in the present work for some compounds discussed later in this paper. It may be noted that where zero splittings were observed by Musher, the methyl bands were in fact broad and not sharp as they should be if the coupling constants were zero. In order to obtain experimental confirmation of the deductions made, the N.M.R. spectra of a number of suitable compounds containing C-methyl groups have been examined.

A very simple spectrum (Fig. 2) is given by the 3,5-dinitrobenzoate of *erythro*-3-bromo-2-butanol. The spectrum shows two different methyl bands, each a well-defined doublet

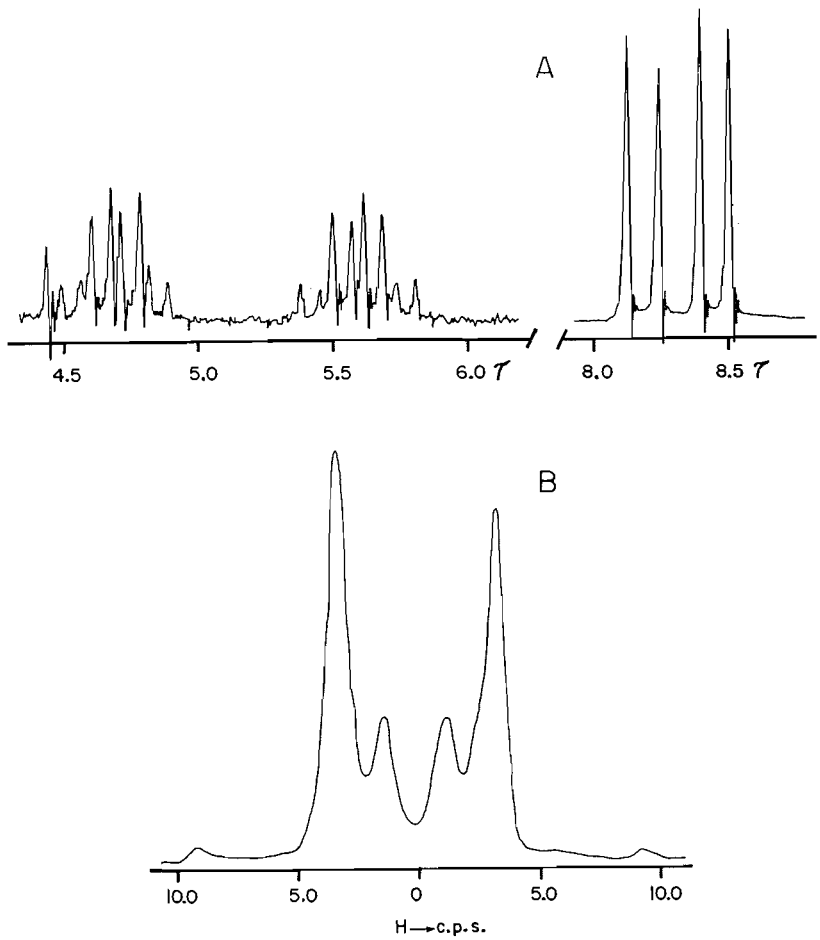

FIG. 2. A. Spectrum of 3,5-dinitrobenzoate and *erythro*-3-bromo-2-butanol, in chloroform solution. The sharp band at the extreme left is that of $C^{13}HCl_3$. The two parts of the spectrum were taken at different recorder gain.

B. Methyl band of meso-2,3-dibromobutane (pure liquid).

in accordance with the X_3 part of an AX_3 system. It should be noted that protons on C2 and C3 are well chemically shifted from one another and from the methyl groups and occur at low fields as doublets of quartets. In contrast to this case is the spectrum of the closely related meso-2,3-dibromobutane, where the chemical shift between the protons

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

on C2 and C3 is zero. The methyl groups here have the same chemical shift so only one methyl band is observed, but this is not a simple doublet (Fig. 2), for other lines appear. The spectrum of this molecule has already been discussed briefly (23) and fuller details will be published in a separate paper.

The spectra of methylsuccinic acid and β-methylglutaric acid are shown in Fig. 3.

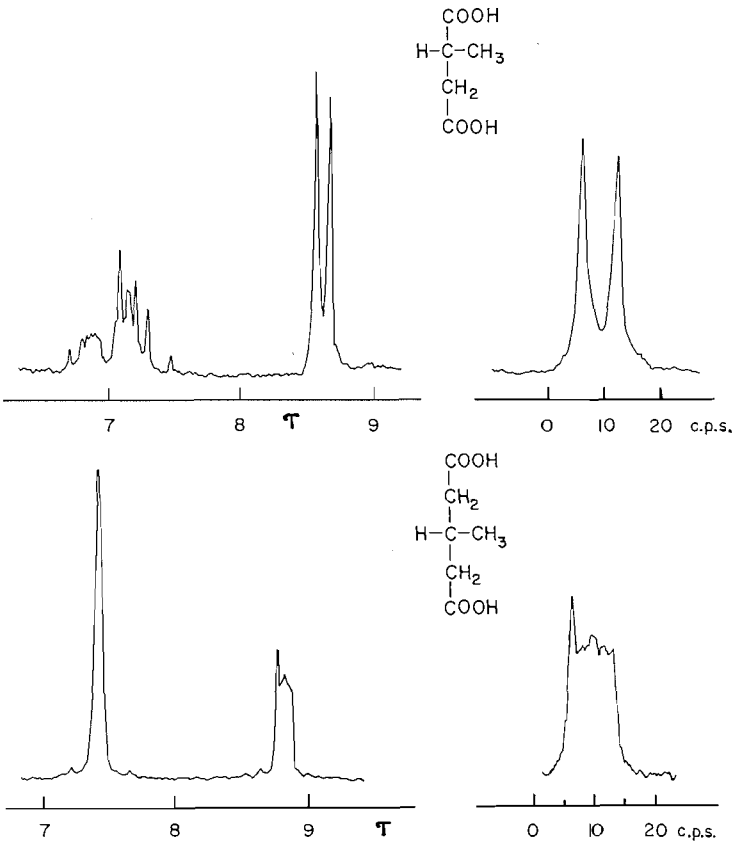

FIG. 3. Spectra of methylsuccinic acid and β-methylglutaric acid in trifluoroacetic acid. The bands of the carboxyl protons are not shown. The methyl bands at slow sweep are shown on the right.

These structurally related compounds give quite different bands for the methyl group. In methylsuccinic acid there is a distinct, though not large, chemical shift between the α and the two α′ protons and, as expected, the methyl group is a fairly good doublet. The coupling constant $J_{CH_3,H(2)}$ is probably a little larger than the observed splitting (6.6 c.p.s.) of the methyl band. In β-methylglutaric acid the α,α′ and β-protons must be only slightly chemically shifted from one another as they give rise to a single, slightly broad band. The result is that the methyl group does not give rise to a doublet at all, but to a wide band which obviously contains many lines.

Other examples of this type are the N.M.R. spectra of 2- and 3-methylcyclohexanone. The band of the methyl group of 2-methylcyclohexanone is a fairly good doublet, as expected, since the 2-proton should be chemically shifted from the 3-methylene protons by the proximity of the carbonyl group. On the other hand, in 3-methylcyclohexanone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the methyl group gives a very poor "doublet" (Fig. 4) which is a result of the carbonyl group shifting the position of the 2-methylene protons so that these are only slightly separated from the 3-proton. Support of this explanation was obtained by deuteration at position 2 (and incidentally at 6 also since an exchange method was used). The deuterated isomer gives a good doublet (Fig. 4) for the methyl group. This also shows that 1,3-coupling of the methyl group is not important as one methylene group (at C4) remains

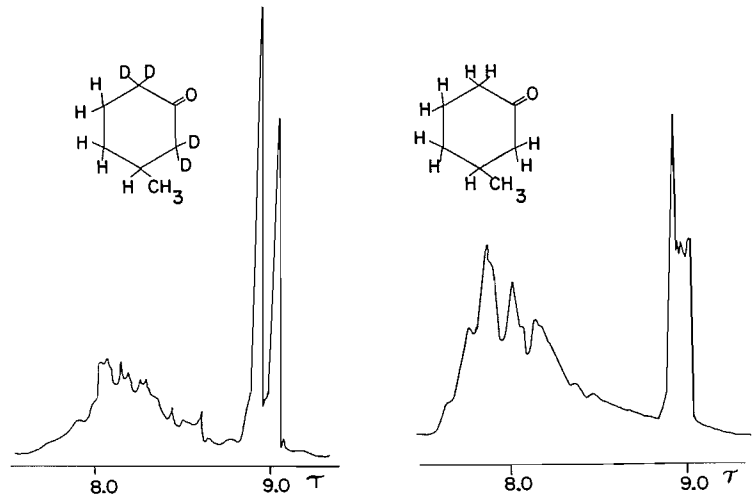

FIG. 4. Spectra of 3-methylcyclohexanone and of 2,2,6,6-tetradeuterio-3-methylcyclohexanone.

in the deuterated isomer. The methyl splitting for the deuterated isomer is 6.1 c.p.s. The splitting of the methyl band in 3-methylcyclohexanone itself depends very markedly on the resolution and sweep rate, owing to the asymmetry of the band. At very high resolution and slow sweep rate the splitting is 5.0 c.p.s., but at lower resolution or faster sweep the observed splitting is only ca. 4.0 c.p.s. Even in the deuterated isomer, the splitting is probably not quite equal to the true coupling constant, as there are still protons on C4 which are not strongly chemically shifted from the proton on C3.

In all the examples described above the chemical shift between the methyl group and the adjacent proton is reasonably large. In methylcyclohexane this shift is much smaller, resulting in a strong skewness in the intensity of the methyl band (Fig. 5) which is an extremely poor doublet with a separation of 4.7 c.p.s. However, this band does not agree with the B_3 part of an AB_3 spectrum. Methylcyclohexane is known to exist largely with the methyl group equatorial (24). It is also known (21) that axial protons are found at slightly higher field than equatorial protons, and that tertiary protons are at slightly lower field than methylene protons, other things being equal (3). These shifts should largely cancel out and the axial proton adjacent to the methyl group should be very close in chemical shift to the protons (especially the equatorial ones) on C2 and C6.

The spectrum (Fig. 5) of 2,2,6,6-tetradeuteriomethylcyclohexane (for isotopic purity see Experimental), on the other hand, gives a methyl band whose structure is consistent with the B_3 part of an AB_3 system. Calculation shows that $J = 6.8$ c.p.s. and that J/ν is about 0.25. It should again be noted that the value of the coupling constant is appreciably greater than the observed splitting in undeuterated methylcyclohexane.

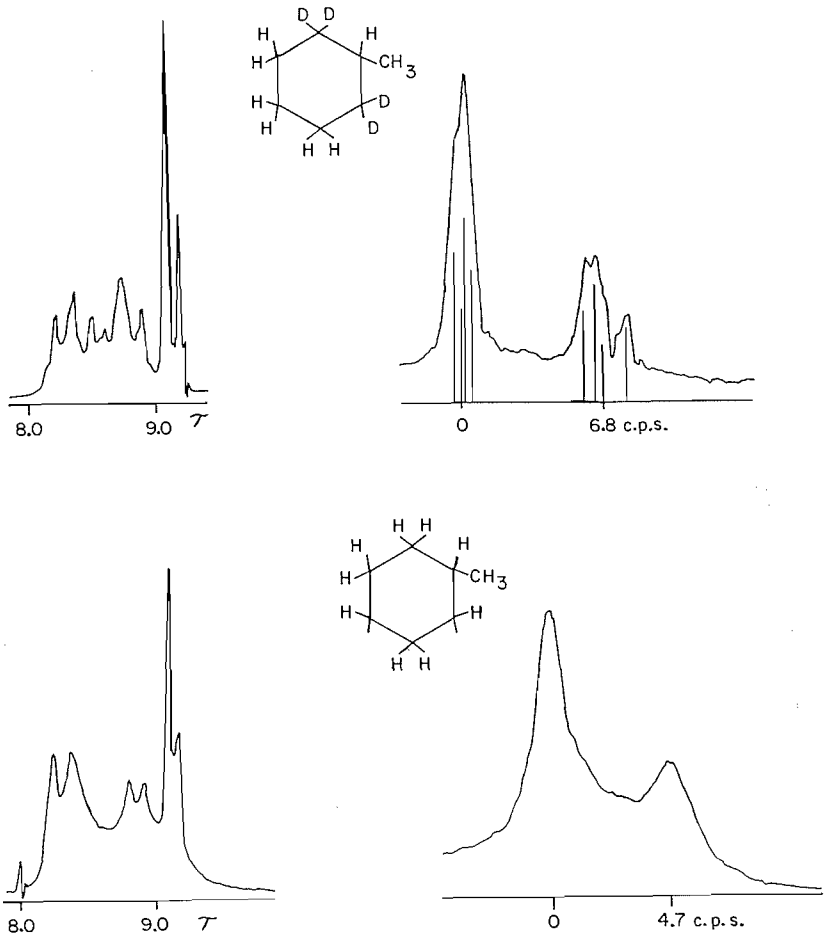

FIG. 5. Spectra of methylcyclohexane and 2,2,6,6-tetradeuteriomethylcyclohexane. The methyl bands at slow sweep are shown on the right. The sharp band at the left of the methylcyclohexane spectrum is a side band of tetramethylsilane.

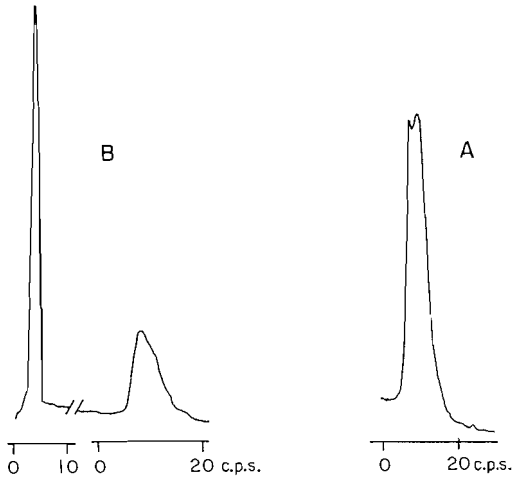
The *Lycopodium* alkaloid lycodine (III*a*) (25) presents a good example of a natural product showing some of the effects discussed in this paper. In the first publication (26) on this alkaloid, the N.M.R. spectrum (40 Mc/sec) was taken as evidence that the methyl group, which was known to be present, was attached to a quaternary carbon atom, as the methyl band was unsplit. However, spectra (Fig. 6) taken (27) at 60 Mc/sec and under somewhat better resolution showed that the methyl band was quite broad and, in fact, could just be resolved as a doublet of separation 1.9 c.p.s. This splitting undoubtedly does not represent the coupling constant. In N-acetyllycodine (III*b*), the methyl band of the lycodine part of the molecule cannot even be resolved into a doublet under the best possible resolution. The band (Fig. 6) is nevertheless broad and does show an inflection on the high-field side. In contrast, the band of the methyl protons of the N-acetyl group is quite sharp and therefore also of much greater height. These effects can be ascribed to the smallness of the chemical shift of the CH proton to the adjacent pairs of methylene protons, partly as a result of the CH proton being shifted upfield from



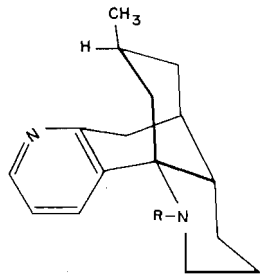


FIG. 6. Methyl bands of (A) lycodine and (B) N-acetyllycodine. The two methyl bands of B were taken under the same instrumental conditions. The magnetic field increases from left to right.

its normal position by the pyridine ring. Molecular models show that the CH proton lies in the region above the plane of the pyridine ring where the circulating π electrons cause a diamagnetic shift. The related alkaloids α- and β-obscurine (28) show the same apparently abnormal methyl band shown by lycodine. Further discussion on the spectra of these alkaloids will be published in a paper dealing with these compounds.

(IIIa) R = H
(IIIb) R = Ac

Another example of "abnormal" behavior is found in 1-β(3,5-dinitrobenzoyloxy)-2α-iodo-3α-methylcyclohexane prepared recently by Lemieux and Kavadias. The N.M.R. spectrum taken at a comparatively fast sweep (29) shows only a single, somewhat broad line for the methyl group. This can be understood if the proton on C3 is only slightly chemically shifted from the protons on C4. In agreement with this interpretation, the proton on C2 gives a broad line, instead of the doublet of doublets expected. In other isomers of the above compound the methyl group is a doublet and the C2 proton shows the expected fine structure.

The spectrum of compounds containing ethyl groups can be expected to show the same behavior as that of compounds containing the $CHCH_3$ group. The methyl group will only be a good triplet when it is well chemically shifted from the methylene protons, *and*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the methylene protons are chemically shifted from other protons to which they are coupled. When the ethyl group is attached to a saturated carbon atom not bearing a strongly electronegative or strongly electropositive substituent, neither of these conditions will generally be fulfilled. Thus valeric acid (3) gives rise to a methyl band which is wide and fairly shapeless. In fact, it is not too easy to differentiate this type of ethyl group from the "abnormal" $CHCH_3$ group discussed previously. *n*-Butyraldehyde (3), where the second condition above is fairly well fulfilled, gives a recognizable, if poor, triplet. Diethyl ketone fulfills both the conditions and indeed gives (3) a good triplet for the methyl group. It should be noted that in molecules containing an asymmetric carbon atom, the two methylene protons of an ethyl group are not identical and may have slightly different coupling constants to the methyl group. The ethyl group of some small molecules have been analyzed as A_3B_2 or A_3B_2X systems (30, 31), and during the course of the present work Cavanaugh and Dailey have investigated the spectra of propyl derivatives (32).

In this paper, the only magnetically active nuclei present have been assumed to be protons. However, the arguments presented can be extended readily to cases where fluorine, phosphorus, etc. occur in an organic compound.

EXPERIMENTAL

The spectra were taken at a frequency of 60 Mc/sec on a Varian V-4302 high-resolution spectrometer. The compounds were dissolved in carbon tetrachloride (except where otherwise stated) containing about 1% tetramethylsilane to make 10–15% solutions. Chemical shifts are reported on Tiers' τ scale (33) (i.e. in p.p.m. increasing to high field, with tetramethylsilane given the value of 10.00). Calibration of the spectra was carried out by the side-band technique. The frequency of the audio-oscillator was monitored on a Hewlett–Packard frequency counter, model 521C. In all cases a number of spectra were taken with increasing as well as with decreasing magnetic fields. The tetramethylsilane peak was always observed as a single, very sharp band. Coupling constants are estimated to be accurate to 0.15 c.p.s.

Preparation of 2,2,6,6-Tetradeuteriomethylcyclohexane

Cyclohexanone (10 g), deuterium oxide (15 ml, 99.7%), and anhydrous potassium carbonate (0.5 g) were refluxed for 2 hours. The cyclohexanone, recovered by ether extraction, was submitted to two more such treatments. The 2,2,6,6-tetradeuteriocyclohexanone was finally distilled through a small column, b.p. 93–96° (142 mm) (4 g), and was free of isomers containing protons α to the carbonyl group, as shown by the N.M.R. spectrum. Treatment of the deuterated cyclohexanone with triphenylphosphinemethylene according to the procedure described in *Organic Syntheses* (34) gave crude methylenecyclohexane, ca. 2 g, b.p. 80–100°. The only impurity was found to be benzene, both by gas chromatography and by the N.M.R. spectrum. The N.M.R. spectrum (bands at 5.52 τ and 8.48 τ only) also showed that the methylenecyclohexane was fully deuterated at positions 2 and 6. The above fraction was hydrogenated at room temperature and pressure in the presence of platinum oxide catalyst (10 mg). The product was shaken with concentrated sulphuric acid at 60° until gas chromatography showed that all the benzene was removed. The product gave a single peak with the same retention time as methylcyclohexane on gas chromatography using a silicone oil column at 110°. The mass spectrum (kindly taken by Dr. F. Lossing of the National Research Council, Ottawa) showed the presence of 65% tetradeuterated, 11% undeuterated, 10% pentadeuterated, 9% trideuterated, 3% monodeuterated, and 2% dideuterated methylcyclohexane. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

presence of unexpectedly large amounts of the undeuterated isomer can be explained most simply if some isomerization (35, 36) to 1-methylcyclohexene took place. This compound could then undergo an exchange of its allylic deuterium atoms prior to hydrogenation. Indeed, gas chromatography of the hydrogenation mixture contained a small peak, not present in the initial product, with a retention time consistent with that expected for 1-methylcyclohexene. This product disappeared, as expected, on treatment with sulphuric acid. Although the final product was only 65% isotopically pure, this should not affect the N.M.R. spectrum too much.

2,2,6,6-Tetradeuterio-3-methylcyclohexanone

3-Methylcyclohexanone was deuterated as described above for cyclohexanone.

3,5-Dinitrobenzoate of Erythro-3-bromo-2-butanol

The compound had m.p. 85° (lit. (37) m.p. 85°). In the N.M.R. spectrum (Fig. 2) the bands centered at 4.68 τ and 5.60 τ can be assigned to the protons on C2 and C3 respectively, and the doublets at 8.44 τ and 8.19 τ can be assigned to the 4- and 1-methyl groups respectively. The coupling constants are $J_{12} = 6.4$, $J_{34} = 6.9$, and $J_{23} = 4.2$ c.p.s. The assignments are consistent with the chemical-shift effects of bromine and oxygen atoms (38).

ACKNOWLEDGMENTS

I wish to thank Mrs. Osgerby for technical help in the preparation of deuterated cyclohexanone and deuterated methylcyclohexanone.

This research was supported by a grant from the National Research Council of Canada.

EXTRACELLULAR ACIDIC POLYSACCHARIDES FROM C. INSIDIOSUM AND OTHER CORYNEBACTERIUM SPP.[1]

P. A. J. GORIN AND J. F. T. SPENCER

ABSTRACT

The extracellular polysaccharide of *Corynebacterium insidiosum*, the causative agent of alfalfa wilt, contains D-glucose, D-galactose, and L-fucose in the proportions 2:3:4, with smaller amounts of an unknown acid. Partial acid hydrolysis of the polysaccharide gives 4-*O*-β-D-glucopyranosyl-L-fucose and 4-*O*-β-D-glucopyranosyl-(3-*O*-D-galactopyranosyl)-L-fucose as neutral oligosaccharides. Also formed are D-galactose, substituted in the 4-position with an unknown acid, and 4-*O*-β-D-glucopyranosyl-(3-*O*-D-galactopyranosyl)-L-fucose, which has the 4-position of the galactopyranosyl moiety substituted in a similar way. It appears that the above oligosaccharides represent the structure of the polysaccharide to a considerable extent.

Phytopathogenic microorganisms of several genera have been shown to form extracellular polysaccharides in synthetic media and in some cases these materials appear to have a phytotoxic effect when they are formed in vivo (1). Three genera are being examined and structural determinations on the extracellular polysaccharides from *Xanthomonas* spp., *Agrobacterium* spp., and *Corynebacterium* spp. are being carried out. Within the latter two genera there is a consistency in the composition of the polysaccharides, as *Agrobacterium* spp. form mainly 1,2-β-D-glucopyranose polymers (2, 3) and the *Xanthomonas* spp. produce gummy polysaccharides containing glucuronic acid, glucose, and mannose in varying proportions and in one case glucuronic acid, galactose, and glucose (4).

In the present study the polysaccharides from *Corynebacterium* spp. have been examined and have been shown to be somewhat more heterogeneous in their properties than those in the other two genera. For instance, *C. insidiosum*, *C. sepedonicum*, and *C. michiganense* contain hexoses with a high proportion of methylpentose(s) and give, on partial acid hydrolysis, acidic sugars with color reactions unlike those given by uronic acids (Table I). However, *C. flaccumfaciens*, *C. tritici*, *C. rathayi*, and *C. poinsettia* appear to be in a different group, giving, on acidic hydrolysis, substances resembling aldobiouronic acids by their color reactions and mobilities on paper chromatograms. In this respect the latter three organisms form polysaccharides that seem to bear a resemblance to extracellular polysaccharides formed by phytopathogenic *Xanthomonas* spp. (4).

The extracellular polysaccharide from *Corynebacterium insidiosum*, the causative agent of alfalfa wilt, was examined in more detail since it had the unusual features described above when the organism was grown on a dialyzed yeast extract medium. The polymer was complex, yielding, on acid hydrolysis, galactose, glucose, and fucose in the proportion 3:2:4 and in addition contained an acidic grouping for every six sugar units. However, this acidic function was not of the usual uronic acid type since no aldobiouronic acids were detected after strong acid hydrolysis. Therefore it was evident that structural determinations on the polysaccharide should be carried out initially by other methods apart from the methylation route.

Much useful information was furnished by partial hydrolysis of the *C. insidiosum* polysaccharide and fractionation of the products by charcoal and cellulose chroma-

tography. Four main products were obtained, two being neutral and the other two sugars containing acidic functions which were not uronic in nature.

One of the neutral sugars was shown to be 4-*O*-β-D-glucopyranosyl-L-fucose (I), which must represent a large proportion of the polysaccharide since no free glucose was present in the partial hydrolyzate although much galactose and fucose were produced. The disaccharide was amorphous, but a crystalline heptaacetate was prepared and also the derived polyhydric alcohol (5) gave an octaacetate which crystallized. The 4-linkage was assigned to the disaccharide since it took up 2.0 moles of lead tetraacetate in acetic acid gradually (6). This was confirmed by periodate oxidation of the derived polyol, which consumed 3.8 moles of oxidant yielding 1.9 moles of formic acid and no acetaldehyde. Since the specific rotation of the 4-*O*-D-glucopyranosyl-L-fucitol was $-30°$ it seemed probable that the linkage configuration was β (7).

The other neutral fragment proved to be a trisaccharide (II) containing galactose, glucose, and fucose. Partial acid hydrolysis, using conditions similar to those used in the preparation of the trisaccharide from the polysaccharide, gave galactose and 4-*O*-β-D-glucopyranosyl-L-fucose, thus suggesting that the trimer also represents structurally a large proportion of the polysaccharide. The reducing end of the sugar was shown to be fucose since it was the only part that was reduced by sodium borohydride. The fucose portion was then shown to be linked in the 3-position by lead tetraacetate oxidation, since the sugar consumed 1 mole of oxidant (6), suggesting a branched-chain 4-*O*-β-D-glucopyranosyl(3-*O*-D-galactopyranosyl)-L-fucose structure (II). This was confirmed by two methods, oxidation with lead tetraacetate in potassium acetate – acetic acid, which gave 2 moles of formic acid slowly by oxidation of the glucose and galactose non-reducing end units (8). In addition, oxidation with sodium periodate gave a product which, on sodium borohydride reduction followed by acid hydrolysis, was degraded to glycerol and 5-deoxy pentitol.

When the two acidic sugars obtained on partial hydrolysis of the polysaccharide were examined it was shown that the unknown acid was attached to the 4-position of the galactose molecule in each case. The sugar with the lower molecular weight (III) crystallized and was shown to contain galactose since this hexose was formed by strong acid hydrolysis. C-1 of the galactose was apparently free since the substance mutarotated from $+70°$ to $+49°$ in water. Titration with alkali indicated a neutral equivalent of 288 and, based on this figure, consumption of lead tetraacetate by the sugar was 0.31, 0.69, 1.13, and 1.32 moles after 2, 5, 10, and 20 minutes respectively, thus indicating 4-substitution. Carbon and hydrogen analyses suggested an empirical formula of $C_{11}H_{20}O_9$, corresponding to a hexose unit attached ethereally to a hydroxy group of a dihydroxypentanoic acid. This formulation, however, does not agree with the infrared data obtained on the free sugar or the derived alcohol, the latter being obtained by methylation (CH_2N_2) followed by sodium borohydride reduction (9). The free sugar has a band at 1705 cm^{-1} corresponding to a carboxyl carbonyl group and there also appears to be a partially obscured band at 1725 cm^{-1} to 1750 cm^{-1}, which could represent an ester carbonyl group. The derived methyl ester gave a sharp band at 1735 cm^{-1} and on treatment with sodium borohydride a neutral substance was obtained which gave a strong band at 1740 cm^{-1}. This product, according to paper chromatograms, contained a little hexitol as well as the expected material so that the weight of evidence so far obtained indicates an ester-type linkage at the 4-position of the galactose residue.

The higher molecular weight material (IV) was amorphous and gave galactose, glucose, and fucose on acid hydrolysis, and on partial hydrolysis 4-*O*-β-D-glucopyranosyl-L-fucose

and the acidic galactose derivative were detected on paper chromatograms (III). Fucose was again shown to be at the reducing end by sodium borohydride reduction and, if a molecular weight of 602* is assumed, lead tetraacetate oxidation studies indicated a 3-linked fucose residue. It thus seemed that a 4-*O*-β-D-glucopyranosyl(3-galacto-pyranosyl)-L-fucose structure with an unknown carboxyl derivative attached (IV) was likely and its position of substitution on the galactose was shown to be at 4 since periodate oxidation of the oligosaccharide followed by sodium borohydride reduction and acid hydrolysis gave erythritol in addition to glycerol and 5-deoxy pentitol.

Periodate oxidation of the polysaccharide gave little information, except to show that non-reducing end groups or 6-linked hexopyranosyl units only are oxidized, and since overoxidation takes place only a rough figure of 28% can be estimated for their presence in the total polysaccharide.

Thus the polysaccharide from *C. insidiosum* is complex, particularly so because of the attachment of an unknown acidic entity on the galactose position. However, this type of substituent appears to be quite widespread at least in the extracellular polysaccharides from *Corynebacterium* spp., and more work is needed to show their true identities.

EXPERIMENTAL

Evaporations were carried out at 50° C under reduced pressure and specific rotations measured at 23° C.

Cultural Methods for Polysaccharide Production

The cultures of *Corynebacterium* spp. were maintained on a medium containing 1.5% glucose, 1.0% yeast extract, 0.5% calcium carbonate, and 1.3% agar.

The organisms were grown in a medium containing 1.5% glucose, 1.0% yeast extract, and 0.2 to 0.5% calcium carbonate. The yeast extract solution was dialyzed before use to remove high molecular weight polysaccharides. Small quantities of gum-producing polysaccharide were produced in 500-ml Erlenmeyer flasks containing 100 ml medium, incubated at 25° C on a rotary shaker, eccentricity 1/2 inch, operated at 250 r.p.m. For production of larger quantities of polysaccharide the organisms were grown in 5-liter glass-jar-type stirred fermentors having a working volume of 3 liters or in 30-liter stainless steel fermentors having a working volume of 20 liters.

Cells were removed in a Sharples supercentrifuge or in a Spinco ultracentrifuge if necessary, generally after about 4 days. Culture supernatants which contained a good deal of suspended matter after concentration were again centrifuged in the ultracentrifuge. After centrifugation the solutions were evaporated under vacuum to as small a volume as possible and the polysaccharide was precipitated by addition of 5 volumes of ethanol. For *Corynebacterium insidiosum* the yields of crude product were approximately 3 g per liter. The precipitate was recovered and redissolved in a large quantity of water and the solution treated with Amberlite IR-120 and Dowex-1. After filtration and evaporation the purified polysaccharide was reprecipitated with excess ethanol, washed with ethanol, and dried.

General Examination Procedure for Polysaccharides

The polysaccharide from each fermentation was hydrolyzed with *N* sulphuric acid at 100° C overnight to obtain the over-all sugar composition as shown by paper chromatograms using *p*-anisidine hydrochloride (10) as spray reagent. Those that did not show

**Based on a trisaccharide with a carboxyl function attached in a manner similar to that on III.*

aldobiouronic acids under these conditions were partially hydrolyzed for 6 hours with *N* sulphuric acid at 70° C, under which conditions other acidic components might be detected. The results are listed in Table I.

Complete Hydrolysis of C. insidiosum Polysaccharide

The polysaccharide (100 mg) was hydrolyzed for 18 hours at 100° C in *N* sulphuric acid. The solution was then neutralized ($BaCO_3$), filtered, and evaporated to give a mixture of galactose, glucose, and fucose. These components were separated on a sheet of Whatman No. 1 filter paper using ethyl acetate – pyridine – water (10:4:3 v/v) as solvent and the relative amounts of sugars present estimated colorimetrically by the benzidine method of Jones and Pridham (11). The ratio of galactose–glucose–fucose was 3:2:4, the fucose composition checking well with a C-methyl estimation on the mixture. A larger scale hydrolysis was carried out and the components were fractionated on a cellulose column using *n*-butanol half saturated with water to yield L-fucose, D-glucose, and D-galactose, which were crystallized and identified.

Partial Hydrolysis of C. insidiosum Polysaccharide

The polysaccharide (20 g) was dissolved in *N* sulphuric acid (2 liters) by stirring the mixture at 70° C for 6 hours. After neutralization ($BaCO_3$) and removal of cations with Amberlite IR-120, the solution was examined on paper chromatograms and was shown to contain galactose and fucose as the monosaccharide fraction. On a paper chromatogram

using the ethyl acetate – acetic acid – water (9:2:2 v/v) solvent a yellow-brown spot ($R_{galactose}$ 0.8) with the *p*-anisidine hydrochloride spray was evident with smaller amounts of yellow spots with $R_{lactose}$ 0.7 and 1.1. The solution was passed down a charcoal column and the galactose and fucose removed by washing with water. Thirty per cent aqueous

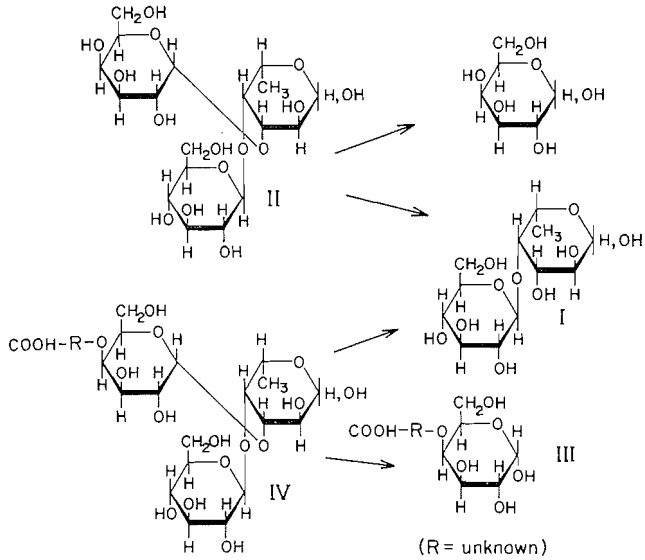

FIG. 1. Partial hydrolysis products of *C. insidiosum* polysaccharide.

ethanol eluted the compounds giving spots with $R_{galactose}$ 0.8 and $R_{lactose}$ 0.7 and 1.1, and in addition, a material running at the same speed as fucose and giving a yellow-brown spot with *p*-anisidine hydrochloride. The materials with $R_{lactose}$ 0.7 and R_{fucose} 1.0 proved to be acidic since they ran slowly in the ethyl acetate – pyridine – water (10:4:3 v/v) solvent.

The above components were fractionated on a cellulose column. Butanol saturated with water separated the materials with R_{fucose} 1.0 and $R_{galactose}$ 0.8 and butanol–ethanol–water (8:2:1 v/v) separated the other slower moving materials with $R_{lactose}$ 1.1 and 0.7. These partial hydrolysis products were examined for their chemical structures.

Identification of 4-O-β-D-Glucopyranosyl-L-fucose ($R_{galactose}$ 0.8) (I)

This material (3.4 g) was isolated in an amorphous form and a portion (300 mg) was converted to its heptaacetate by heating on a steam bath overnight in acetic anhydride (5 ml) containing sodium acetate (300 mg). After the excess anhydride was destroyed with ice-water, the solution was extracted with chloroform. The chloroform extract crystallized on evaporation and two recrystallizations from ethanol yielded a heptaacetate (123 mg) with m.p. 228–230° C and $[\alpha]_D$ −59° (*c*, 1.0, $CHCl_3$). Calculated for $C_{26}H_{36}O_{17}$: C, 50.3%; H, 5.85%. Found: C, 50.2%; H, 6.1%.

Deacetylation with a catalytic amount of sodium methoxide in methanol yielded, after neutralization with acetic acid, the free sugar with $[\alpha]_D$ −71° (*c*, 0.6, H_2O). Acid hydrolysis with *N* sulphuric acid at 100° C overnight yielded glucose and fucose (paper chromatograms). After 2, 5, 15, and 60 minutes the sugar consumed 0.81, 1.58, 1.99, and 2.06 moles of lead tetraacetate in acetic acid, respectively, giving strong indication of a 4-linked disaccharide.

The disaccharide (200 mg) was reduced with sodium borohydride (50 mg) in water (2 ml). After 4 hours the reductant was destroyed with acetic acid and cations were removed with Amberlite IR-120. The solution was filtered and evaporated to a crust which was repeatedly dissolved in methanol, which was then evaporated. The amorphous polyol was converted to its octaacetate by the acetylation procedure used above. Two recrystallizations from ethanol yielded crystals with m.p. 125–126° C and $[\alpha]_D$ −30° (*c*, 1.1, $CHCl_3$). Calculated for $C_{28}H_{40}O_{18}$: C, 50.6%; H, 6.1%. Found: C, 50.6%; H, 6.2%.

Deacetylation gave 4-*O*-β-D-glucopyranosyl-L-fucitol with $[\alpha]_D$ −30° (*c*, 1.1, H_2O), which was oxidized with aqueous sodium periodate and after 18 hours took up 3.8 moles of oxidant giving 1.9 moles of formic acid. No acetaldehyde could be detected (12) in the oxidation mixture.

Identification of 4-O-β-D-Glucopyranosyl(3-O-D-galactopyranosyl)-L-fucose ($R_{lactose}$ 0.7) (II)

This material ($[\alpha]_D$ +23° (*c*, 1.3, H_2O)) gave galactose, glucose, and fucose (paper chromatograms) on hydrolysis with *N* sulphuric acid at 100° C overnight. Reduction for 18 hours with sodium borohydride gave a polyol, which, on acid hydrolysis at 100° C with *N* sulphuric acid overnight gave, as reducing sugar, galactose and glucose and also some fucitol, detectable with the ammoniacal silver nitrate spray (13).

The fucose reducing end-unit was linked in the 3-position since, based on a molecular weight of 488, it took up 1.01, 1.04, and 1.09 moles of lead tetraacetate in acetic acid after 4, 15, and 30 minutes respectively. The trisaccharide was also oxidized with lead tetraacetate in 90% acetic acid containing potassium acetate and the formic acid produced measured as carbon dioxide in a Warburg respirometer (8). The production of carbon dioxide corresponded to the oxidation of two non-reducing end-units, one being oxidized more quickly than the other. At the end of the reaction 4.72 moles of oxidant had been consumed in glycol cleavage.

TABLE II

Time (minutes)	12	20	35	65	95	145	285	325	465
Moles CO_2 produced	0.43	0.64	0.80	0.95	1.08	1.38	1.78	1.87	2.11

The trisaccharide (10 mg) was oxidized overnight with excess aqueous sodium periodate and the ions then removed with mixed Amberlite IR-120 and Dowex-1 (bicarbonate form). The aldehyde was reduced with sodium borohydride by the method described previously and the product hydrolyzed with *N* sulphuric acid (5 ml) at 100° C overnight. The product, after neutralization ($BaCO_3$), was examined on a paper chromatogram (solvent *n*-butanol:ethanol:water, 40:11:19 v/v) and the only detectable spots using the ammoniacal silver nitrate spray corresponded to glycerol and a spot which could be 5-deoxylyxitol. These results agree with the above lead tetraacetate oxidation in that two non-reducing end-units are present.

A sample of the trisaccharide (70 mg) was partially hydrolyzed with *N* sulphuric acid (1 ml) at 70° C for 6 hours. After neutralization ($BaCO_3$) and filtration, the product corresponded to a mixture of 4-*O*-β-D-glucopyranosyl-L-fucose and galactose. These components were separated on sheets of Whatman No. 1 filter paper using *n*-butanol–ethanol–water (40:11:19 v/v) as solvent, and the two sugars were identified, the disaccharide as its heptaacetate and the galactose by its 1-methylphenylhydrazone (14). These were each compared with authentic specimens and had identical X-ray diffraction patterns.

Unknown Acidic Galactose Derivative (R_{fucose} 1.0) (III)

This product crystallized and two recrystallizations from ethanol yielded a material with m.p. 113–114° C and had $[\alpha]_D$ +70° → +49° (*c*, 0.6, H_2O, constant value). Acid hydrolysis at 100° C in *N* sulphuric acid for 18 hours yielded galactose (paper chromatograms). Its neutral equivalent was 288 and this figure and the analysis figures of C, 44.9%; H, 6.9% indicate a $C_{11}H_{20}O_9$ formula. Calculated for $C_{11}H_{20}O_9$: C, 44.6%; H, 6.8%. The infrared spectrum had strong absorption at 1705 cm^{-1} corresponding to acid carbonyl and a shoulder to this peak pointed to ester carbonyl absorption in the region 1725 cm^{-1} to 1750 cm^{-1}. Lead tetraacetate oxidation of the sugar resulted in uptake of 0.31, 0.69, 1.13, and 1.32 moles of oxidant after 2, 5, 10, and 20 minutes respectively based on a molecular weight of 288. These figures, even if this molecular weight is only approximate, indicate 4-substitution on the galactose molecule.

Treatment of the unknown acid (25 mg) in methanol with ethereal diazomethane yielded, on evaporation, its methyl ester (25 mg) having infrared absorption at 1735 cm^{-1}. The ester was dissolved in methanol (1 ml) containing 0.1 equivalent of sodium methoxide at 0° C, and sodium borohydride (20 mg) was added, the solution being kept in the refrigerator for 6 hours. The methanol was then removed by evaporation and the product isolated as described above. On paper chromatograms in *n*-butanol–ethanol–water (40:11:19 v/v) a main spot with $R_{rhamnose}$ 1.3, detectable with ammoniacal silver nitrate, was found together with a minor spot corresponding to a hexitol. Infrared absorption of the product at 1740 cm^{-1} indicated that an ester carboxyl group was still present.

Unknown Acidic 4-O-β-D-Glucopyranosyl-(3-O-galactopyranosyl)-L-fucose Derivative ($R_{lactose}$ 1.1) (IV)

This sugar, having $[\alpha]_D$ +9° (*c*, 0.6, H_2O) was cleaved using conditions identical with those for hydrolysis of the trisaccharide (II), giving galactose, glucose, and fucose. Partial acid hydrolysis gave 4-*O*-β-D-glucopyranosyl-L-fucose and the unknown acidic galactose derivative (III), all these sugars being identified by their chromatographic behavior. Fucose was identified as the reducing end of the sugar since sodium borohydride reduction followed by acid hydrolysis gave fucitol. The fucose was substituted in the 3-position since 0.90, 1.03, and 1.21 moles of lead tetraacetate in acetic acid were taken up after 2, 10, and 45 minutes, respectively, based on a molecular weight of 602. Sodium periodate oxidation* followed by sodium borohydride reduction, then hydrolysis, gave erythritol in addition to glycerol and 5-deoxy-lyxitol, indicating the unknown substituent was located in the 4-position of the galactose unit.

Sodium Periodate Oxidation of C. insidiosum Polysaccharide

The polysaccharide, $[\alpha]_D$ −98° (*c*, 0.7, H_2O), gave analysis figures of C 44.7%, H 6.9%, N 0.3%, ash 0.9%, and Cl 0.22%, and contained an acid group for every 912 of molecular weight. The sodium periodate oxidation data were as follows:

Time (days)	1	2	3	4	5	6	7
Sodium periodate uptake (moles)	0.42	0.46	0.53	—	0.55	0.59	0.60
Formic acid formed (moles)	0.16	0.17	0.21	0.23	0.24	0.25	0.28

The product on sodium borohydride reduction followed by acid hydrolysis in *N* sulphuric acid at 100° C overnight gave glycerol (on paper chromatograms) as the only non-reducing sugar, no erythritol being detected. Glucose, galactose, and fucose were also present.

**In this case sodium periodate and iodate were removed, first by treatment with Amberlite IR-120 and then with barium carbonate.*

STRUCTURAL RELATIONSHIPS OF EXTRACELLULAR POLYSACCHARIDES FROM PHYTOPATHOGENIC XANTHOMONAS SPP.

PART I. STRUCTURE OF THE EXTRACELLULAR POLYSACCHARIDE FROM XANTHOMONAS STEWARTII[1]

P. A. J. GORIN AND J. F. T. SPENCER

ABSTRACT

Xanthomonas stewartii produces an extracellular polysaccharide which is markedly different from those formed by other *Xanthomonas* spp. examined in that it gave glucose, galactose, and an aldobiouronic acid on hydrolysis. Methylation followed by hydrolysis yielded 2,3,4,6-tetra-*O*-methyl-D-glucose (4 parts), 2,3,4-tri-*O*-methyl-D-glucose (2 parts), 2,4,6-tri-*O*-methyl-D-galactose (1 part), 2,3,4-tri-*O*-methyl-D-galactose (2 parts), and 2-*O*-methyl-D-galactose (1.8 parts). Partial acid hydrolysis yielded 6-*O*-β-D-glucopyranosyl-D-galactose, 3-*O*-β-D-glucopyranosyl-D-galactose, 3-*O*-β-D-galactopyranosyl-D-galactose, and 4-*O*-β-D-glucuronopyranosyl-D-galactose.

The extracellular polysaccharides from phytopathogenic species of *Xanthomonas* are being examined and a consistency of structure within the genus, at least as far as the sugar constituents of the polysaccharides are concerned, has been demonstrated. Nine of the 12 *Xanthomonas* spp. studied produce polysaccharides (on dialyzed yeast extract medium) which give viscous aqueous solutions and contain glucuronic acid, glucose, and mannose. Two species examined do not produce appreciable amounts of polysaccharide,* and *Xanthomonas stewartii* (formerly *Bacterium stewartii*), the corn wilt organism, forms a different type of polysaccharide containing glucuronic acid, galactose, and glucose (Table I). This polysaccharide also gives viscous solutions in water. These

Xanthomonas species incertae sedis and plant pathologists have placed it in the *Xanthomonas* genus even though it does not possess all the characteristics of the genus.

Since a large proportion of *Xanthomonas* spp. (Table I) produce polysaccharides which give solutions of high viscosity, it is of interest to observe that the vascular systems of plants can be blocked to some extent by these solutions. This effect has been observed on tomato cuttings by Riker and co-workers (2), using several polysaccharides, and by Leach *et al.* (3), who showed that excised seedlings of tomato, sunflower, and bean wilted under the influence of an aqueous solution of *X. phaseoli* polysaccharide. Also, the authors of the present paper have demonstrated the wilting properties of the *Corynebacterium insidiosum* polysaccharide on alfalfa cuttings and the fact that the polymer is formed in the infected plant itself (4). This physiological action has been observed in a different way by Corey and Starr (5), who studied the morphology of four strains of *X. phaseoli* and showed that the amount of polysaccharide formed by each strain could be correlated with its virulence on the host plant.

Therefore a more detailed structural analysis on the extracellular polysaccharides of the *Xanthomonas* species is being carried out, starting with *X. stewartii*. It is hoped that the polysaccharides from some of the other species containing glucuronic acid, glucose, and mannose (Table I) can be studied later.

The polysaccharide from *X. stewartii* proved to be highly branched, approximately one-third of the sugar residues consisting of non-reducing glucose end units. Studies on the methyl glycosides obtained from the fully methylated polysaccharides were kindly carried out by Dr. C. T. Bishop (6) using the gas–liquid phase chromatography procedure. The presence of the methyl glycosides of 2,3,4,6-tetra-*O*-methyl-D-glucose (4 parts), 2,3,4-tri-*O*-methyl-D-glucose (2 parts), 2,4,6-tri-*O*-methyl-D-galactose (1 part), and 2,3,4-tri-*O*-methyl-D-galactose (2 parts) was shown. Cellulose chromatography (7) of the reducing methyl sugars showed the absence of di-*O*-methyl-D-glucose. However, 2-*O*-methyl-D-galactose was isolated in a proportion equivalent to 1.8 parts taking into account the glucuronic acid in the molecule which is equivalent to 1.3 parts. The above figures also give an estimate of the proportion of sugars in the polysaccharide, which amount to glucuronic acid (11%), glucose (51%), and galactose (32%).

Periodate oxidation of the polysaccharide showed an immediate uptake (18 hours) of oxidant and production of formic acid with little further oxidation over a week. A 1.20-mole quantity of oxidant was consumed with the evolution of 0.58 mole of formic acid, amounts which agree closely with a 1.30 molar uptake and 0.65-mole quantity of formic acid that would be calculated from the methylation results.

Since information was required on the sugar sequence in the polysaccharide, a partial acid hydrolysis was carried out at 80° C with *N* sulphuric acid. Two main disaccharide fractions were obtained by cellulose chromatography, one of which was 6-*O*-β-D-glucopyranosyl-D-galactose, isolated in 13% yield. Although it crystallized only with difficulty, it could be converted readily to crystalline 6-*O*-β-D-glucopyranosyl-D-galactitol nonaacetate by sodium borohydride reduction followed by acetylation. This compound proved to be identical with a specimen prepared similarly from the authentic reducing disaccharide (8). The other disaccharide, 3-*O*-β-D-glucopyranosyl-D-galactose, did not crystallize. However, it gave glucose and galactose on acid hydrolysis and glucose only on sodium borohydride reduction followed by acid hydrolysis. The position of substitution on the galactose reducing end was determined by lead tetraacetate oxidation and since 1 mole was taken up immediately (3 minutes) with little increase over 30

minutes, the linkage was evidently in the 3-position (9). For a glucose–galactose disaccharide its specific rotation of +35° was low, suggesting a β-configuration for the glycosidic linkage.

An aldobiouronic acid was obtained by an isolation procedure similar to that described above except that the hydrolysis in *N* sulphuric acid was carried out at 100° C. The aldobiouronic acid gave a uronic acid and galactose on vigorous acid hydrolysis and when the dimer was oxidized with lead tetraacetate it consumed 1.8 moles of oxidant (after 30 minutes) at a slower rate than that expected for a 6-linkage. The material was therefore 4-linked and the 4-*O*-glucuronopyranosyl-D-galactose structure seemed likely. Treatment with diazomethane and reduction of the methyl ester with sodium borohydride (10) gave a crystalline disaccharide alcohol with $[\alpha]_D$ −13°. Acid hydrolysis gave glucose as the only reducing sugar, thus identifying the uronic acid portion. Since the specific rotations of the neutral derivative (and the parent aldobiouronic acid) were low, the configuration of the glycosidic linkage should be β.

Another type of acid hydrolysis of the polysaccharide was carried out using the procedure of Smith and co-workers (11) wherein the polysaccharide was oxidized with sodium periodate. The oxypolysaccharide was then reduced with sodium borohydride and the product obtained hydrolyzed with acid. However, with this polysaccharide somewhat more vigorous conditions were needed than those recommended by the Minnesota group. The reducing sugars obtained were galactose and a disaccharide, and after cellulose chromatography the dimer was isolated and tentatively characterized as 3-*O*-β-D-galactopyranosyl-D-galactose (12). Although it could not be induced to crystallize, it gave galactose only on acid hydrolysis. When it was treated with lead tetraacetate, the consumption of oxidant corresponded to a 3-linked disaccharide and the product on hydrolysis contained galactose and lyxose. The specific rotation (+52°) corresponded closely to that of authentic 3-*O*-β-D-galactopyranosyl-D-galactose. Since no trisaccharide was obtained in the partial hydrolysis of the modified polysaccharide, it can be safely assumed that there were no more than two successive galactose residues in the starting polysaccharide that were linked in the 3-position.

Methylation of the galactose-containing polysaccharide obtained by successive sodium periodate oxidation and sodium borohydride reduction and hydrolysis under milder conditions than above gave a product which, on hydrolysis, gave three poly-*O*-methyl galactose derivatives. These were isolated from cellulose columns and shown to be 2,3,4,6-tetra-*O*-methyl-D-galactose (characterized as the aniline derivative), 2,4,6-tri-*O*-methyl-D-galactose, and 2,6-di-*O*-methyl-D-galactose in the proportion 1.7:1:1.15, thus confirming the isolation of 3-*O*-β-D-galactopyranosyl-D-galactose. These results also suggest that the 2,6-di-*O*-methyl-D-galactose represents the same fragment that yields 2-*O*-methyl-D-galactose from the undegraded methylated polysaccharide. Also, since the degraded polysaccharide contained galactose only, the glucuronic acid portion in the *X. stewartii* polysaccharide was linked in such a way as to permit periodate oxidation.

Summarizing, the polysaccharide is highly branched and contains no points of single branching, only double branching as represented by the 2-*O*-methyl galactose obtained in the methylation studies. The polymer contains at least four different linkage types. These were demonstrated by the isolation of 6-*O*-β- and 3-*O*-β-D-glucopyranosyl-D-galactose, 3-*O*-β-D-galactopyranosyl-D-galactose and 4-*O*-β-D-glucuronopyranosyl-D-galactose and by identification of the hydrolysis products of the methylated polysaccharide (Table II). The non-reducing end units consist of glucose (and glucuronic acid perhaps) and it seems likely that these are β-linked to galactopyranose residues in the

For personal use only.

6-position. However, further deductions on the structure of this rather complex polysaccharide would be somewhat speculative and would require, for example, the isolation of trisaccharides in good yield in order to furnish a more comprehensive picture.

EXPERIMENTAL

Solutions were evaporated at 50° C under reduced pressure and specific rotations measured at 23° C.

Cultural Conditions for Xanthomonas spp.

The organisms were maintained and polysaccharide produced under conditions identical with those described in a previous paper (13). The yields were generally 1–4 g/liter of crude polysaccharide and this was purified as described previously (13).

Sugar Composition of Polysaccharides

The polysaccharides obtained from various species of *Xanthomonas* were hydrolyzed overnight on a steam bath in *N* sulphuric acid. After neutralization ($BaCO_3$), filtration, and evaporation the sugars were examined on paper chromatograms in various solvents using *p*-anisidine hydrochloride (14) as spray reagent. The results are recorded in Table I.

X. stewartii Polysaccharide and its Periodate Oxidation Characteristics

The polysaccharide had $[\alpha]_D$ +41° (*c*, 0.1, H_2O) and based on an anhydro hexose unit with mol. wt. 162 it contained, by titration, one acidic group per 9 units. Found: C, 43.4%; H, 6.6%; ash, 0.4%. It gave on acid hydrolysis at 100° C overnight in *N* sulphuric acid an aldobiouronic acid, galactose, and glucose. On oxidation with aqueous sodium periodate the following data were obtained:

Time, days	1	2	3	4	5	6
Uptake of oxidant, moles/mole	1.18	1.13	1.03	—	1.26	1.23
Formic acid produced, moles/mole	0.51	0.48	0.54	0.56	0.57	0.54

The end product was dialyzed to remove low molecular weight material and the sample consisting of roughly 50 mg of oxypolysaccharide in water (50 ml) was treated with sodium borohydride (50 mg). After a day, excess reductant was destroyed with acetic acid and the solution was then treated with Amberlite IR-120. The solution was filtered and evaporated to dryness, and the boric acid was removed by repeated evaporations with methanol. The product was hydrolyzed overnight at 100° C in *N* sulphuric acid (2 ml) and after neutralization ($BaCO_3$), filtration, and evaporation the product was examined on paper chromatograms (solvent: *n*-butanol–ethanol–water, 40:11:19 v/v). As would be expected from the periodate data, the only non-reducing sugar that appeared with the ammoniacal silver nitrate spray (15) was glycerol. The only reducing sugar detected was galactose.

Methylation and Hydrolysis of X. stewartii Polysaccharide

The polysaccharide (5.0 g) was dissolved in water (150 ml) to give a very viscous solution. Sodium hydroxide (30 g) in water (60 ml) was added and methylation was carried out by addition of dimethyl sulphate, in 11 separate aliquots of 3 cc each, once every 30 minutes. This process was repeated five times on successive days after which the solution was heated at 100° C for 3 hours. After cooling the methylation mixture was acidified slightly with dilute sulphuric acid and the gummy precipitate which formed was collected and dried. Yield, 3.8 g. The partially methylated polysaccharide was dissolved in dimethyl formamide (200 ml), methyl iodide (200 ml) was added, and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solution shaken vigorously. Silver oxide was added on 6 successive days in 30-g portions and after this time chloroform (1 liter) was added and the solution filtered (16). The chloroform was evaporated to a crust, which was redissolved in chloroform and washed with aqueous potassium cyanide followed by water. The methylated residue, after evaporation, weighed 3.6 g.

This product was refluxed in 10% methanolic hydrogen chloride (50 ml) overnight and the solution neutralized (Ag_2CO_3), filtered, and evaporated to a syrup. This was further hydrolyzed by heating at 100° C in *N* sulphuric acid (20 ml) overnight. Neutralization ($BaCO_3$), filtration, and evaporation yielded a syrupy product with —OCH_3 40.2%.

(a) Cellulose Column Chromatography

The above product appeared to contain, by paper chromatography, tetramethyl, trimethyl, and monomethyl hexoses and a spot corresponding to a methylated substance containing uronic acid. Fractionation of a portion (1.1 g) on a cellulose column using *n*-butanol as solvent gave 2-*O*-methyl-D-galactose (68 mg) and 545 mg of other methylated sugars. Two recrystallizations of the monomethyl sugar from ethanol gave crystals with m.p. 152–155° C. Calculated for $C_6H_{11}O_5(OCH_3)$: OCH_3, 16.0%. Found: OCH_3, 16.0%. X-Ray diffraction patterns prepared on this and an authentic specimen were identical.

(b) Gas–Liquid Phase Chromatography

The mixture of reducing methylated sugars (1.0 g) was refluxed overnight in 3% methanolic hydrogen chloride (20 ml). The acid was neutralized with silver carbonate, and the solution then filtered and evaporated to a syrup. Using a standard Pye unit, Dr. C. T. Bishop carried out quantitative separations at 200° C with a column of Carbowax 20 M on Chromosorb P (1:4 w/w) and a flow rate of 40 ml per minute of helium. Tetra- and tri-methyl hexoses were separated and estimated by integration of the area under the peaks on the flow chart (Table II).

3,4,6-Substituted galactose units	1.8
Glucuronic acid present*	1.3

*Based on titration against the original polysaccharide.

Partial Hydrolysis of X. stewartii Polysaccharide

(*a*) The polysaccharide (7.5 g) was partially hydrolyzed with *N* sulphuric acid at 80° C for 6 hours. The hydrolyzate was neutralized ($BaCO_3$), filtered, and deionized with Amberlite IR-120 and Dowex-1. The neutral portion (2.05 g) was fractionated on a cellulose column using *n*-butanol–ethanol–water (8:2:1 v/v) as the mobile phase. Two disaccharide fractions were obtained with $R_{lactose}$ 1.1 (1.05 g) and 0.9 (0.23 g) on paper chromatograms in the ethyl acetate – acetic acid – water (9:2:2 v/v) solvent.

For personal use only.

Both sugars were amorphous and the one with $R_{lactose}$ 1.1 (150 mg) ($[\alpha]_D$ +10° (*c*, 2.0, H_2O)) was reduced with sodium borohydride by the method described earlier to 6-*O*-β-D-glucopyranosyl-D-galactitol (73 mg), which after two recrystallizations from ethanol had m.p. 160–162° C and $[\alpha]_D$ −17° (*c*, 0.7, H_2O). Calculated for $C_{12}H_{24}O_{11}$: C, 41.9%; H, 7.0%. Found: C, 41.9%; H, 7.1%. Conversion to the acetate was effected by heating the sugar (30 mg) at 100° C for 18 hours in acetic anhydride (1 ml) containing sodium acetate (50 mg). The anhydride was destroyed with ice-water and a chloroform extract of the mixture was evaporated. On two recrystallizations from ethanol the nonaacetate (13 mg) was isolated, having m.p. 149–150° C. Calculated for $C_{30}H_{42}O_{20}$: C, 49.9%; H, 5.9%. Found: C, 50.0%; H, 5.9%. Its X-ray diffraction pattern was identical with an authentic specimen prepared in a similar way from 6-*O*-β-D-glucopyranosyl-D-galactose (8).

The disaccharide $R_{lactose}$ 0.9 was hydrolyzed with *N* sulphuric acid at 100° C overnight to give galactose and glucose. After reduction with sodium borohydride and subsequent hydrolysis, glucose was the only remaining reducing sugar. The reducing galactose unit was linked in the 3-position since, when the disaccharide was oxidized with lead tetraacetate in acetic acid, 0.98, 0.98, and 1.02 moles/mole of oxidant were consumed after 3, 10, and 30 minutes, respectively. The specific rotation of the disaccharide was +35° (*c*, 1.2, H_2O).

(*b*) *X. stewartii* polysaccharide (10 g) was hydrolyzed by heating in *N* sulphuric acid (100 ml) at 100° C for 18 hours. The reaction mixture was neutralized with barium carbonate, and the solution was filtered, treated with Amberlite IR-120, filtered, and evaporated to a crust. This was fractionated on a cellulose column and neutral sugars were eluted with *n*-butanol–ethanol–water (4:1:1 v/v). An aldobiouronic acid fraction (0.90 g) was obtained by using ethyl acetate – acetic acid – water (9:2:2 v/v) as the solvent. This sugar, $[\alpha]_D$ +15° (*c*, 1.0, H_2O), was hydrolyzed overnight at 100° C with 6 *N* sulphuric acid to give a uronic acid and galactose. The galactose portion was 4-linked since the aldobiouronic acid consumed 0.90, 1.52, 1.75, and 1.83 moles/mole of lead tetraacetate in acetic acid after 2, 5, 15, and 30 minutes, respectively.

One hundred and fifty-one milligrams of the aldobiouronic acid in methanol was converted by ethereal diazomethane to its methyl ester (147 mg). This was reduced with sodium borohydride (100 mg) in water (10 ml) for 2 hours and the product was isolated by the method described previously. The product was fractionated on a cellulose column using *n*-butanol saturated with water as solvent to give crude 4-*O*-β-D-glucopyranosyl-D-galactitol, which was crystallized twice from methanol to give a material (15 mg) with m.p. 204° C and $[\alpha]_D$ −13° (*c*, 1.1, H_2O). Calculated for $C_{12}H_{24}O_{11}$: C, 41.9%; H, 7.0%. Found: C, 42.0%; H, 6.85%. Acid hydrolysis with *N* sulphuric acid at 100° C overnight gave glucose (paper chromatogram).

Partial Hydrolysis of Polysaccharide Modified by Periodate Oxidation and Borohydride Reduction

Crude *X. stewartii* polysaccharide (40 g) was stirred with periodic acid (100 g) in 4 liters of water for 3 days, by which time all the polysaccharide had dissolved. Then aqueous barium hydroxide was added until the solution was slightly acid and residual acidity was removed with barium carbonate. The solution was filtered and then treated with sodium borohydride (10 g). After 18 hours the solution was brought to pH 5 with acetic acid and evaporated to a crust that was repeatedly shaken in methanol, which was evaporated. The product was deionized in water with Amberlite IR-120 and Dowex-1

(bicarbonate form), and the solution filtered and evaporated to 200 ml. The polysaccharide was precipitated by addition of 5 volumes of ethanol, and collected on a filter. Yield, 17 g.

Half of this material was dissolved in 0.1 *N* sulphuric acid (2 liters) and the solution heated at 95° C for 4 hours, neutralized ($BaCO_3$), filtered, and evaporated to a small volume. Examination on paper chromatogram indicated the presence of glycerol, galactose, and a disaccharide and these materials were separated by fractionation on a cellulose column. *n*-Butanol saturated with water gave glycerol (2.16 g) and *n*-butanol–ethanol–water (4:1:1 v/v) separated galactose (0.79 g) and the disaccharide (1.74 g).

The disaccharide gave galactose (on paper chromatograms) after hydrolysis on a steam bath overnight with *N* sulphuric acid. It consumed 0.88, 1.03, and 1.19 moles/mole of lead tetraacetate in acetic acid after 3, 10, and 25 minutes, respectively, indicating a 3-linked disaccharide. Since its specific rotation was +52° (*c*, 0.9, H_2O), it appeared to be 3-*O*-β-D-galactopyranosyl-D-galactose.

Methylation of X. stewartii Polysaccharide Modified by Periodate Oxidation and Borohydride Reduction

A sample of crude modified polysaccharide (4.35 g), prepared by the method described above, was methylated in the standard way (see earlier method in this section) with aqueous sodium hydroxide – dimethyl sulphate. After destruction of excess dimethyl sulphate the solution was neutralized with acetic acid and extracted once with chloroform. The extract was evaporated to dryness yielding a material (1.16 g) which was refluxed for 3 days in methyl iodide (50 ml) containing silver oxide (20 g). The product (0.99 g) after filtration and evaporation had —OCH_3 45.6%.

The methylated polysaccharide was hydrolyzed by refluxing overnight in 10% methanolic hydrogen chloride (20 ml) and, to this, water (20 ml) was added and the methanol removed by evaporation. A further hydrolysis at 100° C for 18 hours was carried out and the product after neutralization ($BaCO_3$) and evaporation contained three reducing sugars (paper chromatograms). Fractionation on a cellulose column using benzene–ethanol–water (1000:50:1 v/v) as solvent yielded 2,3,4,6-tetra-*O*-methyl-D-galactose (136 mg), 2,4,6-tri-*O*-methyl-D-galactose (75 mg), and 2,6-di-*O*-methyl-D-galactose (82 mg).

The tetramethyl galactose was characterized as its aniline derivative, m.p. 191–193° C. 2,4,6-Tri-*O*-methyl-D-galactose was recrystallized twice from ether and had m.p. 103–105° C and $[\alpha]_D$ +85° (*c*, 0.9, H_2O). 2,6-Di-*O*-methyl-D-galactose was crystallized twice from ethyl acetate and had m.p. and mixed m.p. 116–119° C and $[\alpha]_D$ +92° → +87° (*c*, 1.0, H_2O, constant value).

ACKNOWLEDGMENTS

The authors appreciate the technical assistance of Mrs. S. F. Hector and Mr. N. R. Gardner. Microanalyses were carried out by Mr. M. Mazurek.

THE ALUMINUM REDUCTION OF MAGNESIUM OXIDE

II. THE VAPOR PRESSURE OF MAGNESIUM OVER THE SYSTEM Al–MgO–CaO[1]

K. GRJOTHEIM, O. HERSTAD, AND J. M. TOGURI

ABSTRACT

The equilibrium vapor pressure of magnesium over the reaction between the calcined dolomite and aluminum was measured by means of the transportation method. In the temperature range 886–1035° C, the reaction was found to proceed according to the equilibrium

$$12CaO_{(s)} + 21MgO_{(s)} + 14Al_{(l)} = 12CaO.7Al_2O_{3(s)} + 21Mg_{(g)}$$

and the measured equilibrium pressure of magnesium can be expressed by the equation

$$\log P_{\text{mm of Hg}} = -(8754/T) + 8.462.$$

INTRODUCTION

Silicon as a reducing agent for magnesium-bearing compounds has been examined by a number of workers (1, 2, 3); however, an analogous examination of the reaction between calcined dolomite and aluminum does not appear to exist. The reaction is reported to proceed as follows (4):

$$5CaO + 9MgO + 6Al = 5CaO.3Al_2O_3 + 9Mg. \qquad [1]$$

In the present investigation, a continuation of the study of the reduction of magnesium compounds with aluminum, the equilibrium vapor pressure of magnesium over reaction [1] was determined and the solid products of the reaction were identified.

EXPERIMENTAL

Preliminary experiments indicated that the expected pressure of magnesium was of the order of 40 mm of Hg at 1000° C, a pressure suitable for the employment of the transportation method. This method of measuring vapor pressures has proved to be successful for a number of similar reactions (1, 2, 3, 5) provided the necessary precautions against diffusion errors and unsaturation of the carrier gas are observed.

The transportation apparatus and procedures adopted for the present study have been fully described previously (5).

The carrier gas utilized throughout this investigation was S-argon gas obtained from Norsk Hydro, the analysis given was 99.94%. The impurities CO_2 and H_2O were removed by passing the argon through ascarite and dehydrite towers respectively.

PREPARATION OF CHARGE

The calcined dolomite used in this investigation was obtained from Hammarfallene (Norway). The chemical analysis was, in weight per cent: 58.3% CaO, 40.3% MgO, 0.06% Al_2O_3, 0.16% Fe_2O_3, and 1.18% insolubles. The aluminum powder (99.9%) was obtained from Merck, Germany.

Before use, the calcined dolomite was dried at 1100° C for 24 hours to expell traces of CO_2 and H_2O. The calcined dolomite and aluminum were then mixed in a stoichiometric ratio (MgO/Al) according to equation [1], and ground in a ball mill for 12 hours. The mixture was then pressed into briquettes, 2.0 cm diameter by 1.0 cm in height, at a pressure of 500 kg/cm^2.

[1]*Manuscript received June 19, 1961.*
Contribution from the Institute of Inorganic Chemistry, The Technical University of Norway, Trondheim, Norway.

These briquettes were broken into approximately 5-mm particle size, and about 150 g of such pieces was used as a charge.

RESULTS AND DISCUSSION

(a) Vapor Pressure Measurements

The vapor pressure of magnesium over the mixture of calcined dolomite and metallic aluminum was measured over the temperature range 886–1035° C. A number of experiments at different flow rates were carried out at each temperature investigated in order to determine the equilibrium vapor pressure which is independent of the flow rate. The observed equilibrium pressures are tabulated in Table I. The estimated probable error in the measured vapor pressure is 1%.

TABLE I

Experimental vapor pressure of magnesium

Temp. (° C)	Pressure (mm of Hg)
887	8.30
925	14.00
955	20.40
968	25.70
992	34.80
1035	60.25

When the results from Table I were plotted as log P versus the reciprocal of the absolute temperature, Fig. 1 was obtained. The data may be represented as a straight line and

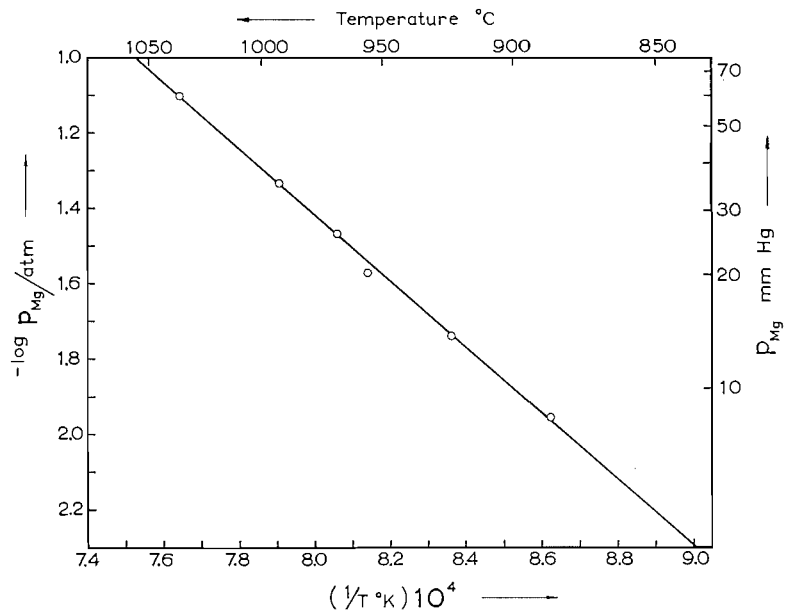

FIG. 1. Log P_{atm} of Mg versus $1/T°$ K.

fitted to the equation

$$\log P_{\text{mm of Hg}} = -(8754/T)+8.462,$$

where P is pressure in mm of Hg and T is the absolute temperature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(b) Analysis of the Reaction Product

Chemical analysis of the condensed magnesium showed no traces of calcium.

The solid residue was analyzed by X-ray diffraction in order to confirm the reaction products of equation [1]. The diffraction patterns obtained (shown in Fig. 2) correspond

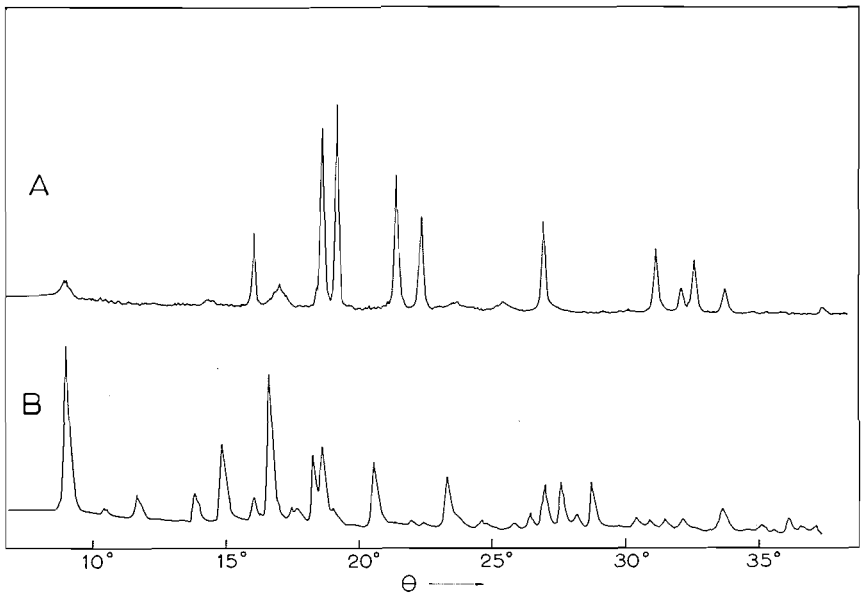

FIG. 2. X-Ray diffraction pattern (Cu target, Ni filter). A. Unreacted mixture of calcined dolomite and aluminum. B. Reacted mixture of calcined dolomite and aluminum.

only to CaO, MgO, Al, and $12CaO.7Al_2O_3$ when compared with the ASTM Index (6).

The literature indicates a difference in opinion regarding the similarity of the two compounds $5CaO.3Al_2O_3$ and $12CaO.7Al_2O_3$. The existence of the compound $5CaO.3Al_2O_3$ was first reported by Rankin and Wright (7). However, later investigators have found that this formula does not satisfy all the known characteristics of the compound. Bussem and Eitel (8) concluded, from a structural analysis of the compound, that it should be $12CaO.7Al_2O_3$. Recently, Aruja (9), following an X-ray analysis, concluded that the X-ray powder patterns of the compounds $5CaO.3Al_2O_3$ and $12CaO.7Al_2O_3$ showed no resemblance. There thus appears to be a controversy as to whether the two compounds are essentially identical or not. Nevertheless, since the X-ray patterns obtained, at all temperatures of this investigation, correspond to the powder pattern of $12CaO.7Al_2O_3$ reported by Swanson *et al.* (6, 10), this formula is used. The reaction is therefore written as follows:

$$12CaO_{(s)} + 21MgO_{(s)} + 14Al_{(l)} = 12CaO.7Al_2O_{3(s)} + 21Mg_{(g)}. \qquad [2]$$

The formation of the compound $12CaO.7Al_2O_3$ is not in accordance with the phase diagram of the system $CaO–MgO–Al_2O_3$ (11). The expected calcium aluminate is $3CaO.Al_2O_3$. However, no evidence could be obtained for its formation in the reaction studied. The possible reason for this might be either (I) that $3CaO.Al_2O_3$ is not a stable compound at the temperatures of the present investigation, or (II) that the kinetics of the formation of $12CaO.7Al_2O_3$ is much faster than that of $3CaO.Al_2O_3$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A number of experiments were carried out in which $3CaO.Al_2O_3$, prepared by heating CaO and Al_2O_3 in stoichiometric amounts at 1350° C for 48 hours and then quenching to room temperature, was held at various temperatures for a period of time and then quenched. X-Ray diffraction patterns for these samples showed that below 1200° C traces of $12CaO.7Al_2O_3$ were formed. When 1% CaF_2 was added, the diffraction lines for $12CaO.7Al_2O_3$ were more intense than in the samples without CaF_2, held at the same temperature and for the same period of time.

When samples of the reaction mixture (calcined dolomite and aluminum) were heated to temperatures beyond 1200° C, both $12CaO.7Al_2O_3$ and $3CaO.Al_2O_3$ appeared, the amount of $3CaO.Al_2O_3$ increasing with longer period of heating.

It is interesting to compare the present results with the aluminum reduction of CaO (12), where $12CaO.7Al_2O_3$ was also obtained rather than $3CaO.Al_2O_3$ for temperatures below 1200° C. Above this temperature, in agreement with the results reported here, $3CaO.Al_2O_3$ was found. It thus appears that $3CaO.Al_2O_3$ disproportionates below 1200° C and that above 1200° C the reaction

$$12CaO.7Al_2O_{3(s)} + 9CaO_{(s)} = 7(3CaO.Al_2O_3)_{(s)}$$

occurs.

In the present case it was concluded that $12CaO.7Al_2O_3$ must be the stable calcium aluminate in equilibrium with CaO at the temperatures of the pressure measurements. The thermodynamic calculations are therefore based on the formation of $12CaO.7Al_2O_3$.

(c) Thermodynamic Considerations

Since the reactions were carried out at temperatures above the melting point of aluminum, some solution of magnesium would be expected. As described previously (1), liquid aluminum at these temperatures can be assumed to form an ideal solution with magnesium. Thus the activity of aluminum can be calculated at each temperature provided the equilibrium vapor pressure of magnesium is known. It was assumed that no solid solution occurred between the solid components; thus the equilibrium constant is written in the form

$$K = P_{Mg}^{21}/a_{Al}^{14}.$$

A "Σ plot" was carried out using the equilibrium constant derived from the experiments and the specific heat functions recommended by Kelley (13). The derived functions are shown in Table II for the over-all reaction.

TABLE II

Thermodynamic functions for the reaction $12CaO_{(s)}+21MgO_{(s)}+14Al_{(l)} = 12CaO.7Al_2O_{3(s)}+21Mg_{(g)}$ in the temperature range 1154–1308° K

ΔC_p	$= -45.49+16.00\times10^{-3}T-5.50\times10^{5}T^{-2}$
ΔH^0_T	$= 909{,}198-45.49T+8.0\times10^{-3}T^2+5.50\times10^{5}T^{-1}$
ΔG^0_T	$= 909{,}198+104.76T \log T-8.0\times10^{-3}T^2+2.75\times10^{5}T^{-1}-908.77T$
$\Delta H^0_{1225°\,K}$	$= +865{,}900$ cal
$\Delta G^0_{1225°\,K}$	$= +180{,}500$ cal
$\Delta S^0_{1225°\,K}$	$= +559.55$ e.u.

Combining the experimental data with the available data on CaO, on Al_2O_3, and on $12CaO.7Al_2O_3$, one obtains for the reaction

$$12CaO + 7Al_2O_3 = 12CaO.7Al_2O_3 \quad [3]$$

the following data: $\Delta H^0_{298°\,K} = -18{,}500$ cal, and $\Delta S^0_{298°\,K} = 46.31$ e.u.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The entropy value reported by King (14) from low-temperature heat-capacity measurements is 50.6 e.u. Thus the value obtained in the present work is considered satisfactory when taking into account the errors involved in calculations of this type. The free energy of formation of the calcium aluminate from the oxides can be represented by the equation

$$\Delta G^0_T = -18{,}500 - 50.6\ T \pm 1.5 \text{ kcal.}$$

CONCLUSIONS

The reaction between calcined dolomite and metallic aluminum proceeds according to the equation

$$12CaO_{(s)} + 21MgO_{(s)} + 14Al_{(l)} = 12CaO.7Al_2O_{3(s)} + 21Mg_{(g)}$$

in the temperature range 886–1035° C. The corresponding equilibrium pressure of magnesium over this reaction can be represented by the equation

$$\log P_{\text{mm of Hg}} = -(8754/T) + 8.462$$

as determined by means of the transportation method.

LIGHT ABSORPTION STUDIES

PART XIX. THE ULTRAVIOLET ABSORPTION SPECTRA OF IODOBENZENES[1]

W. F. Forbes

ABSTRACT

As a sequel to previous studies on the ultraviolet absorption spectra of halogen-substituted benzenes the spectra of iodobenzene in various solvents, and the spectra of a series of substituted iodobenzenes in cyclohexane solution, are reported. It is shown that these spectra can be rationalized qualitatively in terms of simple resonance theory, if the apparent mesomeric effect of the iodine atom is assumed to be greater for iodine than for the other halogen atoms.

INTRODUCTION

In previous papers on the ultraviolet spectra of bromobenzenes (1), chlorobenzenes (2), and fluorobenzenes (3), band nomenclature and other terms used were discussed. Since in the present paper the terms employed are identical, no further introduction is required concerning them. The above-mentioned three papers noted generalizations which could be deduced from the spectra, and the purpose of the present paper is to extend and summarize these observations, particularly those concerning the apparent mesomeric order of the halogen atoms, by the study of the ultraviolet absorption spectra of the iodobenzenes.

EXPERIMENTAL

The ultraviolet absorption spectra were determined by standard methods in matched 1-cm silica quartz cells using both a Beckman DK 2 spectrophotometer and a Unicam SP 500 spectrophotometer calibrated against a didymium filter and solutions of potassium chromate and potassium nitrate. Wavelength readings obtained on the two instruments were found to be within 1 mμ of each other. The accuracy of λ_{max} values is estimated to be ± 1 mμ, and the precision of molar absorptivities, $\pm 5\%$ or better. Most molar absorptivity values were reproducible to $\pm 2\%$. The solvents used were spectroanalyzed cyclohexane (Fisher) and other commercially available spectroanalyzed solvents.

The iodobenzenes were mostly commercial materials, purified by distillation or recrystallization until their boiling points and refractive indices or melting points showed them to be sufficiently pure. Some of the iodobenzenes, including iodobenzene itself, decomposed slightly and afforded a limited amount of iodine. The iodine thus liberated was estimated by its absorption maximum near 525 mμ in cyclohexane solution. The amount formed was usually less than 1%. Whenever possible, the iodobenzene spectra were determined under conditions similar to those under which previous spectra in this series had been determined. For each compound at least two independent sets of observations were made. The ultraviolet maxima are listed in Tables I and II. Some of the spectra have previously been described in this series or elsewhere (cf., for example, refs. 4, 5, and 6, and references cited therein).

THE SPECTRUM OF IODOBENZENE

The absorption characteristics of iodobenzene in different solvents are listed in Table I.

Comparison of the ultraviolet spectral data for iodobenzene and other halogen-substituted iodobenzenes (1, 2, 3) shows that the more intense absorption band of iodobenzene, the *B*-band (7), occurs at longer wavelength and with greater absorption

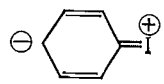
†Intensities not determined.
‡Sodium iodide has a maximum at similar wavelength (226 mμ) in aqueous solution. This maximum, however, is appreciably displaced in ethanolic solution (to 219.5 mμ) and in ether solution (to 248.5 mμ). The iodobenzene *B*-band is therefore not believed to be due to modified iodide ion absorption (cf. ref. 8).



intensity than for other halogen-substituted benzenes. These spectral changes can be interpreted in terms of an apparent mesomeric release of electrons in the order I > Br > Cl > F. Other ultraviolet spectral data (see refs. 1, 2, 3, and 9, and later discussion in this paper) also suggest this order, as do the intensities of the infrared carbonyl bands of halogen-substituted acetophenones (these intensities have been related to mesomeric interaction (10)) and some coupling constants and asymmetry parameters obtained from nuclear quadrupole resonance spectra (11).

On the other hand, it is well known that reactivity and dipole-moment data can best be interpreted by assuming a mesomeric release of electrons in the order F > Cl > Br > I (cf. also refs. 9, 12, and 13, and references cited therein). Other data, which provide information concerning electron density, such as the location and intensities of the ultraviolet *C*-bands and certain solvents effects on spectra (see below), reactivities (14), and ionization potentials (cf. ref. 15), afford various orders for the mesomeric effects of the halogen atoms. The absolute mesomeric order of the halogen atoms therefore remains unknown. In the meantime it may be assumed, as a working hypothesis, that the "apparent mesomeric effect" of the halogen atoms, as indicated by the present ultraviolet spectral data, corresponds to a mesomeric release of electrons in the *electronic excited state* in the order I > Br > Cl > F. The electronic excited state concerned is the state primarily involved in the transitions leading to the *B*-bands of the ultraviolet spectra. On this hypothesis it may be assumed that the net order of release of electrons for the halogens is different in the electronic excited state and in the ground state. The electronic excited state of iodobenzene may be visualized as involving resonance forms of type I, and this simplified resonance picture accounts satisfactorily for a number of the ultraviolet spectral changes.

The *B*-band of iodobenzene shows a characteristic, fine structure in most solvents (see Fig. 1). The wavelength displacement observed between solutions in cyclohexane

and the vapor phase is of the order of 5 mμ (see Table I), which is considerably greater than the corresponding displacements observed for fluorobenzene, chlorobenzene, and bromobenzene (refs. 1, 2, 3; cf. also ref. 16). This observation is consistent with the view that the C—I dipole makes a greater contribution to the relevant electronic excited

I

state of iodobenzene, probably by facilitating solvent orientation, than do the C—F, C—Cl, or C—Br dipoles to the corresponding excited states of the other halobenzenes. This, in turn, is consistent with the resonance picture described above.

Other spectral changes, with change of solvent, are illustrated in Fig. 1. As with bromobenzene and chlorobenzene (1, 2) no appreciable wavelength displacements are

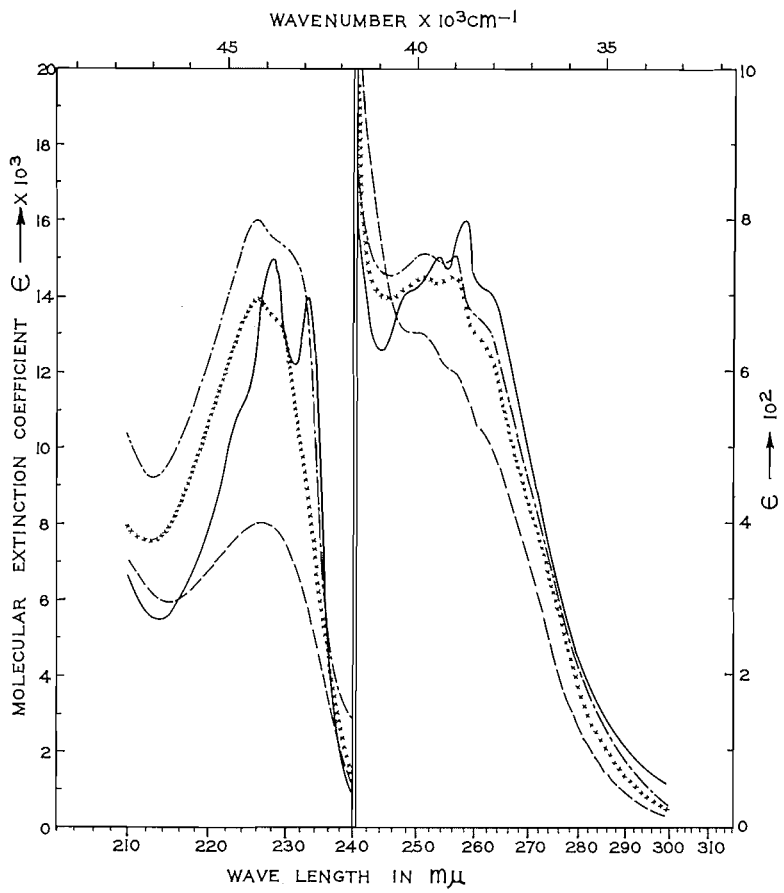

FIG. 1. The ultraviolet absorption spectra of iodobenzene in cyclohexane solution (——), in ether (—·), in ethanol (×××), and in water (— —).

observed on changing the solvent, although the maximal extinction coefficients are decreased in aqueous solution. This decrease, presumably caused by some form of intermolecular hydrogen bonding, appears to be general for halogen-substituted benzenes. Further, the fine structure is decreased in aqueous solution.

The *C*-band of iodobenzene (for band nomenclature used, see ref. 7) is considerably more intense than that of bromobenzene or chlorobenzene. However, in most solvents the band is approximately as intense as that of fluorobenzene (see Fig. 1 and cf. ref. 3). This indicates that the *C*-band of iodobenzene is determined by a combination of electronic interactions different from that used in determining the *B*-band (cf. refs. 13 and 17). Wavelength displacements of the *C*-band for the halogen-substituted benzenes also are not in a definite order with increasing molecular weight of the halogen substituent. However, the *C*-band fine structure in cyclohexane solution becomes progressively less pronounced on passing from fluorobenzene to iodobenzene. For fluorobenzene, the *C*-band fine structure resembles that of benzene (see Fig. 1 of ref. 3), whereas for iodobenzene this is much less pronounced. This may be because the iodo substituent more effectively disturbs the symmetrical vibrations of the benzene ring because of increased mesomeric interactions.

THE SPECTRA OF PARA-SUBSTITUTED IODOBENZENES

As previously noted, in *p*-disubstituted benzenes, where one substituent is electron withdrawing and the other a halogen atom, the *B*-band occurs at its longest wavelength in the iodine derivative. It may be noted that most functions, such as σ^*, σ_p, σ', but not $\sigma_p - \sigma'$, for electron-donating substituents differ in sign from the above-mentioned electron-withdrawing substituents. On the other hand, in the *B*-band of the ultraviolet spectra of *p*-substituted iodobenzenes *both* these types of substituents cause bathochromic wavelength displacements, that is, displacements to lower frequency (cf. also the work reported by Bloor and Copley (18) on spectroscopic constants). Simple valence bond theory can again account for this anomalous behavior in the ultraviolet spectra. This follows since, as illustrated by structure III, an extended dipolar resonance form of type II is no longer favored when both substituents are electron donating, and the molecule consequently tends to absorb to a *locally excited state* with the methoxy substituent exerting only a secondary effect. If resonance structures, crudely represented by IV and V, are assumed to contribute to the electronic excited state, such a secondary effect will, however, still normally facilitate the transition. This can account for the observed bathochromic wavelength displacements on introduction of a *p*-iodo substituent into a monosubstituted benzene derivative.

II III IV V

The predominant locally excited state can usually be identified by characteristic band features of the relevant absorption band; for example, the iodobenzene *B*-band in cyclohexane solution is a doublet with the twin peaks separated by ca. 5 mμ (see Fig. 1), and this doublet can still be discerned in some of the *p*-substituted iodobenzenes. This is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

illustrated in Fig. 2, which shows the absorption spectra of *p*-chloroiodobenzene, *p*-bromoiodobenzene, *p*-diiodobenzene, and iodobenzene, all in cyclohexane solution. The *B*-bands

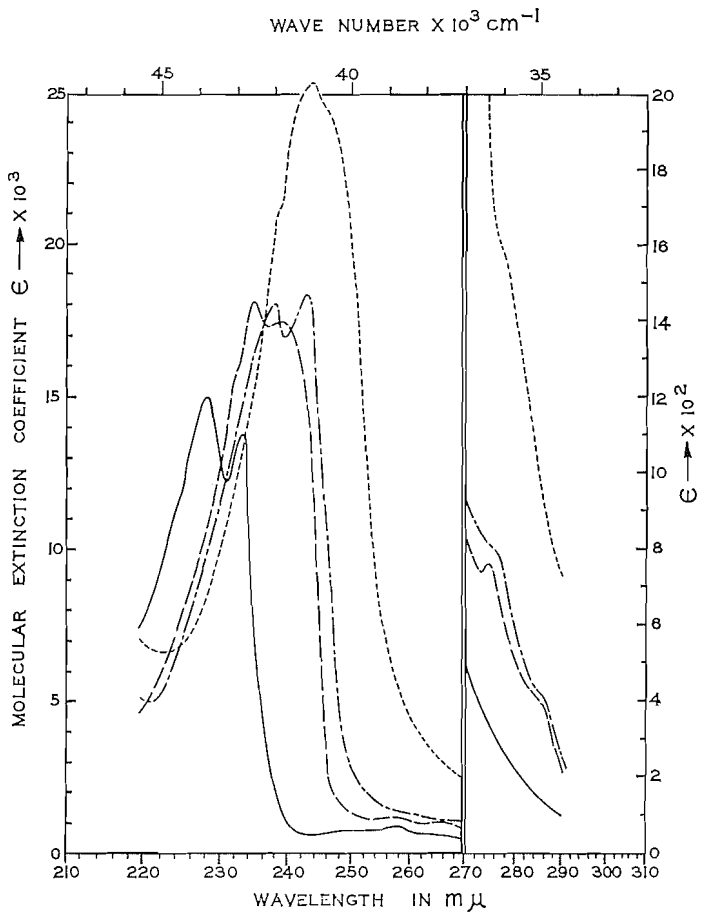

FIG. 2. The ultraviolet absorption spectra in cyclohexane solution of *p*-chloroiodobenzene (— —), *p*-bromoiodobenzene (—·), *p*-diiodobenzene (- -), and iodobenzene (——).

of the four compounds show that the *p*-chloro, *p*-bromo, and *p*-iodo substituents cause the iodobenzene absorption to occur at slightly longer wavelength. Moreover, this secondary effect of a *p*-substituent on the *B*-band absorption of iodobenzene is greater for an iodo than for a bromo or chloro substituent. This secondary effect of the halogen atom thus also follows the order of the apparent mesomeric effects. The maximal molar absorptivity of these *p*-substituted iodobenzenes shows large increases compared with that of iodobenzene (see Fig. 2), the ϵ_{max} values approaching, or even exceeding, those which are observed for *p*-substituted iodobenzenes when the *p*-substituent is electron withdrawing (see Table II). This may indicate a large transition moment which, in turn, suggests that electronic interactions, as crudely represented by structures of type III, and others, are important. Evidence that such structures contribute to the ground or electronic excited state of *p*-substituted iodobenzenes, when both substituents are electron donating, can also be deduced from the *B*-band solvent changes. For example, Fig. 3 shows that the

†Band assignment doubtful.
‡Indicates accompanying fine structure near the maximum.

B-band of *p*-iodoanisole is displaced to slightly shorter wavelength, whereas the *B*-band of *p*-iodophenol is displaced to slightly longer wavelength, on passing from cyclohexane to ethanol solution. These displacements are characteristic of anisole and phenol absorption respectively (19, 20) and consequently indicate that the methoxy and hydroxy groups play a part in determining the transition of the relevant *B*-bands.

The *C*-bands of *p*-substituted iodobenzenes frequently show features of the *C*-bands of both the monosubstituted benzene parent compounds. For example, the *C*-bands of

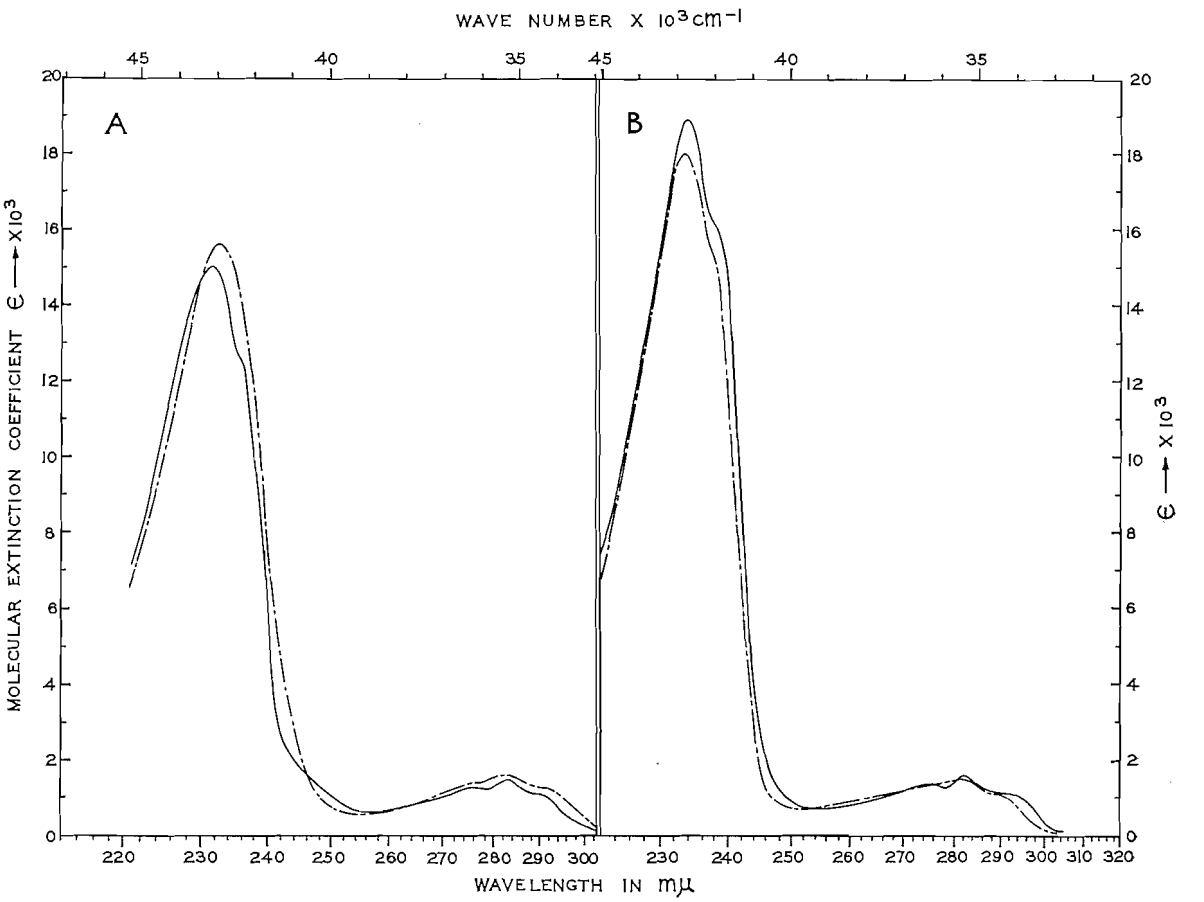

FIG. 3. The ultraviolet absorption spectra of (A) *p*-iodophenol and (B) *p*-iodoanisole in cyclohexane (—) and ethanol (—·) solutions.

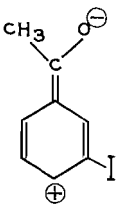
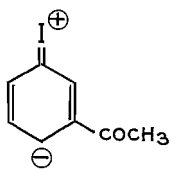


p-iodophenol and *p*-iodoanisole (see Fig. 3) are similar to the *C*-bands of both iodobenzene (see Fig. 1) and, with respect to their locations of maximal absorptions, to the *C*-bands of either phenol or anisole (19, 20). However, the *C*-band of the *p*-substituted iodobenzenes generally occurs at longer wavelength than that of either of the two "component" *C*-bands.

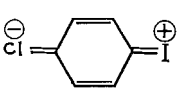
THE SPECTRA OF META-SUBSTITUTED IODOBENZENES



The absorption characteristics of *m*-substituted iodobenzenes can again be rationalized in terms of simple resonance theory by observing that no extended dipolar resonance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

form can be written. Hence one might expect a *m*-substituted iodobenzene, such as *m*-iodoacetophenone, to exhibit one or both of the *B*-bands corresponding either to iodobenzene or to acetophenone absorption. (The latter band is referred to as the second *B*-band in Table II.) In this way the two *B*-bands of *m*-iodoacetophenone for example, are associated with resonance forms of type VI and VII respectively, with the iodo or acetyl group, respectively, causing only a secondary effect.



VI

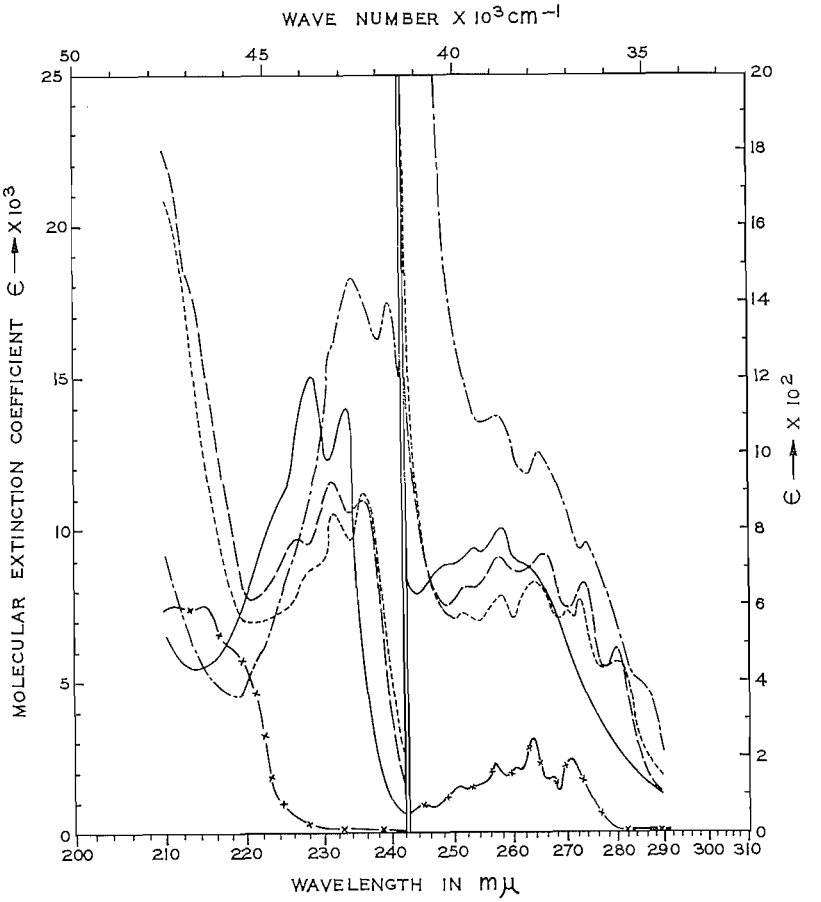
VII

The precise mechanism of this secondary effect remains obscure and appears to vary with different *m*-substituted iodobenzenes, but the following facts may be noted. First, the iodine atom decreases the intensity of the acetophenone absorption (acetophenone in cyclohexane solution absorbs maximally at 238 mμ, $\epsilon = 12{,}500$), and this effect is paralleled in the decrease of the intensities of the infrared carbonyl bands of the *m*-halogen-substituted acetophenones compared with that of acetophenone (10). Secondly, the substitution of an iodine atom in the *m*-position reduces the ultraviolet acetophenone *B*-band absorption intensity more effectively than does the substitution of other halogen atoms (cf. refs. 1, 2, and 3). Hence, it seems that in the electronic excited state of *m*-iodo-acetophenone, forms which may be such as resonance forms of type VII, are preferred to those of type VI. This may be explained if the iodine atom, by *donating* electrons to the benzene ring, facilitates the electronic excited state involving structures such as VII. Also on passing from *m*-fluoroacetophenone to *m*-iodoacetophenone, resonance forms of type VII may be assumed to be more and more favored and this is reflected in the intensification of the absorption band associated with halobenzene absorption and the simultaneous diminution of that associated with acetophenone. The secondary spectral changes, occurring in some of the *m*-substituted iodobenzenes, can therefore again be explained in terms of simple resonance theory if it is assumed that, where the *m*-substituent is electron withdrawing, the electron-releasing abilities of the halogen atoms are in the order I > Br > Cl > F.

When both substituents in a *m*-substituted iodobenzene are electron donating as, for example, in *m*-chloroiodobenzene, the iodobenzene *B*-band intensity appears to be slightly reduced relative to the absorption intensity of iodobenzene. This also applies to the *B*-band of *o*-chloroiodobenzene, but not to *p*-chloroiodobenzene, since in the latter *B*-band the iodobenzene absorption clearly predominates (see Fig. 4). This is presumably because interactions associated with resonance forms of type VIII are sufficiently important in *p*-chloroiodobenzene to cause a predominance of iodobenzene *B*-band absorption.

VIII

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



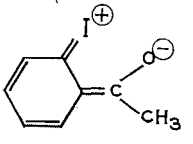


FIG. 4. The ultraviolet absorption spectra in cyclohexane solution of *m*-chloroiodobenzene (— —), *o*-chloroiodobenzene (- -), *p*-chloroiodobenzene (—·), iodobenzene (——), and chlorobenzene (—×).

The *C*-bands of *m*-substituted iodobenzenes appear to be additive as a first approximation, that is, the observed *C*-band approximates to the sum of the two *C*-bands of the corresponding monosubstituted benzenoid parent compounds. However, the *C*-band of the *m*-substituted iodobenzenes is also generally displaced to slightly longer wavelength (see, for example, the *C*-bands in Fig. 4).

THE SPECTRA OF ORTHO-SUBSTITUTED IODOBENZENES

It is well known that the *B*-bands of a number of *o*-disubstituted benzene derivatives frequently resemble the *B*-bands of the corresponding *m*-isomer, that is, two *B*-bands are often observed corresponding to the *B*-bands of the two monosubstituted benzene derivatives. The reason why electronic excitation should occur to locally excited states rather than to so-called electron-transfer states, as symbolized by resonance forms of type IX, is obscure.

IX

Steric interactions are certainly evident from a number of spectral and other data. Ungnade (21) has shown that for *o*-halonitrobenzenes the band near 260 mμ occurs as a shoulder only for *o*-iodonitrobenzene and that its molar absorptivity at 260 mμ is the smallest among the *o*-halonitrobenzenes if the iodine absorption is taken into account. This band near 260 mμ corresponds to nitrobenzene absorption and its decreased intensity may be taken to imply that the *o*-iodo substituent twists the nitro group out of the plane of the benzene ring and thus inhibits the nitrobenzene *B*-band absorption. In other examples also, the "second" *B*-band of *o*-halogen-substituted benzene derivatives, if well defined, is least intense in the *o*-iodosubstituted compound (cf. ref. 22; for evidence of steric interactions in *o*-substituted iodobenzenes see also refs. 23, 24, and 25).

The spectrum of *o*-iodophenol, compared with that of *o*-iodoanisole, does not suggest intramolecular hydrogen bonding in the former compound, although there is evidence that weak intramolecular hydrogen bonding exists (26, 27). This therefore represents an example of an intramolecular hydrogen bond which does not give rise to a spectral change characteristic of hydrogen bonding (i.e. bathochromic wavelength displacement accompanied by an intensity increase) in the main ultraviolet maxima. It emphasizes the caution which is required before the lack of an ultraviolet spectral change is used to show the absence of intramolecular hydrogen bonding. One of the reasons why some intramolecular hydrogen bonds do not give rise to appreciable ultraviolet spectral changes is that a molecule may absorb to locally excited states which do not involve the part of the molecule which contains the intramolecular hydrogen bond (cf. ref. 28).

It may next be noted that in *o*-substituted halobenzenes the iodobenzene *B*-band, like the bromobenzene *B*-band (1), frequently no longer occurs, or occurs only with reduced absorption intensity. Moreover, in compounds such as *o*-iodonitrobenzene, a hypsochromic wavelength displacement also occurs relative to the *B*-band maxima in the corresponding *m*-isomers (see Table II). These spectral changes suggest steric interactions involving the iodobenzene chromophore. A possible explanation of the spectral changes is that the iodine atom is dislodged from the plane of the benzene ring in such a way that certain interactions between the π-orbitals of the benzene ring and the pseudo π-orbitals of the iodine atom are no longer possible.

The *C*-band in *o*-substituted iodobenzenes, on the other hand, sometimes occurs with decreased and sometimes with increased absorption intensity (see Table II). It has already been suggested (see the section on the spectrum of iodobenzene) that increased mesomeric interaction gives rise to a less pronounced *C*-band and this can account for the *C*-band changes in *o*-substituted iodobenzenes. That is, steric interactions may tend to inhibit mesomeric interaction between the substituents and the benzene ring, and this partial inhibition of mesomeric interaction may cause the frequently observed intensity increase of the *C*-band relative to the intensity of the *C*-band of the *m*-isomer (see, for example, the *C*-band of *o*-iodoaniline in Table II). As steric interactions become large, however, the interaction between the chromophores, which initially gives rise to the characteristic *C*-band, tends to be completely inhibited and the *C*-band intensity now *decreases* towards the intensity value observed in the *C*-band of the isolated benzene molecule (see, for example, the *C*-band of *o*-iodotoluene in Table II and also ref. 29). The hypothesis therefore predicts that steric interactions may either increase or decrease the *C*-band intensity of *o*-substituted iodobenzenes.

ACKNOWLEDGMENTS

The author is indebted to Miss V. R. Jellett for the careful determination of the ultraviolet spectral data. Some of the spectra have been determined at the Memorial

THE ELECTRONIC SPECTRA OF $MoCl_5$ AND $NbCl_5$[1]

RICHARD F. W. BADER AND ALAN D. WESTLAND

ABSTRACT

The visible and ultraviolet spectra of $MoCl_5$ and $NbCl_5$ have been investigated in both the vapor state and solution. The number of bands observed indicates that a Jahn–Teller effect may be operative in the $^2E'$ state of $MoCl_5$.

INTRODUCTION

Early electron diffraction studies have indicated that, in the gas phase, both molybdenum and niobium pentachloride possess trigonal bypyramid structures (1, 2). The resulting D_{3h} symmetry produces an interesting splitting of the $4d$ metal orbitals in these compounds, the interest of which is enhanced by the fact that the single $4d$ electron present in the $MoCl_5$ molecule should bring about a Jahn–Teller distortion of the nuclear framework in both the ground and first excited states. For these reasons we have undertaken a complete spectroscopic investigation of $MoCl_5$ and $NbCl_5$. The results for the visible and ultraviolet regions are given here; the infrared investigations will be reported shortly.

A simple application of group theory shows that, in the crystalline field of the five halide ions, the $4d$ atomic orbitals of the metal ion are split into two sets of orbital doublets (e'' and e') and into an orbital singlet (a_1'). Furthermore, crystal-field calculations by Ballhausen and Klixbüll Jørgensen (3) have shown that the order of the orbital levels is $\bar{a}_1' > \bar{e}' > e''$, i.e., the e'' orbital is the most stable, as shown in Fig. 1 (the

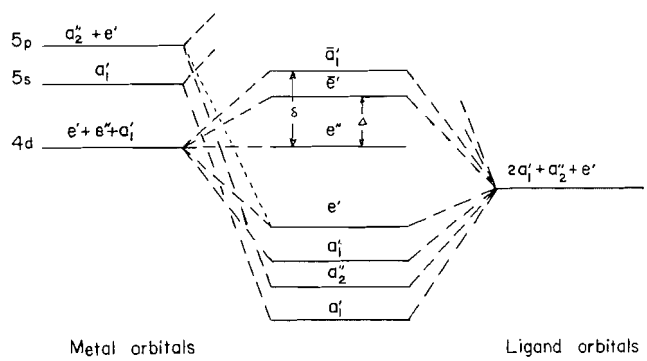

FIG. 1. The ligand field splitting diagram for a trigonal bipyramid molecule.

d–d orbital separations are designated by Δ and δ as shown). Also shown in the same figure are the ligand molecular orbitals for an MX_5 complex. It is seen that the five bonding σ molecular orbitals of the ligands are of symmetries a_1', a_2'', and e'. Thus, of the d orbitals, only those of a_1' (d_{z^2}) and e' ($d_{x^2-y^2}$, d_{xy}) symmetry may participate in the σ-bonding with the ligand molecules, corresponding to the fact that their antibonding combinations (designated by a bar) are raised in energy over that of the e'' (d_{xz}, d_{yz})

orbital. This electronic description may be related to the d^3sp configuration of Pauling.* The electronic structure of the metal ions is $Kr(4d)^n$, giving ground electronic states of $^1A_1'$ for $Nb(V)$ ($n = 0$) and $^2E''$ for $Mo(V)$ ($n = 1$, the single $4d$ electron will occupy the e'' orbital).

The theorem of Jahn and Teller (4) states that a non-linear molecule which possesses a spatial degeneracy in a symmetrical configuration will have an equilibrium configuration of some lower symmetry in which the electronic degeneracy has been lost. Therefore, both the ground electronic state of $MoCl_5$ (with one electron in the e'' orbital) and the first excited state (with one electron in the e' orbital) should exhibit Jahn–Teller distortions. (The electronic spectrum of $NbCl_5$, which possesses a closed shell structure identical with that of the molybdenum compound, was investigated as well to determine the character of the charge transfer bands and hence aid in the assignment of the d–d transitions.)

The Jahn–Teller effect represents a breakdown of the Born–Oppenheimer approximation, for it introduces an intimate coupling of certain of the nuclear motions with the electronic angular momentum, leading to the formation of vibronic states in which the concept of a potential surface has been lost.

The static problem (12) leading to the distortion may be treated as a first-order splitting of the electronic degeneracy by certain of the vibrational motions of the molecule. Which of the vibrational motions will provide such a perturbation is again best determined by the methods of group theory. The structure of the vibrational representation of a trigonal bipyramid is

$$\Gamma_{vib} = 2A_1' + 3E' + 2A_2'' + E''.$$

The only motions which resolve the degeneracy of the $^2E''$ and $^2E'$ electronic states are the three vibrations of E' symmetry. (Only the direct products of species $\Gamma_{E'}$ with $\Gamma_{E''}{}^2$ and $\Gamma_{E'}{}^2$ contain the identity representation aside from the identity representation itself.)

The representation of D_{3h} spanned by the even harmonics of order less than five contains the identity representation three times ($n = 0, 2, 4$). Therefore, the non-spherically symmetric crystal-field contribution to the Hamiltonian has the form

$$H_c = \Sigma_i(A Y_{20} + B Y_{40}) \qquad [1]$$

and in the general case two sets of constants A and B will be required, one set for the axial ligands and another for the equatorial ligands. The Y_{nm} are the usual spherical harmonics. Terms with m values different from zero do not appear in [1] due to the trigonal arrangement of the three ligands in the plane. The matrix of this perturbation will obviously have no off-diagonal elements in the $|l,m\rangle$ basis of the $4d$ orbitals. The orbitals are simply split into two doublets $|2,2\rangle,|2,-2\rangle(e')$, and $|2,1\rangle,|2,-1\rangle(e'')$ and into the singlet $|2,0\rangle$ (a_1'). We may thus conveniently employ the same basis functions to derive the Jahn–Teller splittings with the perturbation of required E' symmetry given by

$$H_{E'} = \Sigma_i[Y_{2\pm2}R_2(r_i) + Y_{4\pm4}R_4(r_i)]Q \qquad [2]$$

where Q is a normal co-ordinate of E' symmetry. It is easily seen that there are no diagonal

*The $5p_x$ and $5p_y$ metal orbitals may also participate to some extent in σ-bonding with the three equatorial ligands as indicated by the light dashed line joining the $5p$ and e' levels in Fig. 1. A trigonal bipyramid may also be formed using the dsp^3 orbitals of the metal. Thus there are in this case a total of seven orbitals (no more than three of them d orbitals) of proper symmetry to participate in the σ-bonding in an MX_5 molecule.

elements of this perturbation; there are only off-diagonal ones, between $|2,2\rangle$ and $|2,-2\rangle$, which are mixed under $Y_{4\pm4}$, and between $|2,1\rangle$ and $|2,-1\rangle$, which are mixed under $Y_{2\pm2}$. (The perturbation $H_{E'}$ will also mix in some of the $|2,0\rangle$ state with the $|2,\pm2\rangle$ states but this can be ignored because of the large energy separation between the two sets of states and, furthermore, it does not change the form of the results.) If we let the matrix elements $\langle l,m \mid H_{E'} \mid l,-m^*\rangle$ have the values kQ and $k'Q$ for $|m| = 1$ and 2 respectively, then the eigenvalues of the two perturbation problems combined with the harmonic restoring force $\frac{1}{2}KQ^2$ are

$$V = \tfrac{1}{2}KQ^2 \pm kQ \qquad \text{for the } E'' \text{ state,}$$

$$V = \tfrac{1}{2}KQ^2 \pm k'Q \qquad \text{for the } E' \text{ state.}$$

This shows that both the E'' and E' states are resolved under the influence of the E' vibrations and that the nuclear potential function is split into two branches. A plot of either value of V versus Q leads to a double cone potential surface with the potential minimum at $Q = k/K$ (or k'/K) as illustrated in the paper by Longuet-Higgins, Öpik, Pryce, and Sack (5). The nuclear motions of E' symmetry are shown in Fig. 2. The E'

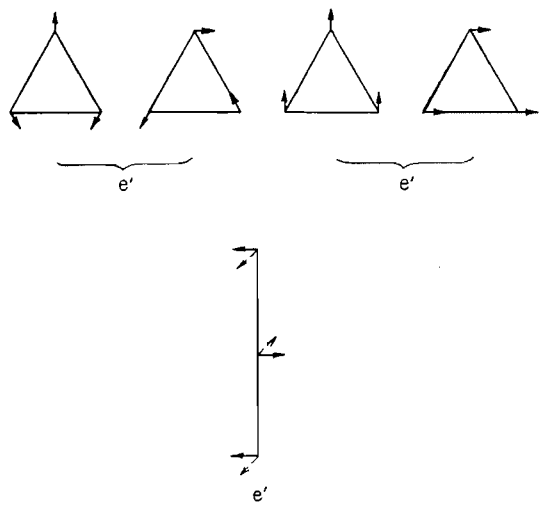

FIG. 2. The nuclear motions of E' symmetry for a trigonal bipyramid molecule.

vibrations will be combinations of these motions, the exact forms of which can only be deduced when the forms of the normal vibrations are known. One of the possible distortions is shown in Fig. 3. It is seen that the result is a lowering of the symmetry to C_{2v} which removes the degeneracy of all the levels.

