Th^{232} $(n,2n)$ Th^{231} CROSS SECTION FROM THRESHOLD TO 20.4 MEV[1]

J. P. BUTLER AND D. C. SANTRY

ABSTRACT

The excitation curve for the reaction Th^{232} $(n,2n)$ Th^{231} has been measured by the activation method from the threshold energy, 6.34 Mev, to 20.4 Mev, relative to the known cross section for the S^{32} (n,p) P^{32} reaction. Monoenergetic neutrons were obtained from the D (d,n) He^3 and T (d,n) He^4 reactions employing a Tandem Van de Graaff accelerator. From threshold to 9.0 Mev, the $(n,2n)$ cross section rises rapidly, reaching its maximum value of 1.88 ± 0.09 barns in the region of 9.5 to 11.0 Mev. Above 11.5 Mev the $(n,2n)$ cross section decreases due to competition of the $(n,3n)$ and $(n,2nf)$ reactions and at 20.4 Mev it has a value of $0.22_5\pm0.01_5$ barns.

INTRODUCTION

Although many measurements of fast neutron cross sections $(n,2n)$, (n,p), and (n,α) have been made with 14-Mev neutrons, relatively few data have been published over a range of neutron energies for which these reactions have appreciable cross sections. Due to the scarcity of data on neutron cross sections as a function of energy and the lack of agreement among existing results, a program has been initiated to measure fast neutron cross sections from threshold energies to about 21 Mev. These cross sections will be determined whenever possible with an accuracy of $\pm5\%$.

The recent development of the Tandem Van de Graaff accelerator now makes it possible to obtain measurements of fast neutron cross sections over a greater energy range. By accelerating deuterons to a precise energy, the reactions D (d,n) He^3 and T (d,n) He^4 can be used to produce monoenergetic neutrons at any energy from about 5 to 21 Mev.

Results have been published on the cross section for absorption reactions of fast neutrons with Th^{232}. The (n,γ) reaction has been measured up to 14 Mev (1) and the fission cross section has been measured by several investigators from threshold energies up to 11 Mev (1, 2) and at 14.5 Mev (1, 3). However, data on the significant $(n,2n)$ cross section are only available at a few energies (4, 5). The present investigation was undertaken to determine the cross section for the reaction Th^{232} $(n,2n)$ Th^{231} from threshold, 6.34 Mev, to 20.4 Mev. The reaction S^{32} (n,p) P^{32} was used to monitor the fast neutron flux. After the irradiation, thorium was purified radiochemically, and the Th^{231} as well as the P^{32} produced were determined by absolute beta counting. The $(n,2n)$ cross section at a particular neutron energy was then calculated from the Th^{231}- and P^{32}-activity measurements and the known cross section for the sulphur (n,p) reaction (6).

EXPERIMENTAL METHOD

A. Neutron Sources

Neutrons with energies from 6 to 11.6 Mev were obtained from the reaction D (d,n) He^3 employing the Chalk River Tandem Van de Graaff accelerator. A gas target cell similar to that described by Johnson and Banta (7) and illustrated in the lower part of Fig. 1 was used to contain the deuterium. The bombarding deuteron beam was magnetically analyzed, focused with a set of quadrupole magnets, and collimated by a 0.125-in. gold aperture. Deuterons scattered off the edge of the collimating aperture were

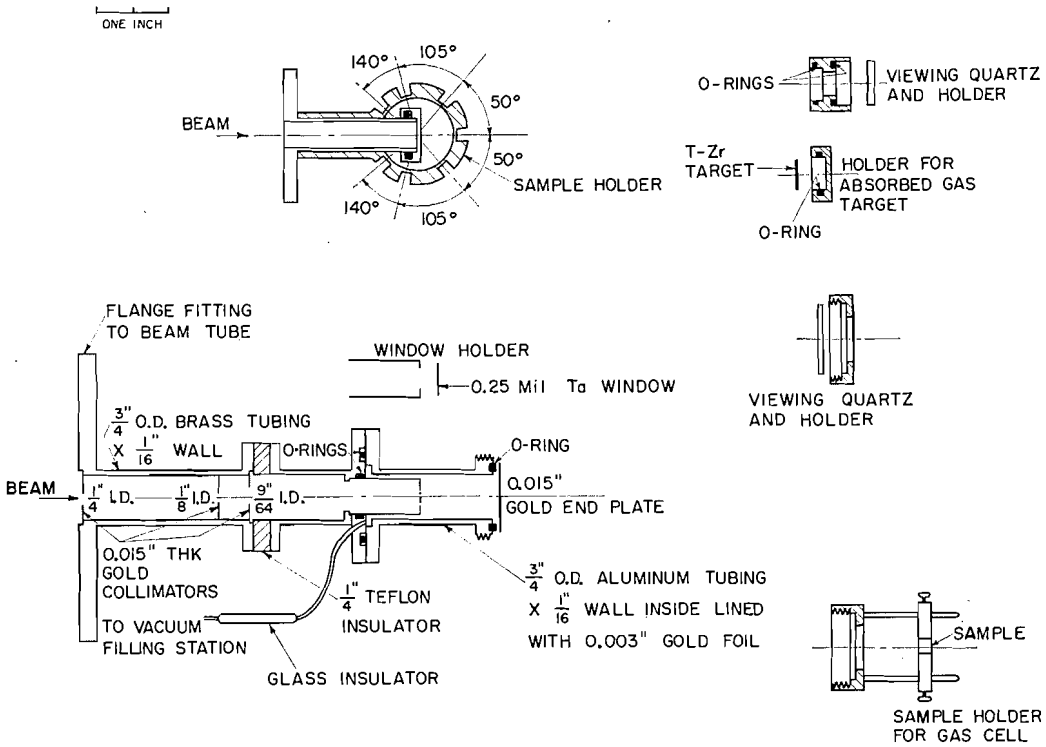

FIG. 1. Irradiation assemblies. The lower section of the diagram shows the deuterium gas target cell with the beam collimators and sample holder; the upper section shows the tritium–zirconium target and the arrangement of the samples.

prevented from entering the gas cell by a second gold aperture of slightly larger diameter, 0.140 in. The target cell was insulated from the beam tube by a 1/4 in. thick teflon ring. This enabled the cell to be used as a Faraday cup to measure the beam current during an irradiation. The cell consisted of three parts: a brass connecting section which is attached to the rest of the assembly with bolts passing through nylon insulating bushings, a brass window holder, and the outer aluminum chamber with a gold end plate. The deuteron beam enters the gas target cell through a 0.00025-in. tantalum foil which is cemented with Araldite to the brass window holder. Tantalum was found to be very suitable as a window material because of its high tensile strength. It has the added advantage that its high atomic number reduces the number of extraneous neutrons formed from (d,n) reactions. The window holder, which is held as a push fit, is aligned by a flange and makes a vacuum seal with the inner O-ring. The holder can readily be replaced if the tantalum foil ruptures. The gas chamber slips over the window holder and forms a vacuum seal with the outer O-ring. Deuterium gas enters the cell through a small hole between the O-rings and through the annular region between the chamber and the window holder. The gas target cell, which is 1.6 cm in diameter and 2.7 cm in length, was filled with deuterium to a pressure of 225 cm of Hg. The cell is made of aluminum to minimize neutron scatter and it was lined with 0.003-in. gold foil to prevent deuterons scattered in the entrance foil from striking the aluminum side walls and producing extraneous neutrons. The deuteron beam

For personal use only.

was stopped in a 0.015-in. gold end plate which is held in position with the sample holder. For aligning and focusing the deuteron beam the gold end plate could be replaced by a piece of optical quartz.

Neutrons with energies from 12.5 to 20.4 Mev were produced by the T (d,n) He^4 reaction using a zirconium–tritium target with the Tandem accelerator providing a beam of 4.0-Mev deuterons. The target consisted of a 0.020 in. thick tungsten foil onto which was melted a thin layer of zirconium metal, 8 mg/cm². Tritium containing about 2% normal hydrogen was absorbed in the zirconium layer, the tritium content being about 1.2 cm³/cm² at N.T.P. or 3.1 curies/cm².* The deuteron energy loss in passing through the zirconium layer was about 600 kev and this was taken into account in determining the average deuteron energy. The irradiation assembly is illustrated in the upper part of Fig. 1. The neutron energy was varied by selecting the angular position of the sample relative to the deuteron beam. Data were obtained for the various energies in a single irradiation with the samples placed on a circular arc at a distance of 1.4 cm from the center of the Zr–T target. The samples were irradiated at angles of 50°, 105°, and 140° on both sides of the axis of the deuteron beam and at 0°. Any slight misalignment of the deuteron beam was corrected by averaging the activities produced in the samples at duplicate angles.

Neutrons of 14.5 Mev were also obtained from a 100-kev accelerator using the T (d,n) He^4 reaction. For these irradiations a Zr–T target as described above was used.

B. Irradiations

The Th^{232} was irradiated as metal disks of 3/16-in. diameter and 0.040-in. thickness. For irradiations employing the deuterium gas target, two thorium disks were stacked together in the sample holder at 0° to the deuteron beam and at a distance of 1.4 cm from the end of the gas target cell. To obtain the required neutron fluxes without excessive energy spread, the samples were only exposed at this position and a separate run was carried out for each neutron energy. At this position the half-angle subtended by the thorium disks from the average point of origin of the neutrons was about 6°. For irradiations using Zr–T targets the corresponding angle was about 9°. Irradiation times varied from 3 to 6 hours and the deuteron beam current from 0.4 to 1.0 μa.

In the irradiations performed with the 100-kev accelerator the thorium and sulphur samples were irradiated at 45° to the beam and at deuteron beam current of 10 to 30 μa.

The neutron beam was monitored with the reaction S^{32} (n,p) P^{32}. The sulphur monitors were prepared by compressing sulphur at 25 tons per square inch into pellets of the same dimensions as the thorium disks. In the irradiations the thorium samples were sandwiched between two sulphur monitors. The neutron beam was also monitored with a neutron long counter identical with that described by McTaggart (8). Besides obtaining a total neutron count for each irradiation, the output of the counter went to a counting rate meter which was connected to a chart recorder. This gave a continuous record of the neutron intensity throughout the irradiation. Normally, the neutron intensity was constant within 10%. Since the half-life of the product nuclide Th^{231} is longer than the irradiation times, it could be assumed that the neutron flux was constant during the irradiation. However, in several irradiations the neutron intensity varied more markedly and in these irradiations the chart record was divided into time increments and each

**The zirconium–tritium targets were obtained from the Radiochemical Centre, United Kingdom Atomic Energy Authority, Amersham, Bucks, England.*

For personal use only.

portion was weighted by the neutron intensity and the exponential decay factor. The fraction of the radioactive nuclei which survived to the end of the irradiation calculated in this manner did not differ by more than 2% from that calculated assuming a constant neutron flux.

C. Radiochemical Analysis

After the irradiation, the thorium samples were dissolved and the thorium was radiochemically purified from fission products and the decay products of natural thorium by a modification of the procedure given by Prestwood (9). The method involved the precipitation of thorium as the iodate, oxalate, and the hydroxide as well as a mesityl oxide solvent extraction. The purified thorium was mounted as ThO_2 and beta counted in a methane flow beta proportional counter of about 2π geometry. The actual counting was done by an automatic sample changer coupled with automatic scaling, timing, and printout devices.

After the samples of thorium had decayed about a day there was considerable radioactivity due to the decay products of Th^{232}–Th^{228}. To correct for this activity, unirradiated thorium was separated from daughter activities and counted as a function of time to determine the growth in activity. The activity of Th^{231} in the irradiated samples was obtained by subtracting the activity due to the growth of the natural decay products of Th^{232}–Th^{228}. The Th^{231} decayed with an accepted value of 25.52 hours (10). The counter was calibrated for Th^{231}, by separating Th^{231} from a weighed amount of its parent U^{235} by means of an anion exchange resin (Dowex A1 100–200 mesh). The separation was performed with a known weight of natural thorium and the counter was calibrated for various weights of ThO_2.

The irradiated sulphur pellets were placed on counting trays and ignited. By measuring the activity ratio of unburnt to burnt sulphur pellets for pellets irradiated in a uniform neutron flux as a function of the pellet thickness, it was determined that $93.0\pm0.5\%$ of the P^{32} activity is left behind on the counting tray as essentially a weightless source. The efficiency of the counter for P^{32} was determined from aliquots of a solution of P^{32} standardized by 4π counting. The P^{32} samples were found to decay with the accepted half-life of 14.22 days (11).

RESULTS AND DISCUSSION

Values of the Th^{232} $(n,2n)$ Th^{231} cross sections were calculated from the observed activities of Th^{231} and P^{32} corrected to the end of the irradiation and the measured cross section for the reaction S^{32} (n,p) P^{32}, as reported by Allen *et al.* (6). Separate analyses were performed on the two thorium disks so that in each irradiation two measurements of the $(n,2n)$ cross section were obtained. Before the measured P^{32} activity could be used to calculate the neutron flux at the position of the thorium samples several corrections were necessary. These corrections took into account: (1) the difference in distance from the neutron source to the thorium and to the sulphur pellets, (2) neutron losses due to absorption and scattering in the pellets, (3) background neutrons which arise from neutrons generated in the beam plumbing, collimators, target window, and the gold end plate, (4) breakup neutrons produced by the reaction $D(d,np)D$, which has a threshold in the laboratory system of 4.45 Mev. The first two corrections were both calculated and measured experimentally by performing irradiations in which the thorium disks were replaced by sulphur pellets.

Typical corrections that were applied for the extraneous neutrons (corrections 3 and 4) in the neutron beam at various neutron energies are listed in Table I. The effect of

TABLE I

Typical corrections for extraneous neutrons

Deuteron energy (Mev)	Neutron energy (Mev)	% Various types of neutrons at 0° to deuteron beam			% Correction applied to P^{32} activity for	
		Monoenergetic $D(d,n)He^3$	Background	Breakup $D(d,np)D$	Background neutrons (obs.)	Breakup neutrons (calc.)
3.25	6.50	99.0	1.0	0	−0.5	0.0
5.30	8.50	95.4	2.6	2.0	−1.7	0.0
7.50	10.62	67.2	4.5	28.3	−4.0	−10.0

background neutrons was determined by performing irradiations with the gas cell evacuated. For T + D neutrons, zirconium targets without absorbed tritium were used. The percentage of breakup neutrons in the beam was calculated from the measurements of Cranberg *et al.* (12). From the table it is seen that their number increases rapidly as the deuteron energy is increased over the threshold for the reaction. The correction applied to the observed P^{32} activity due to the presence of breakup neutrons is listed in the last column of the table. It was calculated by graphical integration from the known spectrum of breakup neutrons (12) and the sulphur cross section. At the highest deuteron energy (8.55 Mev) this correction was 20%. It was not necessary to correct the observed Th^{231} activity for background and breakup neutrons since these neutrons have energies below the threshold for the $(n,2n)$ reaction.

For the angle irradiations, relative cross sections were obtained at various energies (12.5 to 20.4 Mev) by employing the differential cross section data of Bame and Perry (13) for the T (d,n) He^4 reaction to account for the variation in the neutron yield with angle. The values were normalized at a neutron energy of 14.45 Mev (sample at 105° to the deuteron beam) with the Th^{232} $(n,2n)$ cross section measured at this energy with sulphur monitors using the 100-kev accelerator.

The $(n,2n)$ cross section data are tabulated in Table II and displayed in Fig. 2. The cross sections are the average of at least two determinations. The errors quoted refer to the counting data, plus a 4% uncertainty in the absolute counting of Th^{231} and a 2% uncertainty in the counting of P^{32}. The errors do not include any error in the sulphur cross section. The sulphur (n,p) cross sections used in the calculations are also listed in the table and it is seen that the cross section is nearly constant in the energy range in which it was used.

For each irradiation an average neutron energy was calculated using the tables of Fowler and Brolley (14). The neutron energy is a direct function of the deuteron energy and the angle between the incident deuteron beam and the emitted neutron. To obtain the neutron energy, the following factors were considered: the deuteron energy loss in passing through the tantalum window or zirconium layer (15), the energy degradation in the deuterium gas, and the angular spread of the neutrons irradiating the thorium disks, as defined by the finite dimensions of both the disks and the deuteron beam. For each irradiation the effective neutron spectrum at the thorium disks was estimated. For irradiations employing the deuterium gas target, the spectrum was approximately

*Allen *et al.* Phys. Rev. **107**, 1363 (1957).

trapezoidal with a greater number of lower-energy neutrons. An average energy was obtained by graphical analysis. The neutron energies given in Table II are average values and the spread quoted represents the standard deviation in the energy as seen by the thorium pellets.

In the graph of the data, Fig. 2, results from Los Alamos (4) at 7.5 and 8.5 Mev are also plotted. They appear to be consistent with the present measurements. However, the Russian value report by Zysin *et al.* (5) at 14.7 Mev lies outside the experimental errors quoted.

From the graph it is seen that the threshold for the reaction is 6.4±0.1 Mev in agreement with the value of 6.34±0.4 Mev (16) determined for the reaction Th^{232} (γ,n) Th^{231}. The decrease in cross section at about 12 Mev is attributed to competition with $(n,3n)$ and $(n,2nf)$ processes which have thresholds at 11.43 and 11.6 Mev respectively.

EVIDENCE FOR LOW-MOMENTUM-TRANSFER PROCESS IN K^{41} (α,n) $Sc^{44m,g}$ REACTIONS FROM RANGE MEASUREMENTS OF PRODUCTS[1]

TAKU MATSUO AND T. T. SUGIHARA

ABSTRACT

Average forward ranges have been measured for the product nuclides Sc^{43}, Sc^{44m}, and Sc^{44g} as produced in the reactions $K^{41}(\alpha,xn)$ with alpha particles in the energy region 23 to 39 Mev. These ranges, which are determined by a thick target – thick catcher technique, indicate that the (α,n)-produced isomers are formed in part by a low-momentum-transfer process above 30 Mev, its contribution being larger for the ground-state nuclide Sc^{44g}. From a thick target – thin catcher experiment at 40 Mev, it is found that the range distribution for Sc^{43} is that expected for a compound-nucleus reaction. Normalizing the Sc^{44m} and Sc^{44g} activity distributions to that of Sc^{43} for the catchers farthest from the target, we estimate the lower limits for the contribution of a direct-reaction low-momentum-transfer process to the formation of Sc^{44m} and Sc^{44g} at 40 Mev to be about 30% and 46% respectively.

A. INTRODUCTION

The ratio of formation cross sections of Sc^{44m} and Sc^{44g} (the "isomeric ratio") as produced in the reaction K^{41} (α,n) has previously been reported for the alpha energy region 6–30 Mev (1). These experiments have been extended to 40 Mev, and the excitation function for the reaction K^{41} $(\alpha,2n)$ Sc^{43} has also been measured (2). The results are summarized in Fig. 1.

The increase in the isomeric ratio from threshold to 26 Mev can be accounted for by a compound-nucleus mechanism, and the decrease in the region above 26 Mev was interpreted as resulting from the contribution of a non-compound-nucleus reaction (2). The latter reaction is expected to impart less linear momentum to the target nucleus than a compound-nucleus reaction. The linear momentum of the target nucleus is directly related to the recoil range of the product nucleus (3). Thus, a study of the recoil ranges of the Sc^{44} isomers should be useful in understanding the mechanisms by which these nuclides are produced. In this work, we report the average forward ranges in potassium chloride and aluminum of Sc^{43}, Sc^{44m}, and Sc^{44g} as produced by (α,xn) reactions on K^{41} in the alpha energy region 23–40 Mev.

In work by others, the recoil technique has recently been used by Winsberg and Alexander (3) in heavy-ion reactions, by Valyocsik (4) and by Harvey and co-workers (5) in deuteron and alpha reactions of heavy elements.

B. EXPERIMENTAL

Potassium chloride targets were prepared by evaporation on aluminum foil, and their thicknesses measured by weighing a target of known area. Fluctuations in thickness from point to point on the target were estimated to be less than 10%. Aluminum foils of high purity were used as recoil catchers. Stacks made up of target, catchers, and energy-degrading aluminum foils were bombarded in the deflected alpha beam of the 60-in. cyclotron at Brookhaven National Laboratory. The alpha-particle energy at each target foil was calculated from the range-energy curves of Aron (6). Schematic views of the

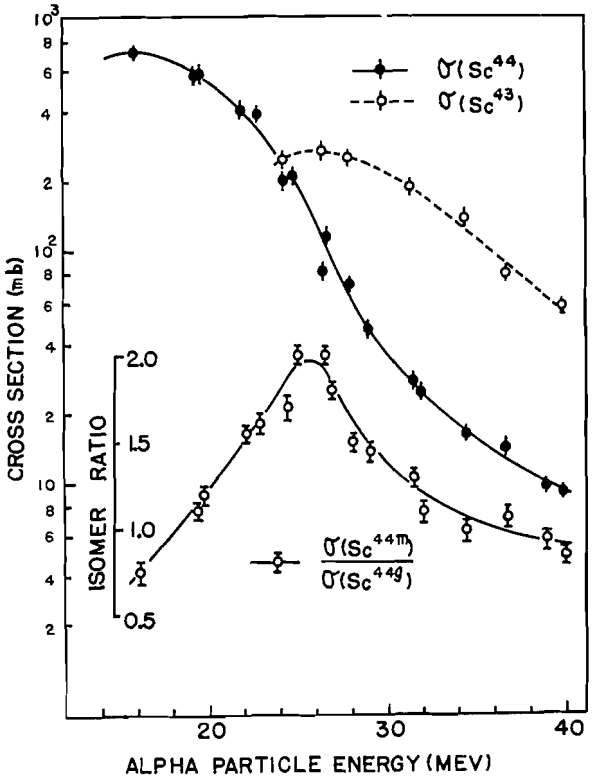

FIG. 1. Excitation functions for the $K^{41}(\alpha,n)$ (solid circles) and $K^{41}(\alpha,2n)$ (open circles) reactions. The (α,n) points include the contribution of both Sc^{44} isomers. The inset curve gives the isomeric ratio $\sigma(Sc^{44m})/\sigma(Sc^{44g})$.

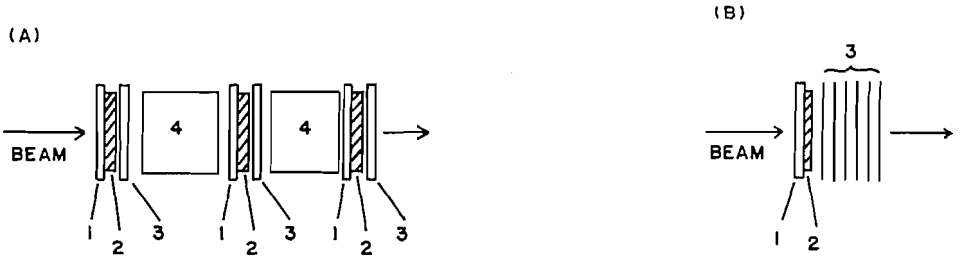

FIG. 2. Schematic diagram of target and catcher arrangement for (A) the thick – target thick catcher experiment and (B) the thick target – thin catcher experiment. 1 refers to an aluminum backing on which the KCl target 2 had been evaporated. The aluminum recoil catchers 3 are thick with respect to the range (A), or thin (B), where several such thin catchers are used. In (A) 4 refers to aluminum absorbers that were used to degrade the alpha-particle energy.

target and catcher arrangement are shown in Figs. 2*a* and 2*b*, and the details are discussed below.

After irradiation, target foils (on their aluminum backing) and catcher foils were separately dissolved in 8 *M* hydrochloric acid. Scandium carrier was added and extracted into tributyl phosphate, back extracted into 0.1 *M* hydrochloric acid, and precipitated as the hydroxide. The hydroxide was dissolved in minimum dilute hydrochloric acid.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Excess sodium carbonate was added, and lanthanum carbonate was precipitated. Scandium remains in solution as a carbonato complex. The supernate was acidified, and carbon dioxide was removed by boiling. Scandium hydroxide was precipitated again, dissolved in dilute hydrochloric acid, and finally precipitated as the salt of hypophosphorous acid (7).

Counting was done on a 3 in.×3 in. sodium iodide crystal, Sc^{43} being detected by its 0.38-Mev γ ray and Sc^{44g} by its 1.16-Mev γ ray. Since Sc^{44m} decays to Sc^{44g}, measurements of the 1.16-Mev γ ray as a function of time lead to a determination of both isomers. The γ-ray spectra of Sc^{43} and Sc^{44g} in equilibrium with Sc^{44m} are shown in Fig. 3. The Sc^{43} spectrum was obtained from a pure sample made by the reaction Ca^{40} (α,n) $Ti^{43} \xrightarrow{\beta^+} Sc^{43}$. From Fig. 3 it is clear that even when the Sc^{43} activity is 10 times that of Sc^{44g}, the 1.05-Mev γ ray of Sc^{43} does not appreciably contribute to the 1.16-Mev photopeak of Sc^{44g}.

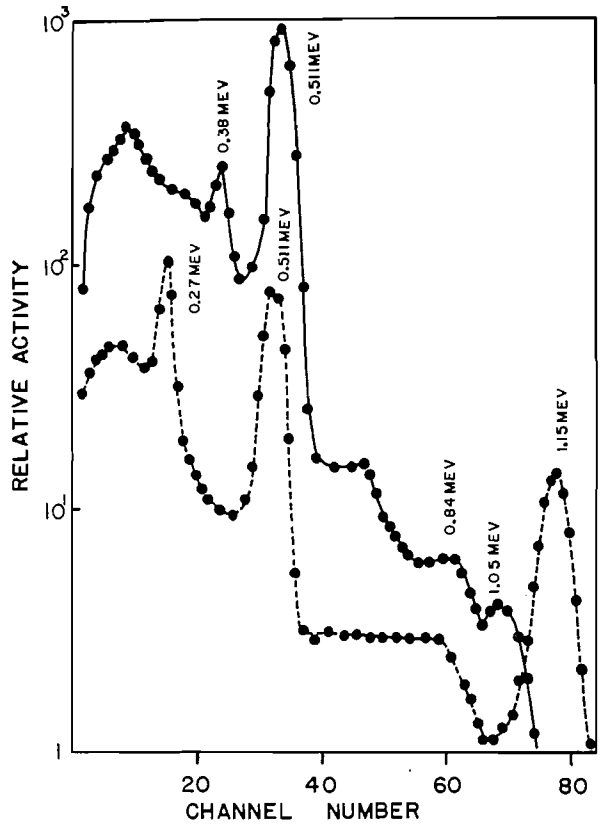

FIG. 3. Gamma-ray spectra of 4.0-hr Sc^{44g} in equilibrium with 2.4-day Sc^{44m} (dashed line) and of 3.9-hr Sc^{43} (solid line), as taken on a 3 in.×3 in. NaI crystal using a 100-channel analyzer. The Sc^{43} source was prepared by the reaction $Ca^{40}(\alpha,n)$ $Ti^{43} \xrightarrow{\beta^+} Sc^{43}$ and was free of Sc^{44}. Sc^{43} does not interfere with the determination of Sc^{44g} (and hence Sc^{44m}) at 1.15 Mev even if Sc^{43} has a 10-fold higher abundance. Sc^{43} was followed by its 0.38-Mev γ ray.

C. RESULTS

The average range (in the target material) of a nuclide can be measured in a thick target – thick catcher experiment such as that shown schematically in Fig. 2*a*. If the target

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

thickness is T and the fraction of the activity found in forward catcher is F, the average range R_0 is given (3) by

$$[1] \qquad R_0 = FT.$$

"Thick" in this context means considerably greater than R_0.

The results obtained for R_0 with a target thickness of 2.47 mg/cm² potassium chloride and an aluminum catcher of 7.3 mg/cm² are shown in Table I for alpha energies 23, 32, and 39 Mev. The estimated error in the determination of F is less than 5%; combined with possible fluctuations in the target thickness T, we estimate the over-all error in R_0 to be about 10%.

TABLE I

Thick-target ranges in KCl (μg/cm²)*

	E_α(Mev)		
Nuclide	23	32	39
Sc^{43}	380	423	575
Sc^{44m}	408	396	495
Sc^{44g}	413	361	430

*The errors are estimated to be about 10%.

The recoil behavior of the scandium nuclides was also studied in a thick target – thin catcher experiment at 40 Mev. A stack of foils similar to that shown schematically in Fig. 2*b* was irradiated. The target was 1.23 mg/cm² potassium chloride and each aluminum catcher 0.17 mg/cm².

The amount of the three nuclides found in each catcher, corrected for chemical yield, is shown in Table II and Fig. 4. The data in Table II and Fig. 4 are in arbitrary units,

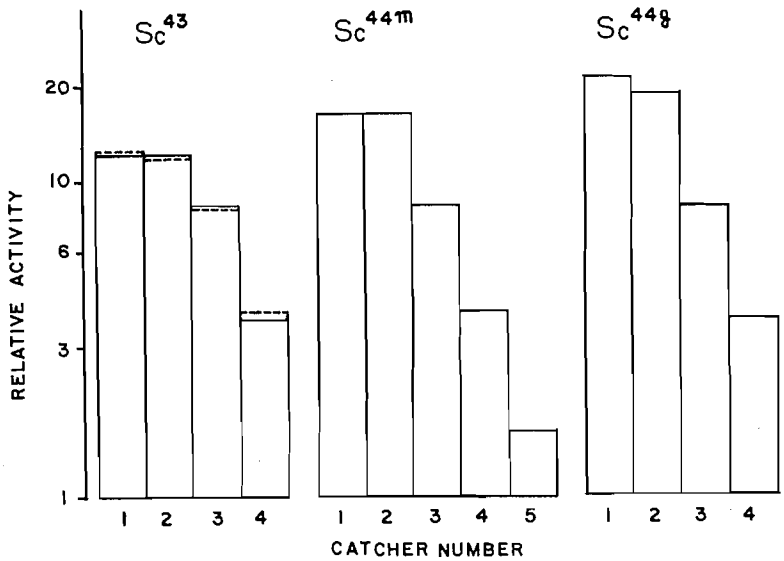

FIG. 4. The activity distribution of Sc^{43}, Sc^{44m}, and Sc^{44g} in thin forward catchers at 40 Mev. The dotted lines in the Sc^{43} distribution are the values expected from equation [7] for $n = 2.1$, $R_0 = 580$ μg/cm², and $\bar{\rho} = 0.45$.

TABLE II

Normalized differential distribution of products at E_α = 40 Mev*

	Catcher number (each 0.17 mg/cm² Al)				
Nuclide	1	2	3	4	5
Sc^{43}	12.2	12.1	8.30	3.62	—
Sc^{44m}	16.3	16.3	8.30	3.87	1.6
Sc^{44g}	21.0	18.6	8.30	3.60	—

*The errors are estimated to be about 5%.

normalized to give the same activity of all three nuclides in catcher number 3. The reason for this normalization procedure is discussed below.

D. DISCUSSION

The distribution in the forward range R of a product nucleus can be expressed (3) as

$$[2] \qquad P(R)dR = \frac{dR}{\sqrt{2\pi}\rho R_0} \exp\left[- \frac{(R - R_0)^2}{2\rho^2 R_0^2} \right]$$

where R_0 is the average range and ρ the straggling parameter. R_0 contains contributions from the momentum imparted by the incident particle, in this case an alpha particle, and from that resulting from emission of nucleons leading to the product nucleus. In reactions such as (α,n) or $(\alpha,2n)$ at relatively low energies, the latter contribution is small and is neglected here. The straggling parameter also consists of two terms (3), one characteristic of the stopping process and the other dependent on the angular distribution of the outgoing particles. The first term predominates over the latter (3).

The thick catcher experiment can give only R_0 as indicated in equation [1]. The data in Table I indicate that the ranges of Sc^{43}, Sc^{44m}, and Sc^{44g} differ from each other at energies above 30 Mev. It will be assumed that Sc^{43} is formed in a compound-nucleus reaction. Evidence to support this assumption is presented below. Lower R_0 values for Sc^{44m} and Sc^{44g} as compared to that for Sc^{43} indicate the contribution of a low-momentum-transfer or non-compound-nucleus reaction. This result is consistent with the interpretation for the decrease in isomeric ratio (2).

It has been shown (8) that R_0 is related to the kinetic energy E (in Mev) of a recoiling atom in a stopping material of atomic weight m and atomic number z in the following way:

$$[3] \qquad \frac{R_0}{E} = 0.600 \frac{m(m + M)}{M} \frac{(z^{2/3} + Z^{2/3})^{1/2}}{zZ} \text{ mg/cm}^2$$

where M and Z are the atomic weight and atomic number of the recoiling atom. R_0 values have been calculated from equation [3] for the compound nucleus formed by complete transfer of alpha-particle momentum to the K^{41} nucleus. These values as well as the observed Sc^{43} ranges are summarized in Table III. The ratio of the values calculated to those observed is about 2.5 and constant within experimental error at the three energies. Other workers (3, 4) have found also that observed ranges are substantially less than those

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

TABLE III
Comparison of calculated and observed ranges

	Ranges in KCl (mg/cm²)		
	E_α(Mev)		
	23	32	39
R_0 calculated for compound nucleus (eq. [3])	0.847	1.18	1.44
R_0 observed for Sc^{43}	0.380	0.423	0.575
Ratio calculated/observed	2.2	2.8	2.5

calculated by equation [3], particularly when the recoiling atom and stopping material are of nearly the same atomic weight and number, as is the case here. The constancy in the ratio implies that the range of Sc^{43} nuclei is increasing with energy in a manner consistent with equation [3]. Since the calculated R_0 assumes compound-nucleus formation, we consider the data of Table III to be evidence that Sc^{43} is formed chiefly by a compound-nucleus mechanism at all three energies. The fluctuations in the ratio are attributed primarily to variations in thickness of the target.

The differential-catcher method gives the straggling parameter ρ as well as R_0. If the recoiling atom traverses both target material and catcher, the probability that the atom will be found at some point x in the catcher is given by

$$[4] \qquad P(x)dx = \frac{dx}{\sqrt{2\pi}\bar{\rho}R_0}\int_0^T \exp\left[-\frac{(cx+t-R_0)^2}{2\bar{\rho}^2R_0^2}\right]dt$$

where x and t are the path lengths in catcher and target respectively as measured in the beam direction, $\bar{\rho}$ is the straggling parameter averaged over the target and catcher material, T is the target thickness, and c is a factor that converts range in catcher to that in the target material as follows:

$$[5] \qquad c = \frac{m_1(m_1+M)}{m_2(m_2+M)}\left(\frac{z_1^{2/3}+Z^{2/3}}{z_2^{2/3}+Z^{2/3}}\right)^{1/2}\frac{z_2}{z_1}.$$

The subscripts 1 and 2 refer to target and catcher respectively; the other symbols are as in equation [3].

The straggling parameter is given by (8)

$$[6] \qquad \rho = [2mM/3(m+M)^2]^{1/2}.$$

In our case both the target material and catcher material affect ρ; their relative importance depends on the ratio of t to x. However, since ρ_{KCl} and ρ_{Al} are 0.405 and 0.396 from equation [6], it is permissible to use an average value $\bar{\rho}$ without introducing appreciable error.

The integrand of equation [4] can be transformed into that of a normal distribution by making the substitution $u = (cx + t - R_0)/R_0$.

$$[7] \qquad P(x)dx = \frac{dx}{\sqrt{2\pi}\bar{\rho}}\int_{(cx-R_0)/R_0}^{[cx+R_0(n-1)]/R_0} \exp\left(-\frac{u^2}{2\bar{\rho}^2}\right)du$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where $n = T/R_0$. The function $P(x)$ of equation [7] is shown in Fig. 5* for several values

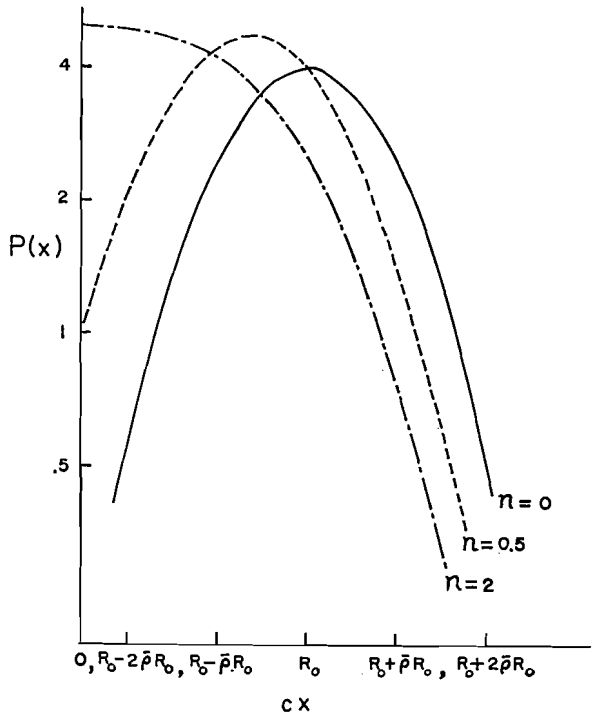

FIG. 5. The distribution function $P(x)$, equation [7], plotted as a function of cx. The various curves indicate the change in shape with reduced target thickness $n = T/R_0$. $\bar{\rho}$ has been taken to be 0.4.*

of n, indicating the shape of the distribution for various target thicknesses. For a given n value, if a nuclide is produced by several mechanisms of different momentum transfer and different R_0, a range distribution different in shape from those of Fig. 5 is expected.

When $n > 2$ and $\bar{\rho} \leqslant 0.45$,

$$[8] \qquad \frac{1}{\sqrt{2\pi}\bar{\rho}} \int_{(n-1)}^{\infty} \exp\left(-\frac{u^2}{2\bar{\rho}^2}\right) du \leqslant 0.013.$$

That is, the range distribution given by equation [7] is represented to a good approximation by

$$[9] \qquad P(x)dx = \frac{dx}{\sqrt{2\pi}\bar{\rho}} \int_{(cx-R_0)/R_0}^{\infty} \exp\left(-\frac{u^2}{2\bar{\rho}^2}\right) du.$$

The change in the upper limit of the integral does not appreciably affect the value of $P(x)$.

Thus it is apparent that probability paper should be used to determine $\bar{\rho}$ from the data of the thin-catcher experiment. The relative activity of a given nuclide found in catcher 1 (Table II) is plotted at $x_1 = 1/2$ thickness of catcher 1. That in catcher 2 is plotted at x_2 = thickness of catcher 1 + 1/2 thickness of catcher 2 and so on. The relative activity for $x = R_0/c$ is estimated by interpolation. The R_0 value is taken from the thick-catcher

*NOTE ADDED IN PROOF: The ordinate scale is in arbitrary units.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

experiment (Table I). If this activity is taken to be 50%, then the range distribution is suitably normalized. This process was followed for each of the nuclides, and the resulting plot on probability paper is shown in Fig. 6. We see that $\bar{\rho} = 0.45 \pm 0.02$ is a reasonable value for all three nuclides, and in fair agreement with the calculated values of $\bar{\rho}$ from equation [6].

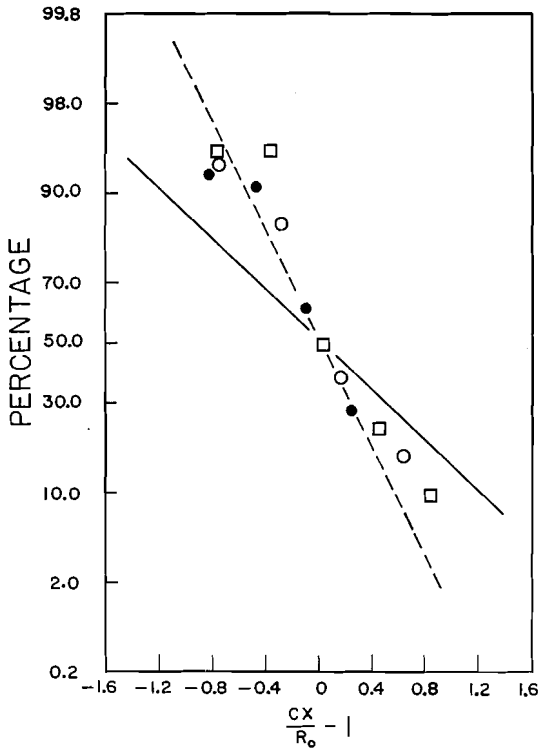

FIG. 6. Probability-paper plot of activity distribution in catchers as a function of $(cx/R_0) - 1$. The open circles refer to Sc^{44g}, the solid circles to Sc^{43}, and the squares to Sc^{44m}. The dashed line corresponds to $\bar{\rho} = 0.45$ and the solid line to $\bar{\rho} = 1.0$.

The activity distribution of Sc^{43} (Fig. 4) corresponds to that expected from equation [7] for $n = 2.1$. Other evidence (isomeric ratio and R_0 values) suggests that above 26 Mev a low-momentum-transfer process contributes to the formation of Sc^{44m} and Sc^{44g}. If we assume that at 40 Mev all of the Sc^{43} nuclei and some of the Sc^{44m} and Sc^{44g} nuclei are formed by a compound-nucleus mechanism, the observed range distributions should be the same for large values of x. Differences in range distribution should appear only for small values of x since a low-momentum-transfer contribution of smaller R_0 value is postulated. Thus the observed yields of the three nuclides in the various catcher foils have been normalized in Table II such that the distributions coincide for large values of x.

These data can now be used to estimate the amount of contribution of non-compound-nucleus reactions. The quantities used in this calculation are summarized in Table IV. The fraction found in the catcher, column (2), is obtained for each nuclide from measured R_0 values (Table I) and the target thickness T (1.23 mg/cm² KCl). Column (3) lists the sum of the activity found in the catchers, and column (4) is the calculated amount left in the target. In columns (3) through (8), the activity units are the normalized units of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Table II. Column (5) is simply the sum of (3) and (4), the total activity produced. In column (6) the activity in the catchers attributed to a direct reaction is calculated, assuming that this is obtained by subtracting the Sc^{43} activity in the catchers from that of Sc^{44m} and Sc^{44g}. The direct-reaction contributions to Sc^{44m} and Sc^{44g} are similarly calculated for the activity remaining in the target in column (7). Column (8), which is the sum of (6) and (7), represents the total contribution of direct reactions. The fractions of Sc^{44m} and Sc^{44g} activity that can be attributed to a direct reaction (column (8)/column (5)) are listed in column (9).

TABLE IV

Direct-reaction contribution to formation of Sc^{44m} and Sc^{44g} at 40 Mev

Nuclide	Fraction out*	Activity†						Fraction by direct reaction
		A	B	C	D	E	F	
Sc^{43}	0.467	37.8‡	43.2	81	—§	—§	—§	—§
Sc^{44m}	0.402	46.4	69.0	115	9	26	35	0.30
Sc^{44g}	0.350	53.1‡	98.6	152	15	55	70	0.46

NOTE: A = Activity in catchers. B = Activity in target. C = Total activity, target and catchers. D = Direct-reaction activity, catchers. E = Direct-reaction activity, target. F = Direct-reaction activity, total.

*Calculated from R_0 values of Table I at 39 Mev and T = 1.23 mg/cm² KCl.

†Normalized activity units used in Table II.

‡Assumed that 1.6 activity units of Sc^{43} and Sc^{44g} would have been found in catcher 5 (as in the case of Sc^{44m}) if detection sensitivity had been higher.

§Sc^{43} assumed to be formed only by compound-nucleus mechanism.

The calculated direct-reaction contributions, 30% for Sc^{44m} and 46% for Sc^{44g}, are only lower limits. It is conceivable that a direct reaction producing products of intermediate or long range could have contributed to the Sc^{44m} and Sc^{44g} activity found in catcher 3 and beyond. In this calculation, it has been assumed that all activity in these catchers could be attributed to a compound-nucleus reaction. If Sc^{43} is formed partially by a direct reaction at 40 Mev, the calculated direct-reaction contributions to Sc^{44m} and Sc^{44g} would also be low.

ACKNOWLEDGMENTS

We are greatly indebted to Dr. R. W. Dodson and Dr. G. Friedlander for their generous hospitality in making available to us many of the facilities of Brookhaven National Laboratory and to Dr. C. P. Baker and members of the cyclotron operating crew for their assistance in irradiations. We gratefully acknowledge some illuminating discussions with Dr. J. M. Alexander.

A GAS-CHROMATOGRAPHIC APPARATUS FOR THE STUDY OF THE HOT-ATOM CHEMISTRY OF ORGANIC HALIDES[1]

M. D. Silbert and R. H. Tomlinson

ABSTRACT

The construction of an easily assembled and inexpensive gas-chromatographic apparatus is described. This system has been designed to determine β-active materials. The operation of this instrument involves the use of a temperature program in order to resolve materials boiling over a wide range of temperature.

INTRODUCTION

Libby (1, 2) made the first attempts to isolate and identify the individual organic products from neutron-irradiated alkyl halides. From the reaction, $Br^{81}(n,\gamma)Br^{82}$, in *n*-propyl bromide he separated some eight active organic products using the technique of fractional distillation. Willard (3) using the same compound and separational method later increased the number of products to 11.

The technique of fractional distillation suffers from one great disadvantage. It cannot operate at the tracer level; carriers must be added for all components present. If carriers are not added the tracers will tend to contaminate each other or any carriers that are present.

Willard and Evans (4, 5) were the first to adapt gas-chromatographic methods to the study of hot-atom reactions of alkyl halides. From neutron-irradiated *n*-propyl bromide they obtained more than 20 active organic products without prior addition of macro amounts of inactive carrier. They had thus shown that gas chromatography was a method of analysis that was suitable not only for operation at the macro level, but also at a tracer level.

EXPERIMENTAL

In Fig. 1 is shown a schematic diagram of the gas-chromatographic apparatus constructed for determination of the β-active products from the hot-atom reactions of alkyl halides. The detection system employed was one designed for detection of active products; it is conceivable, however, that it could be substituted by or complemented with a conventional type of gas-chromatographic detection system for detection of inactive materials or added carriers.

The gas entered through a fine capillary (A) whose resistance to flow was greater than that of the column; thus it determined the flow rate of carrier through the entire system. With this device it was possible to program the column temperature with a minimum variation in flow rate.

The sample introduction system (D) shown in Fig. 2 had been designed to make use of the micropipettes commonly used in gas-chromatographic analysis. The pipette, filled by capillary action, was inserted through the rubber seal up to the stopcock. The stopcock was then opened and the pipette inserted until its tip plugged the hole in the silicone rubber disk. This blocked the normal carrier gas flow and thus forced the carrier gas to flow through the pipette, blowing the measured volume of liquid into the system. The pipette could then be withdrawn.

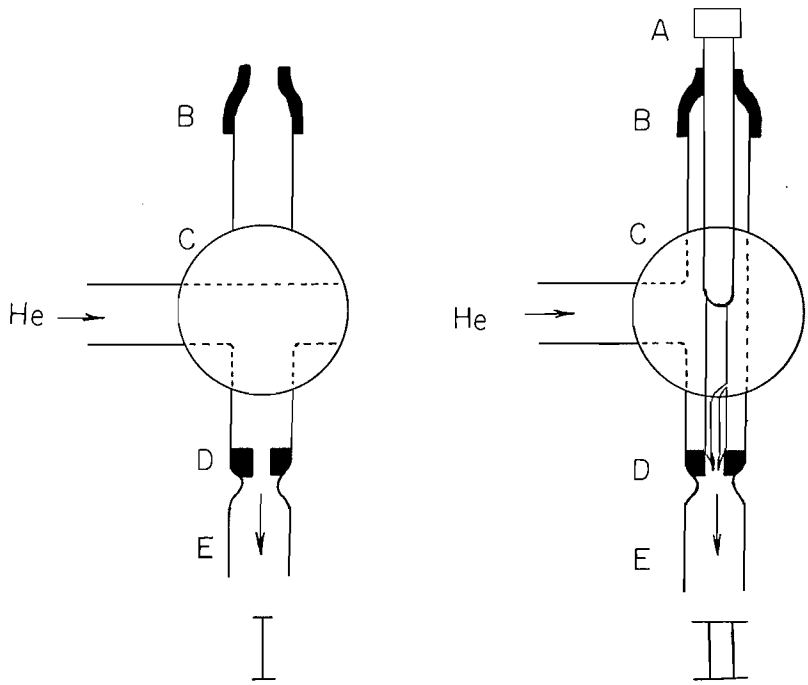

FIG. 2. Sample introduction system. I. Normal flow. II. Sample introduced.
A. Micropipette. B. Rubber seal. C. Large stopcock. D. Silicone rubber disk. E. Column.

A second sample-introduction system made use of a microsyringe and a puncture seal. The sample volume could be increased as a function of time thereby correcting for radioactive decay and normalizing all chromatograms to the same starting time after irradiation.

The column (E in Fig. 1) was heated by an air oven. This consisted of a metal can 30 cm high and 13 cm in diameter. It was wrapped with asbestos, nichrome wire, and aluminum foil. Temperature programing was achieved by increasing the voltage to the nichrome wire heater at preset time intervals.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The column was a helix of 6-mm O.D. pyrex tubing coiled to an outside diameter of 6.5 cm. Lengths of 2 and 4 meters were used. The packing was 30% by weight General Electric SF-96 (40) silicone oil coated on Johns–Manville Chromosorb P (30–60 mesh). This packing gave good resolution and short analysis times for alkyl halides. It also had the property of allowing the components to emerge in order of their boiling points, a help in identification.

The outlet of the column was connected to the flow counter (F in Fig. 1) which is shown in detail in Fig. 3. The connection was kept at 200° C in order to prevent condensa-

tion of the high-boiling components. The carrier gas was mixed with methane (natural gas was also found suitable) before entering the active volume of the counter. The active components present in the carrier gas were then counted as part of the counting gas, inside the counter with a very high efficiency. This system was the most sensitive of all present day systems of monitoring gas streams. The relative sensitivity and resolution could be varied by adjusting the flow of the methane relative to the carrier gas as this determined the length of time the active fraction remains in the counter. A trap was connected to the exit of the counter using a spherical ground joint; this was necessary to dispose of the active waste.

The output of the flow counter was fed into a linear pulse amplifier and rate meter. The rate meter ran a standard 10-mv potentiometer recorder which plotted the radiochromatogram.

RESULTS

Figure 4 shows chromatograms of the products from the reaction Br^{79} (n,γ) Br^{80} in pure *n*-propyl bromide. Results are shown for irradiation at liquid air temperature

(−196° C) and at the reactor temperature (30° C). At the reactor temperature the effects of elemental bromine scavenger are also shown.

The samples sealed in quartz were irradiated in the Rabbit System of the McMaster Nuclear Reactor for 30 seconds at a flux of 5×10^{12} n/cm² sec. The background γ field, as determined by cobalt glass, was 10^5 r integrated over this 30-second irradiation period.

DISCUSSION

The detection system used in this apparatus was a gas-flow proportional counter designed to operate with a mixture of helium and methane. It was of similar design to the counter described by Wolfgang and Rowland (6) for studies of tritiated compounds.

The great advantage of this detection method was its great sensitivity. As the counting was done internally the counter was essentially 100% efficient for β radiation.

Both Willard (4, 5) and Herr (7) passed the carrier gas through external tubing close to scintillation crystals, thereby incurring loss due to both geometry and crystal efficiency. The literature also described several other systems which externally monitor the gas stream; these, however, lose sensitivity by geometrical losses. These included both Geiger–Müeller (7, 9) and scintillation (10) detection systems.

Harris (8) collected fractions in charcoal traps which were counted in a well-type crystal. Although this method is very sensitive it does not give continuous chromatograms and is not as convenient.

Ionization chambers have been described (11, 12) using continuous flow systems. The geometrical losses have thus been reduced but the sensitivity remains less than that of a proportional counting system.

The proportional counter suffers from the big disadvantage that it can not be used at elevated temperatures. In general, Geiger–Müeller and proportional counters do not perform satisfactorily above 75° C. Wolfgang and Rowland (6) have found, however, that their design performed satisfactorily up to 200° C, the only change having been a shortening in the length of the plateau. This result was confirmed with the flow counter used in this laboratory.

SCINTILLATION COUNTING WITH ORGANIC PHOSPHORS[1]

B. LIONEL FUNT

ABSTRACT

Current techniques employed in scintillation detection of beta emitters are reviewed. Internal liquid scintillation counting, with a number of homogeneous mixed solvent systems, is described. Heterogeneous counting systems containing radioactive material in the dispersed phase include scintillating gels, thickened scintillators, and emulsions, and a number of methods embodying direct counting of active deposits on filter paper. Heterogeneous systems with the radioactive material in the continuous phase are described and include plastic capillary counters, plastic filaments, or organic crystals wetted with aqueous solutions.

INTRODUCTION

Internal sample scintillation counting provides inherent advantages of high sensitivity, energy discrimination, 4π geometry, and lower background for a given sample size.

Comparisons between different counting methods are often misleading, but it is nevertheless instructive to try to assess the potentialities and merits of different counting techniques.

Guinn (1), for example, compared Geiger and liquid scintillation counting of beta emitters. He drew the distinction between "absolute sensitivity" i.e. the minimum amount of an isotope detectable to a given standard deviation in a reasonable counting time, and "concentration sensitivity", which represents the minimum concentration detectable under the same conditions. Gas counting methods furnished superior or equal absolute sensitivities to those attainable with liquid scintillation counting. The merits of liquid scintillation counting were evident when the concentration sensitivities were compared. Here results that were superior by orders of magnitude to those attainable with gas counting methods were obtained for isotopes of low energy. The superiority of liquid scintillation counting in this comparison is primarily a reflection of the much larger quantity of isotope which can be introduced into the counting volumes with this method.

The technical problems encountered in the application of internal scintillation counting methods stem primarily from two sources: (1) sample insolubility and (2) quenching effects. The potentialities of the counting technique cannot, in general, be realized if the sample cannot be incorporated effectively into the counting volume. Since the choice of liquid scintillator solvent is limited to relatively non-polar compounds, the assay of many samples is hindered by the relative insolubility of the material in the scintillator solution. The use of mixed solvents may in many instances partially overcome these difficulties, but generally, this is at the expense of a decreased luminescent output with accompanying losses in counting efficiency (2, 3, 4, 5).

Even when the sample is directly soluble in the scintillator solution the quenching effects of various polar groups may result in a serious reduction in luminescent efficiency and of detection sensitivity (6). Furthermore, light absorption, particularly by colored compounds, will reduce the effectiveness of the counting methods (7).

Many of these difficulties have been overcome successfully by a variety of ingenious methods. Although an ideal counting technique cannot be said to exist, an intelligent

[1]*Manuscript received November 3, 1960.*
Contribution from the Chemistry Dept. University of Manitoba, Winnipeg, Manitoba. Paper presented at the Third Symposium on Nuclear Chemistry and Radiochemistry held at Atomic Energy of Canada Limited, Chalk River, Ontario, September 6–8, 1960.

choice of a counting method from those recently described can provide a simple, reproducible, and sensitive solution to most counting problems.

Homogeneous Liquid Scintillation Counting

This method provides the greatest inherent sensitivity and is most adaptable to samples of any size. Frequently the sample is directly soluble in the scintillator solution. For example, in our work on C-14-labelled polystyrene it was sufficient to dissolve the sample directly in the scintillator solution (8). For non-polar hydrocarbons surprisingly little quenching of the scintillations is found. Where quenching is suspected, compensating corrections may be applied. Frequently this is accomplished by the addition of an internal standard (9, 10) of known activity to the sample volume after the completion of the sample count. The counting efficiency of the sample plus standard is assumed to be equal to that for the standard alone.

Dilution of the sample solution with additional liquid scintillator will also serve to determine quenching effects and allow correction by extrapolation to zero concentration of quencher (10). Recently a novel suggestion for correction for quenching in H-3 counting has been made (11). A source of Co-60 on a platinum needle is inserted into the liquid scintillator where the 14-kev beta energy is detected. This procedure eliminated the contamination of the sample inherent in the use of an internal standard.

Where ultimate sensitivity is of the utmost importance, as in archaeological dating of natural radiocarbon, simplicity may be sacrificed to elaborate sample preparation. In such work the sample may be burned and the CO_2 synthesized to an aromatic hydrocarbon, or more simply to a soluble compound of moderate quenching action. The preparation of toluene (12), paraldehyde (13), methyl borate (14), and *p*-cymene (15) for such purposes has been reported.

In the more usual analysis, particularly of inorganic substances, such syntheses cannot be employed. There the expedient of using multicomponent homogeneous solvents is often practiced and solutions containing water–ethanol–toluene (16) or water–dioxane (2, 17, 18) have been described. The addition of naphthalene, as a secondary solvent, greatly reduces quenching effects in such systems (18, 19, 20). A composition employed frequently is that due to Kinard (21) which utilizes xylene–dioxane–ethanol and naphthalene. For inorganic salts, tributylphosphate can be employed in scintillator systems (22). Since this compound is a common extracting agent in various liquid–liquid extractions, its direct use appears to offer potentialities which do not appear to have been fully explored.

The use of the metal salts of 2-ethyl-hexanoic acid offers another method of incorporating many metallic substances into solution at concentrations ranging up to 10% of the metal by weight (23, 24). This procedure, although more elaborate than direct counting of aqueous solutions, will accommodate much greater amounts of the desired isotope, with a lower quenching effect. The weak natural activities of Sm-147, for example, have been studied by this method (25).

Several new solvents, including monoisopropylbiphenyl (26) and silicones (27) have recently been reported, and these deserve special consideration because of their lower quenching behavior and different solvent properties.

Heterogeneous Counting Systems

For routine counting of numerous samples some new methods offer an effective compromise between maximum sensitivity and minimum sample preparation. The use of heterogeneous counting systems circumvents the problems of quenching action and

sample insolubility but introduces new difficulties in the forms of light collection and self-absorption of energy.

Suspensions of solids in aluminum stearate gel scintillators were described by Funt and Hetherington (28) and their method can be applied to the assay of a wide variety of colorless salts or insoluble inorganic materials. The aluminum stearate gel scintillators were modified by White and Helf to suspensions in Thixcin (29), a castor oil derivative, and to liquid scintillators thickened with polymers, by Fleishman and Shadkidzhanyan (30). Another suspending agent, Cab-O-Sil, a finely divided form of silica was suggested by Ott *et al.* (31) and Gordon (32). In addition we have found that the original aluminum stearate gels can be replaced by aluminum-2-ethyl hexanoate which gels immediately without heating in the liquid scintillation medium (23). Alternatively the aluminum stearate suspensions may be gelled by the addition of phenols or cresols without the application of heat (23).

Scintillating emulsions have been described recently by Shapira and Perkins (33). As with suspensions in gels and thickened systems, the opacity of the scintillator does not greatly reduce the counting efficiency, and counting has been performed with 10% efficiency for H^3 and 52% for C^{14}.

We have considered the use of transparent emulsions in order to overcome the opalescence associated with the usual emulsion systems. Bowcott and Schulman (34) have described the preparation of such systems, and their possible application to scintillation detection is obvious.

Another interesting and effective method of scintillation counting in heterogeneous systems employs direct counting on filter paper. In many instances the active material is collected on filter paper or separated on a filter paper chromatogram. Roucayrol (35) reported that wetting the filter paper with a liquid scintillator solution rendered it transparent and made direct counting of the collected material possible. Funt and Hetherington (36) modified this technique by employing monoisopropylbiphenyl as the scintillator solvent thus reducing air quenching effects and overcoming variations in detection sensitivity due to solvent evaporation. Wang and Jones (37) found that the suspension of filter paper strips in counting vials containing liquid scintillator gave good counting efficiencies and reproducibilities and was eminently suitable for the counting of numerous samples in a commercial liquid scintillation spectrometer. The question of the best orientation of the strips was raised by Loftfield (38), who claimed differences in counting efficiency dependent upon orientation which are, however, disputed by other workers (39). Davidson (40) recently reported excellent results with this technique when circles of filter paper were arranged parallel to the phototube surface and this is very similar to the filter paper counting methods described above (36).

An alternative method of heterogeneous counting employs the organic phosphor in the dispersed phase with the active material in the continuous phase. Naphthalene and anthracene crystals were first suggested for the gaseous counting of tritium in 1950, (41, 42, 43) but an adaptation of these methods has only recently gained favor. Steinberg (44) described the use of packed broken filaments of plastic scintillator wetted with active material in aqueous solution. Powdered anthracene crystals were later reported for the same purpose (45). Best reproducibility is achieved when the counting vial is packed with the powdered phosphor and filled above the level of the phosphor with excess active solution.

A device for the counting of active aqueous solutions or gases in flow or static systems was described by Funt and Hetherington (46), who employed a spiral capillary of plastic

scintillator. The wall thickness and bore diameter were designed to provide maximum interaction with the betas and minimum self absorption in the aqueous medium. This device is now available commercially* and has found application in monitoring effluents from chromatographic columns. Its use in the detection of Ca^{45} (47) has recently been described.

Some particularly effective techniques limited to $C^{14}O_2$ counting employ liquid scintillator solutions containing long chain quaternary amines. Passmann, Radin, and Cooper introduced this technique (48) and valuable modifications have since appeared (49, 50, 51). Oppermann, Nystrom, Nelson, and Brown (52) and Radin and Fried (53) described the use of Primene 81-R (a mixture of tertiary alkyl primary C^{12}–C^{14} amines) obtained commercially from Rohm and Haas Co.

The reactions involved in the trapping of $C^{14}O_2$ in such systems are:

$$RNH_2 + C^{14}O_2 \rightarrow RNHC^{14}OOH$$

$$RNH_2 + RNHC^{14}OOH \rightarrow RNHC^{14}OOH_3NR.$$

The complexes formed are stable, particularly at low temperatures, and only moderate quenching action, which is attributed to the methanol employed as solvent, is observed.

Sheets of plastic scintillator have obvious applications for direct counting of beta emitters. Evaporation of an aqueous solution and the resultant deposition of radioactive material may be employed, or a flow system may be utilized (54). Special plastic well units for beta-ray spectroscopy have also been devised (55).

CONCLUSIONS

A comparison of the various counting systems is presented in Table I. It is evident that

TABLE I

Comparisons of counting systems

Method	Advantages	Disadvantages	Typical application	Sample size
Internal liquid scintillation counting	Highest ultimate sensitivity	Limited sample solubility; quenching	C^{14}, H^3 isotopes of low specific activity	Unlimited
Suspension of radioactive substance in gel or thickened liquid scintillator	Little sample preparation; no quenching	Reduced optical transmission	Inorganic salts and organic substances insoluble in aromatic solvents	Sample thickness limited by opacity; 1 g
Filter paper counting	Little sample preparation; no quenching	Self-absorption	Inorganic salts and organic substances insoluble in aromatic solvents	Milligram quantities
Anthracene or plastic scintillator filaments in aqueous medium	Direct analysis of aqueous sample	Self-absorption in aqueous phase. Low efficiency	Aqueous solutions of energetic beta emitters	Three milliliters of aqueous solution
Quaternary ammonium salts or amines in liquid scintillator	Direct absorption of $C^{14}O_2$	$C^{14}O_2$ only	Direct analysis of combustion products	Milligram quantities of $C^{14}O_2$
Plastic scintillator capillary	Continuous analysis of flow systems	Self-absorption in aqueous phase	Chromatographic effluents	<1 ml volume

each of the counting methods has its particular merits and that the choice of the most suitable counting system must represent a delicate balance between maximum convenience and efficiency. Nevertheless it is obvious that the development of new alternative methods has hastened the adoption of scintillation detectors for many applications dependent upon the routine analysis of numerous samples. While the homogeneous liquid scintillator still represents the method of choice for extreme sensitivity, filter paper strips, or suspensions can be effectively employed in commercially available scintillation counters capable of automatically measuring many dozens of samples per day. For very small amounts of substance of high specific activity the heterogeneous detector systems also possess advantages in lower gamma backgrounds due to small scintillator size, and the elimination of quenching effects.

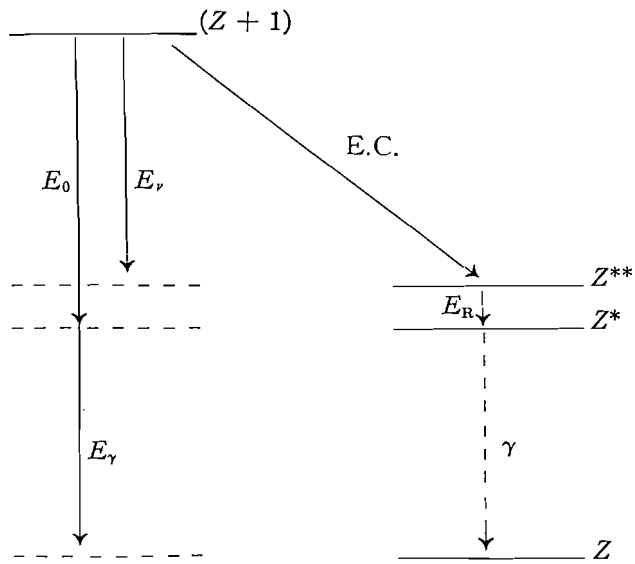
DETERMINATION OF THE DISINTEGRATION RATE OF NUCLIDES DECAYING BY ELECTRON CAPTURE[1]

J. R. S. DROUIN[2] AND L. YAFFE

ABSTRACT

In an attempt to determine disintegration rates of nuclides decaying by electron capture, various properties of a 2π proportional counter spectrometer were studied. These included gas multiplication, energy resolution, and energy linearity. The result of varying anode size, gas pressure, and nature of the gas was also investigated. An experimentally determined average path length for characteristic X-ray energies between 4 and 24 kev was found.

INTRODUCTION



Charged-particle irradiations normally lead to the formation of a new nucleus where the proton-to-neutron ratio is greater than that required for stability. In turn, the proton in excess will decay by one or two different modes, namely positron emission and(or) capture of one of the orbital electrons.

The two transformations can be represented as a nuclear transition from a proton state to a neutron state with accompanying neutrino emission (ν) in the following schematic picture:

$$p \rightarrow n + \beta^+ + \nu,$$
$$p + e^-_{K,L,M\ldots} \rightarrow n + \nu.$$

The first transformation can be ascertained by measuring the radiation due to the annihilation of the positron or by measuring the positrons themselves.

The second transformation can be described by the following energy diagram wherein a parent nucleus with atomic number $(Z + 1)$ captures one of its own orbital electrons and emits a neutrino transforming itself to the nucleus with atomic number Z.

Subsequent de-excitation by γ-ray emission may occur with energy E_γ. Thus the total energy for the transition equals $E_0 + E_\gamma$, where E_γ may be zero. Further,

$$E_0 = E_\nu + E_R$$

where E_ν is the energy available for the neutrino and E_R is the energy of the radiation characteristic of an atomic shell rearrangement, i.e. a characteristic X-ray or Auger electron.

In a small fraction of the cases, a continuous spectrum of internal bremsstrahlung results from the sudden change of nuclear charge. In this case the energy is shared between the bremsstrahlung and the neutrino.

One can attempt to standardize electron-capture transitions in three ways. The first relies on the absolute measurement of the primary radiations due to the internal bremsstrahlung. The second and third methods are based on the absolute measurement of the secondary radiations due to characteristic Auger electrons or characteristic X-rays.

In 1955, Rasmussen (1) suggested an elegant method which involved direct coincidence counting of the internal bremsstrahlung and the shell rearrangement radiation. However, Hayward demonstrated in 1958 (2) that the method was not entirely reliable, especially for low-energy transitions and for high atomic number elements, where the apportioning of the radiations due to capture of K-electrons becomes very difficult. Also, interference by radioactive impurities, background, and gamma de-excitation radiation, and the low probability ($\sim 0.001\%$) (3) of internal bremsstrahlung do not militate in favor of such a method.

A more convenient way would be the absolute measurement of the Auger electrons or the characteristic X-rays. For low atomic number elements (< 30) the Auger electrons give a major contribution but their energies are very low (few kiloelectron volts). With normal source preparation methods, absolute measurement is rendered very difficult due to source absorption problems. The situation is much less difficult if one tries to measure the characteristic X-rays emerging after shell rearrangement. We have attempted to investigate the variables concerned with the operation of a 2π-proportional counter spectrometer. This would then enable the standardization of nuclides, decaying by electron capture, by measure of the characteristic X-rays.

EXPERIMENTAL TECHNIQUE AND RESULTS

The design of the counter is, with minor modifications, similar to that used by others, and is shown in Fig. 1. Curran, Angus, and Cockcroft in 1948 (4) and simultaneously Kirkwood, Pontecorvo, and Hanna (5) used gaseous sources with counters of this type and were the first to apply the spectrometric properties of such counters in the study of low energy β^-- and X-ray spectra. Our instrument is a windowless counter, of 2π-geometrical efficiency, which can be operated at elevated pressures. The experimental data reported here deal only with solid sources.

Various fundamental properties of proportional counters were investigated. These important criteria for performance were checked with a mixture of argon–methane (9:1) as counter gas, although some work was done with krypton–methane (9:1).

First of all the voltage plateaux were studied. Their respective shapes are critically dependent on the counter gas (pressure and nature), the anode to cathode ratio, and the electronic circuit. A block diagram of the electronic arrangement is shown in Fig. 2. It was found necessary to incorporate a White cathode follower (6) with the proper

For personal use only.

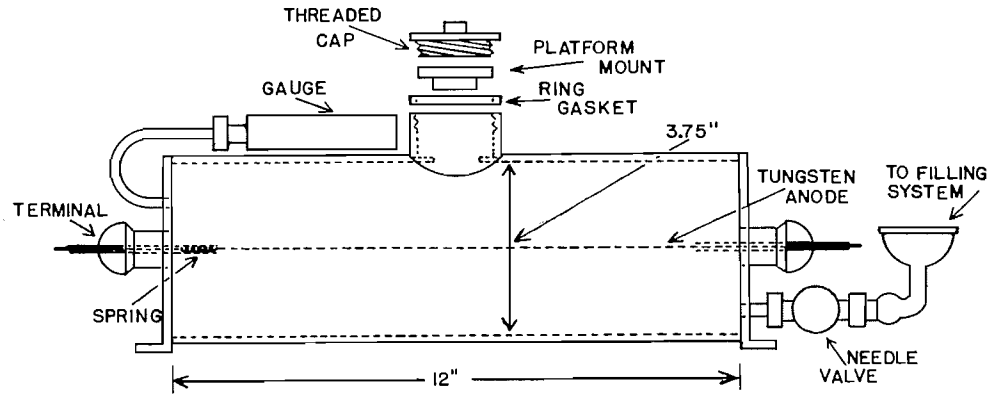

FIG. 1. 2π-Proportional counter.

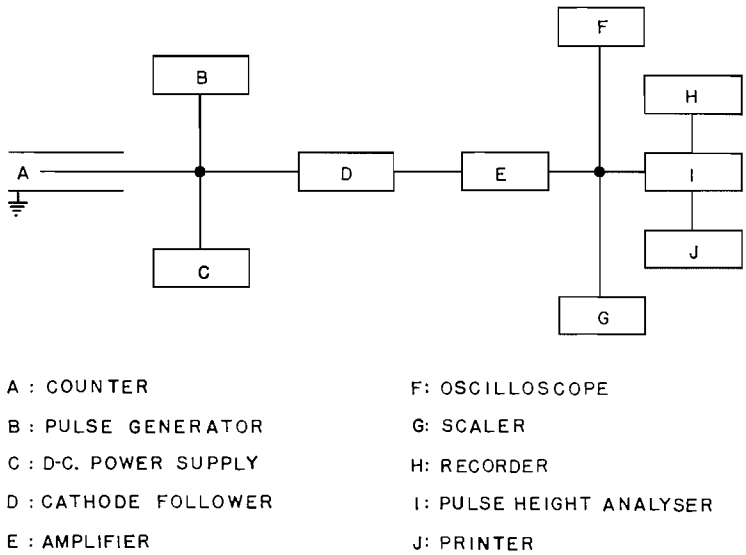

FIG. 2. Block arrangement of electronic equipment.

coupling constant for adequate performance. Figure 3 shows the plateau lengths obtained for different gas pressures and anode sizes. At a pressure of one atmosphere, for example, plateau lengths of about 600 volts with negligible slope were attainable when the anode diameters were 0.002 in., 0.003 in., 0.004 in., and 0.005 in. An anode diameter of 0.002 in. was used in the course of our work, unless otherwise mentioned.

Another intrinsic property of a proportional counter is the gas multiplication factor which is governed by the voltage across the chamber, the pressure and type of gas, and the anode-to-cathode ratio. In 1941, Rose and Korff (7) developed a theoretical treatment of this factor assuming an ionization cross section linear with electron energy up to 40 volts above the ionization threshold. They obtained experimental verification of the following equation, for amplification factors between 10^2 and 10^3 over a small voltage range ($\sim$ 150 volts).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

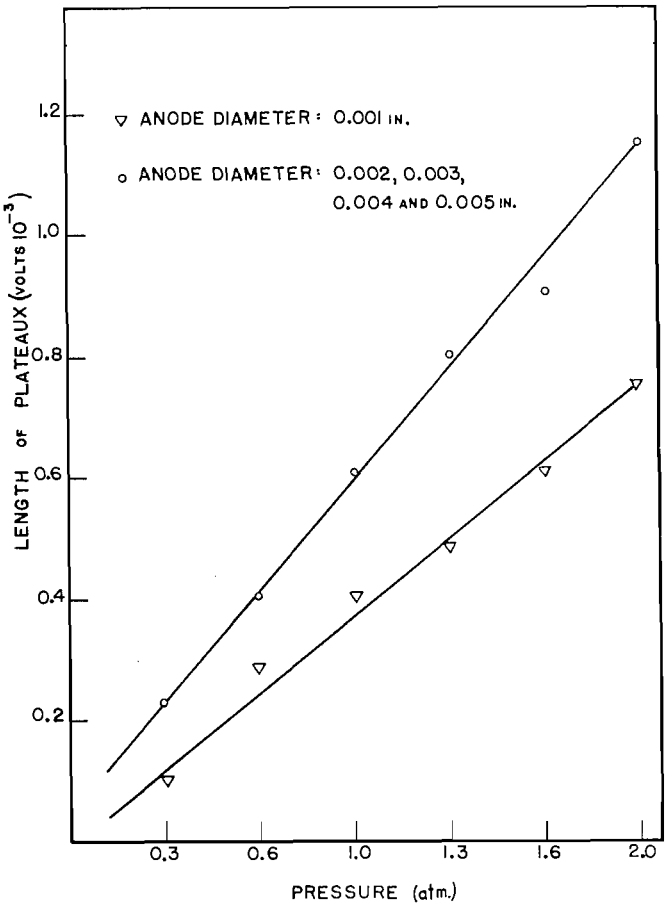

FIG. 3. Variation of length of voltage plateaux with counter gas pressure for various anode sizes.

$$A = \exp 2[a \,.\, N \,.\, c \,.\, r_1 V_0]^{\frac{1}{2}} \,.\, \left[\left(\frac{V_0}{V_p}\right)^{\frac{1}{2}} - 1\right]$$

where a = rate of increase of the ionization cross section with incident energy,
N = number of atoms or molecules inside the sensitive volume,

$$c = \frac{1}{\log_e \frac{r_2}{r_1}}$$

where r_2 is radius of the cathode and r_1 is radius of the anode,
V_0 = operating voltage, and
V_p = proportional threshold voltage.

For amplification factors greater than those used by Korff, it was found necessary to modify this equation by introducing another variable $f(0)$ into the exponential factor as follows:

$$A = \exp 2[a \,.\, N \,.\, c \,.\, r_1 \,.\, f(0) \,.\, V_0]^{\frac{1}{2}} \,.\, \left[\left(\frac{V_0}{V_p}\right)^{\frac{1}{2}} - 1\right]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Fig. 4 shows the variation of $f(0)$ when the anode size and gas pressure are varied over a wide range. From these data one can now calculate amplification factors between 10^3 and 10^6 for voltage ranges up to 1000 volts.

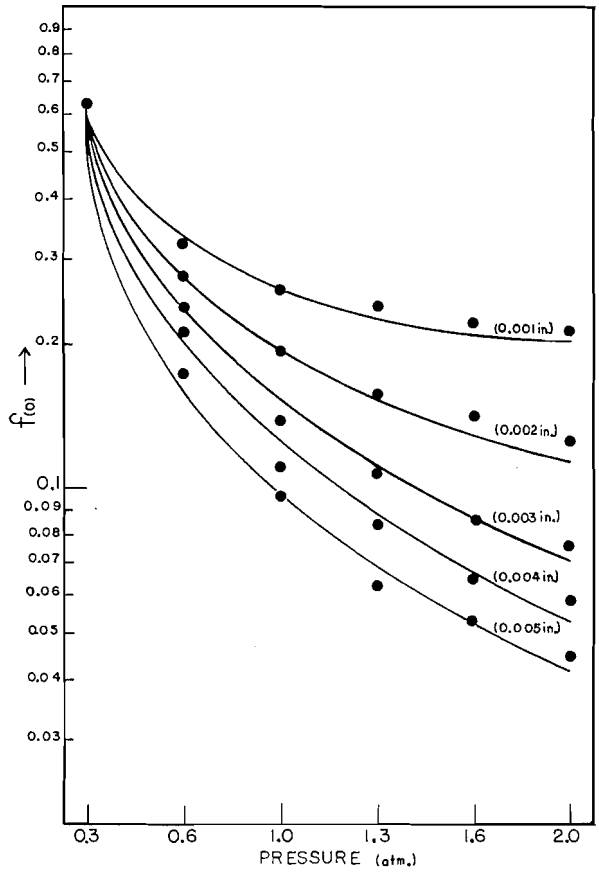

FIG. 4. Variation of $f(0)$ with pressure and anode size.

The energy linearity of the system was investigated for energy pulses between 3 and 24 kev as shown in Fig. 5. Only a very small departure from linearity at high energies was found.

Another important criterion for the operation of the device is the energy resolution. This was checked for anode wires of varying radii at different gas pressures. A standard source of Fe^{55} (5.9-kev X-rays) was used. The results in Fig. 6(*a*) show the variation of the energy resolution when five different anode sizes were employed.

If the anode size is kept constant and the pressure is varied, the mean free path of the electrons producing secondary ionizations will invariably be altered. According to calculations made by Korff (8), the mean free path should approximately be inversely proportional to the pressure. Then, as the pressure is decreased, statistical fluctuations in the pulse formations will increase. The energy resolution of the spectrometer was found to vary with pressure in the manner described in Fig. 6(*b*).

The pulse-size distribution from monoenergetic radiations in the energy range between 4 and 24 kev was analyzed. The size of every output pulse of a proportional counter,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

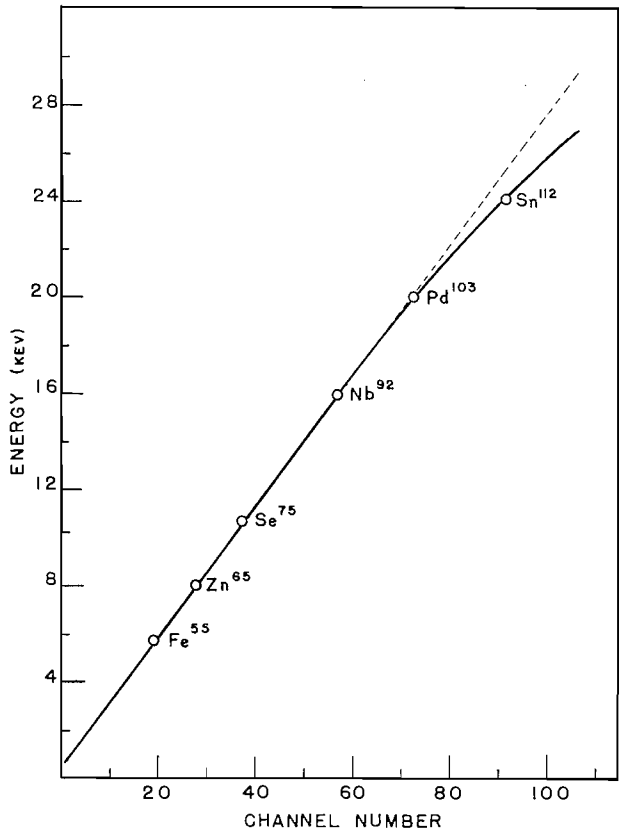

FIG. 5. Energy calibration of system.

arising from absorption of the full energy in the counter gas, is subject to statistical fluctuations. These fluctuations are mainly introduced by the statistics of the multiplication process in the counter.

A theoretical treatment by Frisch (9) and experimental results by Hanna *et al.* (10) have demonstrated that the relative variance (mean square relative standard deviation) of the output pulse size is practically independent of the multiplication factor. The pulse-size distributions produced by the radiations under investigation were studied. They could be fitted with Gaussian curves, at least in an interval of about ± 3 standard deviations.

The standard deviation (σ_P) can therefore be obtained by measuring the width (ΔE) of the peak at half maximum. This leads to $\Delta E = 2.36\ \sigma_P$, where $(\sigma_P/P)^2$ is the relative variance of the output pulse.

As may be seen from Fig. 7, (σ_P/P), the root mean square of the relative variance of the output pulse size, is plotted against the energy (E) of the radiations. The distribution was found to be slightly smaller than would be expected from a Poisson distribution.

The relationship derived from these experimental data can be described by

$$(\sigma_P/P) = 0.17\ E^{-\frac{1}{2}}.$$

Thus, resolving power $= 0.42\ E^{-\frac{1}{2}}$.

Now that the criteria for performance of the counter are ascertained, one needs to define the geometrical properties.

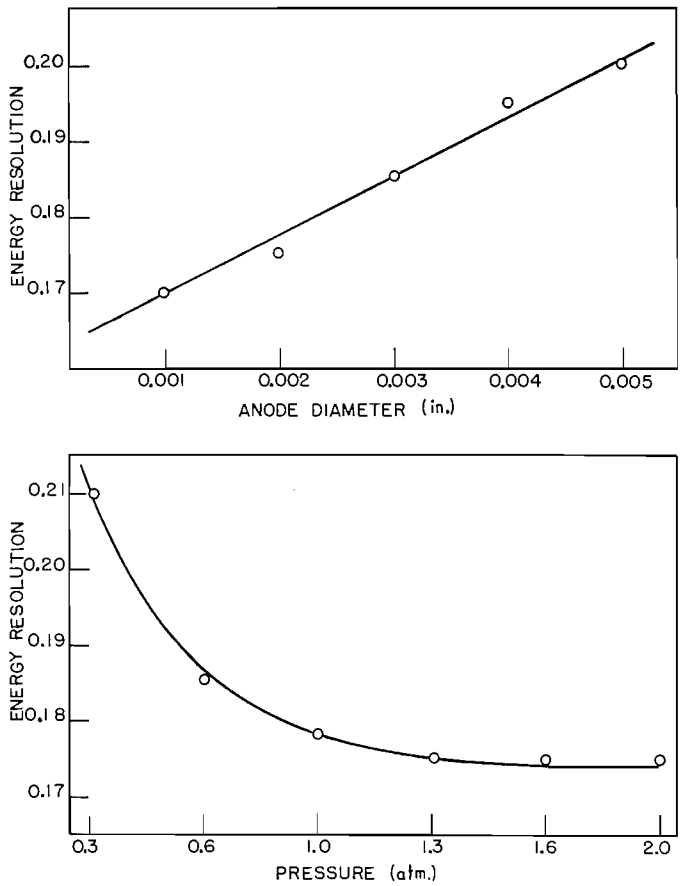

FIG. 6. (*a*) Variation of energy resolution with anode diameter (pressure = 1 atm). (*b*) Variation of energy resolution with pressure.

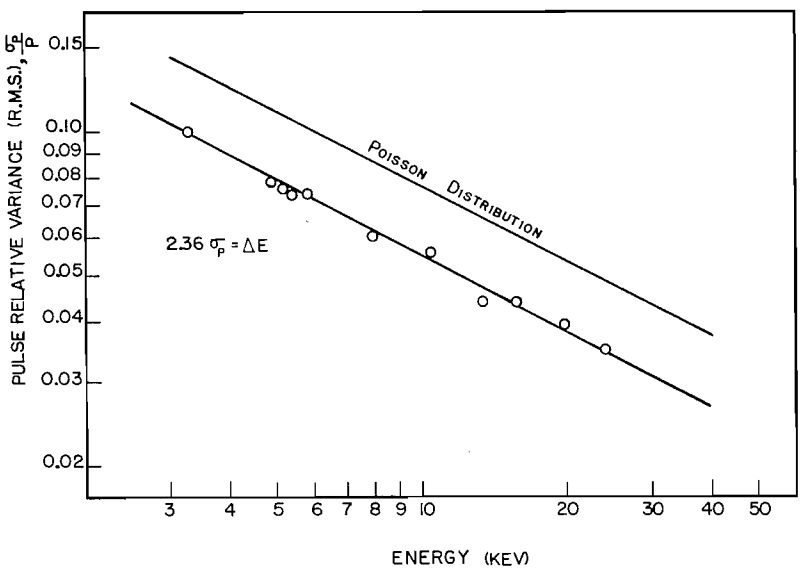

FIG. 7. Relation between the relative variance of the pulse and the X-ray energy.

The first factor is the geometrical efficiency. This was evaluated as 2π steradians when intercomparison was made with two other counters, (*a*) a high pressure proportional counter calibrated by Campion (11) and (*b*) a 4π β-counter calibrated by Pate and Yaffe (12). For this purpose, two different types of radiations were used, namely 5.9-kev X-rays from Fe^{55} and β^- particles emitted by H^3, Ni^{63}, and C^{14}. The values obtained are summarized in Table I.

TABLE I

Geometrical efficiency

Nuclides	This work (c.p.m.$\times 10^{-3}$)	High-pressure proportional counter (c.p.m.$\times 10^{-3}$)	4π β-counter (bottom half) (c.p.m.$\times 10^{-3}$)
Fe^{55}	34.00±0.05	34.07±0.07	—
H^3	41.2±0.2	—	41.5±0.2
Ni^{63}	47.3±0.2	—	47.5±0.2
C^{14}	46.2±0.2	—	46.7±0.2

A second correction which has to be introduced is that for the escape peak. For energies between 3 and 20 kev, Fig. 8 shows the ratio of the area under the escape peak to that of

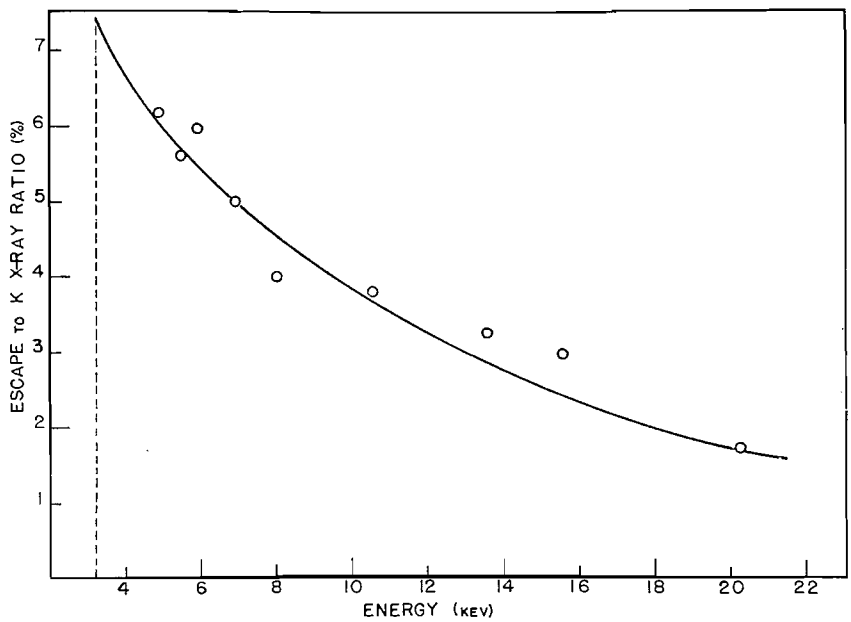

FIG. 8. Relation between the ratio of the escape peak to *K* X-ray and energy of the X-ray emitter.

the area under the *K* X-ray photopeak when the counter is operated at 1 atmosphere.

The third correction which has to be made resides in the absolute transmission of the X-rays through the finite sensitive volume of the counter. An average path length for these radiations in the counter was measured.

This was experimentally determined when four different radionuclides, namely Mn^{54} (5.4 kev), Fe^{55} (5.9 kev), Co^{57} (6.4 kev), and Zn^{65} (8.0 kev) were used. The pressure of the counter gas was increased up to a value where, if the relative count rates were plotted

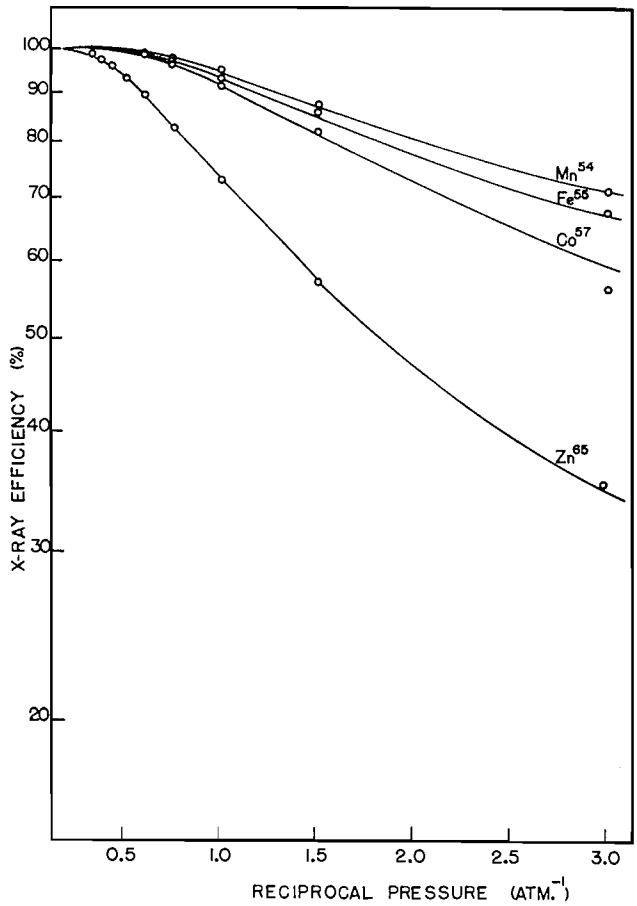

FIG. 9. Relation between X-ray counter efficiency and reciprocal pressure.

against the reciprocal pressures, as shown in Fig. 9, a plateau occurred. This was taken as total absorption in the counter. Such plots were originally investigated by Allen in 1957 (13). From these experimental data, an average path length can be derived from the equation for the absorption of photons passing through matter:

$$I = I_0 \exp -\mu t.$$

I and I_0 are the transmitted and incident radiation respectively, and t is the path length. The values for the linear absorption coefficient μ were obtained from Hagedoorn and Wapstra (14).

The results are summarized in Table II and give an average path length of 6.8 cm. Four of them were obtained from the plateau counting rates, while the other four were derived from integrating the counting rate beneath the K X-ray photopeaks.

With the above experimental path length, the efficiency of the 2π-proportional counter spectrometer was derived for K X-ray energies between 5 and 25 kev when the counter is operated at one atmosphere, argon–methane (9:1). Experimental relative efficiencies are shown in Fig. 10 when the pressure of the counter gas is varied. The contribution due to the escape peak has been included.

TABLE II

Average-path-length determination

Nuclides	t_p (cm)	t_s(cm)	$\bar{t}$ (cm)
Mn^{54}	6.18	6.05	
Fe^{55}	6.75	6.95	6.8
Co^{57}	7.35	7.10	
Zn^{65}	6.90	7.05	

NOTE: t_p = average path length based on calculations on the plateaux. t_s = average path length based on calculations on the spectra.

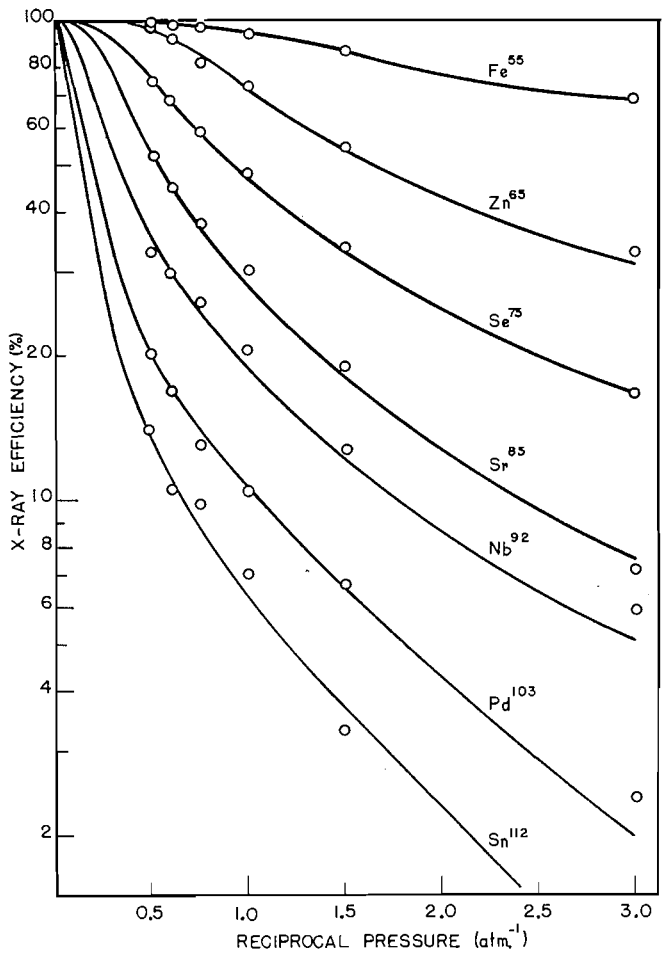

FIG. 10. Relation between X-ray counter efficiency and reciprocal pressure for argon–methane (9:1) (escape peak included).

For higher energy X-ray emitters, it is desirable to use a krypton–methane (9:1) mixture in order to take advantage of the enhanced absorption. These data are shown in Fig. 11 and again include the escape peak contribution.

For personal use only.

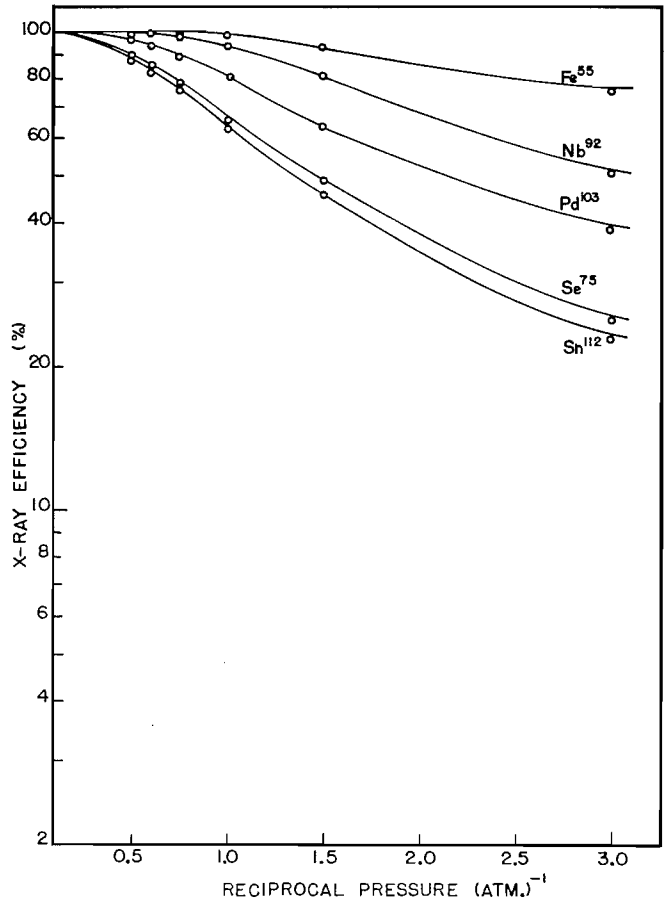

FIG. 11. Relation between X-ray counter efficiency and reciprocal pressure for krypton–methane (9:1) (escape peak included).

Figure 12 gives the ratio of the X-ray efficiencies for the two counter gases as a function of energy.

With a solid source, screened by sufficient aluminum to cut out the Auger electrons, a knowledge of the operational characteristics of the instrument and the evaluation of the correction factors necessary as described, one can now establish an equation for the disintegration rate N_0 of radionuclides decaying by electron capture when the counting rate R has been measured. The following equation applies:

$$R = N_0.G.f_a.f_t.f_{w_k}.f_r$$

where

G = defined source-to-counter geometrical efficiency (Table I).
f_a = factor correcting for total absorption inside the counter (Figs. 10 and 11).
f_t = factor for the transmission of K X-rays through the Auger electron absorber (11).
f_{wk} = factor due to the K-fluorescence yield (15).
f_r = factor due to L-capture events (16, 17).

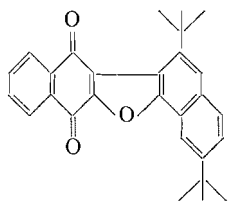
THE STRUCTURE OF DI-*tert*-BUTYLNAPHTHALENESULPHONIC ACIDS[1]

MARCEL MENARD, LEONARD MITCHELL, JACQUELINE KOMLOSSY, AVERIL WRIGLEY, AND FRANCIS L. CHUBB

ABSTRACT

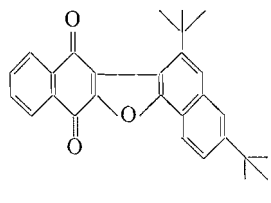
Commercial sodium di-*tert*-butylnaphthalenesulphonate has been resolved into its isomers, which were shown to be sodium 2,6- and 2,7-di-*tert*-butylnaphthalene-4-sulphonates.

Sodium di-*tert*-butylnaphthalenesulphonate is known as an effective central inhibitor of the cough reflex (1). Although some authors (1) refer to this antitussive drug as sodium 2,6-di-*tert*-butylnaphthalenesulphonate, its mode of preparation suggests that it is a mixture of at least two different isomers. It is prepared (2) by a Friedel–Crafts alkylation of naphthalene with 2 moles of *tert*-butyl chloride followed by sulphonation of the butylation product. Since several workers (3) have shown that *tert*-butylation of naphthalene gives a mixture containing about equal parts of 2,6- and 2,7-di-*tert*-butylnaphthalene, the commercial product can be inferred to consist of approximately equal quantities of the corresponding sulphonates. The purpose of this work was to isolate the isomers of sodium di-*tert*-butylnaphthalenesulphonate and to determine their structure.



Reaction of commercial sodium di-*tert*-butylnaphthalenesulphonate with thionyl chloride according to a procedure recently developed by Bosshard *et al.* (4) gave a mixture from which two isomeric sulphonyl chlorides could be isolated by fractional crystallization: one melting at 167–169°, insoluble in cold ligroin; the second melting at 117–118°, moderately soluble in ligroin. Hydrolysis of these sulphonyl chlorides with sodium hydroxide regenerated the pure sulphonates. The sulphonate obtained from the higher-melting isomer was shown to be sodium 2,7-di-*tert*-butylnaphthalenesulphonate by conversion to 2,7-di-*tert*-butylnaphthalene (3) with 60% sulphuric acid. In the same way the sulphonate obtained from the lower-melting sulphonyl chloride was related to 2,6-di-*tert*-butylnaphthalene.

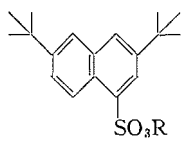
In order to determine the position of the sulphonic acid group of these compounds, sulphonation of 2,6- and 2,7-di-*tert*-butylnaphthalene under conditions which usually bring about α-sulphonation of naphthalene and naphthalene derivatives (5) was carried out. Reaction of these sulphonic acids with thionyl chloride gave the same sulphonyl chlorides as those isolated from the commercial product. On the other hand alkaline fusion of the sulphonates yielded naphthols which readily coupled with phenyldiazonium chloride to give orange-red azo dyes; these were easily reduced by stannous chloride to aminonaphthols, which in turn gave yellow quinones on oxidation. The quinone obtained from the 2,6-di-*tert*-butylnaphthol was found to be identical with the quinone obtained by Fieser and Price (6) from a chromic acid oxidation of 2,6-di-*tert*-butylnaphthalene.



[1]*Manuscript received December 8, 1960.*
Contribution from the Research Laboratories, Frank W. Horner Limited, Montreal, Quebec.

This quinone was later shown by Crawford and Glesmann (3) to be 2,6-di-*tert*-butyl-1,4-naphthoquinone. Chromic acid oxidation of 2,7-di-*tert*-butylnaphthalene under similar conditions also gave a quinone, identical with that resulting from the coupling reaction of the 2,7-di-*tert*-butylnaphthol, reduction of the azo dye, and oxidation of the aminonaphthol. Furthermore, we found that the disubstitution product obtained by Buu-Hoi and Demerseman (7) from the alkylation of α-naphthol with *tert*-butyl bromide, which they suggest may be a 4,*x*-di-*tert*-butyl-1-naphthol, was identical with the naphthol obtained from the alkaline fusion of 2,6-di-*tert*-butylnaphthalenesulphonate. Thus the sulphonic acid group of the starting sulphonates can only be in the 1 or 4 positions.

Of the two possible α-positions, position 4 seemed more probable: sulphonation of 2,6- and 2,7-dimethylnaphthalene occurs preferentially in position 4 (8) and furthermore position 1 is subjected to the steric effect of the tertiary butyl group. Position 1 was finally eliminated by the fact that yellow di-*tert*-butyldinaphthofuranquinones, I and II, giving an intense blue color with sulphuric acid, could be isolated from the reaction of 2,6- and 2,7-di-*tert*-butylnaphthols with 2,3-dichloro-1,4-naphthoquinone. This cyclization reaction was shown by Buu-Hoi and Demerseman (7) to be characteristic of naphthols having an unsubstituted position adjacent to the OH group, which holds only if the hydroxyl group of the 2,6- and 2,7-di-*tert*-butylnaphthol occupies position 4. Consequently the sulphonic acid group in the starting sulphonates must occupy position 4.



I

II

Reaction of 2,7-di-*tert*-butylnaphthalene-4-sulphonyl chloride with alcohols in pyridine solution afforded a series of esters which are reported in Table I. The methyl and ethyl ester of 2,6-di-*tert*-butylnaphthalene-4-sulphonic acid were prepared by reaction of the acid with diazomethane and diazoethane in ether solution.

TABLE I

EXPERIMENTAL

2,6- and 2,7-Di-tert-butylnaphthalene-4-sulphonyl Chloride

The commercial mixture of sodium di-*tert*-butylnaphthalenesulphonate (34.6 g, 0.1 mole), thionyl chloride (25 ml), and dimethylformamide (0.8 ml) were heated for 1 hour on the steam bath. The excess of thionyl chloride was evaporated under reduced pressure and the residue was triturated with 100 ml of cold water, filtered, and dried over sulphuric acid. The dried mixture of sulphonyl chlorides (36.2 g) was recrystallized in 100 ml of ligroin, with the aid of 3 g of decolorizing charcoal; there was so obtained 12.3 g (36%) of 2,7-di-*tert*-butylnaphthalene-4-sulphonyl chloride, m.p. 163–165°. The analytical sample, recrystallized from ligroin, had a melting point of 167–169°. Calc. for $C_{18}H_{23}O_2SCl$: C, 63.79; H, 6.84%. Found: C, 63.97; H, 7.01%.

Concentration of the mother liquors and repeated recrystallization of the residue from isopropanol gave 8.2 g (24.3%) of 2,6-di-*tert*-butylnaphthalene-4-sulphonyl chloride, m.p. 117–118°. Calc. for $C_{18}H_{23}O_2SCl$: C, 63.79; H, 6.84%. Found: C, 64.03; H, 6.97%.

Sodium 2,7-Di-tert-butylnaphthalene-4-sulphonate

To a boiling solution of 5 g of 2,7-di-*tert*-butylnaphthalene-4-sulphonyl chloride in 20 ml of ethanol there was slowly added a solution of 1.2 g of sodium hydroxide in 40 ml of water. The mixture was refluxed for 4 hours, the solvents removed, and the residue recrystallized from water to give 4.8 g (85%) of colorless waxy plates. Calc. for $C_{18}H_{23}O_3SNa.2H_2O$: C, 57.15; H, 7.20; S, 8.47%. Found: C, 57.44; H, 7.12; S, 7.49%.

Sodium 2,6-Di-tert-butylnaphthalene-4-sulphonate

Hydrolysis of 2,6-di-*tert*-butylnaphthalene-4-sulphonyl chloride with sodium hydroxide gave 90% of colorless needles from nitromethane, m.p. >360°. Calc. for $C_{18}H_{23}O_3SNa.2H_2O$: C, 57.15; H, 7.20; S, 8.47%. Found: C, 57.51; H, 7.09; S, 8.08%.

2,7-Di-tert-butylnaphthalene

A mixture of 8 g of sodium 2,7-di-*tert*-butylnaphthalene-4-sulphonate and 100 ml of a 60% solution of sulphuric acid was stirred and heated at 150–160° for 5 hours, cooled, poured into 1 liter of cold water, and extracted with ether. The ether extracts were washed with water, dried, and concentrated. After recrystallization from ethanol the residue yielded 2.8 g of colorless needles, m.p. 103–104°; these gave no depression of melting point when mixed with a sample prepared according to Price *et al.* (3).

2,6-Di-tert-butylnaphthalene

Hydrolysis of 5 g of sodium 2,6-di-*tert*-butylnaphthalene-4-sulphonate in 60% sulphuric acid gave 1.7 g of flat needles, m.p. 145–146°. Identity of this material with pure 2,6-di-*tert*-butylnaphthalene (3) was confirmed by a mixed melting point.

2,6-Di-tert-butylnaphthalene-4-sulphonic Acid

Chlorosulphonic acid (56 g, 0.48 mole) was slowly added, with stirring and cooling, to a solution of 116 g (0.48 mole) of pure 2,6-di-*tert*-butylnaphthalene in 240 ml of dichloroethane. The reaction mixture was allowed to stand for 2 hours at 0–5° and the solvent was removed at room temperature under reduced pressure. The residue, a heavy oil, started to crystallize upon the addition of 0.5 mole of water; recrystallization from dichloroethane gave 155 g (95%) of the hydrate of 2,6-di-*tert*-butylnaphthalene-4-sulphonic acid as colorless plates, m.p. 158°. Calc. for $C_{18}H_{24}O_3S.H_2O$: C, 63.87; H, 7.74%; M.W., 338.5. Found: C, 63.45; H, 7.76%; N.E., 339.3.

2,7-Di-tert-butylnaphthalene-4-sulphonic Acid

2,7-Di-*tert*-butylnaphthalene (3.3 g) dissolved in 7 ml of dichloroethane and treated, as described for the 2,6-isomer, with 1.8 g of chlorosulphonic acid gave 2.6 g (55%) of the hydrate of 2,7-di-*tert*-butylnaphthalene-4-sulphonic acid, m.p. 140–142° (chloroform – petroleum ether). Calc. for $C_{18}H_{24}O_3S.H_2O$: C, 63.87; H, 7.74%; M.W., 338.5. Found: C, 62.54; H, 7.82%; N.E., 339.4.

2,6-Di-tert-butylnaphthalene-4-sulphonyl Chloride

The anhydrous residue obtained from the reaction of 56 g of chlorosulphonic acid and 116 g of 2,6-di-*tert*-butylnaphthalene as described above was mixed, in a distillation apparatus, with 91 ml of thionyl chloride and 3 ml of dimethylformamide. The mixture was stirred and heated on the steam bath until it became homogeneous ($\frac{1}{2}$ hour). During that time most of the excess of thionyl chloride had distilled over; the remainder was removed under reduced pressure. The residue was triturated with cold water and extracted with ether. The combined ether extracts were dried and concentrated; the solid residue, recrystallized from alcohol, gave 133.5 g (86%) of colorless prisms, m.p. 117–118°. These gave no depression of melting point when mixed with a sample of the sulphonyl chloride obtained from the commercial mixture of sulphonates.

The amide was prepared by passing dry ammonia through a solution of the chloride in tetrahydrofuran, removing the solvent, triturating the residue with water, and recrystallizing the dried solid from ligroin: m.p. 160–161°. Calc. for $C_{18}H_{25}O_2NS$: C, 67.67; H, 7.89; N, 4.38%. Found: C, 67.70; H, 7.89; N, 4.37%.

2,7-Di-tert-butylnaphthalene-4-sulphonyl Chloride

The anhydrous 2,7-di-*tert*-butylnaphthalene-4-sulphonic acid, treated as described above with thionyl chloride and dimethylformamide, gave 90% of colorless prisms, m.p. 167–169°; this melting point was not depressed by mixing with the 2,7-di-*tert*-butylnaphthalene-4-sulphonylchloride obtained from the commercial mixture of sulphonates.

The amide was prepared as above, m.p. 165°. Calc. for $C_{18}H_{25}O_2NS$: C, 67.67; H, 7.89; N, 4.38%. Found: C, 67.17; H, 8.06; N, 4.59%.

2,7-Di-tert-butyl-4-naphthol

Potassium 2,7-di-*tert*-butylnaphthalene-4-sulphonate (30 g), 100 g of potassium hydroxide, and 30 ml of water were heated slowly in an iron crucible until the mixture melted and the potassium salt of the naphthol floated on the surface of the melt as a dark-brown oil. The mixture was cooled, dissolved in water, acidified with hydrochloric acid, and extracted three times with ether. The combined ether extracts were washed with water, dried, and concentrated. The residue, a heavy black oil, was distilled under reduced pressure and yielded 14.2 g of a yellow oil, b.p. 170–180°/4 mm. Crystallization of this oil in ligroin afforded 8 g (41%) of colorless needles, m.p. 125–126°. The analytical sample, recrystallized from ligroin, had a melting point of 127–128°. Calc. for $C_{18}H_{24}O$: C, 84.32; H, 9.44%. Found: C, 84.47; H, 9.43%.

2,6-Di-tert-butyl-4-naphthol

Alkaline fusion of potassium 2,6-di-*tert*-butylnaphthalene-4-sulphonate carried out as described above for the 2,7-isomer, gave 63% of a reddish oil, b.p. 190°/3 mm, which afforded 25% of colorless crystals, m.p. 142°. The identity of this compound with the one obtained by Buu-Hoi and Demerseman (7) from *tert*-butylation of α-naphthol was confirmed by a mixed melting point.

2,7-Di-tert-butyl-1-phenylazo-4-naphthol

Aniline (3.4 g), dissolved in 11 ml of concentrated hydrochloric acid and 11 ml of water,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

was diazotized with a solution of 2.8 g of sodium nitrite in 14 ml of water. The resultant solution of phenyldiazonium chloride was added dropwise to a well-stirred mixture of 8 g of 2,7-di-*tert*-butyl-4-naphthol, 30 ml of 10% sodium hydroxide solution, and 20 ml of tetrahydrofuran cooled to 5°. The mixture was then stirred for 30 minutes at 5° and allowed to stand overnight. Most of the tetrahydrofuran was removed under reduced pressure and the water was decanted from the heavy dark oil, which was then boiled with 40 ml of glacial acetic acid and filtered hot. After cooling and filtering, the crude precipitate was recrystallized from 200 ml of acetic acid to yield 2.6 g (28%) of red crystals, m.p. 229–239°. Calc. for $C_{24}H_{28}ON_2$: C, 79.96; H, 7.83; N, 7.77%. Found: C, 79.91; H, 7.88%; N, 7.74%.

2,6-Di-tert-butyl-phenylazo-4-naphthol

The coupling reaction of 4 g of 2,6-di-*tert*-butyl-4-naphthol with phenyldiazonium chloride was carried out as described above for the 2,7-isomer. After removal of the tetrahydrofuran, a solid was obtained which was filtered and recrystallized from acetic acid to give 2.2 g of the orange-red azo compound, m.p. 204–206°. Calc. for $C_{24}H_{28}ON_2$: C, 79.96; H, 7.83; N, 7.77%. Found: C, 79.80%; H, 7.80%; N, 7.42%.

2,7-Di-tert-butyl-1,4-naphthoquinone

(a) From 2,7-Di-tert-butylnaphthalene

A solution of 2.6 g of chromium trioxide in 4.4 ml of acetic acid and 2.9 ml of water was added dropwise to a stirred slurry of 2.0 g of 2,7-di-*tert*-butylnaphthalene in 11 ml of acetic acid maintained at 60°. After the addition was complete, the mixture was stirred for ½ hour at 60°, poured into 150 ml of cold water and extracted with ether. The ether extracts were washed with water, dried, and concentrated; the residue crystallized from dilute alcohol and yielded 2.0 g (89%) of yellow needles, m.p. 72°. Calc. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20%. Found: C, 79.71%; H, 7.92%.

Reaction of the quinone with 2,4-dinitrophenylhydrazine gave a compound which crystallized from acetic acid as orange-red needles, m.p. 250–251°. Calc. for $C_{24}H_{26}O_6N_4$: C, 63.98; H, 5.82; N, 12.44%. Found: C, 63.79; H, 5.90; N, 12.41%.

(b) From 2,7-Di-tert-butyl-1-phenylazo-4-naphthol

A solution of 8 g of stannous chloride in 24 ml of concentrated hydrochloric acid was added to a boiling slurry of 1.9 g of 2,7-di-*tert*-butyl-1-phenylazo-4-naphthol in 80 ml of methanol; the azo compound slowly dissolved and after 1½ hours the solution was colorless. It was concentrated to a volume of approximately 30 ml and cooled. The crystalline 2,7-di-*tert*-butyl-1-amino-4-naphthol hydrochloride was filtered and slurried in a solution of 0.6 ml of sulphuric acid in 12 ml of water. A solution of 0.4 g of potassium dichromate in 6 ml of water was added to the resultant mixture and the whole was heated at steam-bath temperature for 5 minutes, cooled, diluted with water, and extracted with ether. The ether extracts were washed with water, dried, and concentrated. Upon reaction with 2,4-dinitrophenylhydrazine the liquid residue gave an orange-red compound, m.p. 250–251°, found by a mixed melting point determination to be identical with the addition compound obtained as under (*a*).

2,6-Di-tert-butyl-1,4-naphthoquinone

(a) From 2,6-Di-tert-butylnaphthalene

Oxidation of 13.8 g of 2,6-di-*tert*-butylnaphthalene with 18 g of chromium trioxide as described above for the 2,7-isomer yielded a solid compound after the reaction mixture was poured into water. Recrystallization of this solid from ethanol gave 7.4 g (48%) of yellow needles, m.p. 85–86° (lit. (6) m.p. 83.5–84.5°).

(b) From 2,6-Di-tert-butyl-1-phenylazo-4-naphthol

Reduction of this azo compound (0.23 g) with stannous chloride and oxidation of the aminonaphthol with potassium dichromate gave 0.1 g (60%) of yellow needles, m.p. 85–86°, not depressed when mixed with a sample prepared according to (*a*).

Esters of 2,7-Di-tert-butylnaphthalene-4-sulphonic Acid

A solution of 0.15 mole of the appropriate alcohol in 80 ml of anhydrous pyridine was cooled to −10°; 0.08 mole of powdered 2,7-di-*tert*-butylnaphthalene-4-sulphonyl chloride was added at such a rate that the temperature would not exceed −5°; the resultant mixture was stirred for 2 hours at 0–5° and poured into water (500 ml). In those cases where a solid ester was obtained it was separated by filtration and recrystallized from the appropriate solvent; when an oil was obtained, the ester was extracted with ether and isolated by the usual procedure. Physical data for the esters involved are included in Table I.

Esters of 2,6-Di-tert-butylnaphthalene-4-sulphonic Acid

A slight excess of an ethereal solution of the appropriate diazoalkane was added to a cooled solution of the monohydrate of 2,6-di-*tert*-butylnaphthalene-4-sulphonic acid in ether. After standing overnight the solvent was removed and the ester isolated. The methyl ester was obtained as a solid which crystallized from methanol as colorless prisms, m.p. 123–124°. Calc. for $C_{19}H_{26}O_3S$: C, 68.22; H, 7.84; S, 9.58%. Found: C, 68.58; H, 7.95; S, 9.94%.

The ethyl ester was obtained as a colorless oil, b.p. 180–185/1 mm. Calc. for $C_{20}H_{28}O_3S$: C, 68.93; H, 8.10%. Found: C, 68.92%; H, 8.26%.

3′,7′-Di-tert-butyldinaphtho(1′,2′-2,3)(2″,3″-4,5)furan-1″,4″-quinone

A solution of 2.6 g of 2,6-di-*tert*-butyl-4-naphthol and 2.3 g of 2,3-dichloro-1,4-naphthoquinone in 15 ml of anhydrous pyridine was stirred and refluxed for 18 hours. After cooling, the mixture was diluted with methanol and filtered. Recrystallization of the filter cake from toluene gave 0.52 g (13%) of yellow needles, m.p. 354–355°. Calc. for $C_{28}H_{26}O_3$: C, 81.92; H, 6.38%. Found: C, 81.78; H, 6.53%.

3′,6′-Di-tert-butyldinaphtho(1′,2′-2,3)(2″,3″-4,5)furan-1″,4″-quinone

A solution of 4.6 g of 2,3-dichloro-1,4-naphthoquinone and 5.2 g of 2,7-di-*tert*-butyl-4-naphthol in 30 ml of pyridine was stirred and refluxed for 18 hours. After cooling, the mixture was filtered and the filtrate concentrated to a volume of approximately 10 ml. The pyridine solution was then diluted with methanol and allowed to stand overnight. Filtration and recrystallization of the filter cake in toluene–methanol afforded 1.1 g (15%) of orange-yellow needles, m.p. 217–218.° Calc. for $C_{28}H_{26}O_3$: C, 81.92; H, 6.38%. Found: C, 82.21; H, 6.57%.

THE EQUILIBRIUM DIAGRAMS, HEATS OF MIXING, DIPOLE MOMENTS, DENSITIES, AND BOILING POINTS OF THE SYSTEM ACETONE–CHLOROFORM–BENZENE[1]

A. N. Campbell, E. M. Kartzmark, and H. Friesen

ABSTRACT

The equilibrium diagrams show that a compound, stable in the solid state, is formed in the system chloroform–acetone, but no compound is formed in the binary systems chloroform–benzene and acetone–benzene. The ternary equilibrium diagram, the heats of mixing, and the dipole moments, all show that this compound continues to exist in the presence of benzene, up to a high concentration of benzene. Since a series of ternary mixtures is shown to exist having zero heat of mixing, it was thought that this series of mixtures might behave in a pseudoideal manner, but the determinations of density (molar volume) and boiling point show that this is not so.

The existence of a compound, $CHCl_3$—$(CH_3)_2CO$, in mixtures of chloroform and acetone has been shown to be probable (1): the compound is an obvious example of hydrogen bonding. We thought it would be interesting to investigate the effect of adding the non-polar liquid benzene to the acetone–chloroform system. The systems benzene–chloroform, benzene–acetone, chloroform–acetone, and the ternary system benzene–chloroform–acetone, were investigated in regard to the following properties: freezing point diagrams, heats of mixing, dipole moments, densities, and boiling points.

EXPERIMENTAL

Freezing-Point Diagrams

The technique has often been described. It consisted essentially of a double-jacketed vessel containing a system of known composition. By controlling the degree of vacuum in the jacket, any desired rate of cooling could be obtained. The cooling agent was liquid nitrogen. Temperatures were measured by means of a copper–constantan thermocouple and a recording potentiometer.

Heats of Mixing

Heats of mixing were determined by having a weighed amount of one liquid in a magnetically stirred vacuum-walled calorimeter and the second liquid, also weighed, in a second such vessel. One set of junctions of a 20-junction copper–constantan thermopile was in the calorimeter and the other in the other vessel so that the thermopile measured the difference in temperature of the two vessels; allowance was made for slight original difference in temperature. The thermopile had a sensitivity of about 0.2° C, corresponding to the minimum reading of the recorder chart. A suitable quantity of the second liquid was forced through a course capillary into the calorimeter, the amount being determined by weighing at the end of the experiment.

The average rise in temperature was about 7°. The usual method of radiation correction was applied and the water equivalent of calorimeter and contents was determined electrically for each individual experiment. Current through the immersed platinum heating coil was determined from the voltage drop over a standard resistance. By this method temperatures are not measured as such; the electrical input is multiplied by the ratio of two vertical lines on the recorder graph.

[1]*Manuscript received December 1, 1960.*
Contribution from the Chemistry Department of the University of Manitoba, Winnipeg, Manitoba.

The ternary system was treated in the following way. Stock solutions were made up containing fixed mole fractions of benzene, e.g.

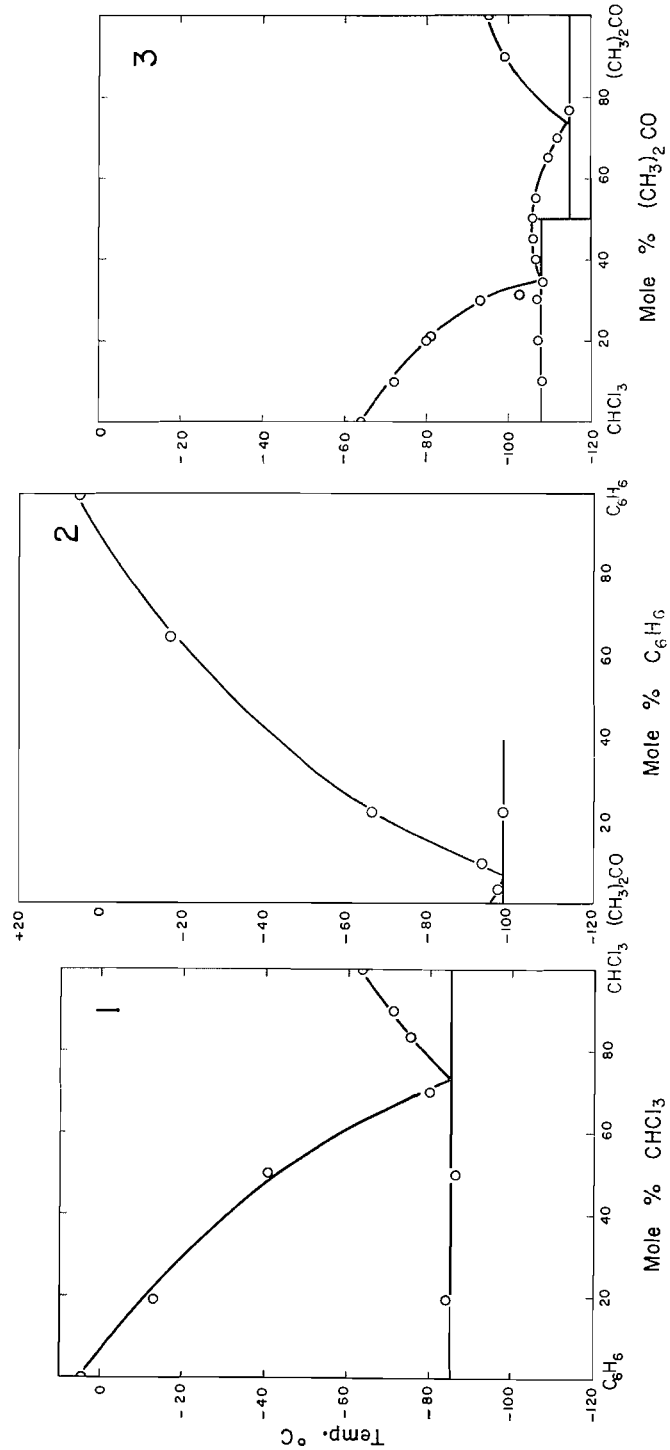
$$0.1\ N_{C_6H_6} \qquad 0.9\ N_{CHCl_3}$$

$$0.1\ N_{C_6H_6} \qquad 0.9\ N_{(CH_3)_2\cdot CO}.$$

These were mixed in varying proportions and the heat effect measured, corrections being applied for the heat exchange that had occurred in the original mixing of the quantities of stock solution used. This procedure was reported for each 1/10th mole fraction benzene; the results were plotted as in Fig. 5. The presence of benzene lowered the heat effect (evolution) with regard to acetone–chloroform because, on mixing benzene with acetone a small quantity of heat is absorbed, and in the case of benzene–chloroform, although heat is evolved, the quantity is small.

Dipole Moments

Dielectric constants of known mixtures of acetone, chloroform, and benzene were determined on a General Radio capacitance bridge, using an audio-frequency oscillator at 1000 cycles to energize the bridge and amplifying the signal to headphones. The arrangement worked well for low dielectric constants. Thus, it reproduced exactly the dielectric constants of pure benzene and pure chloroform but not the relatively high dielectric constant of acetone. Since, however, we were only interested in ternary solutions containing at least 90 mole% benzene, we experienced no trouble.



We argued in our paper on the energy of hydrogen bonding (2) that, however highly dissociated the compound of acetone and chloroform may be when the components are present in equimolecular proportion, the dissociation must be reduced to zero, when one or other component is present in infinite excess. A similar argument should apply to the dipole moment but here both components should be in the presence of an infinite excess of benzene, if the true molecular polarization is to be deduced. For this purpose we determined the dielectric constants over a range of chloroform–acetone ratios, in benzene as solvent. Two series of measurements were made: (1) in 90 mole% benzene; (2) in 95 mole% benzene. Measurements were not carried to greater dilution because the magnification of the experimental error rendered the final result of little value.

Boiling Points

A very complete investigation of the boiling points of the ternary system has been made by Reinders and de Minjer (3). The system is non-ideal, an azeotropic maximum occurring in the acetone–chloroform system. It seemed to us, however, from our measurements of heat of mixing that a curve of pseudoideal behavior might traverse the ternary diagram. At least, there certainly exists such a series of solutions which are formed with zero heat of mixing. If this series were really ideal, members of it would form from the components without volume change and the partial pressures would agree with Raoult's law. For this purpose, we re-established the apparatus previously used by Campbell and Dulmage (4), which comprises the Scatchard equilibrium still and a barostat made up from various suggestions. The apparatus works very well, since there is no detectable fluctuation in pressure and the boiling-point fluctuation is only $\pm 0.01°$ C (at most). Equilibrium liquid and vapor phases were analyzed by density and refractive index determinations using the graphs of Reinders and de Minjer.

FIGS. 1–3. Freezing-point diagrams. System benzene–chloroform (Fig. 1); acetone–benzene (Fig. 2); chloroform–acetone (Fig. 3).

EXPERIMENTAL RESULTS

Equilibrium Diagrams

The binary systems benzene–chloroform, benzene–acetone, and chloroform–acetone are represented in Figs. 1, 2, and 3 and the ternary system in Fig. 4.

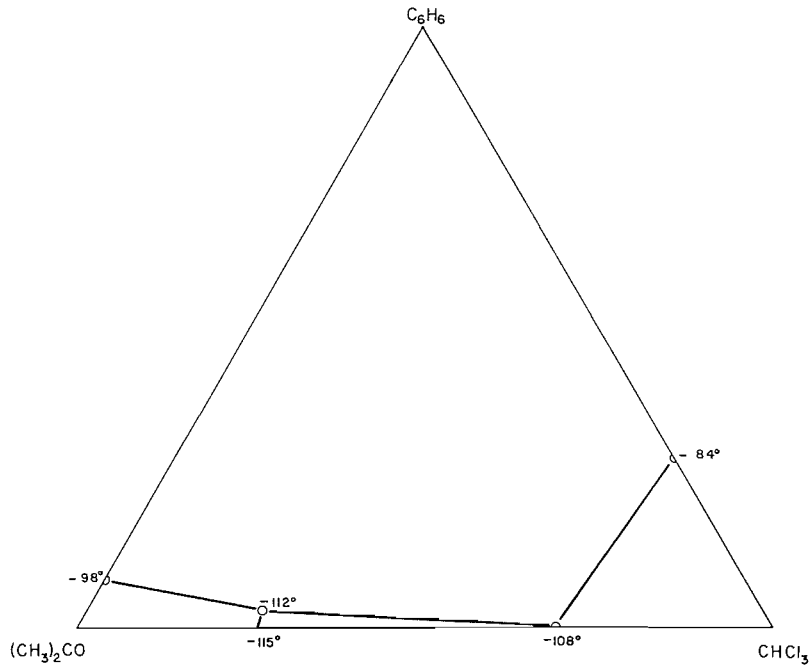

FIG. 4. Ternary freezing-point diagram of system benzene–acetone–chloroform.

Heats of Mixing

The heats of mixing of acetone–chloroform and of acetone – carbon tetrachloride have been published previously (2).

When the molar polarizations of acetone in benzene, in the absence of chloroform, and of chloroform in benzene, in the absence of acetone, are extrapolated to zero concentration, in the usual way, and the dipole moments calculated, using the refractive indices to calculate the distortion polarization, the following values are obtained.

Acetone 2.79 (lit. 2.70 (5))

Chloroform 0.97 (lit. 1.10 (6))

The values for the molar polarization of the "compound", that is of an equimolecular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mixture of acetone and chloroform, are necessarily difference figures and are so scattered that no extrapolation was possible. The average value was used to calculate the dipole moment, which resulted as 2.9, as against 3.76 for the sum of the dipole moments of the constituents.

TABLE III

Densities and molar volumes

Comp. of liquid (mole fr.)		Density	Exptl.	Calc.	%

DISCUSSION

Figures 1 and 2 show that the binary systems benzene–chloroform and benzene–acetone are of the simple eutectic type. Figure 3 shows that acetone and chloroform form a compound, stable in the solid state, but, judging from the flatness of the maximum rather highly dissociated in the molten state. Figure 4 represents the ternary freezing point diagram; it shows that the ternary eutectics occur at very small percentages of benzene. The compound characteristic of the acetone–chloroform system continues to exist in the ternary system.

The heats of mixing of acetone–chloroform mixtures with fixed benzene content are plotted in Fig. 5. It is to be noted that the curves cross at the chloroform end, as they must necessarily do, since the heats of mixing of chloroform with benzene and of acetone with benzene themselves pass through a maximum with changing benzene concentration. The maximum in the heat of mixing curve of acetone–chloroform persists in the presence of benzene, at about the same concentration of chloroform, viz. about 60 mole%, but it becomes increasingly flattened with increasing benzene content, a necessary consequence of the decrease in the ternary heat of mixing.

It is readily possible by drawing horizontals across Fig. 5 to obtain the loci of solutions having identical heat of mixing, including zero heat of mixing. The loci thus obtained have been plotted in Fig. 6.*

The curve of zero heat of mixing was of particular interest to us, since it seemed to indicate a narrow region of pseudo-ideality, in a very non-ideal system. This curve runs from pure acetone to pure benzene, with a very small chloroform content. Accordingly, we performed some rather accurate density determinations on this series of mixtures to determine whether or not the change in volume on mixing was zero. Inspection of Table III shows that this is not so and that there is always a slight but definite contraction when the components are mixed. An inspection of Table IV, which gives the boiling points of mixtures under a fixed pressure of 705.6 mm and the partial pressures as derived from

**These curves of equal heat effect might perhaps be called "idemcals", a term derived from the Latin, since the Greek term "isotherm" has a different and well-known meaning.*

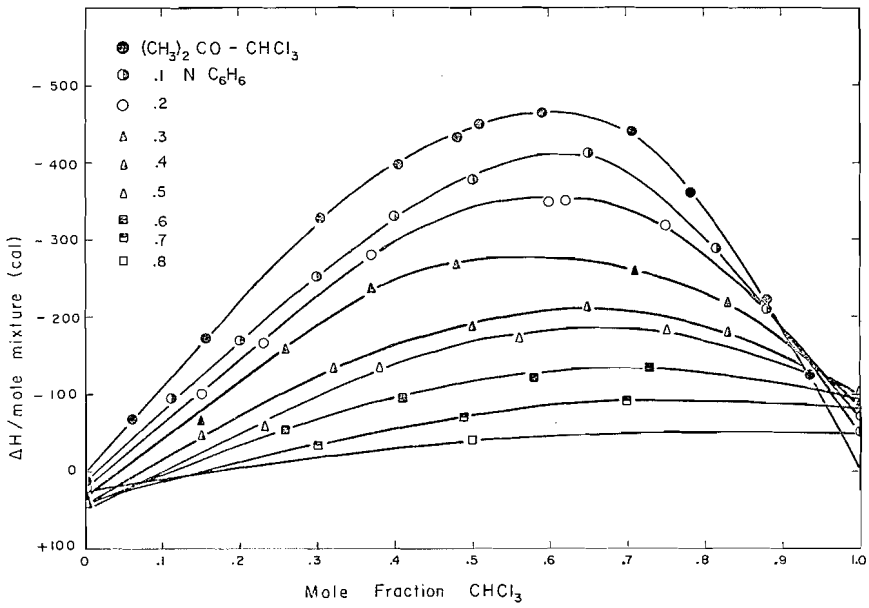

FIG. 5. Heat of mixing per mole of mixture vs. mole fraction of chloroform. Mole fraction calculated for the absence of benzene.

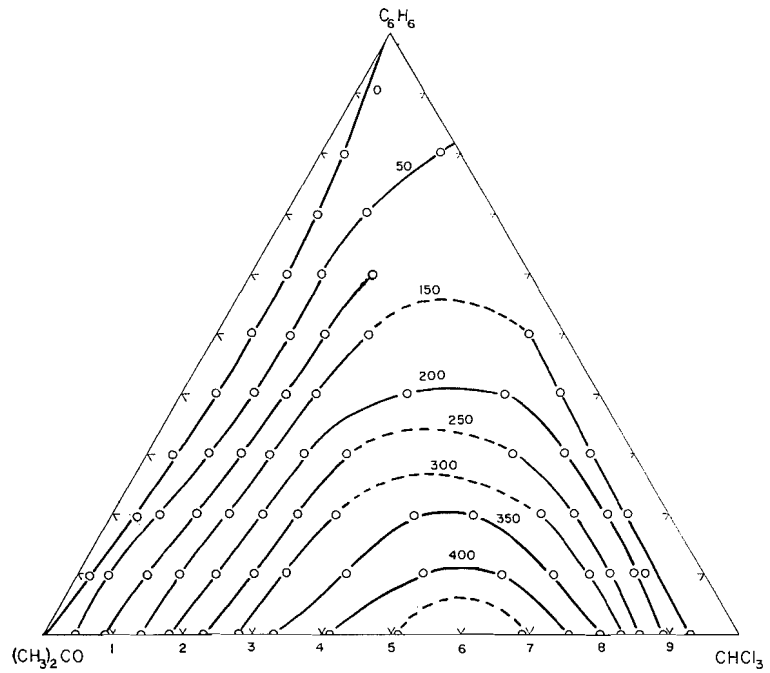

FIG. 6. Curves of equal heats of mixing. Figures on curves give the heat of mixing in negative calories.

Raoult's law and as calculated from the vapor composition, shows that these solutions are far from being ideal. It appears then that this series of solutions is not even pseudo-ideal and that the zero heat of mixing is merely a result of compensating factors.

The dielectric-constant measurements show that the dipole moment of the compound, or rather of a solution of equimolar proportions of acetone and chloroform in benzene, is greater than those of either acetone or chloroform, but considerably less than the sum of the two.

Since it was not possible to extrapolate our measurements to infinite excess of acetone or chloroform, our values must all refer to a compound which is highly dissociated. In view of the high dipole moment of the dissociated acetone, the figure given for the dipole moment of the compound is certainly too high and must be considered as purely qualitative evidence that the compound exists in benzene solution.

INFRARED SPECTRA OF XANTHATE COMPOUNDS

II. ASSIGNMENT OF VIBRATIONAL FREQUENCIES[1]

L. H. LITTLE,[2] G. W. POLING,[3] AND J. LEJA[3]

ABSTRACT

Discrepant interpretations regarding the frequency of the C=S stretching mode are reviewed and assignments of frequencies for the vibrational modes of the xanthate group,  , are presented.

A band at 1020–1070 cm^{-1} is assigned to the C=S stretching mode. Bands at 1200 cm^{-1} and 1110–1140 cm^{-1} are ascribed to the stretching vibrations of the C—O—C linkage.

The effects of the alkyl hydrocarbon chain length and of metal atoms (alkali metals, copper, and zinc) in displacing some of the frequencies are recorded.

In studying adsorption of xanthates on metals and their sulphide minerals by infrared spectroscopy, it became necessary to assign the spectral frequencies to the vibrational modes of the xanthate group. Previous studies of the spectra of xanthates (1, 2) and similar compounds (3, 4) were mainly exploratory in nature, due largely to the uncertain assignment of the C=S stretching mode for thiocarbonyl compounds (5, p. 293; 6; 7), in general.

Spectra of xanthates and similar compounds have been recorded and compared with recent studies of the thiocarbonyl stretching vibration (8, 9). Assignments of the xanthate vibrational frequencies have been made and conclusions reached with respect to the structures of dixanthogens, heavy metal xanthates, and alkali metal xanthates.

PROCEDURE

The spectra were recorded on Perkin–Elmer 21 and 221 double beam infrared spectrophotometers using sodium chloride prisms and on a Beckman IR4 infrared spectrophotometer using a cesium bromide prism. The solid samples were studied as mulls in nujol or in hexachlorobutadiene.

The intensities of the bands given in Table III, measured with the cesium bromide prism, are directly comparable with those of the bands shown in Figs. 1–4 for spectra measured with the sodium chloride prism.

The Raman spectrum of $(n\text{-}C_4H_9\text{—}S)_2C\text{=}O$ was recorded on a Cary Raman spectrophotometer. The other compounds are colored and, thus, are unsuitable for study by Raman spectroscopy.

as described previously (1).

AnalaR grade cupric sulphate and zinc sulphate were used to prepare heavy metal xanthates from solutions of alkali xanthates. It has been shown previously (1) by spectroscopic methods that dixanthogen is produced during the precipitation of copper xanthate from solutions of cupric salts, while no dixanthogen is produced during the precipitation of zinc xanthate. These findings are now confirmed by analytical results (see Table II).

(2) S,S-di-n-butyl Dithiocarbonate n-C_4H_9—S, C=O, n-C_4H_9—S

The dithiocarbonate was prepared by the method described by Bulmer and Mann (10). Phosgene was passed through a solution of sodium *n*-butyl mercaptide in ethanol

Alkyl chloroformates (ethyl and *n*-butyl) were commercial high-purity reagents.

INFRARED SPECTRA OF CARBONYL AND THIOCARBONYL COMPOUNDS

C=S Stretching Mode

Figure 1 shows the spectra of thiocarbonate compounds of the types R—O—C(=S)—S—R and $(RS)_2C{=}S$. It is seen that spectra of both types of compounds have strong bands at 1060–1070 cm^{-1}. Intense bands in this region are absent in molecules which do not contain the C=S group, although some weaker bands appear in this region for diethyl carbonate and ethyl chloroformate (Fig. 1).

The shape of the band at 1060 cm^{-1} is similar throughout the series of spectra of molecules containing the C=S group (Figs. 1, 2, and 3) and is composed of several peaks. This band has been assigned to the C=S stretching mode.

The C=S stretching mode has been assigned over a wide range of frequencies by different workers. Jones *et al.* (11) have discussed the variation of frequencies, depending on the environment of the C=S group, over the range 1000–1400 cm^{-1}. Hazeldine and Kidd (6) assigned to the C=S stretching vibration a band at 1050–1120 cm^{-1} in the spectra of the compounds $(RO)_2C{=}S$ and $(RS)_2C{=}S$, while Marvel *et al.* (7) assigned to this vibration a band at 1170–1195 cm^{-1}. Recently, Mecke *et al.* (8, 9) have investigated the spectra of a considerable number of molecules containing the C=S group and they ascribed its stretching frequency to the range 1053–1234 cm^{-1}; in the trithiocarbonate compounds the range was 1050–1060 cm^{-1}. An extremely intense absorption band between 1110 and 1145 cm^{-1} in the spectra of two mercaptopyridines has been assigned by Spinner (12) to the stretching vibration of conjugated C=S groups.

Felumb (3, 4) studied the spectra of many thiocarbonate molecules and assigned the C=S stretching mode to a band occurring at 1200–1250 cm^{-1}. The series of compounds studied by Felumb was, however, incomplete insofar as the compounds $(RS)_2C{=}S$ and $(RS)_2C{=}O$ were omitted. The former molecule, which contains the C=S group, has no strong absorption band in the region 1200–1250 cm^{-1} (Fig. 1). Moreover, all the molecules studied by Felumb contained the C—O—C linkage, which would be expected to show strong absorption bands at about 1200 cm^{-1} (5, p. 161). The molecule $(RS)_2C{=}O$, which has neither C—O—C nor C=S groups, has no strong bands between 1000 cm^{-1} and 1300 cm^{-1} (Fig. 1).

C—O—C Stretching Modes

Thompson and Torkington (13) have assigned two bands in the region of 1200 cm^{-1} to the stretching of the C—O bonds in esters. The assignment of absorption bands in the range 1000–1200 cm^{-1} in molecules containing the C—O—C group has been discussed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

by Hales *et al.* (14). Their conclusion was that the two bands in this region may be associated with the stretching vibrations of the C—O—C group.

The spectra of copper and zinc xanthates, dixanthogens, and O,S-dioctadecyl xanthate (Figs. 1, 2, and 3) show two bands in the region 1100–1250 cm^{-1}: an intense band at 1200–1250 cm^{-1} and a weaker band at 1110–1140 cm^{-1}. The latter band is of variable intensity, being sensitive to the length of the hydrocarbon chain and the nature of the metal atoms incorporated in the compounds. It can be seen from the spectra of the zinc alkyl xanthates (Fig. 3) that the intensity of this band decreases as the chain length increases.

In the spectra of ethyl and *n*-butyl dixanthogens (Fig. 2), the frequency of the intense band is shifted to 1250 cm^{-1} (from 1200 cm^{-1} for copper and zinc xanthates) and the intensity of the band at lower frequency (1110 cm^{-1}) is greatly decreased for the dixanthogens. These bands appear at 1220 cm^{-1} and 1110 cm^{-1} for O,S-dioctadecyl xanthate (Fig. 1).

The spectra of compounds which do not contain the C—O—C linkage, i.e., $(RS)_2C{=}O$ and $(RS)_2C{=}S$ (Fig. 1) do not have strong bands between 1100 cm^{-1} and 1250 cm^{-1}.

The spectra of ethyl chloroformate and diethyl carbonate (Fig. 1) show the intense high-frequency bands at 1160 cm^{-1} and 1260 cm^{-1}, respectively, for these two compounds, and a considerably weaker band at a lower frequency, 1020 cm^{-1}. This band is weaker than the intense band ascribed to the C=S stretching mode of xanthates.

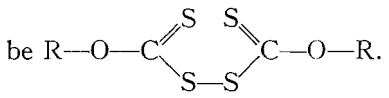
The bands at 1120 cm^{-1} and 1200 cm^{-1} appearing in the spectra of xanthates are here ascribed to the stretching vibrations of the C—O—C linkage.

C=O Stretching Mode

The intense band at 1650–1780 cm^{-1}, which occurs in the spectra of compounds containing the C=O group, viz. dialkyl carbonates, alkyl chloroformates, and $(n\text{-}C_4H_9S)_2C{=}O$, (Fig. 1), is absent from the spectra of trithiocarbonate and of all the xanthate compounds. This band has been ascribed to the C=O stretching mode of the carbonyl compounds.

In addition to the carbonyl absorption of $(n\text{-}C_4H_9S)_2C{=}O$, which occurs as a very intense band at 1650 cm^{-1} (Fig. 1), a weaker band is found at 1750 cm^{-1}. This is probably an overtone or combination band of the intense bands at 870 cm^{-1} and 920 cm^{-1}.

Structure of Xanthates



The spectra of copper and zinc xanthates (Figs. 2 and 3) show well-defined bands at 1200 cm^{-1} and 1120 cm^{-1}, which have been attributed to vibrations of the C—O—C linkage, while the intense band at 1060 cm^{-1} has been assigned to the C=S stretching mode.

The resonance hybrid $\left[R{-}O{-}C(=S){-}S \right]^-$ may be considered to represent the structure of the metal xanthates (2). However, the xanthate esters (Fig. 1), which do not exist as resonance hybrids, have the same C=S band at 1060 cm^{-1} as all the heavy metal xanthates. Consequently the structure of the heavy metal xanthates must be

$$R{-}O{-}C(=S){-}S^-\ .$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

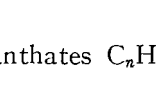
For similar reasons the structure of the dixanthogens, retaining the C=S group, must

be  .

C—S and S—S Stretching Modes

Intense absorption bands occur at 830 cm^{-1} and 870 cm^{-1} in the spectra of $(n\text{-}C_{12}H_{25}S)_2C{=}S$ and $(n\text{-}C_4H_9S)_2C{=}O$ respectively (Fig. 1), while a band of medium intensity appears at 850 cm^{-1} in the spectrum of ethyl dixanthogen (Fig. 2). The intensities of the bands for $(n\text{-}C_4H_9S)_2C{=}O$ and ethyl dixanthogen are far greater than those of bands at lower frequencies (Table III). It is probable, therefore, that the bands at lower frequencies are associated with fundamental vibrations and not with overtones or combinations. An intense band also occurs at 870 cm^{-1} in the Raman spectrum of $(n\text{-}C_4H_9S)_2C{=}O$ (Table III).

The frequencies of these bands are considerably higher in value than those usually associated with the stretching of C—S or S—S bonds. Bellamy (5, p. 290) has discussed the assignments of C—S and S—S stretching modes to weak bands in the spectrum, occurring between 600–700 cm^{-1} and 400–500 cm^{-1}, respectively.



The intense bands (830 to 870 cm^{-1}) may be associated with an asymmetric C—S stretching mode of the C—S—C—S—C chain in the molecules $(n\text{-}C_{12}H_{25}S)_2C{=}S$ and $(n\text{-}C_4H_9S)_2C{=}O$ or the C—S—S—C chain in ethyl dixanthogen. It must be noted, however, that the disulphide $(n\text{-}C_{18}H_{37}S)_2$ (Fig. 1) does not have an intense absorption band in this region. Moreover, the metal xanthates, which have only one C—S bond also show bands in the region 800–950 cm^{-1} (Figs. 2 and 3), although these bands are generally weaker than those discussed above.

Jones *et al.* (11) have tentatively assigned bands occurring at 880–700 cm^{-1} in the spectra of "carbon sulphoxy chloride" and dimeric thiocarbonyl chloride to the stretching of the C—S bond. It is possible that, due to the environment of the C—S bond in the xanthate group, the frequency of the C—S stretching mode may be raised above the normal limits discussed by Bellamy.

An intense band appearing at 600 cm^{-1} in the Raman spectrum of $(n\text{-}C_4H_9S)_2C{=}O$ is probably due to a C—S stretching mode of this compound (5, p. 290).

Several bands appear between 300 and 550 cm^{-1} in the spectra of xanthates (Table III). Although the spectrum of ethyl dixanthogen has more bands in this region than those of the metal xanthates, no definite assignment can be given to the S—S stretching mode of dixanthogens.

Precipitation of Copper Xanthate

Pearson and Stasiak (2) have published spectra of potassium xanthates, heavy metal (Cu, Pb, Zn) xanthates, and potassium oxyxanthates C_nH_{2n+1}—O—  . In general, their spectra of corresponding xanthates are identical with those shown previously (1) and with those reported here. However, their spectrum of cupric xanthate corresponds to our spectrum of cuprous xanthate. The latter material was obtained after washing off the dixanthogen, which was coprecipitated with cuprous xanthate during the addition of cupric salts to solutions of alkali xanthates (1).

*Band frequency (cm^{-1}).

†Half-band width (cm^{-1}).

‡% absorption at band maximum.

Pearson and Stasiak do not state whether their copper xanthate precipitate was washed with solvents, yet in their spectrum no band appears at 1250 cm^{-1}, characteristic of dixanthogen in the precipitate. Nor do they state whether their elemental analysis was made before or after washing with solvents. Results of the analysis of the precipitate both before and after ether extraction are shown in Table II. In the absence of knowledge that the precipitate was a mixture of cuprous xanthate and dixanthogen, the results would indicate that it was cupric xanthate.

Infrared spectra (Fig. 2) and chemical analysis (Table II) suggest that the reaction between cupric ions and xanthate ions results in the coprecipitation of cuprous xanthate and dixanthogen in the molar ratio 2:1; $4\ RX^- + 2\ Cu^{++} \rightarrow 2\ RXCu + (RX)_2$ where X^- denotes the $-O-C(=S)-S^-$ group. With zinc ions a zinc dixanthate, but no dixanthogen, is formed.

Alkali Metal Xanthates

Spectra of some alkali metal xanthates are shown in Fig. 4. The absorption bands in the region 1000–1200 cm^{-1} are not well resolved but it is possible to distinguish three more or less distinct groups of bands, corresponding to the bands at 1200 cm^{-1}, 1130 cm^{-1}, and 1060 cm^{-1} for the heavy metal xanthates in Figs. 2 and 3.

If such a grouping of bands in the spectra of alkali metal xanthates is accepted, then the frequencies of the C—O—C linkage, discussed earlier, would appear to be displaced to lower values than those given for the C—O—C linkage in the heavy metal xanthates. The frequency of the band assigned to the C=S stretching mode varies from 1040 to 1080 cm^{-1} in the spectra of alkali metal xanthates. The presence of this band suggests that the C=S bond is preserved in the structure of the alkali metal xanthates.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the assistance of Dr. K. Noack, Dr. E. C. Horswill, Mr. A. E. Castagne, and Mr. J. A. H. Desaulniers. G. W. Poling and J. Leja express their appreciation for the grants A699 and E140 received from the National Research Council of Canada.

STUDIES ON CHLOROBIUM CHLOROPHYLLS

II. THE RESOLUTION OF OXIDATION PRODUCTS OF CHLOROBIUM PHEOPHORBIDE (660) BY GAS-LIQUID PARTITION CHROMATOGRAPHY[1]

H. V. MORLEY[2] AND A. S. HOLT

ABSTRACT

Methylethylmaleimide, methyl-*n*-propyl maleimide, and dihydrohematinic acid imide are obtained from *Chlorobium* pheophorbide (660) on chromic acid oxidation. The separation and isolation of these products and of other imides and pyrroles by gas–liquid partition chromatography is described.

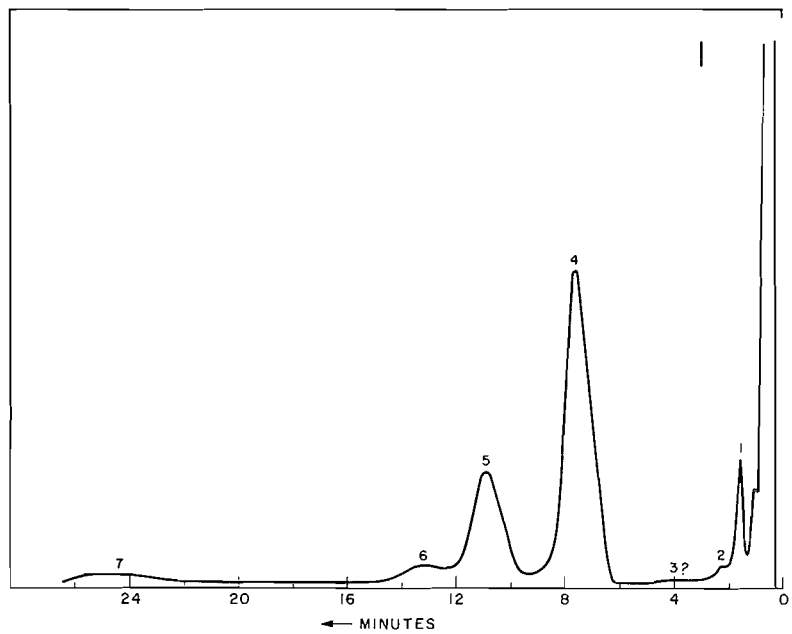
INTRODUCTION

It has been reported that *Chlorobium* chlorophyll (660) gives a negative Molisch phase test and fails to undergo methanolysis with ring opening (1). These observations and others to be published shortly indicate that this pigment differs from other known chlorophylls. An investigation involving degradation of the molecule to identifiable, substituted monocyclic compounds corresponding to the original pyrrole nuclei was therefore undertaken.

Each of the degradative methods described in the literature has disadvantages. Reduction by hydriodic acid (2) greatly complicates the analytical problem since each nucleus can yield up to four different pyrroles. Oxidation by chromic acid (3), while theoretically producing one imide per nucleus, causes loss of nuclei which possess unstable β-groups, e.g. vinyl, formyl, and hydroxyethyl groups (4). In this laboratory, oxidation by permanganate (5) gave yields of pyrroledicarboxylic acids which were too low to permit their isolation for elementary analysis.

Oxidation by chromic acid was chosen as the most suitable method of degrading *Chlorobium* pheophorbide (660). For the resolution of the resulting mixture of imides, gas–liquid partition chromatography (GLPC) required less starting material and proved to be faster and more convenient than previously described methods (3, 4, 6, 7, 8). A study of the separation of synthetic and analytical pyrroles by GLPC was initiated (Table I) but discontinued when imides were shown to be separable by the same technique (9).

TABLE I



Retention volumes of pyrroles at 180°
relative to that of 2,4-dimethylpyrrole = 1

Pyrrole	0.50
2-Methylpyrrole	0.69
2,4-Dimethylpyrrole	1.00
3-Methyl-4-ethylpyrrole (opsopyrrole—fraction 1)	1.56
2,4-Dimethyl-3-ethylpyrrole (cryptopyrrole—fraction 2)	2.18
2,3-Dimethyl-4-ethylpyrrole (hemopyrrole—fraction 3)	2.48
2,4,5-Trimethyl-3-ethylpyrrole (phyllopyrrole—fraction 4)	3.38

Oxidation of *Chlorobium* pheophorbide (660) yielded "neutral" and "acid" fractions. The chromatogram of the "neutral" fraction (Fig. 1) shows two major peaks (4 and 5)

and several minor ones. The compound responsible for peak 4 was readily shown, by GLPC, to be methylethylmaleimide by comparison with an authentic sample prepared from mesoporphyrin IX. From the retention volume (R_v, Table II), the compound

TABLE II

III	Methyl-*n*-propylmaleimide	CH_3	C_3H_7
IV	Hematinic acid imide	CH_3	$(CH_2)_2COOH$

responsible for peak 5 could be assumed to contain one more methylene group than methylethylmaleimide. This assumption was confirmed by elementary analysis. The melting point agreed with that of methyl-*n*-propylmaleimide (10); this structure was also deduced from the proton magnetic resonance spectrum. Subsequently, a synthetic sample of methyl-*n*-propylmaleimide (10) proved to be identical with the analytical sample. It is of interest to note that this is the first time a *n*-propyl side chain has been found in a natural tetrapyrrole.

The chromatogram of a small sample of the methylated "acid" fraction is given in Fig. 2. The products responsible for each of the three main peaks have infrared spectra not unlike those of methylethyl- and methyl-*n*-propylmaleimide. Because no reference specimen was available, dihydrohematinic acid imide was not identifiable among the products. It was thus necessary to isolate it from the remaining "acid" fraction by partition chromatography on silica gel. The eluent samples which were acidic and gave a positive imide test (11, 12) were combined and converted to the benzylamine salt. Analysis, melting point, and infrared spectrum confirmed that the product was the salt of *trans*-dihydrohematinic acid imide obtained previously by Linstead *et al.* (6). The above salt was converted to the free acid and esterified with only a slight excess of diazomethane. Such care was necessary in order to eliminate the possibility of methylating the imide nitrogen atom (13). The infrared spectrum of the colorless oil obtained after removing the solvent and excess diazomethane still showed the NH absorption band at 3390 cm^{-1} indicative of the intact imide nitrogen. A sample subjected to GLPC showed that dihydrohematinic acid imide methyl ester was responsible for peak 3 ($R_v = 3.03$) of Fig. 2. This result was to be expected since hematinic acid imide methyl ester has an R_v value of 2.90 (Table II). The substances responsible for peaks 1 and 2 were not recovered in sufficient quantity, after purification by GLPC, to permit their identification.

The above results identify at least three of the four pyrrole nuclei present in *Chlorobium* pheophorbide (660). Recent studies have shown that *Chlorobium* pheophorbide (650) possesses a hydroxyethyl group which is readily oxidized to an acetyl group, and that *Chlorobium* pheophorbide (660) possesses a similar group (14). Until these studies have been completed, the nature of the fourth nucleus in *Chlorobium* pheophorbide (660) remains in question.

EXPERIMENTAL

The preparation and purification of *Chlorobium* pheophorbide (660) from *Chlorobium* chlorophyll will be outlined in a forthcoming publication. Mesoporphyrin IX was obtained from hemin by a standard procedure (15, 16). Except where stated otherwise, infrared spectra were determined in chloroform on a Perkin–Elmer Model 21 double-beam instrument. Melting points were determined on the Koffler Hot Stage. The instrument used for GLPC was a modified Podbelniak "Chromacon" (Series 9475-3V) described previously (17). Pyrroles were separated on a column (8 ft long, 7-mm I.D.) packed with a mixture (1:4 w/w) of Apiezon M and alkali-washed Celite 545 (60–80 mesh). The operating temperature was 180° C; the carrier gas was helium with a flow rate of 75 ml/minute. The number of theoretical plates was 1300. Imides were separated as described earlier (9). The proton magnetic resonance spectrum of methyl-*n*-propylmaleimide was recorded at 60 Mc/s with a Varian V-4032 high-resolution spectrometer.

Oxidative Degradation of Chlorobium Pheophorbide (660)

The oxidation procedure and the separation of the imides into "neutral" and "acid" fractions followed closely the directions of Linstead *et al.* (6). *Chlorobium* pheophorbide (1.0 g) was dissolved in sulphuric acid (70 ml, 50% v/v); the solution was then diluted with ice (70 g) and cooled to −10° C. Chromic acid (3.3 g) in water (30 ml, 0° C) was added dropwise with stirring during 1 hour. The solution was maintained at −10° C for 2 hours with continued stirring. By this time carbon dioxide evolution had diminished. The mixture was allowed to warm slowly to room temperature with stirring until a total of 5 hours had elapsed since the first addition of chromic acid. The mixture was then extracted and fractionated (6). Later work showed that after a total period of $3\frac{1}{2}$ hours no further increases in the yields of the neutral imides were indicated by GLPC.

"Neutral" Fraction

Since fractions 1, 2, and 3 (Fig. 1) did not separate well they were not investigated intensively. ν_{max} of a crude sample of fraction 1: 3500 (m), 3375 (m), 1698 (s), 1600 (w), and 1565 (m) cm^{-1}. The R_V value (0.59) of fraction 4 agreed with that of methylethylmaleimide obtained from mesoporphyrin IX (see below). Initially 32 mg were obtained; further purification by GLPC yielded 16 mg as white blades, mixed m.p. 67–68°. The infrared spectrum was superposable upon that of an authentic sample. Found: C, 60.2; H, 6.39. $C_7H_9O_2N$ requires: C, 60.4; H, 6.52%.

Fraction 5 (ca. 13 mg) was further purified by GLPC (white needles, 6.7 mg); recrystallized (chloroform–ether), m.p. 52–54°. The yields from several oxidations were bulked. Found: C, 62.6; H, 7.38; N, 8.80. $C_8H_{11}O_2N$ requires: C, 62.7; H, 7.24; N, 9.14%. The proton magnetic resonance spectrum of a 10% (w/v) solution was consistent with the methyl-*n*-propylmaleimide structure. The following shifts, given as τ values (18) and compared to tetramethylsilane as an internal standard were observed: a broad band at 1.04 (=N*H*), a triplet at 7.57 (=C—CH_2CH$_2$—), a sharp singlet at 8.01 (=C—CH_3), six unresolved peaks at 8.47 (—CH$_2$—CH_2—CH$_3$), and at 9.02 a triplet (—CH$_2$—CH$_2$—CH_3). ν_{max} (CCl_4): 3430 (w), 1769 (w), and 1725 (s) cm^{-1}. On comparison with a synthetic specimen (10) this product was found to be identical with respect to mixed melting point, infrared spectrum, nuclear magnetic resonance spectrum, and X-ray powder diagram.

The small quantities of fractions 6 and 7 permitted only the examination of the infrared spectrum. ν_{max} of both were at: 3418 (w), 1768 (w), and 1720 (s) cm^{-1}.

"Acid" Fraction

A small sample (ca. 5 mg) of the acid fraction was esterified with distilled diazomethane. The R_v values of the three main products (Fig. 2) in this sample were 0.49, 1.49, and 3.03 respectively.

The remainder was partitioned on a wet silica gel column (55×2 cm) and eluted with ethyl acetate (6). Six-milliliter samples were collected (50 tubes). Paper chromatograms were developed in ethanol–NH_4OH–water (7:1:2) and sprayed with Universal indicator spray (British Drug Houses Ltd.) for acids or with an imide spray (11, 12). The results showed that tubes 4–8 contained traces of neutral imides and that tubes 8–16 contained the bulk of the acidic imides.

Tubes 8–16 were combined and evaporated to dryness. The residue was converted to the benzylamine salt(s) of the imide acid(s). Recrystallization from methanol – ethyl acetate yielded white needles. The infrared spectrum (nujol mull) had maxima at 1298 (m); 1265 (m); 1217 (m); 1190 (s); 1168 (w); 1160 (w); 888 (w); 872 (m); 823 (m); 795 (m); 772 (m); 755 (s); 741 (m); 719 (w); 696 (m); 686 (w) cm^{-1}, which agree well with data given by Linstead *et al.* (6) for the benzylamine salt of *trans*-dihydrohematinic acid imide, m.p. 158–161° (lit. 164–165° (6)). Found: C, 61.7; H, 6.97; N, 9.71. $C_{15}H_{20}O_4N_2$ requires: C, 61.6; H, 6.90; N, 9.58%. The benzylamine salt was dissolved in a little water and the free acid was extracted into ethyl acetate and ether after acidification. The extracts were combined, dried over sodium sulphate, and evaporated to dryness *in vacuo*. The free acid in the residue from the extract was carefully esterified with distilled diazomethane in ether, by dropwise addition until a faint yellow color persisted for 15 minutes. The R_v value of the resulting colorless oil was 3.03. ν_{max}: 3390 (w), 1775 (w), 1723 (s) cm^{-1}. Found: C, 54.3; H, 6.65. $C_9H_{13}O_4N$ requires: C, 54.3; H, 6.58%.

Oxidative Degradation of Mesoporphyrin IX

Mesoporphyrin IX (250 mg) was oxidized and separated into "neutral" and "acid" fractions essentially by the method of Muir and Neuberger (8). About 5 mg of the "neutral" fraction was analyzed by GLPC; the main fraction (R_v 0.59) was collected as crystals. Methylethylmaleimide was crystallized from an aqueous solution of the remainder of the "neutral" fraction (m.p. 67–68° (lit. 68° (8)). Yield, 45 mg. This sample proved to be identical (mixed melting point, R_v value, and infrared spectrum) with that obtained as crystals from the GLPC separation described above. ν_{max}: 3430 cm^{-1}, (w); 1768, (w); and 1718 (s) cm^{-1}.

Ten milligrams of the "acid" fraction was esterified with diazomethane. Three main fractions with the following R_v values were observed: (1) 0.387, (2) 1.49, and (3) 2.90 respectively. Fraction (3) was shown by comparison with an authentic sample (R_v value and infrared absorption spectrum) to be hematinic acid imide methyl ester. ν_{max}: 3430 (w), 1768 (w), and 1722 (s) cm^{-1}. Fractions (1) and (2) have not been identified. The spectra of each contained N—H bands but differed from those of other available imides in the double bond stretching region. ν_{max}: fraction (1), 1823 (w), 1758 (s), 1720 (s), 1673 (m), and 1600 (w) cm^{-1}; fraction (2), 1815 (w) (shoulder), 1762 (s), 1723 (s), and 1673 (m) cm^{-1}.

Reductive Degradation of Hemin

Hemin (250 mg, British Drug Houses Ltd.) was heated in glacial acetic acid (4.5 ml) containing hydriodic acid (5 g; s.g. 1.96) according to the method given by Willstätter and Stoll (19). Free iodine was reduced by hypophosphorous acid which was added

dropwise during ½ hour. The reaction mixture was adjusted to pH 11 (Na_2CO_3) and pyrroles were then extracted into ether. Strongly basic reduced pyrroles were removed from the ether by aqueous monosodium phosphate. The ether solution was dried (Na_2SO_4) and evaporated.

A sample of the residue from the ether solution was analyzed by GLPC and gave four main peaks, numbered 1 to 4 in the order of their emergence from the column. These products were collected as colorless oils, which darkened rapidly upon exposure to air.

Product 2 was shown to be cryptopyrrole by comparison of its R_v value (Table I) with that of an authentic sample. Product 1 was deduced to be opsopyrrole as follows: an ether solution of the reaction mixture was extracted with 12% (w/w) hydrochloric acid. This strength acid is known to remove crypto-, phyllo- and hemo-pyrrole and leave opsopyrrole in the ether phase (20). The material in the residue from the ether solution was analyzed by GLPC and gave peak 1, with only traces of the other three peaks. Product 4 was presumed to be phyllopyrrole because: (1) it gave a positive Ehrlich test only after heating (21) (products 1, 2, and 3 gave immediate positive tests at room temperature); and (2) it is reasonable to presume it would emerge last from the column since it possesses the highest molecular weight of the four pyrroles obtained from hemin. By elimination, product 3 was assumed to be hemopyrrole. It was later found that steam distillation of the pyrroles from the alkaline solution eliminated some impurities which otherwise appeared on the chromatogram.

ACKNOWLEDGMENTS

The authors are most grateful to the following members of the Division of Pure Chemistry, National Research Council, for gifts of samples: Drs. S. F. MacDonald and E. Bullock and Mr. Keith Chambers. Gas–liquid partition chromatographic separations were performed by Mr. F. Cooper; analyses were determined by Mr. A. Castagne; and infrared absorption spectra were measured by Mr. F. Rollin. For the measurement of the proton magnetic resonance spectrum of methyl-*n*-propylmaleimide the authors are indebted to Dr. R. R. Fraser, Department of Chemistry, University of Ottawa.

FURTHER STUDIES ON THE REACTION BETWEEN HALOGEN-SUBSTITUTED NITRILES AND AMINES[1]

JOHN C. GRIVAS[2] AND ALFRED TAURINS

ABSTRACT

The scope of the reaction of halogen-substituted nitriles and amines was extended by including trifluoro- and dichloro-acetonitrile. Trifluoroacetonitrile reacts easily with primary and secondary aliphatic, primary aromatic, and heterocyclic amines to give the corresponding amidines. N-Mono- and N-di-substituted dichloroacetamidines were prepared from dichloroacetonitrile and amines. Trichloroacetonitrile also affords N-substituted amidines with heterocyclic amines.

INTRODUCTION

The reaction of trichloroacetonitrile with primary and secondary amines has been investigated and discussed (1). The present work deals with the extension of the reaction, using trifluoroacetonitrile and di- and mono-chloroacetonitrile, and a variety of amines. Trifluoroacetonitrile is expected to react even faster than trichloroacetonitrile owing to the stronger inductive effect ($-I_s$) of the trifluoromethyl group. Husted (2) synthesized a series of perfluoroalkylamidines by allowing the corresponding nitriles to react with liquid ammonia in sealed tubes for 2 weeks. Reilly and Brown (3) isolated some N-methyl-, and N,N-dimethyl-perfluoroalkylamidines by treating nitriles with methyl- and dimethyl-amine at $-60°$. They assumed that aniline, being a weak base, could not produce any amidines. There are no literature data concerning the addition of amines to the carbon–nitrogen triple bond of dichloroacetonitrile.

RESULTS AND DISCUSSION

The formation of amidines from nitriles and amines depends on both the basicity of the amine and the electron deficiency of the carbon atom of the nitrile group. The mechanism of this reaction (1) implies that the more mobile the electron pair of the amino nitrogen atom, the stronger will be the interaction between the two reactive centers and the faster the reaction will go. On the other hand, the greater the electron deficiency of the carbon atom, the faster the reaction will be. Acetonitrile does not react with amines because the mesomeric effect of the nitrile group is compensated by the ($+I_s$) inductive effect of the methyl group.

$$CH_3 \rightarrow - C \equiv \overset{\curvearrowright}{N}: \qquad CF_3 - \leftarrow C \equiv \overset{\curvearrowright}{N}:$$

Evidence for this was obtained by conducting a series of reactions involving primary and secondary amines and four α-halogen-substituted nitriles, of decreasing inductive ($-I_s$) effect as follows:

$$F_3C{-}CN > Cl_3C{-}CN > Cl_2HC{-}CN > ClCH_2{-}CN.$$

Trifluoroacetonitrile was found to react not only with primary and secondary aliphatic but also with primary aromatic and heterocyclic amines at room temperature providing excellent yields of products in each case. Trichloroacetonitrile also afforded mono-substituted amidines when treated with 2-amino-5-methylpyridine and 2-aminothiazole

at room temperature. The monosubstituted amidines derived from both nitriles on the basis of infrared spectroscopic studies (4, 5) exist in the imino form (I):

$$\underset{\text{(I)}}{\underset{\displaystyle \underset{\displaystyle \underset{\displaystyle \

The present work has lead to the following conclusions:

(*a*) At least two strongly electronegative atoms are necessary to promote the non-catalyzed addition of amines to the nitrile group. It is of interest to note that ethyl cyanotartronate (V) adds amines in a manner identical with that of trichloro- and trifluoro-acetonitriles (7):

$$N\equiv C-\underset{\underset{OH}{|}}{C}(CO_2C_2H_6)_2.$$

(V)

(*b*) Methanol cannot be used as a solvent in the reaction of trichloroacetonitrile with secondary aliphatic amines, owing to the formation of methyl trichloroacetimidate. This would also occur with trifluoro- and dichloro-acetonitrile.

(*c*) Acetonitrile is an excellent solvent.

(*d*) The reaction between primary aromatic amines and the three nitriles used in these studies does not occur in non-polar solvents.

(*e*) Primary aliphatic amines react much faster than primary aromatic amines. Secondary aliphatic amines react more slowly than primary aliphatic amines, even though the former are the stronger bases. This discrepancy can be attributed to stereochemical factors.

(*f*) Secondary aliphatic amines containing alkyl groups with more than three carbon atoms react preferentially by substitution at the α-carbon atom of trichloroacetonitrile:

$$(n\text{-}C_5H_{11})_2NH + CCl_3—CN \rightarrow (n\text{-}C_5H_{11})_2NCCl_2CN + HCl.$$

EXPERIMENTAL

A. Preparation of Trifluoroacetamidines

1. N-Butyl-α,α,α-trifluoroacetamidine.—A slow stream of trifluoroacetonitrile was passed through pure *n*-butylamine (2.9 g) in a tube which was immersed in an ice-water bath. An exothermic reaction took place. The crude product was distilled in a nitrogen atmosphere to give a colorless liquid (5.5 g, 82% yield) boiling at 39–40°/2 mm. Analysis of this compound is recorded in Table I.

2. N-Benzyl-α,α,α-trifluoroacetamidine.—In a long glass tube was placed 1.9 g of trifluoroacetonitrile (0.02 mole). The tube was cooled in a dry ice – acetone mixture and was connected by a Tygon tubing to a 100-ml pear-shaped flask containing a solution of 2.15 g (0.02 mole) of benzylamine in 10 ml of benzene. The solution was stirred by a magnetic stirrer while a slight pressure of trifluoroacetonitrile was maintained in the closed system. This was achieved by keeping the surface of the liquid trifluoroacetonitrile slightly above the surface of the cooling mixture. After ½ hour the nitrile had been used up but the stirring was continued for an additional 30 minutes. The solvent was evaporated under reduced pressure and the remaining liquid fractioned to give 3.84 g (91%) of a colorless liquid boiling at 88–90°/3 mm. In a few hours, the liquid solidified to white transparent crystals which, after two sublimations at 2 mm pressure, gave pure N-benzyl-α,α,α-trifluoroacetamidine, m.p. 51°.

3. N-Phenyl-α,α,α-trifluoroacetamidine.—A solution of 5 g of aniline in 20 ml of methanol was added to a Pyrex glass tube (20×709 mm) which was cooled in a dry ice – acetone mixture. An equimolar amount of trifluoroacetonitrile was condensed in the tube, which was then sealed and left for 4 days at room temperature. The tube was cooled to condense any unreacted trifluoroacetonitrile and opened. The reaction product was precipitated by addition of distilled water, or by evaporation of methanol at reduced

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

pressure, washed twice with distilled water, and dried. After sublimation the amidine (9.2 g, 91% yield) melted at 81°.

4. N,N-Diethyl-α,α,α-trifluoroacetamidine.—Equimolar quantities of trifluoroacetonitrile and diethylamine were allowed to react in a sealed Pyrex tube at room temperature for 24 hours. The mixture was then fractionated to give a colorless amidine (90% yield) boiling at 119°.

5. N-(5-Methyl-2-pyridyl)-α,α,α-trifluoroacetamidine.—Equimolar quantities of trifluoroacetonitrile and 2-amino-5-methylpyridine in acetonitrile were kept in a sealed Pyrex tube at room temperature for 4 to 6 days. The addition of water caused the separation of a liquid layer which solidified in a few minutes. The crude yellowish product was dissolved in a small volume of acetonitrile and precipitated by addition of water (yield 71%). After sublimation the amidine melted at 102°.

B. Preparation of Dichloroacetamidines

1. N-Methyl-α,α-dichloroacetamidine.—Dichloroacetonitrile (6.87 g, 0.062 mole) was added to an aqueous 25% solution of methylamine containing an equivalent amount of the amine, and the mixture was shaken for a few minutes. The lower reddish-brown layer was separated and distilled in a nitrogen atmosphere to give an almost colorless liquid (4.8 g, 55% yield) boiling at 80–85°/6 mm. Some decomposition of the product occurred during distillation and the pure amidine which was isolated turned black in 2 days.

2. Piperidino-α,α-dichloroacetamidine.—Piperidine (3.15 g, 0.037 mole) was added to a benzene solution (15 ml) of dichloroacetonitrile (4.7 g, 0.037 mole) and left at room temperature for 3 days. The mixture was then fractionated under reduced pressure in a nitrogen atmosphere to give a colorless liquid (6.4 g, 88% yield) at 63–66°/1 mm. The pure amidine changed to a black tar in 3 weeks.

3. N-Phenyl-α,α-dichloroacetamidine.—A mixture of dichloroacetonitrile (0.025 mole), aniline (0.025 mole), and 16 ml of methanol was left in a stoppered flask at room temperature for 1 week. After the evaporation of the solvent under reduced pressure a dark-brown solid was obtained. The product was then sublimed. Unreacted aniline together with a portion of the amidine was collected first but continued sublimation gave colorless N-phenyl-α,α-dichloroacetamidine (3 g, 60% yield), m.p. 62°.

C. Preparation of Heterocyclic Trichloroacetamidines

1. N-(5-Methyl-2-pyridyl)-α,α,α-trichloroacetamidine.—Trichloroacetonitrile (2.88 g, 0.02 mole) was added to a solution of 2-amino-5-methylpyridine (2.16 g, 0.02 mole) in 6 ml of acetonitrile and the mixture was left at room temperature for 4 days. Then addition of 10 ml of water caused the separation of a yellowish liquid layer which solidified in a few minutes. The compound was filtered off, and dissolved in a small volume of methanol. Addition of water to the methanol solution resulted in the isolation of a colorless product (4.1 g, 81% yield) melting at 78–79°. Sublimation at 70°/2 mm raised the melting point to 83.5°.

2. N-(2-Thiazolyl)-α,α,α-trichloroacetamidine.—This compound was prepared by a method similar to that outlined above, m.p. 87°.

THE ABSORPTION SPECTRUM OF DIPHENYLENE IN THE NEAR-ULTRAVIOLET[1]

ROBIN M. HOCHSTRASSER

ABSTRACT

The absorption spectrum of diphenylene has been measured in the vapor at a variety of temperatures, in solution at room temperature, and in an EPA rigid glass at 90° K. From a consideration of the band structure and intensity distribution it was concluded that the weak absorption at 25,041 cm^{-1} (vapor; $f \approx 10^{-3}$) is due to a symmetry-forbidden electronic transition. The theoretical prediction that the excited level is of species B_{1g} was supported by the presence of a strong infrared band at 732 cm^{-1} corresponding to observed perturbing vibration of frequency 792 cm^{-1}. The solution spectrum was found to exhibit a vibrational structure typical of a g–g forbidden excitation.

The electronic levels of diphenylene are somewhat anomalous when compared to those of other alternant hydrocarbons such as the structurally similar naphthalene or phenanthrene and anthracene. The solution spectrum of diphenylene was studied by Carr, Pickett, and Voris (1) and the electronic transitions involved were subsequently classified by Clar (2, p. 279) on the basis of intensity and band position and by analogy with other alternant hydrocarbons. Recently, using the technique of mixed crystal spectroscopy the symmetry of the second molecular level, the absorption to which commences at 27,910 cm^{-1} in liquid solution, was determined (3). This level was found to belong to the $^1B_{3u}$ (long axis polarized) representation in the point group D_{2h}. Such an assignment is at variance with the systematic classification by Clar. The p-band, by analogy with other alternants, would involve excitation to a short axis polarized level. In view of this a closer study of the weak lower-energy band was prompted.

During the past few years the symmetry types of the molecular levels of most of the polyacenes have been determined experimentally. The theorists have correctly predicted both the symmetry and energy of these levels. However, this success is not yet known to extend to the pericondensed hydrocarbons such as pyrene and perylene or to hydrocarbons containing other than six-membered rings such as diphenylene.

There are certain features which become apparent during a qualitative examination of the absorption spectrum of diphenylene in liquid solution at room temperature. There are three obviously separated absorption regions which are taken to be due to absorption to three different electronic levels. The highest energy absorption commences at about 40,250 cm^{-1} with $\epsilon_{max} = 10^5$. This band has little structure and in both band position and intensity resembles the ^1B_b ($^1B_{2u}$) transitions of the polyacenes. The intermediate band occurs at 27,910 cm^{-1} with $\epsilon_{max} = 10^4 - 10^3$. This band resembles the $^1L_a(^1B_{3u})$ transitions of the polyacenes in these respects; however, the vibrational structure is neither regular nor similar to that observed in the ^1L_a bands of polyacenes. The lowest energy transition at 25,530 cm^{-1} with $\epsilon_{max} = 10^2$ has even lower intensity than the ^1L_b bands of benzene ($^1B_{2u}$; $\epsilon_{max} = 500$), naphthalene ($^1B_{2u}$; $\epsilon_{max} = 310$), and phenanthrene (B_1; $\epsilon_{max} = 800$).

Simple molecular orbital theory does predict that transitions to the lowest lying level of diphenylene will be forbidden by molecular symmetry. In this paper we have examined

[1]*Manuscript received November 14, 1960.*
Contribution from the Chemistry Department, the University of British Columbia, Vancouver, B.C. This research was supported by a grant from the National Research Council of Canada.

the lowest energy band of diphenylene in the vapor and in rigid glassy solution at liquid nitrogen temperature and have obtained results which are in accord with the predictions of simple theory.

EXPERIMENTAL

Vapor Spectra

Diphenylene is a reasonably volatile solid and appreciable concentrations of vapor were obtained in a 10-cm cell at around 100° C. A small heating compartment was made which fitted into the Cary spectrophotometer (Model 14). A small crystal of diphenylene was contained in an evacuated quartz cell which could be maintained at temperatures around 100° to within 0.5°. The cell windows were always at a slightly higher temperature than the body so that no crystals could interfere with the light beam. An identical quartz path was placed in the reference beam.

Spectra at Liquid Nitrogen Temperature

The solvent used was a mixture of ether (5 parts), isopentane (5 parts), and alcohol (1 part) to be referred to as EPA. This formed an optically clear glass at the temperature of boiling nitrogen.

The low-temperature cell was constructed to fit into the sample compartment of the Cary spectrophotometer. The Dewar system was made of metal to which was fitted a copper block. The liquid was contained in a cylindrical cell with copper walls and quartz windows which fitted tightly into the copper block of the Dewar. The windows were held in by means of steel springs and the vacuum seal was obtained by pressing the windows onto indium rings. In this way spectra could be run with a perfect optical path at any temperature between 25° C and −190° C. The window assembly used was a modification of that described by Willis (4). The cell thickness was 0.33 cm. In calculating extinction coefficients at liquid nitrogen temperature correction was made for the contraction of the solution on cooling from room temperature.

The wavelength scale of the Cary was calibrated absolutely to within 2 Å in the spectral region which was covered. Often the peaks were sharp enough such that wavelength differences could be measured to ±0.4 Å, which corresponds to ±2.5 cm^{-1} at 4000 Å and ±3.1 cm^{-1} at 3600 Å. The Cary was used with a maximum slit width of 0.015 mm.

RESULTS

Vapor Spectrum

The spectrum of diphenylene vapor at two temperatures is shown in Fig. 1. The main features are as follows:

(1) The weak band system is superimposed on the long wavelength tail of the 3600 Å transition.

(2) Although not well resolved by the instrument, the spectrum at 95° C appears as a typical electronic band system with some indication of red shading.

(3) At higher temperature the very weak member at 3880 Å has gained in relative intensity. Above 125° C all the diphenylene in the cell had vaporized and further temperature increases had little effect apart from broadening and an over-all intensification of the spectra due to an increase in the hot-band intensity from the higher energy transition.

(4) No accurate vapor pressure data were available for diphenylene so it was not possible to measure extinction coefficients or oscillator strengths.

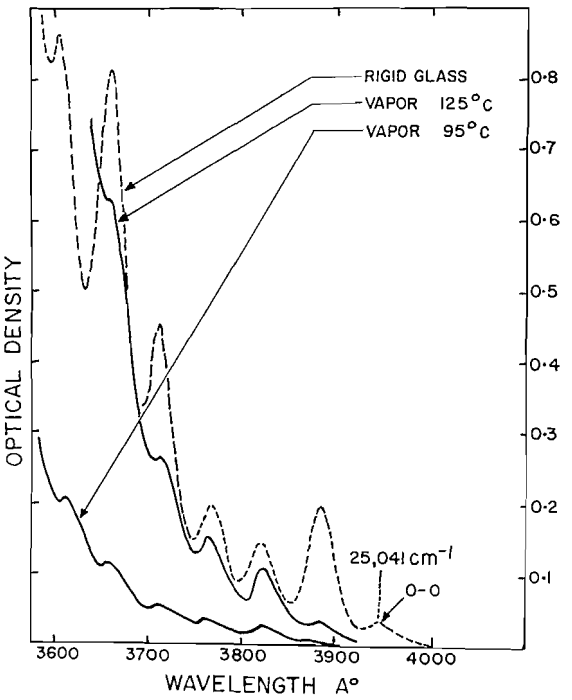

FIG. 1. The absorption spectra of diphenylene in vapor and rigid glass: the lowest energy transition.

Comparison of Vapor and Rigid Glass Spectra

The spectrum of diphenylene in EPA glass at −183° C is shown as a dotted curve on Fig. 1. The whole spectrum was shifted about 370 cm^{-1} to the blue in order to clarify the more important features. The essential dissimilarities between the vapor and rigid glass spectra were as follows:

(1) The 25,780 cm^{-1} lowest-energy vapor band now appears strongly at 3934.9 Å (25,414 cm^{-1}). The one–one correspondence between the bands in the vapor and rigid glass spectra is clearly shown in Table I.

TABLE I

Comparison of the vapor and rigid glass spectra of the weak system of diphenylene

ν_{max} (cm^{-1})		Relative intensity		
Vapor	Glass	Vapor	Glass	$\Delta\nu$ (cm^{-1})
25,407*	25,041	0	0.3	366 (calc.)
25,780	25,414	0.2	1.6	366
26,171	25,833	1.0	1.0	338
26,582	26,195	1.1	1.0	387
26,941	26,578	1.4	2.5	363
27,342	26,928	2.3	5.25	414
27,686	27,320	3.1	2.5	366

*See Table III.

(2) A new band is present at 25,041 cm^{-1} (3993.4 Å). This band is weak in the glass

but does not appear at all in the vapor spectra even at the highest temperatures studied (190° C).

(3) The intensity distribution throughout the band system is quite different to that in the vapor (see Table I). The relative intensities were measured after first subtracting out an estimated contribution from the tail of the higher energy transition.

(4) Each vibrational envelope is shifted to the red of the corresponding vapor band by 366 ± 24 cm^{-1}.

Higher Electronic Transitions

The vapor spectrum of diphenylene at 95° C down to 3000 Å is shown on Fig. 2.

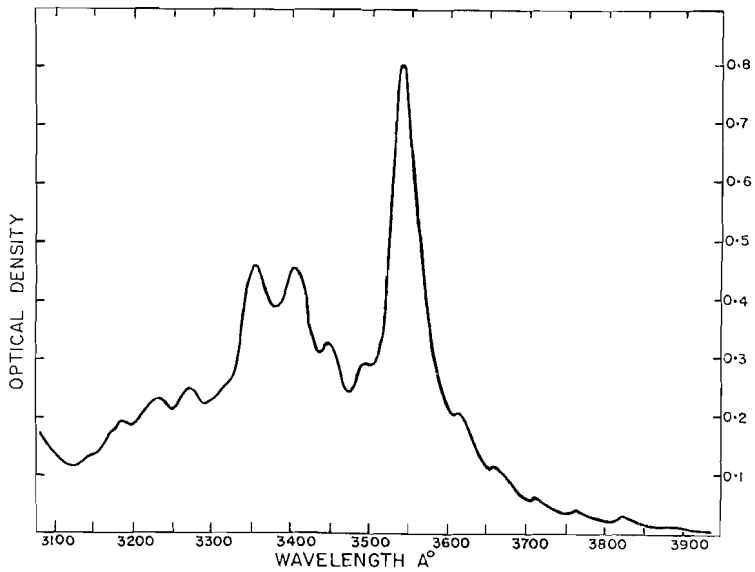

FIG. 2. Vapor spectrum of diphenylene.

Each band in this spectrum correlates with a band in the spectrum of diphenylene in liquid solution.

DISCUSSION

A proposed vibrational analysis of the absorption spectrum is given in Table II. The

TABLE II

Vibrational assignments in the weak system of diphenylene in a rigid EPA glass at 90° K

For personal use only.

frequency 365 cm^{-1} in the upper state. The intensity distribution shows that the nuclear configurations are probably very different in the ground and excited states. The band due to the excitation of three quanta of 365 cm^{-1} is the most intense in the rigid glass. The vibrational interval was about 30 cm^{-1} greater in the spectrum of the vapor. The value of 365 cm^{-1} most probably corresponds to an a_g skeletal mode of diphenylene and may be compared with similar modes in naphthalene (485 cm^{-1} in $^1B_{2u}$) (5) and anthracene (399 cm^{-1} in $^1B_{2u}$) (6) and tetracene (309 cm^{-1} in $^1B_{2u}$) (7).

The 0–0 band of the electronic transition is taken to lie at 25,407 cm^{-1} in the vapor and 25,041 cm^{-1} in the rigid glass. The change in relative intensity of this band between the two media is taken as evidence of a symmetry-forbidden transition. Under these conditions the origin of the totally symmetric sequence was not the 0–0 band but instead was the band at 25,833 cm^{-1}, which is removed by 792 cm^{-1} from the 0–0 band. It is very likely that this interval represents one quantum of an antisymmetric vibration in the upper state. This vibration (represented as b in Table II) makes the electronic transition allowed and thus appears added to each of the other vibrational transitions. If the pure electronic part of the transition was symmetry-forbidden then of course the 0–0 band would not appear at all in the vapor at low pressure. However, in the rigid glass the environmental interactions will probably remove symmetry restrictions to some degree. The same could happen through intramolecular interactions in the vapor at higher pressures or through the excitation of low-lying ground state vibrations at the higher temperatures. The band at 25,414 cm^{-1} (rigid glass) was very weak in the vapor but much stronger in the rigid glass and in liquid solution at room temperature. This band was assigned to an excitation of one totally symmetric vibrational quantum in the upper state. Such a transition is symmetry-forbidden in vibronic symmetry and would either not appear or appear only weakly in the vapor. However, in asymmetric solvent fields a transition of this type might gain considerable intensity over that in the vapor. In other words the intensity of this band is derived from the relaxation of symmetry selection rules due to solvent-induced asymmetry. The lack of detail in the spectra does not permit other than a tentative acceptance of this explanation. The appearance of a vibronic level of this nature could evidence the fact that the molecule has changed its shape during excitation.

To summarize, there were five factors which, when considered together, provided an indication that this lowest electronic transition of diphenylene was forbidden by symmetry and made allowed by the simultaneous excitation of a vibration of the appropriate symmetry. These were as follows:

(1) The extremely low intensity of the electronic absorption. Because of the interference from the higher-energy band it was not possible to obtain an exact value for the f-number of the transition. However, this was estimated to be less than 10^{-3} at liquid nitrogen temperature. This factor alone, although at first sight convincing, was not sufficient evidence of a forbidden transition. The lowest-energy bands in naphthalene and phenanthrene have f-numbers of 2×10^{-3} and 3×10^{-3} (8) respectively and yet are apparently allowed by molecular symmetry. According to the Free Electron Perimeter model (9) these low intensities may be accounted for by the large change in orbital angular momentum associated with these transitions.

(2) The absence of the ascribed 0–0 transition in the vapor phase. Once again this is not a sufficient criterion for symmetry forbiddenness. The 0–0 band of naphthalene is extremely weak or absent in the vapor of naphthalene although it does appear in solution due to the asymmetry field of solvent molecules (2, p. 134). However, the non-appearance

of the 0–0 transition strongly suggests that the electronic transition being studied is forbidden by symmetry.

(3) The marked change in intensity distribution; in particular, the gain in intensity of the 0–0 band in the rigid glass compared to that in the vapor. The over-all intensity distribution and the changes which occur between vapor and rigid glass suggest that Franck–Condon limitations, imposed by a change of symmetry in the upper state, are in operation.

(4) The vibrational analysis, although severely limited by the resolution of the instrument, fully supports the interpretation of a symmetry-forbidden electronic transition. The observed frequencies fit well into the classical series for an electronic transition which is only given intensity by electronic–vibrational coupling in the upper state.

(5) One further piece of evidence which supports our interpretation can be gleaned from the absorption spectrum of diphenylene in solution at room temperature. Figure 3

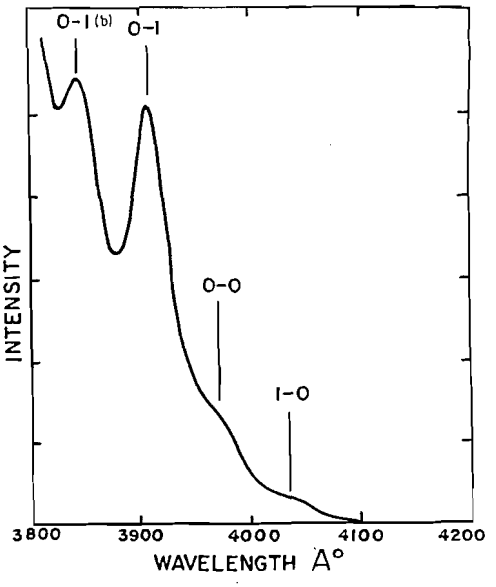

FIG. 3.

shows the absorption spectrum of the long wavelength tail of a highly purified sample of diphenylene in hexane. The two shoulders on the edge are characteristic of the spectra of molecules exhibiting forbidden transitions. In the usual case, when the absorption is to an allowed level, the 0–0 band is very strong. Thus the weak 1–0 band is seldom observed, even as a shoulder, as it is hidden by the strong 0–0 band. In the forbidden case the 0–0 band usually appears very weakly under solvent perturbations and the 1–0 band may then be observed as a shoulder or as a well-defined peak. Thus absorption to a forbidden level would give rise to a strong band (0–1) and then two shoulders corresponding to 0–0 and 1–0 transitions. This is shown quite clearly on Fig. 3. The 1–0 band was naturally not observed in the rigid glass at −183° C because of the Boltzmann factor in the ground state.

Comparison with Theory

The known data for diphenylene is summarized in Table III. The theoretical computations were made by Rowlands (10) using the ASMO–LCAO method. The symmetries were predicted from the table of orbital symmetries of Coulson and Daudel (11).

On the assumption that diphenylene is a planar molecule (see Fig. 4) belonging to

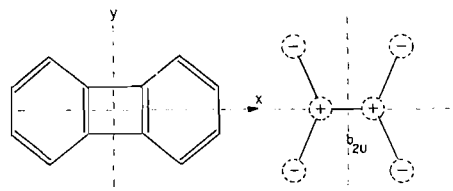

FIG. 4. Diphenylene, $C_{12}H_8$. The axes chosen are those of reference 11. The circles indicate the motion of the nuclei during the execution of a B_{2u} normal vibration within a D_{2h} nuclear framework. The b_{3u} normal vibrations involve asymmetric in-plane motions.

the point group D_{2h} then the lowest excited singlet molecular level is predicted to be $^1B_{1g}$. Transitions from the $^1A_{1g}$ ground state to this level are forbidden by symmetry. They may, however, be made allowed by vibrations of appropriate symmetry which in this case could be b_{2u} or b_{3u}. The symmetry of the resulting vibronic state will be either B_{3u} ($= b_{2u} \times B_{1g}$), which is long axis polarized or B_{2u} ($= b_{3u} \times B_{1g}$), which is short axis polarized. Fundamental vibrations belonging to the representations b_{2u} and b_{3u} should appear in the infrared spectrum of diphenylene.

Our analysis has assumed that the perturbing vibration has frequency 792 cm^{-1}. The infrared spectrum of diphenylene in carbon tetrachloride solution has only two very strong bands in this region. These infrared vibration frequencies are 963 cm^{-1} and 732 cm^{-1}.

The closeness of the 732 cm^{-1} infrared frequency to that of the observed perturbing vibration supports the contention that the electronic transition is of g–g character and made allowed by this b_u vibration. If this deduction is correct then the spectrum should exhibit *two* strong progressions; the first involving the excitation of 1, 2, 3, 4, etc. quanta of an a_g vibration in combination with one b_u quantum; the second involving the successive excitation of 1, 3, 5, etc. quanta of the symmetric b_u vibration. Unfortunately the energy of $0+3b_u$, which is 27,417 cm^{-1}, would place this band right under the strong 27,910 cm^{-1} origin of the next highest electronic state. Such a band could probably not be (and was not) observed in absorption.

The wide discrepancy between the observed and calculated energy of the weak 25,407 cm^{-1} band cannot be explained at the moment. The results of the present experiments do not completely exclude the possibility that this band corresponds to the calculated 25,760 cm^{-1}, $^1B_{3u}$ level.

A detailed examination of the infrared spectrum and of the crystal spectrum should make possible an unambiguous decision as to the nature of the perturbing vibration.

ELECTRODE POTENTIALS OF THE URANIUM CHLORIDES IN FUSED ALKALI CHLORIDE SOLUTIONS[1]

S. N. FLENGAS[2]

ABSTRACT

Using a silver – silver chloride reference electrode, the electrode potentials of the system U, UCl_3(KCl, NaCl) and the redox potentials of the system Pt, UCl_3, UCl_4(KCl, NaCl) were measured at various concentrations of the uranium chlorides and at temperatures between 650 and 850° C.

From the results, the electrode potential of the system U, UCl_4(KCl, NaCl) was calculated. In addition, the activity coefficients and partial molal properties of dilute solutions of UCl_3 and UCl_4 in the equimolar mixture of potassium and sodium chlorides were calculated.

INTRODUCTION

In previous publications (1–7) from the Mines Branch, measurements of the "apparent standard electrode potentials" of several metal – metal chloride systems in dilute solutions in fused alkali chlorides were reported. These measurements were made to provide fundamental information on the activities in fused alkali chloride solutions, to determine the equilibrium constants of chemical reactions in fused salts, and to provide some of the necessary data for studies of the electrolytic reduction of metals from alkali chloride melts.

In determining the electrode potentials, an equimolar mixture of potassium and sodium chlorides was used as the solvent for the metal chlorides, and a silver – silver chloride electrode developed earlier in this work (1) was used as a zero potential reference electrode.

In the experimental work reported here, the technique has been applied to the determination of the potentials of the uranium chlorides dissolved in an equimolar mixture of potassium and sodium chlorides. There are only two stable uranium chlorides at temperatures above 500° C, namely uranium trichloride and uranium tetrachloride. The electrode potentials of the two uranium ions and the redox potentials of the tri- and tetra-valent uranium ions were determined.

EXPERIMENTAL

The cells used for the measurement of the electrode potentials of uranium trichloride, and for the measurement of the redox potentials of the tri- and tetra-valent uranium chlorides, were similar in design to those described in the previous publications (6, 7).

The cell for measuring the electrode potential of uranium trichloride can be represented as follows:

$$\begin{array}{c|c|c|c|c} U_{(s)} & UCl_3\,(x_2) & \text{Asbestos fiber} & AgCl\,(x_1) & Ag_{(s)} \\ (-) & KCl + NaCl\,(1/1\text{ mole}) & \text{diaphragm} & KCl + NaCl\,(1/1\text{ mole}) & (+) \end{array}$$

The cell reaction is:

$$U_{(s)} + 3Ag^{+}_{(AgCl\text{ in }KCl + NaCl)} = U^{3+}_{(UCl_3\text{ in }KCl + NaCl)} + 3Ag_{(s)}$$

[2]*Present address: Department of Metallurgical Engineering, University of Toronto, Toronto, Ontario.*

The relationship between the electromotive force and the metal ion concentration in the cell is given by the Nernst equation in the form:

$$[1] \quad E_{cell} = (E^\circ_{UCl_3} - E^\circ_{AgCl}) - (2.303RT/3\mathcal{F}) \log(x_2/x_1^3) - (2.303RT/3\mathcal{F}) \log(\gamma_2/\gamma_1^3)$$

where $E^\circ_{UCl_3}$ and E°_{AgCl} are the formation potentials of uranium trichloride and silver chloride in their standard states. The standard state will be defined as the state of the pure metal chloride at the temperature of the experiments.

The γ and x terms are respectively the mean activity coefficients and the conventional mole fractions of the metal chlorides in the solutions in the two half-cells. The activity coefficient of silver chloride in these solutions was determined and found to be unity in a previous investigation (6), using a chlorine electrode.

Following the same method as used previously (6, 7), it is possible, from equation [1], to calculate the "apparent standard cell potential" of the system, by plotting the experimental potential E_{cell} against log (x_2/x_1^3) and extrapolating the linear relationship to zero log term. The "apparent standard cell potential" obtained in this way is a constant of the system investigated, and is related to the formation potentials of the metal chlorides and the activity coefficient of uranium trichloride by the equation:

$$[2] \quad E^\circ_{app} = (E^\circ_{UCl_3} - E^\circ_{AgCl}) - (2.303RT/3\mathcal{F}) \log \gamma_2.$$

Since the formation potentials of the metal chlorides in their pure state are listed in the literature (8), equation [2] can be used for the determination of the activity coefficient of UCl_3 in the chloride melt.

The cell for measuring the "redox potentials" of the tri- and tetra-valent uranium ions can be represented as follows:

$$\begin{array}{c|l||l||l|c} Pt_{(s)} & UCl_3\,(x_2) & \text{Asbestos fiber} & AgCl\,(x_1) & Ag_{(s)} \\ (-) & UCl_4\,(x_3) & \text{diaphragm} & KCl + NaCl\,(1/1\text{ mole}) & (+) \\ & KCl + NaCl\,(1/1\text{ mole}) & & & \end{array}$$

The cell reaction is:

$$U^{3+}_{(UCl_3 \text{ in } KCl + NaCl)} + Ag^{+}_{(AgCl \text{ in } KCl + NaCl)} = U^{4+}_{(UCl_4 \text{ in } KCl + NaCl)} + Ag_{(s)}.$$

The relationship between the cell potential and the metal ion concentration in the cell is given by the Nernst equation in the form:

$$[3] \quad E_{cell} = (E^\circ_{UCl_3/UCl_4} - E^\circ_{AgCl}) - (2.303RT/\mathcal{F}) \log (x_3/x_1 . x_2) - (2.303RT/\mathcal{F}) \log (\gamma_3/\gamma_1 . \gamma_2)$$

where the $E^\circ_{UCl_3/UCl_4}$ is the standard redox potential of the system UCl_3, UCl_4 in the standard state. The x and γ terms are, respectively, the mole fractions and the activity coefficients of the metal chlorides.