Molybdenum is from the second transition series; therefore, one cannot overlook the possibility of a strong spin–orbit coupling upsetting the Jahn–Teller effect. As we point out in the Discussion, while we are confident that a large Jahn–Teller effect will be present in the first excited state due to the occupation of the e' antibonding orbital, the spin–orbit coupling may quite easily be of sufficient strength to prevent a distortion from occurring in the ground state where the degeneracy arises from the e'' non-bonding orbital. We restrict the following analysis then, to the $|\pm1\rangle$ states, but actually a similar treatment with corresponding results holds for the $|\pm2\rangle$ kets.

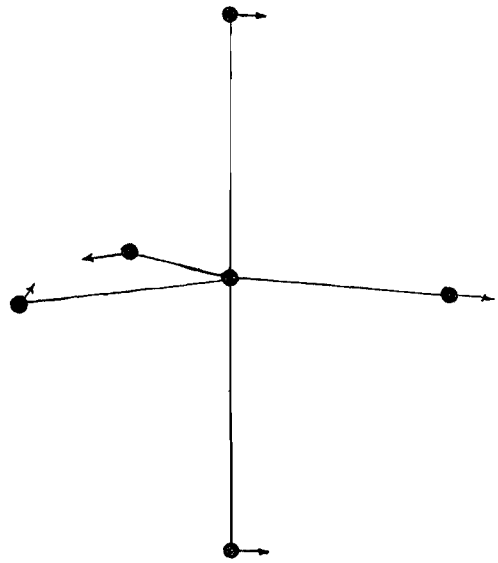

FIG. 3. A possible E' vibrational distortion of a trigonal bipyramid molecule.

In the absence of spin–orbit interactions, the ground state $^2E''$ is fourfold degenerate, $|\pm 1, \pm\frac{1}{2}\rangle$ (in the $|m_l, m_s\rangle$ notation). Spin–orbit coupling alone will result in the formation of two Kramers spin doublets, the degeneracy of which cannot be removed by any electrostatic field. We now investigate the problem of the simultaneous operation of a spin–orbit coupling and a Jahn–Teller effect of comparable magnitude. The secular matrix of the operator

$$H' = H_{E'} + \lambda \bar{L} \cdot \bar{S}$$

is

$$\begin{array}{c|cc} & |\pm 1, \pm\frac{1}{2}\rangle & |\mp 1, \pm\frac{1}{2}\rangle \\ \hline \langle \pm 1, \pm\frac{1}{2}| & \frac{1}{2}\lambda & kQ \\ \langle \mp 1, \pm\frac{1}{2}| & kQ & -\frac{1}{2}\lambda \end{array} . \qquad [3]^*$$

The roots of the corresponding secular equation are (each root occurs twice as all the levels are still Kramers doublets)

$$E = \pm\tfrac{1}{2}(\lambda^2 + 4k^2Q^2)^{\frac{1}{2}}.$$

To obtain the total potential V, we add the harmonic restoring force $\frac{1}{2}KQ^2$ to these roots and obtain

$$V_\pm = \tfrac{1}{2}KQ^2 \pm \tfrac{1}{2}(\lambda^2 + 4k^2Q^2)^{\frac{1}{2}}.$$

Notice that, for $Q = 0$, the spin–orbit coupling has removed the degeneracy of the pairs of states on which the Jahn–Teller effect operates, i.e., $|+1, \frac{1}{2}\rangle$ is now an amount λ above $|-1, +\frac{1}{2}\rangle$ and similarly $|-1, -\frac{1}{2}\rangle$ is an amount λ above $|+1, -\frac{1}{2}\rangle$. The

*The $\bar{L}.\bar{S}$ perturbation will introduce small admixtures of the $|0, \pm\frac{1}{2}\rangle$ states into the $|\pm 1, \mp\frac{1}{2}\rangle$ states and $|\pm 2, \mp\frac{1}{2}\rangle$ into the $|\pm 1, \pm\frac{1}{2}\rangle$ states. The coefficients of these admixtures will be small as they are determined by the ratios $\sqrt{\frac{3}{2}}\lambda/\delta$ and λ/Δ. Furthermore, their inclusion will not change the form of the results.

relative magnitudes of λ and k now determine two possibilities for the forms of V_+ and V_-. These are shown graphically in Fig. 4. Regardless of the relative values of λ and k,

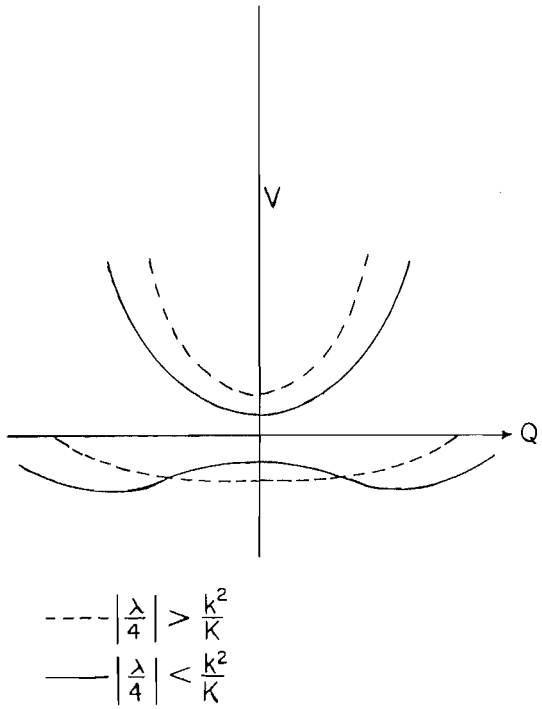

FIG. 4. The splitting of the fourfold degenerate potential level by spin–orbit and Jahn–Teller effects of comparable magnitude. In the text the upper curves are termed V_+ and the lower ones V_-.

the upper level in each case has but one minimum at $Q = 0$. However, the lower level may have two minima at values of $Q \neq 0$, or only one minimum at $Q = 0$, depending on the relative magnitudes of k^2/K and $|\lambda/4|$. Thus, when $k^2/K > |\lambda/4|$ and the Jahn–Teller effect is overriding, the molecule will distort even though the two levels are no longer degenerate but possess only a "near degeneracy". However, as λ is increased, a point is reached when the near degeneracy is, in a manner of speaking, no longer near enough and the Jahn–Teller distortion disappears. This will occur when $|\lambda/4| > k^2/K$. Thus, an absolute degeneracy is not necessary for the operation of the Jahn–Teller effect (12); a near degeneracy, if it fulfills the analytic requirement given above, will suffice. The analysis also shows that a sufficiently strong spin–orbit coupling will effectively quench a Jahn–Teller distortion. Jahn (14) has previously shown that a symmetrical configuration may be stabilized by large spin forces.

RESULTS

The visible and ultraviolet spectra of $MoCl_5$ and $NbCl_5$ vapors were obtained with a Beckmann DK-2 spectrophotometer using a 10-cm all-quartz cell which could be heated to the necessary temperatures (60–100° C).* The spectra of the two pentachlorides were also investigated in the infrared region, on a Perkin–Elmer single beam, double pass

*NOTE ADDED IN PROOF: *M. Gloor and K. Wieland (Helv. Chim. Acta, 44, 1098 (1961)) recently obtained a spectrum for* $NbCl_5$ *between the range 22,000–40,000 cm*$^{-1}$ *which agrees with ours.*

instrument from 4000 to 723 cm^{-1}. A Perkin–Elmer prism grating instrument was employed to search the region from 2,500 to 12,000 cm^{-1} for the $MoCl_5$ compound. The visible and ultraviolet spectrum of $MoCl_5$ is shown in Fig. 5, and the positions of the observed band maxima for both compounds are listed in Table I. The band shown at

*The extinction coefficient for this band cannot be accurately determined as the band occurs on the tail of the chlorine gas absorption. It is by far the least intense of all the bands.

†These bands occur just before the cutoff point of the instrument. The values entered in the table give the wavelength at the ½-peak height.

31,000 cm^{-1} in the spectrum of $MoCl_5$ was shown to be due to chlorine gas. The same band appeared to a lesser extent in the spectrum of $NbCl_5$ at higher temperatures. The dissociation of $MoCl_5$ in the gas phase according to the equation

$$2(MoCl_5)_{gas} \rightleftarrows 2(MoCl_4)_{solid} + Cl_2$$

has been investigated by Vasilkova and Sharupin (6). The result of heating molybdenum pentachloride is to produce chlorine gas at pressures comparable with those of the pentachloride itself. Apparently a similar decomposition occurs to a lesser extent in the case

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of niobium pentachloride. Unfortunately, all the bands are broad and exhibit no vibrational structure. An initial attempt was made to record the spectrum of molybdenum pentachloride on an Hilger E2 spectrograph to obtain a high resolution spectrum. However, no detail was observed.

Spectra were also obtained for the two pentachlorides in solution. The solution spectrum of $MoCl_5$ in cyclohexane and carbon tetrachloride in the visible was unchanged from that of the gas phase but the band in the ultraviolet region was intensified. The solution spectrum of $NbCl_5$ in carbon tetrachloride was completely changed from that found in the gas phase. A very intense band appeared at 475 mμ and more intense absorption was found in the ultraviolet region. This is an interesting observation in that both $MoCl_5$ and $NbCl_5$ are known to exist as dimers in the solid state (7, 8) in the form of double octahedra having a common edge. We believe that, in solution, the dimerization persists in the case of the niobium compound but not in the case of the molybdenum. Further evidence to support this view was obtained from a reflection spectrum of the solid $NbCl_5$, which gave the same intense band at 475 mμ as found in the solution of this compound.*

DISCUSSION

The expected consequences of the Jahn–Teller effect on electronic spectra have been discussed by Longuet-Higgins *et al.* (5). These consequences are twofold. In cases where the vibrational structure of the transitions is resolved a progression in the distorting E' vibration should be observed along with the regular progression in the symmetrical modes. The Jahn–Teller effect, by lowering the effective symmetry of the molecule, breaks down the otherwise rigorous selection rule prohibiting single (or odd number) changes in the E' vibrational quantum number during a transition. The same authors have given the expected band shapes for transitions to Jahn–Teller degenerate states from a non-degenerate state for different values of the distortion parameter k in the cases where only one distorting vibration is allowed. Unfortunately neither of these more elaborate analyses may be carried out in the present case for, as noted above, the bands are very broad and exhibit no vibrational structure. However, we feel that the observed spectrum does indicate a large Jahn–Teller splitting in the first excited state of molybdenum pentachloride. In its simplest terms, the Jahn–Teller effect resolves the degeneracy of an orbital doublet and leads to the appearance of two maxima in the electronic spectrum, where but one would be observed in its absence. Longuet-Higgins *et al.* (5) have discussed how such a double maximum may be roughly interpreted in terms of the Franck–Condon principle. In a transition from a non-degenerate to a degenerate state, the molecule may arrive on either branch of the double cone potential surface referred to previously. Different amounts of vibrational energy will be involved in each case depending on which possibility is the most favorable. Such a situation will lead to a double maximum in the absorption spectrum. In the present case the lowest transition is from one degenerate state to another (the lowest state may well not be Jahn–Teller active because of the spin–orbit coupling). In the degenerate ground state the molecule will, if k (or λ) is of any reasonable magnitude at all, be in the neighborhood of the potential

**The infrared spectrum of niobium pentachloride in carbon disulphide solution was obtained by Gaunt and Ainscough (9) and the assignments so obtained were put forward as proof of the trigonal bypyramidal structure for this compound. We think that their results are not meaningful in this connection as an investigation of the ultraviolet spectrum of a carbon disulphide solution of the niobium pentachloride gave a spectrum radically different from that in the gas phase and different again from that found in carbon tetrachloride. Solution of the niobium compound in carbon disulphide leads to the formation of an intense yellow-orange solution as opposed to the pale yellow solution obtained in carbon tetrachloride, or the pale yellow color of the solid itself. We will report more fully on this point in the infrared investigation of these two pentachlorides.*

minimum with a well-defined nuclear configuration. Thus its transition to the degenerate excited state should give the appearance noted above for a transition from a non-degenerate (where again the ground state is in a well-defined configuration) to a doubly degenerate state. The intensities of the two bands at 15,200 and 21,300 cm^{-1} denote them as allowed, as expected for the E'–E'' transitions. Although the energy separation between the two band maxima of approximately 6000 cm^{-1} cannot be related in any simple way to the value of k', it does suggest a large distortion in the E' state. A very large distortion would also lead to the appearance of two maxima as it would correspond to a permanently distorted molecule of C_{2v} symmetry where the E' state has been split into two new states of B_1 and A_1 symmetries. It should be recalled that the $\bar{e}'$ orbital is a strongly antibonding one and thus a large splitting should be expected just as is observed in the cases of octahedral molecules exhibiting Jahn–Teller effects arising from occupation of the antibonding e_g orbitals. The $\bar{e}'$ orbitals point directly at the ligands in the plane and thus the electrostatic forces exerted on the ligands by an electron in the $\bar{e}'$ orbital will be quite large.

The splitting in the ground state due to the occupation of the e'' orbital will be small as this orbital is directed away from all of the ligands and is not involved in any σ bonding with the ligands. Thus the electrostatic repulsions exerted by the electron density in this orbital will be of much smaller magnitude. The same small splitting is also encountered in octahedral molecules when the degeneracy arises from the occupation of the t_{2g} orbitals as is evidenced by the so far unsuccessful search for distortions in these cases. In fact, there may not be any Jahn–Teller distortion in the ground state due to the presence of a strong spin–orbit coupling. As was pointed out in the Introduction, the spin–orbit interactions cause a splitting of the ground state potential function into two curves (V_+ and V_-) separated in energy by $(\lambda^2 + 4k^2Q^2)^{\frac{1}{2}}$. We suggest that the infrared band observed at 1009 cm^{-1} is due to a transition from V_- to V_+. We base the assignment on the following considerations. First, niobium pentachloride has no corresponding band and thus it is unlikely that the 1009 cm^{-1} band is due to a vibrational motion. Second, the value of λ for the Mo^{+4} ion is 887 cm^{-1} (11) and the value for Mo^{+5} should be somewhat larger. Such a value of λ, coupled with the contribution due to the $4k^2Q^2$ term, would place the band in the observed frequency range. In fact, the theoretical analysis of the spin–orbit coupling effect prompted our search for a band in this region.

The observation of a transition from V_- to V_+ does not necessarily imply the absence of a Jahn–Teller effect in the ground state of $MoCl_5$. As pointed out in the Introduction, k^2/K may still be larger than $|\lambda/4|$ and thus a distortion should still occur. This final question can only be answered by a complete investigation of the infrared spectra of $MoCl_5$ and $NbCl_5$ to see if any indications of band splittings can be determined in the former case. This work, together with a more detailed analysis of the 1009 cm^{-1} band, is now in progress.

The band found at 27,800 cm^{-1} which is superimposed on the tail of the strong absorption due to Cl_2 is assigned to the A_1'–E'' transition, an assignment which is consistent with the low intensity of this particular absorption. Unfortunately, the chlorine gas absorption interferes with this band and no detail beyond its presence may be obtained. The remaining bands at 35,700 and 42,600 cm^{-1} are attributed to charge transfer processes. These assignments are very reasonable because of their observed intensity, short wavelength, and similarity in these properties to the corresponding bands observed for niobium pentachloride (at 35,100 and 41,700 cm^{-1}), which possesses no d–d transitions.

The crystal-field splitting in a trigonal bipyramid molecule involves two parameters if

the five ligands are assumed to lie equidistant from the metal atom. In a simplified approach these may be related to the G_2 and G_4 (for the ionic case) or B_2 and B_4 (for the dipole case) parameters of Ballhausen (10). As in the octahedral cases, neither of these parameters will be determined entirely by simple electrostatic effects but must be interpreted as empirical separations determined by both the electrostatic interactions and the covalent bonding effects of the ligands. We have evaluated the integrals G_2 and G_4 for $4d$ hydrogen-like atomic orbitals to determine their ratio in a rough attempt to justify the above spectroscopic assignments by showing that they can be calculated from reasonable values of the parameters. Assuming the splitting to be linear in Q in the E' state, the mean of the two zero–zero levels in the E'–E'' transition is at approximately 13,500 cm^{-1}. This gives a ratio of the A_1'–E'' to the E'–E'' energy separations ($= \delta/\Delta$) of approximately two. The electron diffraction data for the $MoCl_5$ molecule gave an average over the five bond lengths as 2.27 Å (1). If all five chlorides are assumed to be equidistant from the metal ion, the δ/Δ ratio comes out in the neighborhood of 4.5, i.e., much too large. This discrepancy becomes even larger if it is assumed that the two axial ligands lie closer to the metal ion than do the three ligands in the plane. For example, an axial ligand to metal distance of 2.27 Å and an equatorial – metal ligand distance of 2.40 Å give a δ/Δ energy ratio of 6.6. However, it was found that any shortening of the equatorial bond length or any lengthening of the axial bond length pushes the energy ratio in the desired direction. In fact, an equatorial–metal bond length of 2.15 Å together with an axial–metal bond length of 2.40 Å (which averages to the observed value) gives the observed energy ratio of $\delta/\Delta = 2$. This shortening of the bonds in the plane and the lengthening along the axis in this empirical approach to adjusting the parameters would be equivalent to differing amounts of covalent bonding in the two directions. The apparent increase in bonding found for the equatorial ligands over that for the axial ligands can be related to the fact that the $5p_x$ and $5p_y$ metal orbitals may also contribute to the σ-bonding in the former case. Extra σ-bonding contributions to the axial ligands could only arise from the participation of much higher lying metal orbitals and thus be of little relative significance. It is interesting to note that in the trigonal bipyramid molecules for which all the bond lengths are accurately known, the equatorial bonds are shorter than the axial ones, as is predicted by the present fitting of the observed spectrum. We do not, of course, ascribe this inequality to any Jahn–Teller distortion.

The absorptions in the regions of 1000, 20,000, and 28,000 cm^{-1} are, therefore, reasonably assigned to d–d transitions. The appearance of the double maximum in the intermediate band is consistent with a Jahn–Teller splitting of the E' state.

The low-lying band implies a spin–orbit splitting of the ground state, with or without an accompanying Jahn–Teller distortion.

EXPERIMENTAL

Molybdenum pentachloride which was obtained commercially was analyzed gravimetrically and used without further purification. Anal. Calc.: Mo, 35.78%; Found: 35.74, 35.80%.

Niobium pentachloride was prepared from the oxide by the procedure of Schäfer and Pietruck (13) and purified by vacuum sublimation. The materials were handled exclusively under rigorously dried nitrogen.

In order to ascertain whether there was any interference from oxychlorides, a substance having the composition $MoOCl_3$ was prepared by controlled hydrolysis and its ultraviolet and infrared spectra determined. Cyclohexane used for the solution spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was purified by passage through a column of silica gel and subsequent distillation from an excess of $MoCl_5$. The carbon tetrachloride and carbon disulphide were commercial spectral grade products.

THE N.M.R. SPECTRUM OF CYCLOPENTANONE

F. A. L. ANET

The high-resolution proton nuclear magnetic resonance (N.M.R.) spectrum of cyclopentanone has been stated (1, 2) to consist of a single line at 25 and 40 Mc/sec. Wiberg and Nist (3) have recently reported that at 60 Mc/sec cyclopentanone in carbon tetrachloride gave rise to a closely spaced doublet and concluded that the chemical shift between the α and β protons was very small. By comparison of the spectrum with that expected from an A_2B_2 system (4), these authors also concluded that the coupling constants were abnormally small (< 2.4 c.p.s.). However, this cannot be considered valid, as cyclopentanone is an example of an A_4B_4 system (4) or, by Corio's definition (5), an $AA'A''A'''BB'B''B'''$ system. Analysis as an A_2B_2 system would only be correct if the coupling constants between the vicinal β protons were all zero, which is highly unlikely.

The spectrum of cyclopentanone has been re-examined at 60 Mc/sec and it was observed that although the main band of the spectrum is a (rough) doublet, as reported by Wiberg, the spectrum is actually unsymmetrical, unlike that of an A_2B_2 system (4, 5). There are also a number of weak lines, not previously observed, at an appreciable distance from the main doublet. These lines are not due to impurities or spinning side bands, nor can they be ascribed to protons on C^{13}. Their presence shows that relatively large coupling constants must be present in cyclopentanone. That large coupling constants are present is shown even more clearly by the spectrum of cyclopentanone in benzene solution (Fig. 1). Now there is quite an appreciable chemical shift between the α and β protons and the spectrum is no longer even approximately a doublet.

Unfortunately, a complete analysis of the spectrum of cyclopentanone would be extremely tedious. As well as one (relative) chemical shift there are six different coupling constants to be determined, apart from the probably negligible 1,3-coupling constants. Nevertheless, it is possible to extract some information by the application of the moment method described by Anderson and McConnell (6). In a molecule, such as cyclopentanone, which has protons in only two different chemical environments, the moment method gives particularly simple results for the relative chemical shift ($\Delta\nu$) and for the sum of the squares of the coupling constants between *chemically shifted* protons. If M_2, M_3, and M_4 are respectively the reduced second, third, and fourth moments (i.e. moments taken from an origin where the first moment is zero) and J_{cis} and J_{trans} are the two different coupling constants between vicinal α and β protons, then the following expressions hold (6):

$$\nu = 2\sqrt{M_2},$$

$$J_{cis}^2 + J_{trans}^2 = \frac{M_4 - M_2^2}{M_2},$$

$$M_3 = 0.$$

Calculations on the spectrum in Fig. 1 and on a number of other spectra taken at

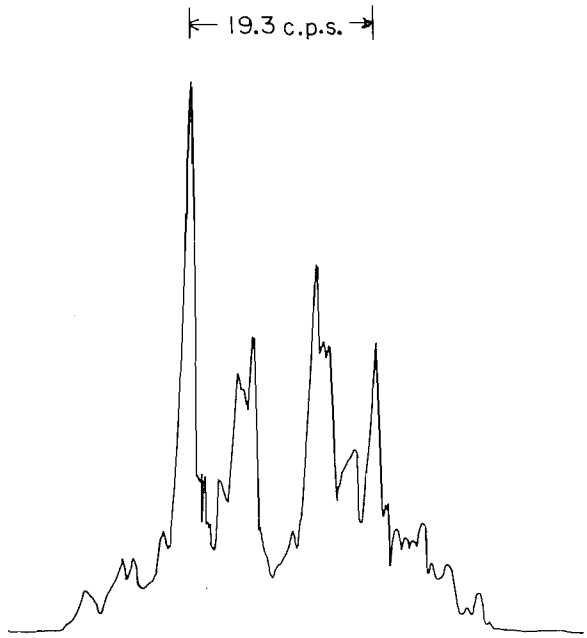

FIG. 1. N.M.R. spectrum of a 20% by volume solution of cyclopentanone in benzene. The magnetic field increases from left to right.

different sweep rates gave, for 20% by volume solutions of cyclopentanone in benzene, $\Delta\nu = 19.5 \pm 0.5$ c.p.s. and $(J_{cis}^2 + J_{trans}^2)^{1/2} = 10.8 \pm 1.0$ c.p.s. In a solution containing equal volumes of cyclopentanone, benzene, and carbon tetrachloride, $\Delta\nu = 10.8 \pm 0.5$ c.p.s. and $(J_{cis}^2 + J_{trans}^2)^{1/2} = 10.1 \pm 1.0$ c.p.s. Thus, as expected, the coupling constants do not vary appreciably on the changing of the solvent. One of these coupling constants must be larger than 6 c.p.s. and could be as large as 10 c.p.s. Correspondingly the other coupling constant must be smaller than 8 c.p.s. and could be zero. These values are entirely consistent with the coupling constants in flexible, five-membered rings (7). The fact that the spectrum of Fig. 1 is unsymmetrical and is much too complicated for an A_2B_2 system shows that the coupling constants between vicinal β protons must also have appreciable values.

EXPERIMENTAL

Spectra were measured on a Varian V-4302 high-resolution spectrometer. Care was taken to obtain a pure absorption mode and the radio-frequency power was set well below saturation level so as to obtain correct intensities. To calculate moments a millimeter grid was superposed on the spectrum, and the intensities (as measured by the heights) at small intervals, usually 1 mm, were measured from an arbitrary zero outside the spectrum. Depending on the case, from 60 to 120 readings were made. These values were fed to a computer (I.B.M. 650) which was programed to calculate M_2, M_3, and M_4. Calculations were made on a number of spectra with both increasing and decreasing magnetic fields and with various sweep rates.

The cyclopentanone (Eastman Kodak pure grade) showed only a single band on gas chromatography with a silicone oil column at 134°. The spectrum was unchanged after

the cyclopentanone had been purified via the recrystallized semicarbazone derivative. At high sensitivity and r.f. power no further bands were observed on the side of the spectrum of Fig. 1 except bands assignable to protons on C^{18}. Spectra taken in pyridine or aniline solutions were very similar to those taken in benzene solution.

PROTON RESONANCE SPECTRA OF 8-HYDROXY AND 8-METHYL QUINOLINE

L. W. REEVES AND K. O. STRØMME

The present study is a comparison of the behavior of 8-hydroxy and 8-methyl quinoline in various nonpolar solvents. The part played by the hydroxyl proton in the intermolecular associations of 8-hydroxy quinoline is of some interest in view of its importance as a chelating agent.

EXPERIMENTAL

8-Hydroxy quinoline of analytical grade was recrystallized and 8-methyl quinoline was used as analytical grade. The solvents were all fractionally distilled and stored over drying agents. A 40 Mc/s Varian spectrometer was used to take spectra, and the 'sideband technique' was used to determine peak positions. Absolute chemical shifts on the cyclohexane scale are accurate to ± 1.0 c.p.s. but internal chemical shifts are accurate to ± 0.2 c.p.s. A 1% cyclohexane internal standard was always included in the solution.

RESULTS

Chemical shifts of the hydroxyl proton and the α, β, and γ protons of the hetero ring have been measured. The hetero ring protons formed an ABX or AMX group (1), and some overlap occurred in most cases between the β-proton spectrum and the spectrum of the second aromatic ring. Chemical shifts in the second aromatic ring were very similar and the main feature was a large, single peak with several small satellites. It was always possible to assign transitions in the β-proton spectrum and thus obtain a complete analysis for the ABX or AMX spectrum.

To illustrate this, Fig. 1(a) shows a spectrum of 18.6 mole% 8-hydroxy quinoline in

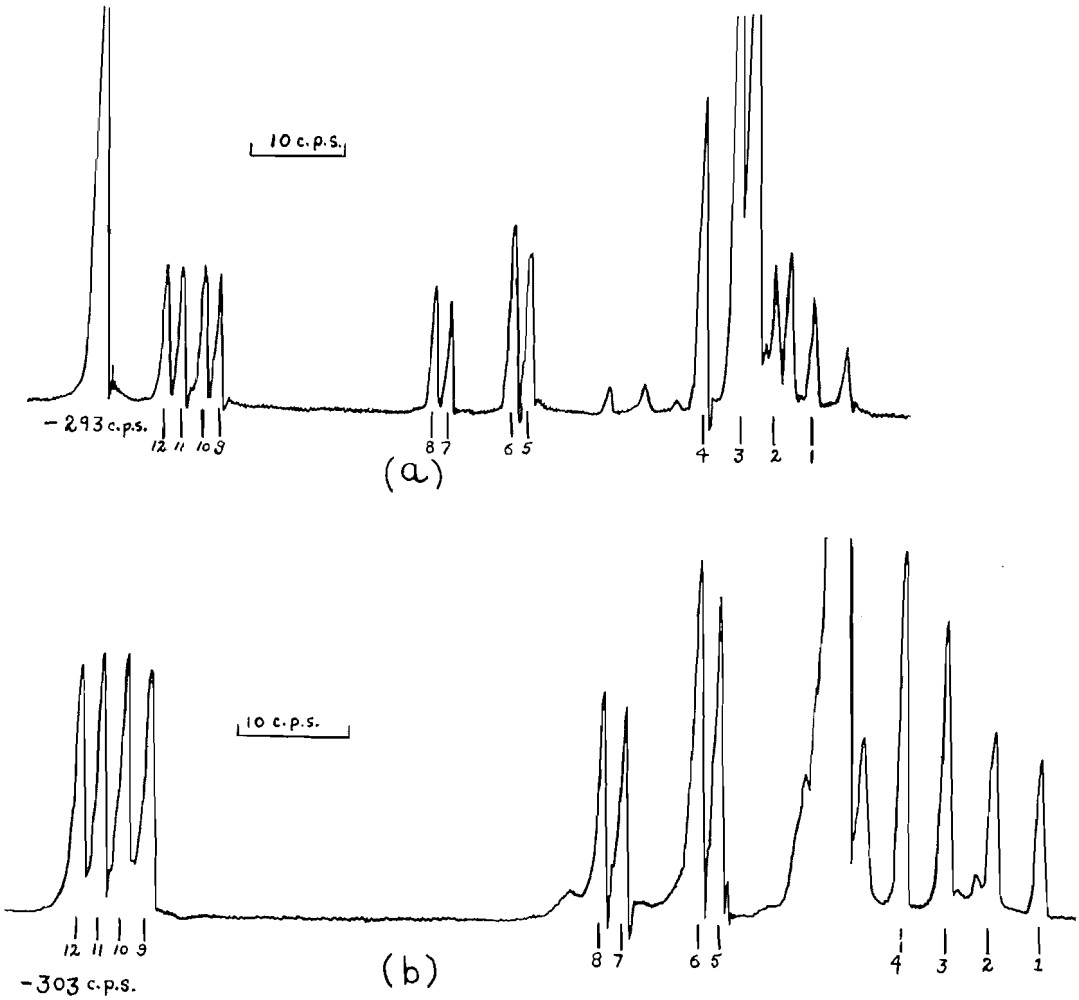

FIG. 1. (*a*) 8-Hydroxy quinoline, 18.6% in CCl_4; spectrum at 30° C. (*b*) 8-Methyl quinoline, pure; spectrum at 30° C.

CCl_4 and Fig. 1(*b*) shows a spectrum of pure 8-methyl quinoline with the methyl peak at high field omitted. The 12 transitions of the *ABX* spectrum are numbered according to the assignments of Bernstein, Schneider, and Pople (1) in each case. Figure 2 gives the results of dilution chemical shifts in CCl_4, benzene, and acetone for the hydroxyl proton resonance. Figure 3 indicates the dilution chemical shifts of the α, β, and γ protons for 8-hydroxy and 8-methyl quinoline in the various solvents and at the conditions given in the legend to this figure. The indirect spin–spin coupling constants evaluated were the same in all spectra analyzed. These were $|J_{\beta\gamma}| = 8.3$ c.p.s, $|J_{\alpha\beta}| = 4.4$ c.p.s., and $|J_{\alpha\gamma}| = 1.7$ c.p.s.

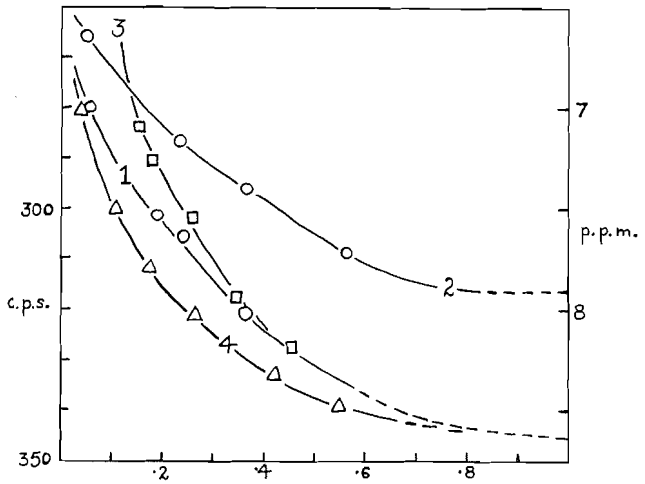

FIG. 2. Chemical shifts of —OH proton resonance of 8-hydroxy quinoline in various solvents: curve 1 (○), in CCl_4 at 29° C; curve 2 (○), in CCl_4 at 80° C; curve 3 (□), in acetone at 29° C; curve 4 (△), in benzene at 29° C. The abscissa of each point is the mole fraction of 8-hydroxy quinoline in the solvent and the ordinate is the chemical shift with respect to an internal cyclohexane standard.

FIG. 3. DISCUSSION

The shape of the dilution chemical shift curves for the 8-hydroxy quinoline OH proton is indicative of exclusively intermolecular hydrogen bonding (2, 3). The estimation of interatomic distances would indicate little interaction within the same molecule between the hydroxyl proton and the nitrogen on the second ring (4).

The behavior of the hetero ring proton resonances of 8-methyl and 8-hydroxy quinoline is very similar in the same solvents (Fig. 3). There is a small shift to low field for the β and γ protons and to high field for the α proton in carbon tetrachloride solutions at room temperature. An increase in temperature of 50° C for the 8-hydroxy quinoline in CCl_4 solutions causes a low-field shift for the β and γ proton consistent with the concentration dependence of these shifts. The approximate extrapolation of these chemical shifts to mole fraction = 1 and 0 indicates a total shift of less than 10 c.p.s. in all cases. The small temperature coefficient amounted to only 2 c.p.s. in 50° C.

The direction of these chemical shift changes is the same in acetone solutions but the magnitude of the change is much larger for the β and γ protons. The dilution chemical shifts in benzene are in the direction of high field for all three protons in the hetero ring but again the magnitude of shifts is much larger for the β and γ protons.

These results are suggestive of preferential hydrogen bonding of solvent molecules at the β and γ positions in view of the fact that they represent difference shifts between cyclohexane and quinoline in the same solvent (5). The magnitude of the difference shifts due to van der Waals, anisotropy effects, and polar effects are probably comparable and difficult to estimate with any certainty (6).

chewing gum, little work has been done on the chemical constitution of the latex of this tree. This latex, also called "crude chicle" or "loaf chicle", is obtained by collecting the liquid exuded from the bark of *Achras sapota* L.

Stillwell, in an X-ray study of chicle (2), concluded that the latex was a mixture of gutta-percha, calcium oxalate monohydrate, and a resinous fraction. Schlesinger and Leeper have shown (3) that this gutta-percha was a mixture of cis and trans polyisoprenes. On the other hand, Lifschutz and Vietmeyer, by extraction of chicle with ethanol, obtained (4) a fraction which they called "isophytosterol" because of the similar behavior of this extract to color reactions with "isocholesterol", later identified as a mixture of lanosterol, agnosterol, and their side-chain dihydro analogues.

This paper reports the preliminary results of an investigation of the alcoholic extracts of chicle from different sources. Ethanol extraction with a Soxhlet of a crude chicle from Guatemala led to the isolation, in about 55% yield, of a yellow resin which crystallized spontaneously on standing. Although repeated crystallizations did not afford a pure compound, extensive chromatography over alumina, followed by several recrystallizations, led to the isolation and identification of two pentacyclic triterpenes and a steroid, namely lupeol acetate, β-amyrin acetate, and α-spinasterol acetate, in approximate yields of 70, 10, and 2–5% respectively.

These three compounds were purified rigorously, hydrolyzed to the corresponding 3β-alcohols, and then further characterized as their benzoates. Each derivative was compared with an authentic sample of the known compound (mixed melting point and infrared spectrum). The physical constants are listed in Table I.

It is worth mentioning that α-spinasterol (Δ^7-stigmasterol or bessisterol) seems to be a more common steroid than suspected earlier (5). Besides spinach (6), *Polygala senega* roots (7), alfalfa (*Medicago sativa* L.) (8), and the rhizomes of *Mormordica cochinchinensis* Spreng. (9), this Δ^7-steroid has been identified recently in *Iresin pringlei* (10) and in *Chenopodium foetidum*, which also contains cineol and a very small amount of a ketone which seems to correspond to piperitenone (2,4-dinitrophenylhydrazone, m.p. 188–189°; calc. for $C_{16}H_{18}O_4N_4$: N, 16.96; found: N, 17.37) (11).

Another crude chicle, from Campeche, Mexico, was found to be a complex mixture; the major constituents, however, again were lupeol acetate and β-amyrin acetate. Interestingly enough, in this chicle no α-spinasterol could be identified.

For personal use only.

The recent development of gas chromatography techniques in the steroid (12), alkaloid (13), and fatty- (14) and amino-acids (15) fields prompted us to apply this method to our chicle mixture. For comparison purposes, authentic samples of the pentacyclic triterpenes and the Δ^7-steroid were chromatographed using this technique, which was later applied to the crude crystalline chicle. Those compounds were analyzed on a Barber-Colman Model 10 gas chromatograph with an argon, β-ray ionization detector and a 6 ft$\times\frac{1}{4}$ in. column containing 1% QF-1 silicone (Vanden Heuvel, Haahti, and Horning (12)) on Gas-Chrom P (16) at 240° C. The retention times, in minutes, measured from the air peak were: α-spinasterol, 3.57; β-amyrin, 3.93; lupeol, 4.64; α-spinasterol acetate, 5.24; β-amyrin acetate, 6.31; lupeol acetate, 7.15. Chicle from Campeche, Mexico, was found to consist of approximately 79% of lupeol acetate, 12% of β-amyrin acetate, together with some unidentified components. The retention time of lupeol acetate on a 6 ft$\times\frac{1}{4}$ in. column of 1.5% SE-30 (Vanden Heuvel, Sweeley, and Horning (12)) on Gas-Chrom P at 240° was 3 minutes. The main component of chicle also had the same retention time.

Work is now in progress to determine the structure of some of the minor constituents in chicle.

The papers that follow were presented at the Symposium on Co-ordination in Chemistry, Inorganic Subject Division, Chemical Institute of Canada, held at McMaster University, Hamilton, Ontario, May 15, 16, 1961.

CO-ORDINATION COMPOUNDS OF HYDRAZINE

PART II. THE INTERACTION OF TRIMETHYLBORANE AND TRIMETHYLALUMINUM WITH HYDRAZINE[1, 2]

W. G. Paterson[3] and M. Onyszchuk

ABSTRACT

Trimethylborane and anhydrous hydrazine react at 25° in vacuum, yielding a 2:1 adduct, $2(CH_3)_3B \cdot N_2H_4$, which is stable at or below −78° and evolves trimethylborane slowly at higher temperatures, leaving a stable 1:1 adduct, $(CH_3)_3B \cdot N_2H_4$ (m.p. 42–43°). The thermal decomposition of the latter at 150–160° is complex, producing nitrogen, methane, ammonia, a mixture of butane and the isomeric butenes, and a heterogeneous solid. At 25° diborane displaces trimethylborane from the 1:1 adduct and reacts with it to form 1,1-dimethyldiborane, in addition to hydrogen, methane, and a heterogeneous solid.

Trimethylaluminum and hydrazine give a complex reaction in vacuum at 25°, but in diethyl ether solution the product was thought to be $(CH_3)_2AlNHNHAl(CH_3)_2$, which decomposes on being touched.

Recently (1) we reported that under appropriate conditions boron trifluoride, like the borane group (2, 3), forms stable 1:1 and 2:1 addition compounds with hydrazine, $BF_3 \cdot N_2H_4$ and $2BF_3 \cdot N_2H_4$, respectively. With the object of obtaining further information about the tendency of hydrazine to co-ordinate with other electron-deficient molecules, we have investigated the reactions of hydrazine with trimethylborane and trimethylaluminum. Since the electron-acceptor powers of trimethylborane and trimethylaluminum are considerably less than those of boron trifluoride or of the borane group (4, 5), hydrazine should form less stable adducts with trimethylborane or trimethylaluminum than with boron trifluoride or with the borane group. The results reported here confirm this expectation.

RESULTS AND DISCUSSION

The interaction of trimethylborane and hydrazine in vacuum at 25° produced the new co-ordination compound 2-trimethylborane-hydrazine (I), $2(CH_3)_3B \cdot N_2H_4$. This adduct was stable either in the presence of an excess of trimethylborane or at temperatures below −78°; otherwise, trimethylborane was evolved ultimately, leaving the new stable addition compound trimethylborane-hydrazine (II), $(CH_3)_3B \cdot N_2H_4$, which melted at 42–43°. By being allowed to react with an excess of trimethylborane, adduct II was converted into I, as represented by the following scheme:

$$2(CH_3)_3B + N_2H_4 \rightarrow \underset{\text{I}}{2(CH_3)_3B \cdot N_2H_4}$$

$$> -78° \quad \downarrow\uparrow \text{ excess } (CH_3)_3B$$

$$(CH_3)_3B + \underset{\text{II}}{(CH_3)_3B \cdot N_2H_4}.$$

[3]*Holder of N.R.C. Studentships, 1957–59. Present address: Department of Chemistry, University of Alberta, Edmonton, Alberta.*

These results suggest that the attraction exerted by trimethylborane on the lone electron pair of one nitrogen atom in the 1:1 adduct induces a significant decrease in the co-ordinating ability of the lone electron pair on the other nitrogen atom. This reduced reactivity of the second lone electron pair in hydrazine appears to be a general rule (6). The instability of I as compared with the analogous borane (2, 3) and boron trifluoride (1) adducts is in agreement with the following order of the electron-acceptor strengths of the three Lewis acids toward molecules in which nitrogen is the donor atom (5): $BH_3 \sim BF_3 > (CH_3)_3B$.

The complex II consisted of white, hygroscopic crystals which hydrolyzed readily. Strong acidification of the aqueous solution resulted in the displacement of trimethylborane, followed by its spontaneous and violent ignition in air.

A comparison of the infrared spectrum of II with that of trimethylborane-ammonia, given in Fig. 1, reveals marked similarities and confirms the presence of a B—N stretching

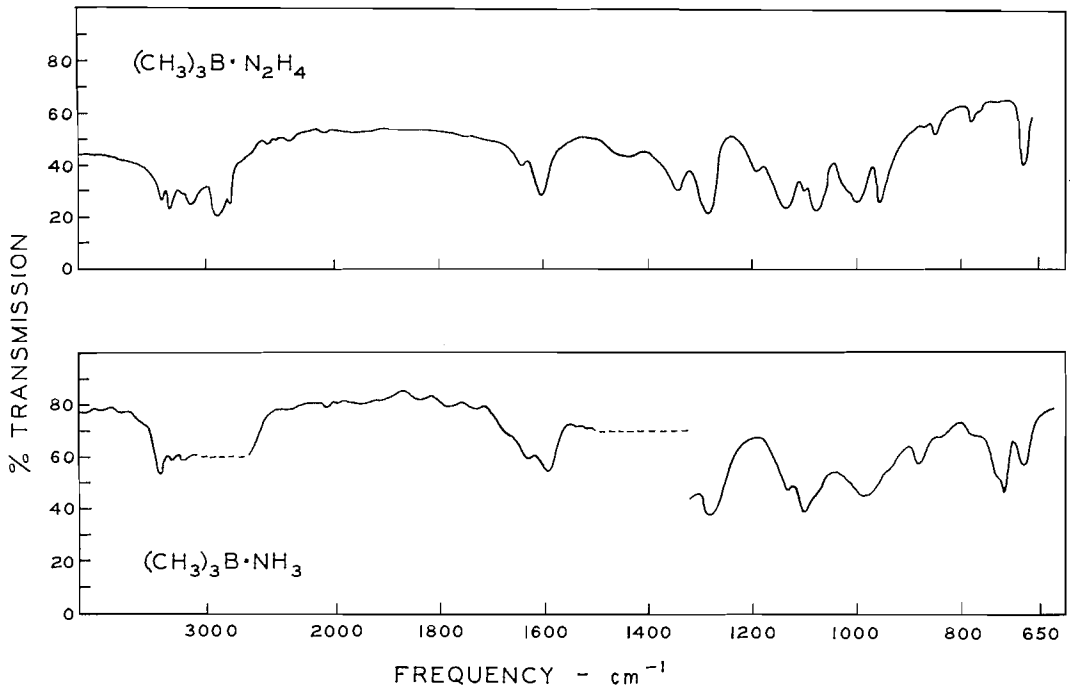

FIG. 1. Infrared spectra of $(CH_3)_3B \cdot N_2H_4$ (in KBr disk) and $(CH_3)_3B \cdot NH_3$ (in Nujol mull).

vibration in II at 1075 cm^{-1}. The frequency assignments listed in Table I were made by analogy with the assignments recorded in the literature for the infrared spectra of trimethylborane (7), hydrazine (8), and hydrazine hydrohalides (9, 10), and for the Raman spectrum of $(CH_3)_3B \cdot NH_3$ (11). Because trimethylborane-ammonia is so volatile at room temperature the potassium bromide pellet method could not be used to obtain its infrared spectrum; therefore, the Nujol mull technique was used instead, and the regions 3100–2800 cm^{-1} and 1500–1325 cm^{-1} were omitted due to interference from the Nujol absorption peaks.

The thermal decomposition of II in vacuum at 150–160° for 16 hours was complex, yielding methane, nitrogen, ammonia, butane, 1-butene, 2-butene, and an unidentified

heterogeneous solid. The presence of C_4 hydrocarbons among the products is remarkable and we are unable to account for their origin. Neither trimethylborane nor hydrazine undergo appreciable decomposition when they are heated separately for 16 hours at 150–160°. The observed decomposition of II is more complex than that recently reported by Mikhailov and Bubnov (12) for complexes of the type $R_3B \cdot N_2H_4$, where R is *n*-C_3H_7, *i*-C_3H_7, or *n*-C_4H_9. These decompose in the presence of excess trialkylborane into the corresponding alkanes, alkenes, and hydrogen, according to the following scheme:

$$R_3B \cdot N_2H_4 \rightarrow [R_2BNHNH_2] + RH + R_{-H} + H_2$$
$$\downarrow R_3B$$
$$R_2BNHNHBR_2 + RH + R_{-H} + H_2.$$

Only alkanes and alkenes containing the same number of carbon atoms as in the original alkyl group of the trialkylborane were reported.

There was no reaction between I and diborane at −80°. At room temperature, however, diborane reacted with II to give trimethylborane, 1,1-dimethyldiborane, hydrogen, and a heterogeneous solid which evolved both methane and hydrogen on heating. Since free trimethylborane was obtained, it was certain that a displacement of trimethylborane from II by the borane group had occurred. Moreover, the formation of 1,1-dimethyldiborane, which could only have occurred by the following reaction (13),

$$2B_2H_6 + 2(CH_3)_3B \rightarrow 3(CH_3)_2B_2H_4,$$

showed that more trimethylborane had been displaced than that indicated by the amount of trimethylborane recovered. In fact the displacement of trimethylborane by the borane group was about 66%, based on the amounts of trimethylborane and 1,1-dimethyldiborane in the product mixture. These data show clearly that, toward hydrazine, the borane group is a stronger electron acceptor than trimethylborane. When the heterogeneous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

solid product was heated, methane and hydrogen were evolved. This suggests that both II and 2-borane-hydrazine (2, 3) were present because these adducts when heated are known to yield methane and hydrogen, respectively.

The reaction of hydrazine with trimethylaluminum in vacuum at 25° produced methane, hydrogen, and a nonstoichiometric residue. In diethyl ether solution, the same reactants gave methane and a white solid, which was recovered after evaporation of the solvent and unreacted trimethylaluminum. The weight of the solid product and the amount of methane formed initially indicated that the solid was probably *sym*-bisdimethylalumino-hydrazine, $(CH_3)_2AlNHNHAl(CH_3)_2$; since it decomposed on being touched, its composition could not be confirmed by analysis.

EXPERIMENTAL

The different experimental techniques have been described previously (1).

The method of Brown (14) for the preparation of trimethylborane was modified in that boron trichloride and methyl iodide were used in place of boron trifluoride and methyl bromide. (Yield: 79%. Found: molecular weight (M), 55.6; vapor pressure (v.p.), 30.7 mm at −78.3°. Calc. for $(CH_3)_3B$: M, 55.9; v.p., 31.3 mm at −78.3°.) Anhydrous hydrazine was prepared by refluxing the 95+% material over potassium hydroxide (1). The reduction of boron trichloride with lithium aluminum hydride in diethyl ether solution was used for the preparation of diborane. (Yield: 62%. Found: M, 27.7. Calc. for B_2H_6: M, 27.7.) Trimethylaluminum (Ethyl Corporation) was purified by several fractional distillations at 0° (Found: v.p., 13.2 mm at 24.7°. Lit. (15): v.p., 12.8 mm at 24.7°), and the infrared spectrum of the pure substance was identical with that reported previously (16).

Interaction of Trimethylborane with Hydrazine

In a typical experiment, trimethylborane (9.69 mmoles) and anhydrous hydrazine (3.26 mmoles) were combined in vacuum and kept at 25° overnight. The reaction was initially rapid, but a long time was required for its completion, as indicated by a slow decrease in the total pressure. A white crystalline material formed gradually on the walls of the vessel. The amount of unreacted trimethylborane (3.26 mmoles. Found: M, 55.2. Calc. for $(CH_3)_3B$: M, 55.9), recovered by distillation at −78°, showed that trimethylborane (6.43 mmoles) had reacted with hydrazine (3.26 mmoles) in a ratio of 2:1, thus forming the adduct $2(CH_3)_3B\cdot N_2H_4$. When this complex was warmed, it evolved trimethylborane slowly at −65 to −70°, but at 0°, trimethylborane (3.24 mmoles; M, 56.0) was removed rapidly. A residue containing trimethylborane (3.19 mmoles) and hydrazine (3.26 mmoles) in a ratio of 1:1, corresponding to the complex $(CH_3)_3B\cdot N_2H_4$, was left. Pressure measurements in the range −78 to 0° indicated that $2(CH_3)_3B\cdot N_2H_4$ did not dissociate reversibly.

However, when an excess of trimethylborane (7.46 mmoles) was added to a sample of $(CH_3)_3B\cdot N_2H_4$ (4.04 mmoles) and the mixture was kept at 25° overnight, the recovery of trimethylborane (3.40 mmoles; M, 55.8), by distillation at −78°, indicated that the compound $2(CH_3)_3B\cdot N_2H_4$ had been regenerated, since 4.04 mmoles of $(CH_3)_3B\cdot N_2H_4$ had absorbed an additional 4.06 mmoles of trimethylborane.

Pyrolysis of $(CH_3)_3B\cdot N_2H_4$

Trimethylborane (8.58 mmoles) and hydrazine (8.58 mmoles) were combined in an all-glass vessel and the white solid adduct, $(CH_3)_3B\cdot N_2H_4$, which formed was heated for 16 hours at 150–160°. The principal products were: (*a*) noncondensable gases (N_2 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

CH_4; 0.67 mmoles), (*b*) ammonia (0.42 mmoles. Found: M, 18.0; v.p., 35.6 mm at −79.5°. Calc. for NH_3: M, 17.0; v.p., 40.0 mm at −79.2° (17)), (*c*) a mixture of butane and the isomeric butenes (2.44 mmoles. Found: M, 56.3. Calc. for C_4H_8: M, 56.1; for C_4H_{10}: M, 58.1), and (*d*) an unidentified heterogeneous white solid. The composition of the C_4 hydrocarbon fraction was confirmed by infrared and mass spectra measurements. The latter indicated that the ratio of C_4H_{10} to C_4H_8 was approximately 1 to 3.

When trimethylborane (7.75 mmoles) was heated in a sealed tube for 16 hours at 150–160°, a quantitative recovery of the gas proved that no significant decomposition had taken place.

Hydrazine (9.33 mmoles) was heated in an all-glass vessel for 16 hours at 150–160°. The reaction products were nitrogen (0.14 mmole. Found: M, 32.8. Calc. for N_2: M, 28.0), ammonia (0.52 mmole. Found: M, 17.5. Calc. for NH_3: M, 17.0), and unchanged hydrazine (8.86 mmoles; analyzed by the iodate method (6)), in accordance with the decomposition (18)

$$3N_2H_4 \rightarrow 4NH_3 + N_2,$$

and the extent of decomposition of hydrazine was only 5%.

Interactions of $2(CH_3)_3B \cdot N_2H_4$ and $(CH_3)_3B \cdot N_2H_4$ with B_2H_6

After $2(CH_3)_3B \cdot N_2H_4$ (3.26 mmoles) and diborane (4.01 mmoles) had been maintained overnight at −80°, the quantitative recovery of diborane, by distillation at −78°, proved that no reaction had taken place.

In another experiment, $(CH_3)_3B \cdot N_2H_4$ (3.26 mmoles) and diborane (4.01 mmoles) were combined and left overnight at 25°. The reaction, which produced a solid and several volatile products, was stopped by surrounding a portion of the reaction vessel with a liquid-air bath. After all the volatile material had condensed, hydrogen (0.75 mmole) was left. The condensable substances were fractionated at −143°, yielding diborane (0.59 mmole; M, 26.6), and repeatedly at −115°, yielding trimethylborane (0.50 mmole) and 1,1-dimethyldiborane (2.46 mmoles. Found: M, 58.9; v.p., 11 mm at −79.5°. Calc. for $(CH_3)_2B_2H_4$: M, 55.7; v.p., 13 mm at −78.5° (19)). The infrared spectrum of the latter was identical with that reported by Lehmann *et al.* (20).

The solid residue was heated gradually, resulting in the evolution of noncondensable gas, as summarized in Table II. These data suggest that methane and hydrogen were

TABLE II

Temperature of residue (°C)	Amount of gas (mmoles)	Molecular weight
100	3.94	17.6
170	0.75	7.21
250	4.13	2.46

evolved. The quantity of condensable gas released during these operations was negligible.

Interaction of Trimethylaluminum with Hydrazine

(i) Reaction in vacuum.—Anhydrous hydrazine (4.72 mmoles) and trimethylaluminum (20.0 mmoles) were left at 25° overnight. The products of the reaction were: (*a*) a pale brown solid which did not change visibly on heating to 300°, (*b*) a mixture of non-condensable gases (20.0 mmoles: 18.58 mmoles CH_4 and 1.42 mmoles H_2. Found: M, 15.0. Calc. for CH_4: M, 16.0; for H_2: M, 2.0. Successive vapor pressure measurements on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

this fraction gradually approached that of CH_4), and (*c*) unreacted trimethylaluminum (12.03 mmoles. Found: v.p., 15.9 mm at 26.7°. Lit. (15): v.p., 13.7 mm at 26.7°). The identity of the latter was also confirmed by its infrared spectrum.

(ii) Reaction in diethyl ether.—In a typical experiment, anhydrous diethyl ether (20 ml) was thoroughly degassed in vacuum and to it were added hydrazine (10.09 mmoles) and trimethylaluminum (27.9 mmoles). The apparatus was sealed and the reactants were stirred overnight at 25°. A white suspension formed in the ether solution. Methane (20.1 mmoles. Found: M, 16.3; v.p., 21.5 mm at −191°. Calc. for CH_4: M, 16.0; v.p., 20.0 mm at −191.8° (17)) was the only noncondensable gas produced. The solvent and unreacted trimethylaluminum were distilled at room temperature, leaving a white crystalline deposit. Analyses of the latter for aluminum were not reproducible, but the weight of the crude product (1.57 g) corresponded approximately to that required (1.46 g) for the formation of the substance *sym*-bisdimethylaluminohydrazine, $(CH_3)_2AlNHNHAl(CH_3)_2$. The formation of exactly 2 moles of methane per mole of hydrazine consumed was supporting evidence. Since the solid compound was extremely sensitive to touch, it could be neither purified nor analyzed.

COMPLEX PERIODATES AND TELLURATES[1]

M. W. LISTER

This paper is concerned with the complex periodates and tellurates formed by some of the transition metals in the first long period. Probably similar salts could be obtained from transition metals in the later periods, but so far only some silver salts have actually been prepared. Periodic acid, H_5IO_6, and telluric acid, H_6TeO_6, have similarities in formula which set them apart from the acids formed by earlier elements of their groups with the same valency, e.g. perchloric acid, $HClO_4$, and selenic acid, H_2SeO_4. They are also much weaker acids: H_5IO_6 has $pK_1 = 1.6$, $pK_2 = 7.0$; and telluric acid has $pK_1 = 6.1$ and $pK_2 = 10.4$. Consequently it is not surprising that they form complexes which do not find analogues in the chemistry of chlorine and selenium.

Periodic acid or periodates are fairly strong oxidizing agents, so that they oxidize the transition metals to their higher valencies. Some of the compounds described below contain the metals in unusually high valency states. However, to reach these valencies, still stronger oxidizing agents are sometimes required; and the periodate then acts rather as a stabilizing agent for these higher valencies, than as the oxidizing agent. The actual oxidizing agents which have been applied are sodium (or other) persulphate or hypochlorite, and electrolytic oxidation.

The compounds which have been prepared are listed in Table I. The oxidizing agent refers to the compound used in the preparation to reach the higher valency.

[1]*Manuscript received June 30, 1961.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ont. Presented at the Symposium on Co-ordination in Chemistry, Chemical Institute of Canada, Hamilton, Ontario, May 15–16, 1961.

The general method of preparation is to mix somewhat acidified solutions of a salt of the central metal and sodium (or potassium) periodate or tellurate, and then to add the oxidizing agent, for instance sodium hypochlorite containing considerable excess sodium hydroxide. The complex salts may crystallize rather slowly, and it is often useful to add alcohol to aid precipitation of them. They can usually be recrystallized from water or dilute sodium hydroxide solution. In practice difficulties arise because the compounds often come down as sticky, poorly crystallized precipitates; and the precipitate may also be contaminated with sodium periodate or tellurate, which has to be removed by recrystallization or reprecipitation.

Valency of Central Metal

As can be seen in Table I, some of these compounds contain Mn(IV), Ni(IV), or Cu(III), which are higher valencies than are common in the bulk of the complex compounds of these elements. The presence of these valencies can be demonstrated by the various methods given below.

1. Titration Methods

This type of method was used by Price in 1903 when he added potassium iodide and acid to $Na_2Mn_2I_2O_{11}$ and titrated the iodine liberated. With trivalent copper it is particularly useful, since sulphuric acid decomposes the compound to give divalent copper again, presumably with liberation of oxygen. Hence if potassium iodide is added to a solution of $Na_7Cu(IO_6)_2$, and then sulphuric acid is added, 18 equivalents of iodine are liberated per molecule; but if the acid is added first, only 17 equivalents are liberated. With the tellurate complex the corresponding numbers are 2 and 1 equivalents of iodine per molecule. Potentiometric titration with ferrous ammonium sulphate (and acid) is also useful since the periodate is then reduced to iodate, and the central metal to the divalent state. Another method along the same lines consists in bubbling in sulphur dioxide and titrating the sulphuric acid formed by its oxidation.

2. Magnetic Properties

A considerable number of magnetic measurements have been made on these compounds, with the results as given in Table II. These are all measurements of the magnetic

TABLE II

Compound	Molar susceptibility $\times 10^6$		Reference

susceptibility, using the ordinary Goüy apparatus. The results on Co(III) compounds make these diamagnetic, as is usual for Co(III). The results on Mn(IV) compounds

agree with the "spin-only" formula for a substance with three unpaired electron spins; this is what is to be expected for Mn(IV), which contains three 3*d* electrons.

It is interesting to note that the Cu(III) compounds are diamagnetic. Cu(III) has eight 3*d* electrons, as does Ni(II), and presumably (as with Ni(II)), there is a possibility of either paired or unpaired spins. If four ligands are arranged around Ni(II) in a plane, the compound is, in general, diamagnetic; presumably the diamagnetism of Cu(III) is evidence of planar stereochemistry in this case also.

The results in $NaNiIO_6$ and $KNiIO_6$ give magnetic moments of 1.1 Bohr magnetons (6). Ray and Sarma suggest that the pure compounds would be diamagnetic but that some dissociation has taken place. This implies that the pure compounds contain spin-paired Ni(IV) in an octrahedral field, a situation found for other tetravalent nickel complexes (9).

General Properties

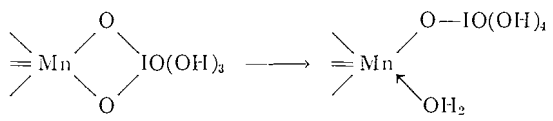
These complex salts are crystalline solids, usually rather moderately soluble in water. Jensovsky has given solubility curves for a few of the copper complexes. The salts with many sodium or potassium atoms (as opposed to hydrogen) are markedly less soluble in water. It is also true of most of them that they are considerably less soluble in sodium hydroxide solutions than in pure water. They are colored compounds, with light-absorption curves of the same shape: the absorption is high in the ultraviolet, falls to a minimum as we go to longer wavelength, and then passes through a single maximum. Table III

TABLE III
Light absorption

Compound	Maximum	Minimum
$Na_7H_4Mn(IO_6)_3$	482	442 mμ
$Na_7H_7Mn(TeO_6)_3$	470	420
$Na_4H_4Mn(TeO_6)_2$	450 (shoulder)	—
$Na_5H_2Co(IO_6)_2$	625	535
$H_7Co(IO_6)_2$	610	545
$K_3H_6Co(TeO_6)_2$	635	562
$Na_7Cu(IO_6)_2$	420	316

gives the positions of the maxima and minima for aqueous solutions. The extinction coefficients are highest for the copper compound, less for manganese, and least for the cobalt compounds.

Acid–Base Reactions



Some of the complex salts are stable enough to exist in acid solution. For instance, it is possible to pass a solution of sodium periodatocobaltate through a cation exchange resin in its acid form and to obtain a stable solution of the free acid; presumably $H_7Co(IO_6)_2$. Consequently, solutions of sodium periodatocobaltate can be titrated against acids such as perchloric acid, and the pH followed, to obtain information on the ionization constants of the acid, and hence to some extent on the structure of the compounds.

The complex copper salts are too unstable to exist in acid solution, where they break up to give divalent copper. Jensovsky has shown that they are stable at least as far as pH = 8.5, when the salt $K_4H_3Cu(IO_6)_2$ can be crystallized out.

Sodium periodatomanganate is stable enough in acid to allow a complete pH curve to be found. In fairly dilute solution (2.5×10^{-3} *M*) the free acid is ionized to the extent of two hydrogens per molecule, i.e.$(H_3O^+)_2.Mn(H_3IO_6)_3^{-2}$. The p*K* values for these first

two stages must be fairly low, certainly 1.5 or less. A detailed study of the pH curve gave for the successive pK values: pK_3 = 2.75, pK_4 = 4.35, pK_5 = 5.45, pK_6 = 9.55, pK_7 = 10.45. These make the main jumps in the ionization constant occur at the stages $Mn(H_3IO_6)_3^{-2}$, $Mn(H_2IO_6)_3^{-5}$, i.e. at the symmetrical ions. The difference between the other pK values is about that expected for hydrogen atoms separated by the number of atoms required by the formula (for instance, the hydrogens in citric acid are separated by the same number of intervening atoms, and have about the same differences in pK).

Unfortunately, this simple, and reasonably satisfactory, explanation is complicated by the observation that, if the solution of sodium periodatomanganate is acidified and the mixture is titrated with alkali, a higher pH curve is found over part of the range. The difference comes mostly in pK_5; pK_1, pK_2, and pK_3 are virtually unaltered, pK_4 is a little higher (5.2), but pK_5 is much higher (9.55). A possible explanation is that in acid the complex is partially dissociated, but that this is not a rapid process, except perhaps in very acid solutions, i.e. it is catalyzed by hydrogen ions. The type of dissociation might be from a ring structure to a structure with periodate attached through one oxygen:

and it is possible to write structures, for the ions, which agree qualitatively with the observed ionization constants. However, the evidence at present is not sufficient to establish these suggestions.

A similar treatment of sodium telluratomanganate gives a similar type of curve, but this time the titration curves are the same in both directions. The acid $H_{14}Mn(TeO_6)_3$ has pK_1 and pK_2 fairly small (averaging 2.2), corresponding to ionization to $(H_3O^+)_2Mn(H_4TeO_6)_3^{-2}$. The values of p$K_3$ to pK_5 are not very different, averaging about 7.5; this involves ionization as far as $Mn(H_3TeO_6)_3^{-5}$. The next ionization constant is about $10^{-11.5}$. A summary of these pK values is in Table IV.

TABLE IV

$H_{14}Mn(TeO_6)_3$ pK_1 = pK_2 = 2.2 pK_3–pK_5 = 7.5 pK_6 = 11.5	$H_{11}Mn(IO_6)_3$ pK_1, pK_2, small pK_3 = 2.75, pK_4 = 4.35, pK_5 = 5.45 pK_6 = 9.55, pK_7 = 10.45
$H_9Co(TeO_6)_2$ pK_1 = 3.0 pK_2 = 8, pK_3 = 9	$H_7Co(IO_6)_2$ pK_1, small, pK_2 = 1.95 pK_3 = 7.1, pK_4 = 8.0 pK_5 = 12.1

A similar treatment of the complex cobalt salts gave the results which are also summarized in Table IV. The behavior of $H_9Co(TeO_6)_2$ is easily explained since the first ionization constant is fairly large, implying easy ionization to $Co(H_4TeO_6)^-$. Then follow two similar constants to give $Co(H_4TeO_6)^{-3}$. However, the acid $H_7Co(IO_6)_2$ has, unexpectedly, two fairly large ionization constants, followed by a pair of fairly similar values. This suggests that the structure of the acid is not as simple as might appear, but at present there is insufficient evidence for any detailed explanation.

Stability Constants of Complex Ions

Various measurements have been made on the stability constants of complex periodates and tellurates, the methods and results being as follows.

1. Copper Compounds

Here use can be made of the fact that uncomplexed copper catalyzes the decomposition of sodium hypochlorite to sodium chloride and oxygen (7). By measuring the rate of gas evolution from solutions containing sodium hypochlorite, sodium hydroxide, copper, and sodium periodate or tellurate in various proportions, it is possible to deduce the equilibrium constant. The uncomplexed copper is probably present as $Cu(OH_4)^-$, and the lack of dependence of the equilibrium constant on hydroxide concentration makes the equilibrium

$$Cu(IO_6)_2^{-7} + 4H_2O \rightleftharpoons Cu(OH)_4^- + 2H_2IO_6^{-3}.$$

With tellurate the main reaction is

$$Cu(HTeO_6)_2^{-7} + 2OH^- + 2H_2O \rightleftharpoons Cu(OH)_4^- + 2H_2TeO_6^{-4}.$$

The equilibrium constants (in 0.4 *M* NaOH for tellurate) are:

	Tellurate	Periodate	
K_1	1.8×10^{-6}	3.4×10^{-5},	40° C
K_2	1.1×10^{-11}	8.0×10^{-11},	40° C

K_1 and K_2 refer to the two stages of complexing:

$$K_1 = \frac{[Cu].[ligand]}{[1:1\ complex]}, \text{ and } K_2 = \frac{[Cu].[ligand]^2}{[1:2\ complex]}.$$

2. Cobalt Compounds

These are much more stable than the copper compounds; but because cobaltic hydroxide is relatively insoluble, the equilibrium is very slowly reached, starting with cobalt hydroxide and aqueous sodium periodate or tellurate. However, if a solution of the complex salt is added to aqueous sodium hypochlorite, it slightly increases the rate of oxygen evolution, and this increase corresponds to the equilibrium constants at 60° C:

$$\text{Cobalt periodate, } K_2 = 1.7\times10^{-16}$$

$$\text{Cobalt tellurate, } K_2 = 2.5\times10^{-16}.$$

These are for solutions containing 0.1 *M* sodium hydroxide. At present there is not enough information to write detailed equations for the reactions.

3. Manganese Compounds

The method of using the catalytic decomposition of hypochlorite ions will not work with manganese as this element does not seem to act as a catalyst. However, other methods are available.

Sodium periodatomanganate changes spontaneously in aqueous solution to sodium permanganate and sodium iodate and periodate by the reaction

$$2Na_7H_4Mn(IO_6)_3 + 2H_2O \rightarrow 2NaMnO_4 + 3NaIO_3 + 3Na_2H_3IO_6 + 3NaOH.$$

The rate of this reaction is found to be given by

$$\text{Rate} = K[\text{complex}].[Na_2H_3IO_6]^{-1}[NaOH]^{-2}.$$

This is probably because the complex ion breaks up, by the equation

$$H_4Mn(IO_6)_3^{-7} + 2H_2O \rightleftharpoons H_3Mn(IO_6)_2^{-3} + H_3IO_6^{-2} + 2OH^-$$

and the simpler ion, $H_3Mn(IO_6)_2^{-3}$, then reacts further. In the absence of added sodium periodate, the rate equation is apparently somewhat modified because the periodate is then derived solely from the complex present. From this, a value for the equilibrium constant of the above reaction can be calculated, and it is found to be 2×10^{-9} at 35° C.

This method cannot be applied to sodium telluratomanganate, since tellurate ions are not strongly oxidizing. However the dissociation of the telluratomanganate ion can be demonstrated in aqueous solution by spectrophotometric measurements. If solutions of sodium telluratomanganate are made up in aqueous solution, with and without added sodium tellurate, the apparent extinction coefficients vary considerably. Measurements made on these mixtures over a considerable range of concentration of sodium tellurate, sodium hydroxide, and the complex gave results agreeing with the equilibrium

$$H_7Mn(TeO_6)_3^{-7} + H_2O \rightleftharpoons H_4Mn(TeO_6)_2^{-4} + H_4TeO_6^{-2} + OH^-,$$

assuming that the complex ion had the same formula as in the solid compound $Na_7H_7Mn(TeO_6)_3\cdot5H_2O$, and that telluric acid is dissociated to $H_4TeO_6^{-2}$ in roughly 0.1 *M* sodium hydroxide. There is evidence to support the contention that the main complex ion contains three tellurate groups since the optical density of a solution made by oxidizing a given amount of manganese in the presence of various amounts of sodium tellurate increases steadily up to three tellurates per manganese, but thereafter remains constant. The equilibrium constant for the foregoing dissociation of telluratomanganate ion is found to be 4.3×10^{-5} at 25° C. This makes the tellurate complex considerably more unstable than the periodate complex, unlike the situation with the cobalt and copper compounds where the stabilities are much the same.

THE STEREOCHEMISTRY OF EIGHT-CO-ORDINATION: THE NATURE OF THE BONDING IN THE $Mo_6Cl_8^{4+}$, $Nb_6Cl_{12}^{2+}$, AND RELATED IONS[1]

R. J. GILLESPIE

ABSTRACT

It is pointed out that the square-antiprism arrangement of eight ligands which is expected for an atom which has eight bonding electron pairs in its valency shell occurs in the polynuclear complex ions found in several basic salts of zirconium(IV), thorium(IV), cerium(IV), and uranium(IV). The nature of the bonding in $Mo_6Cl_8^{4+}$, $Nb_6Cl_{12}^{2+}$, and related ions is discussed, and it is shown that it may be described in a manner which is consistent with a square-antiprism arrangement of eight electron pairs around each metal atom.

The stereochemistry of an atom in a molecule is determined by the arrangements of the electron pairs in its valency shell. These arrangements are determined by the operation of the Pauli exclusion principle which causes electrons with the same spin to keep apart (1). The author has shown previously that on this basis eight electron pairs in a valency shell would be expected to adopt a square-antiprism arrangement (2). Thus the arrangement of the valencies of an atom with a total of eight bonding electron pairs and no non-bonding pairs in its valency shell would be expected to be that of a square antiprism. Only two simple mononuclear complexes have had their structure determined, namely the tantalum octafluoride ion TaF_8^{3-} and thorium acetylacetonate $Th(C_5H_7O_2)_4$; both have the predicted square-antiprism arrangement (3, 4). In this paper it is shown that the same arrangement of eight bonds around a central atom is found in a number of polynuclear complexes, and that the bonding in $Mo_6Cl_8^{4+}$, $Nb_6Cl_{12}^{2+}$, and related ions can be satisfactorily described on this basis; the effects of a non-bonding electron pair on the arrangement of eight bonding pairs are also discussed.

Basic Salts of Ce(IV) and Th(IV)

Lundgren has investigated the structures of a number of basic salts of Ce(IV) and Th(IV) (5, 6, 7). In $Th(OH)_2CrO_4.H_2O$, and $Th(OH)_2SO_4$, there are polynuclear complex ions with the formula $[Th(OH)_2^{2+}]_n$ in which each Th is bonded to four OH groups arranged in the form of a square (Fig. 1). Eight-co-ordination around each

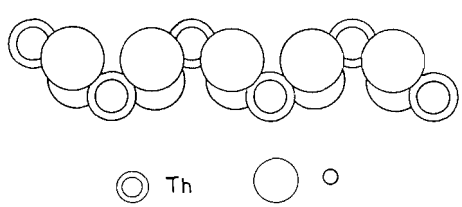

FIG. 1. The structure of the $[Th(OH)_2^{2+}]_n$ ion.

thorium is completed by four oxygen atoms from each of four separate chromate or sulphate groups, these four oxygen atoms being arranged at the corners of a square which is rotated through 45° with respect to the square formed by the OH groups, thus forming a square antiprism of oxygen atoms around each Th atom. The compound

[1]*Manuscript received June 30, 1961.*
Contribution from the Department of Chemistry, McMaster University, Hamilton, Ontario. Presented at the Symposium on Co-ordination in Chemistry, Chemical Institute of Canada, Hamilton, Ontario, May 15–16, 1961.

$CeOSO_4.H_2O$, however, contains infinite complex ions of the formula $(CeO^{2+})_n$ in which each Ce is co-ordinated to three oxygen atoms at three of the corners of a square (Fig. 2).

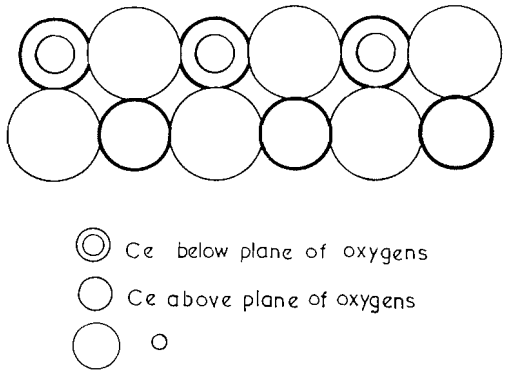

FIG. 2. The structure of the $(CeO^{2+})_n$ ion.

The square is completed by a water molecule, and, again, eight-co-ordination around the Ce is completed by four oxygen atoms from sulphate groups arranged at the corners of a square which is rotated through 45° with respect to the square formed by the oxygen atoms of the $[CeO^{2+}]_n$ chain and the water molecule. Thus there is a square-antiprism arrangement of oxygen atoms around the cerium atom. The basic sulphate with the formula $Ce_6O_4(OH)_4(SO_4)_6$, however, has a different structure containing the finite complex ion $Ce_6O_4(OH)_4^{12+}$. In this ion the metal atoms are situated at the corners of an octahedron, and are surrounded by eight oxygen atoms at the corners of a cube. Thus each cerium is co-ordinated to four oxygen atoms arranged at the corners of a square. Eight-co-ordination around the cerium is completed by four more oxygen atoms, one from each of four sulphate groups, which are arranged at the corners of a square rotated through 45° with respect to the four oxygen atoms in the complex cation. Thus each cerium is surrounded by a square-antiprism arrangement of eight oxygen atoms (Fig. 3).

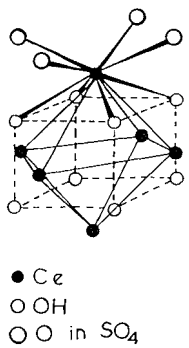

FIG. 3. The structure of $Ce_6O_4(OH)_4(SO_4)_6$.

$ZrOCl_2.8H_2O$

Crystalline hydrated zirconyl chloride has been found to contain the cyclic tetranuclear cation $[Zr_4(OH)_8(H_2O)_{16}]^{8+}$, which has the structure shown in Fig. 4 (8). The

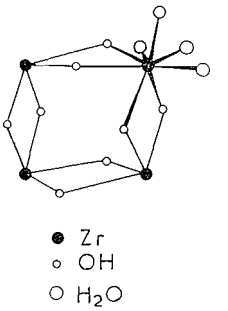

FIG. 4. The structure of the $[Zr_4(OH)_8(H_2O)_{16}]^{8+}$ ion.

four zirconium atoms are arranged in the form of a square, with two OH groups bridging each pair of zirconium atoms along the sides of the square, one OH being above and the other below the plane of the square. Four water molecules are also bonded to each zirconium and they are arranged in such a way as to complete a square-antiprism arrangement of ligands around the zirconium atom.

The $Mo_6Cl_8^{4+}$ Cation

Brosset (9, 10, 11) has determined the structures of crystalline hydrated molybdenum dichloride and also a similar basic hydrated molybdenum chloride and has shown that they should be formulated as $\{[Mo_6Cl_8]Cl_4(H_2O)_2\}6H_2O$ and $\{[Mo_6Cl_8](OH)_4(H_2O)_2\}$-$12H_2O$ respectively. The structure of the $Mo_6Cl_8^{4+}$ ion is shown in Fig. 5; it consists of

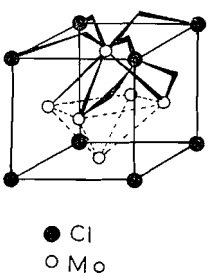

FIG. 5. The structure of the $Mo_6Cl_8^{4+}$ ion.

a regular octahedron of molybdenum atoms circumscribed by a cube of chlorine atoms, each molybdenum atom lying approximately in the plane of four chlorine atoms, constituting a face of the cube. Each molybdenum atom is thus surrounded by, and presumably bonded to, eight other atoms, four molybdenum atoms at the adjacent corners of the octahedron, and four chlorine atoms at the corners of a square which is parallel to, but rotated through 45° with respect to, the square formed by the four molybdenum atoms. There is, therefore, a very distorted square-antiprism arrangement of ligands around each molybdenum atom in which the four chlorine atoms lie in approximately the same plane as the central molybdenum atom. However, the arrangement of the bonding electron pairs is not necessarily the same as that of the ligands.

Sheldon (12) has made the very reasonable suggestion that the bonding of the chlorine atoms in the complex is essentially covalent since the ion retains its identity in solution and the chlorines show no tendency to ionize or to undergo replacement reactions. Each chlorine therefore appears to be forming three bonds to molybdenum atoms and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Mo—Cl—Mo angles are only 60°. However, it is most unlikely that three of the four electron pairs in the valency shell of a chlorine atom could be so close together. The most probable arrangement for four equivalent electron pairs is tetrahedral (1, 2) and even for non-equivalent bonding and non-bonding pairs the angle between the bonding pairs is very unlikely to be less than 90° since, at this angle, repulsions between the electron pairs of a second-row element become relatively large (13). It is very probable that the angles between the three bonding pairs at each chlorine are somewhat greater than 90° and this can only be reconciled with the structure of the complex if the Mo—Cl bonds are bent, i.e. involve a non-linear overlap of appropriate orbitals on the metal and the chlorine atom (Fig. 5). If this is the case, then the arrangement of electron pairs around each molybdenum atom approximates closely the expected square antiprism. Some slight distortion of the regular square antiprism is in any case to be expected since the electron pairs bind either chlorine atoms or molybdenum atoms and are therefore not all equivalent to each other.

The $Mo_6Cl_8^{4+}$ ion is able to co-ordinate six ligands, one opposite each of the molybdenum atoms. In the compounds investigated by Brosset these additional ligands are $4Cl^-$ and $2H_2O$, or $4OH^-$ and $2H_2O$. The presence of an extra ligand will cause some distortion in the square-antiprism arrangement of the eight electron pairs around the molybdenum and if this ligand is attached to the molybdenum as strongly as the eight other ligands, the square-antiprism arrangement of eight bonding electron pairs passes over to the expected arrangement for nine bonding pairs, namely a triangular prism with an electron pair opposite the center of each of the three rectangular faces (2) (Fig. 6). This may also be described as a "3;3;3" arrangement; in this case the 3-fold axis of the trigonal prism is the y-axis.

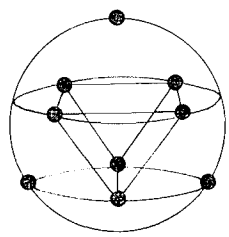

FIG. 6. The "3;3;3" trigonal prism arrangement for nine-co-ordination and its relation to the square-antiprism arrangement for eight-co-ordination.

This formulation of the structure of the $Mo_6Cl_8^{4+}$ ion implies that each molybdenum atom forms eight localized, at least partially covalent bonds, four of which are to other molybdenum atoms. Thus all the molybdenum valency electrons are used in bonding, and each molybdenum therefore has a d^0 configuration, which is consistent with the observed diamagnetism of the compounds containing this complex ion. Sheldon (12) has proposed that four chlorine atoms and one extra ligand are bound to each molybdenum by $d_{x^2-y^2}sp^3$ tetragonal, pyramidal orbitals and that the d_{xy} and d_{yz} orbitals form Mo—Mo bonds, leaving two electrons separately occupying essentially non-bonding d_{z^2} and d_{xy} orbitals, but nevertheless coupling their spins. This description of the bonding seems less satisfactory than that proposed above, for several reasons: it leads to an improbably small angle of 60° between three of the electron pairs on each chlorine atom; it necessitates a somewhat arbitrary assumption of pairing of the two electrons in the non-bonding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

d_{z^2} and d_{xy} orbitals in order to explain the observed diamagnetism; and it implies somewhat weak Mo—Mo bonds since it allows only a total of 12 electrons for these 12 bonds which, however, have a length of 2.64 Å, which is close to the single bond value of 2.59 derived from the metal (14).

The $Nb_6Cl_{12}^{2+}$, $Ta_6Cl_{12}^{2+}$, and $Ta_6Br_{12}^{2+}$ Ions

The complex chlorides of niobium, $Nb_6Cl_{14}.7H_2O$ and $Ta_6Cl_{14}.7H_2O$, and the bromide $Ta_6Br_{14}.7H_2O$ have been shown to form the complex $Ta_6Cl_{12}^{2+}$, $Nb_6Cl_{12}^{2+}$, and $Ta_6Br_{12}^{2+}$ ions in aqueous solution (15). These ions have the structure shown in Fig. 7, in which

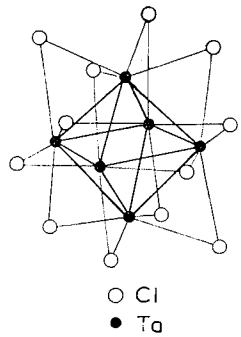

FIG. 7. The structure of the $Ta_6Cl_{12}^{2+}$ ion.

there is a regular octahedron of metal atoms, with a chlorine atom situated above each of the 12 edges of the octahedron. Thus each metal atom is surrounded by eight ligands, four chlorine atoms and four metal atoms arranged at the corners of a distorted cube. However, this is not the arrangement of the bonding electron pairs, firstly because the very small apparent bond angle at chlorine must imply that the metal–halogen bonds are bent and secondly because there are not enough electrons available to form 12 electron-pair bonds between the metal atoms. As only eight electron pairs are available for metal–metal bonds, their most probable arrangement would appear to be that in which there is one pair in the center of each face of the octahedron formed by the metal atoms, each electron pair binding three metal atoms and thus occupying a three-center orbital. If this is the case, the eight electron pairs surrounding the metal atom have the expected square-antiprism arrangement. It is probable that, in the solid, an additional ligand, e.g. Cl^- or H_2O, is bound to each of the metal atoms, thereby distorting the square-antiprism arrangement of eight electron pairs to the "3;3;3" arrangement expected for nine-co-ordination (Fig. 6).

The $U_6O_4(OH)_4^{12+}$ Ion

The basic sulphate of uranium of composition $U_6O_4(OH)_4(SO_4)_6$ has the same structure as the corresponding cerium compound, Fig. 3, and contains the complex cation $U_6O_4(OH)_4^{12+}$ (16). In this ion the metal atom has a valency shell containing eight bonding pairs and two non-bonding electrons.

The possible effect of the non-bonding electrons on the arrangement of the eight bonding pairs is most conveniently discussed in terms of the ligand-field theory. Figure 8 shows the splitting of the *d*-levels produced by the cubic, square-antiprism, and $Mo(CN)_8^{4-}$ arrangements of eight ligands. For the square-antiprism arrangement of ligands the d_{z^2} orbital has a lower energy than the other *d*-orbitals and could accommodate the unshared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

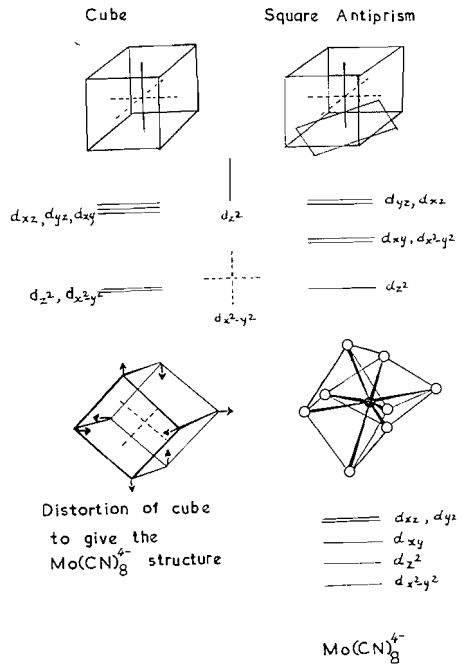

FIG. 8. Ligand-field "splittings" for the cube, square-antiprism, and $Mo(CN)_8^{4-}$ arrangements for eight-co-ordination.

pair without any appreciable distortion of the square-antiprism arrangement. Although this could, in principle, be the situation in the uranium compound, U(IV) compounds are generally paramagnetic and probably have an f^2 configuration with two unpaired electrons rather than a d^2 configuration. These electrons in the "inner" $5f$ orbitals have a negligible effect on the stereochemistry of the eight bonding electron pairs in the "outer" $6d7s7p$ orbitals and this may therefore be described as a weak-field or "outer"-orbital complex.

The $Mo(CN)_8^{4-}$ Ion

This ion does not have the square-antiprism structure but has the dodecahedral, or distorted cube, structure shown in Fig. 8 (17). Although the antiprism has been predicted to be the most stable arrangement for eight-co-ordination it may easily be seen that the dodecahedral structure must have very nearly the same stability, since the smallest bond angles for the square antiprism and the $Mo(CN)_8^{4-}$ structures are 74° 52′ and 74° respectively, whereas the smallest bond angle in the less-stable cubic arrangement is only 70° 32′. Since the interactions between the bonding electron pairs which arise from the operation of the Pauli exclusion principle are of such a nature that they increase very rapidly with decreasing separation of the electron pairs (18) the stability of a given arrangement is particularly dependent on the size of its smallest bond angle.

In the dodecahedral structure two non-bonding electrons may be accommodated in the $d_{x^2-y^2}$ orbital and they would not be expected to cause any appreciable distortion of the structure. In $Mo(CN)_8^{4-}$ the non-bonding pair is almost certainly involved to some extent in double bonding with the CN groups. It does not seem possible at the present time to decide what factors are of importance in determining the relative stabilities of the dodecahedral and square-antiprism structures.

NOTE ADDED IN PROOF

Since this paper was written I have been informed of some new, unpublished determinations of the structures of some eight-co-ordinated complexes: zirconium acetylacetonate (19) has a square-antiprism structure but tetrakisoxalatozirconate(IV) (20) and bis-diarsinetitanium (IV) tetrachloride (diarsine = o-$C_6H_4[As(CH_3)_2]_2$) (21) have the dodecahedral $Mo(CN)_8^{4-}$ structure. These new examples of both types of eight-co-ordinated structures further emphasize their very similar stabilities.

Table I lists all the known mononuclear and finite polynuclear molecules and complex ions in which the stereochemistry is determined by the square-antiprism and dodecahedral arrangements of eight bonding electron pairs in the valency shell of a central atom.

TABLE I

Molecules and complex ions with structures based on the square-antiprism and dodecahedral arrangements of eight bonding electron pairs

CO-ORDINATION COMPLEXES OF TITANIUM (IV) HALIDES

II. PREPARATION AND INFRARED SPECTRA OF THE COMPLEXES OF TITANIUM TETRACHLORIDE WITH DIESTERS OF α,ω-DICARBOXYLIC ACIDS AND COMPARISON WITH ANALOGOUS COMPLEXES OF ZIRCONIUM TETRACHLORIDE AND TIN TETRACHLORIDE[1]

ERNEST RIVET,[2] REAL AUBIN,[3] AND ROLAND RIVEST

ABSTRACT

Co-ordination complexes between diesters of α,ω-dicarboxylic acids and titanium tetrachloride, tin tetrachloride, and zirconium tetrachloride have been prepared. The analytical results, the infrared spectra, the melting points, and the molecular-weight determinations indicate that for the titanium and zirconium complexes, two types of complexes are obtained, one having a general formula $MX_4.1$ diester in which chelate rings from five to nine atoms are formed and the other one, $2MX_4.1$ diester in which there are two 4-membered rings per complex molecule. With tin tetrachloride only one type of complex is formed, which has two tin tetrachlorides and two diesters per complex molecule.

INTRODUCTION

In a previous paper (1) the reaction of diethyl oxalate with titanium tetrachloride has been studied and it was found that a chelated complex involving the two carbonyl groups of the oxalate was formed. The study was extended to diesters of the general formula $CO_2R—(CH_2)_n—CO_2R$, where n varies from 0 to 9, in order to see if very large chelate rings of the same type could be prepared.

In these diesters, the relative independance of every ester group makes it possible to consider that what is true for an ester should apply to a diester. In a carboxylic acid, the acidity is largely due to the possible resonance between the free electron pairs of the oxygen atoms. This makes the implication of the two oxygens of a monocarboxylic acid in the formation of a complex very unlikely. However, an ester is very different from a carboxylic acid. Although Pauling (2) and Wheland (3) mention that the resonance energy of an ester should be of the same order of magnitude as that of a carboxylic acid, Cook (4), using empirical results, has well established the absence of resonance in the esters, and he explained also this finding in terms of orbitals. It is not possible for the π orbitals of the carbonyl group to overlap the sp^3 orbitals of the other oxygen of the ester. Fieser (5) has reached the same conclusion by measuring ultraviolet absorption spectra: the molar extinction coefficients of the esters were larger than those of the corresponding carboxylic acids, thus indicating the presence of an unsaturated bond which is the double bond of the carbonyl group. It is then reasonable to assume that the four oxygen atoms of a diester are almost identical as far as their donor ability is concerned, except for the slight priority of the oxygens of the two carbonyl groups due to the possible steric hindrance of the radical on the two other oxygens. It becomes, then, possible to prepare complexes of diesters with titanium tetrachloride where two 4-membered-ring chelates will be formed. If one does a series of experiments with the diesters $CO_2R—(CH_2)_n—CO_2R$, he measures the relative ease of formation of large rings of seven, eight, nine, or more atoms compared to the formation of two 4-membered rings per diester molecule.

The formation of a four-membered-ring chelate on a Lewis acid requires that the two

[1]*Manuscript received June 30, 1961.*

donor atoms be accepted in a cis position. The work of Osipov (6) and co-workers, in which they obtained a one-to-one addition compound of titanium tetrachloride with ethyl propionate, indicates that this is very possible with $TiCl_4$. However, if the Lewis acid used is tin tetrachloride, the complex formed is $SnCl_4$.2 monoesters and the proposed structure is a trans one. In such a case, it should not be possible to observe the formation of a four-membered ring at both ends of the diester molecule. This was found to be so, and we prepared for the whole series of diesters, one-to-one addition compounds with tin tetrachlorides. In order to see if this difference in behavior between tin tetrachloride and titanium tetrachloride was a size effect, we prepared the same complex with zirconium tetrachloride; this was found not to be the case since zirconium and titanium tetrachlorides behaved similarly.

EXPERIMENTAL

Materials and Manipulation

Titanium tetrachloride was purified as mentioned before (7) and tin tetrachloride was purified by the method patented by Pittsburg Plate Glass Company (8). Commercial zirconium tetrachloride was sublimed in a nitrogen atmosphere at 200° C. The compound so obtained was a white powder. The analytical results were Zr, 39.60%; Cl, 60.49%, the theoretical values being 39.14% for zirconium and 60.84% for chlorine. The esters used were dried over magnesium sulphate or magnesium perchlorate and vacuum-distilled over magnesium perchlorate. One diester, diethyl suberate, was prepared in our laboratory using the esterification method described in *Organic syntheses* (9). It was dried and distilled, as were the other ones. The solvents used were purified by standard methods, dried, and distilled over a suitable drying agent. The water-sensitive complexes were prepared and handled in a dry box continuously flushed with dry nitrogen.

The methods of analysis for titanium and chlorine have been described previously (7); for the determination of tin the method described in Vogel's *Textbook of quantitative inorganic analysis* (10) was used. Zirconium was determined by precipitation with ammonium hydroxide, and ignition to the dioxide (11). All the analytical results are included in Table I.

The setup used to prepare the complexes was the same as the one used in previous experiments (12).

The spectrophotometric measurements were carried out on a Perkin–Elmer infrared spectrophotomer, model 21, using a sodium chloride prism. The spectra of the complexes were determined in solutions of suitable solvents or by the KBr disk method. The melting point determinations were made with a Thiele apparatus. The molecular-weight determinations were made either by cryoscopy or ebullioscopy.

Preparation of the Complexes

The System $SnCl_4$ – Diethyl Succinate

Pure $SnCl_4$ was added dropwise to a certain quantity of the diester. The precipitate formed instantaneously as $SnCl_4$ was added. As the stoichiometric value of $SnCl_4$ for a one-to-one addition compound was approached, the liquid phase became very viscous and then the whole mass more or less solidified. It was washed very carefully with hexane and dried in vacuum at room temperature, leaving a white powder.

The System $SnCl_4$ – Diethyl Adipate

The reaction was performed by the dropwise addition of $SnCl_4$ to the pure ester.

The reaction rate was slower than in the previous case but led to a white solid which, when filtered, washed with hexane, and dried in vacuum at room temperature, gave a white powder.

The System $SnCl_4$ – Diethyl Azelate

This reaction was performed by the previous method, but no precipitation occurred even after many days of agitation. If the reaction mixture is washed with hexane, then there is precipitation of a white powder. This powder was filtered, washed with hexane, and dried in vacuum at room temperature.

The Systems $TiCl_4$–Oxalate and $TiCl_4$–Malonate

Thirty milliliters of a 10% solution of titanium chloride in hexane was added dropwise to 30 ml of a solution of the diester in the same solvent. Precipitation occurred at the very beginning of the addition, giving a yellow powder. The powder was filtered, washed many times on the filter with pure hexane, and dried in vacuum at room temperature.

The Systems $TiCl_4$ – Diethyl Succinate and $TiCl_4$ – Diethyl Glutarate

Thirty-eight milliliters of a 10% solution of titanium tetrachloride was added dropwise to 35 ml of a 10% solution of the diester. A yellow powder was formed at the beginning of the addition, and when the stoichiometric value for one-to-one addition was reached, another compound, somewhat lighter in color, was formed in small quantity. This explains the high values obtained for titanium and chlorine. It indicates that a very small proportion of the solid is probably a two-to-one addition compound of $TiCl_4$ to the diester.

The System $TiCl_4$ – Diethyl Adipate

By using 10% solutions of the reactants in hexane, as for previous preparations, one can obtain three analytical results. One obtains, in stoichiometric proportions, a mixture of compounds, which can be separated by extraction with benzene. The analytical values indicate that a mixture of two compounds, $TiCl_4$.1 diester and $2TiCl_4$.1 diester, was obtained; by using excess diester, one obtains the one-to-one addition compound almost exclusively and by using excess $TiCl_4$, one obtains the two-to-one addition compound. The two compounds have different melting points and their color is different, the first one being yellow, the other one being light yellow.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The Systems $TiCl_4$ – Diethyl Pimelate, $TiCl_4$ – Diethyl Suberate, $TiCl_4$ – Diethyl Azelate, and $TiCl_4$ – Diethyl Sebacate

The preparation of these complexes was performed in hexane with 10% solutions of the reactants. The complexes prepared are all similar in appearance, being light yellow powders. The analytical results indicate that they are all complexes of the two-to-one stoichiometric compositions. If one tries to prepare the one-to-one addition complexes, which would have been very large chelate rings, there is then dissolution of the complex in the excess diester and one obtains a very viscous, dark brown liquid which seems to be the solvated two-to-one addition compound. These results indicate that with these diesters only one compound can be isolated. However, if one uses CCl_4 as solvent and prepares a complex from stoichiometric values for a one-to-one addition compound, one can see that there are really two compounds, one being almost insoluble in CCl_4, the other being soluble. If one tries to isolate this small precipitate by decantation and then filtration, there is a modification of the precipitate on the filter and one gets a very viscous solid which cannot be properly dried. Qualitatively, this insoluble part is almost nil for the last two terms of the series, but is somewhat larger for the pimelate system.

The Systems $ZrCl_4$ – Diethyl Oxalate, $ZrCl_4$ – Diethyl Succinate, and $ZrCl_4$ – Ethyl Butyrate

To 2 g of powdered zirconium tetrachloride partially dissolved in carbon tetrachloride was added dropwise a 10% solution of the ester in the same solvent till a slight excess of the diester was obtained. The reactants were left in contact with each other for 2 or 3 days, then the white powder obtained was filtered, washed with dry carbon tetrachloride, and dried in vacuum at room temperature.

The System $ZrCl_4$ – Diethyl Sebacate

To 2 g of powdered zirconium tetrachloride partially dissolved in hexane was added dropwise a 10% solution of the sebacate, in the same solvent. The reactants were left in contact with each other for 2 or 3 days, then the white powder obtained was filtered, washed with hexane, and dried in vacuum at room temperature.

The analytical results as shown in Table I indicate that for the titanium tetrachloride complexes there is a progressive change from the monochelated complex of the first terms to the dichelated complexes as the length of the diester chain increases. By comparing the experimental results of the stoichiometric preparations with the theoretical values, one can calculate the relative amount of the two possible complexes for a given diester. These values were calculated using the following equations:

$$T_1 \times A + T_2 \times B = F \qquad [1]$$

$$A + B = 1. \qquad [2]$$

In these equations A is the mole fraction of titanium present as one-to-one addition compound, B is the mole fraction of titanium present as two-to-one addition compound, T_1 represents the theoretical value of the percentage of titanium for a one-to-one addition compound, T_2 the theoretical percentage of titanium in a two-to-one addition compound, and F the value of titanium found for the complex. The values so calculated are tabulated in Table II and illustrated in Fig. 1.

Infrared Spectra

The infrared spectra of the titanium complexes have been studied in solutions and by the KBr disk method. With methylene chloride solutions, we have studied the lowering

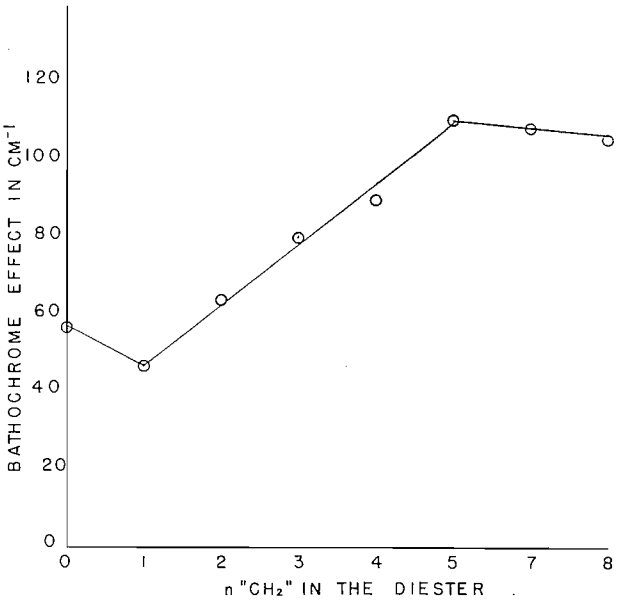

FIG. 2. Infrared spectra in methylene chloride solutions: variation of the bathochrome effect of the carbonyl stretching vibration when co-ordinated to titanium, as a function of the length of the diester chain.

By studying the infrared spectra of co-ordinated complexes containing cyclic ethers as the donor molecules, Sisler (13) has observed that the band attributed to C—O—C vibrations disappears in the spectrum of the complex. In order to see if the ethered oxygens of the diesters were involved in complexing, the spectrum of the diethyl sebacate ester in methylene chloride solution has been compared with the spectrum of the titanium complex dissolved in the same solvent. One can observe in Fig. 3 that in the region of 1200–1100 cm^{-1}, usually attributed to ν_{C-O} and ν_{C-O-C} vibrations (14), there is strong absorption in the spectrum of the ester which almost completely disappears in the spectrum of the complex. This seems to be a confirmation of the fact that the two oxygens of the ester groups of the sebacate act as donor atoms to form a four-membered-ring chelate.

In Fig. 4, we compare the spectrum of diethyl oxalate in *n*-butyl chloride solution with the spectrum of the $TiCl_4$–oxalate complex in the same solvent. The band located at 1165 cm^{-1} and attributed to ν_{C-O}, and the band located at 1152 cm^{-1} and attributed to ν_{C-O-C}, are much stronger in the spectrum of the ester than in the spectrum of the complex, but they still are easily located in the spectrum of the complex. This seems to confirm the proposed difference in the structure of the two types of complexes involved.

The spectra of the solid complexes of titanium studied by the KBr disk method gave different results. Four complexes were studied and all of them gave about the same bathochrome effect: 110 cm^{-1} for the succinate complex, 106 cm^{-1} for the adipate complex, 110 cm^{-1} for the sebacate complex.

The infrared spectra of tin complexes were also studied and the bathochrome effect did not change appreciably for the whole series, being about 100 cm^{-1}.

DISCUSSION

The results tabulated here indicate that the reactions of the diesters studied with titanium tetrachloride lead to two different types of compounds, represented by equations [3] and [4]. The transition from (*a*) to (*b*) seems to be gradual, as it is shown in Fig. 1.

[3]

(*a*)

[4]

(*b*)

This graphical representation is not precise but at least gives an idea of what is happening. The values of A and B for the complexes of the diesters for which the value of n is larger than 4 could not be determined. If one tries to obtain a mixture of (*a*) and (*b*), the (*b*) complex dissolves in the diester and it is not possible to get rid of this diester because of its very low vapor pressure at room temperature. It has been attempted to wash out the diester with suitable solvents but it was found that it is part of a solvated molecule and as such is not removable by solvents.

Figure 2, in which the variation of the bathochrome effect is plotted against the n

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

values of the diester chain, illustrates a variation in the type of complexes obtained. The value of the carbonyl shift is the lowest for the six-membered-ring chelate for which the strain should be at a minimum. For this complex the carbonyl shift is equal in value to the shift observed for the $TiCl_4$.2 acetone complex. As the ring size increases, the carbonyl shift increases until it becomes about equal to the shift observed for a four-membered-ring complex. This is confirmed by the similar shift obtained for the complex $TiCl_4$–butyrate and by vanishing of the band attributed to C—O—C vibration in the type (*b*) complexes.

It is noticable that in the solid state, the carbonyl frequency shifts are about the same for the whole series of titanium complexes. This is certainly due to the fact that in the solid state the OR groups in the type (*a*) complexes are involved in co-ordination to titanium somewhat as ammonia is in complexes like $TiCl_4.4NH_3$. This co-ordination through the OR groups in the solid state explains also the break in the melting points as one arrives at the (*b*) type complexes where this is not possible because the OR groups are already co-ordinated to a titanium atom.

In dilute solutions, the different molecules of complexes are well separated from each other as indicated by the molecular-weight determinations listed in Table V. Great care was taken in these determinations to avoid hydrolysis, which would give a lower molecular weight than the theoretical one. Every solvent used was checked with the Karl Fisher reagent, and the amount of water present could not change appreciably the thermometer readings leading to the molecular weight, but explains the fact that all the values are a little lower than the theoretical ones. The fact that the butyrate complex has a molecular weight which is about half that of the sebacate complex indicates that the formula proposed for the complexes similar to the sebacate one is probably adequate since there should not be any doubt about the formula of the monoester complex.

The behavior of tin tetrachloride in its reaction with diesters is different. The tin complexes obtained are different from the titanium ones as indicated by the melting points and the analytical results. Many experiments were performed to determine the molecular weight of these complexes in solution, but because of the lack of suitable solvents, it has not been possible to get reproducible results. So, we relied on the work of Hieber and Reindl (15), who have proved that $SnCl_4$ gives two-to-two addition compounds with the diesters we used. Since it is possible to obtain complexes $SnCl_4$.2 monoesters, the impossibility of obtaining chelate rings of the (*a*) type can be explained by the fact that the complexing of two ligands with $SnCl_4$ is done in the trans positions; it is then very possible that the four chlorine atoms lie equatorially on the plane of the tin atom and that the two axial co-ordinating positions are longer distances than the Sn—Cl distances, thus giving an elongated octahedron. This is in agreement with the conclusion of Sumarokova and Yarmukhamedova (16) in their work on complexes of stannic halides with thiourea, in which they mention that the complexes SnX_4.2 thiourea have a trans configuration.

ACKNOWLEDGMENTS

The authors are indebted to Professor Camille Sandorfy for valuable discussion on the infrared spectra and to Mr. Gilles Murphy for the preparation and analysis of some of the complexes.

The authors also wish to thank the National Research Council for the grants to one of us (R. R.) and l'Office des Recherches Scientifiques de la Province de Québec for the fellowships to E. R. and R. A.

SOMMAIRE

On a préparé des complexes de coordination entre des esters des acides α,ω-dicarboxyliques normaux et du tétrachlorure de titane, du tétrachlorure d'étain et du tétrachlorure de zirconium. Les résultats analytiques, les spectres infrarouges, les mesures de points de fusion indiquent que le tétrachlorure de titane et le tétrachlorure de zirconium donnent, par leur réaction avec les diesters, deux sortes de complexes de formule $MX_4.1$ diester et $2MX_4.1$ diester respectivement. Les complexes $MX_4.1$ diester sont des chelates contenant cinq à neuf atomes par anneau alors que les complexes $2MX_4.1$ diester contiennent par molecule deux anneaux a quatre situés en bouts de chaine du diester. Avec le tétrachlorure d'étain, on obtient seulement un genre de complexe de formule $2SnCl_4.2$ diesters.

π-BONDING IN INORGANIC COMPOUNDS

IV. ROLE OF UNPAIRED ELECTRONS IN HEXAHALO COMPLEXES[1, 2]

A. D. WESTLAND AND N. C. BHIWANDKER[3]

ABSTRACT

A study of d_π–p_π bonding in paramagnetic compounds having the potassium chloroplatinate structure is described. It is shown that the magnetic superexchange effect is approximately proportional to the number of unpaired electrons in t_{2g}^5 and t_{2g}^4 systems but there is an irregularity in the t_{2g}^3 system of potassium chlororhenate. This singularity of the t_{2g}^3 case is considered to be a result of the orbital and crystal symmetries. The magnetic properties of the compounds are related to the extent of π-bonding stabilization in octahedral complexes having various configurations t_{2g}^n on their central atoms.

As part of a program to obtain quantitative or semiquantitative estimates of the extent of π-bonding in inorganic compounds, we have undertaken studies of the effects of certain variables such as principal quantum number of the orbitals involved and effective nuclear charge of the participating atoms. In the present paper we provide evidence which suggests that the extent of d_π–p_π bonding of the type defined as "semicovalent" (1) varies in proportion to the number of unpaired d-electrons provided that these are contained in orbitals of the appropriate symmetry. This result is not entirely trivial for in some of the cases in which electron-pair π-bonding is invoked to account for enhanced compound stability, there seems to be poor correlation between that stability and electron structure (2). In view of the results of the present investigation, it would seem feasible to ascribe the stability of complexes such as $Cr(CN)_6^{3-}$, in which there are no d-electron pairs, to a system of single electron or "half" π-bonds.

The present study compares the extent of magnetic superexchange in compounds K_2MeCl_6 in which the central atom possesses one, two, or three unpaired $5d_\epsilon$-electrons. In a previous publication (3) it was shown that there is extensive superexchange in K_2OsCl_6, K_2OsBr_6, and K_2ReCl_6. This apparently operates through d_π–p_π bonding orbitals which encompass the metal atom and its ligands and, as well, p_π–p_π overlap between the ligands of the neighboring complex groups (4). This latter exchange is shown by means of diagonal broken lines in Fig. 1. The previous results are herein supplemented with those for K_2IrCl_6, again employing the technique of isomorphous dilution with K_2PtCl_6.

It has been shown that K_2IrCl_6 is antiferromagnetic at low temperatures (5), and the electron spin resonance spectrum likewise provides evidence of a π-bonding mechanism (6, 7, 8). In order to obtain an estimate of the magnitude of d_π–p_π bonding in K_2IrCl_6, we have measured the change in the effective magnetic moment of the chloroiridate ion when it is put into solid solution at high dilution in K_2PtCl_6. The assumption that the change in effective magnetic moment is a measure of the superexchange and, in turn, of the extent of π-bonding in the Me—Cl link is justified as follows.

In order for the superexchange coupling to occur, it is necessary that quantum mechanical exchange should take place between neighboring chlorine atoms on adjacent $MeCl_6^{2-}$ groups as well as within the groups. Since there is only a very small change in lattice constant along this series of isomorphous compounds K_2IrCl_6, K_2OsCl_6, and

K_2ReCl_6, it seems justified to assume that the Cl—Cl distance of adjacent anions is so nearly constant that all differences in the exchange effect are due to differences in the Me—Cl bonds.

RESULTS AND DISCUSSION

Pure Potassium Chloroiridate (IV)

The values of the susceptibilities and effective moments at three temperatures for the pure substance are shown in Table I. These data agree well with the values obtained by

TABLE I

Magnetic susceptibilities and effective moments of K_2IrCl_6

Temperature, °K	Gram susceptibility, $\chi_g \times 10^6$	Mole susceptibility, $\chi_M \times 10^3$	Effective moment, B.M.
298	2.15	1.25	1.72
224	2.96	1.63	1.71
90	5.41	2.86	1.44

Cooke *et al.* (5) but differ slightly from those of Norman and Morrow (9), who obtained $\mu_{eff} = 1.64$ B.M. at 298° K. It was our experience that unless oxidizing conditions were maintained at all times during the crystallization of the compound, slightly low results were obtained.* Cooke *et al.* made no measurements between the boiling point of oxygen and room temperature, and assumed that the spin-only value of the moment obtains in the compound but that a large temperature-independent paramagnetism is present. The former assumption is not justified as will be shown.

It is to be expected that the compound should obey the theories of Kotani (10) or Figgis (11), which take account of spin–orbit coupling. The former predicts that the spin-only value of the moment will be observed for the t_{2g}^5 configuration when kT is small with respect to the spin–orbit coupling constant, λ, and that μ_{eff} should vary in nearly linear fashion with kT/λ for temperatures up to 300° K. Figgis' more detailed theory

*K_2IrCl_6 *is diamagnetic.*

takes account of electron delocalization and states that the moment at 0° K should be progressively lower than the spin-only value, the greater is the delocalization, $1-k$. The plot of μ_{eff} for the pure compound in Fig. 2 shows that moment is far from linear in tem-

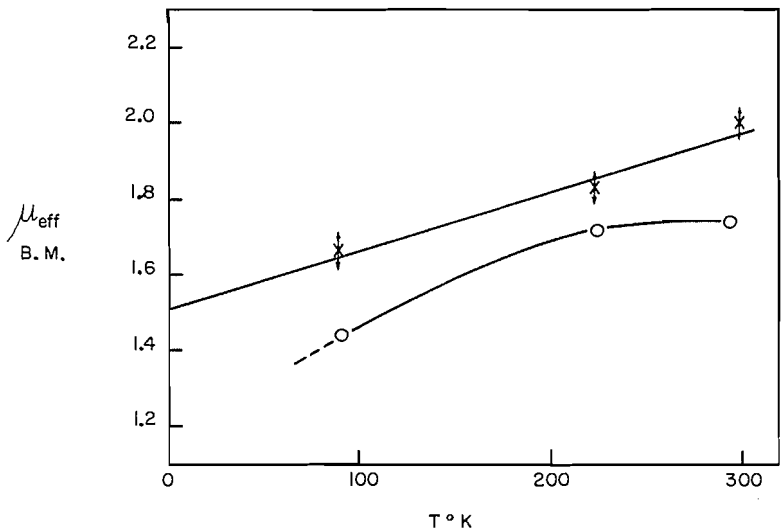

FIG. 2. Plots of effective moment against temperature: O pure K_2IrCl_6; × K_2IrCl_6 at infinite dilution in K_2PtCl_6.

perature and that the value at 0° K is much too low to correspond to a reasonable degree of delocalization ($\mu(0°\text{ K}) = 1.41$ B.M. for $k = 0.7$, for example).

The theories of Kotani and Figgis involve the assumption that there is no exchange between neighboring paramagnetic atoms. It was therefore thought that the discrepancy was the result of superexchange. Some indication of superexchange quenching in Na_2IrCl_6 was provided by Sloth and Garner (12), who found that the moment of the solid was 1.58 B.M. while in aqueous solutions it was 1.75 B.M. A study over an extensive temperature range can be carried out only in solid solution, however.

The System K_2IrCl_6/K_2PtCl_6

The effective moment of the iridium atom in solid solution rises with increasing dilution. The course of this quantity with change of concentration is shown in Fig. 3 for three different temperatures. It is apparent that the paramagnetism is partially quenched in the magnetically concentrated systems and that the behavior is essentially the same as that of the system K_2OsCl_6/K_2PtCl_6. There appears to be initially a slight decrease in the paramagnetism from 100 mole% down to about 50 mole%. We can suggest no convincing explanation for this effect if, indeed, it is real.

The data do not afford a very accurate extrapolation to infinite dilution, for the paramagnetism of the most dilute sample measured (12.5 mole%) is of the same order of magnitude as the accompanying diamagnetism. However, the values obtained from the graphs are given in Table II. The effective moment is plotted in Fig. 2, against temperature, along with the values for pure K_2IrCl_6. It may be seen that in contrast with the pure compound, the infinitely dilute chloroiridate (IV) ion behaves at least within the limits of experimental error, in the manner expected for a substance to which Figgis' theory should apply. The line in the figure has been drawn through the value $\mu = 1.5$ at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

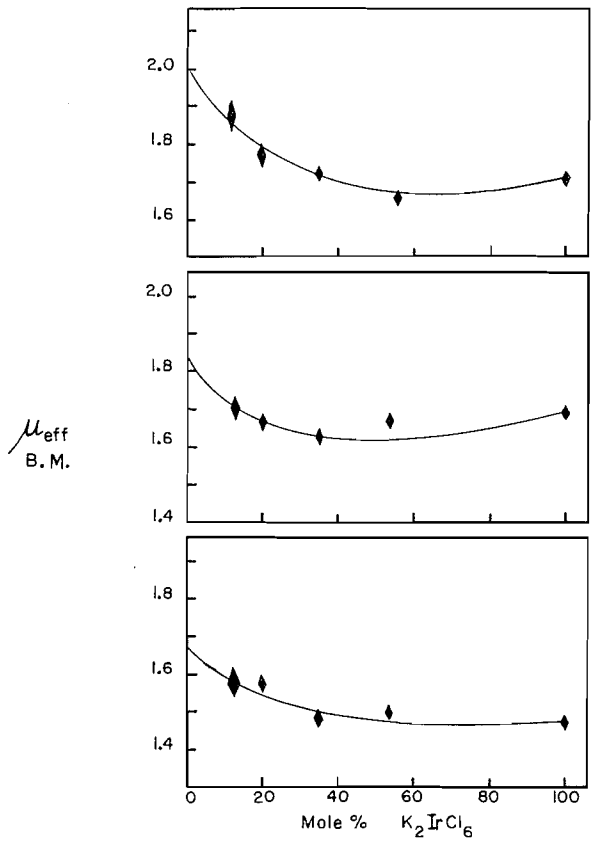

FIG. 3. Plots of the effective moment against concentration of K_2IrCl_6 dissolved in K_2PtCl_6.

$T = 0°$, corresponding to a value of $k = 0.7_6$. This would mean that the electron hole is ~24% in p_π orbitals of the ligands. Griffiths, Owen, and Ward obtained a value of $k = 0.7$ from paramagnetic resonance experiments (6). Although we feel our figure has little accuracy, it is in semiquantitative agreement with the previous results.

From the slope of the line, a value of 630 cm^{-1} is obtained for the spin–orbit coupling constant. This is an extraordinarily low value and makes us doubt the reliability of the estimate. A value of 2000–3000 would seem reasonable. The discrepancy may be the result of an underlying temperature-independent paramagnetism of the order of 0.4×10^3.

Comparison of K_2IrCl_6, K_2OsCl_6, and K_2ReCl_6

We may now compare the extent of superexchange in the compounds K_2MeCl_6. In the case of K_2ReCl_6, the investigation described previously (3) and subsequent measurements (13) suffice to show that the effective moment of chlororhenate (IV) at infinite dilution is 3.75±0.03 B.M. In Table III the room temperature moments of the three pure compounds and the complexes at infinite dilution are presented together with the values of the Weiss constant, Δ, calculated, in the case of iridium and osmium, on the assumption that

$$\mu_{eff} = 2.86[\chi_M(T+\Delta)]^{1/2},$$

where μ_{eff} is the moment for the complex at infinite dilution and χ_M is the mole susceptibility of the pure compound.

TABLE II

Paramagnetism of $IrCl_6^{2-}$ at infinite dilution in K_2PtCl_6

Temperature	Mole susceptibility $\times 10^3$	Effective moment, B.M.
298°	1.68	2.0 ±0.06
224°	1.85	1.82±0.06
90°	3.82	1.66±0.07

TABLE III

	No. of unpaired electrons	Moment of pure K_2MeCl_6, B.M.	Moment at infinite dilution, B.M.	Derived Weiss constant, Δ
Ir (IV)	1	1.7	2.1	104
Os (IV)	2	1.44	2.13	340
Re (IV)	3	3.26	3.75	90

It can be seen that the quenching of the paramagnetism does not depend simply on the number of unpaired electrons. However, the value of the Weiss constant is more than doubled in going from one unpaired electron to two.

Although this quenching is apparently not simply related to the electronic configuration, we believe that there is, in fact, an approximate proportionality between the superexchange and the extent of π-bonding with the number of unpaired electrons, except for an irregularity at rhenium because of the geometry of the magnetic structure. We shall consider this structure forthwith.

Magnetic Structure of the Compounds K_2IrCl_6, K_2OsCl_6, and K_2ReCl_6

Anderson (14) has discussed the possible modes of antiferromagnetic ordering in the face-centered cubic type of lattice which can occur below the Néel temperature and has pointed out that the structure may be described by means of four sublattices, designated A, B, C, and D in Fig. 4. He has further shown that the ordering of the electron spins

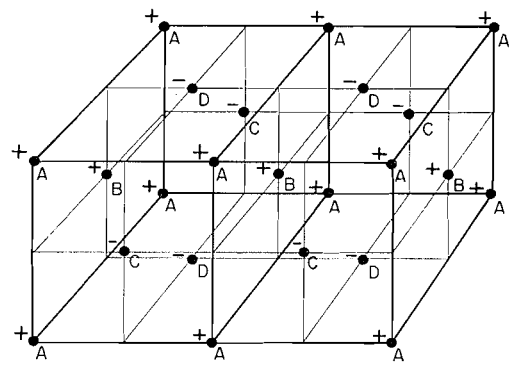

FIG. 4. Magnetic ordering in a face-centered cubic lattice.

in these sublattices may be one of three types depending upon the relative magnitudes of nearest-neighbor and next-nearest-neighbor interactions. Although neutron diffraction shows that the next-nearest-neighbor interactions are more important in many binary

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

compounds, such as NiO,MnSe, etc., the superexchange mechanism responsible for this, namely an Me $\uparrow$ — X — Me $\downarrow$ atomic sequence in which X is an anion possessing an occupied p-orbital lying in the axial direction, is not present in the compounds K_2MeCl_6. In these ternary complexes, the π-orbitals important to the superexchange mechanism are geometrically oriented so as to favor nearest-neighbor interactions. This is pictured in Fig. 1.

A given atom site in the face-centered cubic structure possesses 12 nearest-neighbor sites distributed equally among the other 3 sublattices. It is impossible to find an ordered arrangement in which the atom spin is antiparallel to that of all its nearest neighbors. At best, it can be antiparallel to only two thirds of them. If it be assumed that next-nearest-neighbor interaction is of minor importance, a favorable arrangement is found, with all spins in sublattices A and B, say, pointing west and those in C and D pointing east, as shown in Fig. 4. This will be allowed when the atoms of all four sublattices have an unpaired electron in either or both of the orbitals d_{xy} and d_{yz}. If such is the case, the magnetic structure would consist of an ordered system composed of sublattices A and C with antiparallel spins and, distinct from this, another like system composed of sublattices B and D. It can be seen from the diagram that an atom in sublattice B has four nearest neighbor atoms in sublattice A with the same spin. The same relation is found between the atoms of sublattices C and D. However, as long as d-electrons occupy only the pairs of orbitals d_{xy} and d_{yz}, there is no opportunity for superexchange between nearest-neighbor atoms with parallel spins.

In the event that each central atom possesses three unpaired t_{2g}-electrons, one of these must be accommodated in the d_{xz} orbital. In such a case, coupling between an atom and all of its nearest neighbors is possible. It is clear that this third unpaired electron will work against the ordering process and will decrease the magnitude of the asymptotic Curie temperature, $-\theta$, i.e. the Weiss constant, Δ.

Other ordering schemes can be proposed for the lattice, but the best schemes have the essential features in common, namely, that the ordering is perfect in the (1,0,0), (0,1,0), or (0,0,1) planes, but that each plane is not correlated with adjacent parallel planes except inasmuch as next-nearest-neighbor interactions may be favored, e.g. Anderson's "ordering of the third kind". An analogous arrangement of occupied orbitals will be set up in any case. Thus the irregularity at K_2ReCl_6 is accounted for.

SUMMARY

We conclude that the extent of π-bonding as revealed in the degree of superexchange cannot increase in proportion to the number of unpaired t_{2g}-electrons for more than two such electrons in compounds having a face-centered cubic lattice of paramagnetic atoms. It is presumed, however, that in *isolated* hexaco-ordinated complexes each t_{2g}-electron contributes equally up to the configuration t_{2g}^3 and from the configuration t_{2g}^4 to t_{2g}^6. This would likewise make feasible singly occupied π-bonds of "back-co-ordination" type, for example, in $Cr(CN)_6^{3-}$, and would account for the thermodynamic stability of such compounds.

EXPERIMENTAL

Magnetic measurements were made using a balance of the Gouy type. The maximum field strength was 5320 oersteds. Temperatures were checked by means of a thermocouple. Corrections for the underlying diamagnetism were made by using an experimental value obtained from potassium chloroplatinate. This was prepared from the same stock

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

chemicals as were used in the preparation of the solid solutions. The possible error due to uncertainty in the diamagnetism of the sample having the lowest iridium concentration was estimated at ±4%. The amount of ferromagnetic impurities in the samples was found to be negligible.

Potassium Hexachloroiridate (IV)

Potassium hexachloroiridate (IV) was prepared from iridium sponge supplied by Johnson, Matthey and Mallory, Limited. The metal was heated in a stream of chlorine and the resulting trichloride was dissolved in dilute hydrochloric acid. The solution was saturated with chlorine, and excess saturated potassium chloride solution was added. Anal. Calc. for K_2IrCl_6: Ir, 39.77. Found: Ir, 39.51.

Solid Solutions of K_2IrCl_6 in K_2PtCl_6

Solid solutions of K_2IrCl_6 in K_2PtCl_6 were prepared in a manner similar to that used previously for the osmium and rhenium systems (3) except that the solution of chloroiridic acid was saturated with chlorine at the time of crystallization. Debye–Scherrer diffraction patterns failed to yield an indication of heterogeneity of the products.

The separation of iridium from platinum, and its determination, were carried out using Gilchrist's procedure (15). Platinum was determined by reduction with formic acid (16).

ACKNOWLEDGMENT

This work was made possible through the support of the National Research Council.

THE EFFECTS OF OPTICALLY INACTIVE IONS ON THE ROTATORY DISPERSION OF ASYMMETRIC COMPLEX IONS[1]

MARVIN J. ALBINAK,[2] DINESH C. BHATNAGAR, STANLEY KIRSCHNER, AND ANTHONY J. SONNESSA[3]

ABSTRACT

Considerable interest in the optical rotatory dispersion of asymmetric organic and inorganic compounds and its application to the elucidation of their structures has arisen in recent years. In order to study the effects of optically inactive ions on the rotatory dispersion of asymmetric complex ions, a series of salts was prepared of two active cations: levo *cis*-oxalato-bis(ethylenediamine)cobalt(III) and levo tris(ethylenediamine)chromium(III). Salts prepared included the fluoride, chloride, bromide, iodide, tetrafluoroborate, perchlorate, sulphate, and phosphate. In order to study this effect on an optically active anion, the lithium, sodium, potassium, rubidium, cesium, magnesium, calcium, and barium salts of dextro and levo tris(oxalato)-rhodate(III) were also prepared. Rotatory dispersion curves and absorption spectra were obtained for all salts in water solution. A comparison of the curves within a series showed definite trends in changes of wavelength and intensity of maxima of rotation and absorption with changes in both the ionic charge/size ratio (ionic potential) and polarizability of the optically inactive ions.

INTRODUCTION

It has been known since the time of Biot (1) that the rotation of the plane of polarized light by an optically active compound is a function of the wavelength of the incident light. This relationship between optical rotation and wavelength is known as rotatory dispersion and has been studied by several workers. Drude (2) has given an empirical equation which is sometimes useful in describing the optical rotatory dispersion of substances in wavelength regions outside the vicinity of optically active absorption bands. Reviews of optical rotatory dispersion have been published by Levene and Rothen (3), Lowry (4), Heller (5), Klyne and Parker (6), Moscowitz (7), and others (8). Cotton (9) has described the so-called "anomalous rotatory dispersion" of asymmetric compounds in the vicinity of their optically active absorption bands, and several workers (10, 5, 6, 7, 8, 11) have studied this effect in an effort to correlate it with various structural aspects of the compounds studied.

The rotatory dispersion of asymmetric complex inorganic compounds has been studied by several investigators, including Shimura (12), Izumiya (13), Jaeger (11), O'Brien and co-workers (14), Jonassen and Bailar (15), Martinette and Bailar (16), Pfeiffer (17), Mellor (18), and others.

Kirschner and co-workers (19, 20), Albinak (21), and Sonnessa (22) have noticed that the optical rotation and rotatory dispersion of an asymmetric complex ion change when the optically inactive ion associated with it is changed. A further study of this effect resulted in the initiation of an investigation to determine the effects of optically inactive ions on the rotatory dispersion of asymmetric complex ions. In order to facilitate the study of rotatory dispersion of complexes, a special spectrophotometric photoelectric polarimeter was constructed (19).

In this investigation, it was decided first to prepare and resolve several asymmetric complex cations, each with various optically inactive anions, and then to do the same

for several asymmetric complex anions, each with various optically inactive cations. The rotatory dispersions of all these series of complexes were measured, and they were studied with a view toward determining which characteristics of the optically inactive ions contributed most to the rotatory dispersion changes and which were less important. The first series of asymmetric ions studied contained no asymmetric ligands and their asymmetry was due solely to the configuration of the optically inactive ligands about the central metal ion. Subsequent series of complexes contained asymmetric ligands, e.g., $[Co(NH_3)_4(d\text{-tart})]^+$, but these ions did not have the asymmetric configuration about the metal ion which is found in ions such as tris(ethylenediamine)cobalt(III), $[Co(en)_3]^{+3}$. Additional studies are underway to determine the effects of solvent polarity on rotatory dispersion changes as well as the effects of "loading" a solution containing an asymmetric complex ion with an optically inactive ion of opposite charge on the rotatory dispersion. Further studies are also underway to examine the effects of optically inactive ions on the rotatory dispersion of asymmetric inner complexes and the effects of absolute configuration changes on rotatory dispersion.

EXPERIMENTAL

A High Precision Spectrophotometric Photoelectric Polarimeter for the Determination of Optical Rotation and Optical Rotatory Dispersion

Although photographic spectropolarimetry has certain unique advantages (5) with respect to long exposure possibilities in cases of low intensity, relatively wide spectral range, high sensitivity, and relative ease of measuring extremely large rotations (e.g., 360°) the procedures involved are usually quite inconvenient and time consuming. Consequently, most of the commercially available spectropolarimeters, as well as those constructed by individual research investigators, utilize photoelectric cells as light receptors. Some of the commercially available instruments include those manufactured by the Photovolt Corporation (95 Madison Ave., New York 16, N.Y.) based on an instrument described by Crumpler, Dyre, and Spell (23); Carl Zeiss, Inc. (485 Fifth Ave., New York 17, N.Y.) (24); Bellingham and Stanley (71, Hornsey Rise, London N. 19, England; Epic Inc., 154 Nassau St., New York 38, N.Y.); O. C. Rudolph and Sons, Inc. (P.O. Box 446, Caldwell, N.J., and Little Falls, N.J.) (25, 26); Perkin–Elmer Corp. (Norwalk, Conn.) (27); and others. Several interesting and unique photoelectric polarimeters, spectrophotometric polarimeters, and recording spectropolarimeters have been constructed in research laboratories throughout the world. Among these are those of Gillham (28), Malcolm and Elliott (29), Burer, Kohler, and Gunthard (30), Gates (31), Bruhat and co-workers (32), von Halban (33), Landt and Hirschmuller (34), Levy (35), Brode (36), Gutowski (37), Woldbye (38), and others (39). The foregoing instruments, however, may have, for many scientists engaged in research in optical rotatory dispersion today, one or more of the following shortcomings: (*a*) a limited wavelength range not extending into the ultraviolet region; (*b*) a precision no better than 0.01°; (*c*) a high degree of elaborateness and complexity, often making it impractical for many investigators to reconstruct such an instrument without the aid of professional technicians; (*d*) the need for time-consuming manipulations to operate the instrument; and (*e*) relatively high cost.

An interesting, commercially available attachment for the Beckman DU spectrophotometer has been developed by the Standard Polarimeter Company (6 Banta Place, Hackensack, N.J.), according to a design by Keston (40). This unit has been evaluated by Poulsen (41, 42). It utilizes light sources which are normally associated with the

Beckman spectrophotometer, and Polaroid plates (rather than polarizing prisms) which severely restrict the use of the instrument to solutions of relatively low optical density, to a limited range of wavelengths in the visible region, and sometimes to low precision.

The authors have described the construction and operation of a spectrophotometric polarimeter of high precision which can be assembled in most laboratories at relatively low cost (19, 43). It has a wavelength region of 2,600 Å to 10,000 Å; a precision of 0.002° when measuring small observed angles of rotation ($< 1°$); completely variable angles between transmission planes of polarizer and analyzer prisms, allowing for the measurement of observed angles of rotation greater than 1°; and it requires only about 30 minutes to determine an "average" rotatory dispersion curve from 2,600 Å to 7,000 Å. The mathematical principles of operation governing this type of instrument are in the literature (5, 41, 42, 44).

INSTRUMENTAL RESULTS

Table I shows a comparison between the optical rotations of various solutions determined with a high-precision visual polarimeter equipped with a sodium lamp and filter

TABLE I

Comparison of optical rotations of sugar solutions

Sample number	Observed rotation,* deg (visual polarimeter)	Observed rotation,† deg (spectrophotometric polarimeter)
1	0.053±0.003	0.050±0.002
2	0.102±0.003	0.100±0.002
3	0.184±0.003	0.180±0.002
4	0.213±0.003	0.213±0.002
5	0.368±0.003	0.369±0.002

†Na_D line.

for the D line, and those determined with the instrument constructed by the authors at the same wavelength.

The average deviation of individual determinations of angles less than 1° is 0.002° with this instrument. Although, theoretically, a high degree of elliptical polarization in the region of a strong Cotton effect (9) would produce a shift in the rotatory dispersion (5), the small angles of rotation measured and the small angle used for the sweep of the analyzer prism of this instrument minimize this effect. Actually, this effect was not observed in the optically active absorption band of potassium chromium tartrate, the very compound studied by Cotton (9) in his work on anomalous rotatory dispersion (Fig. 1).

Compounds Studied

A list of the optically active complex ions studied, along with the optically inactive ions associated with them, is given in Table II.

Preparations

1. *L-cis*-$[Co(en)_2(NO_2)_2]Br$ was prepared and resolved according to the method of Dwyer, Gyarfas, and Mellor (45).

2. *L*-$[Co(en)_3]Cl_3$ was prepared and resolved according to the method of Werner (46).

TABLE II

Optically active complex ions studied and their associated optically inactive ions

Optically active complex ion*	Associated optically inactive ions
L-*cis*-$[Co(en)_2(NO_2)_2]^+$	F^-, Cl^-, Br^-, I^-, $SO_4^=$, PO_4^{-3}, ClO_4^-, ClO_3^-, NO_3^-, $(C_6H_5)_4B^-$
L-$[Co(en)_3]^{+3}$	F^-, Cl^-, Br^-, I^-, $SO_4^=$, ClO_4^-, ClO_3^-, NO_3^-, PO_4^{-3}
L-$[Co(edta)]^-$	Li^+, Na^+, K^+, Rb^+, Cs^+, Mg^{++}, Ba^{++}, Al^{+3}
L-$[Cr(en)_3]^{+3}$	F^-, Cl^-, Br^-, I^-, BF_4^-, ClO_4^-, $SO_4^=$, PO_4^{-3}
D-$[Rh(ox)_3]^{-3}$	Li^+, Na^+, K^+, Rb^+, Cs^+, Mg^{++}, Ca^{++}, Ba^{++}
$[Co(NH_3)_4$(*d*-tart)$]^+$	F^-, Cl^-, Br^-, I^-, BF_4^-, NO_3^-, ClO_4^-, $SO_4^=$, PO_4^{-3}
$[Pt$(*l*-alan)$Cl_2]^-$	Li^+, Na^+, K^+, Rb^+, Cs^+, Mg^{++}, Ca^{++}, Ba^{++}, Al^{+3}
$[Pt$(*d*-glut)$_2]^=$	Li^+, Na^+, K^+, Rb^+, Cs^+, Mg^{++}, Ca^{++}, Ba^{++}, Al^{+3}
$[Co(NH_3)_5$(*d*-tart)$]^+$	F^-, Cl^-, Br^-, I^-, BF_4^-, NO_3^-, ClO_4^-, $SO_4^=$, PO_4^{-3}

*Abbreviations used: en = ethylenediamine; edta = ethylenediaminetetraacetate anion; ox = oxalate anion; *d*-tart = dextro tartrate anion; *l*-alan = levo alaninate anion; *d*-glut = dextro glutamate anion.

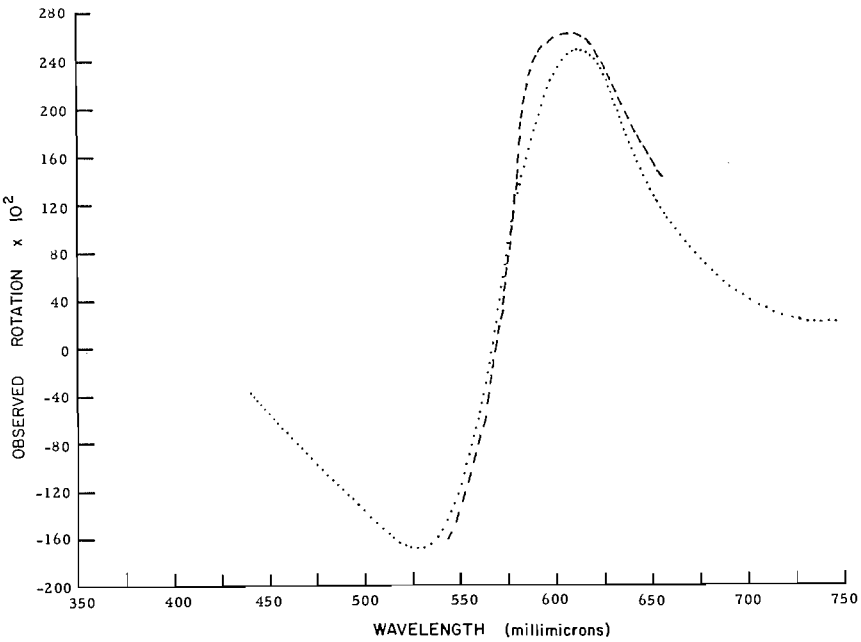

FIG. 1. Elliptical polarization and the Cotton effect. The rotatory dispersion of potassium chromium tartrate: ... curve from spectropolarimeter; – – – curve by Cotton.

3. *L*-K[Co(edta)] was prepared and resolved according to the method of Dwyer and Garvan (47).

4. *L*-$[Co(en)_2Cl_2]Cl$ was prepared and resolved according to the method of Bailar (48). It was converted to *L*-$[Co(en)_2(ox)]Cl$ according to the method of Werner (49).

5. *L*-$[Cr(en)_3]I_3$ was prepared and resolved by Albinak and co-workers of the University of Detroit and presented as a gift to this research group.

6. *D*-$K_3[Rh(ox)_3]$ was prepared and resolved by Dwyer (50).

7. K[Pt(*l*-alan)Cl_2] was prepared according to the method of Ley and Ficken (51).

8. $H_2[Pt($*d*-glut$)_2]$ was prepared according to the method of Grinberg (52).

9. $[Co(NH_3)_5$(*d*-tart)$]Cl$ was prepared according to the method of Duff (53).

10. $[Co(NH_3)_4CO_3]Cl$ was prepared according to the method of Lamb (54). It was converted to $[Co(NH_3)_4$(*d*-tart)$]Cl$ by treating 6.0 g of the carbonato complex in 100 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of water with 100 ml of an aqueous solution containing 4.1 g of dextro tartaric acid. This solution was added dropwise with continuous stirring. After the bubbles of carbon dioxide had ceased to be evolved, the solution was evaporated almost to dryness by passage of a stream of dry air over it. The resulting dark red, viscous semisolid substance was washed with 100 ml of ethanol and then ground in a mortar under absolute ethanol (the compound is hygroscopic). It was then filtered, washed with ether, and dried under vacuum. The yield of the dark red powder was 5.7 g (62%). Analysis: Calc. for $[Co(NH_3)_4(d\text{-tart})]Cl \cdot H_2O$: C, 14.60; H, 5.48; N, 17.02; Cl, 10.80. Found: C, 15.22; H, 5.71; N, 16.82; Cl, 11.33.

Rotatory Dispersion Curves

These were determined either on the instrument constructed by the authors or on a manual Rudolph High Precision Photoelectric Spectropolarimeter (26). The curves show wavelength vs. "equivalent molecular rotation", $[\alpha]_E$, which is used to eliminate nonreal differences in ion effects which may appear when molecular rotations are used for compounds where the cation:anion ratio is other than 1:1, e.g., $[Co(en)_2(NO_2)_2]Cl$ vs. $[Co(en)_2(NO_2)_2]_2SO_4$. Equivalent molecular rotation is defined as

$$[\alpha]_E = [\alpha]M/n,$$

where M = molecular weight, n = number of optically active complex ions per molecule, and $[\alpha]$ = specific rotation.

RESULTS AND DISCUSSION

A typical series of rotatory dispersion curves is shown in Fig. 2. In general, the wavelengths of the peaks, troughs, and crossover points (positive to negative crossover in

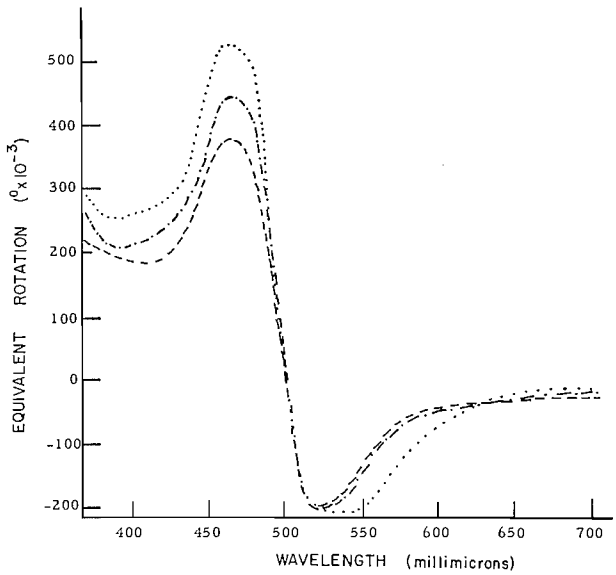

FIG. 2. Optical rotatory dispersion of L-$[Co(en)_3]^{+3}$ salts: – – – chloride; –·– bromide; . . . iodide.

sign of rotation, or vice versa) are fairly constant with change of optically inactive ion, but the magnitudes of rotation at these locations often vary considerably. Data on these magnitudes are given in Tables III–VIII along with the optical absorption maxima.

$SO_4^=$	540	+245	494	480	− 80	450	520
$PO_4^{\equiv}$	540	+495	502	480	− 65	460	520
NO_3^-	540	+305	460	480	0	470	0

NOTE: all wavelengths are in millimicrons.

It appears that the changes in the magnitudes of optical rotation are related to the degree of ion pairing between the optically active and optically inactive ions. Illustrative of this are the plots of equivalent molecular rotation vs. "ionic potential" (ionic charge/ionic radius) (55), an example of which is given in Fig. 3. This effect is observed whether

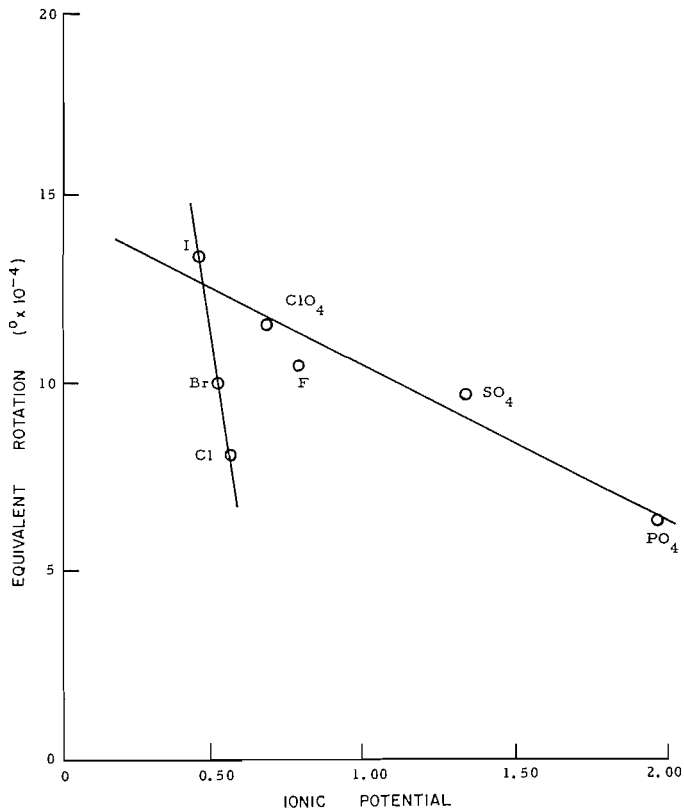

FIG. 3. Equivalent rotation vs. ionic potential for L-$[Cr(en)_3]^{+3}$ cation series.

the optically active complex ions are asymmetric solely because of the configuration of optically inactive ligands about a metal ion or because of the presence of optically active ligands without this type of configuration, e.g., $[Co(NH_3)_4(d\text{-tart})]^+$.

ACKNOWLEDGMENTS

The authors wish to express their sincere appreciation to the National Science Foundation for a grant without which this work could not have been carried out, to the American Cancer Society for an emergency grant which permitted the purchase of an important part of the instrument for which funds were unavailable, to Professor Wilfried Heller of Wayne State University for his helpful suggestions and comments on theory and design, and to Mr. Lee Peterson of Wayne State University for his help in the design and construction of the prism brackets and other metal parts.

SUBSTITUTION AT OCTAHEDRAL CENTERS

II. EFFECT OF SALTS UPON THE RATE OF HYDROLYSIS OF THE HALOPENTAMMINECHROMIUM(III) IONS[1,2]

T. P. JONES,[3] W. E. HARRIS, AND W. J. WALLACE

ABSTRACT

A study of the hydrolysis of the halopentamminechromium(III) ions in the presence of the sodium salts of weak acids reveals a rate acceleration due to specific ion-pair formation. The acceleration is due partly to a charge-transfer effect and partly to the fact that the ion helps to maintain the octahedral configuration of the complex in the transition state. It is concluded that the reaction occurs by dissociation, but without collapse of the structure to a five-co-ordinated intermediate.

INTRODUCTION

In many of the studies of reactions in inorganic systems which have appeared in recent years, the problem of incidental electrolyte has been taken into account by means of a constant "swamping" concentration of some "inert" electrolyte (1). Frequently, but not universally, sodium perchlorate has been used for this purpose. As a result, the literature shows data obtained under circumstances in which both the nature and concentration of the added salts differ markedly. Any attempt to intercompare such data is necessarily attended by assumptions about the effect of the electrolyte upon the reaction. In recent years a number of investigations have indicated a specificity in the influence of electrolytes upon the kinetics of both ionic and non-ionic reactions. Olson and Simonson (2) have shown that such effects are related to the ion which is opposite in charge to the one which is undergoing reaction. The influence of nitrate and sulphate upon the rate of hydrolysis of chloropentamminecobalt(III) had been observed earlier by Garrick (3). Sulphate was observed to have a marked accelerating effect upon the reaction, while nitrate at equivalent concentration exerted only a minor catalytic effect.

Recently, Taube and Posey (4) showed that reaction I, which proceeds predominantly through the ion pair (B), is sensitive to the presence of excess electrolyte. Thus, the rate of formation of the sulphato complex (A) is markedly decreased by the addition of sodium perchlorate. This is not surprising for a reaction which proceeds through the ion-pair intermediate (B). The addition of electrolyte reduces the activity coefficient of the ions in (C) so that the concentration of the ion-pair intermediate is decreased. It is perhaps

$$\underset{(A)}{Co(NH_3)_5SO_4^+} + H_2O \leftrightarrows \underset{(B)}{(Co(NH_3)_5H_2O^{+++}SO_4^{=})} \leftrightarrows \underset{(C)}{Co(NH_3)_5H_2O^{+++}} + SO_4^{=} \qquad [I]$$

surprising, however, that the rate of the hydrolysis was also decreased. There is no theoretical precedent for this. In these circumstances it is tempting to attribute this change in rate to a decrease in the concentration of ion pairs formed by the sulphato complex (A). The force of this interpretation is increased by the observation that both the sulphation and hydrolysis reactions are faster in the presence of increasing concentrations of sulphate. Although such observations as these do not demonstrate conclusively

that specific interaction complexes described as outer sphere ion pairs (4) participate in the rate-determining step of ionic reactions in solution they certainly do not argue against it. The specificity of the electrolyte effect is further borne out by the observations of other workers (5, 6).

The work reported in this paper is an outgrowth of that reported earlier (7) on the pH-independent hydrolysis of the halopentamminechromium(III) ions. It was found that the pH-independent hydrolysis reaction extended far up into the high pH region. Consequently the system proved convenient for the study of the effect of anions of a number of weak acids upon the rate of an uncomplicated hydrolysis reaction. In this way it has been possible to study the specificity of electrolyte effect in hydrolysis reactions on the basis of the base strength of the anion which was involved.

EXPERIMENTAL

Preparation of Materials

The chloro-, bromo-, and iodo-pentamminechromium(III) halides and perchlorates were prepared as described previously (7). Other materials were reagent grade and were used without further purification.

Kinetic Measurements

Solutions were prepared by mixing, in a volumetric flask, the calculated volume of stock solution of the sodium salt of the anion under investigation and enough halopentamminechromium(III) salt to make the final solution 10^{-3} M in chromium, agitating the mixture to dissolve the chromium salt, and diluting it to volume. The solution was placed in a water bath and allowed to come to temperature (10–20 minutes) before measurements were initiated by withdrawing a sample. In those solutions in which the anion concentration was below 0.005 M it was found desirable to increase the buffer capacity of the solution by the addition of an ammonia – ammonium perchlorate buffer. In these cases a pH of 8 was maintained by a buffer mixture whose ammonium perchlorate concentration was 0.01 M.

Samples withdrawn for analysis were run into a polarographic cell maintained at 0° C in a Dewar. The polarographic cell contained sufficient sulphuric or perchloric acid to convert all of the anion to the acid form and leave the final solution 0.1 M in hydrogen ion. The amount of acid required depended upon the nature and concentration of the anion in the reactive solution, but was never great enough to cause significant dilution. The concentrations of chromium species remaining in the solution were then determined polarographically as described previously (7). The initial polarographic measurements were made in the presence of perchloric acid and the later measurements with sulphuric acid. The change from perchloric to sulphuric acid was made when it was found that a better separation between the halo- and aquo-pentamminechromium(III) reduction waves was obtained in a sulphate-containing medium. Presumably this is related to the fact that the aquo complex would be expected to form a stronger ion pair than the chloro complex with sulphate. The anion present during the polarographic measurements did not influence the results in any way other than to increase the ease of interpretation of the polarograms.

The only anions which were polarographically reducible in the potential range of the chromium complexes under the conditions of low pH described above were fumarate and maleate. Fortunately the reduction potential for these anions was pH dependent, and by variation of the acidity of the solution it was possible to change the potential at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

which reduction of these anions occurred to a value where they did not interfere with the determination of the concentration of the chromium species in the solution. The most convenient pH for the polarographic analysis of the fumarate solution was 6 and for the maleate was 8. In the analysis of these solutions the procedure involved quenching the reaction with ice-cold concentrated buffer of the appropriate pH instead of concentrated acid.

EXPERIMENTAL RESULTS

The effect exerted by a number of monovalent anions upon the rate of the reaction represented by equation [II], where X is Cl, Br, or I is shown in Fig. 1.

$$Cr(NH_3)_5X^{++} + H_2O \xrightarrow[\text{base}]{\text{anion}} Cr(NH_3)_5OH^{++} + X^- + \text{base } H^+ \qquad [II]$$

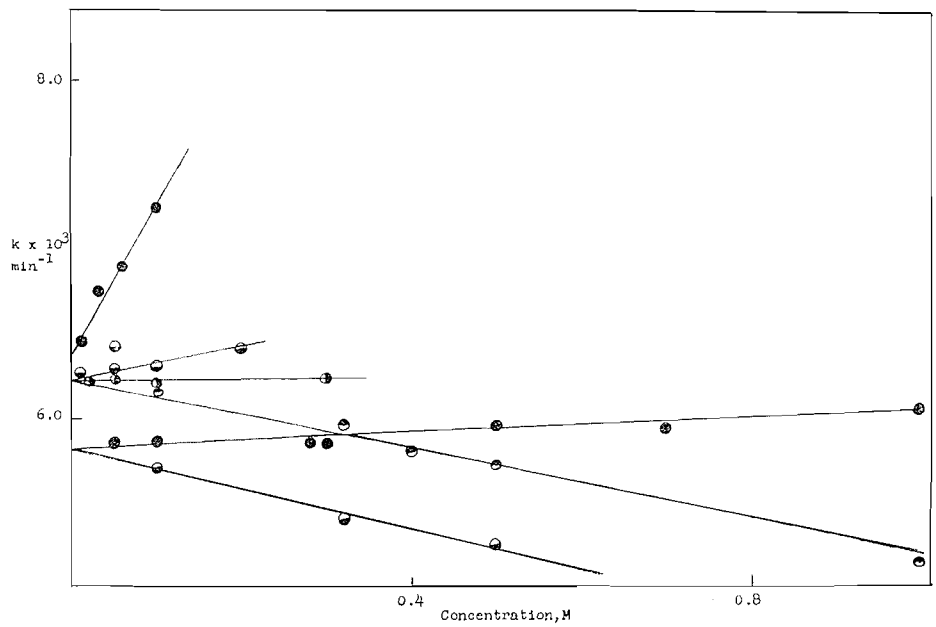

FIG. 1. The effect of monovalent anions upon the rate of hydrolysis of $Cr(NH_3)_5Br^{++}$ (upper set of curves) at 25° and $Cr(NH_3)_5Cl^{++}$ (lower set of curves) at 45°.
Upper curves: ● benzoate, ◒ acetate, ◑ bromide, ◓ perchlorate.
Lower curves: ● chloride, ◒ perchlorate.

The linear dependence of rate upon concentration of salt is evident from the data. Perhaps more surprising than the linearity of the salt effect is the marked variation of the influence of different salts upon the reaction rate. This variation is conveniently reported in terms of the slopes of the curves. The slopes calculated on the basis of a least-squares treatment of the data shown in Fig. 1 are reported in Table I. The specificity of the catalytic effect has been shown to be associated with the anion part of the salt (7).

The data for the monovalent anions are in sharp contrast with those obtained for polyvalent anions. The curves obtained by plotting rate of reaction [II] against concentration do not extrapolate back to a common k_0 at zero concentration of polyvalent anion. Instead the extrapolated value of the rate constant, which will be called $k_{0\ \text{extrap}}$,

is a characteristic property of the catalyzing salt. When the behavior was examined at low salt concentrations it was found that the addition of small amounts of salt produced a very marked acceleration of the reaction. This acceleration was roughly linear in polyvalent anion concentration until the salt was present in the solution at roughly molar equivalence with the chromium salt (about 10^{-3} M). Further addition of the salt caused further increase in the rate of reaction, but the curve was characterized by a markedly smaller slope. Some typical experimental results are plotted in Fig. 2. It has been found

0.004	0.1	6.65
0.0	0.1	5.70
0.004	1.0	4.54
0.0	1.0	4.30

DISCUSSION

The rate of reaction [II] has been shown to respond to the addition of salts in a manner which is not explicable in terms of the simple Debye–Huckel theory. There is, however, some indication that the extended form, involving a term linear in electrolyte concentration, could be applied to the results obtained over the range 0.01 to 0.5 *M*. Alternatively and perhaps somewhat more conveniently, the ideas suggested by Ingold (8) to cover salt effects in the solvolysis of alkyl halides might be applied. Both of these suggestions suffer from the disadvantage, in the present application, of not allowing for specificity of the salt effect. Nevertheless, there is probably sufficient indication that the effect observed is due to the reacting species developing an ion atmosphere. This ion atmosphere promotes the stability of the transition state and suggests charge separation in the reaction intermediate. Such an observation is not surprising for a reaction which results in a net increase in the total number of ions in the solution regardless of the intimate mechanism of the reaction. Such charge separation is expected to be more important in a reaction which occurs by dissociation than in one which occurs by displacement. It is suggested, then, that the catalysis of reaction [II], produced by various salts at high concentration, is an indication of a dissociation mechanism.

More surprising and perhaps more useful in a diagnostic way was the observation of the rapid rise in rate produced by polyvalent anions in a concentration range which was comparable to that of the reacting species. Although this general kind of observation has been made by a number of other workers (3, 6, 9, 10), it has been investigated in somewhat more detail in the present work than previously. These salt effects have been attributed to specific ion-pair formation. It now appears necessary to divide salt effects into two categories. The first of these is the general ionic atmosphere effect discussed above. Ion-pair formation may play a role in this kind of salt effect since a dependence upon the nature of the anion involved was observed, but it does not seem to be the primary factor. The second category suggested involves the formation of specific ion pairs. In this case, it is assumed there are recognizable association units with integral numbers of ions to which ion pair formation constants could be applied. The simplest unit which could be considered in this way is one positive and one negative ion. Since this kind of unit is most easily visualized from a kinetic point of view it is proposed to treat our data on the basis of this model. The alternative of a bimolecular attack upon the halopentammine chromium(III) ion does not need to be seriously considered since the reaction is first order even in the presence of small concentrations of added salt. Furthermore the sole primary product of the reaction is observed to be the hydroxopentamminechromium(III) ion.

Reaction [II] follows the rate law [III], where k_1 is the rate constant for the uncatalyzed

$$\text{Rate} = \frac{(k_1+k_2K[\text{A}])}{1+K[\text{A}]}[\text{RX}] \qquad [\text{III}]$$

reaction, k_2 is the rate constant for the catalyzed reaction, K is the ion-pair association constant, [A] is the concentration of added anion, and [RX] is total concentration of halopentamminechromium(III) ion. Using relationship [III] it is possible to estimate a value for K. This has been done and when citrate is the catalyzing anion the association constant was calculated to be 233. This agrees very well with the value 248 determined experimentally (11). In Fig. 3 are plotted the experimentally observed values of $k_{0\ \text{extrap}}$ for reaction [II] against the constants for association of some of the ions used with the hexamminecobalt(III) ion (12). The order of the agreement is seen to be excellent.

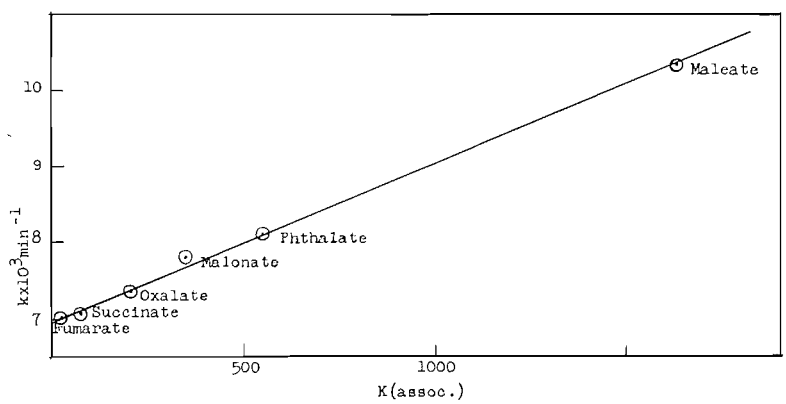

FIG. 3. Relation between the rate constant for the hydrolysis of $Cr(NH_3)_5Br^{++}$ at 25° and the magnitude of the ion-pair formation constant between anions and $Co(NH_3)_6^{+++}$. Data for the ion-pair formation constants are taken from reference 12.

Similar agreement has been obtained between the rate constants and ion-association constants (11) for the interaction between the chloropentamminechromium(III) ion and the polyvalent anions used in this study.

The sensitivity of the salt effect to the total ionic strength of the solution, shown in Table III, is a further indication of the rationality of the suggestion that ion pairs are involved. Unfortunately, the effect of sodium perchlorate upon the activity coefficient of the halopentamminechromium(III) ion is not known. However, the effect of sodium perchlorate upon the rate of the citrate-catalyzed reaction is in agreement with its effect upon the experimentally determined ion-pair formation constant (11).

If the ion pairs promote the hydrolysis reaction they must do so either through charge transfer or by stabilizing the transition state. Charge transfer might occur in a number of ways, but regardless of the mechanism, the result must be an increase in the electron density on the chromium. Such an increase in electron density would not be expected to promote attack upon the chromium by an electron-rich reagent such as water. Stabilization of the transition state might result because the associating anion tends to hold the complex ion in its normal octahedral configuration. This, of course, would tend to prevent the loss of ligand-field stabilization energy (13) which is attendant upon the distortion of the regular octahedron as the molecule proceeds through the transition state. Such stabilization is not compatible with the expansion of the co-ordination sphere which would be necessary to accommodate a displacement reaction. It seems, then, that the rate acceleration produced by ion-pair formation is incompatible with an S_N2 mechanism for reaction [II]. The explanation for the results must be sought in terms of a dissociation mechanism.

$$\begin{array}{ccccccc} & & \begin{array}{c}RH_2O^+ + X^- \\ H_2O \,\uparrow\downarrow \\ R^+X^- \\ A^- \,\uparrow\downarrow \\ RA + X^-\end{array} & & \begin{array}{c}RH_2O^+ + X^- \\ H_2O \,\uparrow\downarrow \\ R^+\ X^- \\ \uparrow\downarrow A \\ RA + X^-\end{array} & & \begin{array}{c}RH_2O^+ + X^- \\ H_2O \,\uparrow\downarrow \\ R^+ + X^- \\ A \,\uparrow\downarrow \\ RA + X^-\end{array} \\ RX & \rightleftarrows & & \rightleftarrows & & \rightleftarrows & \end{array} \qquad [IV]$$

Fainberg and Winstein (14) have shown that the steps indicated in reaction [IV] need to be considered in a reaction which proceeds by a dissociation mechanism. These steps are intended to represent the sequence of events in which the two ionic fragments of the reaction first become separate identities in intimate contact (internal ion pair (14)), then ions in contact but each ion with an independent solvation sheath, and finally separated and independent ions. The stereochemistry of each of these intermediates is shown in Fig. 4. In the initial stage of separation the ions have sufficient influence upon one another that the original stereochemistry is maintained in spite of the lengthening metal to halogen bond. In the other two stages of separation the original octahedron has collapsed to a five-co-ordinate structure which is considered to be the trigonal bipyramid.

Bateman, Hughes, and Ingold (15) have shown that if a reactive intermediate of low co-ordination number is sufficiently stable to have independent existence in solution it should be possible to detect the presence of such an intermediate by a mass law effect. That such an effect is absent in the present case is evident from the data for the effect of chloride, bromide, and iodide salts on the rate of hydrolysis of the chloro, bromo, and iodo complexes. Separated ions do not seem to be involved in the rate-determining step of reaction [II].

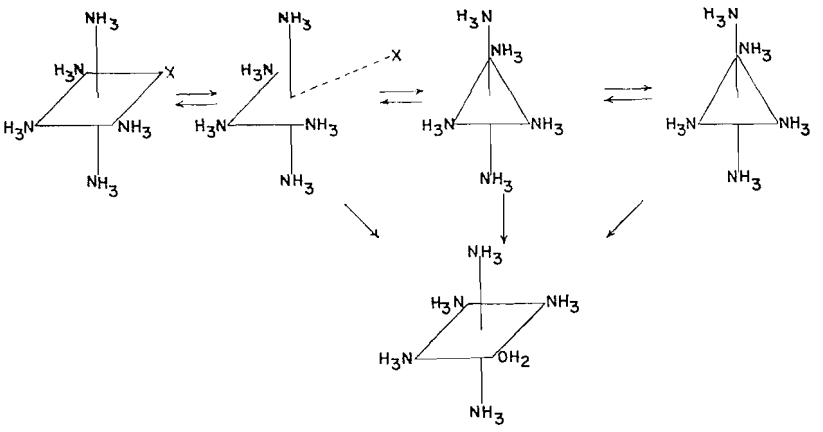

FIG. 4. Configuration relationships among the possible intermediates in the hydrolysis of $Cr(NH_3)_5X^{++}$.

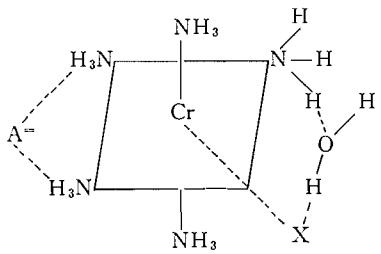

If the octahedral structure collapses to yield the solvent-separated ion pair there are three equivalent positions at which water is able to attack the intermediate to produce the aquo ion. In the case under consideration this intermediate of reduced co-ordination number forms an ion pair with the anion of the salt present. The structure of such an ion pair becomes important. It seems reasonable to place the anion on the side of the complex away from the halogen. This conclusion was reached on the basis that *trans*-dichlorobis(ethylenediamine)cobalt(III) solvolysis is not accelerated by basic anions, whereas that of the corresponding cis complex is accelerated. The cis complex has a permanent dipole, whereas the trans complex does not, and it seems that a permanent dipole is necessary in order to obtain rate acceleration from ion-pair formation. Coupled with this is the observation that maleate produces a much greater change in the reaction rate than fumarate and that *o*-phthalate produces a much greater change than *p*-phthalate. In each case it is the anion with π orbitals suitably situated for overlap with the t_{2g} orbitals of the chromium which has the greater influence upon the reaction rate. This suggests that, in these cases at least, π bonding to the chromium is important and as a consequence the anion must be stretched across the face of the original octahedron. On the basis of these considerations the ion-pairing anion is thought to be stretched across the back side of the chromium complex in such a way that a reactive end is adjacent to each of two of the reactive sites and the body of the anion shields the third such site. Under these circumstances it would be surprising indeed if the ion-paired anion was not able to compete with water for some of these reactive sites. Such competition ought to make its appearance in the form of the aniono complex as one of the primary products of the reaction. For example, the fact that citrato complexes do not appear as primary products in the presence of citrate anion argues against a five-co-ordinated structure having an important role in the transition state. It might conceivably be argued that the anion does enter the complex in the initial step but is quickly eliminated by a subsequent hydrolysis. This seems unlikely because it has been observed that each of the anions reacts slowly with the product hydroxo complex to produce an aniono complex which is not hydrolyzed under the conditions of the experiment (16).

Acceleration of the reaction due to charge transfer is compatible with a dissociation reaction and acceleration due to the anion helping to maintain the original octahedral

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

configuration is compatible with the internal ion-pair intermediate. The internal ion-pair intermediate (14) is also compatible with the observation that the accelerating anion does not appear in the original reaction product. In this intermediate not all potential positions of attack on the molecule are equivalent. The position being vacated by the leaving group, which is most remote from the anion, is most vulnerable to attack. As a consequence one would not expect the accelerating anion to appear in the original reaction product and this is compatible with the experimental observations.

It is suggested that the reaction occurs via a stretching of the chromium to halogen bond. If, when the bond reaches a critical distance, there is a properly oriented water molecule this molecule enters to replace the halide ion. If there is not a properly oriented water molecule the halogen returns to its original position and no reaction occurs. The reaction might be considered to proceed via the following model.

This model represents a reaction which is primarily S_N1 but one which requires the intervention of solvent for completion. The name solvent-assisted S_N1 is suggested.

RADIATION CHEMISTRY OF CYCLOHEXANE

IV. PRIMARY PRODUCT YIELDS IN THE IRRADIATION OF CYCLOHEXANE[1]

P. J. DYNE AND J. A. STONE

ABSTRACT

The radiolysis of cyclohexane has been studied at low total doses and initial G values have been determined. Ninety-nine per cent of the evolved hydrogen has been accounted for in hydrogen-deficient products. Cyclohexene, bicyclohexyl, and cyclohexyl-hexene-1 have been identified as primary reaction products. Cyclohexyl-cyclohexene has been identified as a secondary reaction product. The use of high irradiation doses has been shown to lead to decreases in the initial G values of all primary products.

INTRODUCTION

A common feature of the reported product yields in the radiolysis of cyclohexane is the discrepancy between the hydrogen yield and the sum of the yields of hydrogen-deficient products—principally bicyclohexyl and cyclohexene (1, 2, 3, 4). In all cases the total yield of hydrogen-deficient products is not great enough to account for the observed hydrogen yield. It is generally assumed that high molecular weight products are formed which have remained undetected. There are also disagreements on the identity and yield of some of the minor products.

Cyclohexene, a major product, reduces $G(H_2)$ and is itself destroyed in the radiolysis (5, 6). It follows that accurate initial G values for any product can only be obtained by working at low conversions and by extrapolations to zero dose, thus avoiding the complications of secondary reactions.

This paper describes analytical techniques for the identification and analysis of products at conversion of less than 0.01%. At these low conversions the primary products appear to be cyclohexene, bicyclohexyl, and 6-cyclohexyl-hexene-1. A good hydrogen balance is obtained, all but 1% of the hydrogen being accounted for.

EXPERIMENTAL

Materials

Fisher Scientific Company Spectrograde cyclohexane was used as received. Gas–liquid chromatography showed three small impurity peaks before the main cyclohexane peak, but neither the sizes nor the shapes of these peaks were altered by γ-radiolysis. Cyclohexene (Eastman) was used as a solute.

Preparation of Samples

The 20-ml samples were contained in Pyrex tubes, 2.5 cm in diameter and 25 cm long, each equipped with a break-tip seal and a constricted side arm. The samples were pipetted

[1]*Manuscript received July 14, 1961.*
Contribution from Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 1356.

into the tubes and were then degassed by the freeze–thaw technique. When the residual pressure was less than 5×10^{-6} mm, the sample tubes were sealed off at the constriction. The samples containing solute were made up in bulk and pipetted out as required.

Irradiation of Samples

The samples were irradiated at 22° C by Co-60 γ-rays. Dose rates were determined with the Fricke dosimeter, taking $G(Fe^{+++}) = 15.5$. Two irradiation facilities were used with dose rates of 4.8×10^{20} ev/liter minute, and 2.6×10^{19} ev/liter minute for cyclohexane at 22° C.

Product Analysis

The irradiated sample tubes were attached to a vacuum line and their contents frozen with liquid nitrogen. The gaseous products volatile at −196° C were then taken off with a Toepler pump and their volume measured with a McLeod gauge, the samples being thawed and refrozen to make sure that all the gas had been collected. Hydrogen was diffused through a heated palladium thimble, and the volume of the residual gas measured. In all cases it was found that this residue amounted to less than 1% of the initial volume. This was confirmed by mass spectral analysis of the collected gas.

The liquid products were analyzed by gas–liquid chromatography. Cyclohexene was determined using a 4-meter column of 3-mm internal diameter, containing firebrick on which was deposited 30% by weight of a silver nitrate/$\beta\beta'$ oxydipropionitrile mixture as the stationary phase. The column was at room temperature, the sample injection end being at a slightly higher temperature. The results were checked quantitatively by infrared analysis, using the 717-cm^{-1} cyclohexene band. Products of higher molecular weight than cyclohexane were separated on a 2.5 meter long, 2.5-mm internal diameter column containing 0.1% by weight of Apiezon-L grease on 200-micron diameter glass beads. This column, with a very low concentration of L-grease, gave better separations than a conventional column containing more grease. The more heavily loaded column must be used at a higher temperature to obtain the same separations in a comparable time. With the minimum amount of L-grease, the tailing of cyclohexane was greatly reduced, the less volatile components being eluted at lower temperatures with improved resolution. This column was at a fixed temperature for quantitative work but was temperature programmed for qualitative work.

A simple hydrogen flame detector (7) was used, together with a split-stream device after the column. The output from the detector was fed through the 10^9-ohm input resistor of an electrometer. Ten-λ samples of the irradiated material, without previous concentration, were injected directly onto the columns, the whole sample being passed through the detector. A new calibration curve was used for each series of analyses, standards and unknowns being run alternately. No standards were available for products other than cyclohexene and bicyclohexyl so their concentrations were obtained from measured peak areas, the peak area being assumed to be proportional to molar concentration.

A Consolidated 21-130 Mass Spectrometer was connected to the outlet of the chromatographic column by means of a heated, stainless steel capillary tube. Approximately 90% of the eluted sample passed through the detector, whilst the remaining 10% flowed through the capillary past a gold leak in the spectrometer sample introduction system. The capillary introduced a delay of the order of 5 seconds between the appearance of a chromatographic peak and the initial appearance of the mass spectrum due to the same component. The spectra were recorded on a recording oscillograph, the time taken to scan from mass

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

26 to mass 200 being of the order of 1 minute. Interpretable spectra were obtained when the desired component was present in the chromatographic eluent at a concentration of about 100 p.p.m. To obtain this concentration for the components which were present in very small amounts in irradiated samples, the following procedure was employed. A large sample (~0.5 ml) of irradiated material was injected, 20 λ at a time, onto the narrow L-grease column. Cyclohexane, which comprised 99.9% of the solution, was eluted rapidly at room temperature, leaving the higher-boiling components still at the column inlet. When sufficient material had been deposited on the column the temperature was raised gradually so that a good chromatographic separation was achieved and the mass spectra obtained. To ensure a rapid clearing of the spectrometer inlet system, and therefore no enhancement of the background spectrum, the temperature of the inlet system was maintained at 200° C and that of the spectrometer ion source at 250° C.

Samples from the chromatographic column were trapped out in micro infrared cells cooled in a solid CO_2/acetone mixture. The spectra of these samples were obtained on a Perkin–Elmer model 21 machine equipped with a beam condenser.

RESULTS

1. *Pure Cyclohexane*

The variation of $G(H_2)$ with dose, at a dose rate of 4.8×10^{20} ev/liter minute, is shown in Fig. 1. Each point on this curve represents the result of one measurement except for the initial G value, which was obtained from a series of measurements extrapolated to zero dose. At low doses a sharp decrease in $G(H_2)$ with increasing dose occurs, but at

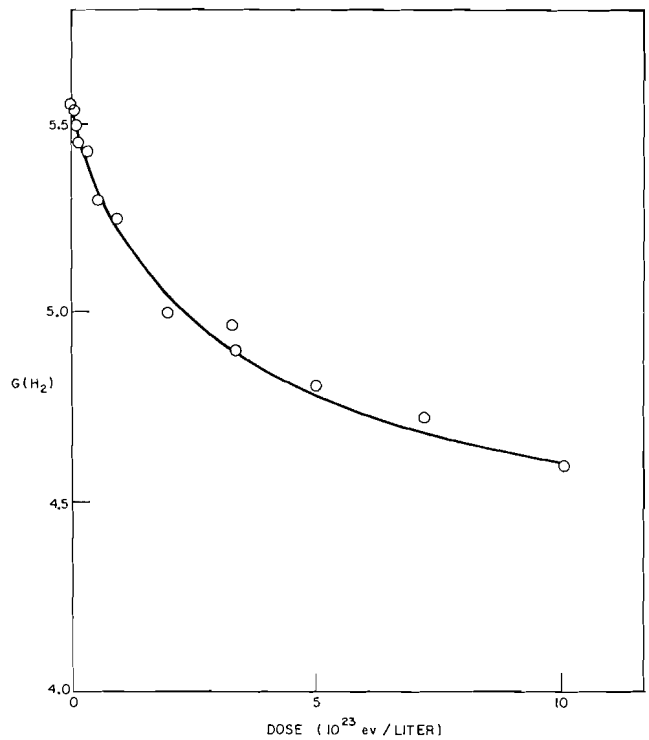

FIG. 1. The variation of $G(H_2)$ with total dose.

For personal use only.

higher doses the rate of decrease becomes smaller. The initial G value is 5.55. The decrease is clearly non-linear with dose. At the lower dose rate of 2.6×10^{19} ev/liter minute a similar decrease in $G(H_2)$ with dose was recorded. The initial G value was the same within experimental error, but at the lower dose rate the decrease was more rapid with increasing dose. Figure 1 represents a refinement on previously published data (3, 5).

The formation of cyclohexene as a function of dose is shown in Fig. 2. The initial G value is 3.27. At the higher doses shown in the figure the G value is beginning to decrease. A similar curve for bicyclohexyl is shown in Fig. 3. The initial G value is 1.95, and again at the higher doses this value decreases.

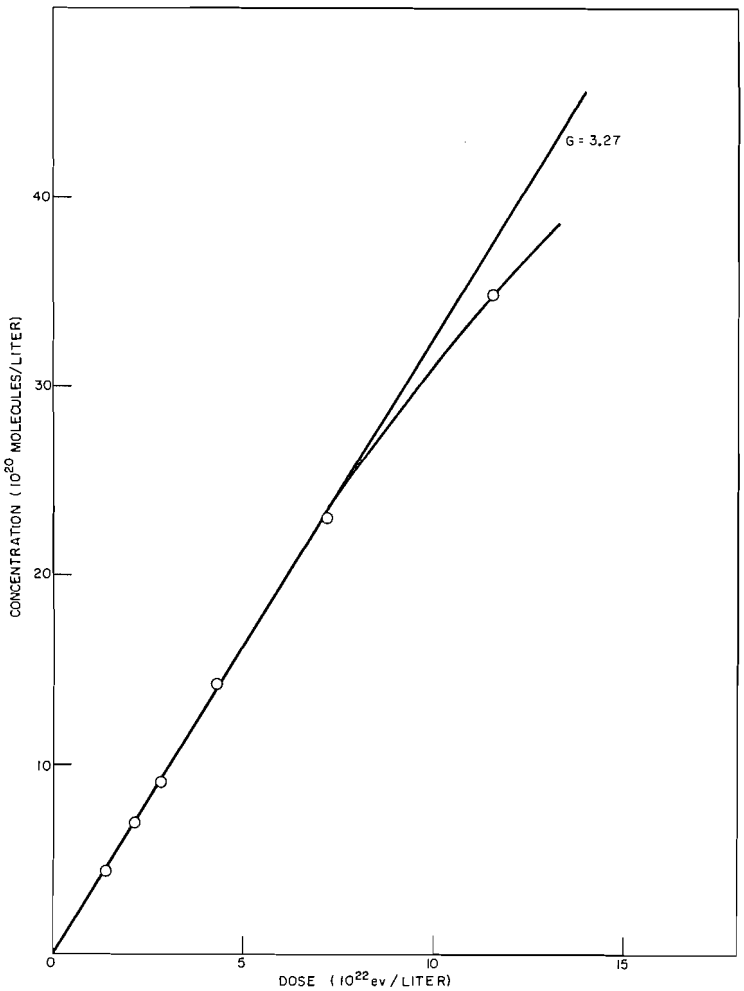

FIG. 2. The formation of cyclohexene.

Figure 4 shows the chromatograms obtained for all products of molecular weight higher than cyclohexane and cyclohexene. Figure 4(a) is from a sample of pure cyclohexane irradiated to the low dose of 2×10^{22} ev/liter; Fig. 4(b) is from pure cyclohexane irradiated to the much higher dose of 2×10^{24} ev/liter, and 4(c) is the chromatogram

obtained from a solution of $4.5\times10^{-2}M$ cyclohexene in cyclohexane irradiated to 10^{23} ev/liter. Only the peak heights and areas in one chromatogram should be compared, as different-sized samples were used in the runs *a*, *b*, and *c*. The column was temperature programmed to give the series of peaks shown. These peaks may be conveniently divided into three groups, (i) those having retention times lower than that of bicyclohexyl, (ii) those with almost the same retention time as bicyclohexyl, and (iii) those with greater retention times than bicyclohexyl. The peak areas in each chromatogram are given in Table I in terms of percentages of the total area.

Group i

For pure cyclohexane irradiated to a low total dose, Fig. 4(*a*), the estimated *G* value for all products in this group is 0.27.

An infrared spectrum of a trapped sample from group i showed an absorption band at 1634 cm^{-1} corresponding to the C=C stretching frequency of hexene-1. The mass spectrum

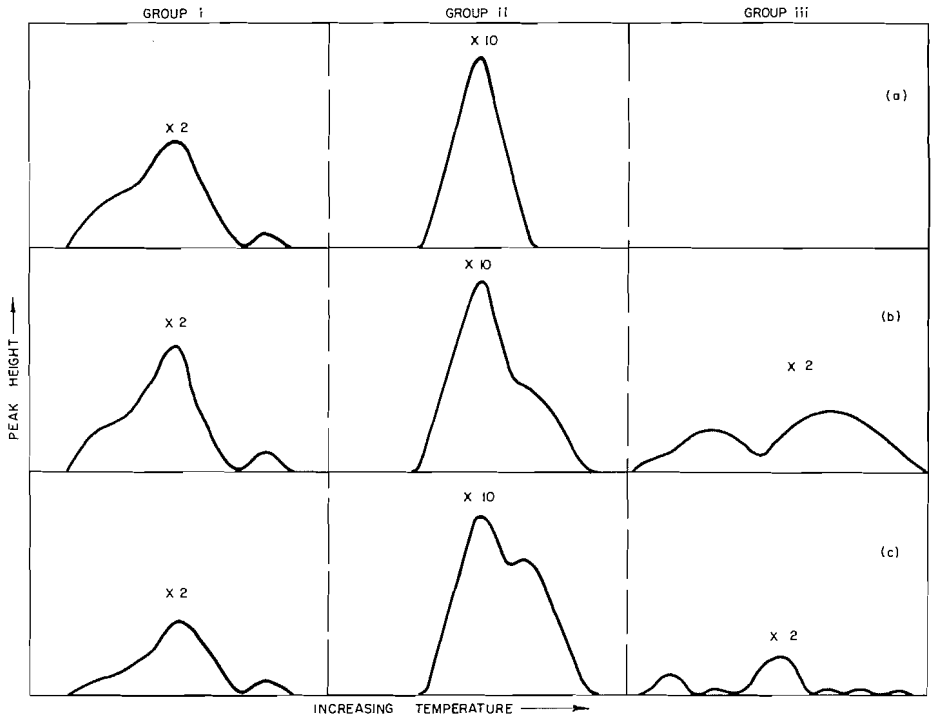

FIG. 4. Gas–liquid chromatograms: (*a*) cyclohexane at low dose; (*b*) cyclohexane at high dose; (*c*) cyclohexane–cyclohexene mixture at low dose. Group i, peaks appearing before the bicyclohexyl peak; group ii, the bicyclohexyl group of peaks; and group iii, the peaks appearing after bicyclohexyl.

TABLE I

Relative chromatographic peak areas from Fig. 4

Chromatogram No.	Relative chromatographic peak areas		
	4(*a*)	4(*b*)	4(*c*)
Group i	12	14	8.5
Group ii	88	70	82
Group iii	0	16	9.5

showed a parent peak at $m/e = 166$, together with fragment ions associated with both cyclohexyl and hexenyl groups. Unlike the spectrum of bicyclohexyl, the most intense peak of which is at $m/e = 82$, the peak at $m/e = 83$ was found to be the largest. This would suggest that a cyclohexane molecule substituted with a straight chain of mass 83 was present. Since the infrared spectrum showed that a cyclohexene group was not present the double bond must be in the side chain. The main chromatographic peak in group i is, therefore, most probably 6-cyclohexyl-hexene-1.

Group ii

Figure 4(*a*) shows that at very low doses a single peak is obtained. This peak is symmetrical with no sign of any other substance present. A symmetrical peak was obtained no matter how the column conditions were varied, showing that, in all probability, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

identification of this peak as due to a single component, bicyclohexyl, was justified (see below). At higher total doses, however, this was not the case, as Fig. 4(*b*) shows. A second peak now appears together with the main bicyclohexyl peak, demonstrating that at higher doses a secondary reaction product appears. This we have identified as cyclohexyl-cyclohexene.

For a $4.5\times10^{-2}M$ cyclohexene solution, Fig. 4(*c*), a double peak is observed. The first maximum has the same retention time as bicyclohexyl whilst the second corresponds in position to the shoulder observed in 4(*b*). At attempt was made to trap the compound associated with the main peak in Fig. 4(*a*). However, the concentration of this product was too low for this to be possible. An infrared spectrum of the compound associated with the first part of the main peak in 4(*b*) was found to be identical with that of bicyclohexyl. The spectrum of the sample trapped during the elution of the whole peak showed a new absorption band appearing at 1642 cm^{-1}, corresponding to the C=C stretching frequency in a cyclohexene ring. The spectrum of the sample trapped during the elution of the main double peak of 4(*c*) showed the same band but in greater strength. From the chromatographic retention time and the infrared results, it would appear that this product, which appears as the radiation dose is increased, is a substituted cyclohexene.

The mass spectrum confirmed the above conclusions. The product provisionally identified as bicyclohexyl had a spectral pattern identical with that of a pure sample. The cyclohexyl-cyclohexene, although not fully resolved from the bicyclohexyl, showed a parent peak at $m/e = 164$, together with fragment ions associated with cyclohexyl groups at $m/e = 83$ and 82. In addition a strong fragment ion peak at $m/e = 81$ was deduced to be the cyclohexenyl ion formed by the rupture of the two ring molecule at the central C—C bond.

Group iii

This group contains the peaks due to compounds of higher molecular weight than bicyclohexyl. No peaks are found at low doses, but some do appear at higher doses and in cyclohexane–cyclohexene mixtures. This group of peaks may therefore be associated with secondary reaction products in pure cyclohexane and with products involving the reaction of cyclohexene in cyclohexane–cyclohexene mixtures. No correlation was attempted between the products found in chromatograms 4(*b*) and 4(*c*).

Attempts were made to trap samples of products in this group but without success. Mass spectra showed that cyclohexyl groups were present but no parent peaks could be detected.

2. Cyclohexane–Cyclohexene Mixtures

Samples of a $4.5\times10^{-2}M$ cyclohexene solution were irradiated at the higher dose rate for varying doses up to 10^{23} ev/liter. The gaseous product volatile at $-196°$ C was more than 99% hydrogen. The initial $G(H_2)$ was 4.76. This value was constant over the dose range studied.

The determination of a G value for the production of cyclohexene was difficult. A value of 0.6 ± 0.3 was obtained. The large error was due to the fact that at the doses used only a small change in cyclohexene concentration occurred.

G(bicyclohexyl) could not be determined since complete resolution from the peak assigned to cyclohexyl-cyclohexene could not be obtained. Both peak areas were measured together and the total area was calibrated against that for pure bicyclohexyl. A total G value of 1.3 was found. The sensitivity of the chromatographic detector for bicyclohexyl only was determined, and so the error involved in using this calibration was not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

known. With the type of detector used the error is, however, probably small. By visual inspection of the peak shape (Fig. 4(*a*) group ii), it is seen that bicyclohexyl constitutes roughly 55% of the total area, which would correspond to a G value of 0.72.

The analyses for products in groups i and iii were less accurate. The G values obtained were 0.13 and 0.15 respectively.

DISCUSSION

The results obtained for the product yields in the radiolysis of pure cyclohexane by Co-60 γ-rays are summarized in Table II.

TABLE II

Initial G values for products in the irradiation of pure cyclohexane

Product	G	
Hydrogen	5.55±0.05	
Cyclohexene	3.27±0.06	Hydrogen equivalent = 5.49
Bicyclohexyl	1.95±0.06	
Cyclohexyl-hexene-1	0.27±0.05	

All these results were obtained by extrapolation to zero dose since it was shown that the G values of all products decrease with increasing dose. An excellent hydrogen balance has been obtained showing that in the initial stages of radiolysis, i.e. at very low doses, a simplicity of products is observed. No dienes or high molecular weight products are observed and indeed none need be invoked since there is no hydrogen deficit.

At higher doses complications arise. The G values of all the initial products decrease and secondary reaction products appear. Cyclohexyl-cyclohexene is one which has been definitely identified. High molecular weight products appear and the hydrogen deficit becomes greater. Dyne and Fletcher (6) have shown that, on prolonged radiolysis of cyclohexane, the cyclohexene reaches a limiting concentration when its rate of formation is equal to its rate of disappearance. In the present work it has been shown that the radiolysis of a mixture of cyclohexane and cyclohexene results in a decrease in G(cyclohexene) of about 2.7, but the decrease in $G(H_2)$ is only 0.9. This implies that the disappearance of cyclohexene is not brought about simply by the addition of hydrogen to the double bond, but some other reaction must be occurring. Since cyclohexyl-cyclohexene is a secondary product, some substitution at a saturated carbon atom takes place.

These results differ somewhat from those of Waight and Walker (8), who found lower yields of bicyclohexane and cyclohexene (1.6 and 2.4 respectively). The dose rate of their irradiation was about one tenth of the dose rate used here and, at the doses used (6×10^{22} ev/liter), it is consequently likely that their G values for these products would be significantly lower than the true initial value. We do not observe cyclohexyl-cyclohexene as a primary product.

THE SEPARATION OF SMALL AMOUNTS OF THE PLATINUM METALS

1. THE COLORIMETRIC DETERMINATION OF RHODIUM AND ITS SEPARATION FROM IRIDIUM[1]

D. E. RYAN

ABSTRACT

A method for separating small amounts of rhodium from iridium is described. In 3 to 9 *M* hydrochloric acid solutions, the amber-to-red complex of bivalent rhodium with 4,5-dimethyl-2-mercaptothiazole is formed after reduction of tervalent rhodium with chromous or stannous chloride. Rhodium is quantitatively separated from iridium by chloroform extraction of this product; separation can be made in solutions that have been fumed with sulphuric acid if chromous chloride is used for the prior reduction of the rhodium. The complex, after removal of the chloroform, is dissolved in dilute hydrochloric acid, and the optical density of the resulting colored solution is measured.

INTRODUCTION

The separation of small amounts of the platinum metals still leaves room for improvement. Palladium can be separated by extraction of the dimethylglyoxime (1, 2), *p*-nitrosophenylamine (3, 4, 5), or 1-nitroso-2-naphthol (6) complexes into organic solvents; similar success is not so readily attained with small quantities of the other platinum metals.

The hydrous oxide procedure of Gilchrist and Wichers (7) provides a means of separating small amounts of platinum from similar quantities of iridium and rhodium (3, 5) and some success has been recorded for the separation of bivalent platinum complexes (1, 4, 8). Ammonium type salts $(R_4N)_2MX_6$, although satisfactory for determining small amounts of platinum metals in the quadrivalent state and for separating from commonly associated base metals, are of little use in the separation of the platinum metals themselves. Selective reduction by copper powder (9) has proved satisfactory for separating both milligram and microgram quantities of rhodium from iridium. Ion exchange methods have been used with varying success for separating microgram amounts of these metals (10). Where molecular chelate species are possible, solvent extraction offers a reasonable means of separation (11); such chelates are not probable for the platinum metals in the quadrivalent state (12). Distinct possibilities, however, lie in the principle of precipitating or extracting bivalent platinum metal complexes. Jackson (13) has quantitatively separated rhodium from iridium as an insoluble bivalent complex with thioacetanilide after reduction with chromous chloride; the method can be used for the determination of small amounts of iridium in rhodium but attempts to separate small quantities of rhodium from iridium by solvent extraction were unsuccessful. The following paper records the results of an investigation into the possibility of separating rhodium from iridium by extraction of a bivalent complex obtained after reduction.

Rhodium, in the bivalent state, reacts with 4,5-dimethyl-2-mercaptothiazole to give a colored complex that can be used for its determination (14). In the original paper the color was produced by boiling hydrochloric acid solutions of tervalent rhodium with excess reagent, the reagent itself acting to reduce the rhodium to the bivalent state; iridium produced a pale yellow color that caused some interference in the rhodium determination unless compensated in the reference cell; both the rhodium and iridium com-

[1]*Manuscript received June 15, 1961.*
Contribution from the Department of Chemistry, Dalhousie University, Halifax, Nova Scotia, and the Imperial College of Science and Technology, London, England; with financial assistance from the National Research Council, Ottawa, Canada.

plexes were extracted by organic solvents so that separation under these conditions is not possible. However, 4,5-dimethyl-2-mercaptothiazole, as many other thio compounds (13), reacts in the cold with rhodium when a reducing agent is added; the determination and separation of rhodium from iridium can be readily achieved by this means.

EXPERIMENTAL

In preliminary studies, a large number of compounds was investigated as possible reagents for reducing rhodium, at room temperature and in acid solution, from the tervalent to bivalent state. The compound was added to acidified rhodium chloride solutions containing 4,5-dimethyl-2-mercaptothiazole, and the development of the amber-to-red color of the complex of bivalent rhodium with this reagent taken as evidence of reduction. Only stannous chloride and chromous chloride, of the following compounds investigated, were useful for this purpose: ascorbic acid, cadmium, chromous chloride, ferrous sulphate, formic acid, *d*-glucose, hydrazine, hydrogen peroxide, hydroquinone, hydroxylamine, potassium hydrogen tartrate, sodium dithionite, sodium hypophosphite, sodium hyposulphite, sodium sulphite, stannous chloride, titanous chloride, zinc.

Reduction with Stannous Chloride

Stannous chloride, as is well known, reacts with acidified tervalent rhodium solutions to give a yellow or red color that is not extracted by chloroform; when it is added to rhodium solutions containing 4,5-dimethyl-2-mercaptothiazole, however, an amber-to-red color develops that is readily extracted by chloroform. The chloroform extract from iridium solutions similarly treated is colorless and free of iridium. Rhodium can be readily separated from iridium by this means in chloride solutions or from hydrochloric acid solutions containing sulphate. The optical densities for chloroform extract from samples containing the same quantity of rhodium are inconsistent. Reproducible results, and optical densities agreeing with those given by the original procedure with 4,5-dimethyl-2-mercaptothiazole (14), are obtained by removing the chloroform on the steam bath and dissolving the residue in a little ethanol and a diluted hydrochloric acid solution.

2-Mercaptothiazole, 2-mercaptothiazoline, 2-mercaptobenzoxazole, 4-methyl-2-mercaptothiazole, and 4-phenyl-2-mercapothiazole react also to give colored chloroform extracts. The extracts obtained for compounds substituted in the 4-position are amber-to-red in color but are yellow for the unsubstituted ones. Colorless chloroform extracts are obtained for 4-methyl-2-hydroxythiazole and 2-aminothiazole; the mercapto group is, therefore, essential to the reaction.

A Spekker photoelectric absorptiometer with an Ilford No. 601 filter (maximum transmittancy at 430 mμ) and a Cenco-Sheard-Sanford 'Photelometer' (filter No. C with maximum transmission at 435 mμ) were used to obtain the recorded data.

Reagents

4,5-Dimethyl-2-mercaptothiazole.—The reagent was made by the method of Buchman, Riems, and Sargent (15) and was recrystallized from 25% ethyl alcohol; a solution was prepared by dissolving 0.5 g in 100 ml of 50% ethanol.

Standard rhodium and iridium solutions.—These solutions were prepared by dissolving known weights of Matthey spectrographically pure ammonium chlororhodite and ammonium chloroiridate in dilute acid solutions.

Stannous chloride solutions.—The stannous chloride solution was a 10% solution of the dihydrate in 2 *N* hydrochloric acid.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Procedure

Solutions containing 0.04 to 0.3 mg of rhodium were transferred to separatory funnels and were made 3 to 9 *M* in hydrochloric acid by addition of the concentrated acid, and 1 ml of reagent solution was added for each 0.1 mg or less of rhodium expected to be present. The rhodium was reduced by adding 10 drops or more of stannous chloride, the solution then extracted with 15 ml of chloroform, and the organic phase transferred to a small beaker or flask; the aqueous layer was again extracted with 10 ml of chloroform. The combined extracts were evaporated on a steam bath and the residue was dissolved in 5 ml of ethanol, then boiled with 25 ml of 2.5 *M* hydrochloric acid. After being cooled, the solution was transferred to a 50-ml graduated flask and diluted to the mark with water. The optical density was measured in a 1-cm cell of an absorptiometer using a filter with maximum transmittancy of 430–435 mμ.

The optical densities obtained under various conditions are shown in Table I. These results are for 0.185 mg of rhodium, 2 ml of reagent, and a 1-cm cell; 10 drops of stannous chloride were used for reduction and the volume of the solution, before extraction, was approximately 20 ml for these samples.

TABLE I

Optical density of solutions of 0.185 mg of rhodium under various conditions

No.	Condition	Optical density
(1)	Hydrochloric acid present, 1.0 ml	0.384
(2)	,, ,, ,, 5.0 ml	0.448
(3)	,, ,, ,, 10.0 ml	0.446
(4)	,, ,, ,, 15.0 ml	0.446
(5)	As in (2) + 2.0 ml of concentrated sulphuric acid	0.447
(6)	As in (2) + 5.0 ml of stannous chloride	0.444
(7)	As in (2) but stannous chloride added before reagent	0.425
(8)	As in (2) but 5.0 ml of reagent added	0.448

The data show that rhodium can be readily separated from 3 to 9 *M* hydrochloric acid solutions and determined by this procedure. Results are satisfactory in chloride solutions containing sulphuric acid, and excess stannous chloride or reagent cause no difficulty. The optical density for the same concentration of rhodium by the boiling procedure (14) is 0.447. Addition of stannous chloride before reagent causes some difficulty in removing the last traces of rhodium complex from the aqueous layer, and slightly low values for rhodium content are obtained. The procedure, using stannous chloride as reducing agent, gives unreliable results when applied to rhodium solutions that have been fumed with sulphuric acid; the chloroform extract from such solutions contains some yellow-colored product, in addition to the rhodium complex, the amount of which is dependent upon reagent, stannous chloride, and sulphuric acid concentration.

As in the original procedure (14) the colored solution obeys Beer's law over the range applicable for a 1-cm cell but the complex is not as stable. The optical density changed from 0.446 to 0.437 when the solution was kept in daylight in a closed container for 1 hour and decreased to 0.383 when the solution was left to stand overnight.

Separation of Rhodium from Iridium

Rhodium can be easily separated from iridium in chloride solutions; however, reagent is added to completely decolorize any quadrivalent iridium before the usual procedure is carried out. Results are shown in Table II.

TABLE II

Separation of rhodium from iridium

No.	Rh taken, mg	Rh found, mg	Ir present, mg	Approx. Ir:Rh ratio
1	0.037	0.036	3.7	100:1
2	0.037	0.039	30.2	800:1
3	0.052	0.053	1.0	20:1
4	0.052	0.054	4.5	85:1
5	0.074	0.073	7.4	100:1
6	0.130	0.129	5.2	40:1
7	0.150	0.150	2.2	15:1
8	0.150	0.153	16.0	100:1
9	0.185	0.181	4.0	20:1
10	0.185	0.185	25.0	140:1
11	0.185	0.185	33.0	180:1

A large excess of stannous chloride (5 ml), although unnecessary, was added for most of the results recorded in Table II; in results 3, 4, 6, obtained independently by H. M. Whitehead, 10–15 drops of stannous chloride were used for reduction.

Reduction with Chromous Chloride

The soluble complex formed on addition of chromous chloride to rhodium solutions containing 4,5-dimethyl-2-mercaptothiazole is extracted by chloroform from chloride solutions or from sulphate solutions containing hydrochloric acid; in chloride solutions the iridium complex is also extracted by chloroform. It is worth while noting that, although the iridium complex is extracted from freshly prepared ammonium chloroiridate solutions, no extraction of iridium occurs from the same solution after it has stood more than 2 weeks.

Procedure

Five milliliters of lithium sulphate:sulphuric acid reagent (13.5 g of Li_2SO_4 in 100 ml of concentrated H_2SO_4) was added to chloride solutions containing rhodium and iridium, and the solutions fumed to crystallization of lithium sulphate. The samples were diluted with 5 ml of water, heated to ensure complete dissolution, cooled to room temperature, and transferred to a separatory funnel. An approximately equal volume of concentrated hydrochloric acid was then added and freshly prepared chromous chloride solution (approximately 1 *N*) added dropwise to reduce rhodium and iridium. An excess of reagent was added, the solutions extracted with chloroform, and the procedure completed as described for stannous chloride. Results are given in Table III. The results show that rhodium can be separated from iridium, in solutions that have been fumed with sulphuric acid, by this procedure.

CONCLUSIONS

Rhodium can be separated and determined colorimetrically by extraction of the complex formed with 4,5-dimethyl-2-mercaptothiazole obtained after reduction with stannous chloride or chromous chloride. Rhodium can be separated from iridium in chloride solutions using stannous chloride as reducing agent; in solutions that have been fumed with sulphuric acid it is necessary to use chromous chloride to obtain satisfactory separation.

This work was carried out, in part, at the Imperial College of Science and Technology, London, England, and was supported by a travel grant from the National Research Council.

THE EFFECT OF HYDROGEN CHLORIDE ON THE NEAR-INFRARED SPECTRUM OF NYLON[1]

P. LAROSE

ABSTRACT

Samples of oriented nylon film and filament were treated with anhydrous HCl and examined in the near-infrared region of 9000 to 3700 cm^{-1} with polarized light. The results are in agreement with previous observations made in the 3600–600 cm^{-1} region, and corroborate earlier evidence that HCl interacts with the peptide linkage. The disorienting effect of the HCl is also reflected in the spectrum of the treated specimens.

INTRODUCTION

The results of experiments on the effect of hydrogen chloride on the infrared spectrum of nylon in the region of 3600 to 600 cm^{-1} have been reported (5). The investigation has now been extended to the overtone region of 9000 to 3700 cm^{-1} since the spectrum of nylon in this region has been studied and the assignment of the bands discussed by several workers (1, 2, 3). It was hoped in this way to confirm our earlier results and possibly to provide additional data to support the assignment proposed for the various absorption bands.

EXPERIMENTAL

Oriented Zytel[2] film was prepared by casting onto glass from ethanol solution and stretching the film in hot water. Nylon 6 film[3] was also oriented by stretching it in hot water, while a sample of nylon 6.6 was examined in the form of a ribbon about 0.3 mm thick prepared by rolling a monofilament lengthwise. The samples were immersed in hexachlorbutadiene and the absorption spectra recorded on a Beckman DK2 spectrophotometer with light polarized by means of a Polaroid HR plastic filter. The samples were studied before and after treatment with anhydrous HCl and also after removal of the HCl *in vacuo*.

RESULTS

The various film and filament specimens yielded results which differed little in character so that no attempt will be made to distinguish between these various forms of nylon in discussing the results.

Figure 1 shows the spectrum of an oriented nylon film before treatment with HCl. It differs little from the spectrum reported by other workers with regard to dichroism and position of the absorption bands. Figure 2 is a portion of the absorption spectrum of a different sample of untreated nylon included here to emphasize a difference between the two vectors to be discussed. Figure 3 represents the spectrum of a sample treated with HCl. Figure 4 shows the spectrum of a thick sample after removal of the HCl, while Fig. 5 is for a thin sample also after removal of the HCl.

Because of form dichroism resulting from differences in the refractive indices of the nylon in directions parallel and perpendicular to the polymer chain direction, and because

of small differences in the transmission of the filter between its horizontal and vertical positions, the extent of dichroism was determined from a line drawn through the absorption minima. However, because of the uncertainties involved in such a method, no attempt has been made to express the dichroism quantitatively.

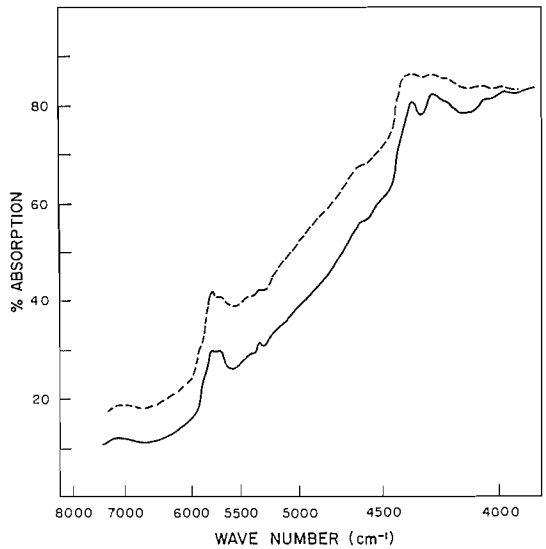

FIG. 3. Spectrum of nylon treated with HCl.

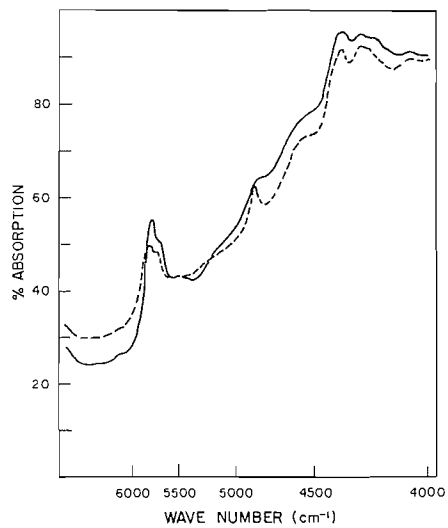

FIG. 4. Spectrum of thick nylon sample treated with HCl and subsequently evacuated.

DISCUSSION

If, as assumed in previous work (4, 5), the HCl acts on the —NH.CO— group, one would expect all overtones or combination modes involving this linkage to be affected by the HCl, whereas the bands due to the —CH_2— groups in the chain should not be so affected. A comparison of the spectra of the nylon treated with HCl with the spectrum of the untreated nylon shows that this was indeed the case. The changes produced by the HCl on the various bands are as follows.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

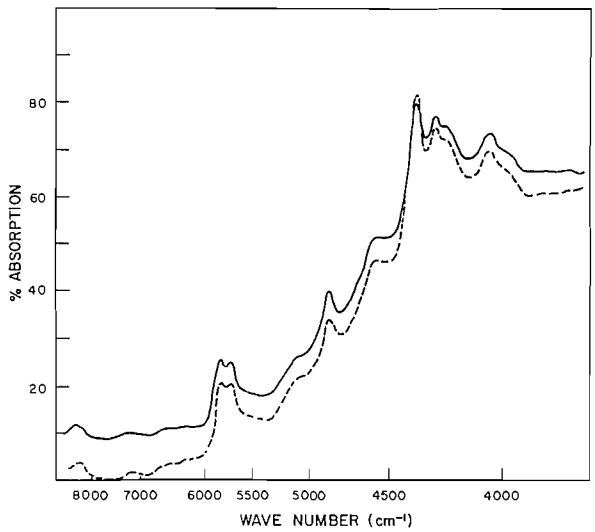

FIG. 5. Spectrum of thin nylon film treated with HCl and subsequently evacuated.

A weak band at 8240 cm^{-1} showing perpendicular (σ) dichroism in the untreated nylon is no doubt the same band as that reported at 8300 cm^{-1} by Hecht and Wood (3) (henceforth H and W) and at 8292 cm^{-1} by Glatt and Ellis (2) (G and E). It has been assigned as the third harmonic of the CH_2 stretching vibration at 2960 cm^{-1} (ν_a) or 2860 cm^{-1} (ν_s). The treated samples still show this band but the dichroism is absent (Fig. 5) because of the disorienting effect of the HCl. The disorientation is irreversible and is found in all HCl-treated samples. Some dichroism will be found remaining in the spectrum shown in Fig. 4. In this case the thickness of the sample prevented complete penetration of the HCl in the time allowed for absorption, and the residual effect is undoubtedly due to some unaffected nylon.

Another weak band at a frequency of 7020 cm^{-1} behaves like the 8240 cm^{-1} band. It does not seem to have been mentioned by other workers. It may be a combination of a —CH_2— deformation mode with twice its stretching frequency ($2\nu+\delta$).

The 6520 cm^{-1} band with σ dichroism falls within the range 6300–6680 cm^{-1} given by H and W (3) for 2νNH. G and E (2) have also given this assignment to a 6523 cm^{-1} band. Being an NH band, it is affected by the HCl and is absent in the spectrum of the treated samples.

Two bands at 5760 and 5660 cm^{-1} show σ dichroism, particularly strong for the first one. These correspond to the 5800–5700 cm^{-1} bands mentioned by H and W (3) and the bands at 5804 and 5695 cm^{-1} cited by G and E (2). The frequencies we have observed correspond more closely to the 5780 and 5656 cm^{-1} frequencies given by G and E (2) for the polyethylene chain. They have been given the assignment $2\nu_a$ and $2\nu_s$ of the —CH_2— vibrations respectively. The behavior of these bands when nylon is treated with HCl is similar to that mentioned for the other bands involving —CH_2— modes. The 5150 cm^{-1} band is generally attributed to water and shows no dichroism.

Another band at 4960 cm^{-1} shows some σ dichroism and is no doubt that given at 4975 cm^{-1} by G and E (2) and assumed by them to be the third harmonic of a C=O vibration at 1640 cm^{-1}. However, Fraser (1) has assigned this band to a combination of the NH

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

vibration at 3300 cm^{-1} with the C=O vibration. The complete disappearance of this band in nylon treated with HCl favors the latter explanation since our earlier work (5) has shown that the effect of the HCl is much more pronounced on the 3300 cm^{-1} vibration than on the 1640 cm^{-1} vibration.

The band showing the greatest degree of dichroism is that at 4880 cm^{-1}. The parallel (π) dichroism agrees with that given by H and W (3) at 4850 cm^{-1}. There is agreement on the assignment of this band as a combination of the NH vibration at 3300 cm^{-1} and the amide II or NH deformation band at 1545 cm^{-1}. The band is absent in the spectrum of the HCl-treated samples, as expected, but it reappears when the HCl is removed, but with no dichroism (Fig. 5) or little dichroism (Fig. 4, for reason previously discussed).

Another absorption band showing π dichroism is found with a frequency of 4680 cm^{-1}. G and E (2) mention a band with low dichroism at a frequency of 4700 cm^{-1}. Fraser (1) gives it the assignment $2\nu_2+\nu_6$ or twice the NH deformation vibration of 690 cm^{-1} plus the NH stretching vibration of 3300 cm^{-1}. The association of this band with the NH group results in its disappearance when nylon is treated with HCl but it does not reappear when the HCl is removed.

A band at 4580 cm^{-1} shows little, if any, dichroism. H and W (3) mention a band at 4590 cm^{-1} as having σ dichroism. Fraser (1) cites this band as having a low dichroism and assigns to it the combination of the NH vibration at 3300 cm^{-1} with the amide III band at 1250 cm^{-1}. In the treated sample this band is just discernible as a shoulder on the broad absorption band covering the 5400–4500 cm^{-1} region. In the evacuated samples it is more pronounced. In the untreated sample, this band is accompanied by a band at 4550 cm^{-1} appearing as a small shoulder on the perpendicular spectrum only and possessing therefore some σ dichroism. Fraser (1) has calculated a band at 4490 cm^{-1} (10 cm^{-1} less than the 4500 cm^{-1} calculated for the 4590 cm^{-1} band) from a combination of twice the 1650 cm^{-1} C=O vibration with the 1280 cm^{-1} NH deformation mode. This might well be the band we observed at 4550 cm^{-1}. In the treated and evacuated samples a broad shoulder probably covers both 4580 and 4550 cm^{-1} bands.

The bands at 4350, 4275, 4230, and 4070 cm^{-1} are all combinations involving the asymmetric or symmetric CH_2 stretching vibrations plus one of the deformation modes. In the treated samples, the large degree of scattering obscures these bands, which, as a result, appear to have a much reduced intensity.

One peculiar feature of these bands is the difference between the parallel and the perpendicular vibrations in the 4220–4280 cm^{-1} region (Figs. 1 and 2). Whereas the 4275 cm^{-1} band is well separated from the 4230 cm^{-1} band in the perpendicular spectrum, the 4230 cm^{-1} band is displaced to a higher frequency, ~4240 cm^{-1}, in the parallel spectrum, and appears to have some π dichroism. Fraser (1) mentions a band with a frequency of 4260 cm^{-1}, which is probably the same as our 4275 cm^{-1} band, and one at 4220 cm^{-1} with π dichroism. G and E (2) give bands at 4257, 4219, and 4202 cm^{-1}. The 4220 cm^{-1} appears as a shoulder in Fig. 2.

A small band at 3900 cm^{-1} with definite π dichroism has not been mentioned by other workers. It is not discernible in the samples treated with HCl. It could be a combination of the NH 3300 cm^{-1} band plus the 690 cm^{-1} deformation mode.

It is evident from these observations that any combination band involving the NH or peptide linkage is affected by the treatment of nylon with HCl whereas any change in the vibrations depending solely on the —CH_2— groups is only of a secondary nature. It is also clear that the HCl treatment results in a loss of orientation of the polymer chains. This is in accord with the conclusions drawn from our previous work in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

region of lower frequencies (5). If one accepts these conclusions a priori, then the results of these experiments can be regarded as confirmation for some of the assignments made in the overtone region of the nylon spectrum.

THE SYNTHESIS OF ACETAMIDO-DEOXY KETOSES BY ACETOBACTER SUBOXYDANS

PART II[1]

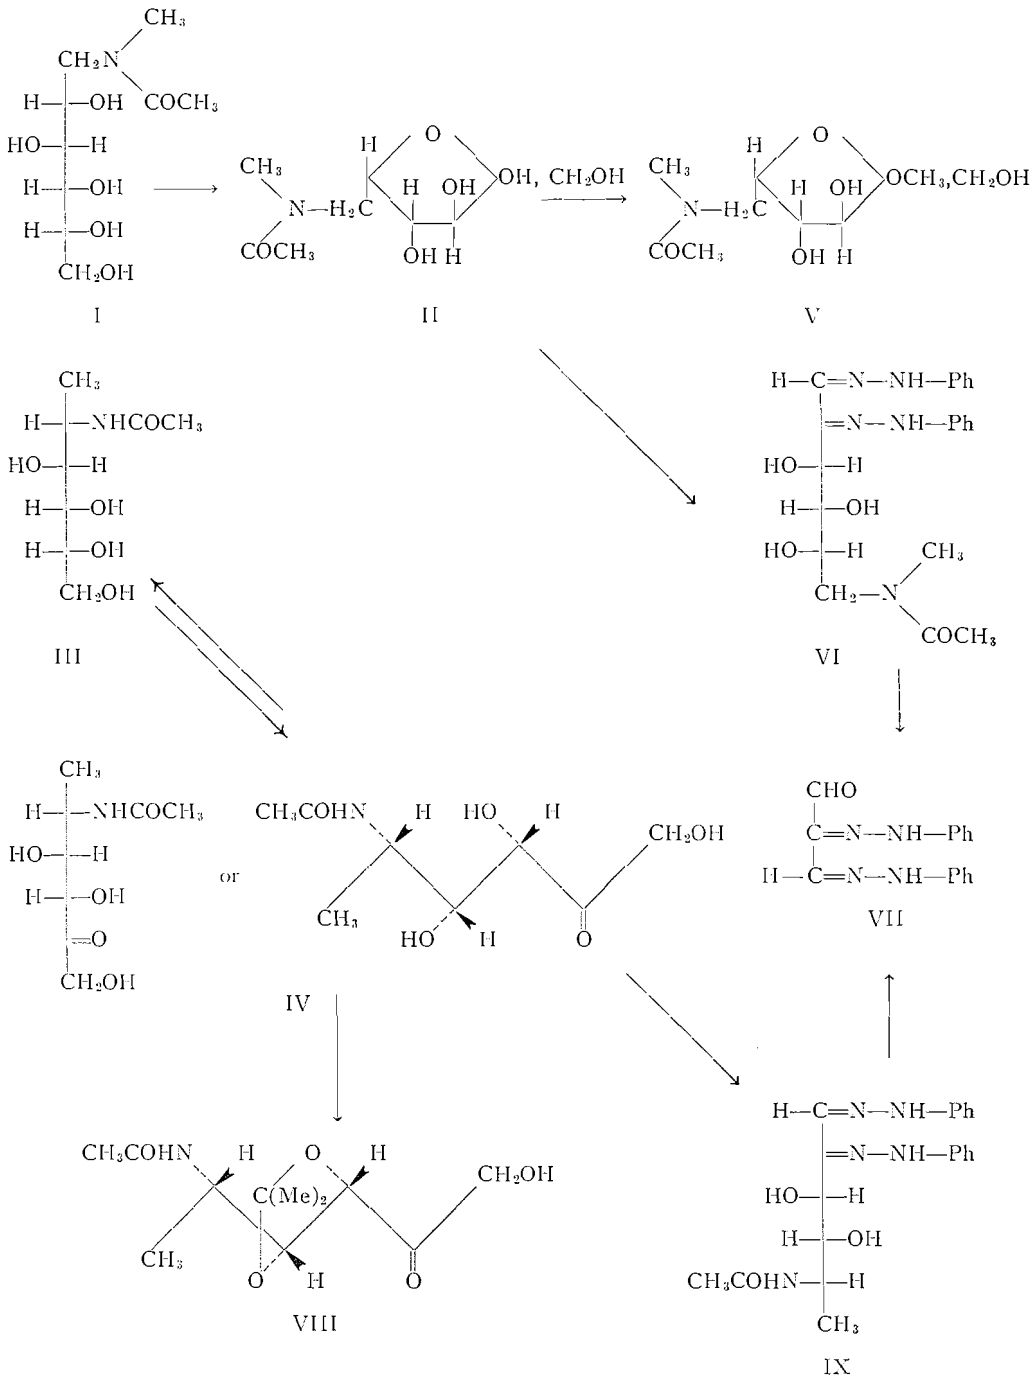
J. K. N. JONES, M. B. PERRY, AND J. C. TURNER

ABSTRACT

The microbiological oxidation of 1-deoxy-1-*N*-methylacetamido-D-glucitol and 2-acetamido-1,2-dideoxy-D-glucitol yielded a syrupy ketose and a crystalline ketose respectively. Crystalline derivatives of each were prepared and structural investigations of the ketoses showed the former to be 6-deoxy-6-*N*-methylacetamido-L-xylohexulose and the latter to be 5-acetamido-5,6-dideoxy-L-xylohexulose.

INTRODUCTION

The microbiological oxidation of unsubstituted polyhydric alcohols has been studied extensively (1, 2, 3, 4, 5, 6), and the oxidation of terminal-substituted polyhydric alcohols has also been investigated in several laboratories (7, 8, 9, 10). Recently we reported the oxidation of the substituted hexitol 2-acetamido-2-deoxy-D-glucitol by *Acetobacter suboxydans* to 5-acetamido-5-deoxy-L-xylohexulose (11) and in this paper we wish to report the microbiological oxidation of 1-deoxy-1-*N*-methylacetamido-D-glucitol (I) to 6-deoxy-6-*N*-methylacetamido-L-xylohexulose (II), and of 2-acetamido-1,2-dideoxy-D-glucitol (III) to 5-acetamido-5,6-dideoxy-L-xylohexulose (IV).



The oxidation of 1-deoxy-1-*N*-methylacetamido-D-glucitol (I) yielded a syrup which gave absorptions in the infrared corresponding to OH, CH, and C=O of the tertiary amide group. A weak band at 1730 cm^{-1} was also observed and was probably due to the presence of a small amount ($\sim$5%) of the acyclic form of the ketose. The results of periodate oxidation indicated that the main bulk of the material existed in the furanose ring form (II). Further evidence for a furanose ring form was given by the ready and rapid formation of a crystalline methyl glycoside (V) which was stable towards alkali but which was readily hydrolyzed with dilute acid. The rate of periodate oxidation of the glycoside (V) indicated that the two free hydroxyl groups, between which cleavage had occurred, were held in the trans configuration by the near-planar furanose ring.

The ketose (II) gave a crystalline phenylosazone (VI) which, when oxidized with periodate by the method of Hough, Powell, and Woods (12), consumed 2 moles of periodate, releasing 0.58 mole formic acid and no formaldehyde. The apparent low formic acid release agreed with the findings of Hough, Powell, and Woods, who obtained similar results from the periodate oxidation of monosaccharide and disaccharide phenylosazones (12). An immediate precipitate of the 1,2-bisphenylhydrazone of mesoxalaldehyde (VII) was obtained from the oxidation. The oxidation results indicated that the osazone (VI) possessed free hydroxyl groups at carbons 3, 4, and 5, and that the ketose (II) from which it was derived was a 2-ketose.

The ketose (II) was very slowly reduced by sodium borohydride to give a syrup which could not be crystallized. This product apparently consisted of the two expected isomeric hexitols although they could not be separated by paper chromatography in several solvent systems.

[1]*Manuscript received June 7, 1961.*
Contribution from the Department of Organic Chemistry, Queen's University, Kingston, Ontario.

The above results showed that the ketose had the indicated structure (II), the major portion being in the furanose ring form, and that the site of biological oxidation in 1-deoxy-1-*N*-methylacetamido-D-glucitol was at carbon 5, in accordance with the well-known enzyme specificity for oxidations at pH 5–6.5.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The oxidation of 2-acetamido-1,2-dideoxy-D-glucitol (III) by *Acetobacter suboxydans* gave crystalline 5-acetamido-5,6-dideoxy-L-xylohexulose (IV). The results of periodate oxidation indicated that enzymic oxidation had not occurred at the primary alcohol group of the hexitol. The formation of aldofuranose rings was thus excluded on this evidence and the ketose therefore probably existed in the acyclic zigzag form (IV). Evidence to support this conclusion was given by (*a*) the strong, sharp peak at 1735 cm^{-1} which was observed in the carbonyl region of the infrared spectrum, and (*b*) by the fact that the ketose (IV) was not oxidized by bromine water or alkaline hypoiodite solution.

The ketose (IV) rapidly reduced Fehling's solution in the cold and epimerized easily when warmed in pyridine solution or allowed to stand in contact with base for a short time, due to the ease of keto-enol tautomerism in the acyclic form.

With acidified acetone the ketose (IV) gave a syrupy isopropylidene derivative (VIII), the infrared spectrum and periodate oxidation of which indicated that acetal formation had occurred across the hydroxyl groups on carbons 3 and 4, which were therefore favorably situated for this reaction.

Reaction of the ketose (IV) with phenylhydrazine gave a crystalline phenylosazone (IX), which, on periodate oxidation, consumed 1 mole of periodate and released no formic acid or formaldehyde. An immediate precipitate of the 1,2-bisphenylhydrazone of mesoxalaldehyde (VII) was obtained. The above evidence indicated that the phenylosazone (IX) possessed free hydroxyl groups on carbons 3 and 4 and that the ketose (IV) from which it was derived was a 2-ketose.

Reduction of the ketose (IV) with sodium borohydride gave crystalline 2-acetamido-1,2-dideoxy-D-glucitol (III), which confirmed that the hydroxyl groups at carbons 3 and 4 of the ketose (IV) were in the D-*threo* configuration since the position of the keto group had been fixed at carbon 2 by previous evidence.

The above results indicated that the biological oxidation product was the acyclic 2-hexulose, 5-acetamido-5,6-dideoxy-L-xylohexulose (IV), as would be predicted from the Bertrand–Hudson rule for enzymic oxidation by *Acetobacter suboxydans* (13, 14).

EXPERIMENTAL

Melting points are uncorrected and were determined on a Fisher-John melting point apparatus. All evaporations were carried out under reduced pressure at 50° C or less. Optical rotations were measured at 23±3° C in water unless otherwise stated. Paper chromatography was carried out by the descending method (15) using Whatman No. 1 paper in the following solvent systems (v/v):

(A) butan-1-ol/ethanol/water, 9:3:3;
(B) butan-1-ol/pyridine/water, 5:3:2;
(C) ethyl acetate/acetic acid/formic acid/water, 18:3:1:4;
(D) 2-butanone/glacial acetic acid/saturated aqueous boric acid, 9:1:1.

The rates of movement of compounds on paper chromatograms are given relative to that of rhamnose (R_{rh} value). Ketose sugars were detected on paper chromatograms with the orcinol – trichloroacetic acid spray reagent (16), other reducing compounds with the *p*-anisidine hydrochloride spray reagent (17), and non-reducing compounds with the alkaline silver nitrate spray reagent (18). Infrared spectra were measured in chloroform solution or as a dispersion in a potassium bromide pellet, using a Perkin–Elmer Model 21 spectrophotometer. Formaldehyde produced in periodate oxidations was determined by the chromotropic acid method (19).

SECTION A. STUDIES ON 6-DEOXY-6-*N*-METHYLACETAMIDO-L-XYLOHEXULOSE

Preparation of 1-Deoxy-1-N-methylacetamido-D-glucitol

1-Deoxy-1-*N*-methylamino-D-glucitol (Aldrich Chem. Co. sample) was twice recrystallized from ethanol containing a little water to give a creamy-white product which had m.p. 128–129° C, $[\alpha]_D$ −14° (lit. values, m.p. 126° C, $[\alpha]_D$ −18.5±1° (20)).

1-Deoxy-1-*N*-methylamino-D-glucitol was *N*-acetylated in aqueous solution, using the method of Levvy and McAllan (21), to give a yellow syrup which slowly crystallized on desiccation. The product was recrystallized from methanol/ether, then from ethanol/ether to give white crystals which had m.p. 119–121° C, $[\alpha]_D$ −22°.

6-Deoxy-6-N-methylacetamido-L-xylohexulose

1-Deoxy-1-*N*-methylacetamido-D-glucitol (7 g), sorbitol (3 g), yeast extract powder (0.5 g), and potassium dihydrogen phosphate (0.05 g) were dissolved in tap water (140 ml), and the solution was distributed among six 250-ml conical flasks and autoclaved at 15 p.s.i. for 20 minutes. After being cooled, the sterile broths were inoculated with several drops of a 48-hour culture of *Acetobacter suboxydans* grown in sorbitol solution. The flasks were stored in the dark at room temperature and samples were removed at intervals, under sterile conditions, for examination by paper chromatography and estimation of copper-reducing value by the Somogyi method (22). The appearance of L-sorbose (R_{rh} 0.52, solvent A) was noted, and of a spot (R_{rh} 1.1, solvent A) which gave a pink color changing to green with the orcinol – trichloroacetic acid spray reagent. The results of the Somogyi estimations are shown in Table I.

TABLE I

Oxidation of 1-deoxy-1-*N*-methylacetamido-D-glucitol by *Acetobacter suboxydans*

Time (days)	% yield of ketose (corrected for the presence of L-sorbose)
6	7.2
12	23.6
19	35.6

Growth was terminated after 22 days by pouring the broths into two volumes of ethanol. The solution was filtered, deionized by passage through Amberlite I.R. 120 (H^+) and Duolite A4 (OH') resins, and concentrated to a syrup. L-Sorbose crystallized out and was removed and the residual syrup was then separated into three components by chromatography on a cellulose column using butan-1-ol half-saturated with water as the irrigant. The three components were L-sorbose, 1-deoxy-1-*N*-methylacetamido-D-glucitol, and 6-deoxy-6-*N*-methylacetamido-L-xylohexulose. The latter was obtained as a clear, light yellow syrup (2.2 g), $[\alpha]_D$ −57°. An infrared spectrum was obtained by smearing a little of the syrup onto the surface of a potassium bromide pellet, and showed the following main absorptions: OH (3410 cm^{-1}, strong), CH (2960 cm^{-1}, strong), saturated ketone C=O (1730 cm^{-1}, weak), tertiary amide C=O (1625 cm^{-1}, strong). The complete spectrum is given in Appendix A.

Periodate Oxidation of 6-Deoxy-6-N-methylacetamido-L-xylohexulose

An aqueous solution of 6-deoxy-6-*N*-methylacetamido-L-xylohexulose was oxidized under unbuffered conditions using a twofold excess of sodium metaperiodate. The results of the oxidation are shown in Table II.

TABLE II

Periodate oxidation of 6-deoxy-6-*N*-methylacetamido-L-xylohexulose

Time (hours)	Periodate uptake (moles/mole)	Formic acid (moles/mole)	Formaldehyde (moles/mole)

Methyl 6-Deoxy-6-N-methylacetamido-L-xylohexulofuranoside

6-Deoxy-6-*N*-methylacetamido-L-xylohexulose (200 mg) was dissolved in anhydrous methanol (5 ml), and anhydrous methanolic hydrogen chloride (1%, 8 ml) added. The solution was allowed to stand at room temperature for $3\frac{1}{2}$ hours, then neutralized with silver carbonate, filtered, and evaporated to dryness. The resulting pale yellow syrup gave a bright yellow spot on paper chromatograms (R_{rh} 1.57, solvent A) with the *p*-anisidine hydrochloride spray reagent. The syrup gave only a faint spot due to unreacted 6-deoxy-6-*N*-methylacetamido-L-xylohexulose with the alkaline silver nitrate spray reagent. After desiccation for 3 days the syrup crystallized and crystallization was speeded by the addition of methanol/ethyl acetate. The crystals were filtered off, dried, and recrystallized twice from methanol/ethyl acetate to give white needles (50 mg) which had m.p. 109–110° C, $[\alpha]_D$ −97°. The glycoside gave absorptions in the infrared corresponding to OH (3480 cm^{-1}), CH (2940, 2880 cm^{-1}), and tertiary amide C=O (1600 cm^{-1}). The complete spectrum is given in Appendix B. Anal. Calc. for $C_{10}H_{19}O_6N$: C, 48.2%; H, 7.6%; N, 5.6%. Found: C, 48.1%; H, 7.4%; N, 5.7%.

Periodate Oxidation of Methyl 6-Deoxy-6-N-methylacetamido-L-xylohexulofuranoside

The glycoside was oxidized with a twofold excess of sodium metaperiodate in unbuffered aqueous solution. The results of the oxidation are given in Table III. No formaldehyde was detected in the oxidation mixture.

TABLE III

Periodate oxidation of methyl 6-deoxy-6-*N*-methylacetamido-L-xylohexulofuranoside

6-Deoxy-6-N-methylacetamido-L-xylohexulose Phenylosazone

The osazone was prepared by the usual method using freshly distilled phenylhydrazine and glacial acetic acid. It was recrystallized twice from ethanol/ethyl acetate and once from ethanol/ether to give a bright yellow powder, m.p. 182–183° C. The osazone gave absorptions in the infrared corresponding to OH (3430 cm^{-1}), NH (3270 cm^{-1}), aromatic

CH (3080 cm^{-1}), aliphatic CH (2940, 2880 cm^{-1}), tertiary amide C=O (1625 cm^{-1}), and the aromatic ring (1610, 1500, 750, 690 cm^{-1}). The complete spectrum is given in Appendix C. Anal. Calc. for $C_{21}H_{27}O_4N_5$: C, 61.0%; H, 6.5%; N, 16.9%. Found: C, 60.5%; H, 6.6%; N, 16.2%.

Periodate Oxidation of 6-Deoxy-6-N-methylacetamido-L-xylohexulose Phenylosazone

The osazone was oxidized in 50% aqueous ethanol by the method of Hough, Powell, and Woods (12). The results of the oxidation are shown in Table IV.

TABLE IV

Periodate oxidation of 6-deoxy-6-*N*-methylacetamido-L-xylohexulose phenylosazone

Time (hours)	Periodate uptake (moles/mole)	Formic acid (moles/mole)	Formaldehyde (moles/mole)
0.42	1.90	0.41	0.00
1.66	2.05	0.59	0.00
3.08	2.14	0.58	0.00

1,2-Bisphenylhydrazone of Mesoxalaldehyde (23)

In the periodate oxidation of 6-deoxy-6-*N*-methylacetamido-L-xylohexulose phenylosazone, a curdy mass of orange-yellow needles was precipitated 30 seconds after oxidation had started. The crystals of the 1,2-bisphenylhydrazone of mesoxalaldehyde were centrifuged off and the supernatant returned to the flask for oxidation studies. The crystals were washed with water, dried, and recrystallized from 50% aqueous ethanol, m.p. 189–191° C. An authentic specimen had m.p. 193–194° C and the mixed m.p. was 189–191° C. The infrared spectra of the authentic and derived specimens were identical over the range 4000–600 cm^{-1}. The spectra were given in a previous publication (11).

Sodium Borohydride Reduction of 6-Deoxy-6-N-methylacetamido-L-xylohexulose

An aqueous solution of 6-deoxy-6-*N*-methylacetamido-L-xylohexulose (100 mg) was reduced with an equal weight of sodium borohydride at 5° C for 18 hours. After removal of sodium borohydride and sodium borate the product was obtained as a syrup (100 mg) which gave two spots, R_{rh} 1.1 (unreduced ketose) and R_{rh} 0.61 (polyhydric alcohols) in solvent A, with the alkaline silver nitrate spray reagent. The polyhydric alcohols were separated from the ketose on Whatman 3 MM paper and obtained as a syrup (75 mg) which gave one spot with the alkaline silver nitrate spray reagent on chromatography in solvents A, B, C, and D. The syrup gave one fraction only, when passed through a column of Dowex 50 W resin (8% cross-linked with divinylbenzene, barium salt form, 200–400 mesh).

The syrup had $[\alpha]_D$ −17° ($[\alpha]_D$ of 1-deoxy-1-*N*-methylacetamido-D-glucitol was −22°) and it was concluded that it contained 1-deoxy-1-*N*-methylacetamido-D-glucitol and probably the isomeric L-iditol derivative. Certainly some 1-deoxy-1-*N*-methylacetamido-D-glucitol was present since oxidation of the syrupy mixture by *Acetobacter suboxydans* gave some 6-deoxy-6-*N*-methylacetamido-L-xylohexulose.

Section B. Studies on 5-Acetamido-5,6-dideoxy-L-xylohexulose

Preparation of 2-Acetamido-1,2-dideoxy-D-glucitol

2-Amino-2-deoxy-D-glucose Diethyl Dithioacetal

2-Amino-2-deoxy-D-glucose hydrochloride (15 g), fuming hydrochloric acid (120 ml), and ethanethiol (45 ml) were shaken in a pressure bottle at room temperature for 20 hours.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The solution was diluted with ethanol, lead acetate was added, and then lead carbonate was added to neutrality. The solution was filtered and the lead salts were washed with ethanol. The filtrate and washings were combined and saturated with hydrogen sulphide, a little charcoal was added, and the solution was filtered and concentrated to a yellow syrup. The syrup was dissolved in water and passed through Duolite A4(OH′) resin. The eluate was concentrated to give crystalline 2-amino-2-deoxy-D-glucose diethyl dithioacetal (10.9 g), m.p. 107–109° C, $[\alpha]_D$ −22° (lit. values, m.p. 109–110° C, $[\alpha]_D$ −24° (24)).

*2-Amino-2-deoxy-*D*-glucose Diethyl Dithioacetal Penta-acetate*

2-Amino-2-deoxy-D-glucose diethyl dithioacetal (10 g) was acetylated with acetic anhydride in pyridine solution at room temperature for 24 hours to give 2-amino-2-deoxy-D-glucose diethyl dithioacetal penta-acetate as a colorless syrup (17 g), $[\alpha]_D$ +2° (*c*, 1.54 in chloroform) (lit. value $[\alpha]_D$ +1° (chloroform) (24)).