The "apparent standard redox" potential of the system is determined by plotting the experimental cell potentials against log $(x_3/x_1 . x_2)$ and then extrapolating the linear relationship to zero log term.

It should be noted that the above-mentioned cells were operated in an inert atmosphere of purified argon gas.

PREPARATION OF MATERIALS

The equimolar mixture of potassium and sodium chlorides was prepared from analytical grade reagents, and was dehydrated by heating under vacuum at 500° C for 12 hours.

Anhydrous uranium trichloride was prepared in a tubular furnace at 500° C, by the reaction between reactor grade uranium metal and oxygen-free anhydrous hydrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

chloride (9). Very pure and dry gaseous hydrogen chloride was prepared in a suitable apparatus by the reaction between concentrated hydrochloric acid and concentrated sulphuric acid (10). The product of the reaction, between uranium metal and hydrogen chloride, was finely divided uranium trichloride which adhered to the surface of the metal. This finely powdered product, which was separated from the coarse unreacted uranium by sieving in a dry box, was of a purity of 98.5%.

Anhydrous uranium tetrachloride was prepared by the reaction between hydrated uranium trioxide ($UO_3.2H_2O$) and hexachloropropene (11). The product obtained from this reaction was purified by sublimation *in vacuo*, and was of a purity of 99.0%.

The uranium chlorides were pelletized in an argon-filled dry box and were transferred to the cell using the piston-type feeding apparatus described previously (7).

The uranium electrode for these experiments was a rod of reactor grade uranium which had been swaged down to $\frac{1}{2}$-in. diameter, and was about 3 in. long. It was connected to a platinum wire. Prior to its use, the electrode was polished to a silver-like finish in a dilute solution of nitric acid. The polished electrode was then washed with distilled water and dried with acetone.

The silver electrode was a rod of pure silver (99.9%) connected to a silver wire. The inert platinum electrode used for the redox potential measurements was a hollow platinum cylinder of $\frac{1}{2}$-in. diameter and 3-in. long. It was connected to a platinum wire.

The thermoelectric potentials due to the bimetallic systems of these electrodes were measured separately, and the appropriate corrections were applied to the measurements of the electrode potentials.

RESULTS

1. *Electrode Potentials of the U/U^{3+} System*

In the preliminary experiments, the stability of a system consisting of uranium metal immersed in a solution of uranium trichloride in molten potassium and sodium chlorides was investigated by following the change of the cell potential with time.

The solutions of uranium trichloride were prepared *in situ* during the run, by adding weighed pellets of the anhydrous salt to the melt in the indicator electrode compartment. After each addition, the equilibrium potential was attained in about 30 minutes. Potential readings were then taken at regular time intervals over a period of about 20 hours. It was found that the shift of potential was of the order of only 1 mv. Furthermore, after the end of the run there was no indication of a chemical attack on the uranium electrode.

It was concluded that uranium metal is insoluble in dilute solutions of uranium trichloride under the conditions of the experiment. However, it was observed that electrodes which accidentally had been placed in contact with the side walls of the silica tubing in the cell were heavily corroded. The potentials obtained under these conditions were erratic and non-reproducible. In all probability, the observed solubility of uranium metal in the melt was due to the formation of a soluble uranium oxide or oxychloride through the exchange reaction between uranium metal and silica. For this reason, during the experiments, the uranium electrode was suspended by the platinum wire in the center of the cell.

The electromotive force of the U/U^{3+} cell was measured first as a function of temperature, at various mole fractions of uranium trichloride.

The variation of the cell potential with temperature, at mole fractions varying between 10^{-4} and 10^{-2}, is shown in Fig. 1. The results in this graph represent three independent runs. It is apparent that the curves are linear over the temperature range between 650

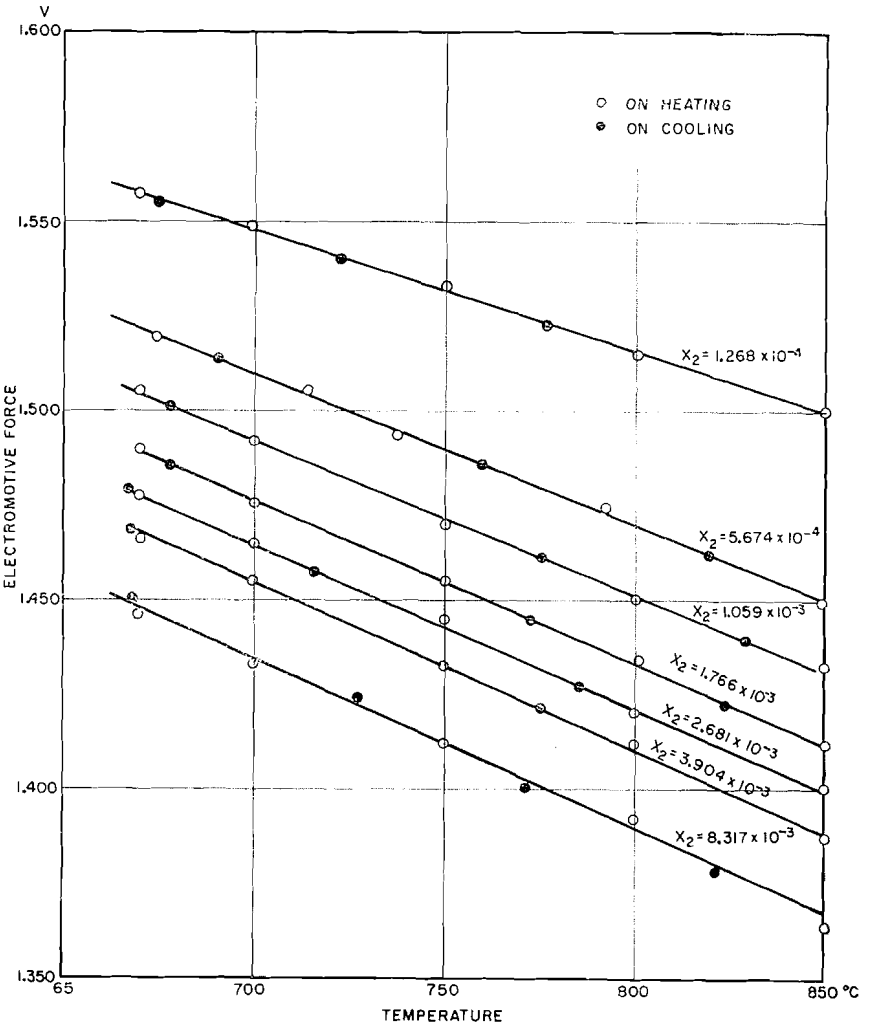

FIG. 1. Electromotive force of the cell:

$$\begin{matrix} \text{U} \\ (-) \end{matrix} \;\Big|\; \begin{matrix} UCl_3\ (x_2) \\ \text{KCl + NaCl (1/1 mole)} \end{matrix} \;\Big\|\; \begin{matrix} \text{AgCl}\ (x_1 = 5.0 \times 10^{-2}) \\ \text{KCl + NaCl (1/1 mole)} \end{matrix} \;\Big|\; \begin{matrix} \text{Ag} \\ (+) \end{matrix}$$

as a function of temperature.

and 850° C, and the cell potentials have a negative temperature coefficient. Potential readings made while temperature was being increased were in good agreement with those made while the temperature was decreasing.

The relationship between the cell potential and the logarithm of the mole fractions, at temperatures between 670 and 850° C, is shown in Fig. 2. In this graph the straight lines through the experimental points are the best straight lines that can be drawn with a slope equal to the slope of the Nernst equation for a three-electron electrode reaction at these temperatures. It is seen that the results are in agreement with the Nernst equation. The linearity of the curves indicates that the activity coefficient of uranium trichloride in these dilute solutions is independent of concentration. The "apparent standard cell potential" of uranium trichloride was obtained by extrapolation of the curves to zero log (x_2/x_1^3) term. These results are given in Table I.

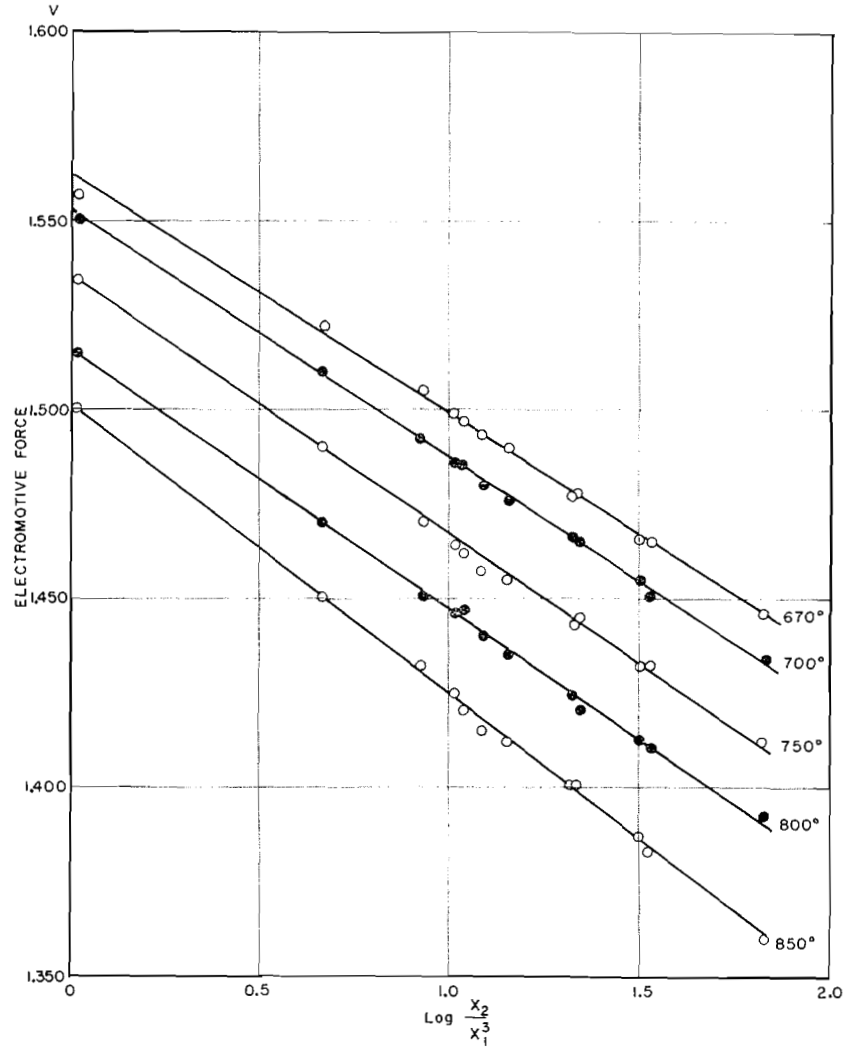

FIG. 2. Electromotive force of the cell:

$$\begin{array}{c|c|c|c|c} \text{U} & \text{UCl}_3\ (x_2) & & \text{AgCl}\ (x_1 = 5.0\times10^{-2}) & \text{Ag} \\ (-) & \text{KCl} + \text{NaCl}\ (1/1\ \text{mole}) & \| & \text{KCl} + \text{NaCl}\ (1/1\ \text{mole}) & (+) \end{array}$$

as a function of log (x_2/x_1^3), at various temperatures.

2. *"Redox" Potentials of the U^{3+}/U^{4+} System*

The electromotive force of the U^{3+}/U^{4+} redox cell was measured, as a function of temperature, at various mole fractions of uranium tri- and tetra-chlorides. The stability of the potential measurements over a period of time exceeding 12 hours indicated that solutions of uranium tri- and tetra-chlorides in the equimolar mixture of potassium and sodium chlorides are very stable.

The results of the redox potential measurements at temperatures between 650 and 850° C, for mole fractions of uranium tri- and tetra-chlorides varying between 10^{-3} and 10^{-2}, are shown in Fig. 3.

It is seen that the curves are linear over the temperature range investigated, and that the potentials of the redox cells have a negative temperature coefficient.

DISCUSSION

From the experimental values for the apparent standard potentials of the system $U/UCl_3(KCl + NaCl)$ and the apparent standard redox potential of the system $UCl_3/UCl_4(KCl + NaCl)$, the apparent standard potential of the system U/UCl_4 $(KCl + NaCl)$ was calculated by application of the equation:

$$[4] \qquad E^\circ_{UCl_4} = (3E^\circ_{UCl_3} + E^\circ_{UCl_3/UCl_4})/4.$$

The results of these calculations are shown in Table I.

The potentials of the chlorine electrode which were measured against the silver – silver chloride reference electrode in a previous investigation (6) are also included in this table. To refer the potentials of the uranium system to a chlorine reference electrode, it is only necessary to subtract the potential of the chlorine electrode, as given at the bottom of the table, from the corresponding uranium potential.

The graph of the "apparent standard potentials" of the uranium chlorides, as a function of temperature, is given in Fig. 5. In this graph, calculated standard potentials of the pure salts (8) are also included for comparison.

Apparent standard cell potentials of uranium tri- and tetra-chlorides, in a melt of potassium and lithium chlorides at 450° C, have been reported recently by Gruen and Osteryoung (13), and by Hill, Ferand, and Osteryoung (14). Inman, Hills, Young, and Bockris (15, 16) also investigated the potentials of uranium trichloride in the potassium chloride – lithium chloride eutectic.

When the results in Fig. 5 were extrapolated to 450° C, the "apparent standard cell potentials" of the uranium tri- and tetra-chlorides were found to be respectively 1.632 and 1.365 volts. These compare well with 1.611 volts for uranium trichloride, and 1.363 volts for uranium tetrachloride given by Gruen *et al.* (13), and Hill *et al.* (14). Also the "apparent standard cell potential" at 450° C, of uranium trichloride which can be calculated from the results of Inman *et al.* (15, 16), is of the same order of magnitude, i.e. about 1.66 volts.

For a variety of metal – metal chloride systems, the agreement between the apparent standard potential measured at 450° C in the eutectic of potassium and lithium chlorides (17), and those measured in the equimolar mixture of potassium and sodium chlorides, has been pointed out in a previous investigation (6). Furthermore, the same agreement was observed by Hill *et al.* (14) in their study of the uranium potentials in chloride melts containing comparatively light metal cations such as potassium, lithium, and magnesium. It appears that the partial molal free energy of mixing of the uranium chlorides is almost independent of the size of the cations present in the solvent, provided that these cations are much smaller than the uranium ions.

From the apparent standard potentials shown in Table I, it is possible to calculate the thermodynamic functions and the equilibrium constants of various reactions of metallurgical interest. The results of these calculations are given in Table II.

The magnitude of the equilibrium constant for reaction [4], shown in Table II, indicates that in the presence of uranium metal, uranium tetrachloride would be reduced quantitatively to the trichloride.

The equilibrium constants of reactions [1] to [3] indicate that uranium metal will displace silver ions from solution, and that at equilibrium, the predominant species will be uranium tetrachloride.

Using the results in Fig. 5, the partial molal properties and the activity coefficients

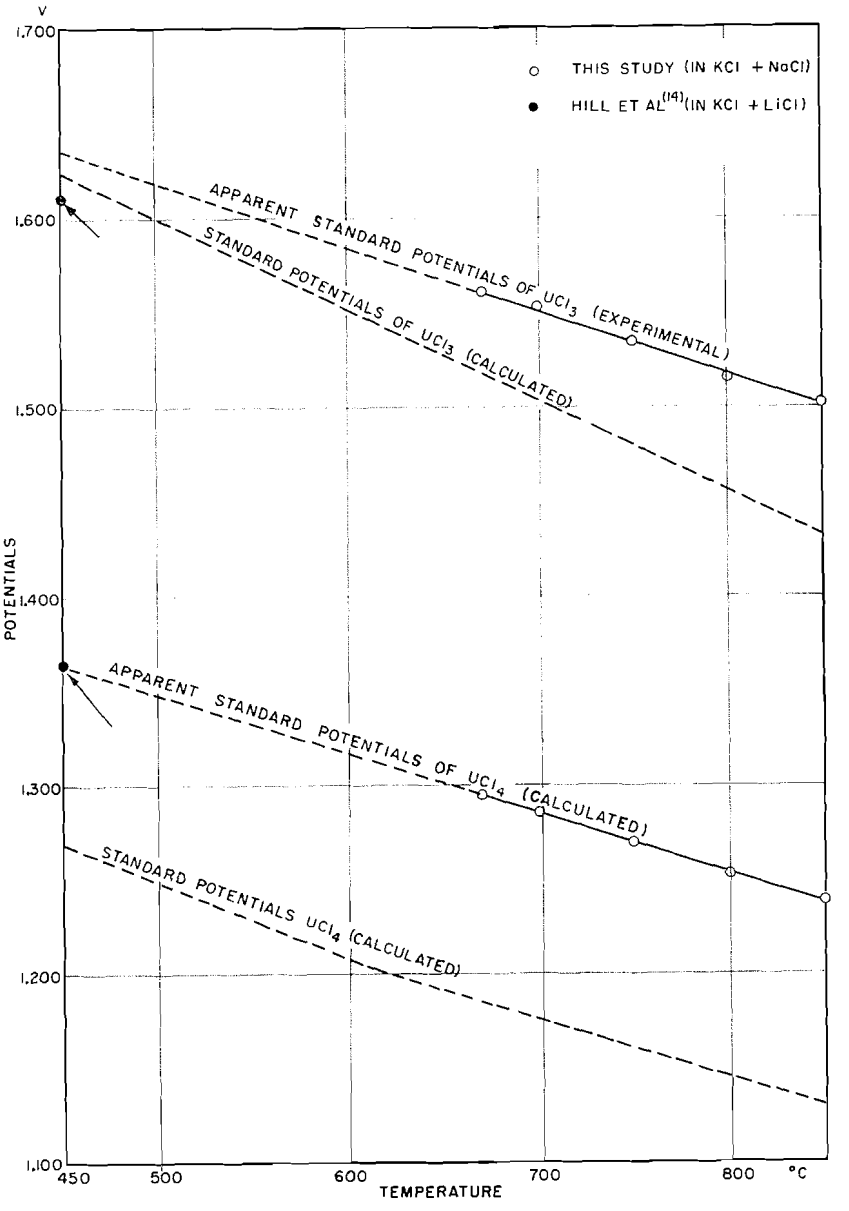

FIG. 5. Apparent standard potentials of UCl_3 and UCl_4 and the corresponding standard state potentials at various temperatures.

of the uranium chloride solutions were calculated from the differences between the "standard potentials" of the pure uranium tri- and tetra-chlorides and the "apparent standard potentials" in the fused salt solution. The results of these calculations are given in Table III.

The partial molal free energy of solution ($\Delta\bar{F}$), given in Table III, represents the difference between the free energy of the salt in its hypothetical standard state as a solute, i.e., "a solution containing a unit mole fraction of the salt but having in all other

respects the thermodynamic properties of the state of infinite attenuation of the solute", as defined by Lewis and Randall (18), and the free energy of the salt in its actual standard state of the pure salt. It is of interest to note that the partial molar free energy of solution of uranium tetrachloride is much greater than that of uranium trichloride.

The activity coefficients and the partial molal entropies of mixing indicate that uranium trichloride and uranium tetrachloride form complexes in solution. A comparison of the activity coefficients indicates that the uranium tetrachloride complex is stronger than the uranium trichloride complex. The variation of the activity coefficients of uranium tetrachloride with temperature shows the expected behavior; i.e., they increase with temperature. On the contrary, the activity coefficients of uranium trichloride decrease with increasing temperature, which indicates that the complexity of uranium trichloride is greater at higher temperatures.

The presence of complexes of tetravalent uranium ions in chloride melts has also been observed by Gruen and McBeth from spectrophotometric studies (19).

The constancy of the activity coefficients over the mole fraction range 10^{-4} to 10^{-2} indicates that the solutions of uranium tri- and tetra-chlorides in fused salts obey Henry's law.

ACCURACY OF RESULTS

It is rather difficult to evaluate the absolute accuracy of the potentials shown in Table I. Individual potential measurements shown in Figs. 1 and 3 were stable and reproducible. The slight scattering of the experimental points, which can be seen in the figures, is probably due to other side effects which are always present in high-temperature systems. These effects are: concentration gradients due to thermal convection currents; difficulties in obtaining a completely oxygen-free uranium metal surface; and slight impurities in the electrolyte. However, judging from the results presented in Figs. 1 to 4, it is reasonable to assume that the potential values obtained in this investigation are accurate to within ±2 mv. This variation would also affect the calculation of the free energy listed in Tables II and III. It has been estimated that the variation of the free energy change should be about ±0.3 kcal/mole for the uranium trichloride system, and about ±0.4 kcal/mole for the uranium tetrachloride system.

ACKNOWLEDGMENTS

The author thanks Dr. T. R. Ingraham for his helpful advice and many useful discussions during the course of this work.

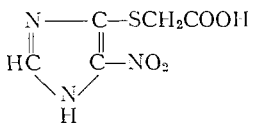
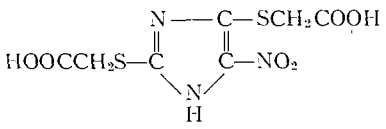
CARBOXYMETHYLMERCAPTO AND CARBOXYMETHYLSULPHONYL DERIVATIVES OF NITROIMIDAZOLE[1]

M. H. Fisher, W. H. Nicholson, and R. S. Stuart



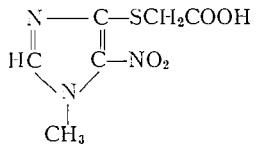
ABSTRACT

Several carboxymethylmercapto and carboxymethylsulphonyl derivatives of nitroimidazole were prepared for biological testing. Reduction or reductive cyclization of these compounds was unsuccessful.

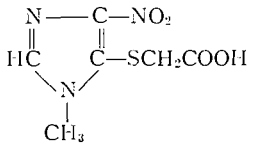


INTRODUCTION

In a previous communication (1) the syntheses of a number of nitro- and amino-imidazolesulphonamides as potential antimetabolites were described. This work has now been extended to the related carboxymethylmercapto compounds and oxidized derivatives. It was hoped that the nitro compounds could be reduced and cyclized but all attempts led to the formation of colored reaction mixtures from which no pure compounds could be isolated.

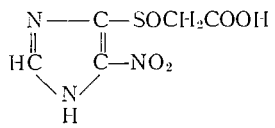


4(5)-Bromo-5(4)-nitroimidazole (2), 2,4(5)-dibromo-5(4)-nitroimidazole (2), 4-chloro-1-methyl-5-nitroimidazole (3), and 5-chloro-1-methyl-4-nitroimidazole (3) on treatment with thioglycolic acid in ammoniacal solution gave the carboxymethylmercapto compounds (I), (II), (III), and (IV).

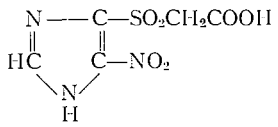


(I)

(II)

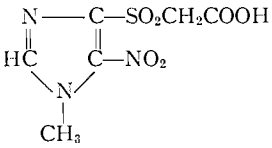


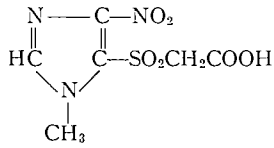
(III)



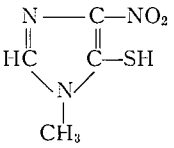
(IV)

Oxidation with hydrogen peroxide in glacial acetic acid yielded the sulphones (V), (VI), and (VII). The disulphide (II) gave an oil which could not be crystallized. The non-methylated compound (I) was somewhat more resistant to oxidation than the others. An intermediate sulphoxide (VIII) was isolated and further oxidized to the sulphone under more vigorous conditions.

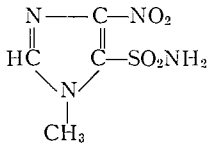




(VIII)



(V)



[1]*Manuscript received December 27, 1960.*
Contribution from the Research Department, Merck & Co. Ltd., Montreal, Que.

(VI)

(VII)

Treatment of the sulphide (IV) or the sulphone (VII) with bromine yielded mixtures containing some brominated material. Either mixture with hydrogen sulphide in ammoniacal solution gave 5-mercapto-1-methyl-4-nitroimidazole (IX) (4) as the major product.

(IX)

(X)

It was subsequently found that hydrogen sulphide readily displaced the carboxymethylmercapto, the carboxymethylsulphonyl, or the sulphonamide groups from compounds (IV), (VII), or (X). In each case the thiol (IX) was produced in good yield.

EXPERIMENTAL

Carboxymethylmercapto Compounds

2,4(5)-Bis-(carboxymethylmercapto)-5(4)-nitroimidazole (II)

Thioglycolic acid (11 ml) was added to a solution of 2,4(5)-dibromo-5(4)-nitroimidazole (20 g) in water (100 ml) and concentrated ammonia (50 ml). The mixture was allowed to stand at room temperature for 64 hours. Addition of isopropyl alcohol (300 ml) precipitated the yellow ammonium salt (12 g), m.p. 136°.

The ammonium salt was converted to the free acid with Amberlite resin IR-120(H^+). Crystallization from water gave yellow needles, m.p. 212–213°. Found: C, 28.5; H, 2.38; N, 14.1; S, 21.9. Calc. for $C_7H_7N_3O_6S_2$: C, 28.6; H, 2.39; N, 14.3; S, 21.8%.

4-Carboxymethylmercapto-1-methyl-5-nitroimidazole (III)

Thioglycolic acid (7.5 ml) was added dropwise with stirring to a suspension of 4-chloro-1-methyl-5-nitroimidazole (15 g) in water (100 ml) and concentrated ammonia (50 ml). After storage at 5° for 16 hours the ammonium salt was collected as yellow needles (18.5 g), m.p. 185°.

The ammonium salt was converted to the free acid by precipitation from water with hydrochloric acid. Crystallization from ethanol gave pale yellow needles, m.p. 163–164°. Found: C, 33.2; H, 3.26; N, 18.6; S, 14.7. Calc. for $C_6H_7N_3O_4S$: C, 33.2; H, 3.22; N, 19.3; S, 14.7%.

5-Carboxymethylmercapto-1-methyl-4-nitroimidazole (IV)

This compound was prepared from 5-chloro-1-methyl-4-nitroimidazole (15 g) in a similar manner. Addition of isopropanol (300 ml) and ether (150 ml) and storage for 18 hours at 5° precipitated the ammonium salt (16.5 g), m.p. 153–154°. The free acid crystallized from ethanol as jagged white lathes (8.5 g), m.p. 209–210°. Found: C, 33.5; H, 3.25; N, 19.3; S, 14.5. Calc. for $C_6H_7N_3O_4S$: C, 33.2; H, 3.22; N, 19.3; S, 14.7%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

4(5)-Carboxymethylmercapto-5(4)-nitroimidazole (I)

This compound was prepared from 4(5)-bromo-5(4)-nitroimidazole (9 g) in a similar manner. The ammonium salt (9.2 g) was collected after 1 hour. After crystallization from methanol it had a melting point of 193–194°. The free acid crystallized from water as yellow needles (6.7 g), m.p. 185–186°. Found: C, 29.6; H, 2.41; N, 20.4; S, 15.7. Calc. for $C_5H_5N_3O_4S$: C, 29.6; H, 2.48; N, 20.6; S, 15.8%.

Oxidations with Hydrogen Peroxide

4(5)-Carboxymethylsulphoxy-5(4)-nitroimidazole (VIII)

4(5)-Carboxymethylmercapto-5(4)-nitromidazole (2 g) in glacial acetic acid (10 ml) and 30% hydrogen peroxide (10 ml) was heated for 1 hour at 75°. The solution was cooled and the product crystallized as white needles (1.6 g), m.p. 219–220° (decomp.). Recrystallization from water raised the m.p. to 220–221° (decomp.). Found: C, 27.3; H, 2.26; N, 18.8; S, 14.8. Calc. for $C_5H_5N_3O_5S$: C, 27.4; H, 2.28; N, 19.2; S, 14.6%.

4(5)-Carboxymethylsulphonyl-5(4)-nitroimidazole (V)

The sulphoxide (VIII) (1 g) in glacial acetic acid (5 ml) and 30% hydrogen peroxide (5 ml) was heated for 4 hours at 90° until a clear solution was obtained. Evaporation to dryness yielded the product (0.8 g), m.p. 284–286°. Recrystallization from water gave white needles, m.p. 295–296°. Found: C, 25.0; H, 2.20; N, 18.0; S, 13.8. Calc. for $C_5H_5N_3O_6S$: C, 25.5; H, 2.12; N, 17.9; S, 13.6%.

4-Carboxymethylsulphonyl-1-methyl-5-nitroimidazole (VI)

Similar oxidation of 4-carboxymethylmercapto-1-methyl-5-nitroimidazole (5 g) for 1 hour at 85° yielded the product (4 g), m.p. 181–182° (decomp.) as white needles from water. Found: C, 28.9; H, 2.83; N,16.5; S, 13.0. Calc. for $C_6H_7N_3O_6S$: C, 28.9; H, 2.81; N, 16.8; S, 12.8%.

5-Carboxymethylsulphonyl-1-methyl-4-nitroimidazole (VII)

Similar oxidation of 5-carboxymethylmercapto-1-methyl-4-nitroimidazole (2 g) for 1 hour at 80° yielded the product (1.25 g), m.p. 170–171° (decomp.) as white needles from water. Found: C, 29.1; H, 2.81; N, 16.8; S, 13.0. Calc. for $C_6H_7N_3O_6S$: C, 28.9; H, 2.81; N, 16.8; S, 12.8%.

Brominations

5-Carboxymethylmercapto-1-methyl-4-nitroimidazole (0.01 mole) or 5-carboxymethylsulphonyl-1-methyl-4-nitroimidazole (0.01 mole) in 1 *N* sodium hydroxide (10 ml) was treated with bromine (0.012 mole). In both cases the precipitated product was a difficultly separable mixture of partially brominated materials.

Displacements with Hydrogen Sulphide

The partially brominated mixtures, 5-carboxymethylmercapto-1-methyl-4-nitroimidazole, 5-carboxymethylsulphonyl-1-methyl-4-nitroimidazole, or 1-methyl-4-nitro-5-sulphamylimidazole (1) were each dissolved in 5 *N* ammonia (1 g in 10 ml) and hydrogen sulphide passed through for 10 minutes. In each case the product was the ammonium salt of 5-mercapto-1-methyl-4-nitroimidazole.

Reductions

Each of the nitroimidazoles was reduced either with hydrogen and Adams platinum catalyst in ethanol or glacial acetic acid or with powdered zinc and glacial acetic acid. In all cases the solutions became highly colored and only dark brown tars could be isolated.

COUPLING CONSTANTS IN RIGID FIVE-MEMBERED RINGS

N.M.R. SPECTRA OF THE CAMPHANE-2,3-DIOLS[1]

F. A. L. ANET

ABSTRACT

The proton nuclear magnetic resonance (N.M.R.) spectra of the four diastereoisomers of camphane-2,3-diol are reported. The coupling constants between the 2-, 3-, and 4-protons agree with the values predicted by Karplus for ethane derivatives. In particular, the cis (0° dihedral angle) coupling constants (7.7 and 8.9 c.p.s.) are much larger than the trans (120° dihedral angle) coupling constants (2.2 and 2.3 c.p.s.). Unexpected 1,3-coupling between *exo*-hydrogen atoms occurs in some of the compounds studied.

INTRODUCTION

Indirect spin–spin coupling constants in substituted ethane derivatives have attracted attention because of the dependence of their values on the dihedral angle between the CH bonds involved (1–7). The dihedral angles are 60° and 180° in non-cyclic substituted ethanes, which, in general, exist in staggered rather than eclipsed forms. These are also the dihedral angles between vicinal CH bonds in six-membered rings existing in chair conformations. In each case the observed coupling constants may be weighted averages if more than one conformation exists to an appreciable extent.

Karplus (8) has used a semiempirical method to calculate the coupling constants with variation of the dihedral angle in the system CH–CH. The values for angles from 0° to 180° are plotted (cf. ref. 7) in Fig. 1. Most of the experimental evidence, as already mentioned, relates to the values of coupling constants for angles of 60° and 180°. Although

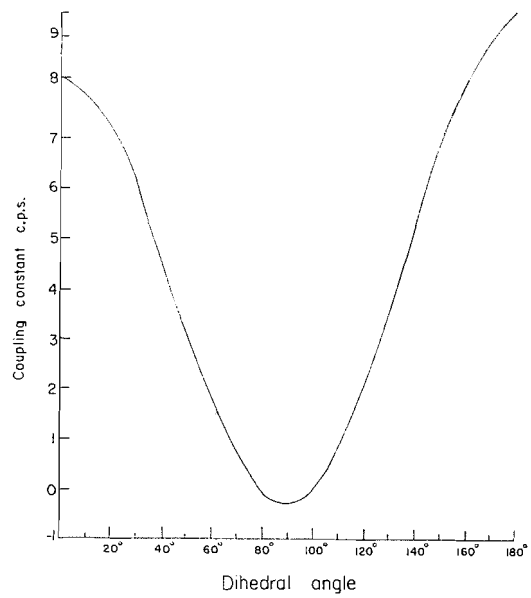

FIG. 1. Variation of coupling constants with dihedral angle in ethane derivatives, as calculated by Karplus (8).

[1]*Manuscript received November 29, 1960.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Canada.

the calculated values for these angles are in satisfactory agreement with the experimental values, it would be highly desirable to determine coupling constants for a whole series of angles from 0° to 180°. The results have a bearing not only in the N.M.R. field (9), but also in other problems, such as that of the origin of the energy barrier in ethane derivatives (10).

There are a few cases in the literature where zero coupling constants have been observed in the case of dihedral angles of about 90°, and these will be referred to at the end of this paper. No case seems to have been reported, however, for 0° or for very small angles. The spectra discussed in this paper provide data for determining coupling constants of the type required for angles of about 0°, 44°, 79°, and 120°.

Owing to the kindness of Dr. S. J. Angyal in providing samples, it has been possible to examine the N.M.R. spectra of the four diastereoisomers of camphane-2,3-diol (11, 12), which are ideal compounds for the present purpose because of the rigid structures of these molecules.

EXPERIMENTAL

The spectra were taken at a frequency of 60 Mc/sec on a Varian V-4302 high-resolution spectrometer. Solutions (10–15%) in pyridine containing a small amount of deuterium oxide and tetramethylsilane were used. Calibration of the spectra was carried out by the usual side-band method. Pyridine solutions were used because the trans isomers were only sparingly soluble in carbon tetrachloride or chloroform. The addition of a small amount of deuterium oxide had the effect of removing the coupling between the OH groups and the adjacent CH groups, thus simplifying the spectra. The OH peak, which had been broad before the addition of deuterium oxide, became quite sharp after the addition. As the OH groups should be strongly hydrogen-bonded with the nitrogen atoms of the pyridine molecules, their occurrence at lower field (ca. 4.6 τ) (5) than the other protons of the camphane diols is not surprising.

RESULTS AND DISCUSSION

The spectra (with the exception of the OH peaks) of the four diols (Fig. 2) are shown in Fig. 3. Slower sweeps of the bands of the 2- and 3-protons are shown in Fig. 4.

In each isomer there are appreciable chemical shifts between the three methyl groups

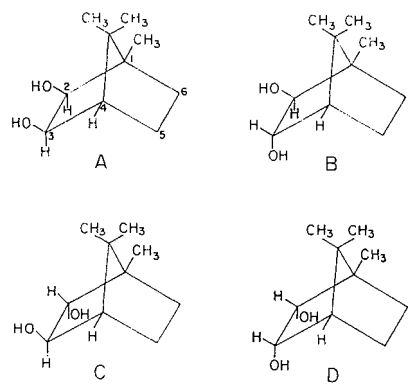

FIG. 2. Stereochemistry of the four camphane-2,3-diols. The diastereoisomers studied were optically active and of the same absolute configuration as (+) camphor (11). A, 2-*exo*,3-*exo*-isomer. B, 2-*exo*,3-*endo*-isomer. C, 2-*endo*,3-*exo*-isomer. D, 2-*endo*,3-*endo*-isomer.

and these shifts are different for the various isomers. However, it is not easy to correlate the chemical shifts with structure. In the solutions used, it would be expected that the diamagnetic anisotropy of the pyridine molecules, especially those hydrogen-bonded to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

the solute, would result in chemical shifts in the solute which would not occur in an isotropic solvent. Slomp and MacKellar (13) have in fact shown that pyridine can be a useful solvent in inducing chemical shifts between protons which otherwise have accidentally the same chemical shifts. Furthermore, the chemical shifts of the methyl groups differ appreciably when the solvent is wet pyridine instead of dry pyridine.

Protons on C4, C5, and C6 lie mostly to low field of the methyl groups. As these five protons are all different, but are not very chemically shifted from one another, an analysis would be extremely difficult and has not been attempted.

The greatest interest in the spectra lies in the bands (Fig. 4) given by the 2- and 3-protons. In the 2-*exo*,3-*exo*-diol,[2] the bands corresponding to these protons form a symmetrical quartet of the easily recognizable AB type (2, 5). The coupling constants obtained are $J_{23} = 7.7$ c.p.s. and $J_{24} = J_{34} = 0$.

In the other cis isomer, the 2-*endo*,3-*endo*-diol, the bands of the 2- and 3-protons have 12 lines. If one ignores for the moment the two smallest spacings, the pattern can be recognized as that of the AB part of an ABX system (2, 5). From this it is calculated that $J_{23} = 8.0$ c.p.s., $J_{34} = 4.4$ c.p.s., and $J_{24} = 0$. It is extremely unlikely that the alternative assignment of $J_{34} = 0$ and $J_{24} = 4.4$ c.p.s. is correct. The additional spacing present in the bands of the 2-proton might be explained as being due to J_{24}, but this cannot explain the fact that there is a similar spacing in the bands of the 3-proton. In that case there must be coupling of the 3-proton to one proton other than the 2- or 4-proton. None of the protons on the methyl groups can be implicated since the rapid internal rotation of the methyl groups (2) means that three protons would be the minimum number involved, and this could not give rise to the observed splitting. Furthermore, none of the methyl bands shows any sign of splitting.

The most reasonable explanation is that there is a small coupling between *exo*-protons on C2 and C6 and also on C3 and C5. The absence of coupling of the *endo*-protons on C2 and C3 in the 2-*exo*,3-*exo*-diol to either the *exo*- or the *endo*-protons on C6 and C5 (not necessarily respectively) makes it unlikely that in the present case the *exo*-protons on one side of the molecules are coupled with *endo*-protons on the other side. This leaves only the *exo*-protons for consideration. The molecular framework of the [1,2,2]-bicycloheptane system possesses symmetry, so that one would expect that if the 2-*exo*-proton is coupled to the 6-*exo*-proton then the 3-*exo*-proton should be coupled to the 5-*exo*-proton, even though the molecule as a whole has no symmetry. Similarly, if the 2-*exo*-proton is coupled to the 5-*exo*-proton, then the 3-*exo*-proton should be coupled to the 6-*exo*-proton. Of these two possibilities the first is preferable as it involves coupling through a lesser number of bonds.

Although 1,3-coupling does not seem to have been observed previously between protons in saturated systems (5), with the exception of three-membered rings, its presence in the [1,2,2]-bicycloheptane system may reflect the strain present and the closeness of the carbon atoms 2 and 6 and of 3 and 5. As in the case of 1,2-coupling, there is a strong angular dependence for only two *exo*-protons 1,3 to one another are coupled to an observable extent. The values of the coupling constants ($J_{24} = 0$, $J_{2\text{-}exo6\text{-}exo} = 1.4$, $J_{3\text{-}exo5\text{-}exo} = 1.0$, $J_{3\text{-}endo4} = 0$, $J_{3\text{-}exo4} = 4.4$ c.p.s.) found for the cis isomers should also hold approximately for the trans isomers. It will be assumed that this is so in the analysis of the remaining two spectra.

[2]*The terms exo and endo are used to indicate a substituent cis and trans respectively to the one carbon bridge of the bicycloheptane system. In the naming of the compounds the substituents are, of course, the hydroxyl groups. The terms exo and endo will also be used as required to denote the position of a proton. Thus in the present case the 2- and 3-protons are both endo.*

For personal use only.

In the 2-*exo*,3-*endo*-diol the doublet at high field must be due to the 2-*endo*-proton and this gives J_{23} = 2.3 c.p.s. The 3-*exo*-proton at low field is coupled to the 4-proton, and presumably, also to the 5-*exo*-proton. The band obviously contains many unresolved lines, which are most probably due to the 4-proton (and also perhaps the 5-proton) being very little chemically shifted from protons on C5 and C6 to which it is coupled. Nevertheless, we may ascribe the large spacing (ca. 4 c.p.s.) to J_{34}; this will be at least a minimum value.

In the 2-*endo*,3-*exo*-diol the doublet at high field can be assigned to the 3-*endo*-proton. This gives J_{23} = 2.2 c.p.s. and J_{34} = 0. The 2-*exo*-proton gives a wide band, roughly a poorly resolved triplet of intensity 1:2:1, indicating that it is not only coupled to the 3-proton but also to another proton, presumably the 6-*exo*-proton. The poor aspect of the band can again be ascribed, as for the 3-*exo*-proton of the previous isomer, to insufficient chemical shift between the 6-*exo*-proton and other protons on C5 and C6.

The chemical shifts of the 2- and 3-protons of the camphane-2,3-diols are difficult to correlate with structure and this difficulty is at least partly due to the reasons previously mentioned in the case of the chemical shifts of the methyl groups. The τ values of the 2- and 3-protons (Fig. 3) are close to the value (6.15) for CH groups of secondary alcohols (5), but exact comparisons cannot be made because pyridine is used as the solvent in the present case.

The observed coupling constants and those calculated from the dihedral angles (Table I) and Karplus' data (8) are given in Table II. The dihedral angles in Table I were

TABLE I

Dihedral angles in the camphane system

CH bonds	Dihedral angle
2-*exo* and 3-*exo*	0°

obtained by measurements made on Barton molecular models. Some bending of the bonds is required to make the models and this results in a change of bond angles from the tetrahedral value. Some of the dihedral angles are uncertain because it is not known exactly how the distortion is spread through the molecule. In the model all bonds are slightly bent so that the strain is distributed more or less uniformly. The uncertainties in dihedral bond angles are most unlikely to affect the conclusions made in this paper.

For personal use only.

The distortion of the molecule does not change the 0° dihedral angles, but does increase, for example, the dihedral angle which would have been 120° otherwise. Unfortunately, no very accurate structure determination seems to have been carried out in the [1,2,2]-bicycloheptane series. The structure of 3-cyanocamphor has been determined (14) but the positions of all the atoms are not accurately known. The [1,2,2]-bicycloheptane system can be considered as two fused five-membered rings. Each ring is approximately in the C_s (15) or envelope (16) conformation. The assumption of complete (or almost complete) eclipsing of carbons 2 and 3 is probably a good one in this case, as any staggering increases the considerable strain already present.

The results shown in Table II also agree with coupling constants found in α- and α'-chlorocamphor (17). In the α-isomer the 3-proton, which is *exo*, is coupled to the 4-proton by 5 c.p.s., whilst in the α'-isomer, where the 3-proton is *endo*, J_{34} is zero. Similarly, in 3,8-cyclocamphor (18) the coupling constant of the 3-*endo*-proton to the 4-proton is zero.

The very good agreement between calculated and observed coupling constants found in Table II is strong support for the validity of Karplus' calculations. It is to be noted that coupling constants in three-membered and four-membered rings (5, 19, 20) do not agree very well with those expected from Karplus' work, in contrast to the situation which exists in most five- and six-membered rings.

It is obvious from the results presented here that in non-rigid cyclopentane derivatives (15, 16) the coupling constants will depend very markedly on the conformation(s) which the molecules adopt. If the stereochemistry and coupling constants are known, it may become possible to deduce the conformation of such rings. In fact, attempts to do this have already been made by Jardetzky (9) in the case of the ribose nucleosides and nucleotides. The conclusions drawn in that paper derive support from the present work.

ACKNOWLEDGMENTS

I wish to thank Dr. S. J. Angyal of the University of New South Wales, Australia, for gifts of the camphane diols which made this work possible.

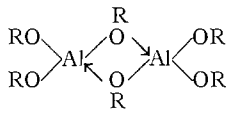
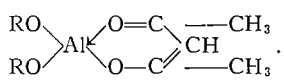
REACTIONS OF ALUMINUM ALKOXIDES WITH ACETYLACETONE, BENZOYLACETONE, AND ETHYL ACETOACETATE[1]

R. K. MEHROTRA AND R. C. MEHROTRA

ABSTRACT



The observed stability of stable bridge structure,  , in aluminum alkoxides has been explained on the powerful tendency of aluminum to attain co-ordination number 4. This would predict the monomeric nature of the derivatives of the type, $(OR)_2Al(lig)$, where ligand (lig) is a diketone like acetylacetone (acac), benzoylacetone (bzac), or ketoester like ethyl acetoacetate (etac). This has been confirmed by actual synthesis of these compounds by reactions between aluminum alkoxides (ethoxide and isopropoxide) and acetylacetone, benzoylacetone, and ethyl acetoacetate in equimolecular ratios. These and also $(OR)Al(lig)_2$ as well as $Al(lig)_3$ have been shown to be monomeric in boiling benzene. The volatility of the derivatives was found in the order $[(OPr^i)_3Al]_2 > (OPr^i)_2Al(acac) > (OPr^i)Al(acac)_2$. This leads to the conclusion that chelation lowers the volatility and the direct relationship between volatility and molecular complexity, observed in the case of simple alkoxides, is not applicable in these derivatives. Further mixed derivatives of the type $Al(acac)(etac)_2$ and $Al(etac)(acac)_2$ have also been synthesized during the course of the above work.



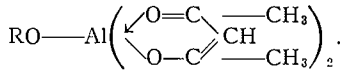
INTRODUCTION

Aluminum alkoxides are generally prepared by the reaction of corresponding alcohols with metallic aluminum with the help of catalysts (1). Mehrotra (2, 3) described the preparation of higher aluminum alkoxides by treating aluminum ethoxide and isopropoxide with the corresponding alcohol and removing the ethanol or isopropanol produced, azeotropically with benzene. The technique has now been extended to prepare acetylacetonate, benzoylacetonate, and ethyl acetoacetate derivatives of aluminum by the simple reactions of the type:

$$Al(OR)_3 + x\text{H lig} \rightarrow Al(OR)_{3-x}(lig)_x + x\text{ROH}$$

(where ligand is acetylacetone, benzoylacetone, or ethyl acetoacetate).

The main interest of the above study arose from earlier observations of one of us (2), that the bridge structure  is very stable in aluminum alkoxides and exists even in the vapor phase. On aging, alkoxides were shown to exhibit greater molecular complexity (2) and this phenomenon has been explained by Bradley (4) to be due to the tendency of 4-co-ordination aluminum to change to the 6-co-ordination. In view of the above, it was conjectured that a monosubstituted product like $Al(OR)_2(lig)$ should be monomeric as co-ordination number 4 would be easily satisfied in the structure:



The above has been confirmed for the mono acetylacetone, benzoylacetone, and ethyl acetoacetate products with R as C_2H_5 (Et) or C_3H_7 (Pr^i). The derivatives further do not show any tendency of polymerization, even after aging for a few weeks. The di and tri derivatives have also shown to be monomeric in benzene. It is of particular interest

[1]*Manuscript received November 25, 1960.*
Contribution from the Chemical Laboratories, University of Gorakhpur, Gorakhpur, U.P., India.

Can. J. Chem. Vol. 39 (1961)

to note that the di derivatives would have a co-ordination number 5 as depicted by the following simple structure:

A point of further interest was the volatility of the above derivatives. This was of special interest as in a number of aluminum (2), titanium, zirconium (5), and other alkoxide derivatives, it has been shown that the decreasing volatility has, in general, a simple relationship with increasing molecular complexity or weights. The above derivatives could be distilled at higher temperatures compared to aluminum alkoxides, indicating that the chelation has the expected effect of lowering the volatility and overcomes the opposite effect of simpler molecular complexity.

EXPERIMENTAL

Materials

Aluminum ethoxide was prepared by the method of Chalmers (6). Aluminum isopropoxide was prepared as described by Young, Hartung, and Crossley (7). Both were purified by distillation under reduced pressure.

Acetylacetone and ethyl acetoacetate (E. Merck) were dried by refluxing with aluminum isopropoxide and fractionating. Benzoylacetone was synthesized (8) and purified by distillation.

Benzene (B.D.H.) was dried by distilling over metallic sodium and carefully fractionated before use.

All glass apparatus fitted with interchangeable joints was used throughout and special precautions were taken to exclude the moisture. Fractionations were carried out in a column packed with Raschig rings.

Analytical Methods

Aluminum was determined as oxinate gravimetrically except in benzoylacetonate derivatives in which cases ignition to oxide was employed.

The amount of alcohol in benzene–alcohol azeotrope was estimated by a back titration method of Bradley and Wardlaw (9).

Alkoxy group in the presence of acetylacetone, benzoylacetone, or ethyl acetoacetate was estimated by liberating the isopropanol or ethanol from the compound by boiling it in benzene with an excess of acetylacetone or ethyl acetoacetate and subsequently estimating the ethanol or isopropanol liberated in benzene alcohol azeotrope.

Molecular Weights

The molecular weights of compounds were determined ebullioscopically in boiling benzene by using a Gallenkamp ebulliometer with a sensitive transistor principle. The elevations (ΔT) were plotted against the weight of solute added and in all cases a straight line was obtained. The constant K for the solvent was determined with naphthalene. The results are recorded in Table I.

Synthetic Reactions

The general method of synthesis was the same in every case and so the details will be given only for acetylacetone compounds with aluminum isopropoxide and mixed acetylacetone – ethyl acetoacetate derivatives. In cases of all other derivatives described in Table II, the method was the same as with acetylacetone derivatives; the amount of alcohol collected in the azeotrope was, within experimental error, equal to the amount expected from the stoichiometry of the reaction. The yields of the pure distilled or crystallized derivatives are also included in Table II.

I. Reaction of Aluminum Isopropoxide with Acetylacetone in Molar Ratio of 1:1

Acetylacetone (3.28 g) was added to a solution of aluminum isopropoxide (6.70 g) in dry benzene (60 g). Heat was evolved during mixing of reactants. The mixture was refluxed for 3 hours at bath temperature of 120–30°. Benzene–isopropanol azeotrope was distilled slowly between 72–80°, followed by benzene, leaving a yellow liquid in the reaction flask. No crystallization occurred even after standing overnight. The remaining benzene was distilled out under reduced pressure and the compound was distilled at 160°/5 mm to give a light yellowish mobile liquid (6.5 g) which solidified on being kept for 3–4 days. The total amount of isopropanol in the azeotrope was found to be 1.90 g against 1.97 g, calculated for 1 mole. (Found: Al, 11.18; OPr^i, 47.6. Calcd. for $Al(acac)(OPr^i)_2$: Al, 11.06; OPr^i, 48.3%.)

II. Reaction of Aluminum Isopropoxide with Acetylacetone in Molar Ratio of 1:2

Acetylacetone (5.89 g) was added to a solution of aluminum isopropoxide (6.01 g) in benzene (80 g). Heat was evolved. The mixture was refluxed for 4 hours and the benzene–isopropanol azeotrope was taken between 72–80°. Pure benzene was distilled out till a light yellowish residue was left. On cooling it gave crystals (8 g) which were dried under reduced pressure for 3 hours. The total amount of isopropanol found in the azeotrope was 3.35 g, against 3.46 g, calculated for 2 moles. (Found: Al, 9.38; OPr^i, 19.6. Calcd. for $Al(OPr^i)(acac)_2$: Al, 9.5; OPr^i, 20.7%.)

The above compound was sublimed at a bath temperature of 300°/5 mm to give a yellowish mass (Found: Al, 9.34%).

III. Reaction of Aluminum Isopropoxide with Acetylacetone in Molar Ratio of 1:>3

Acetylacetone (12.56 g) was added to a solution of aluminum isopropoxide (7.6 g) in benzene (80 g) and the mixture refluxed for 3 hours. Benzene–isopropanol azeotrope was taken out slowly. Afterwards, pure benzene was distilled out, till a light yellowish liquid remained in the reaction flask which on cooling gave crystals. Total amount of isopropanol was found to be 6.6 g, against 6.7 g, calculated for 3 moles, in the azeotrope. (Found: Al, 8.5. $Al(acac)_3$ requires Al, 8.33%.)

IV. Reaction of Aluminum Diisopropoxy Monoacetylacetonate with Ethyl Acetoacetate in Molar Ratio of 1:2

Ethyl acetoacetate (2.34 g) was added to a solution of aluminum diisopropoxy monoacetylacetonate (2.19 g) in benzene (50 g). The mixture was refluxed for 2 hours. Benzene–isopropanol azeotrope was collected slowly between 72–80°; followed by pure benzene leaving a yellow liquid in the reaction flask, which was dried under reduced pressure at 50° to give a yellow semisolid (3.2 g). The total amount of isopropanol in the azeotrope was found to be 1.1 g against 1.07 g calculated for 2 moles. (Found: Al, 7.18. Calcd. for $Al(etac)_2(acac)$, 7.02%.)

V. Reaction of Aluminum Diisopropoxy Monoethyl Acetoacetate with Acetylacetone in Molar Ratio of 1:2

Acetylacetone (3.26 g) was added to a solution of aluminum diisopropoxy monoethyl acetoacetate (4.45 g) in benzene (50 g). Heat was evolved as a result of reaction. The mixture was refluxed for 2 hours and the benzene–isopropanol azeotrope was taken between 72–80°. Pure benzene was distilled out till there was left a yellow liquid which was dried under reduced pressure for 4 hours to give a yellow mass (5.5 g). The total amount of isopropanol was found to be 1.9 g, against 1.94 g required for 2 moles. (Found: Al, 7.7. Calcd. for $Al(etac)(acac)_2$, 7.6%.)

ACKNOWLEDGMENT

The authors are grateful to the Council of Scientific and Industrial Research, India, for providing a research fellowship to one of them (R.K.M.). It is a pleasure to acknowledge the fruitful discussion by R.C.M. on the topic with Prof. D. C. Bradley, University of Western Ontario, London, Ontario.

POTASSIUM DERIVATIVES OF FLUORENE AS INTERMEDIATES IN THE PREPARATION OF C_9-SUBSTITUTED FLUORENES

III. THE INFLUENCE OF SOLVENT AND METAL IN THE FORMATION OF C_9-SUBSTITUTED FLUORENES FROM 9-FLUORENYL METALS[1]

G. W. H. Scherf and R. K. Brown

ABSTRACT

Equimolar quantities of 9-fluorenyl-potassium, -sodium, or -lithium and alkyl or aralkyl halides at room temperature in ether solvents yielded a mixture of unchanged fluorene, C_9-monosubstituted fluorene, and C_9-disubstituted fluorene. The amount of disubstitution never exceeded that of unchanged fluorene, and was found to be maximum (~35%) for the potassium compound in 1,2-dimethoxyethane, somewhat less for the sodium analogue, and small (~5%) for the lithium compound. In hydrocarbon solvents such as hexane, 9-fluorenylpotassium gave only 7% of C_9-disubstituted fluorene. The lithium compound, upon reaction with methyl iodide or ethyl iodide gave, along with unreacted fluorene, only C_9-monosubstituted fluorene. But reaction of 9-fluorenyllithium with benzyl chloride in hexane gave a small quantity (~5%) of disubstituted fluorene as well as the monosubstituted product.

The results are explained in terms of (*a*) the solubilities of the organometallic compounds in ether and hydrocarbon solvents, (*b*) the polarity of the metal carbon bond, and (*c*) the acidity of the hydrogen on C_9 of fluorene.

INTRODUCTION

A recent publication described the infrared spectra of a number of C_9-mono- and -di-substituted fluorenes (1). For the infrared work the 9,9-disubstituted fluorenes were prepared by treating one mole of fluorene in dioxane with two gram equivalents of potassium metal. The metalated product was then brought into reaction with two moles of the appropriate halide. Contaminating monosubstituted and unsubstituted fluorene was then removed either by crystallization, or by chromatography.

Attempts to prepare C_9-monosubstituted fluorene from the reaction between equimolar proportions of fluorene and potassium in dioxane, followed by the addition of an equivalent amount of alkyl or aralkyl halide led to a mixture of C_9-monosubstituted, C_9-disubstituted, and unsubstituted fluorene whose separations were frequently somewhat tedious for routine synthesis. Accordingly, the C_9-monosubstituted compounds required for the absorption studies were prepared more conveniently by the procedure developed by Greenhow, White, and McNeil (2).

This paper describes the results of a study of mono- versus di-substitution at carbon 9 of fluorene when 9-fluorenyl-lithium, -sodium, or -potassium was allowed to react with an equimolar quantity of an alkyl or aralkyl halide in the solvents hexane (or heptane), dioxane, 1,2-dimethoxyethane (DME), 1,2-diethoxyethane (DEE), and tetrahydrofuran (THF).

RESULTS

The Reaction of 9-Fluorenylpotassium with Alkyl and Aralkyl Halides in Ether andHydrocarbon Solvents

The 9-fluorenylpotassium required for this work was prepared from equimolar amounts of potassium and fluorene (1). This could be readily isolated and transferred to the solvent chosen for study.

Two outstanding differences were observed between the reactions at room temperature of 9-fluorenylpotassium with organic halides in *ether* solvents and its reaction with these halides in hydrocarbon solvents. *Firstly*, when dioxane, diethyl ether, diisopropyl ether, or di-*n*-butyl ether was the solvent, reaction of the organometallic compound with the organic halide was relatively fast. Within 5 minutes nearly all of the solid suspension of 9-fluorenylpotassium had disappeared. On the other hand, when *n*-heptane was the suspending solvent, much of the 9-fluorenylpotassium was still unchanged after an interval of 30 minutes. The marked difference in the rate of reaction was no doubt due to the partial solution of the 9-fluorenylpotassium which occurred in the ethers but not in heptane. This was borne out by the observation that the depth of the reddish color of the ether solution could be correlated, if only roughly, with the rate of reaction when, for the experiments concerned, equivalent quantities of reagents were used. No color was observed in the solvent for the heptane suspension, hence, in this medium, the reaction with the halide is considered to occur heterogeneously on the surface of the suspended solid, resulting in a much slower reaction dependent in part upon diffusion rate and efficiency of stirring. *Secondly*, reaction of 9-fluorenylpotassium with an organic halide in molar ratio 1:1 in *ethers* gave considerable quantities of 9,9-disubstituted fluorene along with C_9-monosubstituted and also unchanged fluorene while the same reaction in *heptane* gave essentially monosubstitution with relatively little 9,9-disubstituted fluorene. The amount of disubstituted material obtained from the reaction in dioxane was about 25% of the fluorene originally used to form the potassium compound and fell somewhat short of equivalence to the amount of unchanged fluorene. This extra quantity of fluorene most likely was that which had originally failed to react with the metal. From an examination of the results of alkylation in dioxane solvent with methyl iodide, ethyl bromide, allyl bromide, and benzyl chloride, the ratio of disubstitution to monosubstitution appears to be independent of the size of the alkyl or aralkyl group (Table I).

TABLE I

Conversion of fluorene into the mono- and di-substituted derivatives by reaction of 9-fluorenylpotassium with various alkyl halides in dioxane solvent

Alkyl halide	% disubstitution	% monosubstitution	% fluorene
Methyl iodide	26	43	31
Ethyl bromide	27	43	30
Allyl bromide	27	40	33
Benzyl chloride	23	(*)	(*)

*Accurate amounts unknown since quantitative separation of the monobenzylfluorene from fluorene was not achieved either by crystallization or chromatography.

With heptane as solvent, only about 5% of the original fluorene was converted to 9,9-disubstituted fluorene while the quantity of C_9-monosubstituted product actually isolated was 75 to 85%. The remainder of the product was unchanged fluorene.

The characteristic absorption bands used to identify the presence of C_9-mono- and C_9-di-substitution (1) and to follow the extent of separation are given in Table II. The absorption spectra of 9-ethylfluorene and 9,9-diethylfluorene, previously unreported (1) are shown in Figs. 1 and 2. The small region from 1050 to 1110 cm^{-1} is quite helpful for the determination of mono- versus di-methylfluorene. The absorption is not intense but quite sharp and distinct. Dimethyl fluorene shows a band at 1078 cm^{-1} (with a smaller one at 1085 cm^{-1}). Monomethylfluorene shows no absorption at these positions

*Time allotted for the formation of the organometallic compound in the refluxing solvent.
†9-Fluorenyllithium was prepared in DEE, then isolated, suspended in hexane, and treated with methyl iodide.

In general, it can be seen that in dimethoxyethane (DME), diethoxyethane (DEE), and tetrahydrofuran (THF), 9-fluorenylpotassium and 9-fluorenylsodium, treated with equimolar amounts of methyl iodide, gave from 20 to 35% disubstitution. In addition, at *least* the same amount of unreacted fluorene was formed along with 20 to 40% of monosubstitution. The efficiency of the solvent in promoting conversion to the dimethylated product is, in decreasing order, DME > DEE > THF. This is the same solvent order which was found previously in the study of the influence of solvent on the extent of reaction of potassium with fluorene (3). Hydrocarbon solvents, or ethers mixed with hydrocarbon solvents, generally gave less dimethylation but somewhat more monomethylation than was found when the pure ethers were used.

The exception was the reaction of 9-fluorenylpotassium with methyl iodide in a mixture of heptane and DME (Table III). However, that one obtained results similar to those found when pure DME was employed, can be explained. When the metal had reacted with the fluorene in this mixed solvent, two liquid layers appeared—the lower being essentially that due to the ether containing 9-fluorenylpotassium, while the upper was primarily heptane contaminated with some DME but containing no 9-fluorenylpotassium. Hence, the lower layer, where further reactions with methyl iodide occurred, approximated the conditions which held in the case where the solvent was DME only.

The 9-fluorenyllithium (prepared by precipitation from cold DEE (3)) treated with an equimolar amount of methyl iodide, gave little or no dimethylation in ether or hydrocarbon solvents. In all cases a high yield of monosubstituted fluorene was obtained.

DISCUSSION

The results of the reaction of 9-fluorenyl-lithium, -sodium, or -potassium can be rationalized on the basis of (*a*) the insolubility of the organometallic compound in hydrocarbons such as hexane, but solubility, though limited in some cases, in ethers, (*b*) the relative electropositive nature of the three metals thus giving rise to both the ionic character and reactivity of the carbon–metal bond in fluorene in the order K—C > Na—C > Li—C, (*c*) the acidic properties of fluorene and C_9-monosubstituted fluorenes.

In non-polar and non-ionizing solvents such as hexane, all three alkali metal salts possess closely associated cations and anions having a considerable amount of covalent character in the metal–carbon bond. The degree of covalency is expected to be in the order Li > Na > K. The reaction of the organic halide (RX) in hexane occurs by attack at the surface of the insoluble and suspended solid. The more polar C—K bond should react with the organic halide more quickly than does the C—Li bond. The monosubstituted fluorene, as soon as it is formed, can escape from the surface of the solid into solution. However, if the newly formed 9-monosubstituted fluorene possesses an acidic hydrogen, there will occur on the surface of the solid a reaction such as shown in A

A

between this product and more of the salt, the extent of which depends upon the acidity of the monosubstituted fluorene. This would lead to disubstitution after further reaction with the alkyl halide. Since little or no disubstitution occurred in the reaction of 9-fluorenyl-lithium, and very little 9,9-disubstituted fluorene was formed when the potassium and sodium analogues reacted with alkyl or aralkyl halides in hexane or heptane, it is apparent that the polar halide was absorbed from the solution and reacted with the organometallic compound much more readily than did the 9-monoalkylated fluorene which escaped into solution before it reacted further. The small amount of disubstituted fluorene actually observed in the case of the potassium salt in hexane arose no doubt from a scheme such as that suggested in reaction A due to the greater ionic character of the K—C bond.

The electron-donor properties of ethers, however, causes some of the salt to be soluble in some cases (e.g. dioxane) while most or all of the alkali metal compound is dissolved in others (e.g. DME). In solution, because of this association of the ether and the organometallic compound (3), the ionic character of the metal–carbon bond is increased—more so for the more electropositive metals potassium and sodium than for the lithium. Reaction in solution between the salt and the organic halide therefore is expected to, and actually did, occur more rapidly. The newly formed 9-monosubstituted compound, which is also in solution, is thus able to set up an equilibrium similar to that shown in A but involving the solvated organometallic compound and that portion of the 9-fluorenyl metal as yet unreacted. The 9-alkyl-9-fluorenyl-potassium (-sodium or -lithium) can then react with a second molecule of the organic halide to give the disubstituted fluorene. Thus, there is produced one molecule of unchanged fluorene for every molecule of disubstituted fluorene. In all our experiments, there has been no case where more disubstituted than unsubstituted product has been produced, in agreement with the reaction

shown in A. The position of equilibrium will then depend upon the relative acidities of the fluorene and monosubstituted fluorene and upon the rapidity with which the organic halide reacts with the monometalated fluorene. The assumption that disubstitution is obtained via the above equilibrium occurring primarily *in solution* is supported by the greater extent of disubstitution actually found in solvents wherein almost all, if not all, the organometal was dissolved (Tables III and IV). Since the lithium derivative gave very little disubstitution in any solvent (Table V), even in those wherein it is quite soluble, it is obvious that the extent of ionic character of the carbon–metal bond is an important factor which establishes the degree to which such an equilibrium as portrayed by A can be established in competition with the direct reaction of the monometalated compound with the alkyl halide. Usually alkylation at a carbon atom reduces the acidity while arylation increases the acidity of the remaining hydrogen(s) at the same carbon atom. The greater acidity of 9-phenylfluorene over that of fluorene has been recorded (4, 5), but to our knowledge no report compares the acidity of 9-alkylated fluorenes with that of the parent substance. Since disubstitution was actually observed in this work, especially in the case of the more effective ethers, the acidity of 9-alkylfluorenes should be at least of the same order as, but is more likely greater than, that of the unsubstituted fluorene. The tendency of the C_9-substituent to become coplanar with the planar fluorene molecule would lend stability to the 9-substituted fluorenyl anion. A substituent on C_9 may prefer this coplanar arrangement due to steric factors and thus enhance the acidity of the C_9—H. Furthermore, the acidity of the 9-monoalkylated fluorene must be greater than that of fluorene to compete as successfully as it does with the polar bond in the organic halide for the organometallic compound. That the 9-monoalkylated compound should be more acidic than is fluorene due to steric considerations, is not clearly shown from the results of the reaction of 9-fluorenylpotassium with the halides, methyl iodide, ethyl bromide, allyl bromide, and benzyl chloride in dioxane (Table I) since approximately the same extent of disubstitution occurred in each regardless of the size of the group. This lack of differentiation might be due to the highly reactive and therefore less discriminating, K—C bond. But the results of reaction of the 9-fluorenyllithium and 9-fluorenylsodium with methyl iodide and benzyl chloride do support this point of view. Equimolar mixtures of 9-fluorenylsodium and benzyl chloride gave 16% of the 9,9-disubstituted fluorene while only 10% of the dimethylated fluorene was obtained when the halide was methyl iodide. In the case of 9-fluorenyllithium, although reaction with methyl iodide in hexane gave no detectable disubstituted fluorene, nearly 5% of dibenzylfluorene was obtained from the reaction of the lithium salt with benzyl chloride in hexane. The question of the relationship of the size of the C_9-substituent and the ratio of di- to mono-substituted product obviously requires further study.

There exists the possibility that some, if not all, of the disubstitution might be due to unreacted metal, occluded in the organometallic compound, which would react with the monosubstituted fluorene during the process of the addition of the alkyl halide. A report is to be found in the literature that describes such a highly dispersed state of potassium metal in a solvent so as to render it indiscernible to the eye when the solution is cooled (6). Our rate of stirring certainly would not lead to such an ultrafine state of division of the metal—hence any substantial quantity of it which remained unreacted should be readily seen. In order to determine if the presence of unreacted metal actually does play a part in producing disubstituted fluorene, an experiment was performed in which the reaction between equimolar quantities (0.05 mole) of fluorene and potassium in 50 ml of DME was allowed to proceed for just 15 minutes. To the mixture, containing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

definitely some unreacted potassium, was added 0.05 mole of methyl iodide. By chromatography of the isolated solid on alumina using hexane as eluant, there was obtained 30% dimethylfluorene, 18% monomethylfluorene, and the remainder as unchanged fluorene. Since the experiments in which all the metal had apparently reacted to form 9-fluorenylpotassium gave 35% di- and 30% mono-methylfluorene, the conclusion must therefore be made that in those cases where unreacted metal does remain, the metal does cause dialkylation, somewhat more readily than in those reactions where only 9-fluorenylpotassium is present. This requires that the monomethylfluorene be more acidic than is fluorene. However, in those solutions where complete reaction of the metal with fluorene has occurred, dialkylation would proceed via an exchange such as shown in equation A.

In this connection, attempts to increase above 65% the yields of dialkylated fluorene, from the reaction with alkyl halides of the "9,9-fluorenyldipotassium" reported in the first of this series of articles (1), have met with consistent failure. Further experimentation has shown that the first atom of potassium reacted with fluorene to produce 9-fluorenylpotassium and an equivalent amount of hydrogen. However, treatment of the 9-fluorenylpotassium with a second equivalent of potassium in dioxane evolved *no hydrogen*. The metal, finely dispersed in the precipitated 9-fluorenylpotassium could not be readily perceived as unreacted metal. However, the reaction of two equivalents of potassium metal with one of fluorene in *DME* gave a clear solution of 9-fluorenylpotassium. Under these conditions the second equivalent of potassium remained unreacted and could be clearly seen suspended in the solvent if less vigorous stirring was employed. The existence of this second equivalent of potassium as unreacted metal, which would then react competitively with the alkyl halide and with the monoalkylated product, probably more rapidly with the former than with the latter, would thus account for the inability to produce more than 65% yield of 9,9-dialkylated fluorene (1). If this is so then at least some of the disubstituted fluorenes observed in the present work could arise from direct interaction of the monoalkylated fluorene and the residual metal in those cases of incomplete metalation.

EXPERIMENTAL

The various alkali metal salts of fluorene were prepared essentially according to published procedures (1, 3). For the present experiments a mixture of 0.05 mole of the metal, and 0.05 mole of fluorene in 50 ml of the appropriate refluxing solvent was used. The reaction times for preparation of the organometallic compound depended upon the particular experiment and are listed in the accompanying tables.

The alkyl halide (0.05 mole) was added to the cooled product (22°) slowly in order to avoid uncontrollable reaction. A 1-hour period of stirring at room temperature ensured complete reaction of the salt with the halide. The mixture was then poured into a separatory funnel containing water slightly acidified with dilute hydrochloric acid. The ether layer was separated and then dried over calcium chloride. After removal of the ether, a portion (1 g or less) of the product was passed through an 80 to 200 mesh alumina column, 60 cm × 1 cm, and eluted with pentane or hexane. Identification and estimation of the product in each small fraction (50 to 100 mg) was made by infrared spectroscopy using the absorption bands reported in Table II.

Crude benzylated fluorene was treated repeatedly with small portions of cold ethanol, thus effecting a separation of the soluble fluorene and monobenzylfluorene from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sparingly soluble dibenzylated fluorene. Complete separation of fluorene from the monobenzylfluorene was not achieved.

Experiments using the metal amides instead of metals were carried out similarly using the same quantities of reagents.

Greenhow's method (2) for the preparation of 9-fluorenylsodium was not successful in our hands (1). Since the solid material was required in experiments, the reaction of sodium metal and fluorene in DME, DEE, and THF, although quite facile was of no assistance because the salt failed to precipitate. The reaction of equimolar quantities of fluorene and powdered sodamide in refluxing dioxane gave satisfactory results. From deuteration experiments (1) approximately two thirds of the fluorene had metalated when a mixture of 8.3 g of fluorene, 1.95 g of sodamide, and 25 ml of dioxane was refluxed for 4 hours. Longer reaction time increased the extent of metalation. The 9-fluorenylsodium was readily separated from dioxane, but unreacted sodamide was also retained as a contaminant which could not be removed. Hence, the results of all reactions with 9-fluorenylsodium prepared by this method must be considered with this in mind.

THE INTERACTION OF DISILOXANE WITH BORON TRIFLUORIDE AND TRICHLORIDE[1]

M. ONYSZCHUK

ABSTRACT

Disiloxane does not form stable adducts with boron trifluoride and trichloride, but cleavage of an Si—O bond occurs with formation of the corresponding monohalogenosilane and siloxyboron dihalide. Although siloxyboron dichloride is stable at room temperature, siloxyboron difluoride disproportionates into silyl fluoride, boron trifluoride, and boron trioxide. A stepwise mechanism involving four-center cyclic transition states is postulated for the over-all reaction.

Disilthian does not react with boron trifluoride. This indicates that the sulphur atom in the Si—S—Si linkage system has little, if any, electron-donor activity. The absence of electron-donor activity for oxygen and sulphur in Si—O—Si and Si—S—Si linkages is discussed.

In a previous paper (1) it was reported that boron trifluoride and trichloride do not form stable addition compounds with 1,1′-dimethyl-, 1,1′,2,2′-tetramethyl-, or hexamethyl-disiloxane: instead cleavage of an Si—O bond occurs with formation of the methylhalogenosilane and the methylsiloxyboron dihalide:

$$(CH_3SiH_2)_2O + BF_3 = CH_3SiH_2OBF_2 + CH_3SiH_2F.$$

The methylsiloxyboron dihalides are unstable at room temperature, decomposing into the methylhalogenosilane, boron trihalide, and boron trioxide:

$$3CH_3SiH_2OBF_2 = 3CH_3SiH_2F + BF_3 + B_2O_3.$$

Similarly, the interaction of hexamethyldisiloxane with aluminum chloride or bromide produces trimethylsiloxyaluminum dihalides, but these are much more stable than the boron analogues (2). However, the siloxyaluminum dihalides, SiH_3OAlX_2, which result from the reaction of disiloxane with aluminum halides, are non-volatile, presumably polymeric solids, which appear to react with silyl halide forming silylene halide, SiH_2X_2, and silane, especially when a large proportion of aluminum halide is used initially (3).

The experiments described in this paper were made to examine the interaction of disiloxane and disilthian with boron trifluoride and trichloride.

RESULTS AND DISCUSSION

It was not possible to confirm the formation of a 1:1 adduct between disiloxane and boron trifluoride when they were combined at −78°, since Si—O bond cleavage at this temperature produced silyl fluoride and siloxyboron difluoride:

$$(SiH_3)_2O + BF_3 = SiH_3F + SiH_3OBF_2. \quad [1]$$

Siloxyboron difluoride, which was a white solid at −78°, decomposed gradually at higher temperatures into silyl fluoride, boron trifluoride, and boron trioxide, probably according to the equation:

$$3SiH_3OBF_2 = 3SiH_3F + BF_3 + B_2O_3. \quad [2]$$

An infrared spectrum of the decomposition mixture (Fig. 1, Table I), however, suggested

the presence of siloxyboron difluoride in addition to silyl fluoride and boron trifluoride. Siloxyboron dichloride was much more stable than the difluoride, and a pure sample of the dichloride could be isolated so that its composition was confirmed by analysis.

These results show that cleavage of Si—O bonds in disiloxane by boron trihalides occurs in two stages, each of which probably involves a four-center cyclic transition state similar to those postulated for the interaction of boron trihalides with alkyl ethers (4), alkyldisiloxanes (5), and hexamethyldigermoxane (6). For example, the mechanism for the interaction of disiloxane with boron trifluoride can be represented as follows:

The initial step is thought to produce a 1:1 adduct which is stable only well below −78° and does not dissociate into the original reactants, but decomposes with cleavage of an Si—O bond presumably due to strong polar interactions in the four-center cyclic transition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

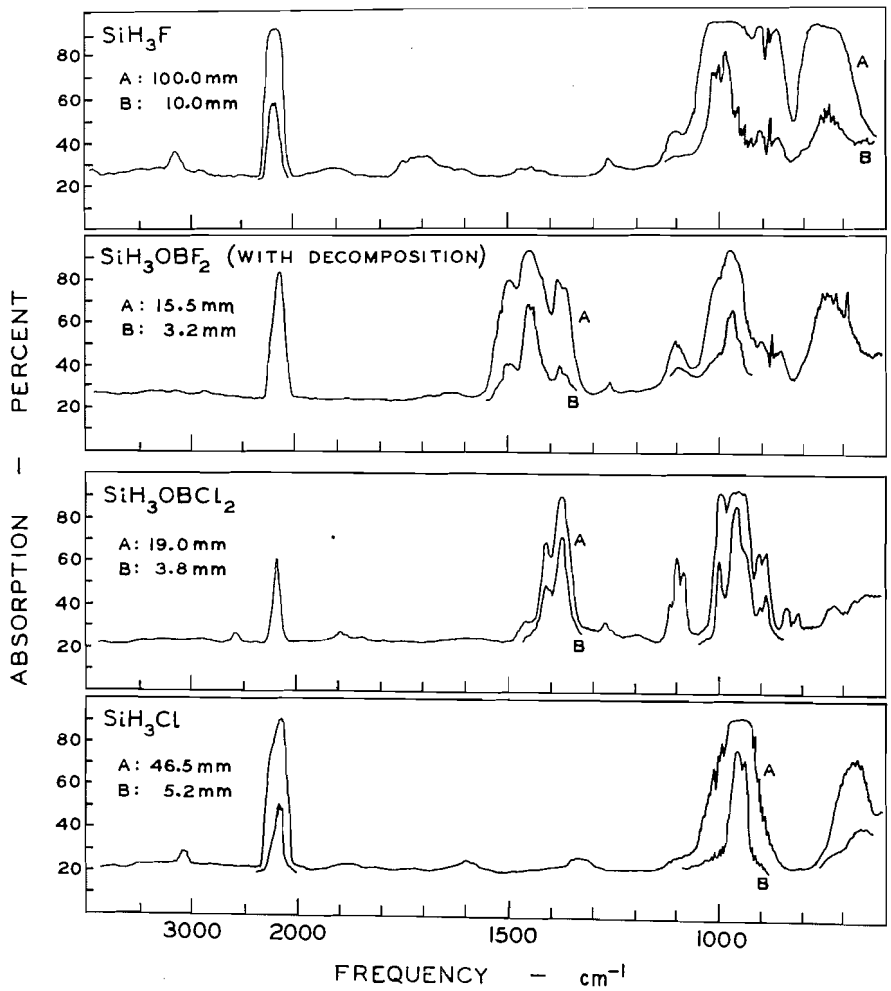

FIG. 1. A comparison of the infrared spectra of siloxyboron dihalides and silyl halides.

state. Probably the instability of siloxyboron difluoride also arises from intramolecular interaction between silicon and fluorine atoms, as indicated in the second step of the mechanism, although intermolecular disproportionation is equally probable. The higher thermal stability of siloxyboron dichloride compared with the difluoride might be attributed to weaker polar interaction between silicon and chlorine than that between silicon and fluorine, since chlorine is less electronegative than fluorine. The fact that boron oxyfluoride, resulting from the decomposition of siloxyboron difluoride, was not isolated is not surprising, because boron oxyfluoride exists as a cyclic trimer only below $-140°$ and disproportionates rapidly at higher temperatures into boron trifluoride and trioxide (7).

The over-all reaction of disiloxane with boron trifluoride at room temperature, which occurs almost quantitatively according to the following stoichiometric equation, provides a new convenient method for the preparation of silyl fluoride in high purity and yield:

$$3(SiH_3)_2O + 2BF_3 = 6SiH_3F + B_2O_3. \quad [3]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Silyl fluoride was first prepared by Emeléus and Maddock (8) in 79% yield and in only 98% purity from the reaction of silyl chloride with antimony trifluoride. Sujishi and Witz (9) obtained tensiometrically pure silyl fluoride in good yield from the reaction of trisilylamine with boron trifluoride.

The failure of disiloxane to form stable adducts with boron trifluoride and trichloride does not necessarily indicate a complete lack of electron-donor activity of the oxygen atom in disiloxane, since Si—O bond cleavage probably concealed the initial formation of a 1:1 adduct. The electron-donor power of disiloxane cannot be high because d_π–p_π back co-ordination between silicon and oxygen atoms might greatly decrease the availability of the electron pairs at the oxygen atom for donation. This partial double bonding effect is thought to be the reason for the Si—O—Si bond angle being approximately 150° (10, 11), much larger than the tetrahedral angle expected if only σ bonding occurs between silicon and oxygen atoms. Since the Si—O—Si bond angle is definitely not 180°, it seems reasonable to suppose that the lone electron pairs on oxygen are not entirely back-bonded to silicon and therefore should still be available for donation, at least to a detectable degree. Co-ordination probably occurs between disiloxane and boron trifluoride or trichloride, but it is difficult to detect due to simultaneous Si—O bond cleavage. Similarly, iodine does not appear to form an oxonium complex with disiloxane, and only Si—O bond splitting is observed (12). Although Kriner, MacDiarmid, and Evers (3) observed a solid adduct when they combined disiloxane with dimethylaluminum bromide at −50°, the adduct did not dissociate at higher temperatures but decomposed instead, with cleavage of the Si—O—Si linkage. In order to determine precisely the degree of electron-donor activity of disiloxane, it will be necessary to examine its behavior with less polarizable acceptor molecules, which are less likely to cause Si—O bond rupture.

Since disilthian did not undergo any recognizable interaction with boron trifluoride, the sulphur atom in disilthian has little, if any, electron-donor activity. This conclusion is in complete agreement with the previous observation that disilthian does not form co-ordination compounds with silyl iodide, methyl iodide, iodine, mercuric iodide, or mercuric chloride (12). It has been suggested that d_π–p_π bonding between silicon and elements of groups V, VI, and VII is greater the more electronegative the donor atom (13). Accordingly, there should be less d_π–p_π bonding in the Si—S bond than in the Si—O bond, since sulphur is less electronegative than oxygen. This, together with the fact that the sulphur atom is larger than the oxygen atom, suggests that in silyl derivatives the lone electron pairs on sulphur should be more available for donation than those on oxygen. It is surprising, therefore, that disilthian does not form an adduct with boron trifluoride, one of the most powerful electron-acceptor molecules.

The infrared spectrum of the siloxyboron difluoride decomposition mixture (Fig. 1, Table I) shows absorption bands at 1385 and 1105 cm^{-1} in addition to those characteristic of silyl fluoride and boron trifluoride. The band at 1385 cm^{-1} undoubtedly includes the B—O stretching vibration, which occurs in the range 1350–1310 cm^{-1} in a large number of borates, boronates, and boronites (14). The 1385 cm^{-1} band probably also contains the B—F stretching mode of the $—BF_2$ group in SiH_3OBF_2 since this vibration is found at 1363 cm^{-1} in methyldifluoroborane (15). The band at 1105 cm^{-1} in the SiH_3OBF_2 decomposition mixture must be the Si—O stretching frequency in SiH_3OBF_2, because the same vibration occurs at 1106 cm^{-1} in disiloxane (12). These assignments are confirmed by comparison with the spectrum of SiH_3OBCl_2, which shows B—O and Si—O stretching frequencies at 1375 and 1100 cm^{-1} respectively. By analogy with the spectra of alkylphenylchloroboronites in which the B—Cl stretching mode is found between 909 and

893 cm^{-1}, the band with peaks at 900 and 885 cm^{-1} in the spectrum of SiH_3OBCl_2 is attributed to B—Cl stretching vibration of the —BCl_2 group. The spectra of SiH_3F and SiH_3Cl shown in Fig. 1 are essentially the same as those previously reported (16, 17, 18, 19), and they are included here for comparison with the spectra of SiH_3OBCl_2 and the SiH_3OBF_2 decomposition mixture.

EXPERIMENTAL

Apparatus and Methods

A glass high-vacuum apparatus of the conventional type with stopcocks lubricated with Apiezon L grease was used for the transfer, separation, and characterization of volatile substances. Prolonged contact of volatile substances with stopcock grease was avoided by using all-glass reaction vessels (100 ml) fitted with break seals, which could be opened magnetically.

Hydrogen bonded to silicon was determined by measurement of the hydrogen liberated after rapid hydrolysis with potassium hydroxide (30%) of an accurately weighed sample of the unknown. Halide ion in the hydrolyzate was estimated gravimetrically. Boron trioxide was determined by titration, to the phenolphthalein end point, of its aqueous solution with standard alkali in the presence of mannitol.

The infrared spectra of the compounds were recorded in the range 4000–650 cm^{-1} on a Perkin–Elmer model 21 double-beam spectrophotometer equipped with a rock-salt prism. The substances were examined in the vapor phase at measured pressures in a cylindrical cell of 5-cm diameter and 10-cm length fitted with 5-mm-thick sodium chloride end plates.

Materials

Samples of disilthian and silyl iodide were kindly provided by Dr. Allan G. MacDiarmid. Disiloxane was prepared by hydrolysis of silyl iodide and disilthian (12). Commercial grade boron trifluoride and trichloride were purified by fractional distillation in the vacuum apparatus. The purity of each substance was checked immediately before use by measurement of its vapor pressure and molecular weight (M).

Reaction of Disiloxane with Boron Trifluoride

When boron trifluoride (0.0581 g, 0.85 mmole) and disiloxane (0.1010 g, 1.28 mmole) were condensed together and kept at −78° for 12 hours, a white solid and a volatile substance were obtained. The latter was removed by distillation at −78° and then it was redistilled at −132°. The component volatile at −132° was silyl fluoride (0.0378 g, 1.44 mmole. Found: M, 51.2. Calc. for SiH_3F: M, 50.1), and the fraction not volatile at −132° but volatile at −78° was unreacted disiloxane (0.0139 g, 0.18 mmole. Found: M, 78.4. Calc. for $(SiH_3)_2O$: M, 78.0). The yield of silyl fluoride was 12% in excess of that calculated for reaction [1], and this additional silyl fluoride probably resulted from decomposition of some siloxyboron difluoride according to reaction [2].

The white solid product, which remained after removal of volatile products by distillation at −78°, decomposed gradually without melting when warmed to 25°. It gave a white non-volatile residue of boric oxide (0.0166 g) and a volatile fraction. The latter decomposed partially, during the measurement of its molecular weight at 25°, into boric oxide and a volatile component (0.0504 g, found: M, 72.4), which was thought to contain mainly siloxyboron difluoride (calc. M, 95.7) and lesser amounts of silyl fluoride (calc. M, 50.1) and boron trifluoride (calc. M, 67.8). Unfortunately this mixture decomposed

For personal use only.

further with each trap-to-trap transfer, leaving white deposits of boric oxide in each trap and therefore a pure sample of siloxyboron difluoride could not be isolated. An infrared spectrum of the decomposition mixture (Fig. 1, Table I) confirmed the presence of silyl fluoride and boron trifluoride, and showed Si—O and B—O stretching bands which were attributed to siloxyboron difluoride.

The over-all yield of pure silyl fluoride (0.110 g, 2.18 mmole. Found: M, 50.4; v.p. 121.0 mm at −112°, lit. (9) v.p. 120.0 mm at −112.3°) was 85%, calculated on the amount of boron trifluoride used in the over-all reaction [3].

Reaction of Disiloxane with Boron Trichloride

After 12 hours at −78°, disiloxane (0.1001 g, 1.28 mmole) and boron trichloride (0.1507 g, 1.28 mmole) gave a colorless, transparent solid and a volatile substance. The latter was distilled at −96° and was found to be silyl chloride (0.1142 g, 1.71 mmole. Found: M, 66.9. Calc. for SiH_3Cl: M, 66.6). Since the yield of silyl chloride was 25% in excess of that calculated for the reaction: $(SiH_3)_2O+BCl_3 \rightarrow SiH_3Cl+SiH_3OBCl_2$, it was thought that the additional silyl chloride had been formed by decomposition of some siloxyboron dichloride. The substance which remained after the distillation at −96°, on distillation at −64°, gave a fraction (0.1167 g, found: M, 119; v.p. 24.0 mm at −45.5° and 55.7 mm at −27.5°) which contained mainly siloxyboron dichloride (calc. M, 128.8) and a small amount of silyl chloride (calc. M, 66.6). The residue was non-volatile white flaky boron trioxide (0.0101 g). A pure sample of siloxyboron dichloride was obtained after several distillations at −112° of the fraction with a molecular weight of 119 (0.0505 g, found: M, 130.0; H, as Si–H, 2.31%; Cl, 61.3%. Calc. for SiH_3OBCl_2: M, 128.8; H, as Si—H, 2.35%; Cl, 61.4%).

Attempted Reaction of Disilthian with Boron Trifluoride

There was no reaction between disilthian (0.1281 g, 1.34 mmole) and boron trifluoride (0.0916 g, 1.35 mmole) at −132°, −78°, or 20°, and in each case unchanged reactants were recovered quantitatively by distillation of the mixture at −132°. Because of this negative result, it did not seem practical to investigate the behavior of disilthian with boron trichloride.

ACKNOWLEDGMENTS

I am grateful to Professor H. J. Emeléus for his advice and many helpful discussions while this work was done in his laboratory at Cambridge University. I am indebted to the Royal Commission for the Exhibition of 1851 for the award of an Overseas Scholarship.

ENZYMIC HYDROLYSIS OF A GLUCOMANNAN FROM JACK PINE (PINUS BANKSIANA LAMB.)[1]

O. PERILA[2] AND C. T. BISHOP

ABSTRACT

A crude glucomannan was isolated from jack pine holocellulose in 17% yield. Repeated delignification and copper complexing of this product provided a purified glucomannan (5% of the holocellulose) containing glucose, mannose, galactose, and xylose in a molar ratio of 10:25:1:1. This polysaccharide was hydrolyzed by a commercial hemicellulase preparation, the cleavage products being removed by continuous dialysis of the reaction mixture. The following oligosaccharides were isolated from the hydrolyzate and identified; yields are based on the glucomannan:

(*a*)	4-*O*-(β-D-mannopyranosyl)-D-mannopyranose	18.5%,
(*b*)	4-*O*-(β-D-glucopyranosyl)-D-mannopyranose	1.4%,
(*c*)	4-*O*-(β-D-mannopyranosyl)-D-glucopyranose	0.7%,
(*d*)	6-*O*-(α-D-xylopyranosyl)-D-glucopyranose	0.5%,
(*e*)	*O*-β-D-mannopyranosyl (1 → 4)-*O*-β-D-mannopyranosyl (1 → 4)-D-mannopyranose	6.5%,
(*f*)	*O*-β-D-mannopyranosyl (1 → 4)-*O*-β-D-glucopyranosyl (1 → 4)-D-glucopyranose	0.7%,
(*g*)	*O*-α-D-xylopyranosyl (1 → 6)-*O*-β-D-glucopyranosyl (1 → 4)-D-glucopyranose	0.1%,
(*h*)	*O*-β-D-mannopyranosyl (1 → 4)-*O*-β-D-mannopyranosyl (1 → 4)-D-glucopyranose	0.04%,
(*i*)	*O*-β-D-glucopyranosyl (1 → 4)-*O*-β-D-mannopyranosyl (1 → 4)-D-mannopyranose	0.03%,
(*j*)	a trisaccharide containing arabinose, glucose, and mannose	0.01%,
(*k*)	a trisaccharide containing two units of arabinose and one of galactose	0.01%.

The constitutions of glucomannans from a variety of softwoods have been studied extensively during the past 10 years and much of this work has been summarized in a review by Aspinall (1). References to later work may be found in some of the more recent papers (2–5). All of these studies have shown that the glucomannans consist basically of β-D-mannose and β-D-glucose residues joined together in a chain by 1 → 4 linkages. Differences between the glucomannans from different woods occur in the presence or absence of small amounts of D-galactose which, when it occurs, has been found as terminal, non-reducing units. There is also some uncertainty about the presence of a slight degree of branching in the main chain of these polysaccharides.

Until recently, every one of the fully defined oligosaccharides obtained by partial acid hydrolysis of glucomannans was found to contain 1 → 4 linkages exclusively (4–10). However, Meier (3) has now reported the isolation of 6-*O*-α-D-galactopyranosyl-D-mannopyranose and this was the first unequivocal evidence of a linkage other than 1 → 4 in a glucomannan. Relative rates of acid hydrolysis of methyl glycopyranosides differ considerably (11) and it may be assumed that various linkages in a polysaccharide are also hydrolyzed at different rates. Oligosaccharides obtained by partial acid hydrolysis of polysaccharides will therefore contain primarily the most stable linkages. Relative rates of hydrolysis of glycosidic linkages by enzymes can be quite different from the rates of hydrolysis by acids because the former are more specific catalysts. Oligosaccharides obtained by enzymic hydrolysis can therefore differ considerably from those obtained by acid hydrolysis of the same polysaccharide and an examination of such products can

yield new information about the linkages in the polymer. It is also possible to obtain higher yields of oligosaccharides through enzymic hydrolysis than acid hydrolysis by using dialysis for continuous removal of partly hydrolyzed fragments before they are degraded further (12).

A previous publication (2) described the gross structural features of a glucomannan from jack pine: this paper reports the isolation and identification of some of the oligosaccharides obtained by enzymic hydrolysis of that polysaccharide.

The crude polysaccharide was obtained in 17% yield from jack pine holocellulose prepared by the chlorine–monoethanolamine method (13). The crude product was purified by alternate delignification and precipitation as its copper complex, this cycle being repeated three times. The resulting polysaccharide (5% of the holocellulose) contained glucose, mannose, galactose, and xylose in a molar ratio of 10:25:1:1. Further precipitations as the copper complex gave products with a lower xylose content but recoveries fell off so sharply that it was difficult to decide whether this was removal of a xylan or simply fractionation of glucomannan molecules to which were attached small and varying amounts of galactose and xylose units. Croon, Lindberg, and Meier (14) have reported that a glucomannan from Scots pine could be freed from galactose- and xylose-containing impurities after further delignification. They believed that different polysaccharides were joined to the same lignin molecule thus preventing their separation prior to delignification. It is unlikely that this could explain the presence of galactose and xylose in the glucomannan used in the present study because the product was delignified three times after its isolation from the holocellulose. The glucomannan isolated from jack pine in the present work differed from that used in the previous study (2) in containing xylose; the molar ratios of the other three monosaccharides were in good agreement. This difference could conceivably be attributed to the two different methods of delignification. Acid chlorite (15) is known to degrade polysaccharides (16) and its use for delignification in the earlier work may have caused hydrolysis of the xylose units. The chlorine–monoethanolamine method (13) causes little degradation (16) and was used here specifically to preserve labile linkages which might then be detected in the products from enzymic hydrolysis.

The enzyme used was a commercially available hemicellulase which undoubtedly contained a variety of enzymes. However, it was lacking in cellulase activity and did not attack the cellophane tubing used for dialysis. Hydrolyses were carried out in dialysis tubing, a technique first developed by Painter (12). The apparatus used in the present work (Fig. 1) permitted stirring of the hydrolysis mixture and continuous removal of the dialyzable products. A purified cellulase (17) did not yield any dialyzable products from the glucomannan and a commercial pectinase yielded only monosaccharides.

Yields of products from hemicellulase hydrolysis of jack pine glucomannan are given in Table I. A mixture of higher oligosaccharides (8.2% of the glucomannan) was also recovered but was not examined further.

The following methods were used, where necessary, to establish identities of the oligosaccharides: total hydrolysis followed by paper chromatography revealed the component monosaccharides; reduction with potassium borohydride (18) followed by hydrolysis and paper chromatography showed which monosaccharide formed the reducing end groups; oxidation by lead tetraacetate and by periodate (19, 20), followed in some cases by reduction, hydrolysis, and paper chromatography (20–22), gave information about specific linkages; partial hydrolysis of trisaccharides yielded disaccharides which were identified by paper chromatography and provided further evidence for the location of linkages; anomeric configurations were based on specific rotations and, for some of the

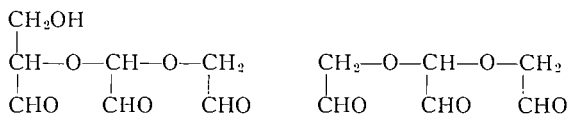
TABLE 1

Products from enzymic hydrolysis of jack pine glucomannan

Monosaccharides (39.9%)	
D-Glucose	14.7%
D-Mannose	21.8%
D-Galactose	2.1%
D-Xylose	1.6%
Disaccharides (20.9%)	
(*a*) 4-*O*-(β-D-Mannopyranosyl)-D-mannopyranose	18.5%
(*b*) 4-*O*-(β-D-Glucopyranosyl)-D-mannopyranose	1.4%
(*c*) 4-*O*-(β-D-Mannopyranosyl)-D-glucopyranose	0.7%
(*d*) 6-*O*-(α-D-Xylopyranosyl)-D-glucopyranose	0.5%
Trisaccharides (7.6%)	
(*e*) *O*-β-D-Mannopyranosyl(1 → 4)-*O*-β-D-mannopyranosyl(1 → 4)-D-mannopyranose	6.5%
(*f*) *O*-β-D-Mannopyranosyl(1 → 4)-*O*-β-D-glucopyranosyl(1 → 4)-D-glucopyranose	0.7%
(*g*) *O*-α-D-Xylopyranosyl(1 → 6)-*O*-β-D-glucopyranosyl(1 → 4)-D-glucopyranose	0.1%
(*h*) *O*-β-D-Mannopyranosyl(1 → 4)-*O*-β-D-mannopyranosyl(1 → 4)-D-glucopyranose	0.04%
(*i*) *O*-β-D-Glucopyranosyl(1 → 4)-*O*-β-D-mannopyranosyl(1 → 4)-D-mannopyranose	0.03%
(*j*) A trisaccharide containing arabinose, glucose, and mannose	0.01%
(*k*) A trisaccharide containing two units of arabinose and one of galactose	0.01%

trisaccharides, were inferred from the identities of products of partial hydrolysis with disaccharides of known configuration; methylation and methanolysis yielded methyl-*O*-methyl glycosides which were identified and estimated by gas–liquid partition chromatography (23, 24) giving qualitative and quantitative data on the specific linkages. The latter method was used on a microscale (0.5–2.0 mg) after it was found that methylation by the Kuhn (25) procedure did not require protection of the reducing groups by prior glycosidation. Neither D-glucose or cellobiose, when methylated by this procedure, yielded any acidic products which would have resulted from oxidation of the reducing group by silver oxide. Furthermore, the fully methylated cellobiose yielded equimolar amounts of 2,3,4,6-tetra-*O*-methyl- and 2,3,6-tri-*O*-methyl-D-glucose on methanolysis proving that no oxidation of the reducing group had occurred.

Oligosaccharide (*a*) was isolated in crystalline form having the same physical constants as an authentic sample of 4-*O*-(β-D-mannopyranosyl)-D-mannopyranose. In addition to the crystalline anhydrous product a crystalline monohydrate (m.p. 122–124° C) was isolated which does not appear to have been reported previously.



Oligosaccharide (*b*) was also obtained as crystals and had the same physical constants as an authentic sample of 4-*O*-(β-D-glucopyranosyl)-D-mannopyranose. Hydrolysis of the oligosaccharide yielded equal amounts of glucose and mannose while hydrolysis after reduction yielded glucose as the only reducing monosaccharide.

Oligosaccharide (*c*) was obtained as an amorphous product having a specific rotation within the range reported for 4-*O*-(β-D-mannopyranosyl)-D-glucopyranose. The compound was chromatographically pure in five different solvent systems and showed the same rates of movement as an authentic sample of this disaccharide. Hydrolysis yielded equimolar amounts of glucose and mannose; reduction and hydrolysis yielded mannose as the only monosaccharide. Oxidation with lead tetraacetate gave 1.3 moles of carbon dioxide per mole disaccharide with consumption of 3.7 moles of oxidant; calculated values are 1.0 and 4.0 moles/mole respectively. Reduction and hydrolysis of the oxidized product yielded erythritol and glycerol in approximately equal amounts. Methylation and methanolysis of the disaccharide yielded methyl glycosides of 2,3,4,6-tetra-*O*-methyl-D-mannose and 2,3,6-tri-*O*-methyl-D-glucose; the molar ratio of these *O*-methyl ethers was 1:1. Oligosaccharide (*c*) was therefore 4-*O*-(β-D-mannopyranosyl)-D-glucopyranose.

Oligosaccharide (*d*) was an amorphous product, chromatographically pure in three different solvent systems. Hydrolysis yielded equal amounts of xylose and glucose; hydrolysis of the reduced disaccharide yielded xylose as the only reducing sugar. Methylation and methanolysis of the disaccharide yielded glycosides of 2,3,4-tri-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-glucose, the two compounds being present in a molar ratio of 1:1. This evidence together with the high positive rotation ($[\alpha]_D+70°$) showed that oligosaccharide (*d*) was 6-*O*-(α-D-xylopyranosyl)-D-glucopyranose. Zemplen and Bognar (26) have reported the synthesis of this compound and obtained it in crystalline form, m.p. 200.5–201.5° C, $[\alpha]_D^{20}+150 \rightarrow 121°$ (16 hours in water). The assigned structure for oligosaccharide (*d*) is supported by the fact that when the compound was treated with lead tetraacetate in the presence of potassium acetate, 4.8 moles of oxidant were consumed per mole and 3.5 moles of carbon dioxide were evolved per mole, without the production of formaldehyde. These data eliminate any likelihood that the D-glucose reducing end unit was substituted at position 2, 3, or 4, and correspond to those expected for a $1 \rightarrow 6$ linked xylopyranosyl-glucose containing about 20% of non-oxidizable impurity.* The fact that the compound was extremely hygrosopic may account for the

I II

low oxidation, as well as rotational values.

Oligosaccharide (*e*) was obtained in two crystalline forms having melting points of 166–167° C and 214–216° C. Whistler and Smith (27) have reported the trihydrate of mannotriose as having a melting point of 137–137.5° C. Aspinall *et al.* (28) obtained the same melting point with rapid heating of the sample but noted that slow heating gave a melting point of 166.5–169.5° C and presumed that this was the anhydrous form of the trisaccharide. The lower melting form of oligosaccharide (*e*) did not depress the melting point of an authentic sample of *O*-β-D-mannopyranosyl $(1 \rightarrow 4)$-*O*-β-D-mannopyranosyl $(1 \rightarrow 4)$-D-mannopyranose having a melting point of 166–167° C. Elementary analysis showed that this compound was the monohydrate of the trisaccharide. Recrystallization of this product from hot, absolute ethanol yielded a crystalline compound with a melting point of 214–216° C. Analysis showed that this was the anhydrous form of mannotriose which does not appear to have been reported previously. It is apparent that the $1 \rightarrow 4$-β-linked mannotriose can be isolated as the trihydrate (m.p. 137–137.5° C), the monohydrate (m.p. 166–169° C), or the anhydrous sugar (m.p. 214–215° C). The specific rotation of oligosaccharide (*e*) was within the range of those reported for *O*-β-D-mannopyranosyl$(1 \rightarrow 4)$-*O*-β-D-mannopyranosyl$(1 \rightarrow 4)$-D-mannopyranose and methylation and methanolysis yielded glycosides of 2,3,4,6-tetra-*O*-methyl-D-mannose and 2,3,6-tri-*O*-methyl-D-mannose in a molar ratio of 1:2.

Oligosaccharide (*f*) was an amorphous product, chromatographically pure in five different solvent systems, and yielding on hydrolysis mannose and glucose in a molar

Other structures not inconsistent with these oxidation data are 6-O-(D-xylofuranosyl)-D-glucose and 5-O-(D-xylopyranosyl)-D-glucose. When oxidized by periodate such compounds should yield trialdehyde I (free aldehyde form) having $[\alpha]_D \pm 85°$ to 100° (the sign and value depending on the stereochemistry); however, 6-O-(D-xylopyranosyl)-D-glucose should yield optically inactive trialdehyde II (A. J. Charlson and A. S. Perlin, Can. J. Chem. **34, 1804 (1956)). When oligosaccharide (d) was oxidized with excess periodate the rotation dropped rapidly to a constant value of zero, evidence for formation of II (A. S. Perlin, Private communication).*

ratio of 1:2. The hydrolyzate of the reduced trisaccharide contained mannose and glucose in a molar ratio of 1:1 showing that the reducing end group in the trisaccharide was a glucose unit. Partial hydrolysis yielded glucose, mannose, and two disaccharides that were chromatographically identical with cellobiose and 4-*O*-(β-D-mannopyranosyl)-D-glucopyranose. Lead tetraacetate oxidation of the trisaccharide yielded 1.0 mole of formic acid and oxidant consumption was 3.7 moles. Assuming oxidation of a pyranosyl non-reducing end and a C_4-substituted reducing end the required values are 1.0 mole of formic acid and 4.0 moles of oxidant consumed. It has been shown that 2,3-trans glycols on the central residues of $1 \rightarrow 4$ linked trisaccharides are not oxidized by lead tetraacetate (29). Reduction and hydrolysis of the oxidation product from oligosaccharide (*f*) yielded glycerol, erythritol, and glucose which arose from the non-reducing unit, the C_4-substituted reducing group, and the central unit respectively of the trisaccharide. Methylation and methanolysis yielded glycosides of 2,3,4,6-tetra-*O*-methyl-D-mannose and 2,3,6-tri-*O*-methyl-D-glucose which were present in a ratio of 1:2. The foregoing results established that oligosaccharide (*f*) was *O*-β-D-mannopyranosyl$(1 \rightarrow 4)$-*O*-β-D-glucopyranosyl $(1 \rightarrow 4)$-D-glucopyranose.

Oligosaccharide (*g*) was isolated as an amorphous product, chromatographically pure in four different solvent systems. A sample crystallized after being kept for several weeks but was too small to permit recrystallization; melting point of the crude product was 147–150° C. Hydrolysis of oligosaccharide (*g*) yielded xylose and glucose in a molar ratio of 1:2 and hydrolysis of the reduced trisaccharide yielded xylose and glucose in a ratio of 1:1. Methylation and methanolysis yielded equimolar amounts of methyl glycosides of 2,3,4-tri-*O*-methyl-D-xylose; 2,3,4-tri-*O*-methyl-D-glucose; and 2,3,6-tri-*O*-methyl-D-glucose. The 2,3,6-tri-*O*-methyl-D-glucose was not present after methylation and methanolysis of the reduced trisaccharide. These results indicated that oligosaccharide (*g*) was *O*-α-D-xylopyranosyl$(1 \rightarrow 6)$-*O*-β-D-glucopyranosyl$(1 \rightarrow 4)$-D-glucopyranose. The anomeric configurations were assumed to be the same as in the other oligosaccharides where these linkages were found; i.e., the xylosyl–glucose $(1 \rightarrow 6)$ linkage was α in oligosaccharide (*d*) because of the high positive rotation and the glucosyl–glucose $(1 \rightarrow 4)$ linkage was β in oligosaccharide (*f*) because cellobiose was obtained on partial hydrolysis.

Oligosaccharide (*h*) was isolated in quantities too small for completely unequivocal identification. Hydrolysis yielded mannose and glucose with the former predominating. Hydrolysis after reduction yielded only mannose. Methylation and methanolysis gave methyl glycosides of 2,3,4,6-tetra-*O*-methyl-D-mannose; 2,3,6-tri-*O*-methyl-D-mannose; and 2,3,6-tri-*O*-methyl-D-glucose. Assuming the anomeric configurations and ring forms to be the same as found previously for these units it appeared that the oligosaccharide was *O*-β-D-mannopyranosyl $(1 \rightarrow 4)$-*O*-β-D-mannopyranosyl $(1 \rightarrow 4)$-D-glucopyranose.

Oligosaccharide (*i*) was also obtained in only small amounts. Hydrolysis yielded mannose and glucose with the former predominating. Methylation and methanolysis yielded glycosides of 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3,6-tri-*O*-methyl-D-mannose in a molar ratio of 1:2. Making the same assumptions as above this oligosaccharide was *O*-β-D-glucopyranosyl $(1 \rightarrow 4)$-*O*-β-D-mannopyranosyl $(1 \rightarrow 4)$-D-mannopyranose.

Oligosaccharide (*j*) yielded approximately equal amounts of arabinose, glucose, and mannose on hydrolysis and oligosaccharide (*k*) yielded galactose and arabinose in a ratio of 1:2. Both of these oligosaccharides were obtained in quantities too small for further investigation.

With a few notable exceptions the results of enzymic hydrolysis were similar to those

obtained by partial acid hydrolysis of glucomannans. The major products, mannobiose and mannotriose (oligosaccharides *a* and *e*) were obtained in a total yield of 25% from the glucomannan and showed the presence of extensive chains of $1 \rightarrow 4$ linked β-D-mannopyranose units. The significance of the relative amounts of oligosaccharides containing more than one monosaccharide is rather difficult to assess because the enzyme system used for hydrolysis contained enzymes of unknown specificities and reactivities. Oligosaccharides (*b*), (*c*), (*f*), (*h*), and (*i*) each contained β-D-glucose and β-D-mannose units joined by $1 \rightarrow 4$ linkages in various combinations. These results support the premise that the backbone of glucomannans is linear and confirm results found by partial acid hydrolysis (3–10); they also confirm the results of periodate oxidation of the glucomannan from jack pine which showed that there was no branching through C_2 or C_3 of any of the units (2). No cellobiose was found among the disaccharides but two trisaccharides (*f* and *g*) were obtained in which two glucose residues were joined together. The yield of trisaccharide (*f*) was of the same order as the other products of hydrolysis with exception of mannobiose and mannotriose, and indicated that some of the glucose residues in the polysaccharide were present in blocks of two or more units. The enzymic hydrolysis must have enriched these components because the enzyme used did not have any cellulase activity and a purified cellulase (17) of known specificity did not yield any dialyzable products from the polysaccharide.

The significance of oligosaccharides (*j*) and (*k*) is doubtful because the quantities were so small that polysaccharide impurities from the paper chromatograms (30) could contribute to the hydrolysis products.

To our knowledge oligosaccharides (*d*) and (*g*) represent the first evidence of a linkage between xylose and glucose units in wood polysaccharides. It was unlikely that these two oligosaccharides were products of enzymic synthesis or transfer reactions because the yields were as high or higher than other oligosaccharides which contained the $1 \rightarrow 4$ linkage. Also, no oligosaccharides were formed from monosaccharides that were incubated with the enzyme mixture under the same conditions used for the hydrolysis. The possibility seems remote that "transferases", if present, would transfer only xylose units and with glucose as the exclusive acceptor. It would therefore appear that oligosaccharides (*d*) and (*g*) were real hydrolysis products of a polysaccharide, either a xyloglucan or a xyloglucomannan, the presence of which has not been suspected before. A number of publications dealing with glucomannans have reported the presence of xylose in the polysaccharide, the amounts ranging from trace amounts to 3.0% (3, 4, 7–10, 14). This xylose has been ascribed to the presence of small amounts of acidic xylans which occur in those woods and which were not removed completely by the fractionation procedures used. The present work indicates that at least some of the xylose units in these preparations may have been attached to a glucose-containing polysaccharide and this could explain the failure to remove them completely by fractionation. Neither a pure mannan or a pure glucan (other than cellulose) has ever been isolated from wood; the evidence available at the present time indicates that glucomannans in the native state exist as linear molecules composed of glucose and mannose residues and containing small and varying amounts of xylose and galactose units as short side chains. This situation is remarkably similar to the xylans where small and varying amounts of 4-*O*-methyl-D-glucuronic acid and L-arabinose are attached to linear xylan molecules. The separation of "pure" polysaccharides from such mixtures, e.g. a glucomannan from a glucomannan containing 2–3% galactose or xylose, is extremely difficult by present methods.

EXPERIMENTAL

Paper chromatograms were run at room temperature (25°±2° C) by the descending method on Whatman No. 1 paper using the following solvent systems (v/v):

(A) butan-1-ol:pyridine:water—6:4:3; 2–3 days for di- and 4–6 days for tri-saccharides;

(B) butan-1-ol:pyridine:benzene:water—5:3:1:3; organic phase, 3–5 days for di- and 6–10 days for tri-saccharides;

(C) propan-1-ol:ethyl acetate:water—7:1:2; 3–5 days for di- and 6–10 days for tri-saccharides;

(D) ethyl acetate:pyridine:water—5:2:5; organic phase, 2–3 days for di- and 4–6 days for tri-saccharides;

(E) ethyl acetate:acetic acid:water—3:1:3; organic phase, 1–2 days for monosaccharides;

(F) ethyl acetate:pyridine:water—8:2:1; 1–2 days for monosaccharides;

(G) ethyl acetate:acetic acid:water—9:2:2; 5–10 days for di- and 10–20 days for tri-saccharides.

Sugars on the chromatograms were detected by aniline hydrogen phthalate (31) or *p*-anisidine hydrochloride (32) spray reagents or by successive dipping in methanolic silver nitrate, ethanolic sodium hydroxide, and aqueous sodium thiosulphate (33). The R_c values cited are migrations of sugars relative to that of cellobiose.

Evaporations were carried out under reduced pressure at 35° C, specific rotations are equilibrium values unless stated otherwise, and melting points are corrected.

Isolation of Glucomannan

Extractive-free jack pine wood was delignified by the chlorine–monoethanolamine procedure to yield holocellulose amounting to 63% of the extractive-free wood. The holocellulose (100 g) was extracted by stirring with 4% aqueous sodium hydroxide (1500 ml) in an atmosphere of nitrogen at 25° C for 24 hours. The residue was filtered and washed with 4% aqueous sodium hydroxide (1500 ml). The extract and washings were discarded. The residue was then extracted with alkaline borate solution (1500 ml) containing 17.5% sodium hydroxide and 4% boric acid (34) under the same conditions used before. The mixture was cooled in ice, filtered, and the residue was washed rapidly with cold, distilled water (1500 ml). Addition of freshly prepared Fehling's solution (250 ml) to the combined extract and washings caused precipitation of a polysaccharide copper complex (35). The precipitate was centrifuged and washed, twice with alkaline borate containing a small amount of Fehling's solution; twice with water containing a small amount of Fehling's solution; and finally twice with water. The copper complex was then dissolved in an ice-cold solution of *N* acetic acid and *N* hydrochloric acid (1:1). The clear solution was poured into an equal volume of ethanol and the precipitated polysaccharide was washed twice with ethanol and twice with water. Yield, determined on an aliquot of the aqueous suspension, was 17% of the holocellulose.

Purification of Glucomannan

Fresh chlorine water (10 g chlorine per liter) was added to the aqueous suspension of the crude glucomannan and the mixture was stirred thoroughly for 5 minutes. Hot 3% ethanolic monoethanolamine was added and the glucomannan was recovered by centrifugation. The precipitate was washed twice with the hot ethanolic monoethanolamine, twice with ethanol, twice with water and dissolved again in alkaline borate from which

it was precipitated as its copper complex by addition of Fehling's solution. The copper complex was washed and the glucomannan was recovered exactly as described above. The delignification and copper complexing were repeated two more times to yield a purified glucomannan, 5% of the holocellulose.

This polysaccharide had $[\alpha]_D^{26} = -25°$ (C, 1.2% in *N* sodium hydroxide) and upon hydrolysis by 30% formic acid in a sealed tube at 97° C for 15 hours yielded glucose, mannose, galactose, and xylose in a molar ratio of 10:25:1:1. The monosaccharides were separated chromatographically in solvent F and were estimated by the colorimetric procedure of Perila and Seppa (36).

Enzymic Hydrolysis of Glucomannan

The glucomannan was suspended in water at a concentration of 1–2% and dialyzed against distilled water through cellophane tubing for 24 hours. Hemicellulase (Nutritional Biochemicals Corporation) was added (10% of the dry weight of glucomannan) and the dialysis tube, closed at one end, was inserted into the large tube (A) of the dialysis apparatus (Fig. 1). The stirrer (B) was placed inside the dialysis tubing, the top of which was then fastened to the stirrer bearing (C), which was clamped in a fixed position. The

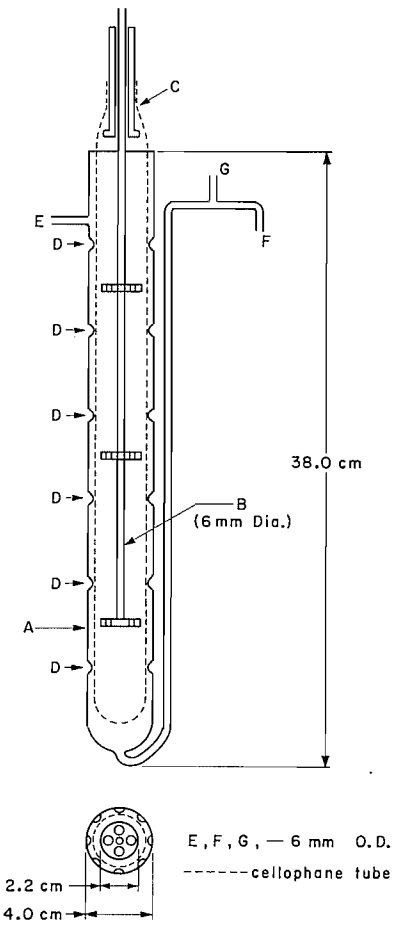

FIG. 1. Apparatus for continuous dialysis of enzymic hydrolyzates of polysaccharides.

stirrer was fastened to a concentric cam mounted on a stirring motor and of such size that the amplitude of the vertical movement of the stirrer was within the distance between the rings of indentations (D). The indentations served to hold the dialysis tubing away from the walls and permitted the passage of water around the entire surface. Water was introduced at E and collected at F at a rate of 1–2 ml per minute; the opening G prevented siphoning. Hydrolyses were carried out at 35° C, pH 6 without buffer, and were stopped when there was a drop in osmotic pressure within the dialysis tubing (100 hours). The dialyzate was evaporated and dried over anhydrous calcium chloride at 0.03 mm pressure. The yield of dialyzable products was 95±2% of the glucomannan.

Isolation of Oligosaccharides

The mixture of dialyzable products was chromatographed on a column of charcoal: Celite (37) using gradient elution (38) with water to 50% ethanol. The 500 fractions that were collected were examined by paper chromatography (solvent D) and similar fractions were combined to give 15 different fractions. Individual components were isolated from these fractions by chromatography on cellulose columns using butan-1-ol nearly saturated with water and by chromatography on large sheets of Whatman No. 3MM paper using solvents D and C. The isolated oligosaccharides were deionized by Amberlite IR-120 and IR-45, filtered through charcoal, and extracted with ether to remove any oils, fats, or waxes.

Hydrolysis of Oligosaccharides

Samples (ca. 0.5 mg) were heated in sealed tubes with 0.3 *N* hydrochloric acid at 97° C for 4 hours. Hydrolyzates were examined by paper chromatography using solvent E.

Reduction of Oligosaccharides

The oligosaccharide (1–2 mg) in water (0.5 ml) was added slowly to a solution of potassium borohydride (0.05 g) in water (1 ml) and the reaction was kept at room temperature for 18 hours. Amberlite IR-120 ion exchange resin was added until gas evolution ceased. The resin was filtered off, the filtrate was evaporated to dryness, and the residue was evaporated to dryness three times from methanol solution.

Methylation of Oligosaccharides

The oligosaccharide (0.5–2.0 mg) was shaken with methyl iodide (0.2 ml), dimethylformamide (0.2 ml), and silver oxide (0.2 g) at room temperature in the dark for 18 hours (25). The mixture was filtered and the residue was washed with chloroform. The combined filtrate and washings were dried (anhydrous calcium sulphate) and evaporated to dryness under 0.03 mm pressure at room temperature. The methylated oligosaccharides were refluxed in 2% methanolic hydrogen chloride for 20 hours and the resulting methyl glycosides were analyzed by gas–liquid partition chromatography (24). Separations were carried out using the following columns:

(*a*) 10% by weight of methylated hydroxyethylcellulose (39) on acid-washed Celite, 60–80 mesh, at 150° C and 180° C;

(*b*) 10% by weight of butanediol succinate polyester on Chromosorb W, 60–80 mesh, at 150° C;

(*c*) 10% by weight of Apiezon M on alkali-washed Celite, 60–80 mesh, at 150° C;

(*d*) 15% by weight of polyphenyl ether, *m*-bis(*m*-phenoxy-phenoxy)-benzene, on Celite, at 150° C.

The instrument used was a Pye Argon Chromatograph and gas flow rates were ca. 200 ml/min for columns (*a*), (*b*), and (*c*), ca. 100 ml/min for column (*d*). The methyl

O-methyl glycosides were identified by comparing their retention volumes with those of authentic samples run under the same conditions. The gas–liquid chromatographic behavior of most of the compounds found had been established previously by their isolation from the effluent gas stream (2, 23, 24, 40).

Oxidation of Oligosaccharides

Dr. A. S. Perlin kindly carried out the lead tetraacetate and periodate oxidations on 5–10 mg samples according to methods described previously by him and his colleagues (19, 20, 29).

Monosaccharides

Monosaccharides in the enzymic hydrolyzate were separated from the aqueous eluate of the charcoal column by paper chromatography in solvent E. Estimation (36) of the component sugars gave glucose, mannose, galactose, and xylose in a molar ratio of 10:15:1:1 respectively.

Oligosaccharides

M = mannopyranose; G = glucopyranose; X = xylopyranose.

Oligosaccharide (a) (M1 $\xrightarrow{\beta}$ 4M)

This component was eluted from the charcoal column by 0–5% ethanol. It was chromatographically identical with 4-*O*-(β-D-mannopyranosyl)-D-mannopyranose and had the following R_c values: solvent A, 1.0; B, 1.1; C, 1.2; D, 1.0; and G, 1.25. Crystallized from ethanol containing a little water the compound had a melting point of 122–124° C. Anal. Calc. for $C_{12}H_{22}O_{11}.H_2O$: C, 40.00%; H, 6.72%. Found: C, 40.32%; H, 6.82%. Crystallized from cold methanol the compound had a melting point of 190–191° C, undepressed by admixture with authentic mannobiose, $[\alpha]_D^{25} = -8.5°$ (*c*, 1.3% in water). Reported values are melting points within the range 193–210° C (4, 5, 8–10, 27, 28) and specific rotations from −5° to −9° (4, 5, 8–10, 28).

Oligosaccharide (b) (G1 $\xrightarrow{\beta}$ 4M)

This component was eluted from charcoal by 5–10% ethanol and was chromatographically identical with an authentic sample of 4-*O*-(β-D-glucopyranosyl)-D-mannopyranose. R_c values in different solvents were: A, 1.15; B, 1.25; C, 1.3; D, 1.2; and G, 1.6. Crystallized from methanol it had a melting point and mixed melting point of 133–135° C, $[\alpha]_D^{25} = +5.5°$ (*c*, 1.9% in water). Reported values (4, 5, 8–10) are for melting points within the range 133–139° C and specific rotations from +5° to +16°.

Oligosaccharide (c) (M1 $\xrightarrow{\beta}$ 4G)

This compound was eluted from charcoal by 0–5% ethanol and was chromatographically identical with an authentic sample of 4-*O*-(β-D-mannopyranosyl)-D-glucopyranose. R_c values in different solvents were: A, 0.8; B, 0.85; C, 0.75; D, 0.7; and G, 0.85. The product could not be crystallized and had $[\alpha]_D^{25} = +12°$ (*c*, 1.0% in water). Reported values range from +5° to +29° (4–10).

Oligosaccharide (d) (X1 $\xrightarrow{\alpha}$ 6G)

This compound was eluted from charcoal by 5–10% ethanol and had the following R_c values in different solvents: A, 1.1; B, 1.15; C, 1.25. The product was extremely hygroscopic but a specific rotation on the crude material showed $[\alpha]_D^{25} = +70°$ (*c*, 0.7% (?) in water; reported (26) for 6-*O*-(α-D-xylopyranosyl)-D-glucopyranose, $[\alpha]_D^{20} = +150° \rightarrow 121°$ (16 hours in water).

For personal use only.

Oligosaccharide (e) (M1 $\xrightarrow{\beta}$ 4 M1 $\xrightarrow{\beta}$ 4M)

This compound was contained in the 5% ethanol eluate from the charcoal column and was chromatographically identical with an authentic sample of *O*-β-D-mannopyranosyl (1 → 4)-*O*-β-D-mannopyranosyl (1 → 4)-D-mannopyranose. R_c values in different solvents were: A, 0.5; B, 0.45; C, 0.5; D, 0.45; and G, 0.3. Crystallized from cold ethanol containing a small amount of water the product had m.p. 166–167° C undepressed by admixture with an authentic specimen. Reported melting points range between 155 and 169° C (4, 5, 8, 10, 28).

Anal. Calc. for $C_{18}H_{32}O_{16}.H_2O$: C, 41.39%; H, 6.58%. Found: C, 41.35%; H, 6.72%. Crystallized from hot ethanol the compound had a melting point of 214–216° C.

Anal. Calc. for $C_{18}H_{32}O_{16}$: C, 42.86%; H, 6.39%. Found: C, 42.71%; H, 6.38%. Specific rotation, calculated for the anhydrous compound, was the same for both forms: $[\alpha]_D^{25} = -23°$ (*c*, 2% in water); reported values range from −15° to −26° (4, 5, 8–10, 27, 28).

Oligosaccharide (f) (M1 $\xrightarrow{\beta}$ 4 G1 $\xrightarrow{\beta}$ 4G)

This component was eluted from the charcoal column by 15% ethanol and had the following R_c values in different solvents: A, 0.4; B, 0.35; C, 0.3; D, 0.25; and G, 0.25. Partial hydrolysis was done with 0.03 *N* oxalic acid for 10 hours at 97° C in a sealed tube. The amorphous compound had $[\alpha]_D^{28} = +9.5°$ (*c*, 1% in water).

Oligosaccharide (g) (X1 $\xrightarrow{\alpha}$ 6 G1 $\xrightarrow{\beta}$ 4G)

This compound was eluted from the charcoal column by 20% ethanol and had the following R_c values in different solvents: A, 0.8; B, 0.7; C, 0.75; and D, 0.5. A small sample crystallized after being kept for several weeks; melting point of the crude product was 147–150° C, $[\alpha]_D^{24} = +150°$ (*c*, 0.2% in water).

Oligosaccharide (h) (M1 $\xrightarrow{\beta}$ 4 M1 $\xrightarrow{\beta}$ 4G)

This compound was contained in the 10% ethanol eluate from the charcoal column and had R_c 0.8 in solvent C.

Oligosaccharide (i) (G1 $\xrightarrow{\beta}$ 4 M1 $\xrightarrow{\beta}$ 4M)

This compound was also in the 10% ethanol eluate and had R_c values in different solvents as follows: A, 0.6; B, 0.5; and C, 0.65.

Oligosaccharides (j) and (k)

These were eluted from charcoal by 5% ethanol and had the following R_c values: oligosaccharide (*j*), A, 0.45; B, 0.4; and C, 0.8; oligosaccharide (*k*), A, 0.40; B, 0.35; and C, 0.8.

Higher Oligosaccharides

Two further fractions were obtained from the charcoal column. One, eluted by 10–25% ethanol, contained mainly tetrasaccharides and amounted to 8.6% of the glucomannan. The other, eluted by 15–30% ethanol was 6% of the glucomannan and contained higher oligosaccharides (penta-, hexa-, hepta-). These two fractions were not examined further at this time.

ACKNOWLEDGMENTS

The authors are very grateful to Mr. F. P. Cooper for carrying out the gas–liquid partition chromatography and to Dr. A. S. Perlin, National Research Council, Prairie Regional Laboratories, Saskatoon, Sask., for performing and interpreting the lead tetraacetate and periodate oxidations. We wish to thank Dr. L. E. Wise, Institute of Paper

A COUNTER FOR MEASUREMENT OF TRITIUM EXCHANGE IN SOLIDS[1]

O. SEPALL,[2] A. R. G. LANG, AND S. G. MASON

ABSTRACT

An apparatus for measuring the exchange of tritium (H^3) between water vapor and solids such as cellulose has been developed which is simpler, less expensive, and more precise than an earlier model.

Both the exchange reaction and the determination of sample tritium activity are performed in a windowless, proportional counter. The background activity in sorbed water on counter surfaces is measured independently of sample activity. Satisfactory reduction of the effect of the electrostatic charge on the sample upon counting rate is achieved by the geometry of the counter.

INTRODUCTION

An exchange of hydrogen usually occurs between water and the hydroxyl groups of other substances, the extent of which can be determined by using tritiated water. The apparatus described in this paper is suitable for the measurement of exchange between water vapor and solid substances such as cellulose and is a much simpler version of a device previously described (1). The measurement consists of (1) exposing the sample to water vapor enriched with tritium, (2) removal of adsorbed water by evacuating, and (3) determination of tritium activity in the sample by a counting technique. The two main difficulties with the method are (1) the measurement of low-energy beta radioactivity from nonconductive solids and (2) elimination from the measurement, of significant background radioactivity from sorbed water on counter surfaces.

Low-energy beta radioactivity is preferably measured with a windowless counter so as to avoid attenuation of the radiation. In such a counter a nonconductive sample such as cellulose can accumulate electrostatic charge which may affect the measurement. The charge is produced by positive ions formed in the counting gas and tends to lower the counting rate by reducing the electric field intensity in the counter. An electrostatic charge was avoided in the earlier model by isolating the sample from the counting chamber by a thin conductive window (1). Bank *et al.* (2) have eliminated the charge by mixing the sample with graphite to render it conductive. The counter described here requires neither conductive window nor modification of the sample; reduction of the charge effect to an acceptable level is achieved by suitable dimensioning of the counter chamber. Windowless flow counters of special design for the detection of tritium in paper chromatograms have been described before (3, 4), but whether electrostatic charges affected counting performance could not be ascertained from the reported results.

The sorption of water on counter surfaces can result in a high contamination background activity which is included in the measurement of activity from the sample. The present counter permits the determination of the background for each measurement, and in this respect possesses a distinct advantage over the previous model (1).

DESCRIPTION

General Description of Apparatus

The apparatus shown schematically in Fig. 1 consists of the methane-filled counter and an arrangement for exposing the samples to tritiated water vapor. The counter is shown

at A with an electrical heater on the lower section at B. The 100-ml Pyrex flask C contains 50 ml of tritiated water (1.5 μc/mg) which is stirred magnetically and is immersed in a water bath at constant temperature. Water vapor enriched with tritium is conducted over the sample through the copper tubes indicated at D. Circulation of vapor is assisted by the convection created by heating one of the tubes electrically at E. The vacuum valves F enable the counter to be isolated from the tritiated water reservoir. At G the apparatus is connected with a vacuum system consisting of a liquid-air trap, a single-stage oil diffusion pump, and a mechanical backing pump. The vacuum in the counter is measured during drying of the sample by the Pirani gauge H. The pressure of the methane gas, which is admitted through line J, is measured by gauge K.

Counter

A vertical section of the counter, which consists almost entirely of commercial fittings, is shown to scale in Fig. 2.

The body E of the counter is a copper bushing, soft soldered to the brass vacuum flanges G and C. Flange G provides access to the counter for inserting samples. Flange C supports the alloy glass insulator B, which carries the high voltage electrode with the 1-mil tungsten collector anode D. At A is shown the standard Amphenol connector for the associated preamplifier. The sample is mounted in holder F and is exposed to tritiated water vapor circulated through tubes H. The counter is evacuated through outlet J and methane counting gas is admitted through inlet K.

The sample holder is supported by two pins fitting into slots cut in the lower vacuum flange and can be rotated on the pins. Figure 3*a* shows the holder assembly in more detail. In the sectional view (A–A) the sample is shown at B, clamped in the steel ring F by the aluminum annulus C. A copper disk D is held centrally in the holder by another

aluminum annulus G and serves to limit the electric field in the counter to the space above the sample holder.

The holder was positioned in the counter so that the closest distance from collector to copper disk was 20 mm or 74% of the diameter of the counter chamber, to satisfy a geometry requirement discussed later.

The sample is rotated and positioned from outside the counter by a magnetic field which interacts with the steel ring of the sample holder. To turn the sample over, a horseshoe magnet is directed along the axis of rotation of the holder and is rotated close to the counter through 180°. The holder is positioned by the arrangement shown in Fig. 3*b*. The vacuum flange which supports the holder is shown at L. Two iron pins K are soldered in holes drilled through the flange and extend to the inside surface. The pins are so positioned that the air gap between them and the steel ring of the sample holder

is minimal when the holder is in the required position for counting. When the magnet H is placed on the ends of the iron pins, as shown in Fig. 3*b*, the magnetic field causes the sample holder to rotate to the counting position. There are thus two stable positions of the holder which differ by a rotation of 180° and permit the measurement of radioactivity from the sample and from the copper disk.

Experimental Procedure

The use of the apparatus is illustrated by considering the steps in a typical measurement. The sample (e.g. cellophane) was used in sheet form with a superficial density of 3 to 5 mg/cm^2, which corresponded to infinite thickness for beta particles from tritium.

The sample was mounted in the holder (Fig. 3*a*) and the counter assembled and evacuated. Tritiated water vapor was circulated over the sample and the relative humidity was kept constant at a desired value during the treatment. The relative humidity was determined by the sample temperature, which was kept constant by heating the counter, and by the vapor pressure in the vessel, which depended upon the temperature of the tritiated water reservoir. After the desired reaction time the counter was evacuated. It has been shown that the complete removal of water from cellulose requires heating the sample at 70° C at 1 μ Hg for many hours (5). It was possible to use these conditions for drying in the present counter, which could be heated to over 100° C, and thus to avoid the error in previous measurements from extraneous activity in sorbed water in the sample. Tritium activity was measured by counting in methane gas at 90 mm pressure. From the counting rates measured from the sample and from the copper disk, the counting rate for the sample only, was calculated by the following relationship:

$$S = M_s - (0.77 \times M_d)$$

where S is the counting rate for the sample, M_s is the counting rate measured from the sample, and M_d is the counting rate measured from the copper disk. The factor 0.77 was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

determined from measurements of the background counting rate for the sample, which was found to be 77% of the counting rate measured from the copper disk and is discussed later.

GENERAL CONSIDERATIONS

Preliminary Remarks

The counter design was based on the results of preliminary studies of (1) the relationship between counter geometry and the effect of electrostatic charges on the sample upon counting rate, and of (2) the reduction of contamination background activity by the selection of a suitable counter material.

The following consideration of factors contributing to the formation of an electrostatic charge on the sample suggested its reduction by adopting a suitable geometry for the counter. The electrostatic charge is produced by positive gaseous ions which drift from the region of the collector electrode to negatively charged surfaces. Some ions strike the sample, which acquires a charge if it is nonconductive, the magnitude of the charge depending on the flux of ions impinging on the sample. To decrease this flux a greater fraction of ions must be constrained to drift to the metal wall of the counter by intensifying the electric field from collector to wall. The required modification of the electric field is achieved by decreasing the distance from collector to wall or by increasing the distance from collector to sample. The reduction of the flux of ions drifting to the sample is therefore related to a parameter $R = h/d$, where h is the least distance from collector to base at the sample position and d is the diameter of the counter. Larger values of R are associated with a more intense electric field between collector and wall. A brief study of the influence of R on the counting characteristics of a windowless counter with a cellophane source is outlined below.

Effect of Counter Geometry on Counting Performance

Four counters were constructed similar to the design described above and having values of R ranging from 0.16 to 4.6. For the two counters with lower values of R, d was 35 mm, while for the other two, d was 27 mm. The source was prepared by exposing cellophane to tritiated water vapor and drying. Counting rates were measured in methane at 90 mm pressure.

Counting rates measured in the region of the plateau with sources of equal activity are shown in Fig. 4*a* for counters with $R = 0.16$ and 0.37. The steeply rising portions

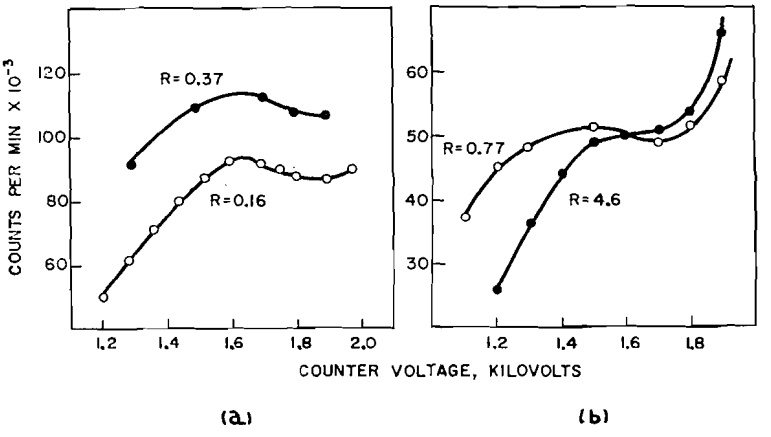

FIG. 4. Effect of R on plateau curves for cellophane sources. Source activities are different for (*a*) and (*b*).

For personal use only.

of the curve at low and high voltages have been omitted in order to use an expanded scale for counting rates and to accentuate the differences from the usual plateau shape. A lower electrostatic charge is indicated on the sample in the counter with higher R by the higher counting rate found at all voltages. The negative slope along part of both curves suggests that a higher counter voltage results in a greater charge on the sample and the reduction of counting rate in the plateau region.

For larger values of R, the counting rates in the plateau region reach a limiting value as shown in Fig. 4*b* by the approximately equal rates measured near counter voltages of 1.55 kv for sources of equal activity and in counters with $R = 0.77$ and 4.6. For the counter with larger R, a negative slope is not found in the shortened plateau region. Although a counter with the larger R would be desirable because of the smaller effect of sample charge, the corresponding greater inside surface area results in increased background activity. The counter with $R = 0.77$ was therefore selected for use.

Counter Material

The influence of counter metal on the level of background activity was estimated by comparing background counting rates in a counter lined with a sheet of each metal. In each case the counter was exposed to tritiated water vapor and evacuated as for the measurement of tritium exchange. The measured counting rates are listed in Table I

TABLE I

Background activity from counter surfaces
$R = 0.37$

Counter material	Counts per minute
Aluminum	15,000
Nickel	57,000
Stainless steel 306	19,000
Copper	7,000

and show copper to be least contaminated of the materials tried, and for this reason was selected.

PERFORMANCE OF COUNTER

Counter Plateau

Plateau curves for the final counter with $R = 0.77$ are shown in Fig. 5 for a benzidine source with tritium incorporated by the method due to Wilzbach (6) and for a tritiated cellophane source prepared by exposing the cellophane to tritiated water and drying. The plateau for the benzidine source has a length of about 400 v and a slope of 4.4%/100 v. The plateau for cellophane appears distorted; it is displaced to higher voltage than the benzidine plateau and has a negative slope presumably because cellophane, unlike benzidine is nonconductive and acquires a residual electrostatic charge. A voltage of 1.5 kv, which corresponded to a counting rate least sensitive to changes in counter voltage, was chosen for measurement of tritium activities in cellophane.

Estimation of Background Activity

To determine the background activity from the counting rate measured from the copper disk, it was necessary to (1) estimate the counting rate resulting from the sample when the sample holder was inverted, and (2) to determine the activity on the copper disk.

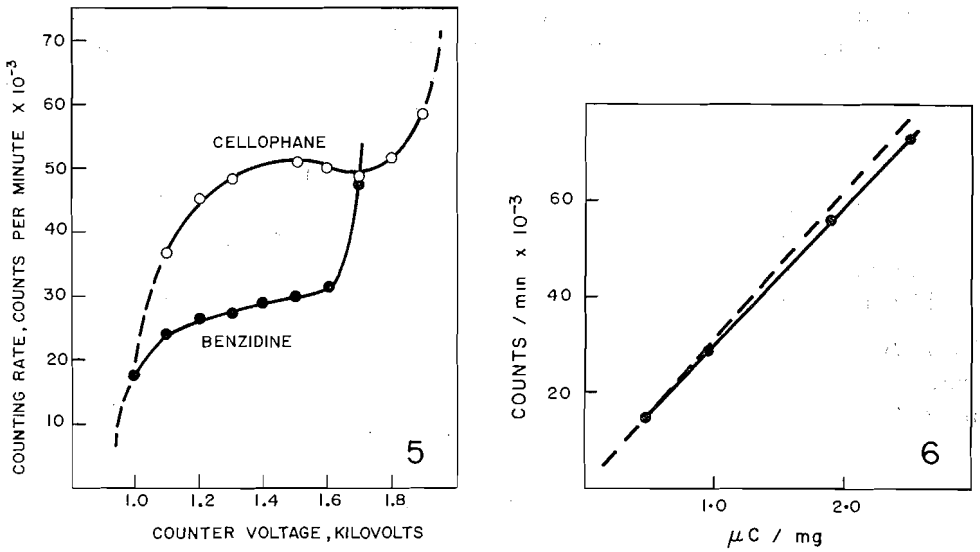

FIG. 5. Plateau curves for counter with $R = 0.77$.
FIG. 6. Sample counting rate vs. specific activity in water.

The transfer of radioactivity through the annular space between holder and counter was estimated by the following experiment. The counting rate from the copper disk was measured with and without a benzidine source of high activity (6×10^5 counts/minute) placed in the inverted sample position. The difference between the two measurements, which was ascribed to transfer of radioactivity to the counter, corresponded to less than 0.05% of source activity and could be neglected. The measured counting rates from sample and from copper disk therefore represented activities for (sample+background) and (copper disk+background), respectively.

To determine the background, a sample of zero activity was used. It was assumed that films of polyethylene, Teflon, and Saran would have no tritium activity after being exposed to tritiated water vapor and drying. Counting rates measured from the films are listed in Table II as percentage of the counting rate from the copper disk. Polyethylene

TABLE II

Ratio of background activity to activity measured with copper disk

Film used for measurement	Ratio %
Polyethylene	77
Teflon	78
Saran	80

was found to be the least contaminated and the value obtained in this case was taken to be the background. For the conditions described, the background count was 20 to 25% of the value for cellophane samples.

Calibration

Since there were indications that the counting rate measured from cellophane was affected by the residual electrostatic charge on the sample, it was desirable to determine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

whether counting rate was proportional to sample activity. It was assumed that the activity of tritium in a cellophane sample, after the exchange reaction and drying, would be proportional to the isotopic concentration in the water vapor. Exchange measurements were conducted with samples of tritiated water ranging in activity from 0.5 to 2.5 μc/mg. The measured counting rates, which are plotted in Fig. 6, were found to vary linearly with specific activity in the water. An increase of specific activity by a factor 2.00 resulted in the increase of counting rate by the factor 1.96 and indicates a small deviation from proportionality between sample activity and counting rate. A correction can be readily applied to measured counting rates to eliminate the error. The dotted line in Fig. 6 shows the ideal relationship where exact proportionality exists between the two quantities.

Reproducibility

Measurements of tritium exchange were repeated with one sample of amylose film and with different samples of cellophane taken from a single sheet and are listed in Table III.

TABLE III

Reproducibility of exchange measurements on cellophane and amylose film

	Counts per minute	
Measurement	Cellophane*	Amylose†
1	43,400	55,650
2	42,100	55,710
3	43,300	55,700
4	43,500	55,400
Mean	43,100	55,620
Range	3.2%	0.54%

*Cellophane samples taken from one sheet.
†Same Amylose film used for each measurement.

The range of 0.54% in the results for amylose is indicative of good precision for the measurement. The greater range of 3.2% found in the measurements on cellophane was probably due to actual differences between samples.

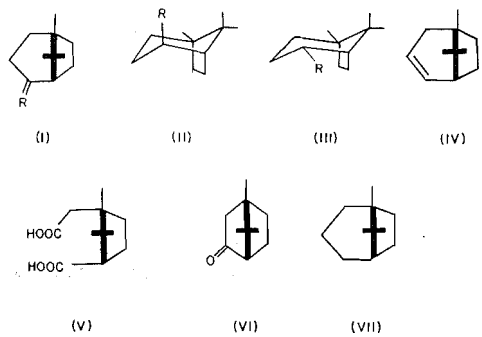
DÉRIVÉS DU TRIMÉTHYL-1,8,8 BICYCLO[3.2.1]OCTANE

VI. SYNTHÈSE DU (+)-TRIMÉTHYL-5,8,8 BICYCLO[3.2.1]OCTÈNE-2[1]

J. M. BILLY,[2] H. FAVRE ET J. M. LALANCETTE[3]

RÉSUMÉ

Les (+)-triméthyl-5,8,8 amino-2α (et 2β) bicyclo[3.2.1]octanes, le (+)-triméthyl-5,8,8 bicyclo[3.2.1]octène-2 et le (+)-triméthyl-1,8,8 bicyclo[3.2.1]octane exempts d'isomères sont décrits.



Au cours de l'étude de certaines réactions d'élimination à partir des alcools II et III (R = OH) nous avons eu besoin de triméthyl-5,8,8 bicyclo[3.2.1]octène-2 très pur et de configuration identique à celle du (+)-homoépicamphre I (R = O).[4] Pour obtenir cet hydrocarbure nous avons mis en œuvre la réaction de Tschugaeff et celle d'Hofmann.

L'un et l'autre des xanthogénates II et III (R = OCS_2CH_3), ayant un hydrogène cis par rapport à R en position 3, devaient conduire à l'hydrocarbure IV.[5, 6] Nous avons choisi de préparer et de pyrolyser le xanthogénate issu du triméthyl-5,8,8 bicyclo[3.2.1]-octanol-2α (III, R = OH), parce qu'étant équatorial l'alcool devait s'estérifier facilement. Le xanthogénate de méthyle en question se prépare aisément et sa pyrolyse conduit au (+)-triméthyl-5,8,8 bicyclo[3.2.1]octène-2 (IV) exempt d'isomères et d'une grande pureté stérique. La constitution et la pureté stérique de cet hydrocarbure furent établies par ozonolyse en acide β-homocamphorique (V) et cyclisation du sel de plomb de ce diacide en épicamphre VI, $[\alpha]_D = -57.4°$. Le pouvoir rotatoire de l'épicamphre VI, de configuration absolue identique à celle du (+)-homoépicamphre et du (+)-camphre (5, 6), est de −58°.

L'amine II (R = NH_2) nécessaire à la dégradation d'Hofmann a été préparée à partir de l'oxime de l'homoépicamphre (I, R = =N—OH). En manipulant de grandes quantités de cette oxime, nous avons pu en isoler deux variétés: p.f. 107.5–108.5°, $[\alpha]_D$ +168° et p.f. 104.5–105.5°, $[\alpha]_D = +107.8°$; il pourrait s'agir des isomères syn et anti, car les deux donnent de l'homoépicamphre par hydrolyse. Ainsi se trouve levée toute ambiguité au sujet de la différence entre les points de fusion et les pouvoirs rotatoires de l'oxime de l'homoépicamphre rapportés par Salmon-Legagneur (6) et par notre groupe; l'oxime que nous avons décrite (7) $[\alpha]_D = +125°$, est un mélange des deux isomères.

Dans un mémoire antérieur (1) notre groupe décrivait les alcools secondaires issus de la réduction du (+)-homoépicamphre I (R = O): l'alcool au platine et l'alcool au sodium reçurent respectivement les formules II (R = OH) et III (R = OH). En partant du fait—montré plusieurs fois (8, 9, 10)—que les réductions des cétones et des oximes suivent

le même cours stérique, nous attribuons la formule II (R = NH_2, axial) à l'amine au platine et la formule III (R = NH_2, équatorial) à l'amine au sodium; fraîchement préparées, ces amines sont des solides; celle au platine est plus dextrogyre que celle au sodium, résultat en accord avec ce que nous avons observé chez les alcools II et III (R = OH) (1); elles sont exemptes d'isomères comme le montre la chromatographie sur papier; elles sont cependant très sensibles à l'air et à l'humidité, ce qui fait que nous n'avons pu obtenir des valeurs analytiques (carbone, hydrogène et azote) satisfaisantes. Les dérivés *p*-nitrobenzoylés sont toutefois stables et facilement cristallisables: ils confirment bien la structure des amines. L'amide issu de l'amine au platine (NH_2, axial) est plus dextrogyre que celui de l'amine au sodium (NH_2, équatorial) ($[\alpha]_D$ +86.4° et +35.1° respectivement), comme c'était le cas pour les *p*-nitrobenzoates issus des alcools correspondants—$[\alpha]_D$ +78.5° (axial) et +24.5° (équatorial) (1).

Haworth, McKenna et Powell (11), puis Gent et McKenna (10) ont montré que les hydroxydes de triméthylammonium quaternaires stéroïdaux (position 3, séries 5α et 5β; position 6, série 5α) ne donnent, par pyrolyse, des hydrocarbures non saturés que s'ils sont axiaux; lorsqu'ils sont équatoriaux les auteurs ont observé une élimination de méthanol avec régénération des diméthylamino-stéroïdes correspondants. McKenna et Slinger (12), dans leur étude de la décomposition des iodures et des hydroxydes de bornyl-, et de néobornyl-, triméthylammonium quaternaires, signalent que seule la pyrolyse des hydroxydes secs conduit au bornène-2 (réaction E_2, sans réarrangement); toute autre forme de traitement augmente la proportion de camphène, de tricyclène et d'amine tertiaire correspondante. À la lumière de ces résultats il était clair qu'il fallait pyrolyser l'hydroxyde d'ammonium quaternaire issu de l'amine axiale: seul le triméthyl-5,8,8 bicyclo[3.2.1]octène-2 était à prévoir.[5]

Nous avons donc préparé l'amine diméthylée II (R = $N(CH_3)_2$) par la méthode à la formaldéhyde/acide formique; il s'est formé au cours de cette opération 49% de cétones, caractérisées par spectroscopie infrarouge; cette formation de cétones est typique pour les amines empêchées (10). La quaternisation a été effectuée par l'iodure de méthyle, à la manière habituelle; l'iodure ainsi obtenu a été transformé en hydroxyde par l'oxyde d'argent; la pyrolyse de cet hydroxyde donne 83% de (+)-triméthyl-5,8,8 bicyclo-[3.2.1]octène-2 (IV) pur, identique à celui obtenu plus haut par la méthode de Tschugaeff.

L'hydrogénation catalytique de l'oléfine IV donne le (+)-triméthyl-1,8,8 bicyclo-[3.2.1]octane (VII), que l'on obtient également par hydrogénolyse du thioacétal I (R = —S—CH_2—CH_2—S—). L'hydrocarbure saturé VII montre de petites variations dans ses propriétés physiques suivant le mode de préparation.

PARTIE EXPÉRIMENTALE[7]

1. *Préparation des amines* II *et* III ($R=NH_2$)

1.1. *Oximes du (+)-homoépicamphre*

On chauffe à l'ébullition à reflux: 50 g d'homoépicamphre, 50 g de chlorhydrate d'hydroxylamine, 250 ml d'éthanol et 500 ml d'une solution aqueuse d'hydroxyde de sodium à 2%. Après 10 minutes de reflux, on abandonne à 5°. Les cristaux sont essorés, lavés à l'eau et dissous dans de l'éther. La solution éthérée est lavée avec Na_2CO_3 aqueux 2% et avec de l'eau, séchée sur sulfate de sodium anhydre et évaporée; on recueille 48.5 g d'oxime brute p.f. 103.5–104°, $[\alpha]_D = +137.8°$ ($c = 4.3$; benzène).

En cristallisant cette oxime dans le mélange éthanol–eau on obtient une oxime p.f. 107.5–108.5°, $[\alpha]_D = +168.0°$ ($c = 2.2$; benzène). Calculé pour $C_{11}H_{19}ON$: C, 72.88; H, 10.56; N, 7.73%. Trouvé: C, 72.69; H, 10.44; N, 7.78%. Dans les eaux-mères on recueille, après deux cristallisations dans le mélange éthanol–eau, l'oxime p.f. 104.5–105.5°, $[\alpha]_D = +107.8°$ ($c = 2.5$; benzène). Trouvé: C, 72.70; H, 10.51; N, 7.68%.

Chacune de ces oximes (500 mg), chauffée pendant 4 heures à reflux avec 20 ml d'une solution aqueuse d'acide oxalique à 20%, donne du (+)-homoépicamphre. Les spectres infrarouges des deux oximes sont identiques, quant aux nombres d'onde des bandes; on remarque toutefois de légères différences dans les intensités des bandes situées à 873, 1007 et 1320 cm^{-1}.

1.2. *Triméthyl-5,8,8 amino-2β bicyclo[3.2.1]octane* (II, $R=NH_2$)

Une solution de 40 g d'oxime d'homoépicamphre ($[\alpha]_D^{23} = +137.5°$) dans 250 ml d'acide acétique glacial fraîchement distillé est agitée en atmosphère d'hydrogène, à pression ordinaire, en présence de 900 mg d'oxyde de platine. Au bout de 18 heures, on filtre et neutralise le filtrat par NaOH aqueux 20%. On épuise par de l'éther, extrait la solution éthérée par HCl aqueux 5%; on neutralise la solution aqueuse et extrait par de l'éther; on lave la couche éthérée jusqu'à neutralité, évapore et recueille 33.3 g d'amine brute solide.

Picrate.—Les 33.3 g d'amine brute sont dissous dans 700 ml d'éthanol; à cette solution bouillante on ajoute une solution bouillante d'acide picrique (45.6 g dans 600 ml d'éthanol). Le picrate cristallise lentement: rendement 54.5 g (69%), p.f. 253–254°, $[\alpha]_D = +30.0°$ ($c = 3.54$; DMF). Un échantillon pour l'analyse présente les constantes suivantes, après cristallisation dans le mélange DMF–méthanol 1–30: p.f. 253–254°, $[\alpha]_D = +30.7°$ ($c = 3.6$; DMF). Calculé pour $C_{17}H_{24}O_7N_4$: C, 51.51; H, 6.10; N, 14.13%. Trouvé: C, 51.41; H, 6.31; N, 14.18%. On peut obtenir jusqu'à 90% de picrate $[\alpha]_D = +30.4°$. Le rendement stérique de la réduction est donc supérieur à 90%.

Amine libre.—On traite 11.0 g du picrate par NaOH aqueux 5% (excès 100%). On extrait par de l'éther, lave à l'eau, sèche et évapore l'éther. L'amine fond à 162°, $[\alpha]_D = +61.0°$ ($c = 1.0$; EtOH 95%). Chromatographie ascendante, papier Whatman No. 1, toluène – acide acétique – eau 50–3–47, développement à la ninhydrine: tache rouge, R_f 0.88.

p-Nitrobenzamide.—Préparé par l'action du chlorure de *p*-nitrobenzoyle sur l'amine libre dans du benzène. Fines aiguilles (MeOH–eau), p.f. 125°, $[\alpha]_D^{25} = +86.4°$ ($c = 1.0$;

[7]*Les points de fusion (p.f.) ont été déterminés dans des tubes capillaires, dans un bloc chauffé électriquement et en utilisant un thermomètre étalonné avec les standards du Bureau des Standards de Washington. Les spectres infrarouges ont été mesurés à l'aide d'un spectromètre "Perkin–Elmer", modèle 21, prisme* NaCl. *Les analyses sont de M. W. Manser, Herrliberg, Suisse. Les pouvoirs rotatoires* $[\alpha]_D$ *sont à* $\pm 2°$ *près, température 23–25°. DMF = diméthylformamide.*

$CHCl_3$). Calculé pour $C_{18}H_{24}N_2O_3$: C, 68.33; H, 7.65; N, 8.85%. Trouvé: C, 68.25; H, 7.69; N, 8.92%.

1.3. Triméthyl-5,8,8 amino-2α bicyclo[3.2.1]octane (III, R=NH_2)

À une solution de 24 g d'oxime d'homoépicamphre ($[\alpha]_D^{23}$ = +137.8°) dans 1500 ml d'éthanol anhydre on ajoute 92 g de sodium, en 15 minutes, par portions de 5 g. Après l'addition on chauffe à l'ébullition à reflux pendant 30 minutes. Le tout est refroidi à 25° et dilué par un égal volume d'eau. On épuise par de l'éther et isole, comme en *1.2*, 18 g d'amine brute.

Picrate (voir section 1.2).—Dix-huit grammes d'amine brute dans 50 ml d'éthanol et 25 g d'acide picrique dans 45 ml d'éthanol donnent 30 g de picrate. Après cinq cristallisations dans le mélange DMF–méthanol (1:30) le picrate fond à 263–265° (décomposition), $[\alpha]_D$ = +22.5° (*c* = 2.9; DMF). Calculé pour $C_{17}H_{24}O_7N_4$: C, 51.51; H, 6.10; N, 14.13%. Trouvé: C, 51.42; H, 6.17; N, 14.23%.

Amine libre (voir section 1.2).—Le picrate (13 g) est traité à la manière décrite en *1.2*; l'amine fond à 83–84°, $[\alpha]_D$ = +25.4° (*c* = 1.5; EtOH 95%). R_f 0.79, tache brune (conditions expérimentales, voir section *1.2*).

p-Nitrobenzamide (voir section 1.2).—Fines aiguilles (EtOH–eau), p.f. 188–190°, $[\alpha]_D^{23}$ = +35.1° (*c* = 3.0; $CHCl_3$). Calculé pour $C_{18}H_{24}N_2O_3$: C, 68.33; H, 7.65; N, 8.85%. Trouvé: C, 68.23; H, 7.64; N, 8.78%.

2. Réaction de Tschugaeff

2.1. Triméthyl-5,8,8 bicyclo[3.2.1]octyl-2α xanthogénate de méthyle

Méthode de Tschugaeff (13). Dix grammes de triméthyl-5,8,8 bicyclo[3.2.1]octanol-2 (III, R=OH) (59.4 mmoles) dans 25 g de toluène anhydre sont chauffés à reflux pendant 20 heures avec 1.5 g de sodium (65 mmoles). La solution de l'alcoolate est ensuite décantée dans 100 ml d'éther anhydre et traitée par 5.0 g de sulfure de carbone (66 mmoles). Le xanthogénate de sodium qui précipite immédiatement est essoré et lavé à l'éther; il est repris dans un mélange de 100 ml d'éther et de 20 ml de méthanol et chauffé à reflux pendant 5 heures en présence de 9.6 g d'iodure de méthyle (67.5 mmoles). On lave le mélange réactionnel à l'eau, on sèche la phase éthérée sur sulfate de sodium anhydre et distille l'éther: on recueille 14.8 g de résidu; huile légèrement jaune qui, à froid, abandonne de grosses aiguilles. Le xanthogénate a été recristallisé dans de l'éthanol aqueux jusqu'à indice de rotation constant: p.f. 48.5–49.5°, $[\alpha]_D^{23}$ = +82.2° (*c* = 1.33; benzène), rendement 11.0 g (72%). Calculé pour $C_{13}H_{22}OS_2$: C, 60.39; H, 8.58; S, 24.81%. Trouvé: C, 60.30; H, 8.52; S, 24.97%.

2.2. Pyrolyse du xanthogénate

Sept grammes de xanthogénate (décrit en section *2.1*) sont chauffés à pression ordinaire dans un appareil à sublimation jusqu'à 220° (température du bain d'huile). Le produit de cette pyrolyse est sublimé quatre fois, afin de compléter la décomposition du xanthogénate qui contamine l'hydrocarbure isolé. On retrouve ainsi 2.0 g (49%) d'un solide blanc, $[\alpha]_D$ = +6.9° (*c* = 2.7; chloroforme). Ce composé est repris dans 25 ml d'éther de pétrole, et fixé sur une colonne d'alumine de 60 g préparée dans le même solvant. Une première élution par 150 ml d'éther de pétrole donne 1.75 g de triméthyl-5,8,8 bicyclo-[3.2.1]octène-2 pur (43% de la théorie); il faut l'isoler par distillation lente du solvant sous une colonne de Widmer et évaporation finale sous vide à froid; $[\alpha]_D$ = +7.0° (*c* = 1.8; chloroforme), p.f. 143.5–145° (tube scellé). Spectre infrarouge (nujol): Bande forte à 3030 cm^{-1} (C=C—H); bande faible à 1647 cm^{-1} (double liaison C=C); bande très forte à 710 cm^{-1}; bande forte à 680 cm^{-1}. Calculé pour $C_{11}H_{18}$: C, 87.93; H, 12.08%. Trouvé: C, 87.87; H, 12.09%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

2.3. Ozonolyse du triméthyl-5,8,8 bicyclo[3.2.1]octène-2

(Adaptation des méthodes (14, 15, 16).) Une solution de 425 mg de l'alcène décrit en section *2.2*, dans 25 ml d'éther de pétrole, est refroidie dans un bain de CO_2 et d'acétone. Un courant d'oxygène de 300 ml par minute contenant 1.2% d'ozone est amené dans la solution; l'ozonide se dépose sous forme de solide blanc amorphe. Après 20 minutes, la couleur bleue qui apparaît indique la fin de la réaction. Le solvant est évaporé à froid par un jet d'air sec et l'ozonide (masse visqueuse) est agité pendant 18 heures en présence de 8 ml d'acide acétique glacial, 8 ml d'éther, 2 ml d'eau et 500 mg de zinc en poudre.

Après l'hydrolyse, le zinc en excès et l'acétate de zinc sont essorés et lavés à l'éther; les produits organiques dans le filtrat sont isolés par addition d'eau et décantation de la phase éthérée. Après séchage sur sulfate de sodium anhydre, l'éther est éliminé par distillation lente sous une colonne de Widmer.

Le résidu aldéhydique de cette évaporation, qui contient un peu d'acide acétique, est repris dans 25 ml d'acétone; 700 mg de permanganate de potassium pulvérisé sont ajoutés à la solution bien agitée, par petites portions, à température ambiante. Après 30 minutes d'agitation, l'excès d'oxydant est détruit par 5 ml d'acide chlorhydrique aqueux 5% et quelques cristaux de bisulfite de sodium. Le bioxyde de manganèse est essoré et lavé à l'éther; l'acide β-homocamphorique brut (454 mg) est isolé du filtrat par deux lavages à la soude caustique aqueuse 5%, acidification (HCl 10%) de cette solution alcaline et réextraction par de l'éther. Après cristallisation dans l'eau on retrouve 327 mg d'acide (54% de rendement qui fond à 244–245°, $[\alpha]_D = +21.5°$ ($c = 1.8$; éthanol 95%). Une seconde recristallisation dans 3 ml de nitrobenzène (rendement de 88%) donne un échantillon d'acide qui apparaît sous la forme de fines aiguilles. P.f. 246–246.5°, $[\alpha]_D = +22.0°$ ($c = 3.1$; éthanol 95%). Calculé pour $C_{11}H_{18}O_4$: C, 61.66; H, 8.47%. Trouvé: C, 61.64; H, 8.41%.

Cet acide ne donne pas de dépression de point de fusion en mélange avec l'acide β-homocamphorique, p.f. 245.5–246.5°, $[\alpha]_D = +22.5°$ ($c = 3.5$; éthanol 95%), obtenu dans ce laboratoire d'après le mode de synthèse de Salmon-Legagneur (6). Cet auteur indique dans son mémoire: $[\alpha]_D^{18} = +27.2°$ ($c = 2.2$; éthanol), p.f. 220–222°.

2.4. Calcination du β-homocamphorate de plomb

Par la méthode de Salmon-Legagneur (6), 514 mg d'acide β-homocamphorique obtenu par ozonolyse en section *2.3* donnent un mélange d'un liquide brun et d'un solide qui est soumis à un entraînement à la vapeur d'eau: 194 mg d'un solide blanc sont entraînés. Ce solide est repris dans 15 ml d'éther de pétrole, fixé sur une colonne d'alumine de 10 g; on élue par 200 ml du même solvant: cette première fraction contient 40 mg d'un solide blanc non étudié. Une seconde élution par 100 ml d'un mélange d'éther éthylique et d'éther de pétrole (1:3) fournit 120 mg d'épicamphre (34% de rendement). Après une sublimation à pression ordinaire à 100° on retrouve 83 mg (23.4%) d'épicamphre, $[\alpha]_D = -55.2°$ ($c = 0.8$; benzène), p.f. 181–183°. Une deuxième sublimation donne un échantillon d'épicamphre; $[\alpha]_D = -57.4°$ ($c = 0.6$; benzène). Le spectre infrarouge (en solution dans CCl_4) montre une bande carbonyle à 1750 cm^{-1}. Salmon-Legagneur (6) donne p.f. 182°, $[\alpha]_D^{23} = -57.5°$ ($c = 3.6$; benzène).

3. Réaction d'Hofmann

3.1. Chlorhydrate de triméthyl-5,8,8 diméthylamino-2β bicyclo[3.2.1]octane
(II, $R = N(CH_3)_2.HCl$)

On dissout 9.64 g (57.6 mmoles) de triméthyl-5,8,8 amino-2β bicyclo[3.2.1]octane (préparé selon section *1.2*) dans 44 ml d'acide formique 98%; on chauffe à reflux pendant 2.5 heures avec 47 ml d'une solution aqueuse de formaldéhyde à 37% et 96 ml d'eau.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Le mélange réactionnel est ensuite refroidi dans un bain de glace et neutralisé par de la soude caustique aqueuse 10% (400 ml). La solution légèrement alcaline est épuisée deux fois par de l'éther; ces phases éthérées sont réunies et lavées trois fois à l'eau, puis par deux portions de 100 ml d'HCl aqueux à 5%. On obtient ainsi une fraction A (HCl aqueux) et une fraction B (éther).

Étude de la fraction A.—Par évaporation sous vide on recueille 7.036 g de chlorhydrate de triméthyl-5,8,8 diméthylamino-2β bicyclo[3.2.1]octane (II, R=$N(CH_3)_2$.HCl). Après deux recristallisations, (MeOH–éther) on obtient 1.71 g de fines aiguilles blanches, p.f. 267° (décomp.), $[\alpha]_D = +39.2°$ ($c = 2.14$; éthanol 95%). Calculé pour $C_{13}H_{26}NCl$: C, 67.36; H, 11.31; N, 6.05%. Trouvé: C, 67.22; H, 11.22; N, 6.08%.

Étude de la fraction B.—L'éther est lavé avec du carbonate de sodium aqueux à 5%, puis deux fois à l'eau et enfin séché sur sulfate de sodium anhydre. On isole, par distillation de l'éther à travers une colonne de Widmer, 4.757 g d'un solide blanc. Cette fraction neutre, qui montre dans son spectre infrarouge des bandes à 1712 cm^{-1} et 1623 cm^{-1}, n'a pas été étudiée.

3.2. Picrate du triméthyl-5,8,8 diméthylamino-2β bicyclo[3.2.1]octane

La mise en contact d'un échantillon du chlorhydrate de l'amine tertiaire obtenu en section *3.1* avec NaOH aqueux 5% en excès a donné l'amine tertiaire libre (liquide à odeur d'amine). Le picrate de cette base préparé comme en section *1.2* et recristallisé dans un mélange de méthanol et de DMF fondait à 168–169°, $[\alpha]_D = +27.4°$ ($c = 1.81$; DMF). Calculé pour $C_{19}H_{28}O_7N_4$: C, 53.76; H, 6.65; N, 13.20%. Trouvé: C, 53.68; H, 6.58; N, 13.30%.

3.3. Iodure de (triméthyl-5,8,8 bicyclo[3.2.1]octyl-2β) triméthyl ammonium quaternaire

L'amine tertiaire (686 mg; 3.52 mmoles) (isolée du chlorhydrate comme en section *3.2*) est dissoute dans 15 ml d'acétone et abandonnée en présence de 10 ml d'iodure de méthyle à température ambiante pendant 15 heures. L'iodure se dépose à l'état pur en grosses paillettes blanches allongées, p.f. 232° (décomp.), $[\alpha]_D = -16.2°$ ($c = 2.66$; méthanol). Rendement: 861 mg soit 73% de la théorie.

3.4. Triméthyl-5,8,8 bicyclo[3.2.1]octène-2 (IV)

À une solution de 1.00 g (2.95 mmoles) de l'iodure (préparé en section *3.3* ci-dessus) dans 50 ml d'eau on ajoute 1.73 g d'oxyde d'argent fraîchement précipité. Après 24 heures d'agitation à la température de la pièce, le mélange est filtré sur de la terre de diatomées et le filtrat est évaporé sous 11 mm à 60° (température du bain). L'hydroxyde du triméthyl-5,8,8 bicyclo[3.2.1]octyl-2β triméthyl ammonium obtenu de cette évaporation est chauffé à 150° dans un ballon de 200 ml surmonté d'un réfrigérant pendant 30 minutes. L'alcène solide, qui s'est déposé au bas du réfrigérant est repris par de l'éther de pétrole. La phase organique est lavée avec HCl aqueux 2%, avec du carbonate de sodium aqueux à 2% et à l'eau, puis séchée sur sulfate de sodium. La distillation lente du solvant à travers une colonne de Widmer abandonne 367 mg de triméthyl-5,8,8 bicyclo[3.2.1]-octène-2 (83% de rendement).

Une sublimation à 100° à pression ordinaire donne 292 mg d'alcène pur, p.f. 144°, $[\alpha]_D = +7.04°$ ($c = 6.45$; chloroforme). Le spectre infrarouge de cet échantillon est identique à celui du même alcène obtenu en section *2.2*. Calculé pour $C_{11}H_{18}$: C, 87.93; H, 12.08%. Trouvé: C, 87.89; H, 12.14%.

4. (+)-Triméthyl-1,8,8 bicyclo[3.2.1]octane (VII)

4.1. Hydrogénation du triméthyl-5,8,8 bicyclo[3.2.1]octène-2

À 438 mg de triméthyl-5,8,8 bicyclo[3.2.1]octène-2 en solution dans 15 ml d'éthanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

95% on ajoute 500 mg de nickel de Raney. Après 2 heures d'hydrogénation à pression ordinaire, 77 ml d'hydrogène sont fixés (calculé 74.6 ml; 743 mm, 23°). Le catalyseur est essoré et le produit de réduction précipité du filtrat par addition d'eau. Le triméthyl-1,8,8 bicyclo[3.2.1]octane (VII) est repris par de l'éther de pétrole. L'évaporation du solvant sous une colonne de Widmer (rendement 286 mg) et une sublimation à pression ordinaire, à 100°, conduisent à l'hydrocarbure, p.f. 168.5–169.5° (tube scellé), $[\alpha]_D$ = +20.3° (c = 1.5; chloroforme). Calculé pour $C_{11}H_{20}$: C, 86.67; H, 13.32%. Trouvé: C, 86.65; H, 13.15%.

4.2. Triméthyl-5,8,8 éthylène-thio-acétal-2 bicyclo[3.2.1]octane
(I, R=—S—CH_2—CH_2—S—)

On refroidit à 0° un mélange de 6.5 g (42 mmoles) de (+)-homoépicamphre et de 4.4 g (47 mmoles) d'éthanedithiol dans un ballon de 50 ml. On y fait passer un courant de HCl sec pendant 2 heures. L'excès d'acide chlorhydrique est éliminé en plaçant le ballon dans un dessicateur contenant des pastilles d'hydroxyde de sodium, et dans lequel on maintient une pression de 11 mm. On agite ensuite le mélange avec une solution aqueuse de soude caustique à 2%, on sèche sur sulfate de sodium anhydre et distille. On recueille 8.39 g (rendement de 83%) de thio-acétal p. éb. 125° sous 0.7 mm, n_D = 1.5642. Calculé pour $C_{13}H_{22}S_2$: S, 26.05%. Trouvé: 26.21%.

4.3. Hydrogénolyse du thio-acétal

On chauffe à l'ébullition à reflux une solution de 0.543 g du thio-acétal décrit en section *4.2* dans 35 ml de dioxanne en présence de 15 g de nickel Raney saturé d'hydrogène. Ce catalyseur fut préparé selon les indications de Mozingo *et al.* (17). Temps de chauffage: 12 heures. La réduction terminée, on essore le catalyseur et précipite le triméthyl-1,8,8 bicyclo[3.2.1]octane (VII) du filtrat par addition d'eau. Après essorage et sublimation, cet hydrocarbure présente les constantes suivantes: p.f. 163–164°, $[\alpha]_D$ = +15.5° (c = 2.75; EtOH 95%). Calculé pour $C_{11}H_{20}$: C, 86.67; H, 13.32%. Trouvé: C, 86.76; H, 13.24%.

REMERCIEMENTS

Nous remercions le Conseil National de Recherches du Canada de son aide financière (subvention de recherche, H.F., et bourse d'étude, J.M.L.) et l'Office de Recherches Scientifiques de la Province de Québec d'une bourse d'études, J.M.B. Nous remercions aussi la Maison Ayerst, McKenna et Harrison, Produits Pharmaceutiques, Montréal, de son aide financière.

SYNTHESIS OF SYMMETRICAL AND UNSYMMETRICAL DIALKYLPHOSPHINOUS CHLORIDES[1]

J. L. FERRON

ABSTRACT

A series of compounds with the generalized formula RR'PCl have been obtained by the metal (antimony or zinc) reduction of $[RR'PCl_2]^+[AlCl_4]^-$. The yields of symmetrical and unsymmetrical dialkylphosphinous chlorides obtained by this method are superior to those obtained in previous syntheses.

INTRODUCTION

The original synthesis of symmetrical dialkylphosphinous chlorides (R = C_2H_5, *i*-C_3H_7, *i*-C_4H_9) has been the pyrolysis of R_3PCl_2 (1),

$$R_3PCl_2 \xrightarrow{\text{heat}} R_2PCl + RCl.$$

The diethyl analogue has also been obtained in 38% yield by the action of lead tetraethyl upon ethylphosphonous dichloride (2),

$$C_2H_5PCl_2 + (C_2H_5)_4Pb \rightarrow (C_2H_5)_2PCl + (C_2H_5)_3PbCl.$$

The complex resulting from alkyl chlorides, phosphorus trichloride, and aluminum chloride was first prepared by Clay (3) and formulated as

$$RCl + PCl_3 + AlCl_3 \rightarrow [RPCl_3]^+ [AlCl_4]^-.$$

The above complexes have been used in these laboratories for the preparation of alkylphosphonous dichlorides (4). These dichlorides have been obtained in good yield when the aluminum chloride complex is dissolved in a high-boiling electron-donating solvent such as diethyl phthalate (DEP) and reduced with antimony powder. The diethyl phthalate apparently forms a more stable complex with the aluminum chloride and the liberated $RPCl_4$ is then reduced by the antimony powder as follows:

$$[RPCl_3]^+[AlCl_4]^- + DEP \rightarrow [DEP][AlCl_3] + RPCl_4$$

$$3RPCl_4 + 2Sb \rightarrow 3RPCl_2 + 2SbCl_3.$$

Since then Ivin and Karavanov (5) have shown that alkylphosphonous dichlorides react with aluminum chloride in an analogous fashion,

$$RPCl_2 + AlCl_3 + R'Cl \rightarrow [RR'PCl_2][AlCl_4],$$

and it occurred to us that the reduction of this complex might provide a simple and direct route to dialkylphosphinous chlorides. The reduction of a DEP solution of these aluminum chloride complexes by zinc dust at room temperature or by antimony powder at 75–80° C has provided dialkylphosphinous chlorides in yields of 60–73%.

EXPERIMENTAL

Apparatus

The apparatus used is shown in the figure and allows dialkylphosphinous chlorides to be prepared and distilled without coming in contact with air. The 10/30 Standard

[1]*Manuscript received December 19, 1960.*
Contribution from the Chemistry Section, Suffield Experimental Station, Ralston, Alberta. Work carried out under Defence Research Board Project No. D52-20-20-20. This paper constitutes Suffield Technical Paper No. 206.

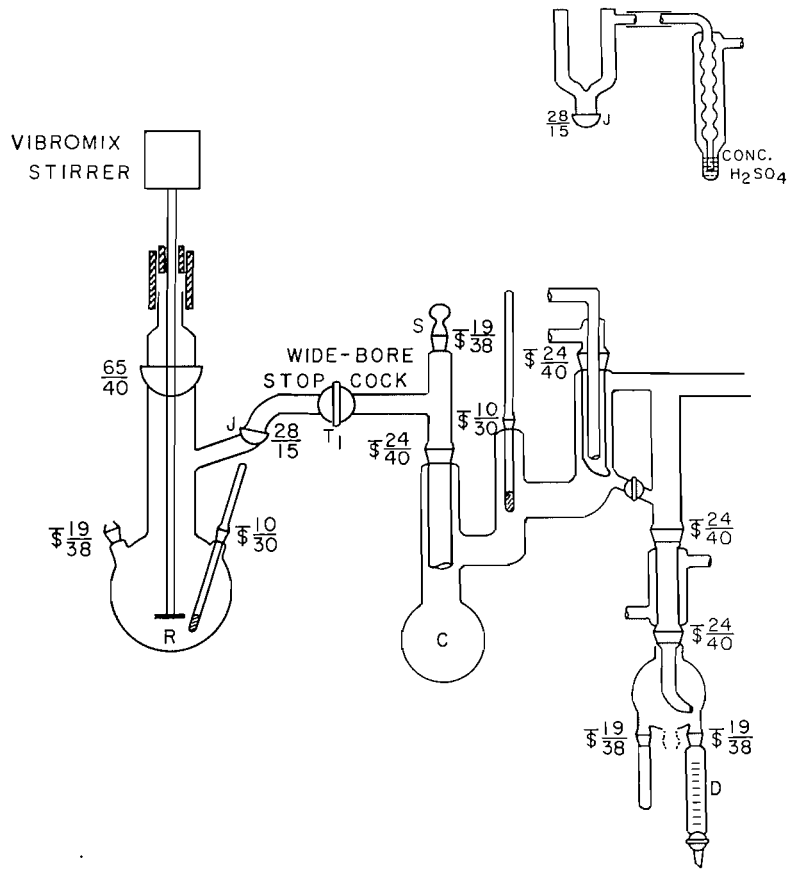

FIG. 1. Apparatus for the preparation of dialkylphosphinous chlorides.

Taper joint carries a thermometer and the 19/38 joint can be used for fitting an inlet tube, a dropping funnel, a bleed for distillations under reduced pressure, or for adding the powdered metal for the reduction. The 28/15 ball joint, J, accommodates the dry ice condenser (upper right of figure) during methyl chloride addition, or a water-cooled condenser during the addition of less volatile alkyl chlorides, as well as the distillation unit shown in the figure. Complexes described under (*a*) and (*b*) were formed in a pressure bottle and transferred into the flask R under a stream of dry N_2; those described under (*c*) and (*d*) were formed at atmospheric pressure directly in the reaction vessel R. All reactions were carried out under a dry N_2 atmosphere.

Reagents

All the reagents were of Reagent Grade and were used as supplied from the manufacturers without further purification. Antimony in lump form was ground in a mortar, pulverized in a ball mill, and sieved through a 250 mesh sieve immediately prior to use.

(*a*) *Preparation of Chloromethyl-methylphosphinous Chloride* $(ClCH_2)(CH_3)PCl$

Aluminum chloride (100 g, 0.75 mole) was weighed directly into a pressure bottle and cooled in a dry ice–acetone mixture. To the cold contents were then added chloromethylphosphonous dichloride (113.8 g, 0.75 mole) and liquid methyl chloride (40 ml,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

0.80 mole). The bottle was stoppered and left standing at room temperature for 16 hours by which time the mixture had turned solid except for a small liquid layer in the bottom of the container. The contents were then heated at 100–102° C for a further 72 hours. After cooling in dry ice–acetone mixture the bottle was opened, the solid broken into pieces and transferred into the reaction flask R under a stream of dry N_2. Diethyl phthalate (DEP) (500 ml) was then added and violent stirring maintained until the solid had completely dissolved. The solution was then degassed under reduced pressure (water vacuum) while the temperature was gradually raised to 60° C. After the solution was cooled to room temperature, dry N_2 was admitted into the system, a dry ice–acetone cooling mixture placed under the receiver C, the wide-bore isolation stopcock closed, and the system evacuated to 0.1–0.5 mm. Finely powdered antimony (60.9 g, 0.5 mole) was added all at once through a Standard Taper joint, a bleed inserted, and the suspension vigorously stirred. The reaction flask R was rapidly evacuated by opening the wide-bore stopcock. The reduction of the complex by antimony was exothermic and the temperature rose slowly from 33° C to 49° C while the chloromethyl-methylphosphinous chloride distilled over into the distillation flask C. When the evolution of heat had stopped, the temperature of the solution was brought up to 80–85° C with the help of a heating mantle and maintained in that range for ½ hour. After all the dialkylphosphinous chloride had been collected, dry N_2 was admitted into the system, a bleed inserted in place of the stopper S, the isolation stopcock closed, and the product redistilled under reduced pressure, and the main fraction collected in one of the receivers. The yield of $(ClCH_2)(CH_3)PCl$ (b.p. 59° C/9 mm) was 72 g (73%). Most of the dialkylphosphinous chlorides are very reactive and cannot be handled readily in an open atmosphere. Analyses are thus cumbersome to perform and most of the compounds prepared have been identified by the formation of derivatives. $(ClCH_2)(CH_3)PCl$ was reacted with sulphur and the chloromethyl-methylthionophosphonic chloride analyzed. Calculated for $(ClCH_2)(CH_3)P(S)Cl$: C, 14.73%; H, 3.10%. Found: C, 14.84%; H, 3.20%.

(b) Preparation of Dimethylphosphinous Chloride $(CH_3)_2PCl$

This compound was prepared on a 0.75 mole scale by mixing in the cold methylphosphonous dichloride, aluminum chloride, and methyl chloride in a pressure bottle and shaking the mixture at room temperature. The complex formed readily and after transfer of the solid into the flask R and solution in DEP, the reduction by antimony (60.9 g, 0.50 mole) at 85–90° C gave 43.7 g (60%) of dimethylphosphinous chloride (b.p. 72–74° C/697 mm). The oxygen addition compound was analyzed for identification purposes. Calculated for $(CH_3)_2P(O)Cl$: C, 21.35%; H, 5.38%. Found: C, 21.33%; H, 5.33%.

(c) Preparation of Isopropyl-methylphosphinous Chloride $(i\text{-}C_3H_7)(CH_3)PCl$

For this preparation the reaction flask R was fitted with a dropping funnel in the 19/38 Standard Taper joint and the dry-ice condenser on the 28/15 ball joint J. Aluminum chloride (66.7 g, 0.5 mole) was placed in the reaction flask and isopropylphosphonous dichloride (73.0 g, 0.5 mole) was added dropwise while stirring violently. The addition was exothermic and the aluminum chloride dissolved completely. The solution was cooled to room temperature and the dropping funnel replaced by an inlet tube extending below the surface of the liquid. Slow addition of gaseous methyl chloride was started while the temperature of the reaction mixture was kept below 45° C by intermittent immersion of the flask in a cold-water bath. The addition of methyl chloride was stopped after the reaction was completed as evidenced by a fast reflux rate of methyl chloride on the dry ice condenser. The addition was complete in approximately 1½ hours. After

cooling to room temperature, the complex was dissolved in DEP (300 ml), degassed under reduced pressure, and the reduction carried out in the usual way using a theoretical amount of freshly powdered antimony (40.5 g, 0.33 mole). The yield of isopropylmethylphosphinous chloride (b.p. 82–85° C/208 mm) was 44.0 g (65.5%).

(d) Preparation of Diisopropylphosphinous Chloride (i-$C_3H_7)_2PCl$

Aluminum chloride (68.5 g, 0.51 mole) was placed in the flask R and isopropylphosphonous dichloride (74.8 g, 0.52 mole) added dropwise, the temperature being kept below 30° C by occasional immersion in a dry ice–acetone cooling bath. After the aluminum chloride had dissolved, isopropyl chloride (40.5 g, 0.51 mole) was added dropwise maintaining the temperature below 30° C. After about two-thirds of the isopropyl chloride had been added, the reaction mixture became very viscous and stirring became inefficient. The addition of isopropyl chloride was stopped, methylene chloride (50 ml) was added after which the addition of isopropyl chloride was resumed. This addition could be carried out rapidly as no appreciable heat was evolved. Once the addition was completed, the solution was heated to reflux for 1 hour, cooled to room temperature, DEP (300 ml) added with stirring, and the solution degassed in the usual way. After degassing, zinc dust (32 g, 0.51 mole) was added and the suspension heated to 45° C. An exothermic reaction set in, the heating source was removed and the reaction mixture reached a temperature of 78° C. The liquid collected in flask C was then redistilled, giving a yield of 51.2 g (67.2%) of product (b.p. 69° C/697 mm).

ACKNOWLEDGMENTS

The author is indebted to Mr. S. A. Gibbens for his technical assistance on the project, and to Mr. T. Stewart for the microanalytical work.

Thanks are due to the Chairman, Defence Research Board for kind permission to publish these results.

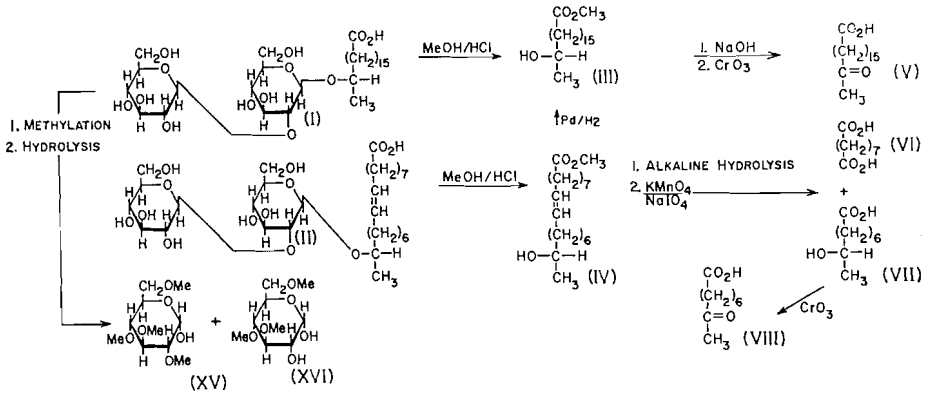
HYDROXY FATTY ACID GLYCOSIDES OF SOPHOROSE FROM TORULOPSIS MAGNOLIAE[1]

P. A. J. GORIN, J. F. T. SPENCER, AND A. P. TULLOCH

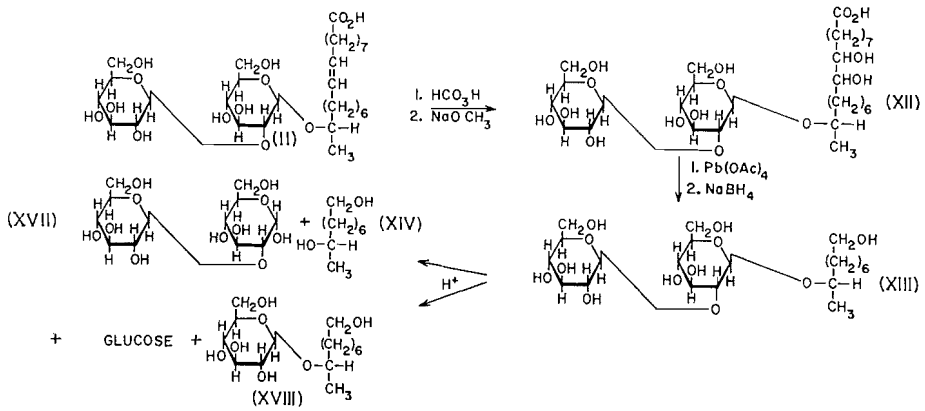
ABSTRACT

The oil formed during fermentation by a strain of *Torulopsis magnoliae* consisted mainly of partly acetylated 2-*O*-β-D-glucopyranosyl-D-glucopyranose units attached β-glycosidically to 17-L-hydroxyoctadecanoic and 17-L-hydroxy-9-octadecenoic acids.



A strain of osmophilic yeast, *Torulopsis magnoliae*, isolated from sow thistle petals, was found to produce (1) an extracellular, heavier than water oil. The main components of the oil are now shown to be glycolipids (I and II) consisting of 2-*O*-β-D-glucopyranosyl-D-glucopyranose units linked β-glycosidically to 17-L-hydroxyoctadecanoic and 17-L-hydroxy-9-octadecenoic acids, the sugar moieties being partly acetylated.

The oil was labile both to acid and alkali. Hot methanolic sodium methoxide removed the acetyl groups, which constituted about 1.5 substituent groups per mole (the positions of these substituents were not determined). The deacetylated product, after fractionation, yielded a solid (I and II),which contained almost equal quantities of lactonic and acidic glycolipids, and it was on this mixture that the characterization studies of the sugar portion were carried out.



Acid methanolysis of the deacetylated oil yielded 2 moles of methyl-α-D-glucopyranoside and 1 mole of a mixture of fatty acid methyl esters. Gas – liquid phase chromatography of the esters on a silicone column showed one principal peak at the C_{20} saturated position with a shoulder suggesting partial resolution of saturated and unsaturated esters (2). However, on a butanediol succinate column (3) no peaks appeared after 2 hours (normal emergence time for a C_{20} ester was 30 minutes). The properties suggested that the major compounds present were C_{18} esters containing a polar substituent, such as a hydroxyl group (4) and the presence of the latter group was confirmed by infrared spectroscopy. From the quantity of permanganate–periodate reagent (5) consumed, the mixture was shown to contain 65% of monoolefinic ester. Fractional crystallization of the methyl esters also yielded 65% unsaturated and 35% saturated ester. However, later fermentations contained only about 10% of the saturated material. Catalytic hydrogenation showed that the unsaturated C_{18} ester (IV) contained one double bond and the product obtained was identical with the saturated C_{18} component (III). The position of the hydroxyl group in these compounds was shown to be at C_{17}, by the formation of 17-oxostearic acid (V) when the saturated acid was oxidized with chromium trioxide. An authentic specimen of V was synthesized by the method of Bergström *et al.* (6) from 15-bromopentadecanoic acid. The latter was prepared from 15-hydroxypentadecanoic acid which was in turn obtained from the 15,16-dihydroxypalmitic acid described by Lemieux (7).

The unsaturated component (IV) was shown to be 17-hydroxy-9-octadecenoic acid methyl ester since the acid on oxidation with permanganate–periodate (5) yielded azelaic

FIGS. 1*a* and 1*b*. Degradation of sophorosides of 17-hydroxyoctadecanoic and 17-hydroxy-9-octadecenoic acids.

(VI) and 8-hydroxy-pelargonic acids (VII). These oxidation products could not be separated by crystallization and an attempt to separate the mixture of monomethyl azelate and hydroxy acid obtained by oxidation of the methyl ester in aqueous tertiary butanol (8) was also unsuccessful. Dimethyl azelate and methyl hydroxypelargonate were not well resolved by gas chromatography on a silicone column but conversion to the corresponding *n*-butyl esters gave a mixture which was easily separated preparatively. Oxidation of sirupy 8-hydroxypelargonic acid gave crystalline 8-oxopelargonic acid (VIII) with the same melting point as that reported by Barger *et al.* (9) for the synthetic acid. The double bond (IV) was considered to have the cis configuration as the infrared spectrum had no band in the 10.36 μ region (10).

The asymmetric center at carbon-17 has been provisionally assigned the L-configuration since the specific rotation of 17-hydroxyoctadecanoic acid was +4.4°. Assuming that the carboxyl group at the end of a long methylene chain has no more effect on the specific rotation than a methyl group the saturated C_{18} hydroxy acid can be regarded as a D-carbinol (IX) of which all known members of the type depicted are dextrorotatory (XI) (11). When the structure is written as (X) it has the L-configuration according to the usual rules of nomenclature (12). Further the acid might be expected to have the

For personal use only.

same configuration as synthetic 12-L-hydroxyoctadecanoic acid ($[\alpha]_D$ +0.8°) (13) as the sign of rotation is the same.

15-D-16-Dihydroxy- and 2-D-15-D-16-trihydroxyhexadecanoic acids isolated from ustilagic acid also possess a hydroxyl group on the penultimate carbon atom and all

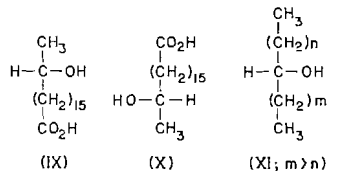

FIG. 2. Hydroxyl configuration in 17-L-hydroxydecanoic acid when regarded as an alcohol.

the optical centers were assigned the D-configuration (7), otherwise acids hydroxylated in this position do not seem to have been found in nature. For saturated acids the common positions for hydroxyl substitution are C_2, C_9, C_{10}, and the terminal carbon atom (14). Only two hydroxy monoenoic C_{18} acids have been reported, 12-hydroxy-9-octadecenoic acid, the major component of castor oil (14), and also occurring in ergot oil (15), which has been assigned the D-configuration (13), and 9-hydroxy-12-octadecenoic acid which is found in the seed fat of *Strophanthus* species (16).

To characterize the linkage types and configurations of the glycosidic linkages in the two disaccharide-C_{18} hydroxy acid glycolipids (I and II) it was necessary to separate them. Since fractionation was difficult the unsaturated portion was modified by oxidation. Treatment of the mixture with performic acid, followed by alkaline hydrolysis, gave *threo*-9,10-dihydroxy derivatives (XII) which were then oxidized by lead tetraacetate in acetic acid. The uptake of oxidant was almost immediate and indicated that 30% of the mixture was olefinic.* The resulting aldehydes were reduced with sodium borohydride, mainly to ω-hydroxypelargonic acid and a crystalline nonanediol sophoroside (XIII). These components were readily separable from the water-insoluble solid containing the 17-hydroxyoctadecanoic acid sophoroside (I). Complete acid hydrolysis of the nonanediol sophoroside yielded glucose and syrupy 1,8-nonanediol (XIV) from which a crystalline bis-*p*-nitrobenzoate was derived. The specific rotation of the diol was positive (+6.5°) indicating an L-hydroxy configuration (11) thus agreeing with the L-configuration already assigned to 17-hydroxy-9-octadecenoic acid. Complete methylation of the nonanediol sophoroside followed by acid hydrolysis gave equimolar amounts of 2,3,4,6-tetra-*O*-methyl-D-glucose (XV) and 3,4,6-tri-*O*-methyl-D-glucose (XVI), which would be expected from two glucose units linked 1,2-glycosidically. Partial acid hydrolysis of nonanediol sophoroside furnished a mixture, from which sophorose (XVII; 2-*O*-β-D-glucopyranosyl-D-glucose) and 1,8-L-nonanediol-β-D-glucopyranoside (XVIII) were isolated by cellulose chromatography (17). The negative rotation of the glycoside indicated a β-configuration for the glucose – fatty acid linkage, as well as that of the glucose-to-glucose linkage. This agrees with the observation that the nonanediol sophoroside was totally hydrolyzed by emulsin, a β-glucosidase.

The amorphous material containing mainly 17-hydroxyoctadecanoic acid sophoroside (I) was similarly methylated and hydrolyzed to yield equimolar amounts of 2,3,4,6-tetra-*O*-methyl-D-glucose (XV), 3,4,6-tri-*O*-methyl-D-glucose (XVI), and 17-L-hydroxyoctadecanoic acid. Although this evidence showed an analogous structure to the 17-L-hydroxy-9-octadecenoic acid sophoroside, the sodium salt was not hydrolyzed by emulsin.

**Since the proportion of unsaturated acid in the solid glycolipid is much less than in the parent oil (65%) it was evident that fractionation had taken place during isolation.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

However, Pigman and Richtmyer (18) note that the effect of emulsin on *n*-alkyl glucosides begins to decrease when the alcoholic aglycones have more than seven carbon atoms. The molecular rotations of the 17-hydroxyoctadecanoic acid (−14,200°, sodium salt) and 1,8-nonanediol sophorosides (−14,500°) agree closely and point to the likelihood that all the glucosidic linkages present are of the β-type.

The 2-*O*-β-D-glucopyranosyl-D-glucopyranose disaccharide unit is a unique structure in microbial metabolites. However, polysaccharides consisting of 1,2-β-D-glucopyranose units are known to be formed by various species of agrobacteria (19, 20, 21). The glycolipid molecule is similar in over-all structure to the ustilagic acids of Haskins (22) characterized by Lemieux *et al.* (7, and references cited therein) as partly acylated β-cellobiosides of 15-D-16-dihydroxyhexadecanoic and 2-D-15-D-16-trihydroxyhexadecanoic acids. Also similar is the acidic glycolipid formed by *Pseudomonas aeruginosa* which was isolated and identified by Jarvis and Johnson (23). This compound consists of a 3-*O*-L-rhamnopyranosyl-L-rhamnopyranose moiety attached glycosidically to a dimeric form of 3-D-hydroxydecanoic acid.

EXPERIMENTAL

Evaporations were carried out under reduced pressure using a bath temperature of 50° C. Optical rotations were measured at 26° C.

Method of Oil Production

The osmophilic yeast, obtained from the petal portion of a sow thistle, was shown to be a strain of *Torulopsis magnoliae* by carbon assimilation tests (1), and was designated strain N_1c.

The medium used consisted of glucose (20%), yeast extract (1.25%), and urea (0.2%) and was agitated at 385 r.p.m. for 8–10 days with an air flow rate of 500 ml/min, and incubated at 30° C in 5-l. New Brunswick fermentors (3-l. working volume). The maximum yield of the oil was about 5% of the volume of the medium and was recovered by allowing it to stand in a separatory funnel until it all settled out.

The aqueous portion of the solution was shown to contain D-mannitol, which is a common product of *Torulopsis magnoliae*, and this was obtained by crystallization of the evaporated residue from methanol. It had m.p. and mixed m.p. 166–167° C.

Deacetylation of the Oil

The oil (240 g), which contained a considerable proportion of water, was dissolved in 10 volumes of ethyl acetate. The solution was dried with $MgSO_4$, filtered, and evaporated to a yellow-brown viscous acidic syrup (148 g); C, 57.2%; H, 8.2%. It was shown to contain C—H, O—H, and carbonyl groups by infrared analysis. When saponified with alkali in aqueous ethanol it had a sap. equiv. of 226. The hydrolyzate was acidified and distilled to give acetic acid (10.2% of oil by weight).

The purified oil (115 g) was dissolved in refluxing methanol (2 l.) and sodium metal was added until the solution became alkaline. Refluxing was continued for 30 minutes, then the solution was evaporated to a syrup and the methanol distillate, which contained the methyl ester of the acetic acid, was collected in a dry-ice trap. Potassium hydroxide (1 g) dissolved in water (5 ml) was added to part of the methanol distillate and refluxed for 2 hours; after the methanol was taken off the residue was diluted with water and made just acid to phenol red by addition of hydrochloric acid. This solution was allowed to react with S-benzyl thiouronium chloride and gave S-benzyl thiouronium acetate, m.p. 131–134° C, which was not depressed by an authentic sample.

For personal use only.

The deacetylated syrup was dissolved in water and acidified with formic acid. A gelatinous precipitate formed and after storage of the liquid at 3° C for a week it was filtered off, washed with cold water, and dried *in vacuo*. The light brown powder (44 g) had m.p. 137–139° C and analyzed as a hexose disaccharide attached glycosidically to a C_{18} hydroxy fatty acid. Roughly half of the material appeared to be in a lactonic form. Calculated for the saturated acid glycoside $C_{30}H_{56}O_{13}$: C, 57.6%; H, 9.0%; sap. equiv., 624. Found: C, 58.2%; H, 8.9%; sap. equiv., 652; neutral equiv., 1213.

Acid Hydrolysis of the Deacetylated Oil

The deacetylated syrup was refluxed with a large excess of 4% methanolic hydrogen chloride for 18 hours, then diluted with water and the fatty acid esters extracted with chloroform. The aqueous layer was neutralized (silver carbonate), filtered, and concentrated to a syrup which on crystallization from ethanol gave methyl-α-D-glucopyranoside, m.p. and mixed m.p. 166–167° C and $[\alpha]_D$ +160° (*c*, 1.0, H_2O).