*2-Acetamido-1,2-dideoxy-*D*-glucitol*

2-Amino-2-deoxy-D-glucose diethyl dithioacetal penta-acetate (17 g) was reductively desulphurized by being boiled under reflux with Raney nickel catalyst for 5 hours in ethanol solution. The solution was filtered and the catalyst was washed several times with hot ethanol. The filtrate and washings were combined and evaporated to dryness, giving 2-amino-1,2-dideoxy-D-glucitol penta-acetate as a semicrystalline syrup (8.6 g). The syrup was dissolved in methanol (400 ml) and cooled to 0° C. A stream of anhydrous ammonia was passed into the solution for 20 minutes and the solution allowed to stand for 2 hours at room temperature, then evaporated to dryness. The crystalline residue was dissolved in methanol and an equal volume of chloroform was added, followed by ether to incipient opalescence. Small needles of 2-acetamido-1,2-dideoxy-D-glucitol crystallized out and were recrystallized by the same method to give a chromatographically pure product (3.9 g) which had m.p. 160–162° C, $[\alpha]_D$ −14° (lit. values, m.p. 162–164° C, $[\alpha]_D$ −9° (25)).

*5-Acetamido-5,6-dideoxy-*L*-xylohexulose*

2-Acetamido-1,2-dideoxy-D-glucitol (3 g), sorbitol (3 g), yeast extract powder (0.5 g), and potassium dihydrogen phosphate (0.05 g) were dissolved in tap water (100 ml). The solution was distributed among five 250-ml conical flasks and autoclaved at 15 p.s.i. for 30 minutes. After being cooled to room temperature, the broths were inoculated with several drops of a 48-hour culture of *Acetobacter suboxydans* grown in sorbitol solution, and stored in the dark at room temperature. Samples were removed at intervals under sterile conditions for chromatographic examination and estimation of copper-reducing values by the Somogyi method (23).

The appearance of L-sorbose (R_{rh} 0.49, solvent A), and a spot (R_{rh} 1.13, solvent A) which gave a yellow color with the orcinol – trichloroacetic acid spray reagent was noted. The results of the Somogyi estimations showed a 16.7% yield of 5-acetamido-5,6-dideoxy-L-xylohexulose after 7 days and a 69% yield after 20 days. Growth was terminated after 31 days by pouring the broths into 2 volumes of ethanol. The solution was filtered and rapidly passed through small beds of Amberlite I.R. 120 (H^+) and Duolite A4 (OH^-) resins at 5° C. The eluate and washings were concentrated at 35–40° C to a brown syrup which slowly crystallized on the addition of ethanol. The crystalline L-sorbose was removed and the residual syrup was fractionated on a cellulose column using butan-1-ol half-saturated with water as the irrigant. Three fractions were obtained: 5-acetamido-5,6-dideoxy-L-xylohexulose, 2-acetamido-1,2-dideoxy-D-glucitol, and L-sorbose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The 5-acetamido-5,6-dideoxy-L-xylohexulose was obtained as a clear brown syrup (2.1 g), $[\alpha]_D$ −38°. The syrup crystallized after several months but unfortunately only after all the structural work had been completed on the syrup. The crystals were recrystallized from ethanol/ether as rosettes of needles (15 mg) and due to the small amount, a completely pure specimen could not be obtained. The crystals had m.p. 91–93° C, $[\alpha]_D$ −40°.

Anal. Calc. for $C_8H_{15}O_5N$: C, 46.8%; H, 7.3%; N, 6.8%. Found: C, 46.0%; H, 7.2%; N, 6.7%.

The crystals gave absorptions in the infrared corresponding to OH (3400 cm^{-1}), NH (3280 cm^{-1}), CH (2960, 2900 cm^{-1}), saturated ketone C=O (1735 cm^{-1}), amide I (1645 cm^{-1}), amide II (1575 cm^{-1}). The complete spectrum is given in Appendix D.

5-Acetamido-5,6-dideoxy-L-xylohexulose rapidly reduced Fehling's solution in the cold. It was not affected by bromine water at room temperature for 3 hours since no other spots could be detected on paper chromatograms run in solvent A, after bromine water treatment.

Periodate Oxidation of 5-Acetamido-5,6-dideoxy-L-xylohexulose

The ketose was oxidized with sodium metaperiodate at pH 7.5, and under unbuffered conditions and the liberated formaldehyde determined. The results are shown in Table V.

TABLE V

Formaldehyde estimations in the periodate oxidation of 5-acetamido-5,6-dideoxy-L-xylohexulose

	Formaldehyde (moles/mole)	
Time (hours)	pH 7.5	pH 3–4 (unbuffered)
0.17	0.97	0.43
1.17		0.43

5	0.89	
9.7		0.39
19	0.76	

Alkaline Hypoiodite Oxidation of 5-Acetamido-5,6-dideoxy-L-xylohexulose

5-Acetamido-5,6-dideoxy-L-xylohexulose was oxidized with alkaline hypoiodite solution by the standard method (26). The results indicated that the 5-acetamido-5,6-dideoxy-L-xylohexulose contained 10% aldose. However, it was found that the pH 11.4 buffer used in the oxidation caused epimerization of the ketose to aldoses which were detected as two new spots on paper chromatograms, R_{rh} 1.6 and R_{rh} 1.8 in solvent A, with the alkaline silver nitrate and *p*-anisidine hydrochloride spray reagents. A similar pattern of spots was obtained when 5-acetamido-5,6-dideoxy-L-xylohexulose was heated at 100° C for 3 hours in pyridine solution. From these results it was concluded that the value of 10% aldose content resulted from epimerization and that the 5-acetamido-5,6-dideoxy-L-xylohexulose contained very little, if any, aldose.

5-Acetamido-5,6-dideoxy-3,4-O-isopropylidene-L-xylohexulose

5-Acetamido-5,6-dideoxy-L-xylohexulose (200 mg) was dissolved in acetone (100 ml) containing concentrated sulphuric acid (4 drops) and shaken for 24 hours at room temperature. The solution was neutralized with barium carbonate, filtered, and evaporated to dryness and the resulting syrup was examined on paper chromatograms run in

For personal use only.

solvent A. Two spots were observed with the alkaline silver nitrate spray, R_{rh} 1.2 (5-acetamido-5,6-dideoxy-L-xylohexulose) and R_{rh} 2.5 (5-acetamido-5,6-dideoxy-3,4-*O*-isopropylidene-L-xylohexulose). The isopropylidene derivative was separated by chromatography in solvent A on Whatman 3 MM paper and obtained as a syrup (74 mg), $[\alpha]_D$ −19° (*c*, 1.16 in ethanol). The syrup rapidly reduced Fehling's solution in the cold and gave absorptions in the infrared corresponding to OH (3500 cm^{-1}), CH (3010, 2980, 2910 cm^{-1}), saturated ketone C=O (1730 cm^{-1}), amide I (1670 cm^{-1}), and amide II (1525 cm^{-1}). The complete spectrum is given in Appendix E.

*Periodate Oxidation of 5-Acetamido-5,6-dideoxy-3,4-O-isopropylidene-*L*-xylohexulose*

The isopropylidene ketose was oxidized with a twofold excess of sodium metaperiodate in 50% aqueous ethanol and the liberated formaldehyde determined. The results are shown in Table VI.

TABLE VI

Periodate oxidation of 5-acetamido-5,6-dideoxy-3,4-*O*-isopropylidene-L-xylohexulose

Time (hours)	Formaldehyde (moles/mole)
0.17	0.07
1.17	0.27
4.4	0.29
9.7	0.31

*5-Acetamido-5,6-dideoxy-*L*-xylohexulose Phenylosazone*

5-Acetamido-5,6-dideoxy-L-xylohexulose (200 mg) was treated with freshly distilled phenylhydrazine and glacial acetic acid by the usual method to give a fine yellow powder (110 mg). The osazone was recrystallized from ethanol and had m.p. 156–158° C (decomposes). It gave absorptions in the infrared corresponding to OH (3460 cm^{-1}), NH (3370 cm^{-1}), aromatic CH (3080 cm^{-1}), aliphatic CH (3000, 2910, 2860 cm^{-1}), amide I (1655 cm^{-1}), amide II (1560 cm^{-1}), and the aromatic ring (1610, 1500, 745, 690 cm^{-1}). The complete spectrum is given in Appendix F. Anal. Calc. for $C_{20}H_{25}O_3N_5$: C, 62.7%; H, 6.5%; N, 18.3%. Found: C, 62.85%; H, 6.6%; N, 18.1%.

*Periodate Oxidation of 5-Acetamido-5,6-dideoxy-*L*-xylohexulose Phenylosazone*

The osazone was oxidized with sodium metaperiodate in 50% aqueous ethanol using the method of Hough, Powell, and Woods (12). The results of the oxidation are shown in Table VII.

TABLE VII

Periodate oxidation of 5-acetamido-5,6-dideoxy-L-xylohexulose phenylosazone

Time (hours)	Periodate uptake (moles/mole)
0.42	1.02
1.75	0.98
4.0	1.07

No formic acid or formaldehyde were detected in the oxidation mixture.

During the oxidation a bright orange-yellow precipitate of the 1,2-bisphenylhydrazone of mesoxalaldehyde (23) was obtained. Its identity was proved by melting point, mixed melting point, and identical infrared spectrum with an authentic specimen as described previously in Section A of this publication.

Sodium Borohydride Reduction of 5-Acetamido-5,6-dideoxy-L-xylohexulose

5-Acetamido-5,6-dideoxy-L-xylohexulose (115 mg) was reduced in aqueous solution with an equal weight of sodium borohydride at 0° C for 3 hours. Excess sodium borohydride was converted to sodium borate which was removed as methyl borate after passage through Amberlite I.R. 120 (H^+) resin. The product was obtained as a clear colorless syrup (90 mg). The syrup was dissolved in methanol, an equal volume of chloroform was added, then ether to incipient opalescence, and the solution was stored at 0° C. The resulting crystals were filtered off, washed with methanol/ether, and dried (21 mg). A second crop of crystals could not be obtained from the mother liquors. The crystals had m.p. 163–164° C and an authentic specimen of 2-acetamido-1,2-dideoxy-D-glucitol had m.p. 160–162° C. The mixed m.p. was 157–159° C. The crystals (and mother liquors) gave one spot on paper chromatograms with the alkaline silver nitrate spray reagent. The infrared spectra of the crystals and the authentic specimen of 2-acetamido-1,2-dideoxy-D-glucitol were identical over the range 4000–600 cm^{-1}. The crystals had $[\alpha]_D$ −16° and the authentic material had $[\alpha]_D$ −14°.

ACKNOWLEDGMENTS

We wish to thank the National Research Council for financial assistance (N.R.C. 706 and T-39) and Queen's University for the award of a scholarship to one of us (J. C. T.).

THE DIFFUSION OF "ATTACHED" INERT-GAS ACTIVITY[1]

ROGER KELLY

ABSTRACT

It was shown previously that, when an inert gas is irradiated with neutrons in the presence of a powdered solid, between 0.1 and 14% of the induced inert-gas activity is firmly "attached" to the solid. The manner in which attached inert-gas activity is released at temperatures between 50 and 800° C has now been studied. Release data were assembled for a number of systems, and it was noted that the release was reproducible and apparently a diffusion phenomenon. Several theoretical treatments based on diffusion theory were then explored. Agreement between theory and observation was poor if a constant activation enthalpy was assumed. Agreement was good, on the other hand, with theory that took account of the damaged condition of the solid, and the existence of composition anomalies, in the surface region where the inert-gas activity was attached. The damage and composition anomalies were assumed to lead to a spectrum of activation enthalpies and thence to a simplified diffusive motion involving a single rate-controlling jump. The activation-enthalpy spectra for the systems Ar–Nb and Xe–Nb were found to be identical, extending from about 25 to 47 kcal. The spectrum for Xe–Nb_2O_5 extended from about 28 to 76 kcal, and was, in general, similar to the spectra for Xe–SiO_2, Ar–TiO_2, and Xe–TiO_2.

In a recent paper (1), experiments were described in which the inert gases argon, krypton, and xenon were irradiated with neutrons in the presence of various powders. It was found that the major portion of the induced inert-gas activity could be pumped off the powders at room temperature, though the last 0.1 to 14% (depending on the gas and powder used) was not released till the powders were heated. The latter activity was said to be "attached", and the ratio of attached to total activity was called the "attachment efficiency" (A). A temperature of about 800° C was necessary for a complete release of attached activity.

The present work concerns the manner in which attached inert-gas activity is released at temperatures below 800° C, in other words, in the temperature region where the extent of release is noticeably dependent on time and temperature. Release data are given for several combinations of inert gas and powder (or other solid). It is noted that the release is reproducible, and apparently a diffusion phenomenon. Several theoretical treatments based on diffusion theory are then examined for consistency with the experimental results. Finally, the concepts involved in the theoretical treatment that is most successful are discussed in connection with the over-all attachment process and in other respects.

EXPERIMENTAL

The apparatus and experimental techniques were similar to those described previously (1). A mixture of a powder (or other solid) and inert gas was sealed in a quartz capsule and irradiated overnight with neutrons at a flux of about 1×10^{13} neutrons cm^{-2} sec^{-1}. The capsule was then placed in a vacuum system (Fig. 1A of reference 1) and cracked open. That portion of the inert-gas activity remaining in the gas phase was pumped off, and, for the present purposes, need not be further considered. (The pumping had to be continued for $1\frac{1}{2}$ to 3 hours before the evolution of activity ceased.) The remaining inert-gas activity was now slowly expelled by heating the solid, firstly to various temperatures in the region 50 to 800° C, and finally to 1000° C. (The heating at 1000° C ensured that the attached inert gas was completely released (cf. p. 665 of reference 1).)

[1]*Manuscript received August 16, 1961.*
Contribution from the Development Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario.
Issued as A.E.C.L. No. 1362.

A trap containing charcoal at liquid-nitrogen temperature served to collect the released activity and to position it over a gamma-scintillation crystal (Fig. 1B of reference 1). Gamma counts were taken at intervals of 1 to 4 minutes, depending on the rate at which the activity was being released.

For some of the experiments, a trap containing charcoal at 300° C was introduced into the vacuum line ahead of the collecting trap. Charcoal, provided it is sufficiently hot, does not noticeably impede the movement of inert gases, though it will stop potential contaminants such as arsine or iodine. (For the behavior of *unheated* charcoal, see Fig. 3 of reference 1.)

The following solids were used:

Nb, Nb_2O_5, SiO_2, TiO_2 (commercial powders),

SiO_2 (quartz rods with 1-mm diameter),

TiO_2 (sintered balls in the size range from 20 to 60 mesh).[2]

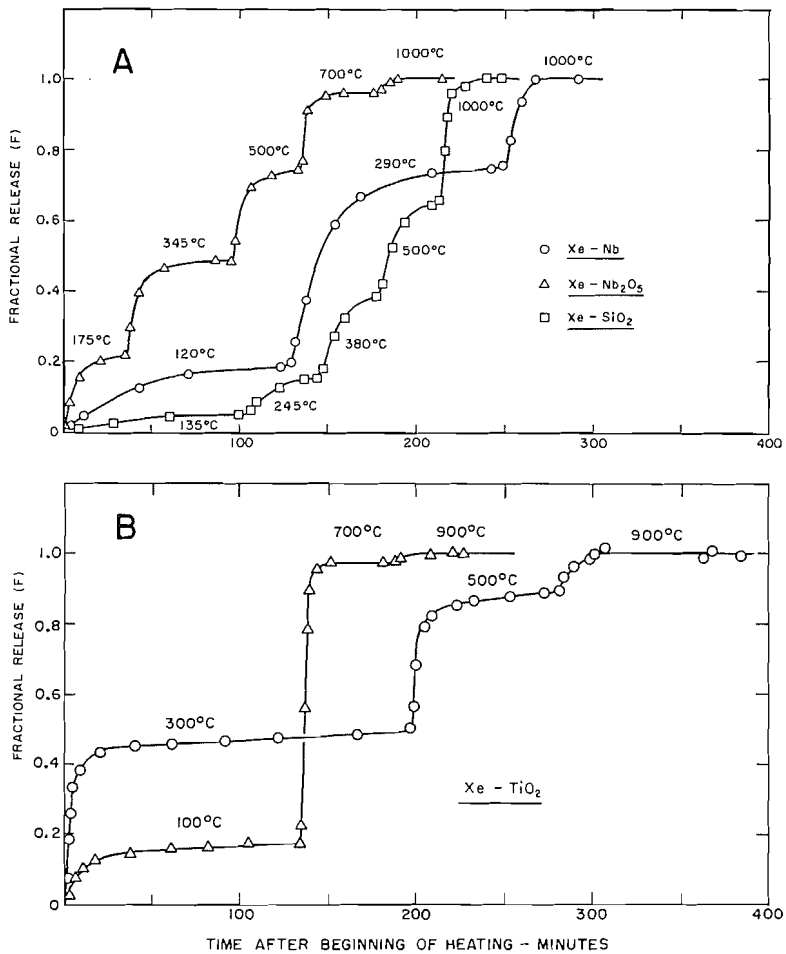
To determine the importance of surface effects, each solid was studied both in an as-received condition, and also after ignition at 500 or 1000° C. The ignitions lasted $\frac{1}{2}$ hour, with the first 10 minutes in air and the remaining 20 minutes in vacuum. Inert gas did not appear to attach to non-ignited quartz rods. This was probably due to the presence of a film of grease, for normal attachment took place with rods that had been washed with ether in a Soxhlet apparatus.

RESULTS

The results will be expressed in terms of the "fractional release" (F), which is defined as the fraction of the total attached inert-gas activity that has been released at a given stage of an experiment. Figs. 1A and 1B give typical curves for fractional release as a function of time. Note how, at a given temperature, activity at first came off rapidly, but its rate of release soon decreased, so that a comparatively level region (i.e. a "plateau") resulted. The plateau effect was less well developed with the niobium than with the other solids.

The initial release of inert-gas activity is seen from Figs. 1A and 1B to be so rapid that, at any given temperature, much of the activity was released in a time which was comparable to *each* of the following: (i) the time to bring the specimens up to temperature (2 to 3 minutes), (ii) the time taken by the activity to move through the vacuum system to the gamma counter (1 to 2 minutes), (iii) the duration of each gamma count (1 minute). As a result, the activities measured during the first 5 to 10 minutes that a specimen was held at a given temperature were probably low, and curves of F-versus-time would be difficult to analyze theoretically.

An alternative way of treating the data, which avoids the effect just described, is to plot fractional release after a fairly long time (e.g. 30 minutes) against temperature; Figs. 2A, 2B, and 2C. A number of conclusions can be drawn from Figs. 2A, 2B, and 2C.



(i) The release phenomenon is reproducible.

(ii) In general, release proceeds linearly over a wide range of temperature. There is a slight deviation from linearity at high temperatures with the oxides, and a much greater deviation with niobium, though the exceptional behavior of niobium is possibly due to the fact that part of the niobium surface is sufficiently oxidized to behave as Nb_2O_5.

(iii) In the two cases where argon and xenon are both used with a given solid (Nb and TiO_2), indistinguishable release behavior is observed. If it is borne in mind that xenon adsorbs much more strongly than argon (2), this observation leads to the conclusion that

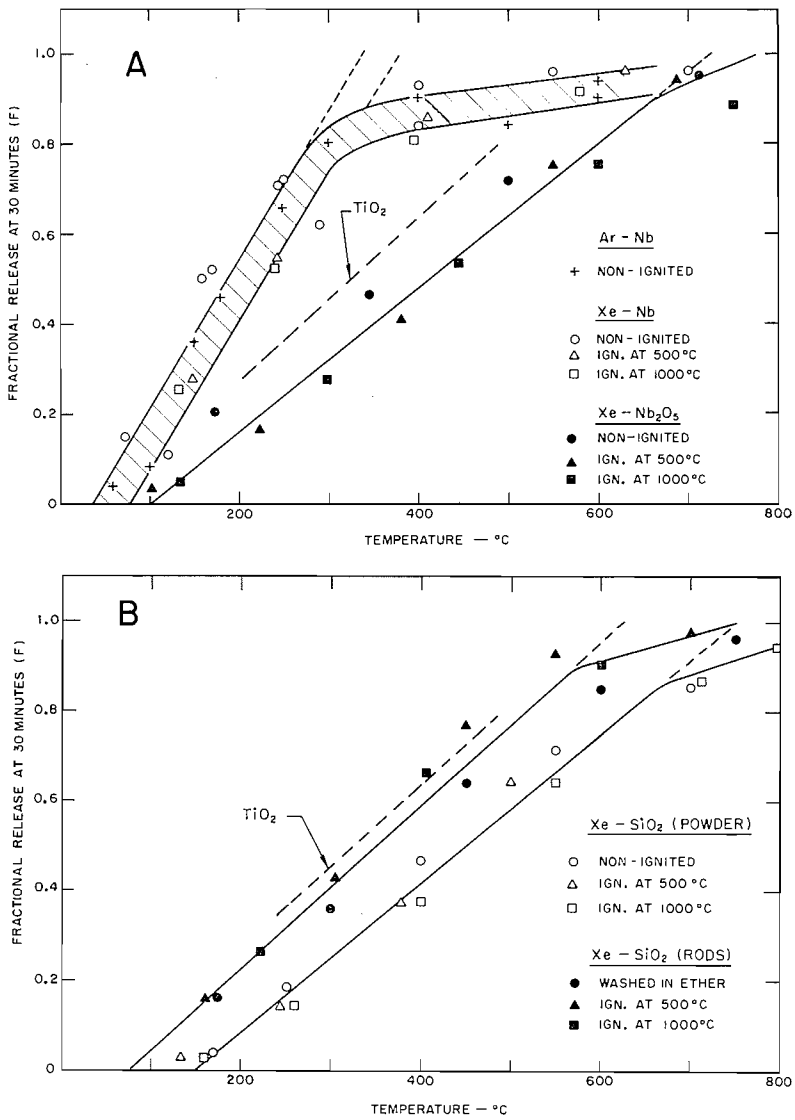
FIGS. 1A and 1B. Fractional release as a function of time for ^{125}Xe activity that has become attached to various solids following (n,γ) events. Selected points from typical experiments are shown for each solid. In each experiment the temperature was raised rapidly (i.e. within 2 to 3 minutes) to a given value, was held constant to within $\pm 0.5°$ C for at least 30 minutes, and was then raised to the next value indicated.

release *is not* a desorption phenomenon, and is therefore presumably an example of diffusion.



(iv) Within the limits of the experimental scatter, there is no pronounced difference in the release behavior between solids in an as-received and ignited condition. This may be taken as evidence that release *is not* due to a recrystallization, sintering, or other alteration of the solid surface that might take place during an experiment. Once again release could be due to diffusion. (The release of I_2 from irradiated TeO_2 at elevated temperatures is an example where sintering is important (3).)

(v) The two forms of SiO_2 and TiO_2 give somewhat different results. Presumably the surface structures are different.

The main error associated with Figs. 2A, 2B, and 2C arises from the fact that each specimen was studied at a series of successively higher temperatures, yet the data at a given temperature were treated without regard to previous heatings. The justification for the procedure followed lies in the nature of the F-versus-time behavior: much of the activity ultimately released at a given temperature comes out in a few minutes; at a

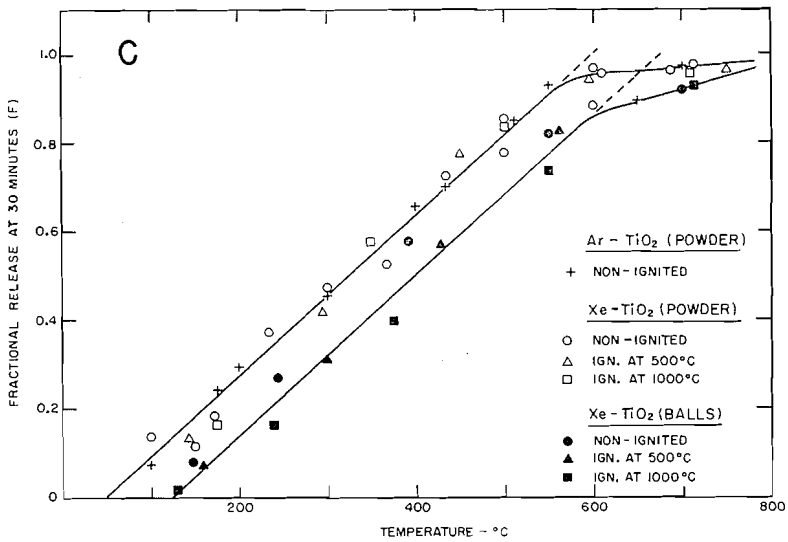

FIGS. 2A, 2B, and 2C. Fractional release at 30 minutes as a function of temperature for ^{41}Ar and ^{125}Xe activities that have become attached to various solids. All results are shown. The curve for niobium is given a second dimension because the results are particularly scattered. The position of the curve for powdered TiO_2 is indicated in Figs. 2A and 2B for comparison.

higher temperature this same activity would therefore have come out in a time appreciably less than a few minutes, and the time scale at the higher temperature would be in error only to this extent.

DISCUSSION

(A) THEORETICAL

It has been shown that the release at elevated temperatures of inert-gas activity that has become attached to a solid is characterized by a plateau effect when F is plotted versus time, and by a wide temperature range when F (at 30 minutes) is plotted versus

"FIG. 2C."

temperature. Moreover, this release is reproducible and is probably due to diffusion. There follows an attempt to explain the release behavior theoretically using the concepts of diffusion theory.

General Considerations

The first step in a diffusion calculation is to decide on the differential equation governing the diffusion. Consider a solid containing diffusing material such that the concentration changes in only one direction. This change in concentration will be referred to as a *gradient*, although the concept "gradient" is not strictly applicable in a discontinuous medium such as a solid. Regard the diffusing material as residing in successive lattice planes located at intervals of λ along the gradient, there being $M(r\lambda,t)$ atoms per unit area at time t in the rth plane. Let τ be the mean time an atom of diffusing material stays in a given site (not *plane*) before jumping to a new site, and β be the probability that a jump will be into a new plane. Assume for the sake of simplicity that, for all jumps of significant probability, τ and β have the same values, while r changes by only 0 or 1 unit. The increment of $M(r\lambda,t)$ in time interval Δt, $\Delta t \ll \tau$, can then be written as follows (cf. references 4 and 5):

$$M(r\lambda,t+\Delta t) = \left(1-\frac{\Delta t}{\tau}\beta\right)M(r\lambda,t)+\frac{\Delta t}{\tau}\cdot\frac{\beta}{2}\{M[(r-1)\lambda,t]+M[(r+1)\lambda,t]\}$$

$$r = 0, \pm 1, \pm 2, \pm 3, \ldots .$$

This difference equation can be simplified in two ways. If $M(r\lambda,t)$ varies slowly with r, i.e. the gradient is always low, it yields the well-known partial-differential equation

$$[1] \qquad \frac{\partial M(x,t)}{\partial t} = \frac{k\lambda^2}{2}\cdot\frac{\partial^2 M(x,t)}{\partial x^2},$$

where $k \equiv \beta/\tau$ is the "diffusion rate constant", i.e. the rate at which diffusing material jumps along the gradient; $k\lambda^2/2 = \beta\lambda^2/2\tau$ is the "diffusion coefficient" (D); and x is the distance along the gradient. The quantity $r\lambda$ has been replaced with x to emphasize the fact that equation [1] is defined continuously in the space co-ordinate. If, on the other hand, no restrictions are placed on the gradient, a less complete reduction is obtained:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$[2] \qquad \frac{dM(r\lambda,t)}{dt} = -kM(r\lambda,t)+\frac{k}{2}\{M[(r-1)\lambda,t]+M[(r+1)\lambda,t]\}$$

$$r = 0, \pm1, \pm2, \pm3, \ldots .$$

It follows from the relation $k\lambda^2/2 = D$ that, in so far as D can be written $D_0\exp(-\Delta H/RT)$ (cf. reference 4), so k can be written

$$[3] \qquad k = k_0 e^{-\Delta H/RT}.$$

The quantity ΔH is the activation *energy* of diffusion, or, more properly, the activation *enthalpy* of diffusion (6).

Diffusion of a Plane Source when the Gradient is Low

Consider firstly the low-gradient differential equation, i.e. equation [1]. To use this equation it is necessary to agree on a geometry. Note, in this regard, that inert-gas activity that becomes attached to a solid following (n,γ) events in the inactive gas will, in general, rest only a very few atom layers beneath the surface of the solid; therefore, no matter how irregular the solid is, it should be possible to regard the inert gas as constituting a plane source parallel to the surface of a semi-infinite medium. The plane-source solution of equation [1] can be obtained using the method of images (page 9 of reference 7):

$$[4] \qquad M(x,t) = \frac{M_0}{\sqrt{2\pi kt}}\left\{\exp\left[-\frac{(p-x/\lambda)^2}{2kt}\right]-\exp\left[-\frac{(p+x/\lambda)^2}{2kt}\right]\right\}$$

$$x \text{ and } p = 0, \lambda, 2\lambda, 3\lambda, \ldots ,$$

where M_0 is the source strength (amount/area), p is the position of the source beneath the surface of the solid in units of lattice planes of spacing λ, and x is distance from the surface. Although equation [4] defines $M(x,t)$ for all x and p, only those values of x and p which are integral multiples of λ are of interest. The fractional release now follows as

$$F = (1/M_0)\left\{M_0-\sum_{x=0}^{\infty} M(x,t)\right\},$$

or, if the sum is approximated by the first two terms in the Euler–Maclaurin sum formula (page 25 of reference 8),

$$[5] \qquad F \approx \frac{2}{\sqrt{\pi}}\int_{p/\sqrt{2kt}}^{\infty} e^{-u^2}du \equiv \operatorname{erfc}\frac{p}{\sqrt{2kt}}.$$

F as given by equation [5] is shown plotted as a function of kt (assuming that $p = 1$) in Fig. 3 and as a function of temperature in Fig. 4. It is apparent that equation [5] fails to reproduce the experimental behavior, both as regards the plateaus and also as regards the wide temperature range over which the diffusion is significant.

Diffusion of a Plane Source when the Gradient is Unrestricted

A possible reason for the lack of consistency between equation [5] and the experimental results lies in the assumption basic to equation [5] that the gradient is always low. As a matter of fact, the attached inert-gas activity is located very close to the surface of the

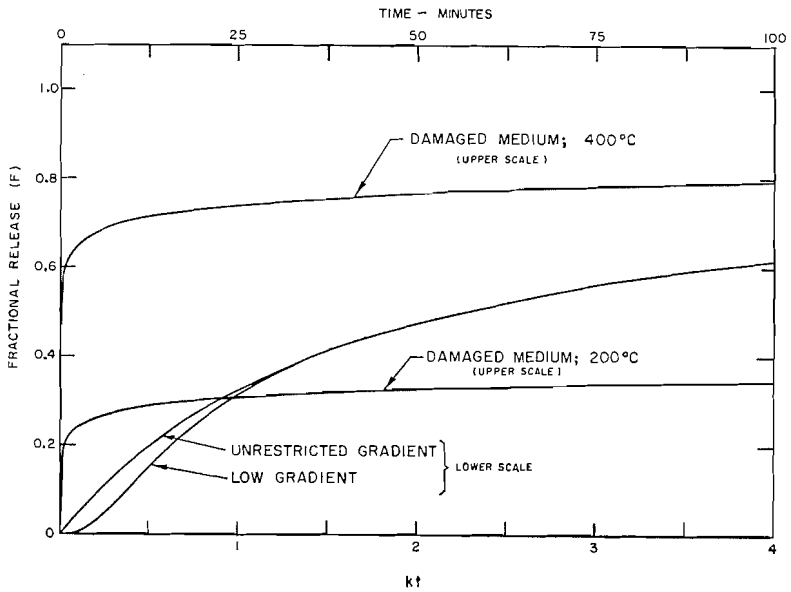

FIG. 3. Theoretical predictions of fractional release as a function of kt or time, derived assuming that the release is a diffusion phenomenon. Three cases are considered: (i) a plane source in a semi-infinite medium when the gradient is always low (equation [5] with $p = 1$), (ii) a plane source in a semi-infinite medium when the gradient is unrestricted (equation [7]), (iii) a source of unspecified nature located in a medium that is extensively damaged, and has composition anomalies, in the region between the source and the exterior (equations [10] or [11] with $k_0 = 10^{13}$ sec^{-1}, $\Delta H_1 = 25$ kcal, and $\Delta H_2 = 60$ kcal).

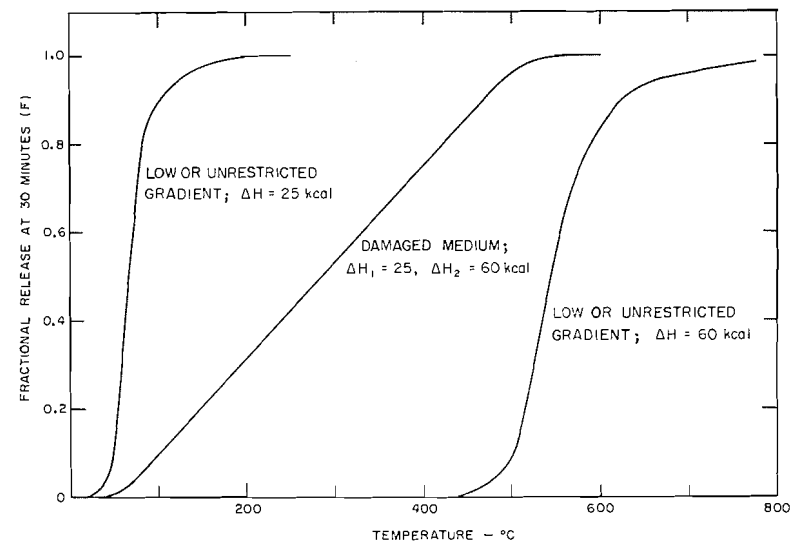

FIG. 4. Theoretical predictions of fractional release at 30 minutes as a function of temperature, derived assuming that the release is a diffusion phenomenon. The same three cases are considered as in Fig. 3, except that equations [5] and [7] have been plotted, not dimensionlessly, but with $k_0 = 10^{13}$ sec^{-1} and $\Delta H = 25$ *or* 60 kcal.

diffusion medium, where extremely high gradients are possible. As a further step in trying to explain the results, one should therefore examine the differential equation which holds for unrestricted gradients (equation [2]).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A solution of equation [2] in closed form has been obtained by Kennedy.[3] A description of the method, and a general comparison of solutions of equations [1] and [2], will be presented in a separate paper, so that for the present purposes only the final results need be given. As before, assume that the geometry can be represented by a plane source in a semi-infinite medium; then, one has corresponding to equation [4],

$$[6] \qquad M(r\lambda,t) = M_0 e^{-kt}\{I_{p-r}(kt) - I_{p+r}(kt)\}$$
$$r \text{ and } p = 0, \pm 1, \pm 2, \pm 3, \ldots,$$

where p is the position of the source in units of λ, r is distance from the surface in units of λ, and $I_n(z)$ is the modified Bessel function of the first kind (9). For integral n, $I_n(z)$ is given by

$$I_n(z) \equiv i^{-n} J_n(iz) = \sum_{u=0}^{\infty} \frac{(z/2)^{n+2u}}{u!(n+u)!}$$
$$I_n(z) = I_{-n}(z).$$

The equation corresponding to [5] is

$$F = (1/M_0)\left\{M_0 - \sum_{r=0}^{\infty} M(r\lambda,t)\right\}$$
$$= 1 - e^{-kt}\{I_0(kt) + I_p(kt) + 2[I_1(kt) + I_2(kt) + \ldots + I_{p-1}(kt)]\},$$

or, for a source located in the first lattice plane beneath the surface of the solid (i.e. $p = 1$),

$$[7] \qquad F = 1 - e^{-kt}\{I_0(kt) + I_1(kt)\}.$$

F as given by equation [7] is shown plotted as functions of kt and temperature in Figs. 3 and 4. The curves are very similar, especially for $F > 0.4$, to those obtained with equation [5], and, like the latter, fail to reproduce the experimental behavior.

Diffusion in a Medium with Damage and Composition Anomalies

A weakness of both equations [5] and [7] is that they neglect the fact that that portion of the solid lying between the attached inert-gas activity and the exterior will tend to be extensively damaged and to exhibit composition anomalies. The damage will be in part an inherent property of the solid surface (a crystal cannot be perfect near a surface), and in part the result of the forcible introduction of foreign material into the solid. Composition anomalies will include surficial oxide, hydroxide, and carbonate layers. It will be assumed that the primary consequences of the damage and composition anomalies are the following: (i) that the activation enthalpies in the solid between the attached inert-gas activity and the exterior occur as a spectrum rather than with a high, discrete value; (ii) that the spectrum lies below the bulk or ordinary activation enthalpy. Further details follow logically: the existence of a *spectrum* of activation enthalpies, coupled with the fact that the enthalpies are *low*, means that the diffusion will not be of the usual type where there is random motion, but rather of a modified form where the release of each inert-gas atom is dependent on *a single rate-controlling jump*. The existence of one-step motion, in turn, means that no assumption about the geometry is necessary.

It should perhaps be pointed out that the assumption that the enthalpy spectrum lies below the bulk enthalpy is reasonable only if damage is the main effect leading to a spectrum. Composition anomalies could give rise to a spectrum extending *above* the bulk

enthalpy with substances that hold inert gas *less* strongly than the corresponding altered surface layers. Niobium is probably an example of such a substance, since it holds inert gas less strongly than Nb_2O_5 (Fig. 2A). The treatment that follows will, accordingly, be more nearly applicable to systems with very high activation enthalpies, for example, those involving Nb_2O_5, SiO_2, and TiO_2. A high enthalpy is less likely than a low one to be increased by an alteration of the solid surface. (That there should be a difference between substances like niobium, on the one hand, and the oxides, on the other hand, is consistent with the anomaly previously noted for niobium (heading (ii) in Results).)

Diffusion under the conditions of the highly simplified motion described above is governed basically by equation [2]. The equation will, however, lack the terms for interplanar migration, so that one is left with

$$dM_H/dt = -kM_H, \tag{8}$$

where M_H is the amount of diffusing material at time t experiencing an activation enthalpy ΔH. If the initial value of M_H is $M_H{}^0$, the solution of equation [8] can be written

$$M_H = M_H{}^0 e^{-kt},$$

whence, making use of equation [3],

$$\begin{aligned} F_H &= (1/M_H{}^0)(M_H{}^0 - M_H) = 1 - e^{-kt} \\ &= 1 - \exp(-k_0 t e^{-\Delta H/RT}). \end{aligned} \tag{9}$$

Now introduce the fact that ΔH varies between a minimum, ΔH_1, and a maximum, ΔH_2. While the actual distribution of ΔH is an experimental unknown, it will be sufficient as a first approximation to assume that all values are equally weighted. Also, the dependence of k_0 on ΔH will be neglected (for sinusoidal vibrations of low amplitude, $k_0 \propto \sqrt{\Delta H}$ (5)). Hence, the over-all value for the fractional release is

$$\begin{aligned} F &= \frac{1}{\Delta H_2 - \Delta H_1} \int_{\Delta H_1}^{\Delta H_2} F_H d\Delta H \\ &= 1 + \frac{RT}{\Delta H_2 - \Delta H_1} \{-\mathrm{Ei}(-k_0 t e^{-\Delta H_1/RT}) + \mathrm{Ei}(-k_0 t e^{-\Delta H_2/RT})\}, \end{aligned} \tag{10}$$

where $-\mathrm{Ei}(-z)$ is the exponential integral (9),

$$-\mathrm{Ei}(-z) \equiv \int_z^\infty \frac{e^{-u}}{u}\, du = -\ln \gamma z + \frac{z}{1 \cdot 1!} - \frac{z^2}{2 \cdot 2!} + \cdots$$

$$\gamma = 1.781 \ldots .$$

To use equation [10], it is desirable to simplify the exponential integrals. The experimental temperature range is necessarily *above* the temperature at which the most weakly bound inert-gas activity is readily released. It therefore follows from equation [9] that $k_0 t \exp(-\Delta H_1/RT)$ will be large and $-\mathrm{Ei}[-k_0 t \exp(-\Delta H_1/RT)]$ negligibly small. Similarly, the temperature range is necessarily *below* the temperature at which the most strongly bound inert-gas activity is readily released, so that one obtains

$$-\mathrm{Ei}(-k_0 t e^{-\Delta H_2/RT}) \approx -\ln \gamma k_0 t + \Delta H_2/RT.$$

Hence, for the experimentally interesting temperature range,

$$F \approx \frac{RT}{\Delta H_2 - \Delta H_1} \ln \gamma k_0 t - \frac{\Delta H_1}{\Delta H_2 - \Delta H_1}. \tag{11}$$

Equations [10] and [11] reproduce the experimental behavior very well indeed, especially with the systems involving oxides (cf. second paragraph in this section). They give plateaus when F is plotted as a function of time (Fig. 3). Moreover, they predict that, for a given value of t, F varies linearly with temperature over a range of temperature which is determined by the values of ΔH_1 and ΔH_2 (Fig. 4). (It is difficult to say whether the expected linearity of F-versus-ln t is also obeyed, because the first 5 to 10 minutes of activity release are perturbed by the effect described in Results.) One concludes that the treatment leading to equations [10] and [11] constitutes a reasonable explanation of the release behavior with which the present work is concerned.

It is perhaps well to restate the main assumptions underlying equations [10] and [11]: (i) the diffusion of inert-gas activity that has become attached near the surface of a solid involves a spectrum of activation enthalpies; (ii) the spectrum lies below the bulk activation enthalpy; (iii) there is approximately equal weighting in the spectrum.

The data of Figs. 2A, 2B, and 2C have been analyzed in terms of equation [11] and values of ΔH_1 and ΔH_2 obtained (Table I). In making the analysis, the deviations from

TABLE I

Activation enthalpies derived using equation [11]

System	ΔH_1* (kcal)	ΔH_2* (kcal)
Ar–Nb or Xe–Nb (powder)	22–28	42–53
Xe–Nb_2O_5 (powder)	25–32	67–85
Xe–SiO_2 (powder)	28–36	68–87
Xe–SiO_2 (rods)	23–30	60–76
Ar–TiO_2 or Xe–TiO_2 (powder)	22–28	58–74
Xe–TiO_2 (balls)	27–34	63–81

*The lower limits of ΔH_1 and ΔH_2 are obtained using the value $k_0 = 10^{11}$ sec^{-1}. The upper limits are obtained with $k_0 = 10^{15}$ sec^{-1}.

linearity in the high-temperature portions of Figs. 2A, 2B, and 2C have been disregarded (cf. heading (ii) in Results). Also, since equation [11] is not sufficiently sensitive to variation in k_0 to yield a value for this quantity, a wide, arbitrary range of values for k_0 was assumed. (Actually, it can be shown that the lower limit of k_0 reproduces the F-versus-ln t behavior somewhat better than does the upper limit.)

(B) General

The success of the theoretical treatment leading to equations [10] and [11] in explaining the observed release behavior of attached inert-gas activity suggests a number of points for discussion.

The Attachment Process

It was shown previously (1) that the attachment process is characterized by the following relations:

$$[12] \qquad \begin{cases} A \ll 1 \\ A_{Ar} > A_{Kr} > A_{Xe} \\ A_{oxide} > A_{metal} \text{ (approximate)}, \end{cases}$$

where A is the attachment efficiency, i.e. the ratio (inert-gas activity attached to target)/(total inert-gas activity). Moreover, it follows from general considerations that the value of A will be governed by the following effects:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(i) *Attachability*—the probability that an inert-gas atom is in a condition to become attached following neutron absorption.

(ii) *Epithermal release*—release that occurs when an inert-gas atom that has entered a solid as if to become attached is immediately expelled due to the existence of a transient epithermal region or hot-spot. Like the epithermal reactions of hot-atom chemistry, this effect would be independent of temperature.

(iii) *Diffusive release*—release that occurs when an attached inert-gas atom diffuses out of a solid after the system has thermalized.

It is of interest to determine whether the present work leads to a correlation between relations [12] and the effects just described.[4]

The relation $A \ll 1$ will obviously be a consequence of all three effects. However, there is some indication that the third effect, i.e. diffusive release, may be of major importance. The argument is based on the fact that the activation enthalpies occur as a spectrum rather than with a high, discrete value as in ordinary diffusion. Assuming that ΔH_1, the *apparent* lower boundary of the spectrum, is merely the minimum barrier height which will retain inert gas at the irradiation temperature, it follows that lower barriers exist, and that a considerable portion of the originally attached inert gas might have experienced such barriers and been subject to diffusive release.[5] Diffusive release also appears to be adequate to explain the relation $A_{\text{oxide}} > A_{\text{metal}}$, for, judging from the values of ΔH_2 for niobium and Nb_2O_5 (Table I), it would seem that attached inert gas is much more tightly bound in an oxide than in a metal.

The remaining relation, $A_{Ar} > A_{Kr} > A_{Xe}$, is probably a consequence of effects (i) and (ii). Diffusive release is ruled out on the basis of the fact that, since argon and xenon show a similar range of activation enthalpies with a given solid (cf. Figs. 2A and 2C), these gases should have comparable probabilities of diffusive release.

The Irradiation Temperature

It has been suggested that inert gas remains attached to a solid only if it experiences a sufficient barrier that it cannot diffuse out at the irradiation temperature. It should therefore be possible to identify the irradiation temperature as that temperature *above which* the rate of release of attached gas becomes significant, for example, the temperature obtained by extrapolating to $F = 0$ a plot of F-versus-temperature. Temperatures in the region of 50 to 150° C are thus indicated for the various solids used in the present work.

The Bulk Activation Enthalpy

The assumption was made earlier that, with certain reservations, the spectrum of activation enthalpies that characterizes the diffusion of attached inert gas lies beneath the bulk or ordinary value, ΔH_{bulk}. One therefore wonders if the upper limit of the spectrum, ΔH_2, is not actually identical with ΔH_{bulk}, i.e.

$$\Delta H_2 \approx \Delta H_{\text{bulk}}. \qquad [13]$$

[4]*A fourth effect, "ejective release", might also be suggested. This is the effect whereby, as the irradiation continues, the incoming inert-gas atoms tend to eject previously attached inert-gas atoms and thus give rise to saturation. That ejective release is not significant in the present work is shown by two facts: (i) saturation is not observed (p. 673 of reference 1), (ii) the number of penetrated atoms per unit area in the present work (about 0.0001 monolayer for xenon attaching to an empty quartz capsule when the xenon pressure is 700 mm, the neutron flux 10^{13}, the irradiation time 4 days, and the attachment efficiency 0.0002) is significantly less than the number required for saturation (about 0.1 monolayer for 200 ev ions (10)).*

[5]*The view that the spectrum of activation enthalpies really extends below ΔH_1 is substantiated by a preliminary experiment in which an Ar–TiO_2 mixture was irradiated for 30 seconds at liquid-nitrogen temperature: a factor of 2 increase in A was observed, and the ΔH spectrum extended down to about 10 kcal instead of the usual 22 to 28 kcal.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Equation [13] should be unaffected by the fact that ΔH_2 was obtained using irregular or poorly crystallized material, since ΔH_2 relates to a process occurring in a region only a few atom layers thick.

Comparison with Other Work

Carter and Leck (10) have recently described work quite closely related to the present work. They bombarded glass with inert-gas ions having energies in the region 80 to 500 ev (cf. Fig. 5 of reference 10), in other words, having the same sort of energies as occur in attachment. (If the attachment of inert-gas atoms is due to the recoil of the atoms following the emission of capture gamma rays, then energies in the region 70 to 210 ev will occur (page 671 of reference 1).) They then caused the inert gas to diffuse out by heating the glass to temperatures up to 350° C. It was concluded, as in the present work, that the diffusion was governed by a spectrum of activation enthalpies. The enthalpy spectrum was found to be the same for neon, argon, krypton, and xenon, to be approximately independent of the ion energy, and to be independent of the thermal history of the glass.[6]

Points of disagreement brought out by the work of Carter and Leck include the following. Carter and Leck assumed that the diffusive motion could be described in terms of a single rate-controlling jump only as an approximation, and did not argue, as in the present work, that a spectrum of activation enthalpies can lead naturally to single-jump motion. They observed a somewhat more restricted range of enthalpies (23 to 45 kcal) than was obtained in the present work for a comparable solid (26 to 68 kcal for SiO_2 rods). They suggested that the existence of a spectrum of enthalpies is attributable to the known heterogeneity of glass, whereas the present work indicates that it is a more general phenomenon, and is, in fact, probably a property of all surfaces.

Comparisons between the present work and ordinary diffusion studies are difficult due to the lack of data. One can point out, however, that the observation that argon and xenon show similar activation enthalpies with a given solid agrees in a general way with the results obtained in studies with silver. Thus ΔH is 33.6 kcal for Ar–Ag (11), 35.0 kcal for Kr–Ag (12), and 37.5 kcal for Xe–Ag (13).

ACKNOWLEDGMENTS

The assistance of Dr. J. M. Kennedy in helping to clarify some of the mathematical problems associated with this work is gratefully acknowledged.

[6] *A further indication of the close agreement between the present work and that of Carter and Leck lies in the numerical values obtained for the attachment efficiencies. Thus, Carter and Leck observed values of 0.08 to 0.2, depending on the ion energy (cf. the "sticking factors" given in Fig. 5 of reference 10). In reference 1, values of 0.001 to 0.14 were observed for various gases and solids.*

CONSTITUTION OF A GLUCOMANNAN FROM THE SAPWOOD OF SUGAR MAPLE (ACER SACCHARUM)[1]

G. A. ADAMS

ABSTRACT

A glucomannan containing D-mannose and D-glucose in a molar ratio of 7:3 has been isolated from sugar maple sapwood. Electrophorectic examination in acetate and borate buffers showed that the polysaccharide was essentially homogeneous. Methylation and hydrolysis of the glucomannan yielded the following *O*-methyl ethers:

2,3,4,6-tetra-*O*-methyl-D-glucose (1.1%),
2,3,4,6-tetra-*O*-methyl-D-mannose (2.3%),
2,3,6-tri-*O*-methyl-D-glucose (23.4%),
2,3,6-tri-*O*-methyl-D-mannose (65.9%),
2,3-di-*O*-methyl-D-glucose (2.6%),
2,3-di-*O*-methyl-D-mannose (2.7%).

These data in conjunction with periodate oxidation results and estimates of the degree of polymerization indicated that the glucomannan was composed of 25–27 hexose units linked $\beta(1 \rightarrow 4)$ in a linear structure. The chains were terminated predominately by D-mannose units; traces of D-xylose were present in terminal positions only and appeared to be part of the glucomannan molecule.

Although glucomannans from many coniferous woods have been extensively investigated (1), no comparable study of the glucomannans of the hardwoods has been made. The relatively small amount of glucomannan in hardwoods as compared with softwoods has probably contributed to the lack of attention directed to this component. Jones, Merler, and Wise (2) isolated a crude glucomannan from poplar wood which had a glucose:mannose ratio of 1:2 and was a relatively straight-chain polymer with mannose end groups. Hemicelluloses of similar composition have been isolated from Western red alder and madrona by Hamilton and Thompson (3) but their structures have not been determined. A procedure has been developed by Timell (4) for isolation of glucomannans from woody angiosperms and it has been applied to seven species of hardwoods. Detailed structural studies on the glucomannan of white birch (5) and red maple (6) showed that both were composed of approximately 70 glucose and mannose residues linked $\beta(1 \rightarrow 4)$ in linear molecules. The present paper reports the isolation and structural study of a glucomannan isolated from sugar maple sapwood.

Extraction of maple sapwood holocellulose with 24% aqueous potassium hydroxide removed a large proportion of the 4-*O*-methylglucuronoxylans and left the glucomannans in the residue. Further extraction of the residue with 17.5% sodium hydroxide containing 4% borate yielded a crude glucomannan containing also approximately 35% xylan and some galactose residues. Purification of the glucomannan was achieved by forming its insoluble barium hydroxide complex (7) and thereby reducing the xylan impurity to 22%. Precipitation with Fehling's solution caused only a slight change in the mannose: glucose ratio and reduced the xylose content to trace levels in the main fraction. Acid hydrolysis of the hemicellulose and chromatographic examination of the sugars showed glucose and mannose and only a trace of xylose. Unlike many of the glucomannans of softwoods (8, 9, 10, 11), the purified maple glucomannan contained no galactose.

The glucomannan showed a single sharp peak on electrophoresis in borate buffer but electrophoresis in acetate buffer showed a small moving peak in addition to the large stationary peak. Analysis of the materials separated by electrophoresis in acetate buffer

[1]*Manuscript received August 28, 1961.*
Contribution from the Division of Applied Biology, National Research Council, Ottawa 2, Canada.
Issued as N.R.C. No. 6542.

proved the small peak to be a xylan impurity; the main homogeneous component contained only glucose and mannose. The xylan impurity was not separated from the glucomannan by ultracentrifugation in borate or acetate buffer.

The fully methylated glucomannan was hydrolyzed and an aliquot of the methyl glycosides was analyzed by gas–liquid partition chromatography. The main portion of the methylated sugars was separated on a cellulose column and on paper sheets with the appropriate solvents. The results are given in Table I. The large proportion of

TABLE I

Methylated sugars from hydrolyses of methylated hemicellulose

Methylated sugar	R_g, solvent B	Yield, mg	%
2,3,4,6-Tetra-*O*-methyl-D-glucose	1.0	22	1.1
2,3,4,6-Tetra-*O*-methyl-D-mannose	0.96	45	2.3
2,3,6-Tri-*O*-methyl-D-glucose	0.69	450	23.4
2,3,6-Tri-*O*-methyl-D-mannose	0.63	1270	65.9
2,3-Di-*O*-methyl-D-glucose	0.32	50	2.6
2,3-Di-*O*-methyl-D-mannose	0.28	52	2.7
Di-*O*-methyl-glucose (unidentified)	0.36	15	0.8
2,3,4-Tri-*O*-methyl-D-xylose (?)	0.86	10	0.5

2,3,6-tri-*O*-methyl-D-mannose and 2,3,6-tri-*O*-methyl-D-glucose showed that most of the mannose and glucose units were joined by $1 \rightarrow 4$ glycosidic bonds in the hemicellulose. Negative specific rotations of both the original hemicellulose and its methylated derivative which changed to positive values on hydrolysis indicated a predominance of β linkages. The tetra-*O*-methyl sugars represented non-reducing end groups in the molecule, the ratio of tetra-*O*-methyl-D-mannose to tetra-*O*-methyl-D-glucose (2:1) showed that approximately two thirds of the molecules were terminated by D-mannose units, the remainder by D-glucose. The proportion of tetra-*O*-methyl sugars showed that there was one non-reducing end group for every 27 hexose units. In accord with this value is that of 29 hexose units per reducing end group as found by hypoiodite reduction. Estimation of molecular weight by a vapor pressure method showed that the fully methylated molecule contained approximately 25 units. Since there is only one terminal unit per 27 units (as shown by methylation data), it is apparent that the molecule is a straight chain of hexose units. The dimethyl sugars must have no structural significance and must have been the result of incomplete methylation and(or) demethylation.

On periodate oxidation the consumption of 1.0 mole of periodate per mole of anhydrohexose sugar was further evidence of $(1 \rightarrow 4)$ linked hexose units. Formic acid production of 0.083 mole per anhydro sugar unit indicated a chain length of 25 units in the good agreement with values provided by other methods. Examination of the periodate-oxidized hemicellulose by Smith's degradation procedure (12) yielded erythritol and glycerol as the only products and these must have originated from $1 \rightarrow 4$ linked hexose units and non-reducing terminal hexose units respectively. The ratio of erythritol to glycerol (27:1) provided a further measure of the degree of polymerization (D.P.) of the molecule and the value of 27 is in good agreement with those reported above.

The glucomannans isolated from hardwoods have a wide range of glucose-to-mannose content. Although the general pattern shows a preponderance of mannose over glucose, the glucomannans of elm and sugar maple as reported by Timell (4) had a mannose: glucose ratio of 0.5:1.0. This latter finding is in contrast to that for glucomannan of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

sugar maple reported in the present paper (mannose:glucose 7:3). Glucomannans of the coniferous woods have a relatively consistent composition with approximately three times as many mannose as glucose residues (6). It is becoming apparent that galactose may also be an integral part of the glucomannan molecule of softwoods. Galactose has not yet been reported in any hardwood glucomannans and the absence of this sugar may possibly distinguish the hardwood glucomannans from those of softwoods.

The glucomannan of maple sapwood contained approximately 25–27 hexose residues per molecule as compared with 70 residues as found in the glucomannans of white birch (5) and in red maple (6). This variation, which may be attributable to species difference, might also indicate that the glucomannans of the sapwood are smaller than those isolated from the entire woody structure. A further structural difference between the glucomannans of white birch (5) and red maple (6), as compared with that of sugar maple, is the termination of the two former molecules by D-glucose units while two thirds of the molecules of the latter are terminated by D-mannose units. The glucomannan of aspen is also terminated mainly by the D-mannose units (2).

The presence of a small amount of fully methylated D-xylose among the products of hydrolysis from the methylated maple hemicellulose indicated that D-xylose is an integral part of the glucomannan. The methylated xylose did not originate from the small amount of xylan impurity in the original polysaccharide otherwise it would have been 2,3-di-*O*-methyl-D-xylose. A similar association of D-xylose with the glucomannan of jack pine has been reported by Perila and Bishop (13), who obtained oligosaccharides containing xylose and glucose on enzymic hydrolysis. In the maple glucomannan the attachment of xylose is terminal but it is not possible to predict whether it terminates a molecule or is a single unit side branch.

Further work on a larger series of hardwood glucomannans will be necessary to establish not only their composition but also their fine structure and sequence of sugar units.

EXPERIMENTAL

All specific rotations are equilibrium values unless otherwise stated, melting points are corrected, and all evaporations were done at 35° C or less.

Paper Chromatography

Chromatographic separations were carried out using the following solvent systems (v/v):

(A) pyridine: ethyl acetate:water (2:1:2),
(B) methyl ethyl ketone: water: ammonia (100:50:3),
(C) ethanol: benzene: water: ammonia (47:200:14:1),
(D) *n*-butanol: ethanol: water (40:11:19).

Separations were made by the descending method on either Whatman No. 1 or No. 3 MM filter paper. Reducing sugars were located on the paper by the *p*-anisidine spray reagent (14); non-reducing sugar components were detected by silver nitrate and sodium hydroxide sprays (15).

Preparation of the Hemicellulose

A freshly cut log of sugar maple (*Acer saccharum*) was stripped of its bark and the sapwood portion was removed on a veneer lathe. After being air-dried for 48 hours, the thin sheets were passed through a Wiley mill. The milled wood was screened, and the fraction passing through 40 mesh and retained on 100 mesh was used. This wood fraction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

was extracted with benzene:ethanol (2:1) for 24 hours, then with ethanol (8 hours), and was dried in air. Extraction with water at room temperature yielded a mixture of water-soluble polysaccharides (0.5%). From the extractive-free wood (1 kg) chlorite holocellulose was prepared (16) in 82.3% yield. Holocellulose (413 g) was stirred in 24% aqueous potassium hydroxide solution (4100 ml) for 6 hours at room temperature in an atmosphere of nitrogen. After filtration the residue was re-extracted once more and then washed with water. While still wet the residue was extracted as above with 17.5% sodium hydroxide containing 4% boric acid (4). The crude hemicellulose was recovered by adding the alkaline extract (9 l.) to the ethanol (24 l.) containing acetic acid (2.4 l.). The precipitate was washed thoroughly with ethanol (80%), the residual ethanol was removed by evaporation, and the crude polysaccharide was recovered by freeze drying (16.5 g). The glucose:mannose:xylose ratio in the polysaccharide was approximately 1:2.5:2 and there was a small amount of galactose present. The sugars were determined by the phenol sulphuric acid method (17).

Purification of the Crude Glucomannan

Crude glucomannan (15 g) was dissolved in 10% sodium hydroxide (750 ml) and 5% barium hydroxide solution (1250 ml) was added slowly with constant stirring over a period of 3 hours. The precipitate that formed was removed by centrifuging, washed twice with water acidified with acetic acid, and poured into ethanol (4 liters). The hemicellulose was recovered by centrifuging, dialysis, and freeze drying. Yield, 8.1 g. The glucose:mannose:xylose ratio was approximately 1:2.5:1.

Further purification of the glucomannan was achieved by forming a series of copper complexes through stepwise addition of Fehling's solution. The complexes were washed sparingly with water, in which they were soluble, dissolved in cold *N* hydrochloric acid, and poured into 5 volumes of ethanol to recover the hemicelluloses. Chromatographic examination of the fractions showed that each contained some xylose in addition to glucose and mannose. Further copper complexing yielded another series of fractions; of these, approximately 60% were pure glucomannans. Galactose and traces of arabinose and rhamnose were in the non-complexing material.

The hemicellulose had $[\alpha]_D^{25} = -24°$ (*c*, 0.76% in 0.5 *N* sodium hydroxide). Hydrolysis for 12 hours with *N* sulphuric acid and examination of the sugars by paper chromatography in solvents A and D showed the presence of glucose, mannose, and trace of xylose. Quantitative determination of sugars (17) in the acid hydrolyzate gave mannose: glucose 7:3. The more accurate method provided by gas–liquid chromatography of the fully methylated sugar as described by Adams and Bishop (18) gave the same value.

Examination of the hemicellulose in 0.05 *M* borate buffer by moving boundary electrophoresis carried out in a Spinco Model H apparatus showed a single peak indicating homogeneity of the polysaccharide. Similar examination in acetate buffer (pH 5.2) (ionic strength 0.2) showed two peaks, a main large stationary peak and a small moving one. Analysis of the separated materials after a migration time of 1020 minutes showed that the large peak represented the glucomannan while the moving peak represented the xylan. Centrifugation of both the borate and the acetate solutions in a Spinco Model E ultracentrifuge at 59,000 r.p.m. showed that each had only a single symmetrical peak. In a separate experiment using a mixture (50:50) of the glucomannan and the acidic xylan it was found that only electrophoresis in acetate buffer gave any separations; no separation was effected in the ultracentrifuge in either borate or acetate buffer.

Periodate Oxidation

Duplicate samples of the hemicellulose (100 mg) were dissolved in water (50 ml) and oxidized by 0.1 *M* sodium metaperiodate (50 ml) in the dark at room temperature. Suitable reagent blanks were prepared under the same conditions. Analyses were made for periodate consumption and formic acid production (19). The results given in moles per mole anhydrohexose unit were as follows.

Time, hours	24	48	72	96	168	216
Periodate consumption	0.57	0.71	0.90	0.91	0.98	0.99
Formic acid production	0.038	0.053	0.064	0.067	0.077	0.083

In a separate experiment the glucomannan (1.0 g) was oxidized by 0.1 *M* sodium metaperiodate (200 ml) at 15.6° C for 23 days. Barium acetate (0.5 *M*) (100 ml) was added to precipitate the iodate and excess periodate, which were removed by filtration. The filtrate was deionized by Amberlite IR-45 and IR-120. Potassium borohydride (1.0 g) was added and the reduction was allowed to proceed for 48 hours. The solution was neutralized with acetic acid, deionized with Amberlite IR-45 and IR-120, and evaporated to dryness several times with methanol. Acid hydrolysis of a portion of the residue and chromatographic examination of the hydrolyzate (solvent A and C) gave two components that were identical with erythritol and glycerol; no monosaccharides were found. Another portion of the hydrolyzate was dried thoroughly *in vacuo*, dissolved in pyridine (15 ml), and acetylated in acetic anhydride (5 ml) at room temperature for 36 hours. The acetylated polyols were examined directly by gas–liquid partition chromatography (8) (using 4′ apiezon M, 20% on celite 545, 197° C, 40 ml helium per minute). The acetates under examination had the same retention volumes as authentic samples of glycerol triacetate and erythritol tetraacetate respectively, and hence their identity was established. The ratio of erythritol to glycerol was 27:1.

Methylation of the Hemicellulose

Hemicellulose (5.0 g) was dissolved in 20% sodium hydroxide (60 ml) and methylated by dropwise addition of dimethyl sulphate (50 ml) and 45% sodium hydroxide (100 ml). The methylation procedure was repeated six more times. The partially methylated material was recovered by chloroform extraction of the neutralized solution, yield 6.8 g. The product was methylated once with Purdie's reagents using methyl iodide (100 ml) and silver oxide (11.5 g), yield 6.14 g, MeO, 35.6%. The product (6.1 g) was methylated by the Kuhn procedure (20) using dry dimethyl formamide (120 ml), methyl iodide (50 ml), and silver oxide (45 g), the solution being shaken for 48 hours at room temperature. The methylated hemicellulose was recovered by the described procedure (20), yield 3.80 g. Infrared spectroscopy showed the presence of hydroxyl groups. Methylation by Purdie reagents, repeated 3 times, gave a product having a methoxyl content of 44.3%, and no hydroxy bands in the infrared spectrum, yield 3.72 g. Fractionation from chloroform solution by addition of light petroleum gave a white product, wt. 3.60 g, $[\alpha]_D^{25}$ −16.3 (*c*, 1.04% in chloroform), methoxyl, 44.9% (theoretical for fully methylated hexosan 45.6%).

Methanolysis and Hydrolyses of the Methylated Hemicellulose

Methylated hemicellulose (1.93 g) was refluxed in 4% methanolic hydrogen chloride (45 ml) for 21 hours. After removal of the solvent the glycosides were hydrolyzed by heating for 20 hours in 0.5 *N* hydrochloric acid. The acid was neutralized with silver carbonate and the methylated sugars were recovered as a syrup (1.91 g).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

A small portion of the glycoside mixture was examined by gas–liquid partition chromatography (21). The molar ratio of tetra-, tri-, and di-*O*-methyl glycosides was 2:50:3. The ratio of 2,3,4,6-tetra-*O*-methyl-D-mannose to 2,3,4,6-tetra-*O*-methyl-D-glucose was 2:1. Complete methylation of the mixture of tetra-, tri-, and di-methyl glycosides and re-examination of the glycosides by gas–liquid chromatography showed a ratio of tetra-*O*-methyl-D-mannose to tetra-*O*-methyl-D-glucose of 7:3.

Separation of Methylated Sugars

The mixture of methylated sugars ($[\alpha]_D^{25}$ +13°, water) was separated on a cellulose column (38×3.3 cm) using solvent C with a flow rate of 10 ml/15 minute. The tetra-, tri-, and di-methyl fractions separated on the column were separated into their individual component sugars by chromatography on paper sheets using solvents B. The yields of methylated sugars with their R_g values are given in Table I.

Identification of Methylated Sugars

2,3,4,6-Tetra-O-methyl-D-glucose

The crude syrup was taken up in water and clarified with charcoal; its mobility on a paper chromatogram in solvent B and on electrophoresis in borate buffer was identical with authentic 2,3,4,6-tetra-*O*-methyl-D-glucose. The sugar (98.2 mg) was dissolved in methanol (5 ml), aniline (49 mg) was added, and the mixture was refluxed for 2 hours. Fine white needles separated which, on recrystallization from ethyl ether – light petroleum (b.p. 30–60°), yielded 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-glucosylamine, m.p. 136–137°, reported value 137–138° (22).

2,3,4,6-Tetra-O-methyl-D-mannose

The syrup had the same R_g value (0.96) in solvent B as an authentic sample of 2,3,4,6-tetra-*O*-methyl-D-mannose. The sugar (133 mg) was dissolved in methanol (5 ml), aniline (67 mg) added, and the mixture was refluxed for 2 hours. Slow removal of the solvent in a desiccator yielded crystals which were recrystallized from ethyl ether – light petroleum to give 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-mannosylamine, m.p. 144°, reported value 144–146° (2).

2,3,6-Tri-O-methyl-D-glucose

After clarification with charcoal, the sugar crystallized on slow evaporation of its solution in ethanol–water. Recrystallization from ethanol – ethyl ether – light petroleum yielded 2,3,6-tri-*O*-methyl-D-glucose, m.p. 121° C, $[\alpha]_D^{25}$ +70.0° (*c*, 1% in water); reported values m.p. 121–123, $[\alpha]_D$ +70.0° (23).

Preparation of the 1,4-di-*O*-*p*-nitrobenzoate yielded the crystalline derivative, m.p. 189–190°, recrystallized from methanol, $[\alpha]_D^{25}$ −34° (*c*, 1% in chloroform); reported m.p. is 189–190° (24).

2,3,6-Tri-O-methyl-D-mannose

This sugar had the same mobility on paper chromatograms (solvents B and D) as authentic 2,3,6-tri-*O*-methyl-D-mannose. The 1,4-di-*O*-*p*-nitrobenzoate derivative was prepared and after one recrystallization from methanol had a melting point of 187–188°; reported value 187–188° (24).

2,3-Di-O-methyl-mannose

Mannose was the only sugar found on demethylation with boron trichloride (25). On paper electrophoresis in borate buffer the sugar had the same mobility as 2,3-di-*O*-methyl-D-mannose. Examination by gas–liquid partition chromatography indicated the presence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of 2,3-di-*O*-methyl-D-mannose. The sugar was converted to its 1,4,6-tri-*O*-*p*-nitrobenzoate derivative, which, after several recrystallizations from methanol, had a melting point of 192°, reported value 194° (26).

2,3-Di-O-methyl-D-glucose

This sugar gave only glucose on demethylation (25). It had the same mobility on paper electrophoresis as 2,3-di-*O*-methyl-D-glucose and on examination by gas–liquid partition chromatography (8), its glycosides had a retention volume identical with that of the glycosides of 2,3-di-*O*-methyl-D-glucopyranose. The aniline derivative was prepared as described above and yielded crystalline 2,3-di-*O*-methyl-*N*-phenyl-D-glucosylamine, which, on recrystallization from ethyl acetate, had m.p. 132°; reported value 134° (27).

Other Methylated Sugars

In addition to the di-*O*-methyl sugars identified above, another dimethyl sugar was present in small amounts. It gave glucose on demethylation and, on chromatographic and electrophoretic examination, appeared to be either 2,4- or 2,6-di-*O*-methyl-D-glucose. A sugar having R_g 0.83 (solvent B) and giving a red color with *p*-anisidine spray was recovered in small amounts. On demethylation it gave xylose only. Chromatographic examination (solvent B and C) indicated that it may be 2,3,4-tri-*O*-methyl-D-xylose.

Estimation of Molecular Weight

Two methods were used: (i) end group determination by hypoiodite (28) and (ii) vapor pressure measurements (29, 30).

(i) Triplicate samples of the hemicellulose (100 mg) were dissolved in 2 *N* sodium hydroxide, and 0.1 *N* iodine (10 ml) was added. The solutions, along with suitable blanks, were kept in stoppered flasks in the dark for 2 hours. After acidification of the solution with 2 *N* sulphuric acid, the iodine was titrated with 0.05 *N* sodium thiosulphate. Number average molecular weights calculated from reducing power values were 4400–4700, which corresponds to a D.P. of 27–29.

(ii) The methylated hemicellulose was dissolved in benzene and the difference in vapor pressure between the pure solvent and the solution was measured at concentrations of 7.16, 5.67, 3.79, 1.95, and 1.48% (g/100 g solution) and extrapolated to infinite dilution. Calculation of molecular weight according to Raoults's law gave a value (number average) of 5450 and hence D.P. = 25.

ACKNOWLEDGMENTS

The author is indebted to Dr. A. F. Sirianni for the determination of molecular weight by his vapor pressure method; thanks are also due Mr. W. R. Rowsome for valuable technical assistance.

THE COMPOUNDS $KMnIO_6$ AND $NaMnIO_6$[1]

ILSE REIMER AND M. W. LISTER

ABSTRACT

Two compounds, originally formulated by Price as $Na_2Mn_2I_2O_{11}$ and $K_2Mn_2I_2O_{11}$ have been shown to be $NaMnIO_6.1/2H_2O$ and $KMnIO_6.1/2H_2O$. Consequently they are compounds of tetravalent manganese, a conclusion confirmed by their magnetic susceptibilities, and by their reactions with a variety of reducing agents; the reactions with ferrous ions, iodide ions, sulphur dioxide, hydroxylamine hydrochloride, and hydrazine hydrochloride were examined. Some of the properties of these compounds are described, and their X-ray powder diagrams show them to be analogous to the nickel salts $NaNiIO_6.H_2O$ and $KNiIO_6.1/2H_2O$.

In a relatively early paper, Price (1) described two complex periodates to which he gave the formulae $K_2Mn_2I_2O_{11}$ and $Na_2Mn_2I_2O_{11}$. Since periodates do not seem to form I_2O_{11} groups, these formulae seemed doubtful, a suspicion which was supported by the variable analyses reported in Price's paper. The present paper describes a re-examination of these compounds, which are shown in fact to be $KMnIO_6$ and $NaMnIO_6$, analogous to the nickel compounds $KNiIO_6$ and $NaNiIO_6$, prepared by Ray and Sarma (2). These compounds may contain a small amount of water of crystallization, being again similar in their behavior to the nickel compounds. It will be noticed that Price considered these to be compounds of trivalent manganese, while they are here formulated as containing tetravalent manganese; considerable evidence supporting this is given below.

PREPARATION OF COMPOUNDS

Price prepared these compounds by mixing manganous sulphate (or nitrate) in fairly strongly acidified solution with a similarly acidified solution of sodium or potassium periodate. He gave practically no details of quantities, so that the method described in the present paper is only approximately the same as his. The methods used by us were as follows.

Sodium Manganese (IV) Periodate

Manganese sulphate (8 g) monohydrate was dissolved in about 400 ml of water containing a few drops of sulphuric acid. Sixteen grams of sodium periodate, $Na_2H_3IO_6$, was dissolved in 600 ml of 0.75 *N* sulphuric acid. The solutions were mixed, whereupon a red precipitate gradually separated. The mixture was kept at 40° C for some hours, after which the mixture was filtered through a sintered-glass disk. The product was washed thoroughly with water, and dried over calcium chloride.

With the quantities used above, some manganese remained in solution, in agreement with the over-all equation

$$MnSO_4 + 2Na_2H_3IO_6 \rightarrow NaMnIO_6 + NaIO_3 + Na_2SO_4 + 3H_2O.$$

The quantities chosen were chosen partly to meet the requirements of Price's formula, and partly to avoid other complexes known to occur with excess sodium periodate (3). However, a better yield would probably be obtained with 2 gram-molecules of sodium periodate to 1 of manganese sulphate.

[1]*Manuscript received July 18, 1961.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.

Potassium Manganese (IV) Periodate

This was prepared similarly using potassium periodate, KIO_4, in somewhat more acid solution (2 to 3 *N* sulphuric acid). A red precipitate formed, which was filtered, washed, and dried, like the sodium salt.

Analysis

The compounds were analyzed as follows. The water of crystallization was determined by heating to constant weight at 110° C. The water was rapidly lost at this temperature, and no appreciable further loss was observed on heating the compounds to 150° C. Iodine was determined by suspending a weighed sample in water, and bubbling in sulphur dioxide till all was dissolved. Silver nitrate was added and the silver iodide was filtered off and weighed. After removal of excess silver by hydrochloric acid, the manganese was determined by adding excess ammonia, filtering off the manganese hydroxide, dissolving this in dilute sulphuric acid, and evaporating to dryness. The residue of $MnSO_4$ was weighed. It was found that the manganese hydroxide dissolved rather slowly in acid, but this was much speeded up by bubbling in a little sulphur dioxide. Sodium or potassium were determined by acidifying the filtrate with sulphuric acid and evaporating it to dryness. Any sodium bisulphate in the residue was removed by adding ammonium carbonate and a little water, and again evaporating to dryness. In some samples the manganese was precipitated as manganese ammonium phosphate and ignited to $Mn_2P_2O_7$; the alkali metal was then found in a separate sample.

Results of the analyses were as follows.

Sodium salt.—Na 8.00, 7.84%; Mn 18.01, 17.87%; I 40.65, 39.8%, H_2O 3.3%. Calculated for $NaMnIO_6.1/2H_2O$: Na 7.42%, Mn 17.72%, I 40.95%, H_2O 2.9%.

Potassium salt.—K 12.24, 13.05%; Mn 16.32, 17.31%; I 39.59, 39.58%, H_2O 4.3%. Calculated for $KMnIO_6.1/2H_2O$: K 12.00%, Mn 16.86%, I 38.93%, H_2O, 2.8%.

These analyses do not, of course, settle the question of the valency of the manganese, since formulae such as $KHMnIO_6.1/2H_2O$ are sufficiently close in composition as to be indistinguishable. The evidence for tetravalent manganese is given in the next section.

VALENCY OF MANGANESE

This was determined from measurements of (i) oxidation equivalents and (ii) magnetic susceptibilities.

1. Oxidation Equivalents

The substances are too insoluble in water to titrate directly, but they react with excess acidified ferrous ammonium sulphate, and the excess can be titrated with potassium permanganate. Since ferrous ions reduce periodate to iodate ions, a formula with tetravalent manganese would require reduction by four ferrous ions per molecule; trivalent manganese would require reduction by three ferrous ions. The results obtained were as follows.

Sodium salt.—Equivalent weight 78.1. Calculated for $NaMnIO_6.1/2H_2O$ 77.5; $NaHMnIO_6.1/2H_2O$ 103.7.

Potassium salt.—Equivalent weight 85.9. Calculated for $KMnIO_6.1/2H_2O$ 81.5; $KHMnIO_6.1/2H_2O$ 109.0.

These results support a formula with tetravalent manganese.

A second equivalent weight can be obtained by adding a known weight of compound to acidified potassium iodide, and titrating the liberated iodine with sodium thiosulphate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In this case tetravalent manganese will give 10 equivalents per molecule; trivalent manganese will give 9. The results were as follows.

Sodium salt.—Equivalent weight 31.7, 32.6. Calculated for $NaMnIO_6.1/2H_2O$ 31.0; $NaHMnIO_6.1/2H_2O$ 34.6.

Potassium salt.—Equivalent weight 33.2. Calculated for $KMnIO_6.1/2H_2O$ 32.6; $KHMnIO_6.1/2H_2O$ 36.3.

These results also support a formula with tetravalent manganese.

It had been found (3) with similar compounds that a check on the formula could be obtained by bubbling in sulphur dioxide, and after boiling out the excess sulphur dioxide, titrating the acid formed with sodium hydroxide. Bromcresol green was used as indicator to avoid any precipitation of manganese. However, with the present compounds the results were found to be rather variable, and the equivalent weight was always lower than that calculated even for tetravalent manganese. The results were as follows.

Sodium salt.—Equivalent weight 37.9, 36.1. Calculated for $NaMnIO_6.1/2H_2O$ 38.7; $NaHMnIO_6.1/2H_2O$ 44.4.

Potassium salt.—Equivalent weight 36.1, 37.2, 34.5. Calculated for $KMnIO_6.1/2H_2O$ 40.7; $KHMnIO_6.1/2H_2O$ 46.7.

Hence more acid is formed than would be expected; possibly there is some air oxidation of the sulphur dioxide. So far as they go, the results support tetravalent rather than trivalent manganese.

The reactions with two other reducing agents that might similarly produce acid were investigated. Firstly, hydroxylamine hydrochloride was tried, which was found to react with potassium periodate, KIO_4, producing 4 gram-molecules of acid from 1 gram-molecule of potassium periodate:

$$KIO_4 + NH_3OHCl \rightarrow KI + 2N_2O + 6H_2O + 4HCl.$$

Note that this requires oxidation to nitrous oxide. Sodium manganese (IV) periodate also oxidized hydroxylamine hydrochloride, but produced 3.51 gram-molecules of acid from 1 gram-molecule of the complex salt; potassium manganese (IV) periodate produced 3.58. The expectation was 3 gram-molecules (a formula with Mn(III) would give 2.5 gram-molecules of acid):

$$2KMnIO_6 + 10NH_3OHCl \rightarrow 2KI + 2MnCl_2 + 5N_2O + 17H_2O + 6HCl.$$

However, if the nitrogen of the hydroxylamine was converted to elementary nitrogen, the expectation would be 8 gram-molecules, and the most probable conclusion is that the manganese gives some oxidation to nitrogen as well as to nitrous oxide. The closeness of the result to $3\frac{1}{2}$ is probably accidental.

Similarly hydrazine hydrochloride reacts (a little slowly) with potassium periodate thus:

$$KIO_4 + 2N_2H_5Cl \rightarrow KI + 2N_2 + 4H_2O + 2HCl,$$

the amount of acid produced exactly agreeing with this equation. This led to the expectation that 0.5 gram-molecule of acid would be produced by 1 gram-molecule of sodium manganese (IV) periodate (Mn(III) would give 0.25 gram-molecule):

$$2NaMnIO_6 + 5N_2H_5Cl \rightarrow 2NaI + 2MnCl_2 + 5N_2 + 12H_2O + HCl.$$

However, it was found that addition of the complex salt to a solution of hydrazine hydrochloride (adjusted to the neutral point of bromcresol green or methyl orange) made the solution alkaline, and it remained so even on boiling. If acid was added till the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

neutral point of the indicator was again reached, the solution produced more acid spontaneously, and this was then titrated with sodium hydroxide. The total effect was that 1 gram-molecule of the complex salt did in fact produce nearly 0.5 gram-molecule of hydrochloric acid: $NaMnIO_6$ gave 0.61 gram-molecule, and $KMnIO_6$ gave 0.51 gram-molecule of acid. There is evidently a slow stage in the reaction which is catalyzed by acid. Hence both the reactions with hydroxylamine hydrochloride and hydrazine hydrochloride, though not too clear cut, support a formula with tetravalent manganese.

2. Magnetic Susceptibilities

The magnetic susceptibilities of the compounds were measured on a Goüy balance at room temperature. The balance was calibrated with ferrous ammonium sulphate. The observed susceptibilities were: $NaMnIO_6.1/2H_2O$, 23.42×10^{-6} e.m.u./g at 24.8° C; $KMnIO_6.1/2H_2O$, 18.20×10^{-6} e.m.u./g at 22.5° C. If the compounds obey Curie's law, these results make the magnetic moments: sodium salt 4.17 Bohr magnetons; potassium salt 3.76 Bohr magnetons. These are evidently close to the calculated 'spin only' value of 3.87 Bohr magnetons for three unpaired electrons, which would be present in manganese (IV).

PROPERTIES OF COMPOUNDS

The sodium and potassium salts are both red microcrystalline solids. They are virtually insoluble in water, the solubilities not being above 10 mg/liter at room temperature. Consequently no absorption spectrum in solution could be obtained. As mentioned in the description of the analysis, they readily lose their water of crystallization at 110° C, but the anhydrous salts are stable up to a much higher temperature: no decomposition was apparent at 230° C, though iodine vapor was evolved at a red heat. They show no tendency to decompose in water to give permanganate ions, as the complex salts containing more periodate do (3); this is true of suspensions either in water or alkali: in neither case was any reaction apparent on prolonged standing.

STRUCTURE OF COMPOUNDS

Debye–Scherrer X-ray diffraction photographs were obtained from the powdered compounds in the usual way. Similar photographs for $NaNiIO_6.H_2O$ and $KNiIO_6.1/2H_2O$ were obtained at the same time. The nickel compounds were prepared by the method

given in *Inorganic syntheses* (4). It may be mentioned in passing that while these hydrated formulae are given for the nickel compounds, the reported analyses are closer to the anhydrous salts, especially for the potassium compound. This is doubtless due to the relatively weak attachment of the water, as with the manganese compounds. The object of the present X-ray work was to demonstrate a similarity between the manganese and nickel compounds, which would be expected from their formulae; it is hoped to obtain a more detailed picture of their structure shortly. The values of the interplanar spacings, calculated from the observed lines, are given in Table I. These were obtained using copper K_α X-rays, and a camera of 114.6-mm diameter. The patterns for the corresponding manganese and nickel compounds show considerable similarity, and there can be little doubt that the compounds are isomorphous. This also supports the view that tetravalent manganese is present. The interplanar spacings are not far from what would be calculated for a cubic unit cell, particularly in the case of the potassium salts. This suggests that both the metal and iodine atoms are octahedrally co-ordinated to the oxygen atoms, giving a polymerized structure that would explain the insolubility of these compounds.

REACTION OF OXYGEN ATOMS WITH BENZENE[1]

G. Boocock[2] and R. J. Cvetanović

ABSTRACT

The reaction of benzene with oxygen atoms produced by mercury photosensitized decomposition of nitrous oxide has been studied in a circulating system at room temperature. The main reaction product is a non-volatile material probably largely aldehydic in character. This is tentatively assumed to result from the rearrangement and polymerization of the initially formed adduct. Smaller amounts of phenol and carbon monoxide are also formed. The rate of formation of carbon monoxide decreases with increasing pressure, suggesting an energy-rich precursor.

Oxygen atoms react with benzene much more slowly than with olefines. At 120° cyclopentene reacts about 150 times more quickly than benzene. The activation energy of the reaction of oxygen atoms with benzene has been estimated at 4.6 to 4.9 kcal/mole, with an uncertainty of about 0.7 kcal/mole.

INTRODUCTION

Reactions of a number of unsaturated hydrocarbons with oxygen atoms generated by the mercury photosensitized decomposition of nitrous oxide have been studied in some detail in this laboratory, but attention has previously been concentrated on alkenes and cycloalkenes (1–3). The present investigation is a further stage in these studies and has been undertaken in an attempt to derive some information on the attack of ground state oxygen atoms on an aromatic nucleus. Unfortunately, the major part of the reaction product, a polymeric material of low volatility, could not be characterized; only a fragmentary picture of the process has therefore been obtained. This is in sharp contrast to the relatively well-understood major features of the reactions of oxygen atoms with alkenes.

Early attempts to obtain approximate values of the rates of reactions of a number of compounds with oxygen atoms (4) led to the conclusion that benzene reacted very rapidly with oxygen atoms. In the present work, however, this reaction is found to be much slower than the corresponding reactions of alkenes. In view of the electrophilic character of oxygen atoms (3), this finding is not unexpected.

Several workers (4–7) have investigated the reaction of benzene with oxygen atoms generated in electrical discharges. Chu, Ai, and Othmer (8) used a flow system and generated oxygen atoms by electrical discharge in molecular oxygen. They obtained phenol yields of up to 13% per pass, in substantial agreement with the previous findings of Avramenko and co-workers (7). However, with water vapor instead of oxygen discharge they found no detectable amount of phenol although Avramenko *et al.* claimed yields of up to 27% under similar conditions.

The presence of other reactive species and the need to maintain relatively low over-all pressures seriously complicate the use of electrical discharges in molecular oxygen or in water vapor for fundamental studies of the reactions of oxygen atoms with organic compounds. Some of the potential complexities have been discussed elsewhere (8) in connection with a study of the reaction of oxygen atoms produced by electrical discharge in molecular oxygen with 1-butene.

[1]*Manuscript received May 31, 1961.*

[2]*National Research Council Postdoctorate Fellow 1957–1958. Present address: Shell Chemical Company, Carrington Research Laboratory, England.*

In the present work oxygen atoms were generated by the mercury photosensitized decomposition of nitrous oxide (9). At not too elevated temperatures nitrous oxide reacts extremely slowly with oxygen atoms in their ground state and with other free radicals. In the presence of benzene the process can be represented by the following reactions:

$$Hg(^1S_0) + h\nu\ (2537\ \text{Å}) \longrightarrow Hg(^3P_1), \quad [1]$$

$$Hg(^3P_1) + N_2O \longrightarrow N_2(^1\Sigma) + O(^3P) + Hg(^1S_0), \quad [2]$$

$$O(^3P) + C_6H_6 \longrightarrow \text{products}. \quad [3]$$

Depending on the quenching efficiency of benzene and on the relative pressures of benzene and nitrous oxide present, there may also be appreciable quenching of $Hg(^3P_1)$ atoms by benzene. However, Scott and Steacie (10) have investigated the mercury photosensitized reactions of benzene and found that appreciable reaction occurs only at higher temperatures. In agreement with this no products due to quenching by benzene have been detected in the present work. The amount of nitrogen formed in reaction [2] serves as an internal actinometer and is used as a measure of the number of oxygen atoms generated.

EXPERIMENTAL

A conventional vacuum apparatus was used, with stopcocks replaced by mercury cutoffs where necessary to prevent the absorption of hydrocarbons by tap grease. The cylindrical quartz reaction cells were 10 cm long and 5 cm in diameter. Early experiments were made in a system of approximately 450 ml in volume, which included an all-glass plunger-type circulating pump. Later, a second reaction cell was added. This was connected to the vacuum line through a metal "Hoke" valve and gave a reaction volume of about 200 ml.

The analysis line contained a Le Roy still (11), a pumped-down trap, and a diffusion pump delivering into a Töpler pump and thence into two gas burettes. One of these latter was greaseless and the other was connected to a small combustion furnace packed with copper oxide. Non-volatile polymeric products remaining in the reaction cells were either extracted by solvents or combusted to carbon dioxide, which was then measured. The low-pressure mercury vapor lamp was run at a constant current of 100 ma, and most experiments were made at 25° C.

Benzene (Nichols reagent grade) was dried over calcium hydride and given several bulb-to-bulb distillations, with rejection of light and heavy fractions on each transfer. It was stored over calcium hydride in a bulb closed by a mercury cutoff. Nitrous oxide (98%) (Matheson Co.) was purified by bulb-to-bulb fractionation. Cyclopentene (Phillips research grade) was passed through an activated alumina column to remove peroxide contamination and then further purified by bulb-to-bulb fractionation. All reactants were degassed before each run.

Nitrous oxide with benzene was irradiated for periods of between 10 minutes and several hours. The reactor was then cooled in liquid nitrogen and the non-condensable gases were collected for analysis by combustion and mass spectrometry. The condensed material was removed to the Le Roy still for fractionation, a process which was normally abbreviated in later experiments to a separation of nitrous oxide at $-80°$ C or $-120°$ C. The fractions of least volatility from the Le Roy still, including unreacted benzene, were subjected to a variety of analytical procedures.

RESULTS

Preliminary experiments showed that non-condensable gaseous products always contained some carbon monoxide but no significant quantities of hydrogen or methane. Spot tests (12) of the condensable products gave a positive reaction for phenol but showed absence of acetylene and formaldehyde. An opaque yellow film on the walls of the reaction cell and a pronounced decline in nitrogen production with time indicated the formation of important quantities of a non-volatile product. The amounts of carbon dioxide formed by combustion of this material proved it to be sufficient in quantity to be a major product of the reaction.

In order to determine more accurately the quantity of non-volatile product by combustion and subsequent measurement of the carbon dioxide evolved, a static reactor which could be heated to redness almost in its entirety was built. Several experiments were carried out with approximately equal initial concentrations of benzene and N_2O but with different irradiation times. The results are shown in Table I.

TABLE I

Effect of the extent of reaction on the ratios R_{CO}/R_{N_2}, $R_{CO_2}/6R_{N_2}$, and $-R_{C_6H_6}/R_{N_2}$ (temperature 25±2° C)

16	7.55	81.8	~200	80	44.4	0.177	n.d.	0.46

NOTE: n.d. = not determined.
[a]Any CH_4 present is neglected.

It is evident from Table I that within the investigated range R_{CO}/R_{N_2} is independent of the extent of reaction, as measured by the amount of N_2 produced. The amount of non-volatile material ($R_{CO_2}/6R_{N_2}$), on the other hand, appears to increase somewhat with increasing conversion. In three of the experiments in Table I, runs 14, 15, and 16, the consumption of benzene per oxygen atom consumed ($-R_{C_6H_6}/R_{N_2}$) has been determined. This was done by recovering the unreacted benzene and measuring it both manometrically and by G.L.C. At these relatively low partial pressures of benzene the number of moles of benzene consumed per gram-atom of oxygen was found to be considerably lower than unity. Comparison of runs 14 and 15 shows the benzene consumption under these conditions to be approximately independent of the extent of reaction.

The early experiments indicated that the production of carbon monoxide decreased as the over-all pressure in the system was increased, as shown in Table II, A. However, in these experiments the partial pressure of benzene was also varied. A separate series of experiments was therefore carried out in which the partial pressure of benzene and the extent of reaction were kept approximately constant. The results are shown in Table II, B, and in Fig. 1 and they confirm a distinct decrease in the carbon monoxide formation with increasing over-all pressure.

In order to obtain some quantitative information on the amounts of phenol formed, two runs were carried out with larger partial pressures of benzene and relatively long irradiations. In this manner high percentage conversions of benzene were avoided.

Yield of phenol in the reaction of oxygen atoms with benzene
(temperature 25±2° C)

Run	C_6H_6 (mm)	N_2O (mm)	ΔN_2 (μmole)	ΔC_6H_5OH (μmole)	$\frac{\Delta C_6H_5OH}{\Delta N_2}$	$\frac{-\Delta C_6H_5OH}{\Delta C_6H_6}$
19+20	~26	490	64.5	3.6±0.7	0.056±0.011	0.127±0.025
28	83.1	505	640	40±4	0.062±0.006	0.141±0.014

As shown in Table III, some 13% of the benzene consumed during the reaction was found to be converted to phenol. Although the amount of nitrogen produced in run 28 is about 10 times larger than in the combined runs 19 and 20, the amount of phenol formed per gram-atom of oxygen consumed is, within the analytical uncertainty, the same in the two cases.

The non-volatile polymeric material evidently represents the major product of the reaction of oxygen atoms with benzene. Attempts were made to obtain some information on the nature of this material, but with relatively little success. Carbon tetrachloride washings of the reaction cell after runs 27 and 28 were colorless, showed absorption peaks at 279, 272, and 267 mμ in the ultraviolet, and gave a positive reaction to both Brady's reagent and Schiff's reagent, the compound formed with Brady's reagent being soluble in carbon tetrachloride. The presence of aldehyde groupings in this fraction was thus strongly suggested. The reaction cell was subsequently extracted with acetone, which appeared to dissolve the bulk of the deep yellow component of the deposit. The ultraviolet absorption showed single sharp peaks at 323.5 mμ. An infrared spectrum of the acetone extract deposited on a KBr pellet showed a heavy general absorption with a set of broad peaks superimposed at 694, 757, 1225, 1490, 1591, 1667, 1705, 2860, and 3300

cm^{-1} suggestive of aliphatic rather than aromatic groupings. After careful removal of acetone, these extracts also gave, with Brady's reagent, a definite orange color extractable in carbon tetrachloride.

After extraction with carbon tetrachloride and acetone, combustion of the remaining material showed that the two solvents removed only about 50% of the polymeric deposit.

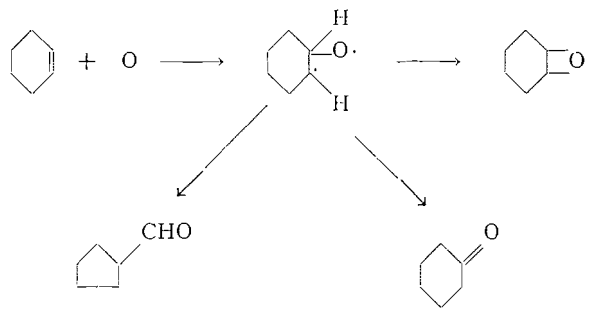
An approximate carbon balance can be obtained for runs 14 and 15 of Table I. Taking $100\ (R_{CO}+R_{CO_2})/6R_{C_6H_6}$ as an approximate measure of the carbon balance, a mean value of about 72% is arrived at. However, the phenol produced ought to be added to this figure. Table III shows amounts of phenol which on the basis of the benzene consumption in runs 14–16 would indicate that about 13 to 14% of benzene is converted to phenol. However, the data in Table III were obtained at much higher partial pressures of benzene and it is conceivable that the consumption of benzene, $-R_{C_6H_6}/R_{N_2}$, under such conditions is closer to unity. In view of this the mean carbon balance for runs 14 and 15 comes to about 75 to 85%. Deposition of non-volatile tarry material in the gas burette used for storing the volatile products, together with the characteristic odor, slight color, and positive reaction to Schiff's reagent of these, suggested that unidentified lower molecular weight products of a very reactive and possibly aldehydic nature were formed. Such products must have been responsible, at least partly, for the failure to obtain 100% carbon balance.

The rate constant of reaction of oxygen atoms with benzene (k_B) relative to that of cyclopentene (k_C) was determined by the competitive technique described in detail elsewhere (3). This technique is based on the measurement of the decline in ethylene production from the reaction of oxygen atoms with cyclopentene when another substance which consumes oxygen atoms is added. Early experiments showed that at room temperature cyclopentene reacted more than 200 times as fast as benzene. It was consequently very difficult to obtain quantitative competitive data. A number of determinations were therefore made at two higher temperatures and the mean values of k_C/k_B obtained were 152.6 ± 13.9 at 119.8° C, and 54.3 ± 4.6 at 220.4° C. The relatively large mean deviations resulted from the large disparity in the rates and from the use of small partial pressures of cyclopentene in order to maintain large benzene to cyclopentene ratios. High partial pressures of benzene were used (close to the saturation pressure at room temperature) and the assumption was made that, under these conditions and at the higher reaction temperatures of these experiments, oxygen atoms were consumed only in the primary attack on benzene and cyclopentene.* Using Arrhenius' equation, the mean values of k_C/k_B at the two temperatures give $E_C-E_B = 4.0$ kcal/mole and $A_C/A_B = 1.0$. It has been established (13) that $E_C-E_{TME} = 0.6$ kcal/mole (where the subscript TME stands for tetramethyl ethylene) and E_{TME} is probably quite small (perhaps not greater than 0.1 to 0.3 kcal/mole) so that $E_B = 4.6$ to 4.9 kcal/mole. The experimental uncertainty in this value is estimated from the mean deviations in k_C/k_B at the two temperatures at about ±0.7 kcal/mole.

DISCUSSION

Two modes of attack of atomic oxygen on benzene are possible: abstraction of a hydrogen atom or addition to the aromatic nucleus. Abstraction of a hydrogen atom would lead to the formation of a hydroxyl radical and a phenyl radical. Attack of benzene by hydroxyl would then be expected, with the subsequent production of diphenyl and phenol by radical association according to the following scheme (14).

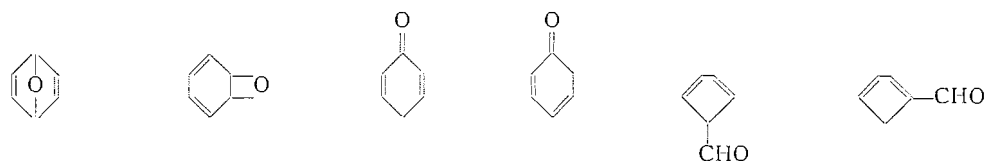
**A slight thermal reaction occurs at 220° C but this was found to be unimportant under the experimental conditions used.*



$$C_6H_6 + O \rightarrow C_6H_5\cdot + OH\cdot \quad [4]$$

$$C_6H_6 + OH\cdot \rightarrow C_6H_5\cdot + H_2O \quad [5]$$

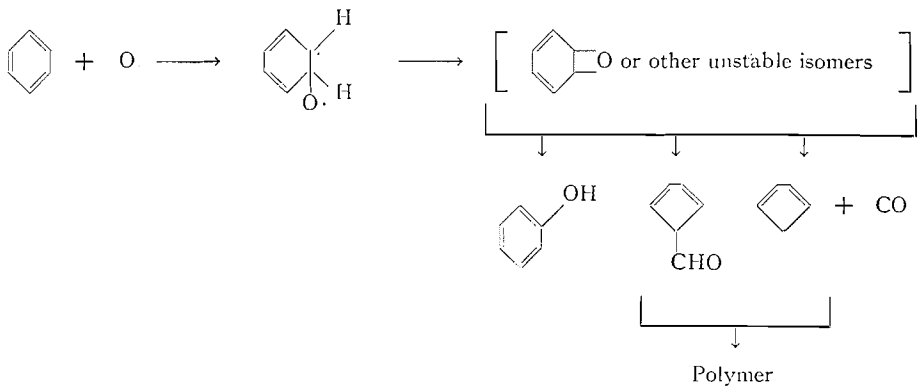
$$C_6H_5\cdot + OH\cdot \rightarrow C_6H_5OH \quad [6]$$



$$C_6H_5\cdot + C_6H_5\cdot \rightarrow \text{diphenyl} \quad [7]$$

Alternatively, as with the olefins and cyclo-olefins, the oxygen atom may add directly to the benzene molecule. Cyclohexene reacts in this fashion to produce a biradical which quickly rearranges to a mixture of cyclohexene oxide, cyclohexanone, and cyclopentyl formaldehyde (2).

[8]



The analogous scheme for benzene presents a larger number of possibilities, as shown below, since in principle either 1:2 or 1:4 addition may occur (although in the case of 1,3-butadiene only 1:2 addition of oxygen atoms is observed (15)).

I II III IV V VI

However, none of these compounds is reported in the literature although some derivatives are known. This is probably because I, II, III, and IV isomerize quickly to the stable structure of phenol whilst V and VI are undoubtedly prone to a variety of condensations and polymerizations.

On the basis of the present experimental results it is clearly impossible to suggest a definite reaction mechanism. It would, however, appear likely that initially an addition complex is formed between an oxygen atom and a benzene molecule and that this becomes in part stabilized as phenol. A larger fraction of the complex, on the other hand, suffers rupture of the aromatic ring with production of unsaturated aliphatic compounds, perhaps such as cyclopentadienyl formaldehyde, which readily undergo further reactions to form non-volatile polymeric material. Such a mechanism is analogous to the attack of oxygen atoms on olefins (2) and is to some extent supported by the type of products observed, the absence of diphenyl, and the pressure effect in the carbon monoxide formation (Table II and Fig. 1). Nevertheless, the evidence is not strong and the proposed mechanism, depicted approximately in the reaction scheme [9], is at present only of a tentative character.

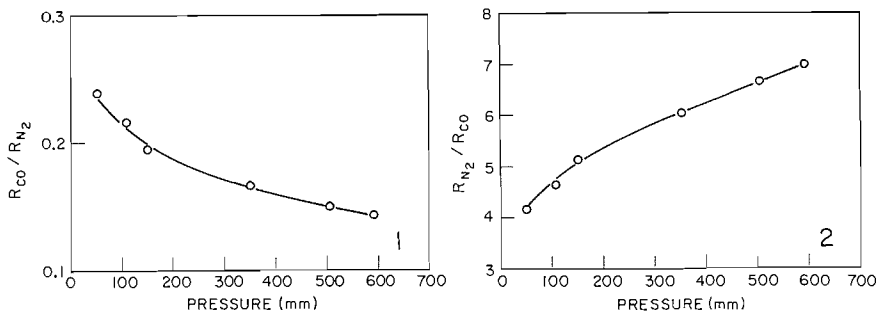


FIG. 1. The effect of pressure on carbon monoxide production.
FIG. 2. Plot of $-R_O/R_{CO}$ (*i.e.* R_{N_2}/R_{CO}) against pressure.

It is probable that the large fraction of oxygen atoms which are not consumed in the initial reaction with benzene at low partial pressures of benzene are involved in the secondary attack on the primary products formed, and especially on those rendered more reactive by loss of their aromatic character.

The pressure effect in the rate of formation of carbon monoxide strongly suggests that this compound is formed from decomposition of an energy-rich adduct as has been observed in the same pressure range in the cases of propylene (2) and 1,3-butadiene (15). With increasing pressure the excess energy tends to be removed by collisions from the "hot" product before it decomposes and carbon monoxide production therefore decreases. Inasmuch as the rate of this collisional deactivation is proportional to the pressure in the system, a linear plot should be obtained by plotting R_{N_2}/R_{CO} against pressure. Actually, as shown in Fig. 2, the plot appears to show a slight curvature. This could be explained by more complex collisional deactivation or by production of carbon monoxide from more than one "hot" species; however, more elaborate treatments are at present not warranted.

In their reactions with olefins oxygen atoms behave as electrophilic reagents (3, 16) and their relative rates are simply related to the basicity of olefins. Insofar as the same holds true for the reactions of aromatic compounds, the much slower rate of reaction with benzene is in qualitative agreement with the observation of West (17) that simple aromatic compounds are generally weaker bases than olefins as measured by the magnitude of the frequency shift of the C—H infrared absorption bands of alcohols or phenols

forming hydrogen-bonded complexes with these compounds. Quantitatively, however, the difference in the reactivity of benzene is much greater than would be anticipated from a comparison of the frequency shifts. Rate data for reactions of oxygen atoms with a number of aromatic compounds are required before these differences can be further discussed.

ACKNOWLEDGMENTS

The authors are grateful to Dr. A. W. Tickner for mass spectrometric analyses, to the Analytical Section of this Division for infrared analyses, and to Mr. L. C. Doyle for assistance with some of the experiments.

REACTION OF OXYGEN ATOMS WITH TOLUENE[1]

G. R. H. JONES[2] AND R. J. CVETANOVIĆ

ABSTRACT

The reaction of toluene with oxygen atoms produced by mercury photosensitized decomposition of nitrous oxide has been studied at room temperature. The reaction shows a general similarity to the corresponding reaction of benzene. Relative rates have been determined at 120 and 220° C and the activation energy estimated at close to 4 kcal/mole.

INTRODUCTION

An attempt was recently made in this laboratory to study the reaction of oxygen atoms in their ground electronic state with benzene as the first representative of aromatic compounds (1). Information was obtained on the rate and the activation energy of the reaction, but the major part of the reaction product was unfortunately a material of low volatility which could not be characterized. Therefore only a fragmentary picture of the process was obtained.

The present work was undertaken in the hope of obtaining additional information on the mode of attack of oxygen atoms on an aromatic ring. Another objective was to compare the reactivity of toluene towards oxygen atoms with that of benzene and of unsaturated aliphatic compounds. The relative rate and activation energy of the reaction of oxygen atoms with toluene have been determined but the major reaction product is again a material of low volatility, difficult to handle under conditions used in these experiments. As a result, as in the case of benzene, only a limited amount of information has been obtained on the mechanism of this reaction and in this respect the work has therefore only a preliminary character.

EXPERIMENTAL

A circulating reaction system was used, similar to the one described previously (1). The reaction vessel was a cylindrical quartz cell 10 cm long and 5 cm in diameter. The gases were circulated by means of an all-glass vertical plunger pump. Total volume of the circulating system was 504 ml. Mercury cutoffs were used instead of stopcocks, where necessary, to prevent absorption of hydrocarbons by stopcock grease.

The toluene used was Merck reagent grade, dried over CaH_2, purified by bulb-to-bulb distillation with retention of the middle fraction only, and stored over CaH_2. No impurities could be detected in a sample analyzed by gas chromatography. Nitrous oxide was obtained from Matheson Co. and was further purified by bulb-to-bulb fractionation. Phillips research grade cyclopentene was used. It was freed from peroxides by passage through an activated alumina column, after which it was subjected to bulb-to-bulb distillation *in vacuo*.

The analysis system has been described in the earlier work (1). It incorporated a Le Roy still (2), a Toepler pump, two constant volume burettes, and a copper oxide tube maintained at 240° for combustion of CO and H_2 in the non-condensable gases. Nitrogen

and methane were recovered from the copper oxide tube unchanged and were further analyzed mass spectrometrically. The amount of CO in the non-condensable gases was estimated from the amount of CO_2 formed in the copper oxide tube and H_2 was found by difference. Ethylene was recovered from the Le Roy still at $-182°$ and contained a small amount of N_2O which was determined by a mass spectrometer and deducted from the total amount of this fraction.

It was difficult to determine toluene consumption accurately since at small conversion this was given as a small difference between two large quantities. Because of relatively low volatility of toluene, direct manometric measurements were not accurate enough and the same held for gas chromatographic determinations. The following technique was found to be better although the experimental uncertainty remained appreciable. Aliquots were taken and the amounts of toluene initially introduced and remaining at the end of a run were determined from the CO_2 produced by combustion (after dividing by 7). For this purpose, oxygen was generated by heating reagent grade $KMnO_4$ and the combustion was carried out for 12 hours on a platinum wire maintained at dull-red heat. After removal of excess oxygen, carbon dioxide was recovered at dry ice temperature and measured. Initially an aliquot was taken from toluene before the introduction of nitrous oxide. At the end of a run, the nitrous oxide was first removed with the Le Roy still kept at $-125°$ after which the toluene and the volatile products (cresols) were allowed to expand again in the reaction volume and an aliquot was taken and combusted. To correct for the cresols present, assumption was made that the aliquot contained the toluene and the cresols in the same ratio as in the bulk retained in the reaction system. The cresols formed were therefore assumed not to exceed their saturation vapor pressures. This assumption was probably valid although there is some uncertainty in the vapor pressure of cresols at room temperature.

The cresols produced in the reaction were determined gas chromatographically. After the removal of N_2O and withdrawal of the aliquot for determination of the residual toluene as described above, all the volatile material remaining in the reaction vessel was distilled over into a small tapered tube immersed in liquid nitrogen and containing a weighed amount (approximately 0.04 g or 40 μl) of a standard solution of an internal standard in a solvent of known concentration. The distilling over was extended for $2\frac{1}{2}$ to 3 hours after which dry air was admitted. Samples of solutions obtained in this manner were analyzed on a Perkin–Elmer 154 C vapor fractometer using 2-meter UCON or, in the later stages of the work, polyester succinate (on chromosorb W) columns at 200° C. Helium was used as carrier gas at a flow of 120 ml/minute. The ratios of peak areas of the *o*- and *p*-cresols to that of the internal standard were determined and compared with those obtained with standard solutions of known concentrations of *o*-cresol, *p*-cresol, and the internal standard. The latter were run between each sample of the solution containing the products of the reaction. With the UCON column the internal standard used was diphenyl and the solvent cumene, and with the polyester succinate column the internal standard was naphthalene and the solvent benzene. The latter column gave better resolution of *o*- and *p*-cresol. The internal standards and the solvents were so selected that the standard was well resolved from the cresols and there was no interference from the large excess of the solvent.

The recovery of cresols was checked by following a $2\frac{1}{2}$-hour distillation for transfer of cresols into the tapered tube with a second 2-hour distillation into a fresh sample of standard solution. No detectable amounts of cresol were recovered in the second distillation.

RESULTS

The products observed in the reaction of oxygen atoms with toluene at room temperature have been *o*-cresol, *p*-cresol, carbon monoxide, water, and a reddish-yellow material of low volatility which was not further characterized (referred to in the following as "polymer").

The identification of the two cresols was based on their gas chromatographic elution times and their infrared spectra. The third isomer, *m*-cresol, was not resolved from *p*-cresol on the columns used. However, the infrared spectra of the condensable volatile products showed that *m*-cresol constituted at most only 4 to 5% of the total cresols and perhaps less. Between about 15 and 20% of the oxygen atoms reacting with toluene (as measured by the amount of nitrogen produced) were recovered as cresols. On the average, about 3–4 times as much *o*-cresol was formed as *p*-cresol.

Water was estimated approximately by gas chromatography. After removal of N_2O, the volatile condensable products were collected and passed at room temperature through a 12-ft dimethyl sulpholane column on glass beads. For water, the peak areas were not linearly related to the amounts taken and the determinations were based on an empirical calibration curve. Relatively long exposures had to be used in order to produce sufficient amounts of water for analysis and the mean of two determinations showed the presence of an amount of water corresponding to 7% of the oxygen atoms reacting with toluene.

Attempts were made to estimate the amounts of non-volatile "polymer" formed by admitting oxygen into the evacuated reaction cell and heating the cell to redness. The carbon dioxide produced was determined and the amount obtained, divided by 7, was taken as the measure of the "polymer" formed. However, the combustion of the "polymer" was not quantitative since it partially distilled and deposited on the walls of the glass tubing outside the reaction cell. Nevertheless, there could be little doubt that this material represented the major part of the reaction product, in agreement with the observed low carbon and oxygen atom balance.

Solutions of the products analyzed gas chromatographically for cresols showed complete absence of dibenzyl. The vapor pressure of dibenzyl at room temperature is approximately one-fifth of that of *p*-cresol and under conditions under which most of the cresol is recovered it would seem reasonable to expect recovery of at least some dibenzyl if an appreciable amount is formed. In view of this it appears that in the reaction of oxygen atoms with toluene, at most only negligible amounts of dibenzyl are formed.

Some of the experimental results are summarized in Table I. In most of these experiments an approximately constant amount of toluene was initially used while the exposure times were varied. Because of "polymer" deposit on the reaction cell window the amount of incident light varied with time and from experiment to experiment. The extent of reaction should therefore be judged from the amount of nitrogen formed rather than from the exposure time. For four- to five-fold increase of nitrogen production no drastic changes in the rates of formation of the products are evident. There is perhaps a slight decrease with the extent of conversion in the rates of cresol formation and toluene consumption, although the experimental scatter is large and makes this uncertain. The average rate found for toluene consumption per oxygen atom is 0.80 but it is difficult to say whether the difference from the expected value of unity is real or due to imperfections of the analytical procedure used. As already mentioned, the values obtained for the "polymer" represent only lower limits.

In these experiments the partial vapor pressure of toluene was relatively high so that some quenching of the excited mercury atoms by toluene did occur. However, this is

unlikely to have influenced to any appreciable extent the course of the studied reaction. When toluene alone was subjected to mercury photosensitized reaction for a period of 19 hours, only about 2 μmoles of non-condensable material were collected and of this only about one-third appeared to be combustible. No significant amounts of C_2, C_3, and C_4 fractions were found and infrared analysis of the condensable material in the reaction vessel revealed no significant amounts of products.

The effect of pressure on the products has been studied by varying the partial pressure of nitrous oxide at a constant small pressure of toluene and irradiating for 1 hour. The results are given in Table II. There do not appear to be any drastic changes in the rates

per gram-atom of oxygen (R/R_{N_2}) for a substantial variation in total pressure although small trends could be hidden by the experimental scatter of points. In the case of carbon monoxide the analytical accuracy is greater and there is a distinct decline in the rate of carbon monoxide formed per gram-atom of oxygen consumed (R_{CO}/R_{N_2}) with increasing pressure. This is shown in Fig. 1 and resembles the trend previously observed in the reaction of oxygen atoms with benzene (1).

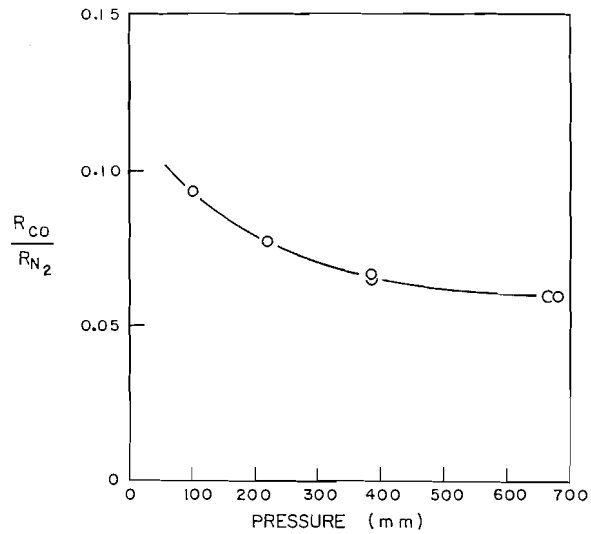

FIG. 1. Pressure effect in the rate of carbon monoxide formation.

The rate constants of reaction of oxygen atoms with toluene (k_T) relative to those of cyclopentene (k_C) were determined at 120 and 220° C by the competitive technique described in detail elsewhere (3). This technique is based on measurements of the decrease in the amount of ethylene formed by attack of oxygen atoms on cyclopentene when another substance consuming oxygen atoms is present. At room temperature it was found that toluene reacted much more slowly than cyclopentene and reliable values of relative rate constants would be very difficult to obtain. At 220° C a very slow thermal reaction producing nitrogen occurred. With the total residence times of the reactants in the reactor under 2 hours the extent of the thermal reaction was almost negligible. Nevertheless, a correction for the very small amount of nitrogen produced thermally was made. No measurable thermal reaction was observed at 120° C.

The relative rate constants (k_T/k_C) obtained at 120 and 220° C are given in Table III.

TABLE III

Determination of relative rate constants of addition of oxygen atoms to cyclopentene (k_C) and toluene (k_T)
(the amounts of reactants and of the nitrogen produced are given in millimeters, in 1107[a] ml at 25° C; the amounts of ethylene are given relative to the nitrogen produced)

Run	Temp. (°C)	N_2O (mm)	Toluene (mm)	Cyclo-pentene (mm)	Irradiation (min)	N_2[b] (mm)	C_2H_4[c]/N_2	k_C/k_T

Mean	222.1							24.9±0.7

[a]In these experiments the reaction cell was a 1-liter quartz round flask provided with a glass stirrer on teflon bearings magnetically operated from outside. This larger reaction volume permitted smaller cyclopentene pressures to be used and consequently somewhat larger toluene to cyclopentene ratios.
[b]At 220° C, N_2 values are corrected for thermal reaction: the uncorrected values are given in parentheses to show the extent of the corrections made. No thermal reaction occurred at 120° C.
[c]Several determinations gave for cyclopentene alone (i.e. in the absence of toluene but otherwise under comparable conditions) mean C_2H_4/N_2 ratios of 0.274 and 0.282 at 220 and 120° C respectively. These values were used in calculating the rate constants from equation (5) of reference 3.

The large mean deviations are primarily due to the large disparity in the rates of attack of oxygen atoms on cyclopentene and toluene, respectively. With the practically usable mixtures of the two hydrocarbons under conditions of the present experiments the reaction always occurred predominantly with cyclopentene. As a consequence even slight errors in the measured amounts of ethylene formed caused large errors in the values of the rate constants, especially so at the lower temperature where the disparity in the two rates is greater.

From the mean values of the relative rate constants at 120 and 222° C a difference in the activation energies of attack of oxygen atoms on toluene (E_T) and cyclopentene (E_C) of 3.2 kcal and a ratio of the pre-exponential factors (A_T/A_C) of unity are obtained. In view of the likely value (4) of E_C a value for E_T of about 3.8 to 4.1 kcal/mole is thus arrived at. The mean deviations indicated in Table III introduce an uncertainty in $E_T - E_C$ of ±0.3 to 0.4 kcal and a factor of about 1.5 in the ratio of the pre-exponential

factors. Because of large disparity in the rates between toluene and cyclopentene, as pointed out above, toluene presents an unfavorable case for accurate determination of relative rates by the cyclopentene technique and the margin of uncertainty in $(E_T - E_C)$ and (A_T/A_C) may be even greater.

DISCUSSION

Reaction of oxygen atoms with toluene shows great general similarity with the reaction of oxygen atoms with benzene (1). As in the case of benzene, (1) the major reaction product is a material of low volatility, probably polymeric in character; (2) smaller amounts of phenols are formed; (3) there is a pressure effect in the rate of carbon monoxide formation, suggesting an energy-rich precursor; and (4) products expected for a primary hydrogen abstraction reaction are not detected.

In view of these findings it is most likely, as was postulated for benzene (1), that in the case of toluene also the primary step is an addition of oxygen atoms to the aromatic ring rather than hydrogen abstraction. In agreement with this no dibenzyl is detected. Small amounts of water formed (equivalent to about 7% of the oxygen atoms consumed) could mean that some hydrogen abstraction does occur; however, water could equally well be formed in secondary processes. The initial adduct could be visualized as either being stabilized into cresols or rearranging into products which partially decompose or, to a much greater extent, undergo polymerization. These matters have been speculatively discussed for the benzene reaction (1) and in view of the similarity of the two processes there is no need for further discussion here. Until the nature of the "polymeric" material is established, any attempt to establish the mechanism of these reactions will necessarily remain only speculative.

The pressure effect in carbon monoxide formation is very similar to that observed with benzene (1) although in the case of toluene carbon monoxide is a less important product. As with benzene, the plot of R_{N_2}/R_{CO} is not linear but shows instead a distinct curvature. Smaller production of carbon monoxide from toluene rather than from benzene at comparable pressures may be compared with the formation of fragmentation products in the reaction of oxygen atoms with alkenes. In this latter case, again the "hot" addition products formed by reaction of oxygen atoms with olefins containing a smaller number of carbon atoms (C_2H_4, C_3H_6) are shorter lived and undergo fragmentation much more easily (at comparable pressures) than products from olefins containing a greater number of carbon atoms (5). This is readily understandable in terms of the number of internal degrees of freedom available for dissipation of energy, although the stability of the fragments formed must play also an important role, as evident from the reaction of oxygen atoms with 1,3-butadiene (6).

Formation of large amounts of ortho- and para-cresol and at most of very small amounts of metacresol in the reaction of oxygen atoms with toluene is understandable in view of the electrophilic character of oxygen atoms. Relatively large ortho-to-para ratio is to be noted since it suggests little or no steric hindrance to the addition of oxygen atoms ortho to methyl group. The upper limit for metacresol obtained from infrared spectra seems to be below the amount that would be expected if the "selectivity relationship" for electrophilic substitution reactions of toluene (7) were applicable to the present reaction. However, more quantitative information on metacresol is required before this matter can be further discussed.

The relative rates of addition of oxygen atoms to toluene confirm the previous finding with benzene (1) of a slower attack of oxygen atoms on an aromatic ring than on an

For personal use only.

olefinic double bond. At the same time, as expected, toluene reacts appreciably faster than benzene (1). It is of interest that the pre-exponential factors for benzene and toluene appear to be similar to those of olefins (4), although there may be an appreciable margin of uncertainty in the activation energies and pre-exponential factors for the two aromatic hydrocarbons.

ACKNOWLEDGMENTS

The authors are grateful to Dr. A. W. Tickner for mass spectrometric analyses, to the Analytical Section of this Division for infrared analyses, and to Mr. L. C. Doyle for assistance with some of the experiments.

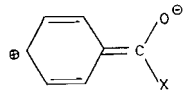
LIGHT ABSORPTION STUDIES

PART XX. THE ULTRAVIOLET ABSORPTION SPECTRA AND INFRARED CARBONYL BANDS OF BENZOYL CHLORIDES[1]

W. F. FORBES[2] AND J. J. J. MYRON[3]



ABSTRACT

The ultraviolet absorption spectra and infrared carbonyl bands of a number of substituted benzoyl chlorides are determined. It is found that as a first approximation the *B*-bands of the ultraviolet spectra are similar for benzoyl chlorides and for the corresponding benzaldehydes and acetophenones. The spectra are discussed in terms of previously stated hypotheses. In this way the order of the apparent negative mesomeric effect is deduced to be $-NO_2 > -COCl > -CHO > -COCH_3$, and the effective size of these substituents is confirmed to be in the order $-NO_2 > -COCH_3 > -COCl > -CHO$.

The infrared carbonyl band occurs as a well-defined doublet in most of the ring-substituted benzoyl chlorides. The most probable explanation is that these doublets occur because of an intramolecular vibration.

INTRODUCTION

In previous parts of this series (see, for example, refs. 1, 2, 3) it was shown that spectral changes in the main ultraviolet absorption band of substituted benzene derivatives could be rationalized by assuming that such changes are predominantly caused by mesomeric and steric interactions, but are not appreciably affected by other short-range interactions such as inductive and field effects. In compounds such as benzoyl chloride, benzaldehyde, and acetophenone this would imply that the main ultraviolet band, the *B*-band (for nomenclature see previous parts of this series and ref. 4), may be associated with resonance forms of type I, which schematically represents mesomeric interactions between the carbonyl group and the benzene ring. If this is correct, the *B*-band of benzoyl chloride should be similar to the *B*-band of benzaldehyde and acetophenone, and should undergo

(I)

X = Cl, H, or CH_3

changes on ring substitution similar to the corresponding *B*-band changes occurring in acetophenone or benzaldehyde on substitution.

The purpose of the present paper is to investigate this hypothesis and also to determine the infrared carbonyl band in substituted benzoyl chlorides. These latter bands are of interest because the infrared carbonyl band of benzoyl chloride is well known to occur as a doublet, the origin of which is unknown. Information concerning the nature of this doublet may thus be provided by investigating this carbonyl band in a number of substituted benzoyl chlorides.

EXPERIMENTAL

The ultraviolet absorption spectra were determined by standard methods in 1-cm cells using a Unicam SP 500 or a Beckman Model DU or Model DK 2 spectrophotometer.

For each compound at least two independent sets of observations were made. The Unicam SP 500 instrument was calibrated against a didymium filter, and wavelength readings obtained on the Unicam and Beckman instruments were found to be within 1 mμ of each other. The precision of λ_{max} values is estimated to be 1 mμ, and the precision of ϵ_{max} values, 5% or better. Values were reproducible for most compounds to 2%. The main ultraviolet maxima in cyclohexane solution are listed in Tables I and IV. The spectra could not be determined in ethanol solution due to reaction of the benzoyl chloride with the solvent.

The infrared spectra were determined on a Unicam SP 100 double-beam spectrometer with an SP 130 sodium chloride prism-grating double monochromator. The resolution in the 1700 cm^{-1} region was ca. 0.5 cm^{-1}. The solute concentration was kept within the limits of 4.7×10^{-2} and 9.2×10^{-2} mole/liter (usually 0.5-mm cells with KBr windows), except when as otherwise stated. The infrared absorption bands are shown in Tables I, II, and III and in Figs. 3, 5, and 7. Infrared spectra were also used to show the absence of any appreciable amount of acid which might have been formed through decomposition of the benzoyl chlorides.

The benzoyl chlorides were either prepared by standard methods or obtained from commercial sources; they were purified by distillation or recrystallization until their boiling points and refractive indices or melting points showed them to be sufficiently pure. The solvents used were spectroanalyzed cyclohexane (Fisher) or other commercially available spectroanalyzed solvents.

THE ABSORPTION CHARACTERISTICS OF BENZOYL CHLORIDE

The main ultraviolet absorption bands and the infrared carbonyl and adjoining bands of benzoyl chloride and related compounds are shown in Table I.

Table I shows that both *B*- and *C*-bands of benzoyl chloride are similar to the corresponding bands of benzaldehyde and acetophenone, that is, the bands occur at similar wavelength, are not appreciably affected if the ultraviolet spectra are determined in ether solution, do not show an appreciable concentration dependence, and tend to exhibit some fine structure at longer wavelength. (In acetophenone, the fine structure becomes apparent in the vapor phase (2).)

In the vapor phase, benzoyl chloride affords the usual displacement to shorter wavelength (5). All these observations can be rationalized by assuming that as a first approximation the ultraviolet *B*-band is predominantly determined by mesomeric interactions (as crudely represented by resonance forms of type I), to which the chlorine atom does not appreciably contribute.

The infrared carbonyl band, on the other hand, is appreciably affected by the chlorine atom and causes a displacement to higher frequency, compared with the location of this band in benzaldehyde. Conversely, replacement of an hydrogen atom by a methyl group, as in acetophenone, causes a displacement to lower frequency. These displacements can be readily related to the over-all electronegativities of the chlorine atom and the methyl group (cf. ref. 6 and also ref. 7 for the yet higher carbonyl band frequency of benzoyl fluoride). Moreover, the carbonyl band in most benzoyl chlorides exhibits a doublet (see Table II and cf. refs. 8, 9, and 10) which is not appreciably affected either by a change in solute concentration (within the solute concentration range 0.05 to 2.5 *M*) or by determination of the absorption in ether solution (see Table I). Therefore it is unlikely that the carbonyl band doublet is caused by a monomer–dimer equilibrium. Further, neither in the 800–900 cm^{-1} region, nor in the 600 cm^{-1} region, are there absorption bands, overtones, or combination bands which can quantitatively and convincingly account for the observed doublets in all of the benzoyl chlorides (see later discussion). The infrared carbonyl bands of benzoyl chloride and of a number of substituted benzoyl chlorides are listed in Table II. The effect of altering the solvent from chloroform to carbon

tetrachloride and the effect of temperature on the infrared carbonyl band of benzoyl chloride in carbon tetrachloride solution has recently been reported by Jones *et al.* (10). These workers note that the behavior of the infrared carbonyl band under these conditions parallels the behavior of the infrared carbonyl band in a number of unsaturated lactones. Jones *et al.* (10) have also confirmed the absence of any concentration dependence of this band over a 200-fold range.

Benzoyl chlorides also exhibit two infrared absorption bands in the region 1560–1600 cm^{-1} (cf. ref. 11), which are listed in Table III. The generally more intense band near

1590 cm^{-1} presumably corresponds to the "1600 cm^{-1} aromatic vibration band", which is reported to occur within the range 1625–1575 cm^{-1} for most aromatic compounds (11). It was also found (cf. ref. 11) that the halogen-substituted benzene derivatives, particularly the iodo compounds, absorb near the lower limit of this range, while the locations of the absorptions of the nitro-substituted benzoyl chlorides occur at a frequency higher than average. Neither the location nor the intensity of the band appears to be quantitatively related to electronegativity, σ value, other electronic property, or to the size of the *o*-substituent. However, the more intense bands occur in the *p*- and *o*-isomers. Hence the band intensity may be related to mesomeric interaction.

The other infrared aromatic vibration band occurs in the 1600–1560 cm^{-1} region (cf. ref. 11). The data in Table III show that the band is more intense for *p*- and *o*-methoxybenzoyl chloride and this again indicates that mesomeric interaction enhances the band intensity. Moreover, the band appears to be weakest if mesomeric interaction is limited, as in nitrobenzoyl chlorides where both substituents are electron withdrawing, or as in *o*-toluoyl chloride where the methyl group could twist the chlorocarbonyl group out of the plane of the benzene ring and in this way inhibit mesomeric interaction. However, again neither band location nor band intensity could be quantitatively related to σ values or other electronic properties.

THE SPECTRA OF PARA-SUBSTITUTED BENZOYL CHLORIDES

The main ultraviolet absorption maxima of substituted benzoyl chlorides are listed in Table IV and are found to be essentially similar to the corresponding bands in *p*-substituted benzaldehydes and acetophenones (2, 3). This is further illustrated in Fig. 1, which shows the band similarity between a similarly *p*-substituted benzoyl chloride and benzaldehyde.

Since resonance forms of type I, sometimes favored by an electron-donating *p*-substituent, have previously been used to rationalize the observed spectral changes in *p*-substituted benzaldehydes (2) and acetophenones (3), these resonance forms can likewise rationalize the ultraviolet *B*-band spectral changes in *p*-substituted benzoyl chlorides. The wavelength displacements in *p*-substituted benzoyl chlorides relative to benzoyl chloride are, as expected, proportional to the wavelength displacements observed

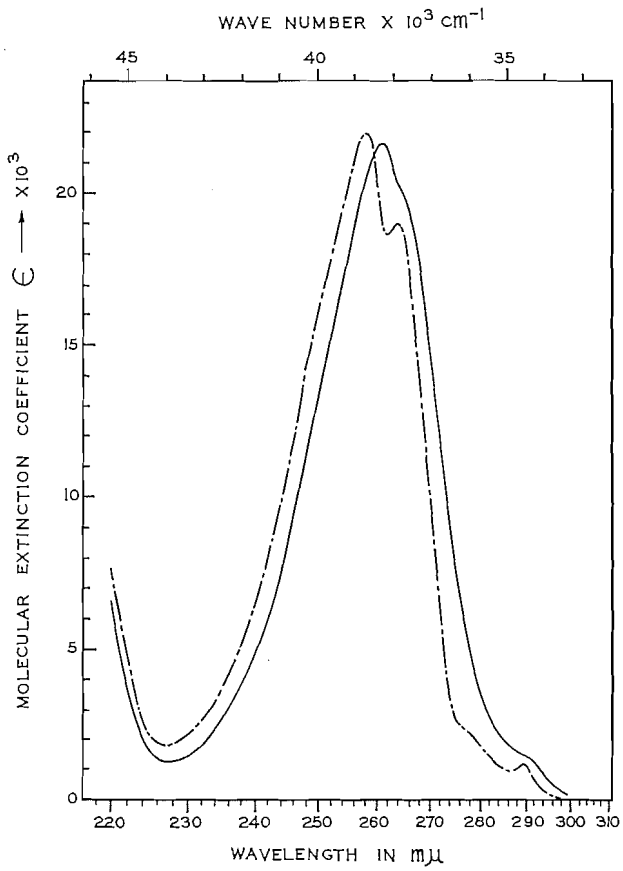

FIG. 1. The ultraviolet absorption spectra in cyclohexane solution of *p*-bromobenzoyl chloride (——) and *p*-bromobenzaldehyde (—·).

for *p*-substituted acetophenones, benzaldehydes, and nitrobenzenes relative to the non-*p*-substituted parent compounds. This is illustrated in Fig. 2, which uses the corresponding frequency displacements ($\Delta\nu$) instead of wavelength displacements ($\Delta\lambda$) (cf. ref. 2).

The slopes of the lines in Fig. 2 are in the order $—NO_2$ > (—COCl) > —CHO > $—COCH_3$ (cf. also ref. 2). This order represents a measure of the different effects of a *p*-substituent on the various electron-withdrawing substituents (NO_2, COCl, etc.) when attached to the benzene ring. If it is assumed, as seems reasonable, that a substituent possessing a greater negative mesomeric effect can more effectively involve the electrons of an electron-donating *p*-substituent, the above order may also provide a measure of the negative mesomeric effect of the electron-withdrawing substituents. The order for the apparent mesomeric effect obtained in this way from Fig. 2 is as shown above (cf. also ref. 1 for the use of the term "apparent mesomeric effect"). Moreover, the maxima of the *B*-bands of nitrobenzene, benzoyl chloride, benzaldehyde, and acetophenone are located at 252, 242, 241, and 237.5 mμ respectively (see Table I and refs. 12, 2, and 3) and this also indicates increasing mesomeric interaction in the same order.

It may next be noted from the data listed in Table IV that the *B*-band of substituted benzoyl chlorides is again slightly unsymmetrical, with a shoulder usually occurring at

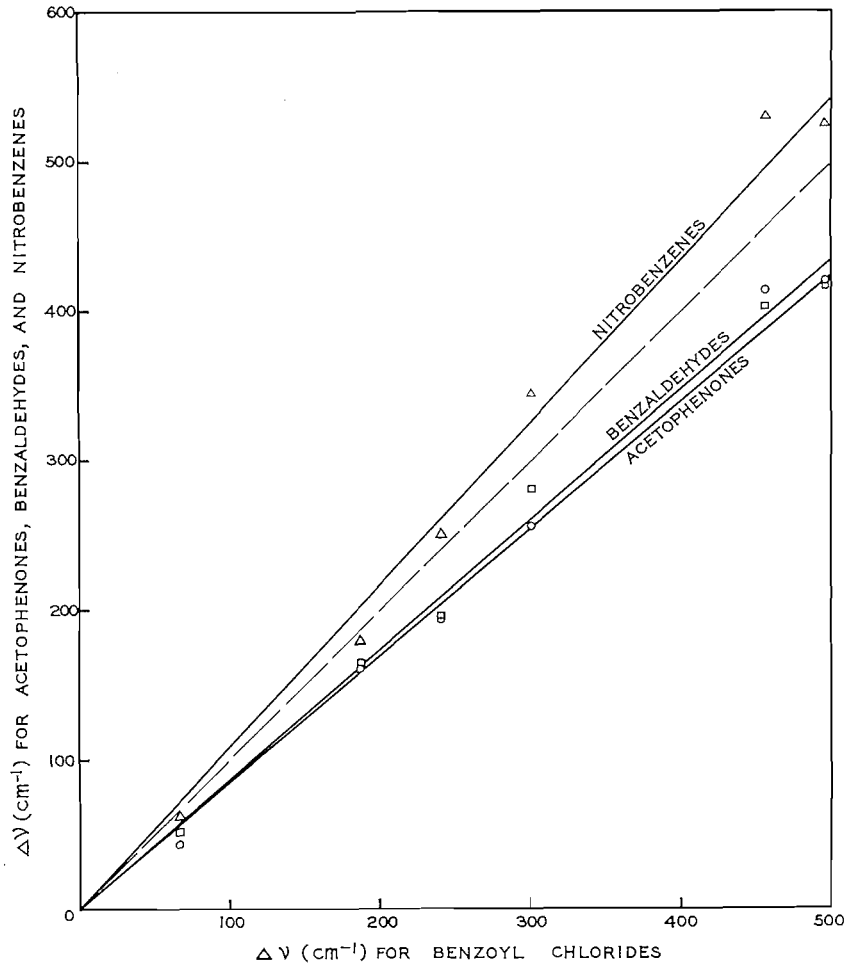

FIG. 2. Frequency displacements ($\Delta\nu$) in the *B*-band obtained on introducing para substituents in benzoyl chloride, benzaldehyde, acetophenone, and nitrobenzene (1, H; 2, F; 3, CH_3; 4, Cl; 5, Br; 6, MeO; and 7, I). Values (1 to 7 as $\Delta\nu$ increases) are for hexane solutions and are obtained from Table IV and from refs. 2, 3, and 12. △, nitrobenzenes; □, benzaldehydes; ○, acetophenones.

the longer wavelength side. Sometimes, as for the *p*-iodo- and *p*-methoxy-benzoyl chlorides the *B*-band occurs as a twin peak, but more frequently the second band occurs only as an ill-defined shoulder. The absence of this shoulder for the band at 255 mμ may also be taken as evidence to show that this band is not to be associated with benzoyl chloride but with nitrobenzene absorption.*

The ultraviolet spectra of *p*-substituted benzoyl chlorides also afford other bands in the 210–250 mμ region, which may either be *B*-bands, corresponding to locally excited states, or *A*-bands (for band nomenclature, see ref. 4). These bands are listed in Table IV,

**Further evidence that the band at 255 mμ in p-nitrobenzoyl chloride is a nitrobenzene B-band is provided by analogy with the spectrum of m-nitrobenzoyl chloride, which also shows an inflection near 255 mμ and, in addition, a band near 228 mμ (see Table IV). The m-isomer would be expected to show two B-bands, one more-intense B-band associated with benzoyl chloride absorption and one less-intense band associated with nitrobenzene absorption (13). The band at 228 mμ shows the characteristic shoulder associated with benzoyl chloride absorption and the inflection near 255 mμ in the m-isomer is therefore almost certainly a nitrobenzene B-band. This in turn suggests that the band at similar wavelength in the p-isomer is also a nitrobenzene B-band.*

*B-band assignment doubtful.

the doubtful band assignments being indicated. The *B*-band assignment is favored if in the *m*-isomer there occurs a similar band, absorbing with increased absorption intensity, which is a *B*-band. For example, the bands at 211 and 215 mμ in *m*-chlorobenzoyl chloride are believed to correspond to chlorobenzene *B*-band absorption. Since reduced absorption maxima still occur at 211 and 215 mμ in the *p*-isomer, it is supposed that these maxima are also to be associated with chlorobenzene *B*-band absorption, which competes with *B*-band absorption involving the whole molecule.

The ultraviolet *C*-band affords the expected spectral changes (see ref. 3), that is, as mesomeric interaction increases, the *C*-band becomes less intense or disappears.

The infrared bands of the *p*-substituted benzoyl chlorides are listed in Tables II and III, and Fig. 3 shows the spectral tracings in the region 1550–1800 cm^{-1}. These data

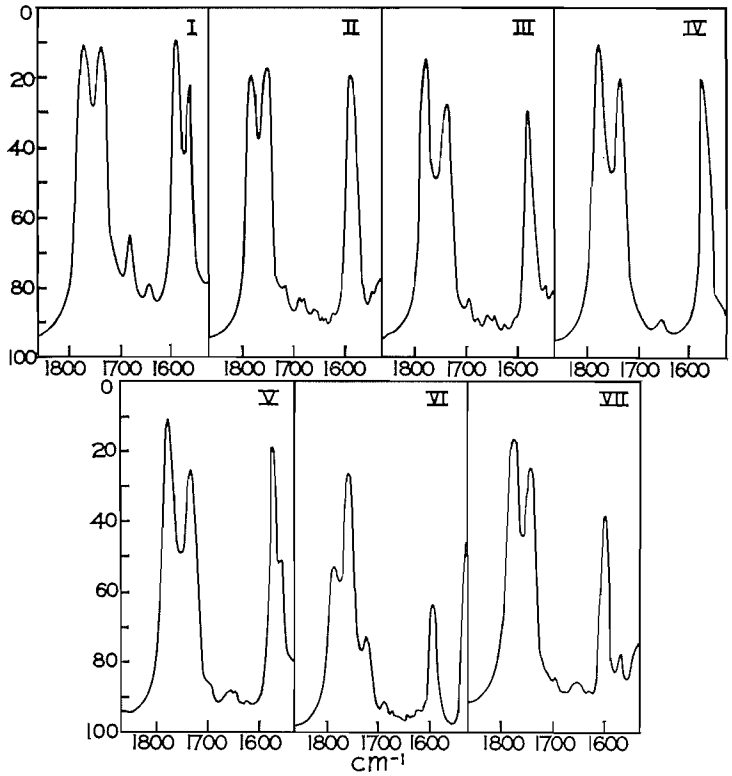

FIG. 3. The infrared bands (carbon tetrachloride solution) in the region 1550–1800 cm^{-1} of (I) *p*-methoxybenzoyl chloride, (II) *p*-fluorobenzoyl chloride, (III) *p*-chlorobenzoyl chloride, (IV) *p*-bromobenzoyl chloride, (V) *p*-iodobenzoyl chloride, (VI) *p*-nitrobenzoyl chloride, and (VII) *p*-toluoyl chloride.

show that the carbonyl band doublet occurs in all the *p*-substituted benzoyl chlorides investigated. Somewhat surprisingly, although carbonyl band frequencies of ring-substituted acetophenones showed a direct relationship with Hammett's σ values (14), no similar simple relationship is obtained between these σ values and either of the carbonyl band frequencies listed in Table II or with the arithmetic mean of the two carbonyl band frequencies. Plots of the carbonyl band frequencies against the functions σ^* and $(\sigma_p - \sigma')$, derived by Taft, Roberts, and Moreland (15), likewise all failed to show significant linearity. These observations point towards the possibility that in benzoyl chlorides an overtone or combination band occurs near the carbonyl band, and that the former bands,

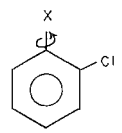
For personal use only.

because of a vibrational resonance effect, displace the carbonyl band from the position where it would otherwise have been expected to occur.

THE SPECTRA OF META-SUBSTITUTED BENZOYL CHLORIDES



The ultraviolet spectra of *m*-substituted benzoyl chlorides frequently show two *B*-bands (cf. refs. 1, 2, and 12; for an explanation of this phenomenon in terms of molecular orbital theory, see ref. 16). One of these bands is associated with benzoyl chloride *B*-band absorption whereas the second *B*-band is associated with the other, non-benzoyl-chloride, monosubstituted benzene derivative. This latter *B*-band is designated in Table IV as the second *B*-band and it is usually the more intense band. This greater intensity may be related to the electron-withdrawing effect of the chlorocarbonyl group. Such an explanation may also account for the reverse relation in *m*-nitrobenzoyl chloride where the benzoyl chloride *B*-band absorption is more intense, that is, it may be assumed that this is so because the nitro group withdraws electrons even more effectively than the chlorocarbonyl group (for a discussion of how the spectral characteristics of one meta-substituent are affected by the presence of a second such substituent, see refs. 13 and 17).

As anticipated, the spectra of the *m*-substituted benzoyl chlorides and benzaldehydes are similar (see Table IV and ref. 2). This similarity is further illustrated in Fig. 4 for the spectra of the *m*-substituted nitro compounds. No new concept is therefore required to rationalize the spectra of *m*-substituted benzoyl chlorides, since the explanation of the spectra of benzoyl chlorides and benzaldehydes in terms of resonance forms of type I still holds (cf. also ref. 2).

The investigated infrared bands of the *m*-substituted benzoyl chlorides are shown in Tables II and III and in Fig. 5. The carbonyl bands again all show a doublet, even though for some of the compounds one of the peaks is only weak. A plot of the infrared carbonyl band frequencies (see Table II) against either Hammett's σ values or the functions σ^* or $(\sigma_m{-}\sigma')$ (15) again showed a wide scatter (cf. ref. 14). Two additional points may be noted. First, in compounds such as *m*-chlorobenzoyl chloride, where one of the peaks is considerably more intense than the other, there is no evidence of any further band splitting such as might have been expected if the molecule existed in two *s*-cis, *s*-trans conformations which absorb maximally at slightly different frequencies (cf. ref. 14). Secondly, in *m*-substituted benzoyl chlorides the peak at lower frequency is frequently more intense (cf. Figs. 3, 5, and 7).

THE SPECTRA OF ORTHO-SUBSTITUTED BENZOYL CHLORIDES

The ultraviolet absorption spectra of *o*-substituted benzoyl chlorides, like those of the corresponding *m*-isomers, again generally exhibit two *B*-bands. Steric interactions in compounds such as *o*-substituted benzoyl chlorides would be expected to cause intensity

(II)

X = CHO, $COCH_3$, COCl, or NO_2

decreases in the *B*-band compared with the intensities in the *m*-isomers, and such intensity decreases are in fact observed (see Table IV). This is further illustrated in Fig. 6 for *o*-chlorobenzoyl chloride (II, X = COCl).

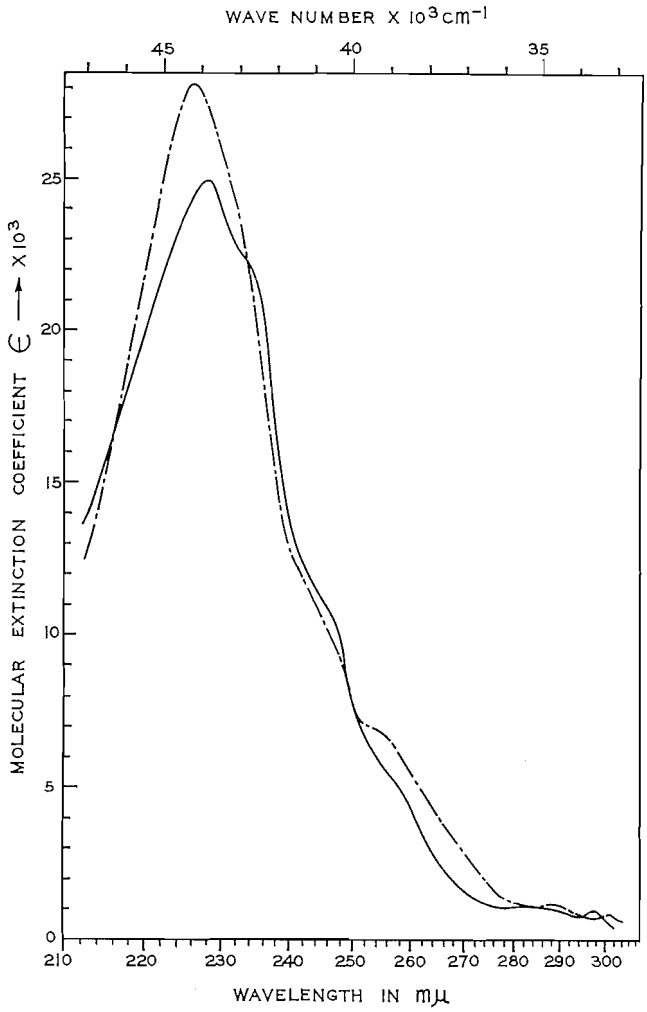

FIG. 4. The ultraviolet absorption spectra in cyclohexane solution of *m*-nitrobenzoyl chloride (——) and *m*-nitrobenzaldehyde (—·).

Figure 6 shows that the *B*-band of *o*-chlorobenzoyl chloride is less intense than that of the *m*-isomer, and further, that the *B*-bands of *o*-chlorobenzoyl chloride and *o*-chlorobenzaldehyde are again similar but that the former *B*-band is also less intense than the *B*-band in *o*-chlorobenzaldehyde. If it is assumed that in *o*-chlorobenzoyl chloride steric interactions predominantly affect the molecule by twisting the group X out of the plane of the benzene ring (as indicated in structure II), the intensities of the *B*-bands associated with the PhX chromophores can be taken as a semiquantitative measure of the steric interactions (cf. ref. 18). The relevant absorptivities of both *o*- and *m*-isomers as well as the ratio of the absorptivities of the two *B*-bands for compounds II (X = —CHO, —COCl, —$COCH_3$, and —NO_2) are listed in Table V. The absorptivity ratios, thus obtained, are in the order —NO_2 > —$COCH_3$ > —COCl > —CHO and this order may be taken as a measure of the effective interference radii of these substituents. Other factors may also affect the absorptivity ratios. For example, the different compounds II

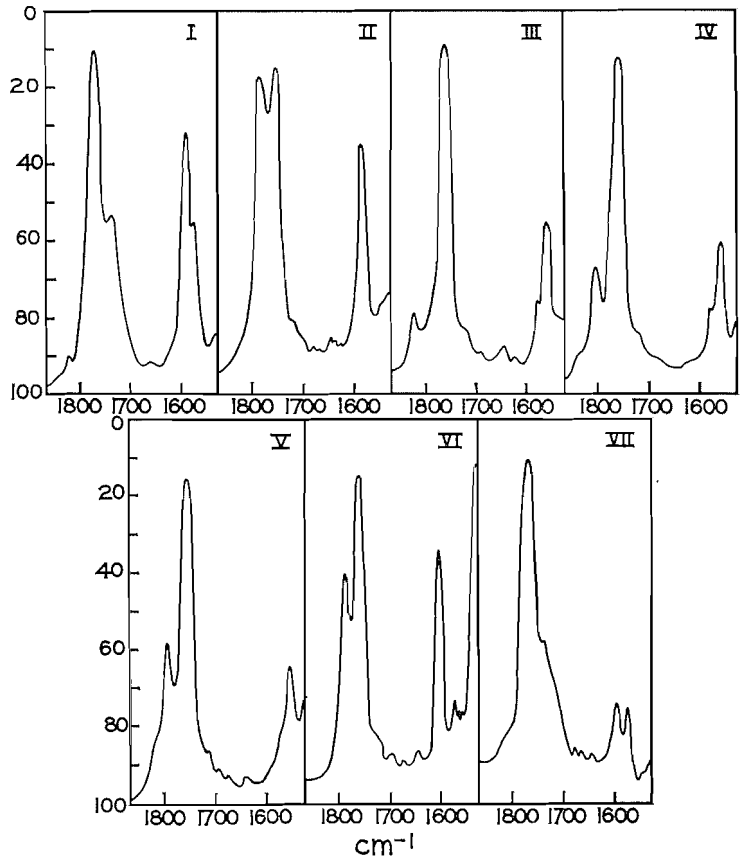

FIG. 5. The infrared bands (carbon tetrachloride solution) in the region 1550–1800 cm^{-1} of (I) *m*-methoxybenzoyl chloride, (II) *m*-fluorobenzoyl chloride, (III) *m*-chlorobenzoyl chloride, (IV) *m*-bromobenzoyl chloride, (V) *m*-iodobenzoyl chloride, (VI) *m*-nitrobenzoyl chloride, and (VII) *m*-toluoyl chloride.

may not all exist in one and the same *s*-cis or *s*-trans conformation. However, orders for the effective interference radii similar to those deduced from the chloro-substituted compounds can be obtained from the absorptivity ratios of the corresponding *o*-bromo, *o*-iodo, *o*-methoxy, and *o*-nitro compounds, and this increases our confidence in the proposed order.

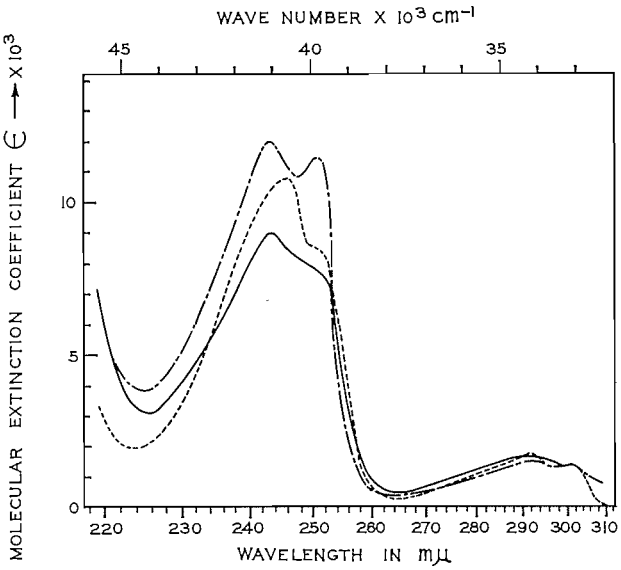

FIG. 6. The ultraviolet absorption spectra in cyclohexane solution of *o*-chlorobenzoyl chloride (——), *m*-chlorobenzoyl chloride (—·), and *o*-chlorobenzaldehyde (– –).

The ultraviolet *C*-bands of both *m*- and *o*-substituted benzoyl chlorides exhibit the usual changes (cf. ref. 3), that is, the C-bands generally become progressively more pronounced in the order *p*-isomer < *m*-isomer < *o*-isomer (see Table IV).

The investigated infrared bands of the *o*-substituted benzoyl chlorides are shown in Tables II and III and in Fig. 7. The carbonyl bands again all show a doublet, but as in the *m*-isomers one of the peaks is usually weaker. However, in the *o*-isomer the less-intense band is the band at *lower* frequency, whereas in the *m*-isomer the less-intense band is usually the band at *higher* frequency. In the *p*-isomer the two bands seem to be generally of similar intensity (see Table II, and cf. Figs. 3, 5, and 7).

SOME CONCLUDING REMARKS CONCERNING THE CARBONYL BAND DOUBLET IN BENZOYL CHLORIDES

The origin of the doublet in the infrared carbonyl band is not clear. One explanation is that the band occurs because of Fermi resonance between the carbonyl vibration and a close-lying overtone. In fact, benzoyl chloride shows an intense band at 875 cm^{-1} and doubling this frequency would place the overtone at 1750 cm^{-1}—reasonably close to the observed "carbonyl bands" at 1782 and 1740 cm^{-1} (see Table II). Hence it is possible that an anharmonicity effect brings the two vibrations sufficiently close together to cause the observed doublet (cf. ref. 20 for an explanation on these lines to account for the carbonyl band doublet in cyclopentanone). Likewise an overtone near 1740 cm^{-1} of the band at 870 cm^{-1} in *p*-toluoyl chloride can account for the doublet at 1777 and 1744 cm^{-1}. Similar explanations could hold for other benzoyl chlorides. Sometimes, the overtone of the band near 850 cm^{-1} is not sufficiently close to account satisfactorily for the doublet. For example, in *m*-nitrobenzoyl chloride the doublet occurs at 1792 and 1764 cm^{-1} and the overtone would be expected to occur near 1690 cm^{-1} (2×845 cm^{-1}). However, there are other bands (for example, *m*-nitrobenzoyl chloride affords a band at 925 cm^{-1}), overtones of which could also account for the observed doublets. Moreover,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

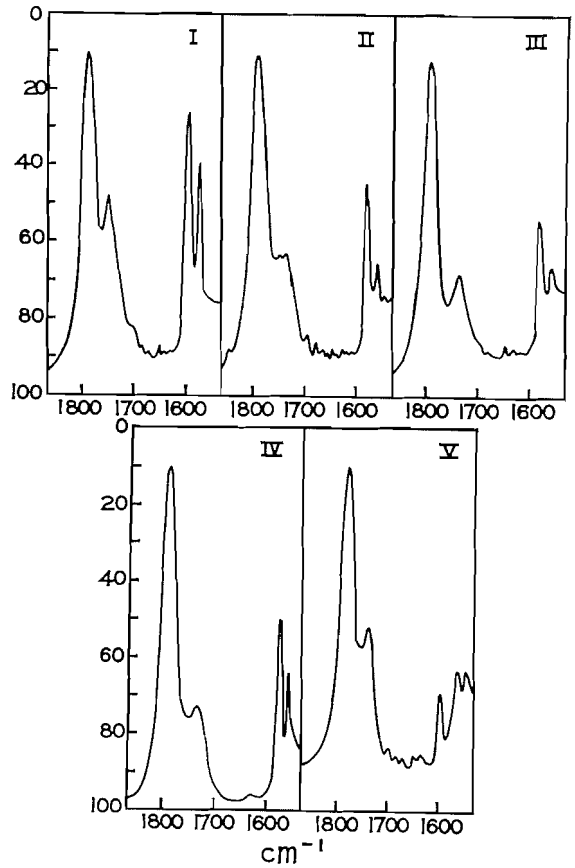

FIG. 7. The infrared bands (carbon tetrachloride solution) in the region 1550–1800 cm^{-1} of (I) *o*-methoxybenzoyl chloride, (II) *o*-chlorobenzoyl chloride, (III) *o*-bromobenzoyl chloride, (IV) *o*-iodobenzoyl chloride, and (V) *o*-toluoyl chloride.

it is also possible to postulate a combination band (cf. ref. 21) which may account for the observed doublet.

This type of explanation is probably the best that can be put forward, but it is not entirely satisfactory. Thus it accounts for the doublet in what is, at best, a semiquantitative manner. For example, in *p*-fluorobenzoyl chloride the overtone of the band at 880 cm^{-1} is expected to occur near 1760 cm^{-1} and this would be anticipated to lead to a *weak* band on the low-frequency side of the carbonyl band at 1786 cm^{-1}. However, the peak at lower frequency (at 1754 cm^{-1}) is *more intense*, although for most other benzoyl chlorides there is the expected reverse relation, that is, the peak on the overtone side is less intense. Moreover, the unusual absence of any direct relationship between either of the carbonyl band frequencies or their means and Hammett's σ values suggests that the original carbonyl frequency is appreciably modified.

Other explanations, such as involvement of intermolecular interactions, or the existence of different conformational isomers in equilibrium, are even more unsatisfactory. Consequently, in the absence of any other more satisfactory explanation, the most probable explanation is that the doublet occurs because of an intermolecular vibration. The understanding of the precise mechanism of this vibration clearly requires further study.

THE REACTION OF ETHANOL VAPOR WITH Hg 6($^3P_1$) ATOMS[1]

ARTHUR R. KNIGHT AND HARRY E. GUNNING

ABSTRACT

The reaction of ethanol vapor with Hg 6($^3P_1$) atoms has been investigated under static conditions at 25° C. To determine the nature and efficiency of the primary process, the reaction has been studied in the presence of nitric oxide, and also under conditions of intermittent illumination. For the pure substrate the volatile products were H_2 (0.53), CH_3CHO (0.08), CO (0.025), C_2H_6 (0.006), and CH_4 (0.002), with the bracketed numbers representing the quantum yields at zero exposure time. The heavy product was a mixture of butanediols containing 90% 2,3-, 8% 1,3-, and 2% 1,4-butanediol. With 20% added NO, the products were EtONO (0.25), N_2O (0.14), H_2O, and H_2 (0.017). Under intermittent illumination, the quantum yield (Φ) of H_2 formation for pure substrate was measured as a function of the light period (t_L) and the dark period (t_D). For maximum values of $\Phi(H_2)$, it was found that t_D had to exceed ca. 120 msec. Under these conditions, $\Phi(H_2)$ rose linearly with decreasing log t_L to a maximum value of 0.96 at t_L less than 0.4 msec.

From the study it is concluded that ethanol reacts with Hg 6($^3P_1$) atoms to form ethoxy radicals and H atoms with at least 96% efficiency. The primary ethoxy radicals disappear by hydrogen abstraction from the substrate to form mainly CH_3CHOH radicals. Under continuous illumination the low value (0.53) for $\Phi(H_2)$ is caused principally by the addition of H atoms to the CH_3CHOH radicals.

INTRODUCTION

Recent studies (1, 2) have shown that the primary reaction between methanol vapor and Hg 6($^3P_1$) atoms leads almost exclusively to the formation of CH_3O and H. In addition, by the use of special intermittent-illumination techniques, it has been found in this laboratory (3) that the primary quantum yield (Φ) for H-atom formation is at least 0.89, and likely unity. Thus, with a light period (t_L) of 0.156 msec and a dark period (t_D) of 160 msec, $\Phi(H_2)$ was 0.89; whereas, under steady illumination, $\Phi(H_2)$ was only 0.46 when extrapolated to its maximum value at zero extent of reaction (2, 3). The low value of $\Phi(H_2)$ under steady illumination was ascribed mainly (3) to the combination of H with CH_2OH.

If O—H bond scission is a general characteristic of the primary reaction of Hg 6($^3P_1$) atoms with the alcohols, these substrates could provide convenient sources for studying the properties of alkoxy radicals.

The ethanol reaction was the subject of an early investigation by Bates and Taylor (4). In the present study the decomposition has been examined under both continuous and intermittent illumination. Emphasis has been placed on the nature and efficiency of the primary process.

The details of the investigation follow.

EXPERIMENTAL

For the static runs at 25°, under continuous illumination, the apparatus was essentially identical with that used for the methanol reaction (2). The single- and double-sector equipment used for the intermittent-illumination studies has also been described previously (3). Light intensities, at 2537 Å, were determined as before (3) by propane actinometry (5, 6).

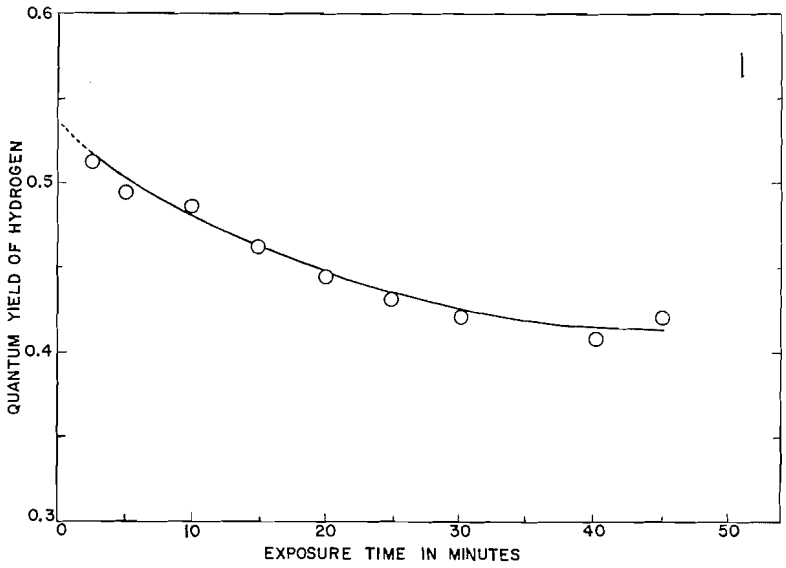
Benzene-free ethanol, 99.9% pure, was degassed, trap-to-trap distilled, and the middle fraction used without further purification.

[1]*Manuscript received July 27, 1961.*
Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta. A portion of this paper was presented at the 139th Meeting of the American Chemical Society, St. Louis, Missouri, March, 1961.

Analysis of the condensable products, excluding the glycols, was done by G.L.P.C. with "Ucon" and "Apiezon L" columns as previously described (2). Identification by retention time for each condensable product, except the glycols, was confirmed by mass spectrometry. The moles of product, non-condensable in liquid nitrogen, were determined from the PV/RT ratio in a calibrated gas burette. By mass spectrometry this product was shown to contain H_2, CO, and CH_4. The mole fractions of CO and CH_4 in the product were determined by G.L.P.C., on a 30/60-mesh molecular-sieves column, operating at room temperature, with H_2 carrier at a flow rate of 50 cc/minute.

The high-boiling glycol products were determined by dissolving the cell deposit in acetone, and analyzing this solution by G.L.P.C. The glass column used was 2.5 m in length, with 6 mm O.D., and filled with 15 wt-% didecyl phthalate on Celite. The column was operated at 120° with the flow rate of the H_2 carrier at 70 cc/minute. The katharometer was maintained at 150° and a current of 300 ma. A series of calibrations were performed with authentic samples of the three butanediols at various concentrations in acetone. The relative detector responses for the three glycols were found to depend slightly upon concentration. Correction was made in each case for this concentration effect. For each heavy-product analysis, the ratio of glycol to solvent was determined, and the appropriate relative responses were employed in the calculation of the percentage yields.

RESULTS



The runs with pure ethanol, under steady illumination, were carried out at a substrate pressure of 40 mm. The absorbed light intensity (I_a) was 1.60 ± 0.03 μeinsteins/minute. During the reaction the heavy product was observed to form in fine droplets, largely on the incident face of the cell.

The volatile products of the reaction were H_2, CH_3CHO, CO, C_2H_6, and CH_4, in order of decreasing importance. From Fig. 1, it is seen that $\Phi(H_2)$ rises with decreasing duration of exposure (t). By a short extrapolation, $\Phi^0(H_2) = 0.53$. The Φ's for CH_3CHO and C_2H_6 are shown in Fig. 2, as a function of t. $\Phi(CH_3CHO)$ falls rapidly with increasing t, indicating consumption by secondary reaction; whereas $\Phi(C_2H_6)$ is invariant in t. We find $\Phi^0(CH_3CHO) = 0.08$ and $\Phi^0(C_2H_6) = 0.006$. From Fig. 3, $\Phi(CH_4)$ rises linearly with t from $\Phi^0(CH_4) = 0.002$. $\Phi(CO)$ also rises with t, approaching a constant value of ca. 0.05. For $\Phi^0(CO)$ we find 0.025.

Long runs were required to obtain sufficient yields of the heavy product for total analysis. For runs with $t = 3$ and 6 hours, the heavy product was found to contain at least 85–90% of 2,3-butanediol. Complete analyses were performed on three separate runs with $t = 10$ hours. The composition of the heavy product was: 90% 2,3-butanediol, 8% 1,3-butanediol, and 2% 1,4-butanediol.

For the study of the reaction in the presence of nitric oxide, a mixture of 40 mm of EtOH and 10 mm of NO was used. The products were found to be EtONO, N_2O, H_2O, and H_2. No quantitative analysis was made for the water product. It should be noted that CH_3CHO was not detected in the reaction, whereas in the CH_3OH—NO system, HCHO was a minor but significant product (2). In Fig. 4, Φ(EtONO) is shown as a function of t. In order to correct the yield for competitive quenching by NO, the quenching cross section for EtOH was taken as 9 Å^2. The resulting quenching correction factor was 1.7. From Fig. 4, it is apparent that ethyl nitrite is being decomposed in secondary reaction. For Φ^0(EtONO) we obtain 0.25. Figure 5 shows the behavior of $\Phi(H_2)$ and $\Phi(N_2O)$ for the inhibited reaction. There is a gradual rise in $\Phi(N_2O)$ with decreasing t;

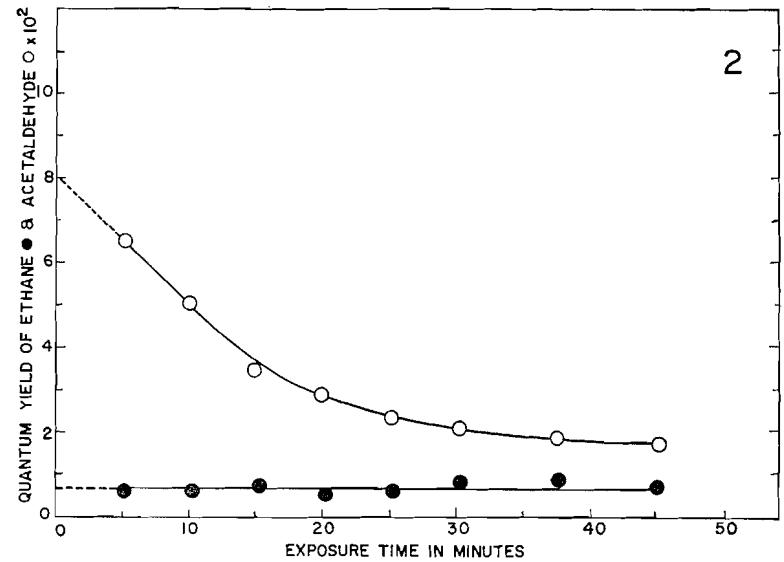

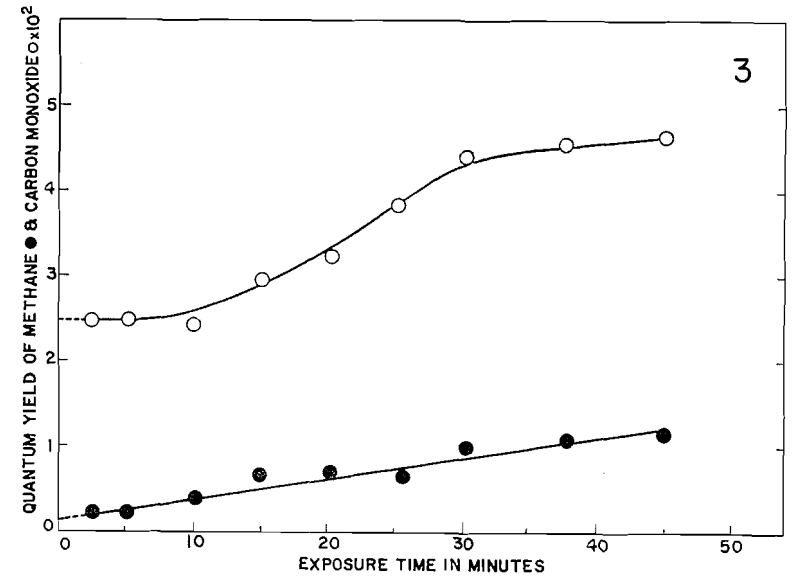

FIG. 1. $\Phi(H_2)$ vs. t for ethanol vapor at a pressure of 40 mm.
FIG. 2. $\Phi(C_2H_6)$, ●, and $\Phi(CH_3CHO)$, ○, vs. t for ethanol vapor at a pressure of 40 mm.

whereas $\Phi(H_2)$ is invariant in t. Extrapolation gives $\Phi^0(N_2O) = 0.14$, and $\Phi^0(H_2) = \Phi(H_2) = 0.017$.

In the intermittent-illumination studies, $\Phi(H_2)$ was determined as a function of both t_L and t_D. In all runs, pure substrate was used at a pressure of 40 mm. In order to assess the influence of t_D on $\Phi(H_2)$ at constant t_L, a series of runs were done with $t_L = 2.04$ msec, and t_D varying from 22.7 to 148 msec. For these runs, I_a values of 1.30, 1.43, and 1.60 μeinsteins/minute were used. The net duration of exposure in all cases was under 5 minutes. There was no dependence of $\Phi(H_2)$ on t under these conditions. The plot of $\Phi(H_2)$ vs. t_D is shown in Fig. 6. With increasing t_D, $\Phi(H_2)$ rises sigmoidally from 0.58

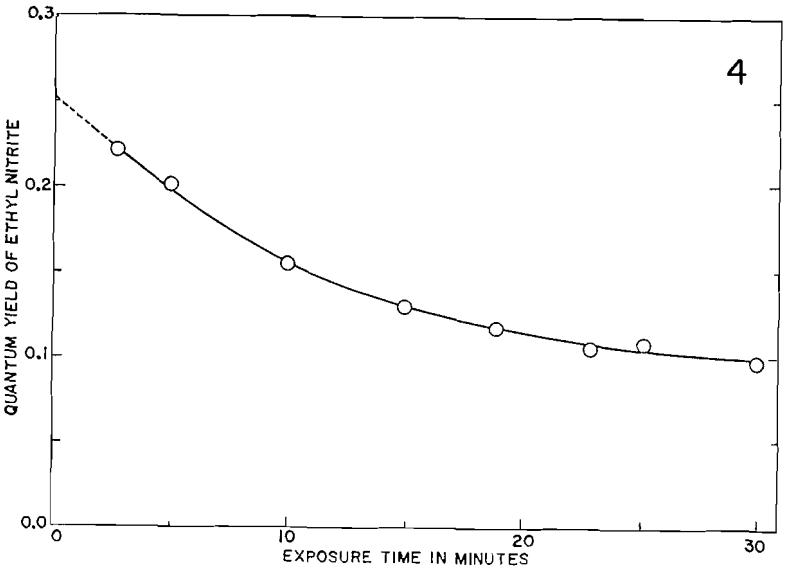

FIG. 3. $\Phi(CH_4)$, ●, and $\Phi(CO)$, ○, vs. t for ethanol vapor at a pressure of 40 mm.
FIG. 4. $\Phi(EtONO)$ vs. t for a mixture of 40 mm of ethanol and 10 mm of nitric oxide.

at t_D = 22.7 msec, to 0.76 at t_D = 148 msec. The value of $\Phi(H_2)$ becomes independent of t_D for t_D ca. 120 msec.

The relation between $\Phi(H_2)$ and t_L is shown in Fig. 7, using a logarithmic abscissa. Two separate series of runs are shown on the same curve. For t_L in the range 0.835 to 5.09 msec, the single sector was used with t_D at 103 msec. The I_a values were 0.72 and 1.43 μeinsteins/minute, and the net durations of exposure were in the range 1.00 to 5.00 minutes. For t_L values between 0.125 and 0.589 msec, the double sector was employed, with t_D at 160 msec. For these runs, I_a was 1.25 μeinsteins/minute, and the net durations

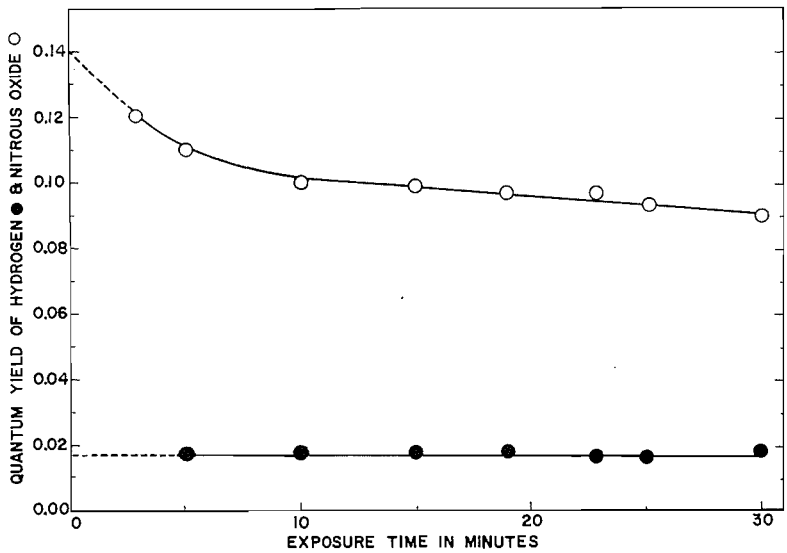

FIG. 5. $\Phi(H_2)$, ●, and $\Phi(N_2O)$, ○, vs. t for a mixture of ethanol and 10 mm of nitric oxide.

of exposure were between 0.77 and 1.08 minutes. Since the two series of runs fall on the same curve, as can be seen in Fig. 7, this is taken as evidence that $\Phi(H_2)$ is independent of t_D in the region 103–160 msec. From Fig. 7, it is apparent that $\Phi(H_2)$ rises linearly with decreasing log t_L to a t_L value of ca. 0.4 msec, beyond which the curve begins to flatten out. The maximum value of $\Phi(H_2)$ was found to be 0.96.

DISCUSSION

From the results of the present investigation, it is apparent that ethanol resembles methanol (1, 2) closely in its primary reaction with Hg $6(^3P_1)$ atoms. Thus, considering first the decomposition of the mixture of 40 mm EtOH and 10 mm NO, we find as products EtONO (0.25), N_2O (0.14), H_2O, and H_2 (0.017), where the numbers in parentheses give the Φ^0's. For the MeOH–NO system with the same NO concentration, Φ(MeONO) was 0.20 with $t = 5.0$ minutes (2). From Fig. 4, it can be seen that Φ(EtONO) has the same value at the same t. Again for methanol containing 10 mole% NO, $\Phi^0(H_2)$ was 0.012, and we obtain 0.017 for ethanol containing 20 mole% NO.

For the inhibited reaction, the products can be accounted for by the following sequence:

$$CH_3CH_2OH + Hg^* \rightarrow CH_3CH_2O + H + Hg, \quad [1]$$

$$CH_3CH_2O + NO \rightarrow CH_3CH_2ONO, \quad [2]$$

$$H + NO \rightarrow HNO, \quad [3]$$

$$HNO + HNO \rightarrow H_2O + N_2O, \quad [4]$$

$$HNO + HNO \rightarrow 2NO + H_2. \quad [5]$$

For reaction [2], Gray and Williams (7) estimate an exothermicity of 35–40 kcal/mole. Levy (8) has shown that [2] occurs in the thermolysis of Et_2O_2 in the presence of NO, and in the decomposition of ethyl nitrite (8) and ethyl nitrate (9). There is also some evidence (8, 10) that in the photolysis of Et_2O_2–NO mixtures, ethyl nitrite forms by [2].

In the above sequence, reactions [3], [4], and [5] have been discussed previously (2).

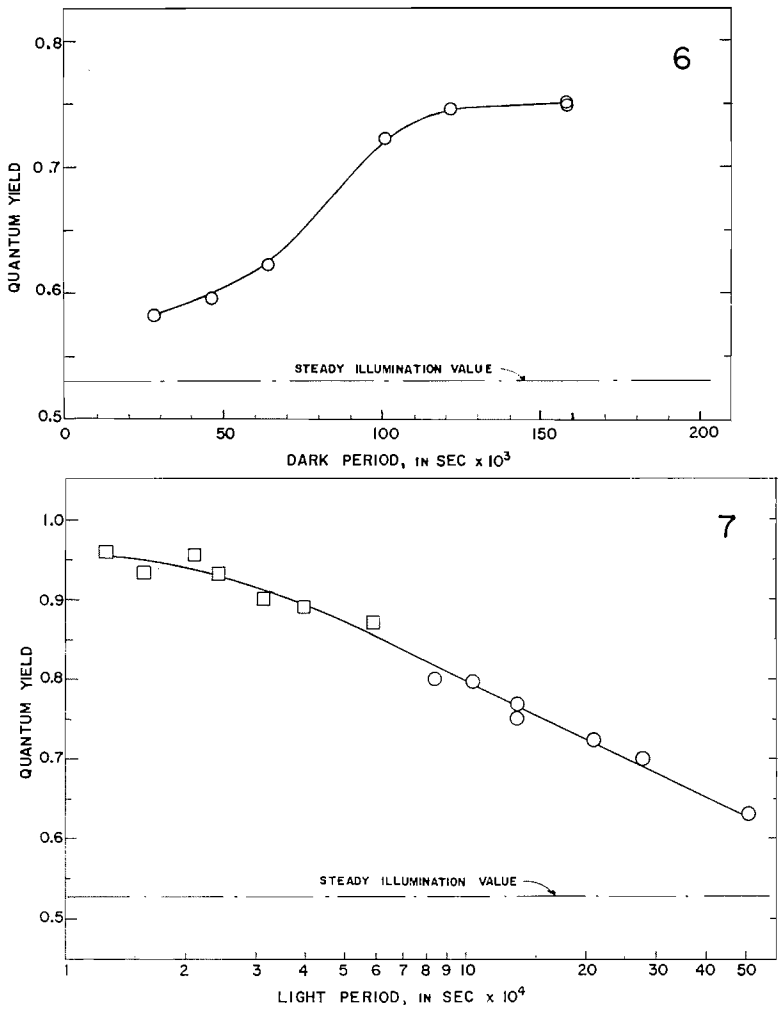

FIG. 6. $\Phi(H_2)$ as a function of dark period, for a constant light period of 2.04 msec, for ethanol vapor at a pressure of 40 mm.

FIG. 7. $\Phi(H_2)$ as a function of the logarithm of the light period, for dark periods of 103 msec, ○, and 160 msec, □, for ethanol vapor at a pressure of 40 mm.

From the ratio $\Phi^0(N_2O)/\Phi^0(H_2)$, k_4/k_5 is estimated to be ca. 8. To explain the fact that Φ^0(EtONO) is only 0.25, we suggest the reaction

$$CH_3CH_2O + HNO \rightarrow CH_3CH_2OH + NO. \qquad [6]$$

Since D(EtO–H) is 99 kcal/mole (7), step [6] should be highly exothermic. The fact that CH_3CHO was not detected as a product would suggest that there is no abstractive attack of ethoxy radicals on the ethyl nitrite. Here it is pertinent to note that Levy found that both ethyl nitrite (8) and ethyl nitrate (9) are relatively inert to ethoxy radicals at 181°. In the previous study (2), on the CH_3OH–NO reaction, HCHO was shown to be a minor secondary product which increased in importance with the exposure time. On energetic grounds, one would expect that EtO radicals would similarly remove a secondary hydrogen from EtONO, leading to the formation of CH_3CHO as a product. In our opinion, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

difference in the behavior of the two systems is due to the higher efficiency of the association reaction, [2], for EtO radicals compared with the analogous reaction for MeO radicals. Thus in the pyrolysis of MeONO the first-order rate constant falls off at substrate pressures less than 50 mm, indicating a dreierstoss restriction on the association reaction (7). This restriction should be less stringent for [2]. Hence it is likely that the stationary-state concentration of EtO radicals is lower than that for MeO radicals at the same NO concentration in the two systems. Since the aldehyde yield will be proportional to $(RO)^{\cdot}$, it is probable that CH_3CHO is formed in quantities too small for detection by our analytical methods. Presumably the decrease in Φ(EtONO) with t (cf. Fig. 4) is due to the photolysis of this product into EtO and NO. The resulting EtO radicals could then disappear by [6].

In the decomposition of the pure substrate, step [1] would be followed by:

$$CH_3CH_2O + CH_3CH_2OH \rightarrow CH_3CH_2OH + CH_3CHOH, \quad [7]$$

$$H + CH_3CH_2OH \rightarrow H_2 + CH_3CHOH, \quad [8]$$

$$2(CH_3CHOH) \rightarrow CH_3CHOHCHOHCH_3. \quad [9]$$

From the relative yields of the three butanediols, it follows that CH_2CH_2OH radicals must also be formed in [7] and [8], by abstraction at the methyl group of the ethanol. From the composition of the heavy product, $(CH_3CHOH)/(CH_2CH_2OH)$ must be ca. 11.

The activation energy for [7] has not been determined. If we assume that the C—H bond energy in ethanol does not exceed that in ethane, step [7] should be exothermic to at least 3 kcal/mole. Recently Wijnen (11) has reinvestigated the photolysis of ethyl propionate, and for the reaction

$$CH_3CH_2O + EtCOOEt \rightarrow CH_3CH_2OH + R \quad [10]$$

he finds an activation energy of 5.5 kcal/mole. It is unlikely that the activation energy of [7] would exceed that of [10].

The only other product in the ethanol reaction which is clearly of primary origin is acetaldehyde, for which $\Phi^0 = 0.08$. In this system, it seems unlikely that the acetaldehyde arises by disproportionation of ethoxy radicals. The absence of hydroxy-ethers among the products would suggest that the stationary-state concentration of EtO is very low. Now from the analysis of the heavy fraction, we know that the radicals (R) undergoing combination consist of a ca. 11:1 mixture of CH_3CHOH and CH_2CH_2OH. If the disproportionation of the R radicals is the source of the acetaldehyde, the dominant reaction would be:

$$CH_3CHOH + CH_3CHOH \rightarrow CH_3CH_2OH + CH_3CHO. \quad [11]$$

This reaction would involve an intermediate $\dot{C}H_2CHOH$ structure, which should rearrange readily to CH_3CHO. Since $\Phi^0(H_2) = 0.53$, Φ(R) must have the same value. Thus k_{11}/k_9 would be $(0.08)/(0.26_5-0.08)$, or ca. 0.3. This value is likely low, since, as will be seen, CH_3CHO is suffering decomposition by secondary reaction.

The rapid decrease in $\Phi(CH_3CHO)$ with t is evident from Fig. 2. Since the weakest C—H bond in CH_3CHO is 80 kcal/mole (7), the reaction

$$R + CH_3CHO \rightarrow RH + CH_3CO \quad [12]$$

will be highly exothermic, and the one likely to be responsible for CH_3CHO consumption. From our data, the mean rate of CH_3CHO formation during the first 5 minutes of reaction is 0.10_4 μmoles/minute. With no secondary destruction of this product, there should be $45\times0.10_4$ or 4.7 μmoles at $t = 45$ minutes. Since only 1.2 μmoles were found at $t = 45$ minutes, 3.5 μmoles have been consumed. The yield of CO at $t = 45$ minutes was 3.3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

μmoles. We are, of course, assuming that the CO arises from the decomposition of the CH_3CO radicals formed in [12]. The accountability in CH_3 is not quite so satisfactory. At $t = 45$ minutes, there were 1.1 μmoles of CH_4 and 0.45 μmoles of C_2H_6. We can therefore account for 2.0 of the 3.3 μmoles of CH_3 in this manner.[2]

From the results of the studies under intermittent illumination, as shown in Fig. 7, we can now say that the primary quenching reaction [1] is at least 96% efficient. Furthermore, since in the inhibited reaction there is no evidence of any other radical association product than ethyl nitrite, it appears justifiable to say that $\Phi(H) = \Phi(CH_3CH_2O) = 0.96$. Since the effect of intermittent illumination has been discussed in some detail for the methanol reaction (3), we will limit ourselves here to the conclusion that the low $\Phi(H_2)$ under steady illumination is due mainly to substrate re-formation by the addition of H atoms to the radicals present in the system. For ethanol the dominant reaction would be:

$$H + CH_3CHOH \rightarrow CH_3CH_2OH. \qquad [13]$$

The main difference between methanol (3) and ethanol is that the $\Phi(H_2)$ for the latter rises more rapidly toward unity with decreasing t_L. Now at the same I_a and primary quantum efficiency, the reactions controlling the H-atom concentration will be [8] and [13] and their analogues for methanol. An obvious conclusion is that the abstraction reaction [8] is faster for ethanol than methanol, which would result in a lower value for (H) in the ethanol system, and a reduced rate of substrate re-formation by [13]. For both methanol (3) and ethanol (Fig. 6), it was necessary for t_D to be at least 100 msec to obtain the maximum value of $\Phi(H_2)$ at a given t_L. It seems reasonable to conclude that the t_D value of 100 msec represents the minimum time required for the radical concentration to decay to zero between successive light pulses.

CONCLUSIONS

As a result of the present investigation, it can be concluded that ethanol molecules react with Hg $6(^3P_1)$ atoms by O—H bond scission to form ethoxy radicals and H atoms with at least 96% efficiency. The ethoxy radicals and H atoms react with the substrate by abstraction to form mainly CH_3CHOH radicals. The low value for $\Phi(H_2)$ under continuous illumination is due largely to the addition of H atoms to CH_3CHOH radicals.

ACKNOWLEDGMENTS

The authors would like to express their appreciation to Dr. Willard F. Allen of this laboratory for assistance in the experimental work and many helpful discussions.

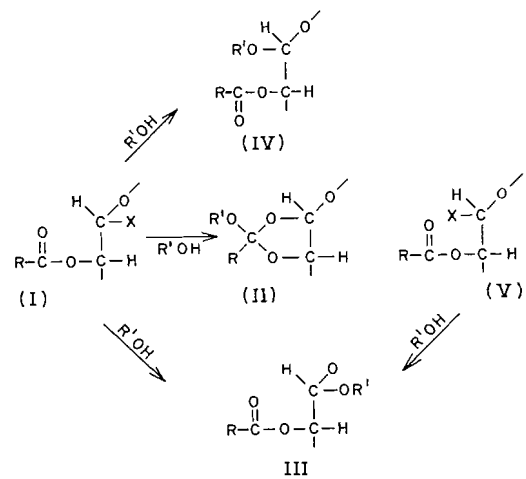
CONFIGURATION OF GLYCOSIDIC LINKAGES IN OLIGOSACCHARIDES

IX. SYNTHESIS OF α- AND β-D-MANNOPYRANOSYL DISACCHARIDES[1]



P. A. J. Gorin and A. S. Perlin

ABSTRACT

The Königs–Knorr condensation of 4,6-di-*O*-acetyl-2,3-*O*-carbonyl-α-D-mannopyranosyl bromide with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose provides a synthetic route to 6-*O*-β-D-mannopyranosyl-D-glucose. When some other derivatives of α-D-mannopyranosyl bromide—the 2,3,4,6-tetra-*O*-benzoyl-, 3,4,6-tri-*O*-acetyl-, or 3,4,6-tri-*O*-acetyl-2-*O*-benzyl derivative—are used as the halide component the α-D-linked isomer of this disaccharide is produced. The steric outcome of Königs–Knorr syntheses involving these and other derivatives of α-D-mannopyranosyl bromide is discussed in terms of the influence of neighboring groups, and of conformational and solvent effects.

Lead tetraacetate oxidation of 6-*O*-β-D-mannopyranosyl-D-glucose, followed by reduction, affords 4-*O*-β-D-mannopyranosyl-D-erythritol, a metabolite produced by *Ustilago* species (PRL 627).

In an earlier study (1) it was found that the major disaccharides produced by the Königs–Knorr condensation of 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose and -mannose possess the α-D-, rather than the β-D-linkage assigned originally (2). This finding was consistent with current views (3–7) on the reactions of acylated glycosyl halides with alcohols, according to which a 1,2-*trans*-halide (I, R = CH_3 or phenyl) due to participation of the 2-acyloxy group, is expected to yield either an orthoester (II) or the 1,2-*trans*-glycoside (III), although a small amount of inversion may also occur to yield the 1,2-*cis*-glycoside (IV). Predominant inversion would be expected with the 1,2-*cis*-halide (V), the *trans*-glycoside again being formed. In several instances, however, 1,2-*cis*-glycosides have been prepared by modifying or eliminating (6, 7, 8) the neighboring-group effect of the 2-substituent. Therefore, in attempting now to synthesize D-mannopyranosyl oligosaccharides possessing the β-(1,2-*cis*-)-linkage, this type of approach has been examined using various derivatives of α-D-mannosyl bromide in the Königs–Knorr reaction.

Ness, Fletcher, and Hudson found that treatment of 2,3,4,6-tetra-*O*-benzoyl-α-D-mannopyranosyl bromide with methanol in the absence of an acid acceptor produced the α-D-glycoside but not an orthobenzoate (9). Since the latter could have only a transient existence under such acidic conditions it is not surprising that this result contrasts sharply with the extensive production of orthoester from the corresponding acetobromo derivative in the presence of silver carbonate (3, 10). The possibility remained, however, that the participating properties of the benzoxy group under Königs–Knorr conditions might differ sufficiently from those of the acetoxy group to permit formation of relatively more of the inverted (β-D-) product than had been obtained with the acetate (3, 10). Accordingly, the tetra-*O*-benzoyl bromide was treated with methanol containing silver carbonate, but the chief product was an amorphous tri-*O*-benzoyl methyl 1,2-orthobenzoate, and only a small proportion of the β-glycoside was detected. Hence, the characteristics of both acyloxy halides are in reality closely similar. The Königs–Knorr condensation with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose was also examined, and the (1 → 6) linked α-D-disaccharide (1) again was found to be the major biose produced. However, the total yield was considerably better than obtained with the acetobromo derivative (39% vs. 25% (1, 2)), and the proportion of the β-D-linked isomer in the disaccharide fraction was even smaller (5% vs. 14%). It appears advantageous, therefore, to use the *O*-benzoyl bromide rather than the corresponding acetate for the synthesis of D-mannopyranosyl disaccharides possessing the α-configuration.

A high degree of inversion in the reaction of 2-*O*-methyl-α-D-mannopyranosyl fluoride with sodium alkoxide is known to occur (11). The influence of the 2-methoxy group under Königs–Knorr conditions has now been examined using 2,3,4,6-tetra-*O*-methyl-α-D-mannosyl bromide (12). With methanol in the presence of silver oxide this halide produced a mixture of the β- and α-glycosides in the ratio of 3:1, showing again that inversion predominates when the 2-position contains a "non-participating" substituent (see below). Without the acid acceptor, the proportion of β-glycoside was somewhat less, the ratio being 2:1. However, although the effect of the methoxyl group is to favor the formation of β-D-mannosides, its stability limits the usefulness of the *O*-methyl derivative in oligosaccharide synthesis.

For the latter purpose, the *O*-benzyl ether group appeared to offer greater promise as a substituent which should be stable under the condensation conditions but easily removable from the product. 2-*O*-Benzyl-D-mannose (13) was acetylated and the product treated with hydrogen bromide in chloroform, the specific rotation of the bromide indicating that the α-anomer had been formed predominantly. On reaction with methanol in the presence of silver oxide the bromo derivative yielded a levorotatory syrup which was found to contain mainly the β-D-mannoside and only a small proportion of the α-glycoside. However, when the condensation was carried out using 1,2,3,4-tetra-*O*-acetyl-β-D-glucose as the hydroxylic component, the product, following hydrogenolysis and deacetylation, proved to be predominantly 6-*O*-α-D-mannopyranosyl-D-glucose.

The possibility of using a D-mannosyl halide unsubstituted in the 2-position was also examined briefly, by analogy with the use of glycosyl halides containing a free 2-hydroxyl group in the D-glucose (14), 6-deoxy-D-glucose (15), and pentafuranose (see 16) series. For a preparation of a corresponding D-mannosyl halide, 3,4,6-tri-*O*-acetyl-D-mannose (17, 18) was treated with hydrogen bromide, affording a strongly dextrorotatory (and hence presumably the α-1-bromide) syrup. When the latter was condensed under Königs–Knorr conditions with methanol, a mixture of α- and β-glycosides (ratio of approximately 3:1) was formed, and of the disaccharides produced with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose, the β-isomer comprised only a trace proportion.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The properties of a different type of 2-substituted D-mannosyl bromide, the 2,3-*O*-carbonate, were also examined under Königs–Knorr conditions and with this bicyclic derivative inversion was found to occur both with methanol and 1,2,3,4-tetra-*O*-acetyl-β-D-glucose as hydroxylic components. In two previous instances a 2,3-*O*-carbonate derivative has been used successfully to prepare a 1,2-*cis*-glycoside from a 1,2-*trans*-halide, i.e. in the D-mannofuranose (19) and D-ribofuranose series (20). In the current study the halide used was 4,6-di-*O*-acetyl-2,3-*O*-carbonyl-α-D-mannopyranosyl bromide (VI), preparation of which involved the following steps:

benzyl α-D-mannopyranoside (BM) → 6-*O*-trityl-BM
→ 2,3-*O*-carbonyl-6-*O*-trityl-BM → 2,3-*O*-carbonyl-BM
→ 4,6-di-*O*-acetyl-2,3-*O*-carbonyl-BM → 4,6-di-*O*-acetyl-2,3-*O*-carbonyl-D-mannose → 1,4,6-tri-*O*-acetyl-2,3-*O*-carbonyl-D-mannose → VI.

With methanol in the presence of silver oxide, VI afforded a syrupy product which, on treatment with barium methoxide followed by acetylation, gave methyl 2,3,4,6-tetra-*O*-acetyl-β-D-mannopyranoside; only a trace of the α-anomer was detected. The product obtained by condensing VI with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose was also treated with barium methoxide, and the free disaccharide fraction was isolated by cellulose column chromatography. This was found to consist almost entirely of the β-isomer, which crystallized readily from the mixture. A sample of syrupy 6-*O*-β-D-mannopyranosyl-D-mannose was also prepared by condensation of VI with 1,2,3,4-tetra-*O*-acetyl-αβ-D-mannose.

By oxidation of the synthesized 6-*O*-β-D-mannopyranosyl-D-glucose with 2 moles of lead tetraacetate (to obtain the 4-substituted D-erythrose derivative (21)), and then reduction of the product with sodium borohydride, 4-*O*-β-D-mannopyranosyl-D-erythritol (1-*O*-β-D-mannopyranosyl-L-erythritol) (22, 23) was prepared. This result, therefore, confirms by synthesis the earlier assignment based on isotopic data (23) of the configuration of the tetritol unit in this metabolite from *Ustilago* species (PRL 627).

DISCUSSION

The foregoing results, and other data obtained with 2,3,4,6-tetra-*O*-acetyl-α-D-mannosyl bromide (1, 2, 3) show wide variations in the steric properties of different α-D-mannosyl bromide derivatives. However, there are two general patterns evident and these appear to be associated with a change in the reaction medium. The disaccharide syntheses (except those carried out with the 2,3-*O*-carbonate) are characterized by retention of configuration, and necessarily involve the use of an "inert" solvent. For the methyl glycoside syntheses, in which methanol serves both as solvent and hydroxylic component, inversion and orthoester formation are the more prominent features.* These findings are analogous to those of Isbell and Frush (3) on the methanolysis of 2,3,4,6-tetra-*O*-acetyl-α-D-mannosyl bromide in the presence of silver carbonate. They found that the β- (but not α-) D-glycoside is formed, in addition to orthoacetate, when methanol alone is the medium, but that in the presence of ether or benzene as diluent more of the α- than β-D-mannoside, and much less orthoacetate, is formed. A similar mixture of the corresponding dimeric products is obtained using chloroform as solvent when the hydroxylic component is 1,2,3,4-tetra-*O*-acetyl-β-D-glucose (2).

**In one experiment, tetra-O-acetyl-α-D-mannopyranosyl bromide was condensed with 1,2,3,4-tetra-O-acetyl-β-D-glucose using a fourfold excess of the latter and chloroform sufficient only to produce fluidity. Such conditions approximated those used for methyl glycoside synthesis and, in fact, altered the ratio of α- to β-disaccharide produced from about 6:1 to about 2:1.*

Formation of the α-D-mannoside was accounted for by Isbell and Frush in terms of neighboring-group participation by the 2-acetoxy group. In more recent years additional evidence for a neighboring-group effect of this kind in many other nucleophilic substitution reactions that lead to retention of configuration has been accumulated (see especially ref. 24). Hence it may be inferred that the examples of retention observed in the synthesis of α-D-mannopyranosyl disaccharides also involve neighboring-group participation. With the D-mannose derivatives used several such possibilities can be recognized. The 2-*O*-benzoyl, as well as the 2-*O*-acetyl, derivative reacts with methanol to give the 1,2-orthoester in high yield, a direct demonstration of a neighboring-group effect, and also *dimeric* 1,2-orthoesters are known in the acetate series (2, 25). Participation by the 6-acetoxy group appears to be feasible in reactions of the 2-*O*-benzyl and 2-hydroxy derivatives, although in the D-glucose series this group is usually thought to have a minor influence on the steric outcome of substitution reactions at C-1 (14, 26). Also favoring the possibility of retention by the benzyl derivative is evidence that a 1,2-*trans*-alkoxyhalide can form a cyclic alkoxonium ion during silver-ion-assisted replacements (27). With the 2-hydroxy derivative, the 1,2-*trans*-diaxial arrangement is especially favorable for formation of an intermediate 1,2-anhydride (28) which, on further reaction, should afford 1,2-*trans*-products. Apparently this possibility does not arise with the *trans*-diequatorial 1-chloro-2-hydroxy derivatives of 6-deoxy-β-D-glucose (15) and -β-D-glucose (14), which undergo predominant inversion on ethanolysis or acetolysis. However, the structure of the monohydroxy-D-mannosyl bromide is not yet known with certainty, and conclusions about its behavior must therefore be made with reserve.

Although there may be several possibilities for neighboring-group participation in the reactions studied, these possibilities do not account for the marked steric changes that accompany the change in solvent, e.g., little retention or a great predominance of orthoester formation when the diluent is absent. According to current views, substitution reactions of glycosyl halides proceed likely via a unimolecular course (29, 30, 31). This may apply for a solvent of high polarity, such as methanol, but there is the possibility that the characteristics of the reactions themselves may be altered from unimolecular to bimolecular by the transfer to the much less polar media (ether, benzene, or chloroform). However, since the present data do not give information about kinetic order it cannot be assumed that such an alteration occurs. In fact, the direction of the steric changes induced is contrary to what might then be expected: the inverted configuration of the products formed in methanol is even more characteristic of a bimolecular than unimolecular course, whereas the retention found with the media of low ionizing power is rarely a property of S_N2 reactions.

Within the framework of the S_N1 mechanism, Königs–Knorr syntheses involving α-D-mannosyl halides may be considered in terms of ions such as VII and VIII (5, 6, 7, 30). The formation of β-D-mannosides appears to result from attack by the hydroxylic component on VII, at the side opposite to that shielded by the departing halide ion (7). Such a pathway is presumably important when methanol is the solvent. In the media of lower ionizing power the structure of VII may become modified through increased ion pair aggregation, perhaps in such a way as to induce the steric changes observed. Another possibility is that solvation of ion VII in these media involves the formation of intermediates analogous to those described by Doering and Zeiss (32, 24). For example, IX corresponds to the symmetrically solvated ion postulated by them to account for racemization in S_N1 reactions. However, the presence of the various ring substituents on the D-mannosyl analogue in fact renders such an ion unsymmetrical and interactions, notably between the 2,3- and 6-substituents, might favor eventual formation of the 1,2-*trans*-

rather than the less stable 1,2-*cis*- product. Such an outcome should be favored even more when the hydroxylic component is a bulky tetraacetyl hexose molecule than with methanol.

If neighboring-group participation is possible, ion VIII is expected to be more prominent than VII, although an appreciable proportion of the latter may be present (3, 6, 31). It is generally held that orthoester is formed through attack by the hydroxylic component at

(XIII)

C_3 of VIII and that acceptance of the incoming group at C_1 results in retention of configuration (i.e., in formation of the α-D-mannoside). The generation of an intermediate orthoester ion (X) of type VIII during substitution reactions was postulated originally by Winstein and Buckles (33). With cyclohexane derivatives, for example, they found that several solvolysis reactions proceed with complete retention of configuration, which indicated that "open" carbonium ions (analogous to VII) are not involved and that the incoming groups enter at C_1 of the cyclic ion. However, no retention was observed in solvolyses involving hydroxylic components (water or ethanol), which therefore appeared to attack only at C_3 of X, yielding orthoacid or orthoester.

In the Königs–Knorr syntheses it must be assumed that the effect of solvent is such as to favor reaction at C_3 of VIII under some conditions, but also to promote reaction at C_1 under other conditions. According to Isbell and Frush (3), the presence of a high ratio of ether causes a decrease in the yield of orthoacetate and an increase of α-glycoside, from the methanolysis of tetra-*O*-acetyl-α-D-mannosyl bromide, by competitive solvation of a bimolecular transition complex. In accord with more recent views this suggestion has been modified (6, 7) in terms of the ion VIII: in methanol the favored substitution site is at C_3, but competitive solvation by nucleophilic ether (as in XI, e.g. (6)) permits a rearward attack at C_1 to take place. However, the same explanation does not account

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

adequately for the results of the disaccharide syntheses, in which retention occurs to an even greater degree, because the diluents used have much less nucleophilic character. One factor favoring attack at C_1 when the concentration of the hydroxylic component is low, is the possibility (suggested by S. Winstein, private communication) that solvation of the departing halide ion by the hydroxylic component promotes an "orientation" of the latter in the vicinity of C_1. Further, it may be noted that substitution at C_1 involves a ring-opening step, and Winstein and Buckles regard this step as having S_N2 characteristics (33). Hence it is conceivable that an effect of decreasing solvent polarity is to increase the rate of substitution at C_1 relative to that at C_3 (34).

Another type of transition state which may be visualized is one intermediate between solvated forms of ion VII (IX) and solvated forms of VIII; for example, XII. Such an ion should be more prominent with a non-polar diluent present than in methanol, because under the former conditions the neighboring nucleophilic acyloxy (or alkoxy) substituent should be able to compete more effectively with the hydroxylic component as a solvating species. Presumably, an α-D-mannoside would be the product of this pathway.

Still other factors may affect the steric outcome of these syntheses. For example, Talley, Reynolds, and Evans (2) showed that in the reaction of tetra-*O*-acetyl-α-D-mannosyl bromide with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose, the presence of iodine suppresses the yield of dimeric orthoester and increases the yield of (α-linked) disaccharide. Iodine is likewise used in the current disaccharide syntheses. In turn, the iodine appears to depress the catalytic effect of the silver oxide on the rate of dissociation of the glycosyl halide (25).

The 2,3-*O*-carbonyl-α-D-mannosyl bromide is exceptional in that it undergoes inversion under both sets of reaction conditions. Molecular models suggest that the carbonate group present cannot participate readily in substitution reactions at C-1, and hence that retention of configuration should be obviated on this basis. However, it appears much more probable that this halide, in contrast to the monocyclic halides used, can react via a bimolecular course, thus ensuring inversion. This possibility arises from the fact that the fused 5-membered carbonate ring modifies the conformation of the pyranose ring (e.g., as in XIII) (35, 36) in such a way as to resist formation of a planar carbonium ion about C-1.

EXPERIMENTAL

Paper chromatography was carried out with Whatman No. 1 paper using (A) butanol:ethanol:water (40:11:19) and (B) ethyl acetate:pyridine:water (10:4:3) as solvents, and (C) *p*-anisidine hydrochloride or (D) ammoniacal silver nitrate as spray reagents. Evaporations were carried out under reduced pressure at 40–45° C and optical rotations measured at 26°±2° C. Silicic acid used in chromatography had a mesh size of 100 to the inch.

*3,4,6-Tri-O-benzoyl-*D*-mannopyranose-1,2-methyl Orthobenzoate*

Amorphous 2,3,4,6-tetra-*O*-benzoyl-α-D-mannopyranosyl bromide (9) (0.45 g) was added to a suspension of silver carbonate (1.5 g) in absolute methanol (15 ml). The mixture was shaken for 2 hours, filtered, the filtrate and washings were concentrated, and the syrup obtained was extracted into ether. Evaporation of the ether afforded a white, amorphous solid (0.35 g); $[\alpha]_D$ −124° (*c*, 1.4, methanol). Calculated for $C_{35}H_{30}O_{10}$: C, 68.8%; H, 5.1%; total benzoate, 4.0 moles; *O*-benzoate, 3.0 moles. Found: C, 68.5%; H, 4.95%; total benzoate (acid *plus* alkali hydrolyzable), 3.91 moles; *O*-benzoate (cold alkali saponifiable), 3.05 moles.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Examined by deacylation with sodium methoxide followed by paper chromatography, the product was shown to contain a trace of methyl β-D-mannoside. When treated with 0.3% methanolic hydrogen chloride the orthobenzoate (14 mg/ml) showed an optical rotatory change from α_D −1.53° (1 dcm, initial) → −0.37° (3 minutes, constant) (cf. ref. 37).

D-*Mannopyranose-1,2-methyl Orthobenzoate*

The tribenzoyl orthobenzoate (0.1 g) in methanol (5 ml) was treated with a slight excess of barium methoxide for 1 hour, the solution was neutralized with barium carbonate, and evaporated. Water was added to the resulting syrup, the suspension was filtered, and the filtrate extracted three times with chloroform to remove methyl benzoate. On concentrating the aqueous layer an amorphous product ($R_{mannose}$ 3.7, solvent A) was obtained; this product contained a phenyl group (ultraviolet spectrum) but no ester group (infrared spectrum). In 0.02 *N* sulphuric acid (1.2 ml) the observed rotation of the material (22.6 mg) changed from α_D −0.51° (initial, 1 dcm) → +0.18° (20 minutes, constant), and the presence of 0.9 benzoate groups saponifiable with cold alkali was then found (calculated, 1.0 benzoate groups).

6-O-α-D-Mannopyranosyl-D-glucose

To a mixture containing 1,2,3,4-tetra-*O*-acetyl-α-D-glucose (0.52 g), silver oxide (1.0 g), iodine (0.5 g), and Drierite* (5.0 g), in dry dichloromethane (10 ml), was added, with shaking, a solution of 2,3,4,6-tetra-*O*-benzoyl-α-D-mannosyl bromide (1.0 g) in dichloromethane (5 ml); the addition was made in five equal portions over a period of 4 hours. More silver oxide (0.3 g) was added and the mixture shaken for a further 18 hours, filtered, and the filtrate was concentrated to a syrup. Yield, 1.2 g.

A benzene solution of the product was extracted three times with water (which removed most of the monomeric material present), the benzene was evaporated, and the residue was treated for 2 hours with excess sodium methoxide solution. After acidification with acetic acid the reaction mixture was concentrated, taken up in water, and oily material present (methyl benzoate) was extracted into chloroform. The aqueous phase was then transferred to a column of coconut charcoal (38), which was eluted with 5%, and then 15% ethanol. The latter eluate contained most of the disaccharide fraction which, after purification with mixed ion-exchange resins, was recovered as an amorphous solid. Yield, 0.20 g. $[\alpha]_D$ +70° (*c*, 1.8, water); after addition of excess sodium metaperiodate to the solution the equilibrium rotation was $[\alpha]_D$ +73° (assuming conversion of 18 mg of the disaccharide to 10 mg of trialdehyde (39)). (Based on the data given in ref. 39, the latter rotational value corresponds to that of an α,β-mixture of about 95:5.) The product was chromatographically indistinguishable from 6-*O*-α-D-mannopyranosyl-D-glucose (solvent B); none of the β-isomer (see below) was detected. In agreement with the presence of a (1 → 6) linkage the compound rapidly consumed 2.0 moles of lead tetraacetate per mole (21). Calculated for $C_{12}H_{22}O_{11}$: C, 42.1%; H, 6.5%. Found: C, 41.9%; H, 6.6%.†

Reaction of 2,3,4,6-Tetra-O-methyl-α-D-mannosyl Bromide with Methanol

A solution of 1-*O*-acetyl-2,3,4,6-tetra-*O*-methyl-α-D-mannose (12) (0.25 g) in chloroform (0.7 ml) was treated with 30% hydrogen bromide in acetic acid (0.5 ml) for 3 hours. More chloroform was added, the solution was extracted successively with ice water, cold sodium bicarbonate solution, and ice water, and dried. A yellow syrup (215 mg) was obtained on

**Anhydrous calcium sulphate.*

†The β-octaacetate of this disaccharide is amorphous (2). Attempts to convert the compound to a 2,5-dichlorophenylhydrazone or, by reduction, to the corresponding biitol yielded amorphous products.

evaporation of the solvent; $[\alpha]_D$ +210° (*c*, 2, benzene).* This product appeared to be highly unstable and in the following experiments was used immediately after preparation:

(*a*) The bromide (50 mg) in benzene (0.5 ml) was added with vigorous shaking to methanol (5 ml) containing silver oxide (50 mg). After 4 hours the suspension was filtered and the filtrate evaporated to give a syrup (45 mg); $[\alpha]_D$ −39° (*c*, 2, methanol). Examination of this syrup by gas–liquid chromatography, under conditions described by McInnes *et al.* (40), indicated that it consisted of a mixture of methyl α- and β-D-mannosides in a ratio of approximately 1:3.

(*b*) The bromide was treated with methanol as in (*a*) but no silver oxide was added; in 15 minutes the solution showed $[\alpha]_D$ −20° (constant). Excess silver carbonate was added and the solvent was evaporated. Examined by gas–liquid chromatography, the syrup isolated was found to contain an α,β-glycoside mixture in the ratio of about 1:2.

Königs–Knorr Syntheses Using 3,4,6-Tri-O-acetyl-2-O-benzyl-α-D-mannopyranosyl Bromide

2-*O*-Benzyl-D-mannose† (13) (93 mg) was heated at 100° C for 2 hours in acetic anhydride (5 ml) containing sodium acetate (100 mg). Excess anhydride was destroyed with ice water and the solution extracted with chloroform. Evaporation of the extract yielded 1,3,4,6-tetra-*O*-acetyl-2-*O*-benzyl-αβ-D-mannopyranoside (153 mg); $[\alpha]_D$ +7° (*c*, 0.8, $CHCl_3$).

The acetate was dissolved in chloroform (20 ml) containing an excess of hydrogen bromide.‡ The specific rotation soon became constant: $[\alpha]_D$ +40° (2 minutes) → +66° (10 minutes, constant value). After 15 minutes the solution was evaporated and residual hydrogen bromide removed by repeated evaporation of added benzene (3 times).

(*a*) Half of the above bromide was shaken overnight with methanol (3 ml) containing silver oxide (200 mg). The product obtained after filtration and evaporation of the solution had $[\alpha]_D$ −24° (*c*, 1.9, $CHCl_3$) and, after deacetylation, was found chromatographically to contain two components (solvent A, spray C). The main component had R_F 0.69 and the minor R_F 0.77 and by analogy with the R_F's of the corresponding methyl mannopyranosides in the same solvent the slower material should have the β-configuration. This observation agrees with the specific rotation of the product being much closer to that of methyl-β-tetra-*O*-acetyl-β-D-mannopyranoside (−50°) than of the α-anomer (+49°).

(*b*) To the other half of the bromide was added a mixture of tetraacetylglucose (0.4 g) in chloroform (3 cc) containing silver oxide (200 mg), iodine (67 mg), and Drierite (1 g). After it was shaken for 18 hours, the reaction mixture was filtered and the filtrate evaporated. The syrupy product was dissolved in ethanol and debenzylation was effected by shaking with palladium–charcoal in hydrogen at 40 p.s.i. After repetition of the hydrogenolysis the solution was filtered and evaporated. Deacetylation with sodium methoxide in methanol yielded a mixture of which the disaccharide fraction corresponded preponderantly to 6-*O*-α-D-mannopyranosyl-D-glucose, with only a trace proportion of the β-anomer being detected (solvent B, spray C).

Königs–Knorr Syntheses Using 3,4,6-Tri-O-acetyl-α-D-mannosyl Bromide

Crystalline 3,4,6-tri-*O*-acetyl-α-D-mannose (18) (0.11 g) was dissolved in dichloromethane (5 ml) and the solution was saturated with dry hydrogen bromide. A turbidity soon developed and then cleared within 30 minutes, the observed rotation being α_D

**A syrup having the same specific rotation was isolated also when the 1-O-acetyl-tetra-O-methyl derivative was treated with hydrogen bromide in dichloromethane to constant rotation.*

†Prepared in a manner analogous to that used for preparation of 2-O-methyl-D-mannose (41).

‡Use of hydrogen bromide in acetic acid – chloroform resulted in debenzylation of the acetate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

+2.05° (1 dcm, constant). The solution was concentrated *in vacuo* without application of external heat, benzene was then added, and the concentration repeated; yield, 0.10 g of a yellow syrup, $[\alpha]_D$ +140° (*c*, 3.3, benzene). The syrup was dissolved in benzene (3 ml) and used immediately in the following experiments:

(*a*) A portion of the benzene solution (0.6 ml) was added dropwise with shaking to methanol (0.6 ml) containing silver oxide (40 mg) and iodine (20 mg). After 18 hours the supernatant solution (α_D −0.02°) was treated with excess sodium methoxide and then examined chromatographically. The major products detected on the paper (solvent A, spray D) corresponded to methyl α- and β-D-mannoside (approximate ratio 3:1, visual estimation), and mannose (cf. ref. 24).

(*b*) A portion of the benzene solution (0.6 ml) was added dropwise with shaking over a period of 3 hours to a solution of 1,2,3,4-tetra-*O*-acetyl-α-D-glucose (30 mg) in benzene (1 ml) containing silver oxide (40 mg) and iodine (20 mg). After 18 hours the supernatant solution was treated with excess sodium methoxide and examined chromatographically (solvent B, spray C). The major disaccharide detected corresponded to 6-*O*-α-D-mannopyranosyl-D-glucose, and only a trace of the β-isomer appeared to be present.

The paper chromatographic examinations indicated that minor, unidentified, products were also formed in experiments (*a*) and (*b*).

Reaction of 2,3,4,6-Tetra-O-acetyl-α-D-mannosyl Bromide with Excess 1,2,3,4-Tetra-O-acetyl-β-D-glucose

To a mixture of the bromide (2.0 g), silver oxide (2.5 g) and Drierite (5.0 g) a solution of 1,2,3,4-tetra-*O*-acetyl-β-D-glucose (7.0 g) in dry chloroform (5 ml) was added and the mixture stirred overnight. The solution was diluted with methanol, filtered, and the filtrate was treated with sodium (0.2 g) in methanol. After 3 hours the solution was neutralized with acetic acid and examined on a paper chromatogram (solvent B, spray C). The disaccharide fraction consisted of two materials ($R_{lactose}$ 1.0 and 0.7, solvent B) in a ratio of about 2:1, the former corresponding to 6-*O*-α-D-mannopyranosyl-D-glucose and the latter to the β-anomer. Thus the ratio of the β- to the α-disaccharide was about 3 times as great as when equimolar amounts of the bromide and tetra-*O*-acetyl-β-D-glucose were used in the reaction (1, 2).

Benzyl-α-D-mannopyranoside

Mannose (50 g) was stirred with benzyl alcohol (400 ml) saturated with hydrogen chloride at 60° C until the sugar dissolved. The solution was neutralized with silver carbonate, diluted with methanol, filtered, and evaporated. Benzyl alcohol was removed *in vacuo* at 150° C, the residue (containing benzyl mannosides and a little mannose) was dissolved in a small volume of water and the solution extracted 8 times with ethyl acetate. The extracts were evaporated and the product (37 g) was recrystallized twice from ethyl acetate, with m.p. 131–132° C and $[\alpha]_D$ +74° (*c*, 1.3, H_2O). Calculated for $C_{13}H_{18}O_6$: C, 57.8%; H, 6.7%. Found: C, 57.5%; H, 6.8%.

2,3-O-Carbonyl-6-O-triphenylmethyl-benzyl-α-D-mannopyranoside

A solution of benzyl mannoside (37 g), triphenylchloromethane (50 g) in pyridine (150 ml) was heated at 90° C for 4 hours. The mixture was poured into an excess of aqueous potassium carbonate, which was stirred for 1 hour, and the deposit was collected and chromatographed on a silicic acid column using chloroform as solvent in order to separate the triphenylcarbinol from the 6-trityl-benzyl-α-D-mannoside.

The resulting 6-trityl derivative (35 g) was dissolved in pyridine (210 ml) and cooled

to 0° C. A solution of phosgene (7.5 g) in toluene (55 ml) (42) was added dropwise with stirring over 30 minutes, the mixture then being warmed to 40° C for a further 30 minutes. The solution was evaporated to a syrup, which was fractionated on a silicic acid column. Chloroform eluted a crystalline fraction which was recrystallized from ether and corresponded to 2,3-*O*-carbonyl-6-*O*-triphenylmethyl-benzyl-α-D-mannopyranoside. Yield, 12.4 g. A further crystallization from ether yielded material with m.p. 192–195° C and $[\alpha]_D$ +30° (*c*, 1.0, $CHCl_3$). Calculated for $C_{33}H_{30}O_7$: C, 73.6%; H, 5.6%. Found: C, 73.2%; H, 5.7%.

2,3-O-Carbonyl-benzyl-α-D-mannopyranoside and Its 4,6-Di-O-acetate

The trityl mannoside carbonate (12.0 g), in a mixture of chloroform (30 ml) and acetic acid (10 ml), was detritylated by adding, at 0° C, 12 ml of 32% hydrogen bromide in acetic acid. After 1 minute the mixture was treated with an excess of aqueous sodium bicarbonate, and the aqueous solution then extracted 3 times with ethyl acetate. The product recovered from the extract, which apparently contained unchanged material and decomposition products, was put on to a silicic acid column. Chloroform eluted triphenylcarbinol and unchanged trityl derivative, and acetone then eluted a fraction which crystallized from ether. A further crystallization from ether gave 3.3 g of 2,3-*O*-carbonyl-benzyl-α-D-mannopyranoside with m.p. 122–123° C, $[\alpha]_D$ +77° (*c*, 1.0, $CHCl_3$) and absorption at 1810 cm^{-1} in the infrared region (43). Calculated for $C_{14}H_{16}O_7$: C, 56.7%; H, 5.4%. Found: C, 56.7%; H, 5.5%.

The above carbonate (3.2 g) was dissolved in pyridine (10 ml) containing acetic anhydride (6 ml) and left at room temperature for 6 hours. Excess anhydride was destroyed with ice water and the crystalline deposit which formed was filtered off and recrystallized from ether. Yield, 3.6 g, m.p. 114–115° C, $[\alpha]_D$ +37° (*c*, 1.0, $CHCl_3$). Calculated for $C_{18}H_{20}O_9$: C, 56.8%; H, 5.3%. Found: C, 56.6%; H, 5.5%.

4,6-Di-O-acetyl-2,3-di-O-carbonyl-α-D-mannopyranosyl Bromide

4,6-Di-*O*-acetyl-benzyl-α-D-mannoside-2,3-carbonate (3.6 g) was dissolved in acetic acid (50 ml) containing 10% palladium oxide on charcoal (2.0 g). Debenzylation was effected by shaking overnight at room temperature under a hydrogen pressure of 40 p.s.i. The catalyst was filtered off and the process was repeated twice to complete the reaction, yielding syrupy 4,6-di-*O*-acetyl-2,3-di-*O*-carbonyl-D-mannose (2.8 g); $[\alpha]_D$ −7.5° (*c*, 1.0, $CHCl_3$). This material was acetylated (as for 2,3-di-*O*-carbonyl-benzyl-α-D-mannopyranoside) to give 1,4,6-tri-*O*-acetyl-2,3-di-*O*-carbonyl-αβ-D-mannose (2.5 g) with $[\alpha]_D$ +7.5° (*c*, 1.0, $CHCl_3$).

Bromination at C-1 was effected by treatment of the above material (1.02 g) with 32% hydrogen bromide in acetic acid (20 ml) in dry chloroform (100 ml) for 2 hours at 0° C. The chloroform solution was then washed 5 times with ice water, dried, and evaporated to a syrup (960 mg); $[\alpha]_D$ +55° (*c*, 1.0, $CHCl_3$). In the infrared region the compound absorbed strongly at 1815 cm^{-1} and 1740 cm^{-1}, corresponding to the presence of carbonate and acetate groups, respectively.

Königs–Knorr Syntheses Using 4,6-Di-O-acetyl-2,3-di-O-carbonyl-α-D-mannopyranosyl Bromide

(a) Methanol.—The bromo compound (96 mg) was shaken for 30 minutes with methanol (5 ml) containing silver oxide (300 mg). The product had $[\alpha]_D$ −37° (*c*, 1.0, $CHCl_3$) and absorbed in the infrared region at 1805 cm^{-1} (carbonate carbonyl) and 1740 cm^{-1} (acetate carbonyl), and evidently contained 4,6-di-*O*-acetyl-2,3-*O*-carbonyl-methyl-

β-D-mannopyranoside since, after treatment with excess barium methoxide followed by acetylation, it gave 2,3,4,6-tetra-*O*-acetyl-methyl-β-D-mannopyranoside (crystallized from ethanol), m.p. and mixed m.p. 161–162° C. Only a trace of the α-anomer was present as shown by paper chromatography.

*(b) 1,2,3,4-Tetra-O-acetyl-*D*-glucose.*—A mixture of excess 1,2,3,4-tetra-*O*-acetyl-β-D-glucose (3.0 g) in chloroform (8 ml) containing silver oxide (450 mg), iodine (225 mg), and Drierite (5.0 g) was added to the bromo compound (0.30 g) and shaken for 18 hours. It was then diluted with methanol, filtered, and evaporated to a syrup which was redissolved in methanol and de-esterified with 0.1 equivalents of barium methoxide in methanol for 3 hours. The alkali was neutralized with acetic acid and after dilution with excess water the solution was deionized with Amberlite IR-120 and Dowex-1. Evaporation gave a syrup which was fractionated on a cellulose column. *n*-Butanol saturated with water eluted glucose; butanol–ethanol–water (4:1:1 v/v) gave the disaccharide fraction (132 mg; $[\alpha]_D$ +2° (*c*, 1.0, H_2O)), containing mainly 6-*O*-β-D-mannopyranosyl-D-glucose and a trace proportion of the α-anomer (paper chromatogram, solvent B). The product crystallized readily and two recrystallizations from methanol gave the sugar, with m.p. 209–210° C and $[\alpha]_D$ 0° (2 minutes) → −5° (18 hours, constant value; *c*, 1.0, H_2O). Calculated for $C_{12}H_{22}O_{11}$: C, 42.1%; H, 6.5%. Found: C, 41.8%; H, 6.6%.

*(c) 1,2,3,4-Tetra-O-acetyl-αβ-*D*-mannose.*—Using the same proportions and procedure as with the glucose analogue amorphous 6-*O*-β-D-mannopyranosyl-D-mannose (77 mg) with $[\alpha]_D$ −16° (*c*, 1.0, H_2O) was prepared.

*4-O-β-*D*-Mannopyranosyl-*D*-erythritol from 6-O-β-*D*-Mannopyranosyl-*D*-glucose*

Crude mannopyranosyl glucose (163 mg) was dissolved in water (0.5 ml) plus acetic acid (10 ml) and 2.1 molar equivalents of 1% lead tetraacetate in acetic acid added (21). After 15 minutes, 2.0 molar equivalents of oxalic acid in acetic acid was added, the lead oxalate filtered off, and the solution evaporated to a crust (presumably containing di-*O*-formyl-4-*O*-β-D-mannopyranosyl-D-erythrose). The material was dissolved in water (5 ml) containing sodium borohydride (200 mg) and after an hour excess reagent was destroyed with acetic acid. The solution was treated with Amberlite IR-120, filtered, and the filtrate evaporated to a residue which was dissolved in methanol, and the methanol then distilled off, this procedure being repeated several times. The resulting 4-*O*-β-D-mannopyranosyl-D-erythritol was crystallized 3 times from ethanol to yield 20 mg of material with m.p. 160–162° C, $[\alpha]_D$ −38° (*c*, 1.0, H_2O) and an X-ray diffraction powder diagram indistinguishable from that of an authentic specimen. Calculated for $C_{10}H_{20}O_9$: C, 42.25%; H, 7.1%. Found: C, 42.4%; H, 7.2%.

ACKNOWLEDGMENTS

The authors thank Dr. R. A. Abramovitch for helpful discussion, and Mr. J. W. L. C. Christ, Mrs. S. F. Hector, and Mrs. J. Nuttall for valuable technical assistance. Microanalyses were performed by Mr. M. Mazurek. Infrared spectra and X-ray powder diagrams were recorded by Miss Inez Gaffney.

PERFLUOROALKYL ARSENICALS

PART III. THE PREPARATION AND PROPERTIES OF SOME NEW TRIFLUOROMETHYL AND HEPTAFLUOROPROPYL ARSINES[1]

W. R. CULLEN

ABSTRACT

The reaction of heptafluoroiodopropane with the appropriate phenyl-iodo-arsine in the presence of mercury yields the compounds $C_3F_7As(C_6H_5)_2$, $(C_3F_7)_2AsC_6H_5$, and $C_3F_7(CH_3)AsC_6H_5$. However, the compounds $(CF_3)_2AsR$ (R = C_2H_5, C_4H_9) are obtained from the reaction of the compounds R_2AsI with mercury and trifluoroiodomethane. The ultraviolet spectra of the heptafluoropropyl-arsines are discussed.

DISCUSSION AND RESULTS

In previous papers (1, 2) the preparation of methyl- and phenyl-trifluoromethyl-arsines was described, the method of preparation being to react the appropriate iodo-arsine with trifluoroiodomethane in the presence of excess mercury: for example

$$(C_6H_5)_2AsI + Hg + CF_3I \rightarrow (C_6H_5)_2AsCF_3 + HgI_2.$$

Alkyl iodides react similarly, though in this case the reaction goes further and arsonium derivatives of triiodomercury(II) are obtained (3): for example

$$(C_6H_5)_2AsI + Hg + 2CH_3I \rightarrow (C_6H_5)_2As(CH_3)_2.HgI_3.$$

In order to investigate the generality of these reactions, the preparation of ethyl- and butyl-trifluoromethyl-arsines and phenyl-heptafluoropropyl-arsines was undertaken.

Diethyltrifluoromethylarsine, b.p. 111°, is obtained by the reaction of diethyliodoarsine with trifluoroiodomethane in the presence of mercury; however, the bulk of the product from this reaction is ethylbistrifluoromethylarsine, b.p. 77°. Ethyldiiodoarsine does not react with trifluoroiodomethane under the same conditions, so this substance as an impurity could not have been the source of the ethylbistrifluoromethylarsine. Similarly, when di-*n*-butyliodoarsine is reacted with trifluoroiodomethane and mercury, the only product isolated is *n*-butylbistrifluoromethylarsine, b.p. 118°, though in this case the same compound is produced by the corresponding reaction using *n*-butyldiiodoarsine. A reasonable explanation of these anomalous results is that an exchange reaction takes place between the initially formed dialkyltrifluoromethylarsine and trifluoroiodomethane, producing the alkylbistrifluoromethylarsine; reactions of this sort are now being studied. The reactions of heptafluoroiodopropane with phenyl-iodo-arsines in the presence of mercury are not complicated by side reactions, and heptafluoropropyldiphenylarsine (b.p. 99–102° (10^{-3} mm)), bisheptafluoropropylphenylarsine (b.p. 128° (68 mm)), and heptafluoropropylmethylphenylarsine (b.p. 123° (69 mm)) can be easily isolated.

All the new arsines are colorless mobile liquids of faint odor; they are stable to oxygen and moisture at ordinary temperatures. Solvolysis studies have been made on these compounds and the results will be reported later. The ultraviolet spectra of the heptafluoropropyl-phenyl-arsines are very similar to those of the trifluoromethyl-phenyl-arsines (4). The wavelengths and extinction coefficients of maximum absorption of these compounds are given in Table I.

	2175[i]	7.36	2175		

NOTE: i = estimated from point of inflection.
*Band is actually very weak: the recorded intensity is mainly due to contributions from the very strong short-wavelength absorption and from the other bands recorded above.

All the compounds show a weak series of bands in the region 2520–2730 Å, and by analogy with the interpretation of the spectra of the phenyl-trifluoromethyl-arsines (4) these transitions can be characterized as π–π^* absorptions involving electrons localized in the phenyl groups. The remaining bands in the spectra in the region 2100–2500 Å are much stronger. The bands in the heptafluoropropyl compounds correspond in position number and intensity with those of the trifluoromethyl compounds except for the weak band at ca. 2275 Å in the spectrum of heptafluoropropylmethylphenylarsine. The transitions in this region of the trifluoromethyl compounds have been described as involving electron transfer from the non-bonding electrons on the arsenic to the π orbitals of the phenyl groups (4), and again this description of the transitions can probably be carried over to the corresponding bands of the heptafluoropropyl compounds, even though these bands do not shift toward the blue or only shift a little when the solvent is changed from cyclohexane to the more-polar methanol.

The occurrence of two higher-intensity bands in the spectrum of diphenyltrifluoromethylarsine has been interpreted in terms of the steric effect of the CF_3 group being such as to destroy the equivalence of the two phenyl groups with respect to the arsenic lone pair. The intensity of the transition to the interacting phenyl group (the lower-energy transition since interaction would stabilize the phenyl group with a resulting lowering of orbital energies) was much higher than the intensity of the transition to the non-interacting ring. Models such as were used previously (4) show that the more bulky C_3F_7 group has the same effect in the compound heptafluoropropyldiphenylarsine, so the appearance of two bands in the spectrum of this compound, the one of lower energy being the more intense, is not unexpected. Models also indicate that the phenyl group could interact with the C_3F_7 group in the compound heptafluoropropylmethylphenylarsine and almost certainly interacts in the compound bisheptafluoropropylphenylarsine. However, such interaction alone can not account for the presence of two bands in the spectrum of the former compound. The charge transfer band in triphenylarsine occurs

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

at ca. 40,300 cm^{-1} (4) so the effect of substituting a C_3F_7 group for a phenyl group is to increase the transition energy by ca. 4500 cm^{-1} (using the energy of low-intensity transition to the non-interacting phenyl group of the compound heptafluoropropyldiphenylarsine). The charge transfer band in methyldiphenylarsine occurs at ca. 41,600 cm^{-1} and the effect of substituting a C_3F_7 group for a phenyl group is to increase the energy of the transition by ca. 4300 cm^{-1} if the 2175 Å band in heptafluoropropylmethylphenylarsine is chosen as the charge transfer band, or by ca. 2400 cm^{-1} if the 2275 Å band is the charge transfer band. Thus it is likely that it is the 2175 Å band which is the charge transfer band. The second transition at ca. 2275 Å is very weak. This could arise from a shift or split of the benzene transition which normally occurs at ca. 2000 Å, but its intensity seems to be too low. A more likely explanation is that it is due to an impurity.

The charge transfer bands in the C_3F_7 compounds occur at higher or equal energies when compared with the corresponding bands in the CF_3 compounds; a result which could indicate that in the first order the C_3F_7 group has a greater electron-withdrawing effect on the arsenic lone pair than does the CF_3 group.

The infrared spectra of these new arsines are recorded in the experimental section. It is hoped to discuss these in detail at a later date when more correlations can be made.

EXPERIMENTAL

Apparatus and Technique

Conventional vacuum techniques were used for the manipulation of volatile reactants and products out of contact with moisture and oxygen. Reactions were carried out in sealed Pyrex tubes in the absence of air and light. Infrared spectra were measured on a Perkin–Elmer Model 21 double-beam instrument with rock-salt optics. Ultraviolet spectra were recorded on the Cary Model 14 spectrophotometer. The solvents were spectroscopic grade methyl alcohol or cyclohexane, and the lower wavelength limit of the instrument was ca. 2100 Å as determined by solvent absorption. Gas-phase molecular weights were determined by Regnault's method. Phenyl-iodo-arsines were prepared by the methods previously described (2).

Reaction of Ethyldiiodoarsine with Trifluoroiodomethane in the Presence of Mercury

Ethyldiiodoarsine was prepared from dichloroethylarsine (5) by reacting the chloroarsine with sodium iodide in acetone (6). The product had a boiling point of 126° (11 mm) (lit. value, 126° (11 mm) (6)). The iodo-arsine (18.2 g), trifluoroiodomethane (57.9 g), and mercury (225 g) were shaken at 20° for 11 days. Trap-to-trap distillation of the volatile contents of the tube showed that only one fraction, trifluoroiodomethane (57.6 g), was present.