Gas–liquid chromatography of the crude methyl ester on 1:6 silicone on Celite in a 6 ft×$\frac{1}{4}$ in. copper column at 235° C suggested the presence of 75% saturated and unsaturated hydroxy C_{18} esters. On oxidation with permanganate–periodate the crude acid, obtained by saponification, consumed 2.6 moles of oxidant corresponding to 65% of unsaturated esters.

17-Hydroxystearic Acid

A solution of the crude fatty acid methyl esters (15.62 g) in petroleum (b.p. 60–80° C) (225 ml) was stored at +2° C for 2 days and a crystalline product (3.97 g) was obtained. This solid was distilled, b.p./0.08 mm 180° C (bath), and repeatedly crystallized from petroleum (b.p. 60–80° C) but did not yield a completely pure ester. Saponification, isolation of the acid, and crystallization from acetone gave 17-hydroxystearic acid, m.p. 78–80° C. Calculated for $C_{18}H_{36}O_3$: C, 71.9%; H, 12.1%; neutral equiv., 300.5. Found: C, 71.8%; H, 11.95%; neutral equiv., 298; $[\alpha]_D$ +4.4° (*c*, 7.9, CH_3COOH). Methyl-17-hydroxystearate was prepared from the acid with diazomethane and crystallized from petroleum (b.p. 60–80° C) as platelets, m.p. 51–53° C. Calculated for $C_{19}H_{38}O_3$: C, 72.6%; H, 12.2%. Found: C, 72.2%; H, 12.1%; $[\alpha]_D$ +4.6° (*c*, 7.3, MeOH).

17-Hydroxy-cis-9-octadecenoic Acid

The solvent was removed from part of the mother liquors of the first crystallization of the crude saturated ester and the residue distilled, b.p./0.1 mm 150° C. After saponification a further small quantity of saturated acid was removed by crystallization from petroleum (b.p. 60–80° C) containing 8% acetone at 0° C and crystallization at −20° C gave almost pure unsaturated acid, m.p. 5° C. Distillation gave the pure acid as a colorless viscous oil, b.p./0.04 mm 160° C (bath). Calculated for $C_{18}H_{34}O_3$: C, 72.4%; H, 11.5%. Found: C, 72.35%; H, 11.3%; $[\alpha]_D$ +4.3° (*c*, 6.1, MeOH). There was no absorption band in the 10.36 μ region of the infrared spectrum. The methyl ester was prepared and had b.p./0.04 mm 145° C (bath). Calculated for $C_{19}H_{36}O_3$: C, 73.0%; H, 11.6%. Found: C, 72.8%; H, 11.5%; $[\alpha]_D$ +3.5° (*c*, 6.5, MeOH).

Hydrogenation of Methyl-17-hydroxy cis-9-Octadecenoate

The crude unsaturated ester (4.95 g) was recovered from the solvent remaining after crystallization of the saturated ester and was hydrogenated in ethanol (60 ml) in the presence of 5% palladium on charcoal (0.5 g). The volume of hydrogen absorbed at N.T.P. was 293 ml; calculated for the reduction of one double bond 353 ml. 17-Hydroxystearic acid was obtained on saponification and crystallized from acetone, m.p. 78.5–80.5° C,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

mixed m.p. with natural saturated acid was 78–80° C. Calculated for $C_{18}H_{36}O_3$: C, 71.9%; H, 12.1%; neutral equiv., 300.5. Found: C, 71.8%; H, 11.95%; neutral equiv., 300; $[\alpha]_D$ +4.1° (*c*, 10.0, CH_3COOH). The derived methyl ester had a melting point of 50.5–51.5° C and the mixed melting point with natural saturated ester was 50.5–52.5° C. Calculated for $C_{19}H_{38}O_3$: C, 72.6%; H, 12.2%. Found: C, 72.4%; H, 12.0%; $[\alpha]_D$ +4.2° (*c*, 9.5, MeOH).

17-Oxostearic Acid

A solution of chromic oxide (2.4 g) in water (5 ml) was diluted with glacial acetic acid (25 ml) and added portionwise to a solution of 17-hydroxystearic acid (8.0 g), prepared by hydrogenation of the unsaturated ester, in acetic acid (80 ml) maintained at room temperature. After 30 minutes the mixture was poured into water (500 ml), the excess oxidant was reduced with sulphur dioxide and the product (6.8 g) was collected, washed, and dried. Crystallization from ethanol gave the pure acid, m.p. 86–87.5° C. Calculated for $C_{18}H_{34}O_3$: C, 72.4%; H, 11.5%. Found: C, 72.2%; H, 11.35%. The acid gave a positive iodoform test. A mixed melting point with 15-oxostearic acid (24) (m.p. 83° C) was depressed to 76–85° C. The melting point was not depressed by synthetic 17-oxostearic acid (m.p. 86.5–87.5° C) and the X-ray powder photographs were indistinguishable. The methyl ester was prepared and crystallized from petroleum as leaflets, m.p. 55–57.3° C, undepressed by admixture with the synthetic ester of m.p. 54.5–56.5° C. Calculated for $C_{19}H_{36}O_3$: C, 73.0%; H, 11.6%. Found: C, 72.9%; H, 11.5%. The infrared spectra and the X-ray powder photographs of the synthetic and natural esters were indistinguishable. 17-Oxostearic acid was similarly prepared from the naturally saturated acid and did not depress the melting point of the above oxo acid.

Oxidation of 17-Hydroxy-cis-9-octadecenoic Acid

The acid (1.73 g) was dissolved in 2% potassium carbonate solution (200 ml) and added all at once to the stock oxidant solution (400 ml, containing 20.86 g sodium metaperiodate and 0.4 g potassium permanganate per liter (5)) diluted with water (1400 ml) and shaken for 4 hours. The excess oxidant was destroyed with sodium metabisulphite, the mixture acidified with sulphuric acid, and the products extracted with ether and the ether removed without drying leaving the mixture of acids (1.88 g). The mixture was taken up in ethyl acetate (10 ml) when part of the azelaic acid (0.25 g) crystallized, recrystallization from the same solvent gave the pure dicarboxylic acid, m.p. 104–107° C undepressed when mixed with authentic azelaic acid. After removing the ethyl acetate the remaining acids were converted to the *n*-butyl esters by 4 hours' reflux with excess *n*-butanol containing 4% HCl. The butyl 8-hydroxypelargonate was separated from the dibutyl azelate by gas chromatography of 100-mg batches using 1:6 silicone on Celite (60–80 mesh) in a 6 ft×¼ in. copper column. The apparatus was operated at 200° C with injector at 225° C, and a flow rate of 75 ml of helium per minute. The *n*-butyl 8-hydroxypelargonate was distilled, b.p./0.05 mm 115° C (bath). Calculated for $C_{13}H_{26}O_3$: C, 67.8%; H, 11.4%. Found: C, 67.2%; H, 11.3%; $[\alpha]_D$ +4.8° (*c*, 6.8, MeOH). Alkaline hydrolysis of this ester yielded 8-hydroxypelargonic acid as a colorless syrup, b.p./0.04 mm 110° C (bath); $[\alpha]_D$ +6.7° (*c*, 10.1, MeOH). Calculated for $C_9H_{18}O_3$: C, 62.0%; H, 10.4%. Found: C, 62.1%; H, 10.3%. Oxidation of the acid with chromic oxide in the same way as for 17-hydroxystearic acid gave 8-oxopelargonic acid, m.p. 41–42° C (lit. (9) gives m.p. 40–41° C). Calculated for $C_9H_{16}O_3$: C, 62.8%; H, 9.4%. Found: C, 62.9%; H, 9.4%. The semicarbazone crystallized from aqueous methanol and had a melting point of 136.5–138.5° C (lit. (10) gives m.p. 136° C).

Hydroxylation of the Solid Glycolipid Mixture (I and II)

The mixed glycosides (44 g) were dissolved in formic acid (120 cc) and then 30% hydrogen peroxide (10 cc) added. After storage at 0° C for 18 hours the solution was evaporated to a dry crust which was then dissolved in refluxing methanol (1 l.). Sodium metal was added until the solution became alkaline and after 30 minutes the solvent was removed by evaporation. The solid was then dissolved in water and cations removed by shaking with Amberlite IR-120. Precipitation of glycosides on the resin took place, but redissolution was effected by adding an excess of methanol. Filtration and evaporation afforded a crusty light-yellow solid (39.5 g) containing unaffected glycoside and its *threo*-dihydroxy counterparts.

The amount of olefin in the original glycoside mixture was then estimated by lead tetraacetate oxidation of the hydroxylated product. The solid (100 mg) was dissolved in acetic acid (5 cc) and to this solution 1% lead tetraacetate (10 cc) was added. The uptake of oxidant after 3, 10, and 25 minutes corresponded to oxidation equivalents, based on 1 molar uptake of lead tetraacetate, of 2260, 2140, and 1940 respectively indicating 30% of olefinic glycoside.

Isolation of 17-Hydroxyoctadecanoic Acid β-Sophoroside, 1,8-Nonanediol β-Sophoroside, and ω-Hydroxypelargonic Acid

The mixed dihydroxy- and unhydroxylated 17-hydroxy-octadecanoic acid sophorosides (23 g) containing 30% of the former was dissolved in acetic acid (250 cc). Lead tetraacetate (13 mM.) in acetic acid (500 cc) was added and after 30 minutes oxalic acid dihydrate (13 mM.) in acetic acid (50 cc) was added and the precipitate filtered off. Evaporation to a residue and addition of water gave a solution from which 17-hydroxyoctadecanoic acid β-sophoroside precipitated. This material was isolated, dried, and boiled in ether to remove fatty acid fragments. It (11.1 g) had a melting point of 139–140° C and $[\alpha]_D$ −22° (*c*, 1.3, aqueous $NaHCO_3$). Calculated for $C_{30}H_{56}O_{13}$: C, 57.6%; H, 9.0%; sap. equiv., 624. Found: C, 57.7%; H, 9.0%; sap. equiv., 566; neutral equiv., 1050. The product was methanolyzed with 4% methanolic hydrogen chloride overnight under reflux. The methyl ester, obtained by neutralization (Ag_2CO_3), filtration, and evaporation, consisted mainly of the C_{18} ester with traces of other hydroxy methyl esters as shown by gas – liquid phase chromatography.

The mother liquor of the above glycoside precipitation was evaporated to a syrup and reduced with sodium borohydride (1.0 g) in water (100 cc). After 1 hour excess reductant was destroyed with acetic acid, cations removed with Amberlite IR-120, and the resulting filtrate evaporated to a crust. Boric acid was removed by repeated evaporation of the solid with methanol to give nonanediol β-sophoroside, which was recrystallized twice from ethanol to give material (3.2 g) with m.p. 188–190° C and $[\alpha]_D$ −30° (*c*, 1.0, H_2O). Calculated for $C_{21}H_{40}O_{12}$: C, 52.1%; H, 8.3%. Found: C, 51.9%; H, 8.3%.

In order to characterize the other fission fragment of the olefin 858 mg of the mixed hydroxylated glycosides was oxidized with lead tetraacetate in a similar manner to that described above, except that after filtration of the lead oxalate the filtrate was evaporated to a syrup to which sodium borohydride (250 mg) in water (25 cc) was added. After 1 hour the mixture was worked up and the product extracted with boiling ether to give a syrup (0.13 g) which crystallized. Two recrystallizations from ether afforded ω-hydroxypelargonic acid, m.p. and mixed m.p. 48–50° C. Calculated for $C_9H_{18}O_3$: C, 62.0%; H, 10.4%. Found: C, 62.1%; H, 10.1%. The material not extractable by ether was dissolved in methanol and precipitated by addition of excess water. Filtration

afforded a powder which gave on methanolysis (4% MeOH–HCl under reflux overnight) mainly two ether-soluble compounds corresponding to a C_{18} hydroxy methyl ester and an octadecanediol (by G.L.P.C.) thus indicating that reduction of a lactone had taken place.

Hydrolysis of 1,8-Nonanediol Sophoroside

The sophoroside (296 mg) was hydrolyzed by heating on a steam bath for 18 hours in *N* sulphuric acid (5 cc). The solution was neutralized ($BaCO_3$), filtered, and evaporated to a syrup which was extracted with boiling ether. Evaporation of the ether afforded the nonanediol (85 mg) with $[\alpha]_D$ +6.5° (*c*, 2.3, H_2O) and 40 mg of this was dissolved in pyridine (2 cc) containing *p*-nitrobenzoyl chloride (300 mg), and kept at 80° C for 30 minutes. To this an excess of aqueous sodium bicarbonate was added and after shaking for 2 hours the precipitate was collected, washed, and dried, and twice recrystallized from ethyl acetate – hexane. The 1,8-nonanediol bis-*p*-nitrobenzoate (93 mg) had a melting point of 94–96° C and $[\alpha]_D$ +21° (*c*, 2.1, $CHCl_3$). Calculated for $C_{23}H_{26}O_8N_2$: C, 60.3%; H, 5.7%; N, 6.1%. Found: C, 60.4%; H, 5.7%; N, 6.1%.

The residual glucose (233 mg) was crystallized from methanol to give crystals (168 mg) with m.p. and mixed m.p. 146–149° C.

Partial Hydrolysis of 1,8-Nonanediol Sophoroside

Nonanediol sophoroside (2.0 g) was partially hydrolyzed by keeping a solution in *N* sulphuric acid (10 cc) for 4 hours at 75° C. After neutralization ($BaCO_3$), filtration, and evaporation the residual syrup was chromatographed on a cellulose column using *n*-butanol one-half saturated with water as the mobile phase. The solvent eluted firstly 1,8-nonanediol β-D-glucopyranoside (396 mg), which was recrystallized twice from ethyl acetate to give material with m.p. 102–104° C and $[\alpha]_D$ −27° (*c*, 1.8, H_2O). Calculated for $C_{15}H_{30}O_7$: C, 55.9%; H, 9.4%. Found: C, 55.7%; H, 9.4%. This was followed by unhydrolyzed glycoside (670 mg) and glucose (396 mg), which were not positively identified. *n*-Butanol – ethanol – water (4:1:1 v/v) was then passed through the column to elute sophorose (163 mg), which after two crystallizations from methanol–ethanol, gave 80 mg of the α-anomer with m.p. 198–202° C (25) and $[\alpha]_D$ +27° → 19° (*c*, 0.9, H_2O; constant, 42 hours). Calculated for $C_{12}H_{22}O_{11}$: C, 42.1%; H, 6.5%. Found: C, 41.9%; H, 6.5%. Acetylation of the disaccharide gave the β-octaacetate with m.p. 192–195° C (25).

Methylation of 1,8-Nonanediol β-Sophoroside

Nonanediol sophoroside (647 mg) was methylated six times by the dimethyl sulphate – aqueous sodium hydroxide method (26). At the end of the methylation excess reagent was destroyed by heating the solution on a steam bath for 3 hours. It was then cooled and neutralized with aqueous sulphuric acid and then shaken three times with chloroform. The extract was dried ($MgSO_4$), filtered, and evaporated to a syrup (754 mg) which was methylated further with silver oxide – methyl iodide under reflux (27). The methylated product (623 mg) had —OCH_3: 39.1% (calculated for $C_{21}H_{32}O_4(OCH_3)_8$: OCH_3, 41.6%), n_D^{27} 1.4583 and $[\alpha]_D$ −4° (*c*, 2.6, hexane).

The fully methylated glycoside was refluxed overnight in 4% methanolic hydrogen chloride (20 cc) and then *N* hydrochloric acid (10 cc) was added and the methanolic component boiled off. After 20 hours heating on a steam bath the solution was shaken with hexane to remove 1-methoxy-8-nonanol (57 mg), which had n_D^{24} 1.4410 and $[\alpha]_D$ +8° (*c*, 1.9, hexane) after vacuum distillation. The aqueous portion was neutralized (Ag_2CO_3), filtered, and taken down to a syrup (443 mg) which was chromatographed

For personal use only.

on cellulose using benzene–ethanol–water (500:50:1 v/v) as solvent. 2,3,4,6-Tetra-*O*-methyl-D-glucose (164 mg) was eluted and recrystallized twice from hexane to give crystals, m.p. and mixed m.p. 80–81° C. Calculated for $C_6H_8O_2(OCH_3)_4$: OCH_3, 51.6%. Found: OCH_3, 51.4%. 3,4,6-Tri-*O*-methyl-D-glucose (144 mg) (28) came off later and two recrystallizations from ether–hexane gave 37 mg of product with m.p. 77–79° C and $[\alpha]_D$ +107° (3 minutes) → 75° (*c*, 0.9, H_2O; 16 hours, constant value). Calculated for $C_6H_9O_3(OCH_3)_3$: OCH_3, 41.9%. Found: OCH_3, 41.4%. On treatment with 1% lead tetraacetate in acetic acid (0.9 molar equivalents) the sugar consumed 0.24, 0.47, and 0.68 molar equivalents of oxidant after 3, 10, and 25 minutes respectively, thus indicating that the 1 and 2 positions of the sugar are not substituted with methoxyl groups (29).

Methylation of 17-Hydroxyoctadecanoic Acid β-Sophoroside

The glycoside (2 g) was methylated with dimethyl sulphate – sodium hydroxide and Purdie's reagent as described for the nonanediol sophoroside. The fully methylated product (1.94 g) n_D^{25} 1.4620 had OCH_3, 32.9%. Calculated for $C_{30}H_{28}O_5(OCH_3)_8$: OCH_3, 33.7%. The fully methylated glycoside was also hydrolyzed under similar conditions and the insoluble residue which accumulated was washed with water and hydrolyzed for 2 hours in 50% aqueous ethanol (20 cc) containing sodium hydroxide (0.5 g). The solution was added to excess water which was acidified (dil. H_2SO_4) and extracted with ether which was dried ($MgSO_4$), filtered, and evaporated to a solid (767 mg). Two recrystallizations from acetone gave 310 mg of 17-hydroxyoctadecanoic acid with m.p. 77–79° C and $[\alpha]_D$ +4.3° (*c*, 10.4, acetic acid). Calculated for $C_{18}H_{36}O_3$: C, 71.9%; H, 12.1%. Found: C, 71.6%; H, 12.0%. Two further recrystallizations from acetone elevated the melting point to 80.5–82° C (constant m.p.).

The aqueous portion of the hydrolyzate was neutralized and chromatographed on a cellulose column as described for the previous methylation. The products consisted of 2,3,4,6-tetra-*O*-methyl-D-glucose (0.43 g), which was crystallized twice from hexane to give a product, m.p. and mixed m.p. 79–80° C, and 3,4,6-tri-*O*-methyl-D-glucose (0.30 g), m.p. and mixed m.p. 77–80° C (two recrystallizations from ether – *n*-hexane).

ACKNOWLEDGMENTS

The authors wish to thank Mr. N. R. Gardner, Mr. L. L. Hoffman, and Miss S. F. Lubin for technical assistance, Miss I. M. Gaffney for infrared measurements and X-ray diffraction diagrams, and Mr. M. Mazurek for microanalytical determinations.

DEUTERATION OF FLUORENE AT C_9 AND THE ASSIGNMENT OF CERTAIN BANDS IN THE INFRARED SPECTRUM TO THE $\rangle CDH$ AND $\rangle CD_2$ GROUPS[1]

G. W. H. Scherf and R. K. Brown

ABSTRACT

Equimolar amounts of 9-fluorenylpotassium and deuterium oxide, or potassium deuteroxide and fluorene, or potassium hydroxide, fluorene, and deuterium oxide gave a mixture of unchanged fluorene, 9-deuterofluorene, and 9,9-dideuterofluorene. In 1,2-dimethoxyethane (DME) deuteration occurs more readily and dideuteration is more extensive than in dioxane. Lithium deuteroxide and fluorene in DME show no exchange, but upon addition of deuterium oxide some monodeuteration occurs. 9-Fluorenyllithium and deuterium oxide in DME gives as much as 80% of 9-deuterofluorene accompanied by a small amount of dideuteration. Dideuteration is practically eliminated, and monodeuteration correspondingly increased when the same reaction is carried out in hexane.

The bands at 667 cm^{-1}, 827 cm^{-1}, and 974 cm^{-1} have been assigned definitely to the $\rangle CD_2$ group while those at 677 cm^{-1} and 832 cm^{-1} are due to the $\rangle CDH$ group in fluorene.

Recently six absorption bands in the infrared spectrum of fluorene have been assigned to the $\rangle CH_2$ group of that molecule (1). Evidence for such assignment was obtained from the study of the spectra of C_9-mono- and -di-alkylated as well as C_9-mono- and -di-deuterated fluorene. Mono- or di-deuteration at C_9 reduced or eliminated the absorption at the frequencies designated but in turn produced new bands at lower frequencies in the positions expected when a deuterium atom replaces an hydrogen atom attached to carbon (2). The new frequencies associated with the C_9—D bond were located at least tentatively, if not definitely, at 2150, 974, 939, 827, and 667 cm^{-1}, respectively. In addition, a band at 677 cm^{-1} was thought to be due to a vibration of the remaining C_9—H group in the monodeuterated molecule but shifted slightly from its normal frequency of

$$\begin{array}{c} | \\ \text{692 cm}^{-1} \text{ by the presence of the deuterium atom (i.e. DC—H). Also, the band at 939 cm}^{-1} \\ | \end{array}$$

was believed to contain a contribution due to the same structural feature.

For the work mentioned above, the 9-deuterofluorene was made by the reaction of excess deuterium oxide with 9-fluorenylpotassium in dioxane at room temperature. The 9,9-dideuterofluorene was prepared by similar addition of excess deuterium oxide to the substance formed when two equivalents of potassium metal reacted with one of fluorene in dioxane (1).

During a more detailed study of the preparation of 9-fluorenylpotassium in various solvents (3) the measurement of the extent of metalation by means of deuterating the organometallic compound (particularly with excess deuterium oxide) was shown to be questionable. It was observed that equimolar quantities of potassium deuteroxide and fluorene in dioxane, under anhydrous conditions, when kept at room temperature for 1 hour, gave 10 to 15% C_9-deuteration while equimolar amounts of potassium hydroxide,

fluorene, and deuterium oxide in dioxane at room temperature for 3 hours produced 5 to 8% C_9-deuteration.

In addition the "9-deuterofluorene" previously prepared was shown to be contaminated with a trace of fluorene and a larger amount of 9,9-dideuterofluorene attributed to exchange due to the presence of potassium deuteroxide and excess deuterium oxide (1). From the tentative assignment of the 677 cm^{-1} and 667 cm^{-1} bands to the structural group DC—H and HC—D, respectively, both these bands should appear in the spectrum of 9-deuterofluorene. However, in the spectrum of 9,9-dideuterofluorene the 677 cm^{-1} band should be absent and the band at 667 cm^{-1} should double its intensity. As actually observed from the spectra of the mono- and di-deuterated fluorenes (Figs. 2 and 3, ref. 1) the 677 cm^{-1} band did nearly vanish while that at 667 cm^{-1} increased considerably, although not to twice its original magnitude. From this information, along with data from N.M.R. analyses of the "9-deuterofluorene", the purity of the monodeuterated compound had been estimated to be about 75%, the bulk of the remainder being the dideuterated material. This was in keeping with the greater area of the 667 cm^{-1} band. Although the N.M.R. spectrum could be interpreted as containing a somewhat greater proportion of the dideuterated fluorene than stated above, the broad but low signal was sufficient to agree fairly well with the above assignments in the infrared. An implicit assumption in this reasoning is that the 677 cm^{-1} and 667 cm^{-1} bands due respectively to the DC—H and HC—D are of about equal intensity for equal concentrations.

Support or modifications of the interpretations outlined above would be gained from the preparation and examination of authentic C_9-monodeuterated fluorene, uncontaminated as much as possible by fluorene and especially by 9,9-dideuterofluorene.

This paper presents results of the study of C_9-mono- and -di-deuteration of fluorene and gives the exact assignment of certain bands in the infrared associated with 9-mono- and 9,9-di-deuterofluorene.

RESULTS AND DISCUSSION

Since 9-fluorenyllithium, prepared by the reaction of fluorene with lithium (or lithium amide) preferably in ethers of ethylene glycol (4), produced essentially C_9-monosubstituted fluorene when treated with an equivalent amount of alkyl halide (5), the lithium salt was thought to be the most promising substance for the production of 9-deuterofluorene. The addition of deuterium oxide to an equimolar portion of 9-fluorenyllithium prepared in 1,2-dimethoxyethane (DME) (4) gave a product whose spectrum is shown in Fig. 1. It is clearly seen that a strong band appears at 677 cm^{-1} while the one at 667 cm^{-1} is quite small. The bands at 692 cm^{-1}, 952 cm^{-1}, and 1400 cm^{-1} show that there is some unchanged fluorene present, roughly to the extent of 12%. The N.M.R. analysis of this compound* shows a signal for the proton at C_9 (Fig. 2*a*) which is nearly half that found for the proton at C_9 of the parent fluorene (Fig. 2*b*). The broadening of the signal in Fig. 2*a* is probably due to spin coupling of the proton with the deuterium atom. Both the infrared and N.M.R. spectra are in agreement with the interpretation that the substance contains a high percentage of 9-deuterofluorene. The band at 677 cm^{-1} is thus due to the group $\rangle$CDH while that at 667 cm^{-1} arises from the structural feature $\rangle CD_2$. The

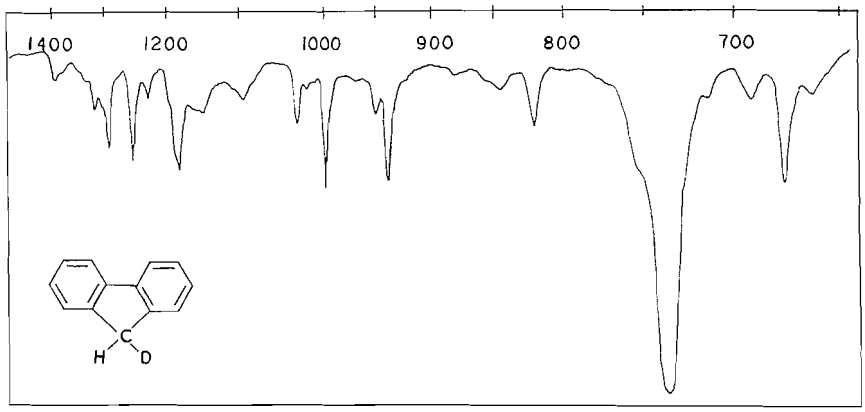

FIG. 1. I. R. spectrum in CS_2 of 9-deuterofluorene prepared from 9-fluorenyllithium and D_2O in 1,2-dimethoxyethane.

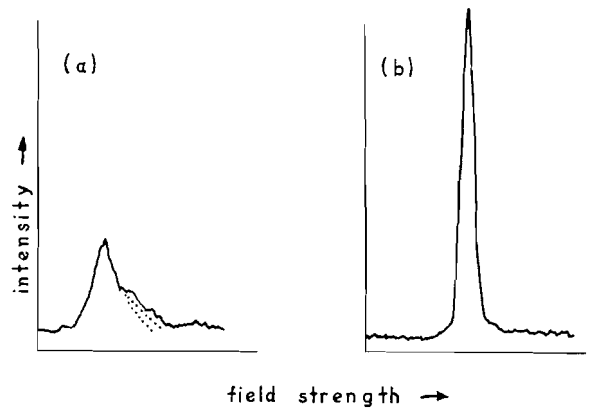

FIG. 2. Partial N.M.R. spectra showing only $\rangle$CHD and $\rangle CH_2$ bands of fluorene. (*a*) 9-Deuterofluorene. (*b*) Fluorene. The 9-deuterofluorene was prepared from 9-fluorenyllithium + D_2O in 1,2-dimethoxyethane.

product, described in the first paper of this series (1) and obtained from the reaction of 9-fluorenylpotassium with excess deuterium oxide in dioxane, therefore must have been composed of a mixture of C_9-mono- and -di-deuterated fluorene in the approximate ratio of 2 to 3. This mixture clearly contained a small amount of unchanged fluorene as a contaminant (Fig. 2, ref. 1).

Comparison of the spectrum of the 80% monodeuterated fluorene (Fig. 1, this paper) with that of the mixture of C_9-mono- and C_9-di-deuterated fluorene (Fig. 2, ref. 1) and 9,9-dideuterated fluorene (Fig. 3, ref. 1) shows that the band at 827 cm^{-1} is due to $\rangle CD_2$ while that at 823 cm^{-1} arises from the group $\rangle$CDH. The 974 cm^{-1} band, which appears much more clearly in the 9,9-dideuterofluorene and is nearly absent in the 80% 9-deuterofluorene, must then also be due to the structure $\rangle CD_2$ rather than to $\rangle$CDH. The band at 939 cm^{-1} appears in both C_9-mono- and C_9-di-deuterofluorene and is due to the carbon–deuterium bond in both $\rangle CD_2$ and $\rangle$CDH.

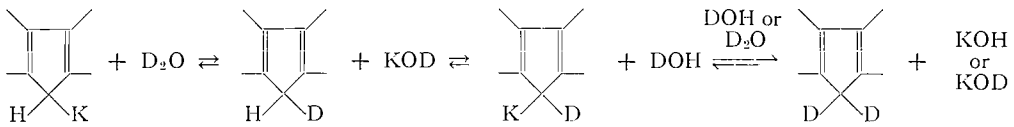
With the knowledge of the exact assignment of these bands due to $\rangle CD_2$, $\rangle CDH$, and $\rangle CH_2$ now available, some experiments on the deuteration of fluorene were carried out. The mixtures, conditions of reaction, and results are presented in Table I. The

TABLE I

Mono- and di-deuteration of fluorene



(Except where specified equivalent amounts of reagents were refluxed in 5 ml of solvent for 1 hour. DME = 1,2 dimethoxyethane)

§Made in DEE (4), isolated, and transferred to hexane.

yields of mono- and di-deuterated fluorene, and unchanged fluorene were estimated from the magnitude of the bands at 677 cm^{-1}, 667 cm^{-1}, and 692 (or 952) cm^{-1}, 667 cm^{-1}, and 692 (or 952) cm^{-1}, respectively.

It is clearly seen that 9-fluorenylpotassium, when treated with an equimolar amount of deuterium oxide, produced less unchanged fluorene and more dideuteration in DME than in dioxane. Such deuteration no doubt occurred via the sequence shown below:

Unchanged fluorene might have come from (*a*) incomplete metalation, (*b*) a small amount of water in the deuterium oxide, (*c*) a combination of 9-fluorenylpotassium with the water or deuterium hydroxide produced in the first part of the reaction. The more extensive dideuteration which occurred in the solvent DME agrees with the greater effectiveness of DME as a solvent in the preparation and reactions of 9-fluorenylpotassium (4, 5) due to the more effective solvation of the ether with potassium deuteroxide, enhancing the latter's basicity.

9-Fluorenyllithium in DME, on the other hand, gave largely C_9-*mono*deuteration accompanied by only a small proportion of dideuterated and unchanged fluorene. But with the solvent hexane rather than DME, dideuteration was practically eliminated and the extent of monodeuteration increased correspondingly (Fig. 3).

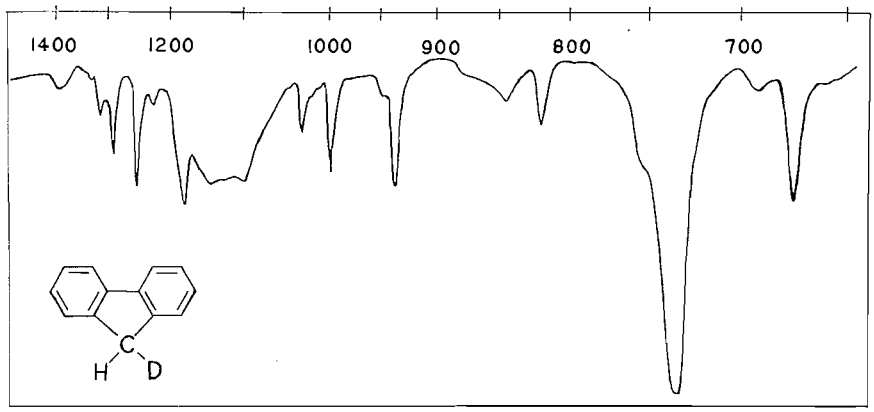

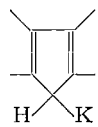

FIG. 3. I. R. spectrum in CS_2 of 9-deuterofluorene prepared from 9-fluorenyllithium and D_2O in hexane.

Potassium deuteroxide and fluorene in dioxane gave more extensive dideuteration than did a mixture of potassium hydroxide, fluorene, and deuterium oxide, in dioxane. This is probably due to the fact that in the reaction of potassium deuteroxide with fluorene, the products of the first step in the exchange,  + HOD, are in close proximity, thus facilitating the next step of exchange, whereas the product of the reaction of potassium hydroxide and fluorene requires time for collision with the solvated deuterium oxide. With DME as solvent, such differences appear to be minimized.

Lithium deuteroxide and fluorene failed to show any exchange, but when deuterium oxide was added, exchange did occur and increased in magnitude with the amount of deuterium oxide added. This agrees with the interpretation that lithium deuteroxide under anhydrous conditions is a much weaker base than is either potassium deuteroxide or sodium deuteroxide and hence will not initiate the first step of the reaction—that of transient formation of the 9-fluorenyllithium. The addition of deuterium oxide yields a solvent which promotes the ionization of lithium deuteroxide and enhances its basicity. Such a levelling effect of solvents has been observed before (6).

EXPERIMENTAL

The 9-fluorenyl-potassium, -sodium, and -lithium were made according to previous directions (1, 4).

Preparation of Potassium Deuteroxide and Lithium Deuteroxide

Into 100 ml of dry hexane was pipetted 1 ml of 98% D_2O. A piece of freshly cut potassium in excess of the amount required to react with all the D_2O was suspended on a length of wire and immersed in the hexane and cautiously allowed to touch the surface of the D_2O at the bottom of the flask and then was immediately withdrawn but not removed from the hexane. This "dipping" process was repeated until a coating of KOD was developed on the surface of the metal. The reaction was quite vigorous at first but soon moderated. The solid was allowed to remain overnight in the flask in contact with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

small amount of D_2O in the lower layer. The KOD was then removed from the metal and, following the elimination of hexane, was weighed for use.

LiOD was prepared by a similar manner but required somewhat longer contact with the traces of D_2O for complete reaction.

Deuteration Experiments

All reactions were carried out under the same conditions. A typical reaction is described.

Equimolar amounts of the reagents, KOD, fluorene, and D_2O (0.01 mole of each) were allowed to react for 1 hour in 5 ml of refluxing solvent. An atmosphere of pure, dry nitrogen was maintained throughout. The cooled solution was then treated with a mixture of ether and water. The ether extract, dried over calcium chloride, was freed from solvent and the solid crystallized from alcohol.

ACKNOWLEDGMENTS

The authors wish to thank the National Research Council of Canada for financial assistance which enabled this work to be carried out. Grateful acknowledgment is made to Dr. W. Schneider who kindly performed the N.M.R. analyses.

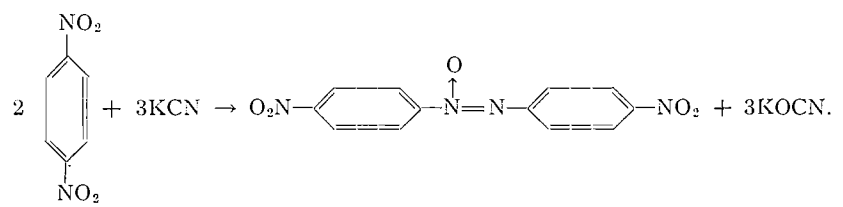
CONTRIBUTION À L'ÉTUDE DE LA RÉACTION DE VON RICHTER

IV. COMMENTAIRES CONCERNANT LA RÉACTION[1]

E. CULLEN[2] ET PH. L'ÉCUYER

RÉSUMÉ

Il existe une relation entre l'anhydride carbonique et les composés azoxyques formés au cours de la réaction. Ces composés azoxyques, dans la série du benzène, ne donnent pas les acides benzoïques attendus, lorsqu'ils sont soumis aux conditions de la réaction. Par contre, dans la série du naphtalène, les composés qui ont été isolés et dont la formule empirique correspond aux composés azoxyques attendus se transforment en acides naphtoïques. Enfin, le 2-nitro-5-chlorobenzonitrile ne produit pas de composé azoxyque, ni d'acide *m*-chlorobenzoïque.



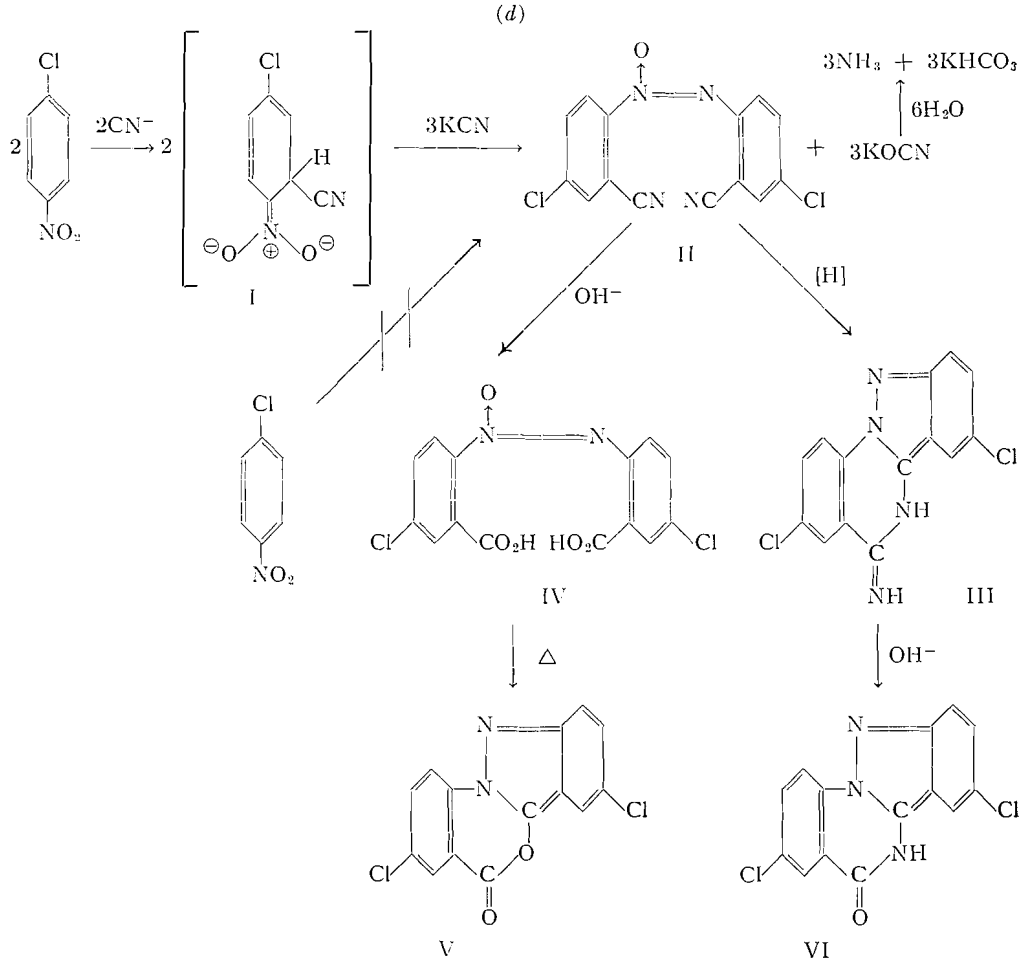
Durant la réaction de von Richter,[3] il se forme de l'ammoniac. Celui-ci peut provenir de l'hydrolyse de la fonction nitrile qui se fixe à l'anneau benzénique et d'une certaine quantité de cyanure ou de cyanate de potassium. L'hydrolyse du cyanure de potassium (*a*) est, toutefois, extrêmement lente à la température d'ébullition. Nous avons constaté que seulement 7% du cyanure s'hydrolyse en acide formique et en ammoniac, lorsqu'on fait bouillir à reflux pendant 48 heures une solution de cyanure de potassium dans l'éthanol à 50%.

$$KCN + 2H_2O \rightarrow HCO_2K + NH_3 \qquad (a)$$

En milieu aqueux, le cyanure de potassium s'oxyde en cyanate aux dépens d'un groupe nitré (1) et le cyanate s'hydrolyse ensuite en ammoniac et bicarbonate de potassium (*b*). Ainsi, dans la réduction du *p*-dinitrobenzène en 4,4′-dinitroazoxybenzène, le rendement du composé azoxyque est proportionnel à la quantité de cyanate qui se forme durant la réaction. Cependant en solution alcoolique, le rendement du composé azoxyque est beaucoup plus faible, le groupe nitré étant en majeure partie substitué par la fonction oxalcoyle. Durant la réaction de von Richter dans l'éthanol à 50%, il se forme aussi de l'anhydride carbonique. Nous l'avons dosé pour nous rendre compte de la proportion de la substance nitrée de départ qui est réduite de cette façon.

$$KCN \xrightarrow{[O]} KOCN \xrightarrow{2H_2O} NH_3 + KHCO_3 \qquad (b)$$

Après 4 heures d'ébullition à reflux dans le 2-éthoxyéthanol à 50%, il s'est formé pour 1 mole de *p*-chloronitrobenzène, 0.148 mole de gaz carbonique et 0.031 mole de 3,8-dichloro-6-iminoquinazolo[1,2,2′,3′]indazol (III) (2). D'après la quantité d'anhydride carbonique dégagé, il aurait dû théoriquement s'être formé 0.049 mole du composé azoxyque II, si on se réfère à (*c*):



(*c*)

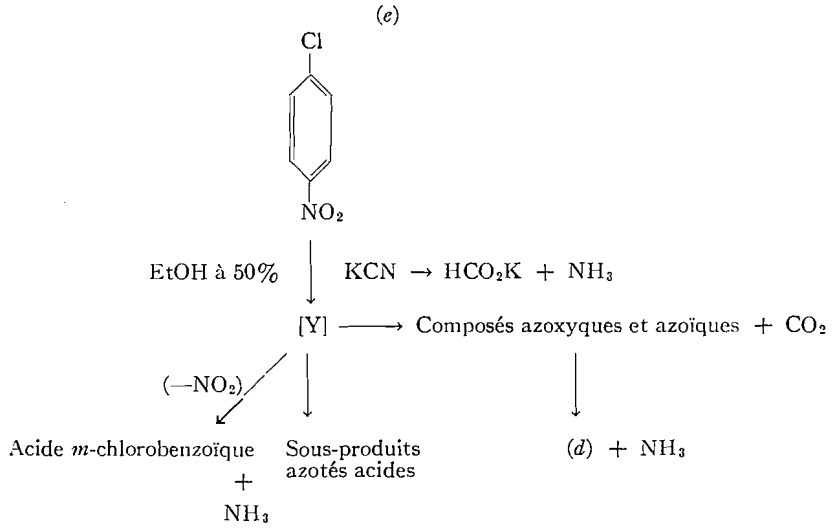
[3]*Consulter la référence 8 pour la bibliographie des mémoires antérieurs concernant cette réaction.*

La différence de 0.018 mole peut provenir d'une part, de l'hydrolyse d'une certaine quantité du composé azoxyque II en l'acide correspondant IV, qui par sublimation se transforme en la lactone de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque (V), et d'autre part, de l'hydrolyse partielle du produit neutre III en 3,8-dichloro-6-cétoquinazolo[1,2,2′,3′]indazol (VI) (3).

La formation de la substance neutre III qui dépend de celle du 4,4′-dichloro-2,2′-dicyanoazoxybenzène (II) (ou du dicarbamyle correspondant), est ainsi, d'après les résultats précédents, indirectement reliée à celle du cyanate et partant de l'anhydride carbonique (*d*).



Nous avons aussi dosé l'ammoniac qui se dégage au cours de la réaction du *p*-chloronitrobenzène avec le cyanure de potassium dans l'éthanol à 50% ou le 2-éthoxyéthanol à 50%. Dans l'un ou l'autre solvant, la quantité d'ammoniac dégagé correspond à environ 75% de la substance nitrée de départ, les corrections étant faites pour l'apport de l'ammoniac attribuable aux réactions secondaires (*a*) et (*b*).

Ces réactions secondaires enlèvent à la réaction de von Richter toute valeur synthétique, parce qu'une réaction d'oxydo–réduction entre le groupe nitré et le cyanure de potassium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

accompagne la fixation du groupement nitrile au noyau aromatique. En nous basant sur les observations précédentes et d'autres faites jusqu'ici concernant cette réaction, nous pouvons déduire que celle-ci, en plus de donner naissance à un acide dans lequel le groupe nitré est éliminé, engendre divers composés azotés plus ou moins réduits selon les transformations indiquées en (*e*), Y représentant un intermédiaire.

Excepté l'acide 4,4′-dichloroazoxybenzène-2,2′-dicarboxylique qui se transforme en la lactone de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque, les sous-produits acides (80% du total) ne se subliment pas. Ceci porte à croire que la majeure partie des substances à caractère acide qui accompagnent l'acide *m*-chlorobenzoïque dans le produit de la réaction ne sont pas des dérivés réduits azoïques, azoxyques, hydrazoïques, indazylbenzoïques ou anthraniliques; car ceux-ci sont tous sublimables.

Dans le but d'observer si un intermédiaire s'accumule durant la réaction, nous avons déterminé la quantité des principales substances qui se trouvent dans le produit de la réaction après une ébullition plus ou moins prolongée des réactifs. Nous présentons au Tableau I les résultats de cette série d'expériences.

Après 2 heures d'ébullition à reflux d'une solution de 0.01 mole de *p*-chloronitrobenzène et de 0.1 mole de cyanure de potassium dans le tétrahydrofurfurol à 50%, tout le *p*-chloronitrobenzène est disparu et le poids des acides bruts ne varie plus, quel que soit le temps de chauffage. Cependant, l'acide *m*-chlorobenzoïque continue de se former lentement pendant encore plusieurs heures au détriment, semble-t-il, des autres produits acides, car le poids de ces derniers diminue proportionnellement à celui de l'acide *m*-chlorobenzoïque qui se forme. De 2 heures à 48 heures, le rendement de l'acide *m*-chlorobenzoïque augmente de 6% alors que celui du résidu acide diminue de 5%. Pendant le même temps, le pourcentage du produit neutre, le 3,8-dichloro-6-iminoquinazolo[1,2,2′,3′]indazol (V), décroît aussi après avoir atteint un maximum. C'est qu'il s'hydrolyse très lentement dans le milieu réactionnel en 3,8-dichloro-6-cétoquinazolo[1,2,2′,3′]indazol (VI) (2).

Rauhut et Bunnett ont observé qu'une solution alcoolique diluée de *m*-nitroanisole et de cyanure de sodium donne du 4,4′-diméthoxy-2,2′-dicarbamylazoxybenzène sans acide *m*-anisique, lorsqu'elle est bouillie à reflux (4), mais qu'elle produit 3% d'acide anisique en plus d'un composé neutre non-identifié, lorsqu'elle est chauffée en tube scellé,

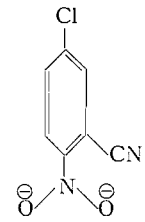
*6-Iminoquinazolo[1,2,2′,3′]indazol.

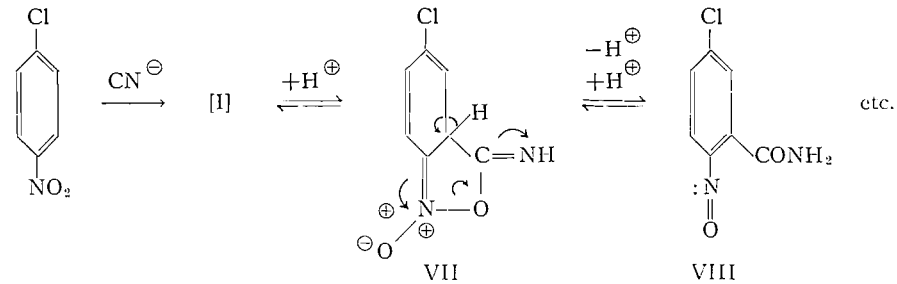
à 180° (5). Ceci laisse supposer que le 4,4′-diméthoxy-2,2′-dicarbamylazoxybenzène peut se transformer en acide *m*-anisique en présence de cyanure de sodium; mais, nous avons vérifié que cela ne se produit dans l'éthanol aqueux, ni à l'ébullition dans le glycol à 50%, ni en tube scellé à 180°. Lorsqu'il est bouilli à reflux dans le méthanol avec de l'hydroxyde de potassium, le 4,4′-diméthoxy-2,2′-dicarbamylazoxybenzène se transforme en acide 4,4′-diméthoxybenzène-2,2′-dicarboxylique et non en acide *m*-anisique (4).

Soumis aux conditions de la réaction de von Richter, l'acide 4,4′-dichloroazoxybenzène-2,2′-dicarboxylique ne subit aucune transformation (5); le 2,2′-dicyanoazoxybenzène donne du 6-iminoquinazolo[1,2,2′,3′]indazol, mais non de l'acide benzoïque (2); le 2-nitro-4-chlorobenzonitrile ne fournit pas d'acide *p*-chlorobenzoïque (6) et nous avons constaté que l'acide 2-nitro-5-chlorobenzoïque, le 2-nitro-5-chlorobenzonitrile et la 2-nitro-5-chlorobenzamide n'engendrent ni l'acide *m*-chlorobenzoïque, ni aucun des produits azoxyques que fournit normalement la réaction. Ceux-ci sont donc formés au cours de la réaction par la réduction de l'intermédiaire dihydroaromatique I et non des substances aromatiques correspondantes (*d*).



Von Richter a proposé un mécanisme de la réaction (7), qui a été temporairement accepté par Bunnett et quelques collaborateurs (8). Ce mécanisme supposait qu'un intermédiaire dihydroaromatique (I) se transforme en nitrile par l'addition et l'élimination successive d'un proton, puis qu'il se produit le départ nucléofuge de l'ion nitrite.

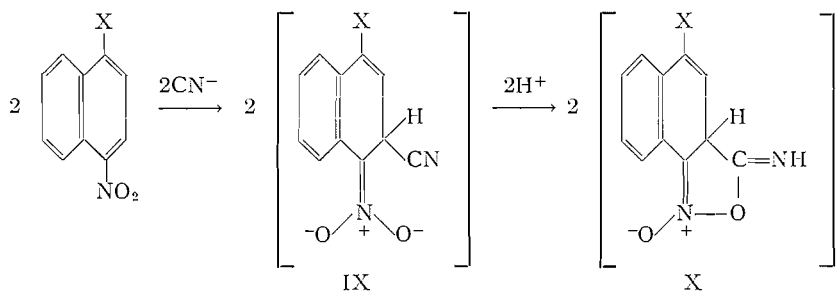
Bunnett et Rauhut (6) ont ensuite suggéré que l'élimination du groupement nitré sous forme de l'ion nitrite passe par l'intermédiaire d'un "imino-anhydride" (imino-isoxazoline) et d'un anhydride mixte de l'acide nitreux et de l'acide carboxylique. Dernièrement, Samuel (9) a observé que, lorsque la réaction est exécutée dans un solvant dont l'eau a été enrichie en isotope ^{18}O, l'acide carboxylique obtenu ne contient que la moitié de l'oxygène ^{18}O qu'il devrait posséder si les deux atomes d'oxygène du groupe carboxylique provenaient de l'eau. Il en conclut que l'un des atomes d'oxygène doit provenir du groupement nitré et que cela confirme le mécanisme proposé par Bunnett et Rauhut.



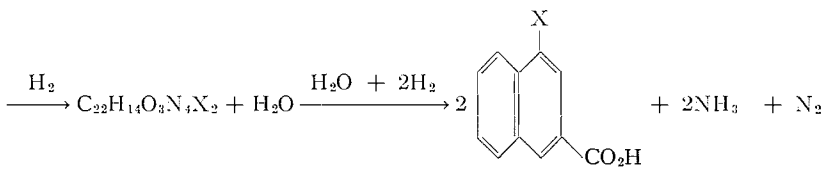
Tout récemment, après avoir constaté qu'il se trouve dans le produit de la réaction du *p*-chloronitrobenzène 50% d'azote et pas plus de 3% de l'ion nitrite qui devrait se former selon le mécanisme précédent, Rosenblum (10) a proposé une ingénieuse modification pour expliquer l'élimination de l'azote qui accompagnerait la formation de l'acide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

m-chlorobenzoïque; mais néanmoins, il y a lieu de douter de l'existence de l'anion aromatique bivalent



que cet auteur considère comme un intermédiaire de la réaction et qui n'est d'ailleurs pas nécessaire pour interpréter la formation du 4-nitroso-3-carbamylchlorobenzène (VIII), clef de ce nouveau mécanisme. En effet, nous sommes d'avis que la formation de l'intermédiaire VIII peut s'expliquer normalement par l'intermédiaire dihydroaromatique I des mécanismes précédents (6, 8, 9), de la façon suivante:



Quoi qu'il en soit, il est certain que dans la série du benzène, lorsque la substance nitrée est réduite en composés azoxyques ou azoïques, ces derniers ne peuvent pas se transformer en acides benzoïques dans les conditions de la réaction et ils sont isolés tels quels ou sous la forme de dérivés de l'indazol (2, 3). Par contre, dans la série du naphtalène, les substances, $C_{22}H_{14}O_3N_4Cl_2$ et $C_{22}H_{16}O_3N_2$, que nous avons respectivement isolées à la suite de réactions de von Richter avec le 4-chloro-1-nitronaphtalène et le nitronaphtalène suivant des conditions quelque peu modifiées, donnent naissance aux acides 4-chloro-2-naphtoïque et 2-naphtoïque (11), lorsqu'elles sont soumises aux conditions normales de la réaction.

À un atome d'oxygène près, la formule brute $C_{22}H_{14}O_3N_4X_2$ (X = H ou Cl) est le double de l'intermédiaire X, analogue à l'intermédiaire imino-anhydride proposé par Bunnett pour la réaction dans la série du benzène. Elle suppose l'union de deux molécules du dérivé nitré du naphtalène par réduction (*f*).

(*f*)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

X = Cl ou H

Si ces composés sont vraiment des intermédiaires de la réaction, il faudrait convenir que le mécanisme (du moins dans la série du naphtalène) fait intervenir un composé de réduction qui réunit deux molécules du produit de départ. Nous tentons présentement de trancher cette question.

PARTIE EXPÉRIMENTALE[1]

La réaction de von Richter a été exécutée en faisant bouillir à reflux une solution de *p*-nitrochlorobenzène et de cyanure de potassium.

Rendement en fonction du temps

On fait bouillir à reflux une solution comprenant une partie de *p*-nitrochlorobenzène et quatre parties de cyanure de potassium dans 10 parties de tétrahydrofurfurol à 50% (en volume). Au moment désiré, la réaction est interrompue. Les produits sont isolés et purifiés selon le mode opératoire déjà décrit (3). Les résultats sont présentés au Tableau I.

Dosage de l'anhydride carbonique

Du *p*-chloronitrobenzène (2.0 g), du cyanure de potassium (6.0 g) et du 2-éthoxyéthanol à 50% (30 ml) sont introduits dans un ballon de 100 ml à trois cols dont l'un est pourvu d'un réfrigérant, un autre d'un entonnoir à décantation et le troisième d'un tube de verre qui plonge dans le mélange réactionnel et peut être fermé à l'aide d'un robinet. Le mélange est bouilli à reflux pendant 4 heures, les robinets de l'entonnoir et du tube de verre étant fermés. Une fois la réaction terminée, après quelques minutes de repos à la température ambiante, on relie le réfrigérant à un flacon contenant 225 ml d'eau de baryte par un tube de verre qui plonge dans la solution de baryte. Tout en faisant barbotter un courant d'azote dans le mélange réactionnel, on y introduit, à l'aide de l'entonnoir, un excès d'acide chlorhydrique concentré suffisant pour rendre acide le produit de la réaction et on chauffe pour en chasser tout l'anhydride carbonique.

Le précipité de carbonate de baryum est filtré, lavé à l'eau, suspendu dans 50 ml d'eau, puis transformé en sulfate. Le précipité de sulfate de baryum est essoré, lavé par l'eau, séché et calciné. On obtient 0.4415 g de sulfate de baryum correspondant à 0.00189 mole (0.083 g) d'anhydride carbonique ou à 0.148 mole pour une mole de *p*-chloronitrobenzène. Dans une expérience témoin, sans *p*-chloronitrobenzène, il ne se forme pas d'anhydride carbonique.

Dosage de l'ammoniac

On introduit dans un ballon de 100 ml à deux tubulures, 2.0 g de *p*-chloronitrobenzène, 6.0 g de cyanure de potassium et 20 ml d'éthanol à 50%. L'un des cols du ballon est muni d'un tube de verre qui s'arrête au-dessus de la surface des réactifs et l'autre, d'un réfrigérant dont l'extrémité est reliée à un flacon laveur renversé et de là à une fiole conique par un tube qui plonge dans 100 ml d'acide chlorhydrique 0.5 *N*. On chauffe à

[1]*Les points de fusion ont été déterminés en tubes capillaires et ne sont pas corrigés.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

reflux pendant 47 heures et laisse ensuite reposer pendant quelques minutes à la température ambiante, tout en faisant circuler un courant d'azote dans l'appareil pour éviter les retours. On ajoute ensuite au mélange réactionnel, 10 ml d'une solution d'hydroxyde de potassium à 50% et fait bouillir de nouveau à reflux pendant une heure.

Pour neutraliser l'excès d'acide chlorhydrique 0.5 *N*, il faut 64.3 ml de soude 0.5 *N*. La différence, 35.7 ml (100−64.3), équivaut à 0.0179 mole (0.304 g) d'ammoniac ou 1.41 mole pour 1 mole de *p*-chloronitrobenzène. Une expérience témoin, en l'absence de *p*-chloronitrobenzène, a fourni 0.10845 g d'ammoniac. Ceci indique que 0.4301 g ou 7.18% du cyanure de potassium est hydrolysé durant la réaction.

Traitement de diverses substances dans les conditions de la réaction de von Richter

(a) 2,2′-Dicyanoazoxybenzène

À une solution de 9.0 g de 2-nitrobenzonitrile dans 75 ml d'acide acétique et 10 ml d'anhydride acétique on ajoute petit à petit (environ $1\frac{1}{4}$ heures) 12.0 g de zinc en poudre, sous agitation mécanique et en maintenant la température du mélange entre 30 et 35°. La pâte est ensuite versée dans 1 litre d'eau glacée et essorée. Le précipité est traité par 300 ml d'une solution de carbonate à 10% pendant 15 minutes à 40°, filtré et lavé à l'eau. Le solide est dissous dans de l'éthanol et la solution traitée au noir animal et filtrée. Le 2,2′-dicyanoazoxybenzène (3.9 g; 53% de la théorie) cristallise en fines aiguilles fondant à 192–193° (p.f. lit. 194° (12)).

Une solution de 1.0 g de 2,2′-dicyanoazoxybenzène et de 30 g de cyanure de potassium dans 200 ml de glycol d'éthylène aqueux (90%) est bouillie à reflux pendant 3 heures. Le produit de la réaction traité de la façon habituelle (2) a fourni 0.08 g de 6-iminoquinazolo-[1,2,2′,3′]indazol, mais pas d'acide benzoïque.

(b) 4,4′-Diméthoxy-2,2′-dicarbamylazoxybenzène

Le *p*-nitrophénol est méthylé, avec un rendement de 70% de la théorie, par le sulfate de méthyle, suivant les données d'Ullman (13) pour la méthylation de l'*o*-nitrophénol, et transformé en 4,4′-diméthoxy-2,2′-dicarbamylazoxybenzène (4). Ce dernier composé (1.0 g) se décompose, lorsqu'il est traité par la potasse (0.05 g) dans le glycol (10 ml) et ne réagit pas, en tube scellé à 150°, avec du cyanure de potassium (3.0 g) dans l'éthanol à 50% (10 ml).

(c) 2-Nitro-5-chlorobenzamide

De la 2-nitro-5-chlorobenzamide (3.5 g), obtenue à partir de l'acide 2-nitro-5-chlorobenzoïque préparé selon Bunnett (4), est bouillie à reflux pendant 24 heures avec 10.0 g de cyanure de potassium en solution dans 35 ml d'éthanol à 50%. Le produit de la réaction traité de la façon habituelle (2) ne fournit que des traces d'un produit acide qui n'est pas de l'acide *m*-chlorobenzoïque et un sublimé différent de la lactone de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl(2)]-benzoïque.

(d) 2-Nitro-5-chlorobenzonitrile

Du pentoxyde de phosphore (8.0 g) est intimement mélangé à de la 2-nitro-5-chlorobenzamide (4.0 g) et chauffé sous pression réduite. Le 2-nitro-5-chlorobenzonitrile distille à 120°/20 mm Hg. Il cristallise dans l'éthanol en aiguilles jaune pâle et on en recueille 1.53 g (40% de la théorie) fondant à 94°. Calculé pour $C_7H_3O_2N_2Cl$: C, 46.30%; H, 1.82%; N, 15.50%. Trouvé: C, 46.20%; H, 1.65%; N, 15.40%. Lorsque 0.70 g de 2-nitro-5-chlorobenzonitrile est bouilli à reflux pendant 24 heures avec 3.0 g de cyanure de potassium dans 20 ml d'éthanol à 50%, il se dégage de l'ammoniac, mais il ne se forme pas d'acide *m*-chlorobenzoïque. Des produits acides (0.346 g) seule une petite quantité (0.086 g)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

d'une substance de p.f. 320° est obtenue par sublimation. Celle-ci n'est pas la lactone de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque.

Après avoir bouilli à reflux pendant 24 heures 5.0 g d'acide 5-chloroanthranilique (5) avec 15.0 g de cyanure de potassium dans 50 ml d'éthanol à 50%, 3.0 g (60%) d'acide 5-chloroanthranilique peuvent être récupérés, mais il ne se trouve pas d'acide *m*-chlorobenzoïque.

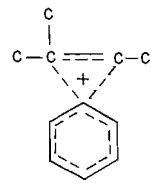
FRIEDEL–CRAFTS REARRANGEMENTS IN BRANCHED CONDENSED RING SYSTEMS

I. OCTAMETHYLOCTAHYDROANTHRACENE[1]



L. R. C. Barclay, A. H. Gray, and C. E. Milligan

ABSTRACT

Treatment of 1,1,4,4,5,5,8,8-octamethyl-1,2,3,4,5,6,7,8-octahydroanthracene ($C_{22}H_{34}$, I) with aluminum chloride produced a new hydrocarbon ($C_{22}H_{32}$, II) containing a conjugated olefinic double bond. Hydrocarbon II was proved to be 1,1,5,5,8,8-hexamethyl-3-isopropyl-5,6,7,8-tetrahydrobenzindene by spectral data, by oxidative studies, and by a synthesis of its reduction product, 1,1,5,5,8,8-hexamethyl-3-isopropyl-5,6,7,8-tetrahydrobenzindane (III). A benzenonium ion mechanism is postulated to explain the 1,2-phenyl shift accompanied by dehydrogenation in the formation of II from I. The detection of hydrogen in the off gas of the rearrangement supports this mechanism. A similar benzenonium ion mechanism can be applied to elucidate the mechanism of isomerization of tertiary to secondary alkylbenzenes reported in the literature.

INTRODUCTION

The branched condensed hydrocarbon octamethyloctahydroanthracene (I) provides an interesting system for conducting isomerizations under Friedel–Crafts conditions. Since in I the tertiary alkyl groups are part of a ring system, the nature of the products of rearrangement is expected to provide information on the mechanism of isomerization of tertiary to secondary alkylbenzenes. Such isomerizations were observed by Schmerling and West (1), who made the general observation that the formation of a tertiary alkylbenzene in the presence of catalysts such as aluminum chloride was really the exception rather than the general rule even when the alkyl halide used was tertiary. In the case of alkylation of benzene with *t*-pentyl chloride, they proposed that the tertiary alkylate is formed first and this is subsequently isomerized to the secondary alkylate by migration of a methyl or of a phenyl group. Schmerling and co-workers (2) later suggested that the rearrangement could take place through the cyclic bridged benzenonium ion—*

Roberts and Han (3) proposed the same mechanism to explain the conversion of *t*-pentylbenzene into 2-methyl-3-phenylbutane. Essentially this mechanism requires that the phenyl group is the migrating species in this arrangement rather than methyl migration. In a recent communication, however, Slaugh and Raley (4) made the general statement that Lewis acids produce no 1,2-phenyl migrations but rather lead to methyl migration processes.

In a system such as octamethyloctahydroanthracene (I) where the tertiary alkyl groups are in a ring system, a rearrangement where the phenyl group migrates through a benzenonium ion mechanism would lead to ring contraction. On the other hand if methyl groups migrate there would be no change in ring size. For this reason I was

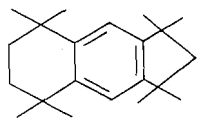
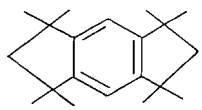
Contribution from the Department of Chemistry, Mount Allison University, Sackville, New Brunswick. Reported in part at the 43rd Annual Conference of the Chemical Institute of Canada, Ottawa, Ontario, June 14, 1960.



The term "benzenonium ion" introduced by W. von E. Doering. Tetrahedron, **4, 178 (1958) is used on the recommendation of the referee.*

selected for some initial experiments on isomerization of tertiary alkylbenzenes under Friedel–Crafts conditions.

DISCUSSION OF RESULTS

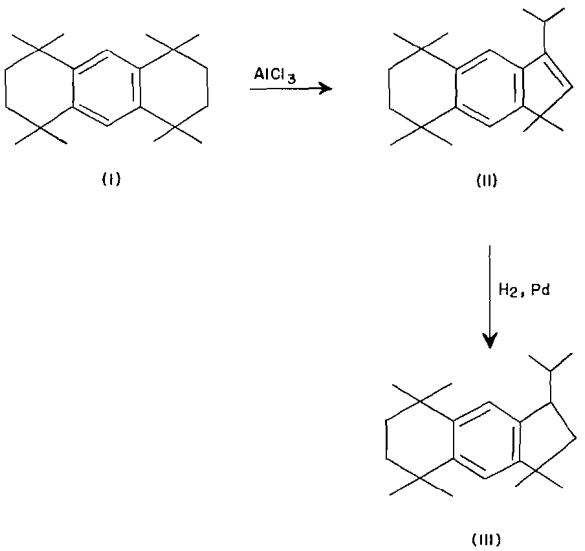


Treatment of octamethyloctahydroanthracene ($C_{22}H_{34}$, I) with aluminum chloride in tetrachloroethane or carbon disulphide converted it into a new crystalline compound, $C_{22}H_{32}$, II. The ultraviolet spectrum of II indicated the presence of a substituted conjugated olefinic double bond. There was a broad band at 260 mμ, ϵ = 11,220 and weaker bands at 288 mμ, ϵ = 2884 and 299 mμ, ϵ = 3162. The infrared spectrum of II showed a strong band at 11.3 microns attributed to 1,2,4,5-tetrasubstitution since this band was also observed for I. High-temperature mass spectral analysis of II established the parent mass to be 296, compared to 298 for I. There was also a strong peak in the mass spectrum of II at mass 253 corresponding to the loss of a C_3H_7 fragment. On catalytic reduction, II was converted into a compound III, $C_{22}H_{34}$, isomeric with I. This reduction product also lost a propyl fragment on high-temperature mass spectral analysis.

An important lead to the structure of III was provided by its ultraviolet spectrum. This spectrum was very similar to that of 1,1,3,3,5,5,8,8-octamethyl-5,6,7,8-tetrahydrobenzindane (IV) prepared by alkylating 1,1,3,3-tetramethylindane with 2,5-dichloro-2,5-dimethylhexane.

(IV)

Hydrocarbon IV showed bands at 279 mμ, ϵ = 2408; 273.5 mμ (side band), ϵ = 1815; 270 mμ, ϵ = 2007; and a shoulder at 265.5 mμ. Hydrocarbon III showed bands at 280.5 mμ, ϵ = 2371; 275 mμ (side band), ϵ = 1908; 271.5 mμ, ϵ = 2067; and a shoulder at 267 mμ. The curves for III and IV had the same shape, the only significant difference was a shift in the spectrum of III of 1.5 mμ to longer wavelengths. On the other hand the spectrum of III showed distinct differences from that of octamethyloctahydroanthracene (I). The latter showed only two bands, at 278 mμ, ϵ = 1096, and 270 mμ, ϵ = 955. Furthermore the ultraviolet spectrum of I was practically identical with that of some other methylated octahydroanthracenes which we have synthesized such as the hexamethyl- and heptamethyl-octahydroanthracenes. The spectra of I and IV are both somewhat different from the spectrum of 1,1,3,3,5,5,7,7-octamethylhydrindacene (V) (5) —



(V)

The latter had bands at 281 mμ, ϵ = 4725; 276 mμ, ϵ = 4243; 271.5 mμ, ϵ = 3760; and 267 mμ, ϵ = 2700. This shows that the degree of substitution around the non-aromatic rings has little effect on the character of ultraviolet absorption of the condensed ring systems. On the other hand the size of the non-aromatic rings has a more pronounced effect on the intensity and shape of the curves. Thus ultraviolet analysis provides a convenient means of deciding whether these ring systems are 6,6,6-, 6,6,5-, or 5,6,5-tricyclic systems.

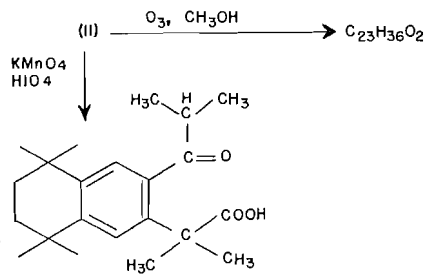
The structures shown below for II and III seemed reasonable from the spectral evidence.

(I) (II) (III)

Compound II was tentatively assigned the endocyclic formulation since the exocyclic form would not be expected to lose a C_3H_7 fragment on mass spectral analysis. The structure suggested for III was confirmed by a classical synthesis which is outlined below—



(VI) (II) (VII) (III) (II)

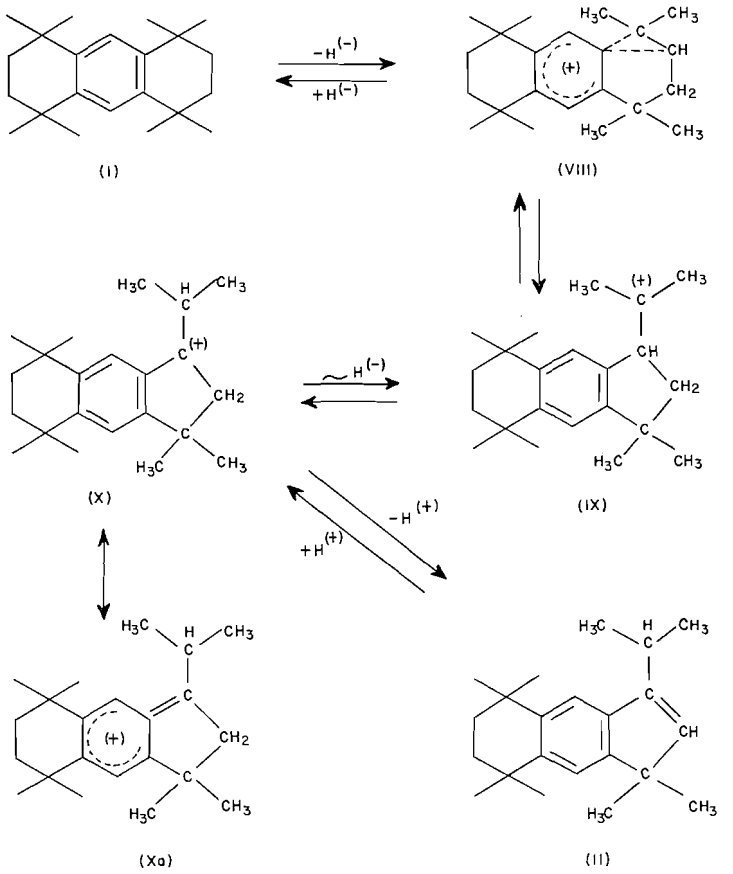
Friedel–Crafts alkylation of 3,3-dimethyl-1-isopropylindane (VII) with 2,5-dimethyl-2,5-dichlorohexane actually yielded the conjugated olefin II instead of the expected reduction product (III). This synthetic product was reduced for further identification and the reduction product proved to be identical with III.

The above synthesis confirmed the structure suggested for III but the position of the olefinic double bond in II remained to be established. The endocyclic formulation is in agreement with the work of Myhre (6), who produced a compound identical with our II by treatment of I with aluminum chloride. Although Myhre did not arrive at the structure of II, he hydroxylated it with permanganate followed by lead tetraacetate cleavage to produce a single product whose infrared spectrum indicated two carbonyl groups, an unconjugated aldehyde and a conjugated ketone. Our attempts to convert II into this dicarbonyl compound by ozonolysis in methanol yielded instead a mixture. By chromatography and recrystallization there was isolated from this mixture a compound of melting point 114–115° which had an ultraviolet spectrum practically identical with that of I. The infrared spectrum of this compound showed no carbonyl absorption but rather had two strong bands in the region of ether absorption at 8.85 and 9.45 microns. The compound analyzed for a methoxyl group and the ultimate analysis corresponded to $C_{23}H_{36}O_2$. The structure of this ozonolysis product was not definitely established. The spectral and ultimate analyses indicate a six-membered cyclic ether containing in addition a methoxyl group. Such a compound could only have formed from an endocyclic olefin, II.

The endocyclic formulation for II was confirmed in a more regular manner by permanganate–periodate oxidation. This oxidation yielded an aldehydic compound and an acidic compound both of which showed two strong carbonyl bands in the infrared at 5.90 and 5.75 microns. The acid had a strong band in the ultraviolet at 253 mμ attributed to the conjugated ketone. Its neutralization equivalent corresponded to the theoretical value for $C_{21}H_{31}OCOOH$. The conclusion arrived at by these degradative studies was later confirmed by the nuclear magnetic resonance spectrum* of II. This spectrum had a peak at −348 c.p.s. removed from tetramethylsilane, the internal standard. This peak was attributed to an olefinic proton which confirms the endocyclic formula II since the alternative exocyclic olefin could not have a hydrogen on the olefinic double bond.



It is apparent that the more substituted exocyclic olefin is not favored in this reaction. A molecular model of the exocyclic olefin was made using Stuart and Briegleb models. In this model the methyl groups on the olefinic double bond are coplanar with the benzene ring resulting in a very strong steric interaction between one methyl and an ortho hydrogen. There is, of course, no such unfavorable interaction in the endocyclic compound II, which is therefore the principal product.

*We are indebted to Dr. Robert R. Fraser of the Chemistry Department, University of Ottawa, who measured and interpreted this spectrum.

Treatment of I with aluminum chloride in benzene did not yield the rearrangement compound (II). In this case the main product was 1,1,4,4-tetramethyltetralin. Thus, in benzene solution, the main reaction is disproportionation of I instead of rearrangement.

THE MECHANISM OF THE REARRANGEMENT

In a preliminary communication (7) it was suggested that the rearrangement of I to II proceeded via a hydrogen-bridged π-complex involving opening of a ring by displacement of a side chain with a proton. A more attractive mechanism for this 1,2-phenyl migration is a benzenonium ion mechanism. In this mechanism it is proposed that the catalyst extracts a hydride ion from a —CH_2— group of a side chain to initiate the reaction. The benzene ring could participate in the displacement of the hydride ion by anchimeric assistance through a cyclic bridged benzenonium ion (VIII). The mechanism is outlined below:

The carbonium ion X would be more stable than IX because the former is stabilized by resonance interaction with the directly attached benzene ring (X*a*). Loss of a proton from X produces the product isolated (II). It is not necessary for the reduction product III to be an intermediate in this reaction. We were unable to detect any of III by chromatographic fractionation of the reaction product. Of course this does not rule out the possibility of III being an intermediate especially since we found that aluminum chloride

treatment of III in carbon disulphide produced II. Treatment of III with aluminum chloride in tetrachloroethane alone did not yield sufficient II for characterization. The product in this case was a complex mixture containing some unchanged III, some non-crystalline products with strong absorption in the 260 mμ region, and a new crystalline compound with a strong band at 241 mμ and bands at 291 and 302 mμ. Such a spectrum is typical of extended conjugation. This material was not available in sufficient amount for a characterization but this spectrum indicates that it may have been formed by a rearrangement–dehydrogenation of both of the non-aromatic rings. Treatment of III with aluminum chloride and *t*-butyl chloride as a promoter in tetrachloroethane yielded II accompanied by the evolution of isobutane.

Nenitzescu (8) proposed that aluminum chloride exerts its strong catalytic action by formation of a strong acid $H^+AlCl_3\bar{O}H$ with traces of water. This strong acid initiates rearrangements by extraction of a hydride ion as follows:

$$R{-}H + H^+AlCl_3\bar{O}H \rightarrow R^+AlCl_3\bar{O}H + H_2.$$

The reaction can then be propagated as a chain reaction through carbonium ions which act as hydride ion acceptors. To support this concept they found traces of molecular hydrogen in the off gases from isomerizations. In this case the hydrogen was detected by combustion to water. Despite this discovery, Deno and co-workers (9) made the general observation that the hydride ion transfer reaction has the characteristic of *not* reacting with labile protons of the medium to form molecular hydrogen. It therefore was desirable to attempt to confirm the findings of Nenitzescu and co-workers by analyzing the off gases from our reaction directly for hydrogen. Vapor phase chromatographic and mass spectral analyses definitely showed the presence of hydrogen in the off gases. The major fraction of the off gases consisted of the hydrocarbons, isobutane and isopentane. Isobutane could have originated from I by side reactions as outlined below:

Elimination of isobutylene takes place by displacement of a side chain by the catalyst followed by fragmentation to yield isobutylene and the intermediate XI. The isobutylene could then be protonated by the catalyst to form a *t*-butyl cation which also would act as a hydride ion acceptor in promoting rearrangement of I. The production of isobutane thus takes place by a process which is just the reverse of the reaction proposed recently (5) to explain the cyclialkylation of 1,3,5-tri-*t*-butylbenzene through a benzenonium ion intermediate analogous to XI yielding I. When a trace of D_2O was added to the reaction during rearrangement of I, the infrared spectrum of the evolved isobutane showed a band in the C—D region at 4.6 microns. Deuterated isobutane would be expected to form if the isobutane originated as postulated. The isopentane could have originated by a process similar to that suggested for isobutane except that rearrangement must have taken place in a displaced side chain before the C_5 fragment was split off. No products were isolated from the rearrangement corresponding to the aromatic fragment XI. This intermediate probably undergoes polymerization to account for the resinous by-product formed in the reaction.

In order to substantiate the proposed mechanism for the conversion of I to II, attempts are being made to isolate the benzenonium ion intermediate as a stable salt.

EXPERIMENTAL

Apparatus and Procedures

The melting points are uncorrected. Ultraviolet spectra were recorded on a Beckman DK-2 ratio recording spectrophotometer using spectro-grade cyclohexane as solvent. Infrared spectra were recorded on a Perkin–Elmer Model 136 Infracord. Mass spectroscopic analyses were determined in an independent laboratory. A high-temperature inlet mass spectrometer was used for solids. The aluminum chloride was Fisher Certified Reagent, anhydrous sublimed, used as received. The rearrangement reactions were carried out at room temperature in an atmosphere of pure nitrogen. The apparatus was attached to a Perkin–Elmer Model 154-D vapor fractometer for direct analysis of the off gases. The product from the aluminum chloride – solvent mixture was worked up in the usual way and then in each case subjected to chromatography from petroleum ether on Fisher chromatographic alumina. The progress of the fractionation was followed by periodic analysis of the eluate from the column on the recording ultraviolet spectrophotometer. In this way the various possible components of the hydrocarbon mixture such as compounds I, II, and III could quite easily be detected and separated.

The Action of Aluminum Chloride on Octamethyloctahydroanthracene (I)

(A) In Tetrachloroethane

Octamethyloctahydroanthracene (10) (m.p. 220°) (5.00 g, 0.017 mole) was dissolved in 100 ml of purified tetrachloroethane and aluminum chloride (7.50 g, 0.056 mole) was added. The reaction was continued with stirring for 24 hours. Gas chromatographic analysis of the off gases showed that isobutane was slowly evolved throughout the course of the reaction. When a trace of water was added to the reaction, hydrogen gas was also detected on the vapor fractometer. Mass spectroscopic analysis of a sample of the off gases gave the following results:

nitrogen + air	98.5%,	*n*-pentane	0.1,
isobutane	0.7,	C_5 olefinic	0.1,
isopentane	0.5,	hydrogen	0.1.

Chromatograph fractionation of the crystalline residue (4.80 g) recovered from the reaction yielded 3.0 g, 60% of compound II from fractions 1 to 3. Fractions 4–8 (0.75 g) apparently consisted of a mixture of compounds. Recrystallization of fraction 4 (0.56 g) from ethanol followed by sublimation yielded colorless crystals, m.p. 96–97°.

Anal. Calcd. for $C_{22}H_{32}$: C, 89.12; H, 10.88. Found:* C, 89.07, 89.29; H, 10.99, 11.00.

The ultraviolet spectrum of this compound shows a broad band at 261 mμ, ϵ = 21,727 and a broad band at 298 mμ, ϵ = 6215. The infrared spectrum of this compound was clearly distinguishable from that of II. They both had a strong band at 11.3 microns attributed to 1,2,4,5-tetrasubstitution but there were differences in the 8–10 micron region and a strong band in II at 12.1 microns was absent in the lower melting compound. This band is most likely due to an out-of-plane =C—H deformation of the olefinic proton in II and its absence in the compound of melting point 96–97° indicates that the latter is the exocyclic isomer of II since this isomer would have no olefinic proton. A sample of this compound was dissolved in methanol and reduced with hydrogen at 4 atm over a palladium – calcium carbonate catalyst. This reduction product proved identical with III (below) by mixed melting point and ultraviolet spectrum. The remainder of the original reaction product was strongly adsorbed on the alumina column. It was removed by elution with acetone to yield 1.0 g of resinous material.

The crystalline material from chromatograph fractions 1 to 3 was recrystallized from ethanol to yield colorless plates, m.p. 133–134°.

Anal. Calcd. for $C_{22}H_{32}$: C, 89.12; H, 10.88. Found: C, 89.15; H, 10.51.

A 0.21-g sample of pure II was dissolved in methanol and reduced with hydrogen at 4 atm over 0.10 g of palladium – calcium carbonate catalyst to give a quantitative yield of product, m.p. 98–99°.

Anal. Calcd. for $C_{22}H_{34}$: C, 88.51; H, 11.49. Found: C, 88.35, 88.85; H, 11.37, 11.26.

This reduction product (III) showed a parent mass of 298 in the mass spectrum. There was also a strong peak at mass 255 corresponding to the loss of a C_3H_7 fragment. The infrared spectrum of III in carbon disulphide lacked the 12.1 micron band which was attributed to the olefinic proton in the infrared spectrum of II.

Another aluminum chloride reaction was carried out on I in tetrachloroethane as described above. In this case, 5 ml of water was added slowly to the reaction mixture and a deep blue-green solution resulted. This solution had an absorption band in the visible at 640 mμ. On standing, a solid separated from the tetrachloroethane solution. This solid was removed by centrifugation and washed twice with tetrachloroethane and three times with carbon tetrachloride. The solvents were removed by centrifugation to leave a blue crystalline powder. This material could be stored for several hours in a vacuum desiccator but it decomposed to a brown amorphous material on exposure to air. The infrared spectrum on a Nujol mull of this material showed strong hydroxyl absorption in the region of 3 microns. There was also a strong band in the unsaturation region at 6.1 microns and a band at 8.3 microns.

(B) In Carbon Disulphide

A rearrangement of I (5.0 g) was carried out in carbon disulphide under essentially the same conditions as described in section (*A*). Isobutane and hydrogen were detected in the off gases. On working up as in section (*A*), there was obtained 30% of the rearrangement product II, 60% of unreacted I and the remainder was resinous material. When the carbon disulphide solution was refluxed, the yield of II was at least 50%.

**Analyses by Geller Laboratories, Bardonia, New York.*

(C) In Benzene

Aluminum chloride (1.0 g) was added to a solution of I (2.0 g) in 50 ml of benzene and the mixture was stirred overnight. On working up the benzene layer, there was obtained 1.4 g of a clear oil. This oil was proved to be tetramethyltetralin by comparison of its ultraviolet spectrum and gas chromatographic analysis with synthetic tetramethyltetralin.

Synthesis of 1,1,5,5,8,8-Hexamethyl-3-isopropyl-5,6,7,8-tetrahydrobenzindane (III)

(A) 3,3-Dimethyl-1-isopropylindane (VII)

To the Grignard reagent, prepared from 6.76 g of isopropyl bromide (0.055 mole) and 1.36 g of magnesium (0.056 mole) in 25 ml of anhydrous ether, was added over 1 hour at 5° a solution of 8.5 g of 3,3-dimethyl-1-indanone (11) in 25 ml of dry benzene. The reaction mixture was refluxed for 2 hours with continuous stirring and worked up in the usual manner to yield 6.7 g (68.5%) of 3,3-dimethyl-1-isopropylindene, b.p. 80–84°/1.5 mm, $N_D^{28} = 1.5295$. This oil was reduced in methanol over a palladium catalyst with hydrogen at 2 atm yielding 6.5 g (98%) of 3,3-dimethyl-1-isopropylindane (VII). Distillation of this product yielded a colorless oil, b.p. 78–80°/2.5 mm. The ultraviolet spectrum of VII showed bands at 272 mμ, $\epsilon = 1175$ and at 265 mμ, $\epsilon = 933$ and was typical of similar indanes.

(B) Alkylation of VII with 2,5-Dimethyl-2,5-dichlorohexane. Characterization of III

To a solution of 1 g of VII (0.0053 mole) and 0.98 g of the dichloride (0.0054 mole) in 25 ml of carbon disulphide, was added 0.70 g of aluminum chloride (0.0053 mole) over a period of ½ hour with stirring which was continued for 3 hours. The product was worked up and chromatographed on alumina from petroleum ether to yield 1.3 g (80%) of white plates of melting point 125°. The ultraviolet and infrared spectra of this compound were identical with those of the rearrangement product II of octamethyloctahydroanthracene.

The alkylation product was reduced (in methanol solution) with hydrogen over palladium catalyst yielding 1.2 g (94%) of colorless needles. Purification was carried out by recrystallization from ethanol followed by sublimation yielding colorless needles, m.p. 100–101°. This compound was proved to be identical with the reduction product of II by mixed melting point and ultraviolet and infrared spectra.

Synthesis of 1,1,3,3,5,5,8,8-Octamethyl-5,6,7,8-tetrahydrobenzindane (IV)

Tetramethylindane (12) (5.00 g, 0.028 mole) and 2,5-dichloro-2,5-dimethylhexane (5.70 g, 0.031 mole) were dissolved in 10 ml of carbon disulphide and the mixture was cooled in an ice–salt bath. Anhydrous aluminum chloride (0.25 g, 0.002 mole) was added with stirring and the mixture allowed to warm to room temperature (2½ hours). The product was worked up and purified by recrystallization from ethanol to yield colorless needles (5.9 g, 74%) m.p. 195–198°; λ_{max} 279, $\epsilon = 2408$; 274.5 (side band), $\epsilon = 1815$; 270, $\epsilon = 2007$; and a shoulder at 265.5 mμ.

The Action of Aluminum Chloride on III

(A) In Carbon Disulphide

A 0.60-g sample of III was dissolved in 100 ml of carbon disulphide and reacted with 1.0 g of aluminum chloride under similar conditions as described for the reaction of aluminum chloride on I. Chromatographic fractionation of the reaction product yielded 45% of II.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(B) In Tetrachloroethane. The Effect of t-Butyl Chloride

A 1.0-g sample of III was dissolved in 100 ml of tetrachloroethane and treated with aluminum chloride as before. Chromatography of the product yielded 20% of III in the first fractions and a new compound (0.17 g, m.p. 177°) in later fractions. This compound had an intense band in the ultraviolet at 241.5 mμ and bands at 291 and 302 mμ. None of the hydrocarbon II was detected in the product.

Another aluminum chloride treatment of III was carried out under similar conditions except that, in this case, an equimolar amount of *t*-butyl chloride was added with the hydrocarbon. The reaction was allowed to continue for 8 hours during which time isobutane gas was detected in the off gases. Chromatographic fractionation of the reaction mixture from this run yielded 61% of the hydrocarbon II. None of the starting hydrocarbon (III) could be detected in the reaction mixture.

Oxidative Studies on II

(A) Ozonolysis

A 0.55-g sample of II was dissolved in 100 ml of absolute methanol. This solution was cooled to −25° and ozone (3%) was passed in slowly until a slight excess of ozone was detected. The ozonide was decomposed by shaking with hydrogen over a palladium – calcium carbonate catalyst. Distillation of the solvent left a non-crystalline residue. This was dissolved in petroleum ether and chromatographed on alumina. Elution with petroleum ether containing methanol removed a crystalline compound (0.1 g) m.p. 114–115°; λ_{max} 278, ϵ = 1222; 270 mμ, ϵ = 1056. The infrared spectrum of this compound in carbon tetrachloride showed no carbonyl absorption but had strong bands at 8.85 and 9.45 microns in the region of ether absorption.

Anal. Calcd. for $C_{23}H_{36}O_2$: C, 80.18; H, 10.05; O, 9.77; OCH_3, 9.01. Found: C, 80.15, 80.04; H, 10.40, 10.22; O, 9.72, 9.50; OCH_3, 11.60, 11.89.

(B) Permanganate–Periodate Oxidation

The hydrocarbon (1.40 g, 0.0047 mole) was dissolved in 200 ml of pyridine and oxidized with permanganate–periodate according to the method of Lemieux (13). The reaction mixture was worked up to yield 0.70 g (45%) of viscous neutral material and 0.50 g (31%) of crystalline acid. Recrystallization of the latter from petroleum ether yielded colorless crystals, m.p. 210°; λ_{max} 253 mμ, ϵ = 10,434. The infrared spectrum showed two strong bands in the carbonyl region, at 5.90 and 5.75 microns.

Anal. Calcd. for $C_{22}H_{32}O_3$: Neut. equiv. 344. Found: Neut. equiv. 344.

N.M.R. Spectrum of II

The N.M.R. spectrum was run on an 11% solution of II dissolved in carbon tetrachloride containing 1% of tetramethylsilane as internal standard. A peak appeared at −348 c.p.s. removed from tetramethylsilane and this peak was assigned to an olefinic proton.

THE HYDROLYSIS OF A SERIES OF STRAIGHT-CHAIN ALKYL METHANESULPHONIC ESTERS IN WATER[1]

P. W. C. BARNARD[2] AND R. E. ROBERTSON

ABSTRACT

Rate data for the hydrolysis of methyl, ethyl, *n*-propyl, *n*-butyl methanesulphonate have been determined over sufficient range of temperature to permit an evaluation of the corresponding enthalpy, entropy, and heat capacity terms for the activation process. Changes in these derived parameters are related to characteristic differences in solvation and mechanism as a consequence of changes in the structure of the hydrolyzing ester.

Our knowledge concerning the details of hydrolysis of simple alkyl esters of strong acids in water have been extended recently by a study of isotope effects arising from changing the medium from H_2O to D_2O (1, 2, 3) and from various secondary deuterium isotope effects (4, 5, 6). In principle, further information should be made available from a consideration of the changes in the derived parameters, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, $\Delta C_p^{\ddagger}$ but the theoretical basis for the interpretation of changes in these parameters suffers from such uncertainty that to an important degree, relating changes in these parameters with changes in structure amounts to no more than confirming changes anticipated from other evidence of mechanism. The greatest uncertainty would appear to lie in $\Delta H^{\ddagger}$ and $\Delta C_p^{\ddagger}$, differences in $\Delta S^{\ddagger}$ being somewhat easier to interpret. Our purpose in this paper, therefore, was to determine the rate data for hydrolysis of a series of alkyl methanesulphonates over sufficient range of temperature that reliable values of the enthalpy, entropy, and heat capacity of activation could be determined, and to show how changes in these parameters are consistent with the solvation of sulphonates and with changes to be expected in mechanism from lengthening the carbon chain.

EXPERIMENTAL METHODS AND MATERIALS

The methanesulphonic esters used in this study were synthesized by conventional methods (7, 8). The physical constants are given in Table I. The method used in determining rates of hydrolysis, in temperature measurement and control were identical in all respects with those used in determining kinetic data for the benzenesulphonates (9)

with the obvious change that sodium methanesulphonate (0.003 M) was used as the backing electrolyte. The conductance cells were the ones used in our study of the benzenesulphonates and initially good agreement between parallel runs in different cells or successive runs in the same cells was not possible. These discrepancies disappeared, however, following repeated washings with the backing electrolyte, interspersed with several hours "aging" at 100° C in the presence of a reaction solution. Similar treatment was found to be necessary for "new" cells, but here the aging process required fewer "dummy" runs to satisfy what was assumed to be the absorptive capacity of the walls. When such equilibrium was established, reproducibility of the rate appears to be independent of the cell within the stated limits shown in the tables.

The temperature was controlled to ±0.01° C or better and was determined with a platinum thermometer and a Mueller bridge (L. and N. 8069).

First-order rates were calculated by the Guggenheim method as described in our earlier paper (9).

RESULTS AND DISCUSSION

The rate data for a series of temperatures together with the average deviation of n repetitive runs at the same temperature are given for the methyl, ethyl, n-propyl, and n-butyl esters in Table II. It was found that the temperature dependence of the rates

in every case could be expressed within the accuracy of reproducibility of the rate determination by an empirical equation of the form

$$[1] \qquad \log k = A/T + B \log T + C$$

and the equations immediately under each section, Table II, give the corresponding constants for each ester as determined by the method of least squares. If we accept the usual transition-state hypothesis for the case where $d\Delta H^{\ddagger}/dT$ is non-zero, but $d\Delta C_p^{\ddagger}/dT$ is invariant with temperature, then the constant of equation [1] may be interpreted as follows: $A = -(\Delta H_0^{\ddagger}/2.303\ R)$; $B = (\Delta C_p^{\ddagger}/R - 1)$; $C = \{(\Delta S_0^{\ddagger} - \Delta C_p^{\ddagger})/2.303\ R + \log_{10} k/h\}$. Thermodynamic parameters characterizing the hydrolysis of the four esters, calculated according to the above assumptions are given in Table III. No claim is made here that

TABLE III

Thermodynamic parameters for the hydrolysis of a series of methanesulphonates for 50.0° C

Ester	$H^{\ddagger}$, cal/mole	$S^{\ddagger}$, cal/mole deg	$C_p^{\ddagger}$, cal/mole deg
Methyl	20,441	−14.08	37.6

n-Amyl	20,440	−15.1	—
n-Octyl	20,100	−15.9	—

the assumption that $d\Delta C_p/dT = 0$ is not in some measure arbitrary; and it may well be that when data over a wider range and with greater precision are available, $\Delta C_p^{\ddagger}$ will be found to vary with temperature. The present data do not suggest, however, that $d\Delta C_p/dT > 0.1$ cal/deg mole. Estimated values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values for *n*-amyl and *n*-octyl methanesulphonate from limited rate data (Table II) are included in Table III but these terms have much larger probable errors than those determined for the preceding compounds.

In the hydrolysis of the alkyl methanesulphonates there seems no basis to doubt that bond fission occurs at the C—O bond just as in the hydrolysis of the alkyl benzenesulphonates (10, 11). This conclusion is supported by product analysis and neutral equivalent determinations which also indicate that the reaction goes to virtual completion under the experimental conditions. The possibility that elimination would become a competing reaction path in this series of straight-chain alkyl methanesulphonates is discounted by the small proportion of olefine found (Table IV) and it is by no means

TABLE IV

Olefine production in the hydrolysis of a series of methanesulphonic esters in water

Ester	Temp., °C	% olefine*

certain that the olefine so formed represents a competing path and is not formed subsequently to the transition state.

In current terminology, the hydrolysis of the methyl methanesulphonate in water occurs by an "intermediate" mechanism, i.e., an S_N2 mechanism in which the solvent provides the nucleophile and in which solvation of the forming anion is assumed to be a significant driving force. Evidence from relative rates of hydrolysis with and without the presence of OH^- (k_{OH^-}/k_{H_2O}) (12) and the relative deuterium isotope effect derived by replacing the methyl hydrogens by deuterium (k_H/k_D) (4, 5) support the contention that in hydrolysis, nucleophilic interaction between oxygen of one particular water molecule and the methyl carbon is less in hydrolysis for the methyl methanesulphonate than for the methyl halides in the transition state, but is not absent. Both methyl halides and sulphonates show an inverse α-deuterium isotope effect on hydrolysis which can be rationalized in terms of interference with the C—H out-of-plane bending frequency by the partially bonded water molecule on the side opposite to the leaving group (Table V).

TABLE V

Deuterium isotope effects for the hydrolysis of the methanesulphonates

Ester	αd_2	βd_2	γd_3	Ref.
Methyl*	0.95	—	—	4
Ethyl	1.037	1.027	—	6
n-Propyl	1.036	1.074	0.94	6

*αd_3

Deuterium substitution of ethyl and *n*-propyl esters in the β-position leads to k_H/k_D values greater than unity. The effect is small and it would be difficult, on the basis of these isotope effects alone, to distinguish between the possibility that the observed effect arises from some weak interaction between the β-H and the partially empty *p*-orbital developing at the rear of α-C or is the consequence of a reduction in non-bonded interactions or arises from other causes. The empirical observation that deuterium substitution on the γ-carbon gives an inverse isotope effect ($k_H/k_D > 1$) analogous to the effect of α-substitution is an indication that the activation process requires a configuration which reduces the freedom of γ-C—H vibration. In a recent paper Leffek, Llewellyn, and Robertson discuss these problems in greater detail (6). Here we shall examine the very much larger indications of mechanistic changes with chain lengthening apparent in the derived parameters, $\Delta H^{\ddagger}$, $\Delta C_p^{\ddagger}$, and $\Delta S^{\ddagger}$, particularly the latter.

Entropy of Activation

The relation of structure to the derived values of $\Delta S^{\ddagger}$ for hydrolysis will be considered in this section with reference to two specific examples (1) a comparison of $\Delta S^{\ddagger}$ values for the hydrolysis of MeBr and MeMes and (2) the changes in $\Delta S^{\ddagger}$ with chain lengthening within the methanesulphonate series.

Example I

The difference in the rate of hydrolysis of methyl bromide and methanesulphonate ($k_{MeBr}/k_{MeMes}=7.6$) is much less than would be expected from differences in $\Delta H^{\ddagger}$ or $\Delta S^{\ddagger}$ alone (Table VI), a circumstance frequently observed (14, 15, 16, 17, 18) and usually associated with solvation differences either in the initial or transition states or both. It is known, of course, from differences in k_{OH^-}/k_{H_2O} ratios (12) that the hydrolysis of methyl bromide requires a greater degree of nucleophilic interaction than methyl methanesulphonate but this could hardly contribute as much as 1–2 e.u. to $\delta_{RX}\Delta S^{\ddagger}$. Hence some 5–6 e.u. must be associated with $\delta_{RX}\Delta S^{\ddagger}$ solvent.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

TABLE VI

A comparison of kinetic parameters for the hydrolysis of MeBr and MeMes

	$k_1 \times 10^{-5}$, sec^{-1}	$\Delta H^{\ddagger}$, cal/mole	$\Delta C_p^{\ddagger}$, cal/mole deg	$\Delta S^{\ddagger}$, cal/mole deg	Ref.
MeBr	1.11	24,142	46.5	−2.91	14
MeMes	8.44	20,441	37.6	−10.83	This work

Following the argument of Robertson, Heppolette, and Scott (17) the charge development on Br^- at the transition state will be about 0.8 e. Hence applying Laidler's hypothesis (19) that $\Delta S_0^0 \alpha z^2$, the entropy change to be associated with the quasi-ionic Br^- will be about $(0.8)^2 \times 12 = -8$ e.u. where the entropy of solvation for Br^- ion is −12 e.u. for a standard state of 1 mole/l. in both phases (20). The corresponding parameter for the methanesulphonate ion is not known but may be estimated from Altschuler's empirical equation (21) for oxy anions. Assuming the same charge development for the methanesulphonate as for the bromide the corresponding entropy change will be −14.3 e.u.

If the above assumptions are correct, there is here a difference of about 6 e.u. in the solvation of the quasi-ionic anions in the transition state and this will account for the major observed differences in $\Delta S^{\ddagger}$. To infer that the initial states are comparably solvated, however, would be incorrect.

In aqueous solutions it is now accepted that a non-electrolyte may be described as being surrounded by a solvation shell in which water–water interaction is greater than the interaction in bulk water or of water–solute interaction in solution (22, 23, 24). The formation of this initial-state solvation shell is characterized by a negative component in the entropy which appears to bear some inverse relationship to the polarity of the solute. Thus the entropy of solution for the gas solution equilibrium for MeBr and methane are both about −18 e.u. (17), indicating that in substituting —Br for —H in methane, the increased size of the substituent, which would imply a more negative shift in entropy of solvation, is cancelled by the increased polarity of the substituent.

Obviously the fraction of this value which must be associated with increased water–water interaction about the Br atom is difficult to judge, but it would seem that a value of 5–6 e.u. implied by the difference

$\Delta S^{\ddagger}_{\text{solvent}}$ (transition state for Br^-)	−8 e.u.
$\Delta S^{\ddagger}$	−2.91
	−5.09

would not be unreasonable. Evidence both from the solvent isotope effect (3) and particularly from the temperature dependence of the solvent isotope effect (25) suggests that the water molecules adjacent to the sulphonic group are already interacting with the sulphonic oxygens in the initial state with a corresponding loss in rotational entropy. The same inference may be drawn from the enhanced solubility in water which the sulphonic groups introduce into organic molecules. Taking the calculated entropy loss associated with the quasi-ionic sulphonic transition state (−14.3 e.u.) and subtracting the observed value of $\Delta S^{\ddagger}$, we may estimate that this initial-state loss corresponds to about 3–4 e.u. Hence, summing up, the entropy difference observed in the hydrolysis of the two esters probably arises largely in the transition state. The differences in the initial state are smaller but the physical characteristics of the initial-state solvation are quite different.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

We have noted above that $(S^0_{solv})^{gas}_{soln}$ for MeBr and methane are both about -18 e.u. but so far have neglected to consider the contribution to $\Delta S^{\ddagger}$ from reorganization about the Me group. The initial-state solvation shell has a large negative component due to increased water–water interaction. Granted that the entropy assignments to the anionic moiety are correct, any change in entropy about the methyl group will have to come out of the respective residuals (-5.09 and -3, or -4). For simplicity we have assumed such differences to be small for the methyl esters.

Example II

In hydrolysis, the structural change Me $\rightarrow$ Et may be assumed to lead to a more ionic transition state and an increase in steric hindrance to nucleophilic interaction. This conclusion based largely on relative rates in solvolysis and the effect of added bases on such rates (12) has gained further support from the results for secondary deuterium isotope effects (6). In the present series the difference in rates of hydrolysis between the methyl and ethyl esters ($k_{Et}/k_{Me} = 0.85$) is much smaller than normal for S_N2 displacements and tends to belie larger changes in the detailed mechanism suggested by differences in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ (Table III).

A more ionic transition state for the ethyl ester would seem to require a more negative $\Delta S^{\ddagger}$ and this is probably true for that component of $\delta_R \Delta S^{\ddagger}$ associated with the quasi-anion even though the net $\delta_R \Delta S^{\ddagger}$ for the structural change Me $\rightarrow$ Et is 1.7 e.u. positive. Of the sources of positive entropy which could contribute to the positive residual in $\delta_R \Delta S^{\ddagger}$ that due to the diminished nucleophilic interaction is probably small. A more likely source is associated with the breakdown of a larger initial-state solvation shell but it is not clear how to estimate this contribution.

The introduction of a γ-methyl group to Et— (to give *n*-propyl) need not produce added steric hindrance to nucleophilic interaction (26) and would not be expected to have a large direct electronic effect on the seat of reaction; nor would the change in reactivity ($k_{n\text{-Pro}}/k_{Et} = 0.72$) lead us to anticipate the observed shift in $\Delta S^{\ddagger}(\delta_R \Delta S^{\ddagger} = -4.12$ e.u.). Such a change in entropy appearing suddenly in a straight-chain series is not unusual and has been attributed to loss of rotational freedom in the transition state (6, 27) due to either increased crowding or to solvent exclusion. The latter is the hypothesis adopted by Evans and Hamann (28) and by Everett, Landsman, and Pinsent (29) to account for the gradual negative shift in entropy with chain lengthening in the ionization of a series of straight-chain acids and amines. While "solvent exclusion" may be a factor here, the contrast between the gradual shift in entropy for ionization of the amines and acids and the abrupt shift at *n*-propyl and also the results of secondary deuterium isotope studies are evidence of some other larger contributing factor. Leffek, Llewellyn, and Robertson (6) showed that whereas the β-H deuterium isotope effect is greater than unity, the γ-substitution led to a value of $k_H/k_D < 0.95$ for four different displaced groups —a result consistent with increased crowding in the transition state. It is suggested that this alteration in spacial relationships is the direct consequence of rehybridization of α-C in the activation process. The normal secondary deuterium isotope effect for β-H is small and may either arise from the same cause or be taken as possible evidence of some degree of weak interaction between the β-H and the partially empty *p*-orbital but is of the wrong sign were solvent exclusion the source of loss of rotational freedom.

The constancy of $\Delta S^{\ddagger}$ for the hydrolysis of the longer straight-chain alkyl mesalates suggests that the above discussion for *n*-propyl may be applied to the higher members of the series and further that solvation changes are not influenced by chain length beyond the second or third member of the series.

Heat Capacity of Activation

The temperature dependence of $\Delta H^{\ddagger}$ is assumed to be linear in T. Although in some measure arbitrary the range of temperature covered by the investigation and the accuracy of the rate determinations would not justify a more-refined treatment.

The actual values of the temperature coefficients of $\Delta H^{\ddagger}$ for the hydrolysis of the methanesulphonic esters are of the same magnitude and sign as for the benzenesulphonates and less negative than for the halides (17). The major factor determining the latter difference would appear to be the same: the temperature dependence for the "stability" of the initial-state solvation shell or that part thereof which must be broken down in the activation process. The change in $\Delta C_p^{\ddagger}$ with the change Me $\rightarrow$ Et is negligible, but there is a significant reduction in the negative value of $\Delta C_p^{\ddagger}$ for the structural change Et $\rightarrow$ *n*-Pro.

Such a change is in qualitative agreement with the shift to be expected where there is a decrease in rotational freedom for a simple model of a harmonic oscillator (31), the entropy becoming more negative and the $\Delta C_p^{\ddagger}$ more positive. The stiffening here, however, arises from a different cause than that suggested by Kirkwood and adopted by Evans and Hamann (26) and by Everett, Landsman, and Pinsent (27) since in the work described by the latter authors chain stiffening was assumed to arise as a consequence of the exclusion of the low polar hydrocarbon from the charge center by the solvent. Here the loss of rotational freedom appears to arise at least in part as an incidental to the decrease in $\Delta H^{\ddagger}$ as a consequence of the β-hydrogen interaction with the forming empty p-orbital coupled with a possible change in the non-bonded interaction between the terminal methyl and the leaving group.

The Enthalpy of Activation

The $\Delta H^{\ddagger}$ values reported in Table III are similar to the corresponding values for the benzenesulphonates and some 4–5 kcal lower than for the halides. The latter difference may be attributed to solvation differences in the initial state, in particular, to the evidence of strong solute–water interaction in the initial state for the sulphonates compared to the enhanced water–water interaction about the halide. Granted this explanation for the difference, we are left with the uncomfortable question of why the residuals are so similar.

The change in $\Delta H^{\ddagger}$ with increasing length of the alkyl group, while small, follows the same pattern as for the benzenesulphonates, with an increase from Me $\rightarrow$ Et where the α-methyl increased the steric hindrance to nucleophilic interaction without supplying through electron release or hydrogen interaction a driving force sufficient to compensate for this loss. The further lengthening of the chain (Et $\rightarrow$ *n*-Pro) leads to increased β-hydrogen interaction, loosening of the β-C—H bond, and a lowering of $\Delta H^{\ddagger}$ which partially compensates the negative shift in $\Delta S^{\ddagger}$ attributed to loss of rotational freedom. The influence of the specific nature of the leaving group is apparent here; $\delta_R \Delta H^{\ddagger}$ having values (17) (in kcal) for I^- of 0.1, Br^- −0.98, methanesulphonate −0.4, and benzenesulphonate −0.56.

ACKNOWLEDGMENTS

The authors wish to acknowledge the assistance of Mr. R. Maillet for the olefine determinations, and of Mr. S. Sugamori for least-square determinations, and other technical assistance.

CONSTITUTION OF A GLUCOMANNAN FROM TAMARACK (LARIX LARICINA)[1]

P. KOOIMAN[2] AND G. A. ADAMS

ABSTRACT

A hemicellulose fraction containing D-mannose, D-glucose, and D-galactose in a ratio of 70:25:3 has been isolated from tamarack wood. The product was homogeneous under conditions of free boundary electrophoresis and of sedimentation in the ultracentrifuge. Hydrolysis of the fully methylated hemicellulose yielded 2,3,4,6-tetra-*O*-methyl-D-glucose (1.2%); 2,3,4,6-tetra-*O*-methyl-D-galactose (2.2%); 2,3,6-tri-*O*-methyl-D-glucose (24.0%); 2,3,6-tri-*O*-methyl-D-mannose (68.8%); 2,3-di-*O*-methyl-D-mannose (1.6%); and 2,3-di-*O*-methyl-D-glucose (1.7%). This data and that from periodate oxidation indicated that the glucomannan had a linear backbone of approximately 35 ($1 \rightarrow 4$) linked β-D-glucopyranose and β-D-mannopyranose units; approximately two thirds of the chains were terminated at the non-reducing ends by D-galactose and the remainder by D-glucose. Branching, if present, must occur through C_6 of the hexoses in the main chain.

Investigations of glucomannans from various gymnosperms have shown a similar basic structure (1–5). They consist of D-glucose and D-mannose units (ratio 1:3–4) joined by β-1,4-glucosidic bonds into linear chains. Two additional structural features about which there are divided opinions concern the presence of branching in the molecule, and the presence and structural attachment of D-galactose units associated with glucomannans. Much of the evidence for branching has been based on the presence of the dimethyl sugars found during methylation studies. It is well known that such evidence may be of questionable significance and the general consensus of opinion at the present time is that most glucomannans are unbranched (2, 6, 7, 8). Galactose units, when present, occur predominantly as non-reducing end groups (2, 7, 8, 9).

The present investigation of the glucomannan of tamarack was undertaken as part of a systematic study of the polysaccharides of this species. It was desirable also to compare the composition and structure of the glucomannan from tamarack with those from other coniferous species.

Extraction of tamarack holocellulose with 17.5% sodium hydroxide yielded a crude hemicellulose fraction which on acid hydrolysis gave D-mannose, D-glucose, D-galactose, D-xylose, L-arabinose, and a uronic acid component. The acidic xylan was precipitated as its "Cetavlon" (cetyl trimethyl ammonium hydroxide) complex. From the soluble residue, the glucomannan was recovered by gradient addition of ethanol. The yield of glucomannan was approximately 20% of the crude hemicellulose, a relatively large proportion having coprecipitated with the xylan–"Cetavlon" complex. Acid hydrolysis of the glucomannan and chromatographic examination of the sugars showed galactose, glucose, and mannose with only traces of xylose and arabinose. Quantitative estimations showed that galactose, glucose, and mannose occurred in the hemicellulose in a ratio of 3:25:70. The hemicellulose behaved as a single compound on examination in the ultracentrifuge and in moving boundary electrophoresis.

The methyl ethers obtained from methanolysis of the fully methylated glucomannan were analyzed by gas–liquid partition chromatography (10, 16). This method provided not only a means of identification of the methylated sugar glycosides but also yielded

[1]*Manuscript received December 29, 1960.*

[2]*National Research Council of Canada Postdoctorate Fellow 1960.*

quantitative data as to the relative amounts of methylated sugars. The free methylated sugars were separated by paper chromatography using the appropriate solvents and the results are shown in Table I. The main methylated sugars were found to be 2,3,6-tri-*O*-methyl-D-mannose and 2,3,6-tri-*O*-methyl-D-glucose which showed that the glucose and mannose residues were joined by 1,4 glycosidic bonds in the original hemicellulose. The linkage was presumably of the β type because of the negative specific rotations both of the original and the methylated hemicellulose; these values were increased on hydrolysis. The 2,3,4,6-tetra-*O*-methyl-D-galactose was the only methylated galactose found and therefore the galactose units must have occurred exclusively as non-reducing end groups. Although less than the required amount of galactose was recovered as 2,3,4,6-tetra-*O*-methyl-D-galactose, no evidence for any other methylated galactose was found. A small amount of glucose occurred as non-reducing end groups as shown by the presence of 2,3,4,6-tetra-*O*-methyl-D-glucose. Apparently mannose did not constitute any end groups as no tetramethyl mannose was detected. Approximately two thirds of the glucomannan chains were terminated by D-galactose and the remainder by D-glucose. One tetramethyl sugar residue was present for every 32 hexose residues. This value is of the same general order as the 34 hexose residues per reducing end group as found by hypoiodite oxidation and the value of 40 as determined by gas–liquid chromatography of the methylated sugars.

Periodate oxidation of the hemicellulose showed that 1.10 moles of periodate per mole of anhydrohexose sugar was consumed. Formic acid production was 0.11 mole per anhydro sugar unit and indicated a chain length of 33 hexose units. The absence of any glucose or mannose in the hydrolyzate of the product obtained by borohydride reduction of the periodate-oxidized hemicellulose showed that all monosaccharide units had been oxidized and there was no branching through C_2 or C_3 of these units. If any branching occurred it would have to be through C_6. The erythritol and glycerol produced in the degradation reactions must have come from $1 \rightarrow 4$ linked sugar units and non-reducing terminal residues respectively.

At variance with the prediction of a straight-chain structure is the finding of dimethyl sugars which may be interpreted as indicating branch points in the molecule. If the amounts of dimethyl sugars found on hydrolysis had their origin from branch points in the hemicellulose, then the amount of recovered tetramethyl sugars which represents terminal groups becomes insufficient. Even allowing for less than a quantitative yield of tetramethyl galactose, there would still be a shortage of end groups. The conclusion that the amount of end groups found is substantially correct is supported by the fact that estimation of the degree of polymerization using these values is in good agreement with that found by periodate oxidation, by gas–liquid chromatography, and also by reducing end group estimation. It seems likely then that the dimethyl sugars do not represent branch points in the molecule but are products of demethylation or incomplete methylation.

It is apparent that D-galactose is an integral part of the glucomannan molecule. If it were to occur as a separate entity, then methylated galactoses other than tetra-*O*-methyl-D-galactose should be found on hydrolysis. So far, these have not been found even by the sensitive gas–liquid chromatographic method. Terminal galactose units could originate from an admixture of galactoglucan or (and) galactomannan with the present polysaccharide. While the presence of such polysaccharides is not excluded no positive evidence for them has been found.

It is apparent that the tamarack glucomannan is similar to most glucomannans of coniferous origin. The glucose-to-mannose ratio, specific rotation, and general structural features correspond clearly to those of other glucomannans (2, 4, 11, 12). While species

differences may well account for variations in composition and structure of the glucomannans, the methods of preparation may also contribute to the differences. For example, a glucomannan prepared from Sitka spruce by Dutton and Hunt (7) had a glucose-to-mannose ratio of 1:9; using another method of preparation Aspinall *et al.* (6) obtained a glucomannan from the same species having a glucose-to-mannose ratio of 1:2.5.

Evidence for branching through C_2 and C_3 in the glucomannans of western hemlock (13), Norwegian spruce (14), and Scots pine (12) have been provided through examination by the Smith degradation procedure (15). Examination of the glucomannan of jack pine (2) yielded neither D-glucose nor D-mannose after periodate oxidation, a result which is in agreement with that reported above for tamarack.

Further differences between the glucomannan of tamarack and those of some other species are the sugars constituting the non-reducing terminal group. Western hemlock (13) and Scots pine (12) have non-reducing terminal units of both D-glucose and D-mannose while Norwegian spruce (14), Sitka spruce (6), and loblolly pine (9) have non-reducing terminal units of D-mannose but none of D-glucose. Some of these differences may have been caused by the difficulty in separating the 2,3,4,6-tetra-*O*-methyl ethers of D-glucose and D-mannose (6) a difficulty which is obviated by the use of gas–liquid partition chromatography (16).

The occurrence of D-galactose in glucomannans has been noted by several investigators and it has not always been found to be a part of the glucomannan molecule. A polysaccharide from loblolly pine (17) having a composition similar to that of tamarack was considered to be a mixture of galactomannan and glucomannan. Further investigation (9) of the same polysaccharide showed that the chains of 27–33 sugar units were terminated by non-reducing units of D-galactose and D-mannose. The methyl ethers of D-galactose obtained from the hydrolysis of methylated glucomannan from western red cedar were considered to have originated from a contaminating galactoglucomannan (8). D-Galactose was found in glucomannans isolated from Sitka spruce (7) and Scots pine (12) but in each instance further purification removed it. Glucomannans prepared from western hemlock (13), Norwegian spruce (14), Sitka spruce (6), and white spruce (4) were devoid of D-galactose.

Fragmentation analyses of the tamarack glucomannan are being undertaken in this laboratory to determine the structural relationships of the D-galactose units and the sequence of the hexose residues in the molecule.

EXPERIMENTAL

All specific rotations are equilibrium values unless otherwise stated, melting points are corrected, and all evaporations were done at 35° C or less.

Paper Chromatography

Chromatographic separations were carried out on filter paper using the following solvent systems (v/v):

(A) pyridine:ethyl acetate:water (2:1:2),
(B) methyl ethyl ketone:water:ammonia (100:50:3),
(C) ethanol:benzene:water:ammonia (47:200:14:1),
(D) *n*-butanol:ethanol:water (40:11:19),
(E) *n*-butanol:pyridine:water (5:4:5).

Separations were made by the descending method on either Whatman No. 1 or No. 3MM filter paper. Sugars were located on the paper by the *p*-anisidine spray reagent (18);

non-reducing sugar derivatives were detected by silver nitrate and sodium hydroxide sprays (19).

Preparation of the Hemicellulose

Starting material for the preparation was a crude hemicellulose obtained from tamarack (*Larix laricina* (Du Roi) Koch) chlorite holocellulose by extraction with sodium hydroxide solution (17.5%). Chromatographic examination of an acid hydrolyzate showed galactose, glucose, mannose, arabinose, xylose, and a uronic acid were present.

Crude hemicellulose (50 g) was added gradually to water (2.5 liters) and stirring was continued at 0° C for 3 days. Undissolved material (4.6 g) was removed by centrifuging and the supernatant was diluted to 4.5 l. with water. An aqueous solution of 2% "Cetavlon" (cetyl trimethyl ammonium hydroxide) (1 liter), hydroxide form was prepared from the bromide form by stirring with silver oxide (13 g) for 1/2 hour and then removing the silver salts by filtration. Addition of "Cetavlon" to the solution of the hemicellulose with stirring gave a sticky precipitate which settled out on standing overnight. The supernatant was removed by decantation and its pH adjusted to 5.0 by acetic acid. The first hemicellulose fraction (I) was precipitated by adding ethanol to a concentration of 24%, after its removal a second fraction (II) was precipitated by adding ethanol to 50% concentration. The precipitates were recovered by centrifuging, washed successively with 50% ethanol (3 times), 100% ethanol (3 times), and ethyl ether (3 times). Ether was removed on the steam bath and the hemicellulose was dried *in vacuo* at room temperature. The yields were: fraction I, 2.14 g, fraction II, 10.0 g. Chromatographic examination of hydrolyzates showed that fraction II contained galactose, glucose, and mannose, fraction I contained xylose in addition to galactose, glucose, and mannose. On the basis of these results, fraction II, which appeared to be a galactoglucomannan, was selected for subsequent investigations.

The polysaccharide was dissolved in dilute alkali to give a clear solution $[\alpha]_D^{25}$ $-30°$ (*c*, 1% in 0.5 *N* sodium hydroxide). Hydrolysis of a sample (12 mg) in a sealed tube with *N* sulphuric acid for 12 hours and examination of the sugars by paper chromatography (solvents A and E) showed the presence of mannose, glucose, a small amount of galactose, and a trace of xylose. No uronic acids could be detected.

The ratio of the sugars in the hydrolyzate was determined using the method of Dubois *et al.* (20) and was found to be mannose:glucose:galactose, 70:25:4. A more accurate measurement of the amount of galactose present was provided by using gas–liquid chromatographic determination of the fully methylated sugars as described by Adams and Bishop (21). This latter method gave the previous ratio of mannose and glucose but the galactose content was 2.7%. Xylose was present in only trace amounts.

Examination of the hemicellulose in a 0.05 *M* borate buffer by moving boundary electrophoresis carried out in a Spinco model H Tiselius-type apparatus showed only a single sharp peak. Mobility measurements gave the value, $\mu = 6.71 \times 10^{-5}$ cm^2 volts^{-1} sec^{-1}. The same solution was centrifuged in a Spinco model E ultracentrifuge at 59,000 r.p.m. and showed only one symmetrical peak which is indicative of a single compound.

End Group Determination by Hypoiodite

A slightly modified Willstätter–Schudel method (22) was used for reducing end group determination of the hemicellulose. Samples in triplicate (50 mg each) were dissolved in 5 ml of *N* sodium hydroxide and then 2.5 ml of 0.02 *N* iodine was added. The solutions along with suitable controls were kept in stoppered flasks in the dark for 3 hours. After acidification with 10 ml of *N* sulphuric acid, the iodine was titrated with 0.01 *N* sodium thiosulphate. One reducing group was found to occur per 34 anhydrohexose units.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Periodate Oxidation

Duplicate samples of the hemicellulose (100 mg) were dissolved in water (50 ml) and oxidized by 0.1 *M* sodium metaperiodate (50 ml) in the dark at room temperature. Suitable reagent blanks were prepared under the same conditions. At the intervals shown in the table below, analyses were made for periodate consumption and formic acid production (23). The results given in moles per mole anhydrohexose unit were as follows.

Time, hours	26	77	130	179	221	300
Periodate consumption	0.84	0.98	1.07	1.10	1.15	1.18
Formic acid production	0.027	0.067	0.078	0.094	0.103	0.130

In a separate experiment, the hemicellulose was degraded according to Smith's procedure (15) as follows: hemicellulose (200 mg) was dissolved in water (100 ml) and oxidized with 0.1 *M* sodium metaperiodate (100 mg) for 240 hours at room temperature. Excess periodate was destroyed by the addition of ethylene glycol and the solution was dialyzed for 24 hours. The non-dialyzable material was concentrated to 25 ml and potassium borohydride (250 mg) was added. After 72 hours, the solution was neutralized with acetic acid and deionized by Amberlite IR-120 and IR-45. The resulting solution was evaporated *in vacuo* to dryness and the boric acid removed by repeated evaporation with methanol. The dried residue (65 mg) was dissolved in water (10 ml) and an aliquot (1 ml) was hydrolyzed with *N* hydrochloric acid for 6 hours at 100° C. Paper chromatography of the hydrolyzate in solvent D showed erythritol as the main component with glycerol present in small amounts. No monosaccharides were detected in the hydrolyzate.

Methylation of the Hemicellulose

Hemicellulose (5.0 g) was dissolved in 20% sodium hydroxide (50 ml) and methylated by the dropwise addition of dimethyl sulphate (50 ml) and 45% sodium hydroxide (100 ml). The methylation procedure was repeated four more times and the partially methylated product recovered by dialysis. Repetition of the methylation gave a product which was extracted by chloroform. Fractionation from chloroform solution by the addition of light petroleum (b.p. 30–60°) gave a methylated fraction (5.1 g) having a methoxyl content of 40.6%. Four further methylations were carried out using Purdie's reagents (methyl iodide (75 ml) and silver oxide (10 g)). The methylated hemicellulose (4.3 g) $[\alpha]_D^{25}$ −25.2° (*c*, 1% in chloroform) had a methoxyl content of 43.5% (theoretical for fully methylated hexosan 45.6%) and showed no hydroxyl absorption in the infrared.

Methanolysis and Hydrolysis of the Methylated Hemicellulose

A solution of the methylated hemicellulose (4.0 g) in 8% methanolic hydrogen chloride (60 ml) was refluxed on a boiling-water bath for 15 hours. A sample of the mixture of the methyl glycosides (5 mg) was removed for examination by gas–liquid partition chromatography (16).

The presence of the methyl glycosides of the following methyl sugars was indicated:

2,3,4,6-tetra-*O*-methyl-D-glucose,
2,3,4,6-tetra-*O*-methyl-D-galactose,
2,3,6-tri-*O*-methyl-D-glucose,
2,3,6-tri-*O*-methyl-D-mannose.

Smaller peaks which were not resolved were glycosides of dimethyl sugars.

The methanolysis mixture was freed of methanol and then hydrolyzed by heating it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with 0.5 *N* hydrochloric acid (25 ml) at 100° C for 22 hours. The acid was neutralized with silver carbonate and the methylated sugars were recovered as a clear syrup (4.1 g), $[\alpha]_D^{25}$ +11.3° (*c*, 1% in water). Chromatographic examination on filter paper (solvent B) indicated the same methyl sugars as found by gas–liquid chromatography, but in addition the dimethyl portion had been resolved into two components.

Separation of Methylated Sugars

The mixture of methylated sugars was separated on sheets of Whatman No. 3MM filter paper using solvent B. The sugars were eluted with water and the solutions were taken to dryness. The residues were extracted with methanol, clarified with charcoal, and the syrups were recovered and dried. Yields of methylated sugars along with their R_g values are given in Table I.

TABLE I

Methylated sugars from hydrolysis of methylated hemicellulose

Methylated sugars	R_g solvent B	Yield (mg)	%
2,3,4,6-Tetra-*O*-methyl-D-glucose	0.98	27	1.2
2,3,4,6-Tetra-*O*-methyl-D-galactose	0.81	50	2.2
2,3,6-Tri-*O*-methyl-D-glucose	0.66	557	24.1
2,3,6-Tri-*O*-methyl-D-mannose	0.55	1587	68.8
Dimethyl sugar 1	0.30	38	1.6
Dimethyl sugar 2	0.23	40	1.7

Identification of Methylated Sugars

*2,3,4,6-Tetra-O-methyl-*D*-galactose*

The syrup had the same R_g value (0.81) in solvent B as an authentic sample of 2,3,4,6-tetra-*O*-methyl-D-galactose. The sugar (24 mg) was dissolved in ethanol (1 ml), freshly distilled aniline (20 mg) was added, and the mixture was refluxed for 3 hours. Removal of the solvent in a desiccator yielded white needles which were recrystallized from ethanol to yield 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-galactosylamine (17 mg), m.p. and mixed m.p. 196–197° C, $[\alpha]_D^{25}$ −138° (*c*, 0.9% in pyridine).

*2,3,4,6-Tetra-O-methyl-*D*-glucose*

This sugar had the same mobility on a paper chromatogram in solvent B and on paper electrophoresis in borate buffer as authentic 2,3,4,6-tetra-*O*-methyl-D-glucose.

The sugar (9 mg) was dissolved in ethanol, aniline (6 mg) was added, and the mixture was refluxed for 2 hours. The fine needles which formed on removal of the solvent had a melting point of 128–130° C. Two recrystallizations from ethyl ether – light petroleum yielded 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-glucosylamine, m.p. 136–137°; reported value 137–138° (24).

*2,3,6-Tri-O-methyl-*D*-glucose*

The sugar separated on paper chromatograms was decolorized with charcoal. The solution was concentrated to a syrup, ethanol was added, and on slow evaporation a portion of the sugar crystallized. Recrystallization several times from ethanol – ethyl ether – light petroleum yielded 2,3,6-tri-*O*-methyl-D-glucose, m.p. 121° C, $[\alpha]_D^{24}$ +70.0° (*c*, 0.5% in water); reported values m.p. 121–123° C, $[\alpha]_D$ +70° (25).

Preparation of the 1,4-di-*p*-nitrobenzoate according to Rebers and Smith (32) yielded the crystalline derivative, m.p. 189–190° after recrystallization from methanol. Reported value m.p. 189–190° (26).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

2,3,6-Tri-O-methyl-D-mannose

This sugar had the same mobility on a paper chromatogram (Solvent B) as an authentic sample of 2,3,6-tri-*O*-methyl-D-mannose. The aniline derivative was prepared as described above and yielded the crystalline 2,3,6-tri-*O*-methyl-*N*-phenyl-mannosylamine, which on repeated recrystallization from ethyl acetate – petroleum ether, had a melting point of 131–133° C (reported value 133° (28)). The 1,4-di-*p*-nitrobenzoate derivative was prepared as described above and after one recrystallization from methanol had a melting point of 187–188°; reported value 187–188° (26).

2,3-Di-O-methyl-D-mannose

Demethylation of a small amount of the syrup (5 mg) with boron trichloride (17) showed that mannose was the main product with minor amounts of glucose also present. On paper electrophoresis in borate buffer the main di-*O*-methyl mannose had an M_g value of 0.11. It was separated from other minor components on paper chromatograms using solvent C. The sugar (32 mg) was converted into the 1,4,6-tri-*p*-nitrobenzoate derivative using the same procedure described above. After several recrystallizations from methanol the melting point was 192°, reported value 194° (29).

2,3-Di-O-methyl-D-glucose

Glucose was the main product found on demethylation along with a minor amount of mannose. Paper chromatography (solvent C) separated the main component which on paper electrophoresis in borate had an M_g value of 0.12. The sugar which appeared to be 2,3-di-*O*-methyl-D-glucose could not be obtained in crystalline form. On refluxing it in ethanol solution with aniline, crystalline 2,3-di-*O*-methyl-*N*-phenyl-D-glucosylamine was obtained. Recrystallization from ethyl acetate gave a product having m.p. 132°; reported value 134° (30).

Other Dimethyl Sugars

Along with the two di-*O*-methyl sugars described above, two others, a di-*O*-methyl mannose (M_g 0.07) (solvent C) and a di-*O*-methyl glucose were recovered in trace amounts. They were tentatively identified as 2,4-di-*O*-methyl-D-mannose and 2,4-di-*O*-methyl-D-glucose on the basis of demethylation and paper electrophoretic and chromatographic evidence.

ACKNOWLEDGMENTS

The authors wish to thank Professor J. K. N. Jones, Queen's University, Kingston, who generously provided a sample of 2,3-di-*O*-methyl-D-glucose. Thanks are also due to Mr. F. P. Cooper for assistance with the gas–liquid chromatography, to Mr. A. E. Castagne for analyses, and to Mr. R. W. Rowsome for electrophoresis measurements.

CHALKOGENIDES OF THE TRANSITION ELEMENTS

III. MOLYBDENUM DITELLURIDE[1,2]

OSVALD KNOP AND RODERICK D. MACDONALD[3]

ABSTRACT

$MoTe_2$ prepared by dry synthesis from the elements at 460° C and annealed at 600° C has a layer structure of the *C7* type with $a_0 = 3.5182 \pm 14$ Å and $c_0 = 13.9736 \pm 40$ Å. The parameter of the tellurium atom has been determined from closely reproducible X-ray diffractometer powder intensities as 0.621 ± 1. The nearest-neighbor co-ordination polyhedron of the molybdenum atom is a trigonal prism with a Mo—Te distance of 2.716 ± 12 Å. The distance of nearest approach of the tellurium atoms between layers is 3.945 ± 25 Å and thus greater than the similar distance between chains in metallic tellurium. It is shown that the observed intensities are not compatible with a stacking sequence of the *C27* type, which differs from the *C7* arrangement in the geometry of the co-ordination polyhedra of the metal atoms.

INTRODUCTION

It has been recently reported that molybdenum disulphide does not always have a crystal structure of the *C7* type, whose prototype it is, but that it can exist as at least two, and possibly three, polymorphs (1, 2, 3, 4). The two structures of the sulphide which are known in detail, i.e., the hexagonal *C7* structure and the rhombohedral form first described by Bell and Herfert (3) and later structurally reinterpreted by Jellinek *et al.* (4), are both layer structures consisting of planar sheets of superposable hexagonal networks of molybdenum and sulphur atoms stacked parallel to the basal plane. They differ in the sequence and period of displacement of the molybdenum and sulphur networks with respect to each other. The sequence is . . .AMABNBAMABNBAMA . . . for the *C7* form and . . . APACMCBNBAPACMCBNBAPA . . . for the rhombohedral form (A, B, C refer to sulphur layers, M, N, P, to molybdenum layers), but in both cases the stacking sequences result in trigonal-prismatic nearest-neighbor co-ordination of the molybdenum atom. Other sequences are theoretically possible, in some of which the environment of the metal atom is trigonal antiprismatic (distorted octahedral). A structure of this type would be, for example, the *C27*-type structure known from β-CdI_2, which Hägg and Schönberg (1) proposed as a possible MoS_2 structure to account for the observed X-ray intensities of some of their MoS_2 samples showing reportedly large disagreement between I_o and $I_c(C7)$.*

Although the crystal structure of the corresponding telluride, $MoTe_2$, has not been determined before, it was usually assumed that it belonged to the *C7* group; in reference 5, for instance, this follows by implication. When evidence for the polymorphism of MoS_2 appeared, it became clear that the telluride need not necessarily have the stacking arrangement of a *C7* compound and even if it does, the structure may be of lower symmetry, as has been found to be probably the case with the corresponding wolfram compound (6).

**The relationship between the C7 and the rhombohedral form of* MoS_2 *is the same as that between the C27 and the C19* ($CdCl_2$) *structure, except that the metal co-ordination is trigonal prismatic in the first pair and distorted octahedral in the second.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

As far as we know, the occurrence of the *C7* type of structure is restricted to chalkogenides of niobium (4), molybdenum, tantalum (7), wolfram, rhenium (8), and possibly hafnium.* These compounds and the rhombohedral polymorphs of the disulphides of molybdenum, niobium, and tantalum are, moreover, almost the only known instances of structures in which the metal atom has trigonal-prismatic nearest-neighbor co-ordination,† which would seem to indicate a strong preference for this rather than for octahedral co-ordination. The observed bulk diamagnetism of MoS_2 (11) (and also of WTe_2 (13)) is in agreement with the assumption that the trigonal-prismatic co-ordination is the result of d^4sp bonding. Further support of this contention comes from the appreciable diamagnetic anisotropy of single crystals of molybdenite, the negative susceptibility parallel to the hexagonal axis being almost twice as large as that in the direction normal to the axis (12). Such magnetic behavior with its strong temperature dependence and the appreciable electrical conductivity of molybdenite along the basal plane both point to the presence of a system of largely delocalized mobile π electrons within the MoS_2 layers; the existence of such a system can again be explained from the d^4sp orbital configuration on the molybdenum atom, or more particularly from its $\pi(p^2d)$ system of trigonal symmetry. The telluride, which, too, has been shown to be diamagnetic (13), can accordingly be expected to have a *C7* structure or its rhombohedral modification. Furthermore, unless Hägg and Schönberg's MoS_2 preparations were paramagnetic, an explanation of the observed discrepancies in the diffraction intensities of these samples cannot be advanced on the basis of a *C27*-type structure with its sp^3d^2 (or d^2sp^3) bonding and its associated magnetic moment.

On the other hand, ReS_2 (14) and WS_2 (15) have been reported to be paramagnetic. The effective magnetic moment of ReS_2 is small and independent of temperature, but natural WS_2, tungstenite, has been stated to be strongly paramagnetic with a curious temperature dependence and a pronounced anisotropy. The effective moment of tungstenite at room temperature was found higher than would correspond to the "spin-only" value for two unpaired 5*d*-electrons. The *ad hoc* explanation for the paramagnetism of tungstenite profered by Dutta and Chowdhury (15) and based on the assumption of a *C7* structure, fails to establish why molybdenite, for which the same qualitative arguments apply, is diamagnetic. If the reported magnetic behavior of tungstenite is genuine and not caused by ferromagnetic or strongly paramagnetic impurities in the natural material‡ the orbital configuration on the tungsten atom cannot be d^4sp. The paramagnetism could be due to d^3p^3 or d^3sp^2 bonding, but then the stereochemistry of the WS_6 group would not be consistent with the $\bar{6}$ symmetry of the regular trigonal prism. The difference in co-ordination could be brought to light by crystal-structure analysis, but a sufficiently accurate detailed study of WS_2 has not yet been made. If orbital configurations of geometries different from that of d^4sp are, however, admitted to explain the paramagnetism of WS_2, one should bear in mind that this last configuration is not the only one to account for the observed diamagnetism of $MoTe_2$, but that this telluride might conceivably exist with a d^4p^2 configuration on the molybdenum atom. Since neither the magnetic properties of WS_2 nor its crystal structure has been established beyond doubt

*This case is now under investigation in this laboratory.

†In the *B8* (nickel arsenide) structure the atoms with trigonal-prismatic co-ordination are the non-metal atoms. A similar situation obtains, for instance, in Re_3B, Ru_7B_3, and other borides (9), and also in some carbides and phosphides. In the borides $RhB_{\sim 1.1}$ and PtB, however, which have been reported to have anti-NiAs structures, the nearest-neighbor co-ordination of the metal atoms is trigonal prismatic (10).

‡The tungstenite used by Dutta and Chowdhury was, to the authors' own admission, impure, but chemical analyses of the mineral are not shown. The impurity content varied with the source of the material; the spread of the experimental densities of the individual crystals (method not stated) was very appreciable, 7.00–8.2.

to either eliminate or include the possibility of co-ordination other than trigonal prismatic in the above group of dichalkogenides, prediction of the crystal structure of $MoTe_2$ is not entirely straightforward.

As for the differences caused by the stacking sequences of MX_2 layers of a particular type, either trigonal-prismatic or octahedral, polymorphs of this kind would not be expected to have widely dissimilar lattice energies. This is borne out by the relative readiness with which mixed sequences are formed in, for instance, cadmium or nickel bromides, although the ratio of the atomic radii does to some extent determine the stacking arrangement (cf. α-CdI_2 and $CdCl_2$).

In view of the contradicting statements in the literature concerning the molybdenum etc. dichalkogenides and since the tellurides of the above elements have so far received only scanty attention, we thought it of interest to investigate whether the trigonal-prismatic co-ordination of molybdenum, which is apparently characteristic for the typical molybdenum disulphide and diselenide, is preserved in the ditelluride; and if this is the case, whether the structure corresponds to the *C7* type, with or without distortion, or to another stacking arrangement.

EXPERIMENTAL

The ditelluride was prepared by dry synthesis from the elements *in vacuo* in much the same way as previously WTe_2 (6). Fansteel molybdenum powder type 352 of average particle size of 4–5 microns and of specified minimum purity of 99.9% and specified minimum impurity content of 0.015% C, 0.125% O, and 0.02% Ni, was reduced before use with purified hydrogen at 690–700° C. The tellurium metal was kindly donated by Canadian Copper Refiners, Ltd., and contained, according to the supplied analysis (in p.p.m.), 0.4 Cu, 3.0 Al, and 0.5 Mg. Hg (detection limit 2 p.p.m.), Pb (0.5), Fe (1), As (10), Sb (0.5), Sn (0.5), Bi (0.5), Ni (1), Cr (0.5), Zn (10), Ag (0.1), Na (4), and Si (1) were not detected.

A stoichiometric mixture of molybdenum and tellurium powders totalling 15 g was sealed in a degassed, evacuated tube of clear quartz and kept at 460° C for 16 hours. On removal from the furnace the tube was opened and the reacted mixture crushed lightly to pass a 125-mesh screen. The thoroughly mixed powder was then resealed and annealed at 600° C for 48 hours. The product was a loose dark-gray powder of uniform appearance consisting of very fine needles and platelets. The crystals were too small and often intimately intergrown to be suitable for a single-crystal study. No foreign particles were detected under magnifications up to 30 diameters.

Specimens for X-ray powder diffraction were prepared by mounting $MoTe_2$ powder that had been crushed to pass completely a 325-mesh screen, on very thin pyrex fibers coated thinly and uniformly with vacuum grease. Powder photographs were taken in 114.6-mm Straumanis-type cameras with filtered Cu K, Fe K, and Cr K radiations. Powder specimens for the Norelco diffractometer were prepared by sifting the annealed powder through a 325-mesh screen on a cylindrical aluminum specimen mount coated evenly with a thin, flat layer of stiff silicon grease. The diffractometer patterns were obtained with rotating specimens using 1/2, 1, and 4° slits and a pulse-height analyzer. They were used for the integrated intensities only. The same wavelengths were used as are quoted in the second paper of this series.

RESULTS

The films were of surprisingly good quality, considering the frequently poor definition of the diffraction lines obtained with tellurides of the transition elements. As could be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

expected, the photographs taken with filtered Cu K radiation had the best appearance and were used in the final determination of lattice parameters. All lines could be indexed on a hexagonal unit cell (Table I). After six cycles of refining a and c by least squares

using Nelson–Riley extrapolation for reflections with $\theta > 30°$ the final values of the lattice parameters were $a_0 = 3.5182 \pm 14$ Å, $c_0 = 13.9736 \pm 40$ Å, and $c_0/a_0 = 3.972$. The volume of the unit cell is 149.79 ± 17 Å^3.

The density of $MoTe_2$ (125−) was determined in the same way as described in Part II of this series. Average of three determinations gave $d_4^{25} = 7.681 \pm 18$ g/cm^3, which corresponds to 1.974 $MoTe_2$ per unit cell. This density compares rather more favorably with the density calculated from the lattice parameters, 7.784 ± 9 g/cm^3, than the value quoted by Morette (13), $d_4^{15} = 7.60 \pm 1$ g/cm^3, and is only −1.28% lower than the X-ray density. It is difficult to say whether the discrepancy has a real significance as regards the existence of molybdenum and tellurium vacancies in the structure.* Unreacted molybdenum and tellurium in amounts lower than the minimum amounts capable of producing observable diffraction lines cannot be detected in a stoichiometric $MoTe_2$ sample by density measurement because of the almost identical densities of $MoTe_2$ and a 1:2 mixture of molybdenum and tellurium.

Reflections of the (hkl) type with $h-k = 3n$, $l = 2n+1$ were absent. This condition is satisfied in eight space groups, viz., D_{6h}^4—$P\,6_3/mmc$, D_{3h}^4—$P\,\bar{6}2c$, C_{6v}^4—$P\,6_3mc$, D_6^6—$P\,6_322$, C_{6h}^2—$P\,6_3/m$, C_6^6—$P\,6_3$, D_{3d}^2—$P\,\bar{3}1c$, and C_{3v}^4—$P\,3/c$, but the symmetries and equipoints of these space groups are compatible not only with the *C7*, but also with, for instance, the *C27* structure, which has been claimed as possible for some MoS_2 samples (cf. Introduction).

The first model tried was a *C7* structure (space group D_{6h}^4—$P\,6_3/mmc$) with 2 Mo in $2(c)$: $\pm(1/3, 2/3, 1/4)$ and 4 Te in $4(f)$: $\pm(1/3, 2/3, z)$; $\pm(1/3, 2/3, 1/2-z)$, $z_{Te} = 0.625$ $(= 5/8)$. A set of intensities was calculated for Cu $K\alpha$ radiation using Thomas–Fermi atomic scattering factors tabulated in reference 18. The agreement between I_o and I_c was good, but it was felt that the integrated powder intensities, which had been obtained by careful planimetering of several diffractometer charts, would justify further refinement. Six other values of z varying from 0.618 to 0.628 were then tried. Since out of the 70 observable reflections with $I_c \geqslant 0.5$ (normalized to $I_o(103)$) only 26 were fully resolved, the extent of agreement could not be assessed from the reliability index, $R = \sum ||F_o| - |F_c|| / \sum |F_o|$, customary in structure analysis from single-crystal data. However, the sum $\sum |I_o - I_c|$, though not an unambiguous measure of the progress of refinement, was found to be quite sensitive to variations in z. The agreement of I_o and I_c for $z = 0.621 \pm 1$, which was the value corresponding to the minimum of the difference sum located analytically for a parabolic least-squares fit, was indeed remarkably good (Table I). The *C7* structure adopted in the first trial can thus be considered correct, the existence of homometric structures compatible with the observed dimensions and symmetry of the unit cell being not very probable.

The close agreement of the intensities also demonstrates that the diffractometer specimens were free from orientation effects which are frequently present in specimens of compounds with fully developed layer structures. Stacking disorder in our $MoTe_2$ preparation must have been negligible for the same reason. The increase of $|I_c - I_o|$ with θ for individual reflections was so small that it did not justify inclusion of an isotropic temperature factor. In particular, there was no systematic weakening of I_o for reflections with $h-k \neq 3n$ with increasing l, nor was there selective line-broadening affecting particular orders.

As for the possibility that $MoTe_2$ has a *C27*-type structure (space group $C_{6v}^4 - P\,6_3mc$),

*Similar, and even greater, differences between pycnometric and X-ray densities have been reported for wolfram disulphide (16, 17).

it is readily seen that a model structure with 2 Mo in 2(*b*): ±(1/3, 2/3, 1/4), 2 Te in 2(*b*): (1/3, 2/3, *z*), (2/3, 1/3, 1/2+*z*), 2 Te in 2(*a*): (0, 0, −*z*), (0, 0, 1/2−*z*), and z_{Te} = 5/8* is not isovectorial with *C7* and cannot account satisfactorily for the observed intensities. In particular, the calculated intensities of the reflections {100} and {200}, whose geometrical structure factors do not contain *z*, differ very considerably from the corresponding I_o values, the ratios $F_{100}(C27)/F_{100}(C7)$ and $F_{200}(C27)/F_{200}(C7)$ being −0.072 and −0.081, respectively, and thus far from unity. A similar situation is obtained with another conceivable model structure, viz. that based on the structure of the recently described hexagonal NbS_2 (4), even though the nearest-neighbor co-ordination of the metal atom is trigonal prismatic.

The interatomic distances and bond angles in the $MoTe_2$ structure are as follows (Fig. 1):

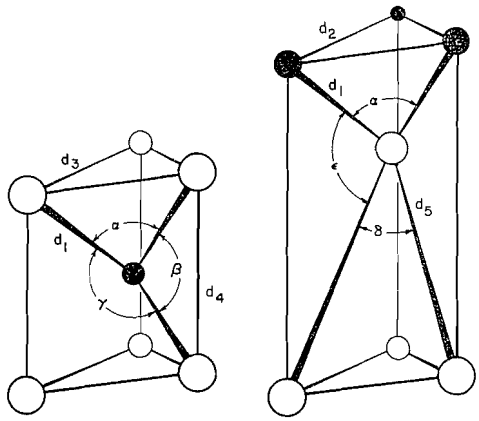

FIG. 1. Nearest-neighbor co-ordination of the molybdenum and tellurium atoms in molybdenum ditelluride. Full circles, molybdenum; open circles, tellurium.

d_1(Mo—Te) = 2.716±12 Å
d_2(Mo—Mo) = d_3(Te—Te) = a_0 = 3.5182±14 Å
d_4(Te—Te) = 3.603±25 Å
d_5(Te—Te) = 3.945±25 Å
d_6(Mo—Mo, between layers) = 7.276±5 Å

α(Te—Mo—Te) = α(Mo—Te—Mo) = 80.74±0.50°
β(Te—Mo—Te) = 83.10±0.60°
γ(Te—Mo—Te) = 135.95±0.60°
δ(Te—Te—Te) = 52.96±0.40°
ϵ(Mo—Te—Te) = 100.59±0.60°.

The Te—Te distance d_5 is about 14% longer than the distance of nearest approach between chains in metallic tellurium, 3.468 Å (19), and the similar Te—Te distance, 3.46±8 Å, in $NiTe_2$(*C6*) (20), but it is fairly close to the Te—Te distance between layers in γ(V, Te)(*C6*), 3.82–3.85 Å (21). The asymmetric Te_I—Te_{II}—Te_I angle between neighboring chains I and II in tellurium which subtends the shortest Te—Te distance in a chain, 2.864 Å, is only 35.4° and thus appreciably smaller than the corresponding angle δ in $MoTe_2$. A symmetric Te_I—Te_{II}—Te_I angle in tellurium is equal to 80.0°, but it subtends not the shortest Te—Te distance but the distance between next-nearest neighbors in the tellurium helix, 4.864 Å. The bond angle δ in $MoTe_2$ is thus almost the arithmetic average of these two bond angles. The Te—Mo—Te angles are very nearly the same as the corresponding S—Mo—S angles in MoS_2(*C7*).

**Origin shifted by (0, 0, 1/4) with respect to the original description of the C27 type as represented by β-CdI_2.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Since the distances d_3 and d_4 are not equal, the axial ratio of the trigonal prism is not exactly unity, as claimed by Pauling (22, p.175) for molybdenite, but slightly different, $d_4/d_3 = 1.024$.

The shortest Mo—Te distance, d_1, agrees quite well with the sum of the appropriate atomic radii, which is between 2.64 and 2.74 Å, depending on whether the value for Te is taken as the "single-bond" or the "double-bond" radius (22).

Allowing for the fact that WTe_2 is orthorhombic with $b \sim a\sqrt{3}$ (6) and taking the unit-cell dimensions for MoS_2 and WS_2 from (23) and (24), respectively, the square roots of the ratio of the basal areas and the cube roots of the unit-cell volumes are nearly the same for corresponding pairs:

	(basal area)$^{1/2}$	(volume)$^{1/3}$
$(WS_2)/(MoS_2)$	0.998	1.008
$(1/2\ WTe_2)/(MoTe_2)$	1.014	1.009
$(MoTe_2)/(MoS_2)$	1.113	1.121
$(1/2\ WTe_2)/(WS_2)$	1.131	1.122.

Since the estimated radius of Mo in molybdenite is 1.37 Å and that of W in tungstenite is 1.44 Å (22), the difference amounting to about 5%, it is clear that the dimensions of the unit cells of these compounds are determined essentially by the chalkogen atoms.

The stability of $MoTe_2$ on heating under orthobaric conditions is greater than that of WTe_2. There is no isothermal transition between room temperature and 1200° C (cf. (6)). The failure to observe melting in this temperature range is in full agreement with the result of Morette (13), who heated a sample of $MoTe_2$ with excess tellurium *in vacuo* up to 1130° without fusion.

The trigonal-prismatic co-ordination of the molybdenum atom in $MoTe_2$ established in this investigation and the observed diamagnetism of $MoTe_2$ and WTe_2 (13) as well as of MoS_2 throw some doubt on the strong paramagnetism of WS_2 reported for natural material in reference 15. Work is in progress in this laboratory to determine whether MoS_2 and WS_2 form mixed phases; and if so, how the magnetic properties of such phases depend on their composition. It is also intended to re-examine the crystal structure of WS_2 in the light of the conceivable structural ambiguities discussed in the introduction and to obtain a more accurate value for the sulphur parameter than the approximate value of 5/8 first proposed by van Arkel in 1926 (25) and quoted ever since.

ACKNOWLEDGMENTS

One of the authors (R. D. M.) wishes to express his gratitude to the Eldorado Mining and Refining Limited for the award of the Charles G. Williams Fellowship, and to Atomic Energy of Canada, Ltd., for leave of absence. The assistance of Dr. R. H. Tuxworth of Atomic Energy of Canada, Ltd., Chalk River, Ontario, who provided the preliminary diffraction charts, and of Mr. Muntaz Ali, who carried out some of the calculations and determined the density of molybdenum ditelluride, is hereby gratefully acknowledged.

THE PROTON RESONANCE SPECTRA OF SOME SUBSTITUTED FURANS AND PYRROLES[1]

R. J. ABRAHAM[2] AND H. J. BERNSTEIN[3]

ABSTRACT

The proton magnetic resonance spectra of some substituted furans and pyrroles have been analyzed for spin coupling constants and chemical shifts.

The relative insensitivity of the spin coupling constants to the nature of the substituent makes it possible to estimate their values in the parent molecules furan and pyrrole. The magnitude of the spin coupling constants is correlated with the angles made by the CH bonds with the CC bonds of the ring.

The chemical shifts are interpreted in terms of an effect due to the electronegativity of the substituent together with the effect due to conjugation with the ring.

The proton resonance spectra of the heterocyclic compounds furan, pyrrole, and thiophene and of their derivatives have been the subject of a number of investigations (1, 2, 3, 4). The present work is an attempt to determine more systematically the effects of substitution on the chemical shifts and spin coupling constants of the ring protons in substituted furans and pyrroles.

These compounds are well suited to a proton magnetic resonance investigation since their spectra are usually capable of a unique interpretation and assignment. The simplest spectra are those of the substituted furans. Here, due to the large difference in the chemical shifts of the α and β protons of the ring, any monosubstituted furan can be classed as an ABX-type spectrum for which a complete analysis is readily achieved. In some cases, where fewer lines are observed than theoretically expected, the spectrum obtained does not give explicit values of any of the coupling constants. This type of spectrum, which is obtained not only for some monosubstituted furans but also for the parent compounds furan and pyrrole, has been the subject of a previous publication (5). The spectra of the substituted pyrroles are complicated by the additional interaction of the N—H proton with the other ring protons. However, a possible interpretation of the spectra of some monosubstituted pyrroles is presented.

EXPERIMENTAL

The compounds used were the commercial samples except for the following. 2-Nitro furan was prepared by nitrating furan with fuming nitric acid and acetic anhydride following the procedure of Marquis (6). 5-Chlormethyl furfural was prepared from sugar and concentrated HCl following the procedure of Aso (7). 3-Furoic acid and its derivatives were kindly supplied by Prof. H. Gilman. The specimen of 2-cyano pyrrole was kindly supplied by Prof. H. J. Anderson.

The spectra of the compounds demonstrated their purity. Only in one case, 2-furoyl-trifluoromethyl ketone, was there any sign of any impurity.

The spectrometer and the techniques for measuring the spectra have been described fully in a previous paper (1). The spectra are shown for 40 Mc/s operation except where stated otherwise, and the convention adopted is that high applied field is positive.

The Analysis of Spectra

The spectra of the monosubstituted furans studied fall into three distinct classes.

The spectrum of 2-furanmethanethiol (Fig. 1) is given as an example of the type of

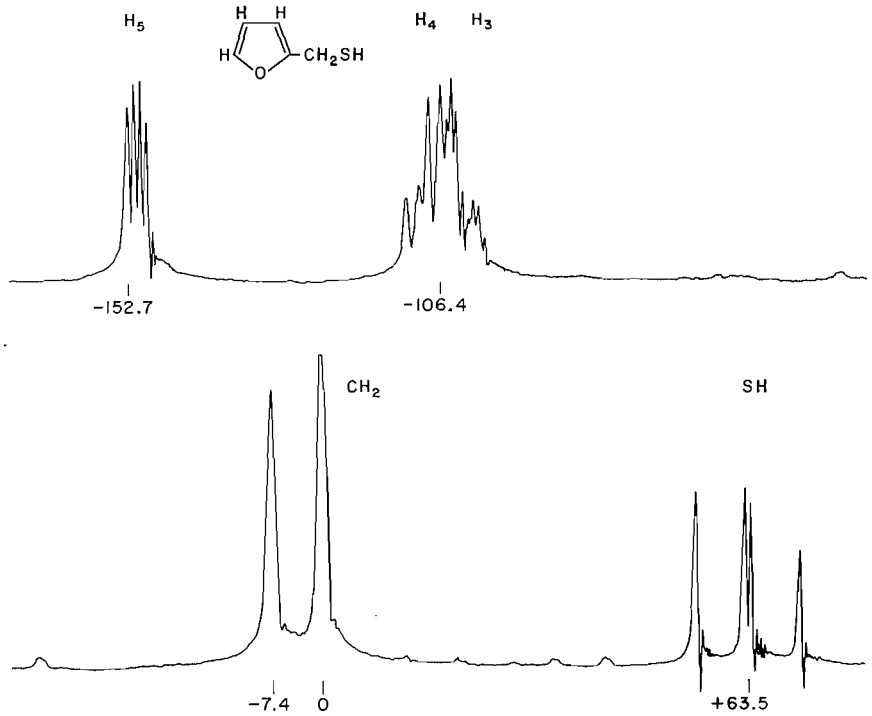

FIG. 1. The proton resonance spectrum of 2-furanmethanethiol (liquid) at 40 Mc/s. (The chemical shifts are in c.p.s. from a dioxane internal reference.)

spectrum obtained from a 2-furfuryl derivative. This is an ABX pattern with one of the normal quartets split into 12 unresolved lines by coupling with the CH_2 group. This interaction would be expected to take place between the methylene group and proton 3 of the ring, identifying the H_3 signals. This assignment is confirmed by the chemical shift data, as the methyl mercapto group is electron donating with respect to the furan ring and thus proton 3 would be expected to be more shielded than proton 4.

The spectrum of 2-nitro furan (Fig. 2) demonstrates the influence of a powerful electron-attracting group in position 2 of the ring. The electron shielding of proton 3 is decreased considerably. Thus the signal due to this proton moves to low field to such an extent that the spectrum is a simple first-order one, with the coupling constants given directly by the separations of the lines in each group. Any strongly electronegative group in position 2, e.g., the carbonyl group, gives the same type of spectrum.

The spectrum of 2-furanacrolein (Fig. 3) is an example of the third class of spectrum. Here the ring proton spectrum is very similar to that of 2-nitro furan, but is partially obscured by the side chain spectrum. The assignment shown in Fig. 3 was confirmed by the spectrum of 2-furanacrylic acid, which is identical with the one shown except that in this case the aldehyde splitting of one of the side chain protons is removed leaving a simple quartet.

The remaining spectra are straightforward examples of one of these classes or are

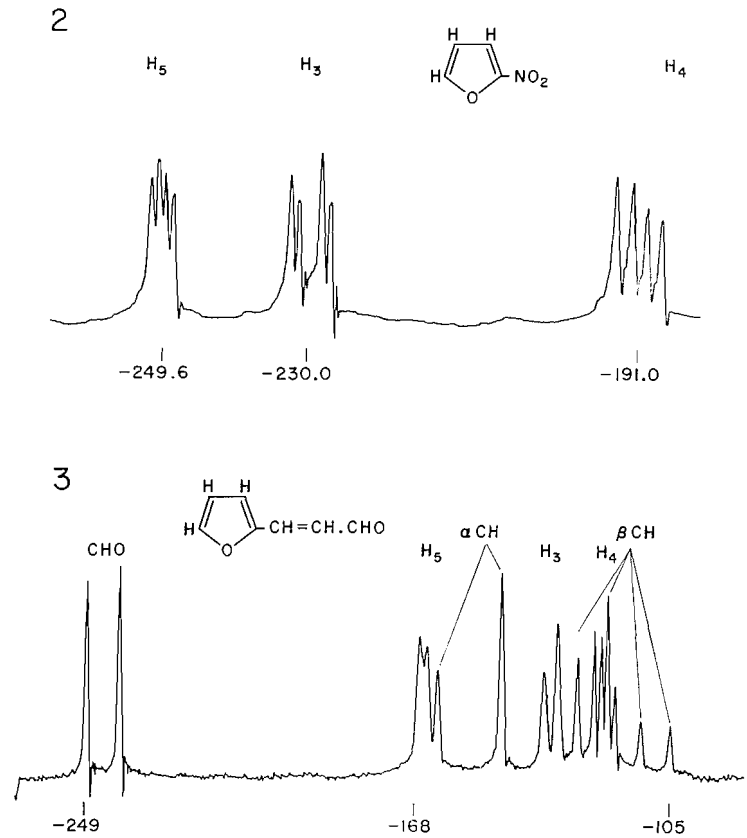

FIG. 2. The proton resonance spectrum of 2-nitro furan (liquid) at 60 Mc/s. The chemical shifts are in c.p.s. from a dioxane internal reference.

FIG. 3. The proton resonance spectrum of 2-furanacrolein in acetone solution at 40 Mc/s. α and β refer to the carbon atoms of the substituent. The chemical shifts are in c.p.s. from a dioxane internal reference.

even more simple spectra, as in the case of the disubstituted furans, and are not reproduced.

The spectra of the 2-substituted pyrroles can be analyzed and assigned in the same general manner as in the furan derivatives; however, there are two additional factors involved. There is the spin coupling of the N—H proton with each of the ring protons which doubles the number of peaks in each spectrum. Also, the chemical shift separation between the α and β protons in the pyrroles is not significantly larger than the change in the chemical shifts due to the substituent group. Thus the assignment of the groups in these spectra is not as certain as the assignments in the furan spectra.

The spectrum of 2-pyrrole aldehyde is shown in Fig. 4. The groups in the spectrum are labelled from left to right, A, B, and X. The problem of the analysis of this spectrum consists in picking out from the observed signals those due to the couplings of the ring protons to the N—H proton and a further coupling of one proton to the aldehyde proton (known to be 1.1 c.p.s. from the doublet separation of the aldehyde proton peak). This process is shown in Table I. The result of this is to leave the three quartets characteristic of an ABX spectrum. The numbering of the lines in these quartets (given in Table I) is unusual due to the fact that J_{AB} is less than J_{AX} or J_{BX}. Apart from this, it is a straightforward ABX analysis (8).

			5.40	1.12	1. 6.61	6.37	2.48		8.32		
5. 5.98	2.41		5.96								
			6.52			7.85					
			7.19	1.34							
			7.86								

$J_{A-NH} = 2.45\ (\pm 0.02)$ $J_{A-CHO} = 1.24\ (\pm 0.05)$ $J_{B-NH} = 2.47\ (\pm 0.02)$ $J_{X-NH} = 2.26\ (\pm 0.06)$

The remaining problem is the assignment of the groups in the spectrum. The *X* peak is readily assigned to proton 4 of the ring, from chemical shift and coupling constant data (1). This leaves two possible assignments for the remaining groups. Here the *A* group is assigned to proton 5. This is supported by (*a*) the values of the coupling constants obtained from this assignment agree with the previous values of the coupling constants in the pyrrole ring (1) and with the values of the analogous coupling constants in the furan and thiophene rings (Table IV), and (*b*) the J_{A-CHO} coupling is analogous to the J_{5-CHO} coupling in 2-furfural (1). The effect of the alternative assignment would be to interchange the subscripts 3 and 5 in the δ and J values given for this spectrum.

The analysis of the spectrum of 2-cyano pyrrole (Fig. 5) is very similar to the analysis of Table I, but simpler due to the fact that the J_{5-CHO} coupling is not present. The assignment of the groups in this spectrum also follows the above assignment. In the spectrum of the pure liquid (not shown) the chemical shift difference between protons 3 and 5 is so small that the groups of peaks overlap. This is analogous to the small chemical shift difference in liquid pyrrole and the shift of the α-proton signal to low field with respect to the β-proton signal on dilution in acetone (9). This is further support for the assignment of the low field signal to proton 5.

deviations measure the extent to which the line separations, and thus coupling constants, are reproducible in different parts of the spectrum. The mean deviations given in Table II for the substituted furans are solely due to experimental difficulties. The larger values given in Table III are due to an additional error caused by the overlapping of many lines

in each part of the spectrum (e.g. see Figs. 4 and 5), so that the actual positions of the individual lines may not be at the center of the component line.

The average values of the coupling constants in the five-membered ring systems of furan, pyrrole, and thiophene are shown in Table IV. The furan coupling constants are

Spin coupling constants in five-membered hetercyclic aromatics

Ring system	J_{12} (=J_{15})	J_{13} (=J_{14})	J_{23} (=J_{45})	J_{24} (=J_{35})	J_{34}	J_{25}
Furan			1.80 (.09)	0.80 (.10)	3.53 (.13)	1.55 (.1)
Pyrrole	2.43 (.16)	2.43 (.24)	2.63 (.03)	1.44 (.05)	3.42 (.42)	
Thiophene			5.2 (.3)	1.3 (.3)	3.6 (.3)	2.7 (.3)

the mean of the results of Table II, the pyrrole coupling constants the mean of the results of Table III and reference 1, and the thiophene coupling constants the mean of the values obtained from the analysis of the thiophene spectrum (10) and those obtained from substituted thiophenes (4).

Considering first the results given in Tables II and IV for the substituted furans. The spin coupling constants are in agreement with the less accurate results of reference 1 and also with the less extensive measurements of Leane and Richards (3). The average values of the coupling constants in the furan ring are also fully consistent with the observed furan spectrum and the 2-furfural 40 Mc/s spectrum (5). The results for the 2-substituted furans of Table II, however, do show one striking feature. Although the variations in the magnitudes of the coupling constants J_{35} and J_{45} are not significantly greater than the experimental error, the magnitude of the coupling constant J_{34} changes markedly over a range of substituent groups. The 2-substituted furans in Table II are listed in the order of increasing "electronegativity" of the substituent group (as determined by the ring proton chemical shifts (see Table V)). It can be seen that, although the total

variation of J_{24} is only of the order of 0.5 c.p.s., there is a close correlation between the magnitude of J_{34} and the "electronegativity" of the substituent group. The measurements on substituted pyrroles (Table III and ref. 1) support this correlation, but since the experimental error is much larger in this case and only a few compounds have been measured, this effect is not seen so clearly.

One more point that might be enlarged upon is the magnitude of the coupling constants J_{23} and J_{34} in the various heterocyclic rings. The angular dependence of the gem coupling constants (11) suggests that there may be a correlation between the sum of the angles $\theta_1+\theta_2$ and the H—H coupling constant J_{34}, and $\theta_2+\theta_3$ with J_{23} (see Fig. 6). Further, this

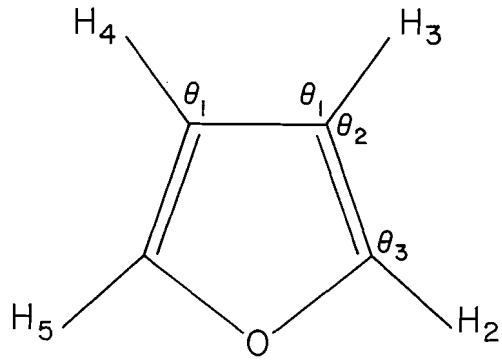

FIG. 6.

correlation might be expected to be different for the two types of coupling constants since J_{23} operates through essentially a double bond (of length 1.35 Å) whereas J_{34} operates over a 'single' bond (of length ~1.44 Å).

In Table V the values of the coupling constants are shown along with the angle sums for coupling constants acting through double bonds, 'single' bonds, and aromatic bonds. The angle θ for the hydrocarbons was calculated on the assumption that the 5-, 6-, and 7-membered rings are regular polygons. These data are plotted in Fig. 7 showing the rather good correlation with the angle sum.

A further point of interest is the interaction between the side-chain protons and the ring protons. It can be seen from Tables II and III that in all cases except 2-furfural and 2-aldehydo pyrrole the side chain protons couple with the neighboring ring proton.

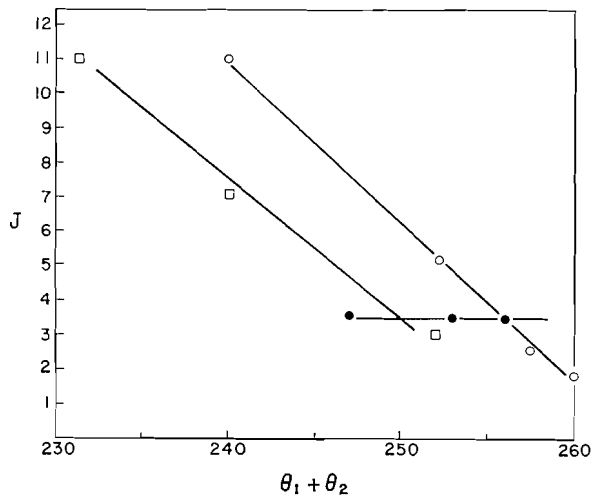

FIG. 7. The relation between spin coupling constant and angle sum. ○ CC length 1.35 Å (double bond). ● CC length ~1.43 Å ('single' bond). □ CC length ~1.40 (aromatic CC bonds).

Thus the apparent coupling of the aldehyde proton to proton 5 of the ring is rather remarkable. There are, however, further experimental facts in this case, in particular there is a change in the fine structure of the signal due to proton 5 of the ring on going from 30 Mc/s (3) to 40 Mc/s (1). Thus this effect may not be a straightforward long-range coupling interaction of the same type as that observed in substituted thiophenes (12). However, more data is necessary before this question can be answered.

(b) The Ring-Proton Chemical Shifts

The results of the chemical shift measurements are shown in Tables VI and VII. The

Table VI gives the results for the substituted furans. Three series of measurements are given. The first set of results (Table VI*a*) was determined by measurements at 40 Mc/s on the pure liquid samples using an internal dioxane reference. They are accurate to ± 1 c.p.s. i.e. to ± 0.3 parts per 10^7. In the second set (Table VI*b*) the compounds were remeasured (at 60 Mc/s) in 10% solutions in acetone, using the acetone signal as reference. From three independent spectra for each solution, the reproducibility of the latter results was ± 0.2 c.p.s. i.e. ± 0.03 parts per 10^7. Also in Table VI*c* are given some measurements of Corey *et al.* (2) using CH_2Cl_2 as solvent.

The three sets of results in Table VI provide a means of estimating the effect of dilution (in acetone) on the δ values and also how the δ values change in different solvents. A comparison of the δ values of the compounds in acetone (VI*b*) and the pure liquids (VI*a*) shows that there is a constant shift to high field in the former case, of 0.9 ± 0.5 parts per 10^7 and this shift is the same for protons 3, 4, and 5 of the ring and is nearly independent of the substituent group. This shows that dilution in acetone does not give rise to a significant change in the internal δ values for these compounds. This is probably due to the fact that the environment of a substituted furan molecule in the pure liquid state is very similar to the environment of the same molecule in acetone. However, when the δ values in the two very different solvents acetone and dichloromethane are compared (Tables VI*b* and VI*c*), a different result is obtained. Here the differences in the δ values depend markedly on the substituent group. For 2-methyl furan and 2-furfurol there is reasonably good agreement but there are larger differences of about 1.5 parts in 10^7 for 2-furfural and 2 furoic acid. This is to be expected since the COOH and CHO groups give rise to much larger δ values than the CH_3 or CH_2OH groups and thus changes due to different solvents would give larger absolute changes in the δ values. It is evident then that the effect of the substituent group on the ring-proton chemical shifts is to some extent a function of the solvent used (13). Further, the chemical shift of proton 3 could be influenced by different neighboring anisotropic effects due to the different substituents. A discussion of the relative chemical shifts of H_3, H_4, and H_5 with substitution can therefore at best be roughly qualitative.

From the data for the 2-substituted furans in acetone (Table VI*b*) the chemical shifts are found to be linearly related. That is

$$\delta_3 = 3.08\delta_4 - 0.42 \text{ with a mean deviation of } \pm 0.8 \times 10^7,$$

$$\delta_5 = 1.23\delta_4 + 0.10 \text{ with a mean deviation of } \pm 0.1 \times 10^7.$$

This implies that the effect of substitution is different from that in a benzene ring where the *m* signals are chiefly due to inductive effects and the *o*, *p* to resonance effects. This difference could arise because in the parent molecule furan, the resonance effect influences *both* the α and β positions (14). The effect of substitution in 5-membered rings is twofold. Firstly, the substituent (due to the electronegativity difference between it and H) tends to shift all signals to low field if more electronegative than H, the closest proton being shifted most and the effect being attenuated as the distance from the substituent increases. Secondly, because of its power to donate or withdraw electrons from "aromatic" rings the substituent can cause the signals to move to high field or low field respectively. Again, the largest effect is felt by the proton closest to the substituent. This mesomeric effect probably behaves in a fashion analogous to that in the parent compound affecting all positions in the same qualitative way (that is, all increase in π-electron density or all decrease). This is consistent with the linear dependences of δ_3, δ_4, and δ_5. Semi-

quantitatively, we may distinguish between the effect of electron-donating and -withdrawing substituents. In the case of the former, the electronegativity of the substituent shifts the signals to low field but the mesomeric effect increases the π-electron density causing greater shielding, which causes the signals to appear at higher field. In the case of electron-withdrawing substituents, however, both the electronegativity and mesomeric effects operate to shift the signals to low field. We expect therefore for 2-methyl furan, where the electronegativity effect is small, that the donor property of the methyl group will cause high field shifts relative to furan. Since all of the substituents used here are more electronegative than CH_3, we expect for the donors (e.g. NH_2, OH) that the shifts will be at lower field than in 2-me-furan, and, as one progresses to electron-withdrawing substituents, that the proton signals appear at increasingly low fields. This is indeed the order of the chemical shifts data given in Table VI*b*. Also as anticipated, the largest changes are exhibited by δ_3. The less complete results for the 2-substituted pyrroles seem to show a similar behavior of the effect of substitution on chemical shift.

It is of interest also to note that the effect of multiple substitution is very nearly additive. For example, if the chemical shifts relative to furan for a $2-x$-substituted furan are δ_{3x}, δ_{4x}, δ_{5x} and for $3-y$, are δ_{4y}, δ_{5y} then for the $2-x$, $3-y$-disubstituted furan the shifts are $\delta_{4x}+\delta_{4y}$ for H_4 and $\delta_{5x}+\delta_{5y}$ for H_5. For example, the calculated shifts for 2,3-difuroic acid are $\delta_3=\delta_5=-5.7$ and $\delta_2=\delta_4=-3.9$, and the observed shifts are -6.4 and -4.2 respectively. Similarly the calculated shifts for 2-methyl-3-furoic acid are $\delta_3=\delta_5=-2.4$ and $\delta_4=\delta_5=+0.4$, which may be compared with the observed shifts of -2.9 and 0.8 respectively.

THE ELECTRICAL CONDUCTIVITY OF LIQUID TIN (II) SULPHIDE[1]

DENIS BOUTIN AND MARCEL BOURGON

ABSTRACT

The electrical conductivity "σ" of tin (II) sulphide in the liquid state has been measured using a capillary type cell. Both a-c. and d-c. methods were used. The conductivity of SnS increases regularly with temperature, from approximately 24 $ohm^{-1}\,cm^{-1}$ at 895° C to 31.2 $ohm^{-1}\,cm^{-1}$ at 930° C. The similarity of results obtained with both a-c. and d-c. methods, the positive temperature coefficient of conductivity, the high value of the conductivity and the absence of electrolysis effects when passing heavy currents in the melt lead to the conclusion that SnS remains a semiconductor in the liquid state. The value of the energy gap has been calculated to be 1.9 ev for the liquid as compared to the value 1.2 ev for the solid. Conductivity measurements have been limited to the temperature of approximately 935° C because of the decomposition of SnS at higher temperatures.

INTRODUCTION

Study of the electrical properties of liquid inorganic salts and oxides has shown that these chemical compounds are often ionic in the liquid state as evidenced by the high value of the conductivities, the positive temperature coefficients of conductivity, and the high current efficiencies (1, 2, 3). The electrical conductivity of a few metallic sulphides in the liquid state has been investigated: NiS (9), Bi_2S_3 (9), and FeS (4, 5, 7) have been reported to behave as typical metallic conductors while Cu_2S (4, 5, 6) and Tl_2S (10) have been shown to be semiconductors. Liquid antimony (III) sulphide Sb_2S_3 has a mixed conductivity, ionic and electronic (8).

Tin (II) sulphide SnS is known to be a semiconductor in the solid state (11) and has been reported to possess mixed conductivity in the liquid state (9). In order to determine whether this compound retains its semiconductivity in the liquid state it was planned to study its electrical conductivity more thoroughly than was done by previous workers.

EXPERIMENTAL

Preparation of SnS

The tin (II) sulphide used in this study was prepared by direct synthesis from the elements: "Reagent" grade tin and recrystallized sulphur were used. The tin sulphide so obtained contains free sulphur and some SnS_2. Consequently, the crude sulphide was heated under vacuum at 450° C to eliminate the free sulphur and melted under a nitrogen atmosphere at 1000° C, this temperature being maintained between 1 and 2 hours in order to decompose the tin (IV) sulphide to tin (II) sulphide and sulphur. The furnace temperature was then brought down to 890° C and a partial vacuum was maintained over the melt to eliminate the last traces of sulphur. The tin (II) sulphide was then distilled at the same temperature under high vacuum using a graphite condenser. The tin (II) sulphide thus prepared has a metallic appearance and is completely soluble in concentrated HCl. Two batches of sulphide were prepared and showed identical X-ray powder patterns (114.8-mm camera, Cu radiation, Ni filter): these patterns were strictly identical with the known X-ray powder pattern of SnS (12). The characteristic X-ray

[1]*Manuscript received December 12, 1960.*
Contribution from the Department of Chemistry, University of Montreal, Montreal, Que. This paper was taken from the thesis of D. Boutin, presented in partial fulfillment of the requirements for the degree of M.Sc., May 1960. Presented at the 43rd Annual Conference, Chemical Institute of Canada, Ottawa, Ontario, June 1960.

lines of SnS_2 and SnO_2 were absent from the X-ray diagrams. The first batch was nevertheless rejected because chemical analysis showed it to contain graphite particles. The second batch was analyzed for tin using the potassium iodate method: found $78.58 \pm 0.05\%$, theoretical 78.73%. According to the analysis figure the tin sulphide used in this study, although very near the stoichiometric composition, is slightly enriched in sulphur.

The Conductivity Cell

The cell used for measuring the electrical conductivity was of the capillary type and is shown in Fig. 1. It is made entirely of "Vitreosil" tubing and has four electrodes made

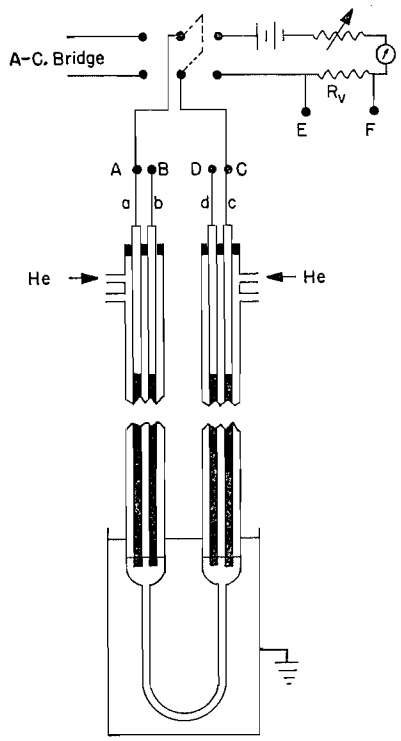

FIG. 1. Cell for measuring the electrical conductivity.

of spectrographic graphite rods: two of these electrodes carry current into the melt and the two others serve as potential probes, this system having the advantage of eliminating lead resistances. The cell is approximately 50 cm long and the over-all length of the capillary tube is approximately 10 cm. In order to obtain good temperature control and to eliminate stray currents in the melt the cell was placed in a liquid tin bath which was connected to ground. The cell and the liquid tin bath were contained in a "Mullite" tube which, in turn, was placed in a furnace heated by means of silicon carbide rods and controlled by a Weston Celectray Controller. Temperature measurements were made by means of calibrated Pt, 10% Rh–Pt thermocouples. The measuring thermocouple was contained in a sheath made of pure recrystallized alumina and placed between the two tubes of the cell so that the junction was in the middle of the capillary portion of the cell. Provisions were made to introduce purified helium gas into the cell. Because

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of the rather high vapor pressure of tin (II) sulphide the helium gas was not circulated in the cell but a slightly positive static atmosphere was maintained over the melt.

The measuring cells were calibrated at room temperature using 0.1 *N* KCl. The cell constants were determined using an a-c. bridge operated at 1000 cycles/sec (13). With cells having a 10-cm-long capillary (I.D. 1 mm or lower) cell constants as high as 1200–1500 were obtained.

Resistance Measurements

Two methods were used to measure the resistance of the melt: a direct-current method and an alternating-current method. With the d-c. method the potential drops were measured across the potential probes of the cell and across a calibrated resistance in series with the latter using a potentiometer. By this method the lead resistances are eliminated.

The a-c. measurements were made using the same bridge as was used for calibrating the cells. This bridge measures the resistance of the melt and the resistance value thus found includes the resistance of the leads. A correction was made for the lead resistances at the different temperatures by using the following procedure.

Referring to Fig. 1, the d-c. potential drops across AC, BD, and EF are respectively:

$$E_{AC} = (R_x + r_a + r_c)i, \quad [1]$$

$$E_{BD} = R_x i, \quad [2]$$

$$E_{EF} = R_v i \quad [3]$$

where R_x, r_a, and r_c are the resistances of the melt and the electrodes respectively and R_v is the standard resistance in series with the cell. The d-c. resistance between points A and C is thus:

$$R_{AC} = R_x + r_a + r_c = R_v \cdot E_{AC}/E_{EF}. \quad [4]$$

The d-c. resistance of the melt is given by:

$$R_x = R_v \cdot E_{BD}/E_{EF}. \quad [5]$$

The difference between [4] and [5] gives the resistance of the electrodes:

$$r_a + r_c = R_v(E_{AC} - E_{BD})/E_{EF}. \quad [6]$$

The a-c. resistance across points A and C as measured by the bridge is:

$$R'_{AC} = R_x + r_a + r_c + r \quad [7]$$

where r is the residual resistance of the bridge and was found to be 0.4 ohm. The a-c. resistance of the melt R″ is thus given by [7]−[6].

RESULTS

Typical curves obtained by measuring the conductivity of liquid tin (II) sulphide as a function of temperature are shown in Fig. 2. Curve A shows the results obtained while increasing the temperature; curve B gives the conductivity values of the same sample obtained while decreasing the temperature from a maximum of approximately 1050° C. Curve C was obtained using a different sample and a different cell while decreasing the temperature: all these results were obtained by means of d-c. measurements. It is noticeable that the results obtained while decreasing the temperature are always

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

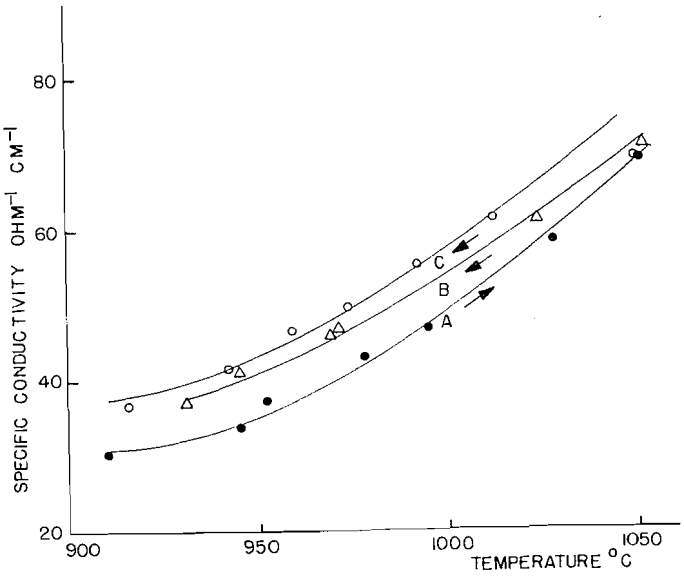

FIG. 2. Specific conductivity of liquid SnS as a function of temperature.

higher than those obtained while increasing the temperature. It is to be noticed also that curves B and C do not coincide and this could be due to the non-reproducibility of the different cells. This latter point was checked by mounting two cells with identical samples in the furnace so that both of them would follow the same thermal program. Conductivity measurements were made while increasing and decreasing the temperature and although the conductivity values obtained during the cooling cycle were, as in earlier experiments, higher than those obtained during the heating cycle the conductivity values obtained while decreasing the temperature were identical in both cells.

The different values of the conductivity obtained when heating or cooling the sample could be due to an increase in the tin content of the melt during the heating cycle. This increase in the tin content could be due to a reduction of the SnS by the graphite electrodes, to a partial electrolysis of the melt caused by the direct current or to the decomposition of the SnS. The first of these hypotheses was verified by heating SnS samples in closed quartz tubes for a few hours at approximately 1050° C; one of the tubes contained in addition a piece of the graphite used for electrodes. After the experiment sulphur deposits could be seen in the upper parts of both tubes showing that SnS does decompose independently of the presence of carbon.

To determine the decomposition temperature it was planned to do conductivity measurements as a function of time. To determine also whether there was partial electrolysis of the melt when using direct current the circuit permitting simultaneous a-c. and d-c. measurements and described in the experimental section was set up.

The results of these experiments are shown in Table I and Fig. 3 where the specific conductivity of the melt is shown as a function of time at several temperatures. Many such time–conductivity curves were determined on different samples in different cells: in the preliminary runs the heating time was extended for at least 30 hours at each temperature. The curves shown in Fig. 3 are those obtained under the best experimental conditions. The same cell was used throughout but because of the volatilization of the

Sulphur deposited at top of the cell.

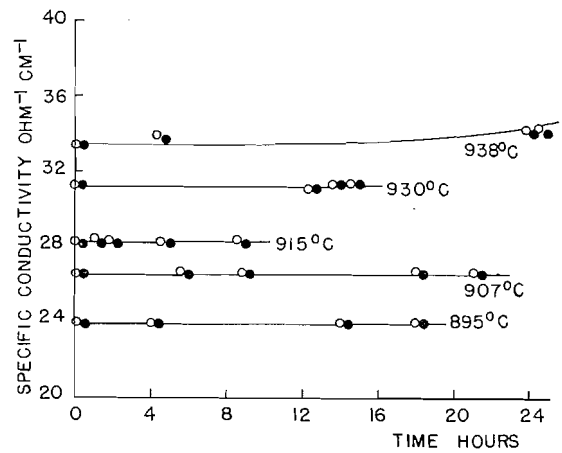

FIG. 3. Specific conductivity of liquid SnS as a function of time at constant temperature. ● a-c. data. ○ d-c. data.

sample additional SnS was added periodically. It was found necessary to bubble helium through the melt before each measurement in order to obtain reproducible results.

As can be seen from the curves an increase in the conductivity of the melt as a function of time occurs at a temperature of approximately 938° C. This is attributed to an increase in the tin content due to the decomposition of the tin sulphide. After completing the measurements the cell was maintained at a few degrees above the decomposition temperature for many hours at the end of which period the conductivity had increased to the point where it was difficult to measure: determination of the tin content of the melt

at the completion of the experiment showed that the latter had increased from 78.58 to 79.80%. The decomposition temperature was reproducible from sample to sample within 3 or 4 degrees. Resistance measurements made at temperatures higher than the decomposition temperature, using uncalibrated cells, showed that the decomposition rate increased as the temperature increased. In all cases sulphur deposition could be observed in the cooler parts of the cell.

The curves plotted in Fig. 3 show the results obtained with both alternating and direct currents. The conductivity values given in Table I are those calculated from the d-c. measurements, which are thought to be more precise. There is a small difference between the resistance values obtained with alternating current as compared with those obtained with direct current: this is probably due in part to a certain uncertainty in the residual resistance of the a-c. bridge and we do not believe it to be significant.

Electrolysis experiments were made on liquid SnS using a graphite crucible which served as the cathode and a graphite rod enclosed in a quartz tube which served as the anode. These experiments were made at 910° C using heavier currents (approximately 2 amperes) than were employed during the conductivity measurements. Preliminary experiments showed that it was difficult to distinguish the tin, which could be produced by electrolysis, from the tin sulphide. The anode compartment was instead observed for signs of sulphur evolution: there was no sulphur deposit in the cool part of the quartz tube even after the current had been passed for 2 hours.

DISCUSSION

Delimarskii and Velikanoff (9) have reported values for the conductivity of liquid SnS; their values range from 69 $ohm^{-1}cm^{-1}$ at 900° C to 103 $ohm^{-1}cm^{-1}$ at 1000° C with a temperature coefficient of 3.8×10^{-3}. They conclude from these results that liquid SnS has a mixed conductivity, ionic and electronic. The high results obtained by these workers are most probably due to the contamination of the melt by metallic tin: they prefused their sulphide at a probably too high temperature as evidenced by the stated analytical figures: they report an initial tin content of 79.7%, which increased to 80.6% at the end of the measurements.

Our results show that the conductivity of liquid tin (II) sulphide increases from approximately 24 $ohm^{-1}cm^{-1}$ at 895° C to 31.2 $ohm^{-1}cm^{-1}$ at 930° C with a temperature coefficient of 6.5×10^{-3}. The conductivity of SnS is somewhat high to be due to the migration of ions under the influence of an electric field. The absence of a considerable amount of ions is indicated by the fact that the d-c. and a-c. values of the conductivity are identical within experimental errors. The absence of sulphur evolution during the electrolysis experiments corroborates these conclusions.

Anderson and Morton (11) have shown SnS to be a semiconductor in the solid state. The conductivity follows the law:

$$\sigma = A_1 \exp(-E_1/kT) + A_2 \exp(-E_2/kT)$$

where the first term is preponderant at low temperatures and is attributable to an excess of non-metal in the lattice (*p*-type semiconduction) while the second term takes importance at high temperatures and is attributed to the intrinsic conduction of the lattice. From the high-temperature term, Anderson and Morton have calculated the width of the forbidden energy gap for intrinsic conduction to be 1.2 ev. These workers also showed that solid SnS can act as a *n*-type semiconductor when treated by hydrogen at high temperature, this operation having the effect of increasing the tin content.

The conductivity values of liquid tin sulphide plotted in Fig. 3 have been replotted in Fig. 4 as a function of the inverse of the absolute temperature to give a straight line.

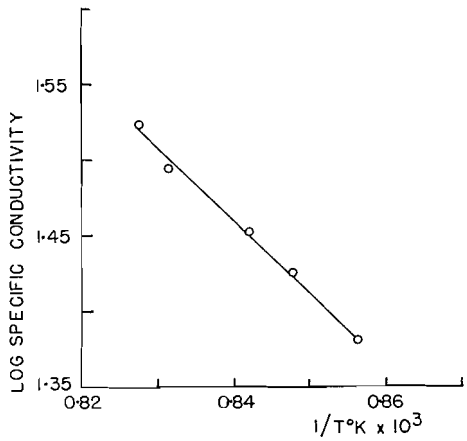

FIG. 4. Log specific conductivity as a function of the inverse of the absolute temperature for liquid SnS.

This line follows the law:

$$\sigma = A \exp(-E/kT).$$

All the facts stated above lead to the conclusion that tin (II) sulphide remains a semiconductor in the liquid state. The width of the forbidden energy gap as calculated from the slope of the line in Fig. 4 is 1.9 ev.

Attempts were made to determine the change in conductivity of SnS as it passes from the liquid state to the solid state. Although the cell design did not permit quantitative estimation of the conductivity, it was observed, in many cases, that the resistance of SnS increases sharply at the freezing point. Comparison of our results for the liquid state with the high-temperature results obtained by Anderson and Morton (11) for the solid state also indicates a sharp decrease of the conductivity at the freezing point.

It should be mentioned that the tin (II) sulphide used in this study is slightly richer in sulphur then the stoichiometric compound. One way of determining the influence of this excess sulphur on the conductivity would be to measure the conductivity of SnS as a function of sulphur pressure using hydrogen – hydrogen sulphide atmospheres: this is somewhat difficult because of the volatility of the tin sulphide.

Besides the liquid semiconductors mentioned in this paper other occurrences of semiconductivity in liquids have been reported. By measuring the electrical conductivity and the thermoelectric power of liquid selenium Henkels and Maczuk (14, 15) have shown this elementary substance to be a semiconductor in the liquid state with a forbidden energy gap of 2.31 ev as compared to 1.8 ev for the solid. Epstein, Fritzsche, and Lark-Horovitz (16, 17, 18) have measured the electrical conductivity, the thermoelectric power and the Hall coefficient of pure tellurium at the melting point and in the liquid state: they find a sharp decrease in conductivity on passing from the liquid to the solid state. Their experimental results indicate that the semiconducting properties persist in the liquid state and that a graded transition to metallic properties takes place at higher temperatures. Inouye, Tomlinson, and Chipman (19) conclude, from conductivity measurements, that FeO remains a semiconductor in the liquid state. Liquid HgSe (20)

has been reported to be a semiconductor with an energy gap of 2.3 ev. Ioffe (10) has reported the compounds Sb_2O_3, Bi_2O_3, Na_2Te_3, Na_2Te_6 to be semiconductors in the liquid state.

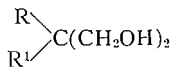
TETRAHYDROFURANS

I. 2,2-DIMETHYL-4-SUBSTITUTED-4-HYDROXYMETHYLTETRAHYDROFURANS AND RELATED COMPOUNDS[1]

B. K. Wasson, C. H. Gleason, I. Levi, J. M. Parker, L. M. Thompson, and C. H. Yates

ABSTRACT



Substituted methallylmalonic esters (I) were reduced with lithium aluminum hydride to the corresponding 2-methallyl-1,3-propanediols (II). These diols II underwent cyclization on treatment with a mineral acid to the isomeric 2,2-dimethyl-4-substituted-4-hydroxymethyltetrahydrofurans (IV). II and IV were converted to the respective carbamates III and V, which exhibited pharmacological activity. The assigned structures of the cyclic compounds IV were proved by infrared analyses and the following transformations. Ring scission of 2,2-dimethyl-4-allyl-4-hydroxymethyltetrahydrofuran (IV*e*) with acetic anhydride – pyridine hydrochloride yielded 2-allyl-2-methallyl-1,3-propanediol diacetate (X*e*). Catalytic reduction of IV*e* gave 2,2-dimethyl-4-*n*-propyl-4-hydroxymethyltetrahydrofuran (IV*d*). Reductive cleavage of the tosylate VIII*b* of 2,2,4-trimethyl-4-hydroxymethyltetrahydrofuran (IV*b*) with lithium aluminum hydride yielded the known 2,2,4,4-tetramethyltetrahydrofuran (IX*b*).

While preparing 2,2-disubstituted-1,3-propanediol dicarbamates, it was noted that an intermediate, 2-allyl-2-methallyl-1,3-propanediol (II*e*), was labile to hydrochloric acid affording a compound assumed to be 2,2-dimethyl-4-allyl-4-hydroxymethyltetrahydrofuran (IV*e*). This assignment, made by analogy with a known method of preparing tetrahydrofurans (1–3), was subsequently verified. Since IV*e* possessed interesting pharmacological activity it was decided to prepare additional 2,2-dimethyl-4-substituted-4-hydroxymethyltetrahydrofurans (IV). Thus substituted methallylmalonic esters (I) were reduced to the corresponding 2-substituted-2-methallyl-1,3-propanediols (II) and subsequently cyclized by means of mineral acid. Both II and IV were converted to the corresponding carbamates III and V (Fig. 1).

Substituted methallylmalonic esters (I) were reduced by lithium aluminum hydride (4) to 2-substituted-2-methallyl-1,3-propanediols (II) (Table I). The use of sodium and

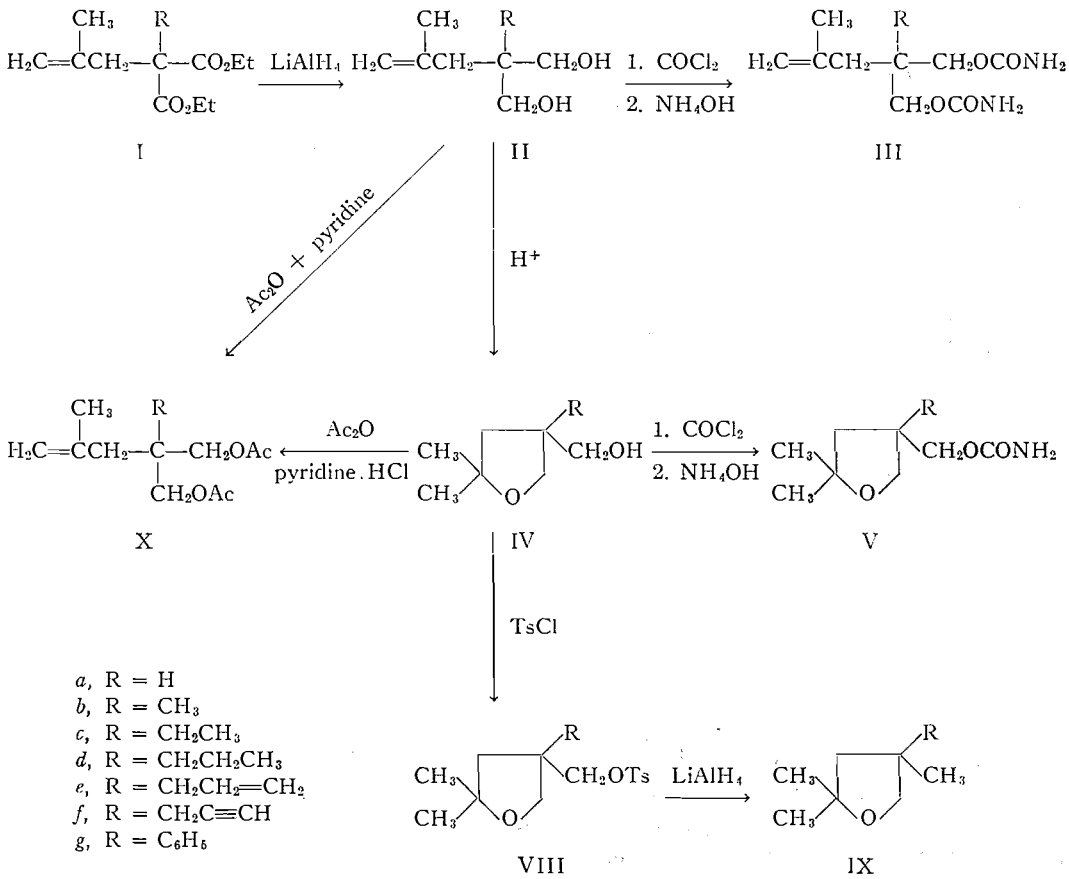

FIG. 1.

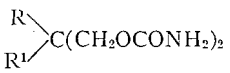
an alcohol (ethanol, 1-propanol, 1-butanol) (5) was unsatisfactory. Decomposition of the excess hydride was effected in two stages by the successive addition of methanol and water. Mineral acid was omitted in order to preclude possible ring closure between a hydroxyl and the methallyl group. The diols II were converted to the crystalline dicarbamates III (Table II).



Tetrahydrofurans have been prepared by the acid-catalyzed ring closure of γ-unsaturated monoalcohols (1–3). When 2-substituted-2-methallyl-1,3-propanediols (II) were contacted with concentrated hydrochloric or sulphuric acid, the hitherto unreported cyclic 2,2-dimethyl-4-substituted-4-hydroxymethyltetrahydrofurans (IV) were obtained. This conversion occurred most satisfactorily when the diols II were treated with 1–3 volume per cent of concentrated hydrochloric acid in the presence of a solvent. Tetrahydrofuran was particularly suitable since the cyclization was readily controlled and the reaction mixture could be used directly in the preparation of carbamates. When methanol was used as a diluent, there was no indication that it supplanted or competed with the primary alcoholic function of II because IV was the sole product. This is an interesting finding in view of the mechanism of cyclization proposed below. The use of a larger amount of acid led to a decrease in the yield of IV. For example, with 2-allyl-2-

methallyl-1,3-propanediol (II*e*), not only did the expected cyclization occur, but also the allyl group and the remaining hydroxyl group tended to interact. Whereas methallyl-substituted diols underwent facile isomerization, 2-allyl-1,3-propanediol (XI) required prolonged treatment with a larger amount of acid. The cyclized products IV (Table III) were converted to the crystalline carbamates V (Table IV).

The cyclization of 2-substituted-2-methallyl-1,3-propanediols (II) may be shown as occurring via an ionic mechanism (Fig. 2). Thus a proton adds to the olefin II to give a

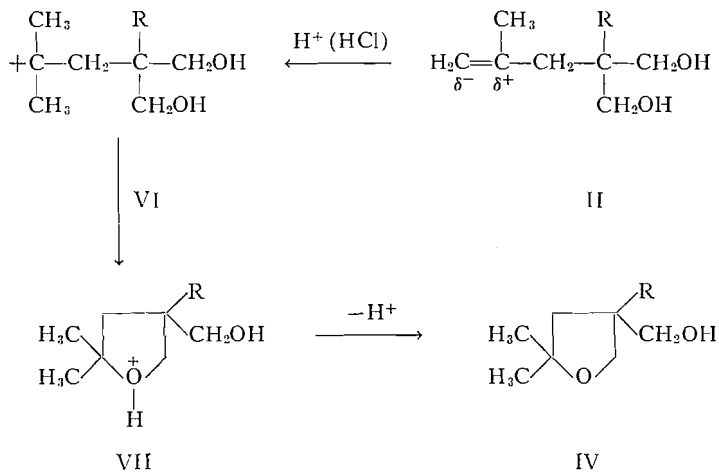

FIG. 2.

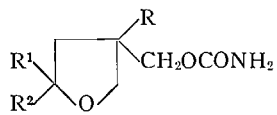

tertiary carbonium ion VI. Intramolecular reaction between the charged carbon atom of VI and one of the primary hydroxyl groups affords an oxonium ion VII from which a proton is expelled giving IV. Such a mechanism allows for the formation, via a Markownikoff addition, of a tetrahydrofuran rather than a tetrahydropyran ring and also depicts the catalytic role of hydrogen ion in promoting such a reaction.

Assignment of structure IV to the products of cyclization was supported by infrared absorption data. The isomerization of 2-substituted-2-methallyl-1,3-propanediols (II) to IV required an increase in the number of methyl groups from one to two, the appearance of a cyclic ether group, and the loss of the methallyl and a hydroxyl group. An inspection of the infrared spectra of II and IV showed that these changes did occur. They were exhibited by the appearance in the 7.25–7.35 μ region of a doublet (*gem*-dimethyl) in place of a single band (methyl), the loss of the 11.2 μ band (methallyl), the narrowing and shifting of the hydroxyl band from 3.0 to 2.95 μ, and finally the shifting of the 9.6–9.8 μ band (hydroxyl) to 9.5–9.6 μ (hydroxyl, cyclic ether) (6). In addition IV possessed a strong unassigned band at 12.95 μ.

Supporting evidence for the formulation of the cyclic compounds IV was obtained by cleaving the ring of IV*e*, a typical member of the group. Surprisingly, in this instance, the use of methods that have been described for the cleavage of tetrahydrofurans (7–11) led to intractable mixtures. However, the conversion was effected by applying a method used successfully in the field of sapogenin chemistry (12–14). Thus acetic anhydride – pyridine hydrochloride (12) readily converted IV*e* in excellent yield to 2-allyl-2-methallyl-1,3-propanediol diacetate (X), identical with a sample prepared by the acetylation of II*e* (Fig. 1). Hence, the methallyl and hydroxyl groups that had disappeared during the cyclization of the diol II to the isomeric IV, have reappeared upon ring opening.

Additional chemical evidence for the structures of 2,2-dimethyl-4-substituted-4-hydroxymethyltetrahydrofurans (IV) was obtained by the elimination of the hydroxyl group. Thus IV*b* was tosylated and the ester VIII*b* reduced with lithium aluminum hydride (15) to 2,2,4,4-tetramethyltetrahydrofuran (IX*b*) (Fig. 1). The infrared absorption curve and boiling point of IX*b* were the same as those previously reported (16). The 4-allyl analogue IV*e* was similarly converted to the expected 2,2,4-trimethyl-4-allyltetrahydrofuran (IX*e*) as judged by infrared analysis, where bands typical of the tosyl group appeared in the spectrum of VIII*e*, and disappeared in that of IX*e*. IV*e*, VIII*e*, and IX*e* exhibited bands denoting the presence of the allylic double bond, methyl groups, and the cyclic ether linkage.

2,2-Dimethyl-4-allyl-4-hydroxymethyltetrahydrofuran (IV*e*) was hydrogenated over platinum giving 2,2-dimethyl-4-*n*-propyl-4-hydroxymethyltetrahydrofuran (IV*d*). IV*d* was also obtained when diethyl *n*-propylmethallylmalonate (I*d*) was reduced with lithium aluminum hydride to 2-*n*-propyl-2-methallyl-1,3-propanediol (II*d*) and subsequently ring-closed with mineral acid.

The monocarbamates V were more active than the dicarbamates III upon the central nervous system of animals. The allyl derivative V*e* was particularly effective as an anticonvulsant (17). More comprehensive results of the pharmacological evaluation will be reported elsewhere.

EXPERIMENTAL

Boiling points and melting points (Fisher–Johns apparatus) are uncorrected. Infrared absorption spectra were obtained with a Beckman IR-5 spectrophotometer equipped with a sodium chloride prism. Solids were examined in potassium bromide pellets and liquids either as thin films or as solutions in carbon disulphide.

Preparation of Mono- and Di-substituted Malonates

Diethyl sodiomalonate and diethyl sodio-alkyl- (and -alkenyl-) malonates were treated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with the appropriate alkyl halide (bromide or chloride) in the customary manner giving the corresponding mono- and di-substituted malonates. These were purified by distillation *in vacuo*. The preparation of some of these malonates has been described (18). Diethyl methylmalonate (Sapon), diethyl ethylmalonate (Distillation Products Industries), diethyl *n*-propylmalonate (Sapon), and diethyl phenylmalonate (Benzol Products) were used without further purification.

Preparation of Substituted 1,3-Propanediols

The following procedure illustrates the general method used for preparing the 1,3-propanediols listed in Table I. A solution of 100 g of diethyl allylmethallylmalonate (I*e*) in 246 ml of anhydrous ethyl ether was added dropwise over a 3-hour period to a well-dispersed and vigorously stirred mixture of 22.5 g of lithium aluminum hydride in 554 ml of anhydrous ethyl ether maintained below 25° C in an atmosphere of nitrogen. The reaction mixture was stored overnight at room temperature. Excess hydride was discharged by the addition of 27.2 ml of methanol in 66 ml of ethyl ether; the resulting complexes were decomposed by the successive addition of 15.6 ml of 50% methanol and 31.2 ml of water while maintaining the temperature of the mixture below 25° C. The ethereal phase was separated and the residual solids were washed four times with ethyl ether. The combined ethereal extracts were washed with water twice, filtered, and evaporated, leaving 65.2 g (97.5%) of crude 2-allyl-2-methallyl-1,3-propanediol (II*e*). Infrared: λ_{max} 3.0 (hydroxyl), 3.25, 6.1 (unsaturation), 7.25 (methyl), 9.6–9.8 (hydroxyl), 10.9 (allyl), 11.25 (methallyl) μ. This product was distilled *in vacuo* and used directly for the preparation of either 2,2-dimethyl-4-allyl-4-hydroxymethyltetrahydrofuran (IV*e*) or 2-allyl-2-methallyl-1,3-propanediol dicarbamate (III*e*).

Cyclization of 2-Methallyl-1,3-propanediols (II)

The general procedure used for the cyclization of 2-methallyl-1,3-propanediol and 2-substituted-2-methallyl-1,3-propanediols to give the 2,2-dimethyl- and 2,2-dimethyl-4-substituted-4-hydroxymethyltetrahydrofurans, listed in Table III, is illustrated by the following example.

A solution of 65.2 g of 2-allyl-2-methallyl-1,3-propanediol (II*e*) in 40.5 ml of dry tetrahydrofuran was treated at room temperature with 1 ml of concentrated hydrochloric acid. The solution was warmed gently until, at approximately 50° C, an exothermic reaction occurred. External heating was discontinued while the temperature of the reaction mixture rose spontaneously to 94° C. The solution was then refluxed for 2 hours. The solvent was removed under reduced pressure and the residue distilled giving 59.9 g of 2,2-dimethyl-4-allyl-4-hydroxymethyltetrahydrofuran (IV*e*), b.p. 122–126° C/5 mm. The cyclization of II*e* was also effected with 0.5–1.0 volume per cent of hydrochloric acid in the absence of solvent. However, the reaction was extremely vigorous and difficult to control by external cooling. The yield of IV*e* was substantially decreased.

Cyclization of 2-Allyl-1,3-propanediol (XI)

2-Allyl-1,3-propanediol (XI) was cyclized by more drastic conditions than those described above. Thus a mixture of 11 g of XI and 1 ml of concentrated hydrochloric acid was refluxed for 17 hours. Following removal of the hydrochloric acid, distillation of the product (10.9 g) yielded 7.3 g (66.3%) of 2-methyl-4-hydroxymethyltetrahydrofuran (XII), b.p. 75–78° C/5 mm. The infrared spectrum possessed a strong band at 7.25 μ (C—CH_3) but no band indicative of a double bond.

Preparation of 2,2-Disubstituted 1,3-Propanediol Dicarbamates (III)

The procedure using tetrahydrofuran as solvent (19) was found to be superior to that wherein chloroform–toluene served as solvent and antipyrine was included as a hydrogen chloride acceptor (20). The products III (Table II) were recovered from the reaction mixtures by chilling the aqueous solutions after evaporating the organic solvent, and were recrystallized from aqueous alcohol. (Infrared: λ_{max} 2.95, 5.85, 6.2 μ (primary amide).)

Preparation of 2,2-Dimethyl-4-substituted-4-carbamyloxytetrahydrofurans (V)

The method used for preparing V (Table IV) was a modification of that applied above. The following example was typical of the procedure. A solution of 57.3 g of IV*e* in 77.6 ml of tetrahydrofuran was added dropwise during 1 hour to 55.2 g of phosgene dissolved in 63.1 ml of cold tetrahydrofuran (−8 to 4° C). The mixture was stirred for 30 minutes at this temperature and then stored overnight at room temperature. The solution was added over a 1-hour period to a stirred mixture of 276 ml of concentrated ammonium hydroxide and 3.4 g of sodium bisulphite maintained at 10–27° C (subsequent study showed that bisulphite could be omitted). After stirring for ½ hour, sufficient water was added to dissolve the solids. Distillation afforded a residue that was extracted four times with ether. The combined ethereal extracts were washed twice with 25-ml portions of water and the ether removed. The residue (72.6 g) was distilled giving 67.7 g of V*e*, b.p. 111–119° C/0.02–0.04 mm, solidifying at room temperature. The material was crystallized from ether – petroleum ether giving 64 g (89.1%) of V*e*, m.p. 55–57° C. When the distillation of crude material was omitted, V*e* was obtained in lower yield. The substance could also be crystallized from acetone – petroleum ether, aqueous methanol, or methanol – petroleum ether. Molecular weight (Rast): calc. 213; found 211, 216. Infrared: λ_{max} 3.0, 5.8, 6.2 (primary amide), 3.25, 6.1 (unsaturation), 10.95 (allyl), 7.25, 7.35 (*gem*-dimethyl), 12.95 μ.

Preparation of 2,2-Dimethyl-4-allyl-4-hydroxymethyltetrahydrofuran (IVe) from the Carbamate Ve

A mixture of 16 g of 2,2-dimethyl-4-allyl-4-carbamyloxymethyltetrahydrofuran (V*e*) (m.p. 54.0–55.5° C), 12 g of sodium hydroxide, and 250 ml of ethanol was refluxed for 8 hours. After dilution with water, the ethanol was removed by distilling *in vacuo*. The aqueous residue was cooled, saturated with sodium chloride, and extracted five times with ethyl ether. The ethereal extracts were washed with water and reduced to dryness. The resulting oily product was vacuum-distilled, yielding 8.2 g (64%) of IV*e*, b.p. 116–117° C/10–15 mm. Analysis: Calc. for $C_{10}H_{18}O_2$: C, 70.56; H, 10.66. Found: C, 70.17; H, 10.45. Main infrared absorption bands: λ_{max} 2.95, 3.25, 3.40, 3.50, 6.10, 6.90, 7.08, 7.23, 7.78, 8.24, 8.40, 8.56, 8.90, 9.4–9.75, 10.05, 10.95, 11.42, 11.60, 12.94 μ.

Preparation of 2-Allyl-2-methallyl-1,3-propanediol Diacetate (Xe)

(a) From 2-Allyl-2-methallyl-1,3-propanediol (IIe) by Acetylation

A solution of 20 g of 2-allyl-2-methallyl-1,3-propanediol (II*e*) in 110 ml of acetic anhydride and 22 ml of anhydrous pyridine was heated for 1 hour on a steam bath and then allowed to stand for 18 hours at room temperature. The solution was poured into 400 ml of cold water and the mixture stirred for 1 hour at room temperature. The mixture was extracted five times with ethyl ether and the combined ethereal extracts washed successively with water, 5% hydrochloric acid, saturated saline solution, 5% sodium bicarbonate, and finally with water. After drying over sodium sulphate, the solvent was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

removed leaving 28.42 g (95%) of the crude acetate. Distillation of this product afforded 2-allyl-2-methallyl-1,3-propanediol diacetate (X*e*), b.p. 153–157° C/16 mm, λ_{max} 5.78, 8.0–8.2, 9.6–9.7 (ester), 3.25, 6.1, 10.9–11.2 (unsaturation) μ.

(b) From 2,2-Dimethyl-4-allyl-4-hydroxymethyltetrahydrofuran (IVe) by Treatment with Acetic Anhydride – Pyridine Hydrochloride

A stream of hydrogen chloride was passed into a mixture of 150 ml of acetic anhydride and 12 ml of pyridine until 5.2 g had been absorbed. After adding 22.86 g of 2,2-dimethyl-4-allyl-4-hydroxymethyltetrahydrofuran (IV*e*) the solution was refluxed for 5 hours and then stored overnight at 5° C. Excess anhydride was decomposed by adding 2000 ml of water and stirring the mixture for 1 hour. The mixture was worked up as described in procedure (*a*) to give 33.8 g (98.9%) of crude product. Several distillations of this material gave X*e*, b.p. 155–160° C/17 mm. The infrared spectrum was identical with that of the product from procedure (*a*).

Catalytic Reduction of 2,2-Dimethyl-4-allyl-4-hydroxymethyltetrahydrofuran (IVe)

A solution of 23.53 g of 2,2-dimethyl-4-allyl-4-hydroxymethyltetrahydrofuran (IV*e*) in 300 ml of ethanol was shaken with hydrogen and 0.5 g of platinum oxide under slightly positive pressure. Approximately 1 mole of hydrogen was absorbed within 30 minutes. Following removal of the catalyst, the solvent was evaporated giving 23.6 g of a yellow oil. Distillation *in vacuo* afforded 20.6 g (87.4%) of 2,2-dimethyl-4-*n*-propyl-4-hydroxymethyltetrahydrofuran (IV*d*) as a colorless oil, b.p. 50–65° C/0.06–0.07 mm. The infrared spectrum of IV*d* indicated the absence of unsaturation and was indistinguishable from that of a sample prepared from diethyl *n*-propylmethallylmalonate (I*d*) by reduction and subsequent ring closure.

Conversion of 2,2,4-Trimethyl-4-hydroxymethyltetrahydrofuran (IVb) to 2,2,4,4-Tetramethyltetrahydrofuran (IXb)

(a) 2,2,4-Trimethyl-4-tosyloxymethyltetrahydrofuran (VIIIb)

p-Toluenesulphonyl chloride (79 g) dissolved in 140 ml of redistilled pyridine was added during 1 hour to a vigorously stirred solution of 39.3 g of 2,2,4-trimethyl-4-hydroxymethyltetrahydrofuran (IV*b*) in 140 ml of redistilled pyridine, maintained at 5° C. The mixture was stirred with cooling for an additional 3 hours and left overnight at room temperature. It was poured onto crushed ice and acidified with concentrated hydrochloric acid. The mixture was extracted six times with ethyl ether, and the combined ethereal extracts washed to neutrality with water and evaporated, affording 79.5 g (97.7%) of crude tosylate VIII*b*. The substance was not purified but used directly for the following reduction. Infrared: λ_{max} 6.25, 7.3–7.4, 8.4–8.5, 10.3–10.5, 10.95, 11.3, 12.7, 14.2, 15.0 μ (aromatic, tosyl).

(b) Lithium Aluminum Hydride Reduction of 2,2,4-Trimethyl-4-tosyloxymethyltetrahydrofuran (VIIIb)

A solution of 79.5 g of tosylate VIII*b* in 400 ml of anhydrous ethyl ether was added dropwise during 1 hour at 25–30° C to 16.2 g of lithium aluminum hydride dissolved in 800 ml of anhydrous ethyl ether. The mixture was refluxed for 8 hours with vigorous stirring, cooled, and decomposed with ice and water. The solids were repeatedly extracted with ethyl ether, and the combined ethereal extracts washed with water and concentrated, yielding 27.8 g of yellow oil. Two distillations of this oil gave 12.9 g of 2,2,4,4-tetramethyltetrahydrofuran (IX*b*) boiling at 116–118° C, n_D^{20} 1.422; reported (16) boiling

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

point 120° C and n_D^{20} 1.4061. The infrared spectrum of IX*b* was identical with that reported (16).

ACKNOWLEDGMENTS

The authors are indebted to Dr. G. W. Holden and E. B. Dechene for their many valuable discussions, to Dr. A. Taurins of McGill University for preliminary infrared spectra, and to H. Williams for invaluable suggestions concerning the possible role of acid in promoting cyclization. We also wish to acknowledge the capable assistance of A. Franck, O. Kristiansen, the late U. Liepins, J. Pollard, and P. Thibodeau, and S. Watanabe for elemental analyses and infrared spectra.

RADIATION-INDUCED EXCHANGE REACTIONS IN SOLUTIONS OF HYDROGEN IN WATER[1]

P. J. Dyne, J. W. Fletcher, W. M. Jenkinson, and L. P. Roy[2]

ABSTRACT

The exchange of H, D, and T atoms between water and dissolved hydrogen has been studied in both heavy and light water solutions. Values of the "exchange yield", G_{tracer}, for the isotopic hydrogen atoms have been deduced and are identified with the yield of D atoms from HDO in H_2O, H atoms from HDO in D_2O, T atoms from HTO in H_2O and from DTO in D_2O. These values are correlated by assuming that the medium, H_2O or D_2O, affects the total probability of dissociation of the tracer molecule (HDO, HTO, DTO) and that in HDO H atoms are more readily dissociated than D atoms.

INTRODUCTION

The radiation-induced exchange of hydrogen atoms (H, D, or T) between water and dissolved hydrogen is a direct observation of the presence and reaction of these atoms and provides a further method of studying the difference in radiolytic yields between heavy and light water.

This exchange was first studied by Gordon and Hart (1), who irradiated a solution of D_2 in H_2O with Co^{60} γ rays and found that HD and H_2 appeared in the dissolved gas. The initial yield of HD in neutral solution was found to be about 2.7 molecules/100 ev, equal to the yield of hydrogen atoms in pure water. They advanced the mechanism:

$$H_2O \sim\sim\sim\rightarrow H + OH \quad [1]$$

$$H_2O \sim\sim\sim\rightarrow \tfrac{1}{2}H_2 + \tfrac{1}{2}H_2O_2 \quad [2]$$

$$H + D_2 \rightarrow HD + D \quad [3]$$

$$OH + D_2 \rightarrow HOD + D \quad [4]$$

$$D + D \rightarrow D_2 \quad [5]$$

In this scheme every hydrogen atom produced in reaction [1] is detected by exchange in reaction [3]. Hydrogen is produced with the "molecular" yield, $G \simeq 0.4$ by reaction [2], but the total amount of dissolved hydrogen ($H_2 + HD + D_2$) remains constant.

If the dissolved hydrogen is a mixture of isotopic species, H_2 and D_2 say, then reaction [3] may be followed by

$$D + H_2 \rightarrow HD + H \quad [6]$$

and this H atom may react again by reaction [3]. A chain reaction is now observable in which the yield of HD is about 60, much greater than the initial yield of H atoms. Chain reactions in this system have been studied in detail by Friedman and Zeltman (2) whose results were in agreement with Gordon and Hart where comparison was possible.

Bardwell and Dyne (3) followed the initial exchange reaction (3) by a tracer technique. Hydrogen gas was dissolved in H_2O containing about 1% HDO. The only exchanges observed are those in which an HDO molecule is dissociated and gives a D atom; on a statistical basis these amount to $\sim$1/200 of the total number of initial exchanges (reactions [1] and [3] in the above scheme). The results were calculated on the assumption

[1]*Manuscript received December 8, 1960.*
Contribution from Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario.

[2]*Present address: Laval Industrial Association, 10510 Notre Dame Street East, Montreal, Que.*

that there was no isotopic discrimination in the production or reaction of the tracer D atoms; the initial "total exchange" yield was found to be much less than the primary yield of H atoms in H_2O.

In a subsequent paper (5) it was suggested that an excited HDO molecule dissociated less frequently to give D atoms than H atoms. The "total exchange" yield calculated from data obtained with D atoms as tracers would therefore be less than the hydrogen atom yield in pure water. This paper describes further tracer experiments using H and T atoms in which the interest centers on the differing availability of H, D, and T atoms from the mixed molecules, HTO, HDO, and DTO.

EXPERIMENTAL

The technique used for isolating gases dissolved in water was that described by Bardwell and Dyne (3). In this method one sample of water is used for several determinations. A check on the consistency of these experiments is obtained when different samples of water, with different concentrations of tracer atoms, give compatible results, when plotted as in Figs. 1 and 2. Reproducible results, comparable with those obtained in other laboratories, were obtained when the following method was used: water was purified by distillation, followed by distillation from alkaline permanganate followed by distillation in a stream of oxygen, the mixture of steam and oxygen being passed through a quartz tube heated to 700° C. In a private communication E. J. Hart tells us that small amounts of peroxide may be formed above 700° C. The water was degassed by freezing with solid CO_2, pumping, and thawing several times using a vacuum system

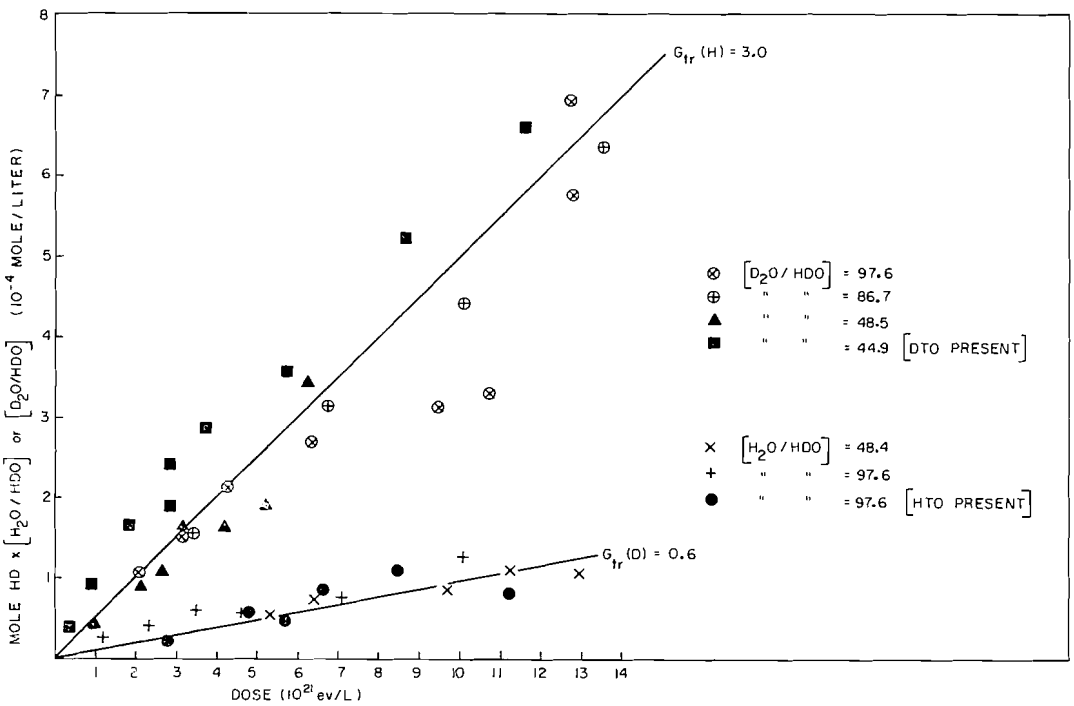

FIG. 1. Formation of HD in tracer experiments on the radiolysis of solutions of H_2 in H_2O and D_2 in D_2O. The upper line is for experiments using H atoms as a tracer in D_2O, the lower line is for D atoms as a tracer in H_2O.

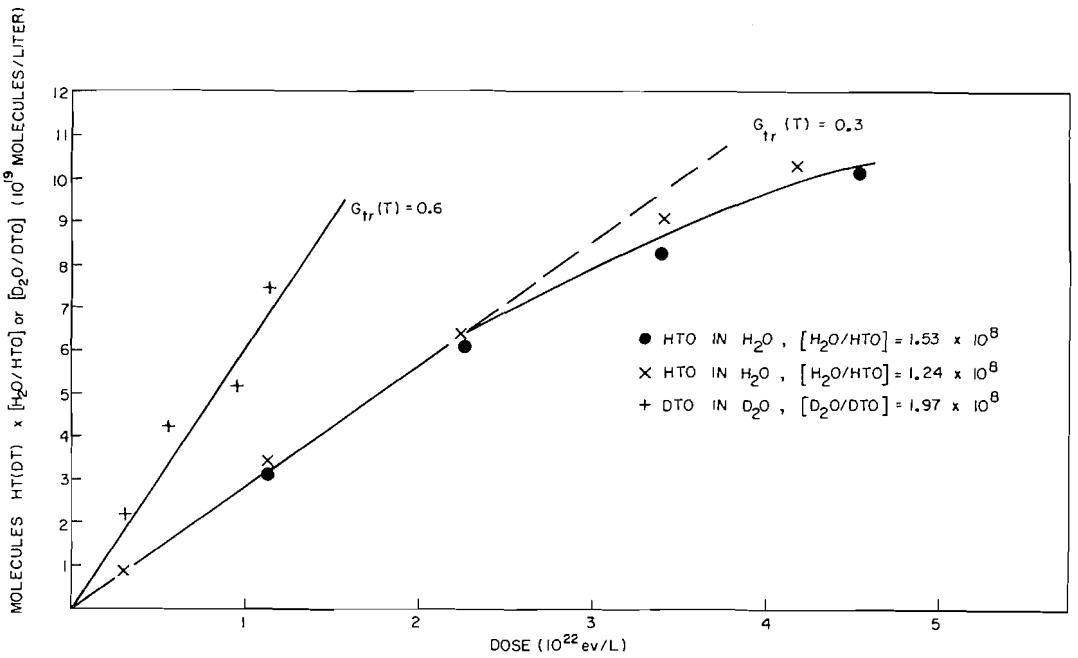

FIG. 2. Exchange of tritium atoms between water, H_2O or D_2O, containing tritium with dissolved hydrogen or deuterium.

with stopcock joints lubricated by Kel-F grease. The sample of water was saturated with H_2 or D_2 which had been passed into the system through a charcoal trap cooled with liquid air, and the saturated solution irradiated overnight. The dissolved hydrogen was pumped away and the cell was then filled with H_2 or D_2 for the first run. Without this preirradiation, low yields were invariably obtained.

Tritiated water with a specific activity of 4.5 mc/g was diluted to give solutions containing in the order of $\sim$10 μcuries T/ml and was purified by distillation as described above. The absolute tritium content was determined by gas-counting a sample of electrolyzed water (10). In the exchange experiments the whole sample of dissolved gas was pumped into the counter. Total counting rates were in the range 100–1000 c.p.m. in a system which detected $\frac{1}{3}$ of the total disintegrations. Corrections were made for the tritium content of the D_2 and D_2O used.

Mass spectrometric analysis for HD, H_2, and D_2 was carried out on a Consolidated 21-610 instrument. The analytical precision at a concentration of 0.5% HD in D_2 is about 10% and improves as the concentration increases.

Irradiations were carried out in the Co^{60} source described previously (3). The dose rate, $\sim 1 \times 10^{22}$ ev/l./hr, was determined by the Fricke dosimeter taking $G(Fe^{3+}) = 15.5$ ions/100 ev.

EXPERIMENTAL RESULTS

Results of tracer experiments are expressed as "total exchanges": the number of exchanges observed (number of atoms T appearing in dissolved gas per liter of solution or the number of HD molecules formed per liter of solution) multiplied by the ratio of unlabelled molecules to labelled molecules e.g. H_2O/HDO, D_2O/HDO, H_2O/HTO,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

D_2O/DTO as the case may be. For experiments with H or D as a tracer this ratio is between 40 to 100, for experiments with tritium it is of the order of 1.5×10^8. We call the G values obtained in this way G(tracer) or G_{tr}. G_{tr}(D) from HDO may be thought of as the yield of D atoms from HDO per 100 ev absorbed in the HDO molecule. In terms of the "reactivity" of H or D atoms, values of G_{tr} must be compared with $\frac{1}{2}G$(H) in H_2O or $\frac{1}{2}G$(D) in D_2O since these molecules contain two labile atoms/molecule.

As will be seen in the discussion, G_{tr} is a quantity determined both by the tracer atom, H, D, or T, and by the solvent. For rigorous definition we refer to G_{tr}(H, D_2O) or G_{tr}(T, H_2O) giving both the tracer atom and the solvent in which the exchange is observed.

In the discussion we estimate values of G_{tr}(H, H_2O) and G_{tr}(D, D_2O), the "total exchange" yields of H atoms from HDO in H_2O, and of D atoms from HDO in D_2O; these quantities are, of course, unobservable but have considerable theoretical significance.

Values of G(tr) determined from the slopes of lines in Figs. 1 and 2 are given in Table I.

TABLE I

Values of G(tracer)

Tracer molecule	Solvent	Solute	G(tr)
HDO	D_2O	D_2	$G_{tr}(H,D_2O) = 3.0\pm0.5$
HDO	H_2O	H_2	$G_{tr}(D,H_2O) = 0.6\pm0.1$
HTO	H_2O	H_2	$G_{tr}(T,H_2O) = 0.3\pm0.05$
DTO	D_2O	D_2	$G_{tr}(T,D_2O) = 0.6\pm0.1$

The limits of error are arbitrarily determined from the scatter of the points and the slopes of the most extreme lines that could reasonably be drawn through them. The experimental points for G_{tr}(H, D_2O) show the largest scatter and it is also noteworthy that some of the initial points lie on a line of significantly greater slope. (G(tr) = 5.0 or more.) In series of results in which this was observed, such as those with (D_2O/HDO) = 44.9, the points for greater doses lay on a line parallel to that drawn in the figure. We have no explanation of this but conclude that G_{tr}(H, D_2O) = 3.0 can be taken as a minimum value.

The value of G_{tr}(D, H_2O) agrees well with that obtained by Bardwell and Dyne (3). It should be noted that their "exchange yield" is twice G(tr) as defined here; consequently their exchange yield of 1.0 is equivalent to G_{tr}(D, H_2O) = 0.5.

Experiments in which D_2 was dissolved in pure H_2O and H_2 dissolved in pure D_2O were also carried out. These experiments are of course not "tracer" experiments, since every exchange is observed. The results are given in Table II. The first series of experiments is simply a repetition of Gordon and Hart's original experiment, and the results are in good agreement with their results. The value of G(HD) from D_2O is the first determination of this quantity in neutral solution.

TABLE II

Values of G(HD) in H_2O and D_2O

Solvent	Solute	G(HD)	$\frac{1}{2}G$ ($\equiv G_{tr}$)
H_2O	D_2	2.9 ± 0.1	1.45
D_2O	H_2	3.7 ± 0.1	1.85

A small pressure dependence was observed in these experiments. Yields measured at small doses (1×10^{21} ev/l.) are shown in Fig. 3. This is negligible in the range of dissolved

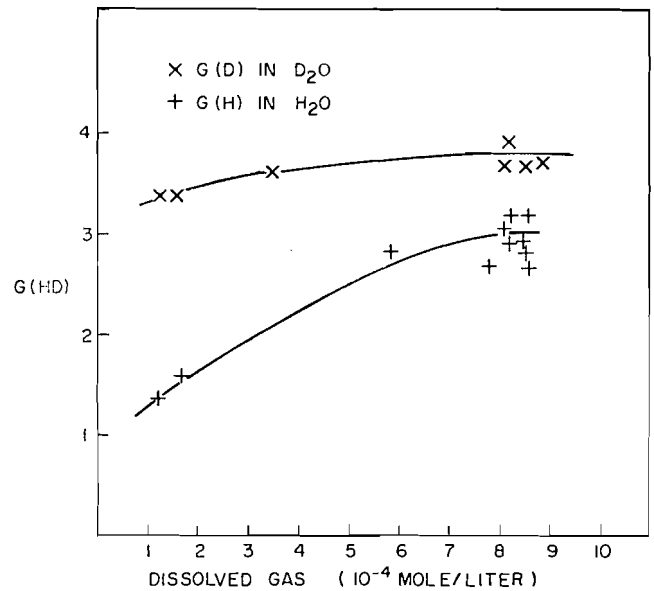

FIG. 3. Variation of G(HD) with partial pressure of dissolved D_2 in H_2O or dissolved H_2 in D_2O. Doses of $\sim1\times10^{21}$ ev/l. were given for all the data presented.

gas concentrations of $5–10\times10^{-4}$ mole/liter but is appreciable at lower concentrations. In this matter our data are not in serious disagreement with other workers who were working in the higher-pressure ranges.

In agreement with Gordon and Hart, yields of H_2 in H_2O solutions and D_2 in D_2O solutions were also observed which are identified with the molecular process, reaction [2]. Values of $G(H_2)$ lay in the range 0.4–0.5, and values of $G(D_2)$ in the range 0.3–0.35. $G(H_2)$ increased as the pressure of dissolved deuterium decreased.

DISCUSSION

In comparing values of G_{tr}, G(H), and G(D) two effects must be distinguished: there are effects of the medium (H_2O or D_2O) on the effective probability of dissociation of the tracer molecule, and effects due to the differing detachment probabilities of, for instance, H and D atoms from an excited HDO molecule.

The first effect, the influence of the properties of the medium on the initial radiolytic steps, is possibly the origin of the isotope effects in the primary yields in heavy and light water. These isotope effects have been discussed by many workers (4, 5, 7, and 8): the current conclusions are firstly that differences in the rate constants and diffusion constants between H and D atoms and between OH and OD radicals will not affect the product yields. Secondly, Armstrong, Collinson, and Dainton (4) suggest that a more extended initial distribution of D atoms in spurs in D_2O, relative to the initial distribution of H atoms in H_2O, would give the observed isotope effect, viz. $G(D_2) < G(H_2)$ and $G(D) > G(H)$; in the more extended, dilute distribution the probability of atom recombination to give molecular products is smaller and the probability of escape and reaction with the solute is greater. These workers suggested that the distribution of H or D atoms

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was, at least in part, determined by rate of thermalization of the ~100-ev electrons formed in the initial ionization and by the time required for capture by the solvent molecules to form H_2O^- ions (which subsequently dissociate to give H and OH^-). The rates of these processes are intimately connected with the dielectric properties of H_2O and D_2O and may differ appreciably in the two media.

It follows from this suggestion that hydrogen atoms produced from the dissociation of HDO in a D_2O medium will be formed in a distribution characteristic of D_2O. They will have a greater probability of escape from the spur and of reacting with a solute than D atoms produced from the same molecule in a H_2O medium. Calculations have shown that there are no isotopic separations resulting from the reactions of H and D atoms in the same spur (5).

The magnitude of this effect of the medium can be estimated from the values of G(D) and G(H) (given in Table II). In neutral solution the present measurements give $G(D)/G(H) = 1.27$. In acid solution lower values, 1.11 (8) and 1.08 (9) are reported. We conclude that, in the absence of any isotopic discrimination in the detachment of H and D atoms from an HDO molecule, $G_{tr}(H, D_2O)$ would be 10–30% greater than $G_{tr}(D, H_2O)$.

The differing detachment probabilities of H and D atoms from an excited molecule can only be discussed qualitatively and by inference from mass-spectral studies on partially deuterated hydrocarbons. Isotope effects in mass spectra are fully summarized by Field and Franklin (6); the general conclusions are that in a partially deuterated hydrocarbon, detachment of H atoms is more probable than the detachment of D atoms, that detachment of an H atom in a partially deuterated molecule is more probable than the detachment of an H atom in the fully protonated molecule and, lastly, that there are no large changes in the total yields of molecular ions and fragments on isotopic substitution. We postulate that these conclusions are applicable to HDO.

To correlate our experimental results with these ideas, we have to eliminate the effect of the medium, i.e. $G_{tr}(D, H_2O)$ is to be compared with the "unobservable" quantity $G_{tr}(H, H_2O)$. Using our experimental ratio of $G(D)/G(H) = 1.27$ we put $G_{tr}(H, H_2O) = 1/1.27\, G_{tr}(H, D_2O)$. Similarly we correlate results in heavy water by comparing $G_{tr}(H, D_2O)$ with $G_{tr}(D, D_2O) = 1.27\, G_{tr}(D, H_2O)$.

With these corrections the ratio $G_{tr}(D)/G_{tr}(H)$ should be the same in H_2O and D_2O since it expresses a molecular property of HDO and not a property of the medium. The data should also be consistent with our expectation that there are no large isotope effects in the *total* probability of dissociation to give, for instance H and D atoms from HDO or to give two H atoms from H_2O. The approximate equalities $G_{tr}(H, H_2O)+G_{tr}(D, H_2O) \simeq G(H)$, and $G_{tr}(H, D_2O)+G_{tr}(D, D_2O) \simeq G(D)$ should be observed.

Values of $G_{tr}(H, H_2O)$ and $G_{tr}(D, D_2O)$ calculated using our ratio of $G(H)/G(D) = 1.27$ are given in brackets in Table III together with values of the sums and ratios referred to above.

The values of the sums agree well with the values of G(H) and G(D).

While the value of the ratio $G_{tr}(D)/G_{tr}(H)$ is, indeed, independent of the solvent this agreement is probably fortuitous. The limits of error on the ratio are large if upper and lower limiting values of G_{tr} are combined in this ratio; in D_2O for instance the values are 0.25 (+0.12, −0.07). It can only be claimed that the data are consistent with the postulate that the discrimination is analogous to "mass-spectral" isotope effects. The ratio $G_{tr}(D)/G_{tr}(H)$ is, in our interpretation, equivalent to the π factor (probability of dissociation of a D atom from HDO/probability of dissociation of an

H atom from HDO) for the mass spectrum of HDO. The mass spectrum of HDO is unknown but values of the π factor of 0.3–0.5 are observed in light hydrocarbons (6).

The experimental values of $G_{tr}(T)$ are also, in a more limited sense, consistent with the same postulate. No detailed comparison is possible without values of $G(T)$ in pure T_2O. In H_2O solutions one would expect T atoms to be less labile than D atoms in HDO and so $G_{tr}(T) < G_{tr}(D)$, as observed; in D_2O solutions again H from HDO would be much more labile than T in DTO and $G_{tr}(H) > G_{tr}(T)$ as observed.

ACKNOWLEDGMENTS

It is a pleasure to acknowledge the many helpful discussions we had with Dr. R. H. Betts on this problem.

THE MECHANISM OF THE ALCOHOLYSIS OF ALIPHATIC NITRITES

I. ALCOHOLYSIS OF 1-METHYLHEPTYL NITRITE IN ALKALINE AND NEUTRAL SOLUTION[1]

A. D. ALLEN[2] AND G. R. SCHONBAUM[3]

ABSTRACT

A polarimetric study of the kinetics of the alcoholysis of 1-methylheptyl nitrite in alkaline solution has shown that the reaction rate is proportional to both the nitrite and alkoxide ion concentration. The asymmetric carbon center is not involved in the reaction. In strictly neutral solution no reaction occurs; the commonly observed "neutral" reaction is attributed to traces of acid formed in the decomposition of the nitrite ester. The mechanism of the reactions is discussed.

In a previous paper (1) the mechanism of the acid- and base-catalyzed hydrolysis of some organic nitrite esters was discussed, and some preliminary work on alcoholysis reported. With perchloric acid as the catalyst the rapid reaction was first order with respect to both the nitrite and acid concentrations, but with hydrochloric acid or added halide salts an additional catalysis, proportional to the halide ion concentration, was observed. In alkaline solution the much slower reaction was approximately first order with respect to both the nitrite and hydroxide ion concentration, but the second-order rate coefficient decreased slightly with increasing hydroxide concentration. Since this decrease was not a simple salt effect it indicated the possibility of a solvolytic reaction between the nitrite and water. It had been reported earlier that nitrite esters react readily with methanol, in the absence of added catalysts, evolving gaseous methyl nitrite (2). These observations prompted the present investigation into the uncatalyzed alcoholysis reaction. The indications, from our work using aqueous media, were that the solvolytic reaction would be too slow to account for the apparently rapid reaction with methanol.

The reversible reaction between an aliphatic nitrite and an alcohol may be written:

$$RONO + R'OH \rightleftarrows R'ONO + ROH \qquad R,\ R' = \text{alkyl.}$$

Some physical method must be used to follow the course of such a reaction, and the polarimetric method was chosen as the most suitable one. From our previous work (1) it was known that the specific rotation of (+)- or (−)-1-methylheptyl nitrite is just over half that of its hydrolysis product (+)- or (−)-octan-2-ol, and it seemed likely that, under the conditions to be used, complete retention of configuration would be observed. Preliminary experiments confirmed the following relationships, which had to be known precisely before any rate measurements could be made: (*a*) the optical rotations of solutions of the alcohol and nitrite are proportional to their concentrations, (*b*) the total rotation of mixtures of the two optically active compounds in solution is given by the sum of their individual rotations, and (*c*) the asymmetric center is not involved in the reactions to be studied, so that the optical configurations are preserved. During repeated esterification, hydrolysis, and alcoholysis in a wide variety of acidic and basic solutions, the optical purity of the alcohol recovered was always unchanged, confirming exclusive fission of the nitrosyl-oxygen bond. The rotations of these compounds in various solvents are given in Table I.

TABLE I

Optical rotations of 10% (by weight) solutions at 25°

Solvent	(+)-Octan-2-ol α_D^{25} (l = 2)	(+)-1-Methylheptyl nitrite α_D^{25} (l = 2)
1-Propanol	1.58	0.59
1-Pentanol	1.65	0.60
2-Propanol	1.46	—
2-Methyl-2-butanol	1.45	0.56
Dioxane	2.27	—
Nitromethane	—	0.11

It is of interest to note that, whereas the rotation of 1-methylheptyl nitrite in alcoholic solution is relatively insensitive to the alcohol used, it is smaller by a factor of about five in nitromethane solution; also the rotation of octan-2-ol in dioxane is significantly higher than in alcoholic solution.

Equilibrium Measurements

The position of equilibrium for the over-all reaction

$$R^*ONO + R'OH \overset{H^+}{\rightleftharpoons} R^*OH + R'ONO$$

where R* = (+)- or (−)-1-methylheptyl, R′ = alkyl, was determined. The measurements were carried out in acid solution to reduce the time needed to reach equilibrium, and it was shown that the concentration and the nature of the acid present had no effect on the final result. Values obtained for the concentration equilibrium constant $K_c = [R^*OH][R'ONO]/[R^*ONO][R'OH]$ at 25° were as follows.

R′OH	K_c
2-Methyl-2-butanol	0.28
2-Propanol	0.51
1-Propanol	1.6 (In dioxane)

With the tertiary and secondary alcohols the equilibrium position could be determined from simple mixtures of the alcohols and nitrite, but with the primary alcohol the reaction was displaced too far to the right for accurate measurement. Dioxane was used as a solvent to reduce the concentration of the alcohol. These results show that the equilibrium is shifted towards the products as the reagent is changed from tertiary, through secondary, to primary alcohol. Two mutually supporting effects would account for this trend, (*a*) the reactivity of nitrites in acid solution decreases in the order tertiary > secondary > primary, and (*b*) the nucleophilic strength of the alcohols decreases in the order primary > secondary > tertiary (11).

Kinetics and Mechanism of Alcoholysis in Alkaline Solution

The alcoholysis of 1-methylheptyl nitrite in alkaline solution was studied using 1-propanol as the solvent, in the presence of small concentrations of sodium propoxide. It was found that secondary and tertiary alcohols and alkoxides could not be used as reagents, for the following reason. The reversible reaction in alkaline solutions

$$R^*ONO + R'O^- \overset{\text{slow}}{\rightleftharpoons} R^*O^- + R'ONO \qquad (a)$$

is complicated by the further equilibrium

$$R^*O^- + R'OH \overset{\text{fast}}{\rightleftharpoons} R^*OH + R'O^-. \qquad (b)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

If reaction (*b*) is displaced strongly towards the right the reagent alkoxide will be quantitatively regenerated and its concentration will remain constant throughout the reaction. Thus, if the reaction rate is given by $v = k_2$ [R*ONO][R'O$^-$], (as in alkaline hydrolysis) the kinetics observed would be pseudo first order, the rate coefficient being proportional to the (constant) concentration of alkoxide. Alternatively, if reaction (*b*) is displaced strongly towards the left, the reagent alkoxide would be consumed and second-order kinetics could, in principle, be observed. However, since in our experiments the nitrite is in very large excess over the alkoxide, the reaction would cease after a small fraction of the ester had reacted. Finally, if reaction (*b*) has an intermediate equilibrium position it will be difficult to determine with sufficient accuracy the concentrations of the two alkoxides at any point in the reaction and the kinetic order will be obscured. Displacement of equilibrium (*b*) to the left or right will depend on the relative basicities of the two alkoxides. The following order of decreasing basicity has been given (3): tertiary > secondary > primary alkoxide > hydroxide. The position of hydroxide at the lower end of this sequence presents a further problem, since, if there is any water present in the reaction mixture some hydroxide ion will be formed, which will give rise to the irreversible hydrolysis reaction

$$R^*ONO + HO^- \rightarrow R^*OH + NO_2^-.$$

Conversion of alkoxide to hydroxide, followed by production of nitrite ion, would again lead to early termination of the reaction. Extreme precautions were therefore necessary to ensure that all the solutions used were perfectly dry.

The alkoxide of octan-2-ol formed in the reaction is secondary, and it follows from the above that clear kinetic results could only be expected if the reagent were a much more weakly basic primary alkoxide. We should then expect to observe pseudo first-order kinetics. The results obtained are shown in Table II. Good first-order kinetics were

TABLE II

Reaction of 1-methylheptyl nitrite with sodium propoxide in 1-propanol at 25° C

$[R^*ONO]_0$ (M)	$[PrO^-]_0$ (10^2 M)	10^4 k_1 (sec^{-1})	$k_2 = \frac{k_1}{[PrO^-]}$
0.826	1.07	0.091	8.5
0.744	2.14	0.221	10.3
0.772	2.60	0.253	9.7
0.596	4.34	0.432	9.9
0.827	5.24	0.509	9.7

observed, the first-order rate coefficient (k_1) being satisfactorily proportional to the concentration of alkoxide. Several conclusions may be drawn from these results: (*a*) propoxide must be much less basic than octan-2-oxide, (*b*) the solutions were satisfactorily dry, (*c*) any contribution to the total reaction rate by reaction of the nitrite with the solvent alcohol is negligible, since otherwise the second-order rate coefficients would decrease with increasing alkoxide concentration. From this it follows that the alcoholysis reaction in neutral solution should be immeasurably slow, unless some other mechanism is possible which is inhibited by alkali.

Since the alkaline reaction proceeds without disturbing the asymmetric center, we envisage a bimolecular nucleophilic attack by alkoxide on the nitrogen atom of the ester molecule:

$$R'O^- + R^*ONO \underset{\text{fast}}{\overset{\text{slow}}{\rightleftharpoons}} \left[R^*O \cdots \overset{O}{\overset{\|}{N}} \cdots OR' \right]^- \underset{\text{slow}}{\overset{\text{fast}}{\rightleftharpoons}} R'ONO + R^*O^-,$$

followed by

$$R^*O^- + R'OH \xrightarrow{\text{fast}} R^*OH + R'O^-.$$

Alcoholysis Reactions in Neutral Solution

At the beginning of this investigation many kinetic runs were attempted using (+)- or (−)-1-methylheptyl nitrite prepared and purified in the usual way, with various alcohols and solvents similarly purified and dried. Reaction always occurred as soon as the reagents were mixed, but the rates of these reactions were quite random and could not be reproduced. Improvements in experimental technique, e.g. complete exclusion of oxygen, moisture, light, and nitrite decomposition products, gradually reduced the speed of the spontaneous reactions until, under optimum conditions, no reaction occurred on mixing the reagents. Generally a variable induction period of up to 48 hours was observed: reaction then started and in some cases it was possible to follow it kinetically. The results are given in Table III. The initial rates of these spontaneous reactions did not

TABLE III

depend on the length of the induction period, but were generally faster in 1-propanol than in 2-methyl-2-butanol. Induction periods were more usually observed in the tertiary than in the primary alcohol. Addition of traces (10^{-4} M) of alkali prolonged the induction period greatly. The use of mixed solvents containing varying proportions of dioxane and nitromethane showed that the trend is towards shorter induction periods and faster rates as the nitromethane content of the mixture is increased. It is thought that this trend is connected with the decreasing basicity of the medium rather than the increase in its dielectric constant.

It seemed most likely that the reaction was being initiated by the spontaneous production of an acid in the reaction mixture. The following tests were made which confirmed this belief. To a solution of 1-methylhepytl nitrite in 2-methyl-2-butanol was added just enough lacmoid indicator to give a recognizable color. This solution was divided

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

into two. One half was placed in the polarimeter and the rotation observed. After an induction period of about 5 hours reaction started and it was observed that the indicator had changed color. To the other half was added sodium 2-methyl-2-butoxide to give a concentration of about 10^{-4} M. This alkaline solution was further divided into two. After 24 hours both alkaline solutions were unchanged. One of these was then irradiated with a mercury lamp until the color changed; reaction began at once. Addition of just enough alkali to restore the indicator color immediately stopped the reaction.

From our other work (4) it is estimated that a concentration of approximately 10^{-6} M of a strong acid is all that is needed to account for the observed reaction rates. A weak acid, such as nitrous acid, would have to be present in very much higher concentrations, as was shown by the investigation of formic acid as a catalyst (4). A concentration of approximately 0.1 M of this acid, which is comparable in strength to nitrous acid, is needed to produce the observed rate. The most likely catalyst is nitric acid, which could be formed in sufficient quantity if traces of oxygen remained in the solutions or apparatus. The following is a possible reaction sequence;

$$\mathrm{RONO} \rightleftarrows \mathrm{RO}\cdot + \mathrm{NO} \quad \text{(thermal or photochemical decomposition (5))}$$

$$\mathrm{NO} + \mathrm{O} \rightarrow \mathrm{NO_2}$$

$$2\mathrm{NO_2} \rightleftarrows \mathrm{N_2O_4}$$

$$\mathrm{R'OH} + \mathrm{N_2O_4} \rightarrow \mathrm{R'ONO} + \mathrm{HNO_3}. \qquad (6)$$

It is also possible that a much more complex decomposition of the nitrite could produce nitric acid in the absence of oxygen (7). Under normal atmospheric conditions it is obvious that the above reactions could occur readily. The presence of nitric acid in samples of 1-methylheptyl nitrite that had been exposed to the atmosphere was demonstrated by the addition of a small amount of pyridine, which gave a fine white precipitate, m.p. 118°, which gave a positive test for nitrate ion and which did not depress the melting point of synthetic pyridinium nitrate. Samples of the nitrite prepared and preserved as described in the experimental section gave no precipitate with pyridine.

CONCLUSIONS

Our results show that the commonly observed 'uncatalyzed' reaction of an alkyl nitrite with alcohols is caused by traces of nitric acid arising from the thermal or photochemical decomposition of the nitrite in the presence of atmospheric oxygen. In acid-free solutions no reaction occurs. The results in alkaline solution show that the unprotonated ester molecule can only be attacked by strong nucleophilic reagents such as alkoxide, since no solvolytic component of the reaction rate could be detected. The mechanism of the reaction with alkoxide in alcoholic solution appears to be the same as that with hydroxide in aqueous solution, and involves a nucleophilic attack by alkoxide ion on the nitrogen atom of the nitrite molecule.

EXPERIMENTAL

Resolution of Octan-2-ol

Octan-2-ol was resolved into its (+) and (−) optical isomers by Kenyon's phthalic anhydride – brucine method (8). From several such resolutions the following average values were obtained: b.p. 86°/20 mm, $n_D^{25°}$ 1.4244, $[\alpha]_D^{25°}$ +9.53, −9.33°.

Preparation of (+)- and (−)-1-Methylheptyl Nitrite

These were prepared from the (+)- or (−)-octan-2-ol by esterification with nitrous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

acid in weakly acid solution. The procedure of Chretien and Longi (9), using aluminum sulphate as the source of acid, was found to be greatly superior to the more commonly used methods. Yields were generally better than 90% if the temperature was kept below 5° throughout the preparation. The crude product was dried and fractionally distilled at reduced pressure in a nitrogen atmosphere, giving b.p. 61–62°/15 mm, 34°/2.5 mm, $n_D^{25°}$ 1.4067, $d_4^{25°}$ 0.8602, $[\alpha]_D^{25°} \pm 5.00°$ (mean value, no solvent). The pure product was stored over potassium carbonate in a dark flask at 0° to minimize decomposition.

Purification of Solvents

The solvents used were purified and thoroughly dried by standard procedures, and fractionally distilled at high reflux ratio using a 48-in. helix packed column. Purity and dryness were checked by constancy of the boiling point on changing to total reflux. The absence of water in the dried solvents was confirmed by Karl Fischer titration (10). All solvents were collected and stored in an atmosphere of dry nitrogen, and samples for use were taken by siphon, using dry nitrogen pressure.

Equilibrium Measurements

1-Methylheptyl nitrite was mixed with the appropriate alcohol. Acid was added and the change in rotation followed until a constant value was obtained. The rotation for 100% reaction was calculated and hence the position of equilibrium was found. The results are shown in Table IV.

TABLE IV

Alkaline Alcoholysis

Stock solutions of sodium propoxide in 1-propanol were prepared by dissolving clean sodium in the dry alcohol, in an atmosphere of dry nitrogen. The solution was standardized against standard hydrochloric acid. The reagents for each kinetic run were separately brought to 25°, mixed at zero time, and transferred to the polarimeter tube under dry nitrogen. Details of a typical run were as follows:

$[R^*ONO]_0 = 0.596$ M $[\text{Propoxide}]_0 = 4.34 \times 10^{-2}$ M $\alpha_D^{25}(t = \infty, \text{calc.})$ 1.510

Alcoholysis in Neutral Solution

To obtain solutions free from acid and oxygen for this part of the work the following precautions were found to be necessary: (*a*) Small samples of 1-methylheptyl nitrite from stock preparations were freshly distilled from potassium carbonate in the dark at low pressures immediately before each kinetic run. Static distillation into a liquid-air trap at about 10^{-4} mm pressure was used, the distillate being collected in a calibrated tube and used immediately. (*b*) All operations were carried out in an atmosphere of dry nitrogen. (*c*) All solvents were thoroughly degassed and stored in an atmosphere of dry nitrogen. (*d*) The reaction mixture was shielded from light, except for occasional exposure to the sodium lamp during measurement of the rotation. In the following example an induction period of about 3 hours was observed. The first-order rate coefficient for the initial part of the reaction which followed was approximately 0.12×10^{-4} sec^{-1}.

THE MECHANISM OF THE ALCOHOLYSIS OF ALIPHATIC NITRITES

II. ACID-CATALYZED ALCOHOLYSIS OF 1-METHYLHEPTYL NITRITE[1]

A. D. ALLEN[2] AND G. R. SCHONBAUM[3]

ABSTRACT

The acid-catalyzed alcoholysis of 1-methylheptyl nitrite has been studied kinetically. The reaction rate is first order with respect to both the nitrite and the hydrogen ion concentration, and the reaction does not involve the asymmetric carbon center. Addition of lithium salts (chloride and perchlorate) indicates catalysis by chloride ion. Addition of water in low concentrations inhibits the reaction strongly. These results and the mechanism of the reactions are discussed in terms of the properties of the alcohols and the dissociation of the acid catalysts in the alcohols used.

In a previous paper (1) it was reported that the alcoholysis of 1-methylheptyl nitrite in "neutral" solution was, in fact, catalyzed by traces of a strong acid, probably nitric acid, formed in the decomposition of the nitrite ester. The sensitivity of this reaction to very small concentrations of acid led to a study of the mechanism of the acid-catalyzed reaction.

The polarimetric method was again used, and the alcoholysis of (+)- or (−)-1-methylheptyl nitrite in 1-propanol, 1-pentanol, and 2-methyl-2-butanol was studied, using various acids as catalysts.

Catalysis by Strong Acids

In very dilute solutions of perchloric, hydrochloric, or methanesulphonic acid the reaction rate was found to be first order with respect to both the acid and ester concentration, giving the rate expression $v = k_2[H^+][R^*ONO]$ (R*— = (+)- or (−)-1-methylheptyl-). Since the hydrogen ion concentration was constant during each kinetic run, first-order kinetics were observed, the first-order rate coefficient being proportional to the acid concentration. The reagent alcohol was in large excess over the other reagents and does not, therefore, appear in the rate equation. A comparison of the results obtained in 1-propanol with the three strong acids used is shown in Table I.

It is evident that perchloric, hydrochloric, and methanesulphonic acids are equally efficient as catalysts for the reaction. This indicates that, in 1-propanol at these very low (10^{-4}–10^{-5} M) concentrations, all three acids are virtually completely dissociated. It also follows that the hydrogen ion is the only significant catalyst, since changes in the nature of the anion do not affect the rate. Previously (2) we observed catalysis of the hydrolysis reaction by halide ion in aqueous dioxane, resulting in faster rates in hydrochloric acid than in perchloric acid solutions of the same concentration. In the present case, however, the acid concentrations are very much smaller and it is probable that any catalysis by chloride ion would be too small to be detected. The effect of added chloride ion will be discussed later.

In 1-pentanol and the tertiary alcohol 2-methyl-2-butanol a similar dependence of rate on acid concentration was observed. The results obtained are given in Table II.

			12.8	26.8	21.0

NOTE: $[R^*ONO]_0 \simeq 0.5$ M.

The rate of the reaction with the tertiary alcohol is about twice as fast as that with the two primary alcohols. The mechanism appears to be the same in each case, and is also the same as that observed in aqueous dioxane (2). The rate-determining step is preceded by a proton transfer equilibrium:

$$R^*ONO + SH^+ \overset{\text{fast}}{\rightleftharpoons} (R^*ONOH)^+ + S, \qquad (S = \text{solvent})$$

which is established rapidly and is maintained throughout the reaction. This is followed by the rate-determining step:

$$(R^*ONOH)^+ + R'OH \overset{\text{slow}}{\rightleftharpoons} (R'ONOH)^+ + R^*OH.$$

For this we envisage a bimolecular nucleophilic attack by the alcohol on the nitrogen atom of the protonated ester, preserving the configuration of the asymmetric carbon center:

$$R'OH + (R^*ONOH)^+ \underset{\text{fast}}{\overset{\text{slow}}{\rightleftharpoons}} \left[R'O\overset{H}{\ldots}\overset{O}{\overset{\|}{N}}\ldots\overset{H}{OR^*} \right]^+ \underset{\text{slow}}{\overset{\text{fast}}{\rightleftharpoons}} (R'ONOH)^+ + R^*OH.$$

Two important factors will influence the rate of this reaction, (*a*) the nucleophilic power of the reagent alcohol, and (*b*) the concentration of the protonated ester. The nucleophilic power of the alcohols used decreases in the order 1-propanol $\sim$ 1-pentanol $>$ 2-methyl-2-butanol, steric factors being the main reason for the relatively weak nucleophilic power of the tertiary alcohols. If this were the only factor it would result in a

much slower rate in the tertiary alcohol, contrary to our observations. To explain the observed faster rate we propose that, at equivalent acid concentrations, the concentration of the protonated ester is much greater in 2-methyl-2-butanol than in the primary alcohols. This means that the equilibrium:

$$R^*ONO + R'OH_2^+ \rightleftarrows R^*ONOH^+ + R'OH$$

is displaced to the right when R′ changes from primary to tertiary. Thus the tertiary alcohol is apparently much more weakly basic than the primary alcohol, despite the obvious inductive effects of the tertiary amyl group. There is much evidence to support this view. Absence of significant hydrogen bonding in liquid 2-methyl-2-butanol has been shown by infrared and dipole moment studies (3, 4). The relation between hydrogen bonding and basicity has been studied by Gordy and Stanford (5, 6), who found that the shift to lower frequencies of an infrared band of CH_3OD, due to deuterium bonding, is proportional to the basicity of the solvent used. The available data (7, 8) indicate that the basicity of hydroxy compounds decreases in the order: water $\gg$ primary $>$ secondary $>$ tertiary alcohols. It should be noted that this sequence is quite different from the order of relative basicities of the corresponding alkoxides, illustrating the importance of steric strain in the protonated molecule, ROH_2^+ (8, 9).

Catalysis by Organic Acids

As part of the investigation into the cause of the so-called "neutral" reaction, a study was made of the catalytic effect of trichloroacetic and formic acids. Reaction rates in 1-propanol and 2-methyl-2-butanol, in the presence of trichloroacetic acid, are shown in Table III.

TABLE III

Catalysis by trichloroacetic acid at 25°

1.31	1.11	8.5	2.90	0.94	3.2
2.84	2.27	8.0	5.40	1.75	3.2
3.75	3.02	8.1	8.40	2.82	3.4
5.41	4.54	8.4			

NOTE: $[R^*ONO]_0 \simeq 0.5\ M$.

In both alcohols the rates are again first order with respect to both the ester and acid concentrations. For a given acid concentration, however, the rate is some 100 times slower than that found when the catalyst is a strong acid. This shows that trichloroacetic acid is only weakly ionized in these solvents, as would be expected. The faster rate in 1-propanol than in 2-methyl-2-butanol (in contrast to the previous results with strong acids) is readily explained on the basis of greater acid ionization in the medium of higher dielectric constant. The linearity of the dependence of rate on acid concentration is, however, surprising. From mass law considerations, we would expect a deviation from linearity due to a decrease in the degree of dissociation of the weak acid with increasing concentration. This will only be found, however, if the acid dissociation constant is independent of concentration. In solvents of moderately low dielectric constant, such as these alcohols, an increase in acid concentration has a marked effect on the activity

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

coefficient of the ionic species, resulting in an increase in the classical dissociation constant of the acid. For example, the dissociation constant for iodic acid (which is similar to that of trichloroacetic acid) in methanol increases from 2.4 to 14×10^{-8} when the acid concentration is raised from 9 to 64×10^{-4} M (10). It appears that a similar increase occurs with trichloroacetic acid in the alcohols used in our experiments, and that the linearity between rate and acid concentration is fortuitous. Assuming that hydrogen ion is the only catalyst, we can calculate the following dissociation constants (K_c) for trichloroacetic acid in these solvents at 25°.

[Acid] 10^3 M	1-Propanol 10^8 K_c	2-Methyl-2-butanol 10^8 K_c
1	8.1	—
3	19	0.83
5	31	—
6	—	1.5
9	—	2.2

A value of $K_c=34\times10^{-8}$ has been given (11) for this acid in 1-butanol at 25°, which is in good agreement with our results.

Formic Acid Catalysis

In 2-methyl-2-butanol the addition of formic acid in concentrations up to 0.01 M gave no measurable initial reaction. At 0.1 M acid concentration reaction occurred with a first-order rate coefficient of 0.29×10^{-4} sec^{-1}. Thus formic acid is about 100 times less effective as a catalyst than trichloroacetic acid. This is approximately the figure that would be expected if hydrogen ion were the only catalyst, bearing in mind the increase in the dissociation constant of formic acid at the very much higher concentrations used. The results with trichloroacetic and formic acids indicate that catalysis by the undissociated acid is negligible, even, in the case of formic acid, at concentrations of some 10^5 times greater than that of the hydrogen ion concentration. It also follows that, since formic acid is comparable in strength to nitrous acid, the spontaneous "neutral" reaction is not caused by traces of nitrous acid in the reaction mixture.

Salt Effects: (1) Strong Acids

The effect of added salts (lithium perchlorate and lithium chloride) on the reactions catalyzed by hydrochloric and perchloric acids in 1-propanol are given in Table IV.

TABLE IV

Salt effects on catalysis by strong acids at 25°
$[R^*ONO]_0 \simeq 0.6$ M; $[HClO_4] = 6.5\times10^{-5}$ M; solvent: 1-propanol

0	7.0	0	7.0
.99	10.2	3.11	9.9
1.44	11.6	4.69	11.0
2.52	13.1	6.70	11.2
4.10	14.4		
4.72	14.6		
9.02	14.5		

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Lithium chloride has a much greater effect on the rate than lithium perchlorate, but the increase in rate is not linear with respect to concentration. The rate reaches a maximum value at about 4×10^{-3} *M* chloride ion, i.e. at about 60 times the concentration of acid used. It is not possible, on the basis of these few results, to attempt a full analysis of these salt effects, but the results are at least consistent with (*a*) significant catalysis by chloride ion, as observed in hydrolysis, and (*b*) depression of the hydrogen ion concentration by its association with chloride ion to form hydrogen chloride. The results obtained are consistent with a dissociation constant of between $3–4\times10^{-3}$ for hydrogen chloride in this medium. Owen and Waters (12) give a value of 2×10^{-4} for this acid in 82% dioxane–water, which has a lower dielectric constant than 1-propanol.

Salt Effects: (2) Trichloroacetic Acid

Addition of lithium chloride and lithium perchlorate to reactions catalyzed by trichloroacetic acid in 1-propanol and 2-methyl-2-butanol gave the following results (Table V).

TABLE V

Salt effects on catalysis by trichloroacetic acid at 25°

1-Propanol				2-Methyl-2-butanol			
[Acid] = 2.5×10^{-3} *M*				[Acid] = 2.8×10^{-3} *M*			
[LiCl] 10^3 *M*	$10^4 k_1$ sec^{-1}	[$LiClO_4$] 10^3 *M*	$10^4 k_1$ sec^{-1}	[LiCl] 10^3 *M*	$10^4 k_1$ sec^{-1}	[$LiClO_4$] 10^3 *M*	$10^4 k_1$ sec^{-1}
0	2.10	0	2.10	0	0.95	0	0.95
0.98	3.60	1.68	3.75	0.50	4.67	0.79	1.85
1.70	4.95	3.03	4.90	1.01	7.45	1.61	2.15
2.42	6.25	4.16	6.15	1.26	10.55	2.32	3.20
				1.62	12.5	2.95	3.75

NOTE: $[R^*ONO]_0 \simeq 0.5$ *M*.

Addition of lithium perchlorate produces an increase in rate in both alcohols, the relative increase being greater in the tertiary alcohol. These increases are presumably due to an increase in the dissociation of the weak acid with increasing ionic strength of the medium, and would be expected to be greater in the medium of lower dielectric constant.

Addition of lithium chloride produces a greater effect in both solvents, but the effect is particularly marked in the tertiary alcohol. This is consistent with catalysis by chloride ion, which would be greater in the system involving the combination of a greater concentration of the protonated ester and a weaker nucleophilic reagent. It was argued earlier that the reaction in the tertiary alcohol fulfills both these requirements in comparison with the reaction in the primary alcohol.

Effect of Added Water on the Acid-Catalyzed Reaction

The difference in the rates of the acid-catalyzed reactions in the primary and tertiary alcohols was attributed to a marked difference in the basicity of the reagents. If this is so, then the addition of a small amount of a very much more basic substance to the reaction mixture should decrease the rate strongly, and should have the most marked effect on the system involving the weakest base. Since water is very much more basic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

than these alcohols, addition of small amounts of water to the reaction mixture will set up the following equilibria, which will be displaced strongly towards the right:

$$R'OH_2^+ + H_2O \rightleftarrows R'OH + H_3O^+,$$
$$R^*ONOH^+ + H_2O \rightleftarrows R^*ONO + H_3O^+.$$

Thus addition of water should result in a decrease in the concentration of the protonated nitrite, which will retard the reaction rate strongly, provided that the concentration of water is sufficiently low to prevent its being able to act significantly as a nucleophilic reagent. In this connection it has been shown (10) that addition of water to dilute alcoholic solutions of strong acids decreases the conductivity, the decrease being linear with water concentration up to about 1% water, above which concentration the conductivity begins to increase.

The effect of addition of small amounts of water on the reaction in 1-propanol, 1-pentanol, and 2-methyl-2-butanol, catalyzed by perchloric acid, is shown in Fig. 1.

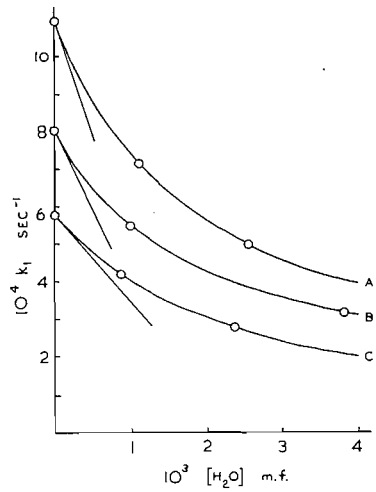

FIG. 1. Effect of added water on acid catalysis. First-order rate constants at 25° in A = 2-methyl-2-butanol, B = 1-propanol, and C = 1-pentanol, at constant (5.66×10^{-6}) acid mole fraction.

Significant decreases in rate were observed even at very low (10^{-3} *M*) concentrations of water. From the smooth curves obtained it is possible to estimate the slope at zero water concentration. The steepest slope occurs with the least basic alcohol, 2-methyl-2-butanol, and it appears that 1-pentanol is more basic than 1-propanol. These results, together with the effects of added salts, provide strong support for the argument that the basicity of the reagents is one of the important factors in these reactions. They also emphasize the importance of carrying out any alcoholysis reaction rate studies in perfectly dry solvents, since random traces of water would completely invalidate any results obtained.

EXPERIMENTAL

(1) Materials

Octan-2-ol was resolved into its (+) and (−) optical isomers, (+)- and (−)-1-methylheptyl nitrite was prepared and purified, and all solvents and reagents were purified and dried as described previously (1).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(2) Optical Rotations of Reaction Mixtures

The results previously reported (1) were used to determine the progress of the various reactions from changes in optical rotation and in the calculation of rate constants.

(3) Kinetic Measurements

All operations were carried out in an atmosphere of dry nitrogen. The (+)- or (−)-1-methylheptyl nitrite and the reagent alcohol were separately brought to thermostat temperature (25°) and then mixed. After allowing 1–2 minutes to regain thermostat temperature the appropriate acid solution was added at zero time. The mixture was then transferred rapidly to the polarimeter tube, using a self-sealing rubber diaphragm cap. Changes in optical rotation (sodium D line) with time were observed, the following being typical examples:

Example 1

$[R^*ONO]_0 = 0.560\ M$ $[HCl] = 5.26\times10^{-5}\ M$ 25° Solvent = 1-propanol

ISOTOPE EFFECTS IN CARBONIUM ION REACTIONS
V. SOLVOLYSIS OF METHYL AND ETHYL *p*-BROMOBENZENESULPHONATES

EDWARD S. LEWIS, JUDITH C. BROWN, AND WILLIAM C. HERNDON

It has been suggested that various secondary hydrogen isotope effects in solvolytic reactions are related to changes in hyperconjugation (1), to alterations in vibrational frequencies on change of hybridization (2), and to changes in extent of non-bonded interactions (3) on activation. Among the data leading to these conclusions were those showing solvent dependence of the effect of β-hydrogens on solvolysis rates (4). The reverse hydrogen isotope effects (5) in the reactions of methyl esters were attributed to increases in bending force constants resulting from steric interactions of the methyl hydrogens with the attacking and leaving groups, and this suggestion was supported by more extensive studies on the reactions of methyl halides in water (6).

Table I shows some rates and isotope effects for the solvolysis of methyl and ethyl

p-bromobenzenesulphonates in two solvents of widely differing nucleophilic character. These results can be shown to be consistent with explanations in terms of either electronic or essentially steric factors. We need only assume that there is virtually no carbonium ion character in any methyl ester solvolytic transition state, but that the transition state for the ethyl compound has a little carbonium ion character in acetic acid but less in the more nucleophilic methanol. This assumption then leads to the prediction that the isotope effect with methyl *p*-bromobenzenesulphonate will be insensitive to solvent, whereas in the ethyl case the value of k_H/k_D should increase as the nucleophilic character of the solvent decreases. The values in the table, although not highly precise, support this idea. The very small effect on β-substitution also is consistent with only minor carbonium ion character, even in acetic acid. This result is the same as that reported recently for water solutions (7).

EXPERIMENTAL

Materials

Ethyl *p*-bromobenzenesulphonate was prepared from the alcohol by conventional procedures (8). Ethanol-2-d_3 was prepared by the lithium aluminum hydride reduction of sodium acetate-d_3 (Isotopes Specialties Corp.). A rather crude deuterium analysis by

combustion indicated 75% D in the β-position, but the n.m.r. spectrum indicated a much larger extent of deuteration.

Ethanol-1-d_2 was prepared by the reduction of cyclohexyl acetate with sodium and acetic acid-*d* in dibutyl ether (9). Infrared and n.m.r. showed nearly complete deuteration, but the exact extent is not established.

Methyl-d_3 *p*-bromobenzenesulphonate was prepared by R. R. Johnson, by the sequence

$$\text{methyl bromide-}d_3\ (10) \xrightarrow[\text{acetone}]{\text{NaI}} \text{methyl iodide-}d_3 \rightarrow \text{methyl-}d_3\ p\text{-bromobenzenesulphonate,}$$

using silver *p*-bromobenzenesulphonate. It was the same material reported in ref. 5.

Rate Measurements

All rates were measured by titration of the acid produced using an electrometric end point by familiar methods. Solvents were Reagent Grade materials and the hydrogen and deuterium compounds were run concurrently to avoid errors attributable to variations in water content of the solvents, thermostat temperatures, and the clock. The rates in Table I are therefore not known absolutely as well as are the isotope effects. All entries are the averages of at least two runs, agreeing in isotope effect within the estimated precision.

ARSENIDES OF THE TRANSITION METALS
IV. A NOTE ON THE PLATINUM METAL ARSENIDES*

R. D. Heyding and L. D. Calvert

In the current literature increasing attention is given to the binary compounds formed by the VA elements (pnigogens†) and the platinum metals. Rundqvist has undertaken a systematic study of the phosphides (1), and Zhuravlev and Zhdanov the antimonides and bismuthides (e.g., 2, 3, 4). To our knowledge there are no reports on the formation and structure of platinum metal arsenides, with the exception of Thomassen's early study of palladium and platinum arsenides (5), Schubert's recent note on the compound Pd_3As

Issued as N.R.C. No. 6197.

†*The terms pnigogen and pnictide have been suggested by Prof. A. E. van Arkel for the elements and compounds of the nitrogen family, N, P, As, Sb, and Bi. The root is the Greek word to choke, and the allusion to the Germanic name for nitrogen, Stickstoff, or choking gas.*

(6), and Kjekshus' redetermination of the unit cell dimensions of $PtAs_2$ (7). We have prepared binary alloys corresponding to M_3As, M_2As, MAs, MAs_2, and MAs_3 with all of the platinum metals, and have examined their structures by X-ray powder diffraction techniques. The results of this preliminary survey are reported here.

All alloys were formed by reaction of the elements in sealed vycor tubes at 700° C in the usual manner. High-purity metal sponge was obtained from Baker Platinum, and semiconductor grade arsenic from ASARCO and COMINCO. The products were ground and annealed for a minimum of 2 days at 700° C and cooled slowly to room temperature. Debye–Scherrer patterns were obtained in 11-cm Norelco cameras using copper K_α radiation.

Two compounds are formed in the ruthenium/arsenic system: RuAs, with the orthorhombic B31 (MnP) structure, and $RuAs_2$, with the orthorhombic C18 (marcasite) structure. With the single annealing scheme followed no other compounds could be detected.

$OsAs_2$, also with the marcasite structure, was the only compound observed in the osmium/arsenic system.

At least four compounds are formed in the rhodium/arsenic system: The compound Rh_2As has the f.c.c. C1 (antifluorite) structure; RhAs, the orthorhombic B31 structure; and $RhAs_3$ the cubic DO_2 (skutterudite) structure. The structure of the fourth compound, $RhAs_2$, is complicated and as yet unknown.

Iridium and arsenic form $IrAs_3$ with the cubic DO_2 structure. In this system there are two other phases, the diarsenide $IrAs_2$ whose structure has not been determined, and apparently one other compound in the composition region between $IrAs_2$ and $IrAs_3$.

There are at least two compounds in the palladium/arsenic system. Pd_3As has the b.c. tetragonal Fe_3P structure, which confirms Schubert's description, and $PdAs_2$ has the cubic C2 (pyrite) lattice, in agreement with Thomassen's data. A complicated series of phases has been observed in the region between Pd_3As and Pd_2As.

Only one compound has been obtained in the platinum/arsenic system, $PtAs_2$ with the C2 structure, again in agreement with Thomassen's data.

Unit cell dimensions for the compounds whose structures have been identified are given in Table I.

TABLE I

Structures and unit cell dimensions of platinum metal arsenides

Structure type	Compound	a (Å)	b (Å)	c (Å)	Ref.
Tetragonal DO_e (Fe_3P) S_4^2, $I\bar{4}$	Pd_3As	$9.95_1\pm0.01$ (9.98_6)		$4.81_7\pm0.01$ (4.83_6)	(6)
Cubic C1 (antifluorite) O_h^5, $Fm3m$	Rh_2As	5.674 ± 0.001			
Rhombic B31 (MnP) V_h^{16}, $Pnma$	RuAs	5.70 ± 0.01	3.25 ± 0.01	6.27 ± 0.01	
	RhAs	5.62 ± 0.01	3.58 ± 0.01	6.00 ± 0.01	
Rhombic C18 (marcasite) V_h^{12}, $Pnnm$	$RuAs_2$	5.41 ± 0.01	6.17 ± 0.01	2.96 ± 0.01	
	$OsAs_2$	5.40 ± 0.01	6.16 ± 0.01	3.00 ± 0.01

It is remarkable that all of the 1:1 compounds crystallize in the distorted NiAs (MnP) structure rather than the NiAs structure itself. In the palladium and platinum systems where one might anticipate the NiAs structure no 1:1 compounds were obtained.

The diphosphides, diarsenides, and diantimonides of ruthenium and osmium have the marcasite structure, while the corresponding compounds of palladium and platinum have the pyrite structure. The rather complicated diffraction patterns of $RhAs_2$ and $IrAs_2$ are most certainly related, and bear a distinct similarity to the pattern of $CoAs_2$ (8). A strong low-order reflection in the $CoAs_2$ pattern is split in the $RhAs_2$ and $IrAs_2$ patterns; this leads us to doubt the orthorhombic cell we proposed earlier for $CoAs_2$. These diarsenides may prove to be isostructural with the rhodium and iridium diphosphides mentioned by Rundqvist.

Since the triphosphides and triantimonides of cobalt, rhodium, and iridium are known to have the cubic $CoAs_3$ structure, it is not surprising that $RhAs_3$ and $IrAs_3$ have the same structure. The list of compounds crystallizing in the skutterudite system now stands at 11, and insofar as binary pnictides are concerned, can be considered to be complete. With the exception of NiP_3 and PdP_3 they are formed only by the cobalt family of transition metals. Bismuthides with this structure have not been observed.

These systems are now being studied in some detail.

We are indebted to Miss M. McClellan and Mr. G. J. G. Despault for their assistance in preparing alloys and obtaining diffraction patterns.

SOLVATION EFFECTS AND RELATIVE RATES
III. SALT EFFECTS IN THE SOLVOLYSIS OF exo-NORBORNYL BROMIDE*

Kirk D. McMichael and Robert A. Clement

As part of our study of solvation effects in organic reactions (1, 2), it seemed desirable to examine the nature of the kinetic salt effect for a simple organic reaction in a typical organic solvent. The system we chose for study was exo-norbornyl bromide in 85% (w/w) aqueous dioxane at 25.06°, and our approach was that used in an earlier paper (1) in which analysis of kinetic and thermodynamic data is in terms of the Bronsted rate law (3).

**This paper is abstracted from a portion of the Ph.D. dissertation of Kirk D. McMichael, University of Chicago, 1960, and was presented before the Organic Division, American Chemical Society, at the 138th National Meeting, New York, September 11–16, 1960.*

Existing information (4, 5) on the solvolyses of exo-norbornyl derivatives indicates the operation of unimolecular reactions possibly complicated, however, by internal return from a reactive ion-pair intermediate. Hence, the appropriate form of the Bronsted rate law for the system under study is equation [1] (1, 6)

$$k'/k = (H'/H)F$$

where k is the observed first-order specific rate constant for the production of acid, H is the Henry's law constant for distribution of exo-norbornyl bromide between the solution and the gas phase, F is a factor of constitution dependent upon the precise course of reaction (1), the primed symbols refer to a salt solution, and the unprimed symbols to the reference solution, the pure solvent. The ratio k'/k is the total kinetic salt effect and the ratio H'/H is that portion of the kinetic salt effect due to the influence of salt on the activity coefficient of the substrate. It is the factor F, alone, which yields information on the effect of salt upon the stability(ies) of the critical complex(es); in general, it will be greater than unity if salt stabilizes the critical complex(es) and less than unity if salt destabilizes the critical complex(es).

In the present study, initial first-order specific rate constants, k, for the production of strong acid were obtained for solutions of exo-norbornyl bromide in 85% (w/w) aqueous dioxane in the absence of salt and in the presence of lithium chloride, bromide, and perchlorate and sodium perchlorate at concentrations of 0.100 M and of magnesium perchlorate at a concentration of 0.0333 M. The results are recorded in Table I. From

TABLE I

First-order specific rate constants for the development of acid, Henry's law constants for exo-norbornyl bromide, and related data for exo-norbornyl bromide in 85% (w/w) aqueous dioxane at 25.06° in the presence of various salts at ionic strengths of 0.100 molar

Salt	$10^5 k$, sec^{-1}	H, $mm(mole/l.)^{-1}$	p_{H_2O}, mm	$p_{dioxane}$, mm	k'/k	H'/H	F
None	3.57	0.72	18.5	29.1	(1.000)	(1.000)	(1.000)
LiCl	5.0	0.68	17.7	29.4	1.40	0.94	1.49
LiBr	5.2	0.69	17.9	29.4	1.46	0.96	1.52
$LiClO_4$	7.4	0.72	18.1	29.2	2.07	1.00	2.07
$NaClO_4$	7.0	0.71	18.1	29.0	1.96	0.99	1.98
$Mg(ClO_4)_2$	6.2	0.70	18.1	29.0	1.74	0.97	1.80

the ratios k'/k it is apparent that the solvolysis of exo-norbornyl bromide in this solvent is subject to very large kinetic salt effects.

Henry's law constants, H, for the distribution of exo-norbornyl bromide between the vapor phase and the same solutions utilized for the kinetic experiments were obtained by the dynamic vapor pressure technique essentially as described earlier (2), and are also recorded in Table I. The Henry's law constant for exo-norbornyl bromide in this solvent is *essentially insensitive to the presence of salts.*

Although irrelevant to the use of equation [1], the vapor pressures of water (p_{H_2O}) and of dioxane ($p_{dioxane}$) above the various solutions were obtained, necessarily, during the measurements of the Henry's law constants and are recorded in Table I. They are also insensitive to the presence of salts.

Consideration of the entries in Table I in terms of equation [1] shows clearly that for the solvolysis of exo-norbornyl bromide in 85% (w/w) aqueous dioxane the kinetic salt effect is due, almost exclusively, to the factor F. In this system, then, it is proper to

regard the kinetic salt effect as a reflection of the nature of the critical complex(es), and the usual qualitative deduction that a positive kinetic salt effect identifies a critical complex that is more ionic than the reactant is completely justified.

It should be noted that the result of this study stands in marked contrast to the results of previous studies (1, 6, 7, 8, 9, 10, 11) where, in every case, the ratio H'/H was found to make a significant contribution to the over-all kinetic medium effect, k'/k. Further investigation is necessary to ascertain whether this result is general for reactions in mixed aqueous–organic media or is due to a peculiarity of the present system.

EXPERIMENTAL

Kinetic and thermodynamic measurements were made at a temperature of 25.06+0.02° as established by an N.B.S.-calibrated thermometer.

Materials

Anhydrous salts were prepared from commercial reagent-grade materials which were dried to constant weight in an oven at the appropriate temperatures and were stored in a desiccator over anhydrous magnesium perchlorate.

Dioxane was purified by the method of Fieser (12) and was stored frozen, in the dark and under nitrogen, in glass-stoppered bottles which were sealed with paraffin.

exo-Norbornyl bromide (exo-2-bromobicyclo[2.2.1]heptane) was prepared by the method of Roberts (13) from purified norbornene, m.p. 43–44°, sealed cap. (lit. (14) m.p. 44–46°). In order to remove reactive impurities, the exo-norbornyl bromide (b.p. 81.0–81.8° (30 mm)) obtained initially was mixed with ethylene glycol and heated on the steam bath for 20 minutes, at the end of which ca. 25% (by acidimetry) of the bromide had been destroyed. The mixture was then poured into water, the organic layer was isolated, washed twice with water, and dried over magnesium sulphate. Distillation afforded pure exo-norbornyl bromide, b.p. 78.7–79.5° (29 mm), n_D^{25} 1.5124 (lit. (13) b.p. 82° (29 mm), n_D^{25} 1.5126). The kinetic homogeneity of the material was demonstrated by solvolysis of a sample in 80% (v/v) aqueous ethanol at the boiling point of acetone. Precise conformation to first-order kinetics was observed with a specific rate constant of 5.3×10^{-5} sec^{-1} (lit. (15) $k = 5.6\times10^{-5}$ sec^{-1} at 55°) and an experimental infinity titer (10 half lives) 98% of the calculated value.

Kinetic and Vapor Pressure Measurements

Kinetic and vapor pressure measurements were made in tandem on portions of the same solution which was prepared by diluting to volume with freshly prepared solvent (85 parts of dioxane and 25 parts of water, by wt.) weighed amounts of exo-norbornyl bromide and anhydrous salt. The final solutions were all 0.100±0.001 M in exo-norbornyl bromide and the salt solutions possessed molar ionic strengths of 0.100±0.001. Solvent was prepared as required for each run, and as a check on the reproducibility of its composition, the kinetic behavior of exo-norbornyl bromide was determined in each preparation; the average deviation of the first-order specific rate constants obtained from 12 such determinations was less than 2%.

The rate of development of strong acid was followed titrimetrically as before (2), the reactions being followed to 1.5–5% completion. First-order specific rate constants were determined by the increment method (1), plotted vs. % reaction and extrapolated back to 0% to yield the initial first-order specific rate constants, k, reported in Table I. Each k in Table I is the average of at least two runs involving different batches of solution and possesses an average deviation of 2–4%. The slopes of the plots of the first-order

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

specific rate constants vs. % reaction were all close to zero, and in most cases the average rate constant was within the limits defined by the average deviation of the extrapolated value.

Vapor pressure measurements were made by the dynamic method essentially as described before (2) except that nitrogen was the entraining gas and that mass flow was induced by a hydrostatic head of mercury which could not exceed 1 mm. The contents of the distillate trap was analyzed for exo-norbornyl bromide by precipitation of silver bromide with acidic aqueous ethanolic silver nitrate and for water by the Karl Fischer technique; dioxane was determined by difference. The values of the Henry's law constant, H, for exo-norbornyl bromide, and of the partial pressures of water, p_{H_2O}, and of dioxane, p_{dioxane}, obtained for each solution are recorded in Table I as the averages of at least two separate determinations which involved different flow rates (6.5–9.5 l./hr) of the entraining gas and different batches of solution. The average deviations noted were 1–2%.

KINETICS OF ETARD'S REACTION

R. A. STAIRS AND J. W. BURNS*

The oxidation of toluene and similar compounds to aldehydes by chromyl chloride has been known (1) since Etard's work (1877–1893, see reference 2) but has never been thoroughly understood. It is characterized by the formation of a brown, insoluble substance, readily hydrolyzed to the aldehyde (and inorganic substances). Etard formulated the precipitate:

Note that the oxidation state of chromium is IV (see ref. 7). This structure has been much criticized, but never discredited.

Some mechanisms have been proposed (3, 4) for other reactions of chromyl chloride, but no work has been done on the kinetics or the mechanism of the Etard reaction proper. The present note records an attempt to fill this gap.

EXPERIMENTAL

Three compounds were chosen that were expected to show significant differences in rate. They were toluene, diphenylmethane (which yields benzophenone), and triphenylmethane (which yields triphenylcarbinol). In addition one run was done with benzyl chloride. Carbon tetrachloride was the solvent.

The reactions were carried out in 10 or 12 Hinton flasks. The flasks were supported on a simple stand in a thermostat. Aliquot portions of chromyl chloride solution were pipetted into one compartment of each flask, the other reactant into the other, and the flasks stoppered. When the stand was shaken, the contents of all the flasks were simultaneously mixed. The reaction was then stopped in each flask in turn by the addition of 50 ml of a 1% aqueous sodium hydroxide solution. The color of chromyl chloride was rapidly discharged.

The contents of the flasks were then analyzed for residual Cr (VI) by iodometric titration. Assuming that the precipitate contains Cr (IV), which would give, on hydrolysis, 2/3 Cr (III) + 1/3 Cr (VI), one can calculate the concentration of CrO_2Cl remaining. It was shown that this method leads correctly to $[CrO_2Cl_2]_\infty = 0$ when the hydrocarbon is in excess.

Chromyl chloride was prepared by Sisler's method (5), and probably contained some sulphate (1). Reagent grade toluene, diphenylmethane, triphenylmethane, and benzyl chloride (Eastman) were used without further purification. Reagent grade carbon tetrachloride was dried over calcium sulphate and once distilled.

The reaction curves found with toluene were not of any simple form. For example, the curve reproduced in Fig. 1, is concave downwards in the early portion. Diphenylmethane yielded apparently normal, second-order curves (Fig. 2). Triphenylmethane

yielded curves that appeared normal at first but levelled out before reaching zero concentration (Fig. 3). A separate experiment showed that this was due to an oxidizing

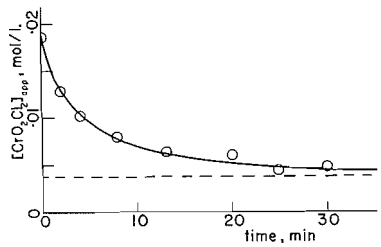

FIG. 3. Typical reaction curve with triphenylmethane (run III-B).

agent formed during the reaction, which was not extracted from the CCl_4 solution by aqueous NaOH, but which reacted slowly with aqueous KI. Such an agent could be a peroxide, resulting from air oxidation.

In view of these two complications, it was decided to base most of the conclusions on the initial rates. The partial order with respect to each reactant was determined for the three reactions by varying the initial concentrations one at a time, and noting the effect on the initial rates. The orders found are shown in Table I. They were considered close enough to unity, and the totals to two, to justify calculation of second-order rate constants. Some typical values of the rate constants are also shown in Table I, the

TABLE I

Hydrocarbon	T, °C	Order			k, l. mole^{-1} sec^{-1}	ΔH^*, kcal	p
		CrO_2Cl_2	HC	Total			
$PhCH_3$	22.1	0.94	0.98	1.92	1.28×10^{4}	14.9	10^{-4}
Ph_2CH_2	21.8	1.04	0.83	1.87	1.67×10^{-2}	12.5	10^{-2}
Ph_3CH	13.7	1.14	0.82	1.96	0.11	~3	—
$PhCH_2Cl$	30.0	—	—	(2)	1.02×10^{-4}	—	—

best known for each reaction, irrespective of temperature. For comparison, the value of k for Ph_3CH at 22° C is 0.16. That for $PhCH_2Cl$ is presumably somewhat less than 1×10^{-4}. All data are summarized in Table II.

DISCUSSION

It is clear from the reaction curves that the attack mechanism for triphenylmethane is different from that for toluene and diphenylmethane and probably involves a free radical, possibly thus:

$$(a) \quad CrO_2Cl_2 + Ph_3CH \rightarrow Ph_3C + HOCrOCl_2,$$

$$(b) \quad Ph_3C + HOCrCl_2 \rightarrow Ph_3C.O.CrCl_2OH \text{ etc.}$$

This suggestion would account for the observed oxygen absorption and would be in agreement with the known stability of the Ph_3C radical.

Ionic attack by the reagent has been postulated already by Cristol and Eilar (4) in the olefin reaction. Involvement of Cl^+ in this case is unlikely as ring attack is not observed, although it does take place in polar solvents (Carstanjen, see Hartford and

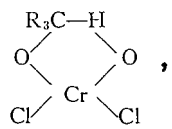
Darrin (1)). If $(CrO_2Cl)^+$ is the attacking species and if it is formed from chromyl chloride so rapidly that this ionic dissociation is not rate-determining, the kinetic data would be consistent with the following two-step process:

$$(CrO_2Cl)^+ + \text{hydrocarbon} \rightarrow \text{complex I} \qquad (k_1),$$

$$\text{complex I} + CrO_2Cl_2 \rightarrow \text{complex II} \qquad (k_2).$$



Complex I contains one chromyl chloride residue for each hydrocarbon molecule; complex II contains two for one. Such a kinetic system (6) of two consecutive, second-order steps, gives rate curves of forms dependent on the relative magnitudes of k_1 and k_2. When $k_2 \gg k_1$, the over-all reaction should approach first order with respect to chromyl chloride. This is the form of the diphenylmethane result (Fig. 2). The reaction of chromyl chloride with toluene (Fig. 1), of variable apparent order would be accommodated by having k_1 and k_2 the same order of magnitude.

The single experiment with benzyl chloride indicates a rate constant comparable with that found for toluene whereas the ionic mechanism above might be expected to predict a faster reaction. A free radical mechanism, such as that postulated for triphenylmethane, would also be expected to be faster.

Attack by the neutral chromyl chloride molecule could also fit these kinetic data. Such an attack may result in proton expulsion thus:

$$CrO_2Cl_2 + R_3CH \rightarrow (R_3C.O.CrOCl_2)^+ + H^+$$

or it may make a "four-center" activated complex of the form

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

which in turn could rearrange to $R_3C.O.CrCl_2OH$, or, if R_3C is a stable radical, decompose by a homolytic route. Wheeler (7) favors a π complex in solution, changing to a precipitate with two moles of chromyl chloride for each mole of hydrocarbon and with the chromium tetravalent. Both hypotheses of neutral chromyl chloride attack, as well as the $(CrO_2Cl)^+$ postulate, are in agreement with the two-step kinetic scheme advanced above.

THE SYNTHESIS OF ACETAMIDO-DEOXY KETOSES BY ACETOBACTER SUBOXYDANS

PART I[1]

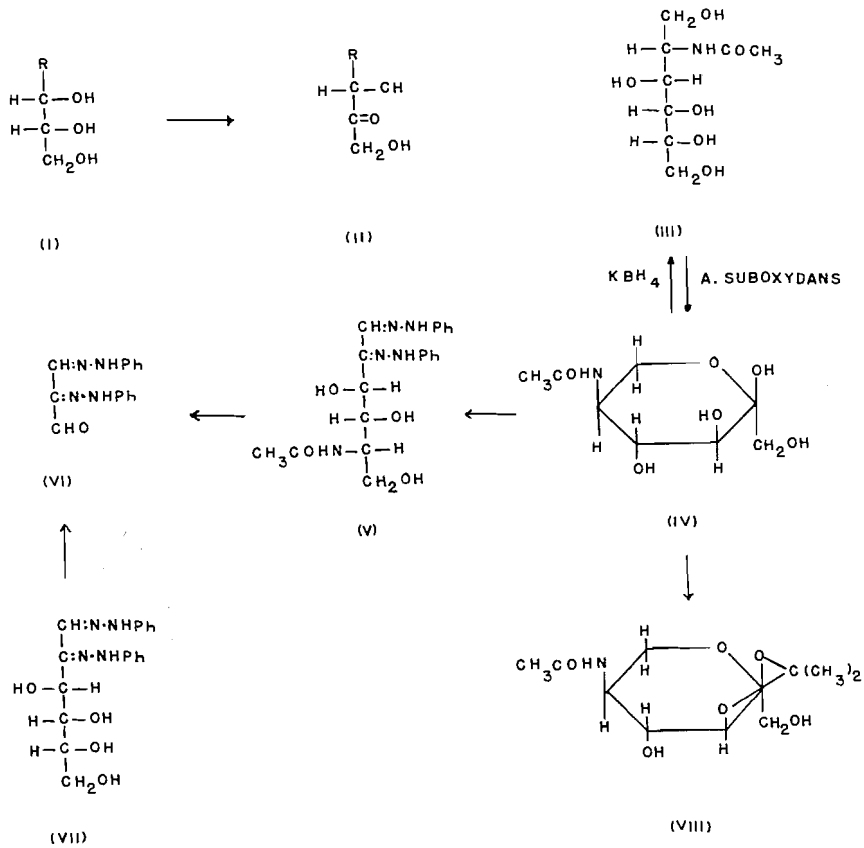
J. K. N. JONES, M. B. PERRY, AND J. C. TURNER

ABSTRACT

The microbiological oxidation of 2-acetamido-2-deoxy-D-glucitol by *Acetobacter suboxydans* yielded a crystalline ketose which is shown to be 5-acetamido-5-deoxy-L-xylohexulose.

INTRODUCTION

The oxidation of unsubstituted polyhydric alcohols by proliferating cells of *Acetobacter suboxydans* has been studied intensively (1, 2, 3, 4, 5, 6), and has given rise to the Bertrand–Hudson rule for oxidations occurring in the pH range 5 to 6.5 (7, 8). Thus, a polyhydric alcohol possessing the D-erythro configuration (I) is oxidized mainly at the secondary alcohol group adjacent to the terminal primary alcohol to give a ketose (II). Bollenback and Underkofler (9), Richtmyer, Stewart, and Hudson (10), Hough, Jones, and Mitchell (11), and Jones and Mitchell (12) investigated the microbiological oxidation of terminal-substituted polyhydric alcohols. The latter authors reported the oxidation of several alcohols, giving chromatographic evidence for the presence of oxidation products, and characterizing completely the ketoses produced from 1-deoxy-1-*S*-ethyl-D-glucitol (11) and 1-deoxy-1-*S*-ethyl-D-arabitol (12).



We now wish to report the isolation and proof of structure of the ketose 5-acetamido-5-deoxy-L-xylohexulose (IV), produced by microbiological oxidation at pH 5 to 6.5 of 2-acetamido-2-deoxy-D-glucitol (III). Oxidation was slow when the culture medium contained only 2-acetamido-2-deoxy-D-glucitol, and was more rapid when glycerol (0.3%) was included. However, oxidation was not complete after 21 days.

The product (IV) was obtained as a white crystalline solid. Analysis indicated an acetamido-deoxy hexulose and the compound gave absorptions in the infrared corresponding to OH, NH, and the amide linkage. On periodate oxidation of (IV) in unbuffered solution it was found to consume 2.85 moles of periodate with the liberation of 0.85 mole formic acid and 0.8 mole formaldehyde per mole of sugar, which indicated that the ketose (IV) possessed a pyranose ring form. The ketose (IV) gave a crystalline phenylosazone (5-acetamido-5-deoxy-L-xylohexose phenylosazone) (V, acyclic form) which possessed an acetamido-deoxy group and gave absorptions in the infrared corresponding to OH, NH, the aromatic ring, and the amide linkage. The phenylosazone (V), when oxidized with periodate by the method of Hough, Powell, and Woods (13), consumed 1 mole of periodate immediately and released no formic acid or formaldehyde. Periodate oxidation gave an immediate precipitate of the 1,2-bisphenylhydrazone of mesoxalaldehyde (VI) (14),

[1]*Manuscript received January 12, 1961.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario.

which was identified by mixed melting point and comparison of its infrared spectrum with that of an authentic sample obtained from the periodate oxidation of D-glucose phenylosazone (VII, acyclic form). These results indicated that the osazone (V) possessed hydroxyl groups at carbons 3 and 4 and that the acetamido-deoxy group was located at carbon 5. Considered with the preceding evidence, these results indicate that the site of biological oxidation in 2-acetamido-2-deoxy-D-glucitol (III) was at carbon 5, in accordance with the well-known enzyme specificity for oxidations at pH 5 to 6.5.

The ketose (IV) was shown to be a derivative of L-sorbose by its reduction with sodium borohydride to 2-acetamido-2-deoxy-D-glucitol, which had melting point, optical rotation, and infrared spectrum identical with those of an authentic specimen. The ketose (IV) gave, with acidified acetone, a non-reducing *O*-isopropylidene derivative (VIII) which was not attacked by periodate under unbuffered conditions, indicating that the mono-*O*-isopropylidene group spanned carbons 2 and 3 as in the case of 2,3-mono-*O*-isopropylidene-L-sorbose.

The microbiological oxidations of 1-acetamido-1-deoxy-*N*-methyl-D-glucamine and 1,2-dideoxy-2-acetamide-D-glucitol have been carried out and structural studies are in progress on the ketoses isolated.

EXPERIMENTAL

Solutions were concentrated under reduced pressure (ca. 15 mm) below 40° C. Melting points are uncorrected and optical rotations were determined in water at 23±3° C unless

400106

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

otherwise stated. Paper chromatography was carried out on Whatman No. 1 paper using the descending method (15). The following solvent systems were used (v/v):

(*a*) ethyl acetate – acetic acid – formic acid – water (18:3:1:4);
(*b*) butan-1-ol – pyridine – water (5:3:2);
(*c*) butan-1-ol – ethanol – water (9:3:3).

Reducing compounds were detected with the *p*-anisidine hydrochloride spray reagent (16) and ketoses with the orcinol/trichloroacetic acid spray reagent (17). Non-reducing compounds were detected with the alkaline silver nitrate spray reagent (18). Rates of movement of the sugars on paper chromatograms are given relative to that of rhamnose (R_{rh}). Infrared spectra were measured as a 6% solution in chloroform or as a 0.8% dispersion in a potassium bromide disk, using a Perkin–Elmer Model 21 spectrophotometer.

Acetobacter suboxydans (A.T.C.C. No. 621) was obtained from the American type culture collection and maintained at 5° C on slopes of agar (3% w:v) containing sorbitol (5% w:v), yeast extract powder (0.5% w:v), potassium dihydrogen phosphate (0.05% w:v), and D-glucose (0.05% w:v). At approximately 2-month intervals a broth containing sorbitol (7% w:v), yeast extract powder (0.5% w:v), and potassium dihydrogen phosphate (0.05% w:v) in tap water was inoculated from the slopes. After 72 hours, when growth of the organism was apparent, fresh slopes were inoculated from the broth and left 2–3 days at room temperature when cream-colored colonies became visible. The slopes were then stored at 5° C.

*5-Acetamido-5-deoxy-*L*-xylohexulose*

A broth consisting of 2-acetamido-2-deoxy-D-glucitol (8.5 g), prepared by sodium borohydride reduction of 2-acetamido-2-deoxy-D-glucose, glycerol (0.5 g), yeast extract powder (0.8 g), and potassium dihydrogen phosphate (0.16 g) in tap water (160 ml) was distributed among eight 250-ml conical flasks giving a surface:volume ratio of ca. 2.5:1. The broths were then autoclaved at 15 p.s.i. for 30 minutes, allowed to cool, and each inoculated with one drop of a 48-hour culture of *Acetobacter suboxydans* grown in glycerol (6%). The broths were stored at room temperature in the dark, without agitation, for 21 days. At intervals small samples (2 ml) were withdrawn using sterile pipettes and the broth examined on paper chromatograms. The gradual disappearance of glycerol and the appearance of dihydroxyacetone (1,3-dihydroxypropanone) and a spot which had R_{rh} 0.59 (solvent (*c*)), 0.73 (solvent (*a*)), 0.65 (solvent (*b*)), and gave a yellow color with orcinol/trichloroacetic acid spray were noted. A quantitative measure of the rate of oxidation was obtained by estimation of the copper-reducing power of the broth using the Somogyi method (19). The results are recorded in Table I. After 21 days the broths

were combined and poured into 2 volumes of ethanol. The cell debris was removed by filtration and the filtrate was evaporated to about 20 ml and then deionized by

For personal use only.

passage through columns of Amberlite IR 120 (H) and Duolite A4 (OH) resins. The eluate was concentrated to a syrup which crystallized. The crystalline material was washed with ethanol and dried, m.p. 154–155° C, mixed m.p. with 2-acetamido-2-deoxy-D-glucitol, 154–155° C. The mother liquors from the crystallization were concentrated to a syrup (2.4 g) which was deposited on cellulose powder and packed as a level band on top of a cellulose column (54 cm × 4.5 cm). The column was irrigated with butan-1-ol half saturated with water, and 5-ml fractions of the eluate were collected using an automatic fraction collector (20). The fractions were examined on paper chromatograms run in solvent (*c*) and sprayed with alkaline silver nitrate spray reagent. A good separation of the sugars was obtained and the appropriate fractions were evaporated to dryness yielding crystalline 5-acetamido-5-deoxy-L-xylohexulose. One recrystallization from ethanol/ether gave crystals m.p. 174–176° C, $[\alpha]_D$ −62. Anal. Calc. for $C_8H_{15}O_6N$: C, 43.4; H, 6.8; N, 6.3. Found: C, 43.3; H, 6.9; N, 6.35. Absorptions in the infrared due to OH and NH (broad fused peak at 3300 cm^{-1}) and the amide linkage (1625 cm^{-1} and 1570 cm^{-1}) were observed. For infrared spectrum see Appendix (A).

Periodate Oxidation of 5-Acetamido-5-deoxy-L-xylohexulose

The ketose (50.62 mg) was dissolved in about 40 ml of water, 0.3 *M* sodium metaperiodate (5.0 ml) was added, and the volume was made up to 50 ml with water. A blank was prepared with 0.3 *M* sodium metaperiodate (5.0 ml), which was made up to 50 ml with water. The solutions were stored in the dark at room temperature and 5-ml aliquots were removed at intervals from each of the two solutions for the determination of periodate uptake (21) and formic acid production (22). Formaldehyde production was measured by the chromotropic acid method (23). The results are recorded in Tables II and III.

TABLE II

Oxidation of 5-acetamido-5-deoxy-L-xylohexulose

Time (hr)	Periodate uptake (moles/mole)	Formic acid production (moles/mole)
0.12	1.15	0.31
1.83	1.79	0.59
8.5	2.68	0.82
24	2.85	0.85

TABLE III

Time (hr)	Formaldehyde production (moles/mole)
0.2	0.36
1	0.53

45	0.80

5-Acetamido-5-deoxy-L-xylohexose Phenylosazone

5-Acetamido-5-deoxy-L-xylohexulose (45 mg) was dissolved in water (2.4 ml), and acetic acid (0.24 ml) and freshly distilled phenylhydrazine (0.24 ml) were added. The mixture was heated in a boiling-water bath for 15 minutes, after which time the phenylosazone had crystallized. The solution was cooled and the phenylosazone was collected by filtration, washed with ice-cold dilute acetic acid, ice water, and cold (−60° C)

For personal use only.

methanol, and then dried. One recrystallization from ethanol gave a yellow powder (small needles) m.p. 202–203° C (decomposes). (An optical rotation could not be measured due to the intense color of the osazone.) Anal. Calc. for $C_{20}H_{25}O_4N_5$: C, 60.15; H, 6.3; N, 17.5. Found: C, 59.7; H, 6.35; N, 17.3.

Absorptions in the infrared due to OH and NH (broad fused peak at 3300 cm^{-1}), the aromatic ring (3030 cm^{-1}, 1605 cm^{-1}, 1500 cm^{-1}, 745 cm^{-1}, 690 cm^{-1}), and the amide linkage (1647 cm^{-1}, 1583 cm^{-1}) were observed. The infrared spectrum is given in the Appendix (B).

*Periodate Oxidation of 5-Acetamido-5-deoxy-*L*-xylohexose Phenylosazone*

The method of Hough, Powell, and Woods (13) was used. The results are shown in Table IV. (Formaldehyde was estimated by the chromotropic acid method (23).)

TABLE IV

Time (hr)	Periodate uptake (moles/mole)	Formic acid (moles/mole)	Formaldehyde (moles/mole)
0.25	1.1	0.00	0.00
3.15	1.14	0.00	0.00
18.65	1.22	0.00	0.00
40.65	1.18	0.00	

On oxidation a bright yellow precipitate of the 1,2-bisphenylhydrazone of mesoxalaldehyde was obtained. The material was collected by filtration, washed with water, recrystallized from aqueous ethanol, and obtained as orange needles, m.p. 188–189.5° C.

1,2-Bisphenylhydrazone of Mesoxalaldehyde (14)

D-Glucose phenylosazone was prepared (300 mg) and dissolved in 50% aqueous ethanol (500 ml). Sodium metaperiodate (20 ml; 0.3 *M*) was added with vigorous stirring and after about 15 seconds a curdy mass of fine orange-yellow needles was precipitated. The mixture was allowed to stand for 15 minutes, then the crystals were collected by filtration, and washed with cold 50% aqueous ethanol and dried. One recrystallization from aqueous ethanol gave orange needles, m.p. 188.5–190.5° C.

The two specimens of the 1,2-bisphenylhydrazone of mesoxalaldehyde had mixed m.p. 188–189.5° C and had identical R_{rh} values on paper chromatograms run in solvents (*a*), (*b*), and (*c*) (R_{rh} 2.03, 1.58, and 2.9 respectively). The infrared spectra were identical and showed absorptions due to NH (3310 cm^{-1}), the aromatic ring (3050 cm^{-1}, 1605 cm^{-1}, 1500 cm^{-1}, 745 cm^{-1}, 687 cm^{-1}), and the unsaturated aldehyde group (1675 cm^{-1}). Further details of the infrared spectrum are given in the Appendix (C).

*Potassium Borohydride Reduction of 5-Acetamido-5-deoxy-*L*-xylohexulose to 2-Acetamido-2-deoxy-*D*-glucitol*

5-Acetamido-5-deoxy-L-xylohexulose (100 mg) was dissolved in water (10 ml) and the solution was cooled in ice. A solution of potassium borohydride (100 mg) in water (10 ml) was added dropwise, with stirring, over a period of 30 minutes and the solution was then stirred at 0° C for 3 hours, after which time it was non-reducing towards Fehling's solution. Amberlite IR-120 (H) resin was added to decompose excess potassium borohydride and the solution was then passed through a column of Amberlite IR-120 (H). The eluate and washings from the column were concentrated to a white amorphous residue which was repeatedly evaporated to dryness with methanol to remove boric acid as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

methyl borate. The residue was dissolved in hot methanol and ether added to incipient turbidity. On cooling, white needles (57 mg) of 2-acetamido-2-deoxy-D-glucitol were deposited. A further crop of crystals (30 mg) was obtained on concentration of the mother liquors. The material had m.p. 154–156° C, mixed m.p. with an authentic specimen of 2-acetamido-2-deoxy-D-glucitol, 153–156° C, and $[\alpha]_D$ −10.8°. The crystalline material gave one spot when run on paper chromatograms in solvents (*a*), (*b*), and (*c*), detected with the alkaline silver nitrate reagent. The spot had R_{rh} values identical with those of the authentic specimen (solvent (*a*) 0.79; solvent (*b*) 0.62; solvent (*c*) 0.50). The infrared spectra of the derived and authentic specimens were identical and showed absorptions due to OH and NH (very broad peak at 3300 cm^{-1}) and the amide linkage (1645 cm^{-1}, 1587 cm^{-1}). Further details are given in the Appendix (D).

2,3-Mono-O-isopropylidene-5-acetamido-5-deoxy-L-xylohexulose

5-Acetamido-5-deoxy-L-xylohexulose (100 mg) was shaken with dry acetone (50 ml) containing concentrated sulphuric acid (2 drops) for 24 hours. At the end of this time the clear solution was neutralized with barium carbonate, filtered, and the filtrate was concentrated to a clear colorless syrup (120 mg) which was examined on paper chromatograms run in solvents (*a*), (*b*), and (*c*). The *p*-anisidine hydrochloride spray reagent showed only a very faint spot due to 5-acetamido-5-deoxy-L-xylohexulose. However, the orcinol/trichloroacetic acid spray reagent revealed also a strong spot due to the *O*-isopropylidene compound with the following R_{rh} values (Table V). An ethanol solution of

TABLE V

Solvent	R_{rh} (f = faint, s = strong)	
	p-Anisidine hydrochloride	Orcinol/trichloroacetic acid
(*a*)	0.73 (f)	0.73 (f)+1.86 (s)
(*b*)	0.65 (f)	0.65 (f)+1.73 (s)
(*c*)	0.59 (f)	0.59 (f)+1.95 (s)

the syrup was applied to Whatmann 3 mm paper and developed in solvent (*a*) overnight. The section containing the *O*-isopropylidene ketose was cut out and eluted with 50% aqueous ethanol. The eluate was passed through Amberlite IR-120 (H) and Duolite A-4 (OH) resins and then concentrated to a clear colorless syrup (108 mg) which was chromatographically pure. The syrup had $[\alpha]_D$ −51° (*c*, 2.16 in ethanol), and was non-reducing towards Fehling's solution. The infrared spectrum showed absorptions due to OH and NH (broad peak at 3360 cm^{-1}), the amide linkage (1665 cm^{-1}, 1560 cm^{-1}), and the C-methyl group (1460 cm^{-1}, 1380 cm^{-1}). A considerable reduction of the OH peak as compared to that of 5-acetamido-5-deoxy-L-xylohexulose was observed. Further details are given in the Appendix (E).

Periodate Oxidation of 2,3-Mono-O-isopropylidene-5-acetamido-5-deoxy-L-xylohexulose

The *O*-isopropylidene ketose (75 mg) was dissolved in 50% aqueous ethanol (ca. 40 ml). A 0.3 *M* quantity of sodium metaperiodate (2 ml) was added and the volume made up to 50 ml with 50% aqueous ethanol. A blank solution was prepared containing 0.3 *M* sodium metaperiodate (2 ml), which was made up to 50 ml with 50% aqueous ethanol. The solutions were stored in the dark at room temperature and 5-ml aliquots removed at intervals for estimation of periodate uptake (22). No periodate was taken up by the *O*-isopropylidene ketose.

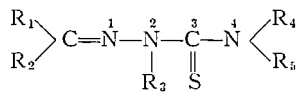
THE PREPARATION OF SOME THIOSEMICARBAZONES AND THEIR COPPER COMPLEXES

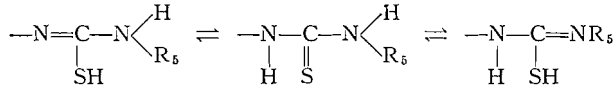
PART II[1]



B. A. GINGRAS, R. L. SOMORJAI,[2] AND C. H. BAYLEY

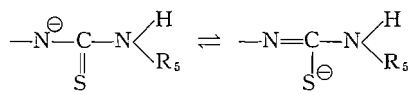
ABSTRACT

Reactions of N- and S-substituted thiosemicarbazones with Cu(I) have been examined. No complexes are formed when the S atom is substituted and(or) when the N^2 hydrogen atom is replaced by Me. 4,4-Dimethyl derivatives not only give the usual 1:1 complexes, but also 2:1 complexes (2 thiosemicarbazones to 1 copper) in which copper has been oxidized to Cu(II). Reactions of thiosemicarbazones with Cu(II) give 1:1, 2:1, and probably a mixture which corresponds to 2:3 complexes. A discussion on the possible structures for the 1:1 complexes is given and they are best represented as polymers, the metal being bonded to the sulphur and to a nitrogen atom of the thiosemicarbazide portion of the molecule. Infrared spectra of these compounds have been examined, particularly in the 1100 cm^{-1} region where a strong to medium band disappears in going from thiosemicarbazones to copper complexes. It is suggested that this band is due to the C=S vibration.

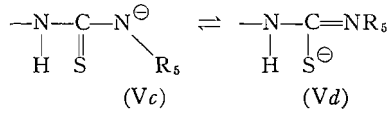


Various metallic complexes of organic sulphur compounds are described in the literature (1–10). Many of these were prepared for physiological studies and their structures are not discussed fully (7, 10). In earlier publications we have reported the preparation of Cu(I) complexes of thiosemicarbazones* (1 tsc:1 Cu) (11) and their fungicidal action (12). This paper presents a discussion of the possible structures for these complexes based mainly on the reactions of several *N*-methyl thiosemicarbazones with copper ions in ammoniacal and neutral media.

Thiosemicarbazones have the structure (I) (R = alkyl, aryl, or H).

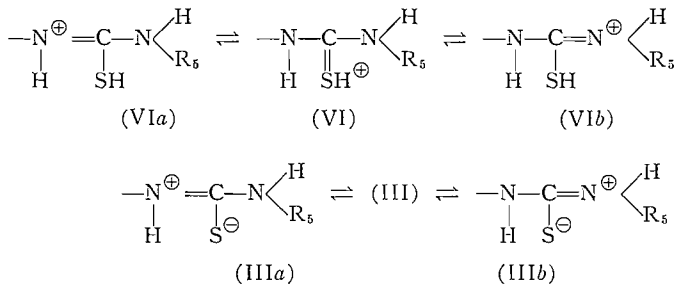


(I)



When R_3 and R_4 and(or) R_5 are hydrogen atoms, tautomeric thiols (II) and (IV) and thione (III) forms are possible, these being interconvertible through their common anions (V) and cations (VI). The dipolar structures (III*a*) and (III*b*) may contribute to (III).

(II) (III) (IV)



(V*a*) (V*b*)

(V*c*) (V*d*)

[1]*Manuscript received November 28, 1960.*

[2]*Present address: Chemistry Department, Princeton University, Princeton, New Jersey, U.S.A.*
* *tscs.*

(VI*a*) (VI) (VI*b*)

(III*a*) (III*b*)

Infrared absorption spectra of tscs in the solid state indicate the absence of tautomerism, the thione form (III) being the exclusive structure (13). On the other hand most tscs dissolve in alkali (13, 14) and form metallic complexes in alkaline solution (5, 8, 11) thus suggesting the important role of one of the anions (V) in solution. The observation that N^2-methyl tscs (I, R_3 = Me) do not dissolve in alkali (13) and that hydrazides of type (R—CO—NH—NRR) do not form copper complexes if the H atom is replaced by Me (15), suggest that the N^2 hydrogen atom is essential for the complex formation in these compounds. Apparently the resonance structure (III*a*) and consequently anion (V*b*) are the main contributing forms in alkaline solutions. This is plausible because of the greater stability conferred on anion (V*b*) through the formation of a conjugated unit, C=N—N=C, where the delocalization of the π electrons lowers the free energy of the system. Anion (V*a*) is probably less important as a contributing form partly because of the lack of the above-stated conjugation and partly because the sulphur atom has more available orbitals to accommodate extra electrons than the nitrogen atom (16). These observations agree with a number of published data. Wilson and Burns (14) found that the sodium salt of acetone tsc had retained the terminal NH_2 group. Jensen *et al.* prepared several substituted thiosemicarbazides (4, 5, 6) and found that neither in alkaline nor in acidic media did S-substituted thiosemicarbazides form complexes (6), indicating the necessity of a metal–sulphur bonding. Jensen also concluded that co-ordination in M(II)-thiosemicarbazide and M(II)-semicarbazide complexes is through the N^1 atom (4, 5, 6, 17). He arrived at this conclusion from the observation that 1-aryl thiosemicarbazide, ($ArN^1H—N^2H—C^3S—N^4H_2$), did not form Ni(II) complexes, and 1-acyl ($RCON^1H—N^2H—C^3S—N^4H_2$), 1,1-disubstituted thiosemicarbazides ($R_1R_2N^1—N^2H—C^3S—N^4H_2$) as well as tscs (I) gave no Cu(II) complexes in acidic media (6).

The fact that thiobenzhydrazide (Ph—CS—$NHNH_2$) forms a Ni(II) complex similar to the corresponding thiosemicarbazide complex, supports the theory of co-ordination through the N^1 atom (1).

In Part I (11) it has been found that Cu(I) ions in ammoniacal solution formed 1:1 complexes with tscs, one hydrogen atom being presumably replaced by Cu. We have now prepared a series of *N*-methyl and S-substituted tscs (Table I) and examined their reaction with Cu(I) ions in ammoniacal solution (Table II) and with Cu(II) ions in alcoholic solution (Table III).

With Cu(I) ions, complexes were formed in all instances, except with the N^2-methyl (I, R_3 = Me) and *S*-methyl tscs. These various reactions are summarized in Table II. These observations support the conclusions concerning the importance of anion (V*b*) (N^2-hydrogen being replaced) and the S–metal linkage.

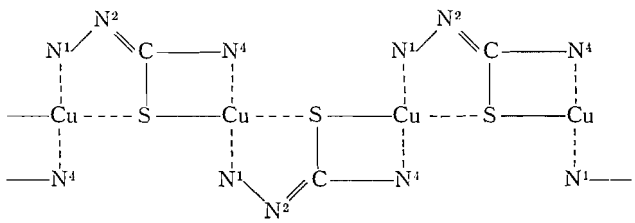
Magnetic moment measurements on two typical complexes indicated zero magnetic moment, and thus the presence of monovalent copper.

Crystal field theory shows that d^{10} ions may co-ordinate octahedrally (sp^3d^2), tetrahedrally (sp^3), or linearly (sp), depending on the nature of the surrounding field (18). Although linear co-ordination occurs in cuprite (19), cuprous chromite (20), and cuprous ferrite (21), only one example of this type of co-ordination with an organic ligand is well-known (e.g. diazoaminobenzene-Cu(I) (22).

Since most Cu(I) ions co-ordinate tetrahedrally (23) and in many cases, the resulting complexes were found to be polymers (24), it is possible that in the case of tsc copper complexes, the metal is bonded to a sulphur and an N^1 atom and co-ordinated further tetrahedrally to a sulphur and N atom of another molecule in a polymeric chain.



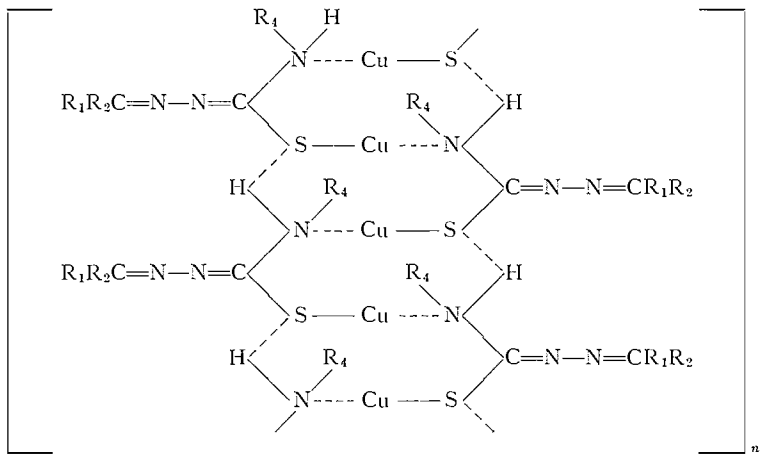
Experimental results obtained with 4,4-dimethyl derivatives of tscs indicate that N^4 nitrogen is probably involved in this co-ordination.

It was found that 4,4-dimethyl tscs form mostly 2:1 complexes when they react in the usual manner with Cu(I). Magnetic moment measurements on (benzaldehyde-4,4-dimethyl tsc)$_2$-copper showed one unpaired electron indicating oxidation of the Cu(I) ion to the Cu(II) state. This change was brought about by an extra Me group on the N^4 atom, since 4-methyl tscs behave normally giving 1:1 complexes only. These observations are difficult to explain unless the Cu ion is actually co-ordinated to the N^4 atom. Oxidation of the metal could have happened by disproportionation (25) as follows:

$$2\text{Cu(I)} \rightarrow \text{Cu(II)} + \text{Cu(0)}.$$

Material balance of starting materials and products in the case of benzaldehyde-4,4-dimethyl tsc supports this view.

Molecular models of various polymeric structures were examined and a few were discarded because of steric factors and(or) too much strain particularly in small rings. Two possible structures are (VII) and (VIII) below.



(VII)

Structure (VII) comprises a series of 5- and 4-membered rings in which Cu(I) is co-ordinated tetrahedrally to a sulphur and N^1 atoms of a tsc and a sulphur and N^4 atoms of another molecule. Molecular model of this structure shows a certain amount of strain in the 4-membered ring. Although such a structure accounts for many of the experimental facts, it does not explain easily the anomalous behavior of 4,4-dimethyl tscs.

Structure (VIII) in which copper is linearly co-ordinated to N^4 and sulphur atoms is even more likely and is completely strainless. Molecular models show that the copper atoms lie in a straight line very close to each other suggesting that there may be bonds between them. This would contribute to the insolubility of the complexes as pointed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

out by Frasson *et al.** Structure (VIII) accounts for all the facts including the reaction of 4,4-dimethyl tscs and is to be favored.

(R_4 = H or Me)

(VIII)

Several attempts to determine the molecular weight of these complexes failed, but a polymeric structure would conveniently explain their stability and their high insolubility.

Table I lists the various derivatives of tscs prepared and examined in the present work. They were made by the usual method (11) using an aldehyde and the appropriate substituted thiosemicarbazide. The reactions proceeded as expected in all cases except with 2-methyl-*S*-methyl thiosemicarbazide which did not give the corresponding 2,*S*-dimethyl tscs. Instead, benzaldehyde and *p*-chlorobenzaldehyde when treated with that reagent gave the corresponding 2-methyl semicarbazones, the S—Me group being obviously replaced by an oxygen atom. The reaction proceeded normally, however, in the case of *S*-methyl-4-methyl thiosemicarbazide.

Table II is a summary of the reactions of these substituted tscs with Cu(I) ions in alkaline solution, and the products obtained. In all cases where the N^2-hydrogen atom has been replaced by Me, there were no complexes formed. Only about 50% of the original tsc could be recovered as there was some decomposition. Likewise, when the sulphur atom was substituted with a methyl or benzyl group, there were no complexes formed. The fact that, with all other derivatives complexes of some kind were obtained, emphasizes the importance of the N^2-hydrogen atom, and the S—Cu bond and thus the significance of anion (V*b*).

We have also examined the reaction of various tscs with Cu(II) acetate in alcoholic solution (see Table III). The results were quite surprising since, instead of obtaining the expected 2:1 complexes, aromatic tscs gave 1:1 complexes identical with those obtained using Cu(I) in ammoniacal solution. Benzaldehyde 4,4-dimethyl tsc gave a mixture of 2:1 and 1:1 complexes identical with those obtained using Cu(I) as the reagent. Aliphatic tscs gave an insoluble compound which analyzed fairly close to a 2 tsc

to 3 Cu, and in some cases, in addition, the usual 1:1 complexes. The yields were, in every case, much lower than with Cu(I). Kuhn and Zilliken (8) had also found that aromatic tscs gave the same complexes both with Cu(I) and Cu(II), the yield being lower with the latter. It is likely that tscs reduce part of the Cu(II) to Cu(I) which then reacts with the unoxidized tscs. This type of reduction is quite common with organic sulphur compounds containing an oxidizable sulphur (2, 6, 8, 26, 27).

$$2R—S^- + 2Cu^{++} \rightarrow R—S—S—R + 2Cu^+$$

In some cases the disulphides and their copper complexes were obtained (2, 26). We did not isolate the disulphide–Cu complexes but we have identified from the soluble part of the reaction mixture some 2:1 complexes.

Infrared spectra of all these compounds have been taken in Nujol (Part I) and(or) KBr (Tables I, II, and IV). Table IV lists the typical bands in three regions, obtained from KBr disks, of a few tscs and their corresponding Cu(I) complexes. Contrary to the results reported in Part I from infrared spectra taken in Nujol mulls, it can be seen that both classes of compounds show three bands in the N—H stretching region. It appears that the very strong absorption of Nujol overlaps with the band at around 3100 cm^{-1} in certain cases. The two bands at about 3400 and 3200 cm^{-1} are shifted to higher frequencies by about 70 cm^{-1} in the complexes and the third band at 3150 cm^{-1} remains constant or is shifted down by 50 to 70 cm^{-1}. It is known that if a metal co-ordinate bond is formed with a nitrogen atom already bonded to H atoms, a shift of the N—H stretching bands to lower frequencies occurs, probably due to the increase in the polarity of the N—H bond (32). Although the shift to higher frequencies is difficult to explain, there is no doubt that the electronic environment of the NH_2 group has changed.

By examination of the spectra of various methyl-substituted tscs (Table I), it can be seen that differentiation between those three bands is difficult. The N^2-methyl compounds, although they have one less N—H group than free tscs, show the same number of bands in this region. The 2,4-dimethyl derivatives show only one band at around 3370–3340 cm^{-1} while the 4,4-dimethyl derivative of benzaldehyde tsc, with only one N—H group in the molecule shows two bands at 3260 and 3180 cm^{-1}. 4-Methyl compounds have two bands in this region.

The complexes in general show one additional band in the 1600 cm^{-1} region which can be attributed to an extra —C=N— as would be expected from any of the structures discussed above.

Tables I, II, and IV, also contain the region 1130–1010 cm^{-1} where a tentative assignment for the C=S vibration can be made. This vibration has been studied widely with many types of thio compounds and its assignment varies from about 1500 to 800 cm^{-1}. Davies and Jones (33), from a study of thioformamide, point out the difficulty of assigning a characteristic frequency for the C=S. The range 1400–1300 cm^{-1} has been suggested (34), and in thioacetamide the C=S was assigned at 1302 cm^{-1} (35). Lieber *et al.* (36) suggest the region 1395–1346 cm^{-1} in 4-substituted thiosemicarbazides. The band at 1100 cm^{-1} was assigned to C=S in thiopeptides (37), while the region 1200–1000 cm^{-1} was suggested for this vibration in thiocarbonyl compounds (38), and the region 1000 cm^{-1} in secondary thioamides (39). More recently, Bellamy (40) suggested the band at 1080 cm^{-1} in cyclic trithiocarbonates, 1200 cm^{-1} in dithioesters, and near 1000 cm^{-1} in some thioamides.

By comparing the spectra of tscs and their copper complexes (Tables I, II, and IV), it can be seen that a band disappears in the 1130–1080 cm^{-1} region. It is reasonable to

*From KBr pellets.

assume that this band is due to the C=S of the free tsc. Yamaguchi *et al.* (9) found that a strong band at 1083 cm^{-1} in thiourea is extremely weakened or disappears upon complex formation with a metal and they attributed this band to C=S.

In the region where the "thioureide" band has been assigned by Randall (41) between 1613 and 1471 cm^{-1}, Ettlinger (42) at 1508 cm^{-1} and at 1495 cm^{-1} (43), there are no noticeable differences between spectra of tscs and their copper complexes.

EXPERIMENTAL

Thiosemicarbazones were generally prepared by the method of Sah and Daniels (44). Preparations of the various substituted thiosemicarbazides were carried out according to the procedures referred to in Table I, except for *S*-methyl-4-methyl thiosemicarbazide, which is described below. Reactions of substituted tscs with Cu(I) (Table II) were carried out as described in Part I (11). Melting points (corrected), yields, solvents used in purification, bands in three regions of the infrared spectrum, and analyses are shown in the tables.

Preparation of S-Methyl-4-methyl Thiosemicarbazide.HI

A mixture of 4-methyl thiosemicarbazide (32) (14.3 g, 0.1 mole) and methyl iodide (20.5 g, 0.15 mole) dissolved in isopropyl alcohol (115 ml) and acetone (200 ml) was refluxed for 1.5 hours. The solution became yellow and after cooling, the white solid that precipitated out was collected by filtration and recrystallized from absolute alcohol. It had m.p. 164° C; yield: 15 g, 59%. The compound is sensitive to moisture and was kept in dry alcohol and recovered only before use in the next step.

Preparation of Benzaldehyde-S,4-dimethyl tsc (No. 4, Table I)

S,4-Dimethyl thiosemicarbazide.HI (4.94 g, 0.02 mole, corresponding to 2.38 g, 0.02 mole free base) was dissolved in water (60 ml) and neutralized with NaOH *N*/1 (20 ml). The solution turned dark yellow probably due to some liberated iodine. Two drops of acetic acid were added followed by 50 ml of an alcoholic solution of benzaldehyde (2.12 g, 0.02 mole). The clear solution obtained was heated for 15 minutes on the steam bath and cooled. The dark red oil that separated was taken up in ether and dried over drierite. After evaporation of the solvent, the residue was dissolved in *n*-hexane and after cooling, benzaldehyde-*S*,4-dimethyl tsc crystallized out.

Reaction between Benzaldehyde-4,4-dimethyl tsc and CuCl

To a boiling solution of benzaldehyde-4,4-dimethyl tsc (2.4 g, 0.11 mole) in MeOH (50 ml) was added, dropwise, a solution of CuCl (1.16 g, 0.11 mole) in ammonia (25 ml, sp. gr. 0.9). A brown precipitate was formed and heating and stirring were continued for 15 minutes after the addition had been completed. The mixture was allowed to cool and the precipitate was collected by filtration and washed with HCl 3% and water. Part of this solid was soluble in acetone from which it was recrystallized; this was the 2:1 complex (No. 5*b*, Table II). The insoluble fraction was washed successively with ammonia, water, HCl 3%, water, acetone, ether, and alcohol, after which it gave fairly good analysis for the 1:1 complex (No. 5*a*, Table II).

Reaction between p-Chlorobenzaldehyde-4,4-dimethyl tsc and CuCl

This was carried out as above except that the precipitate obtained was not too soluble in acetone. It was dissolved in toluene from which it was recovered by evaporation. This corresponds to the 2:1 complex (No. 7, Table II). No 1:1 complex was isolated in this case from the insoluble residue.

For personal use only.

Attempt to React Benzaldehyde-2-methyl tsc with CuCl

The following is typical of attempts made to react 2-methyl-substituted tscs with CuCl.

To a refluxing solution of benzaldehyde-2-methyl tsc (5.8 g, 0.03 mole) in MeOH (200 ml) was added, dropwise, a solution of CuCl (4 g, 0.04 mole) in ammonia (50 ml). A small amount of a precipitate was observed and this when collected was found to be inorganic and had a high copper content (50%). The remaining solution was neutralized with HCl, diluted with water, and cooled. The starting material (3 g) crystallized out; m.p. and mixed m.p. 175° C.

Reaction between p-Chlorobenzaldehyde tsc and Copper Acetate

To a boiling solution of *p*-chlorobenzaldehyde tsc (5.3 g, 0.025 mole) in ethanol (200 ml) was added slowly a solution of cupric acetate (5 g, 0.025 mole) in the same solvent (150 ml). A light yellow compound precipitated out and, after cooling, was collected by filtration and washed on the filter with hot acetone. This precipitate was found to be the 1:1 complex, identical with the one described in Part I; m.p., mixed m.p., and infrared spectra. No other products were isolated from the mother liquor.

Other reactions with cupric acetate were carried out in a similar manner and the various products obtained are described in Table III.

ACKNOWLEDGMENTS

We are indebted to Mr. E. C. Goodhue of the Analytical Section for the copper analyses and infrared spectra, and also to Dr. M. L. Hair of the Chemical Engineering Section for the magnetic moment measurements.

THE INTERACTION OF BORON TRIFLUORIDE WITH HYDRAZINE[1]

W. G. PATERSON[2] AND M. ONYSZCHUK

ABSTRACT

Boron trifluoride and anhydrous hydrazine react rapidly at 25° *in vacuo* yielding a 1:1 complex compound, $BF_3 \cdot N_2H_4$ (m.p. 87°), while at higher temperatures, or with diethyl ether as solvent, they form complex mixtures containing 52.2 to 63.5 mole percent BF_3; but in tetrahydrofuran solution the 2:1 adduct, $2BF_3 \cdot N_2H_4$ (m.p. 260°) is formed. The X-ray powder diffraction pattern of $BF_3 \cdot N_2H_4$ consists of 28 lines from which a unit cell with triclinic symmetry was calculated. The thermal decomposition of $BF_3 \cdot N_2H_4$ is complex, yielding in part N_2, NH_3, NH_4BF_4, and BN. Hydrolysis of $BF_3 \cdot N_2H_4$ yields a mixture of hydroxyfluoroborate ions. At −80°, $BF_3 \cdot N_2H_4$ absorbs NH_3 to form a diammoniate which liberates NH_3 slowly at higher temperatures. Partial displacement of BF_3 from $BF_3 \cdot N_2H_4$ by HCl and partial absorption of HCl by $BF_3 \cdot N_2H_4$ occur simultaneously at 110°.

Infrared spectra of $BF_3 \cdot N_2H_4$ and $2BF_3 \cdot N_2H_4$ have been measured in the range of 4000 to 650 cm^{-1} and frequency assignments have been made.

Boron trifluoride forms co-ordination complexes with a variety of nitrogen compounds such as ammonia, amines, imines, amides, nitriles, and nitrogen-containing heterocyclics (1, 2, 3). The lone electron pair on the nitrogen atom in these compounds readily forms a co-ordinate bond with the electron-deficient boron trifluoride molecule. Since hydrazine has two available electron pairs, one on each nitrogen atom, it is interesting to determine whether this molecule will co-ordinate with one or two molecules of boron trifluoride. In two independent studies (4, 5) it was found that diborane reacted with hydrazine to form the addition compound $H_3B \cdot NH_2NH_2 \cdot BH_3$, indicating that both nitrogen atoms in hydrazine are capable of co-ordinating with borane groups. This paper is the first of a series dealing with the reactions of electron-deficient molecules with hydrazine. Since boron trifluoride is one of the most active electron acceptors, its reaction with hydrazine was investigated first.

RESULTS AND DISCUSSION

It was found that the reaction of boron trifluoride with anhydrous hydrazine at −80°, in the absence of a solvent, was extremely slow. At room temperature, however, a solid white 1:1 complex compound, boron trifluoride-hydrazine, $BF_3 \cdot N_2H_4$ (m.p. 87°), was formed within a few minutes. With reaction times of 2 and 3 hours, complexes having ratios of boron trifluoride to hydrazine of 1.09 and 1.16, respectively, were obtained. The latter complex, when treated with additional boron trifluoride in diethyl ether as solvent for 11 hours, gave a substance with an empirical composition of $(BF_3)_{1.72}N_2H_4$. The reaction of boron trifluoride with hydrazine in diethyl ether produced complexes of different stoichiometry. Depending upon such experimental conditions as efficiency of mixing, reaction time, and temperature, substances were obtained with boron trifluoride to hydrazine ratios in the range 1.42 to 1.88, but the ratio was never 2.* Similar results were obtained for the reaction of boron trifluoride with hydrazine at 140 and 200°. With tetrahydrofuran as solvent, however, the product was 2-boron trifluoride-hydrazine, $2BF_3 \cdot N_2H_4$ (m.p. 260°). It is noteworthy that tetrahydrofuran also promoted the for-

mation of 2-boron trifluoride-ethylenediammine (6), whereas the 1:1 adduct resulted in diethyl ether solution.

The formation of 1:1 and 2:1 addition compounds between boron trifluoride and hydrazine indicates that both nitrogen atoms in hydrazine are strong electron-pair donors. This is expected on the basis of the configuration of the hydrazine molecule (7), which shows that the electron pairs on each of the two nitrogen atoms are probably located in tetrahedral (sp^3) hybrid orbitals and are readily accessible for the formation of one or two co-ordinate bonds with suitable acceptor molecules. While the 1:1 adduct formed easily by direct interaction of boron trifluoride with hydrazine, the 2:1 adduct could not be obtained in the same way. Apparently the formation of one co-ordinate link reduces the availability of the lone electron pair on the other nitrogen atom for bonding with a second boron trifluoride molecule. The decreased reactivity of the second electron pair in hydrazine seems to be a general rule (8). In tetrahydrofuran solution both electron pairs appear to be readily available so that the 2:1 complex was the only product.

The hydrazine – boron trifluoride phase diagram in the range 46.5 to 66.7 mole% boron trifluoride (Fig. 1) clearly shows a maximum at 50 mole% boron trifluoride corresponding

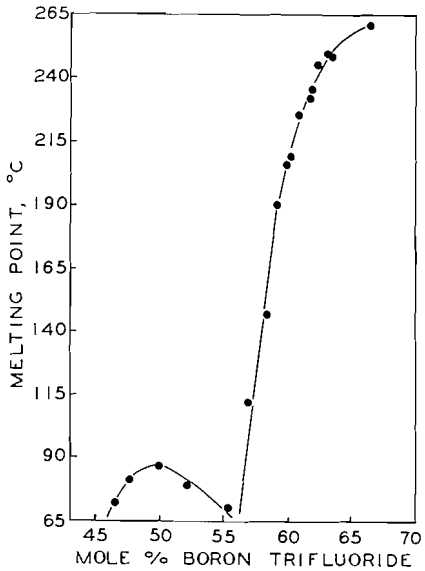

FIG. 1. A portion of the phase diagram of the system hydrazine – boron trifluoride.

to the 1:1 adduct. A second maximum at 66.7 mole% boron trifluoride, corresponding to the 2:1 adduct, is inferred since at the extreme right of the complete phase diagram, i.e. at 100 mole% boron trifluoride, the curve must drop to −127°, the melting point of pure boron trifluoride. The absence of a peritectic point in the region investigated rules out the possibility of incongruently melting compounds of intermediate stoichiometry, such as, $3BF_3 \cdot 2N_2H_4$. The phase diagram was investigated only in the range 46.5 to 66.7 mole% boron trifluoride because it was not possible to obtain, by direct interaction or by reaction in a solvent, solid complex compounds with boron trifluoride contents outside this range.

The compound boron trifluoride-hydrazine was insoluble in diethyl ether and slightly

soluble in acetone. The compound 2-boron trifluoride-hydrazine was soluble in tetrahydrofuran. Both new compounds were hygroscopic and dissolved readily in water yielding acidic solutions, which retained the reducing properties of hydrazine in that these aqueous solutions decolorized instantly an aqueous solution of potassium permanganate.

Infrared spectra of the 1:1 and 2:1 complex compounds (Fig. 2), obtained by the

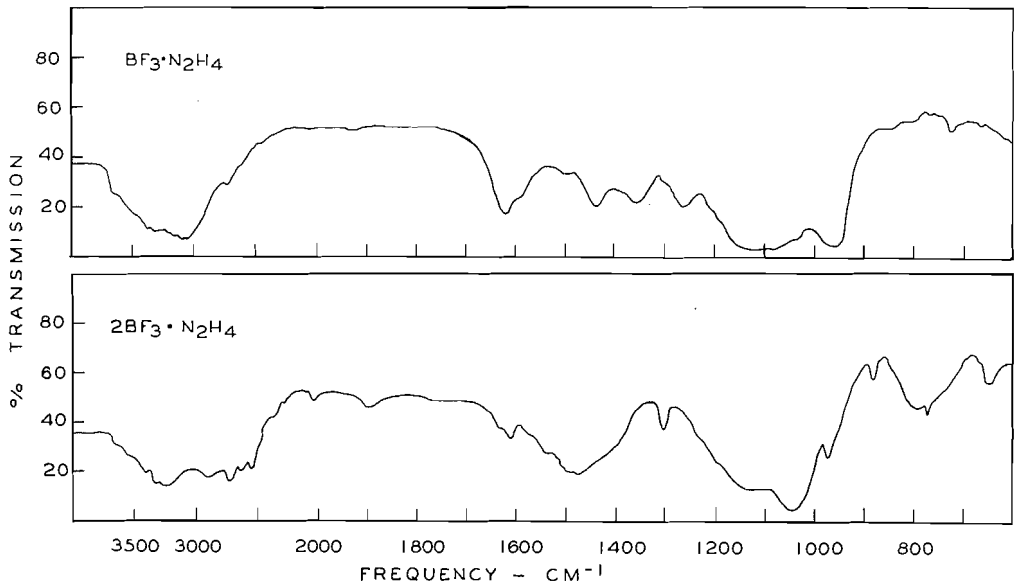

FIG. 2. Infrared spectra of $BF_3 \cdot N_2H_4$ and $2BF_3 \cdot N_2H_4$ in KBr disks.

potassium bromide pellet technique, consist of broad and unresolved bands which nevertheless indicate vibration frequencies (Table I) characteristic of the constituent BF_3 and N_2H_4 molecules together with a B—N stretching frequency in the vicinity of 1035 cm^{-1}. The assignments in Table I have been made by analogy with the infrared spectra

TABLE I

*A 57.30-mm camera was used.

measurements the following dimensions of a crystallographic unit cell with triclinic symmetry were calculated by applying Ito's reciprocal lattice method (14): $a = 6.93$ Å, $b = 5.50$ Å, $c = 6.78$ Å; $\alpha = 111.5°$, $\beta = 64.0°$, $\gamma = 88.3°$. While these dimensions represent a solution of the observed X-ray powder pattern, they must be confirmed by X-ray pattern measurements on a single crystal of $BF_3 \cdot N_2H_4$ before they can be accepted as the dimensions of the true unit cell. Other boron trifluoride adducts such as $BF_3 \cdot NH_3$, $BF_3 \cdot CH_3NH_2$, and $BF_3 \cdot (CH_3)_3N$ have orthorhombic, monoclinic, and hexagonal symmetry respectively (15).

Boron trifluoride-hydrazine was stable indefinitely *in vacuo* at room temperature. Decomposition occurred slowly at 190° and was almost complete at about 300° after 5 hours, yielding mainly nitrogen, ammonia, ammonium fluoroborate, and boron nitride. Since the boron–nitrogen bond is probably the weakest one in the addition compound, it seems reasonable to assume that the first step in the pyrolysis was the dissociation reaction,

$$N_2H_4 \cdot BF_3 \rightarrow BF_3 + N_2H_4.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Boron trifluoride is stable at 300° (1) while hydrazine decomposes slowly at this temperature into ammonia and nitrogen (16, 17)

$$3N_2H_4 \rightarrow 4NH_3 + N_2.$$

Subsequent interaction of ammonia with boron trifluoride to give a 1:1 adduct,

$$NH_3 + BF_3 \rightarrow NH_3 \cdot BF_3$$

could be followed by its thermal decomposition into ammonium fluoroborate and boron nitride (18),

$$4(NH_3 \cdot BF_3) \rightarrow 3NH_4BF_4 + BN.$$

The over-all reaction, taken as the sum of the above reactions,

$$12(BF_3 \cdot N_2H_4) \rightarrow 4N_2 + 4NH_3 + 9NH_4BF_4 + 3BN$$

accounted quantitatively for the nitrogen production (the ratio of $BF_3 \cdot N_2H_4$ used to N_2 produced was 2.98), but only qualitatively for the other observed products.

The apparent molecular weight of $BF_3 \cdot N_2H_4$ in aqueous solution (49.5 and 54.5 in separate experiments) was approximately one half of the calculated formula weight (99.9), suggesting that the initial action of water gave two ions per formula weight, probably by the following reaction:

$$BF_3 \cdot N_2H_4 + H_2O \rightleftarrows N_2H_5^+ + BF_3OH^-.$$

Since positive tests for fluoroborate ion, BF_4^-, were obtained, it appeared that the hydroxyfluoroborate ion might have been involved in a disproportionation reaction:

$$2BF_3OH^- \rightleftarrows BF_4^- + BF_2(OH)_2^-.$$

Disproportionation of $BF_2(OH)_2^-$, as represented by (19):

$$2BF_2(OH)_2^- \rightleftarrows BF_4^- + B(OH)_4^- \quad \Updownarrow \quad B(OH)_3 + OH^-$$

was presumed to occur in view of the fact that the basicity of the aqueous solution increased slightly on standing. Although the various ionic species (except BF_4^-) were not identified, the results were consistent with the observation that the hydrolysis of boron trifluoride itself yields a mixture of hydroxyfluoroboric acids (1).

No significant reaction occurred between anhydrous hydrogen chloride and boron trifluoride-hydrazine either at −96° or at 25°, but at 110°, the results shown in Table III were obtained. Three points seem noteworthy: (i) evidently HCl displaced BF_3

TABLE III

from $BF_3 \cdot N_2H_4$, (ii) the amount of HCl absorbed by the complex was much greater than the amount of BF_3 liberated, suggesting that 1:1:1 complex $BF_3 \cdot N_2H_4 \cdot HCl$ was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

formed in substantial quantities, and (iii) the extent of displacement of BF_3 decreased when the initial amount of HCl was lower.

At −80°, $BF_3 \cdot N_2H_4$ readily absorbed ammonia, forming a diammoniate, $BF_3 \cdot N_2H_4 \cdot 2NH_3$. On warming to room temperature ammonia was evolved in two stages, but it was not possible to isolate complexes of definite stoichiometry such as $BF_3 \cdot N_2H_4 \cdot NH_3$. Ammonia was thought to be bound to $BF_3 \cdot N_2H_4$ by weak dipole–dipole forces.

EXPERIMENTAL

Since most of the materials used in this work are gaseous and react rapidly with atmospheric moisture, it was necessary to manipulate them in a standard vacuum system (20) equipped with stopcocks and ground-glass joints lubricated with Kel-F grease. Prolonged contact of vapors with this grease was avoided by using all-glass reaction vessels and storage bulbs fitted with capillary break-seals instead of stopcocks. The purity of a volatile compound was checked by determination of its vapor pressure and molecular weight (M). Molecular weights were determined by the vapor density method with an accuracy usually better than 1%. Debye–Scherrer X-ray powder diffraction patterns were obtained from samples sealed in glass tubes of 0.01-mm wall thickness. The pictures were taken on a Seifert apparatus using the Cu $K\alpha$ radiation filtered by nickel. Infrared spectra were measured with a Perkin–Elmer Model 21 double-beam spectrophotometer fitted with sodium chloride optics.

Anhydrous hydrazine was prepared by refluxing the 95+% material (Eastman Kodak) for 3 hours over potassium hydroxide pellets in an atmosphere of dry nitrogen. The fraction boiling in the range 111–113° was found to be 100% pure by the iodate method (8). Commercial boron trifluoride, hydrogen chloride, and ammonia were purified by low-temperature fractionation.

Interaction of Boron Trifluoride with Hydrazine

In a typical experiment boron trifluoride (11.63 mmoles) and anhydrous hydrazine (5.89 mmoles) were brought together *in vacuo* and kept at room temperature for 30 minutes before the mixture was frozen with liquid air. A vigorous exothermic reaction yielded a white solid which was involatile at room temperature and contained boron trifluoride and hydrazine in a 1:1 ratio, corresponding to the compound $BF_3 \cdot N_2H_4$ (found: N_2H_4, 33.3%. $BF_3 \cdot N_2H_4$ requires: N_2H_4, 32.1%). The amount of unchanged boron trifluoride (5.81 mmoles. Found: M, 67.8. Calc. for BF_3: M, 67.8) recovered by distillation at −80°, also indicated that boron trifluoride (5.82 mmoles) had reacted with hydrazine (5.89 mmoles) in a 1:1 ratio. The melting point of the adduct was 87°. Using identical procedures and longer reaction times, complex mixtures with BF_3/N_2H_4 ratios of 1.09 and 1.16 were obtained (Table IV). The latter product (0.237 g) was treated with additional

TABLE IV

Boron trifluoride-hydrazine complex mixtures

boron trifluoride (15.3 mmoles) in diethyl ether (15 ml) for 11 hours. A substance of empirical composition $(BF_3)_{1.72}\cdot N_2H_4$ (found: N_2H_4, 21.6%) was recovered after distillation of the solvent and excess boron trifluoride at room temperature.

Additional complexes with different compositions, were obtained by the interaction of boron trifluoride and hydrazine in diethyl ether as solvent (Table IV). Similar results were obtained for the reaction *in vacuo* of boron trifluoride with hydrazine above room temperature. In a typical experiment, boron trifluoride (11.7 mmoles) and hydrazine (3.87 mmoles) were sealed in an all-glass reaction vessel and kept for 4 hours at 140°. The amount of boron trifluoride recovered (4.67 mmoles; found: M, 67.5; calc. for BF_3: M, 67.8) by distillation at room temperature showed that the white solid reaction product contained BF_3 and N_2H_4 in a ratio of 1.84:1 (found: N_2H_4, 20.9%; calc. for $(BF_3)_{1.84}\cdot N_2H_4$: N_2H_4, 19.8%).

In another experiment boron trifluoride (34.5 mmoles), hydrazine (10.1 mmoles), and anhydrous tetrahydrofuran (25 g) were condensed together in an all-glass reaction vessel which was then sealed off *in vacuo*. The reactants were stirred (magnetically) overnight at room temperature; a clear solution resulted. The solvent and the excess of boron trifluoride were removed by distillation under low pressure at room temperature; this left a white crystalline deposit of a new compound, 2-boron trifluoride-hydrazine, $2BF_3\cdot N_2H_4$ (found: N_2H_4, 19.25%; calc. for $2BF_3\cdot N_2H_4$: N_2H_4, 19.12%). Its melting point was 260°.

Pyrolysis of $N_2H_4\cdot BF_3$

Vapor pressure measurements in the range 140 to 220° showed that the compound decomposed irreversibly, with nitrogen and ammonia as the only volatile products. Pyrolysis of the adduct (5.65 mmoles) at 275–300° for 4.5 hours in an all-glass vessel gave nitrogen (1.72 mmoles; M: found, 27.8; calc., 28.0) together with a white solid residue which contained some unchanged 1:1 compound (0.52 mmole). An X-ray powder diffraction pattern showed that ammonium fluoroborate and boron nitride were the major components, with the former present in much larger amount. The presence of at least one unidentified solid compound in the residue was suggested by the X-ray data. Although reproducible analytical results were obtained for fluoroborate ion, these were considered unreliable in view of the fact that the hydrolysis of unchanged 1:1 compound yields an uncertain amount of fluoroborate ion.

Hydrolysis of $BF_3\cdot N_2H_4$

Two aqueous freezing point depression measurements indicated apparent molecular weights in solution of 49.5 and 54.5, or approximately one half the formula weight of $BF_3\cdot N_2H_4$, which is 99.9. Potassium chloride (1), cesium sulphate (1), and nitron acetate (21) solutions all gave precipitates when added to an aqueous solution of $BF_3\cdot N_2H_4$, thus confirming the presence of fluoroborate ion, BF_4^-. It was also noted that the initial acidity (pH = 4.35) of a dilute aqueous solution of $BF_3\cdot N_2H_4$ decreased slightly (pH = 4.65) on standing for 35 minutes.

Interaction of $BF_3\cdot N_2H_4$ with Hydrogen Chloride

Anhydrous hydrogen chloride (8.05 mmoles) and boron trifluoride-hydrazine (3.73 mmoles) were sealed in an all-glass vessel and left overnight at 110°. The products of the reaction were a non-volatile solid and a gas which was recovered by distillation at −80° (4.97 mmoles; found: M, 40.3; calc. for HCl: M, 36.5; calc. for BF_3: M, 67.8). The infrared spectrum of the gas showed clearly that it was a mixture of HCl (22) and BF_3 (23).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

From the molecular weight value of 40.3, it was calculated, assuming ideal gaseous behavior, that this volatile fraction consisted of 4.36 mmoles HCl and 0.61 mmole BF_3. Thus 3.69 mmoles of HCl reacted with 3.73 mmoles of $BF_3 \cdot N_2H_4$ yielding a solid residue and 0.61 mmoles BF_3. The solid residue was probably a complex mixture of $BF_3 \cdot N_2H_4 \cdot HCl$, $N_2H_4 \cdot HCl$, and $N_2H_4 \cdot 2HCl$, which could not be separated by fractional sublimation.

In an attempt to prepare pure $BF_3 \cdot N_2H_4 \cdot HCl$, $BF_3 \cdot N_2H_4$ (2.71 mmoles) and HCl (2.73 mmoles) were condensed together and kept overnight at 110° in an all-glass reaction vessel. Again the products were a non-volatile solid and a gas (0.835 mmole; found: M, 45.2), which was shown by its infrared spectrum to be a mixture of BF_3 and HCl. The composition of this volatile mixture was estimated to be 0.60 mmole of HCl and 0.23 mmole of BF_3. Thus, as before, it appeared that both displacement of BF_3 from $BF_3 \cdot N_2H_4$ by HCl and absorption of HCl by $BF_3 \cdot N_2H_4$ occurred simultaneously.

Interaction of $BF_3 \cdot N_2H_4$ with Ammonia

When anhydrous ammonia (10.38 mmoles) and $BF_3 \cdot N_2H_4$ (1.86 mmoles) were left in contact for 1 hour at −80°, the amount of ammonia (6.66 mmoles; found: M, 17.0; calc. for NH_3: M, 17.03) recovered by distillation at −80° indicated that the diammoniate, $BF_3 \cdot N_2H_4 \cdot 2NH_3$, had been formed at −80°. Above −80°, this crystalline compound dissociated irreversibly, evolving ammonia in what appeared to be two distinct stages as evident from the results summarized in Table V, but it was not possible to confirm the

TABLE V

Dissociation of the diammoniate of $BF_3 \cdot N_2H_4$

−26	None	—
0	1.50	17.4
+28	0.75	17.2

presence of the monoammoniate. Measurements of the dissociation pressure were not reproducible and the conventional plot of log $p_{(mm)}$ against $1/T$ was always concave to the reference axes.

ACKNOWLEDGMENTS

We are grateful to the Defence Research Board for financial assistance and to the National Research Council for the award of two Studentships to one of us (W.G.P.). We are indebted to Dr. R. St. J. Manley of the Pulp and Paper Research Institute of Canada for X-ray diffraction measurements and for assistance in their interpretation.

ORTHO-SUBSTITUTED CHLOROBENZENES RELATED TO METAMECONINE[1]

J. A. McRae,[2] Marjorie Allen,[3] and R. Y. Moir[4]

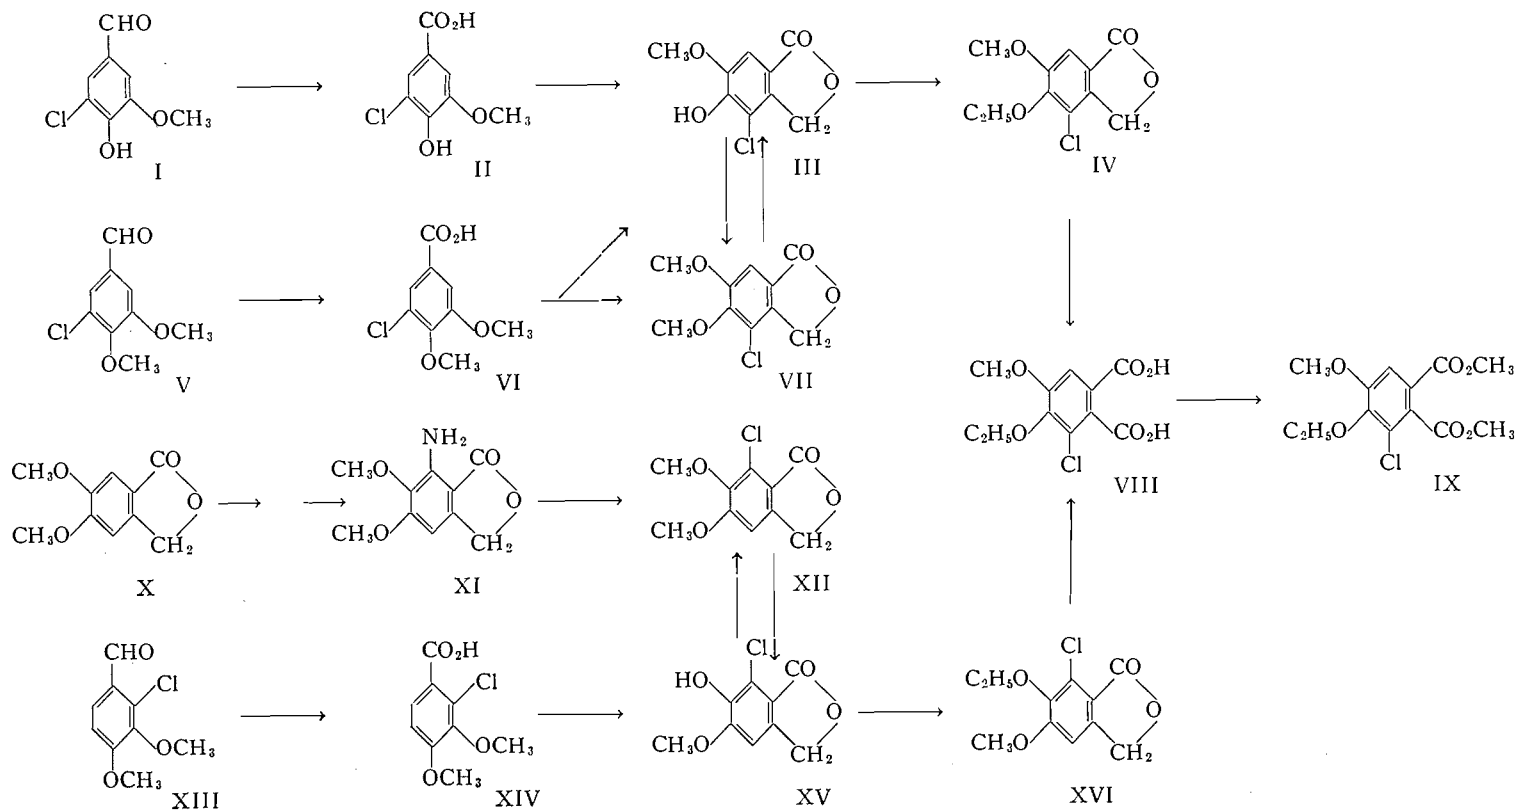
ABSTRACT

Chlorinated derivatives of metameconine were formed for the first time. Partial demethylation of the derivatives with sulphuric acid occurred in highly selective fashion at the methoxyl ortho to the halogen, without regard to the relative position of the carbonyl group which is known to be highly directive for demethylations in the absence of halogen. The phenolic products of the demethylations are needed for the synthesis of sterically hindered diphenyl ethers. They showed a type of intermolecular hydrogen bonding in the crystal which was markedly subject to steric interference by the halogen atoms.

Our work with the chlorinated derivatives of metameconine (X) was first undertaken many years ago as a check upon the results we had obtained in the corresponding bromine series (1, 2, 3); these results had differed sharply from those reported by others (4). The need for a check was emphasized when our more recent work (5) led to somewhat surprising conclusions as to the direction of bromination, nitration, and selective demethylation in the metameconines. This paper reports the independent characterization of the chlorine series of compounds, shows that the chlorine series is an almost exact parallel to the bromine series, and therefore thoroughly verifies our previous results.

Two more reasons for proceeding with the chlorine series appeared later in our work. (*a*) A subject of continuing interest to us is the study of steric hindrance in diphenyl ethers (3, 6); obviously the ortho-chloro- and ortho-bromo-phenols obtained in this work will allow the preparation of corresponding diphenyl ethers with blocking groups of different sizes. (*b*) We hope to study the effect of crowding upon the quadrupole resonance frequency of the halogens; measurement of these frequencies is, of course, easier for chlorine compounds than for bromine or iodine compounds.

The main novelty of the present work lies in the description of an interesting steric hindrance of hydrogen bonding in the solid phase.



Synthesis and Structure

The most easily available of the chlorine derivatives was 7-chlorometameconine[5] (XII), made from metameconine (X) by nitration, reduction to the amine (XI) (1, 2, 4), diazotization of the amine, and the Sandmeyer reaction. No doubt the structure was obvious, since 7-bromometameconine (1, 2, 4) and 7-iodometameconine (1, 3), formed in corresponding ways, have had their structures thoroughly verified. Nevertheless the present work offered a quite independent proof that the new substance was indeed 7-chlorometameconine, its indirect formation from 2-chloroveratric acid (XIV), as shown in the chart, leaving no room for doubt as to its structure.

The isomeric 4-chlorometameconine (VII) was formed by the action of formaldehyde upon 5-chloroveratric acid (VI) in acid solution. The structure of the resulting phthalide

For personal use only.

was not immediately obvious, since the phthalide ring might have closed on either of the positions ortho to the carbonyl group in VI. That it did actually close as shown in structure VII followed from the fact that the phthalide could be converted to the phthalic ester IX which (as shown on the chart) could also be formed from metameconine (X) or from 2-chloroveratric acid (XIV).

Interesting phenolic compounds were obtained by selective demethylation of the chlorinated metameconines with sulphuric acid. Preparative yields were obtained of the easily purified products, much desired for future synthetic work. From 4-chlorometameconine (VII) there was obtained 4-chloro-5-hydroxy-6-methoxyphthalide (III), and from 7-chlorometameconine (XII) the isomeric 7-chloro-6-hydroxy-5-methoxyphthalide (XV). Just as in the bromine series, demethylation of both VII and XII occurred overwhelmingly at the methoxyl group ortho to the halogen, and without regard to the position of the carbonyl group, even though with veratraldehyde (7), veratric acid (7), and metameconine (5), highly selective demethylation occurred at the methoxyl meta to the carbonyl.

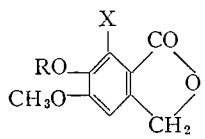
The methods used to show the structures of the phenolic compounds will be obvious from the transformations shown on the chart, the properties given in the experimental part, and the description of the corresponding bromine compounds (5).

Formaldehyde and 2-chloroveratric acid in acid solution gave none of the expected 7-chlorometameconine (XII); instead, very small amounts of 7-chloro-6-hydroxy-5-methoxyphthalide (XV) were obtained, along with large amounts of tars; the product was exceedingly difficult to purify. This miserable reaction was of central importance in our investigation, since it formed an exact parallel with the corresponding reaction of formaldehyde and 2-bromoveratric acid (1, 6), one of the main points in which our previous work disagreed with that of Rây and Robinson (4). Formaldehyde and 5-chloroveratric acid gave a mixture of the expected 4-chlorometameconine (VII) and the partially demethylated product, 4-chloro-5-hydroxy-6-methoxyphthalide (III). This too was an exact parallel with our experience with the corresponding 5-bromoveratric acid (2, 5). Even the infrared spectra of corresponding bromine and chlorine compounds are very similar throughout the two series, a further confirmation of the work in both. In fact the parallelism of the series broke down in only one respect: reductive dehalogenation, easy and convenient in the bromine series (5), in our hands failed completely in the chlorine series.

The correct orientation of the compounds of the metameconine series (1, 2, 3, 5, 6) has rested upon the correct orientation of the derivatives of vanillin used as reference compounds. It seems proper to point out how heavily we have relied upon the careful work of Dr. Raiford[6] and his students; of some 25 derivatives of vanillin needed in our structure proofs, only two (noted in the experimental part) have differed significantly from the descriptions given by these workers. One of the necessary intermediates, 5-chlorovanillic acid (II), has been made for the first time by Pearl's method (10), as shown in the experimental part.

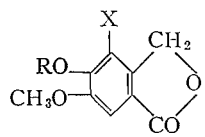
Physical Properties

Jones, Angell, Ito, and Smith (12) reported that unsaturated lactones in solution sometimes show double peaks in the region of the carbonyl stretching frequency, though the two phthalides they investigated both showed single peaks. When their paper appeared



[6]*We especially wish to acknowledge the kindness of Professor Raiford in sending us an authentic sample of 2-chloroveratric acid nearly a year before its description was published (8), at a time when our work was delayed by the erroneous description of the acid then available (9), and not long before Professor Raiford's death (11).*

we had already observed, among the spectra of about 20 *solid* phthalides, a number of double peaks as well as some exceptionally large displacements of the carbonyl stretching frequency. A suggestion by Dr. R. N. Jones then enabled us to gain some understanding of the phenomena we had observed. Repetition of the spectra of the phthalides, but using solutions in tetrahydrofuran rather than solid samples in potassium bromide, immediately eliminated both the doubling of the peaks and the large displacements. Both factors were therefore due to intermolecular effects in the crystals; they were not due to impurities, incorrectly determined structures, or to unusual situations within the molecules.



If one is interested in infrared spectra only for the determination of molecular structures, then the spectra of the crystals might simply be dismissed as inferior to the spectra of solutions. But the crystal effects are interesting in themselves, and had a special urgency for us, since quadrupole resonances *must* be observed in the solid state. We were able to make some progress in understanding the crystal effects because of the very large number of closely related phthalides at our disposal.

Spectra of Phthalides in Tetrahydrofuran

No double peaks were observed in the carbonyl stretching region, even in the acetylated derivatives (XVII A*d*, XVII C*d*, and XVIII C*d*) which have two different carbonyl groups. The peaks were all at positions normal for phthalides (13). In view of the results

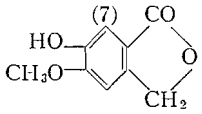
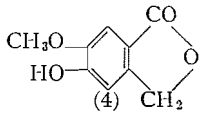
Examples: XVII A*b* is structure X; XVII B*c* is XVI.

with the solid phthalides reported below, it was especially noteworthy that the phthalides bearing free phenolic groups had their peaks in the normal position, in agreement with previous work on related compounds (13, 14). Twelve halogenated phthalides (XVII and XVIII, with all possible combinations of B, C, *a*, *b*, and *c*) had their maxima in the region 1769–1773 cm^{-1}. Three unhalogenated phthalides (XVII A*a*, XVII A*b*, and XVIII A*a*) absorbed in the region 1766–1769 cm^{-1}. The available acetylated phthalides (XVII A*d*, XVII C*d*, and XVIII C*d*) showed absorption at the noticeably higher values of 1775–1777 cm^{-1}.



Spectra of Solid Phthalides in Potassium Bromide

We discuss only effects which are both large and reproducible, since the peaks were, of course, broader and had less sharply defined maxima than those obtained with solutions, and because of the well-known smaller spectral variations possible with this technique. Two remarkable phenomena were noticed.



(*a*) *Steric interference with intermolecular hydrogen bonding.*—The reality of this effect was evident because the effect was reproducible, extremely large, and beautifully correlated with structure. Two phthalides (XVII A*a* and XVIII A*a*) (5) both showed absorption at the abnormally low frequency of 1715 cm^{-1}. The displacement of the band was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

due to an intermolecular effect, since it vanished in solution; even phthalides having hydroxyl ortho to the carbonyl show but little intramolecular association (13, 14). Clearly too the displacement involved the hydroxylic hydrogen since methylation of the free hydroxylic group returned the maximum absorption (of solid XVII A*b*) to 1755 cm^{-1};

XVII A*a*

XVIII A*a*

acetylation of the free phenolic group brought the peak (in solid XVII A*d*) to 1753 cm^{-1}. Both values represent complete elimination of the effect. Direct hydrogen bonding from the phenolic group to the carbonyl group of another molecule would in any case be suspected from the great effect on the carbonyl stretching frequency, and confirmation of this was afforded by a most interesting steric effect. Substitution of either chlorine or bromine at position 7 in XVII A*a* also abolished the displacement effect, even though the hydroxyl group was still present, since solid XVII B*a* absorbed at 1760 cm^{-1}, and solid XVII C*a* at 1768 cm^{-1}. In view of our other results, by far the main effect of halogen at position 7 must have been due to steric blocking of the carbonyl group. Halogen at position 4 was very much less effective in interfering with the hydrogen bonding, solid XVIII B*a* absorbing at 1726 cm^{-1}, and solid XVIII C*a* at 1730 cm^{-1}, and this comparatively small increase from the values for unsubstituted XVIII A*a* may have been due to a combination of effects: a partial steric interference with the phenolic group, a general increase in lattice dimensions, and a small direct effect of halogen on the carbonyl group (see solution values, and reference 13). We have not yet been able to form phthalides having halogen ortho to carbonyl and meta to hydroxyl, so that these three effects cannot yet be separated from each other. Nevertheless, the displacement of the carbonyl peak in the solid phenolic compounds is so clear cut that it might have been used in the structure proofs to fix the relative positions of halogen and carbonyl. Eight solid phthalides in which intermolecular hydrogen bonding was absent showed a single peak in the carbonyl stretching region in the range 1753–1768 cm^{-1}. The rather wide range may be correlated with the lattice effects discussed in the next section.

(*b*) *Double carbonyl peaks with solid phthalides.*—Seven solid phthalides showed very distinct double carbonyl peaks; of the seven all were halogenated, none was phenolic, and none was acetylated. The lower peaks were all in the region 1748–1755 cm^{-1}, but the upper peaks were more variable in position. Four phthalides halogenated at position 4 (XVIII B*b*, B*c*, C*b*, and C*c*) had the upper peak at 1776–1782 cm^{-1}, and three phthalides halogenated at position 7 (XVII B*b*, C*b*, and D*b*) had the upper peak in the noticeably lower range of 1764–1767 cm^{-1}. The peaks varied considerably in relative amplitudes, without any obvious correlation with structure.

The double peaks were certainly due to effects of crystal structure, since only a single peak appeared in the spectra of solutions. For at least one phthalide, the double peak was associated with dimorphism. Fresh preparations of XVIII C*c* (5) consisted of feathery needles and showed peaks at 1753 and 1781 cm^{-1}. Older preparations consisted of heavy prisms and showed only a single peak at 1758 cm^{-1}. We have been unable to obtain a single peak in the spectrum of the less stable form. On the other hand the phthalide XVIII C*d* (5) showed only a single peak at room temperature, though it showed dimorphism at higher temperatures, the long needles melting at 140°, then resolidifying to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

small prisms which melted again at 165°. Although these have been our only direct observations of dimorphism, the phenomenon cannot be ruled out as the explanation of all the double peaks observed with our phthalides.

Double Carbonyl Peaks in the Phthalic Esters

The dimethyl ester of 3-chloro-4-ethoxy-5-methoxyphthalic acid showed double peaks both in solution (at 1730 and 1744 cm^{-1}) and in the solid state (at 1720 and 1735 cm^{-1}); the corresponding bromine compound (5) was very similar in its spectra. The corresponding phthalic acids showed double peaks in the solid state, and single, very wide peaks in solution.

EXPERIMENTAL

All identities claimed in this paper were checked by comparison of the infrared spectra. The spectra were obtained using potassium bromide disks containing 0.8% by weight of sample, and tetrahydrofuran solutions containing up to 6% depending on the solubility of the sample. The spectrometer (a Perkin–Elmer Model 21, using a sodium chloride prism) was repeatedly calibrated by the use of the polystyrene bands at 1802 cm^{-1} and 1603 cm^{-1}. Most melting points were determined in an instrument of high precision (15) and the rest were performed on a Koffler Micro Hot Stage and lowered 3–5° to agree with precision capillary melting points within less than 1° up to 250°.

5-Chlorovanillic Acid (II)

The oxidation of 5-chlorovanillin (I) (m.p. 162.6–163.2°) (16) was accomplished following the method described by Pearl (10) for the preparation of vanillic acid. The product melted at 252–254°. The recorded (17) melting point is 244–245°. Found: C, 47.58; H, 3.39; Cl, 17.25%. Calc. for $C_8H_7ClO_4$: C, 47.42; H, 3.48; Cl, 17.52%.

5-Chloroveratraldehyde (V)

The method described for veratraldehyde (18) was adapted to the methylation of 5-chlorovanillin. The product melted at 55–55.6°; the recorded (11) melting point is 48–49°. Found: Cl, 18.2%. Calc. for $C_9H_9ClO_3$: Cl, 17.69%.

5-Chloroveratric Acid (VI)

5-Chloroveratraldehyde (17.0 g) and sodium bicarbonate (3.0 g) in water (100 ml) were heated to 60°. With vigorous stirring a solution, also heated to 60°, of potassium permanganate (20.2 g) in water (200 ml) was slowly added over 30 minutes whilst the temperature was maintained at 60–80°. The reaction was allowed to proceed for another 30 minutes, and then the reaction mixture was cooled, saturated with sulphur dioxide, and strongly acidified with hydrochloric acid (20 ml, conc.). The white precipitate was recovered by filtration, washed with a small volume of cold water and crystallized from ethyl alcohol to yield the product (15.6 g) with a melting point of 189.0–189.6°. Two more crystallizations from ethyl alcohol raised the melting point to 189.8–190.4°. The recorded (11) melting point is 188–189°. Found: C, 50.14; H, 4.00; Cl, 16.38%. Calc. for $C_9H_9ClO_4$: C, 49.88; H, 4.19; Cl, 16.38%.

2-Chloroveratric Acid (XIV)

This acid was obtained from 2-chlorovanillin by methylation according to the procedure recorded for veratraldehyde (18) followed by oxidation by the method described above for the isomeric 5-chloroveratric acid. The product purified by crystallization from aqueous ethyl alcohol had a melting point of 202°–203°. A mixed melting point determination with an authentic sample supplied by Professor Raiford gave a melting point of 202.5–204.5°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

4-Chloro-5-hydroxy-6-methoxyphthalide (III)

(*a*) 5-Chlorovanillic acid (II) (2.0 g, m.p. 247–249°), glacial acetic acid (80 ml), hydrochloric acid (40 ml, conc.), and formaldehyde (20 ml, 36–38%) were mixed and heated at 80–85° for 2 days. The cooled reaction mixture was poured onto ice (200 g) and after 2 hours the resulting precipitate was recovered by filtration, washed with a little cold water, and dried. The product (1.18 g) had a melting point of 204–206° which was raised to 236.4–237.2° by three crystallizations from ethyl alcohol. Found: C, 50.55, 50.78; H, 3.55, 3.46; Cl, 16.21, 16.55; —OCH_3, 15.45, 15.37 and on the same sample by a different analyst 13.64%. Calc. for $C_9H_7ClO_4$: C, 50.37; H, 3.29; Cl, 16.54; —OCH_3, 14.46%.

(*b*) 5-Chloroveratric acid (VI) (10 g, m.p. 186–187°), glacial acetic acid (400 ml), hydrochloric acid (200 ml, conc.), and formaldehyde solution (100 ml, 36–38%) were combined and heated at 95–100° for 2 days. The white precipitate obtained after pouring the reaction mixture onto ice was extracted with sodium bicarbonate solution. The insoluble fraction yielded after one crystallization from ethyl alcohol 4-chlorometameconine (VII) (1.66 g) with a melting point of 168–171°. (For further details see below.) The sodium bicarbonate extract was acidified and the resulting precipitate recovered and crystallized from ethyl alcohol. The product (2.77 g) had a poor melting point of 168–220°, but a second crystallization raised the melting point to 234–235°. A mixed melting point with the product from method (*a*) showed no depression.

(*c*) 4-Chlorometameconine (VII) (0.13 g, m.p. 171.2–171.8°) was heated in sulphuric acid (1 ml, conc.) at 60° for 2 days. The solution was poured onto ice and the precipitate recovered by filtration and washed with water. The product after two crystallizations from ethyl alcohol melted at 234–235° and gave no depression in melting point when mixed with the product from method (*a*).

The infrared spectra of the three samples of 4-chloro-5-hydroxy-6-methoxyphthalide produced by these methods, are identical throughout the range 4000–600 cm^{-1}.

4-Chlorometameconine (VII)

(*a*) This method of preparation is the same as method (*b*) described for 4-chloro-5-hydroxy-6-methoxyphthalide. The product (1.66 g) was crystallized twice from ethyl alcohol to give the analytical sample with a melting point of 171.2–171.8°. Found: C, 52.77, 52.71; H, 4.11, 4.25; Cl, 15.62, 15.65%. Calc. for $C_{10}H_9ClO_4$: C, 52.50; H, 3.97; Cl, 15.52%.

(*b*) 4-Chloro-5-hydroxy-6-methoxyphthalide (III) (0.2 g, m.p. 234–235°) from method (*a*) above was added to an ether solution of diazomethane (20 ml, 2%) and the mixture was left to stand overnight. The solution was evaporated and the easily solidified residue crystallized from ethyl alcohol to give fluffy needles (0.13 g) which melted at 171.2–171.8°. A mixed melting point with the product from (*a*) gave no depression, and the infrared spectra of the two products were identical.

4-Chloro-5-ethoxy-6-methoxyphthalide (IV)

4-Chloro-5-hydroxy-6-methoxyphthalide (III) (1.63 g, m.p. 234–235°), from method (*a*) above, ethyl iodide (30 ml), and dry acetone (75 ml) were refluxed and stirred in dry apparatus protected from moisture by drying tubes. Drierite (1.0 g) was added and the mixture stirred for 30 minutes. Freshly prepared silver oxide (5.0 g) was added in portions (1.0 g) at intervals over 7 hours, the reaction was allowed to proceed for a further 2 hours, and then the reaction mixture was cooled and filtered to remove the silver compounds. The filtrate was evaporated to dryness and the solid residue crystallized from ethyl alcohol to give white crystals (1.48 g) which melted at 138–139°. Three more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

crystallizations raised the melting point to 141.4–141.8°. Found: C, 54.72, 54.67; H, 4.70, 4.45; Cl, 14.30%. Calc. for $C_{11}H_{11}ClO_4$: C, 54.44; H, 4.57; Cl, 14.63%.

7-Chlorometameconine (XII)

(*a*) 7-Aminometameconine (XI) (2) (15 g crude) was dissolved in hydrochloric acid (45 ml, conc.) and water (300 ml). The solution was mechanically stirred and cooled in an ice and salt bath to −5°. Sodium nitrite (7.5 g) in water (60 ml) was added from a dropping funnel over 20 minutes, and then the mixture was stirred and cooled for 3.5 hours longer. The excess nitrous acid was destroyed with urea and the reaction mixture was slowly poured, with stirring, into a well-cooled solution of cuprous chloride (from 19 g $CuSO_4.5H_2O$) in hydrochloric acid (21 ml, conc.) and water (8 ml). When the frothing had subsided, the reaction mixture was gently heated on a boiling-water bath. The precipitate which settled out of the cooled solution, was recovered by filtration, washed with water, and crystallized once from dilute acetic acid (3:2) and three times from *n*-butanol to yield white needles (5.0 g) with a melting point of 193–193.5°. Two more crystallizations of corresponding material from another preparation gave the analytical sample with a melting point of 195.8–196.6°. Found: C, 52.48, 52.32; H, 3.97, 3.96; Cl, 15.22, 15.37%. Calc. for $C_{10}H_9ClO_4$: C, 52.50; H, 3.97; Cl, 15.52%.

(*b*) 5-Methoxy-6-hydroxy-7-chlorophthalide (XV) (0.5 g, m.p. 234–235°) from method (*a*) below, when methylated with diazomethane yielded white needles (0.42 g), with a melting point of 194.2–195.2° after one crystallization from ethyl alcohol. The infrared spectra of these two samples of 7-bromometameconine are identical, and a mixed melting showed no depression. The material made by method (*b*) below was methylated with methyl sulphate and gave 7-chlorometameconine proved by mixed melting point determination and infrared spectra.

5-Methoxy-6-hydroxy-7-chlorophthalide (XV)

(*a*) 7-Chlorometameconine (XII) (2.0 g, m.p. 193–194°) was heated with sulphuric acid (10 ml, conc.) for 3.5 days at 60°. The cooled viscous solution was poured onto ice and the resulting precipitate recovered by filtration, washed with water, and dried. The solid (1.87 g) was extracted with sodium bicarbonate solution and the soluble fraction recovered by acidifying the extracts. This procedure yielded a solid (1.47 g) with a melting point of 230–231°, which was raised to 235–235.8° by three crystallizations from ethyl alcohol. Found: C, 50.66, 50.48; H, 3.42, 3.28; Cl, 16.23, 16.53; —OCH_3, 14.44%. Calc. for $C_9H_7ClO_4$: C, 50.37; H, 3.29; Cl, 16.54; —OCH_3, 14.46%. A mixed melting point with the isomer 4-chloro-5-hydroxy-6-methoxyphthalide (III) showed a large depression.

(*b*) 2-Chloroveratric acid (XIV) (5.0 g), formaldehyde solution (9.0 ml, 36–38%), hydrochloric acid (31 ml, conc.), and glacial acetic acid (45 ml) were heated at 80–90° for 76 hours and at 100° for 7 hours longer. The combined solutions from three similar experiments were cooled and decanted from a small amount of tar, diluted with water (85 ml), and filtered to remove more tar. A second dilution with water (50 ml) precipitated unchanged 2-chloroveratric acid which after successive crystallizations from ethyl alcohol, aqueous ethyl alcohol, *n*-butyl alcohol, and aqueous acetic acid melted at 200–201.5°. The filtrate was again diluted with water (500 ml) and the solution evaporated to less than 150 ml under a slight vacuum, neutralized with sodium bicarbonate, made very slightly acid with hydrochloric acid, and the resulting precipitate collected after 24 hours. The precipitate (1.95 g) was washed with hot and cold water, and crystallized three times from *n*-butanol to give a product with a melting point of 231–232.5°. Found: C, 51.98; H, 3.84; Cl, 16.85, 16.50%. Calc. for $C_9H_7ClO_4$: C, 50.37; H, 3.29; Cl, 16.54%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Better material, m.p. 234.2–234.8°, was obtained by a further recrystallization from ethyl alcohol. The infrared spectra given by these two products from methods (*a*) and (*b*) were identical.

5-Methoxy-6-ethoxy-7-chlorophthalide (XVI)

5-Methoxy-6-hydroxy-7-chlorophthalide (XV) (2.0 g, m.p. 234–235°) was ethylated by the method described above for 4-chloro-5-hydroxy-6-methoxyphthalide. The product (1.59 g) after one crystallization from ethyl alcohol melted at 174–175°. Three more crystallizations raised the melting point to 177.2–177.6°. Found: C, 54.43, 54.52; H, 4.70, 4.56; Cl, 14.63%. Calc. for $C_{11}H_{11}ClO_4$: C, 54.44; H, 4.57; Cl, 14.63%.

3-Chloro-4-ethoxy-5-methoxyphthalic Acid (VIII)

(*a*) Potassium permanganate (2.5 g) was added over a period of 15 minutes to a well-stirred solution of 4-chloro-5-ethoxy-6-methoxyphthalide (IV) (1.0 g, m.p. 140.6–141.2°) in potassium hydroxide solution (110 ml, 5%) heated on a steam bath. The reaction was allowed to proceed another 45 minutes, and then cooled. Sulphur dioxide was passed until a clear solution was obtained. The solution was evaporated to half volume and after standing at room temperature, crystals with a poor melting point settled out of the solution. The product crystallized from water containing a few drops of hydrochloric acid in two modifications which were separated by hand: (A) long needles (0.2 g) with a melting point of 200–201° and a second melting point due to the anhydride of 133.5–134°; (B) small prisms (0.02 g) with a melting point of 203–207° and a second melting point of 133.5–134°. The infrared spectra in potassium bromide disks of these two modifications showed slight differences in the intensity of the peaks in the region 1500–1450 cm^{-1}, and differences in the positions of the peaks in the region 1000–850 cm^{-1}, which are probably due to variations in the crystalline structure. The two forms were methylated separately (see below) to give identical products as determined by infrared spectra and mixed melting points.

(*b*) 5-Methoxy-6-ethoxy-7-chlorophthalide (XVI) (1.0 g, m.p. 174–175°) was oxidized as above, and the product after one crystallization from water melted at 192–194° and the second melting point was 133.5–134°. This product appeared to be homogeneous, and the infrared spectrum was identical with that given by the modification B above.

Dimethyl 3-Chloro-4-ethoxy-5-methoxyphthalate (IX)

(*a*) 3-Chloro-4-ethoxy-5-methoxyphthalic acid (0.2 g, crystals A) were added to diazomethane solution (20 ml, 2% in ether) and left to stand overnight. The colorless solution was evaporated to dryness and the easily solidified residue was crystallized from petroleum ether (b.p. 30–60°) to give heavy needles which melted at 68.8–70.4°.

The product from crystals B melted at 70.4–70.6°, and a mixed melting point was 68.8–70.4°.

(*b*) 3-Chloro-4-ethoxy-5-methoxyphthalic acid (0.44 g from (*b*) above) yielded white needles (0.38 g) with a melting point of 70.4–71.4°, which did not depress the melting point of the above products. Found: C, 51.70, 51.66; H, 5.12, 4.86; Cl, 12.29, 12.42%. Calc. for $C_{13}H_{15}ClO_6$: C, 51.56; H, 4.99; Cl, 11.72%.

The infrared spectra given by the three samples of dimethyl 3-chloro-4-ethoxy-5-methoxyphthalate were identical.

Attempted Dechlorinations

5-Chlorovanillic acid (II) was used as a model compound in experiments designed to find the conditions for removal of the chlorine atom. The methods tried were: (*a*) sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

amalgam in aqueous medium, (*b*) zinc dust and potassium hydroxide, (*c*) preformed chromous chloride, (*d*) chromous chloride prepared *in situ*. All experiments failed, the only compound isolated being unchanged 5-chlorovanillic acid. The last two series of experiments were repeated with 4-chloro-5-hydroxy-6-methoxyphthalide (III) and once again there was no evidence that chlorine had been successfully removed.

ACKNOWLEDGMENTS

We wish to thank Dr. A. L. Promislow for the preparation of some intermediates used in this work, Miss Shelagh Courtenay for the determination of the infrared spectra, and Dr. C. A. Sankey for a generous gift of vanillin, the ultimate source of all the new compounds produced in our work. The work was made possible by the financial support of the National Research Council of Canada, and by the grants of Fellowships to two of us by Canadian Industries Limited.

THE CARBOHYDRATE–PROTEIN LINKAGE IN GLYCOPROTEINS

PART I. THE SYNTHESES OF SOME MODEL SUBSTITUTED AMIDES AND AN L-SERYL-D-GLUCOSAMINIDE[1]

J. K. N. JONES, M. B. PERRY, B. SHELTON, AND D. J. WALTON[2]

ABSTRACT

The syntheses of *N*-L-seryl-D-glucosamine, *N*-glycyl-D-glucosamine, *N*-L-glutamyl-D-glucosamine, and 1-*O*-β-L-seryl-*N*-acetyl-D-glucosaminide are described. These D-glucosamine derivatives may result from the fragmentation of some glycoproteins. The chemical properties of these compounds indicate that *N*-peptides are relatively stable in acid solution but unstable in neutral and alkaline solution. The seryl glucosaminide is relatively stable in alkaline solution but is hydrolyzed by acid.

INTRODUCTION

The mode of the linkage of sugars to amino acids in glycoproteins and mucoproteins which contain small amounts of carbohydrate, is obscure. Examples of this group are collagen and reticulin. Reticulin (1) is found in fairly large amounts in some internal organs (e.g. kidney and lung), and contains 3–4% of neutral sugars and 0.2% of hexosamine. Collagen (2) contains 0.3–0.7% of glucose and galactose. Several collagens which have been investigated (3) have been shown to contain D-glucosamine. Histochemical work has demonstrated that in some diseases, such as rheumatoid arthritis, there appear to be increases in the carbohydrate content of the glycoprotein of the subcutaneous tissue, which is rich in collagen. It was therefore of interest to investigate the mode of linkage of carbohydrate to amino acid in glycoproteins and mucoproteins. Bovine subcutaneous tissue, which is rich in collagen and elastic fibers, when degraded by proteolytic enzymes yielded a complex mixture of peptides to which were attached sugar residues. It was clear that this subcutaneous tissue did not contain any appreciable quantities of high molecular weight polysaccharides (4). This suggested that carbohydrate residues of low molecular weight were covalently linked to the amino acid residues of the proteins. It was therefore decided to attempt the syntheses of carbohydrate–amino acid derivatives which might result from the degradation of glycoproteins. A survey of the literature indicates that little was known about the type of linkage in such a derivative, but that linkages through glycine, aspartic acid, serine, threonine, and amides have been implicated (5, 6, 7). Many glycoproteins contain D-glucosamine and the possible biological role of *N*-peptides of this amino sugar have been investigated. The syntheses of *N*-glycyl-D-glucosamine (8) and of *N*-L-alanyl-D-glucosamine (9) have been reported in which they were isolated either as the hydrochloride or as some alternative derivative, with the amino group protected. *N*-(L-Alanyl-L-alanyl)-D-glucosamine has been found to be stable (10), as have several other similar dipeptides, the syntheses of which have been reported. A peptide composed of D-glucosamine and L-glutamic acid has been synthesized (11) but this was reported to be unstable even when the amino group was protected. It was of particular interest to examine these *N*-peptides, rather than their more stable substituted derivatives to determine whether they might be expected to survive during the hydrolysis

[1]*Manuscript received October 26, 1960.*

[2]*Present address: 18, Maiden Castle Road, Dorchester, Dorset, England.*

of glycoproteins. Accordingly, we have attempted the syntheses of several amino acids amide linked to D-glucosamine, in order to examine their properties. The *N*-peptide of L-serine was chosen as it had been reported by Masamune (12) to be present in gastric mucin together with glucosamine. Glycine has been reported by Gross (13) to constitute about 30–35% of all collagens investigated, and may therefore be linked to sugar residues. The *N*-peptide of L-glutamic acid was prepared in order to investigate whether the presence of a free carboxylic acid end group might confer stability to the derivative. L-Serine contains a primary hydroxyl group, and is therefore capable of being united glycosidically with a sugar residue: an L-seryl-*N*-acetyl-D-glucosaminide has been synthesized and its properties examined.

N-L-*Seryl*-D-*glucosamine*

N-(*N*-Carbobenzoxy-L-alanyl)-1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine hydrochloride and the corresponding *N*-glycyl compound were synthesized by Bergmann and Zervas (8) by treating 1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine with *N*-carbobenzoxy-L-alanyl chloride or with *N*-carbobenzoxyglycyl chloride. L-Serine, however, contains a primary hydroxyl group which must be protected before a reaction of this type can be used. Accordingly we turned our attention to the possibility of condensing a suitably substituted D-glucosamine derivative with *N*-carbobenzoxy-L-serine by the carbodiimide method (14). Unfortunately the L-serine derivative was not soluble in methylene chloride which is the solvent usually employed in this type of reaction. To overcome this difficulty the primary hydroxyl group of the L-serine derivative was protected by a tetrahydropyranyl group which led to the formation of two separable optical isomers which were soluble in methylene chloride. Racemization does not occur in the formation of the tetrahydropyranyl derivatives (15). Each isomer was then condensed with the suitably substituted 1-*O*-α-acetyl- and 1-*O*-β-acetyl-D-glucosamine derivatives, resulting in the formation of four isomers. The yields were poor when dicyclohexyl carbodiimide was used because of the difficulty in separating dicyclohexyl urea from the products. When diisopropyl carbodiimide was used as a condensation agent, better yields were obtained since the product was more readily separable from the diisopropyl urea by-product. When these isomers were warmed in dilute acetic acid solution, dihydropyran was eliminated and *N*-(*N*-carbobenzoxy-L-seryl)-1,3,4,6-tetra-*O*-acetyl-α- (and β-) D-glucosamine were produced, respectively. When the carbobenzoxy grouping was removed by reduction the resulting *N*-L-seryl-1,3,4,6-tetra-*O*-acetyl-α- (and β-) D-glucosamine decomposed to a brown tar within a few minutes. Presumably this was due to the basic character of the amino group of the amino acid moiety. Despite this instability it was possible to prepare the fully acetylated derivative. However, it was found that in the presence of hydrochloric acid the deacetylated product yielded a stable hydrochloride on removal of the carbobenzoxy grouping by hydrogenolysis.

N-Glycyl-D-*glucosamine*

Bergmann (8) synthesized the hydrochloride of this material but the parent compound has not been reported. *N*-(*N*-Carbobenzoxyglycyl)-D-glucosamine was obtained by the deacetylation of *N*-(*N*-carbobenzoxyglycyl)-1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine. This compound was prepared by Bodanszky and Du Vigneaud's method (16) for condensing amino groups and carboxylic acid groups to form peptide linkages. The condensation is effected between the hydrogen halide of an amine and the *p*-nitrophenyl ester of a carboxylic acid. In this case the amine salt used was 1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine hydrobromide, and the ester was glycyl *p*-nitrophenyl ester. The fully

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

substituted product was then deacetylated and reduced in the presence of hydrochloric acid to give *N*-(glycyl hydrochloride)-D-glucosamine. Hydrogenolysis in neutral solution caused both the acetylated and the deacetylated derivative to decompose rapidly.

N-L-Glutamyl-D-glucosamine

In the synthesis of this compound the method of Bodanszky and Du Vigneaud (16) was again used in an analogous manner to that used in the preparation of the *N*-glycyl-D-glucosamine. The amino acid was converted into *N*-carbobenzoxy-α-*p*-nitrophenyl ester-γ-L-glutamine by condensation of *N*-carbobenzoxy-L-glutamic acid with *p*-nitrophenol, using diisopropyl carbodiimide as a dehydrating agent, to form the diester. The diester was then treated with the calculated amount of methanolic ammonia solution to form the monoester–monoamide. It is reasoned from steric considerations that the replacement is effected in the less hindered γ-position. When the derivative had been formed and the terminal amide group removed, attempts to synthesize the free amine by hydrogenolysis of the carbobenzoxy group yielded very unstable products which could not be isolated. This was also true of the *N*-peptide after deacetylation. The hydrogen reduction was also carried out in the presence of hydrochloric acid, and in this case the stable *N*-peptide hydrochloride was formed.

1-O-β-L-Seryl-N-acetyl-D-glucosaminide

The glucosaminide was formed using a modified Koenigs–Knorr (17) type synthesis. 1-Chloro-1-deoxy-*N*-acetyl-3,4,6-tri-*O*-acetyl-D-glucosamine was prepared by the action of titanium tetrachloride on fully acetylated D-glucosamine in the manner described by Inouye and his co-workers (18). The acetohalogen sugar was allowed to react with *N*-carbobenzoxy-L-seryl methyl ester, using anhydrous alcohol-free chloroform as a solvent, and employing the Koenigs–Knorr conditions.

The initial yields of the product were low owing to steric hindrance, but when the reaction was allowed to proceed for 6 days with vigorous shaking, better yields were obtained. The product was not purified at this stage, but was de-*O*-acetylated with barium methylate. The deacetylated material was purified by chromatography, and was then subjected to hydrogenolysis, under neutral conditions, to remove the carbobenzoxy group. The over-all yield was small and the product at this stage, 1-*O*-β-(L-seryl methyl ester)-*N*-acetyl-D-glucosaminide, was stable and the corresponding hydrochloride was synthesized. The substituted D-glucosaminide was then saponified using sodium hydroxide solution to give the free acid, 1-*O*-β-L-seryl-*N*-acetyl-D-glucosaminide, which was found to be stable.

EXPERIMENTAL

All melting points reported are uncorrected. Solutions were concentrated by rotary evaporation under reduced pressure below 40°, unless otherwise stated.

Paper chromatography was performed by the descending method on Whatman No. 1 paper, using 1-butanol/ethanol/water (3:1:1 v/v) as the mobile phase. The following sprays were used to detect the compounds on the paper chromatograms: (A) 2% solution of *p*-anisidine hydrochloride in 1-butanol, (B) 1% solution of silver nitrate in acetone, followed by 2% ethanolic sodium hydroxide, and (C) 2% ninhydrin in 1-butanol. The rate of movement of the compounds on the chromatograms is given relative to that of D-glucosamine hydrochloride ($R_{GN.HCl}$), *N*-acetyl-D-glucosamine (R_{GNAc}), or pentaacetyl-D-glucosamine (R_{GNpAc}).

The infrared spectra of crystalline compounds were measured as 0.8% dispersions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

in potassium bromide disks, and non-crystalline materials were examined as 6% solutions in chloroform, using a Perkin–Elmer Model 21 spectrophotometer.

Elemental analyses were carried out by the Schwarzkopf Microanalytical Laboratory, Woodside, New York.