Reaction of Diethyliodoarsine with Trifluoroiodomethane in the Presence of Mercury

Diethyliodoarsine was prepared from ethyldiiodoarsine as described by Wigren (7). The diiodoarsine in this case was prepared by the procedure used by Burrows and Turner for the preparation of diiodomethylarsine (8). Crude diethyliodoarsine (35 g), trifluoroiodomethane (76 g), and mercury (250 g) were shaken at 20° for 6 days. The unreacted trifluoroiodomethane was separated from the other volatile contents of the tube by trap-to-trap distillation. The less-volatile fraction (14.5 g) was distilled in a nitrogen atmosphere at 760 mm. The bulk of the material boiled at 77°, but a further small fraction boiling at 111° was obtained. Vapor-phase chromatography was used to obtain samples of these two fractions for analysis. The fraction boiling at 77° was identified as *ethylbistrifluoromethylarsine*. Anal. Hydrolysis with 10% aqueous sodium hydroxide

For personal use only.

at 100° for 2 days gave fluoroform corresponding to a CF_3 content of 56.2%. The vapor phase molecular weight was 241. Calc. for $C_4H_5AsF_6$: CF_3, 57%; mol. wt., 242. The fraction boiling at 111° was identified as *diethyltrifluoromethylarsine*. Anal. Calc. for $C_5H_{10}AsF_3$: C, 29.7; H, 5.0; As, 37.1; F, 28.2%; mol. wt., 202. Found: C, 29.9; H, 5.1; As, 37.3; F, 27.9%; mol. wt., 230. The infrared spectra of these compounds showed the following absorption bands: $(C_2H_5)_2AsCF_3$ (liquid film): 2980 (s), 2940 (s), 2885 (m), 2350 (w), 2200 (w), 1466 (s), 1425 (w), 1382 (m), 1243 (m)(sh), 1223 (m), 1138 (vs), 1093 (vs), 1038 (m), 1025 (m), 978 (m), 730 (m), 721 (s); $C_2H_5As(CF_3)_2$ (vapor phase): 2980 (s), 2940 (m), 2888 (m), 2250 (w), 2220 (w), 1854 (w), 1469 (m), 1427 (w), 1394 (w), 1245 (s), 1176 (vs), 1157 (vs), 1124 (vs), 1105 (vs), 1056 (m), 1032 (m), 994 (m), 729 (s).

Reaction of n-Butyldiiodoarsine with Trifluoroiodomethane in the Presence of Mercury

The diiodo-arsine was prepared by reduction of *n*-butylarsonic acid using the procedure described by Burrows and Turner for the preparation of diiodomethylarsine (9). The crude arsine (21 g), trifluoroiodomethane (55.1 g), and mercury (210 g) were shaken at 20° for 26 days. Trap-to-trap distillation of the volatile contents of the tube gave unreacted trifluoroiodomethane (40.3 g) and a colorless less-volatile fraction (10.4 g). The latter fraction was distilled in a nitrogen atmosphere at 760 mm: all distilled in the range 110–118°. A middle cut was taken, and this sample was again distilled. The boiling point was 118°, and the sample was identified as *n-butylbistrifluoromethylarsine*. Anal. Calc. for $C_6H_9AsF_6$: C, 26.7; H, 3.34; As, 27.8; F. 42.2%; mol. wt., 270. Found: C, 27.0; H, 3.48; As, 27.6; F, 42.5%; mol. wt., 290. The infrared spectrum showed the following absorption bands (liquid film): 2958 (s), 2925 (s), 2868 (m), 2210 (w), 1470 (m), 1422 (m), 1386 (m), 1347 (w), 1298 (w), 1265 (m), 1204 (s), 1168 (vs), 1132 (vs), 1115 (vs), 1093 (vs), 996 (vw), 967 (vw), 892 (m), 774 (w), 730 (s), 715 (m)(sh); vapor phase (omitting medium and weak bands): 2970 (s), 2935 (s), 1206 (s)(sh), 1179 (vs), 1156 (vs), 1126 (vs), 1107 (vs), (1081, 1076, 1069) (vs), (750, 744, 731) (s).

Reaction of Di-n-butyliodoarsine with Trifluoroiodomethane in the Presence of Mercury

Crude *n*-butyldiiodoarsine, prepared as described above, was used to prepare di-*n*-butyliodoarsine using the method described by Wigren for the preparation of diethyliodoarsine from ethyldiiodoarsine (7). The crude product was dried over calcium chloride and then distilled at 10^{-3} mm. The main fraction boiled at 78–82°, and analysis showed it to be mainly di-*n*-butyliodoarsine. Anal. Calc. for $C_8H_{18}AsI$: C, 30.4; H, 5.7; I, 40.2%; mol. wt., 316. Found: C, 27.9; H, 5.3; I. 42.3%; mol. wt., 285. The impure iodo-arsine (10.6 g), trifluoroiodomethane (65.2 g), and mercury (210 g) were shaken at 20° for 20 days. The unreacted trifluoroiodomethane was separated from a less-volatile fraction by trap-to-trap distillation. The less-volatile fraction (13 g) was distilled at 92 mm in a nitrogen atmosphere, and all boiled at 59°. Its infrared spectrum was identical with that of *n*-butylbistrifluoromethylarsine. The fraction, when distilled at 760 mm (in nitrogen), boiled at 116–120°.

Reaction of Iododiphenylarsine with Heptafluoroiodopropane in the Presence of Mercury

The arsine (12.6 g), heptafluoroiodopropane (82.5 g), and mercury (210 g) were shaken at 20° for 3 months. Trap-to-trap distillation isolated only heptafluoroiodopropane (71.8 g). The contents of the reaction tube were extracted with benzene, which was then removed by distillation at 760 mm in a nitrogen atmosphere, leaving a slightly colored involatile liquid (10.6 g). This fraction was distilled at 10^{-3} mm, and all the material boiled in the range 99–102°. The liquid was redistilled under the same conditions, and a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

colorless middle fraction of b.p. 102° was collected, which was identified as *heptafluoropropyldiphenylarsine* (73% yield). Anal. Calc. for $C_{15}H_{10}AsF_7$: C, 45.2; H, 2.51; As, 18.8; F, 33.4%; mol. wt., 398. Found: C, 45.2; H, 2.48; As, 19.0; F, 33.2%; mol. wt., 387. The infrared spectrum showed the following absorption bands (liquid film): 3060 (m), 1976 (vw), 1955 (vw), 1895 (vw), 1877 (vw), 1806 (vw), 1755 (vw), 1650 (vw), 1580 (w), 1485 (m), 1440 (s), 1383 (vw), 1338 (s), 1265 (s), 1227 (vs), 1208 (vs), 1184 (vs), 1174 (vs), 1110 (vs), 1081 (s), 1074 (s), 1034 (s), 1024 (m), 1000 (m), 988 (vw), 968 (vw), 912 (vw), 895 (m), 824 (s), 750 (s), 738 (vs), 732 (vs), 694 (s), 668 (s).

Reaction of Diiodophenylarsine with Heptafluoroiodopropane in the Presence of Mercury

The arsine (22 g), heptafluoroiodopropane (71.8 g), and mercury were shaken at 20° for 2 months. The contents of the tube were worked up as described in the preceding experiment to give heptafluoroiodopropane (59.8 g) and a slightly colored involatile liquid (5.1 g) which boiled in the range 120–124° (63 mm, nitrogen atmosphere). This fraction was redistilled to give a colorless sample of *bisheptafluoropropylphenylarsine*, b.p. 128° (68 mm) (19% yield). Anal. Calc. for $C_{12}H_5AsF_{14}$: C, 29.4; H, 1.02; As, 15.2; F, 54.2%, mol. wt., 490. Found: C, 29.7; H, 1.09; As, 15.6; F, 53.6%; mol. wt., 460. The infrared spectrum showed the following absorption bands (liquid film): 3060 (w), 1890 (vw), 1830 (vw), 1809 (vw), 1756 (vw), 1655 (vw), 1580 (vw), 1485 (m), 1441 (m), 1336 (s), 1274 (s), 1230 (vs), 1210 (vs), 1185 (vs), 1129 (vs), 1117 (vs), 1078 (s), 9040 (s), 1025 (m), 1000 (m), 970 (vw), 935 (vw), 917 (vw), 893 (m), 820 (s), 750 (s), 740 (vs), 733 (vs), 694 (s), 669 (s).

Reaction of Iodomethylphenylarsine with Heptafluoroiodopropane in the Presence of Mercury

The arsine (12 g), heptafluoroiodopropane (70 g), and mercury (215 g) were shaken at 20° for 1 month. Trap-to-trap distillation gave heptafluoroiodopropane (52 g) and a colorless involatile liquid (6.8 g). The latter fraction, when distilled in a nitrogen atmosphere, boiled at 123° (69 mm); it was identified as *heptafluoropropylmethylphenylarsine* (49% yield). Anal. Calc. for $C_{10}H_8AsF_7$: C, 35.7; H, 2.38; As, 22.3; F, 39.6%; mol. wt., 336. Found: C, 35.6; H, 2.47; As, 22.1; F, 39.5%; mol. wt., 322. The infrared spectrum showed the following absorption bands (liquid film): 3060 (w), 2995 (w), 2900 (w), 2400 (vw), 2300 (vw), 2130 (vw), 1980 (vw), 1952 (vw), 1895 (vw), 1875 (vw), 1802 (vw), 1755 (vw), 1645 (vw), 1580 (w), 1485 (m), 1438 (m), 1418 (m), 1338 (s), 1306 (m), 1268 (s), 1224 (vs), 1206 (vs), 1171 (s), 1110 (s), 1080 (s), 1035 (s), 1000 (m), 900 (m), 854 (s), 822 (s), 749 (s), 740 (s), 733 (s), 694 (s), 668 (s).

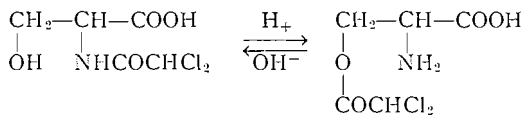
REVERSIBLE N,O-HALOACYL SHIFT IN SERINE DERIVATIVES WITH ANTITUMOR ACTIVITY[1]

I. LEVI, J. W. R. WEED, G. LAFLAMME, AND A. E. KOLLER



ABSTRACT

Large doses of N-dichloroacetyl-DL-serine sodium salt were required to cause regression of Sarcoma-37 in mice. About 56% of the unchanged compound was recovered from the urine. These observations suggest that the antitumor activity may reside in a metabolic product of the N-dichloracetyl serine. It is postulated that the active compound is the corresponding O-dichloroacetyl-DL-serine formed from the N-acyl compound by an in vivo enzymatically controlled shift which takes place via the hydroxyoxazolidine and (or) the oxazoline rings. O-Dichloroacetyl-DL-serine hydrochloride was prepared by treating a suspension of N-dichloroacetyl-DL-serine in anhydrous ether with gaseous hydrogen chloride. The free base, O-dichloroacetyl-DL-serine, is an extremely labile compound and reverts to the N-compound in neutral aqueous solution at room temperature. The hydrochloride salt, however, is stable, in which form it was isolated and characterized. The same compound was prepared from serine and dichloroacetic anhydride in dichloroacetic acid. O-Dichloroacetyl-DL-serine hydrochloride displays an antitumor effect against Sarcoma-37 and Sarcoma-180 in mice. The work has been extended to the monochloro- and trichloro-acetyl derivatives of serine.

INTRODUCTION

It was reported recently (1) that the sodium salt of N-dichloroacetyl-DL-serine (2) depresses the growth of Sarcoma-37 in mice, causing in some animals complete regression of the tumors. Most of the presently known agents which are effective against animal tumors are usually administered in relatively small doses such as milligrams or even fractions of a milligram per kilogram of body weight. The above compound, however, had to be administered in doses of 1 g per kilogram of body weight in order to be effective against the tumor. This considerable non-toxic dose is largely excreted by the kidney as unchanged drug, since approximately 56% of the pure crystalline product was isolated from the urine of cats as well as of humans (3). No metabolic or hydrolytic products were identified.

We would like to suggest, therefore, that the active antitumor agent was not the administered N-dichloroacetyl derivative itself, but rather a metabolic product of this compound. One of the specific characteristics of acyl derivatives of hydroxy amino acids having the hydroxyl and the amino groups in vicinal position is the ability of the acyl residue to migrate reversibly between the nitrogen and the oxygen. It is therefore possible that the compound could readily change into the heretofore unreported O-dichloroacetyl-DL-serine isomer and that, in vivo, both forms of the compound exist in equilibrium

I II

FIG. 1.

(Fig. 1). Such a concept would explain why large doses of the N-derivative are required to elicit an antitumor effect, since the equilibrium favors the stabilized, less active

[1]*Manuscript received August 15, 1961.*
Contribution from Charles E. Frosst & Co., Montreal, Que.

N-dichloroacetyl-DL-serine. We therefore synthesized O-dichloroacetyl-DL-serine hydrochloride as well as its methyl ester, and preliminary experiments with the former compound do indeed indicate that it is active against Sarcoma-37 in mice at approximately 1/40th the dose of the N-compound and against Sarcoma-180 at approximately 1/20th the dose.

Similar reversible acyl migrations have been studied extensively in vitro over a number of years, in a large variety of compounds, and this shift is now well documented in the chemical literature for the N ⇄ O, N ⇄ S, and O ⇄ O systems. For example, acyl migrations for the N ⇄ O system have been reported for orthoaminophenols (4–12), alkylaminoethanols (13–23), adrenaline (24), noradrenaline (25, 26), ephedrine (26–30), phenylserine (31), aminophenylpropanediols including chloramphenicol (32–35), 2-aminocyclohexanol (36, 37), 2-aminocyclopentanol (38), and aminosugars (39, 40). Similar acyl shifts from oxygen to oxygen have been observed in sugars (41, 42) and glycerides (43–47), and more recently in the N ⇄ S system of cysteine (48) and glutathione (49, 50).

Emil Fischer (51) first proposed a mechanism to explain such migrations from oxygen to oxygen in the case of glycerides of fatty acids. He postulated an unstable five-membered hydroxy-orthoester as an intermediate when an acyl group migrated from one hydroxyl group to another in a 1,2-diol, as shown in Fig. 2. This hypothesis received its first confirmatory support from Hibbert and co-workers (52, 53), who isolated 2-hydroxy-2′-trichloromethyl-1,3-dioxolane, which is analogous to the cyclic intermediate IV postulated by Fischer.

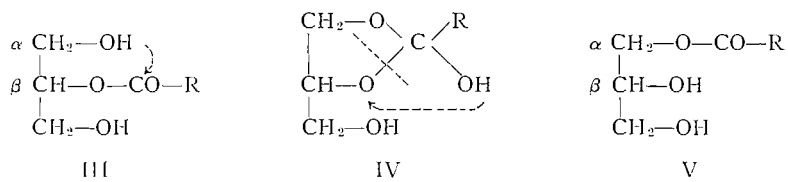


FIG. 2. Acyl migration in glycerides.

Today this mechanism involving transient cyclic intermediates is widely accepted because it satisfactorily accounts for a variety of reversible acyl shifts. Various workers have postulated ortho esters in the case of glycerides (47) and sugars (42), oxazoline or hydroxyoxazolidine rings in the N ⇄ O shifts (20, 28, 38, 39), and the corresponding thiazoline and hydroxythiazolidine rings in the case of N ⇄ S shifts (48). In some cases these cyclic intermediates were actually detected or isolated (20, 48).

More recently Doerschuk (44) carried out the rearrangement of 2-monopalmitin glyceride to the 1-monopalmitin product in the presence of glycerol-1-C^{14} and showed conclusively that the rearrangement mechanism is entirely intramolecular, thus eliminating the possibility of hydrolysis and re-esterification. van Lohuizen and Verkade (45) found that α- or β-monoglycerides in ethanolic hydrogen chloride mutually rearranged to an equilibrium mixture, while Raiford and Lankelma (8) showed a similar equilibrium in the case of acylated orthoaminophenols. It is also established for nearly all the above classes of compounds that the equilibrium distribution of the two different forms in which the acylated molecules can exist in solution depends on pH. Migration takes place from N to O when N-acyl compounds are treated with anhydrous hydrogen chloride with formation of the O-acyl-N-hydrochloride derivatives which in alkaline medium revert to the original N-acyl forms (8, 18, 20, 28, 31, 32, 35, 36, 38, 50, 54). In every case so far studied the N-acyl derivatives were much more stable than either the corresponding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

O or S derivatives and indeed the latter always easily reverted to the more stable N-derivatives.

Since most chemical reactions which are catalyzed by enzymes are also susceptible to catalysis by simpler organic and inorganic agents, we postulate as a working hypothesis that the reversible acyl shifts in amino acid derivatives such as serine and cysteine, which, in vitro, are dependent on changes in pH, can be similarly mediated in vivo via the hydroxyoxazolidine (or less likely, the oxazoline) ring by acyl migratases resulting in an equilibrium mixture of the two tautomeric forms (Fig. 3).

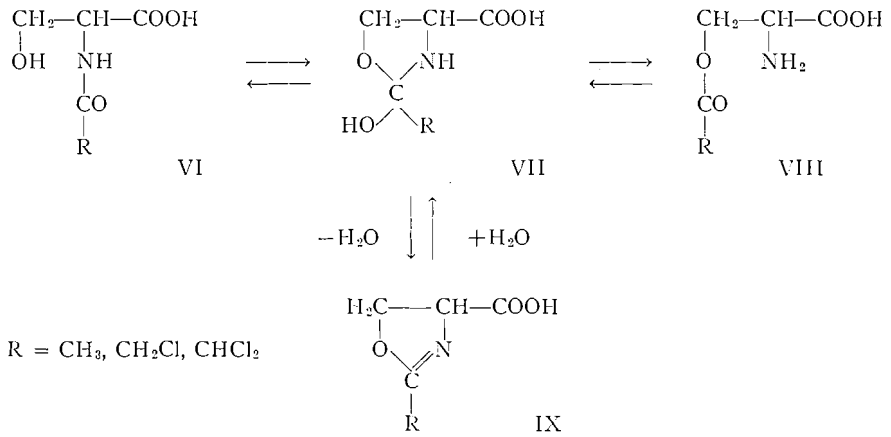

FIG. 3. Reversible N ⇄ O shifts in amino acids.

A corresponding biological shift from O to O, catalyzed by an enzyme, was reported recently by Uziel and Hanahan (55). They described a migratase, which catalyzes the β to α migration of the fatty acyl group on a β-lysolecithin. This enzyme, found in the extracts of *Penicillium notatum* and in commercial pancreatin, is nonhydrolytic in nature. The same migration was effected in the absence of the enzyme by treating the β-lysolecithin with dilute hydrochloric acid. Here again the intermediate formation of an ortho acid was favored to explain this enzymatically controlled intramolecular transesterification. A similar enzyme capable of catalyzing the intramolecular acyl migration in the N ⇄ O or N ⇄ S systems has not yet been described.

The relationship between this type of shift and biological activity has already been observed in the amino acid derivative azaserine (O-diazoacetyl-DL-serine). Here it was shown by Fusari and co-workers (56) that azaserine, in aqueous solution treated with barium hydroxide solution, lost its antibiotic activity as measured against *Kloechera brevis*, and by correlation, its antitumor activity (57), while the diazoacyl group underwent a simultaneous shift from O to N. The resulting barium salt of N-diazoacetyl serine which was isolated possessed little or no microbiological activity in vitro.

DISCUSSION OF RESULTS

It is known that strong acids act as catalysts in the esterification of hydroxy groups with acetic anhydride (58). Acylation of primary amines by acetic anhydride, however, is greatly inhibited when they are present as salts of strong acids (59–61). These facts were utilized in the preparation of O-dichloroacetyl-DL-serine by treating DL-serine with a mixture of dichloroacetic acid and dichloroacetic anhydride. The compound is extremely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

labile, tending to change to the more stable N-dichloroacetyl-DL-serine. The hydrogen chloride salt of the O-derivative, however, is sufficiently stable to allow its isolation and storage at room temperature. All attempts to obtain the O-dichloroacetyl base from the crystalline hydrochloride, even under the mildest conditions, failed. For example, neutralization of the hydrogen chloride moiety with an equimolar amount of sodium bicarbonate, at room temperature, resulted in a shift of the dichloroacetyl group from O to N. Similarly, a methanolic solution of O-dichloroacetyl-DL-serine methyl ester hydrochloride (which was prepared by the above procedure from DL-serine methyl ester), upon treatment with one equivalent of triethylamine at room temperature, also underwent this shift to N-dichloroacetyl-DL-serine methyl ester.

The reverse shift of the dichloroacetyl group from N to O was accomplished in the case of N-dichloroacetyl-DL-serine by treating a suspension of the compound in anhydrous ether with a stream of hydrogen chloride gas over a long period of time. Anhydrous conditions are essential, otherwise complete hydrolysis takes place, yielding DL-serine hydrochloride and dichloroacetic acid. When this shift was attempted with the methyl ester of N-dichloroacetyl-DL-serine in anhydrous ether, the unchanged ester was recovered quantitatively, indicating that this compound does not undergo the N → O acyl shift as readily as does the non-esterified compound. Using anhydrous methanol instead of anhydrous ether an intermolecular shift from the N of the amino acid to the O of the alcohol took place rather than the expected intramolecular shift, with the result that serine methyl ester hydrochloride and methyl dichloroacetate were formed. These experiments are summarized in Fig. 4. Although O-dichloroacetyl-DL-serine is a labile compound, it is nevertheless sufficiently stable under the right conditions to be capable of more than transitory existence.

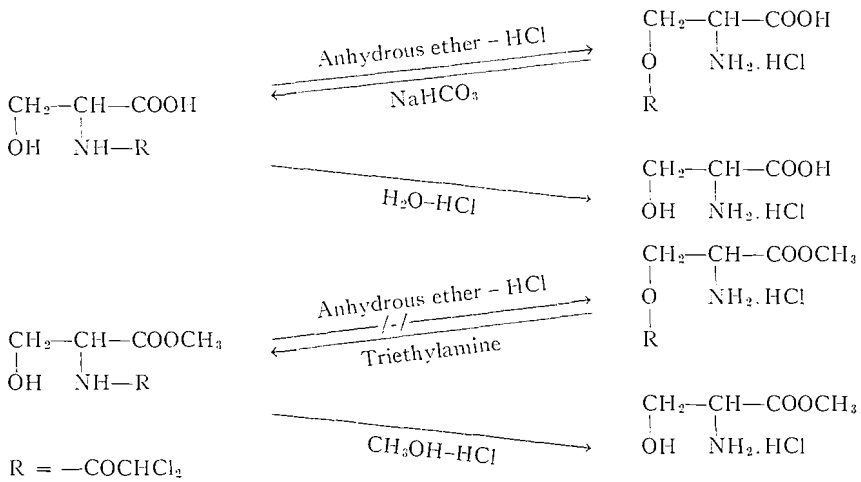

FIG. 4. N ⇄ O dichloroacyl shifts in serine.

Since we were able to show that the postulated reversible N ⇄ O shift of a dihaloacyl group could be effected in vitro, we extended this investigation to the monochloro- and trichloro-acyl compounds of serine. O-Monochloroacetyl-DL-serine was synthesized according to the procedure developed by Sakami and Toennies for the N-acyl derivative (61), and N-monochloroacetyl-DL-serine according to Fischer and Roesner (62). The complete reverse shift of the monochloroacyl group from N to O and O to N was carried

For personal use only.

out as for the dichloroacyl compounds. However, in this case O-monochloroacetyl-DL-serine was sufficiently stable to be isolated as the free base as well as the hydrochloride. After this work was completed Benoiton (63) reported the same reversible shift for N-monochloroacetylserine.

All attempts to date to prepare the O-trichloroacetyl derivative have failed. The first synthetic procedure employed was essentially that used for the preparation of O-dichloroacetyl-DL-serine hydrochloride, using benzene as a solvent due to the crystalline state of trichloroacetic anhydride. This yielded instead of the expected O-trichloroacetyl-DL-serine hydrochloride the hitherto unreported O,N-bis(trichloroacetyl)-DL-serine compound. Titration of this compound with alkali indicated an equivalent weight of 199. This agrees with the calculated equivalent weight of 198 based on the finding that the O,N-bis compound is hydrolyzed during the neutralization by the alkali to N-trichloroacetyl-DL-serine (which was isolated and identified) and trichloroacetic acid. The compound gave a negative ninhydrin test in aqueous solution. Its infrared absorption curve indicated the presence of three different carbonyl groups and elemental analyses agreed with the theoretical values for O,N-bis(trichloroacetyl)-DL-serine.

N-Trichloroacetyl-DL-serine was prepared according to the usual Schotten-Baumann procedure (2). An attempt to shift the trichloroacetyl group from N to O under the same anhydrous conditions which converted the N-monochloro- and N-dichloro-acetyl derivatives to the corresponding O-compounds also failed, the unchanged starting material being recovered quantitatively. It is interesting to note that the stability of the amide bond was such in this case that it was not necessary to observe the stringent anhydrous conditions required for the N $\rightarrow$ O dichloroacetyl shift in order to prevent hydrolysis to serine hydrochloride. Ether saturated with water gave the same result, i.e., there was no hydrolysis of the N-trichloroacetyl group and no N $\rightarrow$ O shift took place. This unexpected stability to acid of the N-trichloroacetyl group was also observed in the failure of aqueous hydrochloric acid to hydrolyze the latter compound.

This stability was again evident when the O,N-bis(trichloroacetyl) compound was treated with acid in an attempt to prepare O-trichloroacetyl-DL-serine by hydrolysis of the N-acyl group. Contrary to expectations, the O-trichloroacetyl group was the more labile one under these conditions and again N-trichloroacetyl-DL-serine was obtained. This instability of the O-trichloroacetyl group in an acidic medium accounts for the failure, to date, to isolate O-trichloroacetyl-DL-serine.

It therefore appears that in the O-haloacyl series, the stability of the ester linkage decreases as the number of halogen atoms increases. In the N-haloacyl series, however, the opposite situation seems to exist, namely, the stability of the amide bond increases as the number of halogen atoms increases. These effects are no doubt the result of the inductive displacement of the electrons in the direction of the strong electron-attracting chlorine atoms; the greater the number of the latter the more stable the amide bond and the weaker the ester linkage.

These various haloacyl derivatives of serine are presently being evaluated for their antitumor activity in the mouse and rat to determine whether a relationship exists between such activity and the ease of interconversion of the three pairs of isomers.

EXPERIMENTAL

Infrared absorption spectra were determined with a Beckman IR-5 spectrophotometer equipped with a sodium chloride prism, using potassium bromide pellets. Melting points obtained with a Fisher–Johns apparatus, boiling points, and temperature readings are uncorrected and are in degrees Centigrade.

O-Dichloroacetyl-DL-*serine Hydrochloride*

DL-Serine (105 g, 1.0 mole) was dissolved in redistilled dichloroacetic acid (500 ml) in a 3-liter, three-necked, round-bottomed flask fitted with a dropping funnel, thermometer, and calcium chloride drying tube. The clear solution was cooled in an ice-water bath and stirred continuously with a magnetic stirrer. A slow stream of dichloroacetic anhydride (312 g, 1.3 mole) was added during $2\frac{1}{2}$ hours at such a rate that the temperature of the reaction mixture did not exceed 32–33°. The flask was allowed to stand overnight at room temperature, and the product was then converted to the hydrochloride salt by passing a slow stream of hydrogen chloride gas into the solution for 1 hour. The excess hydrogen chloride was removed under reduced pressure, anhydrous benzene (1250 ml) was added, and the flask was refrigerated. The product crystallized as a fine white granular material which was removed by filtration, washed with anhydrous benzene, followed by petroleum–ether (30–60°), and dried at 45° in a vacuum oven. Weight 85.0 g, m.p. 115–120°. A second crop of product (5.4 g) was recovered from the filtrate, total yield 35.8%. The product was recrystallized from anhydrous acetone–ether, yielding 29.4% pure crystalline O-dichloroacetyl-DL-serine hydrochloride, m.p. 125–126°, which was soluble in water, ethanol, acetone, tetrahydrofuran, and dioxane, and insoluble in ether, chloroform, and ethylene dichloride. It gave a positive ninhydrin test. Anal. Calc. for $C_5H_8Cl_3NO_4$: C, 23.78; H, 3.19; N, 5.55. Found: C, 23.88; H, 3.29; N, 5.61.

This product was also prepared by saturating a suspension of 3.0 g (0.0286 mole) of DL-serine in 100 ml of dichloroacetic acid with hydrogen chloride gas at 0°. The resulting clear solution was kept at room temperature for 48 hours. The addition of anhydrous ether (100 ml) caused a rapid crystallization of crude product as white crystals. Weight 5.4 g (74.9% yield). The infrared absorption curve of this product was identical with that of the O-dichloroacetyl-DL-serine hydrochloride prepared above.

O-Dichloroacetyl-DL-*serine Hydrochloride from N-Dichloroacetyl*-DL-*serine: N → O Dichloroacyl Shift*

Finely pulverized N-dichloroacetyl-DL-serine (2.0 g) (2) was suspended in 100 ml anhydrous ether in a 200-ml round-bottomed flask. A moderately rapid stream of hydrogen chloride was passed into the suspension for $6\frac{1}{2}$ hours. The flow was discontinued overnight and then resumed for $1\frac{1}{2}$ hours. Anhydrous ether was added occasionally to maintain the volume of the reaction mixture. There was no sensible heat effect during this reaction. The ether suspension was evaporated to dryness, anhydrous ethyl acetate (75 ml) added, and the contents warmed for approximately $\frac{1}{2}$ hour. The insoluble residue of O-dichloroacetyl-DL-serine hydrochloride (1.65 g, 70% yield) was removed by filtration, washed with ethyl acetate and ether, and dried, m.p. 125–126°. The infrared absorption spectrum of this material was identical with that of the product synthesized by the route described above and a mixed melting point of the two was not depressed. The ninhydrin test was positive.

N-Dichloroacetyl-DL-*serine from O-Dichloroacetyl*-DL-*serine Hydrochloride: O → N Dichloroacyl Shift*

A solution of O-dichloroacetyl-DL-serine hydrochloride (5.04 g, 0.02 mole) in 50 ml distilled water was treated at room temperature with a solution of 3.36 g (0.04 mole) sodium bicarbonate in 50 ml of water. The pH of the solution changed from an initial value of 1.10 to 5.60. The neutralized clear solution was concentrated to dryness from a water bath at 30–35° and under reduced pressure. The residue crystallized from water. An infrared absorption curve of the crystalline product was identical with that of pure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

N-dichloroacetyl-DL-serine sodium salt (2). It melted at 172–173° and did not depress the melting point of authentic N-dichloroacetyl-DL-serine sodium salt (2). It no longer gave a positive ninhydrin test, indicating a practically theoretical shift from O to N at pH less than 7.

*O-Dichloroacetyl-*DL*-serine Methyl Ester Hydrochloride*

DL-Serine methyl ester hydrochloride (15.5 g, 0.1 mole) (2) was dissolved, with gentle heating, in dichloroacetic acid (100 ml) in a 500-ml, two-necked, round-bottomed flask fitted with a dropping funnel, calcium chloride drying tube, and magnetic stirrer. Dichloroacetic anhydride (30.0 g, 0.125 mole) was added dropwise to the clear, stirred solution. No attempt was made to control the very small heat rise during this addition, which required 45 minutes. The solution was allowed to stir for 24 hours at room temperature (23–25°) to complete the esterification. Diethyl ether (100 ml) was then added, followed by sufficient petroleum ether (30–60°) to produce a faint permanent cloudiness, and the flask was refrigerated for 5 hours. The white crystalline precipitate of O-dichloroacetyl-DL-serine methyl ester hydrochloride was removed by filtration, washed with ether (50 ml) then petroleum ether (50 ml), and dried at 30–40° in a vacuum oven. The product (18.8 g, 70.6% yield) was recrystallized from methanol–ether, m.p. 106° (with prior softening at 101°), white needles. It was soluble in water, ethanol, and dioxane, and insoluble in ether, petroleum ether, chloroform, and ethyl acetate. Anal. Calc. for $C_6H_{10}Cl_3NO_4$: C, 27.00; H, 3.78; N, 5.25. Found: C, 27.30; H, 4.19; N, 5.26.

*Attempted Conversion of N-Dichloroacetyl- to O-Dichloroacetyl-*DL*-serine Methyl Ester: Attempted N → O Dichloroacyl Shift*

(i) Hydrogen chloride gas was passed through a suspension of N-dichloroacetyl-DL-serine methyl ester (2) (2.0 g) in 100 ml anhydrous ether for 4 hours whereby complete solution took place. Upon evaporation of the ether a quantitative yield of unreacted starting ester was recovered.

(ii) Dry hydrogen chloride gas was passed through a solution of N-dichloroacetyl-DL-serine methyl ester (5 g) in anhydrous methanol (25 ml), for 1 hour. During this period the flask was cooled in an ice–salt bath. The solution was allowed to stand at room temperature for 24 hours and then concentrated to dryness under reduced pressure and at room temperature. The residual pale yellow syrup which solidified completely on refrigeration for several days was crystallized from methanol–ether, yielding 2.65 g of white crystals, m.p. 132–134°, which were identified by mixed melting points and infrared absorption spectra as DL-serine methyl ester hydrochloride.

*Conversion of O-Dichloroacetyl- to N-Dichloroacetyl-*DL*-serine Methyl Ester: O → N Dichloroacyl Shift*

Triethylamine (0.696 ml, 0.005 mole) was added at room temperature to a solution of O-dichloroacetyl-DL-serine methyl ester hydrochloride (1.33 g, 0.005 mole) in anhydrous methanol (15 ml). The solution was shaken mechanically for 10 minutes and then concentrated to dryness under reduced pressure and on a water bath maintained at 25°. The residue, which was a mixture of crystalline triethylamine hydrochloride and oil, was extracted with anhydrous ether (75 ml) whereby the latter dissolved leaving 0.7 g of triethylamine hydrochloride. The ethereal solution on evaporation to dryness under reduced pressure at 25° yielded a pale yellow residual oil which slowly solidified on refrigeration. This was crystallized from ether – petroleum ether (30–60°), yielding 0.95 g (82.6%) of white, fluffy crystals of N-dichloroacetyl-DL-serine methyl ester, m.p.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

82–83°, which, by mixed melting point and infrared absorption spectra, was shown to be identical with N-dichloroacetyl-DL-serine methyl ester (2).

*O-Monochloroacetyl-*DL*-serine*

Monochloroacetic anhydride (121.0 g, 0.708 mole) was dissolved in ethyl monochloroacetate (100 ml) in a 500-ml round-bottomed flask with gentle warming. To the cooled solution there was added, dropwise, a solution of 10.6 g (0.10 mole) DL-serine in 20 g (0.12 mole) of 60% $HClO_4$. The first few increments of this solution did not cause any significant evolution of heat, but, after a period of induction, external cooling was required. On completion of the addition, the solution was heated for 3 hours on a water bath at 55°, then allowed to stand overnight. Slight application of heat was required to redissolve all solids the next day. The dark brown homogeneous solution was diluted with 4 ml of distilled water, which reacted with residual anhydride. Triethylamine (45 g, 0.45 mole) was then added intermittently, with occasional cooling, to neutralize the perchloric acid moiety of the salt. The reaction mixture was poured into 2 liters of ether, whereupon the product separated as a finely divided crystalline powder. It was recovered by filtration, washed and triturated with ether and ethanol, and dried in a vacuum oven. Wt. 16.3 g (89.8% yield), m.p. 122–123° (decomp.). Literature m.p. 122–123° (decomp.) (64). A mixed m.p. with N-monochloroacetyl-DL-serine was depressed. The product was soluble in water, hot ethanol, hot methanol, hot acetone, and insoluble in most other organic solvents. It reacted positive to ninhydrin and positive for chlorine in the flame test with copper wire.

*O-Monochloroacetyl-*DL*-serine Hydrochloride*

Finely powdered O-monochloroacetyl-DL-serine (15.0 g) was suspended in ether (100 ml), and a slow stream of hydrogen chloride gas was passed in for 1 hour. During this process the hydrochloride precipitated as it formed. The particle size of the product was much larger than that of the original O-monochloroacetyl-DL-serine. The excess hydrogen chloride and some of the ether were removed under vacuum. The product (13.2 g, 73.5% yield) was recovered by filtration, washed with ether, and dried in a vacuum oven, m.p. 140–142°. Crystallization from acetone–ether containing a little alcohol yielded 11.0 g of a white crystalline material melting at 141–142°, which was very soluble in the lower alcohols and water, and insoluble in ethyl acetate, chloroform, and ether. Anal. Calc. for $C_5H_9Cl_2NO_4$: C, 27.54; H, 4.16; N, 6.42. Found: C, 27.58; H, 4.16; N, 6.24.

*Conversion of N-Monochloroacetyl- to O-Monochloroacetyl-*DL*-serine: N → O Monochloroacyl Shift*

Finely pulverized N-monochloroacetyl-DL-serine (2.0 g) prepared according to the method of Fischer and Roesner (62) was treated in essentially the same manner as described above for the N → O shift in N-dichloroacetyl-DL-serine. The resulting O-monochloroacetyl-DL-serine hydrochloride 1.27 g (53% yield) after crystallization from ether–alcohol melted at 141–142° and did not depress the melting point of O-monochloroacetyl-DL-serine hydrochloride prepared as above. The infrared absorption spectra of the two compounds were identical.

*Conversion of O-Monochloroacetyl- to N-Monochloroacetyl-*DL*-serine: O → N Monochloroacyl Shift*

O-Monochloroacetyl-DL-serine (10.0 g, 0.055 mole) was dissolved in 27.5 ml of 2 *N* sodium hydroxide solution (0.055 mole NaOH), allowed to stand at room temperature for $3\frac{1}{2}$ hours, and then neutralized with concentrated hydrochloric acid. The solution was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

evaporated to dryness, and the residue extracted with warm ethyl acetate (2×40 ml), which was dried over magnesium sulphate. The ethyl acetate was removed by distillation and the residual oil which solidified at room temperature was crystallized from ethyl acetate – petroleum ether (30–60°), yielding 3.35 g (33.5% yield) of product which melted at 120° and was identical by mixed melting point and infrared absorption with N-monochloroacetyl-DL-serine (62).

O,N-Bis-(Trichloroacetyl)-DL-*Serine*

A solution of trichloroacetic anhydride (250.0 g) and trichloroacetic acid (132.0 g) in anhydrous benzene (600 ml) was placed in a water bath at 25–30° and maintained at this temperature throughout the reaction. DL-Serine (69.4 g) was added in small portions to the rapidly stirred solution. When addition was complete, solids began to separate out and in a short while the mixture set to a gel. It was allowed to stand at room temperature overnight, then the product was removed by filtration, washed with benzene, and air-dried. The product (90.9 g), which was insoluble in water and gave a negative ninhydrin test, was crystallized from ether – petroleum ether (30–60°), m.p. 176–180° (a highly purified sample melted at 185–186°). Anal. Calc. for $C_7H_5Cl_6NO_5$: C, 21.21; H, 1.27; N, 3.54. Found: C, 21.42; H, 1.28; N, 3.51.

A sample of this O,N-bis-(trichloroacetyl)-DL-serine (1.0 g) was suspended in distilled water and neutralized at room temperature to the phenol red endpoint with 4.9 ml of 1.027 *N* sodium hydroxide solution. The material dissolved completely as the neutralization proceeded. The aqueous solution was concentrated to dryness on a water bath at 25° under reduced pressure. The residual oil, upon the addition of ether, solidified immediately to a white, friable powder which was removed by filtration, washed with ether, and dried. The product melted at 193–195° and weighed 0.5 g, representing a yield of 72.6% based on hydrolysis to N-trichloroacetyl-DL-serine, sodium salt, with which it was identified by mixed melting point and infrared absorption.

N-Trichloroacetyl-DL-*Serine*

DL-Serine (10.5 g, 0.10 mole) was dissolved in 2 *N* sodium hydroxide solution (50 ml, 0.1 mole) in a 500-ml, four-necked, round-bottomed flask fitted with a thermometer, motor driven stirrer, and two dropping funnels. The clear solution of the sodium salt of DL-serine was cooled in an ice–salt mixture to approximately 5°. Trichloroacetyl chloride (24.2 g, 0.133 mole) and 2 *N* sodium hydroxide solution (100 ml, 0.2 mole) were then added dropwise and simultaneously from the two dropping funnels to the stirred, cooled solution at such a rate that the reaction mixture remained on the basic side and below 10° throughout the additions. These additions required about 1 hour. The clear, colorless reaction solution was then stirred for 1 hour during which time it was allowed to warm up to room temperature. The solution was then acidified with concentrated hydrochloric acid (10 ml) and evaporated to dryness using a water bath at 55° and reduced pressure. The residual mixture of sodium chloride and clear yellow oil was extracted with hot ethyl acetate (3×100 ml). The combined ethyl acetate extracts, dried over anhydrous magnesium sulphate, were filtered and again evaporated, and the resulting oil was well shaken with petroleum ether (30–60°) (2×50 ml) to remove residual trichloroacetic acid. The product was crystallized from ethyl acetate – petroleum ether, yielding 8.9 g (35.6%) of white crystalline N-trichloroacetyl-DL-serine, m.p. 106–108°. Anal. Calc. for $C_5H_6Cl_3NO_4$: C, 23.97; H, 2.41; N, 5.59. Found: C, 23.62; H, 2.28; N, 5.56.

The sodium salt was prepared by neutralizing a solution of 87 g of N-trichloroacetyl-DL-serine in 100 ml of water with a 2 *N* sodium hydroxide solution, equivalent to 13.9 g NaOH. The clear solution was evaporated under vacuum at 60° to a dry solid, which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was recrystallized from ethanol, yielding 71 g of N-trichloroacetyl-DL-serine, sodium salt, m.p. 192–193°. Anal. Calc. for $C_5H_5Cl_3NO_4Na$: C, 22.04; H, 1.85; N, 5.14. Found: C, 21.96; H, 1.85; N, 5.32.

*Attempted Conversion of N-Trichloroacetyl- to O-Trichloroacetyl-*DL*-serine: Attempted N → O Trichloroacyl Shift*

N-Trichloroacetyl-DL-serine (2.0 g) was suspended in anhydrous ether (125 ml) and treated with a stream of hydrogen chloride gas for 4 hours. After approximately ½ hour, solution was complete and, upon evaporation to dryness, yielded an oil which rapidly crystallized. The product, 2.0 g, m.p. 106–109°, was identical by mixed melting point and infrared absorption with the starting material.

DL-*Serine Hydrochloride*

An analytical sample of DL-serine hydrochloride was prepared by evaporating to dryness an aqueous solution of serine (5 g in 50 ml water) containing 4 ml concentrated hydrochloric acid and crystallizing the residue from hot anhydrous ethanol. The product was recrystallized from ethanol–ether. Weight 5.4 g, m.p. 136°. Anal. Calc. for $C_3H_8ClNO_3$: C, 25.45; H, 5.70; N, 9.90. Found: C, 25.51; H, 5.48; N, 10.05.

Dichloroacetic Anhydride

This compound was prepared according to the procedure employed by Tedder (65). A mixture of phosphoric anhydride (141 g, 1.0 mole) and dichloroacetic acid (129 g, 1.0 mole) in a 500-ml round-bottomed flask was distilled under reduced pressure. The total distillable liquid came over at 116–120° at 16.5 mm, and was collected without regard to boiling point. Infrared absorption analysis indicated that it contained only a trace of unreacted acid. The product was redistilled in the same manner from approximately 3 g of fresh phosphoric anhydride and the distillate was collected at essentially the same boiling point as above. Weight of dichloroacetic anhydride 87.1 g (72.7% yield). In other preparations yields up to 84% were obtained.

Trichloroacetic Anhydride

This product was prepared in the same manner from trichloroacetic acid with phosphoric anhydride and boiled at 145–150° at 110 mm, yield 77.8%.

ACKNOWLEDGMENT

The authors wish to thank Mr. J. Cuthbertson and Miss M. Dillon for the analyses.

STEADY-STATE DEPARTURE IN ENZYME REACTIONS[1]

HYUNG KYU SHIN[2] AND J. CALVIN GIDDINGS

ABSTRACT

A method is described for calculating the departure from steady-state conditions in enzyme reactions. This provides an immediate and simple criterion for the validity of the steady-state approximation. Several variations of the general method, differing in the degree of simplicity and in the treatment of initial transients, are formulated and discussed. These methods are applied to the general case of an enzyme reaction following the Michaelis–Menten mechanism. Specific applications are made using the data of Chance and Gutfreund. While in these specific cases the steady-state concentration of intermediate is reasonably accurate, the extent of reaction may easily vary from that calculated by means of the steady state.

INTRODUCTION

Because of the mathematical difficulties involved in the analysis of enzyme kinetics, it is conventional to employ the steady-state approximation (1–3). This approximation is not, however, always valid, and the conventional methods used to determine validity are usually difficult or erroneous. The two principal methods used for criteria involve (1) making an exact numerical analysis of the kinetics in order to determine the faithfulness of the model or (2) using the assumption that the steady-state approximation is valid when the intermediate or complex concentration is small. Alternative (1) suffers by virtue of its difficulty and by virtue of the fact that each numerical analysis is a special case and must be done again for each change in conditions. Alternative (2) has been found erroneous; in certain chain reactions its use leads to an error of four orders of magnitude in predicting the departure from steady-state conditions (4). In view of the serious problems connected with determining the validity of steady-state approximations, a method has been developed by the authors (4–6) which, for each individual case, offers a simple criterion of steady-state validity. The application of this method to enzyme reactions will be developed in the following sections.

METHOD

The departure from steady-state conditions is given in terms of the departure term ϵ, defined by

$$[1] \qquad (\mathrm{I}) = (\mathrm{I})^*(1+\epsilon),$$

where (I) and (I)* are the actual and steady-state concentrations of the intermediate, respectively. Differentiation of this equation leads to

$$[2] \qquad (\mathrm{I})^* \frac{d\epsilon}{dt} + (1+\epsilon)\frac{d(\mathrm{I})^*}{dt} = r_{\mathrm{I}},$$

where r_{I} is the rate of formation of I, $d(\mathrm{I})/dt$, and is a function of the rate constants, the concentrations of stable species, and the departure term ϵ.

The exact solution of equation [2] is equivalent to any other exact treatment of chemical kinetics. Equation [2] is in a form, however, which lends itself readily to approximate methods which are valid when the departure term is small compared with unity. The first step consists of neglecting all terms in ϵ^2, ϵ^3, etc. (such terms appear as a result of

[1]*Manuscript received July 7, 1961.*
Contribution from the Department of Chemistry, University of Utah, Salt Lake City 12, Utah.
[2]*Present address: Physical Chemistry Division, National Bureau of Standards, Washington 25, D.C.*

the implicit dependence of $d(I)^*/dt$ and r_I upon ϵ). The next step depends upon a choice between the following methods:

Method 1: With the above approximation, equation [2] is a linear, first-order equation which can be integrated directly by standard methods. It is sometimes necessary to replace reactant concentration terms by their steady-state values. Method 1 gives a good picture of the build-up of intermediate concentration at the beginning of reaction.

Method 1*a*: A somewhat simpler approximation is obtained by dropping each ϵ (not $d\epsilon/dt$) appearing explicitly or implicitly on the left of equation [2]. This procedure has been justified elsewhere (4).

Method 2: An alternate simplification of method 1 is obtained by setting $d\epsilon/dt = 0$. This removes the initial transient or radical build-up from consideration, but generally gives an accurate picture of the subsequent reaction. This approximation makes equation [2] a simple algebraic equation.[1] This equation can, however, be further simplified by means of method 2*a*.

Method 2*a*: In addition to dropping the $d\epsilon/dt$ term, each term on the left-hand side containing ϵ is also neglected. This step is equivalent to the one leading to method 1*a*. It is not quite as accurate if ϵ exceeds 0.1, but it is otherwise very simple. This is illustrated by equation [18].

In general, methods 2 and 2*a* give sufficient information about steady-state departure without the necessity of resorting to methods 1 and 1*a*. For completeness, however, method 1*a* will also be used here in connection with the reaction of enzymes.

APPLICATION TO ENZYME REACTIONS

The mechanism proposed by Michaelis and Menten (7) describes the essential features of many enzyme reactions. The following steps are involved:

$$[3] \qquad E + S \underset{k_2}{\overset{k_1}{\rightleftharpoons}} I \overset{k_3}{\rightarrow} E + P,$$

where E represents the enzyme, S the substrate, I the intermediate, i.e., the binary complex between enzyme and substrate, and P the product or products of reaction. The rate equations are

$$[4] \qquad d(I)/dt = k_1(E)(S) - (k_2+k_3)(I),$$

$$[5] \qquad d(S)/dt = -k_1(E)(S) + k_2(I),$$

$$[6] \qquad d(E)/dt = -k_1(E)(S) + (k_2+k_3)(I),$$

$$[7] \qquad d(P)/dt = k_3(I).$$

The steady-state concentration of I is

$$[8] \qquad (I)^* = \frac{k_1}{k_2+k_3}(E)(S).$$

With the substitution of $(E) = (E)_0 - (I)^*$, where $(E)_0$ is the total amount of enzyme, the quantity $(I)^*$ becomes

$$[9] \qquad (I)^* = \frac{(E)_0(S)}{K_m+(S)},$$

where K_m is the Michaelis constant, $(k_2+k_3)/k_1$.

[1]*We have previously stated that method 2 often requires the reactant concentration to be replaced by its steady-state value. This approximation is not necessary when the reactant concentration, rather than time, is chosen as the independent variable. This choice is more convenient, and is used here.*

In order to obtain $d(\mathrm{I})^*/dt$, needed in both methods 1 and 2, equation [9] is differentiated and simplified with the following result:

$$[10] \qquad \frac{d(\mathrm{I})^*}{dt} = \frac{K_m(\mathrm{E})_0}{[K_m+(\mathrm{S})]^2}\frac{d(\mathrm{S})}{dt}.$$

The evaluation of $d(\mathrm{S})/dt$ is made by substituting $(\mathrm{E}) = (\mathrm{E})_0-(\mathrm{I}) = (\mathrm{E})_0-(\mathrm{I})^*(1+\epsilon)$ into equation [5]. The result, after substitution back into equation [10], is

$$[11] \qquad \frac{d(\mathrm{I})^*}{dt} = \frac{K_m(\mathrm{E})_0}{[K_m+(\mathrm{S})]^2}\{-k_1(\mathrm{E})_0(\mathrm{S})+k_1(\mathrm{S})(\mathrm{I})^*+k_2(\mathrm{I})^*+[k_1(\mathrm{S})+k_2](\mathrm{I})^*\epsilon\}.$$

We now proceed to evaluate the expression $r_I = d(\mathrm{I})/dt$ using equations [1], [4], and [9]. This combination gives

$$[12] \qquad r_I = -k_1(\mathrm{E})(\mathrm{S})\epsilon.$$

Substituting $(\mathrm{E}) = (\mathrm{E})_0-(\mathrm{I})^*(1+\epsilon)$, as above, and dropping the term in ϵ^2, we obtain

$$[13] \qquad r_I = -k_1(\mathrm{S})[(\mathrm{E})_0-(\mathrm{I})^*]\epsilon.$$

Equations [9], [11], and [13] provide all the necessary terms in equation [2], and it is now possible to evaluate this equation according to method 1, 1*a*, 2, or 2*a*.

The application of method 1 to the foregoing mechanism proves to be quite complex. While the differential equation is linear, the integral solutions are nonetheless quite involved. Consequently method 1*a*, which gives a result that is nearly as satisfactory, will be employed here. Using this method, equation [2] becomes

$$[14] \qquad \frac{d\epsilon}{dt}+(k_2+k_3)\epsilon = \left[\frac{K_m}{K_m+(\mathrm{S})}\right][k_1(\mathrm{E})_0-k_1(\mathrm{I})^*-k_2(\mathrm{I})^*/(\mathrm{S})],$$

where the term $(k_2+k_3)\epsilon$, equal to $-r_I/(\mathrm{I})^*$, is obtained by combining equations [8] and [12], and the right-hand side of [14] is obtained by combining equations [9] and [11], and dropping the ϵ terms. The term $(\mathrm{I})^*/(\mathrm{S})$ can be replaced by $[(\mathrm{E})_0-(\mathrm{I})^*]/K_m$ in view of equation [8] and the expression $(\mathrm{E}) = (\mathrm{E})_0-(\mathrm{I})^*$. After simplification, equation [14] becomes

$$[15] \qquad \frac{d\epsilon}{dt}+(k_2+k_3)\epsilon = \frac{k_3[(\mathrm{E})_0-(\mathrm{I})^*]}{K_m+(\mathrm{S})}.$$

After the independent variable is changed to (S) rather than t, the solution of [15] can be obtained by the standard methods employed for linear equations:

$$[16] \qquad \epsilon_{Ia} = \left\{\exp\left[\frac{K_m^2}{K_{31}}\int\frac{d\ln(\mathrm{S})}{(\mathrm{E})_0-(\mathrm{I})^*}\right]\right\}\left\{\int\frac{-K_m}{K_m+(\mathrm{S})}\exp\left[-\frac{K_m^2}{K_{31}}\frac{d\ln(\mathrm{S})}{(\mathrm{E})_0-(\mathrm{I})^*}\right]\times d\ln(\mathrm{S})+\omega\right\},$$

where $K_{31} = k_3/k_1$ and ω is the integration constant which can be evaluated knowing the initial conditions, i.e., $\epsilon = -1$ and $(\mathrm{S}) = (\mathrm{S})_0$ when $t = 0$. The second integral in the above expression can be evaluated by plotting

$$\left[-\frac{K_m}{K_m+(\mathrm{S})}\right]\exp\left[-\frac{K_m^2}{K_{31}}\int\frac{d\ln(\mathrm{S})}{(\mathrm{E})_0-(\mathrm{I})^*}\right]$$

against ln (S) and integrating graphically. A similar method may be applied for the evaluation of the integral in the exponential parts.

The expression for ϵ_2, obtained from method 2, is

$$[17] \qquad \epsilon_2 = \frac{\left\{1-[(S)+K_{21}]\frac{(I)^*}{(S)(E)_0}\right\}\alpha}{\left[1-\frac{(I)^*}{(E)_0}\right]-\left\{1-2[(S)+K_{21}]\frac{(I)^*}{(S)(E)_0}\right\}\alpha},$$

while method 2*a* yields

$$[18] \qquad \epsilon_{2a} = \frac{\left\{1-[(S)+K_{21}]\frac{(I)^*}{(S)(E)_0}\right\}}{\left[1-\frac{(I)^*}{(E)_0}\right]}\alpha,$$

where $K_{21} = k_2/k_1$ and $\alpha = K_m(E)_0/[K_m+(S)]^2$.

A numerical example of the method described above has been obtained using results on the kinetics of peroxidase by Chance (8). In this work he found the velocity constant, k_1, for the formation of peroxidase-H_2O_2 (intermediate) to be about 1.2×10^7 l. mole^{-1} sec^{-1}; the velocity constant, k_2, for the reversible breakdown of intermediate is $\leqslant 0.2$ sec^{-1}, and the velocity constant, k_3, for the enzymatic breakdown of intermediate is 4.2 sec^{-1}. The initial concentrations are assumed to be $(E)_0 = 10^{-6}$ mole l^{-1} and $(S)_0 = 10^{-5}$ mole l^{-1}. The departure terms obtained by the above methods are plotted in Fig. 1 as a

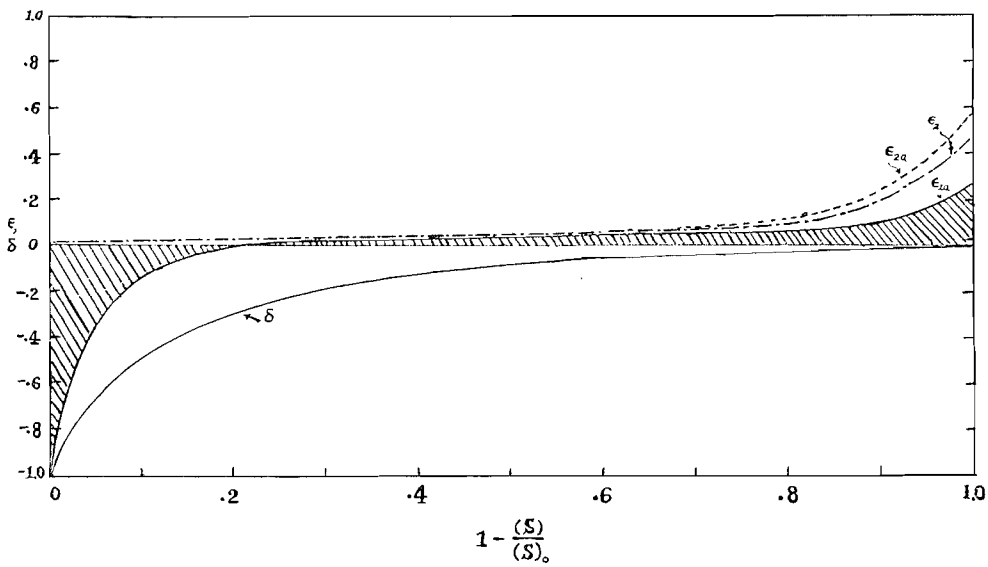

FIG. 1. Departure terms vs. amount of reaction.

function of the fraction of reaction completed. It is seen that ϵ_{2a} is a very good approximation to ϵ_2 over most of the course of the reaction. The values of ϵ_{1a}, which also show the significance of the initial transient, are approximately equal to those of ϵ_2 and ϵ_{2a} after the passage of the initial transient. At 40% reaction, for example, ϵ_2, ϵ_{2a}, and ϵ_{1a} have the values 0.030, 0.032, and 0.028. At 60% reaction the values are 0.034, 0.039, and 0.032, respectively. The departure increases significantly beyond 80% reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

The curve calculated by means of method 1*a* shows that the over-all reaction rate, proportional to the intermediate concentration, is, at first, less than that predicted by the steady-state approximation, and then greater (the transition occurs where $\epsilon_{1a} = 0$ at about 20% complete). It is clear that the concentration of product, (P), is not equal to the steady-state value, (P)*. The difference of the two may be expressed in term of δ, defined by (P) = (P)*(1+δ). This term, representing the fractional departure from the predicted extent of completion of the reaction, is obtained from the equation

$$[19] \qquad \delta = \int_0^t (\mathrm{I})^* \epsilon dt \Big/ \int_0^t (\mathrm{I})^* dt,$$

which is the time average value of the departure of intermediate weighted by the steady-state concentration of intermediate. The integrals in equation [19] are easily evaluated by means of a numerical procedure using previously determined (I)* and ϵ values. The results given in Fig. 1 show that the extent of reaction is significantly less than predicted from steady-state considerations except as the reaction approaches completion.

Another application of the above methods involves two enzyme-catalyzed hydrolysis reactions. Using the Gibson (9) stop-flow method combined with the photoelectric technique, Gutfreund (10) studied the various aspects of these reactions. From this work he estimated $k_1 \geqslant 10^6$ for two systems, trypsin + benzoyl-L-arginine ethyl ester (T + BAEE) and chymotrypsin + acetyl-L-phenylalanine ethyl ester (C + APEE). For both reactions k_3 is of the order of 10. For (T + BAEE), $K_m = 10^{-5}$ and $(k_2 + k_3) \geqslant 10$, whereas $K_m = 7 \times 10^{-4}$ and $(k_2 + k_3) \geqslant 700$ for (C + APEE). For the latter reaction $(k_2 + k_3)$ is so much larger than k_3 that K_m can be regarded as k_2/k_1, the true enzyme–substrate dissociation constant. Applying the same initial concentrations of enzyme and substrate as the previous example, and replacing the equal-to-or-greater-than sign by an equal sign we obtain the values of ϵ_2 for (T + BAEE) as reported in Table I.

TABLE I

Amount of reaction (%)	20	40	60	80	90	95
ϵ_2	.0308	.0390	.0510	.0694	.0826	.0907

It is obvious from equation [17] that $\epsilon_2 \cong 0$ for (C + APEE) since the numerator in equation [17] is negligible when $K_m \cong k_2/k_1$. This is also true for ϵ_{2a} as shown in equation [18].

CONCLUSIONS

The methods proposed in this paper are designed to show the correlation between departure from steady-state conditions and the rate constants used to characterize the mechanism. At this time the major difficulty in applying the above methods stems from the lack of data concerning individual rate constants. Measurement of the rate of product formation or substrate disappearance after the initial transient period does not provide sufficient information for this purpose. Consequently it is usually necessary to resort to some form of transient analysis to obtain the necessary rate constants. One use of the present methods may be found in the simplified transient analysis (method 1*a*) which might be used for the approximate evaluation of rate data. As more such data is accumulated, it should be possible to correlate known rate constants pertaining to a particular step in the general mechanism with the structure of the reactants, and subsequently to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

estimate unknown rate constants. This can now be done quite successfully in the pyrolysis of hydrocarbons and related molecules. In this case the methods developed here can be applied directly to determine steady-state validity.

The above methods can also be used to extend the working range of a mechanism study. If an exact transient analysis has been used on experimental data to calculate the rate constants, the present methods are very convenient for the analysis of concentration effects. By contrast, using the exact method, a new and difficult analysis must be made for every variation in concentration. In addition, the effect of temperature changes on the rate constants can be estimated by means of approximate activation energies, and the current methods can be used to roughly estimate the temperature range of steady-state validity. The exact method, again, would involve a lengthy analysis for each temperature.

The limitations of the methods used here are obvious; the calculation of ϵ values which exceed about 0.20 reflect a good deal of error. To obtain more accuracy one would have to apply exact methods. Since the latter alternative is much more complicated, it is well to remember that the simpler methods, such as $2a$, provide, first, a simple criterion of steady-state validity, and second, an accurate value of ϵ providing only that it is small. Thus, for example, we are able to conclude from Table I that the departure for the (T + BAEE) reaction is not very serious, and also report reliable values for ϵ within the limitations of accuracy of the rate constants. Similarly if we had a system for which ϵ was calculated to be, say, 5.0, we could state conclusively that the steady-state departure is serious, but we could not predict the extent of departure. When considered within this framework, it is felt that the above methods, especially $2a$, might find a great deal of applicability to the common enzyme reactions for which a doubt exists concerning the validity of the steady-state approximation.

THE BASICITIES OF ORTHO-SUBSTITUTED BENZOIC ACIDS[1]

ROSS STEWART AND MAURICE R. GRANGER

ABSTRACT

The basicities of 15 ortho-substituted benzoic acids have been measured in sulphuric acid. The ortho effects of alkyl groups are base weakening and increase in the expected order methyl, ethyl, *i*-propyl, *t*-butyl. Ortho halo benzoic acids have comparable basicities and are weaker than their para isomers. Oxygen-containing ortho substituents, except hydroxyl, all cause substantial base strengthening relative to the para isomers. Even the groups nitro and carboxyl when substituted ortho in benzoic acid cause the basicity to rise, presumably because of hydrogen bonding in the conjugate acids.

INTRODUCTION

It is well known that the reactivities of ortho-substituted aromatic compounds are not as easily predicted as those of their meta and para isomers. The failure of the Hammett equation in the former cases illustrates this (1, 2). The fact that virtually all ortho-substituted benzoic acids, regardless of the electronic nature of the substituent, are stronger acids than benzoic acid itself has been explained on the grounds of steric inhibition of resonance in the neutral molecule. That is, the bulk of the neighboring group forces the carboxyl group out of the plane of the aromatic ring and thus raises the energy of the neutral molecule relative to the anion in which resonance with the ring will be slight (3, 4). Opposing this acid-strengthening effect will be the steric hindrance to solvation of the anion caused by the nearby ortho substituent (4). In addition to these two general steric effects, there is the electronic effect of the substituent and, in some cases, specific interactions between the substituent and either the carboxyl group or the carboxylate anion.

We have determined the *basicities* of a series of ortho-substituted benzoic acids using the general Hammett technique in sulphuric acid (5–8). In this case, resonance with the ring is more important in the ion than in the neutral molecule and inhibition of resonance by an ortho substituent (9) will here serve to decrease the basicity of the acid. (Since basicities are usually referred to in terms of the strength of the conjugate acid this will raise the acidity of the conjugate acid, i.e. it will make pK_{BH^+} less positive.) Steric hindrance by the ortho group to solvation of the cation will operate in the same direction in this case. Thus one might reasonably expect that in the absence of specific interactions all ortho substituents might be base weakening in the benzoic acid series.

RESULTS AND DISCUSSION

The pK_{BH^+} values for the ortho-substituted benzoic acids are listed in Table I together with spectral data for the neutral and cationic forms. In Table II are listed for comparison the differences in the pK_{HA} and the pK_{BH^+} values for ortho- and para-substituted benzoic acids. ($pK_{HA} = pH + \log HA/A^-$ and $pK_{BH^+} = H_0 + \log BH^+/B$, where $BH^+ \equiv H_2A^+$ and $B \equiv HA$.) One can see that here both base-strengthening and base-weakening effects are present. The electrical effect of an ortho substituent operating through the ring can be very roughly cancelled by assuming that the electrical effects of ortho and para substituents are equal (10, 11) and by using the difference in basicity of the ortho- and para-substituted acids as a measure of the ortho effect. When this is

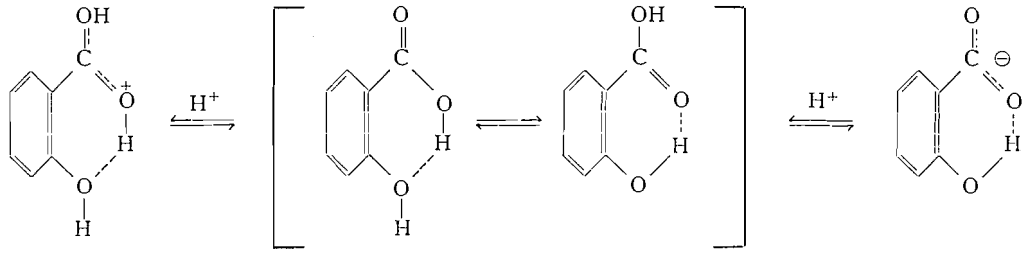
[b] Values from reference 4, p. 588.
[c] Estimated value.

done one can see that most, but not all, of the ortho substituents are now acid strengthening in the $ArCO_2H_2^+$ series, as they are in the $ArCO_2H$ series. It will be convenient to discuss the results in three groups: (*a*) the alkyl groups, (*b*) the halogens, (*c*) the oxygen-containing groups.

The Alkyl Groups

The trend of the ortho effects of the alkyl substituents on the basicities of benzoic acids is particularly clear. Methyl and ethyl groups exert similar effects, the *i*-propyl group a somewhat larger effect and the *t*-butyl group a considerably larger effect. Similar



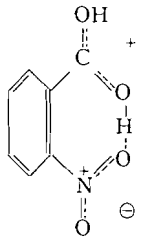
behavior has been observed by Brown and Cahn (12) in the reaction of α-alkyl pyridines with boron compounds. It is interesting that, when ΔpK_{BH^+} (the difference between the basicities of benzoic acid and the ortho isomer) is plotted against the activation energy for the reaction of methyl iodide with the α-alkyl pyridines (12), a linear relation results, indicating that the alkyl substituents are exerting similar effects in both this reaction and the protonation reaction. Since the electrical effects of the alkyl groups are similar, one can conclude that the decrease in basicity as the alkyl groups increase in size is due to steric hindrance to resonance in, and solvation of, the conjugate acid.

The Halogens

Benzoic acids with ortho halogen atoms are all weaker bases than their para isomers and weaker than benzoic acid itself, but their strengths, unlike those of the α-halopyridines, are not greatly different (13). It is probable that hydrogen bonding plus steric effects on resonance and solvation are all operative but it is rather surprising that fluorine, which should have the smallest steric effect on solvation and resonance (base weakening) and which should have the largest hydrogen bonding effect (base strengthening), gives a basicity which is little different from those of the other halogens.

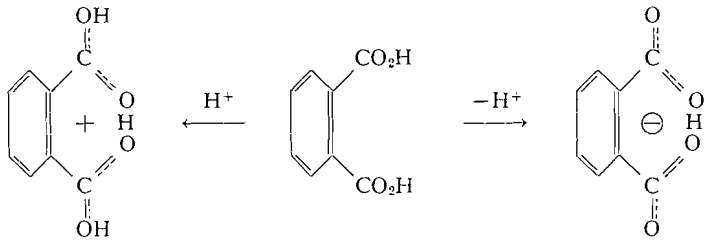
Oxygen-containing Groups

All the oxygen-containing groups exhibit base-strengthening effects relative to benzoic acid itself and all but hydroxyl cause the ortho acids to be stronger bases than their para isomers. The acid-strengthening effect of the *o*-hydroxyl in salicyclic acid is well known and is generally attributed to stabilization of the benzoate anion by internal hydrogen bonding with the hydroxyl group as in II (14, 15).



I II

Undoubtedly hydrogen bonding in I stabilizes the cation as hydrogen bonding in II stabilizes the anion, but assessing the relative importance of the above structures is difficult because of the different kinds of protons present. The case of the ortho alkoxy benzoic acids is simpler and it is clear that structures corresponding to I above are responsible for the base-strengthening effect. (The hydroxyl and alkoxyl groups, as expected from earlier work (7), appear to undergo no protonation themselves.)



The nitro and carboxyl groups provide very interesting examples of specific ortho interactions which stabilize the protonated forms. Because of the small spectral shift on protonation, *o*-nitrobenzoic acid gave a poor ionization curve and the pK_{BH^+} listed in Table I must be regarded as approximate only. Nevertheless, it is clear that *o*-nitrobenzoic acid is a much stronger base than its para isomer and is even slightly stronger than benzoic acid itself. This can be attributed to hydrogen bonding in the conjugate acid, viz.

For personal use only.

(The reason for the acid strength of *o*-nitrobenzoic acid being so much greater than that of its para isomer is less clear, since no hydrogen bonding is possible in the anion.)

Phthalic acid is much more basic than its meta and para isomers just as it is also more acidic. That is, proton loss from and proton addition to, the ortho dicarboxyl system are both much easier than with the meta and para isomers or with benzoic acid itself. The symmetry of the two ions and their structural similarity can be seen in the following equation.

III

Cation III is a species of some interest since the second ring that is formed by virtue of the hydrogen bridging may have some aromatic character (16). If the hydrogen bonding were strong enough to shorten the oxygen–oxygen bond distance sufficiently to allow some orbital overlap one would have a cyclic system containing six π electrons.

The spectral changes that occur with phthalic acid as the sulphuric acid concentration increases are shown in Fig. 2. Leisten (17) has shown by cryoscopic means that anhydride formation occurs in solutions just above 100% sulphuric acid and the spectrum in 104% acid must be that of the anhydride, probably in its protonated form. The second spectral change which leads to this spectrum is centered at $H_0 = -11.4$. No indication of a second spectral change was observed in the case of isophthalic acid or terephthalic acid even up to 30% fuming sulphuric acid. Probably the protonation of the second carboxyl group in these cases does not give rise to a sufficiently different spectrum to allow detection.

Quantitative Correlations

The parameters, σ^* and E_S, which Taft (1) has used with success to correlate the rates of certain reactions of ortho-substituted compounds, fail in the present case presumably because of resonance effects in the conjugate acid and because of the specific hydrogen-bonding interactions referred to above. There is, however, fair agreement with the Taft equation $\log K/K_0 = \sigma^*\rho^* + E_S$. The modified Farthing and Nam equation (2), $\log K/K_0 = \sigma_{E^+}\rho_{E^+} + \sigma_S\rho_S$, also gives a fair correlation if the widely deviating points for $-NO_2$, $-t$Bu, and $-CO_2H$ are ignored.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

It is interesting to note that, when the values for the acidities of ortho-substituted benzoic acids (pK_a) are plotted against the corresponding basicities (pK_{BH^+}) as in Fig. 1,

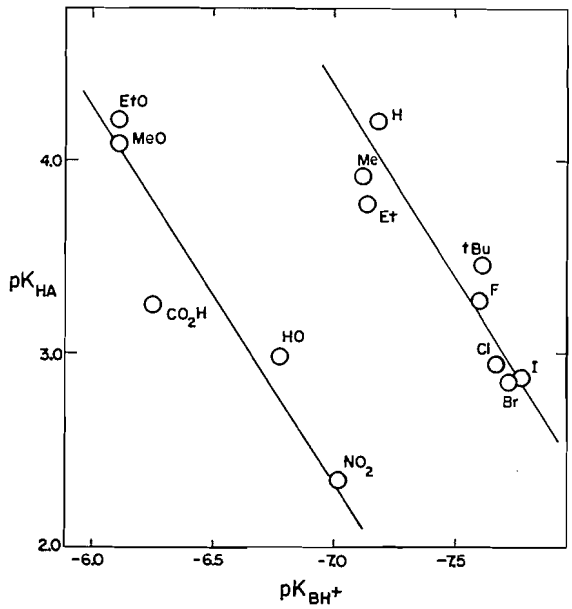

FIG. 1. Plot of the acidities of ortho-substituted benzoic acids (pK_{HA}) against their basicities (as pK_{BH^+}). The point for o-CO_2H has been corrected by 0.3 pK units on each axis for the statistical effect of two carboxyl groups on each ionization.

the substituents fall near two straight lines of approximately the same slope, the oxygen-containing substituents near one line and the other substituents near the other. It will be remembered that of the three general effects mentioned in the Introduction—electronic, steric inhibition of resonance, and steric hindrance to solvation—only the latter was expected to operate in opposite directions in the two series and it thus appears to be of the least importance. The specific interactions between the ionized carboxyl groups and the oxygen-containing substituents also show a surprising degree of regularity.

It has been assumed in this discussion that carbonyl protonation occurs exclusively (7). However, if an ortho substituent inhibits resonance with the ring the energy of the carbonyl-protonated form will rise relative to that of the hydroxyl-protonated form, which is not conjugated with the ring in any case, and it is conceivable that hydroxyl protonation may be significant in some cases. Acylium ion formation, which occurs with 2,6-disubstituted benzoic acids in concentrated sulphuric acid, appeared to be absent in the present work.

EXPERIMENTAL

Reagents

The benzoic acids were purified either by several recrystallizations or by vacuum distillation. Samples of *o*-ethyl, *o*-*i*-propyl, and *o*-*t*-butyl benzoic acids were kindly supplied by Professor Harold Schechter. Sulphuric acid solutions were prepared and standardized as before (7).

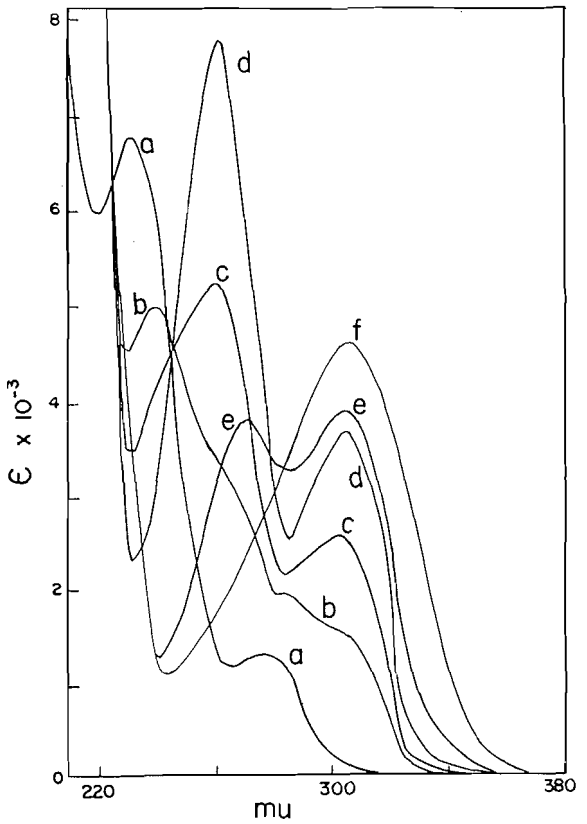

FIG. 2. Ultraviolet absorption spectra of phthalic acid in sulphuric acid solutions: *a* 45%, *b* 70%, *c* 74%, *d* 80%, *e* 100%, *f* 104% H_2SO_4.

Measurement of pK_{BH^+}

This was done by spectrophotometric analysis essentially as previously described (7, 9). In cases of low solubility of the compound in sulphuric acid, stock solutions of the compound were made up in ethanol and 0.05-ml aliquots of this were pipetted into 10-ml volumetric flasks using a 0.100-ml Hamilton syringe with a Chaney adaptor. In these cases the ethanol was not evaporated and a correction was made for the dilution of the sulphuric acid by the ethanol. It was found that the presence of the ethanol in the acid in no way affected the ultraviolet spectrum of the substrate and that identical pK_{BH^+} values, within experimental error, could be obtained by the two methods. Dilution experiments after 1 hour showed that no irreversible changes such as sulphonation were occurring in the concentrated acid.

Calculations

Two methods were used to calculate the pK_{BH^+} values. The first was the graphical method of Davis and Geissman (18) involving the plotting of $D_{\lambda_l} - D_{\lambda_u}$ against H_0 where λ_l and λ_u are wavelengths at which the ion and neutral molecule, respectively, absorb strongly. This produces a "titration curve" from which the inflection point can be read. The following modification of this method was also used (7). Let $\Delta D_B = D_{\lambda_l} - D_{\lambda_u}$ in an acid concentration in which the base is effectively unionized and let $\Delta D_{BH^+} = D_{\lambda_l}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$-D_{\lambda_u}$ in an acid concentration in which the base is effectively completely ionized and let $\Delta D = D_{\lambda_l} - D_{\lambda_u}$ in the acids which partly ionize the base. It can be shown that a plot of $\log(\Delta D_{BH^+} - \Delta D/\Delta D - \Delta D_B)$ against H_0 should give a straight line of unit slope with the intercept equal to pK_{BH^+}. The advantage of this method is that the need for an arbitrary choice of the inflection point of a curve is eliminated since the best straight line may be found by the method of least squares. However, difficulty is often experienced in choosing appropriate optical densities to correspond to zero and complete ionization since solvent shifts usually occur for both the unionized and ionized forms but particularly for the latter as pointed out earlier by Hammett (5, 6). The result of this is that if the spectrum obtained in, say, 98% sulphuric acid, is used for the completely ionized form of a compound which is half ionized in, say, 60% acid an inflated value for D_{BH^+} results since increasing the sulphuric acid concentration usually produces a red shift and an increased extinction coefficient. This, in turn, results in plots by the "linear method" which are, in fact, frequently linear but which often have non-unit slopes.

We have attempted to cancel the solvent shifts partially by choosing as our values of D_u and D_l those which are obtained by moving 1.5 H_0 units in both directions from the pK_{BH^+} determined by the first method above. The choice of 1.5 units is arbitrary and, if there were no solvent spectral shift at all, would result in an error of about 3% in the assigned values of D_u and D_l.

The slopes shown in Table I are close to unity and, in support of the method used here, the plots were all very good straight lines provided values of the logarithmic function between +1.0 and −1.0 were used whereas if D_u and D_l were assigned, using values many H_0 units away from the pK_{BH^+}, the plots were very often non-linear. It may be mentioned that, when the present method was applied to the data previously obtained with aldehydes, ketones, acids, and amides, somewhat lower slopes were obtained than with the ortho-substituted acids reported here. The values for the former were mostly in the 0.9–1.1 range.

There is always the possibility that the irregularities in the log plots are not caused entirely by solvent effects on the spectra. It is conceivable that weak bases of the carbonyl type studied in this and earlier work are following some acidity function other than H_0, a scale which was established chiefly with the aid of nitrogen bases. The deviations from unit slope listed in Table I are not great, except for *o*-iodobenzoic acid, and we believe that they are caused by solvent effects on the spectra rather than by deviations of the ionization process from ideal behavior (8, 19). If, for example, the ionization process was following the h_R' (20) function rather than h_0 a slope of approximately two would result (18). However, in order to shed further light on the matter we are at present examining systematically the variations in the spectra of carbonium ions, ammonium ions, and oxonium ions with changing sulphuric acid concentration.

The values in Tables I and II are quoted to two decimal places. However, in view of the fact that many of the pK_{BH^+} values were measured in the region 70–80% sulphuric acid where the H_0 scale is considered to be not firmly established and in view of the difficulties caused by solvent effects on spectra, there may well be an absolute error of 0.2 pK units although the relative errors within a series will be less than this.

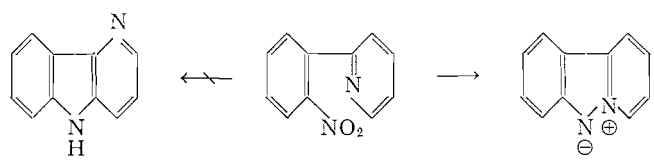
TRYPTAMINES, CARBOLINES, AND RELATED COMPOUNDS

PART IX. THE CYCLIZATION OF SOME NITRO- AND AZIDO-PHENYLPYRIDINES. PYRIDO[1,2-*b*]INDAZOLE[1,2]

R. A. Abramovitch and K. A. H. Adams



ABSTRACT

Heating 2-*o*-nitrophenylpyridine with ferrous oxalate gives rise to pyrido[1,2-*b*]indazole (III). The evidence for the structure of this compound is discussed. Similarly, heating 2-*o*-nitrophenylpyridine methiodide and *N*-oxide with ferrous oxalate gives (III), in each case, demethylation and deoxygenation preceding the cyclization. In the latter case a minute amount of δ-carboline is also formed. Heating pyridine-*N*-oxides with ferrous oxalate is a potentially general method of effecting deoxygenations of these compounds. Contrary to the results of Smith and Boyer (11), it is found that heating 2-*o*-azidophenylpyridine also gives rise to (III). On the other hand, the action of heat on 2-*o*-azidophenylpyridine-*N*-oxide gives a mixture of δ-carboline and δ-carboline-*py*-*N*-oxide in low yield. The mechanism of the cyclization of the azides and of the reaction taking place on heating nitro-compounds with ferrous oxalate is discussed briefly; the formation of a nitrene intermediate is favored.

The catalytic reduction of 2-*o*-nitrophenylpyridine-*N*-oxide giving rise to the azoxy-, azo-, and hydrazo-derivatives is described and the ultraviolet absorption spectra of these compounds are discussed. It is concluded the steric inhibition of coplanarity exists in the azoxy- and azo-compounds leading to the lack of effective conjugation across the N=N bond.

When this work was initiated no suitable method for the synthesis of the δ-carboline ring system was available. Since that time, however, δ-carboline (I) has been obtained in this laboratory by the thermal cyclization of 3-azido-2-phenylpyridine (1). The yields in this reaction are variable, however, and a better method was sought. To this end, the action of ferrous oxalate on 2-*o*-nitrophenylpyridine was investigated.

Ferrous oxalate has been used in a number of interesting cyclizations. Thus, heating it with 2-nitrodiphenyl gives rise to carbazole (2); phenazines have also been obtained from 2-nitrodiphenylamines by this method (2, 3). On the other hand, 4-nitrocarbazole was not obtained from 2,2′-dinitrodiphenyl, but instead 3,4-benzocinnoline was isolated (2). The action of ferrous oxalate on 2-*o*-nitrophenylpyridine (II) at 300° has now been examined. It was anticipated that the pyridine nuclear carbons might be relatively deactivated towards such a cyclization, but that it could conceivably occur at the 3-position of the pyridine ring to give δ-carboline. Cyclization did, in fact, occur but onto the pyridine nitrogen atom to give pyrido[1,2-*b*]indazole (III), no δ-carboline being formed.

(I) (II) (III)

The evidence for the formulation of the cyclization product as pyrido[1,2-*b*]indazole is as follows:

(i) The product is different from any of the carbolines, all of which are now known,

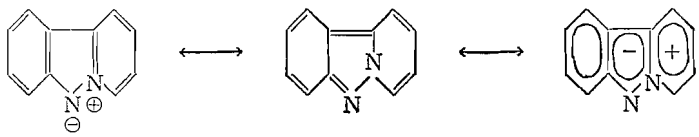
For personal use only.

and melts (83–84°) well below the melting point of the carbolines (~200°). It analyzed correctly for $C_{11}H_8N_2$.

(ii) The infrared spectrum of the compound did not exhibit an N—H stretching absorption and no active hydrogen could be detected. On the other hand, γ-carboline gave an atom of active hydrogen quantitatively. The compound is unaffected by boiling with mineral acids or with aqueous ethanolic alkali (no rearrangement to a more stable structure) and does not take up hydrogen in the presence of Adams' catalyst at atmospheric pressure. It does form an unstable hydrochloride and a picrate.

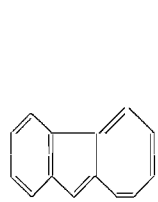
(iii) Unlike the carbolines, it did not form a methiodide readily, but did so to give (IV) under forcing conditions (in ethanol in a sealed tube for 18 hours at 100°). That no C-alkylation had taken place in this reaction was indicated by the absence of a C—CH_3 group (Kühn-Roth).



(iv) The infrared spectrum of the product showed a medium intensity band at 1650 cm^{-1}, somewhat higher than is usually found for aromatic rings. A similarly high frequency (1642 cm^{-1}) was reported (4) for anthranil in which a dipolar form —C_6H_4—$\overset{\ominus}{N}$— contributes greatly to the structure. The ultraviolet absorption spectra of (III) and its derivatives are also interesting. The spectrum of the free base in alcohol, that of the

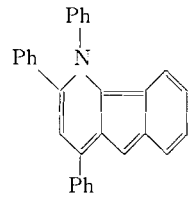
(III) ⟶ 

(IV)



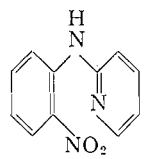
base in alcohol at pH 11, and that of the hydrochloride in alcohol are identical, pointing to the dissociation of the hydrochloride in this solvent. On the other hand, the base in aqueous hydrochloric acid at pH 1 had a spectrum very similar to that of the methiodide (IV) in alcohol, the methyl group having its usual bathochromic effect. The most striking features of the latter ultraviolet spectra are the very high extinction coefficients of the low wavelength bands ($\epsilon \times 10^{-3}$ 182.4 and 196.0 for the hydrochloride and methiodide respectively).

The heterocyclic rings in (III) are isoelectronic with azulene and one could write a number of canonical structures for this molecule:

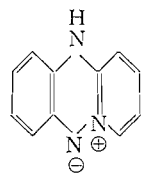


(A) (B) (C)

A number of lines of evidence point to the fact that the orthoquinonoïd anhydro-base structure (B) is probably a minor contributor to the resonance hybrid. Azulene (in which the dipolar structure plays only a small role), 1,2-benzazulene (V), and a variety to pseudo-azulenes such as 1,2,4-triphenylindeno[1,2-*b*]pyridine (VI) (5) are all highly colored; all the carboline anhydro-bases are deep yellow or orange. Paoloni and Marini-Bettòlo (6) have attributed the color of the anhydronium base of 7-azaindole to the



(V)



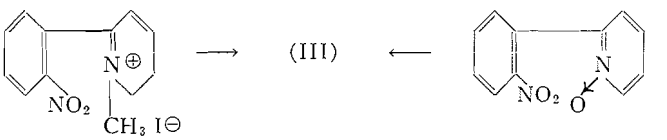
(VI)

orthoquinonoïd form and have suggested that the carboline anhydronium bases as well as sempervirine are best represented by the covalent formulae not bearing separated charges.* From a study of the spectral properties of the δ-carboline anhydronium base Abramovitch, Adams, and Notation (1) suggested that the quinonoïd structure is a more important contributor to the resonance hybrid than the dipolar one. On the other hand, pyrido[1,2-*b*]indazole is colorless, as is its methiodide. In addition, carboline anhydronium bases form *ind-N*-methiodides readily at room temperature (1, 8) whereas (III) only does so under forcing conditions. Similarly, carboline anhydronium bases can be readily hydrogenated (e.g. reduction of cryptolepine (9)) whereas pyrido[1,2-*b*]indazole is not. Gray (10) has interpreted the low base strength of the α-carboline anhydronium base (pK_a 7.75)† as compared with the γ-derivative (pK_a 10.54) on the basis of two factors: (*a*) a much increased stability of the α-anhydronium base as a result of the juxtaposition of the oppositely charged centers (presumably in the dipolar form); and (*b*) a reduced stability of the α-carboline salt owing to the inductive effect of the indole nitrogen attached to the same carbon as the positively charged pyridine nitrogen. It would be expected that in (A) ↔ (C) these effects would be greatly intensified; in fact the pK_a of pyrido[1,2-*b*]indazole has now been found to be approximately 2.48, slightly more than five p*K* units lower than the base strength of the α-carboline anhydronium base!

An attempt was made to obtain further examples of this type of cyclization onto a pyridine nitrogen atom. 2-Nitro-*N*-2′-pyridylaniline (VII) was prepared from 2-bromopyridine and *o*-nitroaniline. The action of ferrous oxalate at 300° on (VII) led to the formation of tars, no product corresponding to (VIII) being detected. This was not totally unexpected since the central ring in (VIII) would be nonaromatic (8 π electrons, compared with 6 π electrons in (III)) so that the incentive leading to its formation may have been lacking. A similar result was obtained using *N*-methyl-2-nitro-*N*-2′-pyridylaniline.

(VII)

(VIII)



It was hoped to force cyclization to occur at C_3 by blocking the pyridine nitrogen atom

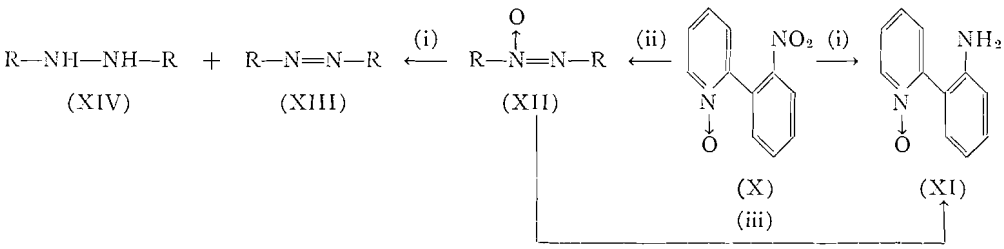
**Paoloni (7) has recently elaborated further on this point. Apart from the fact that his calculations do not lead to correct values for the pK_a and U.V. spectrum of δ-carboline, his conclusion that it is unnecessary to represent the carboline anhydro-bases as hybrids of dipolar and quinonoïd structures in view of the fact that his results "illustrate eloquently the compromise between the tendency to form the (aromatic) sextet and that to neutralize the charges" seems a contradiction in ideas.*

†The pK_a of this compound, as determined by us (1), was 7.55.

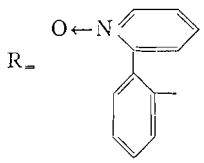
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in (II). Thus, 2-*o*-nitrophenylpyridine methiodide (IX) and 2-*o*-nitrophenylpyridine-*N*-oxide (X) were prepared. It was realized that the *N*-oxide grouping in (X) might not survive the reducing conditions present during the cyclization reaction but it was hoped that cyclization at the 3-position would occur before reduction. In actual practice, heating either (IX) or (X) with ferrous oxalate led to the formation of pyrido[1,2-*b*]indazole. Chromatography on a column of alumina of the crude product from the cyclization of the *N*-oxide yielded, apart from (III), trace amounts of a solid which had an infrared spectrum almost identical with that of δ-carboline. Insufficient material was available to study this product further.

(IX) (X)



It was of interest from the point of view of the mechanism of the cyclization reaction to determine whether elimination of the protecting groups could occur prior to the cyclization, or whether some mode of concerted attack by the intermediate formed from the reduction of the nitro group and elimination of the protecting group was taking place. To this end, the action of ferrous oxalate at 300° on 2-phenylpyridine methiodide and 2-phenylpyridine-*N*-oxide was studied; in both cases 2-phenylpyridine was isolated in yields comparable to the respective reactions using (IX) and (X). In fact, 2-phenylpyridine could be obtained from the corresponding methiodide by heating it at 300° with granulated lead (used to permit the even distribution of heat in the mixture during such cyclization reactions) but without ferrous oxalate. On the other hand, 2-phenylpyridine-*N*-oxide was recovered unchanged under such conditions. It would, therefore, seem that elimination of the protecting group probably precedes cyclization onto the ring nitrogen atom, though the isolation of a trace of a second product in the *N*-oxide case suggests that conditions might be found where the reverse might be achieved. The reduction of the pyridine-*N*-oxide by ferrous oxalate may well be a general reaction of such amine oxides; this is under investigation.



Smith and Boyer (11) attempted to prepare δ-carboline by the thermal cyclization of 2-*o*-azidophenylpyridine in decalin solution but reported obtaining instead 2-*o*-aminophenylpyridine, formed presumably by hydrogen abstraction from the solvent by the intermediate involved. In the present work this reaction gave rise to a 60% yield of pyrido[1,2-*b*]indazole, only a trace of diazotizable material being detected in the crude reaction mixture. No amine could be isolated by chromatography of the crude product on alumina. Attempts at photodecomposition of the azide in solution were unsuccessful though some darkening did occur. This is similar to the experience of Smolinsky, who was working with 2,4,6-trimethyl-2′-azidodiphenyl (12).

Once again, blocking the pyridine nitrogen atom by *N*-oxide formation prior to cyclization was attempted. 2-*o*-Nitrophenylpyridine-*N*-oxide (X) could be reduced catalytically in acetic acid solution with hydrogen and palladium–charcoal to the amine (XI), the *N*-oxide grouping being unaffected. This result is in agreement with previous hydrogenations of pyridine-*N*-oxides (13, 14) which indicated that the *N*-oxide group in 2-substituted pyridine-*N*-oxides was sterically hindered and thus resisted reduction. If, on the

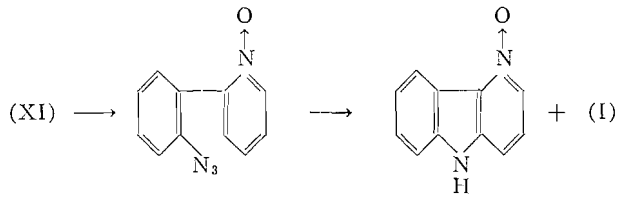
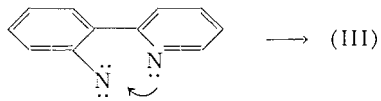
For personal use only.



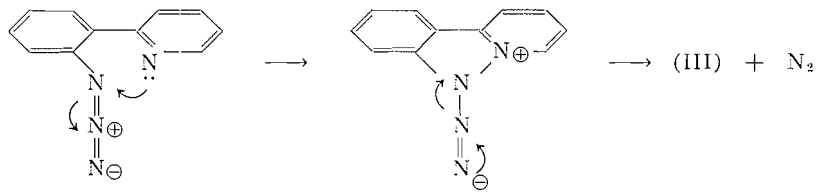
other hand, the catalytic reduction was carried out in alcohol solution the product isolated was 2,2′-di-(*N*-oxido-2-pyridyl)azoxybenzene (XII). This, on catalytic reduction in glacial acetic acid solution gave 2,2′-di-(*N*-oxido-2-pyridyl)azobenzene (λ_{max} 230, 323, 455 mμ; λ_{infl} 260 mμ; $\epsilon \times 10^{-3}$ 44.73, 19.02, 0.58, 28.70) (XIII) together with a small amount of what is probably the hydrazo-compound (XIV), though the latter proved to be very difficult to purify. Its structure was inferred from its infrared spectrum and from its ultraviolet absorption spectrum, which was similar to that of 2-*o*-aminophenylpyridine-*N*-oxide (XI). The azoxy-compound (XII) was reduced directly to the amine (XI) by stannous chloride and hydrochloric acid. These reductions are somewhat similar to those reported by Hayashi, Yamanaka, Iyima, and Matsushita (15), who studied the catalytic reduction of 4,4′-azoxypyridine 1,1′-dioxide. The amine (XI) was converted

(i) 5% Pd–C in AcOH; (ii) 5% Pd–C in EtOH; (iii) $SnCl_2$–HCl.



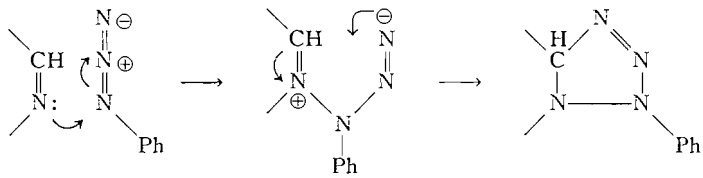
to the azide (XV), which, on thermal decomposition in decalin solution, gave a crude mixture from which δ-carboline (I) and δ-carboline-*py*-*N*-oxide (XVI) could be isolated in low yield by chromatography on alumina. The structure of (XVI) was proved by its synthesis from authentic δ-carboline.

It is interesting to speculate about the mechanisms of the cyclization onto the pyridine nitrogen atom reported here. In the case of the thermal decomposition of the azides two groups of workers have very recently suggested that a nitrene, —N:, may be involved (12, 16). Such an entity, were it formed, would be isoelectronic with a carbene and could be strongly electrophilic. In support of this suggestion is the finding that thermal decomposition of 2,4,6-trimethyl-2′-azidodiphenyl gives rise to 8,10-dimethylphenanthridine (12), which can conceivably arise by attack of a benzylic C—H by a nitrene intermediate.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

This may well explain the present results; such an electrophilic species would certainly tend to attack the pair of electrons on the pyridine nitrogen atom rather than the 3-position of the pyridine ring which is deactivated toward electrophilic substitution. On



(D)

the other hand, one cannot at present eliminate a concerted or perhaps two-stage mechanism involving cyclization concurrent with, or followed by, the elimination of a nitrogen molecule:

Such a N—N bond formation has an analogy in the known reaction of aryl azides with benzaldehyde arylhydrazones which gives rise to tetrazole derivatives (17) for which one might visualize the following sequence:

We tend to prefer the "nitrene intermediate" mechanism at the present time, at least as far as the reaction leading to (XVI) and (I) goes (for arguments in favor of the formation of such an intermediate see ref. 12). A nitrene intermediate is probably formed during the ferrous oxalate cyclization of the nitro-compounds and it would be attractive to visualize a common reactive intermediate species for both of these reactions, leading as they do to the same product. The concerted mechanism for the conversion of the azide to (III) must, however, be seriously considered.

Not much is known concerning the mode of action of ferrous oxalate in these reactions. It presumably decomposes thermally to give a very reactive form of ferrous oxide (some iron may also be formed), which is the actual reducing agent (2, 3). This can either abstract both oxygen atoms from the nitro-group to give a nitrene (D), or else first give rise to a nitroso-derivative which could then add to the pyridine nitrogen atom and lose a second atom of oxygen to form the pyrido[1,2-*b*]indazole. The latter pathway seems a less likely one in view of the above azide cyclizations.

One further matter should be commented on and that is the similarity between the ultraviolet absorption spectra of the azoxybenzene (XII), the azobenzene (XIII), the hydrazo-derivative (XIV), and the amine (XI) (Fig. 1). The spectra of (XIV) and (XI) are almost superimposable (as expected), except that in the case of (XIV) the

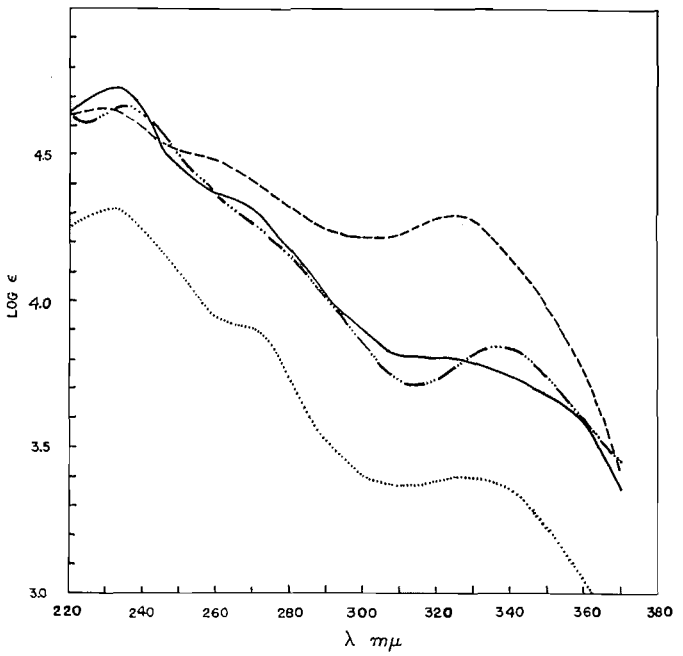

FIG. 1. Ultraviolet absorption spectra in 95% ethanol solution. —— 2,2′-Di-(*N*-oxido-2-pyridyl)azoxybenzene; – – – 2,2′-di-(*N*-oxido-2-pyridyl)azobenzene; —· · · 2,2′-di-(*N*-oxido-2-pyridyl)hydrazobenzene; · · · · 2-*o*-aminophenylpyridine-*N*-oxide.

maxima have all undergone a small bathochromic shift and the intensities are markedly greater. On the other hand, the spectra of azoxybenzene, azobenzene, and aniline are quite different from each other (18, 19), which is not the case for our compounds. One would have to attribute such a result to steric hindrance in the cases of (XII) and (XIII) preventing coplanarity of the two benzene rings and the N=N linkage and thus inhibiting effective conjugation across that linkage. This would result in each of these molecules having an absorption spectrum similar to that of the amine (XI), only more intense, which is what is actually observed.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured using a Perkin–Elmer Model 21 instrument equipped with sodium chloride optics. Ultraviolet absorption spectra were measured on a Cary Model 14 recording spectrometer.

Action of Ferrous Oxalate on 2-o-Nitrophenylpyridine–Pyrido[1,2-b]indazole

2-*o*-Nitrophenylpyridine (20) (1 g) and ferrous oxalate dihydrate (1.3 g) were mixed with granulated lead (10 g) and heated at 300° (internal temperature) (metal bath) for 45 minutes. (At the beginning of the reaction the smell of ammonia being evolved could be detected and a piece of red litmus paper held at the mouth of the flask turned blue.) The cooled mixture was extracted repeatedly with ether, and the combined extracts were dried ($MgSO_4$) and evaporated to give an oil which solidified and was recrystallized from light petroleum (b.p. 60–80°) (charcoal) giving *pyrido[1,2-b]indazole* as rods (0.5 g), m.p. 83–84°. Calc. for $C_{11}H_8N_2$: C, 78.57; H, 4.76; N, 16.66; mol. wt. 168. Found: C,

78.47; H, 4.80; N, 16.90; mol. wt. 152. No active hydrogen was present in the product. An active hydrogen determination on γ-carboline gave 0.61% active H (calc. 0.6%). Infrared spectrum (Nujol mull) (main peaks only): 1650 (m), 1623 (m), 749 (s), 743 (s), and 719 cm^{-1} (s). Ultraviolet absorption spectrum (free base in 95% ethanol or base in alcohol at pH 11): λ_{max} 205, 229, 269, 327 mμ; $\epsilon \times 10^{-3}$ 21.0, 32.7, 23.7, 11.8.

When dry hydrogen chloride was passed through an ethereal solution of pyrido[1,2-*b*]-indazole, an impure hydrochloride, m.p. 161–164°, separated which crystallized from ethanol–ether in needles, m.p. 165–166°. Its ultraviolet absorption spectrum in 95% ethanol, however, was identical with that of the free base, indicating that in this solvent the hydrochloride dissociates to the free base. On the other hand, the base in aqueous hydrochloric acid at pH 1 had λ_{max} 208, 254, 330, 340 mμ; $\epsilon \times 10^{-3}$ 182.4, 140.7, 10.02, 11.37.

The approximate pK_a of pyrido[1,2-*b*]indazole, as determined by potentiometric titration (no solvent correction applied), was 2.48.

Pyrido[1,2-b]indazole picrate separated from alcohol and was recrystallized from acetone, giving yellow needles, m.p. 205°. Calc. for $C_{11}H_8N_2,C_6H_3O_7N_3$: C, 51.50; H, 2.77. Found: C, 51.75; H, 3.00.

The free base was recovered unchanged on:

(i) shaking with hydrogen and Adams' catalyst;
(ii) boiling with 10% hydrochloric acid for 4 hours;
(iii) boiling with 20% aqueous ethanolic potassium hydroxide for 6 hours;
(iv) treatment with an excess of methyl iodide in ethanol at room temperature.

9-Methylpyrido[1,2-b]indazolium Iodide

Pyrid[1,2-*b*]indazole (0.2 g) in ethanol (2 ml) was heated with an excess of methyl iodide (2 ml) in a sealed tube at 100° (water bath) for 18 hours. The product which crystallized out on cooling was taken up in ethanol and combined with the mother liquors and the solution was evaporated to a small volume after boiling with charcoal. Brownish plates (0.3 g) separated which were recrystallized from ethanol to give brownish shiny plates, m.p. 208–209°. These were dissolved in water and filtered from a trace of amorphous brown solid, and the filtrate evaporated to dryness to give the *methiodide*, which on recrystallization from ethanol was obtained as cream-colored prisms, m.p. 226–227°. Calc. for $C_{12}H_{11}N_2I$: C, 46.45; H, 3.55; N, 9.03; I, 40.97. Found: C, 46.88; H, 3.66; N, 8.75; I, 40.63. No C—CH_3 was found in a Kühn-Roth determination. λ_{max} 223, 256, 334, 349 mμ; $\epsilon \times 10^{-3}$ 196.0, 20.0, 9.1, 11.8 (in ethanol).

2-Nitro-N-2'-pyridylaniline

2-Bromopyridine (5 g, redistilled), *o*-nitroaniline (6 g), anhydrous potassium carbonate (4.5 g), and a trace of copper-bronze were heated at 195–210° (metal bath) for 7 hours when no more carbon dioxide was evolved. Water was added and the excess *o*-nitroaniline removed by steam distillation. The residue was extracted with chloroform, the extract dried ($MgSO_4$) and evaporated, and the residue vacuum distilled to give *2-nitro-N-2'-pyridylaniline* as a red oil (2.4 g), b.p. 140–150° at 0.05 mm, which solidified. The product could be recrystallized from light petroleum (b.p. 40–60°) and formed red rods, m.p. 68–69°. Calc. for $C_{11}H_9O_2N_3$: C, 61.39; H, 4.22. Found: C, 61.52; H, 4.00.

The *hemipicrate* separated from ethanol and was recrystallized from the same solvent to give yellow plates, m.p. 172°. Calc. for $C_{11}H_9O_2N_3,\frac{1}{2}C_6H_3O_7N_3$: C, 51.0; H, 3.2. Found: C, 51.1; H, 3.1.

For personal use only.

2-o-Nitrophenylpyridine-N-oxide

2-*o*-Nitrophenylpyridine (0.9 g) was dissolved in glacial acetic acid (20 ml), and 35% hydrogen peroxide (0.44 g) was added. The solution was heated on a water bath at 90° for 9 hours. An additional amount of 35% hydrogen peroxide (0.44 g) was added and heating was continued at 90° for a further 9 hours. The acetic acid was removed by distillation under reduced pressure and the residue was dissolved in chloroform. Anhydrous sodium carbonate was added to neutralize the remaining acetic acid and the solution was filtered and evaporated to dryness. The residue was crystallized from benzene – light petroleum (b.p. 60–80°) and gave the *N-oxide* (0.92 g) as yellow needles, m.p. 156–157°. Calc. for $C_{11}H_8O_3N_2$: C, 61.11; H, 3.73. Found: C, 61.24; H, 3.75.

1-Methyl-2-o-nitrophenylpyridinium Iodide

2-*o*-Nitrophenylpyridine (0.5 g) in 95% ethanol was treated with an excess of methyl iodide and the solution was allowed to stand at room temperature overnight. On concentration the solution yielded small orange crystals (0.55 g) which were recrystallized from methanol to give the *methiodide* as prisms, m.p. 223–224° (decomp.). Calc. for $C_{12}H_{11}O_2N_2I$: C, 42.08; H, 3.19. Found: C, 42.28; H, 3.30.

Action of Ferrous Oxalate on 2-o-Nitrophenylpyridine-N-oxide

2-*o*-Nitrophenylpyridine-*N*-oxide (1 g), ferrous oxalate dihydrate (1.2 g), and granulated lead (12 g) were intimately mixed and heated at 275–300° (internal temperature) in a metal bath. A small amount of strong-smelling gas which was basic to litmus was evolved during the heating period. The cooled mixture was extracted repeatedly with ether and then with hot benzene. The combined extracts were dried (Na_2SO_4) and evaporated to dryness to yield a brown oil (0.22 g) which was chromatographed on neutral alumina. Elution with benzene gave a light brown crystalline compound (0.19 g) which could be recrystallized from light petroleum (b.p. 60–80°) and had m.p. 84–86°. The infrared spectrum of this product was identical with that of an authentic sample of pyrido[1,2-*b*]indazole. The melting point of the base and its picrate were undepressed on admixture with authentic samples. Elution with benzene–ether yielded a tan solid (0.005 g), m.p. 202–205°, the infrared spectrum of which was almost identical with that of δ-carboline.

Action of Ferrous Oxalate on 1-Methyl-2-o-Nitrophenylpyridinium Iodide

1-Methyl-2-*o*-nitrophenylpyridinium iodide (0.6 g) was intimately mixed with ferrous oxalate dihydrate (0.7 g) and granulated lead (6 g). The mixture was heated at 275–300° (internal temperature) in a metal bath for 30 minutes. A small amount of a strong-smelling, basic (litmus) gas was evolved during the heating period. The reaction mixture was cooled and the black residue was repeatedly extracted with ether. The combined ether extracts were dried (Na_2SO_4) and evaporated to give a brown oil (0.1 g) which partly solidified. This product was recrystallized from light petroleum (b.p. 60–80°) giving tan crystals (0.078 g) which proved to be identical with pyrido[1,2-*b*]indazole (mixed melting point, infrared spectrum).

Cyclization of 2-o-Azidophenylpyridine

2-*o*-Azidophenylpyridine (11) (1.2 g, not purified) was dissolved in redistilled decalin (50 ml) and the solution was heated in an oil bath at 160–170° (internal temperature). Gas bubbles began to be evolved smoothly at about 140°. After 10–15 minutes when no more gas evolution could be observed, the solution was cooled and was extracted with 10% hydrochloric acid. The acid extract was washed with ether, basified with 2 *N*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

sodium hydroxide, and extracted repeatedly with ether. The combined ether extracts were dried (Na_2SO_4) and evaporated to give an oil which solidified. Recrystallization from light petroleum (b.p. 60–80°) gave pyrido[1,2-*b*]indazole (0.54 g), m.p. 84.5–85.5°. The melting point was not depressed on admixture with an authentic sample. The picrate, m.p. 199–200°, did not depress the melting point of an authentic sample of pyrido[1,2-*b*]indazole picrate. The infrared spectrum of the base was identical with that of an authentic specimen.

No primary amine could be isolated when the crude reaction product was chromatographed on a column of neutral alumina.

2-o-Aminophenylpyridine-N-oxide

2-*o*-Nitrophenylpyridine-*N*-oxide (0.5 g) was dissolved in glacial acetic acid (25 ml) and hydrogenated at atmospheric pressure in the presence of 5% palladium on charcoal (0.1 g). Three molar equivalents of hydrogen were absorbed in less than 1 hour. The catalyst was removed by filtration and washed with a little acetic acid and methanol. The combined filtrates were evaporated under reduced pressure and the residue dissolved in chloroform and treated with anhydrous sodium carbonate. The filtered solution was evaporated to give an oil (0.42 g) which crystallized on trituration with methanol and was recrystallized from methanol to give the *amine* as white crystals, m.p. 181.5–182.5°. Calc. for $C_{11}H_{10}ON_2$: C, 70.95; H, 5.41. Found: C, 70.72; H, 5.38. λ_{max} 232, 325 mμ; λ_{infl} 270, 220 mμ; $\epsilon \times 10^{-3}$ 20.86, 2.54, 8.06, 17.60 (in 95% ethanol).

2-o-Azidophenylpyridine-N-oxide

2-*o*-Aminophenylpyridine-*N*-oxide (0.30 g) was dissolved in concentrated hydrochloric acid (0.6 ml) and water (1.5 ml) and the solution treated at 0° with a solution of sodium nitrite (0.12 g) in water (1 ml). An excess of a saturated aqueous solution of sodium azide was added, the temperature being maintained between 0 and 5°. The white *azide* which precipitated was filtered, washed with water, and dried. The aqueous filtrate was basified with 2 *N* sodium hydroxide, extracted with chloroform, and the extract dried (Na_2SO_4). Evaporation of the chloroform yielded an additional quantity of azide. The combined solid products (0.286 g) were recrystallized from benzene – light petroleum (b.p. 60–80°) and had m.p. 165–166°. Calc. for $C_{11}H_8ON_4$: C, 62.25; H, 3.80. Found: C, 62.60; H, 3.88.

Cyclization of 2-o-Azidophenylpyridine-N-oxide

2-*o*-Azidophenylpyridine-*N*-oxide (0.5 g) was dissolved in hot redistilled decalin (60 ml) and the solution heated in an oil bath at 175–180° (internal temperature) for 40 minutes during which time nitrogen was evolved and the solution became very dark. It was then boiled under reflux for an additional 10 minutes, cooled, and the solid which separated was filtered. The decalin solution was extracted with 10% hydrochloric acid, and the aqueous solution was basified with 2 *N* sodium hydroxide and extracted with chloroform. The dried (Na_2SO_4) chloroform extract was evaporated under reduced pressure. The residue was combined with the solid which was filtered off after the reaction (total 0.3 g), dissolved in methanol, filtered to remove some black solid (0.150 g), and the filtrate chromatographed on neutral alumina. Elution with benzene gave a solid (0.010 g) which was identified as δ-carboline by its infrared spectrum and mixed melting point with an authentic specimen. Elution with ether–methanol yielded at first a solid (0.046 g) which could be crystallized from benzene containing a small amount of methanol and had m.p. 277–278° (decomp.). Its infrared spectrum was identical

For personal use only.

with that of an authentic sample of δ-carboline-*py*-*N*-oxide and the melting point was not depressed on admixture with a sample prepared from δ-carboline as described below. Subsequent fractions yielded only intractable dark brown residues.

δ-Carboline-py-N-oxide

δ-Carboline (0.050 g) was dissolved in glacial acetic acid (8 ml), and 35% hydrogen peroxide (0.1 g) was added. The solution was heated on a water bath at 90° for 10 hours. More 35% hydrogen peroxide (0.1 g) was added and heating was continued for an additional 9 hours. The acetic acid was evaporated under reduced pressure, and the residue was dissolved in chloroform and treated with anhydrous sodium carbonate. Evaporation of the chloroform gave the *N-oxide* (0.050 g) which was recrystallized from benzene containing some methanol (charcoal). This crude yellow product was dissolved in dilute hydrochloric acid, filtered, basified with 2 *N* sodium hydroxide, and extracted with chloroform. Evaporation of the dried (Na_2SO_4) chloroform solution gave a white residue which was recrystallized from benzene containing some methanol to give white crystals which melted at 277–278° (decomp.). Calc. for $C_{11}H_8N_2O$: C, 71.72; H, 4.38. Found: C, 71.65; H, 4.60. Infrared spectrum (KBr disk) (main peaks only): 1630 (m), 1605 (m), 1574 (m), 1215 (s), 865 (m), 782 (m), 750 (s), 705 cm^{-1} (s).

Catalytic Reduction of 2-o-Nitrophenylpyridine-N-oxide in 95% Ethanol – 2,2′-Di-(N-oxido-2-pyridyl)azoxybenzene

2-*o*-Nitrophenylpyridine-*N*-oxide (0.82 g) was dissolved in 95% ethanol (35 ml) and hydrogenated at atmospheric pressure in the presence of 5% palladium on charcoal (0.17 g). The reduction was complete in about 90 minutes. The catalyst was filtered and washed with glacial acetic acid. The combined filtrates were evaporated to a small volume under reduced pressure, the residue was dissolved in chloroform and treated with anhydrous sodium carbonate to neutralize any remaining acetic acid. The solution was filtered and evaporated to dryness and the residue recrystallized from methanol to give the *azoxy* compound (0.58 g), m.p. 236–237°. Calc. for $C_{22}H_{16}O_3N_4$: C, 68.74; H, 4.38. Found: C, 68.46; H, 4.32. Infrared spectrum (KBr disk) (main peaks only): 1600 (m), 1255 (s), 850 (s), 780 (s), 770 (s), 750 cm^{-1} (sh). λ_{max} 233, 325 mμ; λ_{infl} 220, 270 mμ; $\epsilon \times 10^{-3}$ 53.50, 6.50, 43.20, 21.00 (in 95% ethanol).