*1. N-*L*-Seryl-*D*-glucosamine*

(a) Carbobenzoxychloride

The reagent was prepared by the method of Carter *et al.* (19). Benzyl alcohol (65 ml) was added to a solution of phosgene (69 g) in toluene (200 ml) at 0°. After 3 hours the excess benzyl alcohol and the toluene were removed by distillation under reduced pressure. The remaining solution (104 g) contained 76 g of carbobenzoxychloride.

*(b) N-Carbobenzoxy-*L*-serine*

The method of Moore *et al.* (14) was used in a slightly modified form. Between the additions of the reactants the alkaline solution was transferred to a tap funnel and vigorously shaken, then returned to the reaction vessel. The product (98% yield) had m.p. 116°.

*(c) N-Carbobenzoxy-*L*-seryl Methyl Ester*

N-Carbobenzoxy-L-serine (20 g) was dissolved in 2.5 *N* methanolic hydrogen chloride solution (200 ml). The solution was allowed to stand overnight and it was then deacidified with Duolite A4(OH^-) exchange resin. The solution was concentrated to a syrup (20 g; 94% yield) which was kept in a desiccator.

*(d) N-Carbobenzoxy-O-tetrahydropyranyl-*L*-seryl Methyl Ester*

The procedure of Iselin and Schwyzer (15) was followed. *N*-Carbobenzoxy-L-seryl methyl ester (12.6 g) was dissolved in purified 2,3-dihydro-4-pyran (6 g) and a solution of 2.2 *N* hydrogen chloride in dry ethyl acetate (0.7 ml) was added. The reaction mixture was allowed to stand for 3 hours at room temperature after which it was diluted with ether and then washed with dilute sodium bicarbonate solution followed by water. The solution was dried (anhyd. sodium sulphate), filtered, and then concentrated to a yellow oil (15 g; 88% yield).

*(e) N-Carbobenzoxy-O-tetrahydropyranyl-*L*-serine*

The methyl ester (*d*) was dissolved in methanol (50 ml) and saponified by the method of Iselin and Schwyzer (15). Addition of ether to the final product in ethyl acetate resulted in the separation of one isomer in a crystalline form (I_{e1}), in 14% yield, which had m.p. 129°.

The second isomer (I_{e2}) was obtained from the concentrated mother liquor which gave crystals after 2 days (30% yield) which had m.p. 150°.

The infrared spectra of the products showed absorption bands at 987 cm^{-1} and 1130 cm^{-1} (in chloroform solution). These bands are due to the tetrahydropyranyl group, and are not present in the spectrum of *N*-carbobenzoxy-L-serine. The phenyl band at 695 cm^{-1} was also present.

*(f) 1,3,4,6-Tetra-O-acetyl-N-acetyl-β-*D*-glucosamine*

D-Glucosamine hydrochloride (30 g) was dissolved in a solution of zinc chloride (36 g) in acetic anhydride (250 ml). The solution was kept at 70–80° for 10 minutes and was then poured into ice water (400 ml). Sodium bicarbonate was slowly added to neutralize the excess acid and on allowing the reaction mixture to stand overnight in a refrigerator, a white precipitate of the pentaacetate separated. The material was collected, washed with water, dried, and recrystallized from ethanol solution to give the product (30.8 g;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

52% yield) which had m.p. 187° which rose to m.p. 190–192° after recrystallization. $[\alpha]_D^{25}$ +3° (*c*, 4.0 chloroform).

The infrared spectrum of the product showed the following absorption bands: carbonyl of *O*-acetyl (1740 cm^{-1}); amide I (1682 cm^{-1}); and amide II (1512 cm^{-1}). Important bands referred to later occurred at 1238, 1078, 1042, and 900 cm^{-1}.

The corresponding α-anomer was prepared in a similar manner, but the reaction was carried out at room temperature. Yield 56%, m.p. 139°, $[\alpha]_D^{22}$ +91° (*c*, 4.0 chloroform).

(g) 1,3,4,6-Tetra-O-acetyl-α- (and β-) D-*glucosamine Hydrobromide*

The technique of Inouye *et al.* (18) was used. 1,3,4,6-Tetra-*O*-acetyl-*N*-acetyl-α-D-glucosamine (10 g) was added to a stirred ice-cold solution of dry hydrogen bromide in acetic acid (30 ml) to give the product (4.5 g; 45% yield), which had $[\alpha]_D^{22}$ +129° (*c*, 4.0 water), chars at 205–220°.

The β-anomer was prepared in a similar manner from 1,3,4,6-tetra-*O*-acetyl-*N*-acetyl-β-D-glucosamine and the product (4.5 g; 45% yield) had $[\alpha]_D^{21}$ +12.1° (*c*, 4.0 water), chars above 200°.

(h) 1,3,4,6-Tetra-O-acetyl-α- (and β-) D-*glucosamine*

The hydrobromides (1 g) were respectively dissolved in a slurry of Amberlite IR45 ($CO_3^=$) exchange resin (4 g hydrobromide to 50 ml resin). The mixture was stirred at 5° for 1 hour and then filtered. The filtrates were extracted with chloroform (4×80 ml) and the combined extracts were dried (anhyd. sodium sulphate) and then concentrated to a small volume. On the addition of ether to the concentrates, the products separated as needle-like crystals, which were collected and recrystallized from ethanol. The α-anomer (65% yield) had m.p. 118° and $[\alpha]_D^{23}$ +145.5° (*c*, 4.0 chloroform). The β-anomer (65% yield) had m.p. 143° and $[\alpha]_D^{22}$ +27° (*c*, 3.6 chloroform).

*(i) N-(N-Carbobenzoxy-O-tetrahydropyranyl-*L-*seryl)-1,3,4,6-tetra-O-acetyl-α- (and β-)* D-*glucosamine*

N-Carbobenzoxy-*O*-tetrahydropyranyl-L-serine (isomer I_{c1}) (2.0 g; 6.2 mmoles), 1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine (2.3 g; 6.2 mmoles), and diisopropyl carbodiimide (0.8 g; 6.2 mmoles) were dissolved in methylene chloride (25 ml) and the solution was shaken mechanically for 20 hours at room temperature. One drop of dilute acetic acid was added, and the shaking was continued for a further 1 hour. The diisopropyl urea by-product was filtered off, and the filtrate was stored at −10° for 24 hours. The solution was refiltered, and the filtrate then washed with dilute hydrochloric acid, followed by 2 *N* sodium carbonate solution and finally with water. The solution was dried (anhyd. sodium sulphate) and the methylene chloride removed by distillation to leave a syrup. The syrup was taken up in the minimum amount of hot ethanol from which the α-anomer was obtained as crystals (40% yield) which had m.p. 201° and $[\alpha]_D^{23}$ +10° (*c*, 4.0 chloroform). Anal. Found: C, 55.8; H, 6.16; N, 4.3%. $C_{30}H_{40}O_{14}N_2$ requires: C, 55.2; H, 6.18; N, 4.3%.

The above synthesis was repeated using 1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine to give the α-anomer as a syrup (35% yield) which could not be crystallized and which had $[\alpha]_D^{23}$ +91° (*c*, 4.0 chloroform).

The second isomer (I_{c2}) of *N*-carbobenzoxy-*O*-tetrahydropyranyl-L-serine was treated in the same way as described above with 1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine to yield a crystalline product (29% yield) which had m.p. 160° and $[\alpha]_D^{23}$ +2° (*c*, 5.0 chloroform). Anal. Found: C, 55.5; H, 6.18; N, 4.6%.

The infrared absorption spectra of the products showed absorption band at the following wave numbers: carbonyl of *O*-acetyl (1745 cm^{-1}), amide I (1682 cm^{-1}), and amide II

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(1495 cm^{-1}). The spectra showed the following absorption bands in common with 1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine: 1235 (s), 1078 (s), 1041 (s), and 900 cm^{-1} (s). Bands characteristic of *N*-carbobenzoxy-*O*-tetrahydropyranyl-L-serine were detected at 1130, 987, and 695 cm^{-1}. The spectra of the isomers were almost identical.

*(j) N-(N-Carbobenzoxy-*L*-seryl)-1,3,4,6-tetra-O-acetyl-α- (and β-)* D*-glucosamine*

The *O*-tetrahydropyranyl group was removed from the products (*i*) by the following method. *N*-(*N*-Carbobenzoxy-*O*-tetrahydropyranyl-L-seryl)-1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine (600 mg) was boiled for 10 minutes in 50% aqueous acetic acid (10 ml) and the cooled solution was then diluted with water (50 ml). The solution was extracted with chloroform (4×20 ml), the combined extracts were washed with water, dried (anhyd. sodium sulphate), and concentrated to a small volume. The residue was dissolved in the minimum quantity of hot ethanol from which the product crystallized slowly in the form of long colorless needles (75% yield) which had m.p. 168° and $[\alpha]_D^{23}$ +25° (*c*, 4.0 chloroform). Anal. Found: C, 53.3; H, 5.73; N, 5.0%. $C_{25}H_{32}O_{13}N_2$ requires: C, 52.8; H, 5.67; N, 4.93%.

The α-anomer was similarly prepared from *N*-(*N*-carbobenzoxy-*O*-tetrahydropyranyl-L-seryl)-1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine as a crystalline product (65% yield) which had m.p. 145° and $[\alpha]_D^{23}$ +102° (*c*, 3.7 chloroform).

The infrared absorption spectra of these products were the same as those of the precursors except that the bands at 1130 cm^{-1} and 987 cm^{-1} due to the tetrahydropyranyl group were absent. The isomerism due to the forms (I_{e1}) and (I_{e2}) disappeared, as the same product was obtained from both isomers.

*(k) N-(N-Carbobenzoxy-*L*-seryl)-α- (and β-)* D*-glucosamine*

N-(*N*-Carbobenzoxy-L-seryl)-1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine (0.4 g) dissolved in anhydrous methanol (8 ml) was treated with 0.4 *N* barium methoxide in methanol (2 ml) at 5° for 20 hours. After testing for the presence of excess barium, a little water was added and the remaining alkali was precipitated by carbonation of the solution. The barium carbonate was removed by centrifugation, and the clear supernatant was concentrated to a small volume. The residue gave a crystalline product (24% yield) from ethanol solution which had m.p. 195° and $[\alpha]_D^{20}$ +75° (*c*, 4.0 chloroform).

The β-anomer was similarly prepared from *N*-(*N*-carbobenzoxy-L-seryl)-1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine as a crystalline product (30% yield) which had m.p. 198° and $[\alpha]_D^{21}$ +8° (*c*, 4.0 chloroform).

The products had R_{GNAc} 2.10 on paper chromatograms and was free from D-glucosamine and L-serine.

The infrared spectra of the two products were very similar, and differed from the spectra of the precursors in that the carbonyl of *O*-acetyl at 1750 cm^{-1} had disappeared, and the hydroxyl band at 3460 cm^{-1} appeared very strongly. The amide linkage bands at 1682 cm^{-1} and 1495 cm^{-1} were still present, though the latter was slightly displaced.

*(l) N-(*L*-Seryl hydrochloride)-*D*-glucosamine*

The carbobenzoxy group was removed from (1*k*) by hydrogenolysis using palladized charcoal as a catalyst. The catalyst was prepared by adding palladous chloride (0.1 g) in a little water to animal charcoal (2 g) and the mixture was then heated to 130° to remove water. Hydrazine sulphate was added, followed by a little *N* sodium hydroxide and the mixture was then stored for 24 hours at −5°. The charcoal was then collected by filtration and dried.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

N-(*N*-Carbobenzoxy-L-seryl)-D-glucosamine (26 mg) was dissolved in a mixture of methanol and chloroform (5 ml) and the solution was added to water (5 ml) containing *N* hydrochloric acid (0.07 ml). Palladized charcoal was added and the mixture was shaken mechanically for 20 hours at room temperature under a slight pressure of hydrogen (2 lb above atmospheric pressure). The charcoal was removed from the product by filtration and the filtrate was concentrated to a syrup which was insoluble in chloroform and alcohol, but soluble in water.

The product was obtained from methanol/ether mixture as fine colorless crystals (19 mg; 86% yield) which decomposed over the temperature range 200–250°. On paper chromatograms developed in the 1-butanol/ethanol/water system the compound was revealed by the ninhydrin spray reagent as an orange spot which reddened on standing, and had $R_{GN\cdot HCl}$ 0.55. Anal. Found: N, 8.9; Cl, 11.7%. $C_9H_{19}O_7N_2Cl$ requires: N, 9.2; Cl, 11.7%.

The infrared spectrum showed a strong hydroxyl band at 3460 cm^{-1} which was very wide due to the amino group absorption. Amide I absorption was present at 1682 cm^{-1}, but was absent at 1495 cm^{-1}. Evidence for the ionic nitrogen was found at 1495 cm^{-1}.

The product prepared from the α-anomer failed to crystallize, and the yield of crude material was very poor.

(m) N-L-Seryl-D-glucosamine

Attempts to synthesize the free amine from *N*-(*N*-carbobenzoxy-L-seryl)-β-D-glucosamine by direct hydrogenolysis in aqueous solution failed, owing to the rapid decomposition of the product in the atmosphere. An indirect method was investigated. A little of the hydrochloride (*l*) (15 mg) was dissolved in an aqueous slurry of Amberlite IR 45 ($CO_3^=$) exchange resin (5 ml) and after removal of the resin the water was removed by distillation under reduced pressure at 30°, methanol being added to speed the evaporation of the water. The product which was a solid, blackened before it could be isolated.

(n) N-(N-Acetyl-O-acetyl-L-seryl)-1,3,4,6-tetra-O-acetyl-β-D-glucosamine

N-(L-Seryl hydrochloride)-β-D-glucosamine (10 mg) was acetylated with pyridine/acetic anhydride mixture (5 ml) at 0° for 2 days. The product was obtained as a syrup (10 mg) which had R_{GNpAc} 1.08 on paper chromatograms developed in the neutral solvent system. The infrared absorption spectrum of the product showed strong carbonyl of *O*-acetyl absorption at 1750 cm^{-1} but no band due to hydroxyl at 3460 cm^{-1}.

2. N-Glycyl-D-glucosamine

(a) N-Carbobenzoxyglycine

Glycine (25 g) was treated with carbobenzoxy chloride in toluene (60 g) using the method of Moore *et al.*, to give *N*-carbobenzoxyglycine (70 g).

(b) N-Carbobenzoxyglycyl p-Nitrophenyl Ester

N-Carbobenzoxyglycine (10 g) was dissolved in ethyl acetate (100 ml) containing *p*-nitrophenol (6.4 g) and dicyclohexycarbodiimide (9.2 g), and the mixture was kept at 0° for 1 hour and was then allowed to rise to room temperature. The precipitated dicyclohexyl urea by-product was removed by filtration and was washed free from the mother liquor with ethyl acetate. The combined filtrate and washings were concentrated and the ethanol solution of the residue gave the crystalline product (15 g; 95% yield) which had m.p. 127°. The infrared spectrum of the product showed the characteristic sharp absorption peaks due to the *p*-nitrophenyl group at 1775, 1635. 1600, 1540, 1500, 1355, and 695 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(c) N-(N-Carbobenzoxyglycyl)-1,3,4,6-tetra-O-acetyl-β-D-glucosamine

N-Carbobenzoxyglycyl *p*-nitrophenyl ester (1 g) was condensed with 1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine hydrobromide (1.25 g) in the presence of dimethylformamide containing triethylamine (0.3 g) by Bodanszky and Du Vigneaud's (16) procedure to give the product, obtained as crystals (0.9 g) from methanol solution, which had m.p. 168°, and $[\alpha]_D^{22}$ +49° (*c*, 4.0 methanol).

The infrared spectrum of the product resembled that of the corresponding L-serine derivative (1*j*) showing absorption bands due to amide at 1675 cm^{-1} and carbonyl of *O*-acetyl at 1750 cm^{-1}. The "fingerprint" regions of the spectra were also similar, with peaks at 1375, 1250, 1058, and 695 cm^{-1}.

(d) N-(N-Carbobenzoxyglycyl)-D-glucosamine

N-(*N*-Carbobenzoxyglycyl)-1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine (0.5 g) in dry methanol (10 ml) was treated with 0.4 *N* barium methylate (1 ml) at −5° for 20 hours and the deacetylated product was isolated as described for (1*k*), as crystals (0.2 g) which had m.p. 188° and $[\alpha]_D^{24}$ +39.5° (*c*, 4.0 methanol).

(e) N-(Glycyl hydrochloride)-D-glucosamine

N-(*N*-Carbobenzoxyglycyl)-D-glucosamine (0.15 g), dissolved in dioxan/water mixture (1:1 v/v) containing palladized charcoal (0.1 g), was placed under a slight pressure of hydrogen (2 lb above atmospheric pressure) and shaken for 24 hours. Hydrochloric acid (1 ml, 10%) was added to the mixture, the charcoal removed by filtration, and the filtrate was concentrated *in vacuo* to a syrup. The syrup was dissolved in hot ethanol from which the product was obtained as crystals (70 mg) which had m.p. 172° and $[\alpha]_D^{23}$ +31.5° (*c*, 1.0 water). Reported constants (8) for the product obtained by a different route are: m.p. 170° and $[\alpha]_D^{18}$ +29.7° (water).

The product was detected on paper chromatograms, developed in the neutral solvent system, by the ninhydrin and silver nitrate spray reagents as a single spot which had $R_{GN.HCl}$ 0.53.

(f) N-Glycyl-D-glucosamine

Attempts to remove the carbobenzoxy group from *N*-(*N*-carbobenzoxyglycyl)-1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine and *N*-(*N*-carbobenzoxyglycyl)-D-glucosamine by hydrogenolysis in neutral solution, to form the free base, failed owing to the rapid decomposition of the product when it was exposed to the atmosphere. Attempts were made to deionize the salt (2*e*) with Amberlite IR 45($CO_3^=$) exchange resin but the product decomposed immediately on isolation.

3. N-L-Glutamyl-D-glucosamine

(a) N-Carbobenzoxy-L-glutamic Acid

L-Glutamic acid (25 g) was treated with 75% carbobenzoxychloride in toluene (44 ml) according to the procedure of Moore *et al.* (14), to give the crystalline product (51 g; 95% yield), which had m.p. 124°.

(b) N-Carbobenzoxy-L-glutamic Acid Di-p-nitrophenyl Ester

The ester was prepared by treating *N*-carbobenzoxy-L-glutamic acid (21 g) dissolved in ethyl acetate (200 ml) with *p*-nitrophenol (26 g) and dicyclohexylcarbodiimide (32 g) for 30 minutes at 0°. The reaction mixture was then kept at room temperature for 1 hour, the precipitated dicyclohexyl urea by-product was filtered off, and the filtrate was concentrated to a syrup which was dissolved in hot ethanol. On cooling, the crystalline product was obtained (21 g), which had m.p. 210° and $[\alpha]_D^{23}$ +17.1° (*c*, 4.0 benzene).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The infrared spectrum of the product showed no absorption due to hydroxy group, but showed bands due to the *p*-nitrophenyl group at 1775, 1540, 1500, 1355, and 1135 cm^{-1}.

(c) N-Carbobenzoxy-γ-L-glutamide α-p-Nitrophenyl Ester

The diester (3*b*) (10 g) dissolved in benzene/methanol mixture (100 ml; 1:1 v/v) was treated with the calculated amount of *N* methanolic ammonia, sufficient to react with one ester group, and the solution was allowed to stand overnight at room temperature. A small amount of precipitated material, identified as the diamide derivative, was removed and on the addition of benzene the crystalline monoamide was obtained (4.6 g; 60% yield) which after recrystallization from methanol had m.p. 158° and $[\alpha]_D^{21}$ −25.1° (*c*, 4.0 DMF). Anal. Found: N, 10.6%. $C_{19}H_{19}O_7N_3$ requires: N, 10.5%.

(d) 1-(1′,3′,4′,6′-Tetra-O-acetyl-β-D-glucosaminyl)-2-N-carbobenzoxy-L-glutamine

1,3,4,6-Tetra-*O*-acetyl-β-D-glucosamine hydrobromide (0.4 g) and the monoamide ester (3*c*) (0.4 g) dissolved in dimethylformamide (2 ml) were treated with excess triethylamine (0.2 g) at 95° for 20 minutes and the reaction mixture was then cooled to room temperature. Ether (4 ml) was added to precipitate the triethylamine hydrobromide which was removed by filtration, and the filtrate was then washed with *N* hydrochloric acid (3×20 ml) followed by water until the yellow color due to *p*-nitrophenol was removed. An ethanol solution of the product, diluted with chloroform, was dried (anhyd. sodium sulphate) and concentrated to a syrup which was dissolved in ethyl acetate and ether was added. The product was obtained as crystals (0.23 g) from the cooled solution which had, after recrystallization from ethanol, m.p. 178° and $[\alpha]_D^{20}$ −6.0° (*c*, 4.0 pyridine). The infrared spectrum of the product showed absorption bands in common with the D-glucosamine reactant at 1750, 1480, 1250, and 1050 cm^{-1}, and in common with the substituted amino acid at 3360, 1650, 1530, 1460, 1090, 1050, 900, and 695 cm^{-1}. The characteristic *p*-nitrophenyl bands were absent.

(e) 1-(1′,3′,4′,6′-Tetra-O-acetyl-β-D-glucosaminyl)-2-N-carbobenzoxy-L-glutamic Acid

The condensation product (3*d*) (50 mg) was treated with an excess of nitrous acid and when the reaction had subsided the solution was diluted with water and extracted with chloroform (3×10 ml). The dried (anhyd. sodium sulphate) chloroform extract was concentrated to a syrup (41 mg) which was purified by cellulose column partition chromatography using 1-butanol half saturated with water as the mobile phase. The final product (30 mg), obtained crystalline from ethanol solution, had m.p. 218° (decomp.) and $[\alpha]_D^{18}$ −7.4° (*c*, 2.0 pyridine).

(f) 1-(N-D-Glucosaminyl)-2-N-carbobenzoxy-L-glutamic Acid

The compound (3*e*) (30 mg) was treated with barium methoxide in the usual way to yield the deacetylated product (9 mg), which had m.p. 184°, and $[\alpha]_D^{18}$ +70° (*c*, 1.0 pyridine).

(g) 1-(N-D-Glucosaminyl)-L-glutamic Acid Hydrochloride

The deacetylated product (3*f*) (63 mg) dissolved in aqueous methanol (4 ml) containing 2 *N* hydrochloric acid (2 ml) was reduced with hydrogen in the presence of palladized charcoal as described for (1*l*). The product, crystallized from ethanol – light petroleum (b.p. 60–80°) mixture (30 mg), had $[\alpha]_D^{24}$ +14.1° (*c*, 1.5 water) and decomposed above 200°. Anal. Found: C, 37.9; H, 6.2; N, 8.0; Cl, 10.0%. $C_{11}H_{21}N_2O_8Cl$ requires: C, 38.3; H, 6.1; N, 8.1; Cl, 10.3%.

*4. 1-O-β-*L*-Seryl-N-acetyl-*D*-glucosaminide*

*(a) 1-Chloro-1-deoxy-N-acetyl-3,4,6-tri-O-acetyl-α-*D*-glucosamine*

The compound was prepared in 25% yield by the method of Inouye (18) and his co-workers. It had m.p. 124° and $[\alpha]_D^{25}$ +116° (*c*, 4.0 chloroform).

*(b) N-Carbobenzoxy-*L*-seryl Methyl Ester*

The methyl ester was synthesized by the action of diazomethane on the carboxylic acid (20). *N*-Carbobenzoxy-L-serine (8 g) dissolved in an alcohol/ether mixture (50 ml; 1:1 v/v) was treated with a solution of diazomethane (3 g) in ether (100 ml) and after the esterification was completed, the excess diazomethane was removed with hydrogen chloride gas. The solution was deacidified with Duolite A4(OH^-) exchange resin and then concentrated under reduced pressure to give the product as a pale yellow syrup (7 g).

*(c) 1-O-β-(N-Carbobenzoxy-*L*-seryl methyl ester)-N-acetyl-*D*-glucosaminide*

The substituted *O*-glucosaminide was synthesized by the Koenigs and Knorr (17) procedure, followed by deacetylation and hydrogenolysis of the product. Dried samples of 1-chloro-1-deoxy-*N*-acetyl-3,4,6-tri-*O*-acetyl-α-D-glucosamine (3.23 g) and *N*-carbobenzoxy-L-seryl methyl ester (2.5 g) were dissolved in anhydrous alcohol-free chloroform (50 ml) containing Drierite (10 g). Silver oxide (3 g) and iodine (5 mg catalyst) were added and the reaction mixture was shaken in the dark at room temperature for 140 hours. The insoluble material was removed by filtration through a Celite pad, the residue washed with chloroform, and the combined filtrate and washings were concentrated to a syrup. Paper chromatographic examination of the syrup in the neutral solvent system revealed the product as the major component having R_{GNAc} 3.2. The syrup was fractionated by cellulose column partition chromatography using 1-butanol half saturated with water as the mobile phase to give the chromatographically pure product (1.78 g) as a syrup which could not be crystallized. The product was deacetylated in absolute methanol (30 ml) containing 0.4 *N* barium methylate (2 ml) for 22 hours at −5°. The syrupy product (0.94 g) was found by paper chromatography to contain the required compound, which had R_{GNAc} 1.88, and *N*-acetylglucosamine. The faster-moving component was isolated by cellulose column partition chromatography using 1-butanol half saturated with water as the mobile phase. The product was crystallized from ethanol/light petroleum (b.p. 60–80°) mixture (219 mg). It had R_{GNAc} 1.89 and R_{GNDAc} 0.50, m.p. 133° and $[\alpha]_D^{23}$ +6.4° (*c*, 10 ethanol).

*(d) 1-O-β-(*L*-Seryl methyl ester)-N-acetyl-*D*-glucosaminide*

1-*O*-β-(*N*-Carbobenzoxy-L-seryl methyl ester)-*N*-acetyl-D-glucosaminide (140 mg) dissolved in aqueous ethanol (4 ml) containing palladized charcoal (200 mg), was placed under a slight pressure of hydrogen and shaken for 24 hours. The charcoal was removed by filtration and the filtrate was concentrated to a syrup (100 mg) which was shown by paper chromatography to contain the product contaminated with *N*-acetylglucosamine. The syrup was fractionated by chromatography on large sheets of Whatman 3MM paper in the neutral solvent system to give the pure derivative (60 mg) which had $R_{GN.HCl}$ 0.28, m.p. 230° (decomp.) and $[\alpha]_D^{24}$ +1.7° (*c*, 1.0 methanol).

The substituted D-glucosaminide was much more stable in air than the corresponding *N*-peptide.

*(e) 1-O-β-(*L*-Seryl methyl ester hydrochloride)-N-acetyl-*D*-glucosaminide*

1-*O*-β-(*N*-Carbobenzoxy-L-seryl methyl ester)-*N*-acetyl-D-glucosaminide (25 mg) was treated in the cold with 0.1 *N* hydrochloric acid (5 ml) for 6 hours, the excess acid was removed on Duolite A4(OH^-) exchange resin and the solution concentrated to dryness.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The product was twice recrystallized from ethanol/light petroleum (b.p. 60–80°) mixture. Anal. Found: C, 40.5; H, 6.7; N, 8.1; Cl, 9.8%. $C_{12}H_{23}N_2O_8Cl$ requires: C, 40.2; H, 6.4; N, 7.8; Cl, 9.90%.

The infrared spectrum of the product supported the assigned structure and showed absorption peaks at 1750 cm^{-1} due to ester carbonyl, 1610 cm^{-1} due to *N*-acetyl, and an ether-type absorption peak at 1100 cm^{-1}.

*(f) 1-O-β-*L*-Seryl-N-acetyl-*D*-glucosaminide*

The glucosaminide methyl ester (4*d*) (48 mg) dissolved in methanol (0.5 ml) was diluted with water (2 ml) and 0.5 *N* sodium hydroxide solution (3 ml) was slowly added and the saponification was allowed to proceed for 3 hours at room temperature. The solution was made slightly acidic by the addition of 0.1 *N* sulphuric acid (0.24 ml) and the solution was concentrated under reduced pressure. The residue was extracted with methanol from ionic material and the concentrated extract was dissolved in ethanol/light petroleum (b.p. 60–80°) mixture which on cooling gave the crystalline product (27 mg) which had m.p. 236°, and $[\alpha]_D^{24}$ −31.0° (*c*, 1.0 water). Anal. Found: C, 42.85; H, 6.4; N, 9.0%. $C_{11}H_{20}N_2O_8$ requires: C, 42.9; H, 6.5; N, 9.1%.

The infrared absorption spectrum of the product showed no absorption peak due to ester group at 1750 cm^{-1} but the strong absorption band at 1610 cm^{-1} due to *N*-acetyl was present.

DISCUSSION

The object of this investigation was to determine the properties of D-glucosamine derivatives of some amino acids, particularly their stability in solution.

The prepared derivatives were dissolved in acidic media in order to investigate their behavior under conditions of acid hydrolysis. The *N*-peptide hydrochlorides were found to be unaffected by *N* hydrochloric acid at 60° for 24 hours, but the 1-*O*-β-L-seryl-D-glucosaminide gave L-serine, *N*-acetyl-D-glucosamine, and D-glucosamine after 1 hour under the same conditions.

The *N*-peptides were stable in neutral or basic media but degraded rapidly in the presence of air, and immediately upon isolation. It is apparent that the *N*-peptides may only be obtained as their salts, from acid media, whereas the D-glucosaminides examined are relatively unstable in acid solution and should be separated only from neutral or basic media.

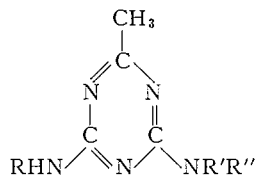
GUANIDINE COMPOUNDS



IV. ACETYLATION OF SOME ALKYL-SUBSTITUTED GUANIDINES WITH ACETIC ANHYDRIDE AND ETHYL ACETATE[1,2]

R. GREENHALGH AND R. A. B. BANNARD

ABSTRACT

The acetylation of some mono-, N,N-, and N,N′-dialkylguanidines was studied using ethyl acetate and acetic anhydride. Except for the N,N-dialkylguanidines, the action of ethyl acetate on the free bases gave monoacetyl derivatives. Acetic anhydride with the acetate salts gave diacetyl derivatives with monoalkylguanidines, acetamido-1,3,5-triazines with N,N-dialkylguanidines, and unstable di- and tri-acetyl derivatives with N,N′-dialkylguanidines. The assignment of symmetrical structures to the mono- and tri-acetyl derivatives and an asymmetrical structure to the diacetyl derivatives was supported by nuclear magnetic resonance spectra. The ultraviolet spectra of the monoacetyl derivatives exhibited one peak in the region 230–235 mμ whilst the diacetyl derivatives showed two peaks in the regions 220–230 mμ and 253–263 mμ. Some comments are made on the infrared spectra of these compounds.

In an earlier paper in this series Cockburn and Bannard (1) reported the formation of amino- (I) and acetamido-*s*-triazines (II) on acetylation of alkylguanidine salts under vigorous conditions.

I. R = H; R′, R″ = H or alkyl
II. R = CH_3CO; R′, R″ = H or alkyl
III. R = CH_3CO; R′, R″ = CH_3

Ryabinin (2) had previously shown that the products obtained on acetylation of guanidine acetate were dependent on the conditions used. Under mild conditions, an acetylated guanidine derivative was obtained rather than an *s*-triazine derivative. The present study, in which the acetylation of several mono-, N,N-, and N,N′-dialkylguanidines with ethyl acetate and acetic anhydride was examined, revealed that the type of alkyl substitution also influenced the product obtained. The opportunity was taken to examine the infrared and ultraviolet spectra of the acetylated guanidines isolated.

Various conditions for the acetylation of *trans*-2-guanidocyclohexanol with acetic anhydride were examined to determine which gave the highest yield of acetylated products. The addition of sodium acetate did not influence the yields and was therefore omitted, since it merely complicated isolation of the products. It was found that a shorter time of heating at 100° than that previously employed for the acetylation of guanidine (3) was beneficial, since even the relatively stable diacetyl derivatives were degraded or cyclized on prolonged heating with acetic anhydride at this temperature.

[2]*Part III, Can. J. Chem.* **37**, *1810 (1959).*

The use of the readily soluble acetate salts rather than the more insoluble hydrochlorides, nitrates, or sulphates enabled a reaction period of 30 minutes to be used.

Acetylation of the monoalkylguanidines under these conditions gave the diacetyl derivatives in yields exceeding 79%, together with small amounts of the corresponding acetylated amino compounds. The latter products were shown to result from degradation of the diacetyl derivatives by acetic anhydride, since on warming of diacetyl cyclohexylguanidine for 1 hour at 100° with acetic anhydride, acetyl cyclohexylamine was isolated in 50% yield.

The N,N-dialkylguanidines gave, in general, acetamido-*s*-triazines, although in the case of N,N-dimethylguanidine a diacetyl derivative was also isolated. The results given in Table I show that the amount of diacetyl derivative (IV) decreases as the amount of acetamido-*s*-triazine (III) increases when the heating period is prolonged. It thus appears that diacetyl derivatives are intermediates in the formation of triazines from N,N-dialkylguanidines. This behavior contrasts with that of the diacetyl derivatives of the monoalkylguanidines, which, on being heated with acetic anhydride, are degraded rather than cyclized. The formation of triazines from monoalkylguanidine acetates or monoacetyl derivatives has been reported (4) but more drastic conditions were involved (0.5 hour at 200°).

TABLE I

Variation of product composition on heating N,N-dimethylguanidine with acetic anhydride at 100° for various periods of time

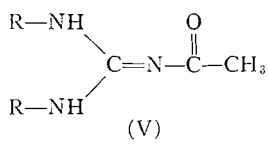
Heating period (min)	Percentage yield of products	
	III	IV
15	24	46
30	32	31
60	49	23

NOTE: III = 2-dimethylamino-4-acetamido-6-methyl-1,3,5-triazine. IV = diacetyl N,N-dimethylguanidine.

With N,N′-dialkylguanidines, the products obtained were very dependent on the individual structure of the guanidine. Both six-membered ring compounds gave unstable diacetyl derivatives which could only be isolated by vacuum distillation. Attempts to purify them by chromatography on alumina, or recrystallization from alcohol gave the more stable monoacetyl derivatives. N,N′-Dimethylguanidine together with 2-iminoimidazolidine gave compounds whose analysis indicated a triacetyl derivative. Because of the peculiar spectral and chemical properties of triacetyl 2-iminoimidazolidine it is discussed more fully later in the paper.

Acetylation of alkylguanidines with ethyl acetate was studied with the object of preparing monoacetyl derivatives. Ostrogovich (5) reported the acetylation of aminotriazines by boiling them with ethyl acetate or acetic acid. The reaction most likely occurs by nucleophilic attack of the π electrons of the guanidine on the ester, similar to the mode of action formulated by Gordon *et al.* (6) for the ammonolysis of esters. Simons and Weaver (4) showed that ethyl acetate reacts with monoalkylguanidine free bases in the cold to give the monoacetyl derivatives. We modified their procedure by using Amberlite IRA-400 (OH) resin prepared in absolute alcohol to generate the free base. This procedure had the advantage over the usual one in which the hydrochloride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



is treated with sodium ethoxide in that it gave quantitative conversion to the pure free base, uncontaminated with inorganic material. The type of alkyl substituents again affected the type of product obtained. With the exception of the N,N-dialkylguanidines all the alkylguanidines gave monoacetyl derivatives by this method. Since Angyal and Warburton (7) and Neivelt *et al.* (8) have shown that methyl guanidines, regardless of the type and degree of alkyl substitution have a pK_a greater than 13.4, basicity is obviously not the reason for lack of reactivity. It is interesting to note that 2-imino-5-hydroxyhexahydropyrimidine gave only a mono-N-acetyl derivative, indicating that the method could be used to selectively monoacetylate a guanidine moiety in a molecule also possessing a hydroxyl function. Acetylation of guanidine itself gave a monoacetyl derivative which is still basic (pK_a 8.2) but would not form a diacetyl derivative on further treatment with ethyl acetate.

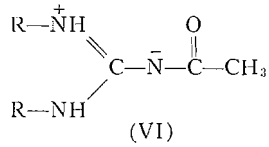


TABLE II

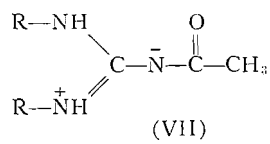
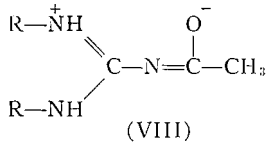
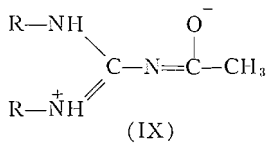


Ultraviolet absorption of monoacetyl guanidines in absolute alcohol



Compound	λ_{max} (mμ)	log ϵ_{max}
Acetyl guanidine	230	4.24
Acetyl methylguanidine	234	4.31
Acetyl cyclohexylguanidine	232	4.30
N-Acetyl guanidocyclohexanol	234	4.26
Acetyl N,N′-dimethylguanidine	234	4.23
Acetyl 2-iminoimidazolidine	230	4.24
Acetyl 2-iminohexahydropyrimidine	234	4.23
Acetyl 2-imino-5-hydroxyhexahydropyrimidine	235	4.31
Acetyl guanidine acetate	230	3.92



The ultraviolet spectra of the monoacetyl guanidines, when measured in ethanol, all exhibit one peak in the range 230–235 mμ as shown in Table II. This absorption is independent of the type of alkyl substitution possessed by the guanidine moiety. A similar observation was reported by McKay *et al.* (9) for alkyl nitroguanidines.

(V)

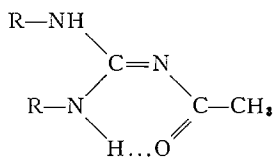
(VI)

(VII)

(VIII)

(IX)

Since neither guanidine nor primary or secondary amides absorb strongly above 210 mμ, the absorption indicates conjugation of the acetyl carbonyl group with the guanidine moiety. It was therefore concluded that monoacetyl guanidines exist in the acetylimino form (V, R = alkyl or H) and this was confirmed in the case of acetyl 2-iminoimidazolidine by measurement of its nuclear magnetic resonance spectrum.



Some contribution to the structure from the other canonical forms of the guanidine moiety (VI) and (VII), together with a small contribution from forms (VIII) and (IX)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

would also be expected. Bryden *et al.* (10), from crystallographic studies, showed this to be the case for nitroguanidine, which is best formulated as a resonance hybrid which combines both the forms postulated by McKay *et al.* (9) and by Kirkwood and Wright (11).

The infrared spectra of monoacetyl guanidines would be expected to show two bands in the region 1700–1500 cm^{-1} corresponding to the stretching vibrations of the C=N and the C=O of the acetyl group (amide I (12)). Table III shows the results obtained.

The spectra mainly show one very strong broad band at 1620–1580 cm^{-1} with shoulders on the high and low frequency sides. This strong band is presumably due to the unresolved vibrations of the C=N and C=O groups. Two bands are observed only in the cases of the monoacetyl derivatives of 2-iminoimidazolidine and 2-imino-5-acetoxyhexahydropyrimidine. The stronger band, at 1580 cm^{-1} and 1595 cm^{-1} respectively, was assigned to amide I vibrations, since it is doubtful whether the intensity of the C=N vibration, even though it is known to increase on conjugation (13), would approach that of an amide I. Also, the amide I is known to be more susceptible to displacement than the C=N vibration. The large shift found for the amide I band can be attributed partly to intramolecular hydrogen bonding as shown in X and partly to conjugation. Examination of the spectrum of triacetyl 2-iminoimidazolidine, a compound which contains no NH bond shows a normal amide I vibration with no absorption around 1600 cm^{-1}.

(X)

The second band found in the spectra of both monoacetyl 2-iminoimidazolidine and monoacetyl 2-imino-5-acetoxyhexahydropyrimidine occurs at 1620 cm^{-1} and is assigned to the C=N stretching vibration, the shift to lower frequency resulting from conjugation with the acetyl group. In the literature, the C=N vibration for substituted nitroguanidines is variously assigned, Leiber *et al.* (14) give 1680–1661 cm^{-1}, Randall *et al.* (15) 1695–1639 cm^{-1}, and Kumler (16) 1689–1618 cm^{-1}. Kumler's assignment for the C=N vibration in 2-nitriminoimidazolidine at 1618 cm^{-1} agrees closely with that of the acetyl analogue, but his assignment of a band at 1664 cm^{-1} in nitroguanidine itself seemed high. Monoacetyl guanidine also shows a band at 1660 cm^{-1} which we thought was most likely due to the NH_2 deformation vibrations as suggested by Jones (17) for guanidine. Attempts to deuterate acetyl guanidine resulted in hydrolysis, but deuteration of nitroguanidine caused the band at 1664 cm^{-1} to disappear whilst another band appeared at 1290 cm^{-1}. Hence Kumler's assignment of the 1664 cm^{-1} band in nitroguanidine to the C=N appears to be in error and it must appear at lower frequencies together with the vibration for the nitro group.

The diacetyl guanidines possess characteristic ultraviolet spectra by means of which they can be readily distinguished from mono- or tri-acetyl guanidines. All the diacetyl guanidines show two peaks in the regions 212–225 $m\mu$ and 243–263 $m\mu$ as shown in Table V.

In all cases examined the extinction coefficient of the low wavelength peak was just

about half that for the peak at higher wavelength. Unlike monoacetyl guanidines, alkyl substitution does affect the chromophore for the diacetyl guanidines, resulting in a variation of 13 mμ for the first peak and 20 mμ for the second. The bathochromic shift observed in the ultraviolet spectra in going from mono- to di-acetyl derivatives is compatible with a further lengthening of the π electron path. An asymmetrical structure XI was assigned to the diacetyl derivatives based on nuclear magnetic resonance studies with the diacetyl derivative of 2-iminohexahydropyrimidine.

(XI)

Korndorfer (18) postulated the existence of both symmetrically and asymmetrically substituted diacetyl guanidines. Later Ryabinin (2) established that only one isomer exists, but did not specify which one. The infrared spectra of the diacetyl guanidines also give ample evidence for the asymmetric structure, the results being given in Table IV.

The spectra exhibit a very strong broad band in the region 1620–1585 cm^{-1} together with a strong band in the region 1705–1670 cm^{-1}. The first band is similar to that exhibited by the monoacetyl guanidines and, as in that case, is ascribed to the unresolved stretching frequencies of the C=N and the C=O of the acetylimino group. The second band is assigned to the amide I vibration of the second acetyl group by analogy with the absorption observed for the acetamido group in 6-methyl-2-cyclohexylamino-4-acetamido-1,3,5-triazine at 1680 cm^{-1}, 6-methyl-2-dimethylamino-4-acetamido-1,3,5-triazine at 1685 cm^{-1}, and 6-methyl-2-piperidino-4-acetamido-1,3,5-triazine at 1690 cm^{-1}. The shift to higher frequencies of the amide I band of the second acetyl group is expected, since Richards and Thompson (19) showed that substitution of an amide nitrogen with an electrophilic group produces this effect. We found the amide I band above 1700 cm^{-1}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

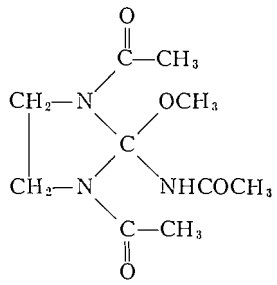
if the second acetyl group is present as a secondary amide and below if present as a tertiary amide, e.g. diacetyl N,N-dimethylguanidine absorbs at 1705 cm^{-1} (KBr) and diacetyl hexahydropyrimidine at 1670 cm^{-1} (KBr). Since the main difference between the amides is in the nature of the third group attached to the amide nitrogen, i.e. either a hydrogen or an alkyl group, the spectral data can be explained in terms of the electron-donating power of the third group. The alkyl group is able to contribute a greater share of its electrons to the amide nitrogen than the hydrogen, thus reducing the demand placed on the nitrogen by the acetyl and acetylimino groups. Hence the increase in frequency is not as great for the tertiary amide. In diacetyl guanidines possessing a secondary amide group, a third band in the range 1575–1560 cm^{-1} is found, due to the amide II vibration.

The ultraviolet spectra of the triacetyl derivatives obtained from N,N′-dimethylguanidine and 2-iminoimidazolidine were similar, showing only one peak at 232 $m\mu$ and 234 $m\mu$ respectively. This absorption is similar to that obtained with the monoacetyl derivatives, although it seems unlikely that the same chromophore is involved. The infrared spectra showed no absorption above 3000 cm^{-1} or near 1600 cm^{-1} in either case, and this was interpreted as evidence for intramolecular hydrogen bonding between the N—H and acetylimino groups in mono- and di-acetyl guanidines. The spectra differed in that triacetyl N,N′-dimethylguanidine shows two strong bands at 1690 and 1620 cm^{-1} (film), whereas triacetyl 2-iminoimidazolidine shows three in chloroform solution at 1745, 1690, and 1645 cm^{-1} and four for a KBr pellet at 1725, 1690, 1680, and 1620 cm^{-1}. The band at lowest frequency is thought to be due to the amide I of the non-hydrogen-bonded acetylimino group, whilst bands at 1690 cm^{-1} are due to the amide I of the tertiary amides. The band found at 1745 cm^{-1} (chloroform) and 1725 cm^{-1} (KBr) in triacetyl 2-iminoimidazolidine appears to be associated with the C=N, since it is missing from the methanol adduct of triacetyl 2-iminoimidazolidine where addition has taken place across the C=N bond. Since it is also missing from triacetyl N,N′-dimethylguanidine, it appears to be associated with the cyclic structure. The shift in the amide I frequently observed for the lactam group in ethylene urea from 1652 cm^{-1} to 1752 cm^{-1} (KBr) in the diacetyl ethylene urea lends credence to this idea.



The proof that triacetyl 2-iminoimidazolidine has a symmetrical structure (XII) was obtained from its nuclear magnetic resonance spectrum, which showed three peaks at 3.41, 4.96, and 5.12 p.p.m. upfield from chloroform with relative intensities 4:6:3. The first peak was assigned to the methylene hydrogens and as no splitting was apparent, it was taken as evidence that they were equivalent. The two remaining peaks were assigned to the methyl hydrogens of the acetyl groups, the intensities indicating that two of the three methyl groups were similar. Formation of an addition product on warming of triacetyl 2-iminoimidazolidine with alcohol is of interest in view of the fact that dinitro-2-iminoimidazolidine also exhibits such a property with alcohols and amines (20). The cyclic structure (XIII) was assigned to it on the basis of its analysis and infrared spectrum. The presence of bands at 3142(m), 1650(s), and 1525(m) cm^{-1} (KBr pellet) was taken as indicative of the formation of a secondary amide. The absence of the C=N group was indicated by the stability of the addition product to boiling water, since under these conditions triacetyl 2-iminoimidazolidine readily yields diacetyl ethylene urea.

To summarize, this work has shown that the products obtained on acetylation of alkylguanidines depend on the degree and position of alkyl substitution, as well as the

conditions used. Analogies have been shown to exist between the chemistry of the nitro and acetyl derivatives of alkylguanidines. This is to be expected, since a similarity does exist between the inductive and mesomeric effects of the two groups, although it is of a qualitative nature. However, the extent to which a guanidine moiety is nitrated or acetylated is not necessarily the same, e.g. 2-iminoimidazolidine forms a dinitro (20) but a triacetyl derivative.

(XII)

(XIII)

The difference in reactivity of the five- and six-membered cyclic N,N′-dialkylguanidines on acetylation must be attributed to the effect of the geometry of the ring on the guanidine moiety, since no difference exists in the basicity of these guanidines.

EXPERIMENTAL

All melting points are uncorrected unless otherwise stated. Microanalyses are by Micro-Tech Laboratories, Skokie, Ill., and J. Helie of these laboratories. Ultraviolet spectra were measured on a Cary Model 14 P.M. recording spectrophotometer, while the infrared spectra were measured on a Baird double beam recording spectrophotometer.

Starting Materials

Methylguanidine was purchased from Mann Research Laboratories. Cyclohexylguanidine, 2-guanidocyclohexanol, N,N-dimethylguanidine, guanylpyrrolidine, and guanylpiperidine were prepared from the corresponding amines by the action of 1-guanyl-3,5-dimethylpyrazole nitrate as described by Bannard *et al.* (21). The method of Mold *et al.* (22), employing cyanogen bromide and methylamine, was used to prepare N,N′-dimethylguanidine. Synthesis of 2-iminoimidazolidine, 2-iminohexahydropyrimidine, and 2-imino-5-hydroxyhexahydropyrimidine involved first preparation of the corresponding cyclic nitrimines as described by McKay and Wright (23), followed by treatment of the nitrimines with liquid ammonia as reported by Stefanye and Howard (24). We isolated these compounds as the acetate salts, which are described in Table VI.

All the other alkylguanidines were converted into the acetate salts by ion exchange and dried prior to acetylation with acetic anhydride.

Acetylation of Guanidine Free Bases with Ethyl Acetate

An Amberlite IRA-400 (OH^-) resin column (15 ml) was prepared in the usual manner, then washed for 24 hours with absolute ethanol excluding carbon dioxide. Guanidine hydrochloride (500 mg, 5.2 millimoles) was dissolved in absolute ethanol (15 ml) and the solution passed through the column, after which the column was washed with absolute ethanol, a total of 100 ml eluate being collected. Evaporation of the latter to dryness

in vacuo gave a colorless oil which was dissolved in absolute alcohol (0.5 ml), to which solution freshly distilled ethyl acetate (0.5 ml, 5.2 millimoles) was slowly added. Although colorless crystals formed instantly, the solution was allowed to stand overnight at room temperature before they were filtered off, washed with ethyl acetate/ethanol and finally recrystallized from ethanol/acetone to give 475 mg (89%) of monoacetyl guanidine as colorless prisms, m.p. 188–190°. The compound was characterized by its acetate, m.p. 178–180°, lit. 180° (3), picrate m.p. 237–239°, lit. 238° (2).

All the other monoacetyl derivatives shown in Table VII were prepared in a similar manner.

Acetylation of Guanidine Acetate Salts with Acetic Anhydride

Cyclohexylguanidine

Cyclohexylguanidine hydrochloride (500 mg) was converted to the acetate salt by ion exchange using Amberlite IRA-400 (OAc) resin. The acetate salt was thoroughly dried *in vacuo* (0.05 mm) at room temperature before addition of acetic anhydride (5 ml). The mixture was heated at 100° for 1/2 hour, after which the acetic anhydride was removed *in vacuo* leaving 493 mg of brown oil. The oil was chromatographed on Woelm IV neutral alumina and gave two fractions. Elution with 2:1 hexane/benzene yielded a crystalline material, which, after recrystallization from pentane, gave colorless prisms, m.p. 71–72°, and analyzed for diacetyl cyclohexylguanidine. Calc. for $C_{11}H_{19}O_2N_3$: C, 58.64; H, 8.50; N, 18.65. Found: C, 58.87; H, 8.64; N, 18.36%. Yield: 445 mg (86%). Further elution with ether gave more crystalline material which was recrystallized from ether/pentane yielding fine white needles, m.p. 106–107°, lit. 107° (25), yield 37 mg (10%). Analysis and melting point indicated it to be N-acetyl cyclohexylamine, and this was confirmed by preparation of an authentic sample and comparison of the infrared spectra.

2-Guanidocyclohexanol

2-Guanidocyclohexanol sulphate (500 mg) was acetylated as described above yielding 530 mg of light brown oil which gave two products on chromatography. The first was obtained by elution with 2:1 hexane/benzene, and after recrystallization from pentane yielded colorless crystals, m.p. 69–70°, which analyzed for a triacetyl derivative, the infrared spectrum indicating O,N,N′ substitution. Calc. for $C_{13}H_{21}O_4N_3$: C, 55.11; H, 7.47; N, 14.83. Found: C, 55.04; H, 7.53; N, 14.53%. Yield: 498 mg (79%). The second product which was eluted with 1:1 ether/chloroform, appeared from analysis, infrared spectrum, and m.p. 117–118°, lit. 117° (26), to be O,N-diacetyl *trans*-2-aminocyclohexanol. Yield: 26 mg (5%). Verification was obtained by synthesis of the compound and comparison of the infrared spectra.

N,N-Dimethylguanidine

N,N-Dimethylguanidine sulphate (475 mg) was acetylated as above and the crude material chromatographed on neutral alumina yielding two products. The first product was obtained by elution with 1:1 pentane/benzene and after recrystallization from benzene/ether gave colorless prisms, m.p. 115–117°, which analyzed for 4-acetamido-2-dimethylamino-6-methyl-1,3,5-triazine. Calc. for $C_8H_{13}ON_5$: C, 49.22; H, 6.77; N, 35.88. Found: C, 49.44; H, 6.83; N, 35.83%. Yield: 77 mg (32%). The infrared spectrum was in agreement with this assignment. A second substance was obtained by elution with 2:1 chloroform/ether which gave colorless prisms after recrystallization from methanol/ether, m.p. 176–178°, and analyzed for diacetyl N,N-dimethylguanidine. Calc. for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$C_8H_{13}O_2N_5$: C, 49.11; H, 7.65; N, 24.55. Found: C, 49.24; H, 7.74; N, 24.90%. Yield: 92 mg (31%).

2-Iminoimidazolidine

2-Iminoimidazolidine hydrochloride (500 mg) was acetylated as above and the oily product remaining after removal of the acetic anhydride slowly crystallized. Further recrystallization from acetone gave long white needles, m.p. 141–142°, which, from its analysis, appeared to be triacetyl 2-iminoimidazolidine. Calc. for $C_9H_{13}O_3N_3$: C, 51.17; H, 6.20; N, 19.9; CH_3CO, 61.13. Found: C, 51.25; H, 6.33; N, 19.85; CH_3CO, 60.82%. Yield: 441 mg (51%).

Warming the triacetyl derivative with methanol for 20 minutes at 50° gave a quantitative yield of the methanol adduct, which was recrystallized from the same solvent, giving white rhombohedral crystals, m.p. 165–167°. Calc. for $C_{10}H_{17}O_4N_3$: C, 49.39; H, 7.04; N, 17.28; CH_3CO, 53.60; CH_3O, 12.77. Found: C, 49.56; H, 7.00; N, 17.06; CH_3CO, 53.63; CH_3O, 12.43%.

2-Iminohexahydropyrimidine

2-Iminohexahydropyrimidine acetate (500 mg) on acetylation under the usual conditions gave an oily product which distilled at 105–110° at 0.01 mm, giving a clear oil which slowly crystallized. Recrystallization from pentane/ether gave colorless thick prisms, m.p. 61–63°, which after drying *in vacuo* analyzed for diacetyl 2-iminohexahydropyrimidine. Calc. for $C_8H_{13}O_2N_3$: C, 52.44; H, 7.15; N, 22.94. Found: C, 52.70; H, 6.91; N, 22.61%. Yield: 371 mg (65%).

Attempts to chromatograph the crude product on neutral alumina or to recrystallize the diacetyl derivative from solvents containing alcohol led to the isolation of monoacetyl 2-iminohexahydropyrimidine, m.p. 187–189°, identified by its infrared spectrum.

2-Imino-5-hydroxyhexahydropyrimidine

The acetate salt (500 mg) was acetylated in the usual manner giving an oily product which distilled at 115–125° at 0.01 mm. The oil crystallized from pentane/ether giving fine white needles, m.p. 117–119°, which analyzed for a triacetyl derivative, with the infrared spectrum indicating O,N,N′ substitution. Calc. for $C_{10}H_{15}O_4N_3$: C, 49.78; H, 6.27; N, 17.42. Found: C, 49.49; H, 6.92; N, 17.62%. Yield: 325 mg (57%).

Recrystallization of the triacetyl derivative from solvents containing alcohol, or chromatography on alumina, caused decomposition. The resulting product could be purified either by sublimation *in vacuo* at 140–150° at 0.01 mm or by recrystallization from methanol/ether, which gave white microprisms, m.p. 230–232°, analyzing for a diacetyl derivative. The infrared spectrum indicated the compound to be the O,N-diacetyl derivative. Calc. for $C_8H_{13}O_3N_3$: C, 48.23; H, 6.58; N, 21.18. Found: C, 48.28; H, 6.53; N, 21.40%.

Methylguanidine

Methylguanidine acetate (500 mg) was acetylated at 100° for only 15 minutes, and the oily product was chromatographed on neutral alumina. Elution with benzene, followed by recrystallization from ether/pentane furnished colorless thick needles, m.p. 80–82°, analysis of which indicated diacetyl methylguanidine. Calc. for $C_6H_{11}O_2N_3$: C, 45.85; H, 7.05; N, 26.74. Found: C, 46.15; H, 6.91; N, 26.99%. Yield: 289 mg (49%). Further elution with 1:1 chloroform/benzene gave a solid, which, after recrystallization from methanol/ether, had m.p. 158–160° and was identified as monoacetyl methylguanidine by comparison of infrared spectra. Yield: 53 mg (12%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Guanylpiperidine

Guanylpiperidine hydrochloride (500 mg) was converted to the acetate salt by ion exchange, after which it was acetylated with excess acetic anhydride for 30 minutes at 100°. The resulting yellowish oil was chromatographed on Woelm IV neutral alumina yielding only one product which was eluted with 1:1 pentane/ether and gave colorless crystals, m.p. 147–148°, from acetone/hexane. Comparison of its infrared spectrum with that of an authentic sample (1) together with its analysis proved it to be 4-acetamido-6-methyl-2-piperidino-1,3,5-triazine. Yield: 202 mg (56%).

Guanylpyrrolidine

Guanylpyrrolidine acetate (500 mg) was acetylated as described above producing a dark red oil together with some crystals. Treatment with cold acetone removed the oil leaving yellow needle-like crystals, which after recrystallization from methanol/ether had m.p. 173–175° and analyzed for 4-acetamido-6-methyl-2-pyrrolidino-1,3,5-triazine. Calc. for $C_{10}H_{15}ON_5$: C, 54.28; H, 6.83; N, 31.66. Found: C, 54.40; H, 6.25; N, 31.38%. Yield: 203 mg (67%).

N,N'-Dimethylguanidine

Dimethylguanidine acetate (500 mg) was acetylated in the usual manner, giving a clear oily product. Chromatography on neutral alumina caused decomposition so the product was purified by distillation at 100–110° at 0.05 mm, giving a colorless oil which analyzed for the triacetyl derivative. Calc. for $C_9H_{15}O_3N_3$: C, 50.69; H, 7.09; N, 19.71. Found: C, 50.39; H, 7.32; N, 19.92%. (λ_{max} 234 mμ, log ϵ 4.2.) Yield: 444 mg (61%).

ACKNOWLEDGMENTS

We are indebted to Miss S. Head and Mr. R. Gravelle for the ultraviolet and infrared spectra and to Miss M. Green for assistance with the experimental work. Finally we also express our gratitude to Dr. M. A. Weinberger for the nuclear magnetic resonance spectra and their interpretation.

CO-ORDINATION COMPOUNDS OF NICKEL (II)

PART II. NEW SPECIES OF NICKEL (II) – SALICYLALDIMINE COMPLEXES[1]

H. C. Clark and R. J. O'Brien

ABSTRACT

The preparation of two solid paramagnetic forms, one light green and the other buff-colored, of bis-N-methyl-5-chloro-salicylaldimine nickel (II) is reported. Their magnetic and spectral properties are correlated with those of solutions of the originally diamagnetic complex, and it is concluded that in both of these species and also in some of the solutions association of the complex occurs. On this basis a general explanation of the properties of bis-N-alkyl-salicylaldimine nickel (II) complexes is given.

INTRODUCTION

The ability of certain nickel (II) – salicylaldimine complexes, which are diamagnetic as solids, to become paramagnetic when dissolved in organic solvents has been examined by many workers (1–4). As indicated in the first paper of this series (5), several different explanations have been proposed. The earliest suggestion (1) was that in non-co-ordinating solvents such as chloroform, a temperature-dependent, partial conversion from a square planar to a tetrahedral configuration occurred. Later views required either the formation of distorted octahedral species as a result of solvent interaction, or a sufficient modification of the crystal field to give essentially a paramagnetic square planar form.

Recent work has ruled out any possibility that the complexes assume tetrahedral configurations. Dielectric polarization measurements (6) give values of the dipole moments which are too low for tetrahedral forms, and also the spectra of the salicylaldimine complexes (1–5, 7) show no similarities to those of known tetrahedral nickel (II) complexes (8, 9). That paramagnetism may arise from solvent interaction with the square planar complexes to give a distorted octahedral configuration has been concluded by Maki (10) on the basis of detailed quantum mechanical calculations. With a suitable choice of parameters, this approach appears to explain satisfactorily the spectra both of the solid complexes and of their solutions. However, Maki's interpretation of the solution paramagnetism is really based on calculations of the distribution of the planar molecules between singlet and triplet states, between which a small, temperature-dependent energy separation is produced by an axial perturbation of the molecule. Such a situation may result from any suitable axial perturbation, of which solvent interaction is just one possibility. Moreover, if solvent interaction occurred in all solvents, one might expect there to be some correlation between the base strength of the solvent and the degree of occupation of the triplet state. Magnetic measurements of a series of bis-N-alkyl-salicyl-aldimine nickel (II) complexes in various solvents (4) show no relation between base strength of the solvent and the degree of paramagnetism. Also, bis-N-methyl-salicyl-aldimine nickel (II) can be converted to a buff-colored, paramagnetic form on heating to 180° (11, 12) in the complete absence of solvent. Although the very low solubility of this form, as well as its color, suggest that it is not the species responsible for solution paramagnetism, it is clear that solvent interaction is not necessary to produce paramagnetism. The low solubility has been taken (12) as an indication that this species is an associated form of the planar complex, association possibly occurring through Ni—O intermolecular links.

Ballhausen and Liehr (13) have also examined the problem theoretically and have concluded that paramagnetism may result from a decrease in the effective crystalline field seen by the complexes on melting, or on dissolution in "non-complexing" solvents.

[1]*Manuscript received December 12, 1960.*

Such a decrease may well lower the splitting between the low-lying singlet and triplet states so that $h\nu$ is comparable with thermal energies. In this event the complex will show paramagnetism, and these authors presented an equation which would describe such a system. This is a general equation of state describing the thermal distribution of electrons between two energy levels. Although the application of this equation to the results of some magnetic measurements (14) leads to reasonable values of the energy separation between the two levels, this does not "prove" the equation nor is it possible to draw any conclusions from these measurements as to the true state of co-ordination of the nickel atoms in this situation.

There is general agreement, then, that the partial paramagnetism of the nickel (II) – salicylaldimine complexes arises from a distribution between singlet and triplet states, but there is still no agreement as to the geometry of the paramagnetic species. The occurrence of paramagnetism in the absence of a solvent is attributed to association giving an octahedral configuration about the Ni (II) atoms. Ferguson (15) has very recently found that spectroscopic and molecular weight studies of benzene and chloroform solutions of bis-N-methyl-salicylaldimine nickel (II) show that associated forms are present at the concentrations at which partial paramagnetism is observed. Hence the axial perturbation of the planar complex, causing a thermal distribution between singlet and triplet states, may be due to association of the molecules in "non-complexing" solvents, rather than to direct solvent interaction. With this in mind, it seemed worth while to attempt to isolate paramagnetic species from solutions of these complexes, and also to investigate the formation of paramagnetic species by heating of the solid complexes.

EXPERIMENTAL

Of 14 complexes prepared and studied, only three showed interesting features. They were bis-N-methyl-salicylaldimine nickel (II) and its 5-chloro and 5-bromo analogues; their preparation has been described previously (5).

The species of bis-N-methyl-5-chloro-salicylaldimine nickel (II) obtained were as follows.

(i) On heating the dark green diamagnetic complex (A) at 165° for 30 minutes, conversion to a light green form (B) occurred. This was very soluble in organic solvents, and paramagnetic. Values of the molar susceptibility at temperatures in the range 80° to 298° K are listed in Table I, and the resultant plot of $1/\chi_M$ versus T_1 gives a value of

TABLE I
Corrected molar susceptibilities $\times 10^6$ c.g.s. units

Temperature (°K)		110	177	231	298
Species (B)		19080	8950	5965	4606
Temperature (°K)	80	118	157	221	298
Species (C)	20370	12910	9489	6606	4909
Temperature (°K)	81	104	151	208	298
Species (G)	18650	13550	8905	6389	4494

NOTE: Species (G) = buff-colored form of bis-N-methyl-salicylaldimine nickel (II).

+72° for the molecular field constant, whence the effective magnetic moment at 25° is 2.90 Bohr magnetons. That this product has the same composition as the original compound was shown by analysis. (Found: Ni, 14.46; N, 6.89; C, 48.51; H, 3.41. Calc. for $NiC_{16}H_{14}O_2N_2Cl_2$: Ni, 14.83; N, 7.07; C, 48.51; H, 3.56%.)

(ii) Exposure to temperatures of 200–205° for 4 hours, or considerably longer periods at 170°, converted bis-N-methyl-5-chloro-salicylaldimine nickel (II) into a buff-colored

solid (C) almost insoluble in all common organic solvents. The values of molar magnetic susceptibilities over a temperature range are also shown in Table I, from which the molecular field constant is found to be $+10°$ and $\mu_{(eff)}$ (25°) = 3.38 Bohr magnetons.

Analysis showed it to have the same empirical formula as both the original compound (A) and the light green form (B). (Found: Ni, 14.22; N, 7.17. Calc. for Ni $C_{16}H_{14}O_2N_2Cl_2$: Ni, 14.83; N, 7.07%.)

(iii) Since earlier magnetic measurements (2, 3) have shown that the paramagnetism of this type of complex in chloroform solution approaches the normal value for two unpaired electrons as the temperature is lowered towards −78°, such solutions provide an alternative means of isolating paramagnetic species. Repeated partial freezing of chloroform solutions of bis-N-methyl-5-chloro-salicylaldimine nickel (II) in solid CO_2–ethanol mixtures, followed by decantation of the concentrated solution from the solid chloroform, eventually caused precipitation of a light green species (D), quite different in properties from the original form (A). The same product was obtained by the removal of the solvent under vacuum from a cooled (−46° to −64°) chloroform solution, or by precipitation from a cooled chloroform solution by the addition of ligroin. Each of these procedures gave only small amounts of species (D) which in all instances contained a small amount of the original diamagnetic complex (A). It was therefore not possible to make accurate magnetic measurements, although a measurement at 25° gave a gram susceptibility of 8.3×10^{-6} c.g.s. and therefore an approximate effective magnetic moment of 2.8 Bohr magnetons. Species (D) was not a solvate since there was a negligible weight loss on heating at 100° and conversion to the diamagnetic form (A) occurred.

The positions of the absorption bands in the diffuse reflectance spectra of these various species are listed in Table II together with the bands observed for solutions of bis-N-methyl-salicylaldimine nickel (II) in chloroform and pyridine (10). The diffuse reflectance spectra were kindly determined by Dr. M. C. R. Symons by a procedure previously described (16).

TABLE II

Species	Observed maxima(mμ)			
A	440	620	—	—
B	480 (sh)	630	820 (sh)	ca. 1000
C	420 (sh)	560	780 (sh)	900
D	430 (sh)	610	780 (sh)	ca. 930
A* in $CHCl_3$	490 (sh)	610	(800 (sh)?)	1150
A* in C_5H_5N		570	785 (sh)	960

NOTE: A* = bis-N-methyl-salicylaldimine nickel (II); sh = shoulder.

The X-ray diffraction powder photographs of the various solid species were obtained with a G. E. model XRP-SF11 X-ray diffraction unit. The photographs of species (B) and (D) were very similar in line spacings and relative intensities, although not completely identical. Both were quite different from that of either species (A) or (C). Some slight differences might be expected in the crystal packings of (B) and (D) in view of the very different conditions under which they were obtained.

Previous reports (11, 12) of the effect of heat on bis-N-methyl-salicylaldimine nickel (II) are in disagreement. Harris, Lenzer, and Martin (12) obtained a buff-colored compound, while Sacconi *et al.* (11) reported the isolation of a light green product. An examination of the magnetic measurements of Sacconi's product shows that their original sample was slightly paramagnetic, presumably due to traces of bis-salicylaldehyde nickel (II), which would certainly give the final product a green color. We have found that on

heating a sample of the diamagnetic complex ($\chi_g = -0.307\times10^{-6}$ c.g.s.) to 200° for 2 hours conversion to a paramagnetic, buff-colored product occurred. There was no sign of the formation of any green paramagnetic product in the temperature range 150–210° and our results entirely confirm those of Harris *et al.* Measurements of the magnetic susceptibility are indicated in Table I, and these give a value of 10° for the molecular field constant and hence μ_{eff} (25°) is 3.23 Bohr magnetons in good agreement with the results of Harris *et al.*

Bis-N-methyl-5-bromo-salicylaldimine nickel (II) was converted to a light green form (at 175°) and then to a buff-colored form (at 220°). For both this complex and bis-N-methyl-salicylaldimine nickel (II), light green products were obtained from their chloroform solutions at low temperatures but no detailed studies of these were made. The heating of 14 other nickel (II) – salicylaldimine complexes to 350° for several hours did not cause conversion to other forms, although in certain cases decomposition occurred.

Analyses of nickel were made gravimetrically by precipitation with dimethylglyoxime. Nitrogen was determined by the standard semimicro Kjeldahl method.

Magnetic susceptibilities were measured with a Gouy magnetic balance fitted with a cryostat similar to that described by Figgis and Nyholm (17). The magnetic balance consisted of a Varian 4-in. electromagnet, model V4084, with 2-in. tapered pole caps, in conjunction with a Spoerhaese Model 10 M microbalance with a sensitivity of ±0.01 mg. Current regulation was provided by a Varian Model U 2300 A power supply and Model 2301 A current regulator. The cryostat used for temperature control of the sample is shown in Fig. 1. The general principles of design and the associated electrical circuits

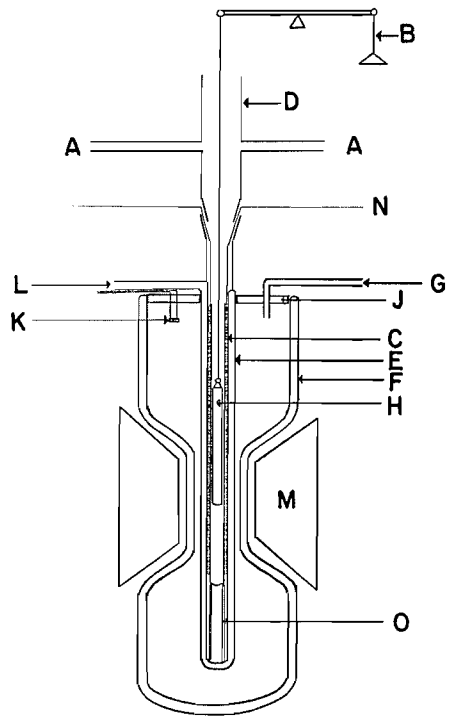

FIG. 1. Cryostat for the magnetic balance. of the cryostat are the same as described by Figgis and Nyholm. With this apparatus, temperatures can be maintained constant at any point in the range 78°–300° K by suitable control of the current passing through the electrical heating coil and of the pressure within the inner Dewar. A device is provided for maintaining constant the level of liquid nitrogen in the outer Dewar. The main modification of Figgis and Nyholm's design is in the shape of the outer Dewar. In our apparatus, the outside diameter of the outer Dewar is only 2.6 cm between the pole caps, compared with 7 cm. This makes it much simpler to obtain a reasonably large homogeneous region of the field and still use tapered pole caps and a shorter sample. Moreover the temperature control is perhaps improved by having a reservoir of refrigerant both above and below the constriction. The sample tube and apparatus were calibrated using mercury (II) cobaltitetrathiocyanate (18) as standard. Magnetic moments were calculated using the formula $\mu = 2.839 \sqrt{\{\chi_M \times (T+\theta)\}}$ Bohr magnetons.

DISCUSSION

The above results indicate the ability of bis-N-methyl-5-chloro-salicylaldimine nickel (II), and its 5-bromo analogue, to become paramagnetic under four sets of conditions, namely (i) heating to 165° to give the light green species (B), (ii) heating to 200–205° to form the buff-colored product (C), (iii) dissolution of the diamagnetic complex in organic solvents, and (iv) separation as a light green species (D) from such solutions in organic solvents. The experimental results show that there is considerable similarity between species (B) and (D). Their absorption spectra are very similar, both in the positions of the bands and in their relative intensities. Their X-ray diffraction powder photographs are also very similar although not quite identical. It is then reasonable to conclude that forms (B) and (D) are identical and also that they are probably identical with the paramagnetic species present in the chloroform solution from which form (D) was obtained. Species (C), the buff-colored product, is quite different from the other forms, as shown by its color, its very low solubility in organic solvents, and its very different diffraction pattern. For bis-N-methyl-salicylaldimine nickel (II), only the buff-colored form was obtained on heating the solid diamagnetic complex, and it seems that quite minor differences in the properties of the complexes determine whether conversion to this buff form will take place directly or through the light green form. In general, it seems a reasonable conclusion that these complexes are capable of existing as diamagnetic species, as green, paramagnetic soluble forms, or as buff-colored paramagnetic insoluble forms. Since both paramagnetic species exist in the absence of solvent, they presumably have distorted octahedral configurations about the nickel atoms as a result of association of the complex molecules. This has already been suggested for the buff form of bis-N-methyl-salicylaldimine nickel (II) (12) and the results of Ferguson, indicating association of the complex in chloroform solution, make it probable also for the green paramagnetic species.

Satisfactory explanations can now be made for all observations of these anomalous complexes. Clearly the paramagnetism of their solutions in strongly co-ordinating solvents such as pyridine results from the formation of octahedral, presumably monomeric species, some of which have been isolated (3, 19). In solvents which are normally considered non-co-ordinating (e.g. chloroform, cyclohexane, carbon tetrachloride), the removal of the crystalline forces which have restrained the molecule in its diamagnetic form, allows association of the complex and a decrease of the energy separation between

singlet and triplet states. Thus, an axial perturbation does occur, not through solvent interaction but rather by association. The same effect occurs on heating the solid when some breakdown of the crystal structure leads to the formation of the same associated green product. These conclusions are consistent with the dielectric polarization measurements (6), with the spectra of the complexes and their solutions (1, 15, 20), and with the magnetic measurements (3, 6).

Sacconi *et al.* (14), from magnetic and viscosity measurements, conclude that there is no evidence for the association of the nickel (II) – N-alkyl-salicylaldimine complexes. They report a practically linear relationship, for bis-N-octyl- and bis-N-nonyl-salicylaldimine nickel (II) in the molten state, between ln η and $1/T$ over a wide temperature range. However, examination of their results shows that while there is certainly linearity for temperatures above about 120° C, below this temperature there are small but definite departures from linearity. Moreover, magnetic measurements of the N-octyl complex in dibutyl phthalate solution (14) show, in a plot of μ versus T, a minimum in μ which is shifted towards higher temperatures and approaches 120° at higher concentration. Both this concentration effect and the non-linearity of viscosity can be explained in terms of association of the complex. It is interesting to note that magnetic measurements (21) of the melts of many of these N-alkyl-salicylaldimine complexes give a minimum value of the magnetic moment at approximately 120° in the plots of μ versus T.

Different effects therefore seem to be occurring below and above 120°. At temperatures below and up to approximately 120°, we conclude that there is a distribution between singlet and triplet states, the small energy separation between these two states being a consequence of association. The degree of association will be concentration dependent and also temperature dependent, so that as the temperature increases towards 120°, the population of the triplet state will decrease. Above approximately 120°, it is possible that the energy separation between the two energy levels may remain practically constant, as suggested by Sacconi *et al.* (14) so that an increase in thermal energy may increase the population of the lowest triplet state. Alternatively the observed increase in magnetic moments (14) for temperatures higher than 120° may be due to conversion to the insoluble buff-colored species. However, this conversion has only been observed for the N-methyl compounds and not for the higher members of the alkyl series.

The question of the manner of association of the complexes cannot be settled unambiguously without complete structure determinations of both the buff-colored and light green paramagnetic species of bis-N-methyl-5-chloro-salicylaldimine nickel (II). The magnetic moments unfortunately do not allow a distinction to be made between tetrahedral and octahedral configurations since although tetrahedral nickel complexes containing four identical ligands have moments of 3.5 Bohr magnetons or higher (9), tetrahedral complexes with several different ligands about the nickel atom are known to have moments of about 3.0 Bohr magnetons (22). However, the large values of the molecular field constant, at least in one case, can be explained as due to distortion from a regular octahedral arrangement and also by the fact that the splitting between the lower triplet and next singlet state is not large. It has already been suggested (12) that the buff-colored species of bis-N-methyl-salicylaldimine nickel (II) is polymeric with a six-covalent arrangement about each nickel atom due to interaction of each such atom with oxygen atoms of the molecules above and below it. If this be accepted, then the associated light green paramagnetic forms may involve interaction between the nitrogen atoms of one molecule with the nickel atoms of other molecules to give an octahedral arrangement. It is also interesting to notice that Ferguson (15) has recently prepare and orthogonal

form of bis-N-methyl-salicylaldimine nickel (II) in which the Ni—Ni distance is 3.30 Å, compared with 5.32 Å in the monoclinic form, emphasizing the possibility of quite close packing of the molecules in associated forms.

ACKNOWLEDGMENTS

A grant from Research Corporation for the purchase of the magnetic balance, and the financial support of the National Research Council is gratefully acknowledged.

ARYLATION OF QUINONES BY DIAZONIUM SALTS

VII. SYNTHESIS AND STRUCTURE OF SOME ARYL-CHLORO-*p*-BENZOQUINONES[1]

JEHANBUX F. BAGLI[2] AND PH. L'ÉCUYER

ABSTRACT

A careful re-examination of the arylation (P. Brassard and P. L'Écuyer. Can. J. Chem. **36**, 814 (1958)) reaction with chlorobenzoquinone[3] has revealed in its products the presence of all the three possible disubstituted isomeric quinones. Arylation using diazotized *p*-nitroaniline has resulted in the isolation of the three new isomeric quinones, whose structures are assigned, based on chemical and spectral evidences. Mechanistic implications in the arylation and halogenation of benzoquinones are discussed.

The Meerwein reaction (2) provides a general method of arylation of activated double bonds, using aryl diazonium salts, in the presence of copper salts as catalysts. Arylation of benzoquinone by diazotized aniline using typical Meerwein conditions (80% acetone–water solvent system, cupric chloride catalyst, and acetate buffer) is found to give crude phenylbenzoquinone in poor yield (<10% of crude product). Modified Meerwein conditions[4] (variation of the solvent system or the type of buffer) have been used for the arylation of benzoquinones. It has been recently (3) demonstrated that excellent yields of monoaryl benzoquinones are obtained by conducting the reaction in a completely aqueous medium, in the presence of an acetate buffer, and without the copper catalyst. An application of the procedure to the arylation of the monosubstituted benzoquinones has also been described (1, 4). However, the latter reactions are complicated by the fact that theoretically three isomers can be formed. The substituent present in the starting quinone and the stability of the diazonium salt are the major factors responsible for influencing the yields of these isomers. The arylation of toluquinone and phenylbenzoquinone with $ArN_2^+Cl^-$ (Ar = *p*-chlorophenyl) yields a single isolable disubstituted benzoquinone in reasonable yield (86% and 43% respectively) as against that of chlorobenzoquinone (1) which gives two isomeric chloro-*p*-chlorophenylbenzoquinones (III*a* and III*c*). The last mentioned result strongly suggests the possibility of the formation of all three isomers in the course of this reaction.

The investigation of the arylation of chlorobenzoquinone was therefore resumed with a view to the preparation of these isomers using benzene, *p*-chlorobenzene, and *p*-nitrobenzene diazonium chlorides as the arylating agents.

In the previous studies (1, 4) and in synthetic studies with benzoquinones in general little or no attempt has been made to use chromatography as a means of separation of the products. The use of ordinary alumina is impeded by the ease with which a molecule of benzoquinone can accept two electrons from a nucleophile to go over to the dianion of the corresponding hydroquinone. We found that such a conversion on acid alumina is slow but nevertheless unavoidable. Silica gel has proved to be a satisfactory adsorbent for the separation of substituted benzoquinones with complete inhibition of reduction on the column. It is of interest to note that the order of elution of the chloro-aryl-

[1]*Manuscript received August 22, 1960.*

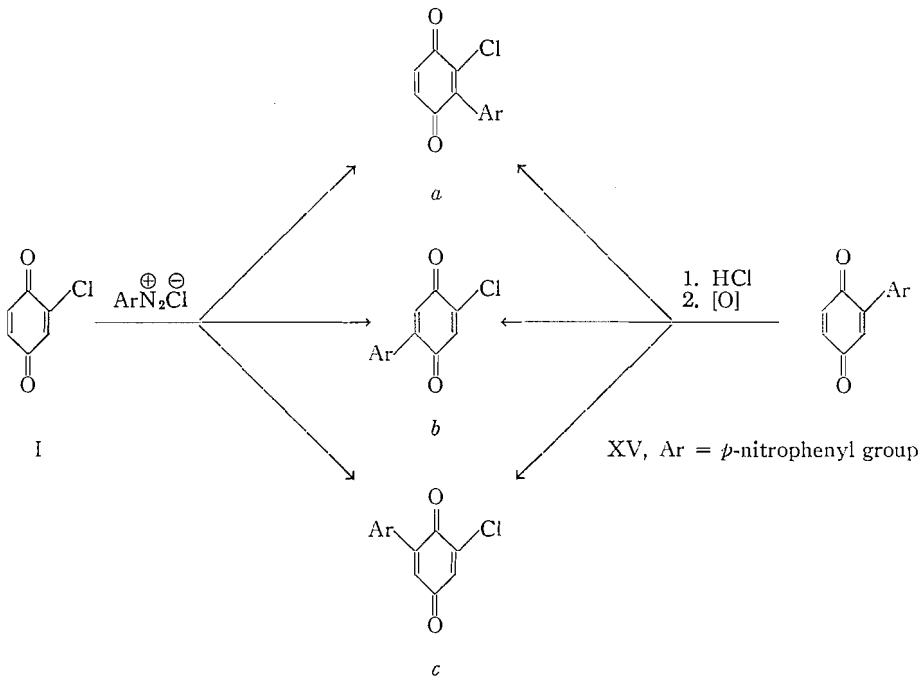
[2]*National Research Council postdoctoral fellow 1959–60.*
[3]*The term "benzoquinone" throughout this publication refers to p-benzoquinone.*
[4]*For earlier references see reference 3.*



benzoquinones from a column bears a definite relationship to their structure. In all the cases studied, the degree of adsorbability of the disubstituted isomers follows the order: 2,3 > 2,6 > 2,5.

RESULTS AND DISCUSSION

Arylation of chlorobenzoquinone (I) (Chart I) with diazotized aniline gives the three isomers: 2-chloro-3-phenylbenzoquinone (II*a*), 2-chloro-5-phenylbenzoquinone (II*b*), and 2-chloro-6-phenylbenzoquinone (II*c*), in contrast to one isomer (II*b*) reported before (1).

CHART I

Arylation of chloroquinone and chlorination–oxidation of quinone XV

I

XV, Ar = *p*-nitrophenyl group

II, III, or IV

II, Ar = phenyl group

III, Ar = *p*-chlorophenyl group

IV, Ar = *p*-nitrophenyl group

Their structures are proven by their unequivocal synthesis (5). From the reaction of *p*-chlorobenzene diazonium chloride with I, besides 2-chloro-3-*p*-chlorophenylbenzoquinone (III*a*) and 2-chloro-6-*p*-chlorophenylbenzoquinone (III*c*) already described (1), the third isomer, 2-chloro-5-*p*-chlorophenylbenzoquinone (III*b*) is also isolated. The structures of all the three isomers of this series are confirmed by their infrared spectra (6).

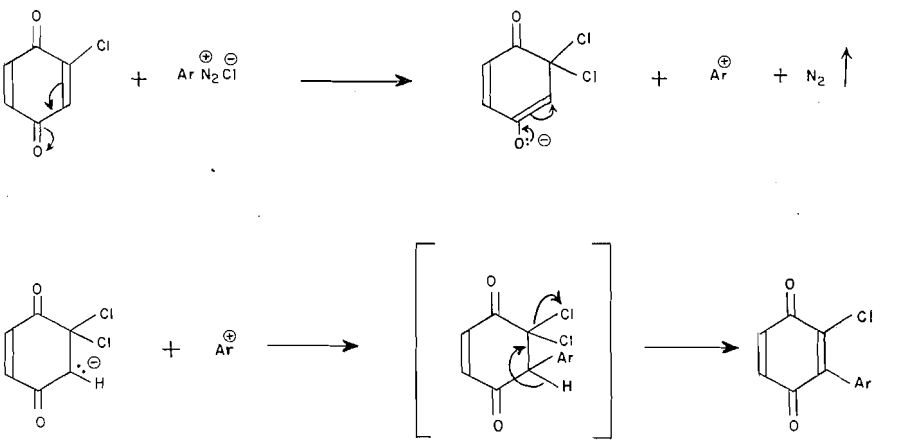
The arylation of I with diazotized *p*-nitroaniline yields three disubstituted benzoquinones: 2-chloro-3-*p*-nitrophenylbenzoquinone (IV*a*), 2-chloro-5-*p*-nitrophenylbenzoquinone (IV*b*), and 2-chloro-6-*p*-nitrophenylbenzoquinone (IV*c*). The same three compounds are also obtained from the chlorination of *p*-nitrophenylbenzoquinone (XV) with concentrated hydrochloric acid, followed by oxidation with ferric chloride. The ratio of the isomers IV*a*, IV*b*, IV*c* obtained from the arylation of chloroquinone is 2:1:1; whereas that of the isomers secured from the chlorination–oxidation of *p*-nitrophenylquinone is about 0.1:2:1. Variation of the conditions for chlorination, e.g. passing dry HCl gas in a benzene or chloroform solution of the quinone XV, gave essentially the same results. The structures of these three isomers are assigned on the basis of their infrared (6) and nuclear magnetic resonance spectra. The N.M.R. spectrum of the compound IV*a* showed a nine-cycle spin coupling between the two adjacent quinoid hydrogen atoms whereas that of compound IV*c* showed a relatively weaker coupling of 2.5 cycles. Benzoquinone IV*b*, on the other hand, does not exhibit spin coupling between the two adjacent quinoid hydrogen atoms.

The above structural assignments are further substantiated by chemical evidence, obtained from the results of chlorination–oxidation experiments with each of these isomers (Chart II). Compound IV*c* on treatment with HCl followed by oxidation yields 2,3-dichloro-6-*p*-nitrophenylbenzoquinone (X) and 2,5-dichloro-3-*p*-nitrophenylbenzoquinone (VIII) in the ratio 1:5. Isomers IV*a* and IV*b* under identical treatment give respectively as a predominant product quinones VIII and X, together with traces of 2,6-dichloro-3-*p*-nitrophenylbenzoquinone (IX) as evidenced by infrared spectra (*vide*: Experimental). Trichloro-5-*p*-nitrophenylbenzoquinone is also isolated in small amounts (10–20%) from the chlorination–oxidation experiments with IV*a*, IV*b*, and IV*c*. Authentic samples of VIII, IX, and X are prepared by coupling diazotized *p*-nitroaniline with the corresponding 2,5-dichlorobenzoquinone (V), 2,6-dichlorobenzoquinone (VI), and 2,3-dichlorobenzoquinone (VII).



Treatment of hydroquinone with bromine as described (18), followed by oxidation with ferric chloride, results in the formation of 2,5-dibromobenzoquinone (XII), 2,3-dibromobenzoquinone (XIII), and tribromobenzoquinone (XIV), which are separated chromatographically.

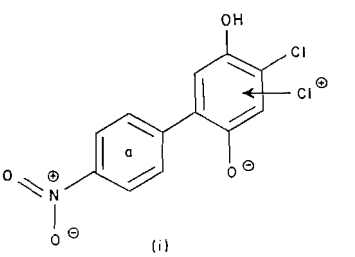
The free radical nature of the Meerwein reaction is conclusively established by the recent work of Kochi (7). The oxidation–reduction capacity of the copper catalyst in presence of acetone is a unique feature of this mechanism. Absence of both the acetone and the copper catalyst makes such a mechanism highly improbable for the arylation under consideration. However, the problem of whether the arylation in the aqueous acidic medium proceeds via a free radical or an ionic pathway is still unresolved.

It is observed (from infrared spectra) that the decomposition of the diazonium salts into phenols and azo compounds according to their stability and the conversion of the quinones into quinhydrones (8) according to their redox potential compete with the main reaction.

It has been demonstrated by DeTar *et al.* (9) that the course of SN_1-type decomposition of the diazonium salts is largely governed by the pH of the mixture. The reaction follows a free radical pathway (10) under basic conditions, in contrast to an ionic pathway in an aqueous acidic medium. In view of these facts, a possible ionic mechanism for

the arylation may be formulated as follows:

Ar = aryl group



The experimental results from the chlorination–oxidation treatment of arylated chloroquinones IV*a*, IV*b*, and IV*c* are noteworthy.

In the predominant product X obtained from 2-chloro-5-*p*-nitrophenylbenzoquinone (IV*b*), the second chlorine atom enters ortho to the first one. On the other hand, in the formation of compound VIII from 2-chloro-6-*p*-nitrophenylbenzoquinone (IV*c*), the second chlorine atom enters ortho to the phenyl group. The substitution therefore seems to be independent of the bulk of the groups present. The generally accepted concept of 1,4 addition (11, 12) of HX (X = Cl or CN) to benzoquinone, by itself fails to explain the variation in the proportions of the isomers obtained from quinones XV, IV*a*, and IV*b*. This concept, however, assumes the prior chlorination of the quinone nucleus followed by aromatization to yield the chlorohydroquinones.

If one assumes that the aromatization of the quinone nucleus by an anion precedes the substitution as suggested by Clark (13) and more recently by Dewar (14), the subsequent substitution will then be governed by the principles of electrophilic aromatic substitution. The formation of compounds VIII and X as a major product from quinones IV*a* and IV*b*, now becomes readily explicable.[5]

The results of chlorination–oxidation of the quinone XV are, however, not explained by this latter view. Thus it seems reasonable that the addition of HX (X = Cl or CN) type reagents to benzoquinones does not involve either one or the other mechanism

[5]*The prior aromatization can generate a transition complex of the type (i) from IV*b*, in which the nitro group can exert its electronic influence through the phenyl ring (a).*

exclusively. It is suggested that both pathways may be operative, depending upon the substituents present on the quinone nucleus and therefore upon the oxidation–reduction potential of the benzoquinone involved.

EXPERIMENTAL

General

All the melting points are uncorrected. Davison grade-923 silica gel (100–200 mesh) and Woelm grade-I acid alumina were used for chromatography. Unless otherwise mentioned, the term pet. ether refers to that fraction of petroleum ether with b.p. 30–60°. Ether extracts were all dried over sodium sulphate and ether always removed under vacuum. All infrared (IR) spectra were recorded with a Beckman IR-4 spectrophotometer using a NaCl prism; and reported spectra were all calibrated by the use of a polystyrene film. Chloroform and carbon disulphide used for IR spectra were ANALAR grade (B. D. H.) and reagent grade (Merck) respectively. Ultraviolet spectra were all recorded with a Beckman DU spectrophotometer using hexane (B. D. H., spectroscopic grade) as a solvent. Unless otherwise stated, diazotization of amines was conducted using amine (1 mole), in approximately 8% hydrochloric acid (3 moles) and adding, to the precooled (0–5°) solution, a concentrated solution of sodium nitrite (1 mole), maintaining the temperature between 0–5°.

Oxidation with ferric chloride was conducted as follows: to a solution of hydroquinone in acetic acid, was added a solution (60%, w/v in water) of ferric chloride. The reaction mixture was heated for about 10 minutes on a steam bath, cooled, and diluted with water. The quinone thus precipitated was collected, washed with water, dried, and recrystallized.

Preparation of Isomeric Chloro-phenylbenzoquinones

A solution of benzene diazonium chloride (from aniline, 4.7 g) was added to a stirred suspension of chlorobenzoquinone (I) (7.15 g) in a solution of sodium acetate (15.3 g) in water (650 ml). The reaction mixture was stirred overnight at room temperature. The oil thus separated was extracted with ether, the ether extract was washed and dried, and the ether was removed. The residue (13 g) was dissolved in pet. ether – benzene (1:1) and chromatographed on acid alumina (390 g). Elution with the same solvent gave first 2-chloro-5-phenylbenzoquinone (II*b*) (1.3 g), which crystallized from ethanol in platelets, m.p. 129–130° (reported m.p. 130–131.5° (15)). Its identity was confirmed by a mixed melting point and IR spectra. Further elution with benzene and a mixture of benzene–ether of gradually increasing polarity up to 50% ether gave an oily eluate (5.4 g). This oil was mixed with the residue from the mother liquor obtained from the first crystallization of II*b* above. The mixture (5.7 g) was dissolved in benzene – pet. ether (33:67) and rechromatographed on acid alumina (174 g). Initial fractions gave more of II*b* (0.61 g). Further elution with the same solvent followed by pure benzene gave unidentified oils (1.73 g). Elution with benzene–ether (98:2) gave an oil (0.82 g) which was rechromatographed on silica gel (65 g). Elution with benzene – pet. ether (1:1) gave a solid (0.42 g) which, after two crystallizations from ethanol, yielded 0.3 g of 2-chloro-6-phenylbenzoquinone (II*c*), m.p. 106–110°. Further purification from the same solvent provided an analytical sample, m.p. 112–113°, ν^{CHCl_3}: 919, 1659, and 1688 cm^{-1}; ν^{CS_2}: 916 (=C—H deformation, on the quinone nucleus), 1656, and 1684 cm^{-1} (=C=O stretching). λ_{max}: 230 mμ (4.37), 300 mμ (3.87), 378 mμ (3.56). Calc. for $C_{12}H_7O_2Cl$ (218.63): C, 65.92; H, 3.21. Found: C, 66.10; H, 3.31. The proof of structure was provided by its unequivocal synthesis (5).

Further elution with the same solvent pair gave an eluate (0.29 g) which crystallized, when triturated with ether at dry-ice temperature. The solid (0.24 g) was dissolved in

benzene – pet. ether (1:3) and passed through silica gel (15 g). The eluate (0.2 g), crystallized from pet. ether (b.p. 65–110°), gave 2-chloro-3-phenylbenzoquinone (II*a*) (0.15 g), m.p. 115–116°. Two more crystallizations provided an analytical sample, m.p. 117–118°, ν^{CHCl_3}: 849, 1683 cm^{-1}; ν^{CS_2}: 844 (=C—H deformation, on quinone nucleus), 1681, 1669 cm^{-1} shoulder (=C=O stretching). λ_{max}: 250 mμ (4.19), 376 mμ (3.32). Calc. for $C_{12}H_7O_2Cl$ (218.63): C, 65.92; H, 3.21. Found: C, 65.95; H, 3.22. The structure of this compound was proved by mixed m.p. and infrared spectra of a sample synthesized by an unequivocal route (5).

Preparation of the Isomeric Chloro-p-chlorophenylbenzoquinones

A solution of *p*-chlorobenzene diazonium chloride (from *p*-chloroaniline, 6.4 g) was poured into a suspension of chlorobenzoquinone (I) (7.15 g) in a solution of sodium acetate (15.3 g) in water (675 ml). The reaction mixture was stirred overnight at room temperature. The oily solid which had then separated, was extracted with ether, the ether extract was washed and dried, and the ether was removed. The residue (13 g) was taken in benzene – pet. ether (1:3) and chromatographed on silica gel (420 g). The chromatogram was developed[6] over a period of 8 hours and eluted with the same solvent. Earlier fractions yielded an unidentified oil (0.43 g). Further elution gave 2-chloro-5-*p*-chlorophenylbenzoquinone (III*b*) as a crystalline solid (2.43 g), m.p. 135–140°. Crystallizations from acetone–ethanol afforded an analytical sample, m.p. 147–148°, ν^{CHCl_3}: 914, 1674 cm^{-1}; ν^{CS_2}: 910 (=C—H deformation, on quinone nucleus), 1674 cm^{-1} (=C=O stretching). λ_{max}: 239 mμ (4.34), 303 mμ (3.85), 380 mμ (3.51). Calc. for $C_{12}H_6O_2Cl_2$ (253.06): C, 56.96; H, 2.39; Cl, 28.02. Found: C, 56.98; H, 2.39; Cl, 27.98.

Further elution with solvents of increasing polarity up to benzene – pet. ether (2:3), yielded a crystalline solid (2.63 g). One crystallization from ethanol gave bright red needles of 2-chloro-6-*p*-chlorophenylbenzoquinone (III*c*) (1.73 g), m.p. 150–151°. A mixed melting point with an authentic sample (1) was undepressed and the I.R. spectra were superimposable. Elution with benzene – pet. ether (1:1) yielded an oily solid (4.0 g). Trituration of this solid with ether at dry-ice temperature followed by one crystallization from acetone – pet. ether provided golden yellow plates of 2-chloro-3-*p*-chlorophenylbenzoquinone (III*a*) (2.1 g), m.p. 104–105° (reported m.p. 103–104° (1)).

Preparation of the Isomeric Chloro-p-nitrophenylbenzoquinones

(a) By Arylation of Chlorobenzoquinone

p-Nitroaniline (3.45 g) was diazotized as described (16). The solution of *p*-nitrobenzene diazonium chloride was added to a stirred suspension of chlorobenzoquinone (I) (3.55 g) in a solution of sodium acetate (7.65 g) in water (325 ml) and the reaction mixture stirred overnight. The brown amorphous powder thus obtained was collected, washed thoroughly with water, and dried. This solid (5.3 g) was dissolved in benzene and chromatographed on silica gel (260 g). Eluates obtained were combined into three fractions based on I.R. analysis: I (1.14 g), II (1.70 g), and III (1.20 g).

Fraction II was dissolved in benzene and rechromatographed on silica gel (93 g). Initial eluates gave 2-chloro-6-*p*-nitrophenylbenzoquinone (IV*c*) (0.77 g) which crystallized in reddish-brown needles (0.31 g) from chloroform, m.p. 205–211°. An analytical sample recrystallized from acetone – pet. ether had m.p. 212–213°. ν^{CHCl_3}: (saturated

[6]*Preliminary development was found to be essential. Changing the solvent to the next higher polarity (benzene – pet. ether, 3:7) resulted in poorer separation.*

solution) 919 (=C—H deformation, on quinone nucleus), 1353, 1531 (N—O stretching), 1657, 1682 cm^{-1} (=C=O stretching). Calc. for $C_{12}H_6O_4NCl$ (263.63): C, 54.67; H, 2.24. Found: C, 54.63; H, 2.14.

The residue from the mother liquor of the chloroform crystallization above was pooled with fraction I. A first crystallization of their mixture from chloroform yielded 0.2 g more of IV*c*. The filtrate was evaporated to dryness and the residue, when crystallized from ethanol, yielded 2-chloro-5-*p*-nitrophenylbenzoquinone (0.47 g) (IV*b*), m.p. 129–132°. An analytical sample had m.p. 134–135°. ν^{CHCl_3}: 913 (=C—H deformation, on quinone nucleus), 1353, 1533 (N—O stretching), 1679 cm^{-1} (=C=O stretching). λ_{max}: 260 mμ (4.26), 360 mμ (3.26). Calc. for $C_{12}H_6O_4NCl$ (263.63): C, 54.67; H, 2.24; N, 5.31. Found: C, 54.99; H, 2.22; N, 5.53.

Further elution of fraction II with benzene gave a solid (0.72 g) which crystallized from acetone – pet. ether (b.p. 90–120°) in yellow rhombs (0.58 g), m.p. 147–155°. This was combined with 0.78 g of crystals, m.p. 146–157°, obtained from crystallization of fraction III, from the same solvent pair. The mixture was crystallized twice to yield 2-chloro-3-*p*-nitrophenylbenzoquinone (IV*a*) (1.0 g), m.p. 157–158°. An analytical sample melted at 160–161°. ν^{CHCl_3}: 845, 853 (=C—H deformation), 1354, 1533 (N—O stretching), 1686, inflection at 1671 cm^{-1} (=C=O stretching). λ_{max}: 256 mμ (4.33), 350 mμ (3.41). Calc. for $C_{12}H_6O_4NCl$ (263.63): C, 54.67; H, 2.24; N, 5.31. Found: C, 54.61; H, 2.34; N, 5.47.

(b) By Chlorination of p-Nitrophenylbenzoquinone (XV)

p-Nitrophenylbenzoquinone, m.p. 135–136°, (5 g) was refluxed with concentrated hydrochloric acid (500 ml) for 2 hours, cooled to room temperature, and the reaction product filtered. The precipitate was washed free of acid with water, dried, dissolved in acetic acid (78 ml), and oxidized with ferric chloride solution (50 ml), to give a mixture of quinones (5.3 g). The quinones were dissolved in benzene and chromatographed on silica gel (300 g). Initial fractions yielded a semisolid (0.43 g). This solid was crystallized three times from acetone–ethanol to give pale yellow crystals (0.18 g), m.p. 196.5–198° which proved to be identical with 2,5-dichloro-*p*-nitrophenylbenzoquinone (VIII) by a mixed melting point with an authentic sample and I.R. spectra. Further elution gave 2-chloro-5-*p*-nitrophenylbenzoquinone (IV*b*) which, after being purified through silica gel and crystallized from acetone–ethanol, gave crystals (1.0 g), m.p. 134–135°. Continued elution yielded a solid (0.74 g), m.p. 200–207°. Crystallization from acetone – pet. ether gave 2-chloro-6-*p*-nitrophenylbenzoquinone (IV*c*) (0.5 g), m.p. 208–211°. The residue (0.14 g) from the mother liquor of this crystallization was crystallized from acetone – pet. ether (b.p. 90–120°) and 2-chloro-3-*p*-nitrophenylbenzoquinone (IV*a*) (0.055 g), m.p. 153–156°, was isolated. The I.R. spectrum of this sample was essentially superimposable with that of the analytical sample of IV*a* obtained by method (*a*) above.

Preparation of 2,5-Dichloro-p-nitrophenylbenzoquinone (VIII)

To a stirred solution of 2,5-dichlorobenzoquinone, m.p. 160–161°, (1.77 g) in a mixture of acetic acid (130 ml), water (12 ml), and sodium acetate (3.06 g), was added a solution of diazotized (16) *p*-nitroaniline (1.38 g). The reaction mixture was stirred overnight and the temperature was then raised to 45° for 2.5 hours. The reaction mixture was cooled and filtered. The precipitate was thoroughly washed with water, dried, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

crystallized from acetone–ethanol. Pale yellow crystals (0.66 g), m.p. 196–198°, were isolated. The filtrate was then poured on ice while a solid (1.14 g) separated. This solid was crystallized from ethanol, dissolved in benzene, and passed through silica gel (25 g). The eluate was evaporated to dryness and the residue (0.28 g), m.p. 194–198°, was added to the first crop of 0.66 g of yellow crystals, m.p. 196–198°, and recrystallized from acetone–ethanol. Pure 2,5-dichloro-*p*-nitrophenylbenzoquinone melts at 197–198°.

ν^{CHCl_3}: 889 (=C—H deformation, on quinone nucleus), 1354, 1533 (N—O stretching), 1686 cm^{-1} (=C=O stretching). Calc. for $C_{12}H_5O_4NCl_2$ (298.08): C, 48.33; H, 1.69; N, 4.68. Found: C, 48.51; H, 1.87; N, 4.77.

Preparation of 2,6-Dichloro-p-nitrophenylbenzoquinone (IX)

To a stirred solution of sodium acetate (3.06 g) in acetic acid (80 ml) and water (100 ml) 2,6-dichlorobenzoquinone, m.p. 120–121° (1.77 g) and finally a solution of diazonium salt (16) obtained from *p*-nitroaniline (1.38 g) were added. The reaction mixture was stirred overnight and then the temperature raised to 50° for 45 minutes. After cooling, the precipitate was collected, washed with water, dried (1.63 g), dissolved in benzene, and chromatographed on silica gel (102 g). Initial fractions gave a solid (0.85 g), which was further purified by passing through silica gel. 2,6-Dichloro-*p*-nitrophenylbenzoquinone (0.65 g), m.p. 138–139°, thus obtained, crystallizes from acetone – pet. ether in pale yellow prisms, m.p. 140–141°. ν^{CHCl_3}: 890 (=C—H deformation, on quinone nucleus), 1353, 1533 (N—O stretching), 1663, 1698 cm^{-1} (=C=O stretching). Calc. for $C_{12}H_5O_4NCl_2$ (298.08): C, 48.33; H, 1.69; N, 4.68. Found: C, 48.19; H, 1.75; N, 4.66.

Further elution yielded a solid (0.44 g), which was crystallized twice from acetone – pet. ether to provide yellow crystals (0.22 g) of 2,6-dichloro-3,5-di-*p*-nitrophenylbenzoquinone (XI), m.p. 222–224°. An analytical sample had m.p. 229–230°. ν^{CHCl_3}: 1350, 1534 (N—O stretching), 1663, 1692 cm^{-1} (=C=O stretching). Calc. for $C_{18}H_8O_6N_2Cl_2$ (419.17): N, 6.68. Found: N, 6.67.

Preparation of 2,3-Dichloro-p-nitrophenylbenzoquinone (X)

2,3-Dichlorohydroquinone (16 g), prepared as described by Conant and Fieser (17), was dissolved in acetic acid (133 ml) and oxidized with ferric chloride solution (130 ml) into dichlorobenzoquinone (VII) (13.04 g), m.p. 100–101° (reported m.p. 100–101° (18)).

ν^{CHCl_3}: 840 (=C—H deformation), 1692 cm^{-1} (=C=O stretching).

To a stirred solution of 2,3-dichlorobenzoquinone (1.77 g) and sodium acetate (3.06 g) in acetic acid (100 ml) and water (63 ml) was added a solution of the diazonium salt (16) prepared from *p*-nitroaniline (1.38 g). The reaction mixture was stirred overnight and the temperature then raised to 50° for 45 minutes. After cooling, the mixture was filtered and the residue washed and dried. The solid (1.3 g) thus collected, was dissolved in pet. ether – benzene (3:7) and chromatographed on silica gel (104 g). Initial fractions yielded 2,3-dichloro-*p*-nitrophenylbenzoquinone (0.59 g), m.p. 162–164°, which after two crystallizations from acetone–ethanol melted at 164–165°. ν^{CHCl_3}: 906 (=C—H deformation, on quinone nucleus), 1353, 1533 (N—O stretching), 1688 cm^{-1} (=C=O stretching). Calc. for $C_{12}H_5O_4NCl_2$ (298.08): C, 48.33; H, 1.69; N, 4.68. Found: C, 48.20; H, 1.70; N, 4.67.

Chlorination of Isomeric Chloro-p-nitrophenylbenzoquinones

Chloro-*p*-nitrophenylbenzoquinones (IV*a*), m.p. 159–160°; (IV*b*), m.p. 134–135°; (IV*c*), m.p. 210–211°, were refluxed with concentrated hydrochloric acid (0.29 mole per mole of quinone) for 1.5 hours, cooled, diluted with water, and the reaction product extracted with ether. The ether extract was dried and the ether removed. The residue thus obtained was oxidized with ferric chloride solution into a mixture of quinones.

(*a*) 2-Chloro-3-*p*-nitrophenylbenzoquinone (IV*a*) (0.211 g) gave a crude mixture of quinones (0.17 g). This was dissolved in benzene – pet. ether (2:3) and chromatographed on silica gel (10 g). Eluate in the first three fractions gave a material (0.02 g) the I.R. spectrum of which showed no characteristic bands due to $=\overset{|}{C}—H$ out-of-plane deformation on the quinone nucleus. This observation, coupled with the fact that this material was present in small amount in the crude mixtures obtained from chlorination of all the three isomers, suggested it to be trichloro-*p*-nitrophenylbenzoquinone. This was further confirmed by chlorination of 2,5-dichloro-*p*-nitrophenylbenzoquinone (VIII) under the above conditions. The I.R. spectrum of the addition product was superimposable with that of the material obtained from the chromatogram. Further elution gave a quinone (0.11 g) which crystallized from acetone–ethanol, yielding crystals (0.08 g), m.p. 197–198°. A mixed melting point and I.R. spectra proved this to be 2,5-dichloro-*p*-nitrophenylbenzoquinone (VIII). The residue (0.02 g) from the mother liquor showed in its I.R. spectrum a band at 1056 cm^{-1} and a pronounced hump at 1664 and 1699 cm^{-1} on the carbonyl maxima at 1686 cm^{-1}. These are characteristic absorptions of 2,6-dichloro-*p*-nitrophenylbenzoquinone (IX). Further processing of this residue by one crystallization from acetone–ethanol gave another 0.012 g of 2,5-dichloro-*p*-nitrophenylbenzoquinone. The I.R. spectrum of the residue from the mother liquor of this last crystallization showed a marked increase in the intensity of the bands at 1056, 1664, and 1699 cm^{-1}, indicating strongly the presence of 2,6-dichloro-*p*-nitrophenylbenzoquinone (IX) in the crude product. Further elution gave 0.031 g of an oil which the I.R. spectrum (3560 cm^{-1}, O—H stretching) indicated it to be unchanged hydroquinone.

(*b*) 2-Chloro-6-*p*-nitrophenylbenzoquinone (IV*c*) (0.203 g), when treated with hydrochloric acid and oxidized as described previously, gave 0.205 g of a crude product. This was dissolved in benzene – pet. ether (1:1) and chromatographed carefully on silica gel (20 g). Fractions eluted were combined based on their I.R. spectra.

Fractions 1 to 17 (0.027 g) consisted exclusively of 2,5,6-trichloro-*p*-nitrophenylbenzoquinone. Fractions 18 to 23 (0.007 g) were found to be a mixture of this quinone and 2,3-dichloro-*p*-nitrophenylbenzoquinone (X) from the I.R. spectra of the intermediate fractions. From fractions 24 to 32 a solid was obtained which crystallized from acetone–ethanol to yield reddish brown needles of X (0.011 g), m.p. 160–163°, identified by a mixed melting point and the I.R. spectra. Fractions 33 to 45 (0.056 g) yielded in one crystallization a solid (m.p. 150–170°) suggested by its I.R. spectrum to be a mixture of X and 2,5-dichloro-*p*-nitrophenylbenzoquinone (VIII). Fractions 46 to 71 (0.076 g) were crystallized from acetone–ethanol to yield pale yellow needles (0.06 g) of a quinone, m.p. 192–194°, found to be VIII by mixed melting point and their I.R. spectra.

(*c*) 2-Chloro-5-*p*-nitrophenylbenzoquinone (IV*b*) (0.204 g), when treated with hydrochloric acid and ferric chloride as described above, yielded 0.206 g of crude quinones. This was dissolved in benzene – pet. ether (1:1) and carefully chromatographed on silica gel (20 g). Fractions eluted were pooled based on I.R. spectra.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Fractions 2 to 25 (0.049 g) consisted mainly of trichloro-*p*-nitrophenylbenzoquinone as identified by their I.R. spectra. Combination 26 to 65 (0.076 g) from the spectra of the intermediate fractions was found to contain 2,3-dichloro-*p*-nitrophenylbenzoquinone (X). It crystallized from acetone–ethanol in clusters of reddish-brown needles (0.07 g), m.p. 160–162°. A mixed melting point with an authentic sample and comparison of their I.R. spectra, confirmed its identity. An I.R. analysis of fractions 66 to 84 (0.048 g), eluted with pet. ether – benzene (3:7) showed the carbonyl band at 1688 cm^{-1} flanked by shoulders of varying intensities (increasing from 66 to 84) at 1663 and 1699 cm^{-1} and appearance of a band of increasing intensity in the same order at 890 cm^{-1}. These were strongly suggestive of the presence of 2,6-dichloro-*p*-nitrophenylbenzoquinone (IX) but crystallization of combination 66 to 84 from acetone–ethanol gave 0.02 g of 2,3-dichloro-*p*-nitrophenylbenzoquinone (X). An I.R. spectrum of the residue from the mother liquor showed marked increase in the intensity of the bands at 1663, 1699, and 890 cm^{-1}. However, an attempt to isolate IX either by chromatography or by crystallization proved fruitless.

Preparation of 2,5- and 2,3-Dibromobenzoquinones (XII and XIII)

Treatment of hydroquinone (11 g) with 2 moles of bromine as described (18), gave a mixture of dibromohydroquinones. This was oxidized with a ferric chloride solution (100 ml) to yield a mixture of quinones (26 g). A 5.1-g portion of this was crystallized from benzene – pet. ether to give 2,5-dibromobenzoquinone (XII) (2.7 g) which, after one crystallization from acetone–ethanol, melted at 189–190° (m.p. 191° (19)). The residue (2.13 g) from the mother liquor of the first crystallization was dissolved in benzene – pet. ether (1:1) and chromatographed on silica gel (126 g). Elution gave in the first two fractions a solid (0.27 g). After three crystallizations of this solid from acetone – pet. ether tribromobenzoquinone (XIV) (0.15 g) was obtained as pale yellow platelets, m.p. 152–153°, (m.p. 155° (19), 150° (20)). λ_{max}: 295 mμ (4.01), 375 mμ (2.75); reported (20) λ_{max}: 296 mμ (4.03), 375 mμ (2.76). ν^{CHCl_3}: 886 (=C–H deformation), 1674, 1696 cm^{-1} (=C=O stretching).

By further elutions more 2,5-dibromobenzoquinone (0.42 g) crystallized from acetone – pet. ether and finally 2,3-dibromobenzoquinone (XIII) was obtained. This quinone crystallized from pet. ether (b.p. 65–110°) in prismatic needles (0.5 g), m.p. 124–125°. ν^{CHCl_3}: 836 (=C–H deformation), 1681 cm^{-1} (=C=O stretching). λ_{max}: 256 mμ (4.28), 362 mμ (3.45). Calc. for $C_6H_2O_2Br_2$ (265.91): C, 27.10; H, 0.76; Br: 60.13. Found: C, 27.29; H, 0.77; Br, 60.54.

ACKNOWLEDGMENTS

We are grateful to Dr. Le Roy F. Johnson of the Varian Associates for taking nuclear magnetic resonance spectra. One of us (J.F.B.) is greatly indebted to the National Research Council of Canada for a postdoctorate fellowship.

THE EFFECT OF BETA-DECAY ON THE EXCHANGE PROPERTIES OF THE RARE EARTH–EDTA COMPLEX IONS[1]

P. GLENTWORTH[2] AND R. H. BETTS

ABSTRACT

It is shown that the rare earth ion Yb^{3+} is very resistant towards ordinary thermal exchange when it is complexed with the chelating agent EDTA in aqueous solution. However, when the complexed rare earth atom, as the 1.8-h Yb-177, emits a beta-particle, the daughter atom Lu-177 escapes readily from the chelate structure. Nuclear recoil arising from the beta-particle emission is shown not to be the cause of the escape of the daughter atom. It is suggested that the observed lability of the daughter atom is a result of a high degree of chemical reactivity of the chelate ion arising from the sudden change in atomic number of the central metal ion of the chelate structure.

INTRODUCTION

The emission of nuclear radiation from an atom is always accompanied by a corresponding recoil of the residual atom. Enhanced chemical reactivity of the daughter atom, as a result of the nuclear event, is also frequently observed. This paper reports the results of a preliminary study of these so-called "hot-atom" effects for the lanthanide isotope Lu-177, in a particular chemical environment, when it is formed as a result of β^- decay of its 1.8-h Yb-177 parent. The decay sequence may be written as:

$$^{177}\text{Yb} \xrightarrow[T_{1/2} = 1.8\ \text{h}]{\beta^- = 1.3\ \text{Mev}} {}^{177}\text{Lu} \xrightarrow[T_{1/2} = 6.8\ \text{d}]{\beta^-} {}^{177}\text{Hf}_{\text{stable}}.$$

As is shown above, the daughter Lu-177 is also radioactive, a fact which greatly facilitates observations of its chemical behavior.

The particular system examined was the exchange reaction in aqueous solution between hydrated Yb^{3+} cations and $^{177}LuX^-$, where X stands for the tetrabasic chelating agent ethylenediaminetetraacetic acid (EDTA). The entity $^{177}LuX^-$ was formed in solution as a result of the β^- decay of $^{177}YbX^-$. This system was chosen because previous work from this laboratory had shown that these complex ions are remarkably stable, and in particular the thermal exchange reaction between the chelated lanthanide ion and the simple ion is very slow (1, 2). Any enhancement of reactivity of the chelate ion, as a result of β^- decay of its central lanthanide atom, was therefore expected to be readily observable.

The parent nuclide, Yb-177, was made by neutron irradiation of samples of pure ytterbium which were highly enriched in the isotope of mass 176. The use of this enriched material, rather than natural ytterbium (for which Yb-177 is not the predominant radionuclide (3)) permitted some simplification in the experimental methods and also aided in the interpretation of the results.

EXPERIMENTAL METHODS AND RESULTS

Radioactive ytterbium was produced by neutron irradiation of a known quantity of ytterbium (as an aqueous solution of the nitrate salt) for 1 hour in an empty fuel rod

[1]*Manuscript received December 1, 1960.*
Contribution from the Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 1213.

position of the NRX reactor. The nitrate solution was prepared from ytterbium oxide which had been mass-separated at Oak Ridge National Laboratories, and contained 97.5% Yb-176, and 1.81% Yb-174. It was initially free of lutetium. The principal activity formed was 1.8-h Yb-177, by neutron capture in the 97.5% abundant Yb-176. A minor activity, 4.2-d Yb-175, was also produced by neutron capture in Yb-174. It will be shown below that the presence of this Yb-175 activity permitted the correction for thermal exchange to be determined directly.

After the irradiation, sufficient Na_4EDTA solution was added to the irradiated solution to complex approximately two-thirds of the Yb^{3+} ions present. The remaining uncomplexed Yb^{3+} ions were quantitatively removed by absorption on a Dowex-50 cation resin column. This procedure ensured that all the radioactive atoms were initially complexed with EDTA and that no excess of EDTA was present. Non-radioactive Yb^{3+} ions were then added to the test solution, together with 0.01 *M* ammonium acetate, pH = 6.5. (The time at which these additions were made was recorded as "zero time".) The concentration of both ionic species YbX^- and Yb^{3+} was 2.5×10^{-4} *M*. The pH of 6.5 was chosen to minimize the normal thermal exchange between these two species, previous studies (1) having shown that the rate of the thermal exchange between M^{3+} and MX^- ions varies directly with the acidity of the solution.

The decay of the 1.8-h Yb-177, and the concurrent "hot-atom" or thermal exchange reactions in solution, were allowed to proceed for 4.6 hours. During this time, 81.2% of the Yb-177 atoms present had decayed to Lu-177. The free Yb^{3+} ions (and any $^{177}Lu^{3+}$ ions which had found their way into this so called free-ion fraction as a result of recoil or thermal exchange processes) were then quantitatively removed from the test solution by absorption onto a Dowex-50 resin column. The absorbed species were then eluted off the column with 0.4 *M* α-hydroxyisobutyric acid solution of pH 6.5. Sufficient time, approximately 24 hours, was then allowed for the residual Yb-177 to decay completely to Lu-177, and then the latter nuclide in the free-ion fraction was separated from 4.2-d Yb-175 by chromatographic elution from a Dowex-50 resin column; this method has been described by Choppin and Silva (4). The separated Yb-175 and Lu-177 were set aside for further measurements outlined below.

1. The Number of Yb-177 Atoms in the Test Solution at Zero Time

This quantity was determined by absolute 4π-β^- counting of an aliquot of the test solution, the radioactive decay of the Yb-177 being followed for 10 half-lives. A total of 11.37×10^{10} atoms of Yb-177 was present in solution as $^{177}YbX^-$ at zero time. Of this number, 81.2% or 9.23×10^{10} atoms had decayed to Lu-177 in the 4.6-hour period allowed.

2. Measurement of the Number of Lu-177 Atoms in the Free-ion Fraction

Lu-177 atoms in the free-ion fraction could have found their way there by one or more of the following routes:

(i) "Hot-atom" effects associated with the β^- decay of $^{177}YbX^-$.

(ii) Thermal exchange of Yb^{177}: $^{177}YbX^- + Yb^{3+} \rightarrow YbX^- + {}^{177}Yb^{3+}$, followed by β^- decay of the Yb-177 atoms so released.

(iii) Thermal exchange involving the reaction: $^{177}LuX^- + Yb^{3+} \rightarrow YbX^- + {}^{177}Lu^{3+}$.

(Lu-177 atoms in the form $^{177}LuX^-$ are present in significant and calculable amount at zero time as a result of β^- decay of Yb-177 during the irradiation in NRX, and also in the time between the end of the irradiation and the time at which the EDTA chelate was formed.) The sum of these three contributions was determined in the following

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

way. The Lu-177 activity isolated from the free-ion fraction was measured on a 100-channel γ-ray spectrometer which had been previously calibrated with an independently standardized Lu-177 source. A total of 5.85×10^{10} atoms of Lu-177 was found in the free-ion fraction. It is now necessary to distinguish between the "hot atom" and thermal exchange contribution to this quantity.

3. Extent of Thermal Exchange

Earlier studies (1) suggested that thermal exchange would not be a significant effect for the conditions used in the present work, and this was confirmed by measurements of the extent of transfer of Yb-175 from the chelate ion to the free-ion fraction. These measurements were made by comparing the areas under the photopeak characteristic of Yb-175 in the γ-ray spectra of an aliquot taken from the test solution and an aliquot of the Yb-175 part of the free-ion fraction referred to earlier. A value of 2.8% was obtained for the extent of thermal exchange, a result somewhat higher than would have been predicted from earlier studies (1) but not grossly inconsistent with these earlier results. This result can be used to estimate the contribution of process (ii) above (thermal transfer of Yb-177), to the appearance of Lu-177 in the free-ion fraction. Thus, the *average* number of Yb-177 atoms available for thermal exchange during the 4-hour period may be taken to a good approximation as one-half the original number present, i.e., $0.5\times11.37\times10^{10} = 5.68\times10^{10}$ atoms. Transfer of 2.8% of these represents 0.16×10^{10} atoms of Lu-177 contributed to the free-ion fraction.

A similar assessment can be made of the extent of thermal transfer of Lu-177 from the form $^{177}LuX^-$ to $^{177}Lu^{3+}$. Earlier studies (1, 2) showed that the rate of thermal exchange of the lanthanide elements in the form MX^- decreases slowly with increasing atomic number. The 2.8% transfer of Yb-175 therefore represents also an *upper* limit of the percentage of lutetium atoms present as $^{177}LuX^-$, which underwent normal thermal exchange during the experiment. The number of Lu-177 atoms present in this form at zero time was 7.44×10^{10} atoms. This number was readily calculated from the number of Yb-177 atoms present at zero time, together with the time of irradiation, and the time between the end of the irradiation and the formation of the EDTA chelate. The number of $^{177}LuX^-$ present at the end of the run was 10.8×10^{10}. An average value of 9.1×10^{10} may be used for estimating the extent of thermal transfer. A maximum of 2.8% of these 9.1×10^{10} atoms would be transferred to the free-ion fraction in 4.6 hours, i.e., 0.25×10^{10} atoms.

The pertinent numerical results obtained above are summarized in Table I. Comparison of items B and C in Table I shows clearly that the number of Lu-177 atoms found in

TABLE I

Source and distribution of Lu-177 atoms

	No. of atoms $\times10^{-10}$
A. Formed in solution from decay of $^{177}YbX^-$ in 4.6 hours	9.23
B. Found in free-ion fraction	5.85
C. No. expected in free-ion fraction from thermal exchanges:	
(i) $^{177}YbX^- + Yb^{3+} \rightarrow YbX^- + {}^{177}Yb^{3+}$, $^{177}Yb^{3+} \rightarrow Lu^{3+} + \beta^-$	0.16
(ii) $^{177}LuX^- + Yb^{3+} \rightarrow YbX^- + {}^{177}Lu^{3+}$	0.25
Total contribution to B from thermal exchange processes	0.41
D. No. transferred by "hot-atom" processes = (B–C)	5.44
Net fraction of A transferred by "hot-atom" processes = D/A =	0.590

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the free-ion fraction was very much greater than can be accounted for by thermal exchange processes. The presence of these extra Lu-177 atoms in the free-ion fraction is ascribed to "hot-atom" processes associated with the β^- emission from Yb-177, when this nuclide is present in the chemical form $^{177}YbX^-$. A comparison of items D and A, shown in the last entry of Table I, shows that 59% of the Lu-177 atoms formed by β^- decay of $^{177}YbX^-$ escape from the chelate and turn up in solution in the cationic form $^{177}Lu^{3+}$.

The results described above appear to be quantitatively reproducible; a second essentially identical experiment gave a value of 56% for the percentage of the Lu-177 atoms escaping from the chelate ion as a result of β^- decay of $^{177}YbX^-$. This is in good agreement with the value of 59% listed in Table I.

DISCUSSION

The maximum energy of the β^- particle emitted by Yb-177 is 1.3 Mev. A free, isolated Lu-177 daughter atom then receives, as a result of nuclear recoil, a *maximum* of 9 ev of kinetic energy. This value is given by the expression

$$E_R = \frac{541\,E_\beta}{M} + \frac{536\,E_\beta^2}{M}.$$

E_R is the recoil energy in electron volts, E_β is the maximum energy of the beta particle in Mev, M is the mass of the recoiling atom.

However, it is well known that the average β^- energy is approximately 0.4 E_β, so that an isolated Lu-177 atom will receive on the average only 3.5 to 4.0 ev of recoil. (The relation between the average recoil energy given to an isolated atom and the maximum β^- energy of the disintegration has been discussed by several authors, e.g. Libby (5).) Moreover, in the present study, the daughter atom is in fact not a free, isolated atom, but is linked by at least four strong co-ordinate bonds to the chelating agent EDTA (2, 6). The recoil energy is therefore shared by a more massive configuration, with the result that the average kinetic energy of translation of the recoiling Lu-177 will be significantly less than 3–4 ev. On the other hand, 2–3 ev would be a reasonable estimate of the binding energy associated with each of the four co-ordinate bonds in the chelate. It appears highly unlikely therefore that nuclear recoil, as such, contributes appreciably to the observed escape of Lu-177 from the chelate environment.

A more likely cause for the observed escape is the abrupt change in atomic number of the central atom of the chelate. The loss of a negative charge from the nucleus produces a rearrangement of the electronic energy levels of the daughter atom, and thereby introduces a high degree of electronic excitation (see, for example, a recent review by Baulch and Duncan (7)). One may suppose therefore either that this excitation leads directly to dissociation, or alternatively that an excited species is formed. A necessary corollary of the latter alternative is that the excited species, during its lifetime, is very much more labile with respect to exchange than an ordinary lanthanide–EDTA chelate. Further speculations would appear unwarranted at present, in view of the limited amount of experimental evidence yet available. In this connection, a useful line for future investigation would be to discover whether or not changes in the chemical environment (pH, temperature, concentration of free lanthanide ions) have any effect on this "hot-atom" system.

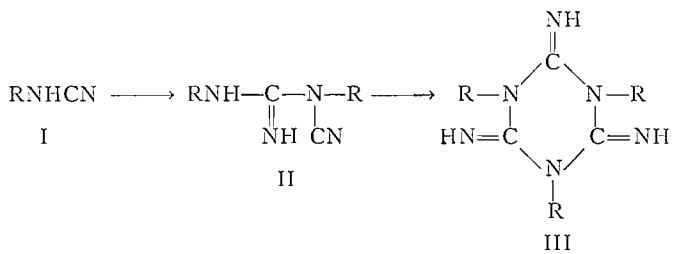
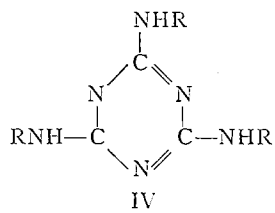
SOME STABLE DIMERS OF SUBSTITUTED BENZYLCYANAMIDES[1]

D. L. Garmaise and A. Uchiyama



ABSTRACT

2,4- and 3,4-Dichlorobenzylcyanamides dimerize on standing to 1-cyano-1,3-di-(2,4-dichlorobenzyl)-guanidine and 1-cyano-1,3-di-(3,4-dichlorobenzyl)-guanidine respectively. Apart from dicyandiamide itself, no other cyanamide dimers appear to have been described. The dimers on heating are converted into the corresponding trisubstituted isomelamines. 1-Cyano-1,3-di-(3,4-dichlorobenzyl)-guanidine condenses with 4-nitrobenzylcyanamide to form 1,3-di-(3,4-dichlorobenzyl)-5-(4-nitrobenzyl)-isomelamine. No dimers were obtained from the 4-chloro-, 4-bromo-, 4-nitro-, or 4-methyl-benzylcyanamides.



Monosubstituted cyanamides trimerize slowly on standing, more rapidly when heated, and, in some cases, when subject to the action of strong alkali (1).

Alkylcyanamides (2, 3) and aralkylcyanamides (4) give trisubstituted isomelamines, while arylcyanamides may also yield the corresponding melamines (5).

No stable intermediate would be expected in the formation of melamines (IV), but the formation of isomelamines (III) should involve as intermediates, 1,3-disubstituted dicyandiamides (II).

a: R = 3,4-$Cl_2C_6H_3CH_2$—
b: R = 2,4-$Cl_2C_6H_3CH_2$—
c: R = 4-$ClC_6H_4CH_2$—
d: R = 4-$BrC_6H_4CH_2$—
e: R = 4-$O_2NC_6H_4CH_2$—
f: R = 4-$H_3CC_6H_4CH_2$—

Derivatives of this type have not been previously reported.

It is now shown that when R = 3,4-dichlorobenzyl (*a*) or 2,4-dichlorobenzyl (*b*), the second step is sufficiently slow to permit the isolation and characterization of the dicyandiamides II*a* and II*b*.

Six substituted benzylcyanamides (Table I) were prepared by treating benzylamines with cyanogen bromide in ether (6). The products were readily isolated, generally in good yield, by operating at room temperature. The infrared spectra of the cyanamides showed the C≡N band at 2220–2240 cm^{-1} with no absorption in the C=N region except in the case of 3,4-dichlorobenzylcyanamide (I*a*). Even freshly prepared samples of I*a* showed a weak band at 1675 cm^{-1} in addition to the C≡N band.

*Not isolated free of the dimer.

Birkofer (4) reported that in attempting to purify benzylcyanamide by extraction with 30% sodium hydroxide solution in accordance with an earlier procedure (7), he observed an immediate precipitation of tribenzylisomelamine. We have found that 4-methylbenzylcyanamide (I*f*) is slowly converted to the isomelamine in 30% sodium hydroxide solution, but that benzylcyanamides with electron-withdrawing substituents (I*a*, I*b*, I*c*, I*d*) hydrolyze in this medium to the corresponding ureas instead of trimerizing. The 4-nitro analogue (I*e*) did not yield an identifiable derivative.

All of the cyanamides are converted to the isomelamines (III) when heated at 100°. The infrared spectra of the isomelamines show characteristically strong C=N bands at 1610–1620 cm^{-1}, with no adsorption in the C≡N region. I*c*, I*d*, and I*f* also formed the corresponding isomelamines on standing at room temperature for periods of 10–30 days, while the nitro analogue (I*e*) was unchanged in 30 days. The 2,4-dichloro analogue (I*b*), m.p. 60–61°, on being allowed to stand in an open vessel for 3 days, gave a 95% yield of a substance melting at 142–143°. This product (II*b*) showed strong bands at both 2245 cm^{-1} and 1690 cm^{-1}, indicating the presence of both C≡N and C=N bands. II*b*, on being melted and then heated at 100° for 4 hours was converted to the isomelamine III*b*, m.p. 220–222° in 75% yield.

Similarly, the 3,4-dichloro analogue (I*a*) (m.p. 48–50°), on standing in an open dish for 24 hours, gave a 63% yield of II*a*, m.p. 138–139°. II*a* also showed strong bands at 2240 cm^{-1} and 1674 cm^{-1}, and was converted in refluxing methanol to the isomelamine III*a*, m.p. 170–171° (8) in 70% yield. Paper chromatography in butanol:acetic acid:water, with development by bromcresol green gave R_f values of 0.73, 0.86, and 0.93 for I*a*, II*a*, and III*a* respectively.

Although reliable molecular weight determinations could not be made, the dimeric nature of II*a* was established by benzoylation to a monobenzoyl derivative, m.p. 200–201°. The benzoyl derivative analyzed for the formula $C_{23}H_{16}Cl_4N_4O$, which could be derived only from a dimer of the formula $C_{16}H_{12}Cl_4N_4$. The structure of the benzoyl derivative was not established.

The dicyandiamide (II*a*) and 4-nitrobenzylcyanamide (I*e*) were allowed to stand in alcohol solution for 6 days, giving 1,3-di-(3,4-dichlorobenzyl)-5-(4-nitrobenzyl)-isomelamine in 20% yield. This result supports the assumption that 1,3-disubstituted dicyandiamides of the structure II are true intermediates in the trimerization of cyanamides to

For personal use only.

isomelamines. 4-Nitrobenzylcyanamide was chosen for this reaction because of its relative stability at room temperature.

For purpose of comparison, a number of N^2,N^4,N^6-tribenzylmelamines (IV*b*, IV*c*, and IV*f*) were prepared by the reaction between cyanuric chloride and benzylamines. N^2,N^4,N^6-Tri-(3,4-dichlorobenzyl)-melamine has been previously described (8). The infrared spectra of the melamines showed C=N absorption at 1613–1624 cm^{-1}.

EXPERIMENTAL[2]

Preparation of Benzylcyanamides

Example.—Cyanogen bromide (7.55 g, 0.075 mole) in ether (100 ml) was added to a stirred solution of 4-chlorobenzylamine (21.4 g, 0.15 mole) in ether (100 ml) at 5° during 15 minutes. The suspension was stirred for 1 hour, and the precipitated 4-chlorobenzylamine hydrochloride was filtered. The ether solution was washed with 1 *N* hydrochloric acid (2×200 ml) and with water, and was then dried and evaporated. The crystalline residue of 4-chlorobenzylcyanamide (12.3 g), m.p. 67–70°, was recrystallized from ether to a constant melting point of 91–92°, yield 9.5 g (76% of theory).

Preparation of Isomelamines

4-Chlorobenzylcyanamide (0.50 g) was heated at 100° for 4 hours. Trituration with methanol gave 1,3,5-tri-(4-chlorobenzyl)-isomelamine, m.p. 162–165°, yield 0.40 g (80% of theory). Recrystallization from methanol raised the melting point to 165–166°.

In the case of the 4-nitro analogue (III*e*), the product had to be separated from relatively large amounts of colored by-products. The 4-chloro, 4-bromo, and 4-methyl analogues (III*c*, *d*, and *f*) could also be obtained by allowing the cyanamides to stand at room temperature for periods of 10–30 days.

[2]*All melting points are uncorrected. Analyses were performed by Micro-Tech Laboratories, Skokie, Ill., and Dr. Claude Daessle, Montreal, Quebec.*

Behavior of Benzylcyanamides in Aqueous Alkali

4-Methylbenzylcyanamide.—A solution of 4-methylbenzylcyanamide (1.5 g) in 30% sodium hydroxide (35 ml) was allowed to stand for 3 days. 1,3,5-Tri-(4-methylbenzyl)-isomelamine, m.p. 203–204°, slowly precipitated, yield 1.0 g (67%). There was no depression on admixture with a sample prepared as described above.

4-Chlorobenzylcyanamide.—4-Chlorobenzylcyanamide (0.50 g, 0.003 mole) was allowed to stand in 30% sodium hydroxide solution (20 ml) overnight. The precipitated 4-chlorobenzylurea, m.p. 185–186°, was filtered, yield 0.30 g (48%). Recrystallization from methanol raised the melting point to 189–190°. Acidification of the alkaline filtrate gave 0.11 g of unchanged 4-chlorobenzylcyanamide. Anal. Calc. for $C_8H_9ClN_2O$: C, 52.05; H, 4.91; Cl, 19.20; N, 15.18. Found: C, 51.96; H, 4.99; Cl, 19.08; N, 14.92.

3,4-Dichlorobenzylcyanamide.—Under the same conditions as described above, 3,4-dichlorobenzylcyanamide gave 3,4-dichlorobenzylurea, m.p. 163.5–164.5° (from methanol) in 77% yield. Anal. Calc. for $C_8H_8Cl_2N_2O$: C, 43.81; H, 3.68; N, 12.78. Found: C, 43.67; H, 3.58; N, 13.01.

4-Bromobenzylcyanamide.—Similarly, 4-bromobenzylcyanamide gave 4-bromobenzylurea, m.p. 201–203° (from ethanol), in 52% yield. Anal. Calc. for $C_8H_9BrN_2O$: Br, 34.89; N, 12.23. Found: Br, 34.75; N, 12.64.

Preparation of Melamines

Example.—Cyanuric chloride (3.7 g, 0.020 mole) was added to 4-methylbenzylamine (20.0 g, 0.165 mole) in *o*-xylene (100 ml) during 15 minutes, and the mixture was refluxed for 4 hours. The precipitated 4-methylbenzylamine hydrochloride was filtered, and the filtrate was evaporated to dryness. Crystallization of the residue from ethanol gave N^2,N^4,N^6-tri-(4-methylbenzyl)-melamine, m.p. 123–127°, yield 8.8 g (quantitative). The analytical sample melted at 129–130° after recrystallization from ethanol and from acetone. Anal. Calc. for $C_{27}H_{30}N_6$: C, 73.90; H, 6.91; N, 19.18. Found: C, 73.92; H, 7.05; N, 19.38.

N^2,N^4,N^6-Tri-(4-chlorobenzyl)-melamine.—N^2,N^4,N^6-Tri-(4-chlorobenzyl)-melamine, m.p. 158–159° (from ethanol) was obtained in 69% yield. Anal. Calc. for $C_{24}H_{21}Cl_3N_6$: C, 57.67; H, 4.24; Cl, 21.28; N, 16.81. Found: C, 57.65; H, 4.17; Cl, 21.27; N, 16.79.

N^2,N^4,N^6-Tri-(2,4-dichlorobenzyl)-melamine.—N^2,N^4,N^6-Tri-(2,4-dichlorobenzyl)-melamine, m.p. 155–157°, was isolated in 88% yield. Anal. Calc. for $C_{24}H_{18}Cl_6N_6$: C, 47.81; H, 3.01; Cl, 35.26; N, 13.95. Found: C, 47.64; H, 3.08; Cl, 35.26; N, 13.95.

1-Cyano-1,3-di-(2,4-dichlorobenzyl)-guanidine

2,4-Dichlorobenzylcyanamide (1.0 g, m.p. 60–61°) was allowed to stand in an open crystallizing dish for 2 days. Trituration with ether yielded the product melting at 140–143°. The ethereal mother liquors on standing for 24 hours deposited an additional quantity of the same substance, m.p. 140–142°. Total yield 0.95 g (95%). Recrystallization from methanol (30 ml/g) raised the melting point to 142–143°. Anal. Calc. for $C_{16}H_{12}Cl_4N_4$: C, 47.80; H, 3.01; Cl, 35.27; N, 13.93. Found: C, 47.35; H, 3.04; Cl, 35.37; N, 13.70.

The product (0.20 g) was heated above its melting point (150–160°) for 10 minutes and then heated at 100° for 4 hours. Trituration with methanol yielded crude 1,3,5-tri-(2,4-dichlorobenzyl)-isomelamine, m.p. 210–217°, yield 0.15 g (75%). Recrystallization from dimethylformamide–methanol–water raised the melting point to 220–222°. There was no depression on admixture with an authentic sample prepared by direct trimerization of 2,4-dichlorobenzylcyanamide.

1-Cyano-1,3-di-(3,4-dichlorobenzyl)-guanidine

3,4-Dichlorobenzylcyanamide (13.0 g, m.p. 48–50°) was allowed to stand in an open crystallizing dish for 24 hours. During this period the starting material melted and later partially resolidified. Trituration with ether yielded the product, m.p. 128–134°, yield 8.2 g (63%). The product was recrystallized to a constant melting point of 138–139° by dissolving in preheated methanol (30 ml/g) and cooling rapidly. Anal. Calc. for $C_{16}H_{12}Cl_4N_4$: C, 47.80; H, 3.01; Cl, 35.27; N, 13.93. Found: C, 47.57; H, 3.24; Cl, 35.58; N, 13.93.

A solution of 1-cyano-1,3-di-(3,4-dichlorobenzyl)-guanidine (0.50 g) in methanol (50 ml) was refluxed for 3 hours. The solution was evaporated and the residue was crystallized from ether, giving 1,3,5-tri-(3,4-dichlorobenzyl)-isomelamine, m.p. 167–169°, yield 0.35 g (70%). There was no depression on admixture with a sample, m.p. 171–172°, prepared by direct trimerization of 3,4-dichlorobenzylcyanamide.

Benzoylation of 1-Cyano-1,3-di-(3,4-dichlorobenzyl)-guanidine

Benzoyl chloride (1.01 g, 0.00712 mole) was added to 1-cyano-1,3-di-(3,4-dichlorobenzyl)-guanidine (2.86 g, 0.00712 mole) in pyridine (25 ml) at 5° and the solution was allowed to stand overnight. The solution was diluted with ether (200 ml), washed with 1 *N* hydrochloric acid (3×200 ml) and with water (2×100 ml). The crude product, m.p. 173–180°, separated at the interface, yield 1.0 g (28%). Repeated recrystallization from methanol raised the melting point of the monobenzoylated derivative to 200–201°, yield 0.50 g (14%). Anal. Calc. for $C_{23}H_{16}Cl_4N_4O$: C, 54.56; H, 3.19; Cl, 28.02; N, 11.07. Found: C, 54.53; H, 3.26; Cl, 28.09; N, 11.18.

1,3-Di-(3,4-dichlorobenzyl)-5-(4-nitrobenzyl)-isomelamine

A solution of 1-cyano-1,3-di-(3,4-dichlorobenzyl)-guanidine (0.75 g, 0.00187 mole) and 4-nitrobenzylcyanamide (0.33 g, 0.00187 mole) in methanol (150 ml) was allowed to stand at 25° for 6 days. The solution was evaporated, and the residue was crystallized from ether (25 ml) to give 0.50 g of a gummy solid. Suspension of the crude product in ether (50 ml) at 5° for 1 week gave the product melting at 170–172°, yield 0.22 g (20%). Recrystallization from methanol raised the melting point to 177–179°. Anal. Calc. for $C_{24}H_{19}Cl_4N_7O_2$: C, 49.76; H, 3.30; Cl, 24.49; N, 16.93. Found: C, 49.90; H, 3.38; Cl, 24.07; N, 16.67.

CONSTITUTION OF A 4-*O*-METHYLGLUCURONOXYLAN FROM THE WOOD OF TREMBLING ASPEN (POPULUS TREMULOIDES MICHX.)[1]

J. K. N. Jones, C. B. Purves, and T. E. Timell

ABSTRACT

A 4-*O*-methylglucuronoxylan has been isolated in almost quantitative yield from the wood of trembling aspen (*Populus tremuloides* Michx.). The hemicellulose was electrophoretically homogeneous and had a number-average degree of polymerization of 212. Partial hydrolysis gave D-xylose, galacturonic acid, 4-*O*-methylglucuronic acid, and 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose. Methanolysis and hydrolysis of the fully methylated polysaccharide, which contained 108 xylose residues per average molecule, gave 2-*O*-methylxylose, 2,3-di-*O*-methyl-D-xylose, 2,3,4-tri-*O*-methyl-D-xylose, and methyl 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucopyranosyluronic acid)-3-*O*-methyl-D-xylopyranoside in a mole ratio of 0.2:95:1:11. It is concluded that the hemicellulose contained a linear framework of approximately 200 (1 → 4)-linked β-D-xylopyranose residues and that, on the average, every ninth xylose unit carried a (1 → 2)-linked 4-*O*-methyl-α-D-glucuronic acid residue directly attached to the xylan backbone. The polysaccharide is evidently similar to the 4-*O*-methylglucuronoxylans occurring in the wood of all arborescent angiosperms so far investigated.

The xylan present in trembling aspen was the first wood hemicellulose to be subjected to detailed structural investigations. Jones and Wise (1) on hydrolysis of aspen wood obtained several monosaccharides, xylobiose, xylotriose, D-galacturonic acid, 4-*O*-methyl-D-glucuronic acid, and 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose, all of which were unequivocally identified. Milks and Purves (2) isolated from the same wood four fractions containing various amounts of hexuronic, 4-*O*-methylglucuronic and (1 → 4)-linked xylose residues. Partial hydrolysis yielded a crystalline aldotriuronic acid containing one 4-*O*-methylglucuronic acid and two xylose residues. The polysaccharide appeared to be extensively branched and was considered to possess non-reducing end groups of hexuronic acid rather than xylopyranose residues.

Jones, Merler, and Wise (3), on direct extraction of aspen wood with alkali, obtained a hemicellulose fraction in a yield of 19%. This material had a specific rotation of −75° and contained 1.7% methoxyl and 9.2% uronic anhydride groups. Hydrolysis yielded mostly xylose in addition to minor amounts of hexoses, arabinose, and rhamnose. On electrophoresis, the material was resolvable into two components, while on enzymic hydrolysis, 20% was enzyme-resistant. On the basis of results obtained by the methylation technique, the authors concluded that the xylose-containing hemicelluloses consisted of (1 → 4)-linked xylose residues to which were attached, through positions 2 and 3, end groups of L-arabinofuranose and side chains terminated by uronic acid residues. It was pointed out that the acid side chains might contain both glucose and xylose residues, since 2,3,6-tri-*O*-methyl-D-glucose and 3,4-di-*O*-methyl-D-xylose were obtained on hydrolysis of the methylated polysaccharide.

All other xylans so far isolated from the wood of arborescent angiosperms have been found to consist of a linear framework of (1 → 4)-linked β-D-xylose residues, approximately every tenth of which, on the average, carried a (1 → 2)-linked single, terminal side chain of a 4-*O*-methyl-α-D-glucuronic acid residue (4–6). While L-arabinofuranose residues are evidently integral parts of most softwood xylans (7, 8), no such residues have been detected in any hardwood xylan with the exception of that isolated from aspen wood.

Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario, the Pulp and Paper Research Institute of Canada, and the Department of Chemistry, McGill University, Montreal, Quebec.

The rather exceptional characteristics of the aspen xylan prompted the present re-investigation of this hemicellulose. Another aim was to establish the degree of branching and the average length of the xylan backbone, properties which had not been dealt with in the earlier studies.

RESULTS

Aspen wood meal was delignified by alternate treatments with gaseous chlorine and alcoholic monoethanolamine (9), a procedure which, when applied to hardwoods, appears to cause no degradation of the polysaccharides (10). The resulting holocellulose was extracted with aqueous potassium hydroxide (11) to give a product in a yield of 21.4% of the wood. Besides xylose and uronic acids, this material also contained glucose, mannose, and arabinose residues. Complexing with copper lowered the yield to 15.0%, eliminating all hexose- and arabinose-containing polysaccharides. When the wood was directly extracted with aqueous potassium hydroxide, a product was obtained in a yield of 18.1% which gave only xylose and uronic acids on hydrolysis.

The yields and properties of the three products isolated are summarized in Table I.

TABLE I

Yields and characteristics of aspen hemicelluloses

Source	Yield, %*	$[\alpha]_D$†	Xylose per uronic acid calc. from:		
			Methoxyl	Uronic anh.	Equiv. wt.
Wood (A)	18.1	−81°	8.7	9.3	8.6
Holocellulose (B)	21.4	−75°	9.5	7.5	7.5
Copper complex (C)	15.0	−78°	9.5	8.2	7.1

*Based on extractive-free wood.
†In 10% aqueous sodium hydroxide.

It is evident that they differed little in specific rotation or chemical composition and that they contained on the average nine xylose units per *O*-methylglucuronic acid residue. The yields obtained are comparable to the *O*-methylglucuronoxylan content, 19%, calculated from the amount of xylose residues in the wood. The hexose and arabinose residues in the material obtained from the holocellulose were probably not integral parts of the glucuronoxylan since they could be eliminated by complexing with copper and did not appear when the wood was extracted without prior delignification.

The hemicellulose, on boundary electrophoresis, gave only one mobile peak which was very distinct, thus indicating the homogeneity of the material. On oxidation with periodate, the expected 9 moles of oxidant were consumed per repeating unit of the polysaccharide. Attempts to determine the weight-average molecular weight of the polymer by light scattering measurements (12) failed, the value obtained, 200,000, probably being a result of molecular association (13). Osmotic pressure measurements with the acetate derivative (14) gave a number-average degree of polymerization of 212.

A portion of the hemicellulose was partially hydrolyzed and the hydrolyzate was resolved on a column of anion exchange resin into a neutral and an acidic portion. The former crystallized and was identified as D-xylose. The sugar acids were separated on a charcoal–Celite column (15) by gradient elution. Two of the acids obtained were probably galacturonic acid, presumably derived from contaminating pectic material, and 4-*O*-methylglucuronic acid. A third acid had a methoxyl content and an equivalent weight

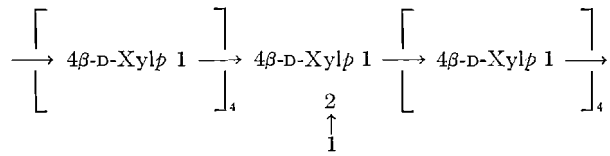
For personal use only.

corresponding to that of an *O*-methylhexuronosyl pentose. This compound was identified through the crystalline tetraacetate of its methyl ester methyl glycoside (16) as 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose, the same aldobiouronic acid as that first characterized by Jones and Wise (1).

Another portion of the hemicellulose was methylated to completion, first according to Haworth and subsequently by the procedure of Kuhn and co-workers (17). The fully methylated polysaccharide, $[\alpha]_D$ −67°, contained 108 xylose residues as estimated by osmotic pressure measurements, indicating that degradation had occurred during the methylation. The methylated hemicellulose was subjected to methanolysis under conditions known to effect no cleavage of aldobiouronic acids. The resulting mixture of glycosides was resolved into an acidic and a neutral portion on an anion exchange resin. The acid fraction, which contained only one component, was esterified and reduced with lithium aluminum hydride to yield a crystalline, partly methylated glycoside which was identified as methyl 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucopyranosyl)-3-*O*-methyl-α,β-D-xylopyranoside (18, 19).

The neutral portion was hydrolyzed to a mixture of reducing sugars which was resolved by gradient elution on a charcoal–Celite column. The three fractions obtained were 2-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, and 2,3,4-tri-*O*-methyl-D-xylose. Paper electrophoresis of the di-*O*-methyl fraction indicated the absence of any 3,4-di-*O*-methyl-D-xylose. A minor portion of the mixture was resolved by paper chromatography and subjected to quantitative analysis (20), giving a molar ratio of 0.2:95:1 for the mono-, di-, and tri-*O*-methylxyloses.



DISCUSSION

The large quantity of 2,3-di-*O*-methyl-D-xylose obtained, in conjunction with the high negative rotation of the original and the methylated hemicelluloses, showed that the xylose residues in the backbone of the macromolecule were linked together by β-(1 → 4)-glycosidic bonds. Methanolysis of the methylated xylan produced no monouronic acids and the partly methylated aldobiouronic acid was unsubstituted at C_4 in the xylose moiety. These facts, together with the absence of any 3,4-di-*O*-methylxylose in the neutral portion, showed that the xylose residues were attached *directly* to the (1 → 4)-linked xylan framework. The constitution of the aldobiouronic acid showed that the side chains were composed of (1 → 2)-linked 4-*O*-methyl-α-D-glucuronic acid residues.

The non-reducing end groups of the polysaccharide undoubtedly gave rise to the 2,3,4-tri-*O*-methyl-D-xylose. The results indicated that 107 xylose residues were present per non-reducing end group while the average macromolecule contained 108 such residues. Only one non-reducing end group was therefore present per average molecule and the xylan framework was accordingly linear. The very small quantity of mono-*O*-methylxylose isolated had probably been formed by demethylation during degradation of the methylated hemicellulose.

From the evidence adduced it is now possible to suggest a tentative structure for the 4-*O*-methylglucuronoxylan present in the wood of trembling aspen. This hemicellulose contains slightly more than 200 β-D-xylopyranose residues linked together by (1 → 4)-glycosidic bonds to a linear framework. Every ninth xylose residue, on the average, carries a single, terminal side chain of a 4-*O*-methyl-α-D-glucuronic acid residue attached to C_2. The acid groups are probably distributed at random along the macromolecules (14). In analogy with similar hemicelluloses present in two species of birch (21, 22), the aspen xylan probably contains *O*-acetyl groups in its native state.

4-*O*-Me-α-D-G*p*A

The xylan present in aspen wood is evidently very similar to the 4-*O*-methylglucuronoxylans previously isolated from the wood of various species of arborescent angiosperms, including American beech (*Fagus grandifolia*) (23), European beech (*F. sylvatica*) (24), Finnish birch (*Betula verrucosa*) (21, 25), white birch (*B. papyrifera*) (26), yellow birch (*B. lutea*) (27), white elm (*Ulmus americana*) (28), and sugar maple (*Acer saccharum*) (29, 30). It is also similar to the 4-*O*-methylglucuronoxylan occurring in the inner bark of white birch (31). The presence of fewer acid side chains and the absence of terminal L-arabinofuranose residues are the main characteristics in which these polysaccharides differ from the xylans present in the wood of most gymnosperms.

EXPERIMENTAL

All specific rotation are equilibrium values and were determined at 20° C. Melting points are corrected. Evaporations were carried out *in vacuo* at 40–50° C.

Paper Chromatography

Solvents (v/v) used for separating the sugars were (A) ethyl acetate – pyridine – water (8:2:1), (B) ethyl acetate – acetic acid – water (9:2:2), and (C) butanone–water (90:10). Separations were carried out on Whatman No. 1 filter paper. Paper electrophoresis was carried out on Whatman No. 3 MM filter paper in a 0.05 *M* borate buffer at 700 v for 4 hours. The spray reagent was *o*-aminodiphenyl. The same reagent was used for quantitative sugar analyses (32).

Composition of the Wood

Aspen wood (33), 40–60 mesh, was exhaustively extracted with ethanol–benzene (1:2). Analyses according to standard methods gave the following analytical data: cellulose (53.3%), pentosan (18.9%), lignin (16.3%), acetyl (3.4%), ash (0.2%), uronic anhydride (3.3%), residues of galactose (0.8%), glucose (57.3%), mannose (2.3%), arabinose (0.4%), and xylose (16.0%).

Isolation of Hemicelluloses

A. From wood.—Extractive-free wood meal (361 g) was treated with 24% (w/w) aqueous potassium hydroxide (2 liters) in an atmosphere of nitrogen at room temperature for 7 hours. The filtrate and washings were poured into four times their volume of ethanol containing an excess of acetic acid, cooled to 0° C. The precipitate formed was recovered by filtration and washed in succession with 70% ethanol, ethanol, and petroleum ether (b.p. 30–60° C). Drying *in vacuo* at room temperature gave a white powder (65.2 g, 18.1% of the wood), $[\alpha]_D$ −81° (*c*, 1.0 in aqueous 10% sodium hydroxide). Anal: OCH_3, 2.33%; uronic anhydride, 12.4%; equiv. wt., 1330. All analyses were carried out with the free acid form of the hemicellulose.

B. From chlorine holocellulose.—Wood meal (765 g) was subjected to three treatments with gaseous chlorine in ice water, followed by extraction with alcoholic monoethanolamine according to the procedure of Timell and Jahn (9). Yield: 692 g, 90.5% of the wood.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The holocellulose (688 g) was exhaustively extracted with 24% aqueous potassium hydroxide as described above to yield a white powder (163 g, 21.4% of the wood), $[\alpha]_D$ −75°. Anal: K salt: Potassium as potassium sulphate, 6.30%, corresponding to 8.7 xylose residues per acid group. Free acid: OCH_3, 2.10%; uronic anhydride, 15.0%; equiv. wt., 1170. Residues of glucose, 1.3%; mannose, 1.7%; arabinose, 1.2%; xylose, 82.4%; 4-*O*-methylglucuronic acid, 13.4%. Extraction of the solid residue with 17.5% aqueous sodium hydroxide to which 4% of boric acid had been added gave a crude glucomannan (20.6 g, 2.7% of the wood) containing 15% of *O*-methylglucuronoxylan, corresponding to 0.4% of the wood.

C. By copper complexing of xylan B.—A portion of xylan B (50 g) was dissolved in 5% aqueous sodium hydroxide (2 liters) and Fehling's solution (1300 ml) was added. The blue precipitate was washed with water until it started to swell, when it was decomposed with ice-cold 0.1 *N* hydrochloric acid in a Waring blendor. The aqueous mixture was poured into 15 liters of ethanol and the precipitate was washed five times on the centrifuge with 80% aqueous ethanol. The material, which was still green, was treated with aqueous ethylenediaminetetraacetic acid for removal of the last traces of copper salts. After neutralization with sodium bicarbonate, the solution (2 liters) was poured into ethanol (10 liters) to give a granular precipitate and a blue solution. The solids were recovered in the usual way and dried to give a white powder (35 g, 15.0% of the wood), $[\alpha]_D$ −78°. Anal: OCH_3, 2.10%; uronic anhydride, 13.9%; equiv. wt., 1130. Hydrolysis and subsequent examination by paper chromatography indicated the presence of uronic acid and xylose only.

Electrophoresis of the Hemicellulose

Free-boundary electrophoresis was carried out with a 2% solution of xylan A in an aqueous solution containing 7.5 g of boric acid and 4.0 g of sodium hydroxide per liter. The apparatus was a Spinco Model H instrument and photographs were taken at three stages of migration. Only one mobile peak was observed.

Determination of the Molecular Weight of the Hemicellulose

Attempts to determine the weight-average molecular weight of the polysaccharide by light scattering measurements with 0.2–1.0% solutions in dimethyl sulphoxide (12) failed. The value obtained, 200,000, was deemed to be the result of fortuitous molecular association.

A portion of the hemicellulose was converted to the fully substituted acetate derivative as described elsewhere (14) to give a product (4.0 g) containing 37.1% acetyl (34). Osmotic pressure measurements were carried out with a 9:1 mixture of chloroform and ethanol (v/v) at 30° C and with Stabin–Immergut (35) osmometers provided with gel cellophane membranes. The results obtained (Table II) gave a number-average molecular weight of 51,400, corresponding to 212 xylose residues in the xylan framework of the average molecule.

Periodate Oxidation of the Hemicellulose

Samples of hemicellulose (A, acid form, 150 mg) were shaken in the dark at 30° C for various lengths of time with 50 ml of 0.05 *M* sodium metaperiodate. The consumption of oxidant was determined by the excess arsenite method. The following moles of periodate were consumed per repeating unit (1378) of the polysaccharide during the first eight days: 1 (9.1), 3 (9.3), 4 (10.2), 6 (10.9), and 8 (11.3). Extrapolation to zero concentration gave a consumption of 9.0±0.1 moles of oxidant per repeating unit.

Hydrolysis of the Hemicellulose

The hemicellulose (B, 80 g) was partially hydrolyzed as described earlier (16). After treatment with Amberlite IR-120 exchange resin (acid form), the solution (200 ml) was resolved into a neutral and an acid portion on a column with Dowex 1-X4 exchange resin (acetate form) (16). The neutral sugar fraction contained only D-xylose, m.p. and mixed m.p. 147.5–149° C, $[\alpha]_D$ +20.6° (c, 5.0 in water). The dibenzylidene dimethyl acetal derivative (36) had m.p. and mixed m.p. 211–212° C.

The acid fraction contained three sugar acids as indicated by paper chromatography (solvent B). A portion of the mixture (5 g) was added to the top of a Darco G-60 charcoal–Celite (15) column (1:1, 5.5×70 cm). Gradient elution was carried out with aqueous ethanol (37, 38) to give three fractions, corresponding in rate of movement on the paper chromatogram to galacturonic acid (900 mg), 4-*O*-methylglucuronic acid (500 mg), and an aldobiouronic acid (2.3 g). Anal. Calc. for $C_{12}H_{20}O_{11}$:OCH_3, 9.1%; equiv. wt., 340. Found: OCH_3, 9.5%; equiv. wt., 380; $[\alpha]_D$ +100° (c, 1.1 in water). The white solid had an infrared diagram identical with that of an authentic specimen of 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose (7).

A portion of the aldobiouronic acid was converted to the methyl ester methyl glycoside of the tetraacetate derivative (16), as described earlier (27). Recrystallization from ethanol gave crystals, m.p. and mixed m.p. 199–200° C, $[\alpha]_D$ +100° (c, 1.3 in chloroform). Anal. Calc. for $C_{22}H_{32}O_{15}$: C, 49.2%; H, 6.02%; OCH_3, 17.3%. Found: C, 49.6%; H, 5.85%; OCH_3, 17.0%. The infrared spectrum of the compound was indistinguishable from that of an authentic sample of methyl 2-*O*-[methyl(2,3-di-*O*-acetyl-4-*O*-methyl-α-D-glucopyranosyl)uronate]-3,4-di-*O*-acetyl-D-xylopyranoside (16).

Methylation of the Hemicellulose

Hemicellulose (A, 24.0 g) was subjected to three methylations with dimethyl sulphate and sodium hydroxide as described earlier (27) to give a white powder (24.7 g). This product was further methylated according to Kuhn and co-workers (17) with methyl iodide, silver oxide, and dimethyl formamide in the presence of Drierite. The product was recovered in the usual way (17) to yield a white, fluffy material (21.5 g), $[\alpha]_D$ −67° (c, 2.0 in chloroform). Anal. Calc. for a product containing nine xylose and one 4-*O*-methylglucuronic acid residue: OCH_3, 39.2%. Found: OCH_3, 38.7%.

Methanolysis of the Methylated Hemicellulose and Identification of the Acidic Component

The methylated polysaccharide (15.0 g) was boiled under reflux with 0.8 N methanolic hydrogen chloride (650 ml) in the presence of some Drierite for 8 hours. The solution was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

neutralized with silver carbonate, filtered through Celite, and evaporated to dryness to give a sirup (15.2 g) which was kept in aqueous barium hydroxide at 60° C for 2 hours. Barium hydroxide was removed by treatment with solid carbon dioxide followed by filtration through Celite. The aqueous solution was treated with Amberlite IR-120 exchange resin (acid form), filtered, and evaporated to a sirup (13.0 g). An aqueous solution of the latter was added to the top of a column with Dowex 1-X4 exchange resin (acid form) (8×20 cm). A mixture of neutral glycosides (10.1 g) was eluted with water (6 liters) after which an acid fraction (2.5 g) was recovered by elution with 30% aqueous acetic acid (4 liters).

The acid glycoside (2.5 g) was re-esterified by boiling with methanolic hydrogen chloride, dissolved in dry tetrahydrofuran (100 ml), and reduced with lithium aluminum hydride (3.0 g) (39). The product was recovered in the usual way to give a sirup (2.0 g) which crystallized spontaneously on evaporation from ethyl acetate. Two recrystallizations from ethyl acetate yielded pure crystals, m.p. and mixed m.p. 165–166° C, $[\alpha]_D$ +91° (*c*, 1.5 in water). Anal. Calc. for $C_{16}H_{30}O_{10}$: C, 50.3%; H, 7.92%; OCH_3, 40.6%. Found: C, 49.7%; H, 8.60%; OCH_3, 40.6%. The infrared spectrum of the compound was identical with that of an authentic specimen of methyl 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucopyranosyl)3-*O*-methyl-α,β-D-xylopyranoside (27).

Separation and Identification of the Neutral Sugars

The mixture of neutral glycosides eluted from the exchange resin was hydrolyzed with *N* sulphuric acid to give a pale yellow sirup (9 g). A portion of the mixture of reducing sugars (700 mg) was added to the top of a column (3.5×60 cm) containing a 1:1 mixture of Darco G-60 charcoal and Celite. The sugars were separated by gradient elution with 4 liters each of 5% aqueous ethanol → 20% ethanol and 20% ethanol → 40% ethanol. Three fractions were obtained in duplicate experiments in the order given below.

2-O-Methylxylose.—This fraction (2 mg) on electrophoresis had a rate of movement identical with that of 2-*O*-methylxylose.

*2,3-Di-O-methyl-*D*-xylose.*—The main fraction (500 mg) crystallized spontaneously. Two recrystallizations from ethyl acetate – petroleum ether gave crystals with m.p. 94–95° C (40), $[\alpha]_D$ −20° (2 minutes) → +22° (equilibrium, *c*, 2.0 in water). Anal. Calc. for $C_7H_{14}O_5$: OCH_3, 34.8%. Found: OCH_3,3 4.8%. The 2,3-di-*O*-methyl-*N*-phenyl-D-xylopyranosylamine had m.p. and mixed m.p. 124–125° C (41).

*2,3,4-Tri-O-methyl-*D*-xylose.*—This fraction (7 mg), $[\alpha]_D$ +20° C (*c*, 0.5 in water), could not be induced to crystallize. Its rate of movement on the paper chromatogram (solvent C) and its infrared spectrum were identical with those of an authentic sample of 2,3,4-tri-*O*-methyl-D-xylose.

Quantitative Analysis of the O-Methylxyloses

The mixture of neutral *O*-methylxyloses was resolved on filter papers with solvent C. The appropriate strips were excised and eluted with water. The concentration of the sugar solutions were determined by a recent modification of the phenol – sulphuric acid procedure of Smith and his co-workers (20, 42). The reagents used were 3% phenol in water (1 ml), concentrated sulphuric acid (5 ml), and sugar solution (1 ml). The following concentrations in mg/ml corresponded to one absorbance unit (10% transmittance): 2-*O*-methylxylose (118), 3-*O*-methylxylose (63), 2,3-di-*O*-methylxylose (139), and 2,3,4-tri-*O*-methylxylose (87). Paper blanks were analyzed for each compound and the absorbance obtained was deducted from that of the sugar. The average ratio between mono-, di-, and tri-*O*-methylxyloses from several analyses was 0.5:95:1.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Mr. E. Bleichert, who carried out a part of the experimental work. Financial assistance from the National Research Council of Canada is gratefully acknowledged.

THE STRUCTURE AND RESISTANCE TO METHYLATION OF 1,2-β-GLUCANS FROM SPECIES OF AGROBACTERIA[1]

P. A. J. Gorin, J. F. T. Spencer, and D. W. S. Westlake

ABSTRACT

The structures of extracellular polysaccharides produced by the plant pathogens *Agrobacterium tumefaciens* (2 strains), *A. rhizogenes*, *A. radiobacter*, *A. rubi*, *A. gypsophilae*, and *A. pseudotsugae* were investigated. Polymeric material was formed in good yield from all organisms except *A. gypsophilae*. Periodate oxidations of the polysaccharides and their sodium borohydride reduction products indicated linear 1,2-glucopyranose structures for *A. tumefaciens* (2 strains), *A. rhizogenes*, *A. radiobacter*, and *A. rubi* polymers. Optical rotational considerations led to the assignment of β-configurations. The linear structure for the *A. radiobacter* polysaccharide was confirmed by the isolation, after partial acid hydrolysis, of five 1,2-linked oligosaccharides with chain lengths of two to six. Periodate and chromatographic data indicated that the polysaccharide from *A. pseudotsugae* contained glucose and galactose and 1,6- as well as 1,2-glycopyranose links. It is noteworthy that the polysaccharides from the genus *Agrobacterium* are shown to be mainly 1,2-β-glucans, a structure not yet found in other genera.

Treatment of linear 1,2-β-glucans from *A. tumefaciens*, *A. radiobacter*, and *A. rhizogenes* with sodium hydroxide – dimethyl sulphate, followed by silver oxide in methyl iodide – dimethyl formamide, did not cause full methylation. Some of the 3-hydroxyl groups were not substituted and possible reasons for this unreactivity are discussed.

Hassid and co-workers (1) have shown that *Agrobacterium tumefaciens* (*Phytomonas tumefaciens*) produces in artificial media a polysaccharide consisting mainly of 1,2-D-glucopyranose units joined with the β-configuration (2). It has now been found that several other species of phytopathogenic Agrobacteria form polysaccharides of a similar type. The organisms examined were strains of *Agrobacterium tumefaciens* (virulent and non-virulent), *A. rhizogenes*, *A. radiobacter*, *A. rubi*, *A. pseudotsugae*, and *A. gypsophilae*. The latter organism did not form appreciable amounts of polysaccharide. The yields of 2-linked glycans varied from 2 to 4 g per liter of crude material, depending on the run and the species of organism used.

A striking property of the glucan from *A. tumefaciens* was its resistance to complete methylation (1). Attempts in this laboratory to fully methylate the glucans from *A. tumefaciens* (virulent strain), *A. rhizogenes*, and *A. radiobacter* also did not succeed using, as the final step, the Kuhn procedure (3). In each case, after acid hydrolysis of the methylated product, no 2,3,4,6-tetra-*O*-methyl-D-glucose was isolated, the main product being 3,4,6-tri-*O*-methyl-D-glucose. The undermethylated component was 4,6-di-*O*-methyl-D-glucose, indicating, in the light of periodate data described later, unreactivity of the C_3 hydroxyl group. In the methylation of cellulose, starch, and xylan, the 3-hydroxyl groups are substituted less readily than the other positions, and Croon (4) has suggested that this lower activity is due to hydrogen bonding with the ring oxygen of the adjacent pyranose unit (attached by its reducing end). A molecular model (Courtauld) of 2-*O*-β-D-glucopyranosyl-D-glucopyranose, each unit having the C-1 conformation, shows that this type of bonding can take place in a 1,2-β-glucan. The infrared spectrum of the partly methylated 1,2-β-glucan from *A. radiobacter* contained a strongly hydrogen-bonded hydroxyl band with $\Delta\nu_s$ 195 cm^{-1}.* Since the magnitude of $\Delta\nu_s$ varies with the strength of the hydrogen

**Difference of frequency between hydrogen-bonded and non-bonded hydroxyl absorption bands.*

bond (5) it is noteworthy that methyl α,β-2,4,6-tri-*O*-methyl-D-glucopyranoside had $\Delta\nu_s$ 75 cm^{-1}, showing that the two possible hydrogen bonds between the C_3 hydroxyl group and the C_2 or C_4 methoxyl groups are weaker. However, this evidence does not rule out interaction between the C_3 hydroxyl in the polymer and the glycosidic oxygen at C_2, but a molecular model suggested that this oxygen atom cannot approach the hydroxyl group as closely as the ring oxygen when the pyranose ring is in the C-1 conformation.

The lower reactivity of the C_3 hydroxyl in a 2-linked glucose dimer can be found in work by Rabaté, who methylated kaempferol sophoroside (6) in a conventional way. Acid hydrolysis of the methyl ether yielded as an unidentified product crystals with m.p. 169° C and $[\alpha]_D$ +113° → 62°, constants corresponding to those of 4,6-di-*O*-methyl-D-glucose. However, when 17-L-hydroxyoctadecanoic acid- and 1,8-nonanediol-sophorosides were methylated under vigorous conditions, no undermethylation was noted (7). It is therefore apparent that the low reactivity of the C_3 hydroxyl in these disaccharide derivatives is merely one of degree. Although strongly hydrogen-bonded hydroxyl groups react more slowly than those less bonded, this property alone does not explain the total unreactivity to methylation of some of the C_3 hydroxyl groups in 1,2-β-glucans. Since there is no reason to believe that the strength of the hydrogen bonds should increase during the course of the methylation to a point of total unreactivity of the group, it is now suggested that the C_3 hydroxyl is increasingly hindered sterically by the rest of the molecule as the methylation proceeds until the group is blocked by the increased bulk of the surrounding methoxyl groups.

Sodium periodate oxidation of the 1,2-β-glucans and derivatives from *A. tumefaciens* (virulent and non-virulent), *A. rhizogenes*, *A. radiobacter*, *A. rubi*, and *A. pseudotsugae* provided more complete structural information than the methylation technique. Excepting the product from *A. pseudotsugae*, the polysaccharides each consumed approximately 1.0 molar equivalents of oxidant, and a little formic acid was produced. As would be expected, overoxidation took place over the observed time of 1–8 days excluding any accurate deductions. *A. pseudotsugae* polysaccharide, which contained galactose as well as glucose, consumed oxidant more gradually up to 0.99 mole after 6 days and gave a high initial production of 0.21 mole of formic acid. After oxidation the dialdehyde units in each of the products were reduced with sodium borohydride and the materials obtained were hydrolyzed with acid. Glycerol was the only detectable hydrolysis product, confirming the linear poly-1,2-D-glucopyranose structure for the polysaccharides from the two strains of *A. tumefaciens*, *A. rhizogenes*, *A. radiobacter*, and *A. rubi*. Since *A. pseudotsugae* polysaccharide gave formic acid on periodate oxidation, it must contain some 1,6-linkages also. The low consumption of oxidant compared with formic acid production therefore shows that the polysaccharide must be impure. All of the above-mentioned polysaccharides except the one from *A. pseudotsugae* have specific rotations near −10°, strongly suggesting β-linkages are present. The polysaccharides from *A. tumefaciens* (two strains), *A. rhizogenes*, *A. radiobacter*, and *A. rubi* were first reduced with sodium borohydride to the derived alcohols, which obviated overoxidation of the reduced end-units (8, 9). The observed consumption of periodate was then 1.0 mole per anhydroglucose unit and small yields of formic acid were produced. However, since no tetramethyl glucose was isolated from methylated polymers on hydrolysis the acid formed may not give a true indication of chain length and may only provide evidence to show that there are differences between the polysaccharides from different species.

The polysaccharide from *A. radiobacter* was examined further and evidence was found to show that the glucan contains at least five consecutive linear 1,2-links. Graded acid

hydrolysis of the polymer yielded a homologous series of oligosaccharides detected on paper chromatograms. Cellulose chromatography of the mixture gave six apparently pure components varying from glucose and sophorose (2-*O*-β-D-glucopyranosyl-D-glucose) to a hexasaccharide. Attempts to crystallize these components, their derived alcohols, or their acetates did not succeed except for sophorose and the trisaccharide identified as *O*-β-D-glucopyranosyl(1 → 2)-*O*-β-D-glucopyranosyl(1 → 2)-D-glucose. Periodate oxidation data on the amorphous alcohols obtained by sodium borohydride reduction of the tri-, tetra-, penta-, and hexa-saccharides, was consistent with linear 1,2-glucopyranosyl linkages only being present (Table I). Also, the oxidation products were reduced with sodium

TABLE I

Specific and molecular rotations and sodium periodate oxidation data of oligosaccharides from *A. radiobacter*

	Dimer	Trimer	Tetramer	Pentamer	Hexamer
Reducing oligosaccharides

Molecular rotations	+5100°	+5500°	+6700°	+6300°	+5000°
Oligosaccharide alcohols					
Specific rotations (*c*, 1.0, H_2O)	−17.5°	−15°	−7.5°	+7.5°	+17.5°
Molecular rotations	−6000°	−5150°	−5000°	+6200°	+17,300°
Periodate consumed (moles/mole)	—	6.18 (6)*	7.01 (7)	8.12 (8)	9.25 (9)
Formic acid formed (moles/mole)	—	2.91 (3)*	3.08 (3)	3.00 (3)	3.21 (3)

*Figures in parentheses are the calculated values.

borohydride and hydrolyzed to yield glycerol only, thus confirming this observation. Although there is no evidence that there are α-linkages in the polysaccharide, the molecular rotations of the oligosaccharides (and derived alcohols) are not, as governed by the Freudenberg and Kuhn equation (10), proportional to their chain lengths (Table I), a situation which applies in other homologous series of oligosaccharides. Possibly this unusual behavior is related to the arrangement, which was such as to contribute to the over-all optical rotation of the molecule, of the sugar units in the chain.

Since *Agrobacterium* species are the only organisms that have yet been shown to produce 1,2-β-glucopyranose polysaccharides or to contain this linkage to some degree, this property provides further justification for placing these organisms in a particular genus. Other work, now at an early stage, on the polysaccharides produced by phytopathogenic organisms of the genera *Corynebacterium* and *Xanthomonas* indicates that in the main there are definite regularities in polysaccharide structure within the genera.

EXPERIMENTAL

Solutions were evaporated under reduced pressure using a bath temperature of 50° C and specific rotations were measured at 26° C. *A. tumefaciens*, strains IIBV7 and IIBNV6, were supplied by the Rockefeller Institute; *A. radiobacter*, strain 1000 by Dr. A. W. Hofer; *A. rhizogenes*, strain TR102, and *A. pseudotsugae*, strain TG102, by Dr. M. Starr; and *A. gypsophilae*, strain 13329, and *A. rubi*, strain 13335, by the American Type Culture Collection.

Isolation of Extracellular Polysaccharides of Agrobacteria

Stock cultures were maintained at 25° C on slants containing 1.5% glucose, 1% yeast extract, 0.2% calcium carbonate, and 1.3% agar. Shake cultures were grown in 500-ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Erlenmeyer flasks containing 100 ml of the above medium, but without the agar (yeast extract was dialyzed to remove high molecular weight material). Flasks were incubated at 25° C on a rotary shaker having an eccentricity of 1/2 in., operated at 240 r.p.m. Larger volumes of culture were produced in stirred fermentors having volumes of 3 liters or 20 liters using the same medium and growing conditions as for the flask cultures. Cells were removed, after 5 days, by centrifugation in the Sharples supercentrifuge. In a 20-liter fermentation the solution was evaporated to 1 liter and ultracentrifuged to remove small amounts of gelatinous material. The supernatant liquid was added to 4 volumes of ethanol to precipitate the polysaccharide, which was then filtered off and washed with ethanol. The yields of crude polysaccharide varied from 2 to 4 g per liter of medium from *Agrobacterium tumefaciens* (virulent and non-virulent strains), *A. radiobacter*, *A. rhizogenes*, *A. rubi*, and *A. pseudotsugae*, which all proved to contain the 1,2-β-glucan structure. The yield from *A. gypsophilae* was less than 1 g per liter and gave galactose, glucose, and an aldobiuronic acid on acid hydrolysis.

The 1,2-β-glucan-containing polysaccharides were further purified for specific rotation and periodate oxidation measurements. Polysaccharides were dissolved in water, the solutions deionized with Amberlite IR-120 and Dowex-1 and then filtered and evaporated to a small volume. The polysaccharides were isolated by ethanol precipitation and in each case dissolved readily in water to yield non-viscous solutions. The only exception was the polysaccharide from *A. pseudotsugae*, which dissolved only with difficulty to form a somewhat viscous solution. This material was also different in having a higher specific rotation than the other polysaccharides (Table II). When polysaccharides from

Sodium Periodate Oxidations of Polysaccharides

Twenty-five cubic centimeters of water containing 25 mg of polysaccharides was treated with 10 cc 0.1 *M* sodium periodate at 26° C. Uptake of oxidant was measured by addition to aliquots of buffered sodium arsenite containing potassium iodide followed by back-titration with iodine. Acid production was estimated by direct titration against sodium hydroxide. With each polysaccharide except that of *A. pseudotsugae* approximately 1.0 mole of periodate per mole of anhydroglucose unit was consumed within 21 hours reaction time; during the next 120 hours a further uptake of 0.1 mole was observed. Formic acid production increased from 0.10 mole/mole to 0.18 mole/mole when measured simultaneously. The *A. pseudotsugae* polysaccharide consumed 0.78 mole/mole of periodate releasing 0.21 mole/mole of formic acid after 21 hours, these values increasing gradually to 0.99 mole/mole and 0.36 mole/mole, respectively after a further 120 hours. After the oxidations were complete the solutions were deionized with Amberlite IR-120 and Dowex-1. The periodate-oxidized polysaccharides (10 mg) were reduced in the aqueous filtrate (20 cc) with sodium borohydride (10 mg) over a period of 3 hours. Excess reductant was destroyed with acetic acid, Amberlite IR-120 was added and, after shaking, the resin was filtered off and the filtrates evaporated to crusts. Boric acid was removed as trimethyl borate by repeated evaporations with methanol. The residues were hydrolyzed by heating in *N* sulphuric acid (5 cc) at 100° C for 3 hours. The acid was then neutralized with barium carbonate, the solutions filtered, and the filtrates evaporated. Paper chromatographic examination (solvent: butanol:ethanol:water, 40:11:19 v/v) of each hydrolyzate using the ammoniacal silver nitrate spray (12) showed that glycerol only was present. For the polysaccharides from *A. tumefaciens* (two strains), *A. rhizogenes*, *A. rubi*, and *A. radiobacter* 1,2-glucopyranose structures were indicated. However, the *A. pseudotsugae* polysaccharide gave a higher proportion of formic acid on periodate oxidation than the other polysaccharide, thus showing that some 1,6-linked glycopyranose units were present also.

Sodium Periodate Oxidations of Borohydride-Reduced Polysaccharides

Since the above described polysaccharides were overoxidized on treatment with aqueous sodium periodate, the reducing ends were modified with sodium borohydride in order to avoid the possibility of overoxidation starting from this site. Samples (1.00 g) of each polysaccharide were reduced with sodium borohydride (100 mg) in water (100 cc). After 6 hours the reaction mixture was worked up (in a similar manner to that described above for the reduction of the periodate-oxidized polysaccharides) to yield solids which were then oxidized with periodate. The same proportions of oxidant was used for the reduced polysaccharides, as in the oxidation of the unmodified polysaccharides. The results of this oxidation are recorded in Table II.

Methylation of Polysaccharides from A. tumefaciens (virulent), A. rhizogenes, and A. radiobacter

A portion of each polysaccharide (5.0 g) was dissolved in water (20 cc), dimethyl sulphate (3.3 cc) was added and the mixture was stirred vigorously. Sodium hydroxide (3.0 g) in water (10 cc) was introduced dropwise at such a rate as to keep the solution slightly alkaline over a period of 30 minutes. Then sodium hydroxide (30 g) in water (60 cc) was poured into the reaction mixture and methylation was effected using dimethyl sulphate which was added, in 11 separate aliquots of 3 cc each, once every 30 minutes. This process was repeated five times on successive days and then the solution was heated at 100° C for 3 hours. After it was cooled, the methylation mixture was neutralized with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

dilute sulphuric acid, and then extracted by shaking four times with chloroform. The extract was dried ($MgSO_4$), filtered, and evaporated to a crust (—OCH_3, 35.8% for the *A. radiobacter* polysaccharide derivative).

The partially methylated polysaccharides (yields 3.9 g to 4.2 g) were dissolved in a dimethyl formamide (30 cc) – methyl iodide (30 cc) mixture and shaken vigorously with portions of silver oxide (100 g total), fresh additions of oxide being made when the suspension had become yellow-brown. After 5 days the solutions were filtered and evaporated to brittle crusts (—OCH_3 contents for *A. tumefaciens*, *A. rhizogenes*, and *A. radiobacter* derivatives, 38.7%, 39.8%, and 39.5% respectively). Remethylation of the partially methylated *A. radiobacter* polysaccharide over a further 9 days under identical conditions did not increase the methoxyl content appreciably. The yields of methylated polysaccharides at the end of the Kuhn procedure appeared to be quantitative.

Samples (2.5 g) of the three partially methylated polysaccharides were refluxed in 10% methanolic hydrogen chloride (25 cc) for 16 hours. The acid was neutralized with silver carbonate and the solutions filtered and evaporated. The sirupy products were hydrolyzed on a steam bath in *N* sulphuric acid (10 cc) for 16 hours and after cooling the solutions were neutralized with barium carbonate, filtered, and evaporated. Paper chromatographic examination with the *p*-anisidine hydrochloride spray showed that, with each hydrolyzate, the main product was trimethyl glucose with a relatively smaller quantity of dimethyl glucose. No tetramethyl glucose was detected. Portions of the hydrolyzates (250 mg) were fractionated on cellulose columns using benzene:ethanol:water (500:50:1 v/v) as the mobile phase, which gave a complete separation. The proportion of each sugar was estimated gravimetrically and the percentages present of the dimethyl hexoses (on a molar basis) in the mixtures from *A. tumefaciens*, *A. rhizogenes*, and *A. radiobacter* were 27%, 20%, and 21% respectively. The trimethyl glucoses were converted to 3,4,6-tri-*O*-methyl-D-gluconic acid phenylhydrazide by the method of Haworth and co-workers (13). This derivative from the polysaccharides of *A. tumefaciens* (virulent), *A. rhizogenes*, and *A. radiobacter* melted at 130–131° C, 130° C, and 129–130° C respectively, and the melting points were not depressed on mixing with an authentic specimen. Also, the X-ray diffraction patterns of these phenylhydrazides and known material were identical. The dimethyl components of the mixtures crystallized readily and were recrystallized from ethyl acetate. The constants obtained on the crystals were consistent with 4,6-di-*O*-methyl-D-glucose (14). Examination of the mother liquors showed that no other dimethyl glucose components were present. The product from *A. tumefaciens* (virulent) polysaccharide had m.p. 160–164° C and $[\alpha]_D$ +110° → +64° (*c*, 1.1, H_2O; 18 hours, constant value). Calculated for $C_6H_{10}O_4(OCH_3)_2$: —OCH_3, 29.8%. Found: —OCH_3, 29.3%. The 4,6-di-*O*-methyl-D-glucoses from *A. radiobacter* and *A. rhizogenes* polysaccharides melted at 161–164° C and 161–162° C respectively. The dimethyl glucoses from the three different sources did not have their melting points depressed on intermixture.

Infrared Spectrum of the Partially Methylated A. radiobacter Polysaccharide

The partially methylated polysaccharide was dissolved in dry chloroform as 0.04 *M* and 0.2 *M* solutions. At 27° C both of these solutions showed strong absorption at 3465 cm^{-1} and a weak band at 3660 cm^{-1}, thus giving a $\Delta\nu_s$ of 195 cm^{-1} between hydrogen-bonded and undissociated hydroxyl groups.

A sample of methyl α,β-2,4,6-tri-*O*-methyl-D-glucopyranoside had its infrared spectrum measured under similar conditions. In this case there was a strong band at 3605 cm^{-1} and a very weak one at 3680 cm^{-1} indicating a $\Delta\nu_s$ of 75 cm^{-1}.

Partial Hydrolysis of A. radiobacter Polysaccharide

The polysaccharide (8.75 g) was dissolved in *N* sulphuric acid (200 cc) and the hydrolysis mixture was kept at 70° C for 18 hours. The acid was neutralized ($BaCO_3$), the solution was filtered and evaporated to a syrup which was fractionated on a cellulose column. *n*-Butanol saturated with water eluted glucose (1.62 g); butanol:ethanol:water (4:1:1 v/v) gave a disaccharide (0.79 g) and a trisaccharide (0.37 g); butanol:ethanol:water (8:3:3 v/v) gave a tetrasaccharide (0.49 g); and butanol:ethanol:water (2:1:1 v/v) a pentasaccharide (0.27 g) and a hexasaccharide (0.13 g).

The disaccharide crystallized from methanol–ethanol to yield sophorose with m.p. and mixed m.p. 198–200° C and $[\alpha]_D$ +28° → +16° (*c*, 1.0, H_2O; 18 hours, constant value). The trisaccharide was twice crystallized from aqueous methanol to give *O*-β-D-glucopyranosyl-(1 → 2)-*O*-β-D-glucopyranosyl-(1 → 2)-D-glucose with m.p. 218–223° C and $[\alpha]_D$ +16° → +11° (*c*, 1.0, H_2O; 18 hours, constant value). Calculated for $C_{18}H_{32}O_{16}$: C, 42.9%; H, 6.4%. Found: C, 42.55%; H, 6.7%.

The tetra-, penta-, and hexa-saccharides and their acetates were amorphous as were the derived polyols (by sodium borohydride reduction) and their acetates. The specific and molecular rotations of the five reducing oligosaccharides and their derived alcohols are recorded in Table I. The polyols were oxidized in aqueous sodium periodate and the uptake of oxidant and formic acid production measured after 18 hours (Table I) using the proportions in the oxidation of the reducing polysaccharide described earlier in the paper. The values obtained correspond to the presence of 1,2-linked hexapyranose units only.

ACKNOWLEDGMENTS

The authors wish to thank Dr. M. Starr for cultures of *A. rhizogenes* and *A. pseudotsugae*. The technical assistance of Mr. N. R. Gardner and Mrs. S. F. Hector is appreciated, as were the services of Miss I. M. Gaffney and Mr. M. Mazurek, who determined infrared spectra and carbon, hydrogen, and methoxyl analyses respectively.

A STUDY OF THE CN EMISSION FROM ACTIVE NITROGEN FLAMES[1]

KYLE D. BAYES[2]

ABSTRACT

When organic compounds are added to active nitrogen, the red and violet bands of the CN radical are emitted. The relative intensities of these red bands have been measured for a variety of added compounds, temperatures, and pressures. It is shown that there are at least three processes producing electronically excited CN radicals, two yielding CN($A^2\Pi$) and one yielding CN($B^2\Sigma$). The behavior of the flames indicates that a chain mechanism is involved. Adding ammonia, which does not react with nitrogen atoms, quenches the CN emission and inhibits the consumption of nitrogen atoms. It is concluded that a second reactive species in active nitrogen, possibly metastable $N_2(A^3\Sigma)$ molecules, initiates the reactions which result in light emission.

INTRODUCTION

When organic compounds are added to active nitrogen, a red or lilac flame appears which consists mostly of bands of the red ($A^2\Pi \rightarrow X^2\Sigma$) and violet ($B^2\Sigma \rightarrow X^2\Sigma$) systems of the CN radical (see Fig. 1). Winkler and co-workers have studied the products of the

The low-lying vibrational levels are indicated by the short horizontal lines within each curve.

reactions of active nitrogen with various compounds (1). They have proposed reaction mechanisms which could account for the observed products: however, they only speculate on the nature of the CN emission. Recently Kiess and Broida (2) have systematically studied the spectra of active nitrogen flames using various organic compounds. They concluded that there are at least two different reactions which produce electronically excited CN radicals. The present work was undertaken to learn more of these reactions which are responsible for the CN emission. In order to simplify the investigation as much as possible, only simple compounds have been used.

EXPERIMENTAL

The active nitrogen was formed in an electrodeless discharge (Deutsche Elektronik, 2500 Mc, 1000 w) operated at 0.6 to 30 mm Hg nitrogen pressure. A minimum of 0.5 second was required for the gas to flow from the discharge through 110 cm of Pyrex tubing (7-mm i.d.) to the reaction zone. The observation cell was a Pyrex tube of 30-mm inner diameter, 40 cm long, with a flat Pyrex window at the end where the active nitrogen stream entered. The organic compounds flowed through a capillary tube into the active nitrogen stream 3 cm before it entered the observation cell. A second capillary 40 cm upstream from the observation cell was used for adding ammonia and hydrogen in the quenching experiments. The pressure was measured by a small McLeod gauge at the exit of the observation cell. A cold trap prevented the products of the reaction from entering the rotary oil pump. All of the glass surfaces between the discharge and the cold trap were treated with a dilute solution of hydrofluoric acid in order to minimize atom recombination on the walls.

The observation cell and the entrance tubing were wrapped with Nichrome wire and asbestos so that spectra at elevated temperatures could be taken. A glass thermometer inside the cell measured the gas temperature. It was also possible to surround the cell with dry ice for low-temperature studies.

Commercially purified nitrogen (Nachgereinigter Stickstoff, Linde's Eismaschinen) was used without further purification. The CCl_4, $HCCl_3$, $HCBr_3$, and BrCN were chemically pure commercial products and were used without further purification. The HCN was produced by dropping concentrated sulphuric acid on NaCN and collecting the evolved gas in a dry-ice trap. The ClCN and $(CN)_2$ were prepared by standard procedures (3). The ClCN was redistilled twice, and only the most volatile half was retained, in order to separate it from the CCl_4 which was used in the preparation. Pressure drops across the flow capillaries were measured with mercury manometers. Gas flows were calculated using the Bernoulli equation for a compressible fluid. Standard viscosities were used when available (4). The viscosities of ClCN, BrCN, and HCN were assumed, for simplicity, to be equal to the viscosity of $(CN)_2$. The smaller capillaries were calibrated empirically by measuring the rate of pressure change in a known volume.

A small condensing lens focused the light from the observation cell onto the entrance slit of a Steinheil Universal Spectrograph which was equipped with $f/5$ glass optics and a plane grating (600 lines/mm). The reciprocal dispersion at the exit slit was 60 Å/mm. The spectrum was scanned by slowly turning the grating. Both entrance and exit slits were 0.5 mm wide, giving a resolution of about 30 Å. The use of glass optics should have resulted in some defocusing of the image as the grating was rotated; however, the effect was small and did not appreciably effect the resolution.

An infrared-sensitive photomultiplier tube (RCA 7102) was placed 4 cm behind the exit slit. A chopper between the cell and the condensing lens modulated the light at about 180 c.p.s. An ordinary 6-v bicycle generator was mounted on the same axis as the chopper to provide a reference signal of the same frequency and with a fixed phase difference compared to the light signal. The signal from the phototube and the reference signal were amplified and compared by a lock-in amplifier, the output going to a 5 mv Siemens strip chart recorder. The phototube was used at dry-ice temperature, and the other usual precautions were taken to minimize the noise level. A Jena OG 5"A" filter, which transmitted only wavelengths longer than 5300 Å, was used at the condensing lens to prevent the second-order blue spectrum from overlapping the red bands. For the very strong flames it was necessary to use neutral filters (Mikro-Siebblech) of 10

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and 1.5% transmission in order to prevent overloading the amplifier. A pip marker was used to correlate the rotation of the grating with the strip chart record.

The spectral sensitivity of the system was measured by taking the spectrum of a calibrated Osram tungsten filament bulb, said to have a black-body temperature of 2300° K. A calcium sulphate reflector was used just before the observation cell window to simulate the intensity and position of the flames. Since the present study was more interested in changes in the relative intensities of the bands, the small corrections for the emissivity of tungsten or the reflectivity of calcium sulphate were not made. The system had a maximum sensitivity per quantum at about 7000 Å, which decayed to about 20% of maximum at 10,000 Å and 5% at 11,000 Å. Toward the end of this study the photocathode sensitivity beyond 10,000 Å decayed considerably, making the intensity of the $A(0)$–$X(0)$ band* much less certain.

The areas of the peaks on the strip chart were measured with a compensating planimeter. These areas were divided by the relative sensitivity determined in the calibration in order to obtain the relative band intensities. Since the sensitivity of the photomultiplier did not extend far enough into the infrared to measure all of the CN bands, and since for some of the conditions used in this study the overlapping nitrogen afterglow spectrum was of comparable intensity with the CN bands, only one band was used as a measure of the total emission from a given vibrational level of $A^2\Pi$. The bands used ($A(0)$–$X(0)$, $A(1)$–$X(0)$, $A(2)$–$X(1)$, $A(3)$–$X(1)$, $A(4)$–$X(2)$, $A(5)$–$X(1)$, $A(6)$–$X(2)$, $A(7)$–$X(3)$, $A(8)$–$X(3)$, $A(9)$–$X(3)$, $A(10)$–$X(4)$) were chosen to have a minimum of overlap by other bands. When necessary, corrections were made for overlapping by weak nitrogen afterglow bands. These corrections never amounted to more than 30% of the CN intensity, and were usually much less. Minor corrections were usually made on the spectra to account for slight changes in intensity or in the base line during a run. The emission curves were reproducible to within several per cent of the total emission.

The intensity of a measured band, $A(v')$–$X(v'')$, was converted to the total emission from the level $A(v')$ by using the previously measured intensities of the CN red system (5). The total emissions from the various levels $A^2\Pi(v')$ were then plotted against the vibrational quantum number v' to give an "emission" curve as is shown in Fig. 2. Such

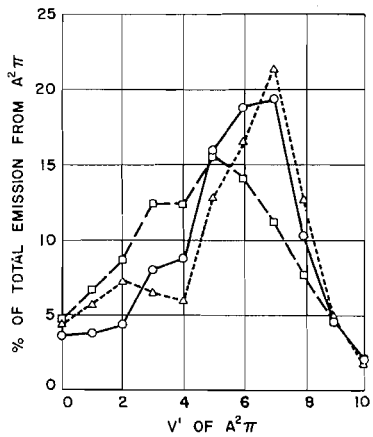

FIG. 2. Emission curves for the CCl_4 – active nitrogen flames. The percentage of the total emission from $A^2\Pi$ which originates in the level $A^2\Pi(v')$ is plotted against v'. Total pressure 3.0 mm Hg, CCl_4 flow 6×10^{-8} mole/sec. Temperature: □ 450° K; ○ 300° K; △ 200° K.

*This abbreviated notation will be used for the transition $A^2\Pi(v'=0) \rightarrow X^2\Sigma(v'=0)$.

a curve represents the relative number of quanta that are emitted from each vibrational level of $A^2\Pi$. If it can be assumed that the electronically excited molecules undergo no deactivating collisions, and that there is a steady-state concentration of excited CN molecules, then the emission curve would also represent the relative number of molecules which are being formed in the various vibrational levels of the $A^2\Pi$ state.

RESULTS

The spectrum of the CCl_4 – active nitrogen reaction was studied for a variety of conditions. For total pressures lower than about 5 mm Hg and CCl_4 flow rates lower than 10^{-7} mole/sec the spectral distribution of the CN red system did not change within the experimental error for changes in pressure (0.6 to 5 mm Hg) or CCl_4 flow.* There did appear to be a slight shift to higher vibrational levels with decreasing temperature as is shown in Fig. 2. At pressures greater than 5 mm and for higher flow rates of CCl_4 the distribution shown in Fig. 2 for 300° K (solid line) began to shift to lower vibrational quantum numbers in a manner which suggested that vibrational relaxation within the $A^2\Pi$ state was becoming important. Thus at 9.3 mm pressure (N_2 flow 2.6×10^{-5} mole/sec) and a CCl_4 flow of 2.4×10^{-8} mole/sec it was possible to obtain an emission distribution similar to that reported by Dixon and Nicholls (5) for similar conditions. Since vibrational relaxation masked the original distribution, further runs were limited to the lower pressures and flow rates.

The $HCCl_3$ flame at room temperature had an emission curve similar in shape to that of the CCl_4 flame, but with a less pronounced peak at $v' = 5$, 6, and 7. The emission curve for a $HCBr_3$ flame also had a peak centered on $v' = 6$ and 7, but it was significantly broader than the peak observed for the CCl_4 flame, especially toward higher vibrational levels. The stronger emission from the 10th vibrational level of $A^2\Pi$ for organic bromide flames has been noted previously (2).

In order to determine the effect of the reaction products on the spectral distribution of the CN emission, a study of the compounds XCN (X = H, Cl, Br, CN) was made. HCN is the main nitrogen-containing compound which is formed in active nitrogen–hydrocarbon reactions (1). The only detectable products of the CCl_4 flame were found to be ClCN and Cl_2 (6), so that it is expected that BrCN would be formed when organic bromides are used. Cyanogen is usually formed in small amounts in most of these reactions.

When HCN was added to active nitrogen, the CN emission was rather weak but the spectrum was very interesting and, therefore, was extensively studied. The distribution of the CN red emission for a HCN – active nitrogen mixture is shown in Fig. 3. A distribution almost identical with that shown in Fig. 3 was observed when ethylene at a flow rate of 1.9×10^{-8} mole/sec was added to active nitrogen at a pressure of 2.3 mm. In contrast to the CCl_4 flame, the relative intensities within the CN red system depended on both the flow rate of HCN and on the total pressure.

The curve of Fig. 3 can be divided up into two peaks. P_1 is arbitrarily defined as the emission from $A^2\Pi(v' = 0, 1, 2)$ and half of the emission from $v' = 3$, and P_2 is the remaining emission from $v' = 3$ and from the higher vibrational levels. It is believed that P_1 is not the result of vibrational relaxation of CN molecules originally formed in $A^2\Pi(5, 6, \text{and } 7)$. The pressure and flow of fuel are below the values mentioned above, at which vibrational relaxation is first apparent in the CCl_4 flame. Also the

**The spectra of reference 2 show a slight shift to lower v' in going from 1 mm to 4 mm Hg pressure. No reason for this disagreement is apparent.*

distribution in Fig. 3 is not what is theoretically expected for such a partially relaxed system (7).

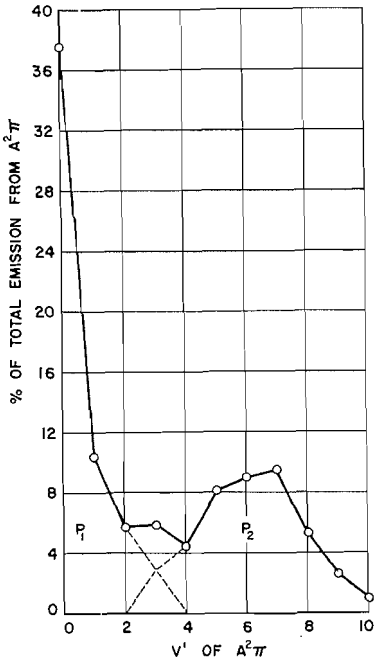

FIG. 3. Emission curve for a HCN – active nitrogen mixture. Pressure 3.3 mm Hg, temperature 300° K, HCN flow 8×10^{-8} mole/sec.

While holding the active nitrogen flow constant (total pressure 3 mm) and increasing the HCN flow, the ratio P_1/P_2 varied as is shown in Fig. 4. Adding HCN did not decrease the intensity of the nitrogen afterglow initially: however, there were gradual changes in intensity whenever hydrogen-containing compounds were added, probably because of changes in wall conditions. Therefore, it is necessary to compare the ratio of intensities within a given spectrum. The change of the inverse ratio, P_2/P_1, with nitrogen flow is shown in Fig. 5. It appears that in the limit of small HCN flow the ratio P_1/P_2 approaches

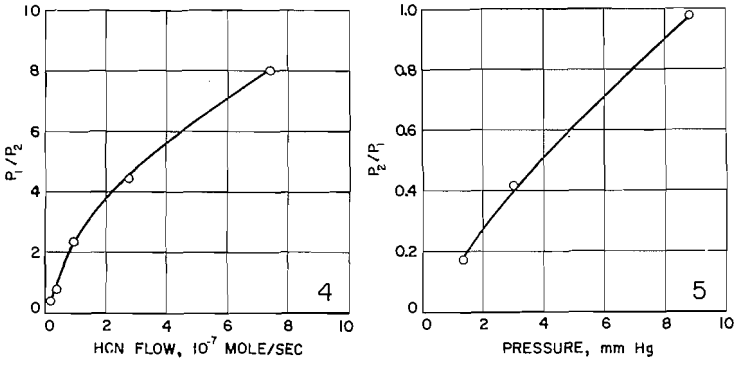

FIG. 4. The ratio P_1/P_2 for constant total pressure (3.0 mm Hg), constant temperature (300° K), and varying HCN flow.

FIG. 5. The ratio P_2/P_1 for constant HCN flow (9×10^{-8} mole/sec), constant temperature (300° K), and varying total pressure.

zero, while in the limit of low active nitrogen flow (or low pressure) the ratio P_2/P_1 approaches zero.

When cyanogen was added to active nitrogen the emission from the lowest vibrational levels of $A^2\Pi$ was comparable, both in intensity and spectral distribution to that observed with HCN. But the emission from the 5th, 6th, and 7th vibrational levels (P_2) was approximately 10 times weaker. In spite of this, the ratio of intensities $A(1)$–$X(0)/A(8)$–$X(3)$ showed the same shape curve as was found for P_1/P_2 with HCN (Fig. 4). Although small additions of cyanogen (10^{-8} mole/sec) did not reduce the normal afterglow intensity, larger flow rates quenched it almost completely, in agreement with previous work (8).

In contrast to the weak CN emission associated with HCN and $(CN)_2$, both ClCN and BrCN gave very bright flames, much brighter even than the CCl_4 flames. At 3 mm nitrogen pressure the reaction was so rapid that the flame was confined to the 7-mm tubing between the capillary and the observation cell. For this confined flame no afterglow could be observed downstream, and a brown deposit rapidly built up on the glass walls in contact with the flame. Thus it was necessary when studying these compounds to introduce the fuel capillary directly into the cell volume. When this was done, a roughly spherical flame formed, from 1 to 3 cm in diameter depending on the flow conditions. The distributions of CN emission from such ClCN and BrCN flames are shown in Fig. 6. Changing the ClCN or BrCN flow only changed the size of the flame, without

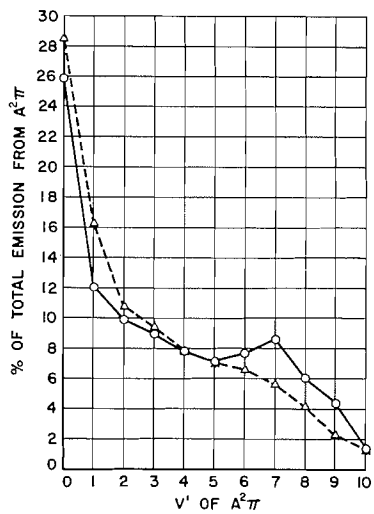

FIG. 6. Emission curves at 3.0 mm Hg pressure and 300° K, for ○ ClCN and △ BrCN flames.

changing the relative intensities of the emission. Runs at 1.3 mm nitrogen pressure, for which there was no bright flame but a diffuse emission throughout the cell volume, gave emission curves equal, within experimental error, to those shown in Fig. 6.

Since it is known that ammonia quenches certain of the first positive bands in the nitrogen afterglow faster than others (9), it was decided to test its quenching effect on the CN emission. With the nitrogen flow rate 1.4×10^{-5} mole/sec, the pressure in the cell was 3.0 mm and the Lewis–Rayleigh afterglow filled the entire system. Addition of 0.2% BrCN gave a bright flame and no afterglow could be observed downstream. Then 0.7% ammonia was added to the active nitrogen stream 40 cm (0.1 second) before it entered the observation cell. This weakened the CN emission by a factor of 62 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the nitrogen afterglow could once again be observed downstream, although it was not quite as intense as for the pure nitrogen. Increasing the BrCN flow sevenfold increased the total CN emission by less than 10% although it did shift the distribution somewhat to low vibrational levels. Essentially complete quenching of the CN emission occurred for larger ammonia flows. When 0.2% BrCN was added to active nitrogen containing 2% ammonia, there was no change in the relative intensities of the nitrogen first positive bands (i.e., no overlapping CN emission) but the total intensity of the afterglow was reduced by about 20%. Similar quenching by ammonia was observed for the HCN and CCl_4 reactions.

When the filter was not used before the entrance slit, the CN blue system in the second order was superimposed on the red system. For the conditions of this study the emission from the lowest vibrational level of the $B^2\Sigma$ state was much stronger than the emission from higher vibrational levels. The photomultiplier tube was not calibrated in the blue region of the spectrum, but the intensity of the $B^2\Sigma(v' = 0) \rightarrow X^2\Sigma(v'' = 0)$ band, in arbitrary units, divided by the total emission in the red system is plotted in Fig. 7 against the total pressure for a constant flow of CCl_4.

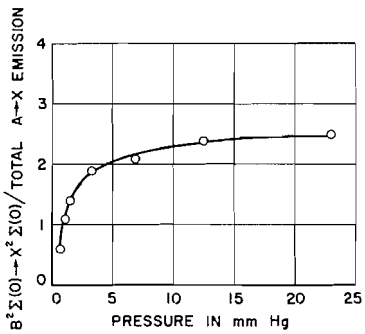

FIG. 7. The intensity of the $B^2\Sigma(0)$–$X^2\Sigma(0)$ band, in arbitrary units, divided by the total emission in the $A^2\Pi$–$X^2\Sigma$ system, plotted against the total pressure.

DISCUSSION

The variation of intensity of the $CN(B^2\Sigma(0) \rightarrow X^2\Sigma(0))$ band with total pressure (Fig. 7) was expected on the basis of the spectra previously reported by Kiess and Broida (2). They resolved the rotational structure of this band in a CH_2Cl_2 – active nitrogen flame, and showed that at low pressure (0.15 mm Hg) the blue emission originates almost entirely in those rotational levels of $B^2\Sigma(0)$ which are perturbed by rotational levels of $A^2\Pi(10)$. As the pressure was increased, the emission from the other, non-perturbed rotational levels of $B^2\Sigma(0)$ increased, until approximate rotational equilibrium was attained at 11 mm pressure. This behavior could be interpreted in the following way. The CN molecules are originally formed in the $A^2\Pi$ electronic state, some with 10 quanta of vibration. Because of the mixing of eigenfunctions (10) of the perturbed rotational levels of $A^2\Pi(10)$ and $B^2\Sigma(0)$, transitions between these two states can take place easily for certain J's. If the pressure is high enough, collisions can redistribute the $B^2\Sigma$ molecules among the other nonperturbed rotational levels before the allowed emission of radiation occurs. If one assumes a rapid equilibrium of molecules between the perturbed rotational levels of $A^2\Pi(10)$ and $B^2\Sigma(0)$, then the total emission from $B^2\Sigma(0)$ will depend on the rate of approach to equilibrium between the perturbed and unperturbed rotational levels of $B^2\Sigma(0)$, and thus on the total pressure. This mechanism

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

cannot explain the "tail bands" of CN, originating from high vibrational levels of $B^2\Sigma$, which sometimes appear in active nitrogen flames (11).

It is now generally accepted that active nitrogen contains nitrogen atoms in their ground state (12, 13). However, there is strong evidence that at least one other reactive species is present. Kaufman and Kelso (14) reported a temperature increase when N_2O, which is known not to react with nitrogen atoms (15), is introduced into active nitrogen. Freeman and Winkler (16) found that ammonia was decomposed by active nitrogen, and their experiments indicated that atomic nitrogen was not responsible. Kistiakowsky and Volpi (17) showed that the atomic nitrogen concentration was not reduced by additions of up to 7% ammonia. Since it was observed in this study that the intense CN emission could be completely quenched by the addition of 2% ammonia, it seems apparent that the second reactive species is important in at least initiating the reaction which leads to the CN emission.

Any of the electronic states of molecular nitrogen which participate in the afterglow mechanism might be the second reactive species. These include the proposed $^5\Sigma$, the $B^3\Pi$, and the $Y^3\Sigma$, which are the upper states of the afterglow emission, and the $A^3\Sigma$, which is the lower electronic state of the emitting molecules (9). Vibrationally excited ground state molecules should also be present since they will be formed by direct recombination of nitrogen atoms and by deactivation of $A^3\Sigma$ molecules. However, the observation that ammonia quenches the CN emission eliminates the possibility that the $^5\Sigma$, $B^3\Pi$, and $Y^3\Sigma$ states are the initiators of the CN emission. The small concentration of ammonia which was used quenches the nitrogen afterglow only slightly. This requires that the concentration of all the electronic states of nitrogen which precede the afterglow emission remain approximately constant. Since the CN emission is reduced drastically by the addition of ammonia, the concentration of the reactive species initiating the CN emission must also be changed significantly.

It has been suggested that ground state nitrogen molecules in high vibrational levels are responsible for the decomposition of ammonia by active nitrogen (18). If this is so, the ammonia molecules must absorb a large amount of the excess vibrational energy (since the ammonia is decomposed) and in this way prevent the reactions which result in the CN emission. To test this possibility, methane was substituted for ammonia in the quenching experiment previously described. Methane was chosen because it does not react significantly with active nitrogen at room temperature (19), and because its efficiency of transferring vibrational energy from N_2O is comparable to that of ammonia (20). The CN emission was reduced by a factor of two when 0.7% methane was added to a BrCN – active nitrogen flame, as compared with a factor of 62 for 0.7% ammonia. If vibrationally excited ground state nitrogen molecules are the second reactive species in active nitrogen, it is difficult to understand this large difference in the quenching effect of ammonia and methane. But because of the complexity of such an energy transfer, this experiment cannot be considered conclusive evidence against the vibrationally excited ground state hypothesis.

Nitrogen molecules in the lowest triplet state, the metastable $A^3\Sigma$, could also be the second reactive species in active nitrogen. Such molecules are certainly being formed in active nitrogen since this is the lower electronic state of the afterglow emission. Also it has been estimated that only 1 out of 20 recombining pairs of nitrogen atoms emits a quantum in the afterglow (21), the other pairs must recombine directly into the $X^1\Sigma$ and $A^3\Sigma$ states. On a statistical basis it is expected that three fourths of these recombining pairs will form $A^3\Sigma$ molecules. Thus approximately 16 molecules are formed in the $A^3\Sigma$ state for every quantum emitted in the Lewis–Rayleigh afterglow.

Several unsuccessful attempts have been made to observe $A^3\Sigma$ state molecules in active nitrogen. Exposures of 60 hours (22) failed to detect emission of the Vegard–Kaplan bands, $A^3\Sigma \rightarrow X^1\Sigma$, or the Lyman–Birge–Hopfield bands, $a^1\Pi \rightarrow X^1\Sigma$, from active nitrogen. But the latter have since been observed with much shorter exposures (13). Worley could find no absorption from the $A^3\Sigma$ state using a 13-m path length in active nitrogen (23), from which he concluded that the concentration of $A^3\Sigma$ was smaller than 10^{10} molecules/cm^3. However, mercury vapor was present in his experiments which might have reduced the concentration of triplet molecules by collisional deactivation.

It can be argued that if $A^3\Sigma$ molecules are the second reactive species, then Freeman and Winkler's estimate (16) that the second species is about one-sixth as abundant as nitrogen atoms is incompatible with the failures to observe the $A^3\Sigma$ state in emission or absorption. However, for the apparatus used in reference 16 the elapsed time between the discharge and the reaction cell was comparable with the radiative lifetime of the $A^3\Sigma$ state (0.026 second or longer (24)), so that metastable molecules formed in the discharge might be responsible for the high concentration of the second reactive species. This interpretation is consistent with their observation that increasing the voltage on the discharge increased the relative amount of the second reactive species (18).

The $N_2(A^3\Sigma)$ molecule could transfer its electronic energy to XCN, exciting it to a repulsive triplet state (I) which would then dissociate to CN and X radicals (II).

$$N_2(A^3\Sigma) + XCN \rightarrow N_2(X^1\Sigma) + XCN^* \quad (I)$$

$$XCN^* \rightarrow X + CN \quad (II)$$

It is known that such transfers in which the total spin is conserved can occur readily (25). The energy available from the triplet state of nitrogen, assuming a transition from $A^3\Sigma(0)$ to $X^1\Sigma(0)$, is 142 kcal/mole. The bond energy of X—CN has been calculated using the recently favored value for D(CN—CN) of 146 kcal (26) and accepted thermodynamic data (27, 28), and is presented in the second column of Table I. The energy necessary to break the X—CN bond and excite the CN radical to the $A^2\Pi(0)$ level (an additional 26 kcal) is shown in the last column in Table I. It is seen that the 142 kcal provided

TABLE I

The bond energies of X—CN (second column); the energies necessary to break the X—CN bond and excite the CN radical to the $A^2\Pi(v' = 0)$ level (third column)

Compound	Bond energy D in kcal	D + 26 kcal
$(CN)_2$	146	172
HCN	130	156
ClCN	107	133
BrCN	94	120

by the transition $A^3\Sigma(0)$–$X^1\Sigma(0)$ is sufficient to break the X—CN bonds, with the possible exception of $(CN)_2$. However, to break the X—CN bond and excite the CN radical to the $A^2\Pi$ state requires more than 142 kcal for HCN and $(CN)_2$. This might explain the weak CN emission associated with these compounds as compared to the more weakly bonded halogen cyanides. If the $A^3\Sigma$ molecules are vibrationally excited when they react, there would be correspondingly more energy available to excite the CN radical.

The decomposition of more complex molecules (at least those whose flames are quenched by ammonia) might occur by a similar mechanism. A transfer of electronic energy from

$N_2(A^3\Sigma)$ to the complex molecule, similar to step (I), could cause an initial bond rupture. Any polyatomic radicals formed should react rapidly with atomic nitrogen, yielding CN compounds or the CN radical directly.

The behavior of the flames observed in this work seemed to indicate that a chain reaction is involved. Sometimes, when adding very small amounts of fuel to the active nitrogen stream, an oscillating flame front would form. This was especially noticeable for the CCl_4 reaction at 80° C. This flame front, which gave the usual bright CN emission, would sometimes pulsate at about 5 c.p.s. with an amplitude of 1 cm. But it could be made to slowly sweep the entire length of the observation cell in an upstream direction once every several seconds, the flame completely disappearing at the window end of the cell before reforming again downstream. In between the passage of the flame the normal afterglow filled the tube, but the passing of the flame weakened it considerably. The effect was very sensitive to changes in fuel flow and total pressure, and was not entirely reproducible from day to day, possibly because of wall conditions. Such a lower concentration limit to a fast reaction is typical of a chain mechanism (29).

The complete consumption of nitrogen atoms in the BrCN and ClCN flames also suggests a chain mechanism. The second reactive species is, at most, one-sixth the concentration of nitrogen atoms (16), and is probably much less in these experiments because of the long flow time between the discharge and the reaction cell. But the removal of the second reactive species by ammonia prevents, essentially completely, the consumption of nitrogen atoms. Such behavior could be explained if the second reactive species initiates a chain reaction which consumes nitrogen atoms.

It was suspected, from the behavior of the CN emission in the HCN – active nitrogen mixtures, that the P_2 peak in Fig. 3 was associated with a reaction of free CN radicals. This possibility was tested by further experiments. It is known that CN radicals will react with molecular hydrogen (30). Therefore, the addition of hydrogen to a HCN – active nitrogen mixture should reduce the CN concentration, and thus the height of the P_2 peak, if the above suspicion is correct. With a total pressure of 3.0 mm and a flow rate of HCN of 2.5×10^{-8} mole/sec, the ratio P_2/P_1 was 1.1. Addition of 1.2×10^{-5} mole/sec of hydrogen between the discharge and the cell increased the total pressure to 3.3 mm and decreased the ratio P_2/P_1 to 0.2, as predicted above. The results of a similar experiment using ClCN instead of HCN are shown in Fig. 8. The response of the photomultiplier at 11,000 Å had decayed considerably by the time this experiment was done, so the intensity of the $A^2\Pi(0)$–$X^2\Sigma(0)$ band was rather uncertain. The two

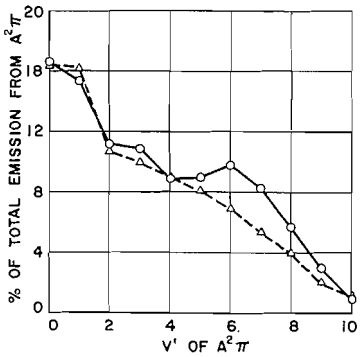

FIG. 8. Emission curves at 300° K. ○ Pressure 3.1 mm Hg, flow ClCN 7×10^{-8} mole/sec. △ Pressure 3.7 mm Hg, flow ClCN 7×10^{-8} mole/sec, flow hydrogen 2.4×10^{-5} mole/sec.

For personal use only.

emission curves have been normalized so that the total emission from the lowest three vibrational levels of $A^2\Pi$ is equal. It is seen that the emission from the 5th through 8th vibrational levels is reduced by the addition of hydrogen, and the difference between the two curves has the same shape, within experimental error, as the P_2 peak for the HCN spectrum. It thus appears that the population curve for the ClCN flame shown in Fig. 6 could also be interpreted as consisting of a P_1 and a P_2 peak. But the P_1 peak for ClCN extends to higher vibrational levels than the P_1 peak for HCN.

One possible behavior of the free CN radical would be to catalyze the recombination of nitrogen atoms, as is shown in steps (III) and (IV).

$$N + CN \rightarrow CN_2 \qquad \text{(III)}$$

$$CN_2 + N \rightarrow CN + N_2 \qquad \text{(IV)}$$

The CN_2 radical should be stabilized by several resonance structures. If at least some of the nitrogen molecules formed in step (IV) were in the $A^3\Sigma$ state, this catalytic recombination could explain the chain characteristics of these flames since the $N_2(A^3\Sigma)$ molecule could initiate further reactions (step (I)). Two nitrogen atoms recombining into the lowest vibrational level of the $A^3\Sigma$ state provide 83 kcal, which could be used to excite the CN radical. Since the CN_2 radical would probably have a significant binding energy, and since it is possible to form $N_2(A^3\Sigma)$ molecules in vibrational levels other than the lowest, it is expected that any $CN(A^2\Pi)$ formed during such a cycle would have less than the full 83 kcal. The average amount of excitation energy of the CN molecules which are responsible for the P_2 emission peak is 56 kcal.

Since the emission curve for the CCl_4 flame (Fig. 2, solid line) is very similar to the P_2 peak in the HCN reaction (Fig. 3), it was thought that the same mechanism was responsible for both emissions. However, the addition of 1.2×10^{-5} mole/sec of hydrogen to a CCl_4 flame (CCl_4 flow 1.0×10^{-8}) did not strongly quench the CN emission. The emission from the 6th, 7th, and 8th vibrational levels of $A^2\Pi$ appeared to be reduced slightly, compared to the rest of the spectrum, but the effect was comparable with the experimental error. Thus it appears that the CN emission in the CCl_4 flame and the P_2 emission in the HCN reaction occur by different mechanisms, in spite of the similar spectral distributions.

The conclusions of this study can be summarized. (1) The second reactive species in active nitrogen, which is responsible for decomposing ammonia, initiates the reactions which cause the CN emission. (2) Chain reactions are involved in the CN emission. (3) There are at least three reactions producing electronically excited CN radicals, one yielding $B^2\Sigma$ state molecules and two yielding $A^2\Pi$ state molecules. (4) The CN emission from CCl_4, $HCCl_3$, and $HCBr_3$ flames cannot be accounted for by a reaction between active nitrogen and the products of the primary reactions.

The helpful discussions and criticism of Professor E. F. Greene and Professor W. Groth are gratefully acknowledged. Thanks are expressed to Dr. H. P. Broida and Dr. H. T. Knight for permission to see their data before publication. I wish to thank the National Science Foundation for the postdoctoral fellowship which made this work possible, and the personnel of the Institute für physikalische Chemie der Universität Bonn for their hospitality.

SOME NEW COMPONENTS OF ROYAL JELLY[1]

WILLIAM H. BROWN,[2] ETHEL E. FELAUER, AND ROBERT J. FREURE[3]

ABSTRACT

Two additional acids, 10-hydroxydecanoic and *p*-hydroxybenzoic, have been isolated from the ether-soluble fraction of royal jelly. A sterol, 24-methylenecholesterol, has been found in the ether-insoluble, methanol-soluble fraction of royal jelly.

Until recently, the only acid known to be present in royal jelly was 10-hydroxy-2-decenoic acid (I) isolated by Townsend and Lucas (1), and characterized by Butenandt and Rembold (2). In 1959 Brown and Freure (3) reported the isolation and identification of two additional acids, sebacic (II) and 2-decendioic (III).

By further investigation of the ether-soluble fraction of royal jelly we have isolated and identified two more acids, 10-hydroxydecanoic (IV) and *p*-hydroxybenzoic (V).

$HOCH_2-(CH_2)_6-CH=CH-COOH$ I

$HOOC-(CH_2)_6-CH_2-CH_2-COOH$ II

$HOOC-(CH_2)_6-CH=CH-COOH$ III

$HOCH_2-(CH_2)_6-CH_2-CH_2-COOH$ IV

 V

When the mixture of ether-soluble acids from royal jelly, after removal of the neutral compounds and phenols as previously described (3), is allowed to stand at room temperature for a week a layer of water forms in the bottom of the container and the oil gives a positive ester test. From the oil a neutral compound (probably a mixture of lactones) can be separated which on saponification gives 10-hydroxydecanoic acid (IV). Lactone formation is undoubtedly due to the catalytic effect of residual sulphuric acid which is present in the mixture of acids, A (3). Lactones of IV have been prepared and described by Stoll and Rouvé (4). Authentic 10-hydroxydecanoic acid was prepared from castor oil by a modification of a patented procedure (5). No previous report of the finding of IV as a naturally occurring acid could be found although higher hydroxy acids such as 14-hydroxypalmitic acid are present as esters in common beeswax (6). Subsequent to the submission of this communication Weaver and Law (7) reported the presence of IV in royal jelly.

Following chromatographic methods as previously described (3) we have also isolated *p*-hydroxybenzoic acid (V) from royal jelly. This acid is widely distributed in nature. Borner (8) isolated V by chromatographic means from the aqueous extracts of straw from grains such as rye, wheat, and barley. Jarczynski, Kiermerier, and Gossel (9) have shown that V is a natural ripening agent of cheese. Also, Davis (10) in studies using *E. coli* and *A. aerogenes* associated with their enzyme systems has demonstrated vitamin activity with V. The concentration of V in royal jelly is very small (30 p.p.m.).

Table I gives the concentrations and R_f values of the acids which have been isolated from royal jelly to date.

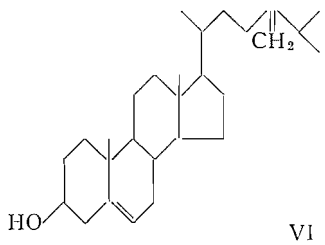
TABLE I



Concentrations and R_f values of acids present in royal jelly

Acid	Concn. in p.p.m. (basis lyophilized royal jelly)	R_f value*
I	70,000	0.79
II	200	0.44
III	300	0.39
IV	5,000	0.83
V	30	0.27

*Determined at 25° using a 7:3 ratio by volume of propanol and 28% aqueous ammonia solution as the developing solvent on Whatman No. 1 chromatography paper.

Methanol extraction of lyophilized royal jelly, previously extracted with ether, led to the isolation of a sterol, m.p. 139–141°, concentration 500 p.p.m.

The infrared absorption spectra of both the free sterol as well as its O-acetyl derivative are identical with those of authentic 24-methylenecholesterol (VI) and O-acetyl-24-methylenecholesterol, published by Barbier and Schindler (11). A mixture melting point between the O-acetyl derivatives was not depressed.

VI

Various melting points have been given for VI, depending upon the source from which it has been isolated. The reported melting points of the free sterol and the acetate derivative are listed in Table II.

TABLE II

Comparison of melting points of 24-methylenecholesterol (VI)

Source	Free sterol	Acetate derivative
From oysters (12)	142°	136°
From queen bees (13)	138–145°	131–136°
From worker bees (13)	138–140°	130–134°
Synthetic compound (14)	143°	135°
From royal jelly	139–141°	129–133°

The occurrence of VI in biological material has been reported twice. Barbier *et al.* (13) demonstrated the presence of VI in the neutral fraction of whole-bodied queen and worker bee extracts. Idler *et al.* (12) reported the isolation of VI from acetone extracts of the oyster (*Ostrea gigins*) and the clam (*Saxidomas giganteus*). Idler *et al.* (14) synthesized VI from 24-ketocholesterol and showed its identity with the natural product.

EXPERIMENTAL

All melting points reported by us have been corrected against reliable standards. Infrared data were determined by us on a Beckman IR5 instrument.

Isolation and Identification of 10-Hydroxydecanoic Acid (IV)

When 44 g of the mixture of ether-soluble acids, A (see Brown and Freure (3)), obtained from 390 g of lyophilized royal jelly, was allowed to stand at 25° for 1 week the oil did not crystallize but a second liquid phase appeared in the bottom of the flask. This liquid, 1.5 g, was removed and identified as water. The non-aqueous phase, which gave a positive test for sulphate ion, was processed again for the removal of neutral compounds as previously described (3). It yielded 1.85 g of a neutral colorless liquid, b.p. 270°; d_4^{20} 0.946; η_D^{20} 1.4472. The liquid gives a positive ester test.

Saponification of 1.5 g of the neutral liquid with 5% aqueous sodium hydroxide solution yielded 1.5 g of crude acid, m.p. 56–64°. One crystallization from water and two crystallizations from hexane (250 ml/g) gave 0.5 g of white needles melting at 71.5–72.5° both by itself and in admixture with authentic 10-hydroxydecanoic acid (IV).

Isolation and Identification of p-Hydroxybenzoic Acid (V)

The initial separation of V from the mixture of acids present in A (ether-soluble carboxylic acids. See Brown and Freure (3).) was carried out by chromatographing 0.30 g of A on 9×22.5 in. sheets of Whatman seed test paper as previously described (3). The area of paper, R_f 0.22–0.30, was cut out and extracted with propanol in a Soxhlet apparatus for 15 hours. The propanol extracts were combined, concentrated to a volume of 2 ml, and fractionated on four, 9×22.5 in. sheets of 3MM chromatography paper in order to remove residual amounts of the acids II and III. The area of paper, R_f 0.22–0.28, was cut out and extracted with propanol. The propanol extract was evaporated to dryness and the residue processed as described for the isolation of acids II and III (3). From 15 g of A, 0.014 g of crude V, m.p. 205–214°, was obtained. The crude V was washed with four 2-ml portions of cold chloroform (5°) to remove a sticky brown residue extracted from the chromatography paper. The resulting white residue, 0.011 g, had m.p. 211–215°. Crystallization from chloroform (55 ml/g) gave 0.0035 g of acid, m.p. 214–215°. Inspection of the infrared spectrum (KBr disk) of the sample suggested that it is *p*-hydroxybenzoic acid, a supposition which was confirmed by mixture melting point.

Blank determinations showed that V came from A and not from the possible breakdown of small amounts of lignin in the chromatography paper.

Isolation and Identification of 24-Methylenecholesterol (VI)

Ether-extracted, lyophilized royal jelly, 647 g, was placed in a Corning 3885 Soxhlet apparatus in 2-in. layers alternating with Pyrex glass fibers and extracted with absolute methanol for 2.5 hours. The dark orange extract was concentrated by distillation to 500 ml and cooled to 5°. White, plate-like crystals, which formed, were removed by filtration, weighed 0.278 g and had m.p. 122–135°. By concentrating the mother liquor and cooling, another 0.037 g of crystals, m.p. 125–137° was obtained. The crude product, 0.315 g, (500 p.p.m.) was crystallized twice from acetone (100 ml/g) including treatment with decolorizing charcoal. By this process there was obtained 0.029 g of white plates, m.p. 139–141°.

The compound gives a positive Liebermann–Burchard test and ferric chloride – sulphuric acid reaction (15) thus indicating that it is a sterol. The acetate, prepared according to the procedure of Barbier and Schindler (11), has m.p. 129–133°. A mixture melting point with authentic O-acetyl-24-methylenecholesterol was not depressed. Finally, the infrared spectra of the free sterol and the acetate are identical with those of authentic 24-methylenecholesterol and its acetate.

ACKNOWLEDGMENTS

Financial support for one of us (E.E.F.) was through a Public Health Research Grant. W. C. Hardesty Co. of Canada, Ltd. supplied generous amounts of 10-hydroxydecanoic acid. Professor G. F. Townsend, Department of Apiculture, O.A.C., Guelph, Ont., made available to us the lyophilized royal jelly used in the project. Dr. E. Reiner, Fisheries Research Board of Canada, Vancouver, B.C., kindly provided us with an authentic sample of 24-methylenecholesterol.

LYCOPODIUM ALKALOIDS

PART IV. ALKALOIDS OF JAMAICAN LYCOPODIUM CLAVATUM LINN.[1,2]

R. H. Burnell and B. S. Mootoo

ABSTRACT

Seven alkaloids have been isolated from *L. clavatum* Linn. collected in Jamaica, clavolonine $C_{16}H_{25}NO_2$, fawcettiine $C_{18}H_{29}NO_3$, base A (now named fawcettimine), lycopodine, dihydrolycopodine, and L.2 (acetyldihydrolycopodine). Fawcettimine is a secondary amine now shown to be $C_{16}H_{25}NO_2$. The isolation of deacetylfawcettiine $C_{16}H_{27}NO_2$ in quantity from a later extraction indicated that there was a seasonal variation in the alkaloid content of the plant. These bases differ from those obtained from *L. clavatum* of Canadian or European origin.

Lycopodium clavatum Linn. occurs in many areas of the world and at least two previous extractions are reported of the plant collected in Poland (1) and Canada (2). Since different bases were obtained from these previous extractions it seemed worth while to investigate material from a tropical source such as Jamaica. Club mosses do not grow in abundance in the tropics except at relatively high altitudes so the plant used for this work was collected in the Blue Mountains of Jamaica (ca. 5500 ft).

The extraction procedures follow closely the method used by us to extract *L. fawcettii* (3) and the yield of crude base amounted to 0.2% of the weight of dried plant when collected in April. Upon subjecting the crude alkaloid to a diagonal distribution between chloroform and buffer, three distinct fractions were obtained: (i) weak bases, (ii) a base of intermediate basicity, and (iii) strong bases. The latter afforded a crystalline base $C_{16}H_{25}NO_2$, m.p. 238°, which showed both hydroxyl and carbonyl absorption in the infrared and so was named clavolonine. The structure of the latter became apparent during work on fawcettiine (4).

The clavolonine mother liquors were acidified with perchloric acid and gave, in high yield, a perchlorate $C_{18}H_{29}NO_3.HClO_4$, m.p. 272–275°, which has been shown by the usual methods to be fawcettiine perchlorate, previously isolated from *L. fawcettii* (3, 5). Chromatography of the base regenerated from the mother liquors yielded more fawcettiine and clavolonine and another base, m.p. 168°, which proved to be dihydrolycopodine, $C_{16}H_{27}NO$.

The compound of intermediate basicity could not be crystallized but gave a methiodide, m.p. 240–242°, and a perchlorate, m.p. 225–226°, neither of which depressed the melting point of the corresponding derivative of base A, also obtained previously from *L. fawcettii*. Analyses of the free base, its hydrochloride, and perchlorate have prompted us to correct the molecular formula of base A to $C_{16}H_{25}NO_2$. We have named this compound fawcettimine since analysis of the methiodide, $C_{18}H_{30}NO_2I$ and the conversion of the base to an N-nitroso derivative (6) show it to be a secondary amine. Acetylation affords neutral N-acetylfawcettimine but this derivative has never been obtained crystalline. An infrared spectrum of the compound in carbon tetrachloride solution shows one carbonyl band at 1730 cm^{-1} whereas the methiodide shows two peaks at 1692 and 1730 cm^{-1}. The salts (perchlorate and hydrochloride) show only the 1690 cm^{-1} band in the carbonyl region.

The weak bases consisted of lycopodine, acetyldihydrolycopodine (Marion's L.2 (7, 8), and an extremely labile, feebly basic substance which has, as yet defied all attempts at characterization.

In a later extraction using plant material collected in the same locality, but in July (of the same year) the yield of crude base amounted to only a little over 0.1%. Clavolonine, fawcettiine, and lycopodine were obtained but fawcettimine, easily recognized by the green coloration it gives with the platinic chloride – potassium iodide spray used for chromatograms, was absent. The work-up of the strong bases from this extraction differed from that of the earlier work due to the presence of deacetylfawcettiine $C_{16}H_{27}NO_2$ in abundance. The latter was obtained in trace amounts from *L. fawcettii* (5) but it was felt at the time that the conditions used for the extraction could have hydrolyzed some of the fawcettiine present. Using a milder extraction such as employed in this case excludes this possibility.

EXPERIMENTAL

All infrared figures are for nujol mulls unless otherwise stated.

Crude Base (April)

Through the dried, ground plant (42 kg) was percolated 2% aqueous tartaric acid, which was then concentrated to about one-tenth of its volume and continuously extracted with chloroform. After basification with ammonia, the crude alkaloid (73.6 g) was obtained by further chloroform extraction. The crude base was distributed between chloroform and phosphate buffer, pH 6.98 in large separatory funnels in a diagonal manner to give 10 fractions. The buffer layers contained the strong bases (27 g) and the first two chloroform fractions the weak bases (25 g). The intermediate funnels contained only one base in abundance (14 g).

Clavolonine

The strong base (27 g) was dissolved in acetone and allowed to cool and the crystalline material filtered off (9.67 g). After recrystallization from acetone, the clavolonine was sublimed for analysis, m.p. 238°. Found: C, 72.9; H, 9.7; N, 5.1; O, 12.0; C—CH_3, 5.8. $C_{16}H_{25}NO_2$ requires: C, 73.0; H, 9.6; N, 5.3; O, 12.1; C—CH_3, 5.7.

Infrared peaks at 1693 cm^{-1} (C:O) and 3180 cm^{-1} (OH). A well-defined peak at 1412 cm^{-1} is indicative of the grouping —CH_2—CO—.

The methiodide was recrystallized from ethanol/acetone, m.p. 325–328° (decomp.). Found: C, 50.5; H, 6.6; N, 3.4; O, 8.2; I, 31.8; N—Me, 3.9. $C_{16}H_{25}NO_2.CH_3I$ requires: C, 50.4; H, 7.0; N, 3.4; O, 79; I, 31.3; N—Me, 3.7.

Fawcettiine Perchlorate

The clavolonine mother liquors were made acidic with an acetone solution of perchloric acid and a little ether added. The perchlorate was filtered and washed with acetone/ether and dried (11.3 g). The salt, recrystallized from acetone melted at 272–275° and showed no depression on admixture with fawcettiine perchlorate obtained from *L. fawcettii* (3). The infrared traces were superimposable.

Dihydrolycopodine

The base regenerated from the fawcettiine perchlorate mother liquors (8.0 g) was chromatographed over alumina in benzene. The first benzene eluate containing base afforded a pale yellow oil (1.28 g) which was taken up in ethyl acetate and cooled. The

lustrous prisms which separated (440 mg) were recrystallized from acetone, m.p. 168°. A second crop (170 mg) was obtained on further standing. Found: C, 77.4; H, 11.2; N, 5.4. $C_{16}H_{27}NO$ requires: C, 77.1; H, 10.9; N, 5.6.

The infrared showed hydroxyl absorption at 3150 cm^{-1}, showed no bands in the carbonyl region, and was identical with that of a sample of dihydrolycopodine prepared from lycopodine (9). Mixed melting points of the bases or the methiodides prepared from them (m.p. 283–287°) showed no depression. The methiodide was recrystallized from ethanol/acetone. Found: C, 52.3; H, 7.8; N, 3.7; I, 32.0. $C_{16}H_{27}NO.CH_3I$ requires: C, 52.2; H, 7.7; N, 3.6; I, 32.4.

Base A (Fawcettimine)

The intermediate funnels from the distribution yielded 14 g of crude base which was partitioned again between chloroform and phosphate buffer, pH 6.69, in a multiple extractor. The strong and weak bases were combined with the respective fractions from the first distribution and the intermediate base (4.48 g) run over alumina in benzene. The base obtained (4.07 g) was shown to be homogeneous by paper chromatography and sublimed as a glass (130° at 2 mm). Found: C, 72.7; H, 9.3; N, 5.6; O, 12.7; C—Me, 4.7. $C_{16}H_{25}NO_2$ requires: C, 73.0; H, 9.6; N, 5.3; O, 12.2; C—Me, 5.7.

The infrared spectrum of the base in carbon tetrachloride showed a carbonyl peak at 1730 cm^{-1} but in nujol mulls of the salts of fawcettimine the carbonyl peak was at 1690 cm^{-1}.

The methiodide was prepared in acetone and recrystallized from ethanol/acetone, m.p. 240–242°. Found: C, 51.5; H, 7.2; N, 3.1; I, 29.6. $C_{18}H_{30}NO_2I$ requires: C, 51.6; H, 7.2; N, 3.3; I, 30.3.

The hydrochloride was recrystallized from ethanol/acetone, m.p. 235° (decomp.). Found: C, 63.8; H, 8.7; N, 4.7; O, 10.8; Cl, 11.6. $C_{16}H_{25}NO_2.HCl$ requires: C, 64.1; H, 8.7; N, 4.7; O, 10.7; Cl, 11.8.

The perchlorate was recrystallized from isopropanol/acetone, m.p. 225–226°. Found: C, 52.4; H, 7.0; O, 26.7; Cl, 9.9. $C_{16}H_{25}NO_2.HClO_4$ requires: C, 52.8; H, 7.2; O, 26.4; Cl, 9.7.

N-Nitroso-fawcettimine

Fawcettimine (170 mg) was dissolved in glacial acetic acid (1 ml) and water (3 ml) and cooled in ice. A cold solution of sodium nitrite (170 mg) in water (2 ml) was added dropwise with stirring. Crystals appeared on standing in the cold (106 mg), m.p. 137–138°. The derivative was recrystallized from ethanol/water and showed a peak in the ultraviolet at 235 mμ (ϵ: 7000) (6). Found: C, 65.1; H, 8.8; N, 9.4; O, 16.4. $C_{16}H_{24}N_2O_3$ requires: C, 65.7; H, 8.3; N, 9.6; O, 16.4.

Active hydrogen determinations in anisole and pyridine gave 0%.

Lycopodine

The weak base (25 g) was distributed diagonally between chloroform and acetate buffer, pH 5.59, to remove traces of stronger bases and neutral materials. A portion of this purer base (4.15 g) was run over alumina in benzene and the first benzene eluate (2.97 g) dissolved in 2 *N* acetic acid and saturated potassium nitrate solution added. The turbid solution deposited crystals of lycopodine nitrate (1.2 g) on cooling (10). The base regenerated from the nitrate melted over the range 116–118° and showed a carbonyl peak in the infrared at 1710 cm^{-1}.

The methiodide was recrystallized from ethanol/acetone, m.p. 322–323° (inserted at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

280°). Found: C, 52.5; H, 7.5; N, 3.8; O, 4.1. $C_{16}H_{25}NO.CH_3I$ requires: C, 52.4; H, 7.3; N, 3.6; O, 4.1.

Obtaining the lycopodine via the nitrate does not afford an effective separation since more of the base remains in solution than crystallizes out, so the weak base (8.5 g) regenerated from the nitrate solution and remaining on the column was shaken between chloroform and acetate buffer, pH 4.27, for 20 transfers. The lycopodine (plus one other base) was mostly in tubes 6–14 (3.09 g) and was obtained by conversion to the perchlorate (2.11 g). Tubes 17–19 contained a small amount of clavolonine (120 mg).

Acetyldihydrolycopodine (L.2)

Solution infrared spectra of the fractions from the weak base distribution showed that tubes 6–14 contained, in addition to lycopodine, another base containing an O-acetyl grouping and no hydroxyl. Fraction 8 (0.58 g) was hydrolyzed in methanolic sodium hydroxide and the product chromatographed over alumina. Lycopodine (0.29 g) was obtained and the only other base was dihydrolycopodine, m.p. 168° (105 mg). Since the latter is far too strong a base to be present as such the acetylated base in the plant must be L.2 (acetyldihydrolycopodine).

The first tubes of the distribution contained an extremely labile base which has, as yet, resisted all attempts at purification or characterization.

Crude Base (July)

The dried, ground plant (22 kg) was extracted as described above affording the crude base (25.0 g), which was diagonally distributed in funnels as described above. Funnels 1 and 2 (weak base: 9.9 g) contained lycopodine and funnels 3–8 (7.9 g) afforded clavolonine (2.22 g) and fawcettiine perchlorate (2.45 g). No fawcettimine was found.

Deacetylfawcettiine

Funnel 10 from the distribution (2.44 g) solidified on evaporation of the solvent and afforded a crystalline base (1.18 g) m.p. 205–208° from acetone. A second crop (300 mg) of the same base was obtained on further concentration. A comparison of the infrared spectrum of this base with that of deacetylfawcettiine and a mixed melting point determination showed that the two bases were identical.

ACKNOWLEDGMENTS

The authors would like to thank Mr. C. G. Chin for technical assistance.

PRESSURE EFFECT AND MECHANISM IN ACID CATALYSIS

VII. HYDROLYSIS OF METHYL, ETHYL, AND *t*-BUTYL ACETATES[1]

A. R. OSBORN[2] AND E. WHALLEY

ABSTRACT

The effect of pressures up to 3 kbar on the rate of the acid-catalyzed hydrolysis of methyl, ethyl, and *t*-butyl acetates in dilute aqueous acid and of ethyl acetate in concentrated hydrochloric acid has been measured. The volume of activation for *t*-butyl acetate is zero within experimental error, showing that the mechanism is unimolecular. Those for methyl and ethyl acetates are near -9 cm^3 mole^{-1} in both dilute and concentrated acid. We deduce from this that the mechanism is the same in 9.2-*M* hydrochloric acid as in dilute acid, that the transition state is not highly polar, and that if the proton in the reactive protonated ester is on the carbonyl oxygen then the attacking water molecule adds, and if the proton is on the ether oxygen then the attacking water molecule substitutes.

1. INTRODUCTION

In spite of a large amount of experimental work, the hydrogen-ion-catalyzed hydrolysis of simple aliphatic esters is not well understood. There is little doubt, because, for example, of the relative rates in water and heavy water (1–3), that a pre-equilibrium proton transfer occurs, but the location of the proton in the reactive conjugate acid is not known. There is little doubt, mainly because of substituent effects (4, p. 770), that hydrolysis occurs by an attack of a water molecule on the conjugate acid, but it is not known whether the attack is an addition to a water molecule to form a stable intermediate or whether it is a simple substitution. It is, however, known that when ethyl benzoate is hydrolyzed by acid catalysis, the carbonyl oxygen of the unhydrolyzed ester exchanges with the oxygen of the solvent water (5, 6), but it is not known whether the hydrolysis and exchange follow similar or unrelated mechanisms. There are differing opinions (e.g. refs. 7–11) about whether the transition states that determine the rates have high dipole moments or not.

The effect of pressure on the rates of acid-catalyzed hydrolyses can provide useful information about the mechanisms (11–16), and a preliminary discussion of the hydrolysis of methyl acetate based on a few results reported by Bogojawlensky and Tammann (17) has already been given (11). In this paper we report measurements of the effect of pressures up to 3 kbar on the rates of hydrolysis of methyl and ethyl acetates in dilute hydrochloric acid.

Tal'vik and Pal'm (18) have argued that in concentrated acids ethyl acetate becomes essentially completely protonated, and that if allowance is made for the protonation, then the rate becomes nearly proportional to Hammett's acidity function h_0 rather than to the concentration of hydrogen ion. By using the Zucker–Hammett hypothesis (19, 20) they deduced that the slow step is

$$CH_3{-}C(=O)(H)({}^{+}OC_2H_5) \rightarrow CH_3CO^{+} + C_2H_5OH. \qquad [1]$$

An attempt to verify this mechanism in concentrated acids has been made by measuring the volume of activation in concentrated hydrochloric acid.

t-Butyl acetate hydrolyzes by acid catalysis (21–26) with alkyl–oxygen fission (26) and with an Arrhenius energy of 27.6 kcal $mole^{-1}$ and an entropy of activation of 14.2 cal deg^{-1} $mole^{-1}$ (22, 25) and it seems likely that the mechanism is unimolecular. The effect of pressure on the rate of hydrolysis in water has been measured to test this mechanism.

2. EXPERIMENTAL METHODS

The methyl and ethyl acetates used were of analytical grade and were not further purified. The *t*-butyl acetate was a commercial sample and it was distilled, the fraction b.p. 94–96.5° C being retained.

The high-pressure technique was similar to that used previously (12), except for the following modifications. In the original apparatus oil was pumped by hand into the pressure vessel to prevent loss of pressure when a sample was taken. We have added an air-driven oil pump to the apparatus, which automatically maintains the pressure constant when a sample is taken. The pump was modified from one made by the Sprague Engineering Co. by fitting it with a high-pressure end capable of generating a pressure of 4 kbar when 100 p.s.i.g. of compressed air is supplied to the low-pressure end.

In the original apparatus the reacting solution was in contact with an austenitic-stainless-steel capillary tube, which corrodes in strong acid. The sampling system was modified so that the solution is in contact with only glass, tantalum, Hastelloy B (Haynes Stellite Co.), and neoprene, all of which are unaffected for practical purposes by concentrated perchloric and hydrochloric acids up to at least 8 *M* near room temperature and will withstand more dilute acids up to at least 100° C. The new sampling system is shown in Fig. 1. The hypodermic syringe which is used as the reaction vessel is attached to the tantalum capillary sampling tube by means of the stainless-steel union and the small neoprene seal which isolates the reaction solution from the hydraulic oil. A small nut and lock nut at the upper end of the union allows the force on the neoprene seal to be adjusted. The union is held in place on the syringe by means of an o-ring which fits into a groove in the neck of the syringe. The two parts of the union are held together by means of a bayonet-and-socket device similar to that used on some lamp bulbs. The sampling valve is made of Hastelloy B, and the connection between the valve and the tantalum tube is shown in the upper part of Fig. 1. A metal–metal seal isolates the hydraulic oil from the atmosphere, and an o-ring seal isolates the oil from the sample. This connection can be easily dismantled when necessary. The stem of the valve is also made of Hastelloy B. The outlet of the valve is connected to a water-jacketed tantalum capillary tube.

The hydrolyses were followed by titration with standard alkali of the acid produced during the hydrolysis, using phenolphthalein as indicator.

3. RESULTS

The reactions follow first-order kinetics and the first-order constants were obtained graphically in the usual way. The accuracy was about 2%. For reactions in dilute aqueous acids, the second-order constants k_a were obtained by dividing the first-order constants by the concentration of acid at the temperature and pressure of the experiment, assuming that the compression and thermal expansion of the solution are the same as that of pure water (27). For reactions in concentrated acids the first-order constants k_1 are reported because the compressibility of concentrated hydrochloric acid has not been measured. The rate constants are given in Tables I and II and are shown graphically in Fig. 2.

TABLE III

Acid-catalyzed hydrolysis of t-butyl acetate in water at 60.00° C with 0.01-M HCl

p/bar	$10^3\ k_a$/l. mole^{-1} sec^{-1}
1	17.9
500	18.0
1000	18.0
1500	17.8
2000	18.2

sec^{-1} for k_a at 35.00° C in water. For t-butyl acetate interpolation of Palomaa *et al.*'s results (22) gives 17.6×10^{-3} l. mole^{-1} sec^{-1}. The agreement is satisfactory.

The volumes of activation $\Delta V^{\ddagger}$ were obtained graphically (Fig. 2) using the usual relations

$$\partial \ln k_a/\partial p = -\Delta V^{\ddagger}/RT \text{ or } \partial \ln k_1/\partial p = -\Delta V^{\ddagger}/RT + \kappa,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where κ is the compressibility of the solution. For methyl acetate,

$$\Delta V^{\ddagger} = -9.1 \pm \sim 0.7 \text{ cm}^3 \text{ mole}^{-1} \text{ at } 35^\circ \text{ C in water.}$$

For ethyl acetate

$$\Delta V^{\ddagger} = -9.3 \pm \sim 0.7 \text{ cm}^3 \text{ mole}^{-1} \text{ at } 35^\circ \text{ C in water.}$$

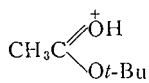
These compare with -8.3 cm^3 mole^{-1} for methyl acetate in water at 30.5° C calculated (11) from Bogojawlensky and Tammann's (17) rate constants at 1 and 500 atm. Rothmund's (30) measurements, which were the second published on the effect of pressure on reaction rates in solution, yield -10.1 cm^3 mole^{-1} for methyl acetate and -8.4 cm^3 mole^{-1} for ethyl acetate at 14° C. The rates in 9.21-M hydrochloric acid yield graphically

$$RT\partial \ln k_1/\partial p = 9.1 \pm \sim 1.0 \text{ cm}^3 \text{ mole}^{-1}.$$

If the compressibility of 9.21-M hydrochloric acid is taken to be the same as that of pure water then

$$\Delta V^{\ddagger} = -7.9 \pm \sim 1.3 \text{ cm}^3 \text{ mole}^{-1},$$

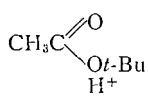
where the error has been increased to allow for the uncertainty of the compressibility of the acid solution.



For t-butyl acetate

$$\Delta V^{\ddagger} = 0.0 \pm \sim 1.0 \text{ cm}^3 \text{ mole}^{-1} \text{ at } 60^\circ \text{ C.}$$

4. DISCUSSION

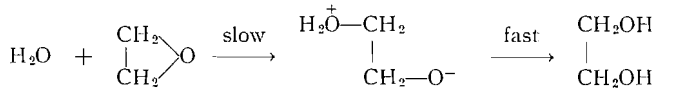


1. *t-Butyl Acetate*

The hydrolysis of t-butyl acetate is the simplest, and it is discussed first. The volume of activation of $0.0 \pm \sim 1.0$ cm^3 mole^{-1} is clearly consistent with either of the likely (see Section 1) unimolecular slow steps

$$\rightarrow CH_3CO_2H + t\text{-}Bu^+,$$

or



$$\rightarrow CH_3CO_2H + t\text{-}Bu^+.$$

2. *Polarity of the Transition States for Methyl and Ethyl Acetates*

The volumes of activation for the acid-catalyzed hydrolysis of methyl and ethyl acetates in dilute aqueous acid at 35° C are about -9.1 and -9.3 cm^3 mole^{-1}. As was pointed out earlier (11) these are approximately the values expected for a bimolecular reaction of a water molecule with a positively charged substrate if no major change in electrostriction due to changes in electrostatic moments occurs. In confirmation of this they are within about 1.5 cm^3 mole^{-1} of the volumes of activation for the acid-catalyzed hydrolysis of several aliphatic epoxides (13) and diethyl ether (14), for which the transition states are unlikely to have high dipole moments. They are much higher than the volume of activation for the spontaneous hydrolysis of ethylene oxide, which is -15.9 to -19.9 cm^3 mole^{-1} at 25 to 70° C (31), whose mechanism is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where the transition state is almost certainly very polar. In addition, all the volumes of activation so far measured of the reactions of small negative ions such as hydroxide and ethoxide with small neutral molecules lie in the range -5 to -10 cm^3 mole^{-1} (31). We conclude therefore that the transition state of the acid-catalyzed hydrolysis of simple esters is not highly polar and in particular that the carbonyl group is not appreciably ionized in the transition state.

Tal'vik and Pal'm's (18) mechanism, equation [1], should give a positive or zero volume of activation like *t*-butyl acetate, sucrose (11), formals and acetals (12), and α-D-glucose-1-phosphate (16), and it can be eliminated by these results, at least in dilute acid. The volume of activation of ethyl acetate appears to be little different in 9.21-*M* hydrochloric acid, in which the acidity function $-H_0$ is about 3.5, from that in dilute acid. In sulphuric acid the rate is reported (18) to be independent of acid concentration for $-H_0 > 2$ and it was deduced that the ester is essentially completely protonated. It is likely from the small change in the volume of activation that no change of mechanism has occurred in concentrated acid.

It has been argued (8–10) that the effect of solvent (7, 10, 29, 32, 33, 34) on the rates of these hydrolyses shows the transition states to be very highly polar, having dipole moments of 26.1 D. It has also been argued (e.g. 7, 34) that the same results show the transition state to be not highly polar. The solvent effects are small, the second-order rate constants typically decreasing by a few tens per cent in the range zero to 50% v/v acetone in water, and by similar amounts in other aqueous solvents. These are very much smaller effects than occur in reactions between two neutral molecules in which a highly polar transition state is formed, for which there is a large decrease in the rate constant as the dielectric constant of the solvent decreases (4, p. 345 *et seq.*). They are similar to, and in fact less than, the solvent effects for the acid-catalyzed hydrolysis of ethylene oxide in methanol–water mixtures (35) and in ethanol–water mixtures (36) for which the transition states are thought not to be highly polar. The solvent effects therefore confirm that the transition states for the acid-catalyzed hydrolysis of simple esters and of ethylene oxide have similar polarity.

Theories (8) that invoke highly polar transition states for the hydrolysis of esters suffer also from the following defects.

(i) They predict a large variation in entropy and enthalpy of activation with varying solvent, whereas the entropy of activation for the acid-catalyzed hydrolysis of methyl acetate differs by less than 10% between solvent water and solvent 50% v/v acetone–water (29).

(ii) They require radii of the transition states that seem too large. Thus, for the hydrolysis of ethyl acetate in dioxane–water mixtures the radius of the transition state is given (8) as 4.6 Å, which corresponds to a volume, calculated as $(4/3)\pi Na^3$ where a is the radius and adding one-third for the unoccupied volume, of 328 cm^3 mole^{-1}, and in methanol–water mixtures a radius of 5.7 Å is required (10), which corresponds to 620 cm^3 mole^{-1}.

Two other objections to the details of Laidler and Landskroener's mechanism are as follows. The hydrolyses are a good deal faster in heavy water than in ordinary water,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

which is difficult to explain on the basis of the assumed transition states because they require two O—H bonds to be broken. However, a slight alteration of two O—H distances in their transition states would meet this objection. Also, the assumed transition state incorporates H_3O^+, H_2O, and ester and so the reaction should be third-order. The third-order rate constants *increase* with increasing concentration of organic solvent (7, 34).

We conclude therefore that the transition state for the hydrolysis of simple aliphatic esters is not very polar.

3. Location of the Proton

The conclusions that we can draw about the location of the proton in the reactive conjugate acid of the ester are intimately connected with the problem of whether the attack by water is a substitution or an addition. The exchange of ^{18}O between hydrolyzing ethyl benzoate and the solvent (5, 6) show that water can add reversibly to the ester, and though it is not unlikely that the adduct is an intermediate in the hydrolysis, this has not yet been conclusively demonstrated. It has been shown (11) that if the transition state is not very polar, then either the proton is on the carbonyl oxygen and the water molecule adds or the proton is on the ether oxygen and the water molecule substitutes. The demonstration given above that the transition state is not very polar confirms this conclusion.

ACKNOWLEDGMENTS

We are greatly indebted to Mr. A. Lavergne for help with the high-pressure apparatus.

PRESSURE EFFECT AND MECHANISM IN ACID CATALYSIS

VIII. HYDROLYSIS OF ACETAMIDE AND BENZAMIDE[1]

A. R. OSBORN,[2] T. C-W. MAK, AND E. WHALLEY

ABSTRACT

The effect of pressures up to 3 kbar on the rate of the acid-catalyzed hydrolysis of acetamide and benzamide in both dilute and concentrated perchloric acid has been measured. The volumes of activation in dilute acid are consistent with a transition state that is not highly polar. It follows from this that if the attacking water molecule adds to the amidium ion then the reactive amidium ion is the O-protonated form, and if the attacking water molecule substitutes then the reactive amidium ion is the N-protonated form.

The volume of activation for acetamide in concentrated acid provides no additional information about the mechanism. That for benzamide in concentrated acid is tentatively interpreted as favoring the O-protonated benzamidium ion as the reactive ion.

1. INTRODUCTION

The acid-catalyzed hydrolysis of amides is in many ways similar to the acid-catalyzed hydrolysis of carboxylic esters, and many of the questions that require solution are similar to those for esters (1). It seems certain that the mechanism is

$$RCONH_2 + H_3O^+ \rightleftharpoons RCONH_2.H^+ + H_2O, \quad \text{equilibrium} \quad [1]$$

$$RCONH_2.H^+ + H_2O \rightarrow \text{products}. \quad \text{slow} \quad [2]$$

The relative rates of hydrolysis of acetamide in dilute acid in water and heavy water (2) show that a pre-equilibrium proton transfer occurs, and mechanisms that omit this (3, 4, 5) are almost certainly wrong. The location of the proton is unknown. Substituent effects (6, 7) indicate that a bimolecular attack of water probably occurs, but it is not known whether the attack is by substitution or by addition. Hydrolyzing benzamide does not exchange its oxygen with the solvent (8, 9) but this does not, of course, prove that an intermediate molecule is not formed, but only that if one is formed then it decomposes to products much faster than it reverts to reactants. Useful information about the mechanism of hydrolysis of simple esters has been obtained by measuring the effect of pressure on the rate (1), and so the effect of pressure on the rate of hydrolysis of acetamide and benzamide has been measured.

It is well known that the rates of hydrolysis go through a maximum as the concentration of acid is increased, and there is no doubt that the amide becomes appreciably protonated in concentrated acids. So that something could be learned about the volume change of the proton-transfer reaction [1] and the volume of activation of the slow step [2], the effect of pressure on the rates in concentrated acid has also been measured.

2. EXPERIMENTAL METHODS

Reagent-grade acetamide was recrystallized from approximately 1:10 ether–ethanol (10). Eastman-Kodak benzamide was recrystallized from water to constant melting point.

The high-pressure technique was as described in previous papers (1). About five samples were taken for analysis during a run. The reaction mixtures were made from perchloric acid and amide solutions of known concentrations.

The hydrolysis of acetamide was followed by analyzing for the acetic acid produced. About 5 ml of reaction solution (initially either 0.2992 *M* in perchloric acid and 0.1980 *M* in acetamide or 3.99 *M* in perchloric acid and 0.0990 *M* in acetamide) were withdrawn and 3.00 ml pipetted into a 30-ml weighing bottle. One drop of thymol blue indicator was added and the solution was titrated with 2-*N* sodium hydroxide solution until the color of the indicator just changed from red to yellow (pH approximately 2.8–3.0). Six milliliters of methanol was added and the solution titrated potentiometrically with 0.1-*N* barium hydroxide solution, using a Beckman Model-G pH meter with a Beckman No. 40463 sleeve-type calomel electrode as reference. The first inflection, at about pH 4, corresponded to neutralization of the perchloric acid, and the second, at about pH 7.3, to neutralization of the acetic acid. The methanol was added to sharpen the first inflection. Both inflections were easily located to ±0.01 or 0.02 ml. A typical titration required 2 ml, so the error is about 1 to 2%.

The same method could not be used for benzamide because if its concentration was much greater than about 0.02 *M* benzoic acid precipitated and it may clog the high-pressure apparatus, and 0.02 *M* is too low a concentration for this method. The ammonia produced was therefore determined by the formol titration method (11, 12). About 5 ml of reaction mixture (initially about either 1 *M* or 4.08 *M* in perchloric acid and 0.02 *M* in benzamide) was withdrawn, weighed accurately, and neutralized approximately with 1-*N* sodium hydroxide solution. It was adjusted to pH 6.6 with 0.1-*N* barium hydroxide solution, using the pH meter described above. A 5-ml blank solution, identical with the above solution except that it contained no benzamide, was treated similarly. Five milliliters of formalin solution (50 ml of Merck formaldehyde (37.0–37.3%) plus 0.5 ml of phenolphthalein indicator (0.5% in 50% ethanol) neutralized to faint pink color with *N* sodium hydroxide) were added to each of the two solutions. The pH of the blank was determined, the sample titrated to the same pH with 0.1-*N* barium hydroxide, and the pH of the blank measured again. If the pH of the blank had changed, alkali was added to either sample or blank and the appropriate allowance made. The alkali was run in from a precision-bore capillary tube with a meter stick attached, so that the amount added was measured to ±0.005 ml. The titer gave the equivalent amount of acid liberated by the reaction of ammonia and formaldehyde to form hexamethylenetetramine. To obtain reproducible results the electrode was flushed frequently with saturated potassium chloride solution.

3. RESULTS

1. Acetamide

For the hydrolysis in dilute acid the second-order rate law is appropriate. The integrated form

$$k_a t = \frac{1}{a-b} \ln \frac{b(a-x)}{a(b-x)},$$

where a and b are the initial concentrations of perchloric acid and acetamide, x is the amount of each reacted per unit volume at time t, and k_a is the second-order rate constant, can be rewritten

$$\log_{10} \frac{a-x}{b-x} = \frac{a-b}{2.303} k_a(t-t_0) - \log_{10} \frac{a-x_0}{b-x_0},$$

where x_0 is the amount reacted per unit volume at any arbitrary starting time t_0. A plot of $\log_{10}[(a-x)/(b-x)]$ against t gives therefore a straight line of slope $k_a(a-b)/2.303$. The appropriate corrections for compression (13) and thermal expansion of the solution were made. The second-order rate constants are given in Table I.

1500	333	
2000	387	248

The volume of activation of the reaction

$$RCONH_2.H^+ + H_2O \rightarrow \text{products}$$

can, at least in principle, be obtained from rates in concentrated acid because in these solutions the amide becomes largely protonated. There is, however, a difficulty, that the rate does not become of zero order in acid, but the first-order (in amide) rate constant passes through a maximum at concentrations of acid that are dependent upon the acid and amide, but are often around 2 to 4 M. What allowance to make in the rate constant for the effect of pressure on the concentration is not entirely clear, and we have preferred to reduce the effect of this uncertainty by using acid concentrations not far above those corresponding to the maximum rate. This gain in using a low concentration of acid is partly offset by the lower degree of protonation of the amide, and the concentration chosen, which was 4 M, was a compromise.

For the hydrolysis in a solution initially 3.99 M in perchloric acid the first-order rate law is appropriate, and the first-order constants were obtained graphically in the usual manner; they are given in Table I. They were not converted to second-order constants because, as mentioned above, the reactions are not second-order in concentrated acid.

By interpolating Rabinovitch and Winkler's (14) results at atmospheric pressure we find that $10^6 k_a$/liter mole^{-1} sec^{-1} in 1-M hydrochloric acid is 186 compared with our 195 in 0.3-M perchloric acid, and that $10^6 k_1$/sec^{-1} in 4-M hydrochloric acid is 133 compared with our 109 in 4-M perchloric acid. The agreement is satisfactory considering that in concentrated acids exact agreement is not expected.

2. Benzamide

The concentration of benzamide was always low enough that the first-order law was followed. The rate constants are accurate to about 5%. The rate constants in 1-M perchloric acid were converted to second-order constants k_a in the usual way and they are given in Table II.

A few kinetic runs were made to determine approximately the acid concentration that gives the maximum rate of hydrolysis. The first-order constants are given in Table III. The high-pressure rate constants were determined in 4.08-M perchloric acid solution. Because the rate is not first order in acid in concentrated acid the first-order constants are listed in Table II.

For comparison, we find by interpolating Rabinovitch and Winkler's (14) results that in M hydrochloric acid $10^6\ k_1$/sec^{-1} is 59 compared with our 60.4 in M perchloric acid, and in 4-M hydrochloric acid $10^6\ k_1$/sec^{-1} is 219 compared with our 99 sec^{-1} in 4.08-M perchloric acid. The cause of the difference in concentrated acid is not immediately obvious.

3. Volumes of Activation

The rate constants as a function of pressure are shown in Fig. 1. The volumes of activation were obtained graphically from the slope of the graph of log k vs. p at zero pressure from the appropriate formula

$$\frac{\partial \ln k_a}{\partial p} = -\frac{\Delta V^{\ddagger}}{RT}, \quad \text{or} \quad \frac{\partial \ln k_1}{\partial p} = -\frac{\Delta V^{\ddagger}}{RT}.$$

The volumes of activation are given in Table IV.

TABLE IV

Curve 2, k_1 for acetamide at 35.00° C in 4-M $HClO_4$ and 0.1-M acetamide. Curve 3, k_a for benzamide at 80.00° C in M $HClO_4$ and 0.02-M benzamide. Curve 4, k_1 for benzamide at 80.00° C in 4-M $HClO_4$ and 0.02-M benzamide, displaced downwards one unit for clarity.

4. Volume Changes of the Proton-Transfer Reactions

We assume for want of anything better that the volume change of reaction [1] and the volume of activation of reaction [2] are the same in dilute and in 4-M perchloric acid and that the pK_a's are independent of temperature (see, for example, ref. 7). There is some disagreement about the value of pK_a for the acetamidium ion (15, 16, 17, 18). The smallest pK_a, −1.40 (18), indicates that about two thirds of the amide is protonated in 4-M perchloric acid and the others indicate that more than this is protonated. It follows therefore that the volume change of the proton-transfer reaction (1) is $3.8 \pm \sim 2.5$ cm^3 mole^{-1} for acetamide.

The value of pK_a for the benzamidium ion has recently been revised from −1.85 (18) to −2.16 (19) and so it seems that benzamide is only about one-quarter protonated in 4-M perchloric acid, instead of about one-third as it seemed when this work was done. The volume change for the proton-transfer reaction [1] for benzamide appears to be therefore about $16 \pm \sim 8$ cm^3 mole^{-1}. These values are unfortunately rather rough, but they do seem to be significant.

4. DISCUSSION

1. Polarity of the Transition State

If the dipole moment of the transition state is much bigger than that of the amide, then there will be an increase in the electrostriction of the solvent when the transition state is formed (see, for example, preceding paper). The object of this section is to determine whether this occurs. Only the reaction

$$H_3O^+ + RCONH_2 \rightarrow \text{transition state}$$

need be considered for the present because in dilute acid, where the amide is only slightly protonated, the volume of activation is the difference between the partial volume of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

transition state and the sum of the partial volumes of the amide and the hydronium ion, and is independent of the partial volume of the protonated amide. This is important because the partial volume of the transition state can be discussed without reference to the partial volume of the protonated amide. This last shall be discussed in the next section.

The volume of activation for the hydrolysis of acetamide in dilute acids is $-9.4\pm\sim 0.5$ cm^3 mole^{-1}, which is almost identical with the volumes of activation for the hydrolysis of ethylene oxide (20), propylene oxide (20), isobutylene oxide (20), diethyl ether (21), methyl acetate (1), and ethyl acetate (1). The same arguments as those used in discussing the hydrolysis of esters (1) show that very little of the volume of activation can be accounted to increased electrostriction. It follows then that the dipole moment of the transition state is probably little different from that of the amide. The volume of activation for the hydrolysis of benzamide in dilute acid is somewhat lower, $-12.1\pm\sim 1.0$ cm^3 mole^{-1}, and it is possible that about 2 to 4 cm^3 mole^{-1} of this may be due to slightly increased electrostriction. It may also be due to the phenyl group's having a greater steric hindrance to the approach of a water molecule than the methyl group. We conclude therefore that no large separation of charges occurs in the transition states.

This conclusion is confirmed by the effect of solvent on the rate of the acid-catalyzed hydrolysis of acetamide in ethanol–water mixtures (4). This is very similar to that of the acid-catalyzed hydrolysis of ethylene oxide in the same solvent (22), confirming the conclusions drawn from the close similarity of the volumes of activation. Laidler and Landskroener (4) and Laidler (5) have argued that this solvent effect implies that the transition state for the hydrolysis of acetamide has a dipole moment of 18.4 D, but this is probably wrong. In addition, the detailed mechanism proposed by Laidler and Landskroener (4) requires two OH bonds to be broken in the transition state, and it is difficult to see how this can be reconciled with the observed faster rate in dilute acid in heavy water than in ordinary water. It seems certain that this demands a pre-equilibrium proton transfer to the amide. However, this can be accommodated in Laidler and Landskroener's transition states by altering two O—H distances.

2. Location of the Proton in the Reactive Amidium Ion

There has been much controversy about whether the extra proton in amidium ions is on the oxygen or the nitrogen atom. Proton resonance spectra (23, 24) appear to show conclusively that acetamide, N-methylacetamide, and N,N-dimethylacetamide are mainly O-protonated. There is no certain information about benzamide. The O-protonated form need not, of course, be the more reactive form.

The conclusions that we can draw about the location of the proton in the reactive form are intimately connected with the question whether the attack of water on the amidium ion is by addition to form a molecule followed by rapid elimination of NH_3 (or NH_2^-) or by direct substitution with simultaneous elimination of NH_3 (or NH_2^-), about which there is no direct evidence. Approximate representations of the transition states for the various mechanisms are given in Fig. 2. The only ones in which a great separation of charges has not occurred, and which therefore are consistent with the evidence discussed in the preceding section are substitution of the N-protonated form or addition to the O-protonated form.

3. Volume Change of the Proton-Transfer Reaction [1]

The evidence that will be discussed in this section is a good deal more uncertain than that discussed in preceding sections.

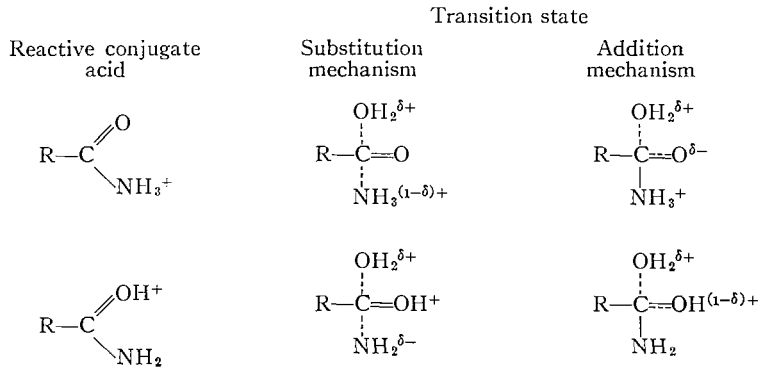

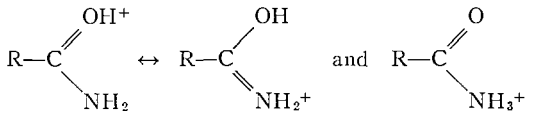

FIG. 2. Transition states for the acid-catalyzed hydrolysis of amides.

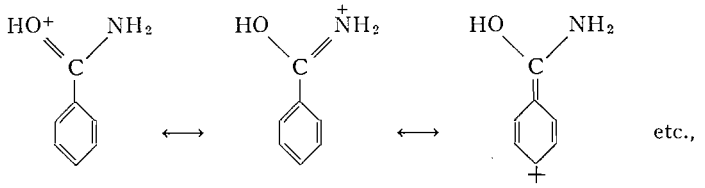
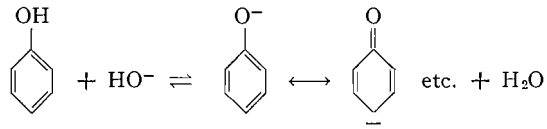


The two most likely amidium ions are

(the double-headed arrow indicates resonating forms). There will probably be an increase in volume when the O-protonated amidium ion is formed from amide and hydronium ion, because the positive charge becomes spread between the oxygen and the nitrogen atoms and this dispersion will decrease the electrostriction of the solvent. A similar, probably more complete, sharing of charge occurs when a proton is transferred from a carboxylic acid to a hydroxyl ion. The volume changes for this reaction for various acids, calculated from the data in the references quoted and the volume of ionization of water of -23.4 cm^3 $mole^{-1}$ (25) are as follows: formic, 15.4 (26); acetic, 10.9 (26); propionic, 9.7 (26); *n*-butyric, 9.7 (26); fumaric, 11.0 (27); benzoic, 12.8 (28); *o*-hydroxybenzoic, 16.2 (28) cm^3 $mole^{-1}$. The increase of volume for the O-protonation of acetamide may not be so great as these because the sharing of the charge between the oxygen and the nitrogen atoms may not be equal. When the N-protonated amidium ion is formed, little dispersion of charge will occur, and so little change of volume is expected (29).

The volume of protonation of acetamide, $3.8 \pm \sim 2.5$ cm^3 $mole^{-1}$, appears to be consistent with either of these protonations, and it does not allow us to choose between them.



The volume change for the protonation of benzamide, $16 \pm \sim 8$ cm^3 $mole^{-1}$, appears to be too big for N-protonation. It is, however, quite consistent with O-protonation because in the O-protonated ion, which has the following main resonating forms

the charge is probably shared not only by the oxygen and the nitrogen atoms, but also

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

by the benzene ring. An example of the effect of dispersal of a charge into a benzene ring on the electrostriction of the solvent is the reaction

for which the volume change is 6.6 cm^3 $mole^{-1}$ (26).

This conclusion is certainly rather tentative at present. However, it does agree with Leisten's (7, 30) observation that while the rate of hydrolysis of substituted benzamides in dilute acid (31, 3) is practically uninfluenced by polar substituents, in concentrated acid, where the rate measured is largely the rate of reaction of the amidium ion with water, there are quite strong polar effects, electron-releasing substituents decreasing the rate and electron-withdrawing substituents increasing the rate. These are the effects that are expected if the attack of water results in the withdrawal of positive charge from the benzene ring.

ACKNOWLEDGMENTS

We are greatly indebted to Mr. A. Lavergne for help with the high-pressure apparatus.

SPECTROPHOTOMETRIC DETERMINATION OF ALUMINUM IN URANIUM METAL AND ITS COMPOUNDS[1]

ALLAN W. ASHBROOK AND G. M. RITCEY

ABSTRACT

A rapid spectrophotometric method for the determination of small amounts of aluminum in uranium metal and uranium compounds is described. The method makes use of the yellow-colored complex formed between aluminum and 8-hydroxyquinoline (oxine) at pH 9.5–10; the complex is extracted with carbon tetrachloride. Elements which interfere are extracted with 8-hydroxyquinaldine. The method is suitable for the determination of up to 0.1% aluminum.

INTRODUCTION

Aluminum is found in trace amounts in uranium metal and its compounds. Specifications limit its amount to 30 p.p.m. in uranium metal; consequently a sensitive and accurate method was required to determine this amount.

Aluminum has been determined by Horton and Thompson (1) after separation of most of the interfering elements by ion-exchange. Aurine tricarboxylic acid (Aluminon) was used as the chromophoric reagent. This procedure gave erratic results in this laboratory, and also suffered from non-uniformity of the reagent. Of four samples of Aluminon used, each gave a different calibration curve for aluminum.

Methods employing mercury cathode electrolysis for the removal of interfering elements are time consuming. Of other reagents available, oxine showed the best sensitivity (2). The use of this reagent has produced a simple and sensitive method for the determination of aluminum in uranium metal and its compounds. With slight modifications, it has also been used for the determination of small amounts of aluminum in uranium-containing steels.

EXPERIMENTAL

Apparatus and Solutions

The spectrophotometer used in these experiments was a Beckman Model B, with matched 5-cm glass cells.

A standard aluminum solution was prepared by dissolving 0.1759 g of aluminum potassium sulphate ($AlK(SO_4)_2.12H_2O$) in water, and diluting to 1 liter. This solution contained 10 μg of aluminum per milliliter.

The buffer solution was a saturated solution of ammonium carbonate, adjusted to pH 9.5–10 with ammonium hydroxide.

The reagent was a 1% w/v solution of oxine in carbon tetrachloride. Other reagents included a 1% w/v solution of 8-hydroxyquinaldine in chloroform, a 10% w/v aqueous solution of potassium cyanide, and diethylammonium diethyldithiocarbamate.

All other chemicals used were of analytical reagent grade.

Development of the Method

Preliminary Studies

Oxine forms extractable complexes with over 40 elements. Of the trace elements usually to be found in uranium metal and its compounds, almost all will form extractable

[1]*Manuscript received January 30, 1961.*

Can. J. Chem. Vol. 39 (1961)

oxinates. It was therefore essential to remove or complex all elements whose oxinates are extracted at the pH at which the aluminum is extracted. Of the reagents studied for either extraction or complexing of these elements, 8-hydroxyquinaldine appeared to be the most suitable. Merritt and Walker (3) have found that 8-hydroxyquinaldine does not complex aluminum, due to steric hindrance, but otherwise behaves almost like oxine in its reactions. Hynek and Wrangell (4) used this reagent for the extraction of interfering elements from a solution buffered at pH 9.2. It was found in this laboratory that this pH was not critical. The removal of interfering elements with this reagent, at a pH of 9.5–10, was studied.

Aluminum Calibration

For extraction purposes, oxine is generally used in chloroform solution. In the presence of uranium a carbon tetrachloride solution was found to give lower blank values, and this solvent was used throughout these experiments.

A calibration curve was determined by adding known amounts of aluminum to an ammonium chloride – ammonia buffer solution, and extracting with 20 ml of the oxine solution. Absorbance measurements of the extracts were determined at 430 mμ, using 5-cm cells. A straight-line calibration curve was given.

Complexing of Uranium

Since uranium precipitates in an ammonia – ammonium chloride solution, various reagents were tried in order to keep the uranium in solution at pH 9–10. Ammonium tartrate and citrate, while keeping the uranium in solution, inhibited extraction of aluminum. Uranium is soluble in ammonium carbonate solutions at this pH, and this solution was found to have no effect on the extraction of aluminum. A saturated solution of ammonium carbonate, adjusted to pH 9.5–10 with ammonium hydroxide, was used, both to keep the uranium in solution and as a buffer solution.

Interfering Elements

Elements found in uranium metal and its compounds which are likely to interfere in the determination are cobalt, manganese, nickel, zinc, copper, and iron. A study of the removal of these elements by extraction with a 1% solution of 8-hydroxyquinaldine in chloroform was carried out.

Known amounts of these elements were added to ammonium carbonate – ammonia buffer solutions, containing uranium and 25 μg of aluminum. Extraction with 8-hydroxyquinaldine showed that up to 100 μg of cobalt, nickel, zinc, copper, lead, and iron could be extracted without effect on the aluminum recovery (Table I). Manganese, however, was

TABLE I

For personal use only.

not extracted by the 8-hydroxyquinaldine, but was extracted by the oxine, giving large positive errors in the aluminum determination. The valency state of the manganese had no effect on its extraction. Small amounts of manganese (5 μg) had little or no effect on the aluminum determination. Larger amounts had to be removed.

Removal of Manganese

There appeared to be no reagent available which would complex manganese under the conditions of the experiments. A study of reagents suitable for its extraction prior to the determination of aluminum showed diethylammonium diethyldithiocarbamate to be the most suitable. This reagent had no effect on the recovery of aluminum. Sample solutions containing more than 5 μg of manganese were extracted with chloroform after the addition of solid diethylammonium diethyldithiocarbamate. Extraction of other interfering elements was completed by extraction with 8-hydroxyquinaldine.

In order to ensure the complete removal of deleterious effects of interfering elements which may not have been completely removed by the extraction with 8-hydroxyquinaldine, potassium cyanide solution was added before addition of the oxine solution. Potassium cyanide did not affect the extraction of aluminum.

Preparation of Samples

Samples of uranium metal and uranium compounds were dissolved in a 3:1 mixture of hydrochloric and nitric acids. The solutions were then boiled to remove oxides of nitrogen, and diluted to a suitable volume.

Recommended Procedure

Dissolve and dilute the sample as described under Preparation of Samples. Transfer by pipette an aliquot containing 5–50 μg of aluminum into a 125-ml, separatory funnel. Add 30 ml of the buffer solution and mix. If the aliquot contains more than 5 μg of manganese, add 1 g of diethylammonium diethyldithiocarbamate, mix thoroughly, and extract with 10-ml portions of chloroform until the extracts are colorless. Add 5 ml of the 8-hydroxyquinaldine solution and shake for 2 minutes. Allow the phases to separate and discard the organic phase. Repeat this extraction until little or no color is given in the organic phase. Extract the aqueous phase with 3×10-ml portions of chloroform. Discard the extracts. Add 5 ml of potassium cyanide solution and mix. By pipette, add 20 ml of the oxine solution into the funnel and shake the mixture for 2 minutes. Allow the phases to separate and filter the organic phase through a coarse, dry filter paper. Measure the absorbance of the extract at a wavelength of 430 mμ, using 5-cm cells, with the spectrophotometer set to zero on a blank.

Calibration Procedure

Measure from a burette 0-, 1-, 2-, 3-, 4-, and 5-ml volumes of the standard aluminum solution into 125-ml separatory funnels, and carry them through the procedure. Plot absorbance readings against micrograms of aluminum. Beer's law is obeyed.

Results and Precision

Table II presents some typical results obtained on uranium metal samples, together with results obtained on a New Brunswick Laboratories Analysed Sample (No. 16) of uranium metal. Also shown is the precision obtained on samples of uranium metal containing low and high quantities of aluminum.

The method gave a standard deviation of 0.8 p.p.m. aluminum at the 13 p.p.m. level, and the 95% confidence limits on a single determination of ±1.7 p.p.m. At the 600 p.p.m. level these were 7.5 and ±16 p.p.m. respectively.

A STUDY OF THE EMISSION INTENSITIES OF Cr LINES FROM SHOCKED GASES CONTAINING $Cr(CO)_6$[1]

S. H. Bauer, John H. Kiefer, and Brian E. Loader

ABSTRACT

Argon–nitrogen mixtures (9/1) were inoculated with traces of $Cr(CO)_6$ (0.026%) and shocked to temperatures in the range 3500° K to 5700° K. The intensities of a violet line ($^7P_2 \rightarrow {}^7S_3$) and a triplet of green lines ($^5P_{3,2,1} \rightarrow {}^5S_2$) were measured concurrently, with a dual-channel spectrograph. Exclusive of runs for which $T > 5000°$ K, the variation of intensity with temperature was brought to agreement with theoretical predictions under the assumption that the N_2 vibrations, the dissociation of $Cr(CO)_6$, and the ionization of Cr attained their equilibrium states, but allowance had to be made for self-absorption. The dependence of the rise times on temperature suggest that the excitation and ionization of Cr is predominantly due to collisions with electrons. The over-all shapes of the recorded light pulses were qualitatively accounted for. It is suggested that extraneous background radiation contributed to the measured intensities for samples shocked to temperatures above 5000° K.

INTRODUCTION

Studies of the excitation of atomic energy states by collisions with heavy particles in the thermal energy range have been limited experimentally by the difficulty of preparing sufficiently intense beams of incident atoms or molecules and theoretically by the inherent complexity of the potential energy hypersurfaces which must be considered in the treatment. Efficiencies for energy transfer in de-excitation processes have been measured for a number of target atoms from the quenching of radiation due to the introduction of a variety of incident molecules. The cross sections (Q) for the forward and reverse processes are, of course, related. For particles which have a high relative kinetic energy (primed),

$$Cr' + Ar' \leftrightarrows Cr^* + Ar,$$

let the p' be the momentum of relative motion prior to excitation and p of the excited pair. Then (1, p. 417),

$$[1] \qquad g_{Cr'}g_{Ar'}p'^2Q' = g_{Cr^*}g_{Ar}p^2Q,$$

where the g's designate the statistical weights, as indicated. Since $p'^2 > p^2$, the cross section for the superelastic process is generally greater than for the excitation process. However, the cross sections for collision-induced electronic transitions are very small unless the change of internal energy is very small. Per impact, the transition probability is low if

$$[2] \qquad a|\Delta E|/hv \gg 1,$$

where a is the range of interaction between the atoms, and v is their relative velocity, since such an event takes place at near-adiabatic conditions. Massey and Burhop (1, p. 515) suggest that the cross section for excitation should then vary as $\exp(-Ca|\Delta E|/v)$ and consequently would increase exponentially with temperature, for a thermalized system.

Investigations of the luminous front in shocked gases provide data on excitation processes in thermalized systems where the average relative kinetic energies of the participating particles are less than one volt. A theory for the excitation of atoms by

[1]*Manuscript received October 24, 1960.*
Contribution from the Department of Chemistry, Cornell University, Ithaca, New York. Presented at the Symposium on Fundamental Aspects of Atomic Reactions, McGill University, Montreal, Que., September 7, 1960.

collisions at elevated temperatures has been outlined by Nikitin (2). In this paper, we describe preliminary work on the excitation of resonance lines in chromium, introduced in trace amounts as $Cr(CO)_6$ in argon–nitrogen mixtures and shocked to temperatures from 3000–5500° K. The possible utility of chromium emission intensity ratios for the estimation of shock temperatures has been analyzed previously (3). Wilkerson (4) obtained time-resolved Cr(I) and Cr(II) emission spectra from incident and reflected shocks in Ne which had been inoculated with 0.3% of chromium carbonyl. Recent studies (5) of the delayed luminosity in highly purified xenon as induced by a shock have proved both interesting and puzzling, since the current predictions suggest that the potential curves for two xenon atoms do not cross over the energy range of collisions which are prevalent in shocked gases at 6000° K. It now appears that the diameter of the shock tube, the composition of the tube walls, and the purity of the driver gas play important roles in determining both the electrical and optical structure of the shock front.

The sensitivity to slight impurities, which appears in accentuated form when one measures the electrical conductivity of shocked gases, is due to free electrons, the concentration of which is probably determined by the lowest ionization potential of any impurity present in the gaseous sample and by the nature of the shock-tube walls. It also seems likely that these electrons play a dominant role in collision-induced electronic excitations. For the excitation of electronic states, the collision cross section becomes appreciable only when the *speed* of the incident particle approaches that of the atomic electron involved in the transition (1, p. 515). Hence, at the temperatures developed in the shocked gases, the average energy per pair is too low to provide an appreciable transition probability for excitation by atom–atom collisions. However, in that energy range, the efficiency of excitation by collision with electrons is much greater, perhaps by a factor of 10^3.

Insofar as there is *structure* to the shock front, no single measure of temperature can be specified. The very difficult problem of determining the velocity distribution of the electrons in this region has yet to be solved. One may argue, however, that beyond a distance of the order of 10 mean free paths following the steep pressure gradient in the shock front the electrons will have attained translation equilibrium and would then possess the same translational temperature as the massive particles present.

SPECTROSCOPIC MEASUREMENT OF SHOCK TEMPERATURES

The gas temperature behind a shock wave may be computed from the measured shock speed, the composition of the gas being subjected to the shock, and its initial temperature and pressure, provided one assumes that thermodynamic equilibrium is attained in the system for specified end products. One must postulate not only definite chemical species but also their allowed states of excitation, so that the thermodynamic state of the shocked gas is determined by a temperature, a density, and a set of mole fractions. When the chemical kinetics of a system are being studied in a shock tube, such detailed information and its dependence on distance behind the shock front are not available. However, it is meaningful to consider the translational temperature of the gas and to inquire whether the temperatures which may be associated with rotations, vibrations, and electronic states are in equilibrium with translation.

Various techniques have been developed for directly estimating temperatures in very hot gases. Stark shifts (6) and the broadening of spectral lines (7) have been used for very strong shocks and gases heated by electrical discharges. Gaydon and co-workers

(8) described a modified form of the sodium-line-reversal technique to deduce temperatures with an estimated accuracy of ±20° C. Although this method is capable of higher precision when long measuring times are available as in steady-state conditions for flames (9), it is accompanied by considerable difficulties when the data must be recorded with microsecond resolution. To produce a sufficiently dense suspension of sodium chloride particles in the gas to be shocked, they found it necessary to pass the sample through a hot tube (~800° C) over the molten salt. Very few gases of chemical interest may be treated in this manner. It is interesting to note that electronic temperatures deduced for flames by the reversal technique utilizing various spectral lines from iron, lead, etc. (10), were found to be higher than the maximum theoretical temperature for the specified composition. The origin of these excessive temperatures is not known, but it is surmised that they arise partly from chemical excitations.

The relative emission intensities of two atomic lines characteristic of a trace impurity are a measure of temperature, provided one may assume that the electronic states of the emitter have attained equilibrium with translation or vibration. Then, the intensities can be readily converted to a temperature from the known location of the corresponding upper states and the absolute f numbers or by a calibration procedure. If the concentration of emitter is sufficiently low so that self-absorption may be ignored, the results are independent of emitter density (3). Sobolev *et al.* (11), tested this procedure with lithium chloride and sodium chloride as trace emitters but obtained badly scattered results due to self-absorption, inhomogeneous gas distribution, etc.

To avoid the difficulty of working with crystallites of a nonvolatile material, we measured the emission intensities of the resonance lines of chromium at λ4290 and λ5206, derived from known concentrations of traces of chromium carbonyl in Ar–N_2 mixtures. Manganese, iron, tungsten, and nickel carbonyls can be similarly used as sources of metal atoms. Flame spectra (2200–3200° K) indicate that the spectral sensitivities of these chromium lines are of the order of 10^{-2} of that of NaD. We thus have controlled concentrations, with pressures which may be as high as 0.3 mm Hg of emitter gas.

THEORY

A rough numerical estimate shows that in the shock front the change of intensity with time is indeed a measure of the rates of excitation of the chromium atoms, that is, of the process:

$$Cr_{(g)}[a,\ ^7S] + X_{(g)} \xrightarrow[k_x]{} Cr_{(g)}^*[z,\ ^7P \text{ or } z,\ ^5P] + X$$

and not that due to the rate of dissociation of the carbonyl. The enthalpy change at 0° K for the reaction

$$Cr(CO)_{6(g)} = Cr_{(g)} + 6CO_{(g)}, \qquad \Delta H^\circ_0 = 173.23 \text{ kcal/mole} \qquad (12a).*$$

It follows that the average ⟨Cr—CO⟩ bond dissociation energy is 28.9 kcal. An order of magnitude for the unimolecular rate constant for the dissociation

$$Cr(CO)_n^* \xrightarrow[k_{uni}^{(n)}]{} Cr(CO)_{n-1} + CO$$

is:

$$[3] \qquad k_{uni}^{(n)} \approx 10^{18} e^{-29,000/RT}, \text{ sec}^{-1}.$$

**The authors reported that the standard heat of formation at 298.2° K of $Cr(CO)_{6(g)}$ is −257.57±0.51 kcal/mole. Correction for the heat of sublimation of $Cr(CO)_6$ (ΔH°_{sub} $Cr(CO)_6$ = 17.18 kcal, as reported in reference 12b), the heat of sublimation of $Cr_{(g)}$ (ΔH°_{sub} $Cr_{(s)}$ = 95 kcal/mole, as reported in reference 12c), and the heat of formation of 6CO molecules leads to ΔH°_{298} = 176.90 kcal for the indicated dissociation reaction.*

If one postulates that on the average this value is typical of each of the six steps, the time required for $(Cr)/(Cr)_{final}$ to reach 0.9 at 1000° K is $t_{0.9} \simeq 10/k_{uni}^{(n)} \simeq 10^{-10.7}$ sec. This is much less than the response times of currently available recording apparatus. For all practical purposes, the metal carbonyl is completely dissociated in the forward portion of relatively weak shocks.

The spectral radiancy from a distributed emitter in thermal equilibrium, of optical depth X ($= pL$, atm cm) and spectral absorption coefficient $P_\omega(\text{atm}^{-1}\,\text{cm}^{-1})$, is (13)

$$[4] \qquad R_\omega = R^\circ_\omega[1-\exp(-P_\omega X)].$$

The black-body radiancy at the specified temperature is given by

$$[5] \qquad R^\circ_\omega = 2\pi hc^2\omega^3[\exp(hc\omega/kT)-1]^{-1}.$$

Since the spectrometer–phototube–oscilloscope system integrates radiation over a selected line, with central position at ω_1, one should use the integral of the spectral absorption coefficient. For a Gaussian shape,

$$[6] \qquad P_\omega X = \alpha \exp\left[-\left(\frac{\omega-\omega_1}{\beta}\right)^2\right]; \qquad \int_{\text{line}} P_\omega d\omega = \frac{\sqrt{\pi}\alpha\beta}{X}.$$

However,

$$[7] \qquad \int_{\text{line}} P_\omega d\omega = \frac{\pi e^2}{mc^2}\frac{N_l}{p} f_{l\to u}\,(1-e^{-hc\omega_1/kT}),\ \text{cm}^{-2}\,\text{atm}^{-1}$$

where

$f_{l\to u}$ = oscillator strength for the transition from the lower (l) state to the upper (u) state (for Cr, refer to the report by Hill and King (14)),

$$\omega_1 = \frac{E_u - E_l}{hc},$$

N_l = number of molecules of emitting species per cubic centimeter, in the lower state,

p = pressure (atm) of emitting species.

Whence,

$$[8] \qquad \alpha = \frac{L}{\sqrt{\pi}\beta}\frac{\pi e^2}{mc^2} N_l f_{l\to u}\,(1-e^{-hc\omega_1/kT}).$$

If $P_\omega X$ is sufficiently small, the exponential in [4] may be expanded and the terms integrated (for the Gaussian shape), provided one assumes that $R^\circ_{\omega_1}$ is constant over the narrow band of wave lengths which is transmitted by the exit slit.

$$[9] \qquad V_{\omega_1} = K_{\omega_1} R^\circ_{\omega_1}\sqrt{\pi}\alpha\beta[1-\alpha/2\sqrt{2}+\ldots]$$

$$= K_{\omega_1}\frac{2\pi^2 he^2\omega_1^3}{m} N_l L f_{l\to u} e^{-hc\omega_1/kT}[1-\alpha/2\sqrt{2}+\ldots]$$

K_{ω_1} is a transmission-amplification constant which relates the oscilloscope-voltage output to the intensity of ω_1 picked up by the spectrometer. The term in α in the bracket is a measure of self-absorption; it is density and temperature dependent.

[10] $$N_i = \rho \frac{g_i}{Q} e^{-E_i/kT}$$

where Q is the total partition function, with the ground state taken as the zero; ρ is the total emitter density, in molecules per cubic centimeter.

[11] $$V_{\omega_1} \propto \frac{\rho g_i}{Q} f_{i\to u} \exp\left(-\frac{hc\omega_1 + E_i}{kT}\right)$$

For a given spectrometer setting, a plot of $\ln [V_{\omega_1} Q/\rho]$ vs. $1/T$ should be a line with slope $-(hc\omega_1 + E_i)/kT$. If appreciable ionization takes place, the concentration of atoms in state l will be depleted by an amount which depends sensitively on the temperature, as given by the Saha equation.

Provided self-absorption is in fact negligible, the 'two-color temperature' (15) is given by the ratio

[12] $$\frac{V_{\omega_1}}{V_{\omega_2}} = \frac{K_{\omega_1}}{K_{\omega_2}} \frac{g_{l_1} f_1}{g_{l_2} f_2} \exp\left[-\frac{E_{u_1} - E_{u_2}}{kT}\right]$$

since $E_{l_1} + \omega_1 = E_{u_1}$, etc. The unknown ratios may be lumped into a single constant which may be determined by calibration with shocks of measured speed under idealized conditions.

The observed rise time for each line depends on many factors. In addition to the response time of the recording electronics and particle passage time past the cone of observation, the rate of approach to the 'equilibrium' emission intensity may be limited by the vibrational and dissociation relaxation of nitrogen, if present, and by the finite rates for excitation and ionization of the chromium atoms. Since $dV(t)/dt \propto |f_{u\to l}| dN_u/dt$ and $V_e \propto g_l f_{l\to u} (N_u)_e / g_u$,

[13] $$\left[\frac{1}{V_e}\frac{dV(t)}{dt}\right]_{corr} \propto \frac{1}{(N_u)_e}\frac{dN_u}{dt}$$

is an experimental 'rise time' characteristic of the atomic state and of the excitation processes. There are at least three distinct processes which populate the specified upper state:

(a) excitation from a lower state by collision with a heavy particle:

$$Cr(i) + Ar' \xrightarrow[k_i]{} Cr(u) + Ar$$

(b) excitation by collision with an electron:

$$Cr(j) + e^- \xrightarrow[k_j]{} Cr(u) + e^-$$

(c) radiative recombination with an electron:

$$Cr^+ + e^- \xrightarrow[k_c]{} Cr(u) + h\nu.$$

The total rate is the sum over all states i and j.

The mechanism for ionization in shock fronts has been discussed by a number of authors (16, 17). Electron–atom processes have the largest cross sections. This is also the case for excitation reactions (b) (1, p. 515; 18). Some electrons are initially present in the unshocked gas; some of these may have been generated photoelectrically by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

photons downstream from the shock front, others by residual radioactivity. Their concentration is rapidly increased when the gas is compressed by the shock. Because of their low mass, these electrons diffuse ahead of the shock front and establish a double layer across which there exists a considerable potential drop. In the co-ordinates of the moving shock, rapidly moving atoms enter from the upstream side and collide with relatively energetic electrons to produce excited atoms and more electrons.

The depopulation of the upper state can occur via:

(a') the reverse of (a):

$$\mathrm{Ar} + \mathrm{Cr(u)} \xrightarrow[k_i']{} \mathrm{Cr}(i) + \mathrm{Ar}'$$

(b') the reverse of (b):

$$\mathrm{e^-} + \mathrm{Cr(u)} \xrightarrow[k_j']{} \mathrm{Cr}(j) + \mathrm{e^-}$$

(d) radiation:

$$\mathrm{Cr(u)} \xrightarrow[f_{\mathrm{u}\to i}]{} \mathrm{Cr}(i) + hc\omega_i$$

(e) ionization from the excited state:

$$\mathrm{Cr(u)} + \mathrm{e^-} \xrightarrow[k_x]{} \mathrm{Cr^+} + 2\mathrm{e^-}.$$

Electrons are also produced via:

(f) ionization from all other states:

$$\mathrm{Cr}(j) + \mathrm{e^-} \xrightarrow[k_+]{} \mathrm{Cr^+} + 2\mathrm{e^-}.$$

Let n be the concentration of electrons in the shocked gas at $t = 0(+)$ and $c(t)$ the additional electrons generated via (e) and (f). For the early stages ($t < t_{\frac{1}{2}}$), one may write

$$\frac{d(n+c)}{dt} \approx [k_x(\mathrm{Cr_u}) + k_+(\mathrm{Cr}_j) - k_c(\mathrm{Cr^+})](n+c).$$

Then, since $(\mathrm{Cr^+}) \ll (\mathrm{Cr})$, an average value of the ionization rate constant may be used,

$$(n+c) \approx n \exp\,[\langle k\rangle \rho_{\mathrm{Cr}} t]; \qquad [14]$$

i.e., the electron concentration initially rises exponentially.

It is very likely that under shock conditions (b') and (e) are more effective in depleting the upper state than are (a') and (d). We estimated that in the experiments described below the mean time between collisions (kinetic-theory cross sections) is between 1×10^{-9} sec to 4×10^{-10} sec, whereas the radiative lifetimes of the ^7P and ^5P states of chromium are of the order of 10^{-8} sec. For the net rate of population of the upper state, assuming that atom–electron processes dominate,

$$\frac{d(\mathrm{Cr_u})}{dt} \approx (n+c)[k_j(\mathrm{Cr}_j) + k_c(\mathrm{Cr^+}) - (k_x + k_j')(\mathrm{Cr_u})]. \qquad [15]$$

Since, at $t = 0(+)$, $k_j(\mathrm{Cr}_j)^\circ \gg (k_x + k_j')\ (\mathrm{Cr_u})^\circ$, the population of the excited state may 'overshoot' its equilibrium value and thus produce a maximum in the emitted

intensity vs. time curve. For comparable rate constants, say $(k_r+k_j') = k_j(1+\alpha)$ with α small, $t_m = 1/k_j$. Whether the maximum is experimentally observable will depend on the temporal behavior of $(n+c)$. If the latter reaches its equilibrium value rapidly, the maximum will be recorded and will become more pronounced in amplitude as $(k_r+k_j')/k_j$ decreases.

There are insufficient data at present to permit a complete kinetic analysis of the above complex mechanism. However, as a preliminary approach, assume that the net rate of excitation to the upper level at the shock front may be expressed in terms of a single rate constant. Let

$$\left(\frac{dN_u}{dt}\right)_{net} = \rho_{Cr}{}^n A \exp(-E_u^*/kT). \quad [16]$$

Hence,

$$\frac{1}{\tau_0} \equiv \frac{1}{V_e}\left(\frac{dV}{dt}\right)_{initial} = \frac{AQ}{g_u} e^{-(E_u^*-E_{(\cdot)})/kT} \rho_{Cr}{}^{n-1}. \quad [17]$$

E_u^* has the significance of an activation energy* and corresponds to the energy at the crossover point of the unperturbed potential function curves for Cr-incident particle and $Cr_{(u)}$-incident particle. A plot of $\ln [1/QV_e\rho^{n-1}(dV/dt)_i]$ vs. $1/T$ should give a line with a slope $-(E_u^*-E_u)/k$. If process (a) dominates, the slope should be steep, whereas under conditions where (b) and (c) control the rate, $E_u^* \approx E_u$.

In the above formulation, it has been assumed that the temperature of the shocked gas was unambiguously defined and independent of time. This is the case for samples which consist solely of argon with traces of chromium carbonyl, since the depletion of energy by the dissociation of $Cr(CO)_6$ and ionization of Cr results in a temperature drop of no more than 10° K at the highest temperatures studied. However, when the ambient gas contains an appreciable amount of N_2 (circa 10%), the shock front consists of several relaxation zones, which are superposed, due to vibrational excitation and dissociation of the nitrogen, as well as the excitation and ionization of the chromium. In the samples shocked to temperatures above 4700° K, an appreciable fraction of the nitrogen is dissociated at equilibrium. Preliminary measurements by Byron (private communication) gave for the dissociation rate constant at 7000° K

$$N_2 + Ar \underset{k^d}{\overset{k^a}{\rightleftharpoons}} 2N + Ar$$

$$(dN/dt)_{initial} = k^d(N_2)(Ar); \quad \begin{aligned} k_{Ar}{}^d &= 2.8\times10^8, \text{ (mole/cc)}^{-1}\,\text{sec}^{-1} \\ k_{Ar}{}^a &= 1.7\times10^{14}, \text{ (mole/cc)}^{-2}\,\text{sec}^{-1} \end{aligned}$$

(As a third body, N_2 appears to be about 2.5 times as effective as Ar. In our system, however, the Ar rate dominates.) We estimated that at 5000° K, in a 10% N_2 – 90% Ar mixture, the half time for the attainment of dissociation equilibrium is 80 milliseconds.

*The product of the time elapsed between ionization onset and the attainment of its maximum value and the initial pressure of the shocked gas ($\tau_i p_1$) was found to decrease approximately linearly with increasing Mach number, for air (Y. Manheimer-Timnat and W. Low. J. Fluid Mech. **6**, 449 (1959); B. Niblett and V. H. Blackman. J. Fluid Mech. **4**, 191 (1958)). Generally, the Mach numbers correlate with the initial pressures. It is suggested, therefore, that these ionization–relaxation times might be more uniquely interpreted in terms of eq. [17].*

EXPERIMENTAL

The following experiments were performed in a stainless-steel tube, 6-in. I.D., Fig. 1.

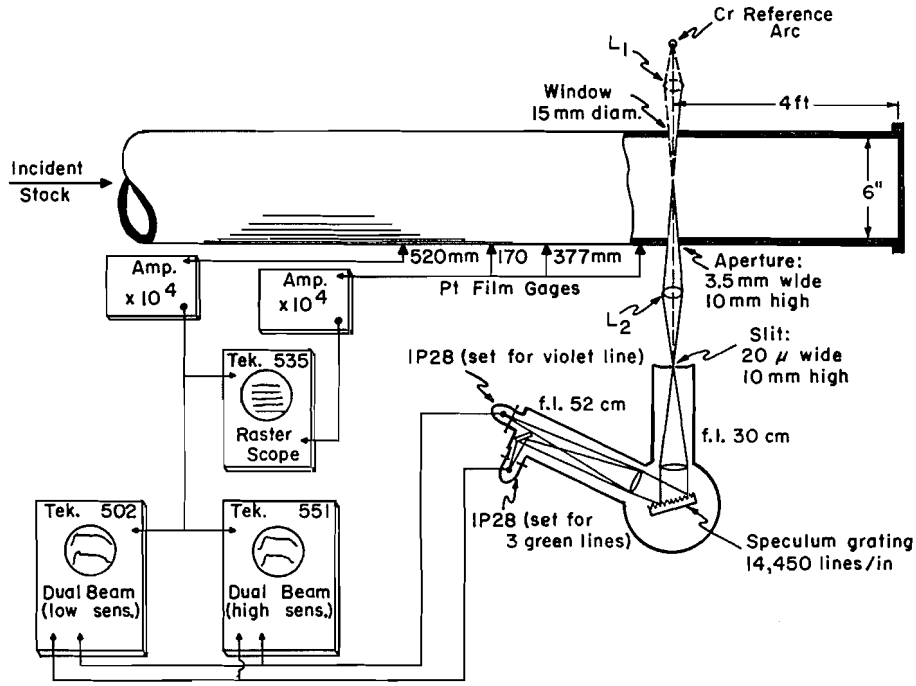

FIG. 1. Schematic arrangement of the optics and a block diagram of the electronic components. The spectrograph had an entrance slit 20 μ wide and 10 mm high. The dispersion at a camera focal length of 52 cm was 30 Å/mm. The exit slit for the violet line was set at 70 μ and for the green lines at 170 μ.

The driver section was 8 ft long. The windows through which the luminosity was observed were located 18 ft downstream from the diaphragm. Beyond the windows, the tube extended 4 ft, so that ample time was provided to avoid confusion with the reflected shock. The diaphragms were of half-hard brass, 0.032 in. thick, precision scribed through half their thickness. In all of the experiments described, the diaphragms were broken by exceeding the predetermined breaking pressure. Depending on the batch of sheet stock used, this was reproducible to within 5 lb. The windows were of quartz, and the aperture for observing the emitted light was limited to a section 3.5 mm wide and 10 mm high. Gauges for detecting shock arrival times were thin platinum films supported on Pyrex, placed at the indicated locations. Hydrogen was used as the driver gas at pressures of 200 to 230 p.s.i. The temperature of the shock was controlled by the pressure of the driven gas, which consisted of argon plus chromium carbonyl or a mixture of argon and nitrogen (9/1) plus the chromium carbonyl. The shock tube was evacuated with a 4-in. diffusion pump to 10^{-5} mm Hg; the leak rate was about one-half micron per minute.

We found it essential to premix the chromium carbonyl with the argon or argon–nitrogen mixture to insure uniformity of the sample. The mixtures consisted of chromium carbonyl vapor as derived from the solid maintained at room temperature and expanded into a 50-gal glass-lined tank to a pressure of 70 μ. To this, 27 cm of the carrier gas

For personal use only.

was added and the mixture allowed to stand for several days prior to use. The concentration of chromium carbonyl in the test samples was 0.026%. Total pressures of the driven gas ranged from 0.65 cm to 3.15 cm to cover the full range of shock temperatures. Shock speeds were measured from a raster display. The optical arrangement is also diagramed in Fig. 1. The two channels of the grating spectrograph (dispersion, 30 Å/mm) were aligned with a chromium arc so set on the opposite side of the tube as to focus to a virtual source in the center of the tube. The violet line at λ4289.7 ($a\ ^7S_3 \leftarrow z\ ^7P_2^0$) was sent along the central axis of the receiver section and the receiving slit set to admit a region in wave length roughly twice the width of the line. The small side mirror was then positioned so that the green triplet [λ5208.4, 5206.0, 5204.5 ($a\ ^5S_2 \leftarrow z\ ^5P^0_{3,2,1}$)] passed through the side receiver; this slit also was set to collect a little more than the triplet (19).*

The two photomultipliers were powered by a single well-regulated voltage supply, and the output of these tubes was split and sent to two dual-beam oscilloscopes, so that the intensity of the two lines could be recorded simultaneously at two sensitivity levels. This was necessary because the level of emission intensity was not always predictable. The time constant for the phototubes, amplifiers, and recording oscilloscopes was of the order of 4 μseconds. In some of the experiments to be described below, another set of phototubes was used. These were constructed with cathode followers which gave an electronic time constant of 0.8 μsecond but were of limited utility since they were easily saturated. The experimental 'rise time' was not limited by the 2- to 3-μsecond passage time of the gas past the cone of observation as viewed by the spectroscope. Typical shock parameters are summarized in Table I for a high-temperature shock and for one

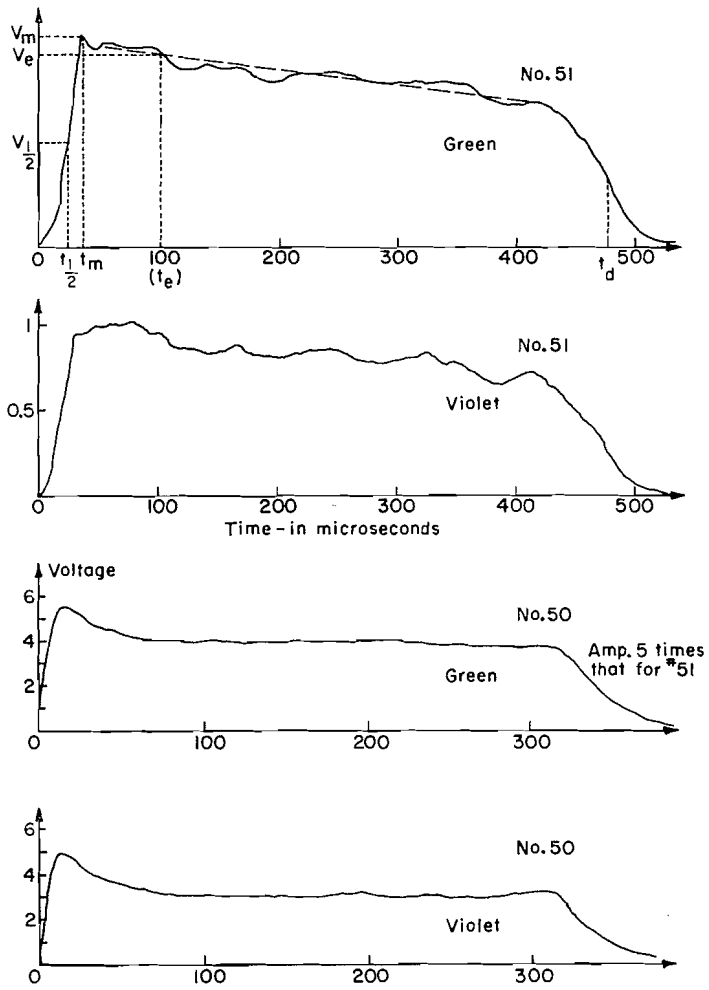

FIG. 2. Tracings of the oscilloscope records of the violet and green line photomultiplier outputs for two runs. Refer to Table I for a summary of the experimental conditions. The characteristic features of these voltage variations are designated in the top curve.

SUMMARY OF OBSERVATIONS

One of the first experiments performed was a spectroscopic examination of the total light emitted. The double-channel photomultiplier unit was replaced by a camera. In order to enhance the intensity of the emitted light, a fairly high concentration of chromium carbonyl was introduced and the spectrum taken in the reflected shock region. The plate showed a very large number of lines. On careful examination, all of the lines were identified and proved to be due to Cr(I). No other lines nor background intensities were observed under these conditions. On these plates, the lines of interest appeared reversed, which suggested that the amount of carbonyl should be reduced from the initial 300 μ to roughly 3 μ.

In another crucial experiment, the initiation of light emission was checked against the arrival time of the shock at the window. For this measurement, the phototube circuitry had a rise time of 0.8 μsecond. To within 1 microsecond, the incidence of light

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

emission coincided with the arrival time of the shock front at the central line of the viewing port; further inspection of the traces suggested that the luminosity started perhaps half to 1 microsecond earlier.

The oscillogram records show a number of features for analysis. Specifically, the following will be considered:

(*a*) for each line, the variation of intensity with shock temperature and density,
(*b*) the rise time of light emission at the shock front and its dependence on temperature, on the composition of the ambient gas (presence of 10% N_2 diluent), and on the specific levels involved, and
(*c*) the general shape of the emission output as a function of time; in particular, the presence of an initial maximum and the duration of the pulse.

ANALYSIS OF THE DATA

Since most of the shocks were run with the 9/1 Ar/N_2 mixture, the question arose as to whether the effective temperature in the shock front should be computed with the vibrational contribution of the nitrogen included or deleted. From Blackman's data (20), we estimated that the vibrational relaxation time for run No. 50 was 7 μseconds, and for No. 51 it was 10 μseconds (assuming no difference in efficiency between Ar–N_2 and N_2–N_2 collisions), with intermediate periods for the other runs. These times are more than twice that required for the particles to pass the cone of observation but about half of the observed rise time (lab. co-ordinates) for emission. Were the populations of the $^7P_2{}^0$ and $^5P^0{}_{3,2,1}$ states to rapidly attain equilibrium with the vibrational temperature (cf. Clouston and Gaydon (8)), the rise time for emission would be considerably shorter than that observed. The lag in the excitation of vibrations should at most affect the *initial* slope of the emission-time curve but should have no influence on the slope at the half-height position ($V_{\frac{1}{2}}$ at $t_{\frac{1}{2}}$, Fig. 2). In view of our estimate of the half time for the attainment of dissociation equilibrium, the temperatures used in Figs. 3–5 were computed on the assumption of partial equilibrium; i.e., we included the excitation of vibrations in N_2 (these reduced the translational temperatures by 60–180° K, over the range 3500–5800° K), the complete dissociation of the chromium carbonyl ($\sim$ 8° K), and the ionization of chromium atoms (0–7° K). The ionization of argon is negligible even at the highest temperatures.

An analysis of a number of runs is presented to illustrate features *a*, *b*, and *c*. In Figs. 3 and 4, eq. [11] was applied to the recorded intensities of the violet and green lines at t_m and t_e, respectively. The ordinates were computed on the assumption that the population of the upper states was proportional to the total chromium concentration. Within the scatter of the data, the slopes of the two sets of curves are independent of the time, for $t > t_m$, and for the lower third of the range in $1/T$ the observed slopes check the theoretical values. At the upper temperatures, the recorded intensities fall below the theoretical curves by a factor which increases with the temperature. This departure is considerably greater for the green line than for the violet lines and is more evident at t_e than at t_m. The same data were replotted on the assumption that the populations of the upper states were proportional to the concentration of chromium atoms which remain unionized; i.e., the abscissa was $\log [V_m Q/7\rho_{Cr}(1-x)]$, where x is the percentage ionized at the equilibrium shock temperature and density, as computed by means of the Saha equation; considerable ionization is present at equilibrium for $1/T \leqslant 2.1\times10^{-4}$. The points were found to lie on the theoretical slopes over the lower two thirds of the

For personal use only.

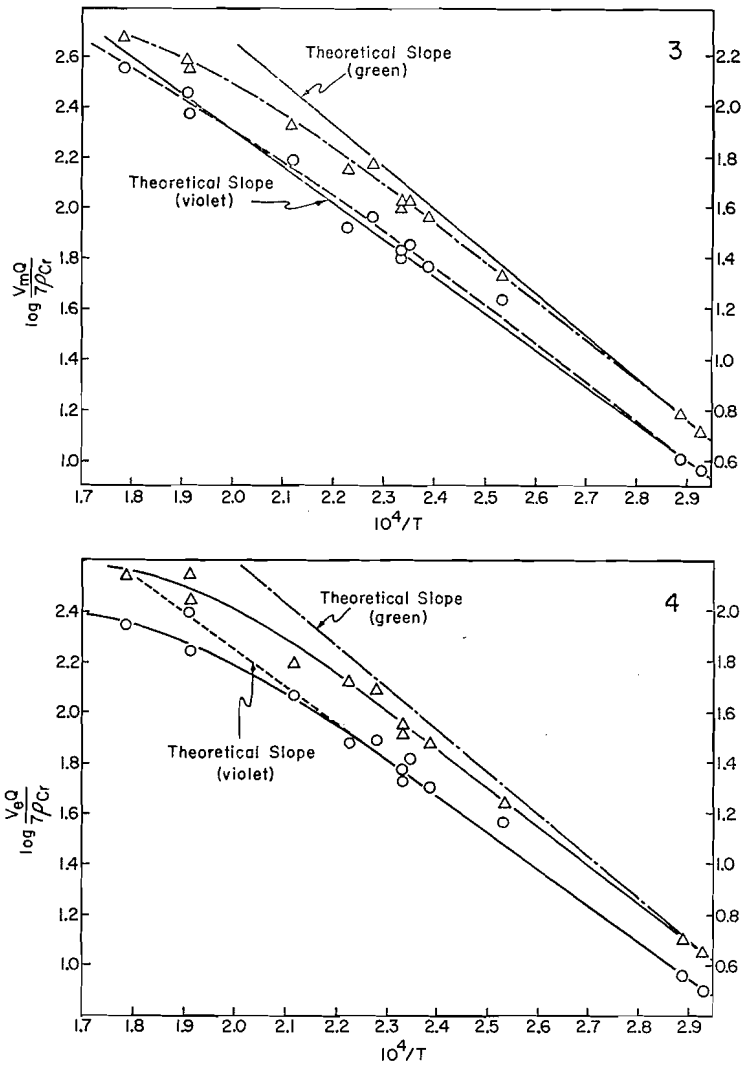

FIG. 3. Plots of $\log[(V_mQ)/(7\rho_{Cr})]$ vs. $10^4/T$ for the violet and green lines. The temperature and density were computed neglecting ionization of the chromium and dissociation of the nitrogen.
FIG. 4. Plots of V_e (at $t = 100$ μsec), similar to Fig. 3.

range in $1/T$. For the upper temperature range, it appears that the correction for ionization has 'overcompensated' the intensity function (Fig. 5 for V_m; a similar curve was obtained for V_e). Note also that the points for the violet line depart more from the theoretical slope than do those for the green lines.

Kinetic data presented below suggest that electron–atom processes control the rate of populating the upper levels and the production of ions. We then tested the possibility that the relaxation time for nitrogen dissociation was appreciably shortened by the presence of Cr^+. These ions, the few negative ions produced by attachment of the electrons, and even the chromium atoms should be highly efficient third bodies for the dissociation reaction. In Fig. 6, the intensities recorded at t_e have been plotted, per eq. [11], against the reciprocal temperatures computed on the assumption of complete

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

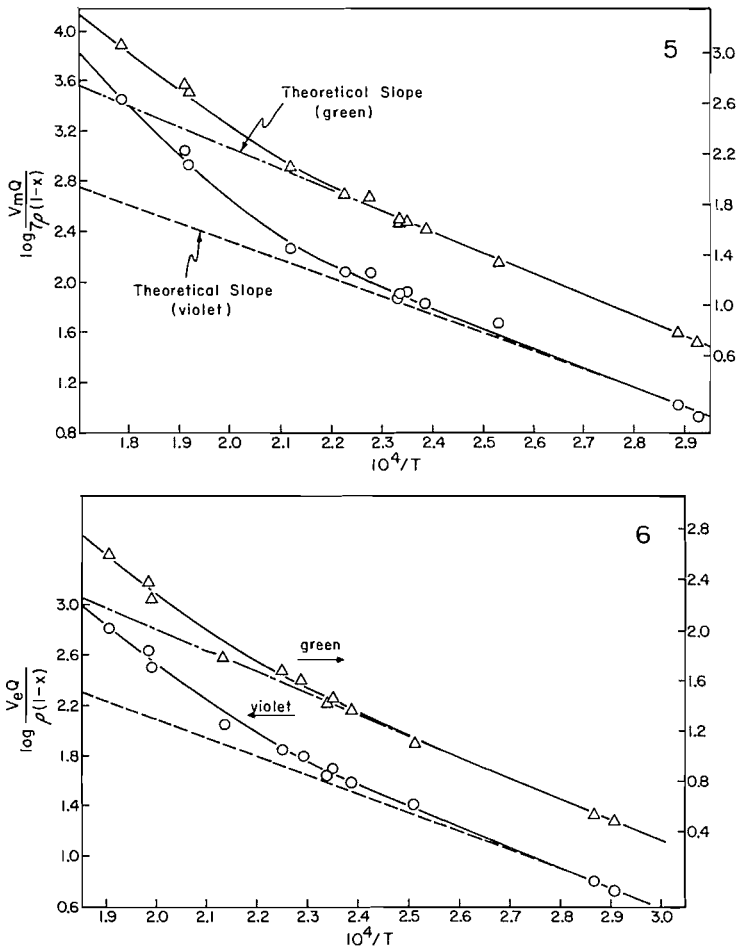

FIG. 5. Plots of $\log [(V_m Q)/7\rho(1-x)]$ vs. $10^4/T$ for the violet and green lines. The temperature and density were computed neglecting the dissociation of nitrogen but allowing for the depletion of chromium by ionization. The fraction ionized is denoted by x.

FIG. 6. Plots of $\log [(V_e Q)/\rho(1-x)]$ vs. $10^4/T$ for the violet and green lines. The temperature and density were computed allowing for the dissociation of N_2 and the ionization of Cr.

equilibrium. Dissociation of the nitrogen, at the highest shock speeds, reduced the computed temperature by $\sim 350°$ K and thereby the magnitude of x. However, the deviations from the theoretical slope were not eliminated due to the concurrent shift of the high-temperature points along the $1/T$ axis with an increase in $(1-x)$.

Except for the points obtained at the highest temperature, the departures from the theoretical slopes may be eliminated by introducing a correction for self-absorption (the term in α, eq. [9]). Since this correction is directly dependent on the population of the lower state, its magnitude for the violet line is proportional to $7\rho_{Cr}(1-x)\,(1-e^{-23,400hc/kT})/Q$ and for the green lines to $5\rho_{Cr}(1-x)e^{-7,593hc/kT}(1-e^{-26,800hc/kT})/Q$. Both functions depend linearly on the density. This is noticeable for the run at $10^4/T = 2.135$ (Fig. 6), which was at a higher density than the adjacent points. In general, the shock densities were lower for the higher-temperature runs. Due to the exp $(-7593hc/kT)$ factor, the green lines should self-absorb approximately 1/33 as much as the violet line, and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

over-all variation of the former for the different runs should be less than for the latter. In Fig. 7, V_e data have been replotted after they were corrected for self-absorption, of

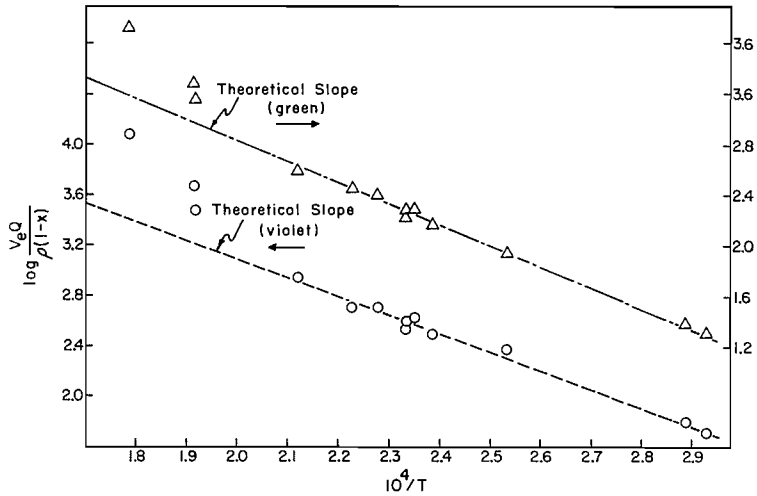

FIG. 7. Plots of $\log [(V_e Q)/\rho(1-x)]$ vs. $10^4/T$ corrected for self-absorption; N_2 dissociation was not included.

such magnitude as to optimize the agreement with the theoretical slope. It is evident that except for the three high-temperature points the experimental slopes coincide with the theoretical values. If these deviations are due to some rate process, a relatively long time constant is involved, since the points for V_m and V_e fall on similar curves; that it is not simply a relaxation in the effective temperature is demonstrated by Fig. 6. Qualitative estimates indicate that these deviations are not due to boundary-layer effects; these would be quite small and of a sign opposite to that observed.* An *ad hoc* explanation is to assume that for $T > 5000°$ K extraneous background radiation contributes appreciably to the recorded intensity due to the relatively broad band passed by the exit slits of the spectrometer.

RISE TIME OF EMISSION

In eq. [16], it is plausible to assume that $(dN_u/dt)_{net} = \rho(1-x)\rho x A \exp(-E_u^*/kT)$ with $(N_u)_e = \rho(1-x) \exp(-E_u/kT)/Q$. This implies that the net rate is proportional to the product of the equilibrium concentration of unionized chromium atoms by the concentration of chromium ions (equal to electrons). A plot of $\log [1/\rho x Q V_m (dV/dt)_{\frac{1}{2}}]$ vs. $1/T$ gave a curve with a suggestion of a minimum in the high-temperature region and a large positive slope as $1/T$ increased. Since no reasonable mechanism can be associated with such a temperature dependence, this assumption must be discarded.

A direct second-order dependence of $(dN_u/dt)_{net}$ on the total density leads to a plot of $\log [1/\rho Q V_m (dV/dt)_{\frac{1}{2}}]$ vs. $1/T$; Fig. 8 is such a graph for the violet line. The change in slope at $10^4/T = 2.3$ implies that two mechanisms are operative, with $(E_u^* - E_u) =$ 18 kcal mole^{-1} and 54 kcal mole^{-1} for the low- and high-temperature ranges, respectively. (A similar set of values was obtained for the green lines.) For these, we find no acceptable explanation. If the dominant processes for the attainment of the steady-state emission

*Roth and Hartunian (21) analyzed boundary-layer temperatures and densities.

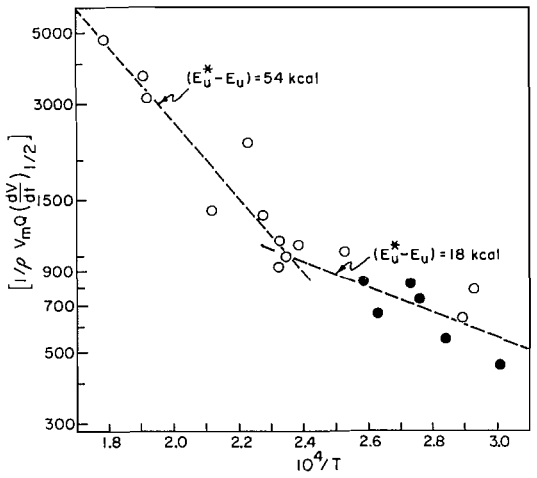

FIG. 8. A plot of $[1/(\rho V_m Q)][(dV/dt)_{\frac{1}{2}}]$, log scale, vs. $10^4/T$ for the *violet* line. The six solid points were taken during the early runs where there was insufficient mixing of $Cr(CO)_6$ and Ar.

involved atom–atom collisions, they would be much slower (18), and the activation energies for excitation, process (*a*), are expected to be much larger.

The simplest assumption is that the rate of excitation, $(dN_u/dt)_{net}$, is dominated by a single process which depends linearly on the density in the same manner as does $(N_u)_e$. This similarity of dependence on density is also imposed on the ionization factor. Graphs of log $[1/V_m Q(dV/dt)_{\frac{1}{2}}]$ vs. $1/T$ for the violet and green lines are shown in Fig. 9; six

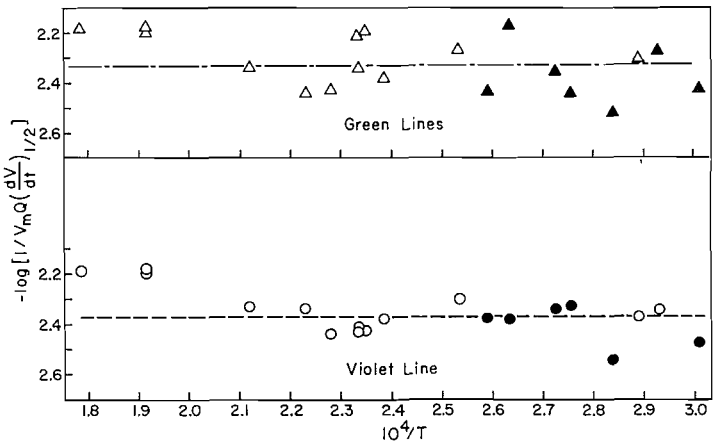

FIG. 9. Plots of $-\log[1/(V_m Q)][(dV/dt)_{\frac{1}{2}}]$ vs. $10^4/T$ for the violet and green lines. The six solid points were taken during the early runs where there was insufficient mixing of the $Cr(CO)_6$ and Ar. The dashed lines have zero slope.

additional points from early runs have been included (full circles and hexagons). Exclusive of the three points for which $1/T < 2\times10^{-4}$, the slopes are nearly zero within the scatter of the data. This is consistent with the postulate that the excitation and ionization of chromium atoms are due mostly to collisions with electrons, for which $E_u^* \approx E_u$ is expected. The initial rise should be exponential in character, as per eq. [14]. Suppose

extraneous background radiation did contribute appreciably to the recorded intensities for runs with $T > 5000°$ K; it may well have done so with a short relaxation time, so that the τ_0's for the three high-temperature points were somewhat shorter than for the others, as observed. Finally, in agreement with the above analysis, the τ_0's for the violet and green lines are equal to within the scatter of the data.

Rather crude measurements obtained with the short response-time circuitry indicate that the rise times for emission were somewhat longer when pure Ar was the ambient medium, compared with the N_2–Ar mixture. This is consistent with the observations of Clouston and Gaydon (8).

SHAPE OF THE LIGHT PULSE

The characteristic shapes of the recorded phototube outputs (Fig. 2) may be accounted for on a qualitative basis. Following the rapid rise, the intensity briefly passes through a slight maximum and levels off to a constant value for the high temperature runs but to a slowly declining magnitude at low temperatures. Finally, it falls rapidly at a time (t_d) which is roughly half the interval from shock front to contact surface, as estimated from ideal shock-tube theory (Table I). It has been established both experimentally (22) and theoretically (23)* that at low initial pressures the flow duration is considerably less than the time computed for ideal shock-tube operation due to effects of the laminar boundary layer behind the shock; low speed gas in the boundary layer near the wall leaks past the contact surface. Quantitative estimates show that this effect is very small for our experiments, even for the lowest initial pressures of 6.3 mm Hg, because of the large diameter of the shock tube. The major source of the short duration flow is the nonideal rupture of the diaphragms, which were comparatively massive (0.032-in. half-hard brass sheets, scored to a depth of 0.016 in., 6 in. in diameter). Under these circumstances, it probably takes more than 10 tube diameters to form the shock, resulting in an effective tube length considerably shorter than the geometrical 18 ft.

Inspection of all the oscilloscope traces showed that the initial maximum was more prominent for the green lines than for the violet line and that it increased in magnitude with rising shock temperature. Reference to Fig. 2 shows that in run No. 51 it is essentially absent for the violet line and of the same order of magnitude as the fluctuation for the green line. From the curves in Fig. 7, we have estimated that for the green line $(V_m - V_e)$ corresponds to 40–100° K for the upper temperature runs. The maximum in emission is accounted for by eq. [15]. In view of our conclusion that $E_u^* \approx E_u$, reasonable estimates of the rate constants are

	$^7P_2 \leftarrow {}^7S_3$	$^5P_2 \leftarrow {}^5S_2$
	(violet)	(green)
k_j	$A_j^v \exp(-23{,}305\ hc/kT)$	$A_j^g \exp(-26{,}796\ hc/kT)$
k_x	$A_x^v \exp(-31{,}236\ hc/kT)$	$A_x^g \exp(-27{,}745\ hc/kT)$
k_+	ground state: $A_+ \exp(-54{,}541\ hc/kT)$	

Since all the pre-exponential factors should be of comparable magnitude for these similar processes, k_j^v at low temperatures may be large enough to place t_m^v within the rising portion of $(n+c)$. As the temperature is raised, $(n+c)$ rises more rapidly to its final value than do other excitation processes (k_+ has the largest activation energy), and the maxima in intensity become more prominent.

We acknowledge with thanks permission to refer to the author's paper "On flow duration in low pressure shock tubes" prior to publication.

CONCLUSIONS

The use of dual-channel data to deduce two-color temperatures to the desired precision still awaits the development of techniques for the measurement of intensities with a reproducibility and precision to the order of 2% and with a time resolution of less than a microsecond. For the range 3000–5000° K, if a known trace concentration of $Cr(CO)_6$ is premixed with the test gas, measurement of the intensity of a single Cr emission line does permit the estimation of temperatures to roughly ±50° K, provided care is taken to calibrate the optical–electronic system. Above 5000° K, it appears that extraneous background radiation leads to too high a value, when the intensity is recorded with a spectroscope of modest resolution. Except at the lowest temperatures, the measured intensities had to be corrected for self-absorption.

The rate of excitation of chromium emission is independent of the carbonyl dissociation rate. Our data suggest that the excitation is due primarily to collision of chromium atoms with electrons. The over-all time dependence of the intensity can thus be accounted for in a qualitative manner.

ACKNOWLEDGMENTS

This work was supported by the Air Force (ARDC) under contract AF33(616)-6694. B. E. L. acknowledges with thanks a NATO Research Studentship Grant for the past year. We also thank Mr. Emmett Sutton and Miss Ann Walbran for the use of their program for the computation of equilibrium shock parameters for a dissociating gas and the Ethyl Corporation for the samples of chromium carbonyl used in these experiments. Finally, we gratefully acknowledge the kindness of Dr. R. E. Duff, who computed the thermodynamic functions of $Cr(CO)_6$ (cf. Appendix) and obtained the least-squares fit of coefficients for the free energy expansion via his IBM 704 program.

APPENDIX

Thermodynamic and Partition Functions

A. The thermodynamic functions of chromium carbonyl were recomputed for the ideal gas at one atmosphere, under the simple harmonic-oscillator, rigid-rotor approximation, over the temperature range 300–6000° K (cf. N. J. Hawkins *et al.* J. Chem. Phys. **23**, 2422 (1955)). The values for the free energy function were least-squares fitted to a polynomial in the temperature:

$$\frac{F^\circ_T - H^\circ_0}{RT} = a(1-\ln T) - bT - \frac{c}{2}T^2 - \frac{d}{3}T^3 - \frac{e}{4}T^4 - k.$$

Values for the coefficients were obtained over two ranges.

	Best fit over 300–2000° K	Best fit over 1500–6000° K
k	-3.8958892	$-5.7940996\times10^{+1}$
a	7.5396309	$2.0163532\times10^{+1}$
b	4.2072684×10^{-2}	9.0970966×10^{-3}
c	-3.6287469×10^{-5}	-2.5055972×10^{-6}
d	1.6024045×10^{-8}	3.3908588×10^{-10}
e	-2.7501040×10^{-12}	-1.7854329×10^{-13}

B. The ratio of the partition functions for chromium in the singly ionized and neutral states were computed, to facilitate estimation of the degree of ionization of the metal vapor, via the Saha equation.

LIGHT ABSORPTION STUDIES

PART XVIII. THE ULTRAVIOLET ABSORPTION SPECTRA OF BROMOBENZENES[1]

W. F. Forbes

ABSTRACT

The ultraviolet absorption spectra of bromobenzene in various solvents, and the spectra of a series of substituted bromobenzenes in cyclohexane solution, are reported. The *B*-band spectral data confirm the hypotheses postulated for the *B*-band spectra of chlorobenzenes in the previous part of this series of papers. That is, the bromine atom usually gives rise to greater steric effects than the chlorine atom and the apparent mesomeric interaction as judged from these spectra increases with the size of the halogen substituent.

Both bromobenzene and chlorobenzene *C*-band intensities are unusually small, and this is assumed to account for the frequent *C*-band similarity between the spectrum of a mono-substituted benzene derivative PhX, where X = OH, OCH_3, NH_2, and the spectrum of the corresponding chloro- or bromo-substituted PhX derivative.

INTRODUCTION

Following a study of the ultraviolet absorption spectra of chlorobenzenes (1) and of fluorobenzenes (2), it is intended to extend the discussion of the properties of halogen-substituted benzenes by the study of the spectra of bromobenzenes. It follows from this that the band nomenclature and other terms used in the present paper are identical with the terms as defined or used in the previous papers (1, 2).

THE SPECTRUM OF BROMOBENZENE

The absorption characteristics of bromobenzene in different solvents are listed in Table I.

Table I shows that the location of the *B*-band of bromobenzene is similar for cyclohexane, ether, ethanol, and aqueous solutions. Three points may be noted on comparing the *B*-band of bromobenzene and chlorobenzene. First, a slight wavelength displacement is observed between the *B*-band of bromobenzene in the vapor phase and in cyclohexane solution, whereas no such wavelength displacement was observed for chlorobenzene (1). Since the dipole moment data (3, and references cited therein), infrared data (4), and other data (which are determined by the ground state alone) are similar for chlorobenzene and bromobenzene, it is possible that the electronic excited state of chlorobenzene (which determines predominantly the observed absorption band) is practically independent of the C—Cl dipole but that the C—Br dipole makes some contribution to the relevant electronic excited state of bromobenzene.

Next, the bromobenzene *B*-band usually exists as a maximum accompanied by subsidiary inflections at longer wavelength, and these latter submerged maxima do not facilitate precise comparisons with the locations of absorption bands of other compounds, and in particular with that of chlorobenzene. However, using the absorption band occurring at the longest wavelength, namely the inflection occurring at ca. 222 mμ, or using the "center of gravity" of the bands, the data suggest that the *B*-band of bromobenzene occurs at slightly longer wavelength than the *B*-band of chlorobenzene (cf. ref. 1 and see Fig. 1).

Thirdly, the intensity of the *B*-band of bromobenzene in most solvents is also slightly greater than for the corresponding chlorobenzenes (see, for example, Fig. 1 and cf. also

[1]*Manuscript received November 28, 1960.*

*Values in italics represent inflections in this and the subsequent table.
†Intensities not determined.

Table I and ref. 1). A simple explanation of these three effects (i.e., the increased solvent–solute interaction, the slight shift to longer wavelength, and the intensification of the *B*-band in bromobenzene compared with these effects in chlorobenzene) is to relate these *B*-band changes to mesomeric interaction as illustrated by resonance structures of type I and to assume that the apparent mesomeric effect is in the order I > Br > Cl

(I)

> F. Since this order of mesomeric interaction is different from that suggested by other data (except for some isolated infrared data (5, 6) which indicate an order of mesomeric interaction parallel to the order as suggested by the ultraviolet data), we refer to it as the *apparent* mesomeric effect of the halogen atoms. Further evidence of the order

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

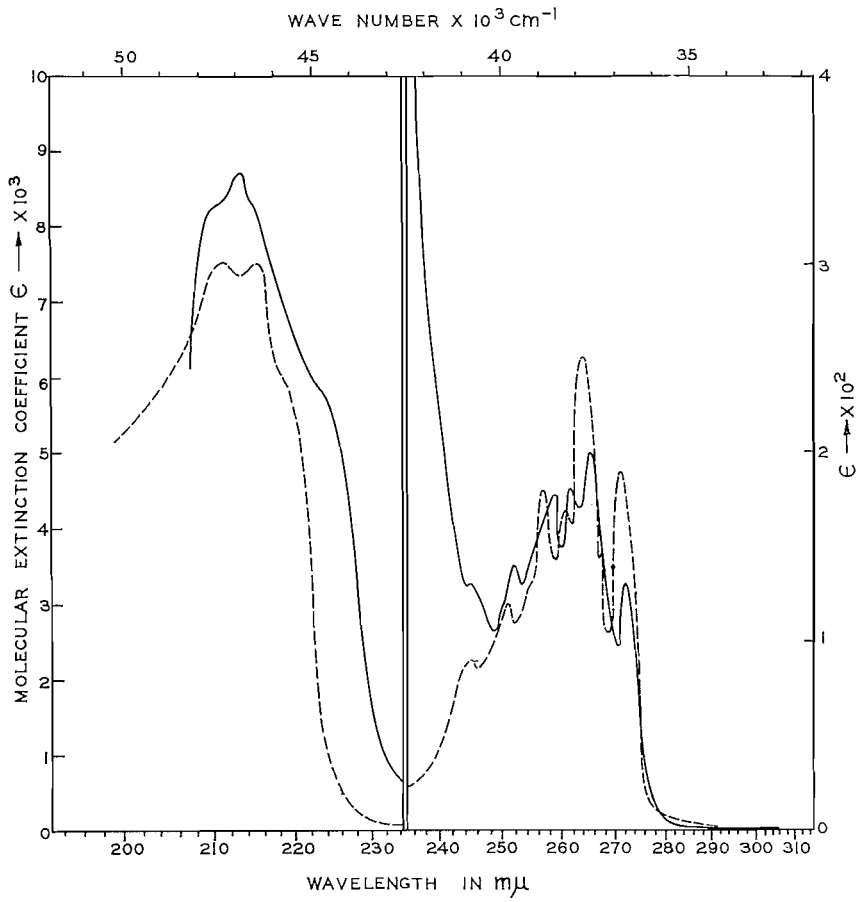

FIG. 1. The ultraviolet absorption spectra in cyclohexane solution of bromobenzene (full line) and chlorobenzene (dotted line).

Br > Cl for the apparent mesomeric effect of the halogen atoms will be presented in the next section.

On the other hand, it should be noted that the majority of ground state data indicate a reverse order of mesomeric interaction, namely F > Cl > Br > I. Moreover, even if the order of mesomeric interaction is as indicated by the present data in the electronically excited state of the observed spectra, it should be pointed out that the order of mesomeric interaction would still be different in these excited levels from the order prevailing in the activated complexes involved in chemical reactions.*

The *C*-bands of bromobenzene and chlorobenzene are similar (see, for example, Fig. 1 and cf. also Table I and ref. 1). Both *C*-bands are unusually weak and this may account for the frequent "overshadowing" of these *C*-bands when another substituent is present, as for example in the spectra of *p*- and *m*-bromofluorobenzenes, which show *C*-bands of comparable intensity to that of fluorobenzene (see Fig. 2).

**A referee has pointed out that ground state calculations have shown that the resonance integrals which measure the π-orbital overlap of two bonded atoms decrease in the order* F > Cl > Br > I *for* =C—X *systems. In support, however, of the arguments presented in this paper, the referee suggests that the excited states for the heavier halogens are more energetically stable and this might tend to reverse the series "in the excited state".*

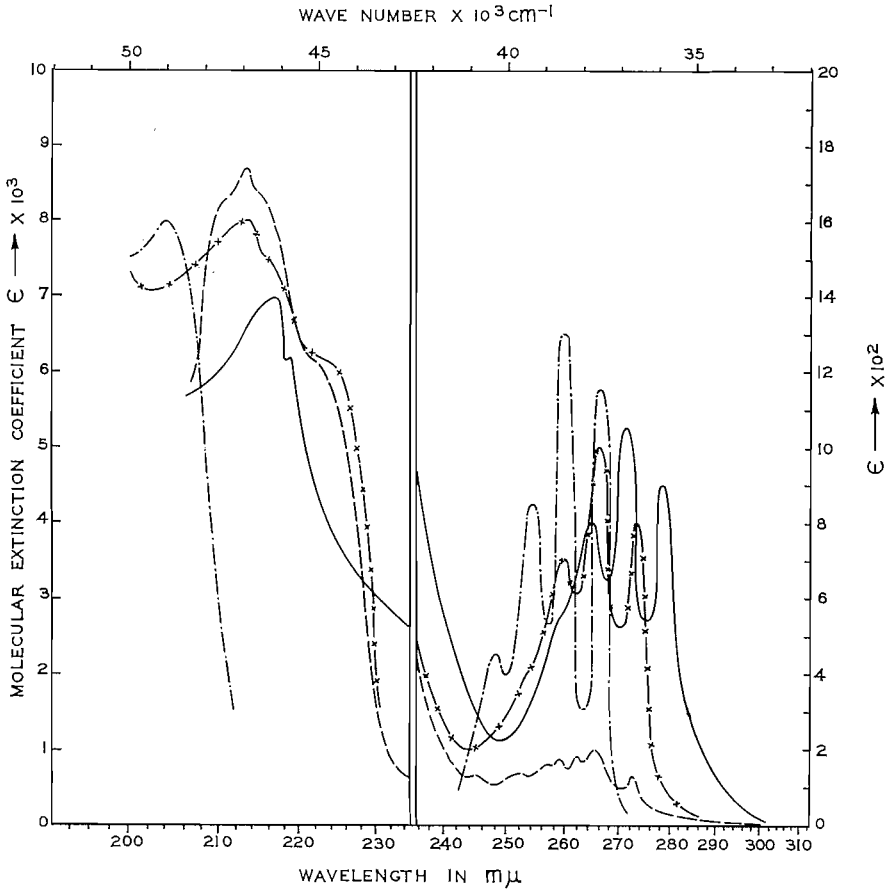

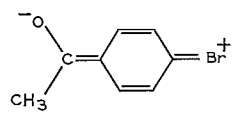

FIG. 2. The ultraviolet absorption spectra in cyclohexane solution of *p*-bromofluorobenzene (——) *m*-bromofluorobenzene (— ×), fluorobenzene (— ·), and bromobenzene (— —).

THE SPECTRA OF PARA-SUBSTITUTED BROMOBENZENES

Using the simplified resonance concept illustrated by structures of type I, electron-withdrawing substituents in the *p*-position of bromobenzene, which permit the extension of the conjugated system as illustrated by resonance structures of type II, would be

(II)

expected to lead to *B*-band absorption at longer wavelength and with increased absorption intensity. In fact, the *B*-band data for *p*-substituted bromobenzenes, where the *p*-substituent is —CHO, —$COCH_3$, or —NO_2, show that the *B*-band now occurs at longer wavelength and with increased absorption intensity (see Table II). Moreover, comparison with the *B*-band data of the related *p*-substituted chlorobenzenes, given in reference 1, shows that the *B*-bands of these *p*-substituted bromobenzenes absorb at slightly longer wavelength and with greater absorption intensity than the corresponding *p*-substituted

*B-band assignment doubtful.

chlorobenzenes (cf. also refs. 7, 8 for the *B*-bands of the *p*-chloro and *p*-bromo derivatives of nitrobenzenes and acetanilides). This indicates that the bromine atom has a greater ability to release electrons in the electronic excited state than the chlorine atom and again confirms the order of apparent mesomeric interaction Br > Cl for the halogen atoms as suggested in the previous section. It is also worth noting that the reported dipole moment of compounds like *p*-bromonitrobenzene is slightly greater than that of *p*-chloronitrobenzene (3) although dipole moment data are determined only by the ground state.

A plot of the wavelength displacements (in cm^{-1} units) for four *p*-substituted bromobenzenes, where the *p*-substituent was —H, —CHO, —$COCH_3$, or —NO_2, against various functions such as σ^*, $(\sigma_p - \sigma')$ values for the above substituents did not give rise to a straight line. Nor was a straight line obtained when the wavelength displacements in cm^{-1} units for *p*-substituted acetophenones, when the *p*-substituent was H, F, Cl, Br, or I, were plotted against the σ^* or $(\sigma_p - \sigma')$ values of these substituents. However, as noted by Schubert and co-workers (9), a graph relating ν_{max} values of the *B*-band in the gas phase against molar refraction values does afford an approximately linear relationship for the *p*-halonitrobenzenes, *p*-haloacetophenones, and *p*-haloanisoles, in this way confirming the relationship between molecular polarizability (as measured by molar refraction values) and certain absorption spectra.

Table II not only includes the *p*-substituted bromobenzenes discussed in the previous paragraph, but also includes *p*-substituted bromobenzenes where the *p*-substituent does not extend the conjugation in the most probable resonance form. These spectra, as expected from simple resonance theory, involve so-called locally excited states; that is, these spectral data (which are listed at the beginning of Table II) indicate that the *B*-bands of these compounds usually resemble the *B*-band of one of the monosubstituted parent compounds. Of the two substituents, normally the substituent with the greater electron-donating power will predominantly determine the wavelength and intensity of the monosubstituted benzene *B*-band, while the other substituent will exert only a "secondary" effect on the *B*-band. For example, the *B*-band of *p*-bromoiodobenzene in cyclohexane solution shows the characteristic *B*-band doublet near 240 mμ fairly close to the *B*-band absorption doublet of iodobenzene, near 230 mμ, and the spectrum of *p*-bromoaniline resembles that of aniline. In both these examples the corresponding *C*-bands resemble the *C*-bands of iodobenzene and aniline respectively. This is further illustrated by Fig. 3, which shows the similarity of the spectra of *p*-bromoaniline and aniline and the dissimilarity from the absorption spectrum of bromobenzene.

For other compounds the assignments are more doubtful. For example, the *B*-band of *p*-bromofluorobenzene in cyclohexane solution resembles the band of bromobenzene more than the *B*-band of fluorobenzene (see Fig. 2) since the latter band occurs below 205 mμ (2); however, the *C*-band of *p*-bromofluorobenzene resembles the *C*-band of fluorobenzene more than the *C*-band of bromobenzene. Next, the *B*-bands of *p*-bromophenol, *p*-bromoanisole, and *p*-chlorobromobenzene are tentatively ascribed to phenol, anisole, and bromobenzene absorption respectively with the *p*-bromo or *p*-chloro substituents facilitating the transition by means of a secondary interaction (cf. also ref. 1). Partial support for these assignments is provided by the lack of fine structure in the *B*-bands of *p*-bromophenol and *p*-bromoanisole, and by the relevant *C*-bands (see Table II), which may readily be identified as phenol or anisole *C*-bands (see also Fig. 4, a fact that illustrates the similarity of the spectra of *p*-bromoanisole and anisole and the dissimilarity from the absorption spectrum of bromobenzene). On the other hand, *C*-band

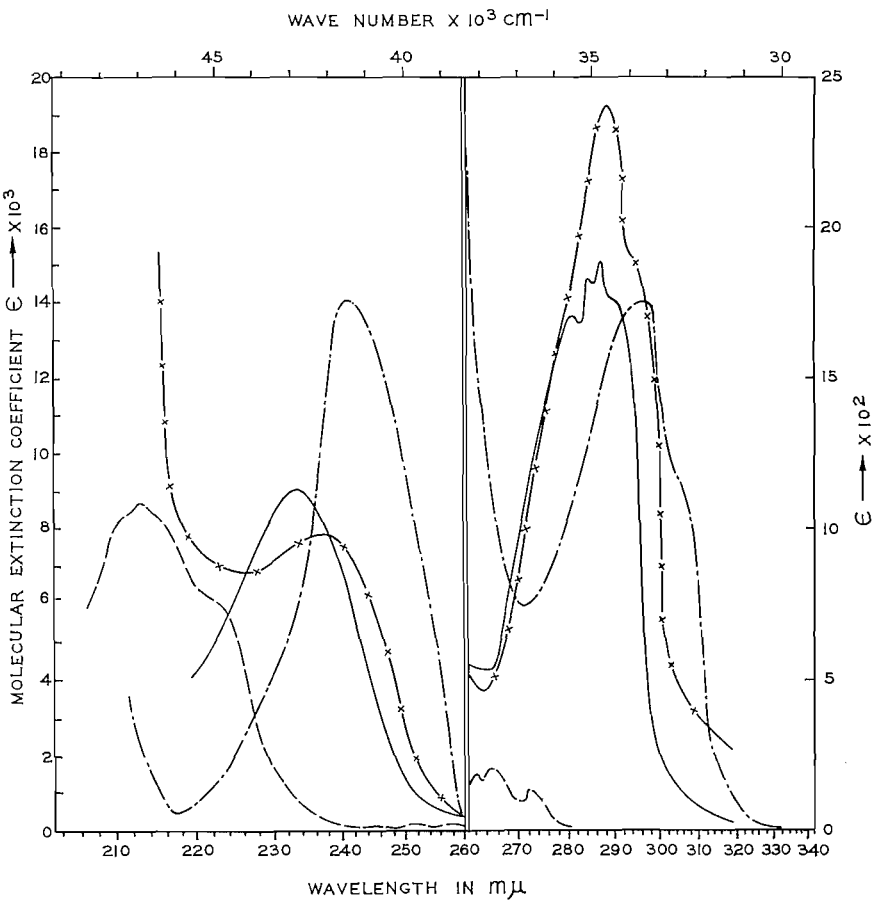

FIG. 3. The ultraviolet absorption spectra in cyclohexane solution of aniline (——), *p*-bromoaniline (—·), *m*-bromoaniline (—×), and bromobenzene (— —).

similarities can be misleading (see the preceding discussion of the spectra of *p*-bromofluorobenzene) and also some of the solvent changes suggest a different assignment. For example, the wavelength displacement observed on determining the *B*-band of *p*-bromoanisole in the vapor phase and in an inert solvent medium (2.8 mμ (9); 550 cm^{-1}) is closer to the wavelength displacements observed under similar conditions for bromobenzene (ca. 2 mμ (see Table I); 440 cm^{-1}) than to that observed for anisole (4.6 mμ (9); 980 cm^{-1}).

A *p*-bromo substituent generally appears to cause the *B*-band absorption to occur at longer wavelength even if both substituents are electron-donating as in *p*-dibromobenzene; the wavelength displacement relative to the non-bromo-substituted reference compound is usually not less than ca. 10 mμ and the absorption intensity is appreciably enhanced (see Table II and previous parts of this series of papers). This displacement may be visualized as the bromine atom donating electrons in the electronic excited state and this effect of the *p*-bromo substituent is again slightly larger than the previously noted similar effect of a *p*-chloro substituent (1).

Concerning *C*-band absorption it may be noted that a *p*-bromo substituent generally (except in examples where resonance structures of type II may be assumed to be involved)

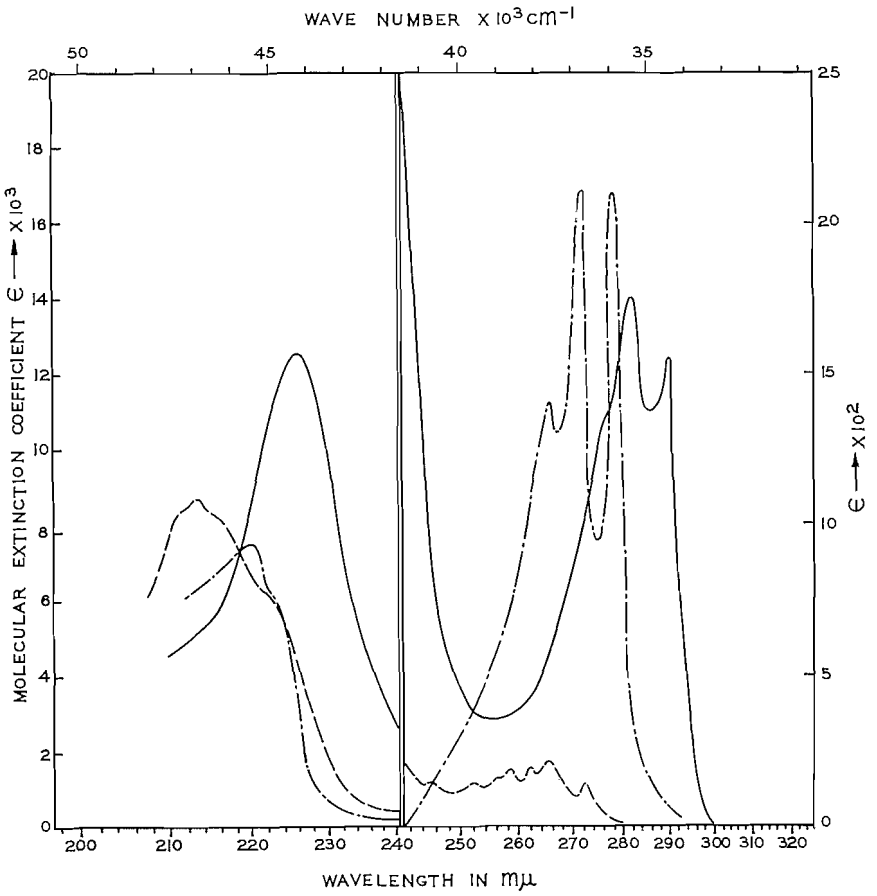

FIG. 4. The ultraviolet absorption spectra in cyclohexane solution of *p*-bromoanisole (——), anisole (—·), and bromobenzene (— —).

does not appear to affect the *C*-band structure of a number of *p*-substituted bromobenzenes; that is, the *C*-bands of these *p*-substituted bromobenzenes may occur at slightly longer wavelength and with slightly decreased absorption intensity but are otherwise similar to the *C*-bands of the corresponding non-bromo-substituted parent compounds (see, for example, Figs. 2, 3, and 4 and cf. ref. 10). The absence of any marked evidence of bromobenzene *C*-band absorption on the structure of the *C*-band may again be related to the low-intensity *C*-band absorption in bromobenzene. That is, the bromobenzene *C*-band absorption is normally hidden by other more intense *C*-band absorption except in compounds like *p*-bromochlorobenzene where both constituent *C*-bands, namely the *C*-bands of chlorobenzene and bromobenzene, are weak.

THE SPECTRA OF META-SUBSTITUTED BROMOBENZENES

For *m*-substituted bromobenzenes, a *B*-band associated with the bromobenzene *B*-band can usually be ascertained; the *C*-band only rarely corresponds to bromobenzene *C*-band absorption (cf. last paragraph of previous section). For example, for *m*-bromofluorobenzene the *B*-band absorption at 213 mμ is associated, at least partly, with bromobenzene *B*-band absorption (see Tables I and II), whereas the *C*-band absorption of

m-bromofluorobenzene is similar to that of fluorobenzene (see Fig. 2). Frequently the *C*-band similarity for *m*-substituted bromobenzenes and the corresponding non-bromo-substituted parent compounds is more pronounced than the previously referred to *C*-band similarity for *p*-substituted bromobenzenes and the corresponding non-bromo-substituted benzene derivatives (see Table II and the relevant reference compounds described in previous papers of this series). This may be interpreted in terms of resonance theory since electronic perturbations, such as may be associated with resonance interactions in the *p*-isomer, would be of less importance in a *m*-disubstituted benzene derivative.

For a number of *m*-substituted bromobenzenes, instead of the bromobenzene *B*-band, a "second" *B*-band—for example, the *B*-band of *m*-bromoaniline associated with the aniline *B*-band—is readily identified (see Fig. 3; reasons why *m*-disubstituted benzene derivatives sometimes show two *B*-bands have been discussed in previous papers of this series (e.g. refs. 1, 2)). The *m*-bromo substituent generally causes this *B*-band absorption to occur at slightly longer wavelength. This displacement is less pronounced than for a *p*-bromo substituent and about equally effective for *m*-chloro and *m*-bromo substituents. It may be noted that both *m*-chloro and *m*-bromo substituents have the effect of enhancing the integrated intensities of the O—H infrared absorption band in phenol (integrated absorption intensities are well known to relate to mesomeric interactions) to a similar extent (11).

The effect of the non-bromo substituent on the *location* of the maximal wavelength of the bromobenzene *B*-band absorption in *m*-substituted bromobenzenes appears to be small but the intensity of the bromobenzene *B*-band is sometimes enhanced (see Tables I and II for the relatively more intense "bromobenzene *B*-bands"). However, since the bromobenzene *B*-band occurs at shorter wavelength, it seems likely that *A*-band transitions contribute to the observed band (see Table II).

THE SPECTRA OF ORTHO-SUBSTITUTED BROMOBENZENES

The ultraviolet spectra of *o*-substituted bromobenzenes would be expected to show the effects of appreciable steric interactions. In fact, the second *B*-band (that is, the *B*-band *not* associated with bromobenzene absorption) of an *o*-bromo-substituted compound frequently occurs with decreased absorption intensity compared with the second *B*-band of the corresponding *o*-chloro-substituted compound.* (See Table II and ref. 1;

(III)

cf. also the data reported for nitrobenzenes (7), acetanilides (8), N,N-dimethylanilines (12), and 5-phenyltetrazoles (13), which show that the maximal extinction coefficient

**An example of an exception is the B-band of o-bromobenzaldehyde (see Table II) which is more intense than the corresponding B-band of o-chlorobenzaldehyde (1; cf. also the ε values reported (19) for o-chloro- and o-bromophenyl-2,5-diphenyloxazoles). This may be because in o-bromobenzaldehyde and related compounds the effect of mesomeric interactions, as illustrated by resonance forms of type III, is still appreciable and hence the greater apparent mesomeric effect of the bromo substituent leads to increased absorption intensity. For most other o-substituted bromobenzenes resonance structures of type III may be of little importance because the non-planarity of the molecule inhibits the necessary conjugation.*

of the *B*-band of the *o*-bromo derivative is less than the corresponding maximal extinction coefficient of the *o*-chloro derivative.) Moreover, in examples like *o*-bromoacetophenone, where the non-bromo substituent is large, the absorption intensity is also smaller than the intensity of the corresponding *m*-isomer (see Table II). This decreased extinction coefficient, relative to the *m*-isomer, is also accompanied by a hypsochromic wavelength displacement, which in this type of compound is assumed to be associated with steric interactions. Since non-planarity in *o*-bromo-substituted benzene derivatives is also suggested from other data (see, for example, refs. 3, 14, 15, 16, 17, 18), the above spectral data are assumed to indicate that the bromine atom, because of its larger size relative to the chlorine atom (cf. ref. 14), more effectively dislodges the non-bromo substituent from the plane of the benzene ring and in this way gives rise to the observed spectral changes.

However, the ultraviolet data do not consistently indicate that the bromo substituent exerts a greater steric effect than the chloro substituent (see footnote of previous paragraph). A similar lack of consistency is found when comparing the ϵ values of *o*-bromo-substituted benzene derivatives with the ϵ values of *o*-methyl-substituted benzene derivatives. For example, for acetanilides (8) the *o*-bromo derivative shows more intense *B*-band absorption than the *o*-methyl derivative (see also reference 20 for the spectra of the corresponding benzoic acids). However, more frequently, for example, for anilines (21), or benzaldehydes (22), the *o*-methyl derivative shows more intense *B*-band absorption than the *o*-bromo derivative (see also refs. 19, 23). The data thus indicate that the effective interference radius of the bromine atom is greater than that of the methyl group (or than that of the chlorine atom; cf. refs. 14, 15), but it remains to provide an explanation for the minority of anomalous data. This can be done by considering dipole moments. That is, a methyl substituent, which has a dipole moment in the opposite direction to that of the halogen atoms, may cause a considerably different over-all dipole moment and in this way compounds like *o*-toluic and *o*-bromobenzoic acids, for example, may possess appreciably different dipole moments. Moreover, steric interactions (which are assumed to be present) may increase the over-all dipole moment of one molecule while decreasing the dipole of another, similar molecule (cf. ref. 3, where it was pointed out for nitrobenzenes that an *o*-methyl substituent increases the dipole moment by increasing the angle between the C—N and C—Me bonds, whereas an *o*-bromo or *o*-chloro substituent may decrease the over-all dipole moment). Since absorption intensities are determined by transition probabilities which, in turn among other things, are governed by transition moments—which are related to the change in dipole moment on passing from the ground state to the excited state—it is evident that the absorption intensities of the above *o*-disubstituted benzene derivatives are not determined merely by steric interactions.

Although intramolecular hydrogen bonds have been postulated in *o*-substituted bromobenzenes because of evidence from other physical data (24, 25, 26), as for the previously discussed spectra of *o*-substituted chlorobenzenes or fluorobenzenes (1, 2), there is little evidence *from the above ultraviolet spectra* for such a hydrogen bond. That is, no unusual wavelength displacement or unusual change in ϵ_{max} values, such as may be ascribed to the presence of an intramolecular hydrogen bond, is observed in the spectrum of *o*-bromophenol compared with the spectrum of *m*-bromophenol or *o*-bromoanisole (see Table II); only for *o*-bromoaniline small intensity increases are observed in the ϵ_{max} values compared with the ϵ_{max} values of the *m*-isomer, but it is not certain that these intensity increases are caused by an intramolecular hydrogen bond.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The *C*-bands in *o*-substituted bromobenzenes usually occur with increased absorption intensity compared with the *C*-bands of the corresponding *m*-isomers, except in compounds, such as *o*-bromoacetophenone, which are believed to be appreciably non-planar because of steric interactions. For a number of *o*-chloro- and *o*-bromo-substituted compounds the *C*-bands are remarkably similar; for example, *o*-chloroaniline, λ_{max} 291 mμ, ϵ = 2900 and *o*-bromoaniline, λ_{max} 289 mμ, ϵ = 3000 (see ref. 1 and Table II). This *C*-band similarity has previously been discussed (see Introduction).

EXPERIMENTAL

The ultraviolet absorption spectra were determined by standard methods in 1-cm cells using either a Beckman DU or DK 2 spectrophotometer or Unicam SP 500 spectrophotometers calibrated against a didymium filter. Wavelength readings obtained on the Unicam and Beckman instruments were found to be within 1 mμ of each other. The accuracy of λ_{max} values is estimated to be $\pm$1 mμ, and the precision of ϵ_{max} values $\pm$5%, or better. Values of ϵ_{max} were reproducible in most cases to $\pm$2%. For each compound at least two independent sets of observations were made. The ultraviolet maxima are listed in Tables I and II. Some of the spectra have previously been described in this series and elsewhere. Whenever possible, the bromobenzene spectra were determined under conditions identical with those under which previous spectra in this series had been determined. Frequently, but not always, the data were in good agreement with recent values reported by other workers.

The bromobenzenes were mostly commercial materials, purified by distillation or recrystallization until their boiling points and refractive indices or melting points showed them to be sufficiently pure. The solvents used were spectroanalyzed cyclohexane (Fisher) and other commercially available spectroanalyzed solvents.

ACKNOWLEDGMENTS

The author is indebted to Miss V. R. Jellett and Mr. A. A. Sioumis for the careful determination of the spectral data. Some of the spectra have been determined by Mr. J. C. Dearden, assisted by Miss Florence Jackman, in preparation for his Ph.D. thesis at the Memorial University of Newfoundland and the author is indebted to Mr. Dearden for making these data available.

Grateful acknowledgment for financial assistance in support of that part of these studies which was carried out in Canada is made to the National Research Council.

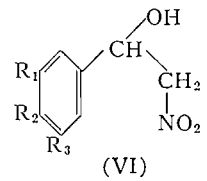
NOTES



A NOTE ON THE PREPARATION OF SOME 1-PHENYL-2-NITROETHANOL DERIVATIVES

R. A. Heacock, O. Hutzinger, and C. Nerenberg*

It has been known for many years that aromatic aldehydes (I) and nitromethane (II) will undergo a condensation reaction, under alkaline conditions, to yield the alkali metal derivatives of the *aci*-form of the monohydric nitroalcohols (III). The free nitroalcohols (IV) can be liberated on acidification of the alkali metal derivative with acetic acid; however, the products will often dehydrate with extreme ease to form the corresponding ω-nitrostyrenes (V), unless certain precautions are taken (cf. ref. 1).

In this laboratory, we have been primarily interested in obtaining certain alkyl, acyl, and aroyl derivatives of 1-(3,4-dihydroxyphenyl)-2-nitroethanol and 1-(3,4,5-trihydroxyphenyl)-2-nitroethanol. A few of these nitroalcohols had previously been described in the literature namely: 3,4-methylenedioxy-α-nitromethylbenzyl alcohol (VI: R_1+R_2 = OCH_2O; R_3 = H) (2, 3, 4, 5); 3,4-diacetoxy-α-nitromethylbenzyl alcohol (VI: R_1 = R_2 =

(VI)

$OCOCH_3$; R_3 = H) (6); and 4-benzyloxy-3-methoxy-α-nitromethylbenzyl alcohol (VI: R_1 = OCH_3; R_2 = $OCH_2C_6H_5$; R_3 = H) (7). The 3,4-diacetoxy derivative was obtained using aqueous sodium bicarbonate as the condensing agent (6); however, the other nitroalcohols were prepared either using sodium methoxide under anhydrous conditions or aqueous alcoholic potassium hydroxide to effect the condensation (1, 2, 3, 4, 5, 7).

Some of the aforementioned procedures are rather tedious to carry out and this note reports a rapid and simple method for preparing nitroalcohols of this general type in good yield. The procedure involves the condensation of a suitable aldehyde with excess nitromethane at about 5° in the presence of sodium hydroxide in aqueous alcoholic solution. The optimum reaction time, which was of very short duration (⩾ 3 minutes), varied from case to case and was determined empirically.

As well as the nitroalcohols mentioned above, the following new 1-phenyl-2-nitroethanol

*Sources of aldehydes: *a* = Eastman Kodak. *b* = Prepared by the acetylation of vanillin and isovanillin respectively by an adaptation of the method described by Kanao for the preparation of 3,4-diacetoxybenzaldehyde (6). *c* = Prepared by the method of Kanao (6). *d* = 4-Benzyloxy-3-methoxybenzaldehyde (m.p. 64°) was prepared from vanillin by benzylation with benzyl chloride in the presence of aqueous potassium hydroxide. This substance has previously been prepared by alternative routes and the melting point is quoted as 63–64° (9). *e* = Aldrich Chemical Company. *f* = Prepared by the acetylation of Syringaldehyde

derivatives have been prepared: 4-acetoxy-3-methoxy-α-nitromethylbenzyl alcohol (VI: $R_1 = OCH_3$; $R_2 = OCOCH_3$; $R_3 = H$); 3-acetoxy-4-methoxy-α-nitromethylbenzyl alcohol (VI: $R_1 = OCOCH_3$; $R_2 = OCH_3$; $R_3 = H$); 3,4,5-trimethoxy-α-nitromethylbenzyl alcohol ($R_1 = R_2 = R_3 = OCH_3$) and 4-acetoxy-3,5-dimethoxy-α-nitromethylbenzyl alcohol ($R_1 = R_3 = OCH_3$; $R_2 = OCOCH_3$). Attempts to prepare a number of related nitroalcohols by this method were not successful: (i) veratraldehyde gave mainly 3,4-dimethoxy-ω-nitrostyrene, even after cooling the reaction mixture below 0°; (ii) protocatechualdehyde, syringaldehyde, vanillin, and isovanillin did not react with nitromethane under the above conditions. This is not altogether surprising in view of the fact that three of these aldehydes have a para hydroxyl group, which has been reported by several workers to hinder this type of condensation (1, 8); (iii) 3,4-dibenzoyloxybenzaldehyde, 3-benzyloxy-4-methoxybenzaldehyde, 3,4-diethoxycarbonyloxybenzaldehyde, and 3-ethoxycarbonyloxy-4-methoxybenzaldehyde gave oily products, for which satisfactory analyses could not be obtained (for the nitroalcohol) even after distillation in high vacuum. It would appear in these cases that condensation had occurred, but partial decomposition of the products took place in the isolation or distillation stages. The infrared spectra of thin films of these oils showed strong absorption in the 2.79 to 2.81 μ region, probably due to the stretching vibrations of the benzyl alcohol hydroxyl group. (The authenticated nitroalcohols all exhibited marked absorption in this region (2.75 to 2.88 μ).) Recently Axelrod, Senoh, and Witkop have reported the OH stretching fre-

(Aldrich Chemical Company) by an adaptation of the method described by Kanao for the preparation of 3,4-diacetoxybenzaldehyde (6), m.p. 115°. Freudenberg and Hübner prepared this compound by a different route and quote m.p. 114° (10).

†The crude product, a yellow oil, was stirred with concentrated sodium bisulphite solution for 20 minutes before recrystallization from benzene.

‡The melting point has been incorrectly reported as 98–99° in Chem. Abstr. **48**, 13,653 (1954).

quency of 4-benzyloxy-3-methoxy-α-nitromethylbenzyl alcohol as 2.81 μ in chloroform solution (7).

In a few cases, the corresponding ω-nitrostyrenes had not been previously described in the literature and these derivatives were prepared in good yield, from the nitroalcohol in question, by an adaptation of the method described by Kanao for the preparation of 3,4-diacetoxy-ω-nitrostyrene from 3,4-diacetoxy-α-nitromethylbenzyl alcohol (6).

EXPERIMENTAL

*General Procedures**

(*i*) *Nitroalcohols.*—Aqueous sodium hydroxide (10%; 1.05 mole) was added with vigorous stirring to a mixture of the aldehyde (1.0 mole) and nitromethane (2–3 mole) dissolved in 95% ethanol at ca. 5°; the reaction mixture was vigorously stirred for a short time (⩾3 minutes), accurately timed on a stop watch. Aqueous acetic acid (2%) was added to arrest the reaction and decompose the sodium derivative of the nitroalcohol; the crude product precipitated out as a yellow or colorless solid or oil. After being allowed to stand at 4° for 4–5 hours, the crude product was filtered and purified by repeated recrystallization from a suitable solvent.

(*ii*) *ω-Nitrostyrenes.*—A suspension of the nitroalcohol and the same weight of fused

PREPARATION AND DEHYDRATION OF DI-(1-HYDROXYCYCLOALKYL)-ALKANES[1]

A. S. Bailey,[2] D. G. M. Diaper, and M. V. H. Schwemin

1-Alkylcycloalkanols have been employed (1, 2) as intermediates in the extension of monofunctional aliphatic chains. An obvious extension of this synthetic method would be the use of di-(1-hydroxycycloalkyl) compounds in chain extension of α,ω-dicarboxylic acids of the aliphatic series. Although there is no record (3) of the use of such intermediates for this purpose, diols of the requisite structural type have been made in isolated previous investigations. We have now prepared diols having five-, six-, seven-, and eight-membered rings and with 2 to 10 methylene groups connecting them, using procedures already described. The results are summarized in Table I.

Method A, reaction of a diester with two moles of a Grignard reagent from a dihalide, has been studied previously only in the synthesis of 1,1′-ethylenedicyclopentanol and 1,1′-ethylenedicyclohexanol from ethyl succinate and respectively tetramethylene dibromide and pentamethylene dibromide (4). We attempted to use hexamethylene dibromide and 1,3-dibromo-2,2-dimethylpropane in similar syntheses but in each case obtained no crystalline product but the major outcome was evidently a polymer. Diethyl 2,2-dimethylglutarate was successfully condensed with 2 moles of the derived Grignard reagent from pentamethylene dibromide although one might have expected the gem dimethyl group to hinder or deactivate one of the ester groups sterically.

*The yield of the coupling reaction is given in methods A, B, and C. The hydrogenation steps of methods C and D and the oxidation step in method D were almost quantitative. The yield recorded for method D is for the ethynylation step.
†1,1′-Ethynylenedicycloheptanol (1,4-dihydroxy-1,1,4,4-bishexamethylene-2-butyne) had m.p. 81–2° (literature, 10, 78–80°).
‡1,1′-Diacetylenedicyclopentanol (1,6-dihydroxy-1,1,6,6-bistetramethylene-2,4-hexadiyne) had m.p. 136–7° (literature, 14, 133.2–134.2°).
§M.p. (thermometer immersed) 8°.
‖M.p. (thermometer immersed) 5°.
¶Hydrogenation equivalent, expressed as a percentage of the theoretical uptake for the diolefin.

Method B (18) was the conversion of a cyclic ketone to the symmetrical diol by reaction with the double Grignard reagent derived from an α,ω-dihalide having from 4 to 10 carbon atoms in the chain. In agreement with Lukes and Blaha (5), good results were obtained in this range, but it is generally recognized that aliphatic dihalides having three carbon atoms or fewer between the halogen atoms are useless in Grignard syntheses (6). We have, however, converted 1,3-dibromo-2,2-dimethylpropane (7) to a Grignard reagent and obtained a condensation product from it with cyclohexanone. The success of this reaction is the more remarkable in the light of the reaction of the dihalide with zinc (8) which gives dimethylcyclopropane in 96% yield. Whatever the reasons for the general failure of trimethylene halides in Grignard reactions, cyclopropane ring closure is evidently not one of them. In this instance it is suggested that the 2,2-dimethyl group functions either to limit polymeric coupling of the dihalide by steric hindrance or to preclude olefin formation as there are no hydrogen atoms α to the halogen.

Method C was the interaction of ethynylenemagnesium bromide (BrMgC≡CMgBr) with 2 moles of the appropriate cyclic ketone. Using cyclopentanone, cyclohexanone, and cycloheptanone, this reaction has been investigated previously (9, 10, 11, 12); we have used cyclooctanone also. The 1,1′-ethynylenedicycloalkanol thus obtained is hydrogenated in good yield to give the 1,1′-ethylenedicycloalkanol. It is possible to arrest the hydrogenation of the acetylenic diol in each case to give the olefinic derivative, but complete hydrogenation may be ensured by using either platinum or palladium catalysts in preference to nickel or by performing the hydrogenation over nickel at high pressures. The use of high temperatures in the hydrogenation must be avoided because the tertiary diols are susceptible to dehydration.

Method D, which also involved acetylenic intermediates, was confined to those diols having four methylene groups between the rings. By oxidation of 1-ethynylcycloalkanols, coupling of two molecules to give a diacetylene derivative results (13, 14, 15). This may be hydrogenated to a 1,1′-tetramethylenecycloalkanol. Both steps are practically quantitative.

All of the polymethylene diols were obtained as crystalline solids. One of the diols with a branched connecting chain, the symmetrical one, was also solid, but its unsymmetrical isomer was liquid. Many tenaciously retained sticky impurities, which were best removed by chromatography, and from the nature of the preparative methods adopted, one may infer that these impurities were polymeric. Attempts to prepare crystalline derivatives were unsuccessful, for the customary reagents for alcohol characterization are acidic and need heating. Under such conditions, dehydration of the diol results.

A detailed study of dehydration of ethylene and trimethylene diols of this series is still in progress. Members with four or more carbon atoms between the rings were found to give the expected olefinic dehydration products, and it may be assumed that they are of the alkylcycloalkene type rather than the less stable alkylidenecycloalkane type. It has been reported (4) that the product of dehydration of 1,1′-ethylenedicyclopentanol is also of this nature, although in this compound the presence of an α,δ-diol system might be expected to give a product with a butadienoid system, namely dicyclopentylidene-ethane. Previous studies also indicate that the dehydration of such an α,δ-diol might give a cyclic ether rather than a diolefin; for example, Henry (16) obtained 2,2,5,5-tetramethyltetrahydrofuran from 2,5-dimethylhexane-2,5-diol and Reppe (17) reported the conversion of 1,1′-ethylenedicyclohexanol to 7-oxaspiro-(5,1,5,2)-pentadecane. The quantitative microhydrogenation data on our dehydration products from both 1,1′-

ethylenedicyclohexanol and 1,1′-ethylenedicyclopentanol indicate that a mixture of diolefin and epoxide was obtained.

EXPERIMENTAL

All melting points, except where otherwise noted, were determined by the capillary-tube method on a thermometer calibrated against an Anschütz set with a National Bureau of Standards certificate. Melting points and other temperatures are recorded as degrees centigrade.

1,1′-Octamethylenedicyclohexanol (Method A, cf. ref. 4) and its Dehydration

Pentamethylenedimagnesium bromide and dimethyl sebacate were condensed by the known procedure (4) but benzene was added to the reaction mixture and it was worked up with ammonium chloride to minimize dehydration loss. The crude product was sticky and melted between 60 and 80°. It was adsorbed from benzene on alumina and eluted successively with benzene and diethyl ether. Crystals were deposited by evaporation of each eluate and these were united and crystallized once from heptane, m.p. 87.5–88°. Further elution of the column with ethyl acetate gave a viscous oil which was not further investigated.

The crystalline diol (7.0 g, 0.025 mole) was heated to 150° for 4 hours in the presence of iodine (10 mg). A further portion of iodine (5 mg) was then added and heating continued for 1 hour at 170°. The product, an oil, was taken up in ether and shaken with sodium thiosulphate solution. After drying, the solvent was removed and the residual oil distilled, yield 4.1 g, 67%, b.p. 157–161°/0.4 mm, n_D^{25}, 1.4911, m.p. (thermometer immersed) 5°. Other diols listed in Table I were dehydrated similarly.

1,1′-Ethylenedicyclooctanol (Method C)

Interaction of cyclooctanone and ethynylenemagnesium bromide (the Iotsitch reagent) (19) was achieved essentially by the method described by Pinkney and Marvel (11) for other ketones. Using ammonium chloride as described above for decomposition of the magnesium complex, 1,1′-ethynylenedicyclooctanol (1,4-dihydroxy-1,1,4,4-bisheptamethylene-2-butyne) was isolated in ether and finally obtained as a solid, m.p. 115°. Found: C, 77.8; H, 10.8, hydrogenation equivalent 132. Calc. for $C_{18}H_{30}O_2$: C, 77.8; H, 10.8%, hydrogenation equivalent 139.

By hydrogenation of the acetylenic diol in ethyl acetate as previously described, 1,1′-ethylenedicyclooctanol was obtained in nearly quantitative yield, m.p. 123–124°.

1,1′-Tetramethylenedicycloheptanol (Method D)

Ethynylation of cycloheptanone was performed in a manner analogous to the recorded ethynylation of cyclohexanone (20, 21). Oxidative coupling of this alcohol to yield the diacetylene derivative was accomplished by copper-catalyzed autoxidation in an experiment similar to that performed by Zal'kind and Aizikovich (13) on its lower homologue. 1-Ethynylcycloheptanol (70 g, 0.5 mole) in ethanol (75 ml) was added during 2 hours to a vigorously stirred solution of ammonium chloride (36 g), cuprous chloride (11.5 g), and hydrochloric acid (10 *N*, 2.5 ml) in water (100 ml) at 50° while a slow stream of oxygen bubbled through. The solution was stirred with oxygen passed in for 4 hours more, and then 250 ml of a saturated aqueous solution of ammonium chloride was added. Next day the solid product was collected by filtration and washed with ammonium chloride solution. It was then washed with hydrochloric acid (2 *N*) until the washings

For personal use only.

were no longer colored. The crude product (70 g, an almost quantitative yield) melted at 164–166°. This was raised to 165–166° by one crystallization from ethanol.

This diacetylenic diol (2.5 g, 0.01 mole) was hydrogenated in ethyl acetate suspension (50 ml) over palladized calcium carbonate at ambient temperature and 32.5 p.s.i. Uptake was complete in 3 hours and the filtered solution deposited crystals of 1,1′-tetramethylenedicycloheptanol (2.5 g, quantitative yield, m.p. 80–84°). This product was stable to aqueous potassium permanganate and was purified by one crystallization from a mixture of petroleum ether and benzene, in which it is very soluble (m.p. 85–86°).

Diethyl 2,2-Dimethylglutarate

In our hands, the previously published procedures (e.g. ref. 22) for conversion of 2,2-dimethyl-4-cyanobutyraldehyde to 2,2-dimethylglutaric acid gave 55 to 60% yields of a sticky product melting at 55–60°. Such procedures employ nitric acid alone or mixed with concentrated sulphuric acid as the reagent for simultaneous hydrolysis and oxidation of the starting material and it is possible that side reactions of polymerization or further oxidation can take place. Much loss of material occurred during purification.

The method adopted resembled that employed by Bruson and Riener (23) for conversion of 2,2-diethyl-4-cyanobutyraldehyde to 2,2-diethylglutaric acid. 2,2-Dimethyl-4-cyanobutyraldehyde (24) was used as soon as possible after it was prepared, because it is unexpectedly susceptible to autoxidation and on one occasion an explosion occurred when a sample that had been kept for some months without precautions against peroxide formation was distilled. The cyanoaldehyde (60 g, 0.5 mole) was boiled with sodium hydroxide (25 g, 0.63 mole) in water (250 ml) until a homogeneous solution was obtained ($\frac{1}{2}$ hour). After cooling, a further 25-g portion of sodium hydroxide and a further 250 ml of water were added. Potassium permanganate (114 g, 0.7 mole) was ground to a slurry with water (1 liter) and added to the cooled, stirred solution at such a rate that the temperature was 35–40°. Following a further $\frac{1}{2}$ hour of stirring, sulphur dioxide was passed until all the manganese dioxide was reduced. The 2,2-dimethylglutaric acid was isolated by ether extraction of the solution (66 g, 86%, m.p. 74–76°). By recrystallizing from a mixture of benzene and petroleum ether the melting point was raised to 83–84°, but the bulk of the product was esterified without purification, yielding diethyl 2,2-dimethylglutarate, b.p. 147/46 mm, $n_D^{22.5}$, 1.4262. (Found: saponification equivalent, 107. Calc. for $C_{11}H_{20}O_4$: 108).

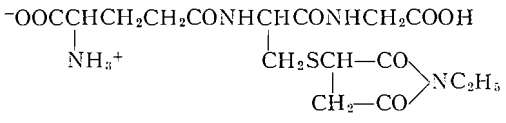
ADDUCTS FROM THE REACTION OF N-ETHYLMALEIMIDE WITH L-CYSTEINE AND WITH GLUTATHIONE



C. C. LEE AND E. R. SAMUELS

Since the first report of a quantitative reaction between thiols and N-ethylmaleimide (NEM) (1), a number of workers have described the use of NEM as a reagent for the assay of the sulphydryl group (2–6). However, it was only recently that the product from the reaction of L-cysteine and NEM was isolated and characterized as S-(N-ethylsuccinimido)-L-cysteine (I) (7). This note reports an independent isolation of I as well

(I)

as the preparation of S-(N-ethylsuccinimido)-glutathione (II), the adduct from the reaction of NEM with glutathione. Adduct II has not been recorded in any earlier publication.

(II)

The present work was undertaken as part of a project involving the determination of relative amounts of sulphhydryl and disulphide groups in certain proteins in which S^{35} has been incorporated. A suitable carrier for the reaction product between NEM and thiols was sought so that isotope dilution studies may be carried out. With this aim in mind, the behaviors of I and II on acid hydrolysis were studied. Somewhat surprisingly, it was found that after treatment for 18 hours in refluxing 6 *N* hydrochloric acid, I was recovered without change. The products from the hydrolysis of II were identified by paper chromatography as glycine, glutamic acid, and adduct I, exactly as expected for hydrolysis of the peptide bonds with I remaining unaffected. It was also noted that paper chromatographic separation of I from II, cysteine, and cystine can be easily accomplished. These observations indicate that it is likely feasible to use I as a

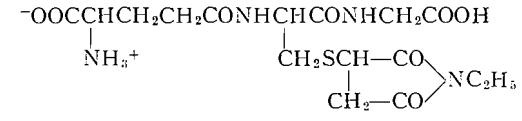
ADDUCTS FROM THE REACTION OF N-ETHYLMALEIMIDE WITH L-CYSTEINE AND WITH GLUTATHIONE



C. C. LEE AND E. R. SAMUELS

Since the first report of a quantitative reaction between thiols and N-ethylmaleimide (NEM) (1), a number of workers have described the use of NEM as a reagent for the assay of the sulphydryl group (2–6). However, it was only recently that the product from the reaction of L-cysteine and NEM was isolated and characterized as S-(N-ethylsuccinimido)-L-cysteine (I) (7). This note reports an independent isolation of I as well

(I)

as the preparation of S-(N-ethylsuccinimido)-glutathione (II), the adduct from the reaction of NEM with glutathione. Adduct II has not been recorded in any earlier publication.

(II)

The present work was undertaken as part of a project involving the determination of relative amounts of sulphhydryl and disulphide groups in certain proteins in which S^{35} has been incorporated. A suitable carrier for the reaction product between NEM and thiols was sought so that isotope dilution studies may be carried out. With this aim in mind, the behaviors of I and II on acid hydrolysis were studied. Somewhat surprisingly, it was found that after treatment for 18 hours in refluxing 6 *N* hydrochloric acid, I was recovered without change. The products from the hydrolysis of II were identified by paper chromatography as glycine, glutamic acid, and adduct I, exactly as expected for hydrolysis of the peptide bonds with I remaining unaffected. It was also noted that paper chromatographic separation of I from II, cysteine, and cystine can be easily accomplished. These observations indicate that it is likely feasible to use I as a

carrier in isotope dilution studies. If a protein containing S^{35} were allowed to react with NEM and then hydrolyzed in 6 *N* hydrochloric acid, any sulphydryl groups originally present in cysteine residues should give rise to S^{35}-labeled adduct I, which may be isolated with the aid of ordinary I as carrier.

EXPERIMENTAL

S-(N-Ethylsuccinimido)-L-cysteine (I)

Equal volumes of 0.1 *M* solutions of NEM and L-cysteine hydrochloride were mixed and allowed to stand at room temperature overnight. The resulting solution was concentrated under reduced pressure at 50–60° C. Ethanol was then added to precipitate the product. The latter was dissolved in distilled water, passed through a column packed with the anion exchanger, Dowex 1-x8, eluted with 0.5 *N* acetic acid, concentrated again under reduced pressure, and then crystallized with the addition of ethanol. The yield of purified S-(N-ethylsuccinimido)-L-cysteine, m.p. 194–195° C, decomp., was 85%. It gave a positive ninhydrin reaction and a negative nitroprusside test, which indicated the absence of the sulphydryl group.

Anal. Calc. for $C_9H_{14}O_4N_2S$: C, 43.89; H, 5.73; N, 11.38; S, 13.02. Found: C, 43.89; H, 5.78; N, 11.05; S, 12.90. This procedure for the preparation of I was essentially similar to that reported by Smyth and co-workers (7). However, it was noted that although, when the reactants were mixed, the pH was 1.8, it was not necessary to add sodium hydroxide to the reaction mixture as was done by Smyth *et al.* (7). It was found that inclusion of sodium hydroxide in the reaction mixture often gave a product containing detectable amounts of ash. The elimination of the base and final purification through the Dowex 1-x8 column proved to be quite satisfactory.

S-(N-Ethylsuccinimido)-glutathione (II)

Equal volumes of 0.1 *M* solutions of NEM and glutathione (reduced) were mixed and allowed to stand overnight. The resulting solution was worked up in the same way as in the isolation and purification of I. The product, S-(N-ethylsuccinimido)-glutathione, m.p. 204–206° C, decomp., was obtained in 90% yield. It also gave a positive reaction with ninhydrin and a negative test with nitroprusside.

Anal. Calc. for $C_{16}H_{24}O_8N_4S$: C, 44.44; H, 5.59; N, 12.96; S, 7.42. Found: C, 44.14; H, 5.59; N, 12.88; S, 7.13.

Acid Hydrolysis

One gram of I or II in 20 ml 6 *N* hydrochloric acid was refluxed for 18 hours. The resulting solution was concentrated to a small volume under reduced pressure, passed through a Dowex 1-x8 column, eluted with 0.5 *N* acetic acid, concentrated again and the product crystallized with the addition of acetone. After this treatment, unchanged I was almost quantitatively recovered. That I was the same before and after hydrolysis was established by mixed melting point; unchanged analyses for C, H, N, S; identical infrared absorption spectrum; and behavior in paper chromatography. Ascending paper chromatography on Whatman No. 1 paper with *t*-butanol – water – formic acid (69.5:29.5:1) as solvent was run for 16 hours and developed with 0.1% ninhydrin in acetone. The same spot was obtained for I before and after hydrolysis. On the other hand, paper chromatographic analysis of the hydrolyzate of II gave three spots. By comparison with behaviors of known compounds, these spots were identified as glycine, glutamic acid, and adduct I.

FINE STRUCTURE IN THE PROTON MAGNETIC RESONANCE SPECTRUM OF 6–6 NYLON

D. J. SHAW[1] AND B. A. DUNELL

Correlation of the nuclear magnetic resonance (n.m.r.) spectra of polymers with their physical properties and mechanical behavior has received considerable attention recently and has been reviewed by Slichter (1, 2) and by Sauer and Woodward (3). The existence of a narrow component of the n.m.r. spectrum superimposed on the broad line above certain temperatures has been associated with extensive molecular motion in the amorphous phase of such polymers as branched and straight-chain polyethylene (4–6) and isotactic polypropylene (7, 8). One might anticipate that a narrow component would also be observed in the n.m.r. spectrum of nylon in the vicinity of room temperature, corresponding to the onset in the amorphous part of the nylon of molecular motion which gives rise to energy dissipation and dispersion of elastic modulus in mechanical experiments (3, 9, 10). Although Slichter (11) had already reported the variation with temperature of line width and second moment of nylon 6–6 and given no indication of the existence of fine structure in the spectrum at any temperature, it was decided to reinvestigate this substance. Woodward, Glick, Gupta, and Sauer (12) have published detailed results of the change with temperature of the n.m.r. line width and second moment of a number of polyamides, both thoroughly dried and containing various H_2O and D_2O contents. They do not, however, mention the existence of any fine structure in the spectra. Illers and Kosfeld (13) have recently obtained evidence of a narrow component in the n.m.r. spectrum of a completely dry sample of nylon 6–12.

EXPERIMENTS AND RESULTS

The nylon used in this work was a multifilament commercial yarn containing no delustrant. It was extracted with boiling ether for 8 hours and dried in a vacuum desiccator over phosphorus pentoxide for 24 hours before any experiments were done on it. Initially, this nylon was sealed, without further treatment, into a sample tube under dry nitrogen and its n.m.r. spectrum taken with a broad-line spectrometer of the marginal oscillator type (14), operating at 28 Mc/sec, and a 6-in. Varian electromagnet.

FINE STRUCTURE IN THE PROTON MAGNETIC RESONANCE SPECTRUM OF 6–6 NYLON

D. J. SHAW[1] AND B. A. DUNELL

Correlation of the nuclear magnetic resonance (n.m.r.) spectra of polymers with their physical properties and mechanical behavior has received considerable attention recently and has been reviewed by Slichter (1, 2) and by Sauer and Woodward (3). The existence of a narrow component of the n.m.r. spectrum superimposed on the broad line above certain temperatures has been associated with extensive molecular motion in the amorphous phase of such polymers as branched and straight-chain polyethylene (4–6) and isotactic polypropylene (7, 8). One might anticipate that a narrow component would also be observed in the n.m.r. spectrum of nylon in the vicinity of room temperature, corresponding to the onset in the amorphous part of the nylon of molecular motion which gives rise to energy dissipation and dispersion of elastic modulus in mechanical experiments (3, 9, 10). Although Slichter (11) had already reported the variation with temperature of line width and second moment of nylon 6–6 and given no indication of the existence of fine structure in the spectrum at any temperature, it was decided to reinvestigate this substance. Woodward, Glick, Gupta, and Sauer (12) have published detailed results of the change with temperature of the n.m.r. line width and second moment of a number of polyamides, both thoroughly dried and containing various H_2O and D_2O contents. They do not, however, mention the existence of any fine structure in the spectra. Illers and Kosfeld (13) have recently obtained evidence of a narrow component in the n.m.r. spectrum of a completely dry sample of nylon 6–12.

EXPERIMENTS AND RESULTS

The nylon used in this work was a multifilament commercial yarn containing no delustrant. It was extracted with boiling ether for 8 hours and dried in a vacuum desiccator over phosphorus pentoxide for 24 hours before any experiments were done on it. Initially, this nylon was sealed, without further treatment, into a sample tube under dry nitrogen and its n.m.r. spectrum taken with a broad-line spectrometer of the marginal oscillator type (14), operating at 28 Mc/sec, and a 6-in. Varian electromagnet.

[1]*Present address: Research Department, Unilever Ltd., Port Sunlight, Cheshire, England.*

With this spectrometer the line widths obtained in the range from liquid nitrogen temperature to 400° K were substantially the same as those reported by Slichter (11), and no evidence of fine structure was obtained. The comparison of line widths is shown in Fig. 1. The widths that we obtained at the three highest temperatures are too great because of instrumental difficulties.

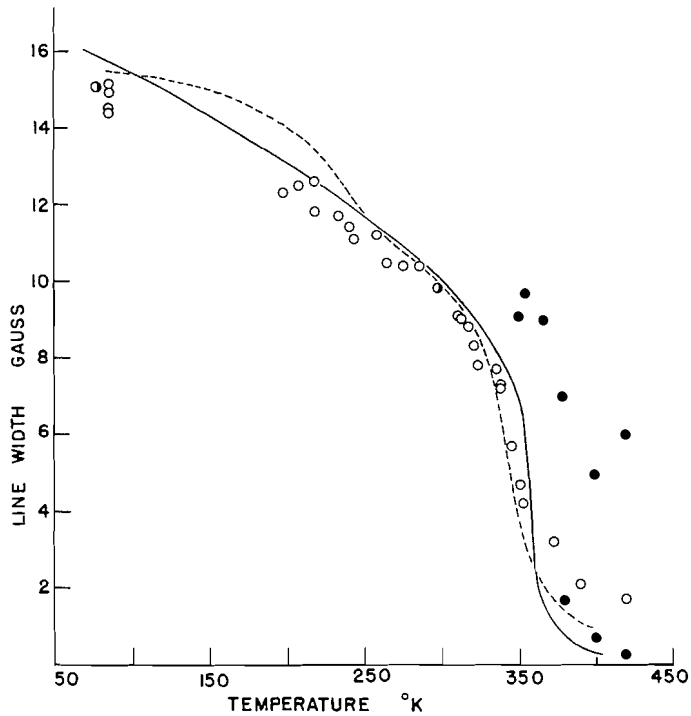

FIG. 1. Nuclear magnetic resonance line width of nylon 6–6 as a function of temperature. ○ This work, using sample dried at room temperature. ● This work, using exhaustively dried sample. ◑ Coincidence of open and filled points. ——— Results of Slichter (11). – – – Results of Glick *et al.* (12).