Catalytic Reduction of 2,2′-Di-(N-oxido-2-pyridyl)azoxybenzene in Glacial Acetic Acid – 2,2′-Di(N-oxido-2-pyridyl)azobenzene and 2,2′-Di-(N-oxido-2-pyridyl)hydrazobenzene

2,2′-Di-(*N*-oxido-2-pyridyl)azoxybenzene (0.050 g) was dissolved in glacial acetic acid (10 ml) and hydrogenated at atmospheric pressure in the presence of 5% palladium on charcoal (0.010 g). The reduction product was isolated as in the previous experiment. The residue was washed with methanol and crystallization took place. The crude product was separated by fractional crystallization from benzene into *2,2′-di-(N-oxido-2-pyridyl)-azobenzene* obtained as orange crystals (0.020 g), m.p. 264° (decomp.) [Calc. for $C_{22}H_{16}O_2N_4$: C, 71.72; H, 4.38. Found: C, 71.62; H, 4.71. Infrared spectrum (KBr disk) (main peaks only): 1585 (w), 1255 (s), 845 (s), 780 (s), 750 cm^{-1} (m). λ_{max} 230, 323, 455 mμ; λ_{infl} 260 mμ; $\epsilon \times 10^{-3}$ 44.73, 19.20, 0.58, 28.70 (in 95% ethanol)], and 2,2′-di-(*N*-oxido-2-pyridyl)hydrazobenzene (0.018 g), obtained as a white solid which, because of its insolubility, was very difficult to purify, m.p. 225° (decomp.). Infrared spectrum (KBr disk) (main peaks only): 3350 (m), 1595 (s), 1247 (s), 842 (s), 780 (m), 750 cm^{-1} (s). λ_{max} 236, 338 mμ; λ_{infl} 265 mμ; $\epsilon \times 10^{-3}$ 46.70, 6.88, 21.15 (in 95% ethanol).

Reduction of 2,2'-Di-(N-oxido-2-pyridyl)azoxybenzene with Stannous Chloride – 2-o-Aminophenylpyridine-N-oxide

2,2'-Di-(*N*-oxido-2-pyridyl)azoxybenzene (0.113 g) dissolved in concentrated hydrochloric acid (3 ml) was treated with a solution of stannous chloride dihydrate (0.24 g) in concentrated hydrochloric acid (1 ml). The solution was heated on the steam bath for 90 minutes. The cooled reaction mixture was basified with 2 *N* sodium hydroxide and extracted with ether. The dried (Na_2SO_4) ether solution was evaporated to give the primary amine (0.090 g) which was recrystallized from methanol–ether and had m.p. 179–181°. The melting point was not depressed on admixture with an authentic sample of 2-*o*-aminophenylpyridine-*N*-oxide and the infrared spectra of the two samples were identical.

2-Phenylpyridine Methiodide

2-Phenylpyridine and an excess of methyl iodide were kept at room temperature for 2 days in the absence of light. The *methiodide* which separated was recrystallized from ethyl acetate – methanol to give colorless needles, m.p. 143–144°. Calc. for $C_{12}H_{12}NI$: C, 48.50; H, 4.06. Found: C, 48.61; H, 4.25.

Demethylation of 2-Phenylpyridine Methiodide

(a) With Ferrous Oxalate

The methiodide (0.14 g) was mixed with ferrous oxalate dihydrate (0.16 g) and granulated lead (2 g) and the mixture heated in a metal bath at 290–300° under an air condenser for 30 minutes. The cooled reaction mixture and condensate were extracted with ether, and the ether layer was washed with sodium thiosulphate solution to remove iodine and dried (Na_2SO_4). Evaporation of the ether gave 2-phenylpyridine (0.037 g, 50%), picrate, m.p. 172–173°, undepressed on admixture with an authentic specimen.

(b) Without Ferrous Oxalate

The procedure was exactly as under (*a*) except that no ferrous oxalate was added. 2-Phenylpyridine (74% yield) was isolated.

Action of Ferrous Oxalate on 2-Phenylpyridine-N-oxide

2-Phenylpyridine-*N*-oxide (0.30 g) (21) was mixed with ferrous oxalate dihydrate (0.40 g) and granulated lead (4 g) and treated as for the methiodide reaction. 2-Phenylpyridine (0.171 g, 63%), b.p. 132–134° at 10 mm, picrate, m.p. 172–173°, undepressed on admixture with an authentic specimen, was thus obtained.

When ferrous oxalate was omitted, the starting *N*-oxide was recovered.

OXIDATION–REDUCTION POLYMERS

I. SYNTHESIS OF MONOMERS[1]

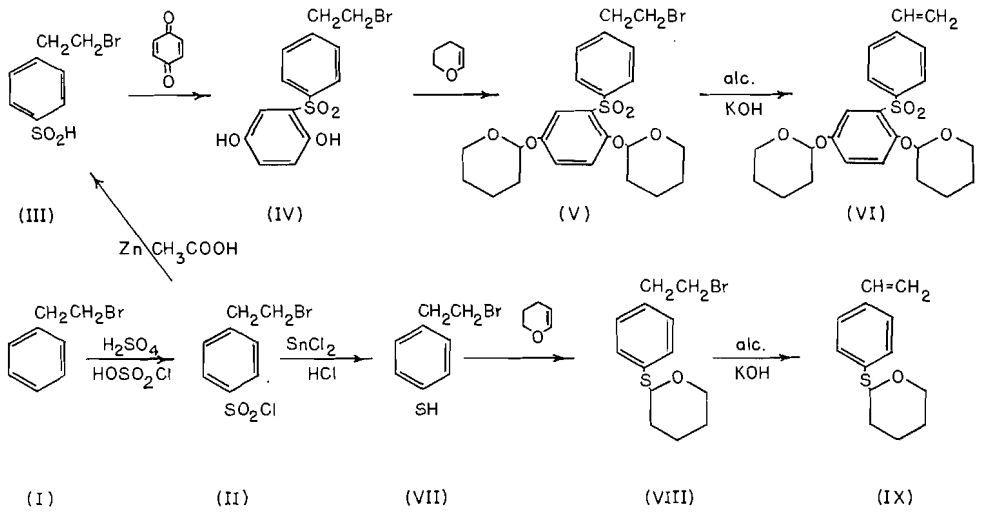
I. H. SPINNER, J. YANNOPOULOS,[2] AND W. METANOMSKI

ABSTRACT

The preparation of two new monomers, 2,5-bis-(2-tetrahydropyranyloxy)-4′-vinyldiphenyl sulphone and 2-tetrahydropyranyl-4′-vinylphenyl thioether, for the synthesis of redox polymers is described.

The first systematic discussion of redox (electron exchange) polymers was presented by Cassidy (1). These polymers were divided into two classes: (i) those in which the active redox group formed a part of the backbone of the polymer chain and (ii) those in which the active group was a substituent on the polymeric chain. Examples of the first class are various condensation resins of hydroquinones, naphthaquinones, and anthraquinones with phenol and formaldehyde (2–6).

Polyvinylhydroquinone (7) is an example of the second class. Monomers such as vinylhydroquinone dibenzoate (8) and diacetate (8, 9) were produced, since it was soon realized that in order to obtain high molecular weight polymers, the hydroxyl groups in the monomer should be protected. Other vinyl monomers were synthesized, such as vinylhydroquinone bis-methoxymethyl ether (10), 1-vinyl-2,4,5-trimethyl-3,6-dihydroxybenzene (11), β-vinylanthraquinone (12, 13), and 2-methyl-3-vinyl-1,4-naphthaquinone (14). A polyhydroquinone was prepared from 3-(2,5-diacetoxyphenyl) propylene oxide (15).



Redox polymers of the second class have also been prepared by reactions with polymers. For example, polyaminostyrene was first diazotized and then reacted with an alcoholic solution of *p*-benzoquinone or 1,4-naphthaquinone (16, 17). Polyaminostyrene was also reacted directly with a naphthaquinone (16). Polyvinyl alcohol was reacted with β-formylanthraquinone (18).

Polymers of known and easily varied structure have obvious advantages in any systematic study of the properties of redox polymers. Our efforts have therefore been directed towards the synthesis of a vinyl monomer for which the oxidation potential could be varied in a simple manner. This was accomplished by joining a hydroquinone group through a stable sulphone bridge with another benzene ring containing $-CH_2CH_2Br$ side chain. The latter can easily be dehydrobrominated to give a vinyl group. A simple hydroquinone could be replaced by a substituted hydroquinone or a naphthahydroquinone. In this way, different redox polymers could be prepared and their oxidation potentials measured and compared with simple homologues.

Vinyl monomers, reported so far, have generally one property in common: the vinyl group is attached directly to the same benzenoid ring which undergoes a redox cycle. It is possible that the interactions between adjacent redox residues will be different from those of a simple polyvinylhydroquinone (1, 7), since the redox group in the monomer reported here is further removed from the backbone chain.

The synthesis of a new monomer, 2,5-bis-(2-tetrahydropyranyloxy)-4′-vinyldiphenyl sulphone (VI) was achieved in five steps according to the scheme shown below.

β-Bromoethylbenzene (I) was chlorosulphonated and then reduced by zinc in acetic acid to *p*-(β-bromoethyl) benzenesulphinic acid (III). The sulphinic acid was reacted with *p*-benzoquinone to give a diphenyl sulphone IV. The hydroxyl groups were protected by making use of a reaction with 2,3-dihydropyran (19) to give a bis-tetrahydropyranyl ether V. Finally, the side chain was dehydrobrominated using an alcoholic solution of potassium hydroxide.

The possibility of the existence of two racemic diastereoisomers of V has not been overlooked. Stern, English, and Cassidy (20) isolated two isomers of bis-2-tetrahydropyranyl ether of hydroquinone, assigning to them the meso and racemic configurations. In our case none of the isomers has a plane of symmetry because of the presence of an additional substituent group —SO_2R, and therefore two racemic diastereoisomers are expected, as shown below.

R= $C_6H_4CH_2CH_2Br$

The hydroxyl groups could also be protected by acetylation or benzoylation, but the esters partially decomposed during dehydrobromination. Dehydrobromination of these esters using other bases, such as pyridine, lutidine, or triethanolamine, is being studied and shows some promise.

The acetal bond, on the other hand, is very stable under strong alkaline conditions. The tetrahydropyranyl groups can be removed from the polymers by an acid treatment, exposing free —OH groups.

Polymers with thiol groups are of interest as another type of redox resin and ion exchanger. Brubaker (21) has patented the synthesis of polyvinylthioacetate and pointed out the oxidation of polyvinylthiol to polyvinyldisulphide. Polythiolstyrene was prepared by Gregor, Dolar, and Hoeschele (22), and Seifert (23) by various reactions on the benzene ring of the polystyrene. Similarly, poly(vinylbenzylmercaptan) was prepared by Parrish (24), Okawara, Nakagawa, and Imoto (25), and Trostyanskaya and Tevlina (26). Hamamura, Tatsukawa, and Uno (27) produced polythiol resins by the condensation of various thiophenols with formaldehyde. Overberger and Lebovits (28) were the first to synthesize a monomer, *p*-vinylphenyl thioacetate, which was polymerized and saponified to give poly-*p*-thiolstyrene.

A new monomer, 2-tetrahydropyranyl-4′-vinylphenyl thioether (IX) was prepared according to the scheme shown above. *p*-(β-Bromoethyl)benzenesulphonyl chloride (II) was reduced to *p*-(β-bromoethyl)thiophenol (VII). This reduction presented some difficulty since with reducing agents evolving hydrogen *in situ*, such as zinc in acidic medium, or lithium aluminum hydride (in the presence of sulphonyl group (29)), there was a simultaneous reduction of both —SO_2Cl and —CH_2CH_2Br groups. The final product of such a reduction was *p*-ethylthiophenol or a mixture of the sulphinic acid III and *p*-ethylthiophenol. The successful reduction of II to VII was achieved by using stannous chloride and hydrogen chloride in acetic acid, in which case no hydrogen was evolved. The thiol group can add across an olefinic bond (28) and therefore this group must be protected before dehydrobromination. Pyranylation with 2,3-dihydropyran has been used for this purpose. After the polymerization tetrahydropyranyl groups can be removed by acid treatment, exposing free —SH groups.

Both monomers were polymerized and copolymerized with other monomers. After acid treatment the polymers exhibited the expected redox properties and, in addition, the polymers with thiol groups had a high affinity for metal cations. A redox membrane was produced and preliminary experiments indicated the transfer of "oxidizing power" through the membrane with an apparent diffusion coefficient of about 5×10^{-7} cm²/second. Investigation of the properties of these redox polymers in bead and membrane form is now in progress.

EXPERIMENTAL*

p-(β-Bromoethyl)benzenesulphonyl Chloride (II)

This compound has been previously prepared by Spinner, Ciric, and Graydon (30). The present procedure is based on the modifications introduced by Worsley (31).

A solution of β-bromoethylbenzene (I) (185 g, 1 mole) and acetonitrile (82 g, 2 moles) was added dropwise to 30% fuming sulphuric acid (265 g) at 20–30°. To the reaction mixture, chlorosulphonic acid (290 g, 2.5 mole) was added, the temperature being kept at 40–45°. Stirring was continued for 1 hour at the same temperature range. The mixture

**Melting points are corrected. Microanalyses were done by Micro-Tech Laboratories, Skokie, Illinois, and Galbraith Laboratories, Inc., Knoxville, Tenn.*

was poured onto crushed ice and allowed to stand in a refrigerator for 30 minutes. The precipitate was filtered and recrystallized from petroleum ether (boiling range 80–100°), yielding 220 g (78%), m.p. 54–54.5° (previously reported 54–55° (30)).

Infrared spectrum: 1179 (s) and 1383 (s) (—SO_2—) cm^{-1} (32).

p-(β-Bromoethyl)benzenesulphinic Acid (III)

The sulphonyl chloride II (50 g, 0.177 mole) was dissolved in glacial acetic acid (250 ml) at room temperature and zinc dust (15 g, 0.23 mole) was added in small portions with constant stirring. The temperature was kept at 25–35°. After 1 hour of additional stirring at 30–35°, concentrated hydrochloric acid (150 ml) and then distilled water (125 ml) were added slowly. The reaction mixture was heated to 80°. On cooling of the mixture in an ice bath a white precipitate formed which, recrystallized from hot water, gave 32.5 g (74%) of a product melting at 95–95.5°. The compound changed rapidly on drying (over 1 hour) (33), on standing, and on further recrystallization, as was evidenced by widely varying melting points. Thus, all attempts to provide a sample suitable for analysis failed.

Reduction of the sulphinic acid III with stannous chloride in glacial acetic acid saturated with hydrogen chloride gave *p*-(β-bromoethyl)thiophenol (VII), a product identical with that produced by a direct reduction of the sulphonyl chloride II, as reported below. B.p. 92.5–93°/1.2 mm. Anal. Calc. for C_8H_9BrS (217.13): C, 44.25; H, 4.18; Br, 36.80; S, 14.76. Found: C, 45.05; H, 4.72; Br, 36.28; S, 14.43%.

2,5-Dihydroxy-4′-(β-bromoethyl)diphenyl Sulphone (IV)

This reaction is based on 1,4 addition of an aromatic sulphinic acid to a quinone, first reported by Hinsberg (34).

After many trials with solutions in various solvents, the following procedure, which yielded best results, was adopted. A suspension of *p*-benzoquinone (13.5 g, 0.125 mole) in water (500 ml) was added slowly to a suspension of the sulphinic acid III (31 g, 0.125 mole) in water (1 liter) at room temperature. A gradual change in the consistency of the suspended solid took place, the final product being very fluffy. The typical yellow color of quinone disappeared. Crystallization from 25% (by volume) ethanol gave a light sandy powder (36 g, 81%) melting at 130–130.5°. Anal. Calc. for $C_{14}H_{13}BrO_4S$ (357.22): C, 47.07; H, 3.67; Br, 22.37; S, 8.97. Found: C, 47.26; H, 3.81; Br, 22.61; S, 9.01%. Infrared spectrum: 1152 (s) and 1302 (s) (—SO_2—) (32), 3390 (s) (—OH) cm^{-1}.

A derivative, 2,5-diacetoxy-4′-(β-bromoethyl)diphenyl sulphone, was prepared by reacting the dihydroxysulphone IV with acetic anhydride and a drop of concentrated sulphuric acid as a catalyst. Crystallization from 50% (by volume) ethanol gave a white product melting at 110–110.5°. Anal. Calc. for $C_{18}H_{17}BrO_6S$ (441.30): C, 48.99; H, 3.88; Br, 18.11; S, 7.27. Found: C, 49.33; H, 3.96; Br, 18.25; S, 7.31%. Infrared spectrum: 1153 (s) and 1324 (s) (—SO_2—) (32), —OH band absent.

Another derivative, 2,5-benzoquinone-4′-(β-bromoethyl)phenyl sulphone, was prepared by oxidizing the dihydroxysulphone IV with silver oxide. Orange needles precipitated by high boiling point petroleum ether from a diethyl ether solution melted at 104–104.5°. Anal. Calc. for $C_{14}H_{11}BrO_4S$ (355.21): C, 47.33; H, 3.12; Br, 22.50; S, 9.03. Found: C, 47.10; H, 3.15; Br, 22.94; S, 9.20%.

2,5-Bis-(2-tetrahydropyranyloxy)-4′-(β-bromoethyl)diphenyl Sulphone (V)

The dihydroxysulphone IV (10 g, 0.028 mole) was dissolved in 2,3-dihydropyran (15 g, 0.178 mole) containing a few milligrams of *p*-toluenesulphonic acid as a catalyst. The solution was stirred at room temperature for 2 hours and left at the same temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

overnight. The volatile materials were then removed under vacuum, and the solid residue taken up in chloroform – diethyl ether (5:2) mixture (150 ml). The solution was shaken with several portions of 5% sodium hydroxide solution to remove the unreacted IV, washed with water, dried over anhydrous sodium sulphate, and concentrated. The precipitate formed was filtered and crystallization from 70% (by volume) ethanol gave 9.8 g (67%) of white crystals melting at 133–134°. Anal. Calc. for $C_{24}H_{29}BrO_6S$ (525.45): C, 54.86; H, 5.56; Br, 15.21; S, 6.10. Found: C, 55.05; H, 5.68; Br, 14.98; S, 5.97%.

This solid is one of the two racemates mentioned in the earlier discussion. Attempts to recover a presumably lower melting and more soluble racemate from the chloroform–ether mother liquor were not successful.

The pyranylated sulphone V decomposed on treatment with hydrochloric acid, giving the dihydroxysulphone IV, melting at 130–131°. This product gave no depression in mixed melting point with the original IV. The other decomposition product was 5-hydroxypentanal, identified by its 2,4-dinitrophenylhydrazone melting at 108.5–109° (reported m.p. 109° (35)).

2,5-Bis-(2-tetrahydropyranyloxy)-4'-vinyldiphenyl Sulphone (VI)

A 10% alcoholic solution of potassium hydroxide (1.6 g KOH, 0.028 mole) was added dropwise to a boiling solution of the diphenyl sulphone V (12 g, 0.023 mole) in benzene (150 ml). The mixture was refluxed on a steam bath for 30 minutes. The precipitated potassium bromide was removed by filtration and the filtrate evaporated to dryness *in vacuo* at room temperature. The residue after a thorough washing with water was crystallized from 50% (by volume) ethanol. The white crystals obtained (6.5 g, 64%) melted at 126.5–127°. Anal. Calc. for $C_{24}H_{28}O_6S$ (444.52): C, 64.84; H, 6.35; S, 7.21. Found: C, 64.67; H, 6.43; S, 7.25; C, 64.60; H, 6.44; S, 7.35%.

p-(β-Bromoethyl)thiophenol (VII)

p-(β-Bromoethyl)benzenesulphonyl chloride (II) was reduced to VII with stannous chloride and hydrogen chloride (36, 37).

Dry hydrogen chloride was bubbled into a suspension of stannous chloride dihydrate (203.5 g, 0.9 mole) in glacial acetic acid (800 ml) at room temperature until the suspension became clear and homogeneous; 71.5 g (1.96 mole) of hydrogen chloride was required. *p*-(β-Bromoethyl)benzenesulphonyl chloride (II) (42.5 g, 0.15 mole) was added and the mixture was shaken for 15 minutes. Evolution of heat was observed during the reaction. On shaking of the mixture with 1:1 hydrochloric acid, a yellowish oil settled. This oil was separated and washed with concentrated hydrochloric acid and then water. Distillation under reduced pressure gave 26.4 g (81%) of a colorless oil* (b.p. 92.5–93°/1.2 mm). Anal. Calc. for C_8H_9BrS (217.13): C, 44.25; H, 4.18; Br, 36.80; S, 14.76. Found: C, 44.53; H, 4.36; Br, 36.76; S, 14.91%.

A derivative, mercuric mercaptide of *p*-(β-bromoethyl)thiophenol, was prepared by adding an excess of 20% mercuric acetate solution in dilute acetic acid to the thiophenol VII. Crystallization from benzene gave snow white crystals melting at 115.5–116.5°. Anal. Calc. for $C_{16}H_{16}Br_2HgS_2$ (632.86): C, 30.36; H, 2.55; Br, 25.26; Hg, 31.70; S, 10.13. Found: C, 30.63; H, 2.67; Br, 25.37; Hg, 31.25; S, 10.33%.

Another derivative, *p*-(β-bromoethyl)phenyl thiobenzoate was prepared by reacting the thiophenol VII with benzoyl chloride dissolved in benzene in the presence of pyridine. Crystallization from ethanol gave white needles, m.p. 49–49.5°. Anal. Calc. for

**This thiophenol (as well as p-ethylthiophenol) was found to be a very strong skin irritant, a well-known property of thiophenols (38).*

$C_{15}H_{13}BrOS$ (321.23): C, 56.08; H, 4.08; Br, 24.88; S, 9.98. Found: C, 56.29; H, 4.70; Br, 24.90; S, 9.74%.

2-Tetrahydropyranyl-4'-(β-bromoethyl)phenyl Thioether (VIII)

The procedure is based on a method of Parham and DeLaitsch (19).

The thiophenol VII (26.3 g, 0.12 mole) was mixed with a 65% excess of 2,3-dihydropyran (27 g, 0.32 mole), 1 ml of ethereal solution of HCl (0.002 mole) was added, and the mixture refluxed for 48 hours at 30°. The mixture was shaken with three portions of 5% sodium hydroxide solution and washed with water. The excess of dihydropyran was removed by evaporation under reduced pressure. Attempts to purify the thioether VIII by distillation were unsuccessful because of its high boiling point and the instability of the brominated side chain at high temperatures.

2-Tetrahydropyranyl-4'-vinylphenyl Thioether (IX)

Approximately 30% excess of 10% alcoholic solution of potassium hydroxide was added to the crude thioether VIII. The mixture was refluxed for 30 minutes. The precipitated potassium bromide was removed by filtration, the filtrate was washed with water, dried over anhydrous sodium sulphate, and distilled under reduced pressure. Traces of *p-tert*-butylcatechol were added as a polymerization inhibitor prior to drying and distillation. The product was a colorless viscous oil (b.p. 134–135°/1.35 mm). Bromination calculated for 1.000 double bond; found 0.998. Anal. Calc. for $C_{13}H_{16}OS$ (220.33): C, 70.86; H, 7.32; S, 14.56. Found: C, 70.86; H, 7.52; S, 13.51; C, 71.72; H, 7.70; S, 15.02%.

PREFERRED RESIDENCE CONFORMATIONS OF DIASTEREOISOMERIC α-β AMINO ALCOHOLS: AN N.M.R. STUDY OF THE EPHEDRINES[1]

J. B. HYNE

ABSTRACT

Nuclear magnetic resonance spectral results including chemical shifts, anisotropy effects, spin coupling constants, and hydrogen bonding phenomena are presented for the diastereoisomeric pair of α-β amino alcohols (−)-ephedrine and (+)-ψ-ephedrine. The results are shown to be in keeping with the existence of a preferred residence conformation for each of the diastereoisomers.

INTRODUCTION

In a recent paper (1) the effect of dilution on the chemical shift associated with the nuclear magnetic resonance of the OH and NH protons of both (+)-ψ-ephedrine and (−)-ephedrine in chloroform solution was reported. This effect, together with a considerable volume of previously available data, was interpreted as evidence for preferred intramolecular hydrogen bonding in the (+)-ψ-ephedrine diastereoisomer compared with (−)-ephedrine. The conclusion was drawn from the assembled evidence that there is a greater probability in the (+)-ψ-ephedrine case of residence in the conformation which permits intramolecular hydrogen bonding than in the (−)-ephedrine case. In summary, (+)-ψ-ephedrine tends to adopt that conformation in which the OH and NH functions have a gauche relationship while (−)-ephedrine shows no such preference.

Freudenberg and co-workers (2) early established the relative configuration of the two asymmetric centers in the ephedrine molecule and found that the two representatives of the diastereoisomeric pairs, (−)-ephedrine and (+)-ψ-ephedrine, differed only in the configuration about the carbon center carrying the hydroxyl group. Assuming, as a first approximation, that the staggered conformations, generated by rotation of the two halves of the molecule about the central carbon–carbon bond, will be the more stable, a set of staggered conformers for the two diastereoisomers can be drawn as shown in Fig. 1. Considering these possible conformations in the light of the hydrogen-bonding evidence (1) it would appear that conformations (*a*) or (*b*) would be the most favored for (+)-ψ-ephedrine since the hydroxyl and methylamino groups are favorably placed for intramolecular hydrogen bonding in these conformers. Since (−)-ephedrine showed no marked tendency toward intramolecular hydrogen bonding, conformer (*y*), with trans disposition of hydroxyl and methylamino groups, must be at least equally favored in conformer population. In an earlier paper on the dissociation constants of the ephedrinium ions Everett and Hyne (3) favored conformers (*a*) and (*y*) for the diastereoisomeric pair on the basis of approximate calculations of repulsive interactions between non-bonded atoms on the adjacent carbon centers.

Recent work (4, 5, 6) on the variation of spin-coupling constants with the dihedral angle between adjacent carbon–hydrogen bonds in ethanic systems suggested the application of this method to the diastereoisomeric ephedrine pair. Figure 1 shows clearly that the dihedral angle between the carbon–hydrogen bond on the hydroxyl center and the carbon–hydrogen bond on the methylamino center varies significantly from one possible conformation to another.

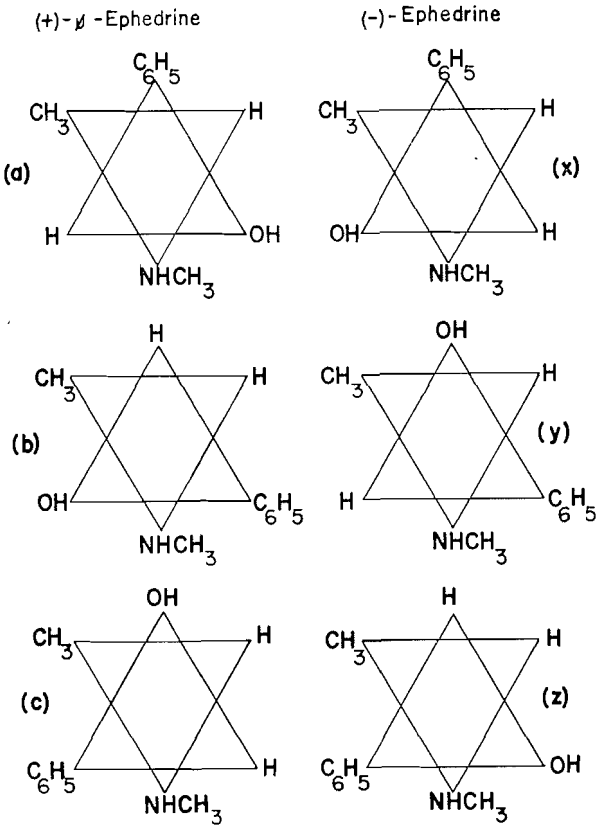

FIG. 1. Possible "pure staggered" conformations of the diastereoisomeric ephedrines.

EXPERIMENTAL

Nuclear magnetic resonance spectra were measured on a Varian V 4300 spectrometer operating at a fixed frequency of 40 Mc; 1.5 molar solutions of BDH (+)-ψ-ephedrine and (−)-ephedrine were prepared in chloroform; the (+)-ψ-ephedrine was used without further purification while the (−)-ephedrine was vacuum-distilled to remove water of hydration. Temperature in the n.m.r. 5-mm spinning sample tube was 20°±1° C throughout. The spectra were scaled by the side band technique using a benzene capillary as an external standard. In obtaining the spin-coupling constant by measuring the splitting of the CHO doublet the side band frequency was set such that the side band appeared a few counts per second before the doublet. As soon as the side band had been traced, the frequency was changed in such a way as to place the side band a few counts per second after the doublet. By this method a trace of the doublet was obtained carrying a side band marker immediately before and after the doublet. At least 10 such determinations were made in obtaining a given spin-coupling constant. The method was cross-checked by using the standard side band superposition technique. All determinations were *within* ±0.2 c.p.s. of the mean value reported. The chemical shifts of all peaks in both spectra together with the spin-coupling constants (J) are recorded in Table I.

DISCUSSION

Spin–Spin Coupling Constant for CH—O/CH—N Interaction

The spin-coupling constant for the interaction of these adjacent protons is twice as great for (+)-ψ-ephedrine (8.2±0.2) as for (−)-ephedrine (4.0±0.2). This observation is of critical importance in establishing the existence of preferred residence in different conformations in the two diastereoisomers. In the first instance the large difference between the constants establishes the fact that a real difference does exist between the time-averaged spin coupling of these two protons. This difference could only arise if preferred residence in different conformations existed. Secondly, the fact that it is the (+)-ψ-ephedrine form which has the higher coupling constant strongly suggests that in this form the preferred relationship between the protons under consideration is trans while in (−)-ephedrine, with the much lower coupling constant, the preferred relationship, if any, is gauche. The order of magnitude of the observed coupling constants and the trans and gauche assignment given above is in keeping with previous observations of Glick and Bothner-By (5) and Lemieux and co-workers (6). The results are also in qualitative agreement with the theoretical calculations of Karplus (4) which predict J values between 8 and 9 c.p.s. for dihedral angles close to 0° or 180° and minimum values of J for angles close to 90°. In terms of the possible conformations shown in Fig. 1, therefore, the J values support a conformation such as (*a*) for the preferred residence form for (+)-ψ-ephedrine but do not support conformer (*y*) as the preferred residence form for (−)-ephedrine. The spectra of the two diastereoisomers, however, contain additional information which is of value in assigning preferred residence conformations.

C—CH_3 Resonance

The chemical shift associated with the C—CH_3 protons is approximately the same in both diastereoisomers. This observation is of importance when compared with the recently observed differences in C—CH_3 shift in the oxazolidone and oxazolidine derivatives of the two ephedrines (7). In these derivatives the ephedrine molecules are bridged across the OH and NH functional groups so that the groups on the adjacent asymmetric centers are constrained to adopt specific spacial relationships to one another. In the (−)-ephedrine form such bridging results in a virtual eclipsing of the phenyl and C—CH_3 groups with a consequent upfield shift of the C—CH_3 resonance due to the diamagnetic anisotropy of the phenyl ring. In the (+)-ψ-ephedrine case bridging in the derivative constrains the phenyl and C—CH_3 groups to adopt a staggered configuration and the upfield shift is not observed. The difference in chemical shift associated with the C—CH_3 protons in the two cases is of the order of 20 c.p.s. The absence of such a difference

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in the spectra of the two ephedrines strongly suggests that the C—CH_3 groups in the two diastereoisomers are in the same spacial environment relative to the adjacent phenyl groups. Furthermore, the fact that the C—CH_3 groups in both diastereoisomers are under the same magnetic influence of the adjacent phenyl suggests that the freedom of rotation of the phenyl group and hence its time-averaged anisotropic influence on the methyl is the same in both diastereoisomers. It might be concluded, therefore, that the steric environment of the phenyl in both isomers is the same thus permitting the same freedom of rotation.

Suggested Preferred Residence Conformers

The experimental results discussed above do not appear to be entirely accommodated by any one of the "pure staggered" conformations shown in Fig. 1. This is not altogether surprising since the assumption that the "pure staggered" forms represent the most stable conformations is based solely upon consideration of the effects of non-bonded repulsions or steric effects. In a molecule of the α-β amino alcohol type there are obviously other forces at work in determining the most stable conformations, not the least of which is the energy of hydrogen bonding.

Distribution of Population Between "Off-Staggered" Conformers

In order to accommodate all the n.m.r. spectral evidence presented in this paper, preferred residence conformers of an "off-staggered" form are suggested in Fig. 2. The various experimental facts which are accommodated by the suggested conformers are considered in turn.

(*a*) The spacial relationship of the methyl and phenyl groups are the same in both isomers and the environment of the phenyl group is likewise identical. These facts meet the requirements, noted previously, for similar resonance frequency of the C—CH_3 protons in both isomers.

(*b*) The dihedral angle between the C—H bonds on the two carbon centers in the conformer suggested for (+)-ψ-ephedrine is 150°–160°. According to Karplus (4) this would yield a J_{calc} = 7–8 c.p.s.; this is in good agreement with the observed value of J_{obs} = 8.2 c.p.s. The corresponding dihedral angle for the suggested conformer for (−)-ephedrine (80°–90°) corresponds to a Karplus $J_{calc} \doteqdot 0$ c.p.s. compared with a J_{obs} = 4.0 c.p.s. Two factors may account for this quantitative disagreement. It has

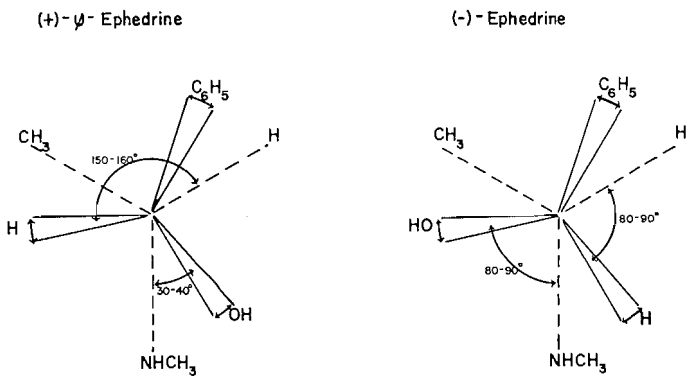

FIG. 2. Suggested preferred residence conformations of the diastereoisomeric ephedrines.

been generally found that the calculated J values tend to be somewhat low, especially in those cases where the coupled protons have a gauche relationship. Lemieux *et al.* (6) reported J values for equatorial proton coupling (dihedral angle approximately 60°) in acetylated sugars between 2 and 4 c.p.s. while the Karplus calculation gives a $J_{calc} = 1.7$ c.p.s. The quantitative disagreement, however, may reflect the fact that other possible conformations are significant in the (−)-ephedrine case since the conformation suggested is not stabilized by intramolecular hydrogen bonding to the same extent as in the ψ-ephedrine case. It should be noted that the dihedral angle in the (−)-ephedrine case cannot be changed without changing the phenyl–methyl relationship. Although a small difference in the C—CH_3 resonance is in fact observed in the two spectra (3–4 c.p.s.), such a difference could easily be due to slight variations in the dihedral angle between phenyl and methyl within the 10° limit of uncertainty shown in the conformers of Fig. 2.

(*c*) For a 30°–40° angle between the C—N and C—O bonds, as suggested in the conformer for (+)-ψ-ephedrine, the N—O center-to-center distance is in the range 2.6–2.7 Å. In the suggested (−)-ephedrine conformer the 80°–90° angle between the amino and hydroxyl groups leads to an N—O distance in the range 3.05–3.15 Å. Pimentel and McClellan (8) report the average O—H- - -N bond distance from 21 examples of such hydrogen bonding to be 2.80 Å with a standard deviation of 0.09 Å. The conformers suggested, therefore, accommodate the experimental evidence presented previously (1) where it was shown that there was a greater tendency to intramolecular hydrogen bonding in the (+)-ψ-ephedrine case; from the bond distances given above it is clear that the N—O distance in the (+)-ψ-ephedrine conformer is within the limiting distance while that for (−)-ephedrine is somewhat greater.

(*d*) It should also be noted that the "off-staggered" conformations suggested in Fig. 2 move the bulky phenyl group further from the bulky methyl and toward the sterically less restrictive hydrogen. In as much as an "off-staggered" conformation is favored this would appear to be a reasonable direction in which to rotate in terms of steric factors.

One outstanding feature of the spectra which has not been considered above is the 55 c.p.s. difference in the chemical shift of the C*H*O protons in the two diastereoisomers. It is admitted that this is a large shift to attribute solely to non-bonding environmental effects and there is no analogous example of this magnitude in the literature. However, it is pointed out that in the (−)-ephedrine case the C*H*O proton is in close proximity to the amino nitrogen lone pair and may experience a downfield shift due to the additional shielding afforded by these electrons. In contrast the same C*H*O proton in the suggested (+)-ψ-ephedrine conformer is partially eclipsed by the C—CH_3 bond on the other center. Bothner-By and Naar-Colin have suggested (9) that the carbon–carbon bond may exert a diamagnetic influence along an axis transverse to the bond axis. If the C*H*O proton experienced such an influence its resonance would be shifted upfield. A combination of these two factors acting in opposite directions on the C*H*O protons in the two isomers might explain the observed shift of 55 c.p.s.

While the observations reported here have been interpreted in terms of unique conformations for the diastereoisomeric pair it is emphasized that these conformations are suggested as the *preferred* residence forms only. In systems such as the ones under study the energy differences between various conformations must, of necessity, be small with the consequence that there will be a distribution of population among the various conformers. The evidence appears convincing, however, that the conformers suggested in Fig. 2 are the most heavily populated in the respective diastereoisomers.

*Distribution of Population Between Pure Staggered Conformers**

While the interpretation offered above accommodates the experimental facts on the basis of a distribution of population amongst "off-staggered" conformers with a preferred residence in the forms shown in Fig. 2, an alternative interpretation is possible based on a population distribution amongst "pure staggered" conformers of the type shown in Fig. 1.

If the gauche proton–proton coupling constant is taken as 2 c.p.s. and the trans value as 12 c.p.s. (these are the more common experimental values and are higher than the calculated Karplus values) then a distribution of (+)-ψ-ephedrine population between the pure staggered forms of Fig. 1 of $a:b:c = 62\%:30\%:8\%$ would yield a value of $J_{calc} = 8.2$ c.p.s. (cf. $J_{obs} = 8.2$ c.p.s.). Similarly for (−)-ephedrine a population distribution of $x:y:z = 40\%:20\%:40\%$ yields $J_{calc} = 4.0$ c.p.s. (cf. $J_{obs} = 4.0$ c.p.s.). Such a population distribution in the diastereoisomeric pair means that there will be 92% of (+)-ψ-ephedrine in conformations having the $NHCH_3$ and OH groups gauche ($a+b$ forms) and favorable for intramolecular hydrogen bonding compared with only 80% in (−)-ephedrine ($x+z$ forms). In addition approximately the same percentages of (+)-ψ-ephedrine ($a+c$ forms = 70%) and (−)-ephedrine ($x+z$ forms = 80%) occupy conformations having the methyl and phenyl groups gauche as required by the observed similarity of the methyl shift in both spectra.

While this explanation of the experimental observations has merit and is probably somewhat less complex than that based on preferred residence in a particular "off-staggered" conformation it also has some dubious features. As pointed out previously, there is no compelling reason to assume that the classical "pure staggered" conformations represent energy minima on the energy versus angle of rotation diagram. In simple symmetrical systems such as ethane, such an assumption is probably correct but the asymmetry of the group interactions in a molecule such as ephedrine does not warrant the assumption that the "pure staggered" conformers represent energy minima. It is also doubtful whether the difference between 80% and 92% population in conformers favorable for intramolecular hydrogen bonding is sufficiently large to account for the considerable difference observed in the intramolecular hydrogen-bonding ability of the two diastereoisomers. This is even more questionable when the difference between 70% and 80% population in the conformers with methyl and phenyl gauche to one another is considered to be sufficiently small to have little effect on the position of the $C-CH_3$ resonance.

Although there is insufficient experimental evidence to distinguish conclusively between the two possible explanations, that based on preferred residence in an "off-staggered" conformation appears to be the more plausible.

CONCLUSION

The problem of determining which conformations represent those in which a molecule resides preferentially in systems where the various possible conformers are separated by low-energy barriers requires the application of the most refined techniques. In this paper it has been shown that in the case of the ephedrines, where the energy barriers between the various conformers are the result of hydrogen-bonding phenomena and no-bond type interactions between adjacent groups on two carbon atoms joined by a single bond, the techniques of n.m.r. spectroscopy may provide the necessary refinement. By utilizing the n.m.r. technique of studying intra- and inter-molecular hydrogen

bonding by dilution, the anisotropic properties of the phenyl group and spin–spin coupling phenomena, assignment of those conformers representing preferred residence forms appears possible.

The further application of this technique seems obvious in such systems as substituted diols, diamines, hydroxy ketones, and similar molecules in which some or all of the necessary phenomena can be observed.

ACKNOWLEDGMENT

The author wishes to express his thanks to the Department of Chemistry, Yale University, for permission to use their n.m.r. spectrometer.

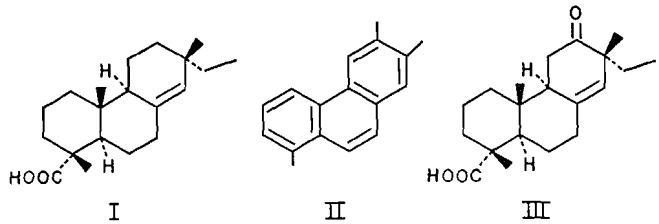
SANDARAC ACIDS: 6β-HYDROXYSANDARACOPIMARIC ACID[1]

J. W. ApSimon[2] and O. E. Edwards

ABSTRACT

The resin from *Callitris quadrivalvis* Vent. Decad. (Sandarac resin) has been shown to contain 6β-hydroxysandaracopimaric acid (6β-hydroxy-7-epipimara-9(14),19-dienoic acid).

Recently we reported the isolation of what appeared to be an hydroxypimaric acid from commercial Sandarac resin (1) derived from the North African tree *Callitris quadrivalvis* Vent. Decad. We now present proof that this is the 6β-hydroxy derivative of sandaracopimaric acid, the structure and stereochemistry of which has been established (1, 2, 3).



The acid, m.p. 269–270°, analyzed correctly for $C_{20}H_{30}O_3$. Characteristic bands for a vinyl group at 904 and 987 cm^{-1} were present in its infrared spectrum. These were absent in the dihydro acid produced by rapid uptake of 1 mole of hydrogen over palladium. The dihydro acid had absorption at 823 cm^{-1}, suggestive of the presence of a trisubstituted double bond. The presence of this feature was confirmed by one-hydrogen signals near $\tau = 5$ (CCl_4) in the N.M.R. spectrum of a number of derivatives of the acid.

The infrared spectrum of the original acid and the dihydro acid had peaks near 3400 cm^{-1} which were absent in their readily prepared monoacetates. Thus all the functions of a hydroxypimaric acid had been identified. The hydroxyl group was shown to be secondary by oxidation of the dihydro acid to a keto acid. The structure and stereochemistry of the skeleton was then established by Wolff–Kishner reduction of the keto acid. The product was identical in all respects with dihydrosandaracopimaric acid (I) (1).

The N.M.R. spectrum (CCl_4) of the methyl ester of the keto dihydro acid had a one-hydrogen signal at $\tau = 4.76$ (vinyl hydrogen) and what appeared to be a fairly sharp two-hydrogen signal (half band width 5 c.p.s.) at $\tau = 7.66$ superimposed on a broad unresolved signal. This had to be associated with a methylene adjacent to the ketone carbonyl. The only locations for the carbonyl which seemed compatible with the apparent lack of coupling of this methylene group with other hydrogens were C-5 and C-10. However, the low field signal was absent for the 13-hydrogen expected if the carbonyl was on C-5, and the methylene signal was at too high field for one flanked by a 10-carbonyl and the double bond (expected around $\tau = 7$). In addition, neither base nor acid treatment of the keto acid moved the double bond into conjugation with the carbonyl. Hence neither of these positions for the oxygen appeared likely.

In order to establish the oxygen location the dihydro keto acid was treated with methyl magnesium iodide. The resulting hydroxy acid was dehydrogenated using selenium. The major product was 1,6,7-trimethylphenanthrene (II), thus proving that the keto acid was 6-keto-19,20-dihydrosandaracopimaric acid (III).

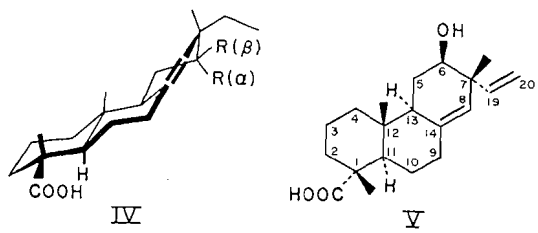
I II III



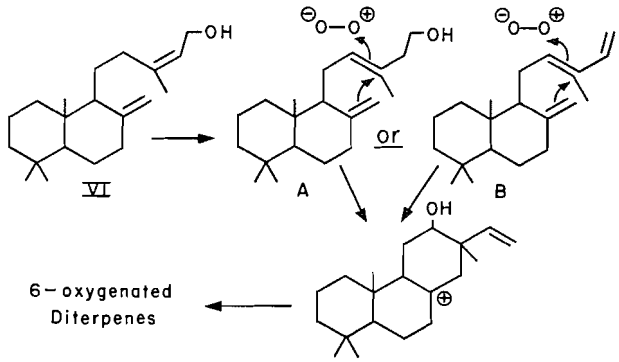
In retrospect, an important clue about the location of the oxygen could have been the chemical shift on the 18-methyl signal in the 6-ketone, as compared with that in the other derivatives (Table I). A comparable shift for the C-18 in 17a-keto-D-homosteroids has been recorded (4).

TABLE I

Chemical shifts in τ in carbon tetrachloride ($Si(CH_3)_4$ as internal standard)

	C_{16}	C_{18}	C_{17}	Vinyl proton	COOH	$COOCH_3$
Methyl dihydrosandaracopimarate	8.89	9.18	9.26	5.02	—	6.48
Methyl dihydro-6-hydroxysandaracopimarate	8.87	9.16	9.21	5.11	—	6.53
Methyl dihydro-6-ketosandaracopimarate	8.89	9.00	9.27	4.76	—	6.38
Dihydro 6-acetoxysandaracopimaric acid	8.88	9.11	9.22	5.18	−1.14	—

There remained the problem of assigning configuration to the hydroxyl group of the original acid. Since the epimeric hydroxyls on C-6 should be true axial and true equatorial in the half-chair conformation of ring C (see IV) we chose to examine the products of borohydride and sodium in alcohol reduction of the 6-ketone. In both cases, high yields of product with the original hydroxyl configuration were formed. This established the hydroxyl conformation as equatorial. Thus the hydroxyl in the original acid is β oriented (see IV) and the new acid is 6β-hydroxysandaracopimaric acid (V) (6β-hydroxy-7-epipimara-8(14),19-dienoic acid).



IV V

This acid takes its place with podocarpic acid, ferruginol, Δ^9-dehydroferruginol, xanthoperol, sugiol (5), nimbiol (6), royleanone (7), hinokiol and hinokione (8), vinhaticoic acid (9), and possibly the tanshinones (10) as a 6-oxygenated diterpene. The occurrence of numerous 6-oxygenated diterpenes leads us to suggest that the cyclization to form ring C of the tricyclic diterpenes can take place not only from VI or manool (11) but also in some plants from the double bond isomer A or triene B.[3] Proton-initiated cyclization of these would lead to hydroxyl-free molecules, but cyclization initiated by oxygen[4] would lead to the 6-oxygenated diterpenes listed above.

[3]*This triene B has recently been isolated from Dacrydium biforme and named biformene (12).*

[4]*The work of Tchen and Bloch (13) established the initiation of squalene cyclization in yeast to give 3-hydroxy steroids to be by atmospheric oxygen, presumably enzyme activated.*

EXPERIMENTAL

Rotations were of ethanol solutions, infrared spectra were of nujol mulls, and melting points were taken on a Kofler hot stage.

6-Hydroxysandaracopimaric Acid

The acid was obtained as described previously (1). It crystallized from acetone as colorless needles, m.p. 269–270°, $[\alpha]_D$ −11° (*c*, 0.4). Its infrared spectrum had weak bands at 904 and 987 cm^{-1} (vinyl group) and 822 cm^{-1} ($\diagdown C{=}C \diagup\!\!\diagdown H$), and a strong band at 3360 cm^{-1} (hydroxyl) and at 1695 cm^{-1} (—COOH).

6-Hydroxy-19,20-dihydrosandaracopimaric Acid

6-Hydroxysandaracopimaric acid (480 mg) in ethanol (250 ml) was reduced with hydrogen in the presence of presaturated 10% palladium on charcoal (400 mg). In 3 minutes, 36 ml of hydrogen were absorbed (calc. for 1 mole 35 ml). The product crystallized from methanol or ethanol as colorless plates (450 mg), m.p. 294–295°, $[\alpha]_D$ +17.5 (*c*, 0.28). Found: C, 75.12; H, 9.98. Calc. for $C_{20}H_{32}O_3$: C, 74.96; H, 10.06%. Infrared spectrum: ν_{max} 3360 cm^{-1} (hydroxyl); 1695 cm^{-1} (—COOH); 823 cm^{-1} ($\diagdown C{=}C \diagup\!\!\diagdown H$).

6-Acetoxysandaracopimaric Acid

6-Hydroxysandaracopimaric acid (200 mg), pyridine (2 ml), and acetic anhydride (2 ml) were allowed to stand overnight at room temperature. The colorless solution was poured into water and the solid product crystallized from *n*-hexane. Recrystallization from the same solvent gave colorless prisms (200 mg), m.p. 170°, $[\alpha]_D$ −51° (*c*, 1.56). Found: C, 73.41; H, 8.79. Calc. for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95. Infrared spectrum: ν_{max} 1730 cm^{-1} (acetate); 1700 cm^{-1} (—COOH); 909 cm^{-1} and 992 cm^{-1} (vinyl group); and 826 cm^{-1} ($\diagdown C{=}C \diagup\!\!\diagdown H$).

6-Acetoxy-19,20-dihydrosandaracopimaric Acid

Treatment of the dihydro acid (100 mg) in the manner described above yielded colorless prisms (90 mg), m.p. 183°, from *n*-hexane. $[\alpha]_D$ −27.5° (*c*, 0.08). Found: C, 73.09; H, 9.21. Calc. for $C_{22}H_{34}O_4$: C, 72.89; H, 9.45. Infrared spectrum: ν_{max} 1725 cm^{-1}, 1700 cm^{-1} (—COOH).

Methyl 6-Hydroxysandaracopimarate

6-Hydroxysandaracopimaric acid (50 mg) in methanol (25 ml) was treated with excess ethereal diazomethane during 15 minutes. Excess diazomethane was destroyed with acetic acid. The solution was washed well with sodium bicarbonate and water; drying and evaporation yielded a crystalline residue (50 mg). Recrystallization from *n*-hexane gave colorless needles (45 mg), m.p. 94°. The analytical sample was sublimed at 80°/10^{-3} mm. Found: C, 76.02; H, 9.61; OMe, 9.12. Calc. for $C_{20}H_{29}O_2(OMe)$: C, 75.86; H, 9.70; OMe, 9.34. Infrared spectrum: ν_{max} 3300 cm^{-1} (hydroxyl), 1730 cm^{-1} (—COOMe), 909 and 992 cm^{-1} (vinyl group), and 827 cm^{-1} ( ).

Methyl 6-Hydroxy-19,20-dihydrosandaracopimarate

The dihydro acid (30 mg) on treatment with diazomethane in the manner described above yielded colorless needles (27 mg), m.p. 112°, from *n*-hexane. Found: C, 75.20; H, 10.06; OMe, 9.04. Calc. for $C_{20}H_{31}O_2(OMe)$: C, 75.40; H, 10.25; OMe, 9.25. Infrared spectrum: ν_{max} 3360 cm^{-1} (hydroxyl), 1730 cm^{-1} (—COOMe), and 828 cm^{-1} ().

6-Keto-19,20-dihydrosandaracopimaric Acid

6-Hydroxy-19,20-dihydrosandaracopimaric acid (570 mg) in benzene (50 ml) and acetic acid (50 ml) was treated with sodium dichromate dihydrate (200 mg) in acetic acid (10 ml) at room temperature. Next day the green reaction mixture was poured into water and the benzene layer separated. The aqueous layer was further extracted with benzene (4×25 ml). The combined benzene extracts were dried and evaporated, yielding a crystalline residue (470 mg). Recrystallization from ether/*n*-hexane in an acetone – dry ice bath gave colorless prisms, m.p. 149°. The analytical sample was sublimed at 120°/10^{-3} mm. $[\alpha]_D$ −79° (*c*, 0.38). Found: C, 75.43; H, 9.61. Calc. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50. Infrared spectrum: ν_{max} 1705 cm^{-1} ( ), 1690 cm^{-1} (—COOH).

Methyl 6-Keto-19,20-dihydrosandaracopimarate

The above keto acid (110 mg) in ether (10 ml) and methanol (5 ml) was treated with excess ethereal diazomethane during 15 minutes. Excess diazomethane was decomposed with acetic acid and the ethereal solution washed with sodium bicarbonate and water. The dried solution on evaporation yielded a colorless crystalline product (112 mg), m.p. 88–89°. On recrystallization from pentane and sublimation, this gave prisms, m.p. 89°. $[\alpha]_D$ −71° (*c*, 1.4). Found: C, 75.77; H, 9.53; OMe, 9.22. Calc. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70; OMe, 9.34. Infrared spectrum: ν_{max} 1714 cm^{-1} (—COOMe), 1706 cm^{-1} (6-membered ketone).

Wolff–Kishner Reduction of 6-Keto-19,20-dihydrosandaracopimaric Acid

6-Keto-19,20-dihydrosandaracopimaric acid (58 mg) in hydrazine hydrate (2 ml) and triethylene glycol (2 ml) was heated to 140° during 45 minutes. Potassium hydroxide (1 g) was added during 5 minutes and the temperature gradually raised to 200° for 5 hours. The reaction mixture was cooled, acidified with 2 *N* H_2SO_4, and ether extracted. The ether extract was washed well with water, dried, and evaporated, yielding a colorless crystalline solid (43 mg), m.p. 175–179°. Recrystallization from aqueous methanol gave needles, m.p. 177–179° undepressed on mixture with dihydro sandaracopimaric acid, and having the requisite infrared spectrum, $[\alpha]_D$ +25° (*c*, 1.25). Found: C, 78.76; H, 10.62. Calc. for $C_{20}H_{32}O_2$: C, 78.94; H, 10.52.

Reaction of Methyl Magnesium Iodide with 6-Ketodihydrosandaracopimaric Acid

The keto acid (1.54 g) in dry ether (20 ml) was added gradually to methyl magnesium iodide at 0°, prepared from magnesium (0.75 g) and methyl iodide (5 ml) in ether (20 ml). A colorless solid was precipitated. The mixture was vigorously stirred overnight at room temperature. It was poured onto a mixture of ice (20 mg) and 2 *N* H_2SO_4 (50 ml), then extracted with ether. The ether extract was washed well with sodium bisulphite and water. Drying and evaporation gave a colorless semicrystalline product (1.3 g). Crystallization from chloroform/*n*-hexane yielded small colorless prisms (750 mg), m.p. 218°, $[\alpha]_D$ +63° (*c*, 0.4). Found: C, 75.30; H, 10.06. Calc. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25. Infrared spectrum ν_{max} at 3500 cm^{-1} (OH), 1700 cm^{-1} (—COOH).

Selenium Dehydrogenation of 6-Hydroxy-6-methyl-19,20-dihydrosandaracopimaric Acid

The Grignard product (600 mg) and selenium (2 g) were intimately mixed and heated at 300° C for 17 hours. Hydrogen selenide production was followed on a tower of bleaching powder. The mixture was cooled and the black solid was extracted several times with boiling benzene. The benzene extract was refluxed with freshly precipitated silver for 1 hour, filtered, and refluxed again with fresh silver. Drying and evaporation yielded yellow prisms (350 mg), m.p. 105–120°. Chromatography on Grade IV alumina in pentane gave colorless prisms (290 mg), m.p. 110–117°. Recrystallization from aqueous ethanol gave colorless needles, m.p. 122–123°. Sublimation at $120/10^{-3}$ mm gave colorless prisms, m.p. 123°. Found: C, 92.52; H, 7.20. Calc. for $C_{17}H_{16}$: C, 92.68; H, 7.32. Its ultraviolet spectrum was identical in all respects with that reported for 1,6,7-trimethyl phenanthrene (14). Its picrate separated as orange needles from ethanol, m.p. 167–168° (reported m.p.167° (15)). Found: C, 61.34; H, 4.39. Calc. for $C_{23}H_{19}O_7N_3$: C, 61.47; H, 4.26. Its styphnate crystallized from acetic acid as orange needles. Sublimation gave the analytical sample, m.p. 171° (reported 111°, error?). Found: C, 59.22; H, 3.91. Calc. for $C_{23}H_{19}O_8N_3$: C, 59.35; H, 4.12.

The phenanthrene (91.5 mg) in acetic acid (5 ml) was oxidized with chromic trioxide (100 mg, 2.2 mole) in acetic acid (5 ml) on a steam bath for 2 hours. The reaction mixture was diluted and extracted with ether. The ether solution was washed with potassium carbonate solution and water. It was then dried and evaporated, yielding an orange crystalline product (80 mg), m.p. 215–220°. Sublimation gave orange prisms of 1,6,7-trimethyl phenanthraquinone, m.p. 223° (reported m.p. 222° (15)). The quinoxaline of the phenanthraquinone formed buff needles from aqueous ethanol, m.p. 188–189° (reported m.p. 189–190° (15)).

Reduction of the Keto Acid

6-Keto-19,20-dihydrosandaracopimaric acid (200 mg) in 80% methanol (30 ml) was treated with sodium borohydride (150 mg) and allowed to stand at room temperature for 1 hour. The mixture was acidified with 2 *N* hydrochloric acid, methanol removed *in vacuo*, and ether extracted. The ether extract was dried and evaporated, yielding a yellow oil (200 mg) which was dissolved in methanol, refluxed with charcoal, filtered, and concentrated (5 ml). On cooling, colorless needles formed (105 mg), m.p. 294–295°, $[\alpha]_D$ +17° (*c*, 0.24). Its infrared spectrum was identical with that of dihydro-6-hydroxy sandaracopimaric acid and a mixed melting point was undepressed. Sodium in alcohol reduction of the keto acid (100 mg) afforded the same product (72 mg), m.p. and mixed m.p. 295°, $[\alpha]_D$ +19° (*c*, 0.34), and having the requisite infrared spectrum.

Attempted Isomerization of the Keto Acid

Hydrogen chloride was passed into a solution of 6-keto-19,20-dihydrosandaracopimaric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

acid (30 mg) in dry chloroform (10 ml) at −5° for 4 hours. The chloroform solution was washed free from mineral acid with water, and then dried and evaporated to give a colorless crystalline product (28 mg), m.p. and mixed with starting material 149° and having the requisite infrared spectrum. The keto acid was unchanged by warm 5% sodium hydroxide or by traces of perchloric acid. Similar results were observed with the dihydro hydroxy acid and the dihydro acetoxy acid.

ACKNOWLEDGMENT

We wish to thank Mr. A. Knoll for technical assistance, Mr. H. Seguin for the analyses, Mr. R. Lauzon for the infrared spectra, and Mr. J. Nicholson for the N.M.R. spectra.

THE Hg $6(^3P_1)$-PHOTOSENSITIZED DECOMPOSITION OF NITRIC OXIDE[1]

OTTO P. STRAUSZ AND HARRY E. GUNNING

ABSTRACT

The reaction of NO with Hg $6(^3P_1)$ atoms has been studied under static conditions at 30°, over the pressure range 1–286 mm. The products were found to be N_2, N_2O, and higher oxides of nitrogen. At NO pressures exceeding 4 mm, the total rate of formation of N_2+N_2O was constant, while the ratio N_2O/N_2 increased linearly with the substrate pressure. The rate was found to vary directly with the first power of the intensity at 2537 Å, and a value of 1.9×10^{-3} moles/einstein was established for the quantum yield of N_2+N_2O production. In the proposed mechanism, reaction is attributed to the decomposition of an energy-rich dimer, $(NO)_2^*$, which is formed by the collision of electronically excited ($^4\Pi$) NO molecules with those in the ground state. The $(NO)_2^*$ species is assumed to decompose by the steps: $(NO)_2^* \rightarrow N_2 + O_2$ and $(NO)_2^* + NO \rightarrow N_2O + NO_2$. The mechanism satisfactorily explains the observed behavior of the system.

INTRODUCTION

Although there have been several studies of the photolysis of NO, the nature of the primary process is still in doubt. Thus MacDonald (1) studied the reaction in the 70–630 mm region, using 1860–1990 Å radiation; he concluded that 1/10th of the reaction led to N_2O formation, and that the remainder yielded N_2. He postulated reaction to proceed through the interaction of excited NO molecules with those in the ground state. Flory and Johnston (2) found, in the low pressure region, 0.02–7 mm, no evidence of N_2O formation; they interpreted the primary process as predissociation. At low pressures they found the active line to be 1832 Å. They concluded that any decomposition by absorption at 1849 Å could only occur at higher pressures. Recently Gaydon (3) has reported that no trace of photodecomposition could be detected when NO, at atmospheric pressure, was exposed to radiation from an iron arc. This polychromatic source gives no emission below 2084 Å.

The reaction of NO with Hg $6(^3P_1)$ atoms was first studied by Noyes (4). He established that the rate was (*a*) first order in light intensity and (*b*) first order in substrate pressure in the range 0.003–0.13 mm. The pressure dependence approached zero order at higher pressures. On a pressure-change basis, it was deduced that N_2 was the only gaseous product. From the kinetic behavior and the energetics of the reaction, Noyes concluded that the rate-determining step was the formation of long-lived vibrationally excited NO molecules.

McGilvery and Winkler (5) found no reaction of NO with Hg $6(^3P_1)$ atoms; however, they observed a fast reaction with Hg $6(^1P_1)$ atoms. Only N_2 and higher oxides were detected as products. The addition of N_2 was found to decrease the rate. Reaction was attributed to N—O bond scission by the Hg $6(^1P_1)$ atoms. Recently Bernstein and Hoffman (6) have reinvestigated the reaction with Hg $6(^3P_1)$ atoms. They measured the rate of N_2 formation, and also the $^{14}N/^{15}N$ isotope effect. In their mechanism they followed the suggestion of Fallon, Vanderslice, and Mason (7) that the quenching collision formed long-lived NO($^4\Pi$) molecules, for which the lowest vibrational level was estimated to lie 4.64 ± 0.10 ev above the lowest vibrational level of the ground state. For this state, radiative reversion to the ground state was considered of low probability. The proposed mechanism (6) included the steps:

[1]*Manuscript received August 3, 1961.*
Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta.

$$Hg^* + NO \rightarrow NO^* + Hg; \quad (a)$$

$$Hg^* + NO \rightarrow NO_v + Hg'; \quad (b)$$

$$Hg^* \rightarrow Hg + h\nu; \quad (c)$$

$$Hg^* + NO^* \rightarrow N + O + Hg; \quad (d)$$

$$N + NO \rightarrow N_2 + O; \quad (e)$$

$$O + NO \rightarrow NO_2 \text{ etc.}; \quad (f)$$

where $Hg^* = Hg\ 6(^3P_1)$; $Hg' = Hg\ 6(^3P_0)$; $NO^* = NO(^4\Pi)$, and NO_v = vibrationally excited NO. An equivalent mechanism was suggested by Cvetanović (8). Here, for (*b*) and (*d*) above, were substituted (*b'*) $NO^* + NO \rightarrow 2NO$ and (*d'*) $NO^* + NO \rightarrow N + NO_2$.

Finally Cojan and Taboue (9) have reported some interesting experiments in which NO at 0.1 mm was exposed to radiation from a cooled Hg arc, in the presence of mercury vapor. By absorbiometric analysis, with the magnetic filter technique, they showed that the mercury strongly bonded to the wall of the reaction cell was enriched in ^{202}Hg. These results will be discussed later in this paper.

The present study was prompted by a recent investigation in this laboratory (10) of the reaction of CO_2 with Hg $6(^3P_1)$ atoms. Here it was shown that decomposition proceeds through a process, second order in the light intensity, involving collision of two excited species. It seemed of interest to determine whether a similar type of process was operative in the NO reaction. The details of the investigation follow.

EXPERIMENTAL

The apparatus and general experimental technique have been previously described (10). The nitric oxide (Matheson) was subjected to several low-temperature distillations before use. Analysis by G.L.P.C. showed that the only impurity was N_2O at a concentration of less than 0.01%. After each run, the products were removed from the unreacted substrate and analyzed by G.L.P.C.

RESULTS

The products of the reaction were N_2 and N_2O, together with higher oxides of nitrogen; the latter were observed to attack the mercury in the reaction cell. Analysis of the cell deposit showed the presence of NO_2^- ion.

The measured rates of N_2 and N_2O formation, in μmoles/hour, are presented, for runs of 60 minutes in duration, in Table I. The absorbed light intensity at 2537 Å(I_a), determined with propane as actinometer (11, 12), was 3.34×10^{-5} einstein/minute. The maximum rate of N_2 formation occurred at a NO pressure of 3.25 mm, where 4.0 μmoles were formed per hour.

In Table II, the total rate, $R(N_2+N_2O)$, is shown as a function of $P(NO)$, for 10-mm pressure intervals up to $P(NO) = 120$ mm. From Table II it is apparent that $R(N_2+N_2O)$ is constant within the experimental error at 3.82 μmoles/hour. For the quantum yield, $\Phi(N_2+N_2O)$, we obtain 1.9×10^{-3} moles/einstein. It should be noted that the run at $P(NO) = 286$ mm was made with $I_a = 7.61\times10^{-5}$ einstein/minute. At this light intensity, $R(N_2)$ and $R(N_2O)$ were respectively 3.79 and 4.60 μmoles/hour. Thus $\Phi(N_2+N_2O)$ was 1.8×10^{-3}, in satisfactory agreement with the data at the lower light intensity. Hence, while $\Phi(N_2)$ decreases with increasing $P(NO)$, and $\Phi(N_2O)$ increases, the sum $\Phi(N_2+N_2O)$ is independent of the substrate pressure, in the complete quenching region.

TABLE II

The total mean rate of N_2+N_2O formation as a function of NO pressure

P(NO) (mm)	$R(N_2+N_2O)$ (μmoles/hour)	P(NO) (mm)	$R(N_2+N_2O)$ (μmoles/hour)
10	4.05	70	3.73
20	3.94	80	3.73
30	3.87	90	3.74
40	3.80	100	3.79
50	3.77	110	3.81
60	3.75	120	3.86

Mean value = 3.82 μmoles/hour

In Fig. 1, the reciprocal rate, $1/R(N_2)$, is shown to vary linearly with P(NO). Similarly, it can be seen from Fig. 2 that the quantity (NO)/$R(N_2O)$ is a linear function of P(NO).

To determine the dependence of the rate upon the light intensity, a doughnut-type Vycor filter was fitted axially over the reaction cell, within the coils of the resonance lamp. The filter, 110 mm in length, 35 mm I.D., and 60 mm O.D., was filled with bromine vapor at a pressure of 170 mm. Its transmission was 55.7% at 2537 Å, and less than 1% at 4047 Å. With the filter, $R(N_2+N_2O)$ was 54% of the value without the filter, confirming Noyes' observation (4) that the rate is proportional to I_a. Since the rate is insensitive to the 100-fold reduction in intensity at 4047 Å, there seems little basis for the stepwise excitation mechanism proposed by McGilvery and Winkler (5).

In Fig. 3, $\Phi(N_2O)/\Phi(N_2)$ is shown as a function of P(NO). The relation is a linear one, within the experimental error.

In order to examine the possibility that the N_2 product might arise in secondary quenching by N_2O, a few runs were performed with added N_2O. In Fig. 4, the rate of N_2O disappearance is plotted against the percentage of added N_2O, for P(NO) constant at 29.4 mm. From the data it is estimated that the rate of decomposition of added N_2O is less than 1/10th of $R(N_2)$ for pure substrate. It is concluded that N_2 is indeed a primary product of the reaction of NO with Hg $6(^3P_1)$ atoms.

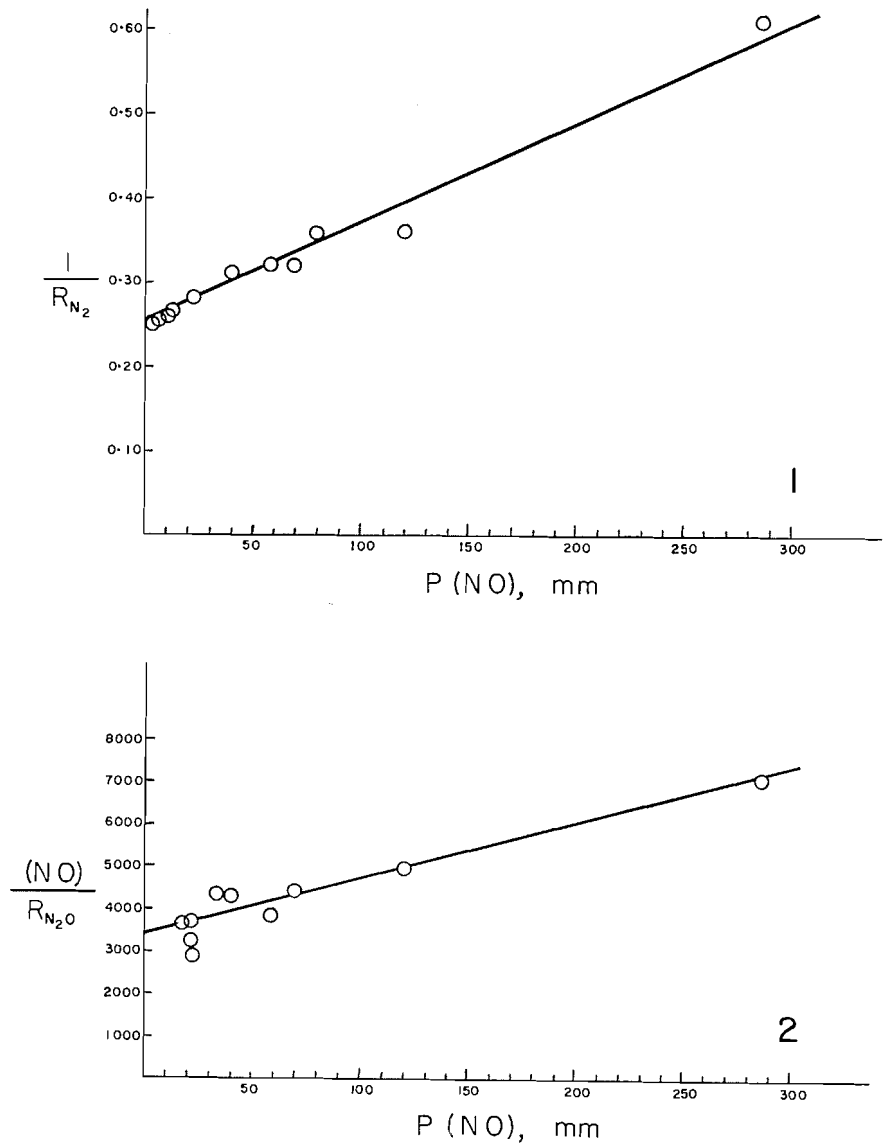

FIG. 1. The reciprocal of the rate of N_2 formation, in $(\mu moles/hour)^{-1}$, as a function of the NO pressure, for $I_a = 33.4$ μeinstein/minute.
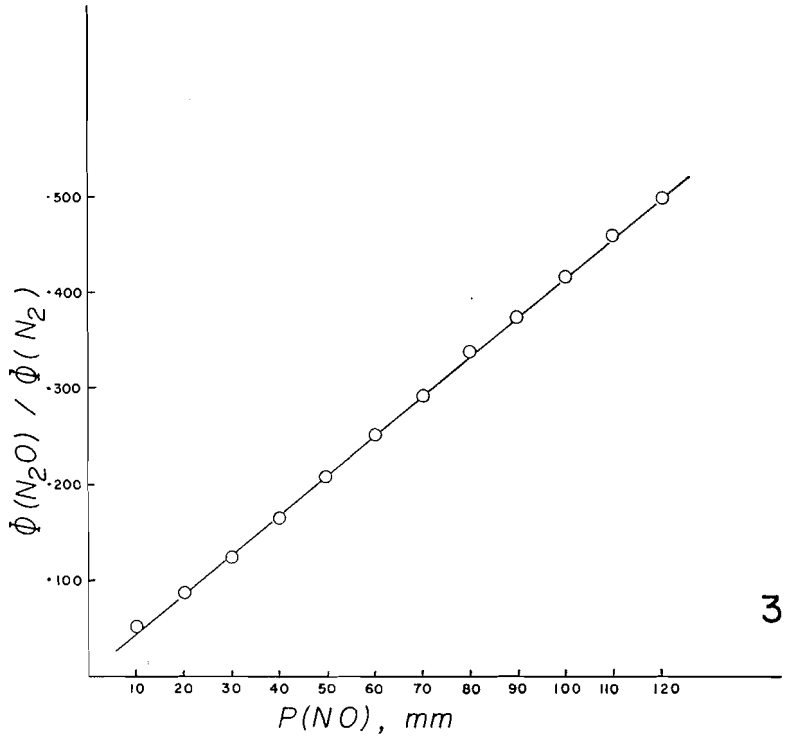
FIG. 2. $(NO)/R_{N_2O}$ in hours, as a function of the NO pressure, for $I_a = 33.4$ μeinstein/minute.



DISCUSSION

The results of the present study lend strong support to the original suggestion of Noyes (4) that the reaction involves primary formation of excited NO molecules. Thus, the presence of N_2O as a major reaction product, a fact not previously reported, could only be explained by interactions of NO molecules in which at least one of the collisional partners is energized. It is also pertinent to note that N atoms react with NO to form N_2, but not N_2O (13).

In order to explain the kinetic behavior of the reaction, as revealed in the present study, the following mechanism is proposed:

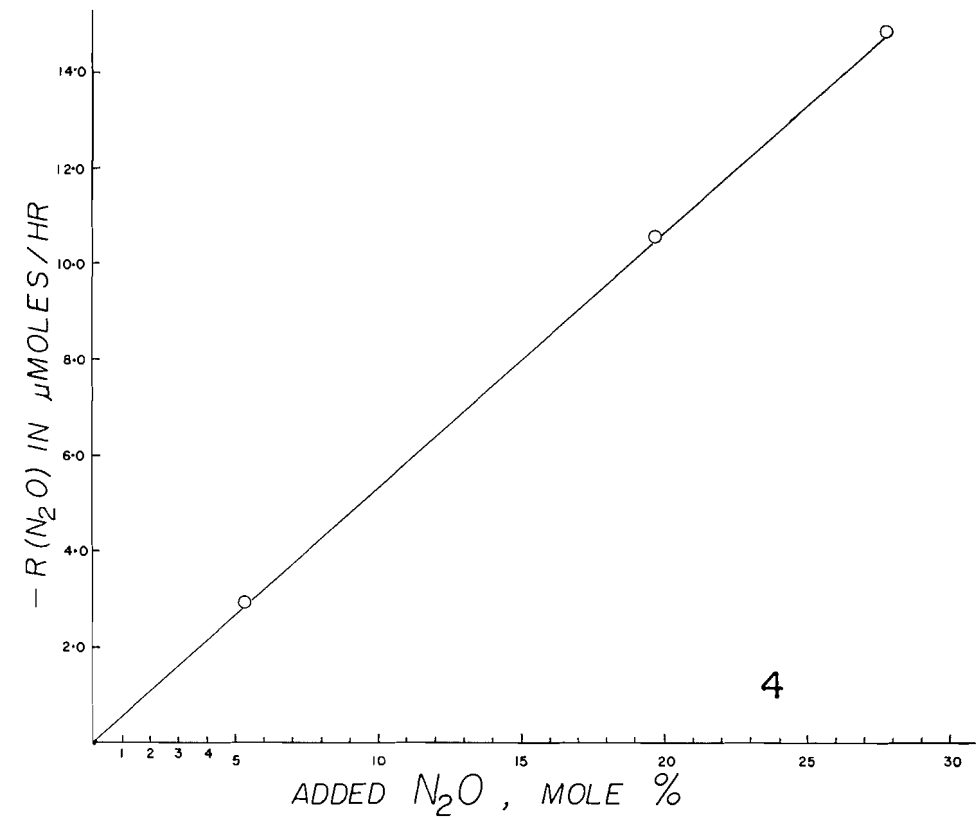

FIG. 3. The variation in the quantum yield ratio, $\Phi(N_2O)/\Phi(N_2)$, with the NO pressure.
FIG. 4. The rate of disappearance of N_2O, in μmoles/hour, as a function of the mole% of added N_2O, for a constant NO pressure of 29.4 mm.

$$Hg + h\nu \rightarrow Hg^* \qquad [I_a]$$

$$Hg^* \rightarrow Hg + h\nu \qquad [1]$$

$$Hg^* + NO \rightarrow NO^* + Hg \qquad [2]$$

$$NO^* + NO \rightarrow 2NO \qquad [3]$$

$$NO^* + NO \rightarrow (NO)_2^* \qquad [4]$$

$$(NO)_2^* \rightarrow N_2 + \text{oxygen} \qquad [5]$$

$$(NO)_2^* + NO \rightarrow N_2O + NO_2 \qquad [6]$$

where $Hg^* = Hg\ 6(^3P_1)$, $NO^* = NO\ (^4\Pi)$, and $(NO)_2^*$ is an energy-rich dimer.

In the complete quenching region, i.e. for $P(NO)$ above ca. 4 millimeters, the rate of (N_2+N_2O) formation from the above mechanism would be

$$R(N_2+N_2O) = I_a k_4/(k_3+k_4).$$

Thus the combined rate would be directly proportional to I_a, and independent of $P(NO)$, in agreement with our findings (Table II).

For the quantum yield ratio, we obtain

$$\Phi(N_2O)/\Phi(N_2) = k_6(NO)/k_5,$$

which requires that the ratio be a linear function of $P(NO)$, passing through the origin, as seen in Fig. 3.

Furthermore, from the mechanism, the rate of N_2 formation would be

$$R(N_2) = I_a k_4 k_5/(k_3+k_4)[k_5+k_6(NO)],$$

and the rate of N_2O formation

$$R(N_2O) = I_a k_4 k_6(NO)/(k_3+k_4)[k_5+k_6(NO)].$$

By rearranging the above rate expressions, the following linear relations are obtained:

$$1/R(N_2) = (k_3+k_4)/(I_a k_4)+(k_3+k_4)(k_6)(NO)/(I_a k_4 k_5)$$

and

$$(NO)/R(N_2O) = (k_3+k_4)(k_5)/(I_a k_4 k_6)+(k_3+k_4)(NO)/(I_a k_4).$$

From Figs. 1 and 2 respectively, it can be seen that the expressions $1/R(N_2)$ and $(NO)/R(N_2O)$ are indeed linear functions of $P(NO)$. Furthermore the mechanism requires that the intercept at $P(NO) = 0$, in Fig. 1, should be equal to the slope in Fig. 2. For the intercept in Fig. 1 we obtain 0.26 hour μmole^{-1}, and for the slope in Fig. 2, 0.24 hour μmole^{-1}, in agreement with the proposed mechanism.

In the proposed mechanism, we have adopted the suggestion of Fallon, Vanderslice, and Mason (7) that reaction [2] leads to the formation of NO ($^4\Pi$). Support for our postulation of the $(NO)_2^*$ species comes from the work of Spindel and Stern (14), who found that a rapid exchange occurs among isotopic nitric oxides at room temperature. At a total pressure of 20 mm, complete exchange occurred in ca. 15–30 seconds. Even at a pressure of 60–100 μ, the exchange was still detectable. It seems likely that the exchange takes place through a square-type dimer intermediate.

The low quantum yield of the reaction, on the basis of the proposed mechanism, would require that [4] be extremely inefficient compared with [3]. Now, from our data, $\Phi(N_2+N_2O) = 1.9\times10^{-3}$, and from the mechanism this quantity would be equal to $k_4/(k_3+k_4)$. Hence k_4/k_3 would be ca. 1.9×10^{-3}.

From the linear slope in Fig. 3, we obtain $k_6/k_5 = 77.5$ liter/mole. Now if we assume a collision cross section of 20 Å^2 for [6], and reaction at every collision, then $k_5 = 2$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$\times 10^{11}/77.5 = 2.6\times 10^{9}$/second. This leads to an estimate for the lifetime, τ, of $(NO)_2^*$ of $1/k_5 = 3.8\times 10^{-10}$ second. The value should be regarded as minimal, since a steric factor less than unity in k_6 would increase τ.

Finally we would like to comment on the isotope effect observed by Cojan and Taboue (9), in the irradiation of a mixture of Hg vapor and 0.1 mm of NO. In unpublished work in this laboratory (15), it has been found that the behavior observed by Cojan and Taboue is characteristic of substrates which convert Hg $6(^3P_1)$ atoms to the $6(^3P_0)$ state. Thus when Hg vapor was admixed with substrates such as N_2, H_2O, and NH_3, and exposed to the radiation from a ^{202}Hg electrodeless discharge, it was observed that the mercury in the cell rapidly became transparent to the ^{202}Hg-hyperfine component at 2537 Å. Apparently the metastable ^{202}Hg atoms had diffused to the wall and become chemisorbed on the surface. The evidence for this is that the normal adsorption could be re-established by heating the cell to drive off the mercury from the wall. Furthermore with addends such as H_2, which quench the $6(^3P_1)$ atoms directly to the $6(^1S_0)$ state, no such change in absorption with time was observed. It is our opinion that the isotope effect found by Cojan and Taboue (9) arises for the following reasons. In the cell the concentration of ^{202}Hg $6(^3P_1)$ atoms will be higher than the natural isotopic abundance for this isotope, owing to its large absorption coefficient (9). By collision with NO, metastable atoms are formed, which will be enriched in ^{202}Hg. These atoms can diffuse to the wall and form a complex with adsorbed NO. It would appear that Hg $6(^3P_0)$ atoms do not possess sufficient energy to convert NO to the $^4\Pi$ state, by reaction [2]. If these conclusions are correct, it would follow that the $^4\Pi$ state must lie between 4.67 and 4.88 ev above the ground state.

CONCLUSIONS

As a result of the present study, it can be concluded that both N_2O and N_2 are major primary products of the reaction of NO with Hg $6(^3P_1)$ atoms at 30°. Reaction must proceed via the initial formation of excited NO, likely in the $^4\Pi$ state, which appears to be inefficiently converted by collision with the substrate to an excited dimer. From this intermediate, N_2 is formed by unimolecular decomposition, while N_2O arises through interaction of the dimer with the substrate.

ACKNOWLEDGMENTS

The authors would like to express their deep appreciation to Dr. Willard F. Allen for many valuable discussions. This investigation was partially supported by a grant from Imperial Oil Limited. This assistance is most gratefully acknowledged.

HALOGEN ATOM REACTIONS

I. THE ELECTRICAL DISCHARGE AS A SOURCE OF HALOGEN ATOMS[1]

E. A. Ogryzlo

ABSTRACT

A number of surface poisons have been found to prevent the rapid recombination of chlorine, bromine, and iodine atoms. Hence these atoms can now be obtained in large concentrations in a flow system.

A chemical titration procedure for both Cl and Br atoms has been developed and has been used to test an isothermal calorimetric detector which can measure the atom concentration along a reaction tube. The detector was used to establish the surface recombination coefficient (γ) for chlorine atoms (4×10^{-5}) and bromine atoms (6×10^{-5}) on oxyacid-covered surfaces.

INTRODUCTION

The electrical discharge has proved a valuable source of hydrogen, nitrogen, and oxygen atoms. In the last few years many of the species produced in the discharge have been identified. In addition, a variety of methods of following the concentration of the atomic species in a flow system have been described (1, 2, 3, 4). As a result, rate constants for a large number of elementary reactions of these atoms are being reported in the literature. Unfortunately, workers have had less success with halogen atoms in a flow system. The statement made in 1933 by Schwab (5) that bromine atoms recombine on every collision with the walls, and chlorine atoms survive fewer than 20 collisions irrespective of the wall materials, seems to have discouraged further work with these species in a flow system.

Recent developments in the theory of atom recombination (6, 7) point to the need for a system capable of studying the low pressure recombination of halogen atoms. In addition, there remain a considerable number of elementary halogen atom reactions which are in need of direct measurements. For this reason we have re-examined the possibility of obtaining halogen atoms in a flow system.

EXPERIMENTAL

Chemicals

Matheson Company chlorine was dried with silica gel and purified by distillation. Reagent grade bromine was dried with phosphorus pentoxide, and purified by distillation. Air was removed from reagent grade iodine by sublimation in vacuum. NOCl from Matheson Company was purified only by trap-to-trap distillation. All other gases and chemicals were of reagent grade purity and were used without purification.

Apparatus

A conventional pyrex flow system with a linear flow velocity between 100 and 400 cm per sec was used. Inert gas flows were controlled with Edwards needle valves, and measured with conventional capillary-U-tube flow meters. All mercury was isolated with a layer of octyl phthalate. Cl_2, Br_2, NOCl, and ICl gases were contained in 22-liter bulbs. A constant pressure was maintained with the appropriate freezing bath. Flow was controlled by glass capillaries only, and measured with H_2SO_4-filled flow meters. All stopcocks in the halogen flow system were greased with Kel-F grease.

[1]*Manuscript received August 18, 1961.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver 8, B.C.

The discharge tube and reaction tube are shown in Fig. 1. The discharge tube was constructed of quartz to prevent breakage while the tube was being heated. It was made

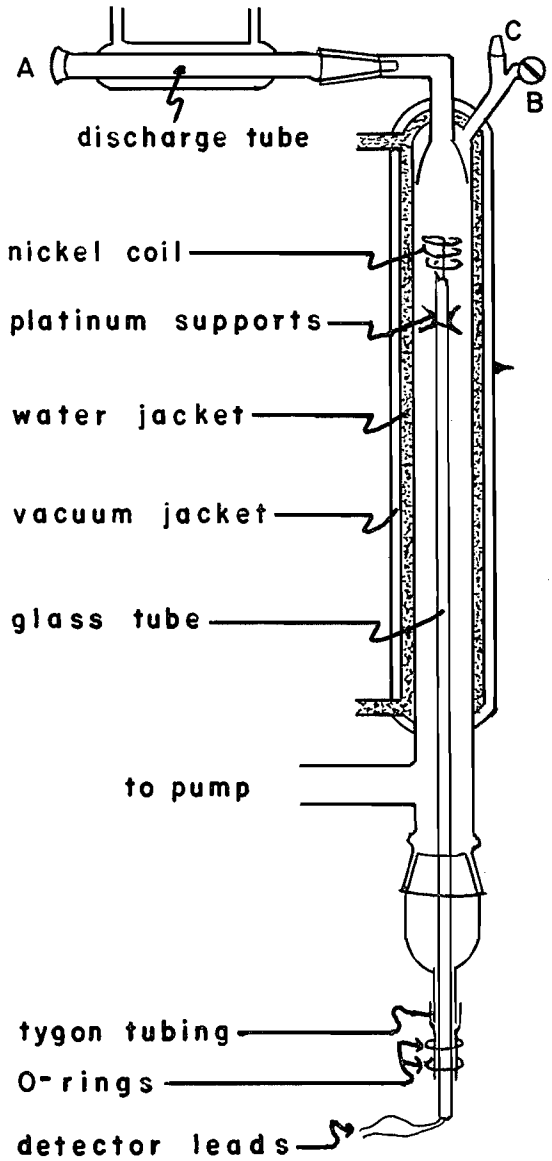

FIG. 1. Discharge tube, reaction tube, and movable detector assembly.

removable to facilitate cleaning since contamination occurred most often in this region. The jacket was used to cool the tube with a stream of air while the discharge was on. A 100-watt, 2450-megacycle generator was used to create the discharge.

The reaction tube was 50 cm long and had a diameter of 2.1 cm. It was surrounded by a water jacket for temperature control and a vacuum jacket to prevent a temperature gradient from forming when the tube is operated at other than room temperature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The halogen gas (at flows between 0.5 and 45 μmoles/sec) could be introduced at A (Fig. 1) together with inert carrier gases such as argon and helium (at flows between 5 and 150 μmoles/sec). Other gases could be introduced after the discharge at B. Another opening at C made it possible to clean the reaction tube and apply different coatings to the reaction tube walls, without affecting the walls leading to the reaction tube. These coatings (hereafter called "poisons") were usually applied in the following manner. The cleaned vessel was filled with a hot, concentrated KOH solution and allowed to stand for 30 minutes. The vessel was then thoroughly washed with distilled water and filled with a 10% solution of the poison in water. This solution was allowed to stand for 1 hour and then drained. Finally, the system was evacuated for about 2 hours. During this period the discharge tube and reaction tube were heated to 250° C and 80° C respectively.

Figure 1 also shows the method which was used for moving both a coil of wire and a wrede gauge along the reaction tube. The movable vacuum-tight junction is provided by pressing a tygon tube against a glass tube with two O-rings. The glass tube is greased with Kel-F grease. No leaking occurred, and the slight degassing of the grease is of no consequence at this point in the flow system. The rack and pinion arrangement described previously (3) was also used for supporting the wire-coil but it cannot be used with a movable wrede gauge.

The principle of the isothermal–calorimetric atom detector (hereafter called the "detector") used in this work has already been described (3). It requires that the atoms in a gas stream recombine on a metal wire, raising its temperature to a value T. The heat liberated is then measured by observing the electrical current necessary to raise the wire temperature to the same value T. For successful operation the following requirements must be met:

(1) the thermal conductivity must be the same in the presence and absence of atoms;
(2) all the atoms must be recombined;
(3) no other species capable of heating up the detector can be present.

The first condition is easily satisfied in a gas simply subjected to an electrical discharge if the atoms recombine on almost every collision with the wire. The second condition can be satisfied by a suitable enlargement of the detector coil. The third condition can be verified by an independent atom measuring device which is insensitive to such species.

A wrede gauge was constructed with four 10-micron pinholes. The pressure difference across the pinholes was measured with an inclined oil-manometer.

RESULTS AND DISCUSSION

Fluorine

An attempt was made to pass F_2 through an electrical discharge. However, the gas was found too difficult to handle in a flow system and the experiment could not be completed.

Chlorine

Our first attempts to produce Cl atoms by passing a stream of the gas through a discharge in a pyrex and quartz tube were unsuccessful. A thin silver mirror which provides a sensitive test for halogen atoms by its discoloration showed no change 1 centimeter away from the discharge. Dry wall coatings of polythene, teflon, NaCl, NaOH, and $Al(OH)_3$ did not help to produce any detectable atoms.

On the other hand, when H_3PO_4, H_2SO_4, H_3AsO_4, H_3BO_3, and $HClO_4$ were used to "poison" the wall, immediate discoloration of the silver mirror occurred when the discharge was initiated. The absence and presence of atoms with these surface poisons was then verified with a wrede gauge. The atom concentrations measured with the gauge

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

were then compared with those measured by the detector using platinum, silver, cobalt, and nickel coils. The atom concentrations measured along the reaction tube by all methods were proportional to each other. However, the wrede gauge and platinum detector yielded a much lower value for the atom concentration than the Ag-, Co-, and Ni-covered detectors. The rapid atom recombination on the glass of the wrede gauge may account for the low value obtained with this instrument. A low catalytic activity for platinum has been observed previously (8) and would account for the low value obtained with this surface. Cobalt and silver detectors possess a number of other disadvantages. They are attacked by halogen atoms and the catalytic activity of the halide is somewhat lower than that of the metal. More troublesome, however, is the formation of some volatile compound that distills onto the walls at temperature above 100° C. Not only does nickel not possess these difficulties, but it also has a larger temperature coefficient of resistivity.

Complete removal of the atoms by the nickel coil was checked by placing a second detector immediately after the first. A 90-cm length of 30-gauge nickel wire wound into a double spiral and extended to a length of 1 cm was found to be effective in removing the atoms at pressures up to 4 mm Hg. At higher pressures it was difficult to prevent the atoms from being swept past the detector unless it was extended to about double this length.

Some typical chlorine atom flows measured 25 cm after the discharge are given in Table I.

TABLE I

Pressure, mm of Hg	Flow, in μmoles per second

0.6	5	30	10

Chemical Titrations

Chemical titration of oxygen and nitrogen atoms has been facilitated by the fact that many of these reactions are accompanied by light emission. Both reactions commonly used for nitrogen and oxygen atoms

$$N + NO \rightarrow N_2 + O$$

and

$$O + NO_2 \rightarrow NO + O_2$$

make use of the light-emitting reaction

$$O + NO \rightarrow NO_2 + h\nu$$

to observe the equivalence point of the titration. We have not found any useful light-emitting reaction in our work with halogen atoms, and hence a different equivalence indicator must be used.

We have found the following reaction most useful for titration of chlorine atoms:

$$Cl + NOCl \rightarrow NO + Cl_2.$$

Subsequent reactions

$$Cl + NO + M \rightarrow NOCl + M$$

$$Cl_2 + 2NO \rightarrow 2NOCl$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

are considerably slower under conditions present in the flow system. Figure 2 gives the atom flow measured by the detector as a function of the NOCl flow introduced through

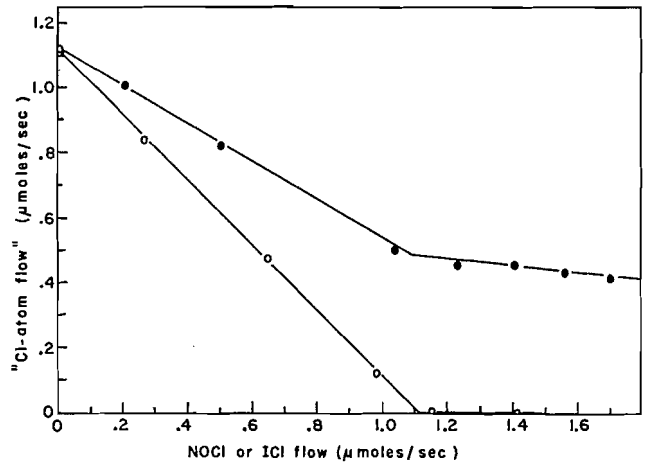

FIG. 2. Chlorine atom titration curves with NOCl (open circles) and with ICl (closed circles).

stopcock B in Fig. 1. The detector was placed 2 centimeters beyond the NOCl inlet. The agreement between the original chlorine atom flow measured by the detector and the NOCl flow necessary to remove all the atoms is excellent.

The titration of chlorine atoms with NOCl was carried out over a variety of experimental conditions. The technique used was to set the NOCl flow at some value in excess of the chlorine atom flow and then decrease the NOCl flow until atoms began to reach the detector. This NOCl flow was then recorded as the chlorine atom flow measured by titration. In all experiments carried out at a total pressure below 4 mm Hg the atom concentration measured by the two methods did not differ by more than 5%. However, the detector readings fell below those of the NOCl titration at higher pressures. This confirms the previous observation that at the higher pressures atoms are swept by the detector without being recombined.

It should be emphasized that though the detector is being used in the titration, the method is still an independent quantitative measurement. This is underlined by the fact that a glass-covered thermistor probe is even more effective in observing the end point of the titration.

Surface Recombination

With the nickel detector, the atom concentration was measured along the reaction tube. At a total pressure not greater than 0.3 mm Hg (due mostly to the carrier gas) the gas phase recombination is slow and can easily be corrected for. Though not unequivocally determined, the wall reaction appears to be of first order in chlorine atoms and can be written

$$\mathrm{Cl} + \text{wall} \xrightarrow{k_w} 1/2\,\mathrm{Cl_2} + \text{wall}$$

for which we have calculated a value of 0.8 $\mathrm{sec^{-1}}$ for k_W at 10° C with all the oxyacids used. The more meaningful recombination coefficient (γ), therefore, has a value of about 4×10^{-5}.

A considerably greater value was obtained until the marked effect of a small amount of water from the surface poison in the discharge was noted. The water not only greatly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

increased the atom concentration but also caused a sharp increase in the rate of recombination of the atoms.

Bromine

The experiments described in the previous section were repeated with bromine. The results may be summarized as follows:

(1) No bromine atoms were detected in a stream of electrically discharged bromine unless the surfaces were coated with one of the oxyacids used for chlorine atoms.

(2) Bromine atoms can also be titrated with NOCl by the same technique used for chlorine atoms. The agreement between the atoms measured by titration and those measured with a nickel detector was satisfactory below a total pressure of about 4 mm Hg.

(3) Water vapor increases both the bromine atoms obtained from the discharge and the rate at which they are removed by recombination.

(4) The value of the surface recombination coefficient (γ) was found to be about 6×10^{-5} at 10° C for all the oxyacids used as surface poisons.

Iodine

To date we have had no success in obtaining iodine atoms from electrically discharged I_2. The difficulty seems to lie in the hot region immediately after the discharge because we have found that the atoms can be maintained if they are created outside the discharge.

The closed circles in Fig. 2 give the pseudo-chlorine atom concentration obtained when ICl is added to the same stream of chlorine atoms used in the NOCl titration. The fast reaction occurring is

$$Cl + ICl \rightarrow Cl_2 + I.$$

Subsequent reactions of iodine atoms are somewhat slower. The break in the curve probably represents the complete titration of chlorine atoms. This point is in reasonable agreement with the end point of the NOCl titration. Beyond this point on the curve the detector must be obtaining its heat from the recombination of iodine atoms. The fact that the heat obtained at the end point is not 36/58 of that originally obtained from the chlorine atoms may be due to the more rapid gas phase recombination of iodine atoms, which could be observed by moving the detector along the tube. This rapid gas phase recombination made it too difficult to estimate the wall recombination rate. Nevertheless, it is apparent that the absence of atoms from electrically discharged iodine vapor must be due to an even more rapid recombination in the hot region of the discharge.

CONCLUSION

The isothermal calorimetric detector has been shown to be capable of measuring accurately the concentration of both chlorine and bromine atoms in a flow system operating in the pressure range from 0.3 mm Hg to 4 mm Hg. The wall recombination coefficient (γ) has been shown to be sufficiently small to allow the use of this halogen atom source for kinetic studies. A number of reactions have been studied with this flow system and will be presented elsewhere.

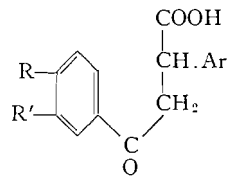
β-AROYL-α- AND -β-ARYLPROPIONIC ACIDS

PART I. THEIR PREPARATION AND LACTONIZATION[1]

SAYED SHERIF

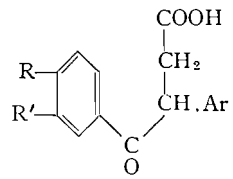
ABSTRACT



Bromobenzene reacts with phenyl- and *p*-methoxyphenyl-succinic anhydride in the presence of anhydrous aluminum chloride to give a mixture of β-*p*-bromobenzoyl-α- and -β-phenylpropionic acid, and a mixture of β-*p*-bromobenzoyl-α- and -β-*p*-hydroxyphenylpropionic acid, respectively.

Similarly, iodobenzene reacts with the same anhydrides to give a mixture of β-*p*-iodobenzoyl-α- and -β-phenylpropionic acid and β-benzoyl-α- and -β-phenylpropionic acid, and a mixture of β-benzoyl- and β-*p*-iodobenzoyl-α-*p*-methoxyphenylpropionic acid, respectively.

Phenyl- and diphenyl-succinic anhydride are cyclized by aluminum chloride to 1-ketoindane- and 1-keto-2-phenylindane-3-carboxylic acid, respectively.



The above keto acids are converted by boiling acetic anhydride into β,γ-unsaturated γ-lactones.

Condensation of phenylsuccinic anhydride with bromobenzene in the presence of anhydrous aluminum chloride gave rise to a mixture of β-*p*-bromobenzoyl-α- and -β-phenylpropionic acid (I*a* and II*a*, respectively) in which the latter was predominant. The structure of the α-phenyl isomer was established by comparison with an authentic specimen prepared after Allen, Normington, and Wilson (1). The structure of the β-phenyl isomer was established by elemental analysis and by the production of *p*-bromobenzoic acid on oxidation with alkaline potassium permanganate. The reaction mixture contained a neutral product which was proved to be *p*-dibromobenzene, probably produced by the action of aluminum chloride on bromobenzene.

(*b*) R = Br; R′ = H; Ar = *p*-HOC_6H_4
(*c*) R = I; R′ = H; Ar = C_6H_5
(*d*) R = R′ = H; Ar = C_6H_5

When phenylsuccinic anhydride was replaced by *p*-methoxyphenylsuccinic anhydride, a mixture of β-*p*-bromobenzoyl-α- and -β-*p*-hydroxyphenylpropionic acid (I*b* and II*b*, respectively) was produced in which the latter was predominant. The structure of the α-*p*-hydroxyphenyl isomer was established by its identity with an authentic specimen prepared from *p*-bromophenyl 4-methoxystyryl ketone. The presence of the hydroxyl group was established by its infrared spectrum (see Experimental). The structure of the β-*p*-bromobenzoyl-β-*p*-hydroxyphenylpropionic acid was established by elemental analysis and by oxidation to *p*-bromobenzoic acid.

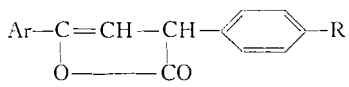
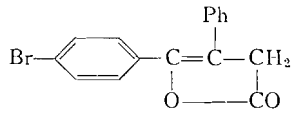
The condensation of phenylsuccinic anhydride with iodobenzene under the same conditions gave a mixture of β-*p*-iodobenzoyl-α- and -β-phenylpropionic acid (I*c* and II*c*, respectively) and β-benzoyl-α- and β-phenylpropionic acid (I*d* and II*d*, respectively). The structure of the first acid was established by comparison with an authentic specimen prepared from *p*-iodophenyl styryl ketone. The structure of the second acid was inferred from its elemental analysis, and from the fact that it gave, on oxidation with alkaline potassium permanganate, *p*-iodobenzoic acid. The structure of the halogen-free acids was established by comparison with authentic specimens (2). The formation of the halogen-free acids is due to the partial dehalogenation of iodobenzene to benzene, under the experimental conditions, and not to the partial dehalogenation of the β-aroylpropionic acids for the following reasons: (i) *o*- and *p*-diiodobenzene were isolated from the reaction mixture, and from a mixture of aluminum chloride and iodobenzene treated under the same conditions, and (ii) β-*p*-iodobenzoyl-α-phenylpropionic acid was recovered unchanged, when heated with aluminum chloride in toluene at 100° for 3 hours.



p-Methoxyphenylsuccinic anhydride reacted with iodobenzene in the presence of aluminum chloride to give a mixture of acids, which, after methylation and hydrolysis, was separated into β-benzoyl-α-*p*-methoxyphenylpropionic acid and β-*p*-iodobenzoyl-α-*p*-methoxyphenylpropionic acid (I*e* and I*f*, respectively); the former acid predominated. The structure of both acids was established by comparison with authentic specimens.

β-3,4-Dichlorobenzoyl-α-phenylpropionic acid (I*g*) was prepared by the addition of hydrogen cyanide to 3,4-dichlorophenyl styryl ketone and subsequent alcoholysis and hydrolysis of the corresponding nitrile.



In the presence of aluminum chloride, succinic anhydride condensed with *o*-dichlorobenzene to give β-3,4-dichlorobenzoylpropionic acid (I*h*), the structure of which was established by oxidation with alkaline potassium permanganate to 3,4-dichlorobenzoic acid. However, under the same experimental conditions, phenylsuccinic anhydride failed to condense with *o*-dichlorobenzene, and instead it cyclized intramolecularly, giving 1-ketoindane-3-carboxylic acid (III*a*); this on decarboxylation gave α-hydrindone. Under the same conditions, α,β-diphenylsuccinic anhydride cyclized intramolecularly to give 1-keto-2-phenylindane-3-carboxylic acid (III*b*), the structure of which was established by comparison with an authentic specimen (3).

IV

V

(*a*) Ar = H
(*b*) Ar = C_6H_5

When the β-aroyl-α- and -β-arylpropionic acids were boiled with acetic anhydride, they were converted to the corresponding β,γ-unsaturated γ-lactones (4, 5) (IV and V, respectively). The lactone structure was established by the appearance of its characteristic stretching frequency (6, p. 153) in the infrared spectra of these compounds (see Experimental).

The results of the present investigation agree with those of Baddar and Sherif (4).

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured with a Perkin–Elmer Infracord spectrophotometer Model 137, using the potassium bromide wafer technique.

β-p-Bromobenzoyl-α-phenylpropionic Acid

A mixture of β-*p*-bromobenzoyl-α-phenylpropionitrile (7) (20 g), ethanol (150 ml), and concentrated sulphuric acid (30 ml) was refluxed for 6 hours on a steam bath. The ester (22 g), which solidified on being cooled, was filtered off and crystallized from light petroleum (b.p. 50–70°) to give ethyl β-*p*-bromobenzoyl-α-phenylpropionate in colorless crystals, m.p. 70–71°. Calc. for $C_{18}H_{17}BrO_3$: C, 59.85; H, 4.74; Br, 22.13. Found: C, 59.83; H, 4.61; Br, 22.00.

The ester (20 g) was hydrolyzed with 10% aqueous potassium hydroxide (200 ml) (1 hour reflux) to give β-*p*-bromobenzoyl-α-phenylpropionic acid (17 g) (from benzene), m.p. 160–161°; Allen and co-workers (1) give the same melting point. Calc. for $C_{16}H_{13}BrO_3$: C, 57.69; H, 3.93; Br, 24.00. Found: C, 57.85; H, 4.00; Br, 23.73.

When the acid was treated with 2,4-dinitrophenylhydrazine in a warm mixture of ethanol and concentrated sulphuric acid, it gave the 2,4-dinitrophenylhydrazone of the ethyl ester in orange-yellow crystals (from dilute acetic acid), m.p. 161–162°. Calc. for $C_{24}H_{21}BrN_4O_6$: C, 53.24; H, 3.91; N, 10.35. Found: C, 53.22; H, 3.75; N, 10.15.

Condensation of Bromobenzene with Phenylsuccinic Anhydride

A solution of phenylsuccinic anhydride (17.6 g, 0.1 mole) in bromobenzene (20 ml) was added gradually to a well-cooled and stirred mixture of anhydrous aluminum chloride (26.7 g, 0.2 mole) and bromobenzene (30 ml). The reaction mixture was heated at 100° for 3 hours, decomposed with ice-cold dilute hydrochloric acid, and the solvent was steam-distilled. The product (20 g, 60% yield), m.p. 85–100°, was crystallized from the least amount of glacial acetic acid, then from ether, to give β-*p*-bromobenzoyl-β-phenylpropionic acid (16 g, 48% yield) in colorless crystals, m.p. 156–157°, depressed to 130–140° when admixed with the α-phenyl isomer. Calc. for $C_{16}H_{13}BrO_3$: C, 57.69; H, 3.93; Br, 24.00. Found: C, 57.90; H, 3.83; Br, 24.00.

On oxidation with alkaline potassium permanganate (1 hour at 100°), it gave *p*-bromobenzoic acid, m.p. and mixed m.p. 250°.

The acetic acid mother liquor was diluted with water, and the precipitated solid was crystallized from benzene to give β-*p*-bromobenzoyl-α-phenylpropionic acid (2 g, 6% yield), m.p. and mixed m.p. 160–161°.

The steam-distillable fraction was dried (Na_2SO_4) and fractionally distilled to give mainly bromobenzene and *p*-dibromobenzene, m.p. and mixed m.p. 89°.

Action of Aluminum Chloride on Bromobenzene

Aluminum chloride was added to cold bromobenzene. The reaction mixture was kept at 25–30° for 3 days and then decomposed and worked up as usual to give bromobenzene and *p*-dibromobenzene.

β-p-Bromobenzoyl-α-p-methoxyphenylpropionitrile

To a solution of *p*-bromobenzoyl 4-methoxystyryl ketone (8) (5 g) in ethanol (150 ml), glacial acetic acid (2.3 ml) and aqueous potassium cyanide (3.5 g in 9 ml water) were added. The reaction mixture was kept at 60–65° for 5 hours, then left overnight. The nitrile (4 g) had m.p. 132–133° (from ethanol), depressed to 115–120° on admixing with the above chalcone. Calc. for $C_{17}H_{14}BrNO_2$: C, 59.31; H, 4.10; Br, 23.21; N, 4.07. Found: C, 59.20; H, 4.16; Br, 22.86; N, 4.00.

β-p-Bromobenzoyl-α-p-methoxyphenylpropionic Acid

A mixture of the above nitrile (4 g), methanol (50 ml), and concentrated sulphuric acid (7 ml) was refluxed for 8 hours and the product (4 g) crystallized from methanol to give methyl β-*p*-bromobenzoyl-α-*p*-methoxyphenylpropionate in colorless crystals, m.p. 79–80°. Calc. for $C_{18}H_{17}BrO_4$: C, 57.31; H, 4.55; Br, 21.18. Found: C, 57.11; H, 4.42; Br, 21.10.

The ester was hydrolyzed by refluxing for 2.5 hours with 5% aqueous potassium hydroxide (100 ml). The reaction mixture was cooled, acidified, and the precipitated acid was crystallized from ethanol to give β-*p*-bromobenzoyl-α-*p*-methoxyphenylpropionic acid (3.5 g) in colorless crystals, m.p. 134–135°. Calc. for $C_{17}H_{15}BrO_4$: C, 56.22; H, 4.17; Br, 22.02. Found: C, 56.00; H, 4.20; Br, 22.00.

When the acid was warmed with 2,4-dinitrophenylhydrazine in ethanol and concentrated sulphuric acid, and the product was crystallized from acetic acid, the 2,4-dinitrophenylhydrazone of the ethyl ester was obtained, in yellow crystals, m.p. 188–189°. Calc. for $C_{25}H_{23}BrN_4O_7$: C, 52.55; H, 4.06; Br, 14.00; N, 9.81. Found: C, 52.41; H, 3.91; Br, 14.20; N, 10.08.

β-p-Bromobenzoyl-α-p-hydroxyphenylpropionic Acid

A mixture of β-*p*-bromobenzoyl-α-*p*-methoxyphenylpropionic acid (2.5 g), aluminum chloride (5 g), and bromobenzene (20 ml) was stirred at 100° for 2 hours, then worked up as usual. The product (2 g) was crystallized from ether to give β-*p*-bromobenzoyl-α-*p*-hydroxyphenylpropionic acid, in colorless crystals, m.p. 171–172°. It gave a deep blue color with warm concentrated sulphuric acid. Calc. for $C_{16}H_{13}BrO_4$: C, 55.05; H, 3.75; Br, 22.90. Found: C, 55.16; H, 3.75; Br, 22.90. Its infrared spectrum showed two bands at 3450 and 1670 cm^{-1} characteristic of a bonded OH group (6, p. 84) and the CO group of the aroyl group (6, p. 114), respectively.

p-Methoxyphenylsuccinic Anhydride

It was prepared from the acid (9) by refluxing with 3 times its weight of acetyl chloride for 6 hours. The excess of acetyl chloride was distilled off, and the residue fractionated, b.p. 205–208° at 5 mm (80% yield).

Condensation of Bromobenzene with p-Methoxyphenylsuccinic Anhydride

A solution of *p*-methoxyphenylsuccinic anhydride (20.6 g, 0.1 mole) in bromobenzene (40 ml) was gradually added to a well-cooled and stirred mixture of aluminum chloride (26.7 g, 0.2 mole) and bromobenzene (50 ml). The reaction mixture was left overnight, heated at 100° for 3 hours, then worked up as usual. The product (20 g, 57% yield) was crystallized from ether to give β-*p*-bromobenzoyl-β-*p*-hydroxyphenylpropionic acid, in colorless crystals, m.p. 198–199° (12 g, 34% yield), depressed to 150–155° when admixed with β-*p*-bromobenzoyl-α-*p*-hydroxyphenylpropionic acid. Calc. for $C_{16}H_{13}BrO_4$: C, 55.05; H, 3.75; Br, 22.90. Found: C, 55.32; H, 3.90; Br, 22.45. It gave a yellowish-green color with concentrated sulphuric acid. On oxidation with alkaline potassium permanganate, it gave *p*-bromobenzoic acid.

Concentration of the ether mother liquor gave β-*p*-bromobenzoyl-α-*p*-hydroxyphenylpropionic acid (6 g, 17% yield), m.p. and mixed m.p. 171–172°.

β-p-Iodobenzoyl-α-phenylpropionitrile

To a solution of *p*-iodophenyl styryl ketone (10) (3 g) in ethanol (75 ml), glacial acetic acid (2.3 ml) and aqueous potassium cyanide (3.5 g in 10 ml water) were added. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

reaction mixture was kept at 70–75° for 4 hours, then left overnight. β-*p*-Iodobenzoyl-α-phenylpropionitrile (3 g) was crystallized from ethanol in colorless crystals, m.p. 148–149°. Calc. for $C_{16}H_{12}INO$: C, 53.21; H, 3.35; I, 35.15; N, 3.88. Found: C, 53.11; H, 3.45; I, 34.76; N, 3.80.

β-p-Iodobenzoyl-α-phenylpropionic Acid

A mixture of the above nitrile (2 g), methanol (25 ml), and concentrated sulphuric acid (5 ml) was refluxed on a steam bath for 8 hours. The reaction mixture was diluted with water and the precipitated methyl β-*p*-iodobenzoyl-α-phenylpropionate (2 g) was crystallized from methanol, in colorless crystals, m.p. 132–133°, depressed to 115–120° when admixed with the corresponding nitrile. Calc. for $C_{17}H_{15}IO_3$: C, 51.79; H, 3.84; I, 32.20. Found: C, 51.70; H, 3.77; I, 32.00.

The preceding ester was hydrolyzed by refluxing for 1.5 hours with 5% aqueous potassium hydroxide (100 ml) to give β-*p*-iodobenzoyl-α-phenylpropionic acid (1.7 g), which was crystallized from ether in colorless crystals, m.p. 155–156°. Calc. for $C_{16}H_{13}IO_3$: C, 50.55; H, 3.45; I, 33.40. Found: C, 50.37; H, 3.60; I, 33.15. Oxidation of the α-phenylpropionic acid with aqueous alkaline potassium permanganate gave *p*-iodobenzoic acid, m.p. and mixed m.p. 270° (11).

Condensation of Iodobenzene with Phenylsuccinic Anhydride

The product from iodobenzene (60 ml), phenylsuccinic anhydride (17.6 g, 0.1 mole), and aluminum chloride (26.7 g, 0.2 mole) (3 hours at 100°) was extracted with boiling aqueous sodium carbonate solution. The extract, on being cooled and acidified, gave a semisolid residue (15 g). This was extracted several times with light petroleum (b.p. 50–70°), and the insoluble portion was crystallized from benzene to give β-benzoyl-β-phenylpropionic acid (2 g), m.p. and mixed m.p. 168° (2). Concentration of the benzene mother liquor gave β-benzoyl-α-phenylpropionic acid (3 g), m.p. and mixed (2) m.p. 154°. Evaporation of the benzene layer gave a semisolid residue which was crystallized several times from light petroleum (b.p. 70–90°) to give β-*p*-iodobenzoyl-β-phenylpropionic acid (2 g, 5.3% yield) in colorless crystals, m.p. 160–161°, depressed to 130–135° when admixed with its α-phenyl isomer. Calc. for $C_{16}H_{13}IO_3$: C, 50.55; H, 3.45; I, 33.40. Found: C, 50.82; H, 3.60; I, 32.47. Oxidation of the β-phenylpropionic acid with alkaline potassium permanganate gave *p*-iodobenzoic acid.

The light petroleum mother liquor was evaporated and the residue left was crystallized from ether to give β-*p*-iodobenzoyl-α-phenylpropionic acid (1.5 g, 4% yield), m.p. and mixed m.p. 156°.

The residue insoluble in sodium carbonate solution was dissolved in hot ethanol, and the oil and crystals, which were precipitated when the solution was cooled, were mechanically separated. The crystals, after crystallization from light petroleum (b.p. 50–70°), melted at 128°, not depressed when admixed with an authentic specimen of *p*-diiodobenzene. The oil was distilled under vacuum, b.p. 153–155° at 15 mm, and the solidified product was crystallized from light petroleum (b.p. below 40°) to give *o*-diiodobenzene in plates, m.p. and mixed m.p. 27° (12).

Action of Aluminum Chloride on β-p-Iodobenzoyl-α-phenylpropionic Acid

The acid (2 g) was dissolved in toluene (15 ml) and the cooled mixture was treated with aluminum chloride (5 g); the reaction mixture was stirred at 100° for 3 hours, then decomposed as usual. β-*p*-Iodobenzoyl-α-phenylpropionic acid was recovered unchanged, m.p. and mixed m.p. 156°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Action of Aluminum Chloride on Iodobenzene

Iodobenzene was cooled to 0–5° and treated gradually with aluminum chloride. The reaction mixture was kept at room temperature (25–30°) for 3 days, then decomposed in the usual manner. *p*-Diiodobenzene and *o*-diiodobenzene were isolated from the reaction mixture as already mentioned.

p-Iodophenyl 4-Methoxystyryl Ketone

A mixture of *p*-iodoacetophenone (13) (18.4 g), ethanol (175 ml), water (60 ml), sodium hydroxide (7.5 g), and anisaldehyde (10.2 g) was stirred at 20–25° for 1.5 hours. *p*-Iodophenyl 4-methoxystyryl ketone (27 g) was obtained from ethanol in pale yellow crystals, m.p. 172–173°. Calc. for $C_{16}H_{13}IO_2$: C, 52.77; H, 3.60; I, 34.86. Found: C, 52.55; H, 3.51; I, 34.52.

β-p-Iodobenzoyl-α-p-methoxyphenylpropionitrile

To a solution of the above chalcone (3 g) in ethanol (175 ml), acetic acid (2.3 ml) and aqueous potassium cyanide (3.5 g in 10 ml water) were added. The reaction mixture was kept at 70–75° for 4 hours, then left overnight. The crystalline precipitate (3 g) was collected and crystallized from ethanol to give *β-p*-iodobenzoyl-*α-p*-methoxyphenylpropionitrile in colorless crystals, m.p. 164–165°. Calc. for $C_{17}H_{14}INO_2$: C, 52.21; H, 3.60; N, 3.58. Found: C, 52.10; H, 3.70; N, 3.41.

β-p-Iodobenzoyl-α-p-methoxyphenylpropionic Acid

A mixture of the preceding nitrile (2 g), methanol (25 ml), and concentrated sulphuric acid (4 ml) was refluxed for 10 hours. The reaction mixture was poured onto ice water and the crude methyl ester was directly hydrolyzed with 10% aqueous potassium hydroxide (100 ml) (1-hour reflux) to *β-p*-iodobenzoyl-*α-p*-methoxyphenylpropionic acid (1 g) from ether, m.p. 156–157°. Calc. for $C_{17}H_{15}IO_4$: C, 49.75; H, 3.69; I, 30.95. Found: C, 50.00; H, 3.60; I, 30.84.

Condensation of Iodobenzene with p-Methoxyphenylsuccinic Anhydride

The product from iodobenzene (60 ml), *p*-methoxyphenylsuccinic anhydride (20.6 g, 0.1 mole), and aluminum chloride (26.7 g, 0.2 mole) (3 hours at 100°) was steam-distilled and the residue extracted with boiling 10% aqueous sodium carbonate solution. The extract, on acidification, gave a semisolid residue (10 g), which was methylated with methyl iodide, potassium carbonate, and acetone. Hydrolysis of the esters (5% aqueous potassium hydroxide) gave a semisolid mass which, after crystallization from benzene, gave *β*-benzoyl-*α-p*-methoxyphenylpropionic acid (6 g), m.p. and mixed (9) m.p. 158°. Evaporation of the benzene mother liquor gave a gummy acid which, on crystallization from ether, gave *β-p*-iodobenzoyl-*α-p*-methoxyphenylpropionic acid (2 g), m.p. and mixed m.p. 156–157°.

The steam-distillable fraction was dried (Na_2SO_4) and fractionally distilled to give iodobenzene and *o*- and *p*-diiodobenzene.

β-3,4-Dichlorobenzoylpropionic Acid

A stirred mixture of aluminum chloride (53.4 g, 0.4 mole) and *o*-dichlorobenzene (75 ml) was treated portionwise with a solution of succinic anhydride (20 g, 0.2 mole in 25 ml of *o*-dichlorobenzene). The reaction mixture was heated at 100° for 3 hours, then worked up as usual. *β*-3,4-Dichlorobenzoylpropionic acid (30 g, 61% yield) came down from ethanol in colorless crystals, m.p. 167–168°. Calc. for $C_{10}H_8Cl_2O_3$: C, 48.61; H, 3.26; Cl, 28.70. Found: C, 48.57; H, 3.11; Cl, 28.61. Oxidation of this acid with alkaline potassium permanganate gave 3,4-dichlorobenzoic acid, m.p. and mixed (14) m.p. 208–209°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

3,4-Dichlorophenyl Styryl Ketone

A mixture of 3,4-dichloroacetophenone (15) (9.5 g), ethanol (100 ml), water (40 ml), sodium hydroxide (5 g), and benzaldehyde (5.3 g) was stirred at 50–55° for 1 hour, then allowed to cool. 3,4-Dichlorophenyl styryl ketone (10 g) was obtained in pale yellow crystals, m.p. 116–117° (from ethanol). Bradsher and co-workers (16) and Lutz and co-workers (17) gave m.p. 112–113° and 110–112°, respectively. Calc. for $C_{15}H_{10}Cl_2O$: C, 65.03; H, 3.63; Cl, 25.60. Found: C, 64.73; H, 3.60; Cl, 25.00.

β-3,4-Dichlorobenzoyl-α-phenylpropionitrile

To a solution of the above chalcone (2 g) in ethanol (50 ml), acetic acid (2 ml) and aqueous potassium cyanide (2 g in 5 ml water) were added. The reaction mixture was heated to the boiling point, then left overnight. The nitrile (2 g) was crystallized from ethanol in colorless crystals, m.p. 119–120°, depressed to 105–110° when admixed with the corresponding chalcone. Calc. for $C_{16}H_{11}Cl_2NO$: C, 63.19: H, 3.65; Cl, 23.31; N, 4.60. Found: C, 63.00; H, 3.60; Cl, 23.11; N, 4.45.

β-3,4-Dichlorobenzoyl-α-phenylpropionic Acid

A mixture of the above nitrile (2 g), methanol (25 ml), and concentrated sulphuric acid (5 ml) was heated on a steam bath for 10 hours. The ester that precipitated on cooling was hydrolyzed with 5% aqueous potassium hydroxide (100 ml) (1.5 hours reflux) to give β-3,4-dichlorobenzoyl-α-phenylpropionic acid (1.5 g) as colorless crystals from methanol, m.p. 170–171°. Calc. for $C_{16}H_{12}Cl_2O_3$: C, 59.47; H, 3.74; Cl, 21.95. Found: C, 59.21; H, 3.75; Cl, 21.46.

1-Ketoindane-3-carboxylic Acid

Phenylsuccinic anhydride (17.6 g) in *o*-dichlorobenzene (20 ml) was added gradually to a well-cooled and stirred mixture of aluminum chloride (26.7 g) and *o*-dichlorobenzene (30 ml). The reaction mixture was heated at 100° for 2 hours, then worked up as usual. The colorless crystalline acid, m.p. 85° (from water), was dried in vacuum to give 1-ketoindane-3-carboxylic acid (12.5 g, 71% yield), m.p. and mixed (18) m.p. 120°.

α-Hydrindone

A mixture of 1-ketoindane-3-carboxylic acid (2 g), quinoline (15 ml), and copper bronze (0.5 g) was refluxed for 1 hour, cooled, and decomposed as usual. The reaction mixture was extracted with benzene. The removal of the solvent left an oil (ca. 1.5 g) which, on trituration with light petroleum (b.p. below 40°), gave colorless crystals, m.p. 42°; it was converted into α-hydrindone 2,4-dinitrophenylhydrazone, m.p. and mixed m.p. 260° (decomp.).

1-Keto-2-phenylindane-3-carboxylic Acid

A mixture of diphenylsuccinic anhydride (8.5 g) and aluminum chloride (10 g) in *o*-dichlorobenzene (30 ml) was heated at 100° for 2 hours, decomposed, and the solvent was steam-distilled. 1-Keto-2-phenylindane-3-carboxylic acid monohydrate (ca. 8 g) was crystallized from dilute ethanol in colorless crystals, m.p. and mixed (3) m.p. 116–117° (decomp.).

Lactonization of β-Aroyl-α- and -β-arylpropionic Acids

The solution of the acid (1 g) in acetic anhydride (10 ml) was refluxed for 2 hours and, after cooling, poured into water. The solid was filtered off and washed with dilute sodium carbonate solution. The lactone (ca. 100% yield) was then crystallized from a suitable solvent (see Table I).

THE CHEMICAL COMPOSITION OF THE WOOD AND BARK EXTRACTIVES OF JUNIPERUS HORIZONTALIS MOENCH[1]

N. NARASIMHACHARI[2] AND E. VON RUDLOFF

ABSTRACT

The wood of creeping juniper was found to contain about 10% acetone-soluble material. Of this, about one quarter was ligroin soluble and, from this portion, thujopsene, α-cedrene, cuparene, cedrol, widdrol, β-sitosterol, esters of fatty acids and β-sitosterol, the lignan savinin, and the recently discovered diterpene communic acid were isolated. Three unidentified hydrocarbons and several unknown alcohols and ketones were also obtained in small amounts. The ether-insoluble portion consisted of intractable polyphenolic material. The composition of the ligroin-soluble extract of the bark of this shrub resembled that of the wood in many respects. Neither the wood nor the bark extractives contained thujaplicins in detectable amounts.

Creeping juniper (*Juniperus horizontalis* Moench; also *Sabina horizontalis* (1)) is a prostrate shrub which is found widely distributed across Canada and occurs frequently in the dry, sandy regions of the Prairie Provinces. A survey of the literature did not reveal any reference to chemical investigations of the components of this plant. This paper deals with some of the components found in the wood and bark of the conifer.

The wood, after removal of the bark, was milled and extracted with acetone, giving 9–10% of soluble material. This extract was then fractionated into various groups of compounds as shown in Fig. 1. When the wood was extracted directly with ligroin, the same yield of ligroin-soluble material was obtained and this was divided into neutral, phenolic, and acidic material in the usual manner. The major portion consisted of neutral components which were fractionated by chromatography on a silicic acid column into five distinct classes of compounds: hydrocarbons, esters, mixed ketones and alcohols, sitosterol, and a lactone, respectively.

Hydrocarbons

The hydrocarbon fraction (0.22% of the weight of wood) was analyzed by gas–liquid chromatography (GLC) (2), which showed the presence of one major and five minor sesquiterpene hydrocarbons. The retention times of these components corresponded with six of the seven sesquiterpene hydrocarbons found in commercial cedar wood oil (from *Juniperus virginiana*). Runeberg (3) has identified three of these to be α-cedrene, thujopsene, and cuparene. The first peak recorded from the mixture from creeping juniper had the retention time and infrared spectrum of α-cedrene. The second and major constituent corresponded in retention time to either thujopsene or the isomer of cedrene (4) which is obtained when cedrol is dehydrated by the method of Motl *et al.* (5). This component was not attacked by cold, dilute permanganate solutions, nor did it yield any identifiable product on dehydrogenation with either selenium or palladized charcoal. On oxidation with selenium dioxide, a crystalline aldehyde, m.p. 71–72° C, was obtained. This, together with the GLC and infrared analysis, suggested the major hydrocarbon to be thujopsene. This was confirmed by oxidizing an authentic sample of thujopsene (kindly supplied by Prof. H. Erdtman and T. Norin, Stockholm, Sweden) with selenium dioxide to thujopsenal (6), m.p. 71.5–72° C, which showed no depression in melting point with

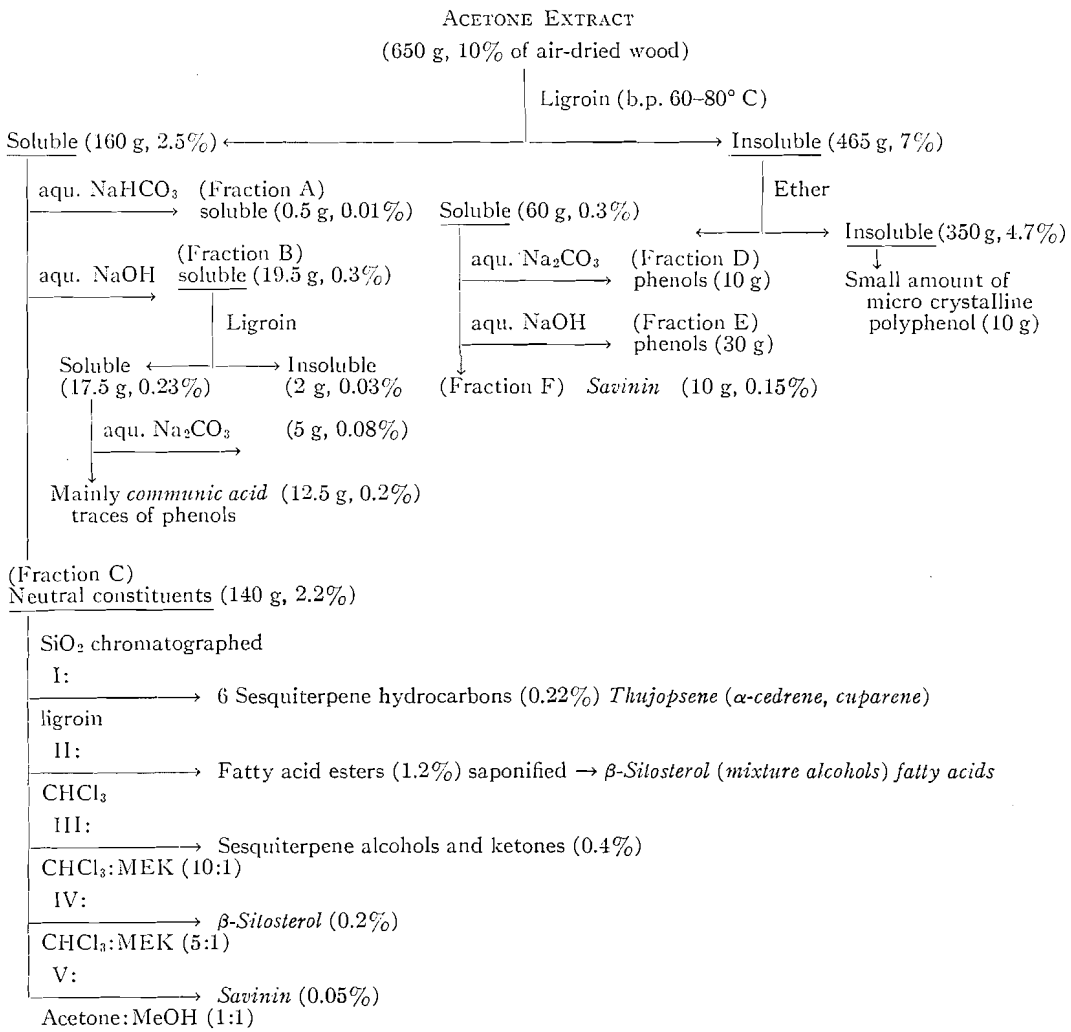

FIG. 1. Fractionation scheme for the wood extractives.

the above aldehyde. It was found that although thujopsene did not react with cold potassium permanganate solution, a liquid diol could be prepared from it with osmium tetroxide. Of the other minor hydrocarbons, none could be obtained pure. However, a concentrate of the second last peak gave an infrared spectrum resembling that of cuparene.

Esters

The ester fraction (1.2%) was saponified and from the non-saponifiable portion β-sitosterol and a small amount of a mixture of aliphatic alcohols were obtained. GLC analysis of the latter mixture showed two peaks in the C-12 range, one in the C-15, and one in the C-20 range. The acid portion consisted of a mixture of long-chain fatty acids which was analyzed by GLC (7). Peaks corresponding to palmitic, palmitoleic, stearic, oleic, linoleic, linolenic, and arachidic acid were recorded in the ratio of 6:1:1:13:37:6:2. The high proportion of the unsaturated C_{18} acids is typical for conifer wood (8).

Ketones and Alcohols

The third fraction (0.4%) from the silicic acid chromatogram was found to be a mixture of sesquiterpene alcohols and ketones. GLC analysis on the adipate polyester column showed the presence of two components having retention times corresponding to those of cedrol and widdrol, four minor constituents, and a major constituent with a very high retention time. Preparative GLC (20 mg scale) led to the isolation of milligram quantities of the cedrol–widdrol mixture, a mixed ketone–alcohol fraction, and the slow-moving major component. The cedrol–widdrol mixture was resolved on the polyester column and the identity of each alcohol was substantiated by its infrared spectrum. The identity of these two alcohols was further verified by dehydrating the mixture with the pyridine-modified alumina catalyst (4) to a product consisting mainly of α-cedrene and thujopsene (GLC). The second fraction had strong hydroxyl and carbonyl absorption bands in the infrared region. Re-chromatography of this fraction on the polyester column gave at least three peaks with strong indications that decomposition took place. The third fraction corresponded to the component having a very high retention time on the polyester column. Its infrared spectrum had absorption peaks at 1665 and 1618 cm^{-1}, and a maximum at 235 mμ with a weak shoulder 285 mμ was recorded in the ultraviolet region. Attempts to isolate and purify the ketones by means of Girard P reagent or column chromatography failed, mainly because of extensive decomposition of one or more of the components.

Sitosterol

Free β-sitosterol (0.016%) was obtained crystalline from the fourth fraction. No volatile constituents could be detected by GLC in the residue obtained from the mother liquors.

Lactone

Of more interest was the last fraction (0.05%) from the chromatogram which was also obtained in crystalline form. The purified, light yellow compound had m.p. 146–147°, $[\alpha]_D^{20}$ −82.3°, and a molecular weight of 362. The ultraviolet spectrum showed maxima at 237, 294, and 334 mμ, whereas the infrared spectrum (KBr disk and $CHCl_3$ solution) had two strong adsorption bands at 1740 and 1640 cm^{-1}, indicating the presence of an α,β-unsaturated lactone. The presence of a lactone ring was confirmed by the solubility of the compound in alcoholic alkali, from which the parent compound was recovered unchanged on acidification. The compound was insoluble in cold ethanol or cold aqueous alkali. Except for the position of the infrared bands discussed above, these data suggested a close resemblance with savinin. The structure of this lignan lactone was elucidated by Hartwell *et al.* (9, 10), who reported infrared absorption peaks at 1751 and 1651 cm^{-1} and also that the compound formed colorless crystals. The mixed melting point of authentic savinin (kindly supplied by Drs. J. L. Hartwell and A. W. Schrecker, Bethesda, U.S.A.) with the yellow compound isolated from creeping juniper was not depressed. The authentic sample also gave absorption bands at 1740 and 1640 cm^{-1} on the infrared spectrophotometer used in these experiments, and agreed in all other respects as well. Thus, there is no doubt that the two compounds are identical.

Acids and Phenols

The acidic portion of the ligroin- and ether-soluble extract was found to consist mainly of a diterpene acid (0.25%) $C_{20}H_{30}O_2$, m.p. 121–122° C, $[\alpha]_D^{25}$ +40.3°. On treatment with diazomethane the acid readily formed a methyl ester having m.p. 108–109° C, $[\alpha]_D^{25}$ +50.5°, which could not be saponified even at 125° C. GLC analysis showed the

methyl ester to be a single compound. The infrared spectrum showed the presence of a terminal methylene group (890 cm^{-1}) and a trisubstituted double bond (1645 and 795 cm^{-1}). Hydrogenation over platinum oxide catalyst resulted in the uptake of hydrogen equivalent to three double bonds. These data suggested that the acid was identical with the sirupy communic acid, isolated recently by Arya *et al.* from the wood of *Juniperus communis* L. (11). This was confirmed by preparing the maleic anhydride adduct of the ester, m.p. 170–171° C, $[\alpha]_D^{25}$ +79.5°. It is to be noted that in the preparation from *Juniperus horizontalis* the acid was obtained readily in the crystalline state.

Small amounts of phenolic materials were also obtained from the acidic portion. Paper chromatography (12) did not reveal the presence of any thujaplicins or related tropolones. This is surprising, since Runeberg and Pilo (13, 14) have found thujaplicins and nootkatin in a large number of juniper species. Thus, the extractives of creeping juniper wood more nearly resemble those of *Chamacyparis thyoides* (15), which are reported to contain no thujaplicins, but α-cedrene, cuparene, thujopsene, cedrol, widdrol, and carvacrol methyl ether. The finding of thujopsene, α-cedrene, cuparene, cedrol, widdrol, and communic acid does show, however, the close biogenetic relationship of the extractive components of creeping juniper with the other juniper species investigated.

The major portion (about 75%) of the acetone-soluble extractives of the wood of creeping juniper consisted of a brown, resinous phenolic material. Various fractionation attempts resulted only in the isolation of a small amount of microcrystalline polyphenolic material. The separation and identification of individual components from this so-called "phlobaphene" fraction will be studied further when more suitable fractionation techniques have been found.

Bark Extractives

It was of interest to determine whether the terpenoid compounds found in the wood could also be isolated from the bark of creeping juniper. The bark was milled to a fine powder, extracted with ligroin, and the extract was divided into neutral and acidic constituents. Column chromatography of the neutral portion gave as the first fraction hydrocarbons which appeared from GLC analysis to contain the same components as found in the corresponding fraction of the wood extractives. However, the component having the retention time of α-cedrene was present in about three times the amount of thujopsene. Treatment of the mixture with aqueous permanganate did not result in the formation of α-cedrene diol (16). Oxidation of the mixture with selenium dioxide produced a liquid aldehydic material in high yield which gave, on GLC analysis, only a peak corresponding to thujopsenal. Thus it may be that the unknown major hydrocarbon is an isomer of thujopsene rather than α-cedrene.

The second fraction from the column was composed of esters of β-sitosterol and a mixture of fatty acids. A mixed ketone–alcohol fraction was also isolated but GLC data showed that the individual components differed from those found in the same fraction obtained from the wood. In addition, an ester fraction was isolated which was composed of alcohols having terpenoid character and a mixture of C_{16}, C_{18}, and C_{20} acids in which the latter predominated. The alcoholic material could not be fractionated by column chromatography and characterization will be attempted by preparative GLC, once this technique has been perfected.

Savinin was isolated from the bark extract in small, though better, yield than was obtained from the wood. The major acidic component was again communic acid. Small amounts of untractable phenolic material were also obtained. Thus, the composition of the ligroin extract of the bark resembled that of the wood in many respects.

EXPERIMENTAL

Melting points were determined on a Leitz hot stage microscope. The identity of known compounds was confirmed by mixed melting point and by comparing the infrared spectra with those of authentic samples unless otherwise indicated. The infrared spectra were recorded on a Perkin–Elmer Model 21 double-beam recording spectrophotometer using the KBr-disk method, the film technique, or solutions in carbon tetrachloride. GLC chromatograms were obtained with a modified Beckman GC-2 chromatograph, using either 6 ft$\times\frac{1}{4}$ in. O.D. coiled copper columns packed with adipate (2) or succinate (7) polyester and "Chromosorb W" (80 to 100 mesh) in the ratio of 1:6, an 18 in.$\times\frac{1}{4}$ in. O.D. column containing washed silicone grease (2) on Celite (100 to 120 mesh) in the ratio of 1:6, or a 3 ft$\times\frac{1}{4}$ in. O.D. stainless steel column containing SE-30 silicone rubber (Dow Corning) on "Chromosorb W" (40 to 60 mesh) in the ratio of 1:3. The commercial cedar wood oil (Fritzsche Bros. of Canada Ltd., Toronto) used for comparison was obtained from the wood of *Juniperus virginiana* L.

Extraction of the Wood

The plants were collected near Saskatoon in the early fall of 1960 and in the spring of 1961. The leaves and bark were separated mechanically from the wood and the wood was milled to a fine powder by means of a hammer and a Wiley mill. The air-dried, milled wood (6.5 kg) was extracted continuously with acetone in a Soxhlet extractor for 24 hours and the extract was reduced to a brown, viscous sirup by distilling off most of the acetone. A small aliquot was evaporated to dryness to determine the yield of acetone-soluble material. The residue was poured into excess ligroin (b.p. 60–80° C) (4 liters) and the clear ligroin solution was decanted from the brown, resinous, insoluble material. The latter was washed twice with ligroin and the washings were added to the ligroin extract. The combined ligroin extract (6 liters) was concentrated to 2 liters by distillation. The yield of acetone-soluble material (650 g) was about 10% of the weight of air-dried wood, and that of the ligroin-soluble portion was 2.5%. The ligroin-soluble material could be obtained in about the same yield by extracting the milled wood directly with ligroin in a Soxhlet extractor.

Preliminary Fractionation

The concentrated ligroin extract (160 g in 2 liters) was extracted with a saturated solution of sodium bicarbonate and washed with water. The aqueous extracts were combined, acidified with cold dilute hydrochloric acid, and extracted with ether. The ethereal solution was dried over anhydrous sodium sulphate and after filtration evaporated to dryness to yield 0.5 g of a brown sirupy material (fraction A). The ligroin solution was then further extracted with two portions (100 ml) of aqueous sodium hydroxide solution (5%). The ligroin layer was again washed with water and the aqueous solutions pooled. The latter was acidified with cold, dilute hydrochloric acid, extracted with ether, and worked up as above to yield 19.5 g of weakly acidic material (fraction B). The residual ligroin solution was dried over anhydrous sodium sulphate and, after filtration, evaporated to dryness to yield 140 g of neutral oil (fraction C). When a small aliquot of the neutral material was distilled on a Widmer column, decomposition was encountered. About 20% of the material distilled between 110° and 140° C at 3 mm pressure. It was observed that chromatography on a silicic acid column, followed by vacuum distillation, gave a better separation of the volatile components.

Silicic Acid Column Chromatography

The neutral oil (10 g) in chloroform was chromatographed on a 2.0-cm diameter column of silicic acid (100 g) slurried in ligroin (b.p. 40–60° C). The column was eluted successively with ligroin (b.p. 40–60° C), chloroform, chloroform–2-butanone (10:1 and 5:1 v/v), and acetone–methanol (1:1 v/v), the solvent being changed when the last 50 ml of eluate gave no residue on evaporation. Five distinct fractions were collected in 1.2, 4.8, 1.6, 0.6, and 0.2 g amounts respectively. The infrared spectra showed the first to contain hydrocarbons, the second esters, the third a mixture of ketones and alcohols, the fourth alcohols, and the last a lactone.

Fraction I: Thujopsene and other Sesquiterpene Hydrocarbons

The material was analyzed by GLC on the adipate polyester column at 180° C. Six peaks were recorded in the sesquiterpene hydrocarbon range in 5, 72, 3, 6, 5, and 8% amounts respectively. The relative retention times (RRT; α-cedrene = 1.00) were 1.02, 1.15, 1.57, 1.74, 1.97, and 2.28 respectively. When commercial cedar wood oil, obtained from *Juniperus virginiana*, was injected, seven peaks were recorded, six of which corresponded in retention times to the above peaks. Fractional distillation gave a middle cut, b.p. 110–120° C (air bath) at 3 mm pressure, which contained about 88% of the major component. Found: C, 87.41%; H, 11.60%; n_D^{26} 1.5049; $[\alpha]_D^{26}$ −44.4 ($CHCl_3$). Calculated for $C_{15}H_{24}$: C, 88.16%; H, 11.84%. The crude hydrocarbon was unaffected by cold neutral or alkaline solutions of potassium permanganate. Selenium dehydrogenation (at 280 to 320° C) did not yield any identifiable product, nor was a crystalline picrate obtained. When the crude hydrocarbon was hydrogenated, using either palladized charcoal or platinum oxide as catalyst, the main hydrocarbon was recovered unchanged (GLC).

The crude hydrocarbon (300 mg), selenium dioxide (200 mg), and ethanol (30 ml) were heated under reflux for 4 hours. The ethanol was removed by evaporation under reduced pressure and ether was added to the residue. The ethereal solution was decanted from the residual selenium metal and the ether-soluble material (which contained appreciable amounts of selenium) was distilled *in vacuo* to give a pale yellow liquid, b.p. 110° C (air bath) at 3 mm pressure, which solidified partially on standing for some time. The distillate was taken up in ligroin (1 ml) and left at 2–5° C for several days, when the product crystallized in colorless, rectangular rods, m.p. 71–72° C after two recrystallizations. Found: C, 82.54%; H, 10.25%. Calculated for $C_{15}H_{22}O$: C, 82.51%; H, 10.16%. When an authentic sample of thujopsene was oxidized in the same manner thujopsenal of m.p. 71.5–72° C was obtained.

A few milligrams of the first peak were obtained almost pure by preparative GLC (20 mg scale) (2). The material had an infrared spectrum similar to that of α-cedrene. The presence of cuparene was inferred from the infrared spectrum of a concentrate of the second last peak, which was similar to that of this aromatic hydrocarbon.

Thujopsene diol.—Thujopsene (85% pure) (250 mg) and osmium tetroxide (250 mg) were dissolved in anhydrous ether (30 ml) and pyridine (1 ml). A brown, fluffy precipitate formed. The mixture was left at room temperature for 24 hours. It was then centrifuged, the solvent removed by decantation, and the solid residue was washed with ether. To the residue was added sodium bisulphite (1.5 g) in water (10 ml) and ethanol (30 ml), and the mixture was heated on a steam bath for 4 hours. The cooled solution was filtered and the alcohol was removed by evaporation *in vacuo*. The residual aqueous solution was extracted

repeatedly with ether and the ethereal extract was dried over anhydrous sodium sulphate. The oily residue obtained on evaporation of the ether contained no starting material (GLC) and showed a strong hydroxyl absorption band in the infrared region. The diol crystallized from ether–ligroin (1:1 v/v) at 2–5° C but liquefied immediately upon filtration, even in the cold.

Fraction II: Esters of β-Sitosterol, Aliphatic Alcohols, and Long-Chain Fatty Acids

This fraction was a viscous oil with a fatty odor. The infrared spectrum showed, as the only significant band, an ester carbonyl absorption (1740 cm^{-1}). The material was, therefore, saponified with alcoholic potassium hydroxide (steam bath, 2 hours) and worked up into the neutral and acidic components in the usual manner. Silicic acid chromatography of the neutral portion gave two distinct fractions. The first (10%) was analyzed by GLC on the silicone column at 160 and 200° C and was found to consist of four alcohols, two in the C-12, one in the C-15, and one in the C-20 range. The second fraction (90%) crystallized from acetone and was found to be β-sitosterol, m.p. 139–140° C, acetate m.p. 132–133° C. An aliquot of the acid portion was methylated with diazomethane and the mixture of methyl esters was analyzed by GLC on the succinate polyester column at 205° C. Peaks corresponding in retention time to palmitic (9.1%), palmitoleic (1.5%), stearic (1.5%), oleic (19.1%), linoleic (55.5%), linolenic (9.1%), and arachidic (3.03%) acids were recorded.

Fraction III: Mixed Alcohols and Ketones

Infrared analysis indicated that this fraction was composed of alcohols (3440 cm^{-1}) and ketones (1667 cm^{-1}). Found: C, 81.93%; H, 10.55%. Calculated for $C_{15}H_{24}O$: C, 81.76%; H, 10.98%. The mixture was analyzed by GLC, using the adipate polyester column at 180° C. Seven peaks were recorded in the ratio of 9:20:1:2:1:2:5:65. The respective RRT (cedrol = 1.00) were 1.02, 1.16, 1.44, 1.62, 1.94, 2.50, and 3.80. Some decomposition appeared to take place. Preparative runs of 20-mg aliquots on the SE-30 column yielded 5 to 10 mg each of three major components. These were re-chromatographed on the adipate polyester column, when the first fraction was resolved into two peaks corresponding in retention time to cedrol and widdrol. Sufficient material could be collected to record the infrared spectra of each component and these corresponded with those of cedrol and widdrol. The mixture (10 mg) was heated with alumina (30 mg) containing pyridine (1%) in a 5-mm glass tube (4) at 230° C for 1 hour. After it was cooled, the product was extracted with ether, and the ethereal solution was filtered and then evaporated to dryness. When the residue was chromatographed on the adipate polyester column, two major peaks, corresponding in retention time to α-cedrene and thujopsene, were recorded. The second fraction from the preparative run was found to decompose extensively on re-chromatographing on the polyester column; one major (RRT 1.62) and two minor peaks (RRT 1.44 and 1.94) were recorded but all were ill-defined. The infrared spectrum of the collected fraction showed strong absorption bands at 3360, 2900, 1675, (1650), 1460, and 1377 cm^{-1} and medium ones at 885, 875, 815, and 705 cm^{-1}. The ultraviolet spectrum showed a broad maximum at 245 mμ. The third fraction was composed of the component having RRT 3.80 on the polyester column. It had a weak infrared spectrum with absorption bands at 2960, 2925, 1665, 1618, 1455, 1435, 1387–1372, 1355, 1295–1285, 1200, and 885–870 cm^{-1}. Its ultraviolet spectrum showed a maximum at 235 mμ with a weak shoulder at 282 mμ.

Fraction IV: β-Sitosterol

This fraction crystallized on reducing the volume of solvent. Recrystallization from methanol gave white plates of β-sitosterol, m.p. 138–139° C, acetate m.p. 132–133° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Fraction V: Savinin

The yellow sirup obtained on evaporation of the solvent was taken up in acetonitrile and allowed to stand at 2–5° C for several days. A crystalline substance, m.p. 135–140° C, was obtained which was recrystallized twice from ethanol; m.p. 146–147° C, $[\alpha]_D^{25}$ −82.3° (*c*, 0.6, $CHCl_3$). Found: C, 68.50%; H, 4.75%; molecular weight (Rast), 362. Calculated for $C_{20}H_{16}O_6$: C, 68.18%; H, 4.58%; molecular weight, 352.

The compound is sparingly soluble in cold alcohol, insoluble in cold aqueous sodium hydroxide solution, and was recovered unchanged on acidifying an alcoholic solution containing sodium hydroxide. The ultraviolet spectrum showed maxima at 334, 294, and 237 mμ and minima at 306 and 266 mμ and alkaline solutions fluoresced strongly. The infrared spectrum had strong carbonyl absorption bands at 1740 and 1640 cm^{-1}. The position of these bands did not change on standardizing the infrared spectrophotometer against indene or polystyrene film. The authentic sample of savinin, m.p. 146.2–147.3° C, $[\alpha]_D^{22}$ −88.2°, also gave absorption bands at 1740 and 1640 cm^{-1} with the standardized instrument.

Acidic Components

Both the fractions obtained from the aqueous bicarbonate (fraction A) and sodium hydroxide solutions (fraction B) were investigated for the presence of tropolones. The paper chromatographic procedure of Wachtmeister and Wickberg (12) did not reveal any thujaplicins or nootkatin. A number of weak spots corresponding to phenols (ferric chloride color reaction) were obtained with butanol – acetic acid – water (4:1:2) as solvent.

The acid fraction B (see above) was triturated twice with ligroin (250 ml each) and the solution was decanted from the insoluble residue. The solution was extracted with aqueous sodium carbonate solution. The alkaline solution was separated, acidified with dilute hydrochloric acid, and extracted with ether. The ethereal solution was dried, filtered, and evaporated. The residue (5.0 g) was chromatographed on a column of silicic acid when three distinct fractions were collected. Paper chromatography again showed the absence of tropolones.

The carbonate-extracted ligroin solution was dried over anhydrous sodium sulphate and, after filtration, evaporated to dryness. The residue (17.5 g) was chromatographed on silicic acid. The major portion was eluted with ligroin (b.p. 40–60° C) and the residue obtained on evaporating the solvent (12.5 g) crystallized from acetone–ligroin in rectangular plates, m.p. 121–122° C; $[\alpha]_D^{25}$ +40.3° (*c*, 0.6, $CHCl_3$). Found: C, 79.31%; H, 9.97%; COOH, 15.23%. Calculated for $C_{20}H_{30}O_2$: C, 79.42%; H, 10.00%; COOH, 15.0%. The acid formed a cyclohexylamine salt from which the free acid could be regenerated. Treatment with diazomethane gave the crude methyl ester, m.p. 101–102° C. On recrystallization twice from methanol, the melting point was raised to 108–109° C. Found: C, 79.64%; H, 10.08%; $[\alpha]_D^{26}$ +50.5° (*c*, 2%, $CHCl_3$). Calculated for $C_{21}H_{32}O_2$: C, 79.70%; H, 10.19%. The methyl ester could not be hydrolyzed, even on prolonged treatment with potassium hydroxide in 2-methoxyethanol at 125° C. Microhydrogenation in methanol – acetic acid (4:1) with platinum oxide gave a hydrogen uptake of 3 mole equivalent. The maleic anhydride adduct of the methyl ester was prepared in the usual manner; m.p. 171° C, $[\alpha]_D$ +79.5°. Arya *et al.* (11) report for the methyl ester m.p. 105–106° C, $[\alpha]_D$ +47.0° and for the maleic anhydride adduct, m.p. 169–171° C, $[\alpha]_D$ +85°. Hydrogenation of the methyl ester in methanol over platinum oxide gave the hexahydro derivative. Found: C, 78.39%; H, 11.50%; $[\alpha]_D^{25}$ +50.75° (*c*, 1.2, $CHCl_3$). Calculated for $C_{21}H_{36}O_2$: C, 78.26%; H, 11.8%. This methyl ester could also not be saponified.

Ether-soluble Material

The resinous residue (465 g) after ligroin extraction was extracted twice with boiling ether (1 liter) and the ether was decanted from the viscous residue. The extract was filtered and concentrated (500 ml). A small aliquot was evaporated to dryness and the total yield was calculated to be 60 g. The ethereal solution was then successively extracted with 5% aqueous solution of sodium carbonate (fraction D) and sodium hydroxide (fraction E), washed with water, dried over sodium sulphate, and the solvent was distilled off (fraction F).

Fractions D and E (40.0 g)

On acidification a bright red oil was obtained which was taken up in ether. Attempts to crystallize the material failed. With alcoholic ferric chloride solution a bright green color was obtained. Paper chromatography (12) did not reveal the presence of any thujaplicins or nootkatin.

Fraction F (10.0 g)

On long standing the concentrated solution in ethanol deposited yellow prisms (0.2 g), m.p. 142–144° C. The infrared spectrum was similar to that of savinin in all respects and the mixed melting point was undepressed.

Acetone-soluble Residue (350 g)

The residue was taken up in acetone (1.5 liter) and allowed to stand in the cold for several weeks when a small quantity (10 g) of microcrystalline brown material was deposited. The filtered and dried material gave a positive ferric chloride reaction. Its infrared spectrum confirmed the phenolic character.

Extraction and Analysis of the Bark

The finely powdered bark (2.1 kg) was extracted continuously with ligroin (b.p. 60–80° C) in a Soxhlet extractor for 24 hours. The soluble material (71 g) was divided into neutral (41 g) and acidic (26 g) fraction as above.

Neutral Components

Silicic acid chromatography (see above) gave again five fractions. The first fraction (3.0 g) was composed of sesquiterpene hydrocarbons and a small amount of the esters of fraction 2. The sesquiterpenes were purified by distillation *in vacuo*. GLC analysis gave seven peaks with RRT, 0.85, 1.00, 1.19, 1.62, 1.76, 2.29, and 2.50 in 1, 63, 21, 8, 2, 1, and 3% amounts respectively. The two major peaks corresponded in retention time to α-cedrene and thujopsene. However, permanganate oxidation did not give the expected α-cedrene diol. Selenium dioxide oxidation gave a liquid aldehyde which showed a single peak with retention time equal to thujopsenal on GLC analysis.

The second fraction (20 g) was composed of fatty acid esters and was again found to yield β-sitosterol, m.p. 136–137° C, and a mixture of fatty acids on saponification. Fraction 3 (5.0 g) differed from fraction III of the neutrals of the wood. The infrared spectrum indicated esters of long-chain fatty acid. Saponification with alcoholic sodium hydroxide gave a sesquiterpene alcohol fraction (infrared, GLC) and a fatty acid mixture in which two C_{20} acids predominated. GLC analysis of the derived methyl esters showed the C_{16}, C_{18}, and C_{20} acids to be present in the ratio of 1:2.5:3. From the mixture of acids a crystalline product, m.p. 65–70° C, was obtained in small yield. GLC analysis of this material showed it to be composed mainly of arachidic acid, with palmitic and stearic acid as contaminants. The fourth fraction (3.0 g) was divided into a volatile (b.p. 140–160° C at 3 mm) and a non-volatile component. The latter (0.6 g) crystallized from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ligroin in colorless needles, m.p. 136–137° C undepressed in admixture with β-sitosterol, m.p. 137–138° C. The infrared of the volatile material showed bands in the hydroxyl and carbonyl region. GLC analysis showed a similar mixture of ketones and alcohols as was obtained from fraction III of the wood neutrals, but the retention times of all components differed from those of the latter. The last fraction (5.0 g), when taken up in a little ethanol, again deposited small amounts of yellow needles of savinin, m.p. 145–146° C after recrystallization.

Acidic Components

The acidic material was chromatographed on silicic acid, using the same solvent as described above. The major portion (15 g) was found to be communic acid (infrared, mixed melting point). The crude acid was converted to the methyl ester with diazomethane and analyzed by GLC on the silicic acid column at 230° C. Only a single peak having the retention time of methyl communate was recorded. Three small viscous fractions were also obtained from the chromatogram, none of which crystallized. The last two gave a positive color reaction for phenols with ferric chloride solution.

ACKNOWLEDGMENTS

The authors wish to thank Prof. H. Erdtman and co-workers for the gift of samples of terpenes and the many useful suggestions made during the discussion of our findings. Thanks are also due to Drs. J. L. Hartwell and A. W. Schrecker for the sample of savinin, to Mr. M. Granat for technical assistance, to Mr. M. Mazurek for the microanalyses, and to Miss I. M. Gaffney for recording the infrared spectra.

THE CONSTITUTION OF A HEMICELLULOSE OF CHERRY WOOD (PRUNUS AVIUM L. VAR. BING)[1]

G. G. S. DUTTON AND SHIRLEY A. MCKELVEY

The hemicellulose isolated by direct alkaline extraction of the wood has been shown to be a 4-*O*-methyl-D-glucuronoxylan. Methylation data indicate a backbone of approximately 110 D-xylopyranose units linked by β, $1 \rightarrow 4$ bonds with single units of 4-*O*-methyl-D-glucuronic acid linked by α, $1 \rightarrow 2$ bonds. The proportion of acid units to xylose is approximately 1:7. 2,3-Di-*O*-methyl-D-lyxose was isolated as an artifact.

In a recent paper (1) attention was drawn to the fact that many of the wood hemicelluloses which have been studied are those from trees of commercial importance for the purpose of pulping. The present paper is concerned with the hemicellulose of cherry wood and is complementary to our recent study on apple wood hemicellulose (1).

Cherry wood was reduced to sawdust in a Wiley mill and extracted first with hot ethanol–benzene (1:2) and then with sodium hydroxide (0.1 *N*). The hemicellulose was extracted with sodium hydroxide (1 *N*), following the method of McDonald (2), and was recovered by pouring the solution into acidified ethanol. The yield was about 22%, based on air-dry wood, and a typical preparation had $[\alpha]_D$ $-28°$, raised to $-38°$ after one reprecipitation, and an ash content of 8%.

A portion of the hemicellulose was hydrolyzed with sulphuric acid and resolved by means of ion-exchange resins into a neutral and an acidic portion. The neutral portion contained mainly D-xylose characterized as the crystalline sugar together with small amounts of D-glucose and traces of rhamnose. D-Glucose was characterized as *N*-(*p*-nitrophenyl)D-glucosylamine and rhamnose by chromatography and electrophoresis. The acidic portion appeared from chromatography to be mainly one aldobiouronic acid which was characterized as the crystalline methyl 2-*O*-[methyl(2,3-di-*O*-acetyl-4-*O*-methyl-α-D-glucopyranosyl)uronate]-3,4-di-*O*-acetyl-D-xylopyranoside. The aldobiouronic acid is thus 2-*O*-(4-*O*-methyl-α-D-glucopyranosyl uronic acid)-D-xylopyranose, which is now known to occur widely (3).

A portion of the hemicellulose was methylated first by Haworth's method and then by Purdie's. Fractional precipitation with petroleum ether from chloroform showed the product to be homogeneous, as shown in Table I. Fraction 4 was cleaved with methanolic hydrogen chloride and separated into neutral and acidic components as previously described (4).

Chromatographic examination of the acidic portion showed only one component corresponding to a partially methylated aldobiouronic acid. Accordingly, this compound was esterified and reduced with lithium aluminum hydride; however, the resulting neutral disaccharide glycoside did not crystallize as anticipated (4). Acid hydrolysis gave 3-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-glucose, each characterized as their crystalline *N*-phenyl glycosylamines.

The neutral sugar glycosides were hydrolyzed with sulphuric acid and the resulting sugars separated on a column of cellulose–hydrocellulose using butanone–water (5).

[1]*Manuscript received August 18, 1961.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver, B.C. The material in this paper was presented at the 138th American Chemical Society meeting in New York, September, 1960, and is taken from a thesis presented for the M.Sc. degree by Miss S. A. McKelvey, October, 1960.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Initially, six fractions were obtained with a recovery of 92% but three of these were mixtures and were separately rechromatographed. The final fractions obtained are shown in Tables II–V. Components 1,4 and 7 were 2,3,4-tri-*O*-methyl-D-xylose, identified chromatographically; 2,3-di-*O*-methyl-D-xylose, identified as the crystalline sugar and the crystalline *N*-phenyl glycosylamine; and a mixture of 2- and 3-*O*-methyl-D-xylose, identified by electrophoresis. Component 2 yielded only 2,3-di-*O*-methyl-D-xylose on hydrolysis and was therefore 4-*O*-(2,3-di-*O*-methyl-D-xylopyranosyl)-2,3-di-*O*-methyl-D-xylose. The high positive rotation indicated an alpha linkage and suggested that this was a reversion product (1).

Component 5 amounted to about 10% of the mixture and had $[\alpha]_D$ −36.6° (*c*, 0.85 in water). The sugar crystallized spontaneously and on recrystallization from ethyl acetate had m.p. 113–117° C. The derived *N*-phenyl glycosylamine was crystalline but difficult to purify and had m.p. 107.5–113.5° C. Complete methylation of this derivative (6) yielded a sirup which, on hydrolysis, gave a compound with R_f 0.77 (butanone–water). These results were not consistent with any D-xylose derivative. Attempted demethylation with hydrobromic acid (7) led to extensive degradation but reaction with boron trichloride (8) gave a clean product chromatographically identical with lyxose. A mixed melting point with a sample of 2,3-di-*O*-methyl-D-lyxose showed no depression, thus confirming the identification of component 5. A re-examination of the sugars produced on hydrolysis of the original polysaccharide failed to reveal the presence of any lyxose. The 2,3-di-*O*-methyl-D-lyxose was undoubtedly produced by epimerization of 2,3-di-*O*-methyl-D-xylose caused by the free base (ca. 0.3%) present in the barium carbonate used to neutralize sulphuric acid. It is of interest that an unknown dimethylpentose with the same characteristics as those described here has been isolated from the methylated "squeegee" fraction of wheat flour (9). In this instance an ion-exchange column was used for neutralization and even with careful washing such columns are known to bleed traces of alkali. It is perhaps worth noting that, in the present work and that on the wheat flour, columns of cellulose–hydrocellulose were used. Superior resolving power has been claimed for these columns (5) and it may well be that this artifact has occurred in other hydrolyzates but has escaped detection.

Component 6 obtained in trace amount was evidently a disaccharide since on hydrolysis it yielded 2,3-di-*O*-methyl-D-xylose, identified chromatographically, and 2-*O*-methyl-D-xylose, identified electrophoretically.

From the weights of the methylated sugars obtained the polysaccharide was calculated to contain 114 xylose units with 17 acid residues per macromolecule. When the ratio of sugars was analyzed by the phenol – sulphuric acid method (10) the figures were 106 and 16. Both of these calculations give a xylose to acid ratio of 7:1, which is in good agreement with that (8:1) computed from the neutralization equivalent of the methylated polysaccharide.

In view of the small amount of monomethylxylose obtained, these results suggest that cherry wood hemicellulose is a linear structure (11, 12, 13). Cherry wood hemicellulose is similar to other glucuronoxylans isolated from deciduous trees but has a higher proportion of uronic acid than sugar maple (14), white birch (15, 16), yellow birch (17), and beech (18) and more closely resembles white elm (19) and apple (1). The present investigation contributes to the study of hemicellulosic materials and, together with the parallel study on apple wood, shows that these two members of the Rosaceae family conform to the general pattern of wood hemicelluloses (3).

EXPERIMENTAL

All evaporations were carried out under reduced pressure and at a bath temperature not exceeding 40° C. Optical rotations were recorded at 22±2° C.

The descending technique was used for paper chromatography with the following solvent systems:

(A) butanone–water azeotrope (20);
(B) ethyl acetate – acetic acid – formic acid – water, 18:3:1:4 (21);
(C) pyridine – ethyl acetate – water, 1:2:2 (22);
(D) 1-butanol–ethanol–water–ammonia, 40:11:19:1 (7);
(E) *s*-collidine (23);
(F) 1-butanol saturated with water (7);
(G) 1-butanol–acetone–water, 4:5:1 (24).

The last solvent system requires that the paper be impregnated with phosphate buffer solution (pH 5). Whatman No. 1 paper was used for all chromatograms except where specified, and sugars were detected with either *p*-anisidine trichloroacetate (7) or aniline phosphate (25).

Paper electrophoresis was carried out with 0.05 *M* sodium borate solution on Whatman No. 1 paper at a voltage of 1000±50 v.

Extraction of Hemicellulose

Cherry wood sawdust (424 g) was extracted for 8 hours with hot ethanol–benzene (1:2). The sawdust was air-dried and then extracted at room temperature with sodium hydroxide (0.1 *N*, 8.8 ml/g of sawdust) for 48 hours and the highly colored solution discarded. The residue was washed with water and air-dried and re-extracted with sodium hydroxide (1 *N*, 8.6 ml/g) for 48 hours at room temperature. The alkaline solution was filtered and the residue washed with water. The hemicellulose was precipitated by pouring the solution into ethanol acidified with acetic acid. The yield (determined on an aliquot) was 22% of the air-dried wood. The hemicellulose had $[\alpha]_D$ −28° (*c*, 1 in 8% NaOH) raised to $[\alpha]_D$ −38° after one reprecipitation. Ash content was 7.8%.

Hydrolysis of the Hemicellulose

Hemicellulose (30 g) was hydrolyzed with *N* sulphuric acid (1 liter) on the steam bath for 16 hours. The residue (4.8 g) was removed by filtration and the filtrate neutralized with barium carbonate. The filtrate was passed through Amberlite IR-120 and Duolite A-4 and the eluate containing the neutral sugars evaporated to a sirup (24.4 g). The acidic components were eluted from the anion exchange resin with sodium hydroxide (1 *N*, 75 ml) and the solution deionized by passage through fresh Amberlite IR-120. Concentration of the acidic eluate gave a sirup (2.2 g).

Identification of Neutral Sugars

Paper chromatography of the neutral sirup in solvents A, B, D, F, and G showed predominantly xylose with small amounts of glucose and rhamnose. When the sirup was dissolved in ethanol the D-xylose crystallized and after recrystallization from ethanol had m.p. and mixed m.p. 146–147.5° C, $[\alpha]_D$ 17.7° (*c*, 0.78 in water).

The mother liquor from the initial crystallization of the D-xylose was streaked on 10 sheets of Whatman No. 3MM (6 in.×22 in.) and the sheets developed in solvent B for 20 hours. The area corresponding to glucose was eluted with three 100-ml portions of water. Evaporation gave a sirup (80 mg), $[\alpha]$ 36° (*c*, 1.6 in water), which was chromatographically identical with D-glucose in solvent C. The extracted sugar (69 mg) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

p-nitroaniline (61 mg) were dissolved in methanol (2 ml) containing one drop of concentrated hydrochloric acid and the solution heated on the steam bath for 5 minutes. On evaporation of part of the solvent the *N*-(*p*-nitrophenyl) D-glucosylamine crystallized and on recrystallization from methanol had m.p. 173–175.5° C (26). A standard derivative had m.p. 174.5–176.5° C and a mixed melting point gave 173–176° C. The corresponding derivative (m.p. 205–207.5° C) was prepared from D-galactose for comparison. The trace of rhamnose was not separated but was identified by chromatography (R_f 0.33 in solvent G) and by electrophoresis (M_g 0.47).

Identification of the Aldobiouronic Acid

Chromatographic examination of the acidic fraction in solvent B indicated that it was essentially an aldobiouronic acid (R_{xylose} 0.97) together with some free uronic acid (R_x 1.13) and a trace of material with R_x 0.72. The acidic portion was streaked on Whatman No. 1 and developed in solvent B for 16 hours. Elution of the aldobiouronic acid (R_x 0.97) gave a sirup (323 mg) which was dissolved in methanol (28 ml) to which was added methanolic hydrogen chloride (5%, 26 ml). The solution was refluxed for 10 hours and the ester glycoside recovered as a sirup (307 mg), which was acetylated. The yield of methyl 2-*O*-[methyl (2,3-di-*O*-acetyl-4-*O*-methyl-α-D-glucopyranosyl) uronate]-3,4-di-*O*-acetyl-D-xylopyranoside was 75 mg with m.p. and mixed m.p. 193–195° C (27).

Methylation of the Hemicellulose

Hemicellulose (22 g) was dissolved in sodium hydroxide solution (8%, 100 ml) and solid sodium hydroxide (31.4 g) added. The polysaccharide was methylated at 50° C by the dropwise addition of dimethyl sulphate (300 ml) and sodium hydroxide (30%, 900 ml) over one and a half hours with the periodic addition of acetone to control foaming. When the flask was heated in a boiling water bath to decompose excess methyl sulphate the partially methylated material separated as a curd on the top of the solution and was readily filtered off. The curd, which contained much inorganic matter, was repeatedly extracted with boiling methanol and evaporation of the solvent after filtration gave the partly methylated polysaccharide (20.9 g). This material was methylated with Purdie's reagents, initially using methanol as a solvent (twice), then acetone, and finally only methyl iodide. The material thus obtained (10.3 g) was dissolved in chloroform (100 ml) diluted with diethyl ether (100 ml) and fractionally precipitated by the addition of petroleum ether to a mechanically stirred solution. The results are shown in Table I. Fractions 1 and 2 contained inorganic matter and were discarded. Fractions 3–5, which initially precipitated as oils, were separately redissolved in chloroform (15 ml) and precipitated as white flocculent solids by pouring the solution into petroleum

TABLE I

Fractional precipitation of methylated cherry wood hemicellulose

Fraction	Total petroleum ether added, ml	Weight, g	$[\alpha]_D^{25}$ ($CHCl_3$)	Methoxyl, %
1	150	—	—	—
2	170	—	—	—
3	200	1.02	−60.0°	39.2
4	275	2.27	−60.0°	39.1
5	350	2.01	−47.1°	38.2
6	450	0.37	—	—
7	550	0.19	—	—
8	—	1.17	—	—

ether (200 ml). Infrared analysis of these fractions showed the absence of a hydroxyl band. Fractions 6 and 7 could be obtained only as oils and fraction 8 was obtained by evaporating the mother liquor from fraction 7 to dryness.

The neutralization equivalent was determined by dissolving a portion of the methylated hemicellulose (211 mg, fraction 3) in potassium hydroxide (0.0810 *N*, 5.00 ml) and back titrating with sulphuric acid (0.1000 *N*) after 4 hours using a pH meter. The titer was 2.65 ml corresponding to an equivalent weight of 1510. Other samples gave 1665 and 1490.

Methanolysis and Hydrolysis of the Methylated Hemicellulose

Fraction 4 (2.27 g) was dissolved in methanolic hydrogen chloride (3%, 50 ml) and the solution refluxed on the steam bath for 7 hours when the optical rotation was constant, $[\alpha]_D$ 70°. The solution was neutralized with lead carbonate, centrifuged, and evaporated to a thick sirup of the methyl glycosides (2.25 g). The methyl esters were saponified with barium hydroxide, volatile highly methylated glycosides were extracted with petroleum ether, and the mixture separated on ion-exchange columns into acidic components (0.478 g) and neutral components (1.69 g) as previously described (4).

Identification of the Acidic Portion

The acidic component (478 mg) was dissolved in methanol (25 ml) and treated with an excess of ethereal diazomethane. The ester (339 mg) was dissolved in tetrahydrofuran (12 ml) and a solution of lithium aluminum hydride (0.5 g) in dry tetrahydrofuran (20 ml) added. The reaction was completed by refluxing for 1 hour when excess hydride was decomposed by the addition of an ethereal solution of ethyl acetate. The reduced material was acetylated without isolation and the acetate (367 mg) deacetylated with aqueous methanolic sodium hydroxide to give the neutral disaccharide glycoside (229 mg) as previously described (4). Since the disaccharide did not crystallize, even on seeding, it was identified as follows. The disaccharide (221 mg) was dissolved in methanolic hydrogen chloride (3%, 10 ml) and refluxed for 5 hours. After neutralization (Ag_2CO_3), treatment with hydrogen sulphide, filtration, and evaporation, there was obtained a clear sirup (208 mg) which was dissolved in sulphuric acid (1 *N*, 5 ml) and heated on the steam bath for 6 hours. The solution was neutralized by passage through Duolite A-4, and concentration of the effluent gave a sirup (215 mg) which was separated on a cellulose–hydrocellulose column using butanone–water and a collecting time of 20 minutes (5). The faster-migrating component (tubes 9–21, 75 mg) was chromatographically identical with 2,3,4-tri-*O*-methyl-D-glucose and had $[\alpha]_D$ 81.6° (*c*, 1.5 in water). Literature (28) $[\alpha]_D$ 86°. The 2,3,4-tri-*O*-methyl-*N*-phenyl-D-glucosylamine was recrystallized from ethyl acetate – petroleum ether and had m.p. 141–143° C undepressed by an authentic sample (29).

The contents of tubes 60–78 gave a colorless sirup (39 mg) electrophoretically identical with 3-*O*-methyl-D-xylose and having $[\alpha]_D$ 22.3° (*c*, 0.78 in water). Literature (30) $[\alpha]_D$ 17°. The 3-*O*-methyl-*N*-phenyl-D-xylosylamine was recrystallized from ethyl acetate – petroleum ether, m.p. 130–131° C.

Identification of the Neutral Sugars

The neutral glycosides (1.69 g) were dissolved in sulphuric acid (1 *N*, 60 ml) and heated on the steam bath for 8 hours. After neutralization ($BaCO_3$) and evaporation, there was obtained a sirup (1.57 g), part of which (1.24 g) was dissolved in butanone–water (2 ml); a few drops of Sudan IV dye were added. The solution was added to the

top of a column (40×3 cm) packed with a 1:1 mixture of cellulose and hydrocellulose (5). Solvent A was used for elution and the effluent was collected at 10-minute intervals

for 117 tubes and then at 30-minute intervals for 18 tubes. Fractions A–F were obtained with a 92% recovery but, of these, B, D, and E contained mixtures and were separately passed through the column again. Pooling the tubes which, by paper chromatography, had been shown to contain similar materials resulted in establishing the presence of eight sugars. The details of these separations are shown in Tables III–V.

TABLE III

Reseparation of fraction B of neutral sugars of hemicellulose

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Component 1.—Chromatographically identical with 2,3,4-tri-*O*-methyl-D-xylose.

Component 2.—Acidic hydrolysis of the contents of tube 30 from the reseparation of fraction B gave only 2,3-di-*O*-methyl-D-xylose. Since the specific rotation of tubes 22–29 was 77.5° (*c*, 0.64 in water) component 2 was assumed to be 4-*O*-(2,3-di-*O*-methyl-α-D-xylopyranosyl)-2,3-di-*O*-methyl-D-xylose.

Component 3.—Acid hydrolysis gave no change. It gave an unusual green color with aniline phosphate spray and was chromatographically unlike 2,3,4,6-tetra-*O*-methyl-D-galactose.

Component 4.—The sirup crystallized spontaneously and after recrystallization from ethyl acetate – petroleum ether had m.p. 98–101° C and $[\alpha]_D$ 21.4° (*c*, 0.58 in water). The mixed melting point was undepressed with an authentic sample of 2,3-di-*O*-methyl-D-xylose with m.p. 95–100° C. The derived 2,3-di-*O*-methyl-*N*-phenyl-D-xylosylamine had m.p. 121–123° C. Literature (31) m.p. 120–122° C.

Component 5.—This was unchanged by acid hydrolysis and did not migrate on electrophoresis. The sirup crystallized spontaneously and on recrystallization from ethyl acetate had m.p. 113–117° C, $[\alpha]_D$ −36.6° (*c*, 0.85 in water). OMe, calculated for a dimethylpentose 34.8%. Found, OMe 34.5%. The reported constants for 2,3-di-*O*-methyl-D-lyxose are m.p. 116–117° C, $[\alpha]_D$ −10.7° (*c*, 0.3 in water) and a mixed melting point of an authentic sample of this compound with component 5 gave no depression (32).

The derived 2,3-di-*O*-methyl-*N*-phenyl-D-lyxosamine had m.p. 107.5–113.5° C. Literature (32) 107–108° C. When this compound (50 mg) was methylated with methyl iodide (10 ml) and silver oxide (200 mg) the recovered fully methylated anilide (41 mg) did not crystallize (9). Hydrolysis of a small portion (33) and chromatographic analysis in solvent A gave a compound with R_f 0.77.

Two attempts to demethylate component 5 using hydrobromic acid (7) led to extensive degradation. Demethylation using the boron trichloride procedure (8) gave a clean product which was readily shown to be identical with lyxose both by chromatography in solvent G (R_f 0.25) and by electrophoresis (M_g 0.83).

Component 6.—This was evidently a disaccharide since hydrolysis of the contents of tube 74 from the reseparation of fraction E gave 2,3-di-*O*-methyl-D-xylose and a monomethylxylose (by chromatography). The latter was shown by electrophoresis to be 2-*O*-methyl-D-xylose (M_g 0.37).

Component 7.—Electrophoresis showed this to be a mixture of 2- and 3-*O*-methyl-D-xylose in which the former predominated.

Qualitative Analysis

The composition of the contents of tubes containing two components was computed from optical rotations and these weights added to the weight of the appropriate pure component previously isolated. Making allowances for the mechanical losses involved in the reseparations the weights of sugars obtained were in the ratio of 2:94:1:17 for mono-, di-, and tri-*O*-methylpentose and aldobiouronic acid respectively.

Standard curves were prepared for the phenol – sulphuric acid method (10) using 2-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, and 2,3,4-tri-*O*-methyl-D-xylose. Each sugar gave a linear plot over the range 0–35 micrograms/ml and the curves for the mono- and di-*O*-methyl-D-xyloses were virtually identical with an O.D. 0.275 for 35 microgram/ml. The tri-*O*-methyl-D-xylose gave an O.D. of 0.40 for 20 microgram/ml. A portion of the neutral methylated sugars was streaked on a sheet of Whatman No. 1 (6 in.×22 in.) and developed in butanone–water. Appropriate sections of the paper were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

eluted each with 20 ml of water. These solutions had to be diluted 1:1, 1:100, and 1:3 for the estimation of the tri-, di-, and mono-methylpentoses and the results gave a molar ratio of 1:88:1, respectively.

ACKNOWLEDGMENTS

We are indebted to the National Research Council for continued financial support and one of us (S. A. McKelvey) is grateful for the award of an N.R.C. bursary.

We appreciate the gift of authentic samples from Dr. Elizabeth Percival, Dr. T. E. Timell, and Dr. J. P. Verheijden.

THE ELECTRONIC ABSORPTION SPECTRA OF DIXANTHOGENS[1]

M. L. Shankaranarayana and C. C. Patel

ABSTRACT

The electronic absorption spectra of diethyl, diisopropyl, di-*n*-butyl, and diisoamyl dixanthogens have been studied in polar and non-polar solvents. The compounds exhibit a low-intensity band around 365 mμ and two high-intensity bands around 285 and 242 mμ. The 365 mμ band is assigned, as a result of the solvent studies, to $n \rightarrow \pi^*$ transition and the 285 mμ band to $\pi \rightarrow \pi^*$ transition. The band around 242 mμ may be due to the $n \rightarrow \sigma^*$ transition, since in polar solvents it shows mainly a blue shift.

The available data on the electronic absorption spectra of organic sulphur compounds having thiocarbonyl group are relatively meager in the literature (1, 2). Janssen (2) has reviewed the previous work on sulphur compounds and studied the nitrogen-containing thiones extensively. Recently, the present authors studied the infrared spectra of dixanthogen compounds (3). In this paper, studies on the near-ultraviolet spectra and solvent effect on the various bands exhibited by dixanthogens are described.

EXPERIMENTAL

Diethyl, diisopropyl, di-*n*-butyl, and diisoamyl dixanthogens were prepared, purified, and analyzed as described in an earlier paper (4). The electronic absorption spectra of these compounds were studied in heptane, cyclohexane, ethanol, and acetonitrile solutions on a Hilger spectrophotometer, Model H 700, using 1-cm quartz matched cells. Since these compounds are non-ionogenic, their spectra could not be studied either in an acid or in water medium. The solvents employed were purified by the methods recommended by Weisberger and Proskauer (5). The wavelengths of absorption maxima are recorded in millimicrons and the molar extinction coefficients are expressed in terms of log ϵ.

RESULTS AND DISCUSSION

The peak wavelengths and molar extinction coefficients of ultraviolet absorption maxima for dixanthogens in various solvents are given in Table I. Typical absorption

TABLE I

Peak wavelengths and molar extinction coefficients for dixanthogens in different solvents

curves of diisoamyl dixanthogen in cyclohexane and acetonitrile are given in Fig. 1.

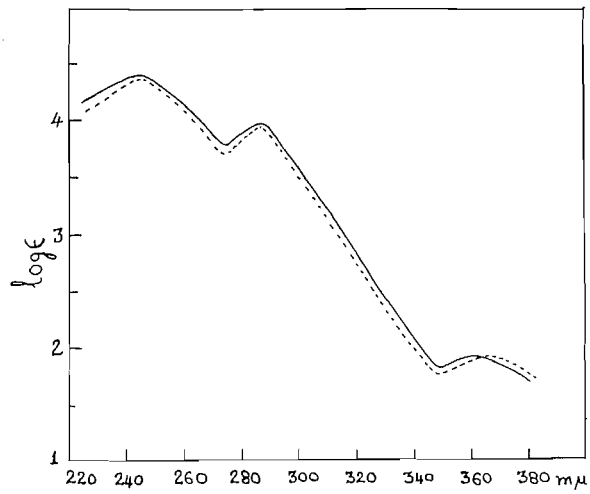

FIG. 1. Ultraviolet absorption spectra of diisoamyl dixanthogen in cyclohexane (- - -) and in acetonitrile (——).

Inspection of the results in Table I shows that all the dixanthogens give three absorption bands. The first low-intensity band is noticed around 365 mμ (log ε 1.9) and two high-intensity bands are observed around 285 mμ (log ε 3.9) and 242 mμ (log ε 4.4.). The molar extinction coefficients (log ε 1.9) for the low-intensity band around 365 mμ compare well with the values given by Treiber (6) and Lowry and Hudson (7) for other dixanthogens. It is well known that the molecules which contain the thiocarbonyl group have a low-intensity absorption band at a longer wavelength similar to the 365 mμ band obtained for the dixanthogens. This band is found to show a blue shift on changing the solvent from a non-polar to a polar solvent. Further, with the increase in the polarity of the solvent, the band shows increased blue shift. This shows that the transition energy involved increases with the increase in the polarity of the solvent. According to an empirical rule (8, 9), this band can be characterized by $n \rightarrow \pi^*$ transition. This absorption is accounted for by the excitation of an electron from the non-bonding lone pair of electrons (n orbital) localized on the double-bonded sulphur into an antibonding π orbital (π^*). Mulliken (10) has pointed out that the thiocarbonyl group has an electronic structure similar to that of the carbonyl group and that the thiocarbonyl absorption regions are expected at wavelengths longer than that of the carbonyl group because the $3p_y$ electron of the sulphur is less firmly bound than that of the $2p_y$ electron of the oxygen. The origin of the $n \rightarrow \pi^*$ blue shift may be attributed to solvation (11) and(or) hydrogen bonding (12) between the non-bonding electrons of the thiocarbonyl group of the solute and the solvent molecules. The $n \rightarrow \pi^*$ blue shift observed, when the solvent was changed from a non-polar to a polar non-hydrogen-bonding (13) acetonitrile, could be explained by the formation of an electrostatic bond between the non-bonding electrons of the thiocarbonyl sulphur atom and the positively charged carbon atom of the nitrile group. Such a bond lowers the energy of the n-electron orbital, and upon excitation, the electrostatic bond is either broken or weakened. A similar explanation has been advanced by Becker (14) to explain the blue shift in the acetonitrile solvent for the $n \rightarrow \pi^*$ band of carbonyl group of benzophenone.

For personal use only.

The intense band around 285 mμ (log ε 3.9) shows a red shift when the solvent is changed from a non-polar to a polar one. A small increase in red shift is observed with the increase in the polar character of the solvents. This band can be ascribed to $\pi \rightarrow \pi^*$ transition (8, 9), where an electron jump occurs from the highest occupied π orbital to the lowest empty (antibonding) π level. A similar band observed around 278 mμ in *s*-ethyl *o*-ethyl xanthate has been assigned as $\pi \rightarrow \pi^*$ transition (2).

The intense band around 242 mμ (log ε 4.4) in dixanthogens is analogous to the 220–250 mμ band exhibited in *s*-ethyl *o*-ethyl xanthate (15), alkali metal xanthates (16), and also in dialkyl disulphides (17). This band in dixanthogens shows mainly a blue shift when the solvent is changed from a hydrocarbon to ethanol and acetonitrile. This band may, therefore, be characterized by $n \rightarrow \sigma^*$ transition. It is expected that the solvent effect on the $n \rightarrow \sigma^*$ transition should be similar to that of the $n \rightarrow \pi^*$ transition but little is known about the solvent effect on this type of transition. The $n \rightarrow \sigma^*$ transition can be explained by the excitation of an electron from the non-bonding lone pair of electrons, localized on the σ-bonded sulphur atoms in the —*s*—*s*— group, to an antibonding level, either 3*d* or 4*s*. This $n \rightarrow \sigma^*$ band assignment finds support from the 225 mμ band of *s*-ethyl *o*-ethyl xanthate, in which case Janssen (2) observed a blue shift to below 215 mμ when concentrated sulphuric acid was used as a solvent.

ACKNOWLEDGMENT

The authors are thankful to Professor M. R. A. Rao for his keen interest in the work.

THE PREPARATION OF ERYTHRO-3-PENTULOSE[1]

R. J. STOODLEY

ABSTRACT

The mercuric acetate oxidation of ribitol yielded a mixture of *erythro*-3-pentulose and DL-erythro-2-pentulose.

INTRODUCTION

The hydroxyl groups of alditols may be oxidized by a variety of chemical procedures. The oxidants may be relatively non-specific, oxidizing both primary and secondary hydroxyl groups, or they may be specific. Non-specific oxidizing agents include Fenton's reagent (1), the halogens (2), and oxygen in the presence of platinum (3). Generally the yield of aldoses and ketoses is low. Nitrogen dioxide (4) and, in some cases, oxygen in the presence of a platinum–carbon catalyst (5) are examples of specific oxidants which oxidize primary alcohol groups to carboxyl groups in reasonable yield. Chromium trioxide has been found to be a valuable reagent for oxidizing secondary alcohol groups to keto groups in alditols, providing all the other hydroxyl groups are suitably blocked (6).

There appears to be no chemical procedure for selectively oxidizing secondary alcohol groups in the presence of unsubstituted primary hydroxyl groups. In some cases, however, this oxidation may be achieved biochemically using *Acetobacter suboxydans*. In fact this organism has been used to prepare 1-deoxy-D-*xylo*-3-hexulose from L-fucitol (7), the preparation being the first recorded for a 3-ketose.

The first chemical synthesis of a 3-ketose was achieved by Jones (8), who prepared 2-*O*-methyl-L-*xylo*-3-hexulose from L-ascorbic acid. In attempting to synthesize an unsubstituted 3-ketose, Sugihara and Yuen (9) prepared crystalline 4-*O*-benzoyl-1,2:5,6-di-*O*-isopropylidene-D-*arabo*-3-hexulose by the chromium trioxide oxidation of 3-*O*-benzoyl-1,2:5,6-di-*O*-isopropylidene-D-mannitol. However, attempts to remove the protecting groups resulted in the formation of a mixture of ketose sugars, presumably because debenzoylation proceeded via an enediol intermediate. Starting with 6-*O*-benzoyl-1,2:4,5-di-*O*-isopropylidene-DL-galactitol, the same authors have recently obtained crystalline DL-*xylo*-3-hexulose (10), realizing the first chemical synthesis of an unsubstituted 3-hexulose.

Schaffer has reported the preparation of D-*manno*-3-heptulose by the lead tetraacetate oxidation of 3-*C*-formyl-D-*glycero*-D-*talo*heptitol (11), and has recently crystallized the material (12).

The isolation of *erythro*-3-pentulose from the mercuric acetate oxidation of ribitol represents the first chemical synthesis of a 3-pentulose. DL-*erythro*-2-Pentulose was also produced, but the failure to detect ribose (or any product obtained by the mercuric acetate oxidation of D-ribose) suggests that the oxidant may be specific for secondary hydroxyl groups.

erythro-3-Pentulose may be an important biological intermediate. D-*erythro*-2-Pentulose 1,5-diphosphate has been shown to be the prime acceptor of carbon dioxide in photosynthesis, and Wilson and Calvin (13) have suggested that its dismutation to phosphoglyceric acid may involve the 3-ketose intermediate. Ashwell and Hickman (14) incubated D-ribose 5-phosphate with a mouse spleen extract and, after dephosphorylating

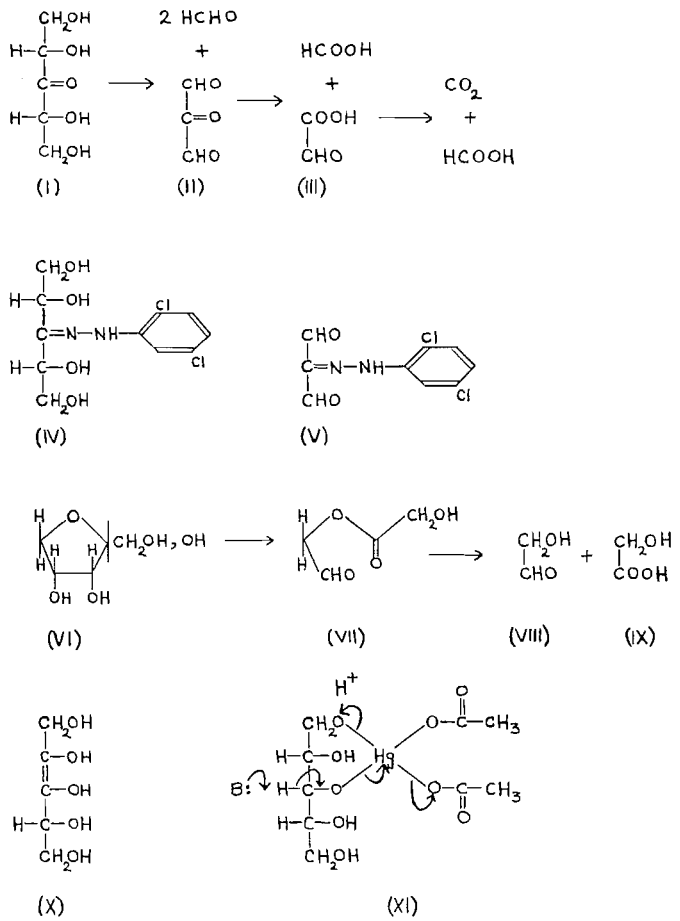
[1]*Manuscript received September 8, 1961.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario.

the products, they isolated D-*threo*-2-pentulose and D-*erythro*-2-pentulose and small amounts of a third material which they tentatively characterized as *erythro*-3-pentulose. They suggested that the phosphorylated 3-ketose was an intermediate in the interconversion of D-*erythro*-2-pentulose 5-phosphate and D-*threo*-2-pentulose 5-phosphate. A similar intermediate was also detected by Dickens and Williamson while they were studying the same reaction using a rabbit muscle enzyme preparation (15).

DISCUSSION

Ribitol was oxidized with mercuric acetate in methanol at 38° C. Removal of the mercury salts after 4 weeks led to the 70% recovery of a syrup which was shown by paper chromatography to contain ribitol and two reducing sugars, distinct from ribose. Part of the ribitol was removed by crystallization and the remaining material was fractionated on an ion-exchange column (16); 50% of the ribitol was recovered in crystalline form.

The faster-moving reducing sugar was obtained in about 18% yield (based on the amount of ribitol oxidized) and was further purified by paper chromatography. The material rapidly reduced Fehling's solution at room temperature and gave a brown coloration with *p*-anisidine. In contrast to the results of Dickens and Williamson (15), the ketose did not give a positive reaction with orcinol – trichloroacetic acid (17) nor when oversprayed (18) with aniline phosphate (19) in the cold. An aqueous solution of the 3-ketose did not react in the cysteine–carbazole assay (20) nor in the supposedly specific 3-pentulose test with cysteine and sulphuric acid developed by Ashwell (21). These results show that the synthetic material is different from the ketose isolated from biological systems.



The sugar was reduced with sodium borohydride and crystalline ribitol was isolated. Examination of the acetylated, reduced syrup by gas–liquid partition chromatography using the procedure of Gunner *et al.* (22) showed the presence of ribitol and xylitol pentaacetates, thus establishing the presence of a keto group at carbon atom 3.

Oxidation of the pentulose with sodium metaperiodate under unbuffered conditions resulted in the rapid liberation of 1.8 moles of formaldehyde. This result demonstrated the presence of two primary alcohol groups in the molecule and left little doubt that the sugar was *erythro*-3-pentulose (I). The consumption of 4.06 moles of periodate and production of 2.05 moles of titratable acid further substantiated this structure. The results indicate that (I) is rapidly cleaved to 2 moles of formaldehyde and mesoxalaldehyde (II), and that the latter molecule is immediately oxidized to formic acid and glyoxylic acid (III). The slower uptake of the fourth mole of periodate (ca. 90 minutes) is consistent with the known rate of oxidation of glyoxylic acid (III) to carbon dioxide and formic acid under unbuffered conditions (23).

The periodate oxidation studies and the presence of a carbonyl absorption in the ultraviolet region (ϵ_{max} 70 at 280 mμ) suggest that the 3-pentulose is in the acyclic form (I) in aqueous solution. However, the ready enolization of the syrup to a mixture of *threo*- and *erythro*-2-pentuloses (which presumably exist as furanose rings) demonstrates the lability of the acyclic structure in the syrupy state.

The pentulose formed a crystalline 2,5-dichlorophenylhydrazone. That enolization did not occur during this reaction was shown by the regeneration of the original pentulose and by periodate oxidation studies. The 2,5-dichlorophenylhydrazone (IV) consumed 2.20 moles of periodate and liberated 0.19 mole of titratable acid and 1.8 moles of formaldehyde. A material presumed to be mesoxalaldehyde-2-(2,5-dichlorophenylhydrazone)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(V) was also obtained. The small uptake of periodate (0.2 mole) and production of formic acid (0.19 mole) in excess of the expected values suggest that (V) is attacked by periodate.

The chemical evidence strongly indicates that the sugar is *erythro*-3-pentulose. It is possible that the material isolated by Ashwell and Hickman and subsequent workers may be D-*glycero*-2,3-pentulose.

The slower-moving reducing sugar was the last component to be eluted from the column and was obtained in about 11% yield (based upon the amount of ribitol oxidized). The product was chromatographically indistinguishable from authentic *erythro*-2-pentulose and contained no *threo*-2-pentulose when examined by paper electrophoresis. The material was estimated by the cysteine–carbazole reaction (20) and characteristic peaks were produced at 540 and 390 mμ. The absorption was measured after 15 minutes and did not change within 2 hours. An authentic specimen of *threo*-2-pentulose increased in absorption during this interval (24).

The pentulose consumed 2.06 moles of periodate and liberated 1.01 moles of formic acid and 0.19 mole of formaldehyde when oxidized under unbuffered conditions for 6 hours. An additional mole of periodate was taken up when the oxidation was performed in phosphate buffer at pH 8 and the formaldehyde liberated increased to 0.93 mole. These results are consistent with the oxidation of *erythro*-2-pentulose in the furanose

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

form (VI) rather than the acyclic form. Presumably the glycolic acid ester of glycolaldehyde (VII) is first formed and is stable under unbuffered conditions, but is hydrolyzed to glycolic acid (IX) and glycolaldehyde (VIII) at pH 8. Glycolic acid (VIII) is known to be stable to periodate (25) while glycolaldehyde (IX) rapidly consumes 1 mole to give formaldehyde and formic acid.

Although there is little information about the mechanism of the oxidation, the ratio of *erythro*-3-pentulose to *erythro*-2-pentulose isolated (approximately 2:1) indicates that the hydroxyl group at carbon atom 3 is more readily oxidized than that at carbon 2 (unless *erythro*-2-pentulose is further oxidized). It seems unlikely that the enediol (X) is an intermediate since *threo*-2-pentulose was not detected in the reaction mixture. If formed, the enediol would be expected to enolize in the direction of the 2-pentuloses (which are presumably stabilized by internal hemiketal formation), especially as the isolated 3-pentulose enolized in this manner.

It is possible to explain the results by predicting the intermediate formation of six-membered rings containing mercury. DL-*erythro*-2-Pentulose may be produced by oxidation of the cyclic intermediate involving the oxygen atoms attached to carbon atoms 2 and 4. The failure to detect ribose (or methyl ribonate) may indicate that the cyclic intermediate involving the primary alcohol is cleaved to *erythro*-3-pentulose as is suggested in (XI).

EXPERIMENTAL

Melting points were determined on a Kofler hot stage and were uncorrected. Solutions were concentrated under reduced pressure at 30–40° C. Paper chromatography was carried out by the descending method on Whatman No. 1 filter paper using the following solvent systems (v/v): (*a*) butan-1-ol, ethanol, water (3:1:1); (*b*) ethyl acetate, acetic acid, formic acid, water (18:3:1:4); and (*c*) butan-1-ol, pyridine, water (10:3:3). Sugars were located on chromatograms by the *p*-anisidine hydrochloride (26) or the alkaline silver nitrate (27) sprays, and their rate of movement is quoted relative to that of D-ribose (R_{rib}). Paper electrophoresis was performed using Whatman 3 MM filter paper impregnated with 0.05 *M* borate buffer (pH 9.2). Sugars were detected on paper electrophoretograms by the periodate–*p*-anisidine spray (28). Infrared spectra were determined on powdered materials dispersed in potassium bromide pellets, using a Perkin–Elmer Model 21 spectrophotometer.

Mercuric Acetate Oxidation of Ribitol (Method A)

Mercuric acetate (42.0 g) was dissolved in hot methanol (250 ml) containing 1% acetic acid. Ribitol (10.0 g) was added to the cooled solution, which was stored in an incubator at 38° C. The mercurous acetate which precipitated was removed by filtration from time to time. After 4 weeks 21.5 g of mercurous acetate was obtained and chromatographic examination of the solution in solvent *b* revealed the presence of two reducing components in addition to unreacted ribitol.

The solution was saturated with hydrogen sulphide and filtered, and the filtrate was concentrated to a syrup (7.03 g) which was dissolved in ethanol and seeded with ribitol. The crystalline material (3.10 g) was collected by filtration and cautiously washed with ethanol; m.p. 100–101° C, undepressed on admixture with authentic ribitol. The filtrate was evaporated to a brown syrup.

Fractionation of the Reaction Mixture

The syrup was fractionated in portions (ca. 1.0 g) on a column of Dowex 50 W X8 (200–400 mesh, Ba^{++}) by the method of Jones and Wall (16). The column (70×2.2 cm)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

was eluted with water and fractions (ca. 3 ml) were collected automatically every 15 minutes. The result of a typical separation is shown in Table I.

TABLE I
Fractionation of sugars

Tube No.	Fraction No.	Suspected component	Weight, g
60–85	1	Ribitol	0.48
86–98	2	Ribitol + *erythro*-3-pentulose	0.05
99–125	3	*erythro*-3-Pentulose	0.23
126–190	4	DL-*erythro*-2-Pentulose	0.14

Characterization of Fraction 1 as Ribitol

The syrup (1.90 g) crystallized on standing. After recrystallization from ethanol, the material melted at 101–102° C, undepressed on admixture with authentic ribitol.

Characterization of Fraction 3 as erythro-3-Pentulose

The fraction was obtained as a pale yellow syrup (0.91 g). Chromatographic examination of the material in solvents *a*, *b*, and *c* showed that it was mainly a single component (R_{rib} 1.23 in solvent *c*), although small amounts of slower-moving materials were also detected. A portion of the syrup was refractionated on Whatman 3 MM paper using solvent *b*. End strips of the chromatogram were sprayed with *p*-anisidine and the requisite area of paper was eluted with water. The solution was lyophilized and the pale yellow syrup obtained was found to be homogeneous when examined in solvents *a*, *b*, and *c*. The material did not give a color with orcinol – trichloroacetic acid (17) nor when oversprayed (18) in the cold with aniline phosphate (19), although, when heated, it developed an orange color. A brown spot was obtained when the sugar was sprayed with *p*-anisidine. The sugar did not react to any significant extent in the cysteine–carbazole assay (20).

When stored in a vacuum desiccator containing silica gel, the syrup slowly darkened and, after 3 weeks, considerable amounts of *erythro*-2-pentulose and *threo*-2-pentulose were detected by paper electrophoresis. The properties of the 3-ketose were therefore determined on a freshly fractionated sample (26.1 mg) which was dissolved in water in a standard flask (25 ml). The solution was stored at 0° C and little enolization of the 3-ketose occurred within 3 weeks.

A solution of *erythro*-3-pentulose rapidly reduced Fehling's solution at room temperature.

Periodate Oxidation of erythro-3-Pentulose

An aliquot of the 3-ketose solution (5 ml equivalent to 5.2 mg of ketose) was added to 0.3 *M* sodium metaperiodate solution (1 ml) and the volume was adjusted to 25 ml with water. A blank was prepared by diluting sodium metaperiodate solution (1 ml) to 25 ml with water. The solutions were stored in the dark at room temperature. Samples (1 ml) were removed at intervals for the determination of the periodate uptake (29) and formic acid production (30). Formaldehyde was determined on aliquots which were diluted fivefold prior to the estimation (31). The results are recorded in Table II.

Ultraviolet Absorption of erythro-3-Pentulose

The ultraviolet absorption of a solution of *erythro*-3-pentulose in water (1.04 mg/ml) was determined with a Beckman Model DK spectrophotometer using 1-cm cells. The spectrum, which is typical of a carbonyl absorption, is shown in Fig. 1.

19.50	4.06	2.05	1.80

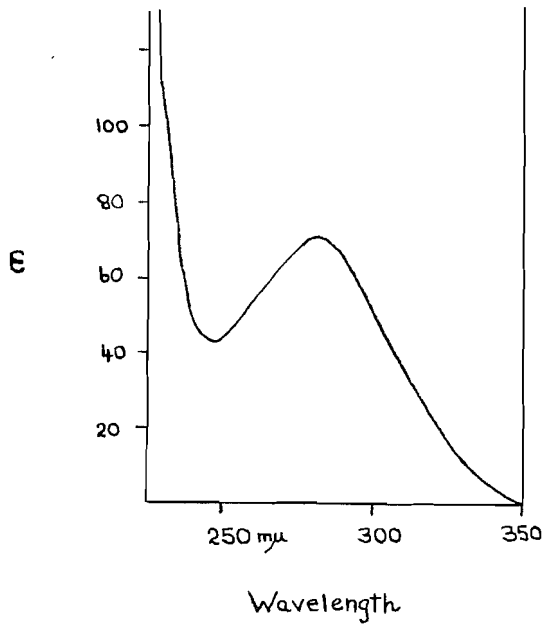

FIG. 1. The ultraviolet absorption spectrum of *erythro*-3-pentulose in water.

Sodium Borohydride Reduction of erythro-3-Pentulose

A portion of the syrup (100 mg) was dissolved in water (3 ml) and the solution was slowly added to a stirred, ice-cold 1% sodium borohydride solution (5 ml). After 1 hour the solution no longer reduced Fehling's solution, and Amberlite IR 120 (H^+) ion-exchange resin was added. The resin was removed by filtration and washed well with water. The filtrate and washings were evaporated to a white residue which was dissolved in methanol and the solution reconcentrated. After three evaporations with methanol, a clear syrup was obtained (95 mg), which partially crystallized. A small volume of methanol was added and the solution was cooled in an acetone – dry ice mixture. The crystals were removed by filtration; m.p. 98–100° C, mixed m.p. with authentic ribitol 99–101° C.

A portion of the syrup (ca. 20 mg) was dissolved in acetic anhydride containing 1% sulphuric acid and the solution was heated on a water bath (80° C) for 4 hours. The reaction mixture was poured into ice water, neutralized with pyridine, and extracted with chloroform. The chloroform extract was washed with dilute sulphuric acid, sodium bicarbonate solution, and water and was dried over anhydrous sodium sulphate. Evaporation of the chloroform left a syrup which was shown to contain ribitol and xylitol penta-acetates by gas–liquid partition chromatography (22).

erythro-3-Pentulose 2,5-Dichlorophenylhydrazone

A solution of the ketose (100 mg) and 2,5-dichlorophenylhydrazine (100 mg) in methanol was allowed to stand in an oven at 80° C. The resulting syrup was dissolved in a small volume of ethyl acetate and chloroform was added until the solution became turbid. Pale yellow crystals (80 mg) were deposited; these were removed by filtration and recrystallized from ethyl acetate – chloroform; m.p. 125–127° C.

Anal. Calc. for $C_{11}H_{14}O_4Cl_2N_2$: C, 42.7; H, 4.5; Cl, 23.0; N, 9.1. Found: C, 42.4; H, 4.8; Cl, 23.0; N, 9.2.

erythro-3-Pentulose was regenerated when the 2,5-dichlorophenylhydrazone was heated with benzaldehyde (cf. Sowden and Fisher (32)).

Periodate Oxidation of erythro-3-Pentulose 2,5-Dichlorophenylhydrazone

The material (8.6 mg) was dissolved in 25% ethanol (20 ml), 0.3 *M* sodium metaperiodate solution (1 ml) was added, and the solution was diluted to 25 ml with water. A bright yellow precipitate, presumably mesoxalaldehyde-2-(2,5-dichlorophenylhydrazone), formed almost immediately and was removed by filtration after 10 minutes. The pale yellow filtrate was used to estimate the periodate uptake and the formic acid and formaldehyde production as previously described. The results are illustrated in Table III.

TABLE III

Periodate oxidation of *erythro*-3-pentulose 2,5-dichlorophenylhydrazone

Time (hour)	Periodate uptake (moles/mole)	Formic acid production (moles/mole)	Formaldehyde production (moles/mole)
0.25	2.16	0.18	1.80
2.50	2.24	0.18	1.71
9.50	2.20	0.22	1.93

The yellow precipitate was recrystallized from aqueous acetone; m.p. 178–185° C. The material was differentiated from hydroxypyruvaldehyde-2-(2,5-dichlorophenylhydrazone), which was obtained by the periodate oxidation of D-fructose 2,5-dichlorophenylhydrazone, by a comparison of their melting points and infrared spectra.

Anal. Calc. for $C_9H_6O_2Cl_2N_2$: C, 44.1; H, 2.5; Cl, 29.0; N, 11.4. Found: C, 44.4; H, 2.6; Cl, 28.5; N, 11.3.

Characterization of Fraction 4 as DL-*erythro-2-Pentulose*

The material (0.58 g) was shown to be homogeneous when examined in solvents *a*, *b*, and *c*. The chromatographic behavior of the sugar was similar to that of *erythro*-2-pentulose, prepared by the epimerization of L-arabinose (33); both gave a red spot with *p*-anisidine (R_{rib} 1.11 in solvent *c*) and a green coloration with orcinol – trichloroacetic acid, which immediately turned pink when oversprayed with aniline phosphate. Paper electrophoresis indicated that the ketose was not *threo*-2-pentulose.

The ketose was estimated by the cysteine hydrochloride – carbazole method (20). The absorption spectrum was measured after 15 minutes and remained unchanged after 2 hours. Authentic *threo*-2-pentulose was also measured by this reaction and the absorption spectrum increased in intensity during the interval (24). The spectra are shown in Fig. 2.

Periodate Oxidation of DL-*erythro-2-Pentulose*

A standard solution of the pentulose was prepared by dissolving the syrup (20 mg) in water in a standard flask (10 ml). An aliquot of the solution (2 ml equivalent to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

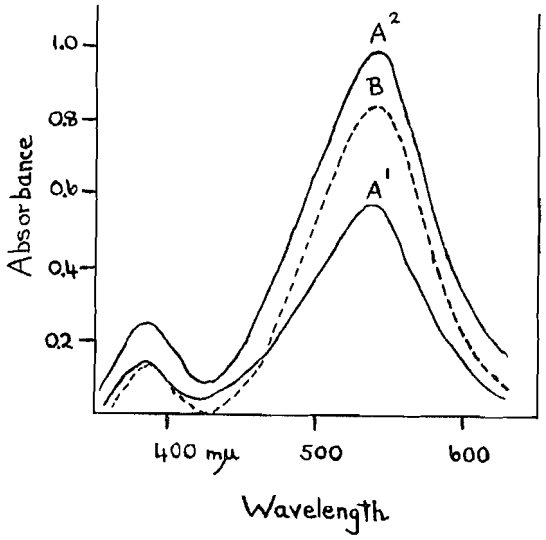

FIG. 2. The visible absorption spectra in the cysteine–carbazole reaction (20) of (A) D-*threo*-2-pentulose (48 γ) after (1) ¼ hour, (2) 2 hours; (B) DL-*erythro*-2-pentulose (43 γ) after ¼ hour and 2 hours.

4.0 mg of ketose) was added to 0.3 *M* sodium metaperiodate solution (0.3 ml) and the solution was diluted to 10 ml with water. The periodate uptake and formic acid and formaldehyde liberation were measured in the manner described previously. The results are shown in Table IV. The oxidation was also performed at pH 8.0 using phosphate

TABLE IV

Mercuric Acetate Oxidation of Ribitol (Method B)

Ribitol (1.00 g) was added to a solution of mercuric acetate (4.2 g) in methanol (25 ml) containing 1% acetic acid. The solution was refluxed on a hot water bath for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

20 hours and the precipitated mercurous acetate (1.8 g) was removed by filtration. The soluble mercury salts were precipitated as their sulphides and the solution was examined by paper chromatography. *erythro*-3-Pentulose and *erythro*-2-pentulose were detected.

2,5-Dichlorophenylhydrazine (0.5 g) dissolved in methanol (10 ml) was added directly to the syrupy mixture (0.90 g) and the solution was evaporated in an oven at 80° C. The syrup was extracted with ethyl acetate and the residual ribitol (0.73 g) was recrystallized from ethanol. Chloroform was added to the ethyl acetate extract and crystalline *erythro*-3-pentulose 2,5-dichlorophenylhydrazone (0.14 g) was obtained; m.p. 124–127° C.

Mercuric Acetate Oxidation of D-*Ribose*

D-Ribose (1.00 g) was oxidized as described for ribitol in method B. The resulting syrup (0.93 g) contained some unreacted ribose and mainly methyl ribonate (detected by paper chromatography). No components corresponding to those obtained in the oxidation of ribitol were detected.

ACKNOWLEDGMENTS

The author wishes to thank Professor J. K. N. Jones for his interest and for helpful discussion. He also thanks the National Research Council for a Studentship.

NOTES

CRYSTAL DATA FOR DIPHENYLARSENICALS

W. R. CULLEN AND J. TROTTER

Very little is known about the detailed structure of arsenic compounds, although it has long been realized that in molecules containing trivalent arsenic the bond arrangement is similar to that found in the layer structure of elemental arsenic (1). The object of the present investigations is to obtain accurate information about the stereochemistry of arsenic by studying compounds containing a variety of substituents; this paper describes the preparation and the determination of the crystallographic data of some diphenylarsenicals.

Bis-diphenylarsenic oxide was prepared from phenyl magnesium bromide and arsenious oxide (2) and recrystallized from 95% ethanol (crystals had m.p. 95°; literature value 92–93°). Chlorodiphenylarsine was obtained by treating the oxide with concentrated hydrochloric acid (2), the resulting oil being separated from the aqueous layer, dried, and purified by distillation at 10^{-3} mm; the fraction boiling at 135–136° was collected. This was a colorless oil which solidified on being cooled in liquid nitrogen, and remained solid on being warmed to room temperature, m.p. 38–40° (lit. value 40–42°). Bromo- and iodo-diphenylarsine were obtained by analogous methods. The bromo derivative boiled at 139–140° (10^{-3} mm) and solidified on being cooled to room temperature. It was recrystallized from 95% ethanol, m.p. 55° (lit. value 52–54°). The iodoarsine was recrystallized from benzene, m.p. 37–39° (lit. value 42–43°).

The unit cell dimensions and space groups of the crystals were determined from single crystal rotation, oscillation, Weissenberg (all with Cu $K\alpha$ radiation, $\lambda = 1.542$ Å) and precession films (Mo $K\alpha$, $\lambda = 0.7107$ Å). These data and other relevant information are given in Table I. Measurement of the densities of the crystals of the halogen derivatives posed a difficult problem, as they were soluble in most organic liquids and were hydrolyzed

by water. However, when a crystal was dropped into an aqueous silver nitrate solution of higher density, it floated on the surface for a few seconds, before sinking, which was apparently due to hydrolysis and subsequent coating with silver halide. By making such

observations in aqueous silver nitrate solutions of various densities, it was possible to obtain approximate values for the densities of all three crystals, these measurements being sufficiently accurate to allow estimations of the number of molecules in the unit cells. The density of the oxide was determined accurately by flotation in aqueous $AgNO_3$ solution.

Crystals of chloro-, bromo-, and iodo-phenylarsine are fairly closely isomorphous; the *b*-axis of the iodo derivative is a little longer than the corresponding axes in the other two compounds, and there is a gradual increase in the length of the *c*-axis and a decrease in the value of the β angle on passing from chloro to iodo. The oxide, not unexpectedly, has a different crystal structure. We hope to carry out detailed analyses of some of these structures.

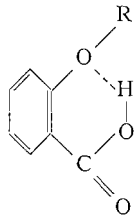
STERIC CONFIGURATION OF THE ETHER GROUP IN ORTHO ALKOXY AND ARYLOXY BENZOIC ACIDS

Owen H. Wheeler



The ether group in ortho alkoxy or aryloxy benzoic acids can assume two configurations (I*a* and I*b*) in which the alkyl or aryl (R) group is directed either away from (as in I*a*) or towards (as in I*b*) the carboxylic acid group. Steric hindrance will be less in the first of these forms, but even so there will be steric crowding between the unshared electrons on the ether-oxygen atom and the carboxylic acid group.

The effect of a para substituent can only be electronic, whereas an ortho substituent exerts both an electronic and steric effect. The electronic effects of ortho and para substituents can be assumed to be approximately the same and any differences between them must be primarily steric in origin (1). The ultraviolet spectra of a number of ortho and para alkoxy (I, R = Me, Et) and aryloxy (I, R = Ph) benzoic acids has been measured (Table I) in relation to those of the corresponding alkyl and aryl benzoic acids (II, R = Me, Et, Ph) to determine the magnitude of the ortho steric effect in relation to the configuration of the ethers.

TABLE I

Ultraviolet spectra of benzoic acids*

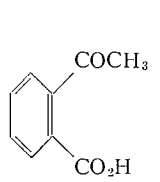
‖Ref. 6 gives *o* λ_{max} 245 (11,800), *p* 264.5 (26,000).
¶Inflection.

Comparing the methyl and ethyl benzoic acids, it can be seen that an ortho ethyl group, due to the extra carbon and hydrogen atoms, had a greater steric effect since *o*-ethylbenzoic acid showed a slightly hypsochromic shift and the ratio of intensities of ortho to para isomer was much less. However, in the case of the two alkoxy benzoic acids, *o*-ethoxybenzoic acid actually showed a small bathochromic shift, while *o*-methoxybenzoic acid had no displacement with respect to benzoic acid. Moreover, the ratio of the intensities of ortho to para isomers was essentially the same for the methoxy and ethoxy compounds. This similarity in steric effect of the methoxy and ethoxy groups is only possible if the alkoxy benzoic acids assume the configuration I*a*, in which the steric hindrance is due primarily to the unshared electrons on the ether-oxygen atom.



In the cases of the ortho phenyl and phenoxy compounds, the phenyl groups can be better accommodated by twisting of this ring with respect to the other. Nevertheless, the steric hindrance of the phenoxy derivative was much less than for the phenyl compound, again supporting the configuration I*a*.

The infrared absorption of *o*-methoxybenzoic acid has been shown to be anomalous (2) since it has a sharp hydroxyl peak at 2.96 μ and the carbonyl peak at 5.76 μ (the para isomer had hydroxyl broad 3.4–3.6 μ and carbonyl at 5.93 μ) and this was attributed to internal hydrogen bonding as in I*c*. *o*-Ethoxybenzoic acid had hydroxyl 2.98 μ medium, 3.4–3.5 μ weak, and carbonyl 5.74 μ strong, 5.91 μ medium, whereas *o*-phenoxybenzoic acid had hydroxyl 2.94 μ weak, 3.4–3.6 μ medium, and carbonyl 5.72 μ medium, 5.88 μ strong (*p*-ethoxy- and *p*-phenoxy-benzoic acids had hydroxyl 3.4–3.6 μ and carbonyl

5.95 μ). This suggests that the amount of the hydrogen-bonded form was less in the case of the *o*-ethoxy acid and still less in the *o*-phenoxy acid, the difference being probably due to the increasing steric size of the substituent.

During the course of this work *o*-acetylbenzoic acid was prepared and it showed λ_{max} 230 mμ, ϵ 10,700,275 (inflection), ϵ 2500 and 282 mμ, ϵ 2400. The main maximum is more characteristic of a benzoic acid (λ_{max} 230 mμ, ϵ 10,000 (1)) than an acetophenone (λ_{max} 240 mμ, ϵ 13,000), although the other maxima are not consistent with the simple structure III*a* and the compound probably exists in solution as the lactol III*b* (cf. phthalide λ_{max} 227 mμ, ϵ 9900; 273, ϵ 1720; and 280, ϵ 1660 (3)). (We are grateful to the referee for pointing out this possibility.) The abnormal infrared carbonyl band (at 5.63 μ) also supports the lactol structure (cf. ref. 4).

EXPERIMENTAL

Benzoic acids.—*o*-Phenoxybenzoic acid was prepared by treatment of phenyl salicylate with sodium (7) and *o*-phenylbenzoic acid by reaction of fluorenone with potassium hydroxide in diphenyl ether (8).

o-Ethoxybenzoic acid.—Methyl salicylate (40 g) was added to sodium (11 g), dissolved in anhydrous ethanol (150 ml), cooled to 0°, and ethyl sulphate (75 g) added slowly over $\frac{1}{2}$ hour. The reaction was stirred for 2 hours when it became nearly solid and was allowed to stand for 2 days before water and 10% sodium hydroxide were added. The methyl *o*-ethoxybenzoate, b.p. 103–105° at 20 mm, so formed was hydrolyzed by refluxing overnight with 20% sodium hydroxide to give the acid, b.p. 175–178° at 20 mm (9).

p-Ethoxybenzoic acid.—*p*-Hydroxybenzoic acid was esterified by refluxing with ethanol and sulphuric acid in benzene, and azeotropically removing the water formed to give ethyl *p*-hydroxybenzoate, m.p. 116° from ethanol (lit. m.p. 112.5° (10)), which was converted to *p*-ethoxybenzoic acid, m.p. 193° (lit. m.p. 195–196° (11)) as above.

o-Ethylbenzoic acid.—*o*-Acetylbenzoic acid (12 g), prepared from phthalylacetic acid (12), was refluxed with amalgamated granular zinc (30 g) in concentrated hydrochloric acid (60 ml) and water (50 ml) for 8 hours, giving the acid, m.p. 64° from water (lit. m.p. 65° (13)).

p-Ethylbenzoic acid.—Aluminum trichloride (15 g) was added to ethylbenzene (10.6 g) in carbon disulphide (50 ml) cooled to 0° and oxalyl chloride (16 g) in carbon disulphide (50 ml), then added over $\frac{1}{2}$ hour with cooling in an ice–salt bath (14). The reaction mixture was allowed to stand overnight and was decomposed with 10% hydrochloric acid. The product was extracted from the organic layer with 10% sodium hydroxide and liberated by acidification. The product was recrystallized (charcoal) from water to m.p. 114° (lit. m.p. 113° (15)).

p-Phenylbenzoic acid.—This was prepared as above from diphenyl and had m.p. 232° from ethanol (lit. m.p. 228° (16)).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

p-Phenoxybenzoic acid.—Similar reaction of diphenyl ether gave *p,p*-diphenoxybenzil, m.p. 125° (from acetic acid), which was oxidized with hydrogen peroxide in boiling acetic acid to *p*-phenoxybenzoic acid, m.p. 161° (from ethanol) (lit. m.p. 160° (17)).

Spectra.—The ultraviolet spectra were determined on 95% ethanol solutions using a Beckman D.U. spectrophotometer. The infrared spectra were determined on solutions in carbon tetrachloride using a Baird-Atomic double beam K.2 spectrometer.

STABILITY OF $CoBr^+$ AND $NiBr^+$

M. W. Lister and D. W. Wilson

In a recent paper (1) one of the present writers reported the stability constants for the formation of the complex ions $CoCl^+$, $NiCl^+$, $CuCl^+$, and $CuBr^+$. Some of these constants, particularly that for $CuBr^+$, showed an anomalous variation with temperature; and although some explanations were suggested, no definite conclusion could be reached. The object of the present note is to report similar measurements for the ions $NiBr^+$ and $CoBr^+$. Previous measurements on nickel bromide have been made by Job (2), who only obtained evidence of $NiBr_2$ with a stability constant of 6×10^{-4} at 18° C. With cobalt bromide he obtained evidence for $CoBr^+$ with a stability constant of 5×10^{-3} at 18° C. References to early semiquantitative work, and work in other solvents, may be found in reference 3.

The present measurements were made by means of cell voltages in a manner very similar to that already described (1). The cell used was Ag, $AgBr/NaBr+M(ClO_4)_2+NaClO_4+HCl_4/NaBr+NaCl_4+HClO_4/AgBr$, Ag. The concentrations of sodium bromide and perchloric acid (about 0.03 *M*) were the same on both sides, as was the ionic strength, which was adjusted to a value of 2.0. Recrystallized 'analar' sodium bromide was used, and other reagents were the same as in the previous work. The electrodes were prepared by the method of Janz and Taniguchi (4). It was checked that the electrodes immersed in two concentrations of sodium bromide gave the calculated voltage over the range 0 to 50° C within 1%.

Since previous work (1) had suggested the possibility of ions of the type M_2X^{+3} (where X is a halogen) measurements were made over a range of concentrations of metal ion

in order to detect ions of this type. In general, all solutions contained high metal and low bromide concentrations, conditions which would favor MBr^+, but it was checked that the calculated stability constants did not vary appreciably with double the concentration of bromide ions. This confirms that the complex ions formed were, in fact, $CoBr^+$ and $NiBr^+$. The results are given in Table I. Most of the voltages in this table are the

average of several measurements. The last column gives the values for the equilibrium constants, $K_1 = [MBr^+]/[M^{++}].[Br^-]$, calculated on the assumption that no other complex is present.

The results give no definite evidence of complexes of the formula M_2Br^{+3}. Although the values of K_1 for $NiBr^+$ are somewhat higher in the series with 0.310 M nickel than with 0.155 M, this trend was not observed in the first series when the nickel concentration was raised gradually from 0.0975 M to 0.2787 M. With cobalt bromide no drift in K_1 was observed with changing cobalt concentration.

The temperature coefficient of K_1 for $NiBr^+$ seems to be larger at low temperatures. ΔH for $Ni^{++} + Br^- \dashrightarrow NiBr^+$ appears to fall from about 3 kcal to 0.5 kcal over the range 0 to 50° C. The same trend in an even more marked form was found for $CoBr^+$. A similar situation had been found earlier for $CuBr^+$ from spectrophotometric measurements (1). There is at present no satisfactory explanation of this behavior, though various possibilities were discussed in the earlier paper. One would be inclined to suspect some irregularity in the performance of the silver bromide electrodes, except that these were found to behave as expected in bromide solutions not containing cobalt or nickel, and that the similar behavior of $CuBr^+$ was detected by the spectrophotometer.

VOLATILITY OF CUPRIC NITRATE

L. R. Pittwell

The volatility of anhydrous cupric nitrate has been reported (1). When hydrated cupric nitrate is ignited the major products are oxides of nitrogen, oxygen, and cupric oxide. If the gases evolved by ignition of hydrated cupric nitrate are piped into the burner of a flame spectrograph, the emission of the green 5105 Å copper line can be detected in the resultant spectrum. In each experiment, care was taken to ensure that the whole apparatus was copper free, and the gases were passed through glass bead filters to remove entrained particles. Blank experiments with aluminum and ferric nitrates in identical apparatus showed no emission at this wavelength due to trace contamination or nitrogen oxides. Similar experiments using calcium and barium nitrates failed to give any spectral emission characteristic of either metal, indicating that the gas filters were effective. It is therefore concluded that small quantities of volatile cupric nitrate are produced during the ignition of the hydrate.

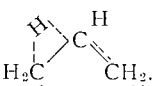
INVERSE INTERMOLECULAR KINETIC ISOTOPE EFFECTS IN UNIMOLECULAR REACTIONS. DIFFERENTIAL QUANTAL EFFECTS IN THE NON-EQUILIBRIUM BEHAVIOR* †

B. S. RABINOVITCH,‡ D. W. SETSER,§ AND F. W. SCHNEIDER

Using cyclo-C_3H_6 and -C_3D_6, Blades (1) has determinedthe kinetic isotope effect for C_3H_6 and C_3D_6 structural isomerization (2, 3) near p_∞ as k_H/k_D (60 cm) = 0.82 exp (1300/RT); the ratio declines with pressure (Table I).

To examine this effect, we use the RRK-Marcus formulation (4) with accurate enumeration of densities of harmonic vibrational energy levels (5, 6); over-all rotations are taken as adiabatic and all vibrations active.

$$k_{unI} = \frac{I_r e^{-E_0/kT}}{Q_v h} \sum_{\epsilon^+=0}^{\infty} \frac{\sum_{\epsilon_v^+ < \epsilon^+} P(\epsilon_v^+)\, e^{-\epsilon^+/kT}}{1 + \frac{I_r}{\omega h} \frac{\sum_{\epsilon_v^+ < \epsilon^+} P(\epsilon_v^+)}{N(E_0+\epsilon^+)}}$$



where I_r is the inertial and symmetry number ratio, Q_v the molecule vibrational partition function, and $P(\epsilon_v^+)$ the vibrational degeneracy at ϵ_v^+ of the activated complex.

p_∞ Region

The expression for k_∞ is identical with Eyring theory (7). The model for $C_3H_6^+$ depends on the mechanism, that is, whether H migration (3) or ring expansion (or trimethylene formation) with H migration (2, 9). We use the model for $C_3H_6^+$ described previously (9, 10)‖ and, redefining $k_\infty = A \exp(E_a/RT)$, A(calc.) = $10^{15.32}$; A(expt. (8)) = $10^{15.30}$. The calculated isotopic ratio is $(k_H/k_D)_\infty = I_{rH}Q_{vD}Q_{vH}^+ \exp(\Delta E_0/RT)/I_{rD}Q_{vH}Q_{vD}^+ = A_r \exp(\Delta E_a/RT) = 0.88 \exp(1300/RT)$. The I_rQQ^+ ratio, and also A_r, is <1 (although not sufficient to counterbalance the exponential) since $I_{rH}/I_{rD} \simeq 1.00$ while quantal behavior of the loosened complexes is more classical than for the molecules.

p_0 Region

For strong collisions, $k_0 = \omega \int_{E_0}^{\infty} N(\epsilon) \exp(-\epsilon/RT) d\epsilon/Q_v$; at high energies, integration

‖*The free energy of activation is higher for structural than for geometrical isomerization, and the former transition state is distinct from the latter (2). The complex is represented as*  *For the alternative H migration mechanism, a ring expansion postulate has also been added (ref. 2, footnote 10) and any difference in complexes is now drastically reduced. In addition to elimination of a* C—H *stretch, frequency lowerings in* $C_3H_6^+$ *relative to* C_3H_6 *correspond principally to a* C≡C *torsion frequency,* C—C *twist frequency, and a skeletal bending mode (545 (3) cm*$^{-1}$*). The complex assignments obey the frequency–bond order rules, and deviate from the Teller–Redlich product rule by <5%, the exact correspondence depending on the reduced mass factor for the reaction co-ordinate. Proper analysis of the reaction co-ordinate for this drastic intramolecular rearrangement is quite complex. Other definitions of this co-ordinate (cf. F. H. Westheimer, Chem. Revs.* **61**, *265 (1961)) could be used to obtain a similar result; bending* C—H *motion may be introduced. The present semiempiricism (i.e. adjustment to fit the experimental* ΔE_a, *particularly, while obeying the previously mentioned rules) gives a useful representation of the characteristic frequency pattern of the complex since the calculations do not depend critically on the few uncertainties in frequencies, relative to the large total frequency pattern for all modes active. Molecular frequencies were taken from H. Gunthard, R. C. Lord, and T. R. McCubbin, Jr. (J. Chem. Phys.* **25**, *768 (1956)) and grouped (6).*

with the correct energy density is proper. The reaction co-ordinate no longer involves $C_3H_6^+$. Then $(k_H/k_D)_0 = \omega_H Q_{vD} \exp(\Delta E_0/RT)R/\omega_D Q_{vH} = 0.25$; R is an integral ratio, and $\Delta E_0 = 1.4$ kcal. Unlike the p_∞ expression for which each energy level sum starts at zero, the integrals here start at higher energies; since the quantal behavior is more classical in C_3D_6, R is $\ll 1$ and outweighs the remaining factor, each ratio of which is >1.

The Fall-off Region

Another aspect of the behavior is this: k_H/k_D should decline as p decreases for the reason, among others, that on the present formulation C_3D_6 is characterized by a classical empirical Kassel (3) s value greater than for C_3H_6, and thus by slower fall-off, since s rises toward the total actual number of active modes as the classical treatment becomes relatively more valid (4, 6). This differential quantal behavior on lowering of frequencies is analogous to the change of non-equilibrium behavior to be expected with temperature rise for a given molecule: the characteristic ratio $h\nu_i/kT$ also decreases with rising T, and the classical s parameter should rise. (The change of fall-off *curvature* accompanying the rise of s is complicated by an opposing temperature effect (11); further discussion will be given elsewhere.)

Experimental fall-off for C_3H_6 at 718° K corresponds (2) to $s = 10.5$ (or Slater $n = 13.5$). The present calculational model gives s (755° K) = 10.3, and s (718°) = 10.0 (the decimals have only qualitative significance). For C_3D_6 at 755° the calculated s is 12.

Table I gives the general isotope comparison. Tunnel effect is not considered. The

TABLE I

Pressure variation of cyclopropane isotope effect (755° K)

p, cm	∞	10^2	10	1	10^{-1}	10^{-2}	10^{-3}	0
$(k_H/k_D)_{exp}$ (1)		1.96	1.88	1.70	1.50	1.30		
$(k_H/k_D)_{calc}$	2.10	2.08	2.00	1.80	1.50	1.19	0.83	0.25

general agreement is satisfactory. Anharmonicity corrections may also be made; they should not affect the present conclusions significantly. The present case involves a combined primary–secondary isotope effect; some interesting formalism arises concerning possible combinations of primary and secondary effects in unimolecular reactions, and their change between the high- and low-pressure limits.

The inverse intermolecular isotope effect at lower-pressure regions of thermal unimolecular reactions should be of common occurrence. However, the differential divergence of isotopic reactions from classical behavior will depend on the characteristic vibrational frequency patterns and isotopic frequency shifts involved, on the energy range, i.e., on E_0, and on the bonding in the complex. In general, there is little connection between either frequency patterns of molecules or ΔE_0, and critical energies for reaction (6).