Since the α' dispersion region (found near 350° K for dry nylon 6–6) moves to lower temperature as nylon sorbs water, and is centered near room temperature when the relative humidity approaches 100% (10); evidence of fine structure in the n.m.r. spectrum of nylon was sought at room temperature using a sample that was in equilibrium with a number of different partial pressures of water vapor. An intense narrow component was obtained under these conditions, but it disappeared when the nylon was soaked in 99% D_2O for several hours, dried in a vacuum system, and exposed to D_2O vapor in the sealed sample tube. The marginal oscillator spectrometer gave the line width of the deuterated and dried nylon sample as 10.2 gauss and of the deuterated sample exposed to saturated D_2O vapor as 9.7 gauss, both at 295° K. The corresponding second moments were 16.3 and 14.4 gauss^2.

A second group of experiments was done using a Varian V-4250 combination high-resolution and broad-line spectrometer operating at 40 Mc/sec. When we used this apparatus we found that samples which were dried under vacuum at room temperature showed a narrow component which may be attributed to residual sorbed moisture in the sample. Illers has found that complete drying of the nylon can be achieved only by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

heating at 100° C or more under vacuum (15). When we heated under these conditions for 6 hours, this narrow component observed at room temperature on the Varian spectrometer disappeared. The exhaustively dried sample was then run in the Varian spectrometer at temperatures up to 420° K. The sample was heated in a small Dewar vessel which fitted inside the spectrometer insert-tube by a stream of heated air, and the temperature measured by a thermocouple (16). The rather small sample and large insert-tube together with high sample temperature give rather poor signal to noise ratio. Nevertheless the appearance and growth in intensity with increasing temperature of a narrow component in the n.m.r. spectrum of exhaustively dried nylon can be distinguished in the traces reproduced in Fig. 2. Because the resolving of each spectrum

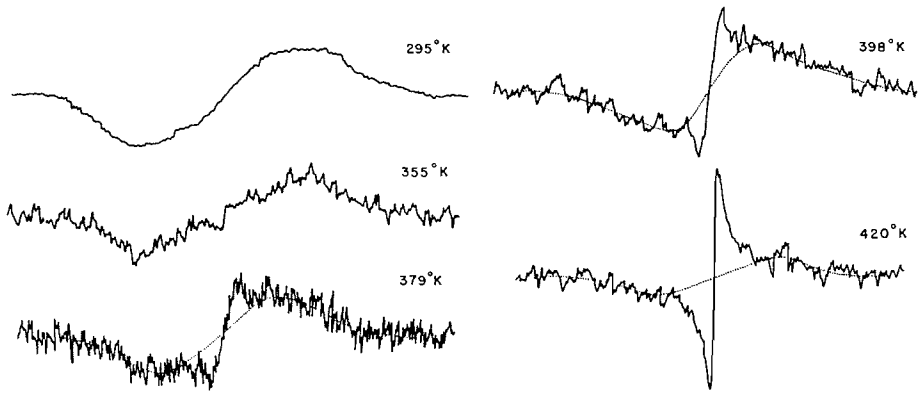

FIG. 2. Nuclear magnetic resonance spectra of exhaustively dried nylon 6–6 at various temperatures. The dotted lines show the assumed resolution into broad and narrow components.

into a broad and narrow component has been done arbitrarily, the width of the resolved broad line is, as Illers (13) points out in his corresponding case, subject to large error. It is estimated that the error may be as great as 40%. Line widths of the broad and narrow components are plotted in Fig. 1.

The deuterated sample was also re-examined on the Varian machine at room temperature. Dry, it gave a line width of 9.8 gauss and a second moment of 14.2 gauss^2; exposed to saturated vapor of D_2O, it gave 9.5 gauss and 13.0 gauss^2. These values are in satisfactory agreement with those obtained from the other spectrometer. A narrow component of very small intensity was observed with the deuterated system after the sample had been exposed to D_2O vapor for several days. This is attributed to traces of proton exchanging with sorbed heavy water.

The density of the nylon was measured in a density gradient tube (17) and used to obtain the percentage crystallinity from the correlation of Starkweather and Moynihan (18). The sample was found to be 35% crystalline.

DISCUSSION

In the exhaustively dried nylon the appearance of a narrow component near 380° K is attributed to the onset of very extensive molecular motion in part of the amorphous region of the substance. Such motion is considered to be the cause of the α' energy loss and dispersion mechanism (9, 10) which occurs at about 350° K at sonic frequencies in dry samples. Exhaustive drying would be expected to raise the temperature of the maximum in mechanical loss by several degrees (19), bringing it closer to 380° K. (An activation energy of 70 kcal/mole for the α' mechanism would correspond to a 20°

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

temperature difference between a correlation frequency of 10^5 for the n.m.r. experiment and a frequency of 650 c.p.s. (10) for the mechanical experiment.) As the temperature rises from 380° to 420° K the intensity of the narrow component increases, and its width decreases from 1.7 gauss (with modulation amplitude 1 gauss) at 379° K to approximately 0.3 gauss (modulation 0.12 gauss) at 420° K. The narrow-component line width indicated that although motion of the molecular chain segments becomes very extensive it is not liquid-like at least by 420° K. Further, it does not appear that even at this temperature the whole of the amorphous region is in the vigorous motion that produces the narrow line. Thus, although the percentage of amorphous component was found to be some 65%, the area under the narrow peak is only 20% of the area under both peaks at 420° K.

The width of the broad component at 420° K is somewhat less than half of the width at liquid nitrogen temperature, and the second moment of 6 gauss^2 is one quarter of the value at 77° K. Slichter (11) has calculated that if the chain segments in crystalline nylon 6–6 all rotate freely, the second moment should be 8.5 gauss^2. Thus both line-width and second-moment reduction are consistent with an interpretation that the part of the nylon which is not in extensive motion at 420° K is involved in motion which, on the average, is slightly more extensive than rotation of chain segments about their long axes.

When there is present even the very small amount of water remaining in a nylon sample dried at room temperature, the temperature at which very extensive motion begins must be reduced considerably and the amount of amorphous phase involved in the motion must be increased to such an extent that the broad component is masked by the now much more intense narrow component and no fine structure is distinguishable in the spectrum. The width of the line is that corresponding to the narrow component.

Our observation that exposure of a deuterated nylon sample to saturated D_2O vapor did not significantly reduce the line width at room temperature is entirely at variance with the results reported by Woodward and his co-workers (12), who found it decreased to about 1 gauss under approximately these conditions (i.e., 7.8 wt.% D_2O sorption at 295° K). We observed the same line width, 9.5 ± 0.1 gauss, 1, 14, 15, and 28 days after exposure to D_2O vapor, using the Varian spectrometer; and, as mentioned earlier, this width agreed with that obtained from the other spectrometer using a different sample. The discrepancy would not seem, therefore, to be of diffusional, equilibrium, or instrumental origin. One must conclude that the difference of results arises from the fact that we have used a drawn-filament sample rather than "bulk polymer". In the drawn filament it is possible that the chain segments in the amorphous regions are restricted in mobility to such an extent, because of great crystallite to crystallite distance in the direction of stretching, that only the first traces of water can be effective in increasing molecular motion at given temperature.

ACKNOWLEDGMENTS

We wish to thank the Defence Research Board for the financial assistance under Grant 7570-07 which made this work possible. Correspondence and discussion with Dr. K. H. Illers, Technische Hochschule, Aachen, was most helpful. We are indebted to Dr. R. D. Bennett of the du Pont Company of Canada (1956) Ltd. for supplying the nylon samples.

THE PROTON MAGNETIC RESONANCE SPECTRUM AND THE CHARGE DISTRIBUTION OF THE PYRIDINIUM ION*

I. C. SMITH† AND W. G. SCHNEIDER

The protonation of pyridine by trifluoracetic acid has been examined by proton resonance techniques. In the presence of excess acid it has been found possible to observe the proton spectrum characteristic of the pyridinium ion. Figure 1 shows the spectrum of pyridine (in a 5 mole% cyclohexane solution) as well as those of trifluoracetic acid solutions containing 20, 10, and 5 mole% of pyridine respectively. A small amount ($\sim$ 3 mole%) of CH_2Cl_2 was added to each solution to serve as an internal reference signal. Modulation side bands of the reference at 140 and 240 cycles/sec are indicated on the individual traces. The assignment of the proton signals is based on the previously reported analysis of the pyridine spectrum (1). Figure 2 shows a more extended spectrum of the 5 mole% pyridine solution in trifluoracetic acid taken under conditions of lower resolution. It shows, in addition to the signal of the carboxyl group of the trifluoracetic acid and that of the α, β, and γ protons, a triplet signal characteristic of a proton bonded to a nitrogen atom. This confirms the presence of the pyridinium ion. The triplet splitting arises from spin coupling with the N^{14} nucleus having spin $S = 1$. The spin-coupling constant has the value 70 cycles/sec.

The position of the N—H proton signal, to the low-field side of the acid carboxyl group, is unusual for protons bonded to nitrogen. In neutral molecules this ordinarily appears at a much higher field. It is evident from Fig. 1 that there is also a low-field displacement, though smaller, for the signals of the protons of the pyridine ring when the ion is formed. Table I shows the actual chemical shifts (relative to CH_2Cl_2 internal reference) for the individual protons in pyridine and in the pyridinium ion. These shifts are necessarily approximate since an exact analysis of the pyridinium ion spectrum, which has broadened

lines, is not possible. As shown by the differences listed in the last column, the largest low-field displacement occurs for the γ-proton, that for the β-protons is almost as large, while the corresponding displacement for α-protons is much smaller. These low-field displacements may be attributed to the decrease in electron charge density at the individual carbon nuclei as a result of adding the positively charged proton at the nitrogen atom. Assuming a simple proportionality between the proton resonance displacement

The local charges shown (in units of the electronic charge) are not the absolute charge densities, but represent the amount, $\Delta\rho$, by which the local charge density of pyridine is altered when the pyridinium ion is formed. In this process one unit positive charge is added to the pyridine nucleus resulting in a decrease in the local charge density, i.e. $\Delta\rho$ is negative. Employing the simple relation, $\Delta\delta = k\Delta\rho$, where $\Delta\delta$ is the observed change in the proton shift (in p.p.m.), the constant k was found to have the value 9.5 p.p.m. per electron. For the present purpose the low-field displacement of the N—H signal, resulting from the charge deficiency at the N atom, was taken to be 336 cycles/sec. This is the difference in chemical shift between the N—H group protons in the pyridinium ion and in pyrrole. The N—H shift in the latter is −96 cycles/sec relative to CH_2Cl_2 which, if pyrrole were an aromatic system, must be corrected for the "ring current effect" (2). This correction is approximately −84 cycles/sec, giving a total shift of −180 cycles/sec. On combining this with the N—H shift in the pyridinium ion, −516 cycles/sec, results in a net low-field displacement of 336 cycles/sec. The results, which are necessarily approximate, show that roughly 60% of the unit charge deficiency in the pyridinium ion is located at the N atom, the remainder being distributed on the carbon atoms in the ring as indicated.

Finally the relative line width of the resonance spectra under the experimental conditions employed are of some interest. In the spectrum of pyridine itself (Fig. 1(*a*)) the signals of the α-protons are significantly broader than those of β and γ protons. This broadening can be attributed to a shorter T_1 relaxation time of the α-protons caused by nuclear quadrupole relaxation effects of the N^{14} nucleus. Such effects are frequently encountered in nitrogen-containing compounds when a proton is directly bonded to the N atom, whereas in this instance the relaxation is evidently transmitted to protons two bonds removed. In the presence of trifluoracetic acid (Fig. 1(*b*), (*c*), and (*d*)), the α-proton signals remain broad, and in addition the β- and γ-protons are broadened. This additional broadening is no doubt due to proton exchange between the acid and the pyridine nitrogen atom. The fact that the triplet structure of the N—H proton is observable in the 5 mole% solution indicates that under these conditions the exchange rate must be considerably less than 400 times per second. With lower acid concentrations the proton exchange rate is much greater than this and the triplet N—H resonance cannot be observed.

Hamer *et al.* (5), for the pure compounds, are shown in Fig. 1. These results are somewhat discrepant. Recently the present authors have repeated their previous measurements with an improved technique in an attempt to clarify the position.

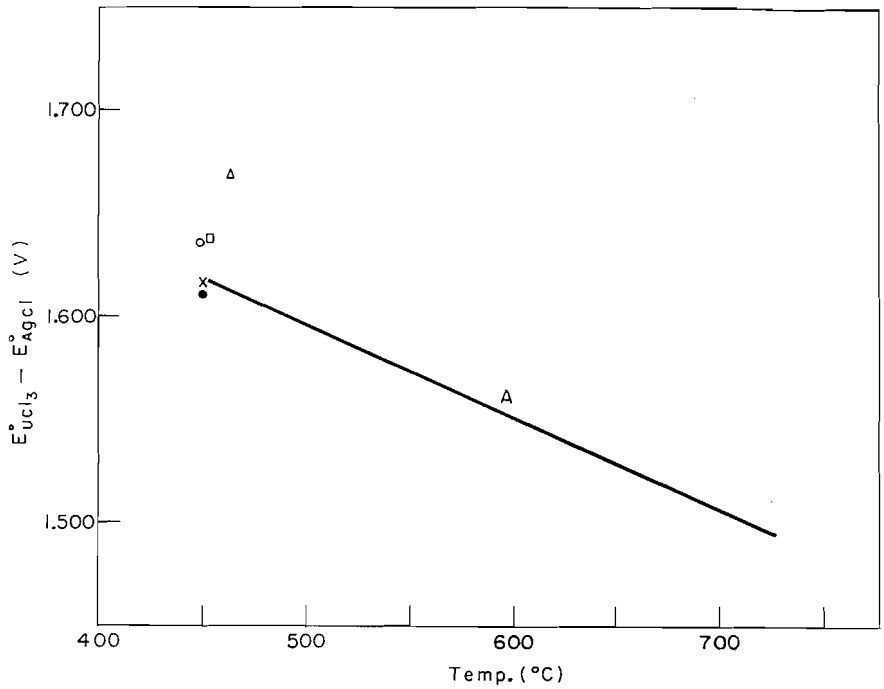

FIG. 1. $E^\circ_{(UCl_3)} - E^\circ_{(AgCl)}$ vs. temperature. (A) Electromotive force data of Hamer *et al.* (5). Experimental $E^\circ_{(UCl_3)} - E^\circ_{(AgCl)}$ values: △ Inman, Hills, Young, and Bockris (4). ● Hill, Perano, and Osteryoung (2). × Gruen and Osteryoung (1). ○ Flengas (3). □ Present work.

The experiments were performed at 453° C in a helium atmosphere. The LiCl–KCl eutectic solvent was purified by a modification (6) of the method described previously (4). The reference electrode was the same as that used before (7). The various concentrations of UCl_3 in LiCl–KCl were prepared by anodic dissolution of U wires into several similar glass diaphragm compartments to that used for the reference electrode. Both these compartments and the reference electrode compartment were immersed in a bath of purified LiCl–KCl eutectic.

The concentrations of UCl_3 in the separate compartments were determined by the dichromate method (8). A standard sample containing 1.025 mg of U was determined as 0.998 mg by this analytical method. The anodic dissolution process was ~100% efficient on the basis of $n = 3$, i.e., when 7.42 mg of uranium were expected in the compartment after the anodic dissolution, 7.60 mg were found.

The electromotive force results are shown in Table I.

A line of theoretical slope for $n = 3$ through these points gives $E^\circ_{(UCl_3)} - E^\circ_{(AgCl)} = 1.638$ v. This value is also shown in Fig. 1. (The previous value (4) at 463° C was 1.668 v.) The corresponding f_{UCl_3} values (standard state pure UCl_3 at the same temperature) are 3.8×10^{-1} and 0.8×10^{-1} respectively.

TABLE I

Electromotive force of the cell U^{-}/UCl_3, LiCl–KCl ¦ AgCl, LiCl–KCl/Ag^{+} at 453° C

e.m.f. (v)	N_{UCl_3}	$\text{Log}_{10}N_{UCl_3} - 3\ \log_{10}N_{AgCl}$	N_{AgCl}
1.472	$1.113.10^{-3}$	3.462	$7.27.10^{-3}$
1.450	$2.880.10^{-3}$	3.875	
1.431	$4.894.10^{-3}$	4.106	
1.416	$1.048.10^{-2}$	4.436	

The present result is seen to be in good agreement with the value obtained by Flengas (3) by extrapolation of his results obtained at a higher temperature. On the basis of the ionic sizes of Pb^{2+} and U^{3+} (9) the implied degree of complexing seems reasonable (10). The results of Gruen and Osteryoung (1) and Hill *et al.* (2), indicate positive deviations from ideality on the basis of the data of Hamer *et al.* (5).

OLIGOSACCHARIDES FROM THE SAP OF SUGAR MAPLE (ACER SACCHARUM MARSH)[1]

S. HAQ[2] AND G. A. ADAMS

ABSTRACT

From the sap of the sugar maple (*Acer saccharum* Marsh) two trisaccharides have been isolated by column and paper chromatography. One was identified as *O*-β-D-fructofuranosyl-(2 → 6)α-D-glucopyranosyl(1 → 2)β-D-fructofuranoside (6^G-fructosylsucrose), the other was tentatively established as either 6^F-fructosylsucrose or 1^F-fructosylsucrose. These trisaccharides are not related in either composition or structure to the polysaccharides present in the sap and wood.

Maple sap is known to contain mainly sucrose, the percentage of which varies from season to season and from tree to tree. It was shown by Bois and Nadeau (1) that maple sap contains two enzymes, namely, "sucrogen-amylase" and "cellobiogen-amylase" which transform starch into sucrose and cellobiose respectively. The claim of these workers was later refuted by Meeuse (2), who found that maple sap contains an enzyme which produces maltose from starch and not sucrose and cellobiose. Porter *et al.* (3) have demonstrated the presence of five oligosaccharides in addition to sucrose in maple sap. The sugars found on complete hydrolysis were glucose, fructose, and galactose, and the presence of raffinose and a glucosylsucrose was also indicated. Smith and Zavarin (4) have investigated the mono- and oligo-saccharides of the heartwood, sapwood, and bark of nine conifers and reported the presence of several monosaccharides, raffinose, stachyose, and two unidentified oligosaccharides. In the foregoing investigations, identification of the sugars was based on chromatographic evidence and no information on the structure of the oligosaccharides was provided. The only proven structure for an oligosaccharide containing D-glucose and D-fructose from wood is that of 1^F-fructosylsucrose isolated from aspen wood by Pridham (5). In the course of an investigation in this laboratory on the polysaccharides of maple sap (6), it was observed on paper chromatograms that there were some oligosaccharides in the sap which had R_f values lower than that of sucrose. It was thought worth while to investigate the structure of these oligosaccharides to shed some light on their relationship to the polysaccharides of the sap and wood. The present paper describes the isolation of two trisaccharides and characterization of the major one.

The sap was collected from a commercial stand of sugar maples in the first week of April 1960. Collection of the sap early in the season and fresh from the tree precluded significant bacterial contamination (7). The sap was immediately concentrated at low

temperature to a small volume and the inorganic material, and some sucrose, were removed by precipitation with ethanol. After removal of most of the sucrose by crystallization, the remaining syrup was fractionated on a charcoal–celite column. The individual sugars were eluted by stepwise increase in the concentration of ethanol (8). This procedure proved more advantageous than the gradient elution technique (9) because of the large amount of sucrose present in the syrup. It was found that 5% ethanol eluted sucrose completely from the column leaving the trisaccharides. Seven and one-half per cent ethanol was needed to elute one trisaccharide (component I, minor) and 10% and 20% ethanol were required for another trisaccharide (component II, major). The major trisaccharide proved to be neokestose, a name suggested by Gross, Blanchard, and Bell (10) for *O*-β-D-fructofuranosyl(2 → 6)α-D-glucopyranosyl(1 → 2)β-D-fructofuranoside which they isolated from sucrose solution which had been acted upon by yeast invertase. This trisaccharide has also been isolated from banana (11) as well as from sucrose solution acted upon by fructose-transferring enzymes of higher plants (*Beta vulgaris*) (12).

The proof of the structure of component II was based on the following evidence. The purity of the trisaccharide was established by paper chromatography and by paper electrophoresis. It had $[\alpha]_D$ +15° on the basis of dry syrup. It gave a positive Raybin (13) test with diazouracil, which is a test, essentially, though not exclusively, for derivatives of sucrose in which the fructose unit is unsubstituted (14). On the basis of its reaction with silver nitrate and orcinol – orthophosphoric acid spray reagents the trisaccharide was non-reducing and contained a ketose sugar. Complete hydrolysis with dilute acid gave D-fructose and D-glucose in the ratio of 2:1. On partial hydrolysis with dilute acetic acid it gave glucose, fructose, sucrose, and a reducing disaccharide, the latter moving on a paper chromatogram between sucrose and the original trisaccharide. This disaccharide is probably β-6-*O*-D-fructosyl-D-glucose (15, 16, 17), which would be produced if the glycosidic bond between glucose and fructose of the sucrose moiety in the trisaccharide were broken. On complete methylation the trisaccharide gave an undeca-*O*-methyl derivative. A portion of the methylated trisaccharide after methanolysis and examination by gas–liquid chromatography (18, 19) revealed the presence of tetra-*O*-methyl fructose (2 moles) and tri-*O*-methyl glucose (1 mole). Hydrolysis with dilute acid and separation of the methylated sugars by paper chromatography afforded 2 moles of tetra-*O*-methyl fructose and 1 mole of tri-*O*-methyl glucose. The tetra-*O*-methyl fructose and tri-*O*-methyl glucose were identified as 1,3,4,6-tetra-*O*-methyl-D-fructose and 2,3,4-tri-*O*-methyl-D-glucose by isolation of crystalline derivatives. The β-fructosylfuranoside linkages were established by the hydrolytic action of invertase (β-fructofuranosidase). The identity of the trisaccharide was established, therefore, as *O*-β-D-fructofuranosyl (2 → 6)α-D-glucopyranosyl(1 → 2)β-D-fructofuranoside (6^G-β-fructosylsucrose).

Component I (minor) was found to be a non-reducing trisaccharide composed of 2 moles of fructose and 1 mole of glucose. On partial hydrolysis it gave glucose, fructose, and sucrose. On methylation and hydrolysis the trisaccharide gave tetra-*O*-methyl glucose, tetra-*O*-methyl fructose, and a tri-*O*-methyl sugar on the basis of gas–liquid chromatographic evidence. The tri-*O*-methyl sugar, on the basis of its reaction on paper with orcinol – orthophosphoric acid spray reagent, was considered to be a tri-*O*-methyl fructose. Therefore, it seems likely that component I is a trisaccharide composed of sucrose and fructose in which the fructose unit is attached to the fructose moiety of the sucrose in the trisaccharide. The point of attachment could not be ascertained because of the lack of sufficient material but it is supposed that this trisaccharide is either 6^F-fructosylsucrose (20) or 1^F-fructosylsucrose (5, 21, 22, 23).

The possibility of component I being raffinose could easily be eliminated because of the absence of galactose in the hydrolyzate of the trisaccharide. The elution of component I before component II from the charcoal column suggested that component I was a kestose type sugar. This behavior has been previously observed by Gross, Blanchard, and Bell (10).

The present investigation has established the presence of 6^G-β-fructosylsucrose, which had not been reported previously as a constituent of maple sap. This trisaccharide may be one of the unidentified oligosaccharides containing glucose and fructose which were isolated from maple sap by Porter *et al.* (3). Raffinose has been reported as a constituent of the sapwood and inner bark of conifers (4), the xylem of aspen tissue (5), and possibly maple sap (3) but was not found in the present study. However, 1^F-β-fructosylsucrose, which has been identified as a component of aspen tissue (5), may be a component of maple sap, as indicated in the present study.

In general, the fructosylsucrose derivatives occur in plant storage tissues which have a high content of sucrose. Both 6^G-fructosylsucrose and 1^F-fructosylsucrose have been isolated from onion, leek, Italian rye grass, and oat grass (24). Since maple sap is a reservoir high in sucrose it is not unexpected that it should contain the same trisaccharide.

The oligosaccharides found in the maple sap undoubtedly have been formed from sucrose by transferase reactions. They bear no resemblance in either composition or structure to the polysaccharides found in the sap (6) and wood of the sugar maple (25, 26). These latter polysaccharides must have their origin from precursors unrelated to the sap oligosaccharides.

EXPERIMENTAL

The organic phase of the following solvent systems (v/v) was used for chromatography: A, ethyl acetate – pyridine – water (2.5:1:2.5); B, butan-1-ol – acetic acid – water (4:1:5); C, ethyl methyl ketone – water (2:1, water containing 2% ammonia).

Paper chromatography was done on Whatman No. 1 and No. 3 MM paper for qualitative and quantitative separations respectively. An ethanolic solution of *p*-anisidine hydrochloride (3%) (27) was used to detect reducing sugars; orcinol – orthophosphoric acid (28) was used for ketoses. All evaporations were done under reduced pressure at 34° C. Specific rotations were measured in water at 25° C unless otherwise stated.

Separation of the Sugars of Maple Sap

About 18 liters of maple sap, freshly collected in the first week of April 1960 from a commercial stand of sugar maples (*Acer saccharum* Marsh), was evaporated to a small volume (1 l.) and centrifuged to remove the suspended impurities. The clear supernatant liquid was poured into ethanol (4 l.) with constant stirring. The precipitate, which consisted mainly of inorganic matter, polysaccharides, and some sucrose, was removed by filtration. The filtrate on evaporation gave a syrup which was dissolved in 70% methanol (500 ml); on cooling of the solution most of the sucrose crystallized. The mother liquor on evaporation gave a thick syrup.

The syrup (13 g) was fractionated on a charcoal–celite (1:1) column (30 cm × 6.5 cm). Sucrose and monosaccharides (glucose and fructose) were eluted with 5% ethanol. Fractions (60 ml/hr each) were collected and from time to time were chromatographically examined to ensure that no trisaccharides were being eluted. When 8400 ml had been eluted all the sucrose had come off and the eluate up to 9900 ml contained no sugar. Then the column was washed successively with 7½% ethanol (3 l.) (fraction A), 10%

ethanol (2 l.) (fraction B), and 20% ethanol (2 l.) (fraction C). Evaporation of these eluates yielded the following products.

Fraction A. A syrup (47.5 mg) which contained traces of sucrose and a trisaccharide (component I) having $R_{sucrose}$ 0.65 in solvent A.

Fraction B. A syrup (106.0 mg) which consisted of component I and another trisaccharide (component II) R_{suc} 0.73 in solvent A.

Fraction C. A syrup (346.2 mg) which contained mainly component II and traces of very slow moving sugars which were not examined.

An additional quantity of syrup (12 g) was fractionated as above to obtain more sugars. The fractions from the two lots were further purified by paper chromatography in solvent A and chromatographically pure sugars, component I (53.5 mg) and component II (430 mg), were obtained.

Component II (Major)

The syrup ($[\alpha]_D$ +15° (*c*, 2.8)) could not be crystallized. About 50 mg of the syrup was hydrolyzed with 0.2 *N* H_2SO_4 for 4 hours, the products were separated on paper in solvent A, and the individual sugars were determined according to Nelson (29). The ratio of D-fructose to D-glucose was found to be 2:1.

Another portion of the sugar (3 mg) was hydrolyzed with 15% acetic acid (0.5 ml) for 10 minutes, 20 minutes, 30 minutes, and 40 minutes, and the hydrolyzates were examined by paper chromatogram in solvent B. The hydrolyzate for 10 minutes gave a spot of reducing disaccharide having R_{suc} 0.82 while the original trisaccharide had R_{suc} 0.64 in the same solvent. The other hydrolyzates did not show this disaccharide spot.

A solution of the trisaccharide (1%) was incubated with invertase (β-fructofuranosidase) for 3 hours at 35° C. Examination of the hydrolyzate by paper chromatography in solvent A showed complete conversion of the trisaccharide to glucose and fructose.

Methylation of Component II

The syrup (305.6 mg) was dissolved in water (3 ml) and 30% sodium hydroxide solution (2 ml) was added. The solution was stirred at room temperature and dimethyl sulphate (1 ml) was added dropwise. Following this procedure sodium hydroxide solution (8×2 ml) and dimethyl sulphate (8×1 ml) were added during 24 hours. Then the solution was heated at 60° for 1 hour to destroy any unreacted methyl sulphate. The partially methylated sugar was recovered by extraction with chloroform for 4 days. After removing the chloroform the partially methylated sugar was methylated three times with Purdie's reagent, whereby an undeca-*O*-methyl trisaccharide (252 mg) was obtained (Anal. OMe 49.33%; $C_{29}H_{54}O_{16}$ requires OMe 51.8%).

A portion of the methylated sugar (2 mg) was refluxed with 0.5% methanolic HCl (1 ml) for 30 minutes and the sample was examined by gas–liquid chromatography (15, 16). It showed peaks of a tetra-*O*-methyl sugar (α and β anomer) and of a tri-*O*-methyl sugar (α and β). The tetra-*O*-methyl sugar peaks corresponded to that of tetra-*O*-methyl fructose and the peaks of tri-*O*-methyl sugar corresponded to that of the tri-*O*-methyl glucose. The ratio of the areas of the peaks of tetra-*O*-methyl to that of tri-*O*-methyl sugar was approximately 2:1.

Another portion of the methylated trisaccharide (2 mg) was hydrolyzed with 0.04 *N* H_2SO_4 on a water bath for 1 hour. The hydrolyzate was examined by paper chromatography in solvent C and showed two spots having R_g 1.02 and R_g 0.71 respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The main bulk of the methylated sugar was hydrolyzed as above giving a syrup (210 mg) which was separated on paper in solvent C. Two fractions were obtained, i, tetra-*O*-methyl fructose (115 mg) and ii, tri-*O*-methyl glucose (60.6 mg).

Identification of the Methylated Sugars

*(1) 1,3,4,6-Tetra-O-methyl-*D*-fructose*

The tetra-*O*-methyl fructose was identified as its tetra-*O*-methyl fructofuranamide derivative according to Avery, Haworth, and Hirst (30). The sugar (115 mg) was oxidized with concentrated nitric acid (1.2 ml, sp. gr. 1.42) at 70° for 1 hour and then the temperature of the bath was raised slowly to 93° and the oxidation continued for another $\frac{1}{2}$ hour. Nitric acid was removed by repeated distillation with water. The product was esterified by refluxing for 10 hours with methanol containing 3% HCl. After neutralization with Ag_2CO_3 and removal of the methanol the product was methylated with Purdie's reagent for 5 hours. The syrup obtained was fractionally distilled.

Fraction	i	0–90°	at .01 mm	34.5 mg
	ii	90–105°	"	43.2 mg
	iii	105–160°	"	6.8 mg

All the fractions were separately dissolved in methanolic ammonia (10 ml) and kept in the cold for 4 days. After removal of the methanol, fractions i and ii gave crystalline residues which after recrystallization from ethyl acetate had the same melting point 99–100° C (reported melting point of tetramethyl fructofuranamide is 99–100° C (30) and 100–101° (22)).

*(2) 2,3,4-Tri-O-methyl-*D*-glucose*

The sugar (60.6 mg) was heated with freshly distilled aniline (35 mg) in ethanol (5 ml) for 3 hours. Ethanol was removed by distillation and the residual syrup was extracted with hot ether. The extract was evaporated to a syrup which crystallized on seeding with 2,3,4-tri-*O*-methyl-*N*-phenyl-D-glucosylamine. After three crystallizations from ether it had m.p. 145–146°, undepressed on admixture with an authentic specimen of 2,3,4-tri-*O*-methyl-*N*-phenyl-glucosylamine (31).

Component I (Minor)

The syrup had $[\alpha]_D$ +22°, $R_{sucrose}$ 0.65 in solvent A. On complete hydrolysis it gave 2 moles of fructose and 1 mole of glucose. On partial hydrolysis with dilute acetic acid (15%) it gave glucose, fructose, sucrose; no other sugar could be detected.

The syrup (45 mg) was methylated as above with dimethyl sulphate (4 ml) and 30% sodium hydroxide solution (8 ml), followed by two methylations with Purdie's reagent. The methylated trisaccharide (36.4 mg) had MeO 49.03%; $C_{29}H_{54}O_{16}$ requires OMe 51.8%.

A portion of the methylated trisaccharide (3 mg) was heated with 0.5% methanolic HCl as above and examined by gas–liquid chromatography. It showed peaks corresponding to the methyl glycosides of 2,3,4,6-tetra-*O*-methyl-D-glucose, 1,3,4,6-tetra-*O*-methyl-D-fructose, and a tri-*O*-methyl sugar.

Another portion of the methylated trisaccharide (2 mg) was hydrolyzed by heating on a boiling-water bath for 1 hour with .04 *N* H_2SO_4 and examined by paper chromatography in solvent C. Two papers were irrigated, one was sprayed with *p*-anisidine hydrochloride and the other with orcinol – orthophosphoric acid spray reagent. The

For personal use only.

tri-*O*-methyl sugar had R_g 0.86 in solvent C and gave an immediate reaction with orcinol spray reagent, which indicated that the sugar was a tri-*O*-methyl derivative of D-fructose. The quantity of methylated sugar was insufficient to permit further characterization.

REDUCTIVE CLEAVAGE OF NITROGEN–NITROGEN BONDS WITH RANEY NICKEL AND HYDRAZINE[1]

F. P. Robinson and R. K. Brown

ABSTRACT

Raney nickel and hydrazine readily cleave the nitrogen–nitrogen bond of a number of N,N′-diacylated hydrazines to produce the corresponding amides in good yield.

INTRODUCTION

During the course of investigations under way in this laboratory it became necessary to prepare several mono- and di-acylated phenylhydrazines in which the specific position of the acyl group(s) on the nitrogen atom(s) was known with certainty. A promising method for this structural determination was thought to be a mild reductive cleavage of the nitrogen–nitrogen bond which would leave the amide linkage undisturbed. Reductive cleavage of the nitrogen–nitrogen bond in carboxylic acid hydrazides and in 1,2-diacylated hydrazines has been accomplished by refluxing these compounds in ethanol in the presence of a large excess of Raney nickel (1, 2). In a study of the scope of this reaction (3) Hinman found that several previously reported resistant compounds could be cleaved by extending the reaction time from the usual 3 hours to one of 15–20 hours. However, by either of these methods yields were generally only fair, ranging from 5 to 60%. In addition, several compounds, notably 1,2-diacetyl-1,2-dimethylphenylhydrazine and phthalhydrazide failed to reduce even after prolonged reaction.

Recent work on the facile reduction of nitro compounds to amines by hydrazine in the presence of Raney nickel (4, 5, 6) shows that the reduction proceeds, at least in part, by way of the bimolecular reduction intermediates, azoxybenzene and hydrazobenzene. Continued reduction readily converted these in turn to the corresponding amine. It was therefore thought that the combination of Raney nickel and hydrazine would reductively cleave nitrogen–nitrogen bonds much more readily than would Raney nickel alone. A series of experiments showed that this was indeed the case.

RESULTS AND DISCUSSION

When hydrazine hydrate was added dropwise over a period of 1 hour to refluxing methanol containing equal weights of acylated phenylhydrazine and Raney nickel, a smooth reaction occurred giving good yields of the expected products. Results of some typical reductions are shown in the accompanying table. The amides which formed were quite unaffected by the reducing medium hence it was possible to deduce the position of the acyl group(s) in mono- or di-acylated phenylhydrazines. By this means it was easily shown that the diacetylation of 2,6-dimethylphenylhydrazine with acetic anhydride did in fact form N,N′-diacetyl-2,6-dimethylphenylhydrazine rather than the unsymmetrically acylated isomer. The symmetrically acylated product had been expected in view of the N,N′-diacetylphenylhydrazine obtained by Michaelis and Schmidt from a similar acetylation of phenylhydrazine (7).

An interesting point is that the quality of the Raney nickel apparently is unimportant

since freshly prepared W-2 Raney nickel (8) gave no better results than those obtained with Raney nickel which had been prepared previously (8) and kept for a period of 6 months under methanol in a refrigerator before use in this reaction. This aged Raney nickel had lost its pyrophoric activity completely.

The synthetic value of this reductive cleavage is shown in the simple *two-step* preparation of maleamic acid anilide (example 2 in the table) by reductive cleavage of maleic acid phenylhydrazide, the product of the reaction of phenylhydrazine and maleic anhydride (9). Maleamic acid anilide has been made previously by reaction of aniline with maleimide (10), the latter compound being formed in reasonable yield by a *five-step* synthesis devised by Berson *et al.* (11).

EXPERIMENTAL

N,N′-Diacetyl-2,6-dimethylphenylhydrazine

An aqueous solution of 8.6 g (0.05 mole) of 2,6-dimethylphenylhydrazine hydrochloride (12) was basified with dilute sodium hydroxide and extracted with 4×50 ml of benzene. To the combined benzene extracts, dried over anhydrous magnesium sulphate, was added 10.2 g (0.10 mole) of acetic anhydride and the resulting mixture refluxed for 30 minutes. When half the solvent had been removed, the solution deposited 8.1 g of crude product melting at 70–72°. Recrystallization from 95% ethanol yielded 7.2 g (65%) of product, m.p. 71–72°. Calculated for $C_{12}H_{16}N_2O_2$: C, 65.43; H, 7.32; N, 12.72%. Found: C, 65.33; H, 7.49; N, 12.77%.

Reduction Procedure

The following general procedure was used for all reductions. A solution of 50 ml of methanol, containing 1 g of the acylated phenylhydrazine and 1 g of W-2 Raney nickel (8) was stirred vigorously and gently refluxed for a period of 1 hour during which time an excess of hydrazine hydrate was added dropwise. At the end of the reaction time the catalyst was separated by filtration, and the solvent removed under reduced pressure. The product, crystallized from a suitable solvent, was identified by its melting point and mixed melting point with an authentic sample. With those compounds which yielded acetamide as one product, the residue obtained after removal of solvent was treated with 20 ml of cold water to dissolve and thus remove the acetamide. Subsequent treatment followed the usual procedure.

STUDIES ON THE PERVANADIUM COMPLEX[1]

G. A. DEAN[2]

ABSTRACT

The 'pervanadium complex' is investigated in a general manner. The kinetics of its thermal decomposition in acid solution are shown to be first order with respect to pervanadium, the apparent activation energy is 26.5±1.0 kcal/mole, and possible mechanisms are suggested. The effect of various acids upon the nature of the decomposition products is determined: almost quantitative yields of vanadium (V) or vanadium (IV) are obtained in very dilute or concentrated acid, respectively. Spectrophotometric studies indicate that in acid solution two separate complexes exist: a red (1:1) cationic complex and a yellow (1:2) anionic complex. The stoichiometry of the equilibrium between the two complexes in solutions of sulphuric acid is investigated by a method of 'discrete variations'. The equilibrium could be described by

$$\text{red} + H_2O_2 \overset{K_{r/y}}{\rightleftharpoons} \text{yellow} + 3/2H_2SO_4$$

where $K_{r/y} = 2.2 \pm 0.2$ at 22° C. The anion is shown to play an important part in determining the nature of the pervanadium complex.

INTRODUCTION

The formation and subsequent bleaching of a red-brown coloration when an excess of hydrogen peroxide is slowly added to an acid solution of vanadium (V) has been known for over a century. The original explanation of the reaction as a simple peroxidation of vanadate

$$HVO_3 + H_2O_2 \rightarrow HVO_4 + H_2O$$

was refuted by Meyer and Pawletta (1), who showed that both the original and peroxidized vanadium existed as cations. According to them, the reaction that occurs in solutions containing sulphuric acid is

$$(VO)_2(SO_4)_3 + 2H_2O_2 \rightarrow [V(O_2)]_2(SO_4)_3 + 2H_2O$$

and the following equilibrium exists on adding an excess of hydrogen peroxide:

$$\underset{\text{red-brown}}{[V(O_2)]_2(SO_4)_3} + 6H_2O \overset{H_2O_2}{\underset{H_2SO_4}{\rightleftharpoons}} \underset{\text{yellow}}{2V(O_2)(OH)_3} + 3H_2SO_4.$$

Although the last equation is often used in text books to explain the bleaching by an excess of peroxide it is difficult to see how it can be justified since peroxide does not occur on either side. In addition, the species (VO^{3+}) used by Meyer and Pawletta to represent vanadium (V) in acid solution does not agree with that currently accepted (VO_2^+) (see ref. 2).

The complex is unstable and decomposes readily on heating to give a mixture of vanadium (V) and vanadium (IV); the composition of the solution has a large influence upon the relative proportions of the latter but has hitherto received but brief mention in the literature (3, 4).

Wright and Mellon (5) performed the first spectrophotometric study of the complex and showed that an absorption maximum occurred in the region 450–460 mμ. Suitable conditions for its analytical use were determined empirically and although a decrease in the absorption maximum was confirmed to be due to an excess of peroxide no attempt

[1]*Manuscript received December 1, 1960.*
Contribution from the Department of Chemistry, Dalhousie University, Halifax, Nova Scotia.
[2]*National Research Council of Canada Postdoctorate Fellow, 1959–61.*

was made to determine quantitative relationships. A later study by Telep and Boltz (6) revealed a second (and larger) absorption maximum at 290 mμ, and this also was decreased by an excess of peroxide, but again no attempt was made to investigate further.

This paper investigates in a general manner various aspects of the complex which have long seemed to demand attention, particularly with regard to its decomposition and formulation.

EXPERIMENTAL

For the kinetic studies, reactions were followed colorimetrically with a Fisher electrophotometer fitted with cell-heating and -stirring devices. Spectrophotometric measurements were made with a Beckman DU spectrophotometer fitted with a photomultiplier attachment.

Vanadium (V) was determined by adding sulphuric and orthophosphoric acids to concentrations of about 1 *N* and 0.5 *M*, respectively, and then titrating with ferrous sulphate solution standardized against recrystallized potassium dichromate. An amperometric ('dead-stop') end point was used in conjunction with a synchronous magnetic stirrer and a Leeds and Northrup mirror-galvanometer type 2285*f* (maximum sensitivity: 0.03 μa for full scale deflection) allowing a very high sensitivity to be obtained. In all determinations comparative titrations were made using an untreated aliquot of stock solution as a reference. Hydrogen peroxide was determined by amperometric titration with permanganate previously standardized against ferrous sulphate.

Stock solutions of vanadium (V) (free from vanadium (IV)) were prepared by dissolving Fisher $NaVO_3$ ('purified') in water redistilled from dilute alkaline permanganate in an all-Pyrex-glass still fitted with splash guards. Solutions of hydrogen peroxide were prepared by dilution of Mallinckrodt reagent-grade 100-volume hydrogen peroxide (stabilized). All other reagents were of reagent-grade quality.

To avoid any reduction of vanadium (V) by traces of grease, organic matter, etc., all glassware was cleaned (where necessary) before use with permanganic – sulphuric acid cleaning mixture; it was then rinsed with dilute acidified hydrogen peroxide to remove any traces of manganese dioxide, rinsed thoroughly with distilled water, and finally steamed for 1 minute with steam evolved from boiling dilute alkaline permanganate.

RESULTS AND DISCUSSION

Thermal Decomposition of Pervanadium

The reactions which occur on heating an acid solution of pervanadium containing an excess of hydrogen peroxide are as follows: initially, the excess peroxide is decomposed catalytically by the vanadium, any decomposed pervanadium being regenerated by the excess peroxide, and the red color remaining unchanged; finally, when the excess peroxide has disappeared, the pervanadium complex itself undergoes decomposition and the red color fades rapidly. The last stage may be followed conveniently and, despite the oxygen evolved during the reaction, fairly accurately by determining colorimetrically the variation of [pervanadium] with time.

The results of experiments at different temperatures and acidities are plotted in Fig. 1. In all cases a linear relationship between log [pervanadium] and time was obtained, indicating that the decomposition is first order with respect to pervanadium and that

$$d[\text{pervanadium}]/dt = -k\,[\text{pervanadium}].$$

Expressing concentrations in mole/liter, k had the value 0.0100 ± 0.0005 sec^{-1} in 2 *N*

sulphuric acid at 90° C; it was not significantly altered by changing the concentration of sulphuric acid from 2 N to 0.2 N (Fig. 1, plots 1 and 2) or by adding iron (III) to a concentration of 10^{-4} M (plot 2).

The products of the decomposition are vanadium (V) and vanadium (IV), the proportion of vanadium (V) being dependent upon the acid and its concentration; values for seven different acids are presented in Fig. 2. It is evident that the anion plays an important part in determining the behavior of the complex.

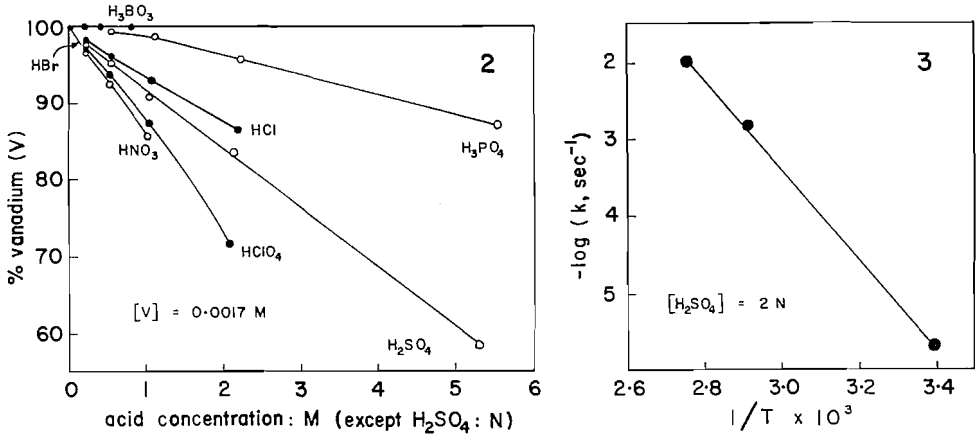

FIG. 2. Effect of various acids on the products from the decomposition of pervanadium in boiling solution.
FIG. 3. Plot of log k against $1/T$ for the thermal decomposition of pervanadium.

The logarithms of the various slopes depicted in Fig. 1 are plotted in Fig. 3 against the reciprocal of the absolute temperature. From the slope of this line the activation energy was calculated to be 26.5±1.0 kcal/mole.

The decomposition can be represented in two ways (in the subsequent account pervanadium is represented by perV$^+$): either as an initial dissociation

$$\text{perV}^+ \rightleftharpoons VO_2^+ + H_2O_2, \quad [1]$$

followed by subsequent reaction

$$2VO_2^+ + H_2O_2 + 2H^+ \rightarrow 2VO^{++} + 2H_2O + O_2, \quad [2]$$

$$2VO^{++} + H_2O_2 \rightarrow 2VO_2^+ + 2H^+, \quad [3]$$

or as a direct decomposition

$$\text{perV}^+ \rightarrow VO_2^+, \quad [4]$$

$$\text{perV}^+ + H^+ \rightarrow VO^{++}. \quad [5]$$

In each case an increase of $[H^+]$ is seen to favor the formation of vanadium (IV) in agreement with the results of Fig. 2.

Unfortunately there appears to be no way of distinguishing directly between these two schemes and it is necessary to consider indirect evidence as follows.

Considering the first scheme, the rate-determining step *in dilute acid* can be one of two consistent with the first-order dependence upon the pervanadium concentration:

(*a*) Dissociation of the pervanadium complex is rapid, when (see later)

$$[\text{perV}^+] \propto [VO_2^+]\,[H_2O_2],$$

suggesting that the kinetics of the rate-determining step (*in dilute acid*) are dependent upon $[VO_2^+][H_2O_2]$, which, in turn, suggests that the rate-determining step is reaction [2], and that, effectively,

$$d[VO_2^+]/dt = -k_1\,[VO_2^+][H_2O_2].$$

Unfortunately the kinetics of this reaction cannot be determined directly. In dilute acid pervanadium is formed at once, and in concentrated acid reduction is rapid (e.g., complete reduction occupies a few seconds in concentrated sulphuric acid at $-5°$ C) with but momentary formation of pervanadium. The kinetics of reaction [3] can be determined directly and were found to be as follows. For a constant $[H_2SO_4]$, the initial rate was proportional to $[VO^{++}]^2$ and to $[H_2O_2]$, giving

$$d[VO^{++}]/dt = -k_2\,[VO^{++}]^2[H_2O_2].$$

With concentrations expressed in mole/liter, and time in seconds, k_2 had the value 1.3×10^2 in 2 *N* sulphuric acid at 21° C. A few experiments were made to determine the effect of $[H_2SO_4]$, and the rate was found to be proportional to $[H_2SO_4]^{-x}$, where $x \sim 0.7$ for $[H_2SO_4] = 0.01-2$ *N*.

The final ratio of vanadium (IV) to vanadium (V) is remarkably constant despite large variations in initial vanadium concentration and temperature (Table I). No evidence

TABLE I

% Vanadium (V) produced by the decomposition of pervanadium

for the direct oxidation in dilute acid of vanadium (IV) by pervanadium was found and it seems reasonable to assume that the ratio of vanadium (IV) to vanadium (V) remains sensibly constant throughout the reaction. It follows from this that $(d[VO^{++}]/dt)/(d[VO_2^+]/dt)$ should also be constant, and hence

$$\frac{k_1[VO^{++}]^2[H_2O_2]}{k_2[VO_2^+][H_2O_2]} = \frac{k_1[VO^{++}]^2}{k_2[VO_2^+]}$$

should be constant, which is impossible. Hence mechanism (*a*) is unlikely.

(*b*) Dissociation of the pervanadium complex is slow and is rate-determining. Attempts to determine the rate of dissociation directly were inconclusive: permanganate solution added to a 0.01 *N* solution of vanadium (V) in *N* sulphuric acid containing an excess of hydrogen peroxide reacted rapidly with the excess, and then only slowly (over ~10 seconds at room temperature) with the 'combined' peroxide (a similar result was observed with the pertitanium complex); the slowness might be due either to slow dissociation or to the small equilibrium concentration of peroxide ($\sim 10^{-6}$ *M*, see later). However, the complexity of the over-all reaction produced by competing reactions [2] and [3] seems unlikely to result in a constant ratio of vanadium (IV) to vanadium (V) over large changes of both concentration *and* temperature, and on these grounds mechanism (*b*) is unlikely.

On the other hand, it is far easier to reconcile the experimental observations with a scheme involving a direct decomposition such as [4] and [5], and in the absence of direct evidence to the contrary is to be preferred. However, the complete explanation of the decomposition is likely to be far more complicated than the simple pictures presented here, and no further attempts to investigate the reaction were made.

Decomposition of Pervanadium at Extreme Concentrations of Acid

At very low acidities almost quantitative recovery of the vanadium as vanadium (V) is obtained (Table II).

TABLE II

Vanadium (V) produced by the decomposition of pervanadium in boiling dilute acid solution

$H_2SO_4 + H_3PO_4$	29	35	14	19

NOTE: Ten milliliters of 0.01 *M* aqueous $NaVO_3$ and 4 ml of concentrated acid were evaporated right down; a few drops of 100-volume hydrogen peroxide were added to the cold solution with stirring, and the process repeated. The solution was then warmed to destroy any traces of peroxide. For experiment B the periods of heating were prolonged.

acid, as a simple extrapolation of the data of Fig. 2 might suggest, gives the higher yield. The reduction in sulphuric acid has long been proposed as a basis for the determination of vanadium by titration with permanganate but experiments using the specified procedure (4) always resulted in incomplete reduction with results similar to those of Table III.

The results of Tables II and III, and of Fig. 2, emphasize the importance of the anion in determining the behavior of the complex.

Nature of the 'Pervanadium Complex'

The absorption spectra of vanadium (V) in solutions of sulphuric acid containing various amounts of hydrogen peroxide were found to exhibit an isobestic point at about 402 mμ (Fig. 4) suggesting at once the formation of a second complex in the presence of

an excess of peroxide. In the subsequent account the initial complex is called the 'red' complex and the second the 'yellow' complex.

Nature of the Red Pervanadium Complex

Shaeppi and Treadwell (7) have investigated the complex colorimetrically (using a mercury lamp with blue filters) by the method of continuous variations. In 7 *M* sulphuric acid the ratio of $V:H_2O_2$ in the complex was shown to be accurately 1:1 and

$$K = \frac{[\text{pervanadium}]}{[VO_2^+][H_2O_2]} = 8.2\times10^4\ M^{-1}.$$

No estimate of the experimental error was made and none of the experimental details or data necessary for its evaluation were given. From their results, however, it is estimated that the possible error in their value of *K* is likely to be about $\pm(5\text{–}10)\%$.

The acid concentration used by them was rather high, and the complex was studied by the same method, but for *N* acid, with the results shown in Table IV. These experiments confirmed the 1:1 nature of the complex; despite the large difference in acid

TABLE IV

Dissociation constant of the red pervanadium complex by the method of continuous variations

Acid	Position of d_{max}, mμ	d_{max}	d_{max}, extrapolated	$K\times10^{-4}$, M^{-1}
H_2SO_4	454	0.502	0.566	3.5±0.2
$HClO_4$	460	0.501	0.566	3.4±0.2

NOTE: Total concentration $[V+H_2O_2] = 0.00398\ M$; acid concentration = 1.0 *N*; temperature = 22° C. All values of *d* are corrected for blank and for the absorbance of the small amount of uncomplexed vanadium (V). Length of optical path = 1.000 cm.

concentration the results are reasonably in agreement with those of Shaeppi and Treadwell, indicating that H^+ does not enter the reaction to a significant extent. The latter may consequently be written in a simplified manner as

$$VO_2^+ + H_2O_2 \rightleftharpoons VO(O_2)^+ + H_2O$$

where (O_2) denotes a peroxy group. The shift in the position of maximum absorbance with a change of anion confirms the participation of the latter in determining the behavior of the complex. It was found that, under suitable conditions, the red complex was strongly absorbed by a cation-exchange resin and hence, in accordance with previous observations (1, 7) and the preceding equation, exists as a cation.

It is interesting to note that from 9 *M* hydrochloric acid rendered 0.1 *M* with respect to hydrogen peroxide the complex is about 50% extracted by an equal volume of methyl-*i*-butyl ketone, and 80–85% extracted by an equal volume of tri-*n*-butyl phosphate, and that in contrast with its bright red-brown color in the aqueous phase the complex is bright green in the organic phase (9). No extraction occurs from solutions in sulphuric acid (9, 10). No attempt is made to explain these observations.

Latimer (8) represents the formation of the red complex by

$$V(OH)_4^+ + H_2O_2 \rightarrow VO_4^- + 2H_2O + 2H^+, \quad \Delta F^0 = -29.8\ \text{kcal.}$$

The above value of ΔF^0 leads to the value

$$\frac{[VO_4^{4-}][H_2O]^2[H^+]^2}{[V(OH)_4^+][H_2O_2]} \sim 10^{22}\ M^3,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and on putting $[H^+] = 1$, and $[H_2O] = 56$, we get

$$\frac{[VO_4^{--}]}{[V(OH)_4^+][H_2O_2]} \sim 0.3\times10^{19}\ M^{-1}.$$

Even allowing for the use of concentrations in place of activities there is a very large discrepancy between the above value and the observed value.

Nature of the Yellow Pervanadium Complex

Meyer and Pawletta (1) observed that a clear yellow solution was obtained by adding hydrogen peroxide to an aqueous solution of V_2O_5 and that this color was the same as that produced in the presence of sulphuric acid by a large excess of hydrogen peroxide. By rather inaccurate distribution experiments they established that in the clear yellow solution at least one molecule of hydrogen peroxide was bound to each atom of vanadium (V); conductivity measurements indicated that an analogy with H_3PO_4 existed and accordingly it was postulated that the clear yellow solution contains $H_3[V(O_2)O_3]$, an orthoperoxy vanadic acid. These conclusions are not supported by the present work.

It is known that in solutions less than reasonably acid widespread changes occur in the nature of the species of vanadium (V) present (2). For this reason experiments were always conducted in strongly acid solutions and any deviation towards less acid conditions and the formation of complex species was carefully avoided.

The yellow complex cannot be investigated by the method of continuous variations, nor by any of the usual methods, owing to inevitable interference from the red complex at some stage. Fortunately, at the wavelength of maximum absorption for the red complex the absorption of the yellow complex is small, and it was found possible to study the stoichiometry of the equilibrium between red and yellow forms by a method of 'discrete variations'.

Assuming that the reaction in the presence of sulphuric acid can be represented by

[6] $$a\ (\text{red}) + b\ (H_2O_2) \rightleftharpoons c\ (\text{yellow}) + d\ (H_2SO_4),$$

then

[7] $$K_{r/y} = \frac{[\text{yellow}]^c[H_2SO_4]^d}{[\text{red}]^a[H_2O_2]^b}.$$

The red complex is known to obey Beer's law (5, 6); assuming that the yellow complex behaves similarly, that there is no interaction between the complexes in an optical sense, and that no additional complexes are formed, then the optical densities of the red and yellow forms, d_r and d_y, respectively, will be related to the observed optical density at 454 mμ, d_{obs}, by

[8] $$d_{obs} = d_r + d_y.$$

Provided, as in these experiments, that the concentration of hydrogen peroxide is sufficiently high to prevent significant dissociation of the red complex, then

[9] $$d_y = (1 - d_r/D_r) \times D_y,$$

where D_r and D_y represent the optical densities when the vanadium is present entirely in the red and yellow forms, respectively, and

[10] $$[\text{yellow}]/[\text{red}] = (D_r - d_r)/d_r.$$

Values of d_r may be calculated from equations [8] and [9] by successive approximation: d_{obs} is inserted for d_r in [9] and the value of d_y thereby obtained is used to calculate a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

new value for d_r from [8]. This is then reinserted in [9], and the process repeated, until the value of d_r becomes sensibly constant. This was usually realized after one procedure. D_r may be determined or calculated as previously; D_y may be estimated fairly accurately by extrapolation of d_{obs} for large relative concentrations of hydrogen peroxide.

From equations [7] and [10] it follows that, with $[H_2SO_4]$ = constant,

$$(D_r-d_r)^c/(d_r)^a = K' \times [H_2O_2]^b.$$

Observed values of $(D_r-d_r)/d_r$ are plotted against $[H_2O_2]$ in Fig. 5. D_r and D_y were

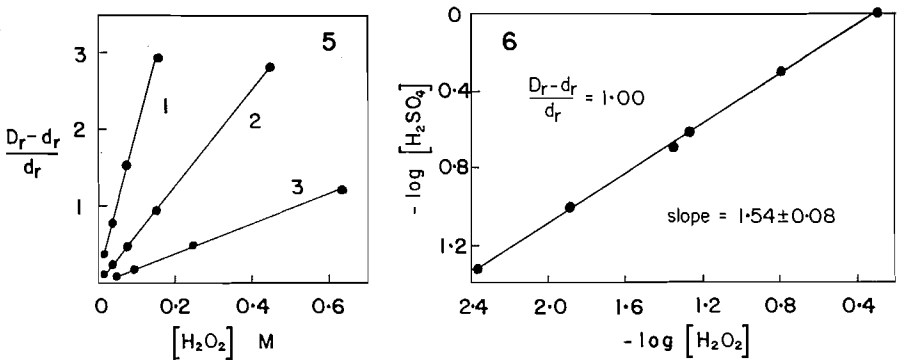

FIG. 5. Variation of $(D_r-d_r)/d_r$ with $[H_2O_2]$. $[H_2SO_4]$, N, = 0.245 (1); 0.502 (2); 1.010 (3). [V] = 0.00199 M.
FIG. 6. Variation of log $[H_2SO_4]$ with log $[H_2O_2]$.

assumed to be constant over the range of acid concentration involved; the concentration of hydrogen peroxide was corrected for the amount consumed by the formation of the red (1:1) and yellow (assumed to be 1:2) complexes; the concentrations of sulphuric acid were sufficiently high to swamp any variations produced by the reaction. The linear relationships obtained indicate that K' is a constant for any one value of $[H_2SO_4]$, and that

$$a = b = c,$$

thereby confirming that in the yellow complex $V:H_2O_2::1:2$.

The influence of sulphuric acid may be evaluated by putting [yellow]/[red] = constant, and by rearranging [7], when

$$\log [H_2O_2] = d/b \log [H_2SO_4] - 1/b \log K_{r/y}.$$

Observed values are plotted in Fig. 6. A linear relationship is again obtained, whence

$$d/b = 1.54 \pm 0.08.$$

No distinction can be made as to whether this result implies the existence of a real dependence on $[H_2SO_4]$ to this power or whether it merely reflects a relationship fortuitously produced by the participation of the anion.

Rearranging in terms of b, and putting $b = 1$, equation [6] may now be written

$$\text{red} + H_2O_2 \rightleftharpoons \text{yellow} + 3/2H_2SO_4;$$

with concentrations expressed as molar, except $[H_2SO_4]$, as normal,

$$K_{r/y} = \frac{[\text{yellow}][H_2SO_4]^{3/2}}{[\text{red}][H_2O_2]} = 2.2 \pm 0.2 \qquad \text{at } 22^\circ \text{ C.}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In contrast with the behavior of the red complex, the yellow complex was not absorbed by a cation-exchange resin, but was absorbed by an anion-exchange resin, and hence exists as an anion; this difference in behavior has been used as the basis for a separation of vanadium from chromium by ion exchange (9).

From the values of K (Table IV) and $K_{r/y}$, and putting $[VO_2^+]/[\text{red}] = [\text{yellow}]/[\text{red}] = n$, it can be shown that

$$n \sim 0.008/[H_2SO_4]^{3/4}.$$

The value of $(1-2n)$ represents the maximum possible amount of vanadium which can exist in the red form under these conditions and is about 0.991 for $[H_2SO_4] = 2\ N$. While this value is in no way directly related to the possible error involved in the colorimetric determination of vanadium with hydrogen peroxide by a *standardized* procedure it does emphasize the empirical basis upon which the method rests.

INFRARED SPECTRA OF 2,6-DIMETHYL-4-PYRONE COMPLEXES[1]

DENYS COOK

ABSTRACT

The infrared spectra of 2,6-dimethyl-4-pyrone in solution, and in complexes with $HgCl_2$, $ZnCl_2$, BF_3, $SbCl_5$, and HBr have been recorded. A band at 1639 cm^{-1} in the free pyrone moves to progressively lower frequencies in the complexes as the Lewis acid strength increases, identifying this band as the carbonyl stretching frequency and the donor site as the carbonyl group. A higher-frequency band, at 1678 cm^{-1} in the free pyrone, moves to lower frequency on complex formation, but to a much smaller extent, and is to be identified with a stretching mode of the ring. The site of protonation in 2,6-dimethyl-4-pyrone salts has been unequivocally shown to be the carbonyl oxygen atom.

INTRODUCTION

The 4-pyrones form an interesting group of compounds whose basic constitution is still somewhat in doubt. An investigation of the structure of 2,6-dimethyl-4-pyrone by X-ray diffraction (1) could not be resolved, though a similar study on the sulphur analogue, 2,6-dimethyl-4-thiopyrone (2) revealed adjacent ring carbon–carbon bond lengths of 1.34_2 Å and 1.42_1 Å. The first value is close to the ethylene value (3), while the second is a little smaller than the value of a single bond between two coplanar, trigonally hybridized, carbon atoms (4). Conjugation, therefore, extends from the 2 to the 6 carbon atom. The degree to which the ring oxygen participates in conjugation, if any, is doubtful. The lengths of the C—O bonds, 1.37_8 and 1.36_7 Å are slightly larger than those of the C—O group in α-resorcinol, 1.34_9 Å (5), where the OH group is not coplanar with the ring and therefore the degree of conjugation, again, if any, is questionable.

Published data on the vibrational spectra of 4-pyrones and complexes is meager. An early work by Ross on the infrared spectrum suffers from experimental limitations (6), while Wolkenstein and Syrkin's Raman study unfortunately gave no polarization data (7). Tarbell and Hoffman (8) gave data on some pyrones and thiapyrones. Glusker and Thompson (9) investigated the spectra of 2,6-dimethyl-4-pyrone in solution in CCl_4 and CS_2 saturated with iodine and found some interesting shifts in certain bands. Some pyrones and some pyronium salts were studied by Tsubomura (10). The most complete data on 1,4-pyrone was the thesis of W. D. Phillips (11) from which some material was published by Lord and Phillips (12).

In a recent paper, Bellamy and Rogasch showed that the 4-pyridones exhibit a reversal of the C=C and C=O vibrational frequencies, the latter being of lower frequency, at ~1580 cm^{-1} (13). It was also suggested that 4-pyrones show the same effect. Solvent effects on the polar carbonyl group of the 4-pyridones were used to prove this point. In the present work we have used the extent to which the carbonyl frequency shifts when the pyrone is complexed with different Lewis acids as an indication of the site and extent of complex formation.

RESULTS AND DISCUSSION

Table I shows the main bands in the various spectra. The band marked $\nu_{C=C}$ decreases from 1678 to 1645 cm^{-1} over the complexes shown, a change of 33 cm^{-1}. The band marked

$\nu_{C=O}$ decreases from 1639 to 1488 cm^{-1}, a change of 151 cm^{-1}. This band is assigned to the carbonyl vibration from the following arguments.

It is widely accepted that when donor–acceptor complexes are formed between carbonyl compounds and Lewis acids, a lowering of bond order, force constant, and stretching frequency occur in the carbonyl group. Susz recently summarized the frequency changes occurring upon complex formation for many adducts of BF_3, $AlBr_3$, $TiCl_4$, etc. with ketones (14). The concomitant increase in the carbonyl bond distance has been observed in one case, the coumarin:$HgCl_2$ (and $HgBr_2$) complex (15), where it is about 0.1 Å. For a given Lewis acid the largest change in carbonyl frequency upon complex formation occurs for the compound with the most polarizable carbonyl bond. In this category are aromatic ketones and $\alpha\beta$-unsaturated ketones. It is likely that $\alpha\beta$-, $\alpha'\beta'$-unsaturated ketones (to which group 2,6-dimethyl-4-pyrone formally belongs) will have an even more polarizable carbonyl group, and will give larger shifts on complex formation. The 2,6-dimethyl-4-pyrone:BF_3 complex shows a shift of 121 cm^{-1} which is somewhat larger than that of the benzophenone:BF_3 complex, namely 112 cm^{-1}.

A similar lowering in frequency of a band at 1635 cm^{-1} has been described in some iodine complexes of 2,6-dimethyl-4-pyrone (9). A new band appeared at ~1584 cm^{-1}. The band in the free pyrone at 1674 cm^{-1} was located at 1658 cm^{-1} in the complex. The molecular arrangement in the 2,6-dimethyl-4-pyrone:iodine complex is probably similar to that in the acetone:bromine complex recently described (16). The iodine:pyrone complexes have been prepared here, using very dilute solutions* of 2,6-dimethyl-4-pyrone in CCl_4 and CS_2, and an iodine concentration equimolar with the pyrone concentration.

A difference spectrum (where the pyrone solution is placed in the reference beam, and the same solution, but with iodine, is placed in the sample beam) showed "negative bands" paired with normal bands of approximately the same intensity, thus identifying the perturbed band with the band in the free pyrone.

It is thus felt that considerable confidence can be placed in the frequencies assigned to the carbonyl bands in the complexes and in the free pyrone.

**A misprint must have occurred in this paper, since the pyrone is certainly not soluble to the extent of 15% in CCl_4; 0.15% by weight would be more reasonable.*

The higher-frequency band at 1678 cm^{-1} in the free pyrone, lowering progressively in the complexes to 1645 cm^{-1} must, therefore, be associated with a carbon–carbon stretching vibration or a nuclear vibration of the ring as a whole. Such a vibration might be similar to the one at 1585 cm^{-1} in benzene (ν_8 using the notation of Wilson (17) and Langseth and Lord (18)).

The lowering of $\nu_{C=C}$ as the Lewis acid in the complex gets stronger might at first sight be ascribed to a real alteration in the force constant and bond order of the C=C bond, as these quantities in the C=O bond alter in different complexes. This idea must be rejected, however, since in the Lewis acid complexes of similar molecules, such as pyridine 1-oxide and 4-pyridone, although the ring modes are different from the parent compound, there is hardly any variation in the ring frequencies as the Lewis acid varies. Because complex formation involves the oxygen atom $\nu_{C=O}$ and ν_{N-O} will vary in different complexes. Table II shows $\nu_{C=C}$ and $\nu_{C=O}$ (or ν_{N-O}) for these compounds (all in chloroform solution). The two bands for the pyrone are much closer together than the other two, and $\nu_{C=C}$ is at a much higher frequency. It is therefore thought that there is a mechanical interaction responsible for splitting two very similar frequencies.

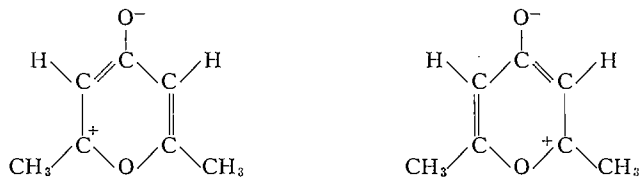
TABLE II

Comparison of $\nu_{C=C}$ with $\nu_{C=O}(\nu_{N-O})$ ($CHCl_3$ solution)

Compound	$\nu_{C=C}$	$\nu_{C=O}(\nu_{N-O})$	Δ
2,6-Dimethyl-4-pyrone	1677	1630	47
N-Methyl-4-pyridone*	1646	1581	65
4-Pyridone	1636	1515	121
Pyridine-1-oxide	1612	1250	362

*Reference 11.

No frequency lower than ~1645 cm^{-1} has been observed for the $\nu_{C=C}$ vibration in any complex. For the strongest Lewis acid, $SbCl_5$, the lowered $\nu_{C=O}$ is at 1493 cm^{-1}, sufficiently removed from $\nu_{C=C}$ to preclude any interaction. It is very probable, therefore, that the unperturbed value of $\nu_{C=C}$ is at approximately 1645 cm^{-1}. In the free pyrone in solution in CCl_4, the separation of $\nu_{C=C}$ and $\nu_{C=O}$ is 39 cm^{-1}. This is similar in magnitude to that in some symmetrical acid anhydrides, where the unperturbed frequencies are identical due to symmetry. The unperturbed values of $\nu_{C=C}$ and $\nu_{C=O}$ are, therefore, probably close to 1645 cm^{-1}. These values seem very reasonable ones for the vibrations involved. The $\nu_{C=O}$ value is close to that in the following similar molecules: tropone, 1642 cm^{-1}; quinone, 1662 cm^{-1}. For the $\nu_{C=C}$ vibration, its precise identity prohibits critical comparison, but either a pure carbon–carbon double bond stretching mode, or a mode similar to the ν_8 in benzene would be at about the right frequency. Olefinic aldehydes and ketones have an absorption due to the C=C stretching vibration around 1624 cm^{-1} (19). The ν_{8a} band in benzene is at 1596; in pyridine at 1580 (20); in the pyridinium ion at 1639 (21); in *m*-xylene at 1618 cm^{-1} (22).



The existence of the interaction between $\nu_{C=C}$ and $\nu_{C=O}$ also does not help to identify $\nu_{C=C}$. Such interaction usually occurs between vibrations of the same species. Since $\nu_{C=O}$ must be of A_1 species, $\nu_{C=C}$ must be the same. However, both the ring mode (cf., ν_8 in benzene) and a symmetrical C=C stretch would also belong to an A_1 species (see Table II for selection rules), so that a decision between the two cannot be made.

Possibly the distinction between these two modes has been a little unduly stressed.

Examination of the normal co-ordinate displacements (23) of the ν_{8a} vibration in deuterobenzene (C_6H_5D has C_{2v} symmetry, as has 2,6-dimethyl-4-pyrone) shows this to be almost exclusively associated with stretching the bonds parallel to the C_{2v} axis. Little clarification of the vibrational assignments would arise from attempting to label it a pure double bond stretching vibration and it is probably best considered as a ring mode.

Usually when such interaction is present there will be alterations in intensity in one of the perturbed bands. In the present case, one would expect $\nu_{C=C}$ to borrow intensity from $\nu_{C=O}$ and as $\nu_{C=O}$ was lowered by complex formation a decrease in intensity might be expected. This is by no means the case as in most spectra both bands are of approximately the same intensity (in chloroform solution $\nu_{C=C}$ is a good deal stronger than $\nu_{C=O}$). What complicates the situation, unfortunately, is the difficulty of comparing solid-state intensities with solution ones. Additionally, as these two main bands are superimposed on other minor bands (the 2,6-dimethyl-4-pyrone molecule has 45 fundamentals), the question of intensity variations is not straightforward. The fact that in the BF_3 and $SbCl_5$ complexes (where presumably there is no interaction) $\nu_{C=C}$ is as intense as $\nu_{C=O}$, suggests that, in resonance language, an important contribution to the real nature of the pyrones must come from structures similar to the following.

A conclusion similar to this has also been drawn from proton-exchange experiments in 4-pyrone (11, 12).

Considering next the salts of 2,6-dimethyl-4-pyrone with mineral acids, it follows that the only site of protonation must be the carbonyl group. This is proved by the lowering of $\nu_{C=O}$ by some 151 cm^{-1} in the HBr salt indicative of a strong interaction at the carbonyl group. Protonation at the ether oxygen, as was earlier suggested (24), would have little or no effect on the carbonyl group vibration.

The strong broad band in the spectrum of 2,6-dimethyl-4-pyrone hydrobromide at 2380 cm^{-1}, shifting to 1860 cm^{-1} in the deuterobromide is identified as a hydrogen stretching motion of the protonated carbonyl group. It is not uncommon for carbonyl oxygen atoms to be sufficiently basic to accommodate a proton. Tropone (25), tropolone (26), N-methyl urea (27), urea (28), and acetamide (29) can all form ionized solids with certain mineral acids and the X-ray diffraction investigations have shown protonation to take place at the carbonyl oxygen atom. Furthermore, many dialkylamides show evidence of protonation at the same site (30). It is significant that those carbonyl compounds capable of forming solid salts with mineral acids are those with low carbonyl stretching frequencies (31).

In such a complicated molecule having 17 atoms, and, therefore, 45 fundamentals, it would be difficult to make a complete assignment, especially when the symmetry is C_{2v}, thus permitting all vibrations to occur in both infrared and Raman spectra with the exception of the A_2 species in the infrared. Table III lists the symmetry properties,

activity, and selection rules. It is possible though to make an approximate description of some bands as Table I shows.

EXPERIMENTAL

The spectra were recorded on a Perkin–Elmer Model 221 prism-grating double-beam spectrometer using sodium chloride optics. Frequencies are believed accurate to ± 2 cm^{-1}.

The complexes were prepared by mixing solutions of the two components, if liquid or solid, or, if the Lewis acid was a gas, by passing it through a solution of the pyrone.

2,6-Dimethyl-4-pyrone:SbCl$_5$.—2,6-Dimethyl-4-pyrone:$SbCl_5$ was prepared according to Meerwein (32).

2,5-Dimethyl-4-pyrone:HBr.—HBr passed into CCl_4 solution of the pyrone gave a white precipitate which was recrystallized from a methanol–acetone mixture. Melting point 185° decomp. % HBr, 39.1; theory, 39.4%.

2,6-Dimethyl-4-pyrone:BF$_3$.—BF_3 passed into a CCl_4 solution of the pyrone gave two phases from which a white solid was precipitated with ether. Melting point 135–137°.

2,6-Dimethyl-4-pyrone:ZnCl$_2$.—An acetone solution of the pyrone was mixed with a methanol–acetone solution of $ZnCl_2$, then poured into ether to give the solid complex. It was recrystallized from a methanol–acetone mixture.

2,6-Dimethyl-4-pyrone:HgCl$_2$.—Concentrated warm solutions of each component were mixed and on cooling gave a white solid. It was recrystallized from a methanol–acetone mixture.

ACKNOWLEDGMENTS

The assistance of Miss C. D. Anderson in preparing some of the compounds and taking their spectra is gratefully acknowledged.

GAS–LIQUID CHROMATOGRAPHY OF TERPENES

PART III. THE USE OF OLEIC ACID ESTERS AS LIQUID PHASES[1]

E. VON RUDLOFF

ABSTRACT

The separation of several cyclic terpene hydrocarbons and some oxygenated derivatives was studied on a variety of triglyceride and dioleate ester columns. Use of rapeseed oil, partially hydrogenated rapeseed oil, olive oil, triolein, tristearin, methyl oleate, and potassium oleate as liquid phases led to the conclusion that the presence of an esterified mono-unsaturated long-chain acid is a desirable constituent of the liquid phase. Dioleate esters of 1,3-propanediol, 1,4-butanediol, 1,6-hexanediol, diethylene glycol, and polyethylene glycol showed useful differences in the degree of separation of both terpene hydrocarbons and oxygenated derivatives. Ether linkages, as in the di- and poly-ethylene glycol ester, also were associated with favorable separations. When the liquid phase contained free hydroxyl groups, the degree of separation of hydrocarbons and ketones was in general less favorable. The spacing of the ester groups was found to have some effect on retention data. The separation of such critical pairs of isomers as tricyclene and α-pinene, α-fenchene and camphene, and also geometrical isomers of oxygenated derivatives is facilitated by use of several of these liquid phases.

During an examination of the essential oil of the leaves of Eastern white cedar (*Thuja occidentalis* L.) by means of gas–liquid chromatography (GLC) (1), the peak corresponding in retention time to camphene was isolated and its infrared spectrum was found to correspond to that of synthetic camphene. Yet the sample failed to crystallize on seeding. Further examination on the rapeseed oil column (2) indicated a second component, presumably α-fenchene (3), to be present (partially resolved peak). There was no indication of this impurity on either the 6-ft adipate polyester (APEG) column or polyphenyl ether columns (2, 4). Other such unresolved or partially resolved pairs of isomeric terpenes are frequently encountered, e.g. tricyclene and α-pinene (3), terpinolene and $\Delta^{2,4(8)}$-*p*-menthadiene (2), or the many geometrical and positional isomers of oxygenated terpenes. Thus, for either qualitative or quantitative analyses by GLC of mixtures of terpenes and especially essential oils, improved separations over those previously obtained seem imperative. Slight improvements were obtained with the apparatus used in this study by some modification of the injector (see experimental part) and by using less than 5 μl amounts, but this did not lead to the desired results. Bernhard (5) has pointed out that the most useful experimental parameter is the choice of stationary liquid phase, and has investigated a large variety of compounds for use in the separation of lemon oil constituents. This aspect was further investigated in this study.

The use of polyesters as liquid phases in GLC separation has been studied fairly extensively (3–10) and the results obtained with adipate polyesters (4, 5) were a considerable improvement over older results. However, columns with these liquid phases failed to separate several of such critical pairs of isomers. In the previous paper of this series (2), it was shown that vegetable oils, such as rapeseed and olive oil, were very suitable for the separation of monocyclic terpene hydrocarbons and it was suggested that triolein may be useful as a liquid phase. This has now been found to be so, and it could also be shown that these triglyceride columns give useful retention data for oxygenated monocyclic terpenes.

[1]*Manuscript received January 30, 1961.*
Contribution from the National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan.
Issued as N.R.C. No. 6276.

During investigations on GLC separations of methyl esters of fatty acids in this laboratory, Craig (11) has observed that the spacing of the ester group along a polyester chain can have significant effects on the degree of separation. Thus, it is conceivable that the close proximity of three ester groups in the triglycerides is not necessarily the most favorable arrangement for the separation of terpenoid compounds. Therefore, a number of dioleate esters were prepared in which the ester groups were spaced progressively further from one another, viz. esters of 1,3-propanediol, 1,4-butanediol, 1,6-hexanediol, diethylene glycol, and polyethylene glycol. Oleate esters were chosen because the data obtained with the triglycerides suggested that oleic acid was the most desirable acidic component in these polyesters. In addition, the polyester of azelaic acid with diethylene glycol was tested to obtain further data on the spacing of the ester groups.

EXPERIMENTAL

Apparatus

A Beckman GC-2 chromatograph equipped with a thermal conductivity cell was modified by placing the injector as close as possible to the head of the column. The temperature of the injector was kept 20–25° C higher than that of the column and the detector cell. All experiments were carried out with an inlet pressure of 55 p.s.i. (3.74 atm) and the column outlet at atmospheric pressure (0.93 ± 0.02 atm). The flow rates were measured with a moving soap bubble at room temperature. The chart speed of the 1-mv recorder was 10 in. per hour, and samples were injected with a hypodermic syringe.

Preparation of Columns

All liquid phases were applied to the solid support Chromosorb W (Johns-Manville) in the ratio of 6 to 1 by weight. The liquid phase (2.0 g) was dissolved in chloroform (45 ml) and to the solution was added, with stirring, the solid support (12.0 g). The resulting thick slurry was stirred for 5–10 minutes, transferred to a shallow tray and stirred intermittently until the slurry became a dry powder. The material was then dried *in vacuo* at 50–60° C for 1 hour and packed with constant tapping into 6 ft by $\frac{1}{4}$ in. O.D. copper columns. The weights of liquid phase and solid support for each column are shown in Table I. All columns were used for a number of runs before critical measurements were taken.

Synthesis of Oleic Acid Esters

The technique described by Youngs *et al.* (12, 13) was followed throughout. In a typical example oleic acid (6.2 g, 22 mmoles, commercial 95%) was dissolved in dry petrol (b.p. 60–70° C) (65 ml) and to this was added phosphorus pentachloride (5.0 g, 24 mmoles). The mixture was heated under reflux with exclusion of moisture for 1 hour, then cooled and quickly washed twice with ice water (13). After the petrol solution was dried over anhydrous sodium sulphate, the solvent was evaporated. To the residual oleyl chloride was added 1,3-propanediol (0.76 g, 10 mmoles) and the mixture was heated on a rotary evaporator at 50–60° C for 6 hours, the initial vacuum being gradually increased to 10 mm Hg to remove the hydrochloric acid liberated. Any attempts to remove unreacted oleic acid by washing a solution of the crude reaction product with aqueous alkali resulted in very stable emulsions. Therefore, the residual reaction product was chromatographed on a 3×50 cm column of silicic acid, the ester being eluted with 100-ml aliquots of petrol:chloroform (1:1 v/v). The first three fractions had an infrared spectrum expected for the diester but acidic impurities could be detected, especially in

*In ml helium per minute.
†Retention time: (*a*) measured to peak base; (*b*) measured to peak maximum.

the third fraction. The material was combined by dissolving in chloroform (10 ml), solid anhydrous potassium carbonate (1.0 g) was added, and the mixture was stirred for 10–15 minutes. It was then rechromatographed on silicic acid to give the crude diester (3.6 g, 60% of theory). The infrared spectrum of the eluted material showed no longer the presence of free acid, but elementary analysis gave low values for the percentage carbon (up to 0.8%). On distilling the crude diester *in vacuo* (b.p. 195° C at 0.2 mm, air bath) the colorless diester was obtained practically pure. Found: C, 76.90%; H, 11.98%; neutral equivalent, 3; saponification equivalent, 297. Calculated for $C_{39}H_{76}O_4$: C, 76.91%; H, 12.58%; saponification equivalent, 304.50.

Where the yield of the diester was poor, a substantial amount of the corresponding monoester was recovered from the silicic acid column by eluting first any unreacted oleic acid with chloroform and then eluting further with chloroform – 2-butanone (1:1 v/v). The crude esters were all light to medium yellow in color and were obtained colorless only after distillation. Polyethylene glycol mono- and di-oleate failed to distill at a pressure of 0.1 mm Hg, and any residual oleic acid which may have been present after chromatography was converted to methyl oleate by treatment with an ethereal solution of diazomethane.

Materials

Triolein, tristearin, and the partially hydrogenated rapeseed oils were kindly donated by Dr. C. G. Youngs. Two different samples of partially hydrogenated rapeseed oil were used: I (HRO I), having a content of 14% saturated fatty acids, and II (HRO II) with 50% saturated acids. The adipate polyester of polyethylene glycol (APEG) and azelate polyester of diethylene glycol (AzDEG) were a gift kindly made by Dr. B. M. Craig (6). The polyphenyl ether [*m*-bis(*m*-phenoxyphenoxy)-benzene], "Tween 85" (polyoxyethylene sorbitan trioleate), and polyethylene glycol (Carbowax 1540) were commercial products.

The terpenes used in this study were either commercial samples or those previously prepared (2). The mixture of *trans*- and *cis*-dihydro-α-terpineol was prepared by hydrogenating α-terpineol with platinum oxide as catalyst (14). In addition a commercial sample of the essential oil of cedar leaf (*Thuja occidentalis* L.) was used.

PRESENTATION OF DATA

In 1958, Ambrose *et al.* (15) and Johnson and Stross (16) put forward proposals for a unified way of presenting GLC data. It was pointed out that reproduction of the actual recorder chart gave the least amount of information in a maximum amount of space. Tables of relative retention times with respect to a standard, or standards, were to be preferred, but far more useful presentation would result from calculation of retention volumes (corrected or uncorrected) and(or) partition coefficients. However, all such calculated data are obtained from the basic equation $V_R = F_c t'$ (15) where V_R is the retention volume, F_c the flow rate of carrier gas at column temperature, and t' the time of emergence of the peak maximum. Now it was shown (4, 17, 18, 19) that the position of the peak maximum of a given compound varies considerably with the size of the injected sample (over the practical range of about 0.1 to 50 μl used with the type of apparatus employed in this study). Also, the retention time may be longer if the compound is preceded by a much larger quantity of another compound (20). Thus, unless all measurements are carried out with identical sample sizes, considerable errors will

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

result in all of the calculated data. The use of equal sample sizes is not only time consuming but is a practical impossibility in essential oils and many mixtures of synthetic terpenes. Thus, for practical purposes at least, comparison of the actual recorder tracing (chromatogram) will remain the most reliable means of comparing column efficiencies. Next best, possibly, is the tabulation of relative retention times (with respect to a standard compound) *as measured from the point of injection to the initial emergence* of the peaks under consideration (2). The latter procedure is also subject to small errors when peaks are not completely separated. Further objections may be raised since the initial emergence is dependent upon detector sensitivity and thus small fluctuations in the base line may obscure detection of the initial emergence of a peak to some extent. These difficulties can be overcome, in part at least, by drawing the tangent to the peak and using the intercept at the base line as reference point. However, this is also subject to small variations with different sample sizes and the initial emergence point is to be preferred. Therefore, the data obtained in the present study was tabulated as relative retention times with respect to a standard and as measured to the initial emergence of each peak.

Retention times, or relative retention times, give no information on the peak width. Thus, whilst the relative retention times of two compounds may be the same on different columns, the actual separation achieved will only become apparent on comparing the recorder charts. Also, in separations involving essential oils different types of organic compounds are involved and the relative peak width of, for example, the hydrocarbons may be different from those of the ketones, alcohols, etc. Separation factors or functions have been put forward (21, 22, 23) to overcome this difficulty, and Jones and Kieselbach (24) have proposed the use of the ratio of retention time to peak width (relative peak sharpness) as a measure of the efficiency of a column. The latter quantity appears to offer advantages since it is a direct measure and not a theoretical concept relating to an idealized mode of operation. However, if the retention time is measured at the peak maximum, the error discussed above will once again make comparison between peaks of different sample sizes unreliable. Also, peak width varies with sample size and a smaller value for the relative peak sharpness will be obtained with larger sample size. These same observations apply to the use of retention indices as developed by Kováts (25). Thus, the visual examination of the charts still remains the most reliable means of determining column efficiency when peaks of varying sample size are involved. However, some measure of the degree of separation can be obtained by comparing the retention time of the point of initial emergence of a peak with that of the peak maximum. This is shown in Table I for all the columns studied for limonene (at 80° C) and for camphor (at 110° C). Flow rates, retention times of air, and the total weight of the liquid phase and solid support are also listed to allow other calculations, if desired.

RESULTS AND DISCUSSION

The relative retention times of monoterpene hydrocarbons, 1,8-cineole and *p*-cymene with respect to limonene as obtained on the rapeseed oil, tristearin, methyl oleate, and potassium oleate columns are compared in Table II with those obtained on a polyethylene glycol (PEG 1540) column. Only insignificant differences in the relative retention times were obtained with the rapeseed oil, olive oil, trioleate, and methyl oleate columns and only the data for the former are shown. Visual comparison showed a slightly better degree of separation for the triolein column, whilst that obtained with olive oil was

slightly worse than that for rapeseed oil. Methyl oleate did not only give very high retention times (see Table I), but was found to bleed at higher temperatures. With the more saturated triglycerides a decrease in efficiency was noted with increasing concentrations of saturated esters. Quite different results were obtained with potassium oleate; the retention times were very low and the resolution was rather poor. Since more unsaturated vegetable oils, such as linseed and sunflower oils, gave also poorer results than rapeseed oil (2), there is little doubt that esterified oleic acid is the most desirable component in this type of liquid phase.

Pure oleate esters will not oxidize as rapidly as when they are contaminated with more unsaturated esters. However, this advantage of synthetic triolein over the vegetable oils may be offset by the difficulties encountered in preparing pure triolein. Deterioration of the vegetable oil columns was conveniently detected by a decrease in the separation between 1,8-cineole and limonene; a 6-month-old rapeseed oil column gave even slightly longer retention times for the oxide. No noticeable differences in the separation of isomeric hydrocarbons were detected, unless the deterioration was severe. This behavior of the oleate columns may be due to slow oxidation of the liquid phase resulting in a gradual increase in polarity and thus approaching the polyether or polyester type of separation. The results obtained with rapeseed oil, triolein, and partially hydrogenated rapeseed oil I (14% saturated fatty acids) show that the purity of the triglycerides with respect to saturation is not critical up to a content of about 10% of saturated acids. Also, small variations in the chain length of the unsaturated moiety (as found in rapeseed oil) do not appear to have a marked effect on the degree of separation of terpene hydrocarbons.

Table III shows the relative retention times of the same terpenes obtained with synthetic dioleates, polyethylene glycol monooleate, "Tween 85", azelate polyester (AzDEG), and adipate polyester (APEG) as liquid phase. 1,3-Propanediol dioleate gave

similar results to those obtained with the unsaturated triglycerides and the relative retention times are therefore not shown. All dioleates gave favorable separation, especially so for the critical pairs of peaks 5 and 6 and peaks 11 and 12. The separation in the α-terpinene to γ-terpinene range were especially good on the di- and poly-ethylene glycol dioleate columns. Noteworthy is also the finding that on most of these columns fenchone was eluted relatively later than on the triglyceride columns. The retention times of 1,8-cineole with respect to limonene varied considerably and no correlation between the degree of separation and the spacing of the two ester groups could be detected. Also, the much shorter retention times obtained on the 1,4-butanediol dioleate (BDDO) column (in part due to the higher flow rate in this column) as compared with those on the propanediol or hexanediol dioleate columns did not result in a markedly different degree of separation, except that 1,8-cineole was eluted later with limonene. The presence of free hydroxyl groups (polyethylene glycol monooleate, polyethylene glycol, and "Tween 85") results in a loss of over-all efficiency. This can also be seen from the data obtained earlier with a polyphenyl ether column (2). Together with the difference in separation obtained on the polyester (APEG and AzDEG), polyphenyl ether (PPE), and polyethylene (PEG 1540) columns these results lead to the conclusion that for the separation of isomeric terpene hydrocarbons, mono-unsaturated hydrocarbon chains and ester groups are favorable, but free hydroxyl groups not. The ether linkage of the polyethers is, in general, favorable, too, and results in a longer retention of 1,8-cineole and *p*-cymene.

For the study of the composition of essential oils, columns which are equally efficient for the separation of oxygenated compounds, including isomeric pairs, are required. The separation of the isomeric menthols on either polyethylene glycol (26) or silicone oil (27) has been reported, and Ofner *et al.* (28) have separated the cis–trans isomers of

aliphatic sesquiterpenoid alcohols on Apiezon. Also, the retention time of the fastest-moving monoterpenoid ketone (usually fenchone) should be such as to allow complete separation of the monoterpene fraction. For this reason the relative retention time of fenchone at 80° C on some of the columns investigated has been included in Tables II and III. The relative retention times with respect to camphor of a number of closely related ketones and alcohols and bornyl acetate as obtained with the above columns at 110° C are shown in Table IV. Though only a relatively small number of oxygenated monoterpenes were studied, the retention data obtained allow conclusions to be drawn as to which column or columns may be suitable for a specific separation. Since the differences obtained with the various triglycerides followed the same pattern as described above, only the results obtained with rapeseed oil and tristearin as liquid phase are shown as typical examples. It is noteworthy that the drop in efficiency in going from the unsaturated to the fully saturated triglyceride was not as marked as in the case of isomeric terpene hydrocarbons. However, this may no longer be true if unsaturated ketones or alcohols are involved. The triglyceride columns tend to separate approximately according to boiling point, showing that these columns are intermediate in polarity as compared with saturated hydrocarbon or silicone and the polyester type of columns.

Very marked differences in relative retention times were obtained on the various dioleate columns. On 1,3-propanedioleate (PDDO) the most remarkable difference is that *trans*-dihydro-α-terpineol and borneol as well as the cis isomer of the former and isoborneol were not separated from one another, whilst on the other oleate columns the cis isomer and borneol would fall together. The relative retention times on the 1,4-butanediol dioleate (BDDO) column were similar to those obtained with rapeseed oil, except that bornyl acetate was eluted more rapidly. This was also so on the polyethylene glycol dioleate (PEGDO) column, only here the separation between *cis*-dihydro-α-terpineol and borneol was superior. The hexanediol dioleate (HDDO) column eluted bornyl acetate more slowly. The most noticeable differences were obtained with diethylene glycol dioleate (DEGDO). Not only are the retention times lower than on the other oleate columns, but the relative retention times of the ketones are noticeably higher. The degree of separation on the polyethylene glycol monooleate column was of the same order as that obtained with tristearin, except that bornyl acetate was eluted ahead of α-terpineol.

Comparison of the retention data obtained on the triglyceride and oleate ester columns with those found on the polyester and polyether columns shows some useful differences. The former columns all gave better resolution of the hydrocarbons. This, however, appears to be at the expense of longer retention times. Regarding the polyester of azelaic acid (AzDEG), also studied in this series (see Tables III and IV), a slight but definite improvement in the separation of hydrocarbons with respect to the adipate polyester polyethylene glycol column was obtained. Since the retention time of limonene was less than half that of most of the oleate ester columns, this liquid phase offers advantages in routine analyses. The separation of oxygenated terpenes on this column was of the same order as that obtained on the adipate polyester column. Previously it was found (2) that succinate polyester was less efficient as liquid phase than adipate polyester as far as separation of terpenes is concerned. Thus, there appears to be a definite advantage in having the ester groups spaced more than four carbon atoms apart. This relationship will, of course, not hold for all types of compounds to be separated, but it confirms the observation made by Craig (11) that the distance of polar groups along the chain of the polymer may have a significant influence on the degree of separation.

GAS–LIQUID CHROMATOGRAPHY OF TERPENES

PART IV. THE ANALYSIS OF THE VOLATILE OIL OF THE LEAVES OF EASTERN WHITE CEDAR[1]

E. VON RUDLOFF

ABSTRACT

The complete analysis of the neutral volatile oil of the leaves of Eastern white cedar (*Thuja occidentalis* L.) by means of gas–liquid chromatography was attempted. The mixture of terpenes was resolved into 28 monoterpenoid components and the major ones were isolated in 5- to 20-mg amounts. Comparison of infrared spectra and retention times with those of authentic specimens led to the positive identification of *d*-α-pinene, camphene, sabinene, *d*-limonene, *p*-cymene, γ-terpinene, *l*-fenchone, *l*-α-thujone, *d*-isothujone, camphor, and bornyl acetate. α-Thujene, β-pinene, myrcene, 1,8-cineole, terpinolene, and terpinen-4-ol were tentatively identified. The percentage composition of a commercial sample of the oil and of one obtained from a tree grown in Saskatoon was determined. The latter oil contained 7.0 to 7.5% of sesquiterpenoid components, which were resolved into four peaks on polyester columns at 180° C.

INTRODUCTION

In the analysis of essential oils difficulties are encountered which are due to the presence not only of a fairly large number of components (up to 40) with a relatively wide boiling point range (about 150° to 250° C), but also of position and geometric isomers and of compounds which isomerize, autoxidize, polymerize, or dehydrate quite readily. Thus, it is not surprising that the analysis of such oils by gas–liquid chromatography (GLC) has not advanced as rapidly as, for example, that of fatty acid or hydrocarbon mixtures. The direct analysis of a number of essential oils has been attempted (1–8) and several of the difficulties encountered have been discussed (1–13). To overcome such difficulties, various prefractionation techniques have been applied. Naves *et al.* (5, 12) have combined fractional distillation, GLC, and infrared spectroscopy, and the problems relating to commercial practices have been eminently discussed (13, 14). Fractional distillation was also used by Cvrkal and Janák (15). Liberti and Cartoni (16), as well as Stahl and Trennheuser (11), combined GLC with silicic acid column or "thin-layer" chromatography. Removal of specific components by use of molecular sieves was described by Brenner *et al.* (17), whereas removal by chemical means (1, 18, 19) has been criticized (8). Most of these techniques require larger amounts of material than GLC and the danger of decomposition or rearrangement of one or more components is increased.

With the finding by the author of several liquid phases which give improved separations of both terpene hydrocarbons and some of their oxygenated derivatives (20), it was hoped that the direct and complete analysis of essential oils by GLC may become feasible. Identification of individual components could then be carried out conveniently by comparison of retention data and infrared spectra of the constituents of an oil with those of authentic specimens. The volatile oil of cedar leaves (*Thuja occidentalis* L.) was chosen as a test mixture because this oil is readily available commercially, its chemical composition is well known (21–24), and this conifer species was available locally for the preparation of small quantities of the fresh oil. Also, its composition appeared to be sufficiently complex to tax the present technique. Since free acids can cause ester interchange in polyester columns (25), only the neutral steam-volatile oil was investigated.

[1]*Manuscript received January 30, 1961.*

Wallach (21) identified the major constituents of cedar leaf oil as *d*-α-thujone and *l*-fenchone and also isolated *d*-α-pinene and *l*-borneol (free and as the acetate). Recently, Shaw (23, 24) has carried out a more complete analysis by fractional distillation and identified, in addition to the above compounds, *l*-α-thujene, *l*-camphene, *d*-sabinene, myrcene, limonene, *d*-isothujone, *l*-camphor, and *d*-terpinen-4-ol. Camphor was also found by Wallach, but he considered this to be an artifact (21, 22). Shaw also obtained a small amount of sesquiterpenoid material (24), but he was not able to resolve the mixture into pure compounds.

EXPERIMENTAL

A modified Beckman GC-2 chromatograph with a thermal conductivity cell as detector was used and the experimental techniques employed have been described in the preceding paper (20). The various 6 ft by $\frac{1}{4}$ in. O.D. columns employed, with the liquid phase and solid support (Chromosorb W) in the ratio of 1 to 6, have also been described. In preparative work a 3 ft by $\frac{1}{4}$ in. column with polyphenyl ether (*m*-bis(*m*-phenoxyphenoxy)-benzene) in the ratio of 1 to 4 was used either alone or placed ahead of the 6-ft analytical columns. Two samples of *Thuja* leaf oil were obtained, one was from a commercial source (Fritzsche Brothers, Inc.) and the other was prepared by steam distillation of the leaves and terminal branches (217 g) of a locally grown Eastern white cedar tree; yield (1.9 g) 0.88% based on the fresh weight of the leaves. The two oils had n_D^{23} 1.4562, 1.4630 and $[\alpha]_D^{23}$ −13.0°, −7.9° respectively. The reference compounds were either of commercial origin or prepared by conventional methods and, where necessary, these were purified in 0.02- to 0.1-g amounts by preparative GLC. The sample of thujone was a mixture of α-thujone and isothujone and was used as such.

In the preparative experiments the runs were carried out "blind", i.e. with the detector current off (26), and the desired fractions were isolated by timing as determined in trial runs, using the same sample size. Collection of these fractions was carried out with the Beckman fraction collector (No. 92730), the traps being cooled with a dry ice–ethanol mixture. The infrared spectra of pure fractions were obtained with a Perkin–Elmer Model 21 spectrophotometer, using both the film technique and dilute solutions in chloroform.

In the analytical GLC experiments, 3–5 μl aliquots of the leaf oil were injected. The percentage composition was then calculated by means of the area under the peaks. Before and after each run, standard samples were run to determine the retention times of reference compounds. The retention times obtained on a 6-ft rapeseed oil column at 110° C and a flow rate of 93 ml helium per minute are shown in Table I. For complete, or nearly complete, resolution of the terpene hydrocarbons 12-ft rapeseed oil, polyethylene glycol dioleate (PEGDO), and azelate polyester (AzDEG) columns were used. High-boiling components (sesquiterpenes) were detected on the adipate (APEG) polyester column at 180° C and azelate (AzDEG) polyester column at 160 to 180° C.

RESULTS AND DISCUSSIONS

Aliquots of the commercial cedar leaf oil were analyzed at 80° C and 110° C on all of the columns described in the previous paper (20). The best over-all resolution was obtained with the rapeseed oil column at 110° C (Fig. 1); 25 peaks were recorded. All of the chromatograms were compared visually and it was concluded that useful differences in the separation of these peaks were obtained with the polyethylene or diethylene glycol dioleate (PEGDO, DEGDO), hexanediol dioleate (HDDO), polyethylene glycol (PEG

1540), and diethylene glycol azelate polyester (AzDEG) columns, and these were used for the more detailed qualitative and quantitative analyses.

Whereas the oxygenated components (peaks 15 to 25 in Fig. 1) were separated readily on the 6-ft columns (at 110° C), the hydrocarbons (peaks 1 to 14) presented difficulties, a finding which is also apparent from the data of Zubyk and Conner (10). The resolution of components 3 and 4, 5 and 6, and 7, 8, and 9 was better at 80–90° C, but even then

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tentative identification by comparison of retention times was difficult; e.g. whereas the retention time of component 4 corresponded to that of α-pinene on all columns, that of component 3 was the same as that of either tricyclene or α-thujene. The incomplete resolution of components 5 and 6 or 7 and 8 made the identification and isolation of these compounds also difficult. For this reason, the oils were also analyzed on 12-ft rapeseed oil, polyethylene glycol dioleate, and azelate polyester columns (at 100 to 110° C). Although this procedure resolved the monoterpene components satisfactorily (see Fig. 2) it was rather time consuming, since the higher-boiling compounds

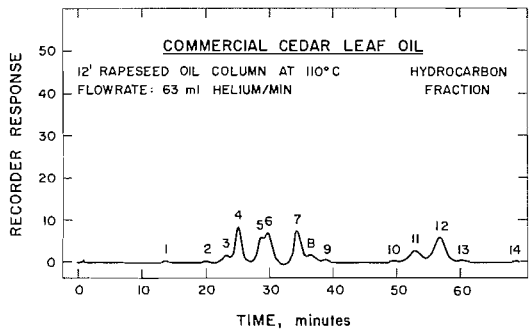

FIG. 2. Chromatogram of the monoterpene hydrocarbon fraction of the cedar leaf oil on a 12-ft rapeseed oil column at 110° C.

had to be eluted (or back-purged) before the next analysis could be carried out. Prefractionation into the monoterpenoid hydrocarbons (peaks 1 to 14), oxygenated monoterpenes (peaks 15 to 25), and higher-boiling components (if present) was thus desirable. This was carried out by preparative GLC on a 0.3- to 0.5-g scale (see below). To determine whether higher-boiling components were present, aliquots of the oils were analyzed on the polyester (APEG and AzDEG) columns at 180° C. The commercial oil showed only three trace components in the geraniol range and two minor components in the sesquiterpene alcohol range (26), but the oil from the local tree contained seven detectable compounds in this region, three of which were present in significant amounts.

Prefractionation was carried out on a 3-ft-long column at 110° C with polyphenyl ether and solid support in the ratio of 1 to 4. Individual peaks were not separated and skewing was very marked when 300- to 500-μl aliquots were used. However, components 1 to 13 or 14, 15 to 18 or 19, and 19 or 20 to 25 were obtained as distinct groups. The higher-boiling components were not recovered at this temperature. Experiments at 150 to 180° C allowed the recovery of the sesquiterpenoid compounds but several of the more labile monoterpenes decomposed to a considerable extent. When azelate or adipate polyester columns were used, decomposition was detected already at 130° C. Also, with all polyester columns trans esterification of the alcohols in the oil may take place (25). Therefore, prefractionation of 0.3- to 0.5-g aliquots was carried out with a polyphenyl ether column at 110° C. The fractions thus obtained were then separated into individual components on suitable analytical columns, when 5- to 20-mg amounts of components 3, 4, 5 and 6, 7, 8, 9, 11, 12, 15, 16, 17, 19, 22, and 24 were isolated. The amounts isolated allowed the determination of the infrared spectra and in some instances the sign of optical rotation. Comparison of the infrared spectra and retention times with those of authentic specimens led to the identification of components 4 (*d*-α-pinene), 6 (camphene),

7 (sabinene), 11 (*d*-limonene), 12 (*p*-cymene), 13 (γ-terpinene), 15 (*l*-fenchone), 16 (*l*-α-thujone), 17 (*d*-isothujone), 19 (camphor), and 24 (bornyl acetate). The separation of components 5 and 6 was incomplete and camphene failed to crystallize on seeding with the synthetic compound. The infrared spectrum of the mixture corresponded in all respects to that of camphene. Since component 5 is present in almost equal amount (see Fig. 2), it follows that its infrared spectrum must be very similar to that of camphene. This, together with the retention data, suggests that component 5 is α-fenchene. Components 3, 8, 9, 10, 14, and 22 were not obtained sufficiently pure to allow a positive identification, but the data agreed with those for α-thujene, β-pinene, myrcene, 1,8-cineole, terpinolene, and terpinen-4-ol respectively. The remaining components (peaks 1, 2, 18, 20, 21, 23, 25, 26 to 28, and the sesquiterpenes) could not be identified, mainly because suitable reference compounds were lacking.

The material having higher retention times than component 25 deserves some comment. Using the adipate polyester (APEG) column at 180° C and a flow rate of 60 ml helium per minute five minor components beyond peak 25 were recorded when 3 μl of the commercial oil was injected. The first three (peaks 26 to 28) amounted to less than 0.3% and had retention times (RT) of 6.2, 7.7, and 10.3 minutes respectively, which are in the geraniol range (RT 7.2 minutes). The other two peaks (RT 22.8 and 27.3 minutes) amounted to 0.4 to 0.6% each and were in the eudesmol range (RT 24.8 and 30.0 minutes). The fresh oil from the local tree showed not only a higher content of these higher-boiling components (7.5 to 8.0%), but had in addition two further components (RT 14.8 and 18.8 minutes). The amounts recorded for these seven components in order of their retention times were about 0.3, 0.1, 0.3, 1.1, 0.4, 1.7, and 4.0% respectively. The separation of these compounds on other columns which could be operated at 160 to 180° C was not as good (see also (26)). Sesquiterpene hydrocarbons, if present, would fall into the monoterpene alcohol range.

In the quantitative determinations, the main question was whether the detector response was the same for all compounds encountered. Zubyk and Conner (10) reported that when a thermal conductivity cell is used with helium as the carrier gas, the area under the peak is approximately proportional to the amount of the compound represented by that peak. Messner *et al.* (27) and Jamieson (28) have shown that the response varies with the molecular weight and branching of the molecule and proposed the use of correction factors to increase the accuracy of the calculated data. The determination of the amount of a compound present in a mixture by the various methods commonly employed (e.g. triangulation) may be subject to some errors in itself (29). For these reasons a mixture of representative terpenes was made up and the percentage composition was determined on all columns used by means of the triangulation method. The values obtained for the hydrocarbons were somewhat high and those for the less volatile oxygenated compounds correspondingly low. A source of this error was the amount of tailing, which was negligibly small for early peaks but increased for later peaks. When the area due to tailing was included in the calculations, the results (Table II) were within the limits of the error of this method, which is about 3 to 8% for the size of peak obtained (29). However, the values obtained for the hydrocarbons still tend to be high and those for the oxygenated compounds low. The use of correction factors would become very cumbersome since these would differ from column to column as well as for different types of compounds. Therefore, the quantitative composition of the essential oils under investigation was determined by calculation of the area under each peak (triangulation method) and including the amount due to tailing where this became

measurable. In Table I the range of the percentages calculated from the data obtained with five columns is shown for both the commercial and the local oils. Allowance was made for the presence of the sesquiterpenes when these were not eluted. This table also shows the composition of a cedar leaf oil analyzed by Shaw (24) by means of fractional distillation.

Comparison of the present data with that reported by Shaw shows that the analysis by GLC leads to more complete data and distinctly better separation of individual components. Since the difference in composition of the commercial oil and that isolated from a locally grown tree was only small, the smaller number of compounds identified by Shaw cannot be due to the source of material only. GLC analysis of the commercial oil at 180° C showed only five minor peaks after component 25 and amounting to about 1%. Thus, it is reasonable to assume that the analysis by GLC covers practically all of the volatile material. If one adds to this the very small amounts required (less than 5 ml in the present study), then the advantage over preceding techniques is considerable. However, the difficulties encountered in identifying 5- to 10-mg amounts of terpenes are a disadvantage, since at no time may agreement of retention times with known compounds be taken as a positive identification. Once the chemical composition of a particular oil has been established, the analysis of a similar oil is rapid and very convenient since only milligram amounts of the oil to be compared are required. In the present study, less than 50 mg of the oil from the locally grown tree was used. This fact should facilitate greatly studies of botanical variations, etc. and the method may become very useful in questions relating to plant physiology, morphology, and taxonomy.

Two observations which may affect the analysis by GLC must be pointed out. On some columns (e.g. with hexanediol dioleate as liquid phase) the retardation of components 17 to 25 due to the large amount of α-thujone (peak 16) in the oil was found to be outside of the error of measuring retention times. Raupp (30) reports similar findings due to preceding peaks. When the charts obtained with, for example, the 6-ft rapeseed oil column at 80° C and the 12-ft rapeseed oil column at 110° C were compared, the increase in separation obtained on the longer column was not very marked. However, the peak height resulting from the same amount of material was larger at the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

higher temperature and thus the definition of the trace components was superior. Also, at the higher temperature somewhat larger samples could be used before a loss in the degree of separation became noticeable, making detection of trace components easier.

CONCLUSIONS

Using several columns with liquid phases having different separation properties, the volatile oil of cedar leaves was resolved into 30 to 32 components. Although comparison of retention data (obtained on columns having different polarities) facilitates the identification of individual components, such identifications should not be accepted without correlation with at least one other reliable technique. Isolation of individual components in more than milligram amounts is as yet difficult, unless the separation factor is relatively large. Prefractionation can overcome this difficulty only in part. Such small amounts of terpenes seldom allow chemical identification, and physical methods have to be relied upon. Positive identification may fail when two components are so closely related that differences in physical properties are too small to be detected.

The quantitative determination of individual components presents less difficulty, and the GLC technique becomes especially attractive when an oil of the same species is to be compared qualitatively and quantitatively with one from a different source.

ACKNOWLEDGMENTS

The author wishes to thank Mr. M. Granat for technical assistance and Miss I. M. Gaffney for recording the infrared spectra.

SULPHONIUM SALT SOLVOLYSIS

PART I. EFFECT OF CONCENTRATION, ANION TYPE, AND SOLVENT VARIATION ON RATE OF REACTION[1]

J. B. HYNE

ABSTRACT

Previous work on the mechanism of sulphonium salt solvolysis is reviewed briefly. Rate data, determined by two independent methods, is presented for the solvolysis of dimethyl-*t*-butyl sulphonium iodide, bromide, and chloride in water and various ethanol–water mixtures. Rate dependence on the anion character and concentration of salt is shown to develop as the dielectric constant of the medium is lowered. The results are interpreted in terms of the increasing importance of an ion-pair mechanism as the composition of the medium is changed. The interpretation is substantiated by independent evidence for ion-pair formation.

INTRODUCTION

The solvolysis of sulphonium salts (R_3S^+, X^-) with the displacement of an electrically neutral thioether molecule (R_2S) represents a type of reaction where the formal charge of the initial state undergoes delocalization in the formation of the transition state. Such a delocalization phenomenon will be operative in solvolytic mechanisms of both the S_N1 and S_N2 type although to a different degree in each case.

S_N1 type:

$$R_3C{-}\overset{+}{S}R_2 \longrightarrow \left[R_3C^{d+}\cdots\cdots SR_2^{d+} \right] \longrightarrow \underset{\text{Solvolysis}}{\swarrow} R_3C^+ \underset{\text{Elimination}}{\searrow} + R_2S,$$

S_N2 type:

$$B^- + R_3C{-}\overset{+}{S}R_2 \longrightarrow \underset{\text{Transition state}}{\left[B^{d-}\longrightarrow R_3C^{d+}\cdots\cdots SR_2^{d+} \right]} \longrightarrow B{-}CR_3 + R_2S.$$

The effect of lowering the dielectric constant of the solvolytic medium on such a mechanism has been shown by various workers (1, 2, 3) to be an increase in the rate of solvolysis. This is as would be predicted on the basis of increased stability of the charge-dispersed transition state over the formally charged initial state as the dielectric constant is lowered. The behavior is the converse of that normally observed in the more fully studied solvolysis of alkyl halides and benzenesulphonates where charge is created on passing from the initial dipolar to the ion-like transition state.

One of the most thoroughly studied cases of sulphonium salt solvolysis has been that of dimethyl-*t*-butyl sulphonium chloride. In this particular system it is now generally accepted that the mode of solvolysis in media of high dielectric constant (e.g. water) is the S_N1 type mechanism (3, 4, 5, 6). Such a mechanism is reasonable in the case of the dimethyl-*t*-butyl sulphonium ion in water in view of the high solvating power of water and the stability of the intermediate *t*-butyl carbonium ion. It has also been shown (6) that the sulphur isotope effect in this solvolysis is considerable, an observation in keeping with the large distortion of the C—S bond in the S_N1 transition state. In cases such as tribenzyl (7) and trimethyl (7, 8) sulphonium halides, however, the stability of the

[1]*Manuscript received January 13, 1961.*
Contribution from the Department of Chemistry, University of Alberta in Calgary, Calgary, Alberta. Work done partly at Yale University.

incipient carbonium ion is reduced to the point where it is questionable whether an S_N1 mechanism could be operative even in high dielectric media such as pure water. This is especially true in the trimethyl sulphonium salt. Recent work on the ethanolysis of trimethyl sulphonium salts (8) has shown that the anion is intimately involved in the rate-determining step and that the S_N1 type mechanism is extremely improbable as might be expected from a combination of the instability of the methyl carbonium ion and the low dielectric constant of the ethanolic medium.

Although the solvolysis of dimethyl-*t*-butyl sulphonium halides in water proceeds by a predominantly S_N1 mechanism the question immediately arises as to whether this mode of reaction persists as the dielectric constant of the medium is lowered and the stability of the carbonium ion decreases. Swain and Kaiser (7) have suggested several other possible mechanisms including the participation of ion-pairs in the rate-determining step at lower dielectric constant. In order to check the possibility of such ion pairing these authors carried out conductimetric measurements on sulphonium salts in 90% acetone–water solution ($D = 25$) and concluded that the agreement between the measured equivalent conductances and those calculated by the Onsager equation for strong electrolytes was sufficiently close to preclude the presence of a significant degree of ion pairing. Jacobson and Hyne (9) have repeated the conductance study for trimethyl sulphonium iodide in various ethanol–water mixtures using the modified Fuoss method of analysis (10) to determine the degree of ion pairing involved. These latter workers found that, below a dielectric constant of 30, ion pairing in such a system *was* sufficiently significant to be observable as a kinetic effect if the ion pairs participated in a rate-determining step. The purpose of the work reported in this paper and subsequent papers of the series was to investigate the possibility of other mechanisms of solvolysis replacing the S_N1 type as the predominant mode of reaction as the dielectric constant of the solvolytic medium is reduced.

CONDUCTIMETRIC KINETIC MEASUREMENTS

Since the solvolysis of dimethyl-*t*-butyl sulphonium halides involves the replacement of the bulky sulphonium ion by a proton, the rate of reaction can be followed conductimetrically under pseudo first-order conditions with the solvent present in great excess.

$$X^- + (CH_3)_2S^+{-}C(CH_3)_3 + ROH \rightarrow \underset{\text{or olefine}}{(CH_3)_2S} + (CH_3)_3COR + HX \qquad (R = H, \text{ or alkyl})$$

Conductance measurements were made in the usual manner using a precision a-c. conductance bridge (11) and the data analyzed to obtain rate constants by the method of Guggenheim (12). Rate constants were reproducible to better than ±0.5%. Table I

contains rate constants measured at several mole fractions of ethanol in water at 78.4° C for dimethyl-*t*-butyl sulphonium iodide, bromide, and chloride. These data are plotted in Fig. 1(*a*). As the dielectric constant of the solvolytic medium decreases, however,

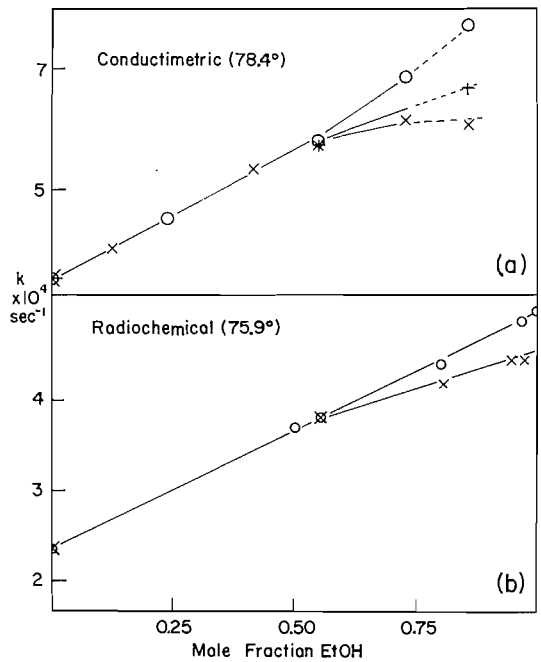

FIG. 1. Rate of solvolysis of 0.001 *M* dimethyl-*t*-butyl sulphonium salts in ethanol–water mixtures; O iodide, + bromide, × chloride.

the hydrohalic acid no longer behaves as a strong electrolyte. This condition is necessary for the valid application of the Guggenheim type of analysis since this method depends upon the assumption that the conductance is a linear function of the concentration. Furthermore at high ethanol compositions the conductance was found to *decrease* as the reaction proceeded, this being shown to be due to the reaction of HX with the alcohol. It is therefore clear that beyond a mole fraction of 0.75 ethanol the conductimetric method is not dependable. Such a back reaction of HX with the alcohol will also introduce errors in rate determinations involving titration of the hydrohalic acid released in the reaction. From Fig. 1(*a*), however, it is clear that it is particularly in this high ethanol composition region that the role of the anion becomes apparent in the rate-determining process.

RADIOCHEMICAL KINETIC MEASUREMENTS

In order to investigate the kinetic behavior of the various dimethyl-*t*-butyl sulphonium salts in the highly ethanolic range of solvent composition the continuous-flow-counting radiochemical technique of Hyne and Wolfgang was applied (13). This method has the advantage of the precision characteristics of the conductimetric technique, but does not suffer from breakdown in low dielectric media. The method depends essentially upon a continuous sampling of C^{14}-labelled dimethyl sulphide as it is produced and swept from the reaction mixture by a stream of inert gas. Labelled materials were prepared as described previously (13). Due to the fact that this method involves an open

reaction system it was not possible to work at 78.4° C as in the conductimetric case due to the proximity of the boiling point of ethanol. It is not necessary, however, to compare (at the same temperature) rate values determined conductimetrically with those determined radiochemically but rather to observe the effect of solvent change on the rates of solvolysis of different salts. Consequently the whole range of solvent compositions was scanned again at a lower temperature using the radiochemical method. In this work, only the chloride and the iodide salts were used. The rates so measured are shown in Table II and plotted in Fig. 1(*b*). It should be noted that the radiochemical

method measures the rate of solvolysis of only the C^{14}-labelled salt.* Consequently if an isotope effect is present the radiochemical and conductimetric methods should not give precisely the same rate even under identical conditions. As was shown previously (13) there is no detectable isotope effect in the hydrolysis (pure water medium) as might be expected due to the fact that at best the effect would be secondary. This does not ensure, however, that the isotope effect might not become important if the mechanism were to change. As stated above, however, the phenomenon under study is the influence of the solvent medium on the rate of reaction, and provided that the labelled salt is used throughout the range of solvents investigated the kinetic data will be internally consistent.

DISCUSSION OF RESULTS

Effect of Anion Type

It is clear from the plots in Fig. 1 that within the solvent range 0.0 to 0.6 mole fraction ethanol any specific effect due to the anion type in the sulphonium salt is not of sufficient magnitude to be detected kinetically. At mole fractions of ethanol greater than 0.6, however, the differences in rates of solvolysis of the various salts become increasingly significant both in conductimetric and radiochemical methods of measurement. It should be noted that it was at approximately the same mole fraction of ethanol that ion pairing was found to become significant (i.e. $>2\%$) in the conductance measurements of Jacobson and Hyne (9).

Effect of Concentration of Salt

In Table III the rates of solvolysis of dimethyl-*t*-butyl sulphonium chloride in water

and 0.55 mole fraction ethanol as reported by various workers are shown. The point of major interest in this data is the effect of change of initial concentration of the salt on the observed rate. At both 78.4° and 50.5° variation in concentration of salt has no measurable effect on the rate of solvolysis in water. In 0.55 mole fraction ethanol, however, the observed rates are significantly different at the three concentrations of the sulphonium chloride used and are higher for higher salt concentrations.

Interpretation of Observed Effects

All the evidence presented in this paper suggests the increasing participation of ion pairing in the rate-determining process as the dielectric constant of the solvolytic medium is reduced. The facts may be summarized as follows.

(*a*) The rate of solvolysis shows an increasing dependence upon the nature of the anion as the solvent dielectric is reduced.

(*b*) The value of the dielectric constant at which the rate begins to show a detectable dependence on the nature of the anion is approximately equal to that at which the degree of ion pairing in sulphonium salts has been shown to become significant.

(*c*) For a given anion the rate of solvolysis shows a dependence on the total initial concentration of salt in low-dielectric media but not in high-dielectric media.

These observations can be explained by the following mechanism.

$$\begin{array}{ccc} R_3S^+ + X^- & \overset{K_A}{\rightleftharpoons} & R_3S^+X^- \\ \downarrow k_+ & & \downarrow k_{ip} \end{array}$$

The sulphonium salt can solvolyze either from an initial free ion state (k_+) or from an initial ion pair state (k_{ip}). When the solvolysis proceeds predominantly from the ion the rate should be virtually independent of the nature of X^- since this species is not involved in the rate-determining transition state. This is as observed in water where K_A (ion association constant) has been shown to be very small (9). As the dielectric constant of the medium is reduced, however, K_A increases and the concentration of ion pairs becomes a significant fraction of the total. An increasing proportion of the reaction can therefore proceed via the ion-pair pathway. The conductance studies of ion pairing of trimethyl sulphonium iodide in ethanol–water mixtures (9) shows less

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

than 2% ion pairs in 10^{-3} M salt below mole fraction 0.55 ethanol, but this figure increases rapidly beyond 0.55 mole fraction ethanol to a value in excess of 10% at 0.95 mole fraction ethanol. It is in such solutions containing greater than 0.55 mole fraction ethanol that rate dependence on anion character is observed.

Although at 10^{-3} M and 0.55 mole fraction ethanol the degree of ion pairing is not sufficient to be kinetically measurable by varying the character of the anion (Fig. 1) higher total concentrations of a given anion will force the equilibrium to the right and the degree of ion pairing will be higher at higher salt concentrations. A greater proportion of the solvolysis will therefore proceed through the ion-pair mechanism. The data of Table III not only substantiate this reasoning by virtue of the variation of rate with concentration but show that the rate of solvolysis from the ion pair must be greater than that from the ion ($k_{ip} > k_+$) since the over-all rate increases with increasing concentration of ion pairs in the system. This relative order of rates is in keeping with the fact that the difference in charge character between the ion pair and the charge-dispersed transition state is less than that between the free ion and the charge-dispersed transition state. Consequently attainment of the transition state from the ion pair will be energetically favored and hence the rate by that path will be greater.

It is seen from Fig. 1 that at a given concentration, temperature, and solvent composition the order of rates of solvolysis, when differences are detectable, is $I^- > Br^- > Cl^-$. This phenomenon could be due to one or both of the following factors. If the order of magnitude of the association constants was $K_A(I^-) > K_A(Br^-) > K_A(Cl^-)$ then under a fixed set of conditions the proportion of the solvolysis proceeding through the ion-pair intermediate would be greatest in the case of the iodide and least in the chloride salt. Since $k_{ip} > k_+$ the observed order of rates would be as found. Assuming the relationship between association constant (K_A) and center-to-center distance (a) in the ion pair (14, 15), $\ln K_A = e^2/aDkT + \text{const.}$, K_A should decrease as the center-to-center distance increases. Presumably as the ionic radius of the anion increases the center-to-center distance in the pair with a fixed cation should also increase. Consequently K_A should *decrease* as the anion is changed from Cl^- through Br^- to I^-. Such an argument would suggest rejection of the explanation of the observed order of rates based on variation of K_A with anion type. However, very few tests have been made of the validity of the relationship where the anion has been varied through a series such as the halides. On the other hand, experimental determination of the degree of association of lithium halides in acetic acid (16) has revealed an order of K_A's LiI > LiBr > LiCl. Similarly the order of association constants for the reaction $Pb^{++} + X^- \rightleftharpoons PbX^+$ in water has been shown to be $I^- > Br^- > Cl^-$ (17). The second possible explanation lies in variation of k_{ip} with the nature of the anion in the ion pair. It would be very surprising if k_{ip} did not vary in such a manner but it is again difficult to predict the direction of the variation without a detailed knowledge of the mechanism of solvolysis of the ion pair. It is noteworthy, however, that the order of rates is that of the order of nucleophilicity of the anions, suggesting a nucleophilic role for these species in the solvolytic mechanism.

CONCLUSIONS

The role of a rate-determining step involving participation of the anion in the solvolysis of dimethyl-*t*-butyl sulphonium salts has been shown to become significant as the dielectric constant of the medium is reduced. Experimental evidence points to the participation being of the ion-pair type but a more thorough analysis of the details of the ion-pair mechanism is required.

AN INFRARED STUDY OF TRIMETHYLAMINE OXIDE, ITS HYDRATE, AND ITS HYDROCHLORIDE[1]

PAUL A. GIGUÈRE AND DAVID CHIN

ABSTRACT

The infrared spectra of trimethylamine oxide, its hydrate, and its hydrochloride in the solid state were measured over the range 300 to 3500 cm^{-1} to ascertain the nature of the bonds in these compounds. From the observed stretching frequencies, 937 cm^{-1} for N—O and 945 cm^{-1} for C—N, the corresponding bond lengths are calculated to be 1.44 and 1.50 Å in agreement with X-ray and electron diffraction data. Both these frequencies remain unchanged in the hydrate and the hydrochloride as could be expected for molecular compounds. However, in the hydrochloride most of the evidence points to an ionic constitution. In both the hydrate and the hydrochloride the hydrogen bonds are particularly strong presumably because of the formal charges.

INTRODUCTION

Trimethylamine oxide $(CH_3)_3NO$ offers the classical example of the so-called "co-ordinate link," an essentially covalent bond between two atoms with opposite formal charges. It was first pointed out by Pauling (1) that the distance between the atoms thus bonded, viz. N^+ and O^-, should not be affected appreciably by the electrical charges. Due to absence of other complicating factors, such as resonance among different valence bond structures, trimethylamine oxide is a suitable molecule to test this hypothesis. A first determination by electron diffraction (2) gave a N—O bond length of 1.36 Å, exactly the sum of the then accepted values (1) for the single-bond covalent radii of the N and O atoms. However, this result now appears inconclusive because, (*a*) the radial distribution method cannot resolve the very close C—N and N—O peaks and, (*b*) in the various models used for the visual comparison method, the N—O bond length was varied only between 1.30 and 1.40 Å since there is no obvious reason why this bond should be much longer than the sum of the covalent radii. In the meantime the latter parameters were found to require a sizable upward revision—to 0.74 Å for both atoms (3). This prompted a reinvestigation of the electron diffraction pattern of trimethylamine oxide (4). Preliminary results (5) indicated a longer N—O bond (1.44 Å) than the original one, and a C—N bond length (1.49 Å) just a little over the sum of the (revised) covalent radii. These two values have been confirmed by a recent X-ray study of the crystalline hydrochloride (6), which gives 1.424 Å for the N—O bond and 1.50 Å for the average of the C—N bond lengths.

The first spectroscopic investigations of trimethylamine oxide were done in Raman effect. Edsall (7) studied the hydrochloride in aqueous hydrochloric acid solution; from the marked resemblance with the spectrum of tertiary-butyl alcohol he concluded to the existence of a trimethylhydroxyl ammonium ion $[(CH_3)_3NOH]^+$. Later Goubeau and Fromme (8) measured the spectra of the oxide dissolved in methanol (Table I). Also by comparison with the spectra of tertiary-butyl alcohol they assigned the band at 947 cm^{-1} to the N—O stretching frequency and estimated the corresponding force constant to lie between 4 and 5×10^5 dynes cm^{-1}. An exploratory infrared study of the crystalline solid carried out in this laboratory (9) revealed some 10 bands between 700 and 3000 cm^{-1}; there also, a band at 943 cm^{-1}, one of the strongest, was assigned to

the N—O bond. While this work was in progress we came across two other communications on the same subject (10, 11) both relating in fact to the hydrate, as we shall see below.

EXPERIMENTAL

The sample of trimethylamine oxide was prepared by oxidation of a 25% aqueous solution of trimethylamine with 5% hydrogen peroxide (12). Repeated crystallizations in methanol gave needle crystals of the dihydrate, from which the anhydrous oxide was obtained by gentle heating under reduced pressure (13). The powder, resublimed twice, was placed in an evacuable absorption cell fitted with rock salt windows. By means of an electric heating tape a thin film of the solid was deposited on the windows. After recording of the spectra, air was admitted in the absorption cell, whereupon the film became hydrated fairly quickly. However, if the film was too thick, complete hydration was very slow. Upon hydration the white, powdery film became transparent. For comparison the spectra of dihydrate crystals were also obtained by the KBr pellet technique.

The same method was used for the hydrochloride, prepared by addition of hydrochloric acid to an aqueous solution of trimethylamine oxide. The crystals, purified by recrystallization, melted at 217–218° C with some decomposition. Two spectrometers were used: a Perkin–Elmer, Model 112, with NaCl and CsBr optics, and a Beckman, Model IR-4. Numerous attempts to secure the spectrum of the amine oxide in the vapor state were unsuccessful. A short (10 cm) glass absorption cell and a long-path (1 m) metal cell were tried in succession. Because of the low volatility of the oxide the sample had to be heated to about 180° C to produce measurable absorption. However, at that temperature the vapor decomposed rapidly and reacted with the salt windows.

DISCUSSION

In interpreting the spectra of trimethylamine oxide (Fig. 1) it is convenient to consider

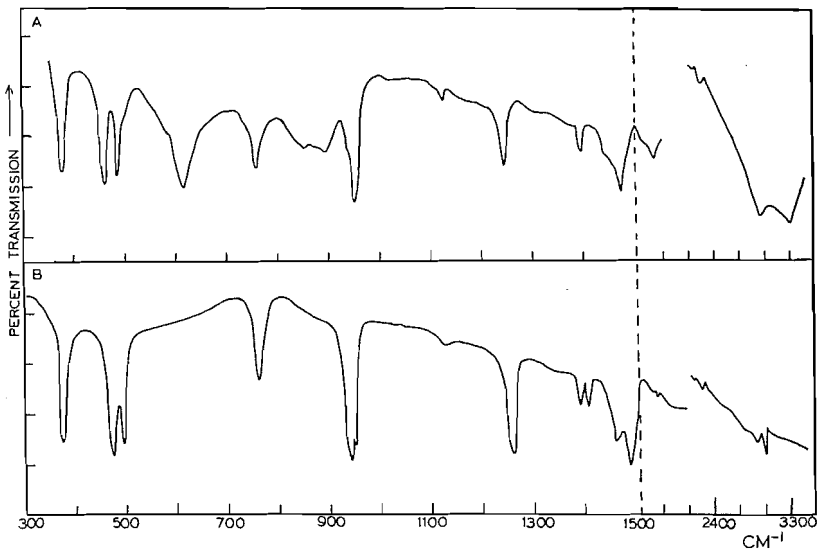

FIG. 1. Infrared spectra of the hydrated (A) and anhydrous (B) trimethylamine oxide.

the CH_3 groups as single atoms R of mass 15. The resulting XY_3Z type of molecule is of C_{3v} symmetry, with six fundamental frequencies all active in infrared and Raman. For further simplification frequencies above 1200 cm^{-1} (Table II) may be ignored here as they arise either from combination tones or from vibrations in the CH_3 groups. The latter are already well known from analysis of the spectra of trimethylamine (14, 15) and similar molecules. Assignment of the various fundamentals of the R_3NO molecule is best made by correlation with those of the isoelectronic tetramethyl ammonium ion R_4N^+ (15). As shown in Table III the two symmetrical vibrations ν_1 and ν_2 of that ion have practically the same frequencies in the oxide, ν_2 and ν_6. On the other hand the two triply degenerate vibrations ν_3 and ν_4 of RN_4^+ are split in the oxide molecule into one non-degenerate and one doubly degenerate vibration: viz. ν_3 at 955 cm^{-1} splits into a doublet at 937 cm^{-1} and 945 cm^{-1}, and ν_4 at 455 cm^{-1}, into a pair at 490 and 472 cm^{-1}.

Present assignment of the infrared frequency at 937 cm^{-1} (missing from the spectra of trimethylamine) to the N—O stretching mode follows that of the strong Raman shift at 947 cm^{-1} (8). Apparently it was not feasible in the latter spectra to separate the two very close stretching frequencies ν_1 and ν_4. Even in this work the doublet could be clearly resolved only in fairly thick samples and with the maximum resolving power available. Gallais and his co-workers (10) have reported a strong band at 1060 cm^{-1} which they assigned to ν_4. No significant absorption could be detected at that frequency in repeated recordings of our spectra of both the oxide and the hydrate (Table II); none was found either in an independent investigation of the latter compound (11). Since no experimental details were given by the French authors on preparation and purity of their samples it is not possible to account for that result. At any rate it is quite certain from the near identity of their reported spectra for trimethylamine oxide and its hydrate

that they were actually working with the same compound, namely the latter, in both cases. Indeed, the partial pressure of water vapor over the hydrate is less than 2.5 mm Hg at room temperature (16) so that unless special precautions are taken, as described above, atmospheric humidity almost always will be sufficient to hydrate completely the very hygroscopic amine oxide.

An attempt was made to calculate from the above frequencies the two bond force constants f_{N-O} and f_{C-N}. Equations of a valence force systems for a tetrahedral XY_3Z molecule (17) were used assuming force constants for bending modes to be one-tenth of those for stretching modes. Unique values could not be obtained, but only the following estimates.

	f ($\times 10^{-5}$ dyne cm^{-1})	r (Å)
N—O	3.8 to 4.8	1.44±0.03
C—N	3.1 to 3.4	1.51±0.01

The bond lengths are from application of Badger's rule. These values agree exactly with the results of the more recent electron diffraction (5) and X-ray diffraction measurements (6). From comparison with other molecules such as NH_2OH, HNO_2, etc. (5) it is obvious that the N—O "co-ordinate link" in trimethylamine oxide has roughly the same length as a "normal" N—O single bond as predicted by Pauling. The relationship suggested by Schomaker and Stevenson (18) also yields a N—O bond length (1.435 Å) very close to the present result; for the C—N bond, however, it gives a slightly shorter distance (1.465 Å) than the experimental value, although the difference is still within the limits of uncertainty of the latter. On the contrary Pauling had predicted for that bond an appreciable shortening (about 0.03 or 0.04 Å) from the normal single-bond length.

The spectrum of the hydrate, or more correctly the dihydrate, is shown in Fig. 1A and the principal frequencies are listed in Table II. Essentially identical spectra were obtained with the two kinds of samples used, viz. thin hydrated films and KBr pellets. Since, in addition, they agreed closely with the results of an independent investigation over the NaCl range (11) there is little doubt about the identity of the compound studied. As may be gathered by comparison, the spectrum of the dihydrate bears strong resemblance to that of the anhydrous oxide; particularly the N—O stretching band which retains the same frequency, 937 cm^{-1}. (The reversed intensity ratio with the C—N band at 950 cm^{-1} may be due to hydrogen bonding.) From this it is safe to infer the molecular nature of the dihydrate crystal. Indeed, the trimethylhydroxide ammonium ion $[(CH_3)_3NOH]^+$ suggested before (7, 10) would normally have a somewhat different N—O stretching frequency from the above. Furthermore, one would expect for that ion an OH bending frequency and a low-lying OH wagging frequency not found in our spectra. The O—H stretching mode cannot, obviously, yield any conclusive evidence, being indistinguishable from that in H_2O. Lüttke found a slightly lower value (3236 cm^{-1}) than that reported here, but the nearness of the C—H stretching frequencies makes these figures rather uncertain.

On the other hand all the new features in the spectra of the dihydrate may be accounted for satisfactorily in terms of vibrations of the H_2O molecules. Besides a strong O—H band at 3 μ, of which there is no trace in the anhydrous oxide, the broad, rather weak band centering around 1690 cm^{-1} must belong to ν_2, the bending mode. This frequency

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

is appreciably higher than in pure water, 1650 cm^{-1} (19), which may be due to loss of symmetry of that mode because of unequal hydrogen bonds. In all probability one of the H atoms of each water molecule is hydrogen bonded to the O atom of trimethylamine oxide; now it is conceivable that the negative formal charge on the latter atom enhances its attraction for the proton, hence a strengthening of hydrogen bonds. The same explanation holds for the three separate broad bands at 893, 852, and 620 cm^{-1} attributable to the three libration modes of H_2O molecules. In pure water these appear to merge into a single broad band with center at about 710 cm^{-1} in the liquid and at 800–850 cm^{-1} in ice (19). Formation of especially strong hydrogen bonds between the two kinds of molecules may be linked with the great stability of the dihydrate as mentioned above. Finally, it is worth recalling here that the low electrical conductivity of aqueous solutions of trimethylamine oxide has long ago been interpreted as proof of non-ionization of the dihydrate (20).

On the contrary, the infrared spectrum of the hydrochloride (Fig. 2) shows some

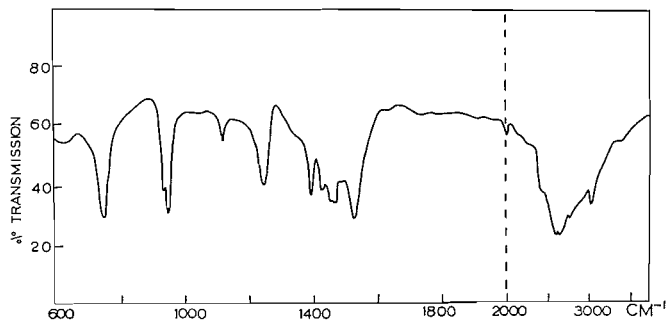

FIG. 2. Infrared spectrum of trimethylamine oxide hydrochloride, $(CH_3)_3NO.HCl$.

significant differences from those of the oxide and the dihydrate. True, the C—N and N—O stretching frequencies are unchanged (939 and 950 cm^{-1}) contrary to expectation for an ionic compound. (In hydroxylamine (21), for instance, the N—O frequency at 926 cm^{-1} is shifted to 1000 cm^{-1} in the hydrochloride.) However, the appearance of new, strong bands, notably at 1530 cm^{-1} and around 2600 cm^{-1}, is certainly due to OH vibrations of the $[(CH_3)_3NOH]^+$ species. Very strong hydrogen bonds between that ion and the chloride anion must be responsible for the rather high OH bending frequency and, correspondingly, for the low OH stretching frequency. Rérat (6) has deduced an ionic structure for the hydrochloride on the basis of his X-ray data, particularly (*a*) the measured O—Cl distance (2.94 Å), which is definitely shorter than the sum of the van der Waals radii (3.2 Å), and (*b*) the near tetrahedral (110.4°) NOCl angle. Yet it should be pointed out that these features are equally compatible with a molecular structure since (*a*) there is no reason a priori why the over-all distance in O—H . . . Cl should be any different from that in O . . . H—Cl and (*b*) hydrogen bonds have a tendency to become oriented along the direction of lone-pair orbitals (22). Thus sp^3 hybridization of the oxygen orbitals could account as well for the observed NOCl angle.

RÉSUMÉ

On a étudié les spectres infrarouges de la triméthylaminoxyde, de son hydrate et son chlorhydrate afin de déterminer la nature de ces composés. La fréquence des vibrations N—O (937 cm^{-1}) et C—N (945 cm^{-1}) permet d'évaluer la longueur de ces liaisons à 1.44 Å et 1.50 Å respectivement en bon accord avec les résultats d'études récentes par diffraction des rayons X et des électrons. Le spectre du dihydrate indique qu'il s'agit d'un composé moléculaire, tandis que le chlorhydrate est très probablement ionique. Dans ces deux composés les charges nominales conduisent à des liaisons hydrogène particulièrement fortes.

THE KINETICS OF THE REACTION OF SILICA WITH GROUP I HYDROXIDES[1]

J. G. Hooley

ABSTRACT

A method is presented for preparing a reproducible silica glass or quartz surface that does not craze during rate of solution measurements in solutions of the five group I hydroxides. For silica glass, initial rates are a maximum at 8 *M* for at least NaOH and KOH and are an inverse function of ion size for the five cations and tetramethyl ammonium ion. A proposed mechanism of water addition followed by reaction with hydroxyl ion is used to explain the maximum rate and the effect of solution products and the substitution of methanol for water as a solvent. For quartz an explanation is offered for the lower rate and for the absence of a maximum rate below 27 *M* NaOH. A common temperature coefficient of 20 kcal mole^{-1} is reported for all reactions in water. The crazing of finely ground or polished silica glass surfaces is related to the presence of surface cracks and their enlargement by possible conversion of some silica to quartz in NaOH solution.

INTRODUCTION

The reactivity of commercial silicate glasses with a variety of aqueous solutions has been extensively studied (1) usually with the object of predicting the behavior of the glass under practical conditions. The reaction of colloidal silica with aqueous NaOH has also received considerable attention (2, 3). The behavior, however, of massive silica glass with alkali solutions has not been studied beyond measuring the rate in a few isolated cases. The object of the present work was therefore to investigate the rate of attack of one of the simplest glasses—fused silica—by alkali solution and thereby to elucidate the mechanism of the reaction. All the group I hydroxides were used as well as tetramethyl ammonium hydroxide and some runs were made with methanol as a cosolvent and others with quartz instead of silica glass.

MATERIALS

1. Silica and Quartz

All the vitreous silica samples were of Vycor 7900, a Corning Glass Works product which is about 97% SiO_2, 3% B_2O_3, 0.3% Al_2O_3, and <0.02% Na_2O. Samples 4×4 cm were cut from 6 mm thick panels and ground against a rotating iron disk using a water suspension of aluminum oxide grit. The edges and corners were rounded and they and all the flat surfaces were ground until perfectly uniform to the eye before etching with HF as described under Methods.

For crystalline silica, eight samples from 1.0 to 1.5 cm on an edge were cut from colorless crystals of natural quartz, ground as described above, and then polished with rouge in water on a rotating felt pad.

2. Basic Solutions

The hydroxides of Li, Na, and K were of the best commercial grade. Exposure to air was minimized to reduce CO_2 absorption and fresh solutions were used in all runs.

The RbOH was made from a mixture of nitrate and chloride of very high purity from atomic weight work. It was converted to the sulphate and then to the hydroxide with $Ba(OH)_2.8H_2O$. The filtered solution was evaporated to 100 ml in a large silver tube in

[1]*Manuscript received February 13, 1961.*
Contribution from the Department of Chemistry, University of B.C., Vancouver, B.C., with financial assistance from President N. A. M. MacKenzie's Research Fund.

a CO_2-free atmosphere. All runs were made with this solution, lower concentrations being obtained by dilution. The normality was determined for each run by titrating a pipetted sample.

The CsOH was prepared and used in a similar manner, the starting material being very pure $CsCl_2I$.

Tetramethyl ammonium hydroxide was prepared from the bromide with a suspension of freshly prepared silver oxide. The AgBr was filtered off and the clear solution was diluted to 1.40 *M*.

METHODS

The following experimental details were first studied in NaOH solution to arrive at a procedure that would give the initial rate of attack of a reproducible surface.

1. Surface Treatment

(a) Vitreous Silica

The surface of Vycor 7900 whether polished with rouge or ground only with fine grit crazed in 2 *N* NaOH at 80° C. Pure fused silica (Vitreosil) behaved similarly. That is, the surface became increasingly covered with visible cracks about 1 mm long and a fraction of a millimeter deep. The surface remained smooth to the touch, however, until the cracks began to shed small chips of glass anywhere from a few hours to a few days after the action began. Weight losses per unit area varied widely even when based on surfaces that had not lost any chips and it is perhaps for this reason that so little work has been done on the reactivity of silica glass with alkali solutions.

If a finely ground or polished surface was treated with a 50 volume% solution of concentrated H_2SO_4 and 60% HF for 15 minutes before immersion in alkali there was no sign of crazing until several days had elapsed in 2 *N* NaOH at 80° C. A surface freshly formed by breaking behaved in the same fashion as did the acid-etched sample. In all the above cases, crazing occurred sooner if the NaOH solution was contained in a tube of Pyrex than if it was in one of iron or silver. If crazing is initiated in the invisible cracks in the surface of ground or polished glass its elimination by etching is explained because this process removes the scratched surface and exposes a virgin one that indeed resembles a freshly formed surface. Whatever the cause of crazing it can be eliminated for the 15-hour runs employed in this work by etching the finely ground surface with HF. Prepolishing is unnecessary because the subsequent etching produces a translucent surface that resembles the nonpolished one and that exhibits the same weight loss in alkali solution.

(b) Quartz

A surface ground with fine grit also crazed in alkali but it was not possible even to try to prevent this by acid etching because the HF also caused crazing. It was found that unlike the surface of silica glass, however, a surface polished with wet rouge on felt showed crazing only after 200 hours in 2 *N* NaOH at 80° C. Polished quartz was therefore used in 72-hour runs and all samples were reground and polished before each run. The regrinding was necessary to remove the irregular surface pattern produced by NaOH solution. These patterns were observed to repeat themselves in subsequent runs.

Finally, for both silica glass and quartz the sample was suspended by a loop of silver wire near the center of a silver tube 5 cm in diameter and 30 cm long. The tube contained 300 ml of solution (less for some of the Rb and CsOH runs) and was immersed in a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

constant temperature bath held to ±0.1° C. A fitted, water-cooled condenser prevented loss of solvent. In handling the samples great care was taken to prevent any scratching against glass or metal. The samples of quartz were warmed and cooled slowly in the reacting solutions to prevent cracking.

2. Stirring

Any effect of stirring on the rate of attack of Vycor by 1 *M* or 16 *M* NaOH at 80° C was found to be less than the experimental error of 3%. In one series of experiments the solution above the suspended sample was stirred at a speed that raised the level at the periphery of the tube about 7 cm. In another series the sample was a sealed Vycor tube 1 cm in diameter and 12 cm long which was rotated in the solution at a similar speed.

3. Time of Reaction

The effect of time and therefore of the dissolved silica on the rate of solution of Vycor in NaOH solution at 80° C was studied by using the same solution for a series of 8-hour runs. Between these runs measured weights of silica were allowed to dissolve from a weighed Vycor sample left in the solution. The concentration of NaOH in the reaction tube was kept constant by washing the samples with water as they were removed from the solution and then adjusting the volume to its original value by evaporating off the excess water introduced in this way. All samples were etched before each run to prevent crazing. In Fig. 1 the average rate for each 8-hour run is plotted against the total weight

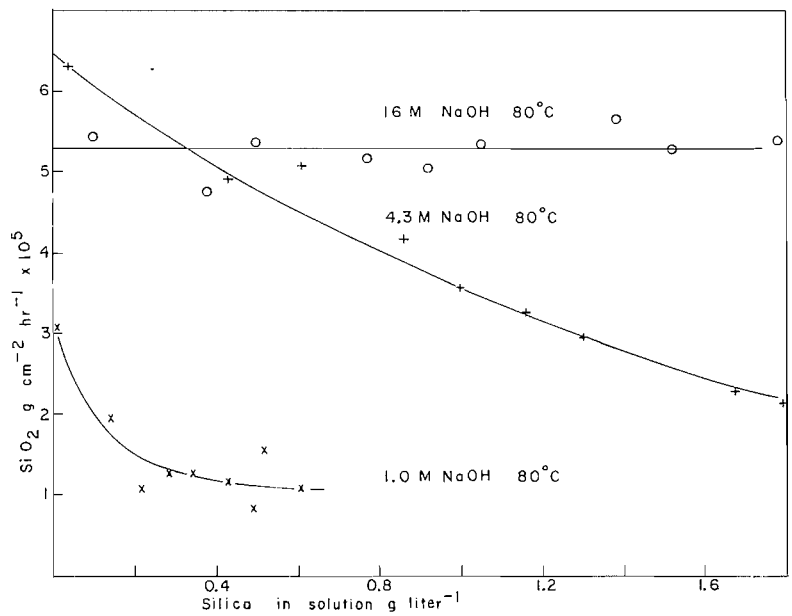

FIG. 1. Rate of solution of Vycor 7900 at 80° C vs. total silica in solution.

of silica that had accumulated in the solution. The reaction products are seen to have an inhibitory effect in 1 *M* NaOH, less in 4 *M*, and none in 16 *M*. Because initial rates are sought in this work the reaction times were later chosen so that the error introduced by dissolved silica would be less than 3%.

RESULTS

1. *Vitreous Silica*

(a) Reproducibility

In one duplicate series of eight concentrations from 0.1 to 10 *M* NaOH at 80° C for 15 hours the weight losses per sq. cm of the Vycor samples showed a root mean square deviation of 3% from the averages. In other duplicate runs the precision was at least that value as long as no crazing had occurred. Area differences between samples were never found to affect reproducibility.

(b) Vycor 7900 Compared with Vitreosil

Clear Vitreosil from the Thermal Syndicate Co. in England is made by fusing quartz and is therefore more pure than Vycor. Four samples of each in 2 *M* NaOH at 80° C showed the same rate of attack within experimental error. Hence for these conditions, at least, the 3% B_2O_3 in Vycor has no measureable effect on the rate.

(c) Concentration of Group I Hydroxide

The initial rate at 80° C is plotted against molarity in Fig. 2. For NaOH and KOH

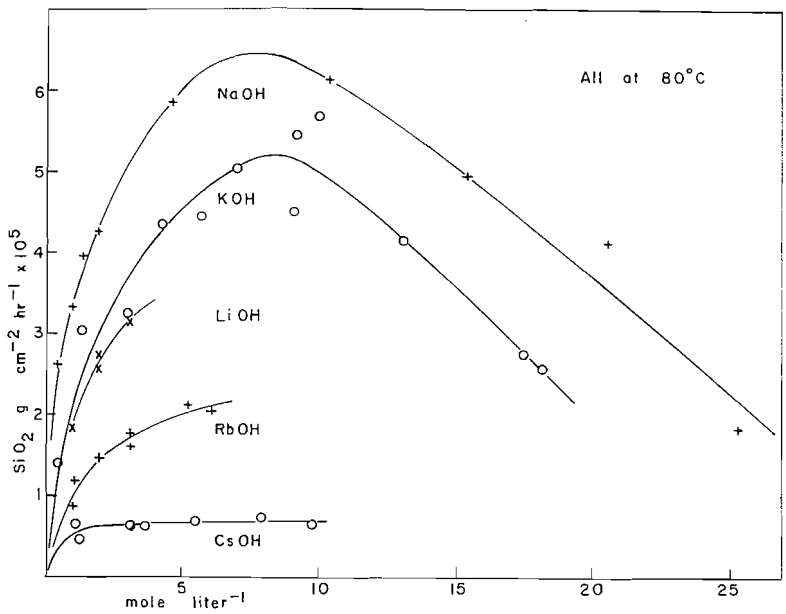

FIG. 2. Rate of solution of Vycor 7900 at 80° C vs. concentration for various alkali hydroxides.

there is a maximum rate at about 8 *M*. For the other three, data at high concentrations are not available because of a solubility limitation for LiOH and lack of material for Rb and CsOH. However, a maximum rate at 8 *M* would not be inconsistent with the data.

One run was made with the eutectic of 2.6% LiOH, 23.6% NaOH, and 73.8% KOH, which, because of impurities (probably water and carbonates), melted at 135° C instead of 70 to 80° C. Its molarity, assuming additive densities, was 41. In a 5-hour run at 146° C the rate was 91×10^{-5} g cm^{-2} hr^{-1}. If the temperature coefficient found in the next section is used to calculate the rate at 80° C, a value of 1×10^{-5} is obtained.

In 1.40 *M* tetramethyl ammonium hydroxide at 91.5° C, duplicate samples each lost 5.8×10^{-5} g cm^{-2} hr^{-1}, which is about the same as in 1.4 *M* KOH.

(d) Temperature Coefficient

The effect of temperature on the rate with NaOH is shown in Fig. 3. The Arrhenius

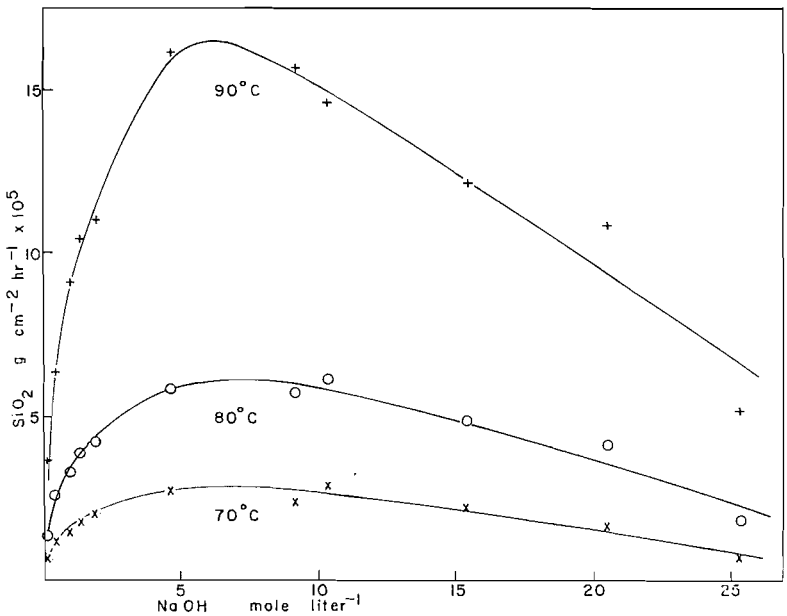

FIG. 3. Rate of solution of Vycor 7900 vs. NaOH concentration for three temperatures.

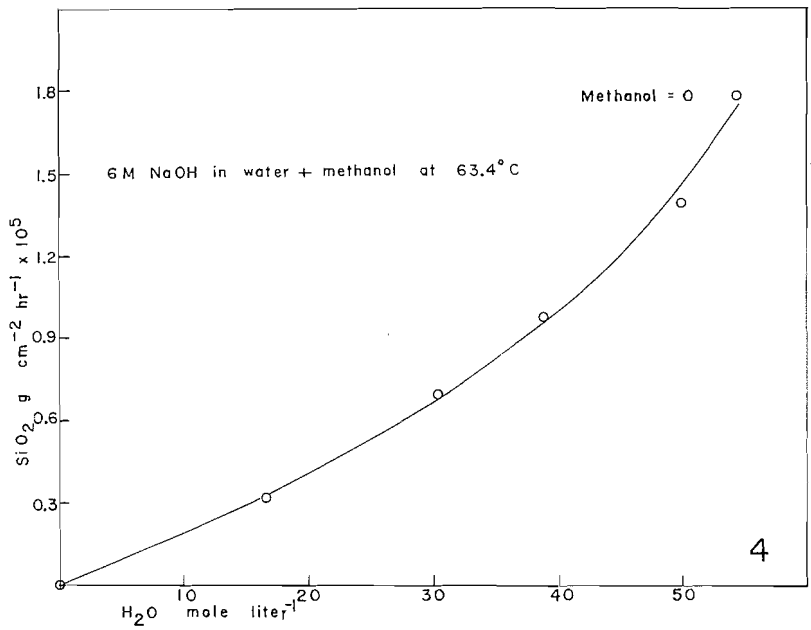
plots made from these curves at 2, 8, and 20 *M* are linear and give activation energies of 22 kcal at each concentration. For the reactions with KOH (2, 9, 18 *M*), RbOH (1, 3 *M*), and CsOH (1, 3 *M*) at 70°, 80°, and 90° C the Arrhenius plots show the same linearity as for NaOH and give activation energies of 20, 18, and 22 kcal $mole^{-1}$ respectively. The variation in calculated energy is not regarded as significant and an average value of 20 ± 2 kcal $mole^{-1}$ for all four hydroxides at all concentrations is suggested.

(e) Solvent

To study the effect of the concentrations of water and of NaOH separately, a mixed solvent of alcohol and water was used. In one series, the molar concentration of NaOH was held constant at 6.0 *M* and the concentration of water was varied by substituting methanol. The rate at 63.4° C is plotted in Fig. 4 against water concentration and is seen to increase smoothly from zero for pure methanol to the value for pure water. A similar curve was obtained for ethanol although the water concentration could not be taken below 750 g $liter^{-1}$ at 78° C because of solubility limitations.

In a second series, the water concentration was held constant at 800 g $liter^{-1}$ and the NaOH was varied, methanol being the third component. The rate at 63.4° C is plotted in Fig. 5 against NaOH concentration and is seen to go through a maximum at 8 *M*.



2. Quartz

(a) Concentration

The rates at 91.5° C plotted in Fig. 6 against concentration are each the average for four different quartz cubes, the standard deviation being equal to the length of the vertical line drawn through the point. The same four cubes were used for each of the

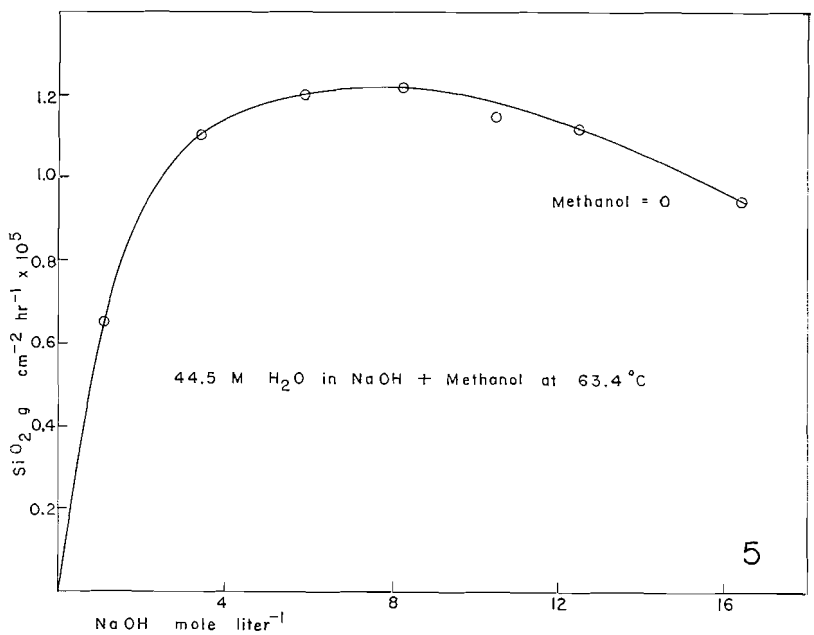

FIG. 4. Rate of solution of Vycor 7900 vs. water concentration for 6 *M* NaOH in water + methanol.
FIG. 5. Rate of solution of Vycor vs. NaOH concentration for 44.5 *M* H_2O in methanol.

three lowest concentrations and the other four for the remaining concentrations. The precision is less than for fused silica because of the much lower rate of reaction. There is, however, no evidence for a maximum rate below 27 *M*.

(b) Temperature

The rates for duplicate runs at two concentrations and three temperatures are listed

rates, the data is only of sufficient accuracy to say that the activation energy is 21 ± 4 kcal $mole^{-1}$.

(c) Solvent

There was no measurable weight loss after 140 hours in 1.4 *M* NaOH in ethanol at 78° C.

DISCUSSION

Any reaction mechanism with silica glass must explain the following.

1. A maximum in the plot of rate against concentration.
2. The variation of rate with cation.
3. The inhibitory effect of dissolved silica at low NaOH concentrations but not at high ones.
4. The small or zero variation in temperature coefficient with concentration.
5. The experiments with NaOH in methanol–water mixtures.

Also of interest in the case of quartz are its low reactivity and the absence of a maximum rate below 27 *M* NaOH.

For both silica glass and quartz two consecutive reactions are proposed. First an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

adsorption of water followed by reaction with hydroxyl ion to produce soluble products. The two can be represented in several simplified ways, one of which is:

$$SiO_2(s) + 2H_2O(l) \rightarrow SiO_2.2H_2O(s), \quad [1]$$

$$SiO_2.2H_2O(s) + 2OH^- \rightarrow [Si(OH)_6]^{-2} \text{ in solution.} \quad [2]$$

In more detail, the surface of the silica being exposed for reaction consists largely of oxygen ions because the small, more highly charged silicon ions are well shielded by the highly polarizable oxygen ions. This concept of the surface of an ionic crystal has been discussed by Weyl (4) and has been recently reviewed by Benson and co-workers (5). It is realized that the silica structure has considerable covalent character and that the actual charges on the "ions" are less than +4 and −2. The important point is that the silicon atom or ion is sufficiently buried below the surface so that hydroxyl ion alone will not react with it. This is supported by the zero rate in methanolic NaOH in which only OH^-, Na^+, and solvent are present. Now the addition of water causes reaction [1] to occur. This equation represents water adsorption on the silica surface by hydrogen bonding to the oxygen "ions" of that surface. This transfer of negative charge toward the water molecules decreases the screening so that the silicon "ions" can now combine with any hydroxyl ions present to form a soluble co-ordination complex. The formula suggested in equation [2] is only for illustrative purposes. If water and no hydroxyl ion is present as in NaCl solution the theory correctly predicts no attack. It also predicts for aqueous solutions of alkali hydroxides the observed maximum rate. Thus at low molarity and therefore high water concentration reaction [2] will be the rate-determining step and so the rate will increase with molarity as observed. However, at high molarity and therefore low water concentration reaction [1] becomes the rate step and hence the rate decreases as molarity increases as observed. A maximum rate at some intermediate concentration is the result. The rate should go to zero for the nonaqueous eutectic mixture of three hydroxides. That it did not quite do this is believed to be caused by a small amount of water in the system.

The theory predicts, of course, a maximum rate not only for silica glass but also for quartz which was not observed below 27 *M*. However, the rate did go to zero for methanolic NaOH in which there is hydroxyl ion but no water. It is therefore believed that for aqueous solutions a maximum rate would be reached above 27 *M*. That it is at a higher concentration than in the case of silica glass means that for quartz, reaction [2] has been slowed more than [1] and therefore remains the rate step to higher molarities. This is reasonable because the surfaces of the two forms of silica are predominately oxygen "ions" and so should react about equally with water as in reaction [1]. Reaction [2], however, involves the penetration of the surface and reaction with silicon ions. These ions have a higher potential energy in the glass and therefore react more rapidly than when in the crystalline quartz.

The variation of rate with cation size is difficult to explain. It may simply be that the larger the cation, the greater the interference with the above reactions by adsorption and the lower the rate as was observed. The apparent discrepancy with LiOH disappears when account is taken of its low dissociation—about 50% in 3 *M* solution (6, 7). Even tetramethyl ammonium ion fits in if the effective area is taken as that of the base of the tetrahedron.

The effect of dissolved silica on the rate is correctly predicted. Thus the inhibitory effect should be greatest at low molarity where [2] is the rate step and should disappear for concentrated solutions where [1] is the rate step.

The temperature coefficient would be expected to depend on whether reaction [1] or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[2] is the rate step and on whether silica glass or quartz is involved. The data, however, were not sufficiently precise to detect differences caused by these factors. Some recent work on finely divided silica (3) reports an activation energy of 18 kcal mole^{-1} for the solution of this material in dilute alkali and 17.8 for solution in water. The agreement of these with the 20 ± 2 for this work is rather good. The comparison, however, should be confined to reaction [2] for complete solution because reaction [1] is only a surface reaction and not a solution process.

In discussing the results with methanol as a solvent it is important to have an estimate of the concentration of hydroxyl ion in a solution of NaOH in pure methanol. Conductivity and transference-number data are available for a dilute solution of KOH in methanol plus 0–100 mole% water at 25° C (8, 9). In this range of solvents the conductivity increases from 90 to 260 ohm^{-1} cm^2 and the transference number of hydroxyl ion changes from 0.5 to 0.7. Hence for a given molarity of KOH the hydroxyl ion is conducting about 25% as much in pure methanol as in pure water. Thus in Fig. 4 the 6 *M* NaOH solution in pure methanol should contain of the order of 1 *M* hydroxyl ion. Because there is no water, however, theory predicts the observed zero rate of reaction. When water is added, the rate increases with water concentration because reaction [1] is the rate step. At a sufficiently high water concentration one would expect reaction [2] to become the rate step and, because the concentration of NaOH is constant, the rate to become constant. However, the dissociation of NaOH is increasing with water concentration so that the rate continues to increase in this region as well. For the other experiment in Fig. 5 at constant 44 *M* water concentration, theory predicts the initial zero rate at zero hydroxyl ion concentration and the subsequent increase. However, the rate should become constant as reaction [1] becomes the rate step. Instead, it goes through a maximum which may be explained by the removal of available water from the system to hydrate the increasing concentration of sodium ions.

Finally, the phenomenon of crazing should be discussed. This occurs on a silica glass surface, whether finely ground or polished, but not when etched with HF or when freshly formed as in breaking. Because the first two surfaces are known to contain invisible cracks and the latter two none, it is believed that crazing starts at or in such cracks. Their enlargement to visible dimensions must now be explained. A simple solution process would do this but if that is the mechanism, then one would also expect crazing in surfaces of Pyrex or soft glasses in general. But these surfaces never craze in alkali even though they are known to contain invisible cracks. Another mechanism that would enlarge cracks is the conversion of the glass to the crystalline form. The resultant volume decrease would explain the enlargement to visible dimensions and the eventual chipping out of a piece of glass from the crack. Such conversion has never been reported in solution for Pyrex or soft glass but is known to take place readily for silica glass at 400° C and 340 atm in solutions of sodium silicate (10) or NaOH (11). It is suggested that even at 80° C this conversion to α quartz occurs to some extent. The fact that crazing is more rapid when sodium silicate is present in the NaOH solution supports this theory. We are now left with the case of quartz for which a finely ground surface crazes in alkali and in HF solution and for which a polished surface does not craze in alkali until after at least 200 hours at 80° C. No theory for this is offered.

CONCLUSION

The rate of reaction of silica glass or quartz with solutions of group I hydroxides is chemically controlled by one or the other of two consecutive reactions depending on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

molarity of the base. In being chemically rather than diffusion controlled, it resembles the reaction with hydrofluoric acid (12). A theory is offered to explain the crazing of silica glass but not of quartz.

PRIMARY METHOXY RADICAL FORMATION IN THE REACTION OF METHANOL VAPOR WITH Hg 6($^3P_1$) ATOMS[1]

ARTHUR R. KNIGHT AND HARRY E. GUNNING

ABSTRACT

A study has been made of the decomposition of methanol vapor by Hg 6($^3P_1$) atoms, under static conditions, at 25° C. A system constructed entirely of quartz was employed to eliminate the dark reaction between methanol vapor and pyrex glass to form trimethyl borate. Emphasis in this investigation was placed on the determination of the nature of the primary processes operative, and to this end, the reaction was studied in some detail in the presence of nitric oxide.

For pure methanol, the major primary products were found to be hydrogen and ethylene glycol. The primary quantum yield for hydrogen was 0.46. Minor products of primary origin were formaldehyde (0.01), ethane (0.005), and dimethyl ether (0.006), with the numbers in parentheses showing the primary quantum yields.

In the presence of nitric oxide, the major products became methyl nitrite, nitrous oxide, and water. The quantum yield of methyl nitrite rose steadily with increasing NO concentrations. For a 1:1 CH_3OH:NO mixture, the primary quantum yield for methyl nitrite was found to be 0.56. The behavior of the reaction in the presence of NO establishes fairly unequivocally that the major primary process involves O—H bond scission to form methoxy radicals and H atoms. These primary radicals then form hydroxymethyl radicals by abstraction reactions with the substrate. The ethylene glycol product arises by recombination of the secondary hydroxymethyl radicals. These conclusions were further substantiated by mass spectrometric analysis of the products of the decomposition of CD_3OH. It was shown that CD_2OD is a significant product of the reaction.

INTRODUCTION

The reaction of methanol vapor with Hg 6($^3P_1$) atoms has been studied previously (1, 2), and in detail by Phibbs and Darwent (3) from 25–500°. From the fact that H_2 ($\Phi = 0.43$) and $HOCH_2CH_2OH$ were the major products at 25°, they concluded (3) quite reasonably that the major primary process was:

$$CH_3OH + Hg\ 6(^3P_1) \rightarrow CH_2OH + H + Hg\ 6(^1S_0). \quad [1]$$

The observed products could also be explained by the two-step sequence:

$$CH_3OH + Hg\ 6(^3P_1) \rightarrow CH_3O + H + Hg\ 6(^1S_0) \quad [2]$$

$$CH_3O + CH_3OH \rightarrow CH_3OH + CH_2OH. \quad [3]$$

For both [1] and [2] the H atoms formed are assumed to attack the methyl group of the substrate:

$$H + CH_3OH \rightarrow H_2 + CH_2OH. \quad [4]$$

Phibbs and Darwent rejected [2] as an important primary process since they found that CH_3OD substrate produced little HD. However, the results of a number of more recent studies have indicated that the methanol reaction should be re-examined. Thus Takezaki and Takeuchi (4) showed that methanol is readily decomposed by CH_3O radicals from the pyrolysis of dimethyl peroxide. From detailed studies on the photolyses of CH_3COOCH_3 and CH_3COOCD_3, Wijnen (5) has concluded that CH_3O radicals are very efficient in abstraction reactions. For reaction [3] specifically, Gray and Williams (6) estimate an exothermicity of 7–8 kcal/mole.

[1]*Manuscript received January 20, 1961.*
Contribution from the Department of Chemistry, University of Alberta, Edmonton, Alberta.

In the photolysis of methanol vapor below 2000 Å, Porter and Noyes (7) found evidence that O—H bond scission is an important primary process. Their ethylene glycol product was attributed to combination of CH_2OH radicals from [3]. In this laboratory interest arose in the reaction of methanol with Hg $6(^3P_1)$ atoms, from an investigation of the decomposition of water vapor by ^{202}Hg $6(^3P_1)$ atoms, photoexcited in natural mercury vapor. Here Pertel and Gunning (8) found that the HgO product of the reaction was enriched in ^{202}Hg, indicating the formation of an Hg—O bond in the primary quenching reaction. Since the oxygen atom was a quenching site in the HOH reaction, it appeared likely that a similar process would be operative in the CH_3OH reaction.

In the present study, emphasis has been placed on the nature and relative importance of the primary reactions. In order to distinguish between reactions [1] and [2], it was decided to use nitric oxide as scavenger. It was presumed the CH_3O radicals would react readily with NO to form methyl nitrite, thereby suppressing reaction [3]. Since the alkyl nitrites are relatively stable compounds, the technique could be of general value in alkoxy radical reactions.

While the results of the present study were being prepared for publication, a paper appeared by Pottie, Harrison, and Lossing (9), wherein important data were reported on the reaction of Hg $6(^3P_1)$ atoms with methanol vapor, at a substrate partial pressure of 5 μ in helium carrier at 55°. The primary fragments from the reaction were identified by mass spectrometry via their combination products with CD_3 radicals from the *in situ* decomposition of $Hg(CD_3)_2$. With CD_3OH as substrate, CD_3OCD_3 was found to be the major combination product. It was estimated that CD_2OH could not account for more than 3% of the primary decomposition. Since CH_3, CH_4, C_2H_6, and CH_3OCH_3 were found as products from the reaction with CH_3OH alone, together with an amount of water roughly equivalent to the CH_3 yield, it was concluded that in addition to [2], a second primary process,

$$CH_3OH + Hg\ 6(^3P_1) \rightarrow CH_3 + OH + Hg\ 6(^1S_0), \qquad [5]$$

was occurring to an extent of ca. 18%. The results of Pottie *et al.* (9) will be compared with those of the present study later in this paper.

EXPERIMENTAL

Exploratory runs were first made in a conventional high-vacuum system of pyrex glass, using cylindrical quartz reaction cells. The reaction was studied under static conditions at 25°. Analyses were made by gas–liquid partition chromatography (G.L.P.C.) and mass spectrometry. Product yields were found to vary erratically under apparently constant experimental conditions. Mass spectrometry revealed the presence of trimethyl borate in the methanol, although this product was not detectable by G.L.P.C. It was confirmed, in agreement with Porter (10), that the trimethyl borate was formed by the reaction of methanol vapor with the pyrex glass of the storage bulb. At a gas pressure of 100 mm 9.7 mole% of this product was found after 24 hours of storage.

All results reported here were obtained from a system constructed entirely of quartz. A Hanovia, model 87A45, resonance tube was positioned 5 cm from the cylindrical quartz cell, which was 5 cm in length and of the same diameter. A Vycor 7910 filter was placed between lamp and cell to remove the 1849 Å line. The absorbed light intensity, with propane as actinometer (11), was found to be 1.92×10^{-6} einstein/min.

For personal use only.

Methanol (Mallinckrodt, reagent grade) was purified by trap-to-trap distillation and stored in a quartz bulb. Neither G.L.P.C. analysis nor mass spectrometry revealed any impurities, including water. The nitric oxide (Matheson) was purified by repeated circulation over KOH, and stored over mercury in a bulb. Methyl nitrite was prepared after Gray and Style (12) and similarly stored.

G.L.P.C. analyses for hydrogen were performed on silica gel columns with N_2 carrier; for the condensable products, the column packings were "Ucon" on Celite and Apiezon "L" on firebrick, with H_2 carrier. Identification of products was made by retention times on two columns, and confirmed by mass spectrometry. The heavy product of the reaction with pure substrate was confirmed (3) to be ethylene glycol by comparing the infrared spectrum of its chloroform solution with that of an authentic sample. The spectra were essentially identical.

RESULTS

In the first series of runs, a substrate pressure of 50 mm and an exposure duration (t) of 105 minutes were used. The products were hydrogen, ethylene glycol, carbon monoxide, methane, ethane, dimethyl ether, formaldehyde, methyl formate, water, and a trace of ethanol. The mean quantum yield (Φ) for hydrogen was 0.24.

In the presence of NO, the only significant products were methyl nitrite, water, nitrous oxide, and formaldehyde. In Fig. 1, $\Phi(H_2)$, Φ(MeONO), and Φ(HOH) are shown

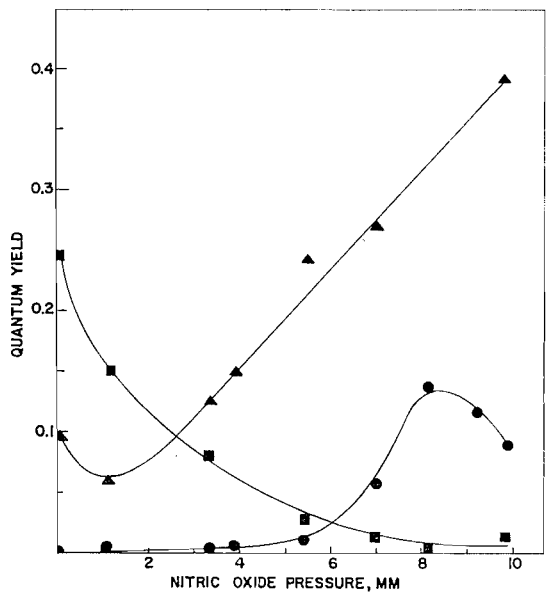

FIG. 1. Mean quantum yields for methyl nitrite ●, hydrogen ■, and water ▲ as a function of nitric oxide pressure, for a methanol pressure of 50 mm and an exposure time of 105 minutes.

as a function of P(NO) for P(MeOH) = 50 mm and t = 105 minutes. With increasing NO pressure, $\Phi(H_2)$ is seen to fall off rapidly, while Φ(HOH) rises linearly. Φ(MeONO) achieves a maximum value of 0.15 at P(NO) = 8 mm. By dissolving the cell deposit

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in $CHCl_3$, and measuring the integrated absorbed intensity for the OH band in the infrared, it was shown that the ethylene glycol yield decreased with increasing P(NO). The minor products, formaldehyde and methyl formate, are shown in Fig. 2. It is

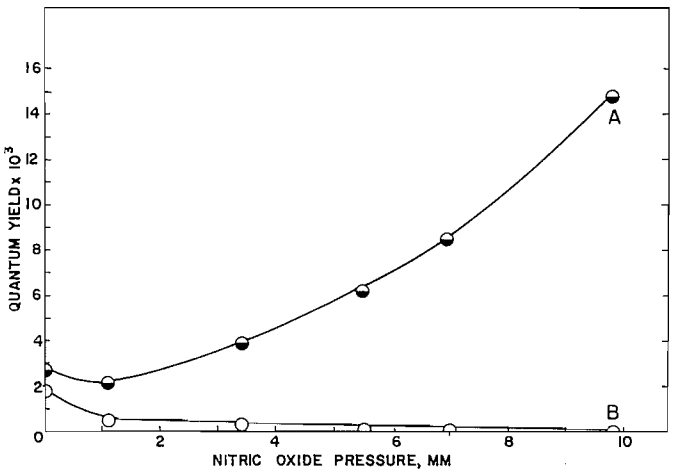

FIG. 2. Mean quantum yield of formaldehyde, curve A, and methyl formate, curve B, as a function of the nitric oxide pressure for a methanol pressure of 50 mm, and an exposure time of 105 minutes.

apparent with increasing P(NO) that Φ(HCHO) rises rapidly, while Φ(HCOOMe) becomes negligible.

To assess the importance of secondary reactions, the effect of exposure duration on the inhibited reaction was studied. For this series P(MeOH) = 50 mm and P(NO) = 5.5 mm. The exposure time was varied from 2 to 105 minutes. The results for Φ(MeONO) and $\Phi(H_2)$ are shown in Fig. 3, and Φ(HCHO) in Fig. 4. The rapid secondary decomposition of methyl nitrite is apparent, with a concomitant rise in Φ(HCHO). From Fig. 4, it can be further seen that formaldehyde is not a primary product of the inhibited reaction. The micromoles of water formed were found to be a linear function of t. At $t = 0$, Φ^0(MeONO) = 0.15 and $\Phi^0(H_2) = 0.012$. The rise in $\Phi(H_2)$ with increasing t was shown to be associated with a depletion of NO in the reaction zone. Thus two runs were made at the same substrate pressure, with P(NO) = 7.0 mm. $\Phi(H_2)$ was found to have values of 0.013 and 0.014 for t-values of 13 and 105 minutes, respectively.

The possibility of dark reaction between NO and substrate was checked by a duplicate run with P(MeOH) = 50 mm and P(NO) = 5.5 mm. The mixture was carried through all stages of the procedure except irradiation. In a second experiment, 2 mm of methyl nitrite—equivalent to the maximum amount formed in any of the exposures—was admixed with 50 mm N_2, and irradiated for 105 minutes. No products were detected in any of the above runs.

The effect of adding large quantities of NO is shown in Fig. 5. For these runs P(MeOH) = 50 mm and $t = 5.0$ minutes. For the equimolar MeOH:NO mixture, Φ(MeONO) = 0.56. The results are, of course, corrected in all cases for competitive quenching by NO.

The results of a series of runs on the uninhibited reaction at P(MeOH) = 50.0 mm

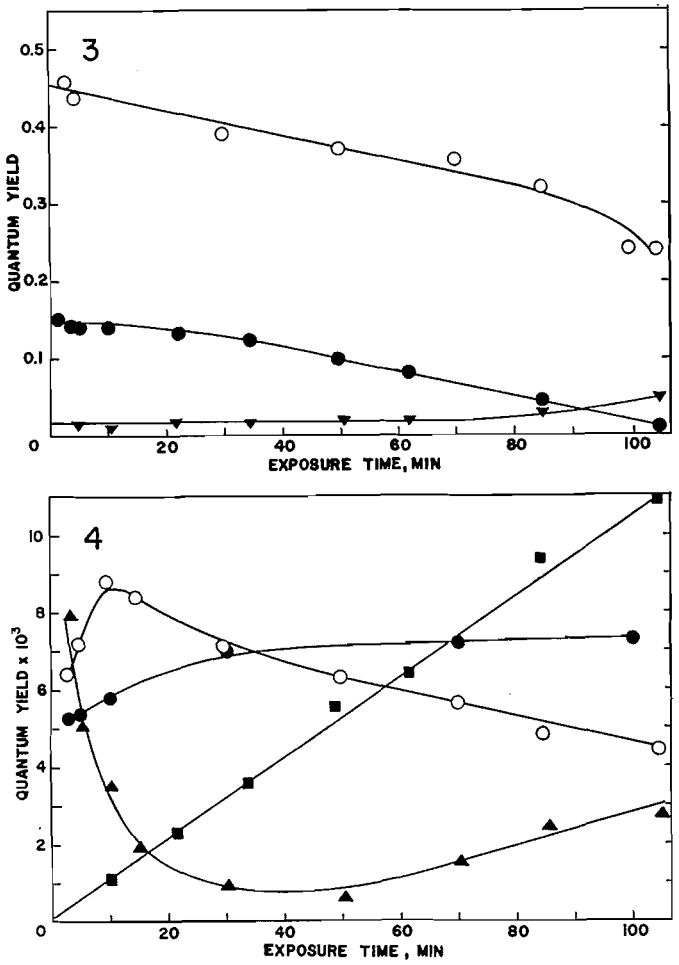

FIG. 3. Mean quantum yield of methyl nitrite ● and hydrogen ▼ as a function of exposure time for a mixture of 50 mm of methanol and 5.5 mm of nitric oxide. Mean quantum yield of hydrogen ○ as a function of exposure time for pure methanol at a pressure of 50 mm.

FIG. 4. Mean quantum yield of formaldehyde ■ as a function of exposure time for a mixture of 50 mm of methanol and 5.5 mm of nitric oxide. Mean quantum yield of formaldehyde ▲, ethane ●, and dimethyl ether ○ as a function of exposure time for pure methanol at a pressure of 50 mm.

are shown in Figs. 3 and 4. From Fig. 3, it is seen that $\Phi^0(H_2) = 0.46$. In Fig. 4, the trends in Φ for the minor products are shown. We obtain $\Phi^0(HCHO) = 0.01$; $\Phi^0(C_2H_6) = 0.005$, and $\Phi^0(CH_3OCH_3) = 0.006$. For water, $\Phi(HOH) = 0.095$ at $t = 105$ minutes. The values decreased rapidly to 0.035 at $t = 25$ minutes. Water is apparently not a primary product of the reaction. Similarly Φ(HCOOMe) fell from 0.0013 at $t = 105$ minutes to 0.0003 at $t = 25$ minutes. Again this product is not of primary origin.

Finally one qualitative run was done with CD_3OH (Merck, 99%). Mass spectrometric analysis of the residual substrate after 105 minutes of exposure showed the presence of appreciable amounts of CD_3OD.

DISCUSSION

The appearance of methyl nitrite as the major reaction product in the NO-inhibited reaction is strong evidence for the formation of CH_3O radicals in the primary reaction via step [2]. The presence of CD_3OD among the products of the CD_3OH run would suggest that both [2] and [3] are occurring. Our findings are therefore in qualitative agreement with the mass spectrometric results of Pottie, Harrison, and Lossing (9). While no evidence could be found for primary CH_2OH formation (3) via [1], the reaction could be occurring to a minor extent.

From the Φ^0's for C_2H_6 and CH_3OCH_3, we estimate that $\Phi^0(CH_3)$ would have a maximum value of ca. 0.02, while $\Phi(H)$ will be at least 0.46, the value for $\Phi^0(H_2)$. Furthermore it is likely that $\Phi^0(H)$ is actually near unity, since H atoms can be consumed by combination with themselves and with the CH_3O and CH_2OH radicals present in the reaction zone, without concomitant H_2 formation. Thus we conclude that reaction [5] cannot be more than five per cent of the primary reaction, and that it is more likely to be roughly two per cent of it. These conclusions would support the suggestion made by Pottie *et al.* (9) that CH_3 formation arises from atomic cracking:

$$CH_3O + H \rightarrow CH_3OH^* \rightarrow CH_3 + OH. \qquad [6]$$

Certainly [6] would be much more probable at the very low pressures (ca. 5 μ) used by Pottie *et al.* (9) than under the conditions of this study.

In the presence of nitric oxide, the significant products are methyl nitrite, nitrous oxide, water, and formaldehyde. With [2] as the primary process, the following secondary reactions are postulated to explain our findings.

$$CH_3O + NO \rightarrow CH_3ONO \qquad [7]$$

$$H + NO \rightarrow HNO \qquad [8]$$

$$CH_3O + HNO \rightarrow CH_3OH + NO \qquad [9]$$

$$HNO + HNO \rightarrow N_2O + H_2O \qquad [10]$$

$$CH_3O + CH_3ONO \rightarrow CH_3OH + CH_2O + NO \qquad [11]$$

Reactions [8] and [10] have been used by a number of investigators (12, 13, 14) to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

explain the appearance of N_2O and H_2O in systems containing H atoms and NO. The analogous reaction to [9], for ethoxy radicals has been postulated by Levy (13) for the thermal decomposition of ethyl nitrite. The reaction should be highly exothermic. Reaction [11] forms a step in the Steacie–Sklar (13) mechanism for the decomposition of the alkyl nitrites. From Figs. 3 and 4, it is apparent that CH_3ONO is being consumed with increasing exposure, and that HCHO is being formed. Reaction [11] would explain this behavior. The fact that the quantum yield of CH_3ONO is only 0.56 with an equimolar mixture of CH_3OH and NO, whereas one would expect a value near unity, would point up the importance of [9] and to a much lesser extent [11]. It should be emphasized here that in mercury photosensitization the reaction zone is confined to a small volume near the incident window, owing to the high absorption coefficient of mercury for its own resonance radiation. Radical concentrations will therefore be high in this zone, and secondary reaction will be very difficult to eliminate. Finally, in the inhibited reaction, it will be noted from Fig. 3 that $\Phi^0(H_2)$ retains a small but finite value of ca. 0.01. Since this value is not appreciably reduced by increasing $P(NO)$, it is likely that hydrogen is forming by a step postulated by Levy (13):

$$NOH + NOH \rightarrow 2NO + H_2. \qquad [12]$$

For pure substrate, at a partial pressure of 5 μ, in 8 mm He carrier, Pottie, Harrison, and Lossing (9) at 55° find HCHO to be an important product whereas at 50 mm pressure, we find this product to be of minor significance with $\Phi^0(HCHO) = 0.01$ (cf. Fig. 4). This is what would be expected if HCHO is formed by the disproportionation of CH_3O radicals:

$$CH_3O + CH_3O \rightarrow CH_2O + CH_3OH. \qquad [13]$$

At high substrate pressures the CH_3O radicals would disappear largely by [3]. Hence it appears unlikely that CH_2OH radicals are involved in HCHO formation. With increasing duration of exposure, it is apparent from Figs. 3 and 4 that extensive secondary decomposition is occurring in the methanol reaction. It would seem unprofitable to discuss these reactions in detail here.

Since the bulk of the reaction in mercury photosensitization is confined to a zone near the incident window, as pointed out above, special techniques must be employed to study the rates of the primary reactions, without complication by secondary processes. In this laboratory chopped-beam techniques are being investigated to this end. During the dark period, products and radicals can diffuse away from the reaction zone, thereby decreasing the extent of secondary reaction. By such studies it is hoped to obtain information on the primary efficiency of the methanol reaction, and on other mercury-photosensitized reactions involving primary bond scission.

CONCLUSIONS

As a principal result of this investigation, it has been shown that the CH_2OH radicals responsible for ethylene glycol formation in the reaction of methanol with Hg $6(^3P_1)$ atoms arise by a secondary reaction of primary CH_3O radicals with the substrate. In this respect our findings are in agreement with the mass spectrometric results obtained by Pottie *et al.* (9). Our study also suggests that nitric oxide should be of value in trapping alkoxy radicals through the formation of the nitrite.

Similar studies on ethanol and isopropanol are in progress in this laboratory and will be published shortly.

ACKNOWLEDGMENTS

The authors would like to express their deep appreciation to Dr. W. F. Allen of this laboratory for valuable assistance and many helpful discussions, and to Mr. A. G. Sherwood for supplying the nitric oxide used in this investigation.

Our program was supported in part by the National Research Council under Block Term Grant No. BT-74. This assistance is most gratefully acknowledged.

RECOMBINATION OF ATOMS AT THE SURFACE OF THERMOCOUPLE PROBES[1]

KIN TSU AND M. BOUDART

ABSTRACT

When atoms produced by a discharge at one end of a closed cylindrical tube diffuse down the tube, their rate of recombination on the walls of the tube can be determined by measuring the temperature of a probe traveling along the axis of the tube. However, the catalytic activity of the probe may, under specified conditions, appear to be the same whatever the catalytic activity of the probe material. This effect is offered as a possible explanation of the findings of Wood and Wise, who recently reported essentially the same recombination probability for hydrogen atoms on 12 different metals.

INTRODUCTION

The rate of recombination of atoms on solid surfaces is a problem of considerable theoretical and practical interest. Recently, Wood and Wise (1), investigating the catalytic effect of various surfaces, have reported almost identical rates of recombination of hydrogen atoms on 12 different metals.*

This result is a very novel and interesting one. If confirmed by further work, it will require an explanation. While such an explanation may perhaps be found ultimately in the mechanism of recombination, it seems worth while to explore the possibility that this lack of catalytic specificity could actually be a result of the experimental technique used in the determination of rates of recombination.

It is shown below how this can happen. To this end, the method of Wood and Wise is reanalyzed first, for the sake of clarity, in an approximate way, then in more detailed fashion. The new solution presented is of general interest and its consequences are of special importance in investigations of recombination of atomic species.

DISK-SHAPED CATALYTIC PROBES: ONE-DIMENSIONAL APPROXIMATION

Consider a cylindrical reactor of radius R_0. It is closed at one end, filled with hydrogen at low pressure, and surrounded at the other end by a coil through which is sent a high-frequency a-c. current, so that an electrodeless discharge in the tube generates hydrogen atoms. These diffuse down the tube (dimensionless co-ordinate x equal to length divided by tube radius R_0). The walls of the tube are sufficiently inactive for recombination. Then there is no appreciable radial gradient in the concentration C of hydrogen atoms in the tube. Yet there is an axial gradient because atoms recombine on the walls of the tube. Transport of atoms is purely diffusive, if Stefan flow can be neglected, as is legitimate in suitable experimental situations where the concentration of atoms is not too high. The diffusivity of the atoms is D, and the probability of the first-order recombination on the walls is 2γ. The reason for the factor two is explained elsewhere (2).

Then, the equation of the problem is:

$$D\frac{d^2C}{dx^2} = R_0 v \gamma C$$

[1]*Manuscript received January 23, 1961.*

**Aluminum was an exception. However, Dr. Wise kindly informs us that further work in his laboratory has not confirmed this anomalous behavior and that aluminum behaves very much like the other 12 metals tested.*

where v is the mean molecular speed of hydrogen atoms as given by gas-kinetic theory.

The first boundary condition, on the side of the discharge will be assumed to be, as usual:

$$C = C_0 \qquad \text{at} \qquad x = 0.$$

The second boundary condition is provided by a disk-shaped catalytic probe, filling the cross section of the tube, at a distance $x = L$ from the discharge. If the rate of recombination on the surface of the probe is first-order and characterized by a probability γ', the second boundary condition is:

$$-D\frac{dC}{dx} = R_0\frac{v}{4}\gamma' C \qquad \text{at} \qquad x = L.$$

With these boundary conditions, the equation of the problem admits the solution:

$$\frac{C}{C_0} = \frac{F e^{m(L-x)} - e^{-m(L-x)}}{F e^{mL} - e^{-mL}}$$

with the following values for F and m:

$$m = \left(\frac{R_0 v \gamma}{D}\right)^{1/2}; \qquad F = \frac{h+m}{h-m}; \qquad h = R_0\frac{v\gamma'}{4D}.$$

This solution gives immediately the concentration C_L of atoms at the surface of the probe, i.e. at $x = L$:

$$\frac{C_0}{C_L} = \frac{1}{2m}[(h+m)e^{mL} - (h-m)e^{-mL}].$$

Now, because of the heat of recombination, the temperature of the probe will be higher than the ambient temperature by the amount ΔT, which must be proportional to the rate of heat release at the probe, i.e. to the concentration of atoms at the probe surface and to the probability of recombination at the probe. Thus:

$$\Delta T = \gamma' K C$$

where K is a proportionality constant.

If the probe is at the origin, $C = C_0$ and $\Delta T_0 = K C_0 \gamma'$, while at a distance L from the origin $C = C_L$ and $\Delta T_L = K C_L \gamma'$. Therefore from measurements of ΔT_0 and ΔT_L at various distances L,

$$\frac{\Delta T_0}{\Delta T_L} = \frac{C_0}{C_L} = \frac{1}{2m}[(h+m)e^{mL} - (h-m)e^{-mL}],$$

it appears possible to determine both h and m and thus also both γ and γ', the probabilities of recombination on the walls of the tube and on the surface of the probe. This is how Wood and Wise (1) have determined the activity of different metal probes. In fact, they have made use of a three-dimensional solution, with probe geometry identical with that used here. If the activity of the wall is small, the difference between the solution shown here and the complete solution (1) is negligible.

The validity of this solution will now be questioned. Is it correct to assume that the concentration of atoms C in the discharge at the origin remains a constant C_0 irrespective of the position of the probe? Is it not expected that an active probe in the vicinity of the origin, that is near the discharge, will deplete the atomic concentration in the discharge? In other words, is the first boundary condition, $C = C_0$ at $x = 0$, a valid one?

For personal use only.

In order to examine this question, a more refined analysis of the situation near the origin is necessary. Two distinct regions are now considered: the discharge zone for $x < 0$ and the measurement zone for $x > 0$. In the discharge, the number of atoms generated uniformly per unit volume per unit time will be represented by Q'. With $Q = R_0^2 Q'/D$, the equations of the problem become:

$$\frac{d^2C_1}{dx^2} + Q - m^2 C_1 = 0, \qquad -\infty < x < 0$$

$$\frac{d^2C_2}{dx^2} - m^2 C_2 = 0, \qquad 0 < x < L$$

$$\frac{dC_1}{dx} + h\,C_1 = 0 \qquad \text{at} \qquad x = L$$

$$C_1 = C_2 \qquad \text{and} \qquad \frac{dC_1}{dx} = \frac{dC_2}{dx} \qquad \text{at} \qquad x = 0.$$

The solution of these equations is:

$$C_L = \frac{Q}{m(m+h)}\, e^{-mL}.$$

Also:

$$C_0 = \frac{Q}{m(m+h)}.$$

Thus:

$$\frac{C_0}{C_L} = \frac{\Delta T_0}{\Delta T_L} = e^{mL}.$$

Consequently, it is seen that an experimental curve of $\Delta T_0/\Delta T_L$ versus distance L depends only on m, i.e., on the rate of recombination at the wall. But it will not depend on h, i.e., on the catalytic activity of the probe. Such profiles of temperature versus distance are therefore unsuitable for measurements of the activity of the probe. An analysis of the data, based on the previous boundary condition $C = C_0$ at $x = 0$, ignoring the effect of the probe on the concentration of atoms at the origin, would reveal an apparently identical catalytic activity of all probe materials.

SPHERICAL CATALYTIC PROBES: THREE-DIMENSIONAL SOLUTION

The analysis of the problem with a disk-shaped probe is only an approximation because, in practice, the catalytic probe is positioned along the axis of the tube and occupies only a small fraction of the cross-sectional area of the tube.

A more realistic analysis will now be attempted in order to corroborate the conclusion just arrived at on the basis of an approximate analysis.

The three-dimensional solution is obtained by first considering the following problem. Atoms are continuously liberated from a point source of unit strength located on the central axis of an infinite cylinder. An atomic sink of variable strength β is also placed on the central axis but at a variable distance from the source. Atoms may recombine on the cylinder walls in the usual manner. The radial co-ordinate r is dimensionless, equal to radial length divided by R_0.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The concentration of atoms in the cylinder is described by the differential balance:

$$\frac{\partial^2 C}{\partial r^2}+\frac{1}{r}\frac{\partial C}{\partial r}+\frac{\partial^2 C}{\partial x^2}=0, \qquad -\infty < x < \infty$$

with the boundary condition

$$\frac{\partial C}{\partial r}+BC=0 \qquad \text{at} \qquad r=1$$

where $B=\gamma v R_0/2D$. Further conditions are: a source of unit strength at $r=0$, $x=0$ and a sink of strength $-\beta$ at $r=0$, $x=L$. Thus β is expressed in number of atoms per unit time.

The solution is readily obtained from the principles discussed in reference 3.

[1] $$C=\frac{1}{2\pi DR_0}\sum_{i=1}^{\infty}\left[e^{-\alpha_i|z|}-\beta\, e^{-\alpha_i|z-L|}\right]\frac{\alpha_i J_0(\alpha_i r)}{(\alpha_i^2+B^2)J_0^2(\alpha_i)}$$

where α_i are the roots of

$$\alpha_i J_1(\alpha_i)-B J_0(\alpha_i)=0$$

and J_0, J_1 are Bessel functions in the usual nomenclature.

Now imagine a sphere of dimensionless radius r' surrounding the sink. This will represent the catalytic thermocouple probe whose surface is covered by a metal under study.

The net flux of atoms into the sink can be represented by the total rate of reaction of atoms on the probe surface.

$$J=-\oint\frac{v}{4}\gamma' C\, dS$$

The integral is taken over the surface of the sphere of radius r'. But the flux must be equal to the strength of the sink $-\beta$.

$$J=-\beta.$$

Therefore

[2] $$\beta=\oint\frac{v}{4}\gamma' C\, dS.$$

The concentration C under the integral in this last equation is evaluated from equation [1] using the relationship

[3] $$r^2+(x-L)^2=(r')^2$$

for all points on the surface of the sphere.

Thus (given the known physical constants: D, R_0, r', v) β can be evaluated in terms of γ, γ', and L by the use of equations [1], [2], and [3]. β is the sink strength and corresponds directly to the temperature measured by the thermocouple probe at any position L.

Fig. 1 shows some calculated results obtained from the present three-dimensional solution. The corresponding three-dimensional solution published by Wise *et al.* (1) is shown by the dashed curves. Our results are plotted as $1/\beta-1$ vs. L and are extrapolated to read zero for $L=0$ (curves 1 and 2). The results of Wise *et al.* are plotted as $n_0/n-1$ vs. L (curves 3 and 4). Following these authors, n stands for atomic concentration. The values of the parameters used in calculating the curves are listed in Table I.

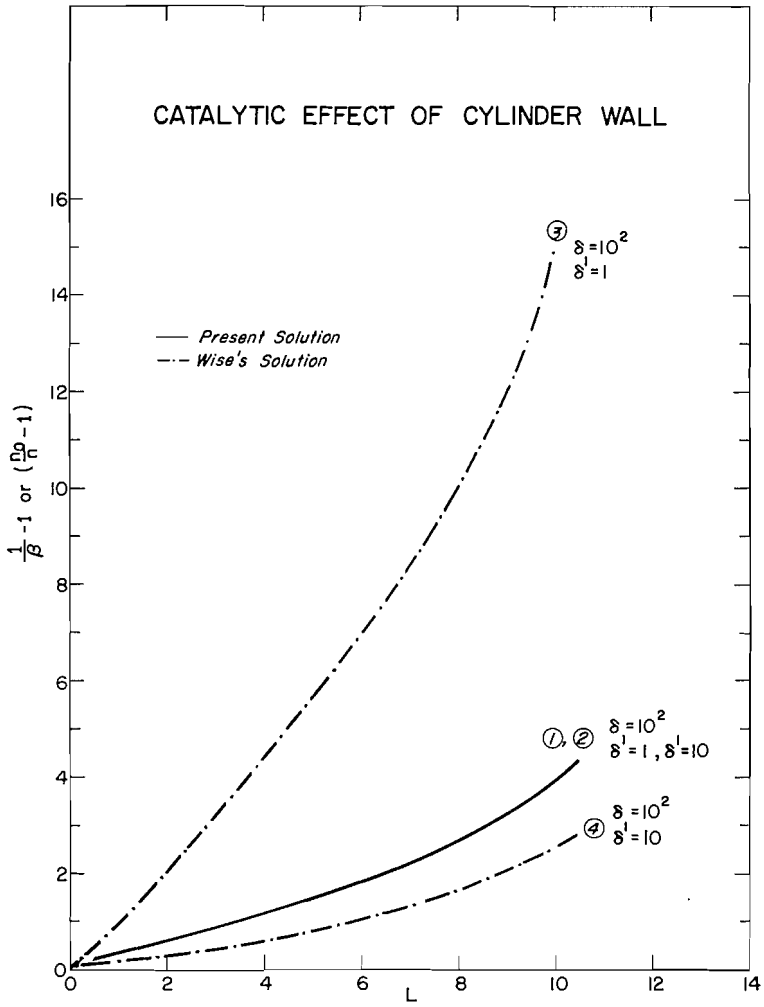

FIG. 1. Depletion of atoms, as expressed by $(n_0/n-1)$ or $1/\beta-1$, as a function of axial distance. Abscissae: L co-ordinate. Ordinates: broken curves, calculated following Wise *et al.*: $n_0/n-1$ vs. L with $\delta = 1/B = 10^2$; upper curve: $\delta' = 1/h = 1$; lower curve: $\delta' = 1/h = 10$; full curve, calculated from equations [1], [2], and [3]: superposed curves (1) and (2) $1/\beta-1$ vs. L for $\delta = 10^2$, $\delta' = 1$, *or* $\delta' = 10$.

TABLE I

Parametric values used in calculating curves in Figs. 1 and 2

Diffusivity, D_{H-H_2}, cm²/sec	2.3×10^4
Tube radius, R_0, cm	1.9
Velocity of H atoms, v, cm/sec	2.6×10^5
Probe radius, r', dimensionless	0.2
Recombination probability on tube walls, γ, dimensionless	9.3×10^{-4}

It is immediately seen that according to the present analysis, curves 1 and 2 are superposed to give a single curve for values of the catalytic activity of the probe differing by a factor of 10, namely $\gamma' = 0.186$ (curve 1) and $\gamma' = 0.0186$ (curve 2). The analysis of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Wise *et al.* based upon the doubtful boundary condition at the origin shows two separate curves for two different probe catalysts. This result had, of course, been anticipated by the one-dimensional solution. Thus the experiments carried out and analyzed by Wise *et al.* should indicate and do indicate that all metals possess the same catalytic activity for atom recombination, if probes of the same size r' are used in all cases.

It must be noted that minor differences in the catalytic activity of various probes may be explained, in the light of the present analysis, by differences in the size of the probes. Indeed, the size of the probe, in the more realistic model presented here, enters into the problem as one of the parameters of the system. This, of course, is not apparent in previous treatments using a hypothetical disk-shaped probe.

DISCUSSION

The present analysis of the technique of thermocouple probes does not purport to show that the technique does not provide a good way to measure catalytic recombination of atomic species.

First of all, for the measurement of the catalytic activity of the walls of the tube, when this activity is not too high, the method is indeed an excellent one as established in a definitive fashion by the work of Linnett *et al.* (4), who showed that identical results were obtained whether the atomic concentration in the tube was measured by a thermocouple catalytic probe or by a Wrede-Harteck gauge. The validity of the method will again be demonstrated below.

The possibility of measuring also the relative catalytic activity of probe materials by means of thermocouple probes is first suggested by the one-dimensional treatment. It was shown that

$$\Delta T = \gamma' K C_L$$

with

$$C_L = \frac{Q}{m(m+h)} e^{-mL}.$$

Therefore, if two different probes with efficiencies γ_1' and γ_2' are positioned in the tube at a distance L from a constant source Q, the value say of γ_2', if γ_1' is known, can be obtained from the temperature rise of the two probes ΔT_1 and ΔT_2:

$$\frac{\Delta T_1}{\Delta T_2} = \frac{\gamma_1'}{\gamma_2'} \frac{(m+h_2)}{(m+h_1)}.$$

The proper way to use the technique of the thermocouple probe in order to determine the catalytic activity of the probe is illustrated in Fig. 2 based on the three-dimensional treatment. Plots of β versus L are shown and the numbering of curves corresponds to that used in Fig. 1. It is noted that curves 1 and 2 of Fig. 2 have exactly the same shape; this is the reason why they become superimposed into one curve in Fig. 1. Results following Wise *et al.* are plotted as $\Delta T/\Delta T_0$ for comparison (curves 3 and 4). Curve 4 has been normalized to read 0.1 at $L = 0$ since the probe catalyst is 10 times less active than for curve 3.

The displacement between curves 1 and 2 (present solution) is the result of the different catalytic activity of the two probes. Thus, as already apparent from the one-dimensional solution, the ratio of the temperature rises measured by two different probes under the same experimental conditions is related to the relative catalytic activities of the two

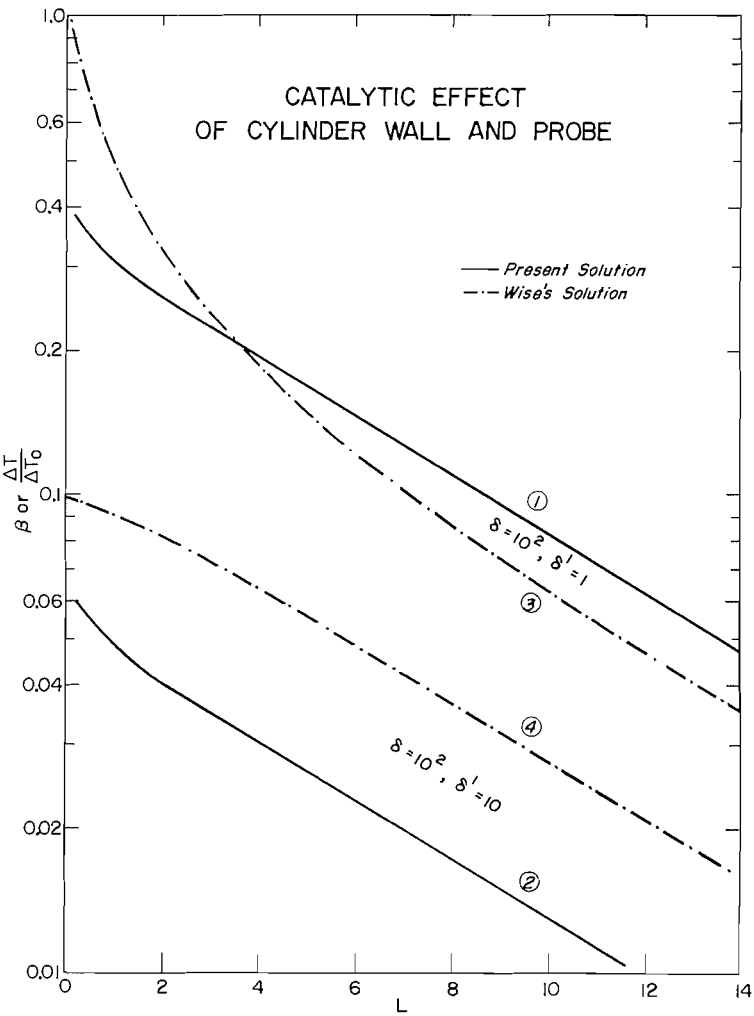

FIG. 2. Semilogarithmic plot showing depletion of atoms as a function of axial distance. Abscissae: L co-ordinate. Ordinates: full curves 1 (upper) and 2 (lower) calculated from equations [1], [2], and [3]: β vs. L for $\delta = 10^2$, $\delta' = 1$ (upper), and $\delta' = 10$ (lower); broken curves 3 (upper) and 4 (lower) calculated following Wise *et al.*: $\Delta T/\Delta T_0$ vs. L for $\delta = 10^2$, $\delta' = 1$ (upper), and $\delta' = 10$ (lower).

probes. It must be noted that this method of obtaining the relative catalytic activities of various surfaces is only an elaboration of the simpler technique used by Katz, Kistiakowsky, and Steiner (5). It is noted that the displacement between curves 3 and 4 (Wise's solution) is not the same as between curves 1 and 2. This is a reflection upon the fact that Wise *et al.* did not take into account the actual size and shape of the thermocouple probe. Since the displacement is also a function of probe radius, a convenient experimental verification of equations [1], [2], and [3] could be carried out by using different sized probes but the same metal catalyst.

In regard to Fig. 2, it is seen that the logarithmic slope at large L becomes identical for all curves.

This common slope is determined only by γ, the probability of recombination on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

tube walls. It is independent of probe activity or radius. Thus the more complete treatment presented here substantiates, as expected, the results of Linnett and Marsden (4): the experimental results of these and other authors (2) who have used a simplified analysis to calculate the small catalytic activity of tube walls remain perfectly valid.

CONCLUSION

When the perturbing effect of a catalytic probe on the concentration of atoms in a discharge is taken into account, thermocouple probes may indicate similar or even identical apparent catalytic activities of metals covering the probes under investigation.

A solution of the problem is presented which, for the first time, assumes a probe of realistic shape and size and not the hypothetical flat disk used in previous treatments. The conditions for the correct application of the probe method then become clearly delineated.

DIPOLE MOMENTS AND STRUCTURE OF MOLECULAR COMPOUNDS

PART I. ALIPHATIC AND AROMATIC AMINE PICRATES[1]

R. RAMAN AND SUNDARESA SOUNDARARAJAN

ABSTRACT

Dipole moment measurements have been made for some aliphatic and aromatic amine picrates in dioxane solution. The fractional ionic character of these complexes in the ground state has been calculated from μ_N, the observed value of dipole moment; μ_0, the vector sum of the moments of the components of the complex; μ_1, the moment resulting from complete one-electron transfer; and known values of S, using the charge-transfer theory of Mulliken. For these complexes of the $n+h\sigma_d$ type, the charge-transfer process lies in the direction of the symmetry axis N^+O^-, the picture corresponding to an energy of interaction U, versus charge-transfer co-ordinate (C) curve with a shallow minimum showing an inner complex corresponding to ($C = 1$), $b \simeq a^2$ or $b^2 > a^2$, and an activated complex (roughly between $C = 0.3$ to 0.5) corresponding to an intermediate.

INTRODUCTION

Molecular compounds have long been known, and theoretical considerations like the formation to a considerable extent of covalent bonds between the two components (2, 19), saturation of residual valencies (23), electrostatic induction (4), and polarization mechanism similar to an oxidation–reduction reaction (11, 13) have been put forth to describe the forces which bind the components of such compounds. Recently Weiss (28) suggested that an extension of the last idea in terms of an electron transfer from the donor to the acceptor can explain their formation and structure in detail. Brackman (3) then put forth the concept of complex resonance, by which the donor can share an electron pair with the acceptor by a process comparable to Lewis acid interaction and suggested that the color of the complex is not determined by either component but is a characteristic feature of the complex itself. This idea is shared by Mulliken (20, 21), who has recently integrated the various views to provide a theory of complex bonding which seems compatible with the known chemical and physical properties of molecular compounds.

Picric acid forms two types of picrates, (*a*) with strong organic bases, compounds having some of the properties of substituted ammonium salts, (*b*) with very weak bases, molecular complexes, which show pronounced color deepening with none of the properties commonly associated with salts. The colored compounds of the picric acid have been the subject of many investigations (5, 9, 12, 24). However, the nature of the binding forces in the complexes are best deduced by a study of the dipole moments of these compounds, since the interaction products are frequently more polar than the constituents. Examples of such systems involving the donor–acceptor type of non-saltlike complexes are given in a review by Andrews (1). Dipole moments of many of the saltlike molecular compounds have also been investigated (10, 14, 17, 18, 27). In this paper dipole moments of some aliphatic and aromatic amine picrates have been reported and interpreted in terms of Mulliken's theory.

EXPERIMENTAL

Materials and Their Purification

Dioxane

This solvent, used in this investigation, was purified by Eigenberger's method (25).

[1]*Manuscript received December 19, 1960.*
Contribution from the Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 12, India.

Aromatic Amine Picrates

Aniline and dimethylaniline picrates were obtained by mixing the base solutions in benzene with hot saturated solutions of picric acid in benzene, both being recrystallized from absolute alcohol. The naphthylamines were treated in alcoholic solutions and the products recrystallized twice from ethyl alcohol:

aniline picrate:	yellowish needles, decomposes on heating;
dimethylaniline picrate:	greenish-yellow glistening crystals, melting point 163° C;
α-naphthylamine picrate:	greenish-yellow prismatic crystals, melting point 181° C (decomposes);
β-naphthylamine picrate:	yellow needles, decomposes into components on heating.

Ethylamine Picrate

Anhydrous ethylamine was dissolved in ice-cold water and was gradually neutralized by adding solid picric acid with stirring. The mixture was kept overnight and the solid cake obtained was washed with alcohol and twice recrystallized from alcohol, melting point 167° C.

Apparatus and Methods of Measurement

Measurements of dielectric constant were made using an a-c. mains operated heterodyne beat apparatus, details of which are given in an earlier paper (25). Densities of the solutions were determined using an Ostwald–Sprengel pycnometer with closed, ground-in caps at both ends. The electron polarization was calculated by the additivity of the bond refractions of Denbigh (7). Atomic polarization was neglected and the polarization of the solute at infinite dilution was obtained using the mean values of the Hedestrand constants α and β (25). In the case of aromatic amine picrates in dioxane solution the variation of dielectric constant with mole fraction of the solute was found to be linear only at dilute concentrations. For very dilute solutions non-linearity was observed below the mole fraction range of 0.0009 for aniline picrate, 0.00055 for dimethylaniline picrate, 0.00088 for α-naphthylamine picrate, and 0.00016 for β-naphthylamine picrate, the trend of the curve being similar in all these cases. Consequently the polarization at infinite dilution in these cases has been calculated using values from the linear portion. The data are given in Tables I and II.

THEORETICAL CALCULATIONS

Calculation of the Ionic Character Using Mulliken's Theory

The theory of Mulliken can be applied to a wide variety of donor D and acceptor A entities. In the present context, the donors are the neutral (n) onium bases (the aromatic and aliphatic amines), while the acceptor is the picric acid, which forms fairly stable compounds, viz. the amine picrates. For the donor–acceptor resonance complex, the wave function of the ground state N is

$$\psi_N = a\psi_0 + b\psi_1. \quad [1]$$

Here ψ_0 is the no-bond wave function of AD in the equilibrium separation r_{AD} without the consideration of exchange forces, i.e. the quantum mechanical first-order value. The wave function ψ_1 is the dative-bond wave function of the polar state D^+A^- corresponding to transfer of an electron from D to A and contains exchange forces; ψ_N is approximated by the sum of the two terms alone and, from the normalization condition $\int \psi_N^2 dv = 1$, the coefficients a and b in equation [1] are related by

$$a^2 + 2abS + b^2 = 1 \quad [2]$$

where S is evaluated from the Slater overlap integral S_{AD} (22) by means of the relationship

$$S \simeq 2^{\frac{1}{2}}[(1+S_{AD}^2)]^{-\frac{1}{2}} S_{AD}.$$

The dipole moment of the charge-transfer process lies in the direction of the symmetry axis N^+O^-. On account of the insignificant overlapping of ψ_A and ψ_D due to large distance (3.22 Å), S is very small. The moment μ_N (the experimentally determined value) is given by

$$\mu_N = \int \psi_N M \psi_N dv = a^2\mu_0 + b^2\mu_1 + 2ab\mu_{01} \quad [3]$$

where μ_0 is the vector sum of the component moments of A and D, $\mu_1 = er_{AD}$ (e, the electronic charge, and r_{AD}, the equilibrium distance between N^+ and O^- atoms, i.e. 3.22 Å taken from the X-ray data for hydroxylamine hydrochloride (16)) and

$$\mu_{01} = \tfrac{1}{2}(\mu_1 - \mu_0)S + S\mu_0 \quad [4]$$

so that

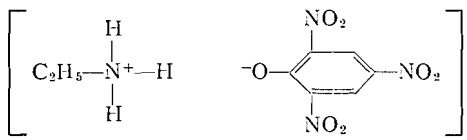
$$\mu_N = a^2\mu_0 + b^2\mu_1 + abS(\mu_1 - \mu_0) + 2abS\mu_0.$$

From known values of S, μ_1, μ_0, and μ_N, the coefficients a and b and the values of $b^2/(a^2+b^2)$ taken as corresponding to the ionic character of the compound have been calculated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The values are given in Table III. (R_{ab} = 3.22 Å taken from N—O distance in hydroxylamine hydrochloride (16); $\mu_1 = 4.803 \times 3.22$ Å = 15.46 D; S = 0.0177, calculated from

TABLE III*



Picrate	Moment of the base	Covalent moment, μ_0	Moment of the complex	a	b	$b^2/(a^2 + b^2)$

*μ resultant of picric acid (1.57 D) (18) was taken as acting at an angle of 71° to the C—O bond. This angle was derived from the bond moment values of 0.8 D for the C—O link and 1.51 D for the H—O link, from which a resultant moment of 1.57 D and an angle of 101° was obtained for the COH angle. In all the aromatic amines the hydrogen or the methyl groups of the amino group were assumed to be in plane with the aromatic rings (consistent with the theoretical treatment of aniline by Coulson (6)) and the resultant moments were assumed to act from N → C (8). For ethylamine the resultant moment was assumed to act from the nitrogen atom in the direction of the lone pair orbital (N → :).

S_{ab}, Slater overlap integral using Slater μ values for N^+ and O^- ions (22); mainly because of its strong dependence on the uncertain quantity S, the value of b can only be relative.)

DISCUSSION

Though the stable compounds of the amine picrate type can be discussed in terms of the same general theoretical framework of Mulliken, there are some important differences. It is convenient to visualize that picric acid be placed near the amine with hydrogen directly between the nitrogen of the amine and the oxygen of picric acid at a distance approximately equal to that in the ionic but undissociated complex, i.e.

Mulliken has outlined the various possible modes of interaction of donor–acceptor pair by plotting the energy of interaction U against a co-ordinate C (called the charge-transfer co-ordinate) which increases continuously with the charge transfer, subject to the added specification that the nuclear skeleton be so adjusted for each value of C as to make U as small as possible. For the above situation C could still be only a little larger than zero. If C is allowed to increase, the hydrogen atom comes towards the nitrogen atom, the tendency being to set up tetrahedral angles around nitrogen (sp^3 hybridization). The N—O distance adjusted according to the above definition very nearly remains constant. According to Mulliken an increase in C corresponds to a likely increase in U because, (i) the non-bonded repulsions with ψ_0 increase, (ii) the amount b^2/a^2 of the higher-energy wave function ψ_1 increases. However, other factors that diminish U as C increases are (i) electrostatic polarization within ψ_0, (ii) decrease in the energy of ψ_1 due to increasing attractions and decreasing repulsions as the H moves towards the nitrogen atom, (iii) decrease in the energy of ψ_1 because of "dative polarization", and (iv) resonance between ψ_1 and ψ_0. In the present case the amine is the lone pair or onium donor (n) and the picric acid an even-bonding electron hydrogen acid ($h\sigma$) acceptor. The ultimate picture of these factors for complexes of the $n+h\sigma_d$ type should probably be a $U(C)$ curve with a shallow minimum showing an inner complex corresponding to (C = 1), $b^2 \approx a^2$ or $b^2 > a^2$, and an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

activated complex (roughly between $C = 0.3$ to 0.5). The variation of ionic character values (b^2/a^2+b^2) from 0.640 for ethylamine picrate to 0.203 for α-naphthylamine picrate in dioxane solution shows that the structure of the picrates varies in between the inner complex with maximum transfer and the activated complex. According to Mulliken for such $n+h\sigma$ pairs the charge-transfer forces may be too weak to give rise to an outer complex.

If the inner complex becomes energetically the stable form, complete dissociation into solvated ions may result if the assisting agent is an ionizing solvent. This electrolytic dissociation occurs at a constant value of 1 for C, the inner complex corresponding to maximum charge transfer and 100% ionic character. In the present case of amine picrates where a σ bond is broken, even assuming that two ions are formed, they still cohere because of the presence of the non-ionizing solvent, dioxane.

Previously Kraus *et al.* (10) and Maryott (18) have determined independently the dipole moments of picrates of alkylamines in benzene and dioxane solutions, the observed moments lying between 12 and 18 D. They explained that these large dipole moments are due to the presence in solution of an ion pair A^-HD^+. Very recently Tsubomura (26) has measured the moments of a series of organic salts (viz. anilinium and pyridinium picrates, trimethylamine–phenol complexes, and trimethylamine–haloacetic acid complexes etc.) with a view to studying the proton transfer in these compounds. Tsubomura concluded that the picrates as well as the amine – haloacetic acid complexes are ion pairs on the basis of the differences in the moment $\Delta\mu$ between the observed moments and the structure moments, which are the vector sum of the component moments. The trimethylamine – acetic acid complex was characterized as having an incomplete proton transfer, whereas the other complexes studied (e.g. hexamethylene tetramine complexes) were characterized as belonging to that of the hydrogen-bonded type. However, his expectation of the possibility of determining whether an acid–base pair is an ion pair or a hydrogen-bonded complex is based on erroneous grounds because a molecular compound cannot be rigidly classified as belonging to one or other of the two types on the basis of the observed moments of the complex as has been pointed out by Sutton *et al.* (15).

ACKNOWLEDGMENTS

The authors wish to record their deep sense of gratitude to Professor K. R. Krishnaswami for his keen interest and guidance during the progress of this work, and to Professor M. R. Aswathanarayana Rao for his invaluable suggestions. One of the authors (R. Raman) is thankful to the Government of India for awarding him a senior research scholarship during the course of this study.

THE HELLMANN–FEYNMAN THEOREM AND CHEMICAL BINDING[1]

RICHARD F. W. BADER AND GLENYS A. JONES[2]

ABSTRACT

The advantages of the electrostatic interpretation of chemical binding are illustrated. It is shown that the forces exerted by the electrons in a molecular orbital may be determined by general expressions. These are functions of only one parameter, the value of which is easily specified for a particular case. From the general expressions it is possible to obtain quantitative measures of the bonding or antibonding power of a molecular orbital. It is shown that the usual interpretations of bonding and antibonding properties in molecular orbital theory are misleading and that few orbitals are, in actual fact, antibonding. If molecular orbitals are classified as *net bonding* or *net antibonding*, terms which are precisely defined and have a definite physical significance, a much closer correlation with previous concepts of bonding is obtained. The effects of mutual orthogonalization within a set of orbitals are studied. It is found that this procedure decreases the bonding ability of bonding orbitals, but increases that of antibonding orbitals. The dangers of disregarding such orthogonalization in a conventional calculation are clearly illustrated.

I. INTRODUCTION

The Hellmann–Feynman theorem permits one to relate the forces acting on a nucleus in a molecule to the classical electrostatic forces exerted on the nucleus by the other nuclei and by the particular distribution of electrons found in the molecule. This relationship may be expressed as

$$F_{\alpha x} = \frac{\partial}{\partial x_\alpha}\left(\sum_{\beta(\neq\alpha)} \frac{Z_\alpha Z_\beta e^2}{r_{\alpha\beta}}\right) - e\int \rho \mathscr{E}_{\alpha x} dr \qquad [1]$$

where $\rho(x, y, z,)$ is the electron density, $\mathscr{E}_{\alpha x}$ the electric field produced by the αth nucleus in the x direction at the position of the ith electron, and Z_α is the nuclear charge of atom α. In a previous paper (1) we have shown that equation [1] is capable of providing reasonable results for the binding energies of simple molecules. At that time it was stated that the Hellmann–Feynman theorem provides a qualitative interpretation of chemical binding that is perhaps more readily understandable than is the usual discussion which is couched in terms of energies. The reason for this is that the electron density present in a molecule is a real three-dimensional quantity. In employing the Hellmann–Feynman theorem one reduces a problem in molecular structure to a problem in classical electrostatics, a problem of the interaction of a system of nuclei and some continuous charge distribution. In this paper we wish to illustrate the advantages of this approach. Rather than press the Hellmann–Feynman theorem by attempting to calculate molecular energies through the use of approximately determined electron densities, we wish instead to demonstrate the ability of the theorem to provide us with useful semiquantitative results regarding the bonding character of various electron distributions.

II. THE HELLMANN–FEYNMAN THEOREM AND THE MOLECULAR ORBITAL APPROACH

When the molecular orbitals used in the description of the electronic structure of a molecule are all orthonormal, the electron density may be expressed as

$$\rho = \sum_i n_i \psi_i^* \psi_i$$

where the summation is over all of the occupied molecular orbitals and n_i (= 1 or 2) is

[1]*Manuscript received February 22, 1961.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa 2, Canada.
[2]*Recipient of a Commonwealth Scholarship.*

the occupation number. (In the general discussion which follows we shall confine ourselves to the case of a homonuclear diatomic molecule simply to avoid cumbersome notations. The extension to more complex molecules is straightforward.) Any of the products $\psi_i^*\psi_i$ may be expressed in terms of the atomic orbitals which are used to approximate the molecular orbital and, for a homonuclear diatomic molecule, this is

$$\psi_i^*\psi_i = N_i^2 (\phi_\alpha^2+\phi_\beta^2\pm 2\phi_\alpha\phi_\beta)$$

where the plus signs represent a bonding and the minus signs an antibonding combination, and N_i is the normalizing factor. The force F_i acting on nucleus α due to a pair of electrons in the ith molecular orbital is

$$F_i = 2e\int \mathscr{E}_{\alpha z}\psi_i^*\psi_i\, d\tau. \qquad [2]$$

The analytical expression for $\mathscr{E}_{\alpha z}$ is $Z_\alpha e \cos\theta_\alpha/r^2_{\alpha j}$. Therefore, the force exerted on nucleus α by a pair of electrons in the ith molecular orbital may be interpreted in terms of the interaction of an ideal dipole centered on nucleus α with the various atomic and overlap charge distributions,

$$F_i = \frac{Z_\alpha}{1\pm S}\left[\int \mathscr{D}_{\alpha z}\,\phi_\alpha^2 d\tau+\int \mathscr{D}_{\alpha z}\,\phi_\beta^2 d\tau\pm 2\int \mathscr{D}_{\alpha z}\,\phi_\alpha\phi_\beta d\tau\right] \qquad [3]$$

where $\mathscr{D}_{\alpha z} = \cos\theta_\alpha/r_{\alpha j}$, and F_i is expressed in atomic units. The total force in atomic units exerted on nucleus α is simply the sum of all the individual F_i's together with the repulsions due to the other nuclei present in the molecule,

$$F_{\alpha z} = \sum_\beta{}' \frac{Z_\alpha Z_\beta}{R^2} - \sum_i (n_i/2)F_i. \qquad [4]$$

By choosing suitable expressions for the molecular orbitals we may calculate the forces exerted on a nucleus. The bonding and antibonding characters of different electron distributions may be compared and semiquantitative predictions made with much greater ease than is possible with the usual discussion in terms of energies. We shall illustrate this with a discussion of the molecular orbitals which are responsible for the bonding found in the homonuclear diatomic molecules composed of the atoms in the first row of the periodic table.

We have chosen to employ Slater's expressions with variable screening constants for the atomic orbitals in a L.C.A.O. approximation to the molecular orbitals. Such expressions give results for the electron densities that are sufficiently accurate to allow meaningful comparisons to be made between the forces resulting from different molecular orbitals. We have previously demonstrated that such expressions give good estimates of bonding energies for simple molecules (1). To this approximation it is possible to write a completely general expression for the forces exerted on a nucleus due to the occupation of any particular type of molecular orbital.

Reference to equation [3] shows that F_i for a homonuclear diatomic molecule is composed of three terms. If the atomic orbital ϕ_α is centrosymmetric, the first integral $\int \phi_\alpha\phi_\alpha\mathscr{D}_{\alpha z}d\tau$ is zero since no force will be exerted on a nucleus by a symmetrically placed charge distribution. The second integral $\int \phi_\beta\phi_\beta\mathscr{D}_{\alpha z}d\tau$ is the force due to the penetration of nucleus α into the charge distribution about the second nucleus.[3] This penetration effect results in an imperfect screening of the second nucleus and, if no other effects

[3]*For example, integration of* $\int \phi_\beta\phi_\beta\mathscr{D}_{\alpha z}d\tau$ *from* R *to* ∞ *for* ϕ_β = *1s a.o. results in the so-called J integral which occurs in the regular molecular orbital calculation of the energies of* H_2^+ *and* H_2.

were operative, it would give rise to a resultant repulsive force between the two nuclei. The third contribution to F_i, $2\int \phi_\alpha\phi_\beta \mathscr{D}_{\alpha x}d\tau$ gives the magnitude of the force on nucleus α due to the charge which is built up between the two nuclei in a bonding orbital. It is well known that $2\phi_\alpha\phi_\beta/(1+S)$ (where S is the overlap integral) is a measure of the amount of charge transferred from regions where ϕ_α^2 and ϕ_β^2 are large to the region where $\phi_\alpha\phi_\beta$ is large. The total amount of charge transferred in the formation of the molecular orbital is simply $2S/(1+S)$. Thus $\int \phi_\alpha\phi_\beta \mathscr{D}_{\alpha x}d\tau$ gives a quantitative measure of the forces arising from the charge which is transferred due to the overlap of the atomic orbitals. (In an antibonding orbital an amount of charge $2S/(1-S)$ is, of course, removed from the overlap region and placed in regions where ϕ_α^2 and ϕ_β^2 are large.) It is this build-up of charge in a bonding orbital which counteracts the repulsive force mentioned above to give a resultant binding force.[4]

All of the integrals encountered in equation [3] may be expressed as a product of $(1/R^2)$ with a dimensionless expression which is a function only of Q where $Q = \beta R$, R being the internuclear separation and β a screening constant. Because of this property, general expressions may be derived from any type of molecular orbital as functions of Q alone, from which the forces are obtained simply by dividing by R^2. Before presenting these general expressions for the forces, it will be instructive to consider the dimensionless functions for the $\int \phi_\beta^2 \mathscr{D}_{\alpha x}d\tau$ and $\int \phi_\alpha\phi_\beta \mathscr{D}_{\alpha x}d\tau$ integrals separately. These we have plotted in Fig. 1 for the molecular orbital composed of $2s$ atomic orbitals. We can, for the sake of

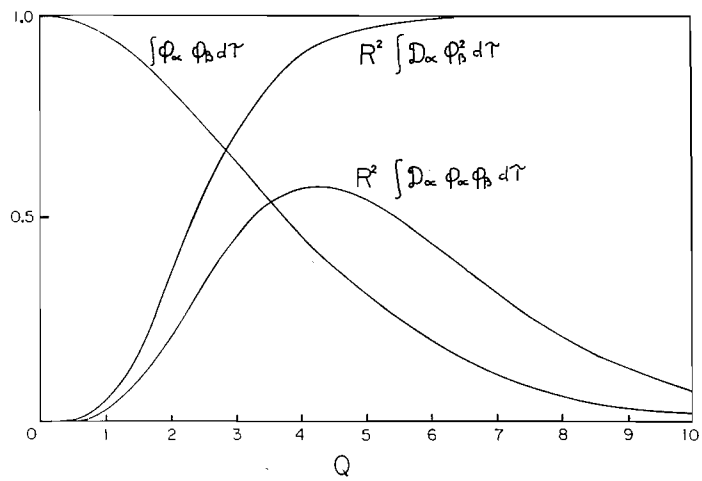

FIG. 1. The overlap integral and the dimensionless expressions for the components of the force due to the $\sigma_g 2s$ molecular orbital.

discussion, consider Q as equal to R, that is, give an arbitrary value of unity to the screening constant. Notice that as R is decreased the value of $\int \phi_\beta^2 \mathscr{D}_{\alpha x}d\tau$ falls steadily from unity to zero. In these same dimensionless units (i.e., multiplication by R^2) the nuclear repulsion is simply -1 for a pair of electrons. Thus for large values of R, the screening is complete and the forces are zero. However, as R is decreased and the penetration of the charge cloud on the second center begins, the net result of the nuclear repulsion and the penetration effect alone is a net repulsive force.

[4]*Hurley (2) has previously discussed the electrostatic interpretation of chemical binding as given in this paragraph.*

The form of $\int \phi_\alpha \phi_\beta \mathscr{D}_{\alpha x} d\tau$ as compared to that of simply S (which is also given in Fig. 1) is of great interest. It reaches a maximum and then returns to zero. That is, initially the charge which is transferred is placed in the binding region and the net attractive force is increased. However, as the overlap continues to increase, much of the charge is now placed in regions which are principally antibinding regions and the net attractive force begins to decrease. How this effect arises can be seen most simply and elegantly by a consideration of some views put forward by Berlin (3). Consider an element of charge which is placed at any point within the two full curves in the field of two nuclei of equal nuclear charge as indicated in Fig. 2. It is evident that the net force

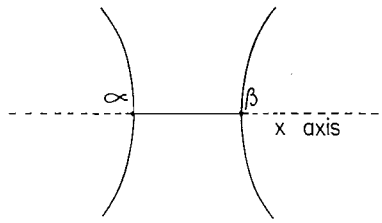

FIG. 2. A Berlin diagram showing the binding and antibinding regions in a diatomic molecule.

in the x direction which this element of charge exerts on the nuclei is one which draws them together. A similar element of charge placed at a point outside of the two curves (at either end of the molecule) produces an unbalanced resultant force in the x direction, one that tends to increase the distance between the two nuclei. It is also clear that there will be positions from which the forces acting on the nuclei will be equal with no net force tending to increase the nuclear separation. These positions in effect lie upon the two boundary curves which divide the "binding" region from the "antibinding" regions. Thus while the amount of charge transferred in the formation of a molecular orbital is proportional to the overlap integral, the position at which this charge is placed is of great importance. The great advantage of the present approach is that a quantitative estimate of the relative bonding or antibonding abilities of molecular orbitals may be made without the necessity of couching the discussion in terms of overlap integrals or other qualitative concepts.

All of the F_i's for the various types of molecular orbitals may be expressed in the form

$$F_i = (Z_\alpha/R^2) f_i(Q) \qquad [5]$$

where f_i is a dimensionless function of $Q(= \beta R)$. Specifically,

$$f_i/R^2 = \frac{1}{1 \pm S}\left[\int \phi_\beta^2 \mathscr{D}_{\alpha x} d\tau \pm 2 \int \phi_\alpha \phi_\beta \mathscr{D}_{\alpha x} d\tau\right] \qquad [6]$$

where again the plus and minus signs refer to the bonding and antibonding combinations respectively. We have derived analytical expressions for the f_i's due to the g and the u combinations of the $\sigma 1s$, $\sigma 2s$, $\sigma 2p$, $\pi 2p$, and sp hybrid molecular orbitals. Coulson (4) has previously given the expressions for the $\sigma 1s$ and $\sigma 2s$ molecular orbitals. All of the expressions are listed in the appendix for the sake of completeness. In Figs. 3 and 4 we have plotted the functions f_i for the various bonding and antibonding combinations. The actual force, expressed in atomic units, exerted on nucleus α by the electrons in the ith orbital in some particular molecule is obtained simply by multiplying the value of f_i as determined by the value of Q, by Z_α/R^2. The curves as shown when divided by R^2

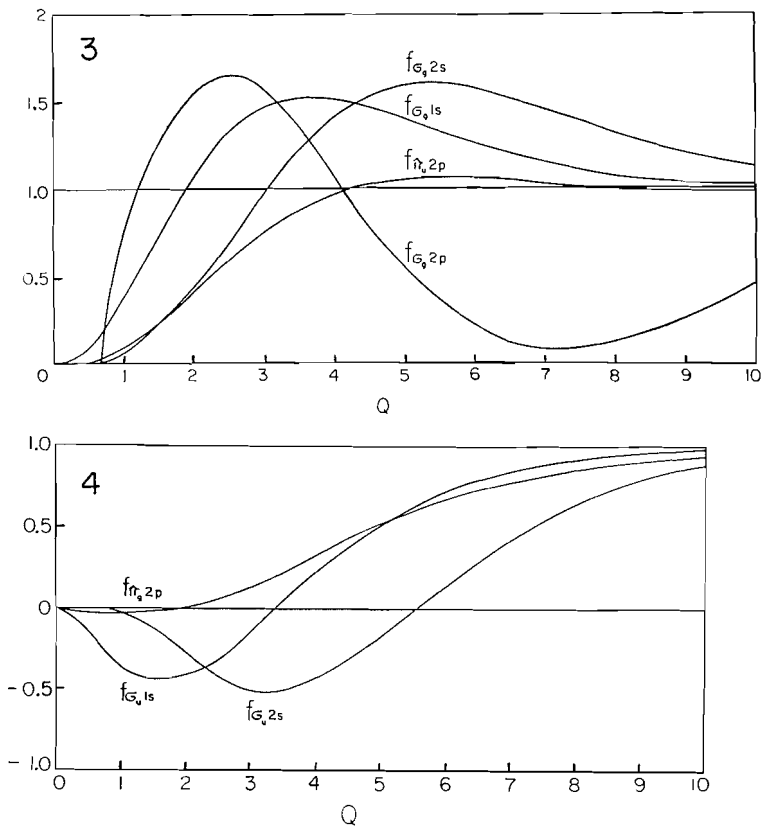

FIG. 3. The dimensionless expressions for the forces due to the bonding combinations $\sigma_g 1s$, $\sigma_g 2s$, $\sigma_g 2p$, and $\pi_u 2p$ ($\sigma_g 2p$ is orthogonal to $\sigma_g 2s$).

FIG. 4. The dimensionless expressions for the forces due to the antibonding combinations, $\sigma_u 1s$, $\sigma_u 2s$, and $\pi_g 2p$.

represent the forces exerted on a nucleus of unit charge by electrons distributed in molecular orbitals with a screening constant equal to unity for all values of R.

III. A DISCUSSION OF THE FORMS OF THE f_i CURVES

Many attempts have been previously made to relate the strengths of various bonds to the magnitude of the overlap between the atomic orbitals comprising the bond. Examples are Pauling's criterion of maximum overlap, the use of the overlap integral by Mulliken (5) and Maccoll (6), and discussions due to Mulliken (7) of atomic and overlap populations. All these discussions are qualitative in nature. By focusing our attention on the forces involved we may make the discussions more quantitative, and less speculative. A number of interesting points emerge from a consideration of Figs. 3 and 4. For instance, while the $\pi_u 2p$ molecular orbital possesses an overlap integral which, for any value of Q, is only slightly less than that for a $\sigma_g 2s$ molecular orbital, the π_u is much less bonding than is the σ_g orbital. A consideration of the forces involved illustrates why this should be expected. First, a comparison of the integrals $\int \mathscr{D}_{\alpha z} 2p\pi_\beta^2 d\tau$ and $\int \mathscr{D}_{\alpha z} 2s_\beta^2 d\tau$ shows that the π_u orbital is much less effective at screening the nucleus than is the σ_g orbital. Second, the π_u orbital, while possessing an appreciable overlap and transferring

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

a considerable amount of charge to the binding region, places most of the charge above and below the internuclear axis. It is evident from the form of the integral $\int \pi_\alpha \pi_\beta^* \mathscr{D}_{\alpha z} d\tau$ that the maximum force will be obtained when the charge is placed along the internuclear axis as it is in this position that the interaction with the nuclear dipole will be a maximum. While the total amount of charge transferred by the σ_g orbital is very nearly the same as for the π_u, the force exerted on the nucleus by this distribution of electrons is much greater since the maximum pile-up of charge is on the internuclear axis. This example illustrates why a mere comparison of the overlap integrals is insufficient to determine the relative bonding properties; one needs to know, rather, the amount of charge transferred and the point to which it is transferred, two facts which the f_t values take into account fully.

The force exerted by the electrons in a $\sigma_g 1s$ orbital reaches a maximum value for smaller values of Q than does that for the molecular orbitals composed of $2s$ and $2p$ atomic orbitals. This result is to be expected as maximum force should reflect the maximum in the radial density function.

The force curves illustrate in a very lucid manner the effect of mutual orthogonalization on the bonding properties of molecular orbitals. The $f_{\sigma_g 2p}$ curve is that for a $\sigma_g 2p$ molecular orbital which is orthogonal to the $\sigma_g 2s$ molecular orbital. Neither the $\sigma_g 2s$ nor the $\sigma_g 2p$ molecular orbitals have been made orthogonal to the $\sigma_g 1s$ orbital. The reasons for this procedure are as follows. When all 10 of the molecular orbitals are made mutually orthogonal the resulting picture is too complicated to be useful in making general observations. Thus one must decide between taking the $\sigma_g 2s$ and the $\sigma_g 2p$ orthogonal to each other and neglecting the non-orthogonality with respect to the $\sigma_g 1s$, or else make both the $\sigma_g 2s$ and $\sigma_g 2p$ orthogonal to the $\sigma_g 1s$ but then not to each other. Coulson and Lester (8) have pointed out the necessity of including the $1s$–$2s$ and $1s$–$2p$ orthogonalities in the calculation of molecular energies. It has been pointed out by them that when a $\sigma_g 2p$ molecular orbital is constructed so as to be non-orthogonal to the $\sigma_g 1s$ function the $2p$ function will contain a significant amount of $\sigma_g 1s$ character. Thus the energy obtained for this non-orthogonal $2p$ molecular orbital will be too large as it contains a contribution due to the $1s$ molecular orbital. This is a very serious discrepancy as the term value for the $1s$ molecular orbital lies about 10 ev below that for the $\sigma_g 2p$ molecular orbital even in H_2^+ and thus a small amount of $1s$ contribution to the $2p$ molecular orbital causes considerable error. Coulson and Lester (8) do not discuss the discrepancies which arise from the lack of orthogonality between the $2s$ and $2p$ molecular orbitals. In the calculation of the forces it is much more important to take into account this latter orthogonality than the former. The *forces* due to the $\sigma_g 1s$ orbital are actually slightly less than those due to the $\sigma_g 2s$ and $\sigma_g 2p$ molecular orbitals at the equilibrium internuclear distances and as can be seen from the graphs, all the curves approach unity for large values of Q. Thus a small amount of $1s$ character in the molecular orbitals constructed from the $2s$ and $2p$ orbitals will be much less serious than in the calculations of energies.[5] However, it is very important in these calculations to ensure orthogonality between the $2s$ and $2p$ functions. In Fig. 5 we show a plot of $f'_{\sigma_g 2p}$ which is the result obtained when the $\sigma_g 2p$ molecular orbital is not orthogonal to the $\sigma_g 2s$. The result is meaningless. The forces predicted by this curve are of such a magnitude as to actually make every other force operative in the molecule insignificant. When the condition of orthogonality is introduced, however, the result for $f_{\sigma_g 2p}$ is very reasonable, as illustrated in Fig. 3. Mulliken (9) has

[5]*It should be pointed out that when one employs the electrostatic method for the calculation of bond energies a mutually orthogonal set of molecular orbitals (including the 1s contribution) must be used.*

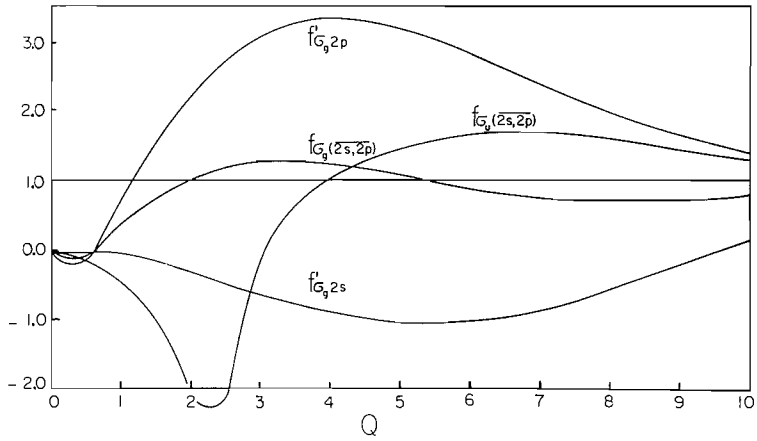

FIG. 5. The dimensionless expressions for the forces due to the $\sigma_g 2p$ and orthogonal $\sigma_g 2s$ molecular orbitals; also shown are the corresponding expressions due to the average electron densities of the mutually orthogonal pairs $\sigma_g 2s$, $\sigma_g 2p$ and $\sigma_u 2s$, $\sigma_u 2p$.

noted that when this "forced" hybridization (i.e., that due to the consequences of orthogonality) is taken into account the $\sigma_g 2p$ and $\sigma_g 2s$ orbitals become less bonding. Notice that the same trend is illustrated in the force curve for $\sigma_g 2p$. If the $\sigma_g 2p$ molecular orbital is made orthogonal to the $\sigma_g 2s$, the force exerted by the $\sigma_g 2p$ molecular orbital decreases to almost zero in the region of $Q = 7$. All this leads to an even more important observation. Included in Fig. 5 is the force curve for a $\sigma_g' 2s$ orbital which is now orthogonal to the $\sigma_g' 2p$ molecular orbital. That is, their roles have been reversed in the orthogonalization procedure. Now it is apparent that the $\sigma_g 2p$ molecular orbital is much more strongly binding than is the $\sigma_g 2s$ molecular orbital, which in fact becomes *antibinding*. Thus it is rather arbitrary to speak of the relative bonding properties of the $\sigma_g 2s$ and the $\sigma_g 2p$ molecular orbitals. When both of these orbitals are occupied there will be a resulting total force. This total force will have some meaning as it is the only contribution from the $n = 2$ orbitals with σ_g symmetry. This total force is, of course, the same as that obtained from the previous pair of orthogonal $\sigma_g 2s$ and $\sigma_g 2p$ orbitals, since an orthogonal transformation leaves the wave function and the total electron density unchanged. We have plotted, in Fig. 5, $f_{\sigma_g(\overline{2s},\overline{2p})}$, which is the average of the $f_{\sigma_g 2s}$ and the orthogonal $f_{\sigma_g 2p}$ curves (or equally well, the average of $f'_{\sigma_g 2s}$ and $f'_{\sigma_g 2p}$ curves), and $f_{\sigma_u(\overline{2s},\overline{2p})}$, which is the average of the values obtained from the orthogonal $\sigma_u 2s$ and $\sigma_u 2p$ molecular orbitals. By this consideration of the forces, we bring into sharp focus the fact that the concept of a molecular electronic configuration in terms of molecular orbitals does have definite limitations. The order of the orbital energies is at the complete mercy of the orthogonalization procedure and has no real significance. All that does possess significance is the total energy (or force) for the electronic state of the molecule, not how this energy is divided into contributions for the different orbitals.

IV. THE BONDING AND ANTIBONDING CHARACTER OF MOLECULAR ORBITALS

Much of what has been written about the bonding character of orbitals is based on spectroscopic observations, e.g., the ionization of an electron from the π_g orbital of the oxygen molecule results in the bond length of the O_2^+ ion being less than that for the neutral molecule. As Coulson (10) points out, this observation serves as the definition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

of an antibonding electron. Nonetheless much more is inferred from the results of such observations, i.e., that the electron when present in the molecule actually did exert an antibinding force. This is rarely the case as we shall demonstrate.

The electrostatic calculations allow for an unusually clear and simple definition of an antibinding and binding molecular orbital.[6] The force curves f_i give immediately the net force due to any particular density distribution. The simplest definition of a binding or a bonding orbital is one for which f_i is positive at the particular value of Q which is of interest, and of an antibinding or an antibonding orbital one for which the pertinent value of f_i is negative. A negative value of f_i implies that the electrons are distributed in such a fashion as to exert a force on the nuclei which tends to draw them apart, and surely this is the simplest interpretation of an antibinding or antibonding electron. Reference to Fig. 4 illustrates that the so-called "antibonding orbitals" possess negative f_i values only for very small values of Q, corresponding to very close approach of the atoms (for values of R usually less than R_e). Charge of total amount $2S/(1-S)$ is transferred in the formation of these orbitals, but it is transferred primarily to binding regions. Figure 4 shows that it is only when a relatively large amount of charge has been transferred that the amount placed in antibinding regions exerts an effect which outweighs that due to the binding regions. Reference to equation [6] shows that the analytical requirement for antibonding is for $2\int \phi_\alpha\phi_\beta \mathscr{D}_{ax}d\tau > \int \phi_\beta{}^2\mathscr{D}_{ax}d\tau$.

An important orbital, which is classed as antibonding, is the π_g orbital of the homonuclear diatomic, and symmetrical linear triatomic molecules. These molecular orbitals are of the form $N(\pi_\alpha-\pi_\beta)$. There are no other orbitals of the same symmetry to be considered in these molecules which allows us to refer specifically to the bonding properties of this particular orbital.

(i) Carbon Dioxide

The ionization of a π_g electron from carbon dioxide results in an increase in the equilibrium bond length from 1.163 Å to 1.177 Å. Mulliken (11) assumed this to imply that the π_g orbital was in reality a bonding orbital. He, however, states that it is impossible for the orbital as ordinarily written ($\pi_g = N(\pi_\alpha-\pi_\beta)$) to be bonding and that if it is bonding it must be due to a participation of a $3d$ atomic orbital of carbon in the molecular orbital. Moffitt (12) excludes this possibility as he maintains that the mixing in of a $3d$ orbital would be energetically very unfavorable. Instead Moffitt (12) tendered the explanation that after the removal of a π_g electron the residual π electron distribution rearranges in such a way that the π-bond order decreases. We can obtain a good estimate of the bonding character of this orbital by the electrostatic method simply by assigning a reasonable value to the screening constant β.[7] Using the expression for β in the footnote we obtain a value of 2.28 for the screening constant, and thus a value of 10 for Q, as the equilibrium bond distance for the O—O separation in CO_2 is 4.396 a.u. Clearly the π_g orbital is well within the region where the electron density is principally in the binding region. The value of f_{π_g} at $Q = 10$ is $+0.94$ and, therefore, the force acting on the nuclei tends to draw them closer together. The orbital is thus binding and has no antibinding properties whatsoever in this range of values for Q. The removal of one electron will leave only three electrons

[6]*Following the suggestion of Berlin we use the terms binding and antibinding when referring to forces and bonding and antibonding when referring to energies.*

[7]*The screening constant β is given by*

$$\beta = Z_s - \Delta Z e^{-R}$$

where $\Delta Z = Z_s - Z_u$, Z_s is the value of the screening constant for the separated atoms ($R = \infty$) and Z_u is the screening constant for the united atom ($R = 0$). R is expressed in atomic units. Both Z_s and Z_u include the factor $1/n^*$ in the Slater recipe (1).

For personal use only.

in the π_g orbital. To a first approximation this will decrease the amount of binding contributed by this orbital by 1/4. The C—O distance should therefore increase as is observed. The decrease in binding will not be as great as might at first be expected, for the removal of the electron has increased the value of the screening constant for the remaining electrons. Thus the value of Q increases *for the same value of* R, and the remaining electrons will exert a greater positive force per electron in the ion than in the neutral molecule. This is part of the effect which Moffitt has termed a rearrangement of the remaining π electrons. However, at $Q = 10$, f_{π_g} has already practically reached its maximum value of 1.00 and hence an increase in Q can result in only a small change in the force exerted per electron. Thus it is not necessary to invoke any special carbon participation to explain why the π_g orbital in carbon dioxide is bonding. The answer lies simply in the fact that at this value of the internuclear distance the atomic orbitals have not overlapped sufficiently to remove a significant amount of charge from the binding region, with the result that the force exerted on the nuclei is positive.

(ii) Oxygen

The ionization of a π_g electron from the oxygen molecule results in the formation of an O_2^+ ion which has a considerably shorter bond length and a higher energy of dissociation than the neutral molecule. This has always been interpreted as implying that the π_g orbital is in this case very strongly antibinding. The present interpretation does not bear this out. The screening constant for the π_g orbital in the oxygen molecule will be approximately 2.12, which places the π_g orbital in the region of Q equal to 4.82, i.e., in the region where the orbital is still definitely binding. Furthermore, it is in a region of the force curve where f_{π_g} is increasing rapidly with increasing Q. In the vertical ionization the screening constant and hence Q for the remaining π_g electron will be greater than the corresponding O_2 values for the same value of R. The force exerted on the nuclei per electron is thus considerably greater in the ion than in the neutral molecule for the same value of R. The end result of the removal of a π_g electron is the formation of an unbalanced force which draws the two nuclei together. This results even though the original molecular orbital itself was not antibinding. The molecule may now collapse and of course all of the deeper-lying orbitals will fall into regions of greater binding until the force due to the nuclear repulsion again matches that due to the electron density. (A glance at the force curves for the 1*s* and 2*s* orbitals will illustrate how these forces may well become appreciable as the value of R and thus Q is decreased.) The net result is an increase in force integrated over a significant distance, or a greater total bonding energy for the O_2^+ ion.

This discussion of the π_g orbital clearly shows the danger of attempting to extract detailed information regarding the binding character of an orbital solely from its spectroscopic behavior.

There is another manner in which the total force may be broken down into individual contributions, in such a way as to be useful in the interpretation of the trend in bond strengths. The values of the f_i's all tend to unity as Q increases. This occurs because the overlap between the atomic orbitals decreases to zero and the nuclei are simply screened by the electrons present in each atomic orbital. The total force thus approaches zero, for at large distances the screening will be complete. The interesting point is the behavior of the f_i values as Q (i.e., R) is decreased. A strongly "bonding" orbital will show an increase above unity in its f_i while an "antibonding" orbital will possess a f_i whose value drops below unity, eventually to a negative value for small values of Q. Thus

certain orbitals not only provide the shielding amount of force (equal to unity) but exceed this due to the favorable transfer of charge into the binding region. Because of this it is of interest to express the total force as

$$[7] \qquad F_{ax} = \frac{Z}{R^2} \sum_{i}^{n} (f_i - 1) \qquad \text{where } n = Z.$$

When written in this form we can see immediately which molecular orbitals provide electron densities which do more than simply screen their share of the nuclear charge.[8]

In fact the term $(f_i - 1)$ can be used as a new definition of bonding and antibonding. When the sign of $(f_i - 1)$ is negative it implies that the two electrons in the ith molecular orbital are distributed in such a way that the resulting density distribution is not sufficient to screen their share of the nuclear charge, and thus their presence contributes a resultant repulsive force to the molecular system. We term this a *net antibonding orbital.* When the sign of $(f_i - 1)$ is positive it implies that the pair of electrons in the ith molecular orbital exert a resultant binding force and hence such a molecular orbital is termed a *net bonding orbital.* According to these definitions, a doubly occupied orbital is bonding when its f_i value exceeds its share of the nuclear repulsive force. An orbital may thus be net antibonding even though its f_i value is positive. Reference to Figs. 3 and 4 illustrates that the definition of net antibonding coincides much more closely with the usual assignment of bonding and antibonding properties of the molecular orbitals. For example, the π_g molecular orbital is net antibonding for the value of Q found in the oxygen molecule. Thus a molecule which is forced to employ the π_g orbital must distribute these electrons in such a fashion that although the electron density in the binding region is still sufficient to result in a force which draws the nuclei together, is insufficient to overcome that portion of the nuclear repulsive force associated with their presence.

The statement is often made that there is no stable helium molecule because the $\sigma_u 1s$ orbital is more antibonding than the $\sigma_g 1s$ orbital is bonding. In fact, it is generally stated that for any molecular orbital, the antibonding combination is more antibonding than is the bonding combination bonding. This is in fact not true. The $\sigma_u 1s$ orbital is binding, that is, draws the nuclei together except for values of Q less than 3.4 (which would correspond to R values of less than 2.0 a.u. in He_2). It is less binding than the $\sigma_g 1s$ orbital but still binding, for values of $R > 2.0$ a.u. What causes the helium molecule to be unstable is that the $\sigma_u 1s$ orbital is *net antibonding.* On proceeding from the hydrogen molecule to the helium molecule we increase the nuclear repulsive force and add a pair of electrons to an orbital which while binding, is not sufficiently binding to meet the increased nuclear repulsion. This is not equivalent to the usual interpretation.

The $\sigma_g 1s$ and $\sigma_u 1s$ molecular orbitals for the homonuclear diatomic molecules, from Li_2 across, all possess a value of $Q > 10$ at R_e. In this region of Q, the quantity $(f_i - 1) = 0$ and this implies that the electrons in these molecular orbitals are doing nothing more than shielding the nuclei of each atom. They are not contributing to either the net bonding or net antibonding, but rather may be classed as *net nonbonding* as $(f_i - 1) = 0$ implies. The $\sigma_g 1s$ and $\sigma_u 1s$ orbitals are truly localized. The force curves illustrate that we are justified in labelling them simply as KK in the molecular orbital description of a molecule.

[8]*Equation [7] as written applies to a neutral molecule with all the molecular orbitals doubly occupied. For a molecule with two singly occupied molecular orbitals the pertinent measure would then be $(f_i/2 - 1/2)$ for each. Fully occupied π orbitals are counted twice.*

Reference to Fig. 5 shows that the result of making $\sigma_g 2p$ orthogonal to $\sigma_g 2s$ is to make the average contribution from these two orbitals net antibinding for large values of Q. However, making $\sigma_u 2s$ orthogonal to $\sigma_u 2p$ results in a net binding force from these orbitals for large values of Q. That is, when orthogonalization is taken into account, the "bonding" orbitals become net antibonding and the "antibonding" orbitals become net bonding above some value of Q.

In general, the f_i curves illustrate that *for any value of* Q, the process of orthogonalization reduces both the bonding properties of "bonding" orbitals and the antibonding properties of "antibonding" orbitals. Mulliken (9), from qualitative considerations of overlap integrals, has stated that the effect of forced hybridization "is to weaken very considerably the bonding power of bonding molecular orbitals but to strengthen markedly the antibonding power of antibonding molecular orbitals". We therefore disagree with Mulliken's predictions regarding the effects of forced hybridization on the antibonding orbitals.

The effect of orthogonalization on the forces and the f_i curves is again easier to see than is the effect it has on the energies. If the molecular orbital σ_2 is to be made orthogonal to another molecular orbital σ_1 of the same symmetry, the resulting electron density is

$$\rho = [\sigma_2^2 + S_{12}^2\sigma_1^2 - 2S_{12}\sigma_1\sigma_2]/(1 - S_{12}^2)$$

where $S_{12} = \int \sigma_2\sigma_1 d\tau$. The amount of density subtracted, $2S_{12}\sigma_1\sigma_2$, from the original density σ_2^2 is greater than the amount added, $S_{12}^2\sigma_1^2$, since S_{12} is less than unity. The orthogonalization diminishes the electron density and hence reduces the force. If σ_1 and σ_2 are of u symmetry, i.e., antibonding combinations, the correction $S_{12}\sigma_1\sigma_2$ is itself negative in sign and both corrections to σ_2 are positive. Thus the effect of "forced hybridization" on an antibonding orbital is to increase the electron density and hence the value of the force. Furthermore, an estimate of the exact extent of the effect of forced hybridization can readily be made by the use of f_i curves.[9]

The N_2 molecule possesses the strongest bond of all the homonuclear diatomic molecules formed from the elements of the first row of the periodic table. The dissociation energy of the O_2 molecule is 5.080 ev, as compared to 9.756 ev for N_2. It is a simple matter to account for this decrease in bond strength. The extra pair of electrons that is possessed by the O_2 molecule is placed in the π_g orbital. This orbital is net antibinding for all values of Q. The added pair of electrons on passing from nitrogen to oxygen does not yield a force large enough to overcome the added nuclear repulsion. The term $(f_{\pi_g} - 1)$ thus detracts from the total force F_{ax} at any value of Q, and will cause F_{ax} to equal zero at a value of Q larger than that found for N_2, corresponding to a weaker and a longer bond. As the fluorine molecule has four π_g electrons, the net antibinding contribution to F_{ax} is still greater for all values of Q, and thus one would predict an even larger value for R_e and a still smaller value for the dissociation energy in this case.

Proceeding in the other direction from N_2, the C_2 molecule should have a smaller dissociation energy than N_2 simply because it has one electron less in the π_u and $\sigma_g 2p$ orbitals, both of which are net bonding when integrated over a large enough range of Q. Thus carbon, in effect, obtains only 3/4 and 1/2 respectively of the net binding forces as does N_2 from these two orbitals, making F_{ax} for C_2 less than that for N_2 at any value of Q.

[9]*The effects of general (as opposed to forced) hybridization on bond strengths as determined by an analysis of the associated force curves will form the subject of a forthcoming publication.*

This explanation of the variation in the bond strengths of the diatomic molecules in terms of the forces involved is essentially the same as that obtained from the usual interpretations if one replaces the terms "bonding" and "antibonding" with the terms net bonding and net antibonding. The present discussion is necessarily less speculative than former ones because of the analytical definitions which may be obtained from the f_i curves for the terms net bonding and net antibonding. This is preferable to qualitative discussions based entirely on bonding abilities which were inferred from the forms of the molecular orbitals.

In addition to this we summarize the other advantages of the present approach: the simple electrostatic interpretation of the chemical bond, in terms of two easily understandable force integrals, one giving the effect of the nuclear penetration into the neighboring atomic charge cloud, and the other relating the magnitude of the forces to the extent of overlap, or to the amount of charge which is transferred in the formation of a molecule. An analytical definition of binding and antibinding, and the ease with which any molecular orbital may be so classified by the assignment of a single parameter. The clarification of the terms bonding and antibonding, together with the definition of net antibonding and net bonding. That the previous concept of bonding and antibonding actually fit in more closely with these later definitions, and that in most instances, the electrons are not distributed in such a way as to give an antibinding force, nor do they exert an antibonding effect on the energy of a molecule when they are placed in an orbital which by symmetry is usually classed as antibonding. The possibility of expressing the resultant forces in terms of the individual f_i functions, which may be plotted as a function of Q only, allows one to see clearly for the first time the total effect of orthogonalization or forced hybridization within a set of orbitals, and what effect this has on their bonding abilities.

THE SULPHURIC ACID SOLVENT SYSTEM

PART II. CONDUCTIVITY MEASUREMENTS ON SOLUTIONS OF SOME ACIDS[1]

J. Barr, R. J. Gillespie, and E. A. Robinson

ABSTRACT

Conductivity measurements have been made on solutions of the following substances in sulphuric acid: $HClO_4$, HSO_3F, HSO_3Cl, HPO_2F_2, $HAs(HSO_4)_4$, CH_3SO_3H, and CF_3CO_2H. Of these substances HSO_3F, HSO_3Cl, $HAs(HSO_4)_4$, and probably $HClO_4$, behave as acids, CF_3CO_2H is a non-electrolyte, and HPO_2F_2, and probably CH_3SO_3H, are bases of the sulphuric acid system. Acid dissociation constants for HSO_3F, HSO_3Cl, and $HAs(HSO_4)_4$ have been determined by comparing the conductivities of their solutions with those of $H_2S_2O_7$, whose dissociation constant is known from other measurements, and also by conductimetric titration with a strong base, e.g. $KHSO_4$. These acids of the sulphuric acid system decrease in strength in the order $HSO_3F > HAs(HSO_4)_4 > HSO_3Cl > HClO_4$.

INTRODUCTION

Very few substances are known that have a sufficiently great proton-donating ability to protonate sulphuric acid i.e., to ionize according to the equation

$$HA + H_2SO_4 = H_3SO_4^+ + A^- \qquad [1]$$

thereby behaving as acids of the sulphuric acid solvent system. It has been shown by cryoscopic measurements (1, 2) that disulphuric acid is partially ionized according to the equation

$$H_2S_2O_7 + H_2SO_4 = H_3SO_4^+ + HS_2O_7^- \qquad [2]$$

with a dissociation constant $K_a = [H_3SO_4^+]\,[HS_2O_7^-]/[H_2S_2O_7] = 0.014$ mole kg^{-1} over the range 10–25° C (2, 3). It was deduced from cryoscopic measurements (4) that tetra-(hydrogen sulphato)boric acid, $HB(HSO_4)_4$, is a rather strong acid ionizing according to the equation

$$HB(HSO_4)_4 + H_2SO_4 = H_3SO_4^+ + B(HSO_4)_4^-. \qquad [3]$$

By conductimetric titration with strong bases a value of $K_a = 0.3$ mole kg^{-1} was deduced (5). From the results of conductimetric and cryoscopic measurements on solutions of lead tetraacetate in sulphuric acid (6), it has been concluded that the $Pb(HSO_4)_6^{2-}$ ion is formed and that it undergoes considerable solvolysis, indicating that the corresponding acid, $H_2Pb(HSO_4)_6$, is rather weak, but solutions of the acid itself have not been investigated. Cryoscopic measurements on solutions of ammonium and nitronium perchlorates showed that they undergo essentially complete solvolysis and it was therefore concluded that perchloric acid is an exceedingly weak acid of the sulphuric acid system (7).

The present measurements were undertaken to extend our knowledge of acids of the sulphuric acid system by finding additional examples of acid behavior and by obtaining quantitative data on acid dissociation constants. The relative strengths of these extremely strong proton donors are of some theoretical interest; no information can be obtained from measurements on aqueous solutions since some of these acids are hydrolyzed by water and all of them would be so extensively ionized that it would not be possible to differentiate among their strengths.

EXPERIMENTAL

The apparatus and general procedure for making the electrical conductivity measurements has been described elsewhere (8). The conductimetric titrations were carried out as previously described (5). The composition of the sulphuric acid solvent was adjusted until it had the conductivity corresponding to the composition 100% H_2SO_4 (κ = 0.010439 $ohm^{-1}\ cm^{-1}$) (8). Fluorosulphuric acid was redistilled twice in a closed system from which all moisture was rigorously excluded and had b.p. 161°. Chlorosulphuric and trifluoroacetic acids were purified by distillation and had boiling points 152° and 72° respectively. Perchloric acid was distilled under reduced pressure from a mixture of one part of 70% aqueous perchloric acid and four parts of 20% oleum and condensed in a trap at liquid-air temperature (9). Difluorophosphoric acid was a sample kindly provided by Dr. W. E. White of the Ozark Mahoning Company, Tulsa, Oklahoma. It was twice redistilled and had b.p. 44–46° at approximately 15 mm. The fluorine n.m.r. spectrum showed that there was no appreciable concentration of any other fluorine-containing compound (10). Solutions of tetra(hydrogen sulphato)arsenious acid $HAs(HSO_4)_4$ were prepared by dissolving arsenious oxide in an oleum (11), whose composition was known from its conductivity (12), in accordance with the equation:

$$As_2O_3 + 3H_2S_2O_7 + 2H_2SO_4 = 2HAs(HSO_4)_4. \quad [4]$$

RESULTS

The results of the conductivity measurements, which were made at 25°, are given in Table I and Fig. 1. Interpolated values from a previous publication (12) are included

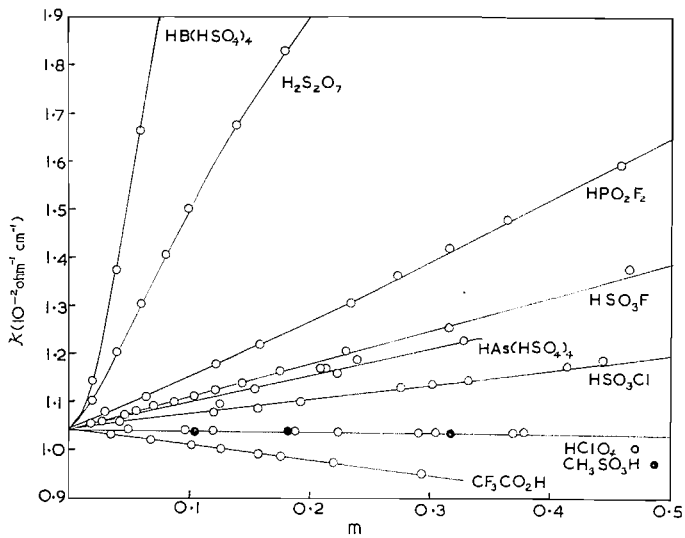

FIG. 1. Conductivities of solutions of acids.

for $HB(HSO_4)_4$ and a new value for its dissociation constant is calculated from these results. In the conductimetric titrations, solutions of the acids HSO_3F, HSO_3Cl, and $HAs(HSO_4)_4$ were titrated with the strong bases $KHSO_4$ or $NaHSO_4$, and disulphuric acid was titrated with the base HPO_2F_2, and in each case the composition of the solution

having a minimum conductivity was determined (5). This composition is conveniently expressed in terms of the ratio, $r_{min} = n_B/n_{HA}$, of the moles of base n_B that have to be added to n_{HA} moles of the acid to obtain the conductivity minimum. The results of the conductimetric titrations are given in Table II and Fig. 2.

DISCUSSION

The $H_3SO_4^+$ and HSO_4^- ions conduct almost exclusively by a proton-transfer mechanism and they have much larger mobilities than all other ions which conduct by the ordinary diffusion process (13). Thus the conductivities of solutions of acids and bases in sulphuric acid can to a reasonable approximation be assumed to be due only to $H_3SO_4^+$ in solutions of acids and only to HSO_4^- in solutions of bases. The conductivity of a solution of an acid is therefore determined almost entirely by the concentration of $H_3SO_4^+$ and is a measure of its extent of ionization according to equation [1]. Thus it is immediately apparent from the conductivities of the acids shown in Fig. 1 that they decrease in strength in the order $HB(HSO_4)_4 > H_2S_2O_7 > HSO_3F > HAs(HSO_4)_4 > HSO_3Cl > HClO_4$.

The Acids HSO_3F, HSO_3Cl, $HAs(HSO_4)_4$, and $HB(HSO_4)_4$

That the electrolytes HSO_3F, HSO_3Cl, and $HAs(HSO_4)_4$ are acids of the sulphuric acid system is shown by the fact that the conductivities of their solutions are decreased by the addition of a base such as $NaHSO_4$ (Fig. 2) because of the neutralization reaction

$$H_3SO_4^+ + HSO_4^- = 2H_2SO_4 \qquad [5]$$

and the consequent diminution in the concentration of the highly conducting $H_3SO_4^+$ ion. Addition of sufficient base causes the conductivity to pass through a minimum and then increase and the value of r_{min} is related to the dissociation constants of the acid and the base, K_a and K_b respectively, by the expression

$$[6] \qquad r_{min} = (1+0.018/K_b).(1+0.013/K_a)^{-1}+0.0007/a$$

where a is the initial stoichiometric concentration of the acid (5). For a strong base such

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

as $NaHSO_4$ this simplifies to

[7] $$r_{min} = (1+0.013/K_a)^{-1}+0.0007/a.$$

Values of the dissociation constants of HSO_3F, HSO_3Cl, and $HAs(HSO_4)_4$ calculated from this expression are given in Table II.

Since the dissociation constant of disulphuric acid is known from cryoscopic measurements, values for the dissociation constants of acids can also be obtained by comparing the conductivities of their solutions with those of $H_2S_2O_7$ solutions. The method is similar to that used previously to determine the strengths of weak bases by comparison of the conductivities of their solutions with those of the strong base $KHSO_4$ (14). Assuming that the conductivity of a solution of any acid HA is determined only by the concentration of $H_3SO_4^+$ the concentration of this ion must be the same in solutions of any acids having the same conductivity. The concentration of $H_3SO_4^+$ in any solution of $H_2S_2O_7$ can be calculated from its known dissociation constant and the equilibrium constants for the self-dissociation reactions of the solvent. Concentrations of $H_3SO_4^+$ at round values of the stoichiometric concentration of $H_2S_2O_7$ taken from a previous publication (12) are given in column 3 of Table III. The stoichiometric concentrations $[HA]^s$ of

the acids HSO_3F, HSO_3Cl, $HAs(HSO_4)_4$, and $HB(HSO_4)_4$, having the same conductivities as solutions of these concentrations of $H_2S_2O_7$, were obtained from the plots shown in Fig. 1 and are given in column 2 of Table III. The concentrations of $H_3SO_4^+$ in solutions of these acids are then as given in column 3. The concentrations of A^- are not exactly equal to the concentrations of $H_3SO_4^+$ because of the self-dissociation equilibria of the solvent but the concentrations of A^- corresponding to given concentrations of $H_3SO_4^+$ have been previously calculated (Table 2 of ref. 13). By interpolating from these values the concentrations of A^- given in column 4 of Table III were obtained. From the relationship

$$[8] \qquad [HA]^s = [HA] + [A^-]$$

the corresponding concentrations of unionized acid [HA] were obtained (column 5) and finally the acid dissociation constants given in the last column were calculated from the expression

$$[9] \qquad K_a = [H_3SO_4^+]\,[A^-]/[HA].$$

In general the values of the dissociation constants determined by the two methods are in reasonable agreement considering the approximations involved in both methods. Table IV lists all the known acids of the sulphuric acid system and gives mean values for their dissociation constants.

Trifluoroacetic Acid

This substance causes a slight decrease in the conductivity of sulphuric acid. A similar behavior has been observed previously for trichloroacetic acid and sulphuryl chloride (15) and for a number of polynitroaromatic compounds (14). It was concluded that these substances are non-electrolytes. The decrease in conductivity was attributed to a decrease in the concentration of the conducting ions $H_3SO_4^+$ and HSO_4^-, resulting partly from dilution by the solute and partly from a decrease in the extent of autoprotolysis and to a decrease in the mobilities of these ions resulting from interference with the proton-transfer mechanism of conduction by the non-electrolyte (14, 15). We conclude that trifluoroacetic acid is a non-electrolyte like trichloroacetic acid and sulphuryl chloride.

Perchloric Acid and Methanesulphonic Acid

These substances cause an almost negligible change in the conductivity of sulphuric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

acid. This could be due either to their being non-electrolytes which, in contrast to other non-electrolytes, do not affect the conductivity of the solvent, or, more probably, to their being just sufficiently ionized to compensate for a decrease in conductivity caused by their non-ionized portions.

Since perchloric acid is more extensively ionized than sulphuric acid in solution in acetic acid (16) it seems reasonable to suppose that it behaves as an acid in solution in sulphuric acid, although it is evidently very weak. It is obviously not possible to calculate a dissociation constant for perchloric acid from the present results.

In contrast to perchloric acid, however, we suppose that the very slight ionization of methanesulphonic acid is as a base rather than as an acid. Benzenesulphonic acid and *p*-toluenesulphonic acid have been found to be weak bases (K_b = 0.011 and 0.026 respectively) (17) and, just as nitromethane (K_b = 0.002) is a somewhat weaker base than nitrobenzene (K_b = 0.01) (14, 18), so methanesulphonic acid might be expected to be a weaker base than benzenesulphonic acid but it is not possible, from the present results, to obtain a value for its dissociation constant.

Difluorophosphoric Acid

The conductivities of difluorophosphoric acid are greater than those of fluorosulphuric acid but in contrast to most of the other electrolytes discussed above it behaves as a base rather than as an acid, i.e. it is partially ionized according to the equation

$$HPO_2F_2 + H_2SO_4 = H_2PO_2F_2^+ + HSO_4^-. \quad [10]$$

Addition of $KHSO_4$ to a solution of HPO_2F_2 increases rather than decreases the conductivity (Table I) and addition of HPO_2F_2 to a solution of $H_2S_2O_7$ causes a decrease in the conductivity. In fact, disulphuric acid can be titrated conductimetrically with the base HPO_2F_2 (Fig. 2) and a value for the basic dissociation constant can be calculated from the value of r_{min} by means of equation [6] (Table II).

Another value for the basic dissociation constant of HPO_2F_2 can be obtained by comparing the conductivities of its solutions with those of the strong base $KHSO_4$ (12, 14). The concentrations of $KHSO_4$ solutions having the same conductivities as those of solutions of round concentrations of HPO_2F_2 were obtained from plots of the conductivities of the two substances and are given in Table III. The concentrations of HSO_4^- in these solutions of $KHSO_4$, which are not equal to the stoichiometric concentration of $KHSO_4$ because of the HSO_4^- ions resulting from the self-ionization of the solvent, were obtained from a previous paper (Table 3 of ref. 13). The corresponding concentrations of $H_2PO_2F_2^+$ were also obtained from this table. Then from the relation

$$[HPO_2F_2]^s = [H_2PO_2F_2^+] + [HPO_2F_2]$$

the concentration of unionized HPO_2F_2 was obtained and finally a value for the basic dissociation constant $K_b = [H_2PO_2F_2^+]\,[HSO_4^-]/[HPO_2F_2]$ was calculated (Table III). The basic strength of difluorophosphoric acid in sulphuric acid ($K_b = 1.0\times10^{-2}$) is the same as that of nitrobenzene. Phosphoric acid is a strong base in sulphuric acid (11); the substitution of two OH groups by more electronegative fluorine atoms has the expected effect of decreasing the base strength.

As difluorophosphoric acid is a base of the sulphuric acid system it is reasonable to conclude that its proton-donating power is less than that of either of the isoelectronic molecules HSO_3F and $HClO_4$. Thus the intrinsic strengths or proton-donating abilities of these acids are in the order $HSO_3F > HClO_4 > HPO_2F_2$. It has been suggested (19, 7)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

that the strengths of inorganic oxyacids are determined largely by the number of equivalent oxygen atoms in the anion over which the negative charge may be spread, the strength increasing with the number of equivalent oxygen atoms. According to this viewpoint fluorosulphuric, chlorosulphuric, and sulphuric acids are all of the same general type, their anions, FSO_3^-, $ClSO_3^-$, and $HOSO_3^-$, each having three equivalent oxygen atoms. All three acids should be weaker than perchloric acid whose anion ClO_4^- has four equivalent oxygen atoms. On the other hand phosphoric acid and difluorophosphoric acid, whose anions, $(HO)_2PO_2^-$ and $F_2PO_2^-$, have only two equivalent oxygen atoms, should both be weaker than sulphuric acid. The observed strength of HPO_2F_2 is consistent with the above ideas but the strengths of HSO_3F and HSO_3Cl are not. It seems reasonable to suppose that some of the charge of the anion is also accommodated on the halogen atom; if the sharing of the charge between the oxygen atoms and the halogen were equal this would put HSO_3F and HSO_3Cl in the same class as perchloric acid, and their strengths would not then be anomalous. A similar sharing of charge would be expected in the anion of difluorophosphoric acid which would also put this acid in the same class as perchloric acid and it would then be expected to be stronger, rather than weaker, than sulphuric acid. It should be noted, though, that we have been comparing the acid strength of dilute solutions of various acids with that of sulphuric acid in bulk. The acid strength of sulphuric acid in bulk may, because of co-operative hydrogen-bonding effects, be considerably greater than that of sulphuric acid in dilute solution. Thus the observed strength of difluorophosphoric acid may not, after all, be anomalous. It would be interesting to compare the extents of dissociation of sulphuric acid and difluorophosphoric acid in dilute solution in some more basic solvent such as acetic acid.

ACKNOWLEDGMENTS

Financial assistance from the National Research Council is gratefully acknowledged. We thank Mr. R. Childs, who carried out the conductivity measurements on methanesulphonic acid.

STEROIDS

II. THE STEREOCHEMISTRY OF THE ADDITION OF GRIGNARD REAGENTS TO 12-KETOSTEROIDS[1]

R. NAGARAJAN AND GEORGE JUST

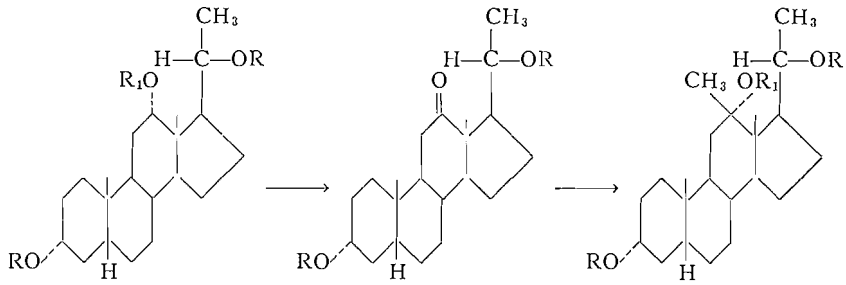
ABSTRACT

The action of methyl magnesium iodide on 3α,20α-diacetoxypregnan-12-one (II*a*) led to the formation of the epimeric 12-methyl-12-hydroxypregnanes III and V, in which the 12α-hydroxy-12β-methyl isomer III predominated.

Infrared measurements on the corresponding 12-hydroxy-12-methylpregnane-3,20-diones VI and IV permitted unambiguous assignment of configuration at C_{12}.

The pregnanedione IV was transformed to 12β-hydroxy-12α-methylprogesterone.

In the first paper of this series (1) we described the conversion of pregnane-3α,12α,20β-triol to 12α-hydroxy-12β-methylprogesterone. We should now like to report on the conversion of pregnane-3α,12α,20α-triol (I) to the epimeric 12-hydroxy-12-methyl-3,20-pregnanediones IV and VI and on the conversion of the former to 12β-hydroxy-12α-methylprogesterone (VII).



Partial succinylation (1) of pregnane-3α,12α,20α-triol (I) with succinic anhydride in pyridine, followed by methylation of the hemisuccinate with ethereal diazomethane, afforded a 91% yield of pregnane-3α,12α,20α-triol 3,20-bis-methyl succinate (I*a*). Oxidation of I*a* with chromium trioxide in acetic acid gave the corresponding 12-ketone II*b*. Our experience in the 20β-hydroxy series (1) indicated that the reaction of methyl magnesium iodide on pregnan-12-ones proceeded in better yield in the presence of a 20-acetate group rather than a 20-succinate function. Hence, the disuccinoxy ketone II*b* was hydrolyzed with methanolic potassium hydroxide to 3α,20α-dihydroxypregnan-12-one (II) and the latter acetylated with acetic anhydride in pyridine. The resulting diacetoxy ketone II*a* was treated with an excess of ethereal methyl magnesium iodide for 20 hours. Acetylation, chromatography, alkaline hydrolysis, and repeated crystallizations gave the epimeric 12-methylpregnane-3α,12,20α-triols III and V. The mono-, di-, and triacetates III*a–c* and V*a* were prepared and interrelated (see Experimental). Since the separation of the epimeric triols III and V by crystallization was tedious and incomplete, the mother liquors of the crystallization of the Grignard product containing the epimeric triols III and V were oxidized with chromic oxide in acetic acid. Chromatography on alumina of the oxidation product afforded 12β-methyl-12α-hydroxypregnane-3,20-dione (VI) and its 12α-methyl isomer IV. The total yield of the Grignard adducts III (VI) and V (IV) was 60.5% and 25.0% respectively. The hydroxy ketone VI was identical with the 12β-methyl-12α-hydroxypregnane-3,20-dione, isolated previously in the 20β-series (1) in 73% yield as the only product of the corresponding Grignard reaction. The infrared spectrum of this hydroxy diketone showed bands at 3680 cm^{-1} (free OH) and 1713 cm^{-1} (3,20-dione).[2]

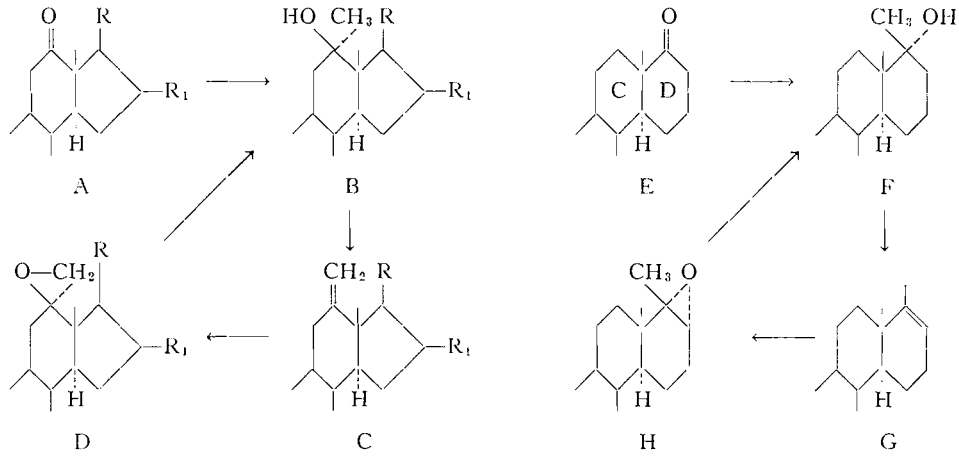
The epimeric 12α-methyl-12β-hydroxypregnane-3,20-dione (IV), obtained as a minor product, absorbed in the infrared at 3450 cm^{-1} (LiF prism; change in concentration did not shift the frequency of absorption; intramolecularly bonded OH); 1716 cm^{-1} (3-ketone), and 1695 cm^{-1} ($\diagdown$C$_{20}$=O $\cdots$ H—O—C$_{12}$—).[2] Inspection of models indicated that only a 12β-hydroxy function would form an internal hydrogen bond to the 20-carbonyl group (minimal distance: 2 Å).[3]

These data made possible an unambiguous assignment of configuration for the epimeric tertiary alcohols IV and VI and proved that the attack of methyl magnesium iodide on pregnan-12-ones proceeded mainly from the β-side of the steroid molecule, contrary, in this case, to the well-known "rule of rear-attack" in steroids (3, 4). The validity of the assignment of configuration at the 12-position was confirmed as follows: The tertiary alcohol VI on treatment with acetic acid, acetic anhydride, and *p*-toluenesulphonic acid (5) gave the acetate VI*a*, m.p. 175–176° (also obtained by partial hydrolysis of the triacetate III*a* to the monoacetate III*c* followed by oxidation) and a product, m.p. 72–73°. Further crystallizations gave a compound, m.p. 100–101°, which was assigned the 12-methylene structure IX, since it showed characteristic bands at 3080 cm^{-1}, 1645 cm^{-1}, and 885 cm^{-1}. The infrared spectrum of the product, m.p. 72–73°, was virtually identical with that of the compound melting at 100°, so that it must have consisted mainly of olefin IX, probably contaminated with olefin XI (compare 8). Treatment of the olefinic product m.p. 72–73° with osmium tetroxide gave predominantly the diol VIII containing probably traces of the diol X, which on tosylation gave the tosylate VIII*a* with probably a minor amount of the tosylate X*a*. Lithium aluminum hydride reduction of the tosylates, followed by chromium trioxide oxidation, gave the hydroxy ketone VI, identified by melting point, mixed melting point, and superimposability of the infrared spectra. Since nucleophilic attack by a Grignard reagent on a 12-ketone, and electrophilic addition of OsO_4 on a 12-methylene pregnane gave rise to products of identical configuration at C$_{12}$, it must be concluded that the nucleophilic and electrophilic reagents add from opposite sides of the steroid molecule. It is suggested that this conclusion, at least as far as it concerns nucleophiles of the Grignard type, applies to all steroidal 12-ketones (A) and 17*a*-ketones (E) where the steric environments are very similar.



Indeed, Ruzicka *et al.* (6) described some time ago the conversion of Δ^5-3β-acetoxy-17*a*-D-homoandrosterone (E) to Δ^5-17*a*β-methyl-3β-17*a*α-D-homoandrostenediol (F) by the action of methyl magnesium bromide. In order to prove the stereochemistry of the Grignard adduct F, it was dehydrated to the olefin G, which was treated with perbenzoic acid. The epoxide H was then reduced with lithium aluminum hydride and gave the original Grignard product F. This meant that attack by the Grignard reagent and the peracid must have proceeded from opposite sides of the steroid molecule. Since the Grignard adduct (F) was biologically inactive, and since its 17*a*-epimer was expected to show androgenic activity, Ruzicka and co-workers assumed that methyl magnesium bromide attacked the carbonyl function from the β-side, and that perbenzoic acid attacked the double bond from the α-side.

Recently, Bladon and McMeekin (7) submitted the tetrahydropyranylether of hecogenin

[3]*Wall and Serota (2) have recently reported two instances of an intramolecular hydrogen bond between a 12β-hydroxy group and a 20-carbonyl function in 3β-acetoxy-12β-hydroxy-12α-methoxy, 5α,16-pregnen-20-one, and 3β-acetoxy-12β-hydroxy-12α-methoxy-5,16-pregnandiene-20-one.*

FLOWSHEET II

(A) to the action of methyl lithium. They assigned a 12α-methyl-12β-hydroxy configuration (B) to the tertiary alcohol obtained in the reaction. Dehydration (C), epoxidation (D), and reduction with lithium aluminum hydride led to the original tertiary alcohol B. Since it is extremely unlikely that both the nucleophilic and electrophilic additions on hecogenin derivatives should proceed differently from the corresponding addition reactions in the pregnane series, and since Bladon and McMeekin's assignment were arbitrary, we suggest that they be reversed.

Levine and Wall (8) have also recently reported the reaction of hecogenin acetate (A) with methyl magnesium bromide, which led to "12β-hydroxy-12α-methyltigogenin" (B). Their proof of configuration rested on a reaction sequence identical with that outlined on Flowsheet I (VI $\rightarrow$ IX $\rightarrow$ VIII, VIII*a* $\rightarrow$ VI). In contrast to the results obtained by Bladon and McMeekin (7), Ruzicka *et al.* (6), and ourselves, the two products obtained by Grignard reaction and osmium tetroxide addition were not identical, but epimeric.[4]

The experiments described lead to the conclusion that in most cases different factors govern the stereochemistry of additions of reagents which form complexes, such as Grignard reagents, and of electrophiles. This statement is corroborated by experiments involving reduction of steroidal 12-ketones with lithium aluminum hydride in which a 50% yield of 12α-hydroxy compound is obtained (β-attack, 9).

Bromination at the 4-position of 12α-methyl-12β-hydroxy-3,20-pregnandione IV afforded the bromoketone IV*a*, which was transformed to 12α-methyl-12β-hydroxyprogesterone VII by the method of McGuckin and Kendall (10). This progesterone analogue did not exhibit any notable progestational, androgenic, diuretic, hypotensive, or anabolic properties.[5]

[4]*Melting point, mixed melting point, and optical rotation of the two "epimers" of Levine and Wall (8) seem to indicate that their products are not epimeric. However, unpublished N.M.R. data (private communication by Dr. S. Levine) show that the two compounds are distinctly different. A clarification of the conflicting results of Levine and Wall (8) and Bladon and McMeekin (7) will probably only be achieved by further experimental work.*

[5]*Biological tests were carried out by Dr. C. I. Chappel and Dr. Clara Revesz, Ayerst, McKenna and Harrison, Montreal.*

EXPERIMENTAL[6, 7, 8, 9, 10]

3α,12α,20α-Pregnanetriol 3,20-bis-Methyl Succinate (Ia)

A solution of the triol I (7.0 g) and succinic anhydride (12.0 g) in absolute pyridine (40 ml) was heated on a water bath at 90° for 4 hours, and left overnight at room temperature. To the reaction mixture was added 1 liter of ice water and it was extracted with ether after 1 hour. The ethereal layer was washed with water, cold 2 *N* hydrochloric acid, and water. The organic solution was dried over magnesium sulphate, filtered, and treated with excess ethereal diazomethane solution. Crystallization from acetone–hexane afforded 10.10 g of the bis-methyl succinate I*a*, m.p. 109–110°. Repeated crystallizations of the mother liquors from acetone–hexane gave 0.571 g of I*a*, m.p. 109–110° (yield 90.8%). Recrystallization did not raise the melting point, $[\alpha]_D^{29}$ 43° (*c* 1.02 in $CHCl_3$).

Calc. for $C_{31}H_{48}O_9$: C 65.92, H 8.57. Found: C 66.09, H 8.41.

3α,20α-Dihydroxypregnan-12-one bis-Methyl Succinate (IIb)

A solution of chromium trioxide (1.19 g) in 90% acetic acid (12 ml) was added to a solution of the bis-methyl succinate I*a* (6.088 g) in glacial acetic acid (210 ml) and left overnight at room temperature. Methanol (5 ml) was added to the reaction mixture, which was then poured into 2 liters of water and extracted with ether. The ethereal layer was washed with 5% sodium bicarbonate solution and water until the washings were neutral. Evaporation of the solvent afforded 6.071 g of the crude keto bis-methyl succinate II*b*, m.p. 65–66°.

Two crystallizations from ether–hexane raised the melting point of the keto bis-methyl succinate II*b* to 65.5–66.5°, $[\alpha]_D^{29}$ 87° (*c* 0.84 in $CHCl_3$).

Calc. for $C_{31}H_{46}O_9$: C 66.16, H 8.24. Found: C 65.94, H 8.04.

3α,20α-Dihydroxypregnan-12-one (II)

A solution of the keto bis-methyl succinate II*b* (6.004 g, crude product obtained from the above reaction) in 5% methanolic potassium hydroxide (500 ml) was heated under reflux for 4 hours. The methanol was removed by distillation until the volume of the reaction mixture was about 150 ml. After cooling, it was poured into 1 liter of water with stirring. The hydroxy ketone II, which separated out, was filtered, washed with water, and dried (3.49 g, m.p. 260–261°). The filtrate was extracted with ether and the ethereal solution was washed with saturated sodium chloride solution. Evaporation of the solvent afforded 0.077 g of II, m.p. 250–260°.

The hydroxy ketone was recrystallized twice from methanol for analysis, m.p. 260–261°, $[\alpha]_D^{29}$ 120° (*c* 0.56 in $CHCl_3$). (A few drops of C_2H_5OH was added to bring the hydroxy ketone II into solution.)

Calc. for $C_{21}H_{34}O_3$: C 75.41, H 10.24. Found: C 75.70, H 10.14.

3α,20α-Diacetoxypregnan-12-one (IIa)

Absolute pyridine (30 ml) and acetic anhydride (25 ml) were added to 3.40 g of the hydroxy ketone II and the mixture heated under reflux for 10 minutes until the crystals dissolved. The reaction mixture was left overnight in a water bath at 90°. Ether extraction gave 4.243 g of the crude ketone II*a*, m.p. 210–212°. Crystallization from acetone–hexane

[6] *All the melting points were corrected.*
[7] *Only the best yields were reported.*
[8] *Unless otherwise stated, the infrared spectra were taken in carbon tetrachloride solution using a 1-mm sodium chloride cell.*
[9] *The commercially available aluminum oxide (Woelm) was used for chromatography.*
[10] *The microanalyses were carried out by Dr. Alfred Bernhardt, Mülheim, Germany and Dr. C. Daesslé, 5757 Decelles St., Montreal.*

afforded 4.082 g of crystals, m.p. 211–212°. Crystallization of mother liquors gave 0.127 g, m.p. 211–212°. The over-all yield for the reaction sequence I*a* → II*b* → II → II*a* was 99%.

Two recrystallizations of the ketone II*a* from acetone–hexane raised the melting point to 212–212.5°, $[\alpha]_D^{29}$ 103° (*c* 1.25 in $CHCl_3$).

Calc. for $C_{25}H_{38}O_5$: C 71.73, H 9.15. Found: C 71.54, H 8.97.

Reaction of Methyl Magnesium Iodide with 3α,20α-Diacetoxypregnan-12-one (II a)

To 300 ml of an ethereal solution of methyl magnesium iodide (from 4.984 g of magnesium and 13.0 ml of methyl iodide) was added with stirring 10.68 g of the ketone II*a*, dissolved in 2 liters of absolute ether. The reaction mixture was heated under reflux for 16 hours and cooled, and a solution of ammonium chloride (50 g) in water (1 liter) was added. Ether extraction afforded 10.28 g of a product, m.p. 194–202°, which was acetylated with 65 ml of pyridine and 55 ml of acetic anhydride at 90° for 14 hours. The usual extraction procedure afforded 12.25 g of foam, which was chromatographed on alumina (4.5% water). The hexane–benzene (3:1) eluates were crystallized from ether–hexane and there was obtained 520 mg of the triacetate III*a*, m.p. 171–172°. Recrystallization from ether–hexane raised the melting point to 172–173°, $[\alpha]_D^{28}$ 90° (*c* 1.11 in $CHCl_3$).

Calc. for $C_{28}H_{44}O_6$: C 70.57, H 9.32. Found: C 70.57, H 9.21.

The hexane–benzene (1:1) and benzene eluates (4.485 g) on hydrolysis with 5% methanolic potassium hydroxide gave 3.587 g of crystals, m.p. 208–216°. Repeated crystallization from methanol afforded 3.216 g of triol III, m.p. 240–241°, $[\alpha]_D^{28}$ 70° (*c* 0.97 in $CHCl_3$).

Calc. for $C_{22}H_{38}O_3$: C 75.37, H 10.92. Found: C 75.33, H 10.83.

The benzene–ether and ether–methanol eluates (4.273 g) were hydrolyzed with 5% methanolic potassium hydroxide and there was obtained 3.604 g of a mixture of epimeric triols III and V, m.p. 204–216°. Fractional crystallization from methanol afforded 1.22 g of the triol III, m.p. 240–241°, and 1.376 g of the triol V, m.p. 201–203°. Recrystallization from acetone did not raise the melting point of the triol V, $[\alpha]_D^{22}$ 38° (*c* 1.07 in $CHCl_3$).

Calc. for $C_{22}H_{38}O_3$: C 75.37, H 10.92. Found: C 75.50, H 10.96.

An ether solution of the mother liquors of the hexane–benzene (3:1) fractions and the hexane–benzene (9:1 and 4:1) eluates were deacetylated with lithium aluminum hydride, and the triol mixture thus obtained was combined with the mother liquors of crystallization of triols III and V. To a solution of the combined triol mixture (3.181 g) in 150 ml of glacial acetic acid was added a solution of 2.13 g of chromium trioxide in 25 ml of 90% acetic acid and the mixture left for 16 hours at room temperature. Ether extraction gave 2.85 g of a pale-brown semicrystalline product, which was chromatographed on 80 g of alumina (4.5% water).

The hexane–benzene (4:1) eluates (170 mg), on crystallization from acetone–hexane, gave 80 mg of pregnane-3,12,20-trione, m.p. 198–200° (1, 11), identified by mixed melting point and comparison of I.R. spectra with an authentic sample.

Hexane–benzene (3:1, 2:1, 1:1) and benzene eluates (950 mg) were crystallized from ether–hexane and there was obtained 741 mg of the hydroxy ketone IV, m.p. 125–126°. The mother liquors were combined with the benzene–ether (95:5) fractions and crystallization from ether–hexane gave 113 mg of IV, m.p. 122–123°.

A portion of the hydroxy ketone IV was crystallized from ether–hexane for analysis, m.p. 125–126°, $[\alpha]_D^{28}$ 30° (*c* 0.90 in $CHCl_3$), $\nu_{max}^{CCl_4}$ 1716 cm^{-1} (3-ketone), 1695 cm^{-1}, and 3480 cm^{-1} ($>C_{20}=O \cdots H-O-C_{12}-$).

For personal use only.

Calc. for $C_{22}H_{34}O_3$: C 76.25, H 9.89. Found: C 76.16, H 9.90.

The rest of the benzene–ether and ether–methanol eluates on crystallization from acetone–hexane afforded 465 mg of the hydroxy ketone VI, m.p. 187–188°, $\nu_{max}^{CCl_4}$ 1713 cm^{-1} (3,20-dione), 3680 cm^{-1} (C_{12}-hydroxyl), found identical with 12β-methyl-12α-hydroxypregnane-3,20-dione (1) by mixed melting point and superimposability of I.R. spectra, thus confirming our assignment of configuration of the 12-hydroxy-12-methyl compound in our previous publication (1). Recrystallization of mother liquors gave 121 mg of VI, m.p. 184–186°.

Taking into consideration the isolation at different stages in the above experiment of the triacetate III*a* by chromatography, the triols III and V by crystallizations, and the hydroxy ketones VI and IV by chromatography, the over-all yields of 12β-methylpregnane-3α,12α,20α-triol and 12α-methylpregnane-3α,12β,20α-triol were 60.5% and 25.0% respectively.

*12β-Methylpregnane-3α,12α,20α-triol 12-Acetate (III*c*)*

A solution of 200 mg of the triacetate III*a* in 25 ml of 5% methanolic potassium hydroxide was heated at reflux temperature for 10 hours. Ether extraction gave 194 mg of oil. Fractional crystallization from ether–hexane afforded 56 mg of III*c*, m.p. 183–184° (yield 34%), and 10 mg of the triol III, m.p. 240–241°. The latter was identified by comparison of I.R. spectra and mixed m.p. with an authentic sample of triol III.

Recrystallization of III*c* with ether–hexane raised the m.p. to 184–185°, $[\alpha]_D^{28}$ 90° (*c* 1.07 in $CHCl_3$).

Calc. for $C_{24}H_{40}O_4$: C 73.40, H 10.27. Found: C 73.23, H 10.20.

*12β-Methyl-12α-acetoxypregnane-3,20-dione (VI*a*)*

To a solution of the monoacetate III*c* (165 mg, crude product obtained by alkaline hydrolysis of 170 mg of the triacetate III*a*) in 5 ml of acetic acid was added with stirring a solution of 112 mg of chromium trioxide in 2.5 ml of 90% acetic acid, and the reaction mixture left overnight at room temperature. Ether extraction gave 140 mg of oil, which was chromatographed on alumina (4.5% water). The hexane–benzene (1:1) and benzene eluates on crystallization from ether–hexane afforded 52 mg of the ketone VI*a*, m.p. 175–176°. Crystallization of mother liquors gave 16 mg, m.p. 174–175° (yield 49.1%). Two crystallizations of the ketone VI*a* from ether–hexane raised the m.p. to 175.5–176°, $[\alpha]_D^{22}$ 102° (*c* 1.04 in $CHCl_3$).

Calc. for $C_{24}H_{36}O_4$: C 74.18, H 9.34. Found: C 74.31, H 9.37.

The ether–methanol (9:1) fractions on crystallization from acetone–hexane gave 15 mg of the hydroxy ketone VI, m.p. 187–188°, identified by comparison of I.R. spectra and mixed melting point with an authentic sample of VI.

*12β-Methylpregnane-3α,12α,20α-triol 3,20-Diacetate (III*b*)*

A solution of 150 mg of the triol III in 5 ml of pyridine and 5 ml of acetic anhydride was left at room temperature for 16 hours. Ether extraction and crystallization from ether–hexane afforded 175 mg of the diacetate III*b*, m.p. 188–189°. Recrystallization of mother liquors gave 7 mg, m.p. 186–188° (yield 98%).

Recrystallization for analysis did not raise the melting point, $[\alpha]_D^{28}$ 80° (*c* 0.98 in $CHCl_3$).

Calc. for $C_{26}H_{42}O_5$: C 71.86, H 9.74. Found: C 71.69, H 9.67.

*12α-Methylpregnane-3α,12β,20α-triol 3,20-Diacetate (V*a*)*

Acetylation of 100 mg of the triol V at room temperature as described above gave upon crystallization from ether–hexane 117 mg of the diacetate V*a*, m.p. 189–190° (yield

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

94.4%). (Mixed melting point of the diacetate V*a* with the diacetate III*b* showed a depression in melting point.) Recrystallization for analysis did not raise the melting point, $[\alpha]_D^{28}$ 56° (*c* 0.99 in $CHCl_3$).

Calc. for $C_{26}H_{42}O_5$: C 71.86, H 9.74. Found: C 71.91, H 9.67.

Chromium Trioxide Oxidation of Triols III and V

To a solution of 200 mg of the triol III in 5 ml of glacial acetic acid was added with stirring 130 mg of chromium trioxide dissolved in 2.5 ml of 90% acetic acid and the mixture was left at room temperature for 18 hours. Ether extraction and crystallization from acetone–hexane gave 156 mg of the hydroxy ketone VI, m.p. 188–189°. Recrystallization of mother liquors afforded 5 mg, m.p. 187–188° (yield 86.5%). The identity of the above product was confirmed by the superimposability of I.R. spectra and mixed melting point with an authentic sample of VI.

Chromium trioxide oxidation of 200 mg of the triol V as described above gave 199 mg of an oil, which on chromatography on alumina and crystallization from ether–hexane afforded 83 mg of needles, m.p. 124–125°. Recrystallization of mother liquors gave 51 mg, m.p. 123–124° (yield 68%). The identity of this compound with the hydroxy ketone IV was proved by a comparison of I.R. spectra and mixed melting point.

12α-Methyl-12β-hydroxyprogesterone (VII)

A solution of bromine (306 mg) in acetic acid (15.2 ml) was added with stirring to a solution of the hydroxy ketone IV (600 mg) in acetic acid (5 ml) containing a drop of 50% (w/v) solution of hydrobromic acid. The reaction mixture was stirred for 5 minutes and poured in 250 ml of ice water. The solid which separated out was filtered, dried, and on crystallization from ether–hexane afforded 332 mg of the bromoketone IV*a*, melting point 172–173° (decomp.), λ_{max}^{EtOH} 285 mμ (ε 60), $\nu_{max}^{CCl_4}$ 1695 cm^{-1}, 3480 cm^{-1} ($>C_{20}{=}O \cdots H{-}O{-}C_{12}{-}$), 1735 cm^{-1} (4β-bromo-3-ketone).

The filtrate was extracted with ether and combined with the mother liquors of the crystallization of the bromoketone IV*a*. Since recrystallization was tedious and afforded only 114 mg of the bromoketone IV*a*, m.p. 168–169° (decomp.), the second crop and the mother liquors (533 mg of oil) were reduced by heating with 550 mg of zinc dust, 5.5 ml of acetic acid, and 0.5 ml of water at 90° for 1 hour. Ether extraction, chromatographic purification, and crystallization from ether–hexane gave 276 mg of the hydroxy ketone IV, m.p. 124–125°. Taking into consideration the recovery of the hydroxy ketone IV, the yield of pure bromoketone IV*a* was 83.2%.

The bromoketone IV*a* (330 mg, m.p. 172–173° decomp.) was dehydrobrominated according to the method of McGuckin and Kendall (10). The resulting oil was chromatographed on alumina (4.5% water). The benzene, benzene–ether, and ether eluates on crystallization from ether–hexane afforded 120 mg of the progesterone derivative VII, m.p. 142–143°. The mother liquors on crystallization afforded 19 mg of VII, melting point 139–142° (yield 48.4%). The second crop was recrystallized and added to the first batch. Recrystallization gave 126 mg of analytically pure VII, melting point 142–143°, $[\alpha]_D^{22}$ 113° (*c* 1.07 in $CHCl_3$), λ_{max}^{EtOH} 238 mμ (ε 18,600), $\nu_{max}^{CCl_4}$ 1695 cm^{-1} and 3480 cm^{-1} ($>C_{20}{=}O \cdots H{-}O{-}C_{12}{-}$), 1680 cm^{-1} and 1622 cm^{-1} (Δ^4-3-ketone).

Calc. for $C_{22}H_{32}O_3$: C 76.68, H 9.37. Found: C 76.68, H 9.41.

Reaction of 12β-Methyl-12α-hydroxypregnane-3,20-dione (VI) with Acetic Acid, Acetic Anhydride, and p-Toluenesulphonic Acid

To a solution of 500 mg of the hydroxy ketone VI in 25 ml of glacial acetic acid was added 5 ml of acetic anhydride and 500 mg of *p*-toluenesulphonic acid (5) and the suspension was stirred until the solid dissolved. The reaction mixture was left at room temperature for 4.5 hours, then poured into 250 ml of ice water and extracted with ether. The ethereal solution was washed with 5% sodium carbonate solution and water until the washings were neutral, and dried over magnesium sulphate. Evaporation to dryness afforded 565 mg of oil, showing bands in the infrared at 3070 cm^{-1}, 1645 cm^{-1}, 890 cm^{-1} ($\diagdown$C=CH_2) (12); 1750 cm^{-1}, 1215 cm^{-1} ($\Delta^{17(20)}$-enol acetate) (13); 1713 cm^{-1} (3-ketone). Under the above reaction conditions the $\Delta^{17(20)}$-enol acetate is known to be formed (14 and 15). The enol acetate was converted to the C_{20}-ketone by heating a solution of the crude reaction product in 25 ml of methanol with 750 mg of potassium carbonate in 10 ml of water under reflux for 2 hours. Ether extraction gave 555 mg of product showing no bands at 1750 cm^{-1} and 1215 cm^{-1} characteristic of enol acetates. It was chromatographed on alumina (4.5% water) and the hexane and hexane–benzene eluates on crystallization from hexane afforded 145 mg of needles, m.p. 72–73°. A portion of it was recrystallized from hexane for analysis, m.p. 73–74°, $[\alpha]_D^{22}$ 139° (*c* 1.03 in $CHCl_3$), $\nu_{max}^{CS_2}$ 3080 cm^{-1}, 1645 cm^{-1}, 885 cm^{-1} ($\diagdown$C=CH_2); 1713 cm^{-1} (3,20-dione).

Calc. for $C_{22}H_{32}O_2$: C 80.41, H 9.82. Found: C 80.02, H 9.66.

Recrystallization of mother liquors gave 45 mg of needles, m.p. 71–73° (yield 40.1%).

The mother liquors were dissolved in 5 ml of hexane and left in an ice box. After 1 week, 80 mg of crystalline compound was obtained. Repeated crystallization gave 63 mg of needles, m.p 100–101° (yield 13.3%). Recrystallization from hexane for analysis raised the melting point to 101–102°, $[\alpha]_D^{22}$ 130° (*c* 0.95 in $CHCl_3$), $\nu_{max}^{CS_2}$ 3080 cm^{-1}, 1645 cm^{-1}, 885 cm^{-1} ($\diagdown$C=CH_2); 1713 cm^{-1} (3,20-dione).

Calc. for $C_{22}H_{32}O_2$: C 80.41, H 9.82. Found: C 80.19, H 9.86.

In view of the close similarity of the infrared spectra of the compounds melting at 73–74° and 101–102° and the presence only of characteristic bands due to a vinylidene group, it was presumed that the compound melting at 73–74° contained, if any, only traces of the olefin XI, the major proportion being olefin IX.

The benzene eluates of the chromatogram on crystallization from acetone–hexane afforded 76 mg of VI*a*, m.p. 175–176° (yield 12.1%). (Also obtained by partial hydrolysis of the triacetate III*a* to the monoacetate III*c*, and subsequent oxidation.)

The later fractions consisted mainly of the starting material VI, as identified by infrared spectra. No attempt was made to recover it.

Conversion of the Olefin IX to 12β-Methyl-12α-hydroxypregnane-3,20-dione (VI)

To a solution of 175 mg of the crude olefin IX (m.p. 71–73°) in 20 ml of absolute ether containing 0.2 ml of pyridine was added 150 mg of osmium tetroxide (1.1 mole equivalent) and the reaction mixture was left at room temperature for 2 days (8). It was then heated under reflux for 30 minutes with 100 ml of an 80% ethanolic solution of sodium sulphite. After cooling, filtering through celite, and ether extraction, 208 mg of an oil was obtained.

Its infrared spectrum showed no characteristic bands due to a vinylidene group. Crystallization from acetone–hexane afforded 36 mg of the crude hydroxylation product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

VIII (possibly containing traces of X). Two recrystallizations from acetone gave 13 mg of fine needles, m.p. 196–199°, $[\alpha]_D^{22}$ 22° (*c* 0.88 in $CHCl_3$).

Calc. for $C_{22}H_{34}O_4$: C 72.88, H 9.45. Found: C 72.81, H 9.42.

The mother liquors (170 mg of oil) were tosylated with 170 mg of *p*-toluenesulphonyl chloride and 5 ml of pyridine at room temperature for 18 hours. Ether extraction afforded 195 mg of oil, which showed absorption bands at 1375 cm^{-1}, 1193 cm^{-1}, and 1190 cm^{-1} in the infrared region, characteristic of tosyl groups (12*a*).

A solution of the oil in 20 ml of absolute tetrahydrofuran was heated under reflux for 16 hours with 200 mg of lithium aluminum hydride. The reduction product was worked up in the usual fashion, and there was obtained 155 mg of semicrystalline compound. Its infrared spectrum indicated the absence of tosyl groups.

To a solution of the above product (155 mg) in 5 ml of acetic acid was added with stirring a solution of 105 mg of chromium trioxide in 2 ml of 90% acetic acid and the mixture was left for 16 hours at room temperature. The reaction mixture was worked up in the usual manner, and when the ethereal extract was evaporated to about 5 ml, there was obtained 58 mg of plates, m.p. 188–189°. Admixture with an authentic sample of 12β-methyl-12α-hydroxypregnane-3,20-dione (VI) did not depress the melting point and the I.R. spectra were also identical. Chromatographic purification and crystallization from acetone–hexane of the mother liquors afforded an additional 27 mg of VI, m.p. 181–186° (yield 56.8%).

ACKNOWLEDGMENTS

We wish to thank the National Research Council, Ayerst, McKenna and Harrison Ltd., and the Department of Chemistry, McGill University, for generous financial support.

We should also like to thank Dr. C. Sandorfy, Department of Chemistry, Université de Montréal, for having taken and interpreted the infrared spectra with a lithium fluoride prism.

π-BONDING IN INORGANIC COMPOUNDS

III. A MAGNETOCHEMICAL STUDY OF HEXAHALOOSMATES AND HEXACHLORORHENATE[1,2]

A. D. WESTLAND AND N. C. BHIWANDKER

ABSTRACT

The anomalously small magnetic moments of osmium(IV) and rhenium(IV) in their hexahalo complexes are investigated by measurement of the magnetic susceptibilities of the mixed crystal systems, K_2OsCl_6/K_2PtCl_6, K_2OsBr_6/K_2PtBr_6, and K_2ReCl_6/K_2PtCl_6. It is shown that only at high dilution is the magnetic behavior of the systems that which is expected from theory; therefore, extensive superexchange through the overlap of *d*-orbitals on the central atom and orbitals on the ligands takes place in the pure substances and in the concentrated systems. Determination of the spin–orbit coupling constant for $OsCl_6^{2-}$ provides a value in agreement with estimates based on spectra.

INTRODUCTION

In Parts I and II of this series, thermochemical aspects and mesomeric effects of d_π–d_π bonding were discussed. The present paper is concerned with π-bonding as manifested in the magnetic superexchange effect. Admittedly, it has been postulated that in this phenomenon the principal overlap is of d_π–p_π type (1) and if this is so, the bond is essentially different from that considered previously. It seems to the present authors, however, that in the compounds being considered in this paper, a contribution to the superexchange effect may be a secondary result of d_π–d_π bonding. Apparently, the superexchange is possible when the ligands possess orbitals of the appropriate symmetry (e.g., t_{2g} for octahedral co-ordination and e_g for tetrahedral co-ordination) and the central ion possesses *d*-electrons in an insufficient number to fill the d_ϵ, or respectively, the d_γ subshell. It is here suggested that unpaired electrons will be subject to "superexchange", i.e. quantum mechanical exchange between neighboring co-ordination groups, providing these groups are in sufficient proximity and are suitably oriented. These conditions are met by alkali hexahalo salts of rhenium (IV) and iridium (IV), for example.

Superexchange has been detected in K_2IrCl_6 and $(NH_4)_2IrCl_6$ by means of paramagnetic resonance spectra (2, 3). We shall proceed to show that superexchange and hence π-bonding does indeed occur in K_2OsCl_6, K_2OsBr_6, and K_2ReCl_6 as well.

A. Potassium Hexachloroosmate and Hexabromoosmate

Osmium(IV) compounds are of "low-spin" type in which there are four electrons in the t_{2g} orbital. Consequently, a moment corresponding to two unpaired electrons is expected, viz. 2.83 Bohr magnetons (B.M.). The observed effective moments are very much less than this, e.g. 1.44 B.M. for K_2OsCl_6. This is generally regarded as a result of the strong coupling between angular and spin moments which is observed in the spectra of the heavy elements. Kotani has predicted that when the coupling constant, *A*, is large with respect to *kT* in the d^4 configuration the magnetic susceptibility will be independent of temperature (4). Syrkin and Belova observed that the susceptibility of K_2OsCl_6 is, in fact, constant from 77° to 292° K (5). Similar results were obtained by Johansen and Lindberg for $(NH_4)_2OsBr_6$ (6).

Figgis and co-workers (7) have collected data for various Os (IV) compounds, part of which are reproduced in Table I. The values of the coupling constant were derived by

TABLE I

Compound	μ_{eff}, B.M. at 300° K	Spin–orbit coupling constant, A, cm^{-1}
K_2OsF_6	1.30	8,800
K_2OsCl_6	1.50	6,700
K_2OsBr_6	1.20	10,300
K_2OsI_6	1.38	7,200
Cs_2OsCl_6	1.66	5,200

extrapolating the susceptibilities to zero temperature and applying Kotani's formula

$$\chi_M = \frac{24\,N\beta^2}{A} \qquad [1]$$

in which N is Avogadro's number and the other symbols have their usual significance. The values of A so obtained are rather greater than the value 3600 cm^{-1} obtained from the spectrum of $OsCl_6^{2-}$ (8). Griffith estimated a value of 4500 cm^{-1} for the free ion (9). The nephelauxetic effect of the ligands is expected to produce a 10 to 30% reduction in the latter value (10).

In order to account for their high values for A, Figgis and co-workers considered one of Kotani's assumptions invalid, namely, that the spin–orbit interaction is much smaller than the interelectronic repulsion and consequently adopted the view that an equivalent of j–j coupling holds within the d_ϵ subshell. On this assumption the susceptibility at zero temperature is given by

$$\chi_M = \frac{16}{3}\frac{N\beta^2}{A}. \qquad [2]$$

Accordingly, the values of A thus derived are smaller than those given in Table I by a factor of 9/2. The modified values are therefore somewhat low. Figgis and co-workers further remark that there should be a variation in the observed susceptibilities of the different haloosmates consistent with the differing degrees of delocalization of the electrons on the central atom and a consequent trend in the values of the coupling constant. However, it may be seen from the table that the distribution of the measured values of the susceptibility is random. We shall return to this point later.

The moments of the osmium in the cesium salts are invariably higher than those in the corresponding potassium salts. This led us to believe that there is a superexchange coupling between neighboring osmium atoms through the intervening chlorine atoms and that this coupling becomes weaker as the osmium atoms are forced apart by the introduction of the larger alkali ion. Further, if the theoretical treatment (11) of the exchange coupling in K_2IrCl_6 is to be accepted there is reason to expect that all analogous paramagnetic salts of the third transition series elements should be similar in this respect. It is evident that infinite isomorphous dilution in K_2PtCl_6 should provide magnetically isolated $OsCl_6^{2-}$ groups and only in such a state can their magnetic behavior be expected to conform to Kotani's expression.

Results for K_2OsCl_6 and K_2OsBr_6

The effective moment of the osmium atom in solid solutions of K_2OsCl_6 and K_2PtCl_6 is plotted against composition in Fig. 1. The marked rise in the moment at low concentrations of osmium indicates that the $OsCl_6^{2-}$ groups must be essentially isolated from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

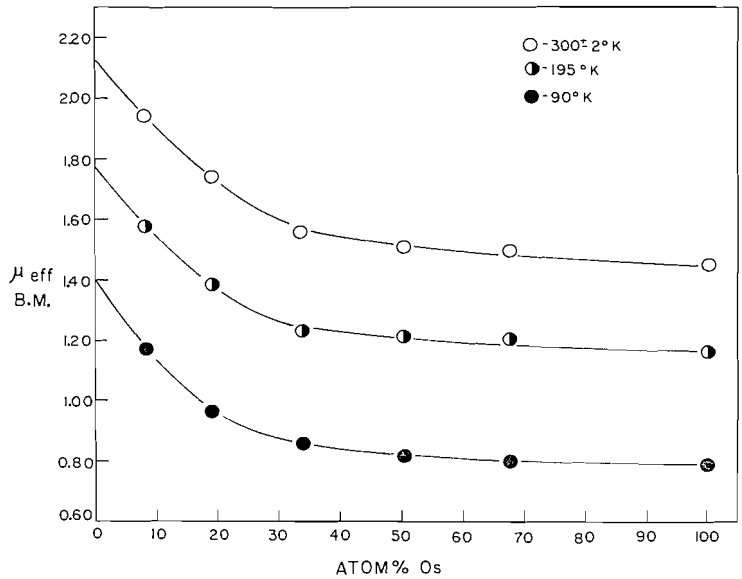

FIG. 1. Plot of the effective moments of osmium at various temperatures against composition of the system K_2OsCl_6/K_2PtCl_6.

other paramagnetic centers before they can exhibit their full paramagnetism. We take this as an indication of superexchange coupling in the concentrated systems. Table II

TABLE II

Temp., °K	Pure K_2OsCl_6		K_2OsCl_6 at infinite dilution	
	$\chi_M \times 10^3$	μ_{eff}, B.M.	$\chi_M \times 10^3$	μ_{eff}, B.M.
298	0.858	1.44	—	—
301	—	—	1.90	2.13
195	0.860	1.16	1.94	1.76
90	0.860	0.79	1.92	1.38

presents our results for pure K_2OsCl_6 and the results of extrapolation to infinite dilution. The results for pure K_2OsCl_6 agree with those of Mellor (12) although they differ slightly from those given in reference 7.

Upon substituting the values of the susceptibility at infinite dilution in equation [1] the value 3240 cm^{-1} is obtained for A. This is in good agreement with the values obtained from spectra which were mentioned earlier.

The uncertainty of extrapolation and the correction for diamagnetism are possible sources of error. The diamagnetism amounted to approximately 60% of the total susceptibility for the most dilute preparation. The value for K_2PtCl_6 was obtained from material prepared from the same stock and in the same manner as was used in the preparation of the solid solutions. The diamagnetism of K_2OsCl_6 was estimated from the value for K_2PtCl_6 by appropriate correction for the change in the central atom using Klemm's values (13). The possible error in the extrapolated values due to the large diamagnetic corrections is $\leqslant 4\%$. It should be emphasized that the measured values of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

susceptibility may be in error due to possible inhomogeneity of the samples. This could only lead to negative errors, however, so the true values of the susceptibilities may be slightly higher. It is to be expected that error from this source is negligible at extreme dilution.

In order to see if bromine can transmit superexchange coupling to any appreciable extent, we have measured the change in atomic susceptibility of the osmium atom in the $OsBr_6^{2-}$ ion in K_2OsBr_6 and in a 10.4 mole% solution of K_2OsBr_6 in K_2PtBr_6. The results are shown in Table III. It is apparent that $OsBr_6^{2-}$ is subject to superexchange

TABLE III

Substance	Temp., °K	$\chi_M \times 10^3$	μ_{eff}, B.M.
K_2OsBr_6	300	0.99_1	1.55
	195	0.98_1	1.24
	90	0.98_2	0.84
K_2OsBr_6/K_2PtBr_6	302	1.59	1.96
	195	1.49	1.52
	90	1.32	0.97

to approximately the same extent as is $OsCl_6^{2-}$ for the increase in the room temperature value of μ_{eff} upon dilution to 10 atom% is about 0.4 B.M. in each case.

Our value of χ_M for K_2OsBr_6 is $9.86 \pm .05 \times 10^{-3}$ over the temperature range 90° to 300° K. This is much higher than the value 6.09×10^{-3} given in reference 7. However, it is very close to Johansen and Lindberg's value for $(NH_4)_2OsBr_6$, viz. 9.80×10^{-3} (6). Since the space requirements of the ammonium and potassium ions are very similar, one must expect the susceptibilities of the two salts to differ but little. We conclude therefore that the value of μ_{eff} for K_2OsBr_6 in Table I is incorrect. If our value of 1.55 B.M. is inserted in Table I it is seen that the magnetic moment increases with increasing atomic number of the halogen except in the case of the iodo compound. This is in good agreement with what was observed by Figgis and co-workers for the series of cesium salts. In order to rationalize this trend in magnetic moments it would be necessary to compare values for magnetically dilute systems. However, we may make a prediction about the direction of the trend for the isolated ions on the basis of the following considerations.

It may be doubted whether there can be superexchange in hexafluoro salts since the *p*-orbitals of the ligands on neighboring groups would overlap little, if at all, and moreover, fluorine cannot engage in d_π–d_π bonding. In fact, most salts containing discrete hexafluoro anions, e.g. RuF_6^{2-}, MnF_6^{2-}, FeF_6^{3-}, appear to be free from superexchange effects (14, 15, 16)* but the quinquevalent d_ϵ^3 fluorides, $MRuF_6$ and $MOsF_6$, give some indication of partial quenching of the magnetic moment (14). Thus it may well be that among the various hexahalo compounds superexchange is least pronounced in the case of fluorides. Moreover, the value of the Weiss constant, Δ, increases as does the change in moment upon dissolving in water, with change of halogen in going from K_2ReF_6 to K_2ReI_6 (7). According to the theory of Kotani, d_ϵ^3 compounds should exhibit a spin-only moment regardless of the value of the coupling constant and the temperature providing that they are free from superexchange. Consequently, if Kotani's theory is valid the trends in question must be due to an increasing degree of superexchange in going from the fluoro to the iodo compound. If these considerations are correct, it must be assumed

**It is suggested that in certain exceptions to this, namely K_3CoF_6 and K_3NiF_6, there may be a mixture of different spin states (17). This postulate is well justified by ligand field theory.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

that the reason for the effective moment of K_2OsI_6 being lower than that of K_2OsBr_6 is that at this point the superexchange supersedes the relatively small increase in the nephelauxetic effect. The increase in superexchange from chloro to iodo compounds is reasonable in view of the increase in spatial extension of *d*-orbitals with increasing atomic number. This matter is receiving further study.

B. Potassium Hexachlororhenate

As indicated above, Kotani's theory predicts a value of 3.87 B.M. for the moment of the d_ϵ^3 configuration at all temperatures. However, experimental values of the moment in rhenium compounds are appreciably lower. Penney and Schlapp have provided an alternative theory (18):

$$[3] \qquad \mu_{obs} = 3.87\left(1-\frac{4A}{30Dq}\right)$$

in which Dq is the ligand field splitting parameter. The measurements made by Figgis and co-workers (7), when applied to this expression, yield a value of 1800 cm^{-1} for A which is of the correct order of magnitude for ions of the third transition series.

Again we questioned the use of moments obtained from magnetically concentrated substances.

Results for K_2ReCl_6

The results of measurements on pure and dilute potassium chlororhenate appear in Table IV. The limits shown provide an estimate of the error to which the method of

TABLE IV

Substance	Temp., °K	$\chi_M \times 10^3$	μ_{eff}, B.M.	μ from Curie–Weiss law, B.M.	Δ
K_2ReCl_6	298	4.45	3.26	3.72	90
	195	6.05	3.07		
	90	9.54	2.62		
K_2ReCl_6/K_2PtCl_6	298	5.48±0.15	3.62	3.76	26
	195	7.9 ±0.2	3.52		
	90	15.3 ±0.4	3.34		

rhenium analysis is subject.

It is clear that in the case of K_2ReCl_6 also there is significant superexchange. The effective moments at infinite dilution would be higher still, but because of the inaccuracy of the method of analysis, it was deemed unprofitable to expend more effort on the system in an attempt to determine the limiting value.

EXPERIMENTAL

The Gouy method was used for the magnetic measurements. The balance was calibrated with purified Mohr's salt as a standard. The maximum field strength was 5320 gauss. The samples were contained in evacuated pyrex tubes.

Preparations

The samples were prepared from metal sponge supplied by Johnson, Matthey, and Mallory, Ltd. Solutions of the quadrivalent halo complexes in the appropriate halogen acid (19, 20) were mixed in various proportions and a solution of potassium chloride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

added rapidly with stirring. The precipitate was removed immediately by filtration through a porous crucible. The products were washed with water and air-dried at 120° C. X-Ray diffraction photographs were unable to detect any inhomogeneity, had it occurred, because of the near identity of the lattice constant of each of the paramagnetic complexes and that of the corresponding platinum compound. The amount of ferromagnetic impurity in the preparations was so small as to be negligible.

Analyses

Duplicate determinations of the concentration of the paramagnetic ion were carried out in each case.

Osmium was separated from platinum by distillation from perchloric acid medium (21) and determined gravimetrically as described in a previous publication (22). Rhenium was separated by heating strongly in a slow stream of air in a quartz combustion tube fitted directly to a receiver which was cooled in liquid oxygen and followed by a bubbler containing 1% hydrogen peroxide. The heating was continued for 30 minutes after the potassium chloride remaining in the sample boat had entirely volatilized. The content of the first receiver was allowed to warm up and was dissolved in 1% hydrogen peroxide. The solutions so obtained were acidified and the rhenium precipitated and weighed as the nitrogen complex. As indicated earlier, the method is not considered highly accurate as the average error of the control analyses was −1.4% on amounts of rhenium between 11 and 23 mg.

PHYTIC ACID: AN ANALYTICAL INVESTIGATION[1]

E. C. Brown, M. L. Heit, and D. E. Ryan

ABSTRACT

Acid–base titrations in aqueous and non-aqueous solutions, titrations with metal ions, and analyses of various metal phytates support beyond question the 18-acid structure of phytic acid. Six of the hydrogens are too weakly acidic to be ordinarily titratable in water; in aqueous solution, two distinct breaks occur in the titration curve corresponding to the titration of 8 and 12 protons of phytic acid.

INTRODUCTION

The structure of phytic acid, a naturally occurring plant acid, has not been clearly demonstrated. Neuberg (1) has proposed a structure, $C_6H_{24}O_{27}P_6$, with 18 acid hydrogens about an inositol phosphate nucleus. Anderson (2) proposed a structure containing 12 acid hydrogens, $C_6H_{18}O_{24}P_6$. The two structures are shown in Fig. 1.

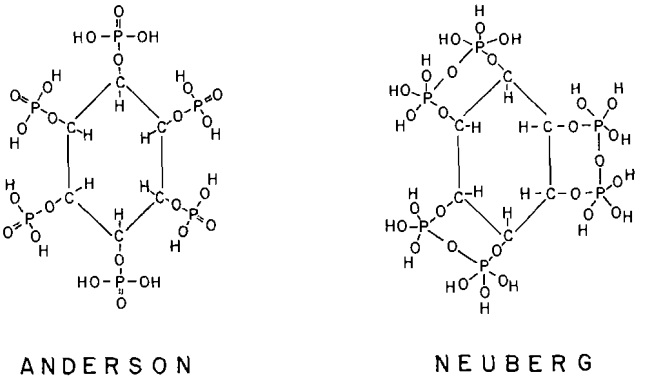

FIG. 1. Proposed structures of phytic acid.

Various studies of the chemistry of phytic acid have produced supporting arguments for both structures. A number of phytic acid salts have been prepared which, on the basis of analysis, have been used to support either the Neuberg (3, 4, 5, 6, 7) or the Anderson (2, 8, 9, 10, 11) structure. Courtois and Mason (12), on comparing acid and phytate hydrolysis curves, favored the Neuberg formula. Desjobert and Fleurent (13) concluded, from a study of chemical hydrolysis, that phytic acid behaved like the Anderson model but they noted certain anomalies. Barre, Courtois, and Wormser (14) produced titration and conductivity curves which they evaluated as indicative of the Anderson formula.

This wealth of conflicting results suggests that an undefined factor may be operative. Analytical difficulties may account for discrepancies in some of the salt analyses but certainly not all of them; nor will they explain the anomalous conclusions from hydrolysis and conductivity investigations. The possible diversity of starting materials used could be an important factor; the source of phytate has been neglected in many papers and purification procedures do not always account for possible contaminants (e.g. orthophosphate).

[1]*Manuscript received February 7, 1961.*
Contribution from the Chemistry Department, Dalhousie University, with financial assistance from the National Research Council.

From the analytical standpoint, phytic acid is of interest because it complexes or chelates metal ions and, by virtue of its many reaction sites, is extremely effective in precipitating or sequestering them. It has been applied to the determination of scandium (15), titanium (3), zirconium (3), and thorium (16); for the removal of copper (17) and iron (18, 19, 20); for corrosion prevention (21); and for stabilizing metal oxides in cooling waters (22).

It was thought, in view of the above considerations, that a further study of phytic acid would be worth while.

EXPERIMENTAL

Equipment and Materials

Measurements of pH were made using either a Beckman Zeromatic or Radiometer 4 pH meter with a glass-saturated calomel electrode pair. Titrations were performed in a pyrex vessel equipped with a water jacket and the temperature of the titration solution maintained at $25 \pm 0.1°$ C, by circulating water from a constant temperature bath through the jacket; a Wilkens–Anderson "Lo-Temp Bath" was used to control bath temperature. The titration vessel was covered with a plastic lid in which holes were drilled to accommodate a 10-ml microburette, two nitrogen inlet tubes, the electrodes, a thermometer, and a glass rod suitable for removing drops from the burette tip. A carbon-dioxide-free atmosphere was maintained by bubbling nitrogen both through the solution and above it.

The starting material was a commercial aqueous phytic acid solution (70%) obtained from the Staley Manufacturing Company, Decatur, Illinois. It is a by-product of the corn liquor industry and contains water-soluble contaminants identified by the company as "nitrogenous organic materials" and a stabilizer for these materials; it is to be expected that orthophosphate is also present.

Analysis of Materials

To study phytic acid it was essential to prepare pure materials and to characterize them by analysis. Phytic acid, sodium phytate, ammonium phytate, and various metal phytates were prepared but a number of difficulties were encountered in analyzing them. Since there are 6 phosphorus atoms in the phytic acid molecule, a method for the determination of total phosphorus was essential. A number of standard methods for the determination of phosphorus, dependent on hydrolysis of phytate and precipitation of orthophosphate, proved unsatisfactory. It was concluded that these procedures were impaired by attendant difficulties with hydrolysis of phytate and that, because of the stability of the phytate nucleus, ordinary methods of phosphorus analysis could not be used.

The phosphorus content of phytates was determined successfully by use of a method reported recently in the literature (23). The method, applicable to solid compounds, involved burning a weighed sample in oxygen and collecting the residue in nitric acid. The orthophosphate resulting from the combustion was then determined by magnesium ammonium phosphate precipitation; the precipitate was either ignited to the pyrophosphate or redissolved and the magnesium determined by an EDTA titration.

Sodium Phytate

Preparation and Analysis

In the preparation of sodium phytate, orthophosphate was first removed from the commercial phytic acid by ether extraction. Three portions of ether were used, each portion being at least equal in volume to the commercial product being treated. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

resulting aqueous solution was diluted with an equal volume of water and neutralized by small additions of concentrated sodium hydroxide solution. The reaction vessel was immersed in an ice bath and the reacting mixture stirred continuously to discourage hydrolysis to orthophosphate. The sodium phytate, after the addition of a large excess of sodium hydroxide, was precipitated by filtering the reaction mixture and allowing it to fall dropwise into a beaker of stirred methyl or ethyl alcohol. The white flocculent precipitate was filtered, washed with alcohol, and redissolved in dilute sodium hydroxide; the sodium phytate was reprecipitated, ground in a mortar under alcohol, and finally oven-dried at 80° C.

This product, analyzed by the combustion method for phosphorus (23), contained 16.5% P. The filtrates from these determinations were analyzed for sodium by uranyl salt precipitation (24) and gave 36.5±1% Na. The compound Na_{18} phytate contains 16.7% phosphorus and 37.3% sodium. The mole ratio of sodium to phosphorus as calculated from analyzed values was 3.0. These results show the prepared sodium phytate to be $Na_{18}Phy$.*

Potentiometric Titration of Sodium Phytate

Samples of sodium phytate were dissolved in water and titrated with hydrochloric acid; on completion of reaction, the reverse titration, of the phytic acid formed, was carried out with potassium hydroxide. Typical curves are shown in Fig. 2. In aqueous solution there were two end points; the first of these occurred at a mole ratio of 8 to 1 and the other was well defined at 12 moles of acid or base per mole of phytate or phytic acid.

In other titrations sodium phytate was dissolved in glacial acetic acid to which acetic anhydride, sufficient to react with contaminating water, was added. The sodium phytate was now titrated using a perchloric acid solution in acetic acid that had been standardized against potassium acid phthalate. Sodium phytate was not readily soluble in acetic acid but 0.1 g was dissolved in 80 ml of the acid when warmed and stirred for 5 hours; hydrolysis of the sodium phytate in this solution was considered possible but tests, both for orthophosphate and phytate, showed that little or no hydrolysis had occurred. A typical titration curve is shown in Fig. 2; only one end point is evident corresponding to 18 moles of hydrogen ion per mole of sodium phytate.

It follows from these titrations of sodium phytate in aqueous and non-aqueous media that there are 18 acid hydrogens in a molecule of the acid but only 12 of these are strong enough to be titratable in aqueous solution.

Phytic Acid

The previous titrations were carried out with samples of the sodium salt but comparable results were obtained when the free acid was titrated. Phytic acid is obtainable only in aqueous solution and different procedures have been used for producing the acid from one of the phytate salts (12, 13, 14). In the present work good results were obtained by passing a solution of sodium phytate through a column of strong cation exchange resin (Amberlite IR-120) in the acid form until the solution was strongly acid and the sodium content was insignificant; the amount of sodium in this acid solution, detected by flame photometry, was only slightly more than that found for a sample of deionized and distilled water. Titrations of phytic acid, however, were generally carried out on solutions of the sodium salt to which sufficient perchloric acid was added to ensure complete

*Phy *will be used to denote the phytate anion,* $C_6H_6O_{27}P_6^{-18}$, *throughout this paper.*

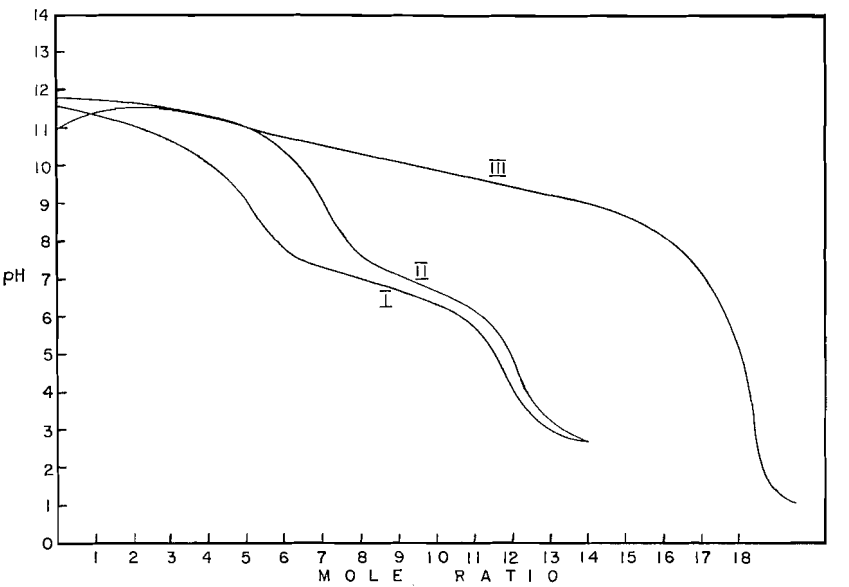

FIG. 2. Titration of sodium phytate. I, 0.4163 g sodium phytate in 50 ml water titrated with 0.1065 *N* HCl; II, resultant solution from titration I back-titrated with 0.0940 *N* KOH; III, 0.0780 g sodium phytate in 80 ml of glacial acetic acid titrated with 0.1040 *N* $HClO_4$ in glacial acetic acid.

conversion to the acid. The titration curve, shown in Fig. 3, was smooth with two inflection points corresponding to the liberation of 8 and 12 moles of hydrogen ion. In the presence of excess metal ion with strong complexing ability, a further 6 moles of hydrogen ion were liberated from a mole of phytic acid; with lead, for example, the inflection at 8 moles of hydrogen ion liberated disappeared completely and well-defined inflections occurred at 16 and 18 moles of hydrogen ion liberated. Results obtained in the titration of phytic acid in the presence of excess magnesium and when the mole ratio of lead to phytic acid was 9 to 1 are shown in Fig. 3; a white precipitate formed immediately upon addition of lead to the phytic acid solution but precipitation did not begin with magnesium until pH 7.5.

These titrations show that phytic acid has 18 acid hydrogens; of these acid hydrogens, 6 are not ordinarily titratable in water, being too weakly acidic to give a break in the titration curve. The first break in the titration curve, which corresponds to the consumption of 8 moles of base per mole of acid, shows that eight protons are more easily removed than the others; removal of a further four protons is also represented by only one break and their acid strengths cannot be very different.

Titration of Phytate with Metal Ions

Solutions of sodium phytate have a high pH due to hydrolysis of the phytate anion; since phytate is itself a base, the reaction of metal ions to form complexes or insoluble substances with it should be accompanied by a change in pH. The sudden decrease in the concentration of phytate ions at an end point, resulting from the addition of metal ion to a solution of the reagent, is accompanied by a sharp decrease in pH.

Since the constant for the reaction

$$Phy^{-x} + yH_2O \rightleftarrows H_yPhy^{-(x-y)} + yOH^-$$

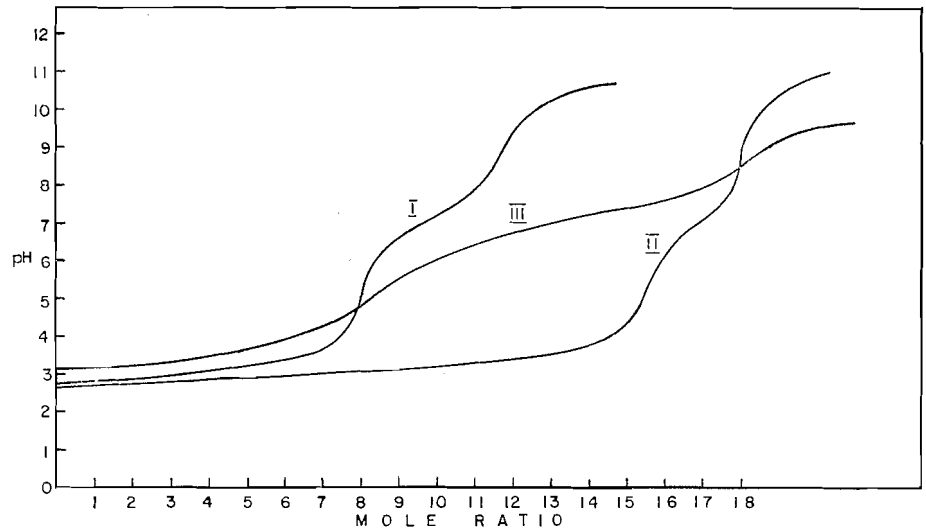

FIG. 3. Titration of phytic acid. I, 2.673×10^{-5} mole phytic acid titrated with 0.09968 *N* NaOH; II, 2.527×10^{-5} mole phytic acid + 2.284×10^{-4} mole Pb^{++} titrated with 0.1018 *N* NaOH; III, 8.48×10^{-6} mole phytic acid + 81.5×10^{-6} mole Mg^{++} titrated with 0.0094 *N* KOH.

is high, it is necessary for the solubility product constant of the metal phytate precipitated to be very small so that the change in the concentration of phytate ion (and thus pH change) at the equivalence point be large. A high stability of metal phytate will mean a sharp pH drop to a low value; if the complex stability is low the pH drop throughout the titration will be slight, the end point poorly defined, and resulting pH value will be high.

In these titrations, then, standard solutions of various metal ions were added dropwise, with stirring, to solutions containing a known quantity of sodium phytate. The change in pH as the metal phytate precipitated was noted and a graphical plot made of this pH change against mole ratio of metal ion added per mole of sodium phytate. Figure 4 shows titration curves obtained from examples of metal ions from each of four valence states—Ag^{+}, Pb^{+2}, Fe^{+3}, Zr^{+4}. Distinct breaks in the titration curves were obtained for 9 moles of lead, 6 moles of iron, and $4\frac{1}{2}$ moles of zirconium per mole of sodium phytate; the break in the silver titration curve was not so well defined but was indicative of 18 moles of silver reacting. The titrations all support the 18-acid form for phytic acid; the equivalence point pH's show an increasing stability order of Ag^{+}, Pb^{+2}, Fe^{+3}, Zr^{+4}.

A few constant pH titrations were carried out in which a solution of sodium phytate was adjusted to a desired pH and a solution of metal ion added to it; reaction of the metal ion with the acid formed caused a pH drop which could be readjusted with a base (potassium hydroxide was used). The point at which addition of metal ion did not lower the pH appreciably and at which addition of base greatly increased the pH was taken as an end point. The pH's chosen for these titrations corresponded generally to the two least-buffered regions of the acid–base titration curve for phytic acid when the dominant phytate species would be $H_{10}Phy^{-8}$ (pH$\sim$5) and H_6Phy^{-12} (pH$\sim$8.5). The method is limited because free acid must be absent in the original metal solution but acceptable end points were found for silver, magnesium, and lead ions.

Description and Analyses of Some Metal Phytates

The composition of metal phytate precipitating from solution is, of course, dependent upon acidity. Normal salts, except for the most basic ions, would be uncommon; the acid strength of phytic acid suggests that salts containing $H_{10}Phy^{-8}$ and H_6Phy^{-12} should be an ordinary occurrence. A description of various phytates prepared, in the course of this work, follows.

Ammonium Phytate

Ammonium phytate was prepared from commercial phytic acid after extracting the commercial product with ether to remove orthophosphate. The aqueous residue was neutralized to pH 6 with 1:1 ammonia and the phytate precipitated with silver nitrate; no yellow orthophosphate was noted. The silver phytate, after washing with water, was ground in a mortar under a deficiency of 1:1 hydrochloric acid to remove silver as silver chloride and liberate the phytic acid. An equal quantity of methanol was added to the resulting solution and ammonia bubbled through the mixture. The white precipitate was filtered, washed with methanol, and dried in a desiccator under slight negative pressure. Analysis of the ammonium phytate for ammonium ion (by Kjeldahl) and for phosphorus (by combustion method) gave $16.5\pm0.5\%$ NH_4^+ and $20.9\pm0.5\%$ P; these figures give a mole ratio of ammonium ion to phytate of 8 to 1 and suggest the incompletely neutralized product $(NH_4)_8H_{10}Phy$.

Silver Phytate

Silver phytate formed as a white precipitate when silver nitrate was added to phytic acid (pH 2); addition of ammonia gave more precipitate up to pH 4 but dissolved when more ammonia was added to pH 8. The silver phytate was light sensitive, the color

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

changing from white through pink and brown to black. The precipitate resulting from the sodium phytate – silver nitrate titration was analyzed for silver by dissolving in nitric acid and precipitating the silver as silver chloride; the silver content of the dried precipitate was 70±1%, corresponding to a mole ratio of silver to phytate of approximately 16 to 1; this result was not unexpected in view of the titration curve obtained (Fig. 4).

Magnesium Phytate

Magnesium ion did not react with phytic acid below pH 3. Above this pH reaction was slight until about pH 7 where constant pH titrations indicated about 4 moles of magnesium ion reacting; however, the titration of phytic acid in the presence of excess magnesium ion showed the eventual reaction of 9 moles (Fig. 3). Precipitation did not begin until the pH was 7.5; the white precipitate was not easily separated from solution.

Lead Phytate

The lead phytate resulting from titration of sodium phytate with lead nitrate was filtered, washed with water, dried at 100° C, and weighed; the agreement between actual and theoretical weights, calculated as Pb_9Phy, was excellent (within 0.05%). The stability of lead phytate in mineral acids made direct determination of lead difficult but successful analyses were obtained after dissolving the lead phytate in aqua regia, destruction of organic matter by addition of sulphuric acid, and three evaporations to incipient dryness, and weighing as lead sulphate; a mole ratio of lead to phytate of 9 to 1 was found. The 9 to 1 phytate forms above pH 5.6 but in more acid solutions lower lead phytates are formed. Analysis of compounds precipitated at both pH 3 and pH 2 showed 4 moles of lead per mole of phytate.

Iron Phytate

Although ferrous phytate was not easily precipitated, ferric phytate separated immediately as a white precipitate on addition of ferric ion to a solution of phytic acid. The precipitate from the titration of sodium phytate with ferric chloride was analyzed for iron, after dissolution in hydrochloric acid, by adding excess potassium iodide and titrating the liberated iodine with thiosulphate (25). Analysis supported the composition shown by the titration curve (Fig. 4) giving an iron to phytate ratio of 6 to 1; the precipitate contained water that could not be removed completely without decomposition, and analysis calculations were based on iron content to phytate used in the titration. At pH 11 a soluble, wine-orange ferric phytate was formed.

Zirconium Phytate

The titration curve of sodium phytate with zirconium ion indicated formation of insoluble compounds containing 2 and 4.5 moles of zirconium per mole of phytate. The final precipitate was coagulated with ethanol, filtered, washed with ether, and dried at 80° C; the weight was 117% that expected for $Zr_{4.5}Phy$. Drying at higher temperatures decreased the weight, apparently by loss of water, but resulted in eventual decomposition of the compound. This phytate was only slightly soluble in concentrated hydrochloric, nitric, and sulphuric acids. Alimarin and Kozel (26) have used phytic acid to precipitate zirconium quantitatively in 0.5 *N* nitric and 6 *N* hydrochloric acid; the precipitate was ignited and weighed as $Zr_2P_6O_{19}$.

CONCLUSIONS

Phytic acid, prepared from the Staley Manufacturing Company product, has 18 acid hydrogens. Of these acid hydrogens, 6 are not titratable in water but are titratable in a more basic solvent. Analysis, titrations of sodium phytate with metal ions, and titration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of phytic acid solutions containing an excess of metal ions support the 18-acid structure and indicate that phytic acid has a structure corresponding to the Neuberg configuration.

It is necessary, in view of these results, to consider possible reasons for disagreement with workers who favor the Anderson model. Titrations in aqueous solution would, of course, support a 12-acid structure since six protons are not titratable in water. Under ordinary conditions normal salts are not readily formed and erroneous conclusions could readily be drawn on the basis of moles of metal ion contained per mole of phytate; the acid strength of phytic acid suggests that salts corresponding to $(M^{II})_4H_{10}Phy$, $(M^{II})_6H_6Phy$, or $(M^{III})_4H_6Phy$, in addition to the more difficultly formed $(M^{II})_9Phy$ or $(M^{III})_6Phy$, should be common. Such considerations would explain Otolski's iron phytates (5) which were analyzed to be A—Fe_4* but which reacted with 6 moles of monovalent amine. Wrenshall and Dyer's iron salt (7), which gave an intermediate analysis between A—Fe_4 and N—Fe_6, could easily be the result of an incompletely neutralized phytate. Bourdillon prepared a mixed calcium and sodium salt, A—$Ca_2Na_8.3H_3O$ (8); this could be written as $Ca_2Na_8H_6Phy$. The possible existence of two phytic acids should not be overlooked; an interesting thought, since they differ only by three water molecules, is that the Anderson phytate is simply the degradation product of Neuberg phytate.

PHOSPHATASE ALCALINE INTESTINALE: CINÉTIQUE DE L'HYDROLYSE DU PHOSPHATE DE *p*-NITROPHÉNYLE*

MICHEL LAZDUNSKI ET LUDOVIC OUELLET

ABSTRACT

The Michaelis constants and the rates at high substrate concentration for the system *p*-nitrophenyl phosphate – intestinal alkaline phosphatase have been measured at 15.3° C and 24.4° C from pH 7.5 to pH 10.4.

The experimental data can be interpreted as indicating the presence of three acid groups in the active center of the enzyme. The observed pK of ionization of these groups are 9.02, 8.39, and 7.65 at 15.3° C, and 9.75, 8.42, and 7.62 at 24.4° C.

These data stress the importance of electrostatic interactions between the groups in the active center and the rest of the enzyme molecule. A heat of ionization of 6 to 7 kcal/mole is attributed to each of these groups. At least one active group of the enzyme would be a thiol function and the other ones imidazole or thiol.

Quelques auteurs seulement ont cherché à identifier les composants du centre actif de la phosphatase alcaline. Les résultats les plus importants ont été obtenus par Morton (1) et Zittle et Bingham (2) dont les études cinétiques suggèrent la présence d'un hydroxyle phénolique essentiel ayant un pK de 9.2 à 38° C. En 1952, Koshland (3) a proposé un mécanisme d'action de la phosphatase alcaline, et en 1958, Engström (4) a réussi à isoler une P^{32} phosphorylsérine venant d'une préparation de phosphatase alcaline incubée avec du phosphate inorganique radioactif.

La présente publication traite, à deux températures, de l'influence du pH sur l'hydrolyse du phosphate de *p*-nitrophényle catalysée par la phosphatase alcaline. Les données permettront de déterminer: (*a*) le nombre de groupes actifs ionisables de l'enzyme; (*b*) les constantes et chaleurs d'ionisation de ces groupes.

PRÉAMBULE

Les hypothèses et définitions usuellement utilisées en cinétique enzymatique sont rapportées dans l'ouvrage de Laidler (5). Le schéma réactionnel fondamental est présenté dans la figure 1.

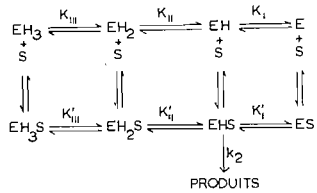

FIG. 1. Schéma représentant les états d'ionisation d'une enzyme E et du complexe enzyme–substrat lorsque le centre actif inclut trois groupes acides.

L'enzyme apparaît sous quatre formes ionisées: EH_3, EH_2, EH, E. Nous supposons que seul, parmi les différents complexes enzyme–substrat, EHS se décompose pour donner les produits. K_I', K_{II}', K_{III}', K_I, K_{II}, K_{III} sont des constantes apparentes d'ionisation.

*Manuscrit reçu le 1 mars 1961.
Contribution du Département de Chimie, Faculté des Sciences, Université Laval, Québec, Qué.

La vitesse de l'hydrolyse est donnée par l'équation de Michaelis–Menten:

$$[1] \qquad v = \bar{V}_m[S]/(\bar{K}_m+[S]).$$

Si le système est à l'état d'équilibre ou de quasi-équilibre (5), $\bar{V}_m$ représente la vitesse à concentration de substrat infinie, $\bar{K}_m$ est la constante de Michaelis. Ces deux grandeurs ont pour valeur:

$$[2] \qquad \bar{V}_m = V_m \Big/ \left(1+\frac{[H^+]}{K_{II}'}+\frac{K_I'}{[H^+]}+\frac{[H^+]^2}{K_{II}'K_{III}'}\right)$$

$$[3] \qquad \bar{K}_m = K_m\left(1+\frac{K_I}{[H^+]}+\frac{[H^+]}{K_{II}}+\frac{[H^+]^2}{K_{II}K_{III}}\right) \Big/ \left(1+\frac{K_I'}{[H^+]}+\frac{[H^+]}{K_{II}'}+\frac{[H^+]^2}{K_{II}'K_{III}'}\right).$$

Les techniques utilisées pour l'estimation des constantes d'ionisation ont été décrites par Dixon (6), Massey et Alberty (7) et Laidler (5). L'évaluation de $\bar{V}_m/\bar{K}_m$ en fonction du pH permet de déterminer les constantes relatives à l'enzyme (équation [4]).

$$[4] \qquad \bar{V}_m/\bar{K}_m = (V_m/K_m)\left(1/1+\frac{K_I}{[H^+]}+\frac{[H^+]}{K_{II}}+\frac{[H^+]^2}{K_{II}K_{III}}\right)$$

Si l'enzyme n'existe que sous trois formes ionisées EH_2, EH, E, les termes K_{III} et K_{III}' deviennent infinis et les équations [2] et [3] se simplifient:

$$[5] \qquad \bar{K}_m = K_m\left(1+\frac{K_I}{[H^+]}+\frac{[H^+]}{K_{II}}\right) \Big/ \left(1+\frac{K_I'}{[H^+]}+\frac{[H^+]}{K_{II}'}\right)$$

$$[6] \qquad \bar{V}_m = V_m\left(1/1+\frac{K_I'}{[H^+]}+\frac{[H^+]}{K_{II}'}\right).$$

PARTIE EXPÉRIMENTALE

Réactifs

Phosphate de paranitrophényle

Le sel disodique utilisé comme substrat provient de "Mann Research Laboratories Inc.". Sa richesse en phosphate de paranitrophényle est de 99.7%; il a été utilisé sans purification ultérieure. Les solutions à différentes concentrations de substrat ont été obtenues par dilution du sel dans l'eau distillée.

Enzyme

L'enzyme utilisée est une phosphatase alcaline intestinale purifiée, vendue par "Mann Research Laboratories". Les solutions à différentes concentrations d'enzyme ont été obtenues par dilution dans l'eau distillée.

Solutions tampons

Les tampons trishydroxyméthyle-amino-méthane (0.01 *M*) – HCl ont été utilisés au-dessous de pH 9 et éthanolamine (0.01 *M*) – HCl pour les valeurs de pH supérieures à 9.

L'éthanolamine provient de Eastman Organic Chemicals et le trishydroxyméthyle-amino-méthane de Fisher Scientific Co.

Les pH ont été mesurés avec un pHmètre Radiometer TTT1b utilisant une électrode de verre Radiometer type B.

Détermination de la vitesse initiale d'hydrolyse v

L'hydrolyse du phosphate de *p*-nitrophényle est suivie par mesure colorimétrique du *p*-nitrophénol libéré lors de la réaction:

$$NO_2C_6H_4OPO_3^{=} + OH^- \rightarrow NO_2C_6H_4O^- + PO_4H^{=}.$$

Des essais préliminaires ont montré que la réaction d'hydrolyse s'arrêtait par passage en milieu très alcalin.

Le déroulement des opérations est le suivant: 14 ml d'une solution de phosphate de *p*-nitrophényle de concentration adéquate sont ajoutés à 15 ml de solution tampon. Ce mélange est porté dans un bain à thermostat (à 15.3° C ou 24.4° C ±0.1° C) et y est laissé pendant 30 minutes. Ce laps de temps écoulé, la réaction est démarrée par injection de 1 ml d'une solution de l'enzyme également à température voulue. La réaction est suivie pendant 5 à 10 minutes suivant les cas. Des prélèvements de 5 ml sont faits chaque minute et versés dans 0.3 ml d'une solution de soude 4 *N*. La réaction s'arrête. Le para-nitrophénol est, dans ces conditions de basicité, sous forme ionisée et les lectures sont faites au spectrophotomètre Beckman DU à la longueur d'onde de 407 mμ correspondant au maximum de densité optique.

RÉSULTATS

Les constantes de Michaelis expérimentales ont été déterminées à deux températures: de pH 7.46 à pH 10.43 à 15.3° C, et de pH 7.5 à pH 10.3 à 24.4° C.

La figure 2 représente trois courbes de Lineweaver–Burk (8) où l'inverse de la vitesse

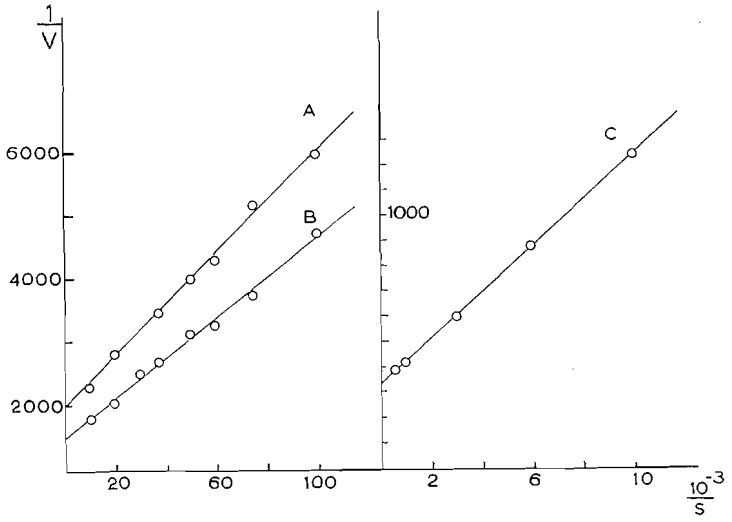

FIG. 2. Courbes de Lineweaver–Burk: (A) pH 8.15, température 24.4° C; (B) pH 8.0, température 24.4° C; (C) pH 9.87, température 15.3° C.

est porté en fonction de l'inverse de la concentration de substrat. Des rapports de 20 entre les valeurs les plus faibles et les plus élevées de 1/[S] ont été couramment atteints. Les valeurs de $\bar{K}_m$ obtenues sont reproductibles à mieux de 10%.

Les résultats expérimentaux confirment la validité de la loi de Michaelis–Menten aux températures et pH étudiés et quelles que soient les concentrations d'enzyme utilisées.

Influence du pH sur $\bar{K}_m$

Les représentations de Dixon traduisent, dans les figures 3 et 4, les variations de

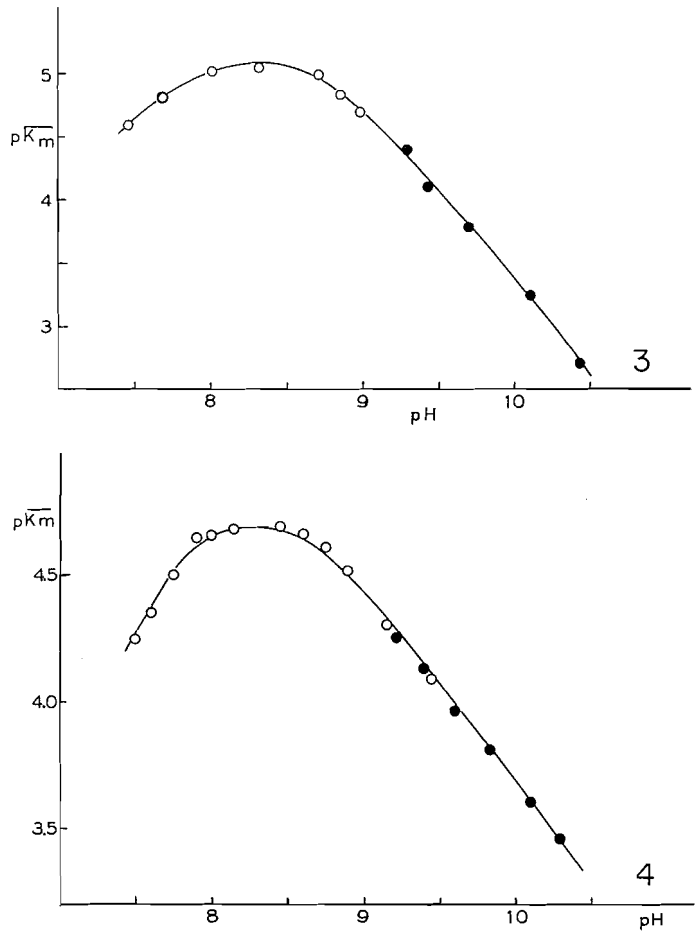

FIG. 3. Courbe de $p\bar{K}_m$ en fonction du pH à 15.3° C.
FIG. 4. Courbe de $p\bar{K}_m$ en fonction du pH à 24.4° C.

$p\bar{K}_m(-\log \bar{K}_m)$ en fonction du pH aux deux températures étudiées. Les courbes obtenues à 15.3° C et 24.4° C ont une allure semblable, seule peut être notée une différence de pente du côté alcalin du maximum.

Les points blancs ont été obtenus en utilisant un tampon trishydroxyméthyle-aminométhane–HCl; les points noirs, en utilisant un tampon éthanolamine–HCl. Le recouvrement des deux parties de la courbe représentée dans la figure 3, indique que, s'il y a effet spécifique du tampon, il est le même dans les deux cas.

Les constantes d'ionisation observées ne peuvent être attribuées au substrat dont le plus haut pK, 5.38, est très au-dessous du domaine de pH étudié (9).

La vitesse maximum est sensible aux variations de concentration de l'enzyme dues, soit à une qualité non-homogène, soit à un vieillissement de la phosphatase utilisée. La détermination de $\bar{V}_m$ a fait l'objet d'une série spéciale d'expériences, effectuée aussi rapidement que possible. A chaque pH étudié, la réaction a été faite à concentration

For personal use only.

de substrat élevée. La valeur de $\bar{V}_m$ est calculée en multipliant la vitesse initiale ainsi obtenue par le terme correctif $(1+\bar{K}_m/[S])$.

Les figures 5 et 6 présentent les données expérimentales sous forme logarithmique

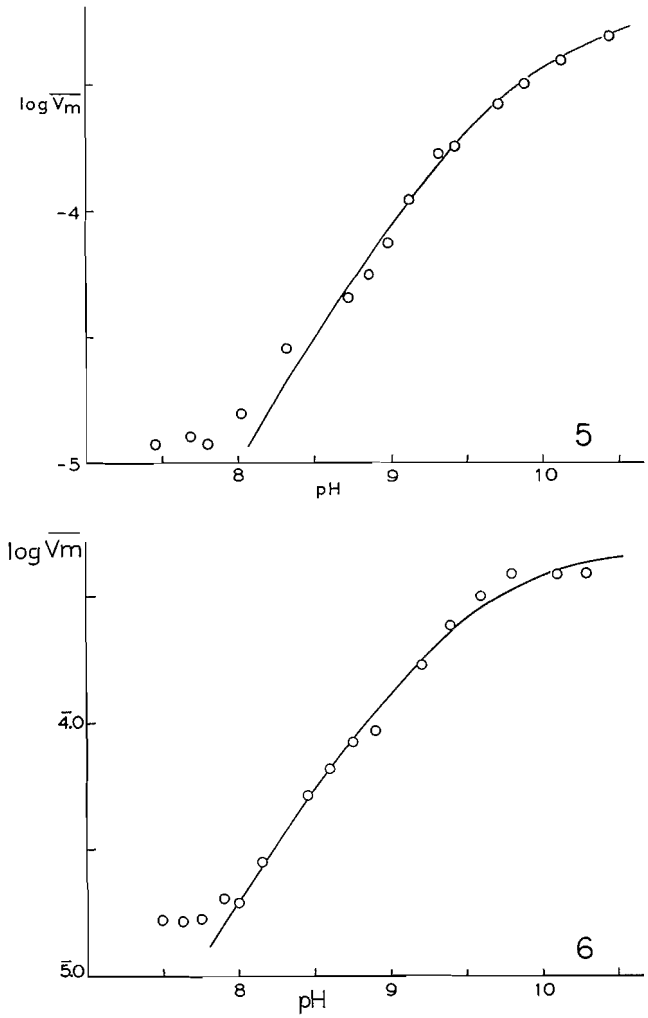

FIG. 5. Courbe de log $\bar{V}_m$ en fonction du pH à 15.3° C. Les vitesses sont en unités arbitraires.
FIG. 6. Courbe de log $\bar{V}_m$ en fonction du pH à 24.4° C. Les vitesses sont en unités arbitraires.

(log $\bar{V}_m$ en fonction du pH). Les points sont expérimentaux, les tracés sont théoriques et ont pour équations:

[7] à 15.3° C: $\log \bar{V}_m = \log [V_m/(1+[H^+]/10^{-9.7})]$

[8] à 24.4° C: $\log \bar{V}_m = \log [V_m/(1+[H^+]/10^{-9.37})]$.

Ces équations sont celles qui décrivent le mieux les données expérimentales.

La valeur de $pK_{II}' = 9.37$, déterminée à 24.4° C, est sujette à caution. Il semble qu'il se produise à cette température, au-delà de pH 9.8, un début de désactivation, peut-être réversible, de l'enzyme. Si, dans la figure 6, les vitesses à pH 10.1 et 10.3 n'ont pas la valeur qui leur est accordée, pK_{II}' pourrait augmenter sensiblement et se rapprocher ainsi de la valeur 9.7 obtenue à 15.3° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Deux possibilités se présentent pour K_I': (1) $K_I' = 0$; le complexe ES n'existe pas. Il y a compétition sur l'enzyme entre les ions hydroxyle et le substrat. (2) $K_I' \ll K_{II}'$: la pente des courbes de Dixon à haut pH (figs. 3 et 4) et l'allure des courbes de log $\bar{V}_m$ en fonction du pH (figs. 5 et 6) indiquent que la constante K_I', si elle existe, est certainement inférieure à 10^{-11}. Aux pH correspondant à pK_I' éventuel, l'enzyme se désactive et en rend la détermination impossible.

De la même manière K_{III}' peut être soit très supérieure aux plus grandes concentrations d'ions hydrogène étudiées, soit infinie, ce qui indiquerait une compétition entre les ions hydrogène et le substrat sur EH_3. Le complexe EH_3S ne pourrait alors exister.

DISCUSSION

Les figures 3 et 4 s'interprètent au moyen des règles établies par Dixon (6). Les changements de pente observés correspondent à l'ionisation de deux groupes essentiels du centre actif de l'enzyme. Leurs pK sont voisins des valeurs 7.8 et 8.6.

Pour la même phosphatase alcaline intestinale, Morton (1) et Zittle (2) obtenaient un changement de pente à pH 9.2 à 38° C et concluaient à la présence d'un hydroxyle phénolique au centre actif. Les courbes de Dixon obtenues par Zittle et Bingham avec la phosphatase du lait et par Motzok (10) avec la phosphatase du plasma ne présentent pas de changement de pente. Dans les trois cas, le domaine de pH étudié est trop étroit pour qu'on puisse prétendre déterminer les pK d'ionisation de tous les groupes ionisables du centre actif. Une étude semblable a permis à Lora-Tamayo et ses collaborateurs (11) de mettre en évidence trois groupes ionisables au centre actif de la phosphatase acide de la pomme de terre. Néanmoins, l'interprétation des courbes de Dixon présente deux inconvénients: (*a*) l'expression de K_m en fonction du pH (équation [3]) fait intervenir les constantes d'ionisation des complexes enzyme–substrat. Aussi bien, l'interprétation des figures 3 et 4 ne peut-elle conduire qu'à des valeurs approchées des constantes d'ionisation de l'enzyme. (*b*) Lorsque la présence de substrat sur l'enzyme a pour effet d'élever les pK des groupes du centre actif, il peut se produire un masquage de constante (figure 7). Seule l'étude de l'influence du pH sur la quantité $\bar{V}_m/\bar{K}_m$ donne le

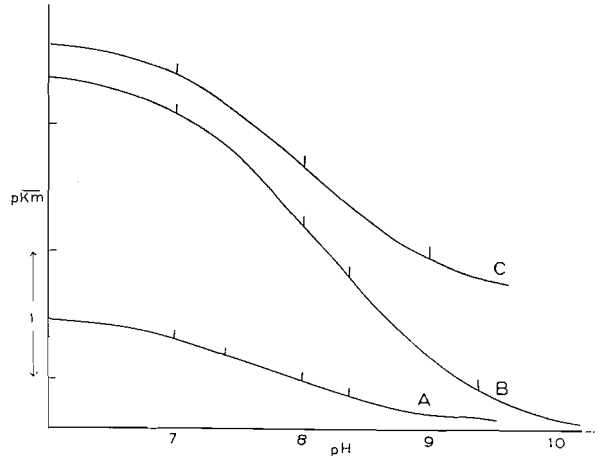

FIG. 7. Influence du pH sur $p\bar{K}_m$ pour un enzyme fictif possédant au centre actif deux groupes ionisables ayant pour pK: $pK_I = 8$ et $pK_{II} = 7$.

Les constantes d'ionisation des complexes enzyme–substrat sont: courbe A $pK_{II} = 7.4$, $pK_I' = 8.4$; courbe B $pK_{II}' = 8.4$, $pK_I' = 9.4$; courbe C $pK_{II}' = 8$, $pK_I' = 9$.

Les valeurs de $p\bar{K}_m$ sont portées en unités arbitraires.

nombre et les constantes d'ionisation exactes des groupes ionisables du centre actif. Tout pK qui apparaît dans les courbes de Dixon doit se retrouver dans les courbes de log $\bar{V}_m/\bar{K}_m$ en fonction du pH avec sa valeur exacte. Le nombre de groupes actifs ainsi déterminé doit être supérieur ou au moins égal à celui déterminé à partir des courbes de Dixon.

Les figures 8 et 9 traduisent l'influence du pH sur log $\bar{V}_m/\bar{K}_m$ à 15.3° C et 24.4° C. Les

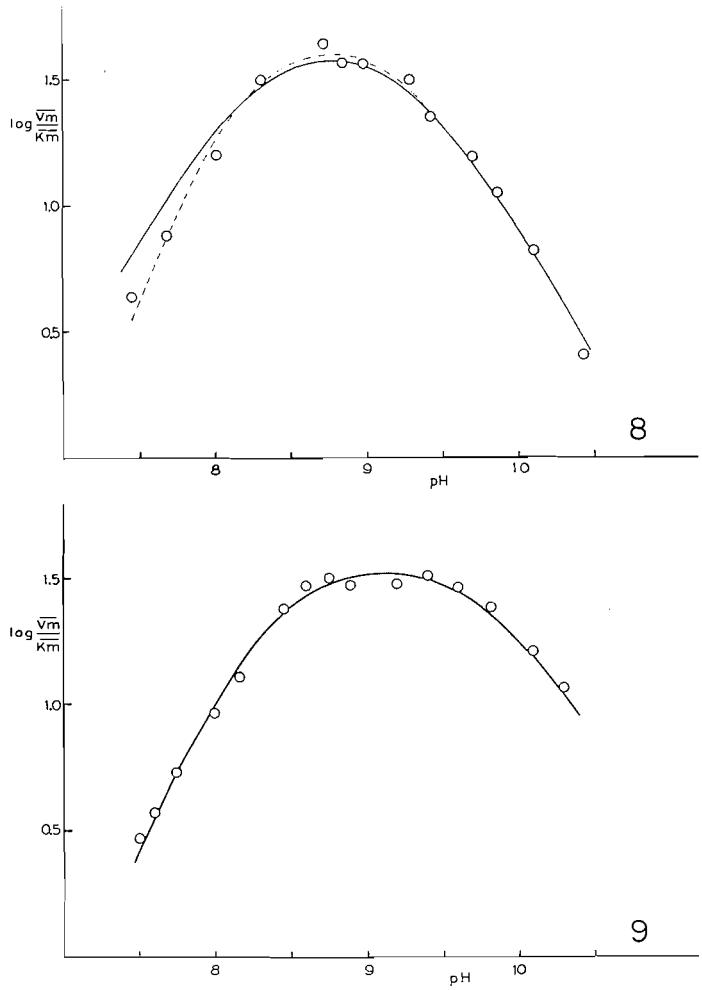

FIG. 8. Influence du pH sur la quantité log $\bar{V}_m/\bar{K}_m$ à 15.3° C. Les points représentent les données expérimentales, le tracé est théorique.

FIG. 9. Influence du pH sur la quantité log $\bar{V}_m/\bar{K}_m$ à 24.4° C. Les points représentent les données expérimentales, le tracé est théorique.

tracés sont théoriques et les points ont été obtenus en additionnant les valeurs expérimentales de log $\bar{V}_m$ et de p$\bar{K}_m$ en fonction du pH. Le tracé (A) de la figure 7 suppose deux groupes ionisables par centre actif et a pour équation:

$$[9] \qquad \log \bar{V}_m/\bar{K}_m = \log \left[(V_m/K_m) \Big/ \left(1+\frac{K_I}{[H^+]}+\frac{[H^+]}{K_{II}}\right)\right].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Les constantes K_I et K_{II} ont été déterminées par la méthode d'Alberty (12): $pK_I = 9.02$, $pK_{II} = 8.39$. Cette courbe (A) s'éloigne sensiblement des points pratiques du côté acide du maximum. Par contre, le tracé (B) qui suppose trois groupes ionisables par centre actif, et a pour équation l'expression logarithmique de l'équation [3], fournit une coincidence satisfaisante. Les valeurs K_I et K_{II} sont celles indiquées ci-dessus. La constante K_{III} est celle qui apparaît dans la courbe de Dixon (fig. 3) dans la région de 7.8. Nous lui avons assigné la valeur de $pK_{III} = 7.65$ pour obtenir un bon accord entre les données théoriques et expérimentales. Le tracé théorique de la figure 8 a été également calculé à partir de l'équation [3]. Les constantes K_I, K_{II} et K_{III} ont été déterminées comme pour le tracé (B) de la figure 7. Le tableau I récapitule les valeurs des constantes obtenues

TABLEAU I

Constantes d'ionisation des groupes actifs ionisables de la phosphatase alcaline intestinale et du complexe enzyme–substrat qu'elle forme avec le phosphate de *p*-nitrophényle

	24.4° C	15.3° C
pK_I	9.75	9.03
pK_{II}	8.42	8.39
pK_{III}	7.62	7.65
pK_{II}'	9.37	9.7

à 24.4° C et 15.3° C. Les valeurs de pK sont valables avec une erreur absolue de ± 0.05 unité de pK. Les trois groupes ionisables identifiés font partie du centre actif de l'enzyme et participent à la formation des complexes enzyme–substrat. Ils peuvent être tous différents, tous identiques ou l'un différent des autres.

Si les groupes sont identiques et s'il n'y a aucune influence électrostatique, les pK apparents pK_I, pK_{II}, pK_{III} doivent être séparés par 0.48 unité de pK (13). Si, les mêmes hypothèses étant posées, les groupes sont différents, leurs pK apparents doivent être séparés par plus de 0.48 unité de pK.

L'influence de la charge électrique sur le processus d'ionisation est en général beaucoup trop importante pour qu'elle puisse être négligée. Les groupes actifs peuvent d'une part s'influencer mutuellement, d'autre part être affectés par l'ionisation des groupes voisins qui ne participent pas directement à la formation du complexe enzyme–substrat. Cet effet électrostatique a pour résultat d'augmenter les différences entre les pK apparents de fonctions identiques. Les données de Britton (14) montrent l'amplitude du phénomène dans les molécules beaucoup plus simples que celles des protéines. Pour l'acide succinique $pK_a = 5.60$, $pK_b = 4.20$, ce qui donne un ΔpK, dû aux effets électrostatiques, de 0.8; pour l'acide glutarique le ΔpK électrostatique est égal à 0.47. L'équation [10] rend compte de l'influence de la charge électrostatique Z sur la constante d'ionisation d'un groupe acide de la protéine.

[10] $$pK = pK_0 - 2wZ/2.3$$

où w est donné par:

[11] $$w = \frac{e^2}{2DkT}\left(\frac{1}{b} - \frac{\kappa}{1+\kappa a}\right)$$

où e est la charge de l'électron, D la constante diélectrique du milieu, k la constante de Boltzman, T la température absolue, b le rayon de la molécule de protéine considérée comme sphérique, $\kappa/(1+\kappa a)$ est la fonction de Debye–Hückel.

Chaleurs d'ionisation

Les ionisations relatives à K_{II} et K_{III} sont pratiquement athermiques et pourraient —si ce n'était des valeurs de pK—être attribuées à la fonction carboxylique ou à un groupe phosphate. L'ionisation relative à K_I, exothermique par 32 kcal/mole, est d'interprétation beaucoup plus difficile. Les groupes ionisables des molécules de protéines ont des ionisations soit athermiques, soit endothermiques, mais jamais exothermiques.

L'interprétation des phénomènes électrostatiques permet d'expliquer ces valeurs anormales des chaleurs d'ionisation. La molécule de phosphatase alcaline est riche en lysine (15), le pK des groupes ϵ amino est environ 10 à 15.3° C et leur chaleur d'ionisation est environ 12 kcal/mole. À pH 8.39 (pK_{II} à 15.3° C), ces groupes contribuent à la charge de l'enzyme. Lorsque la température passe de 15.3° C à 24.4° C, le pK des groupes ϵ amino diminue d'environ 0.3 unités de pK. Si le groupe actif de pK 8.39 a une chaleur d'ionisation de 7 kcal/mole son pK diminue de 0.16 unité pK pour la même élévation de température. Au pH égal au nouveau pK du groupe actif, la protéine est plus négative qu'elle ne l'était à pH 8.39. Cette augmentation de la charge négative a pour effet d'élever le pK d'ionisation (équation [10]).

Les deux effets—abaissement du pK d'ionisation du groupe actif dû à l'élévation de température de 15.3° C à 24.4° C et l'augmentation de ce pK dû à l'accroissement de la charge négative—se compensent en milieu faiblement alcalin. C'est là l'explication des chaleurs d'ionisation nulles obtenues pour pK_{II} et pK_{III}.

À pH élevé, l'élévation de la température produit une telle augmentation de la charge négative de l'enzyme qu'il y a "surcompensation". La chaleur d'ionisation apparente sera négative. C'est certainement là l'explication de l'exothermicité considérable de l'ionisation relative à pK_I. Les influences du pH et de la température sur la charge de la phosphatase alcaline sont très mal connues. L'enzyme n'a pas été titrée et ceci élimine toute possibilité d'un traitement quantitatif des effets électrostatiques. Le point isoélectrique (16) de la phosphatase alcaline est environ 5.6; l'enzyme est riche en groupes carboxyliques, en résidus ϵ amino et possède de l'histidine en quantité appréciable (15). Nous admettrons, en première approximation, que sa courbe de titrage a la même allure que celle de la myosine qui possède des propriétés semblables. Les courbes de titrage obtenues par Mihalyi (17) montrent que l'influence de la température sur la charge négative de l'enzyme, bien qu'appréciable entre pH 7 et 9, est surtout sensible au-delà de pH 9. Ceci justifie l'interprétation donnée précédemment, qui veut que les groupes ionisables du centre actif de l'enzyme aient des chaleurs d'ionisation inférieures à celles des groupes ϵ amino. Des chaleurs d'ionisation de 6 à 7 kcal/mole semblent raisonnables.

Influence du pH sur la vitesse maximum

Aux deux températures et pour les valeurs de pH inférieures à 8, les points expérimentaux sont sensiblement au-dessus des courbes théoriques. Les paliers obtenus peuvent être dus à la décomposition des deux complexes EHS et EH_2S. La vitesse de réaction devient:

$$v = k_1[EH_2S] + k_2[EHS].$$

La participation d'un deuxième complexe à la formation des produits n'affecte que la valeur de $\bar{V}_m$ et n'influe pas sur $\bar{K}_m$.

Si l'enzyme fournit un mécanisme à la réaction, on imagine mal qu'il soit multiple ou comporte divers stades intermédiaires en parallèle. Il semble plus raisonnable d'admettre, ici encore, la participation des effets électrostatiques. La fixation du substrat, avec

ses deux charges négatives élève le pK de l'enzyme de 8.39 à 9.7 à 15.3° C. Il est possible qu'aux pH inférieurs à 8, la charge négative du complexe enzyme–substrat diminue suffisamment vite pour conserver au rapport $[H^+]/K_{II}'$ une valeur constante. Ceci a pour effet de maintenir constante l'expression de la vitesse maximum en fonction du pH:

$$\bar{V}_m = V_m\left(1/1+\frac{[H^+]}{K_{II}'}\right).$$

CONCLUSION

Identification des groupes ionisables du centre actif

Dans les molécules de protéines, les seuls groupes qui aient des chaleurs d'ionisation faibles sont: le groupe hydroxyle phénolique (6 kcal/mole), le groupe imidazole de l'histidine (18) (6.9 à 7.5 kcal/mole), le groupe sulfhydryle de la cystéine (19) ($\sim$7 kcal/mole).

Les pK_I, pK_{II}, pK_{III} apparents sont trop élevés pour pouvoir appartenir au groupe imidazole (pK 5.6 à 7.0) et trop faibles pour pouvoir appartenir au groupe hydroxyle phénolique (pK 9.6 à 10.9). Par contre, ils appartiennent tous au domaine d'ionisation des —SH (pK 7.5 à 10). Les données expérimentales conduisent donc à une seule conclusion: présence au centre actif de trois groupes ionisables qui sont tous des groupes thiols.

La charge négative de la protéine est probablement considérable dans le domaine de pH étudié. Toutes les expériences ont été faites en l'absence de quantités appréciables de cations. Les valeurs de pK obtenues sont des valeurs maximum; les pK_0 correspondants (équation [10]) sont sans doute sensiblement plus faibles. Une étude des courbes de titrage est en cours qui devrait permettre un traitement semi-quantitatif des effets électrostatiques. Il se pourrait qu'alors le ou les deux groupes actifs ayant les pK les plus bas soient attribués à l'imidazole de l'histidine et non plus au groupe thiol de la cystéine.

RÉSUMÉ

Les constantes de Michaelis et les vitesses maxima ont été évaluées à 15.3° C et 24.4° C, de pH 7.5 à pH 10.4.

Les données expérimentales permettent d'identifier trois groupes ionisables au centre actif de l'enzyme. Les pK apparents d'ionisation de ces groupes sont à 15.3° C: pK_I = 9.02; pK_{II} = 8.39; pK_{III} = 7.65; à 24.4° C: pK_I = 9.75; pK_{II} = 8.42; et pK_{III} = 7.62.

Ces résultats mettent en relief le rôle important des phénomènes électrostatiques. Les chaleurs d'ionisation attribuées aux trois groupes actifs sont de 6 à 7 kcal/mole.

L'un des groupes actifs au moins est une fonction thiol. Les deux autres peuvent être des thiols ou des imidazoles.

REMERCIEMENTS

Les auteurs désirent remercier le Conseil national des Recherches du Canada pour l'aide financière qui leur a permis d'exécuter ce travail. L'un de nous (M. L.) était bénéficiaire d'une bourse de la firme C. I. L.

SYNTHÈSES DE COURTS PEPTIDES RENFERMANT DES ACIDES AMINO-1 CYCLOALKYL CARBOXYLIQUES[1]

PATRICE TAILLEUR ET LOUIS BERLINGUET

ABSTRACT

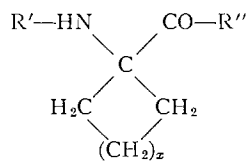
Using classical methods of synthesis nine small peptides containing amino-1 cycloalkyl carboxylic acids have been synthesized. The cyclic acids have been placed either at the N-terminal or at the C-terminal positions or in between two natural amino acids, glycine and DL-phenylalanine.

The cyclization of two dipeptides into a substituted diketopiperazine, and the subsequent hydrolysis of this compound have been studied.

INTRODUCTION

L'acide amino-1 cyclopentane carboxylique présente un intérêt particulier puisqu'on a démontré qu'il pouvait inhiber la croissance de certains types de tumeurs (1, 2). Plusieurs dérivés ainsi que des homologues supérieurs et inférieurs de cet acide amino-1 cyclopentane carboxylique ont été récemment synthétisés (3, 4, 5). Mais il semble que de tous ces dérivés, seul l'acide amino-1 cyclopentane carboxylique ait un effet antitumoral appréciable.

Par ailleurs, l'acide aminé possède une toxicité assez marquée; nous avons alors pensé qu'en l'incorporant dans un court peptide, on pourrait à la fois diminuer sa toxicité et conserver son activité biologique. Connors et Ross (5) ont déjà synthétisé trois dipeptides dans lesquels l'acide amino-1 cyclopentane carboxylique est combiné soit à la glycine, soit à la DL-phénylalanine.



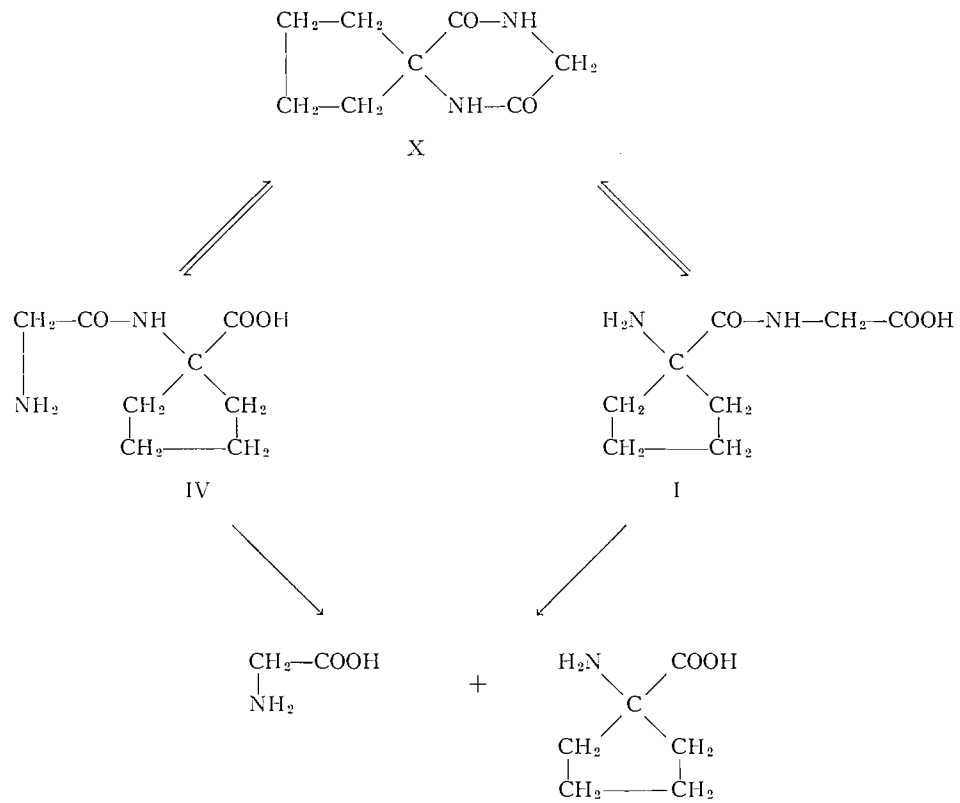
Nous avons voulu obtenir d'autres dipeptides, et surtout placer l'acide aminé cyclique entre des acides aminés naturels. Les peptides non-naturels ainsi obtenus devraient avoir des propriétés biologiques intéressantes, lesquelles seront rapportées ailleurs. Pour ce faire, nous avons surtout utilisé les méthodes classiques de synthèse des peptides, en passant par les dérivés carbobenzoxy et les esters benzyliques, qui ont été condensés par le N,N′-dicyclohexylcarbodiimide, suivant la méthode de Sheehan et Hess (6). Nous avons ainsi obtenu neuf peptides dont trois ont déjà été obtenus par Connors et Ross, mais par une méthode différente des nôtres. Ces neuf peptides contiennent soit l'acide amino-1 cyclopentane carboxylique, soit l'acide amino-1 cyclohexane carboxylique, lesquels sont placés soit à l'extrémité N-terminale de la chaîne, soit à l'extrémité C-terminale, soit entre deux acides aminés naturels. Les acides aminés naturels utilisés ont été la glycine et la DL-phénylalanine.

Les dérivés carbobenzoxy des deux acides aminés cycliques ont été préparés avec des rendements élevés, soit 75%. Mais lorsque nous avons voulu préparer les chlorures d'acides de ces dérivés, nous avons observé une cyclisation spontanée en anhydride correspondant. D'ailleurs MacDonald (7) avait aussi observé la formation spontanée du 3-oxa-1-azaspiro[4.4]nonanedione-2,4 correspondant à l'acide amino-1 cyclopentane carboxylique et du 3-oxa-1-azaspiro[4.5]décanedione-2,4 correspondant à l'acide amino-1

[1]*Manuscrit reçu le 25 janvier 1961.*
Contribution du Département de Biochimie, Faculté de Médecine, Université Laval, Québec, Qué. Présenté en partie aux congrès de l'ACFAS, Montréal et Québec, novembre 1959 et 1960.

cyclohexane carboxylique. Nous avons donc pensé à utiliser la méthode de Sheehan et Hess où l'on condense un dérivé carbobenzoxy avec un ester benzylique. Les esters benzyliques des deux acides aminés cycliques ont été synthétisés en modifiant quelque peu la méthode de Miller et Waelsch (8). Ces esters ont été isolés sous formes de *p*-toluènesulfonates et de chlorhydrates avec d'excellents rendements. La condensation avec le N,N′-dicyclohexylcarbodiimide nous a donné des peptides protégés qui ont ensuite été hydrogénés en peptides libres dont la liste apparaît dans le tableau I.

TABLEAU I



R′	R″	*x*	Nom	
H	Glycine	2	Amino-1 cyclopentane carboxyl-glycine	(I)
H	DL-Phénylalanine	2	Amino-1 cyclopentane carboxyl-DL-phénylalanine	(II)
H	DL-Phénylalanine	3	Amino-1 cyclohexane carboxyl-DL-phénylalanine	(III)
Glycyl	OH	2	Glycyl-acide amino-1 cyclopentane carboxylique	(IV)
Glycyl	OH	3	Glycyl-acide amino-1 cyclohexane carboxylique	(V)
DL-Phénylalanyl	OH	2	DL-Phénylalanyl-acide amino-1 cyclopentane carboxylique	(VI)
DL-Phénylalanyl	OH	3	DL-Phénylalanyl-acide amino-1 cyclohexane carboxylique	(VII)
Glycyl	DL-Phénylalanine	2	Glycyl-amino-1 cyclopentane carboxyl-DL-phénylalanine	(VIII)
Glycyl	DL-Phénylalanine	3	Glycyl-amino-1 cyclohexane carboxyl-DL-phénylalanine	(IX)

Pour obtenir des peptides renfermant une molécule de glycine placée à l'extrémité N-terminale, nous avons préparé les dérivés chloroacétylés des acides aminés cycliques. Ceux-ci, après amination, ont donné avec d'excellents rendements, les deux dipeptides suivants: le glycyl-acide amino-1 cyclopentane carboxylique et le glycyl-acide amino-1 cyclohexane carboxylique. Cette même méthode nous a permis d'obtenir deux tripeptides à partir de l'amino-1 cyclopentane carboxyl-DL-phénylalanine et de l'amino-1 cyclohexane carboxyl-DL-phénylalanine.

La très grande facilité de cyclisation des dérivés N-carbobenzoxy des deux acides aminés cycliques nous a amenés à étudier la formation d'une dicétopipérazine substituée à partir des deux dipeptides renfermant l'acide amino-1 cyclopentane carboxylique et la glycine. Connors et Ross (5) en chauffant à 180°, dans le vide, l'amino-1 cyclopentane carboxyl-glycine (I), ont obtenu la dicétopipérazine (X), sans mentionner le rendement. Théoriquement il était intéressant de comparer la facilité de cyclisation en dicétopipérazine des deux peptides, glycyl-acide amino-1 cyclopentane carboxylique (IV) et amino-1 cyclopentane carboxyl-glycine (I). Nous avons constaté que le glycyl-acide amino-1 cyclopentane carboxylique après un chauffage à 180° pendant 6 heures dans le vide se cyclisait facilement avec un rendement de 80% en dicétopipérazine. Dans des conditions expérimentales identiques, l'amino-1 cyclopentane carboxyl-glycine donne la même dicétopipérazine mais avec un rendement très faible de 10 à 15%.* Vu la différence marquée dans le comportement des deux peptides lors de la cyclisation, il nous a semblé possible que par hydrolyse acide, un des liens peptidiques soit plus facilement coupé que l'autre.

**Les cristaux obtenus lors de ces deux cyclisations ont des spectres aux rayons-X identiques, tel que déterminé par Madame Przybylska du Conseil National de Recherches à Ottawa.*

For personal use only.

Connors et Ross ont observé que l'hydrolyse acide de la dicétopipérazine (X) conduit au peptide amino-1 cyclopentane carboxyl-glycine (I). Nous avons voulu étudier plus en détail cette hydrolyse dans de l'acide chlorhydrique 1 *N*, en identifiant, par chromatographie, les produits formés. Les deux dipeptides et les deux acides aminés qui les composent se séparent bien par chromatographie, mais leur détermination quantitative présente des difficultés. L'acide amino-1 cyclopentane carboxylique ne possède pas d'hydrogène en position α, et de ce fait, se comporte de façon anormale lors de la titration de Sörensen avec le formol (9), et ne réagit pas quantitativement avec la ninhydrine (10). Lorsque cet acide aminé cyclique est placé à l'extrémité N-terminale d'une chaîne peptidique, la fonction aminée semble être encore moins réactive. C'est ainsi que le dipeptide amino-1 cyclopentane carboxyl-glycine réagit très peu avec la ninhydrine et avec le fluoro-1, dinitro-2,4 benzène. Dans ces conditions, il devenait très difficile d'estimer avec précision la proportion relative des deux dipeptides provenant de l'hydrolyse de la dicétopipérazine. La dicétopipérazine ne donnant pas de coloration avec la ninhydrine nous avons alors utilisé la méthode au chlore de Rydon et Smith (11), puis étudié la marche de cette hydrolyse par chromatographie (voir la figure 1). Nous avons pu constater qu'après 10 minutes il ne restait que des traces de dicétopipérazine, et que déjà les deux dipeptides (I et IV) commençaient à s'hydrolyser en acides aminés. La dicétopipérazine était complètement ouverte après 20 minutes. Ludtke (12) et Levene (13) ont démontré déjà que l'hydrolyse d'une dicétopipérazine se faisait en deux étapes: l'une rapide, donnant un ou des dipeptides, et l'autre lente, libérant les acides aminés. Si les deux

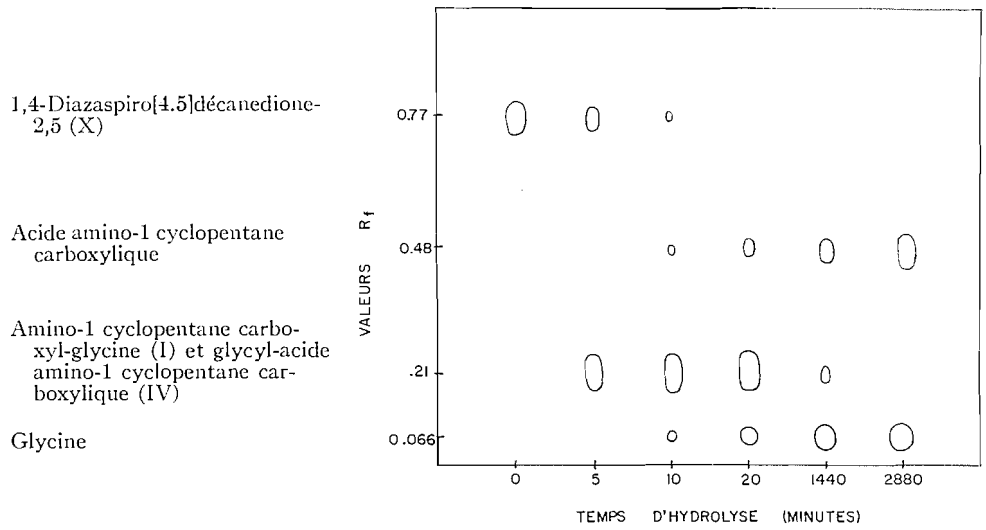

FIG. 1. Représentation du chromatogramme des produits d'hydrolyse de la dicétopipérazine (X). Le solvant est le suivant: *n*-butanol (225), acide acétique (75) et eau (25).

dipeptides se cyclisent en une même dicétopipérazine substituée avec des rendements bien différents, par contre, l'ouverture de cette dicétopipérazine donne naissance de façon indifférente aux deux peptides attendus, contrairement à ce qui a été rapporté (5).

PARTIE EXPÉRIMENTALE

Acide amino-1 cyclopentane carboxylique

On dissout 46.26 g (0.3 mole) de 1,3-diazaspiro[4.4]nonanedione-2,4 et 110.05 g (0.35 mole) d'hydroxyde de barium octahydraté dans 500 ml d'eau chaude. On porte ensuite à l'autoclave pendant une heure à 165°. Après refroidissement à 60°, on ajoute 35.5 g (0.37 mole) de carbonate d'ammonium pour précipiter l'excès de barium. Après filtration, on concentre la solution, et l'acide aminé cristallise par refroidissement. Rendement: 27.8 g (71.8%). Anal. Calc. pour $C_6H_{11}O_2N$: N, 10.84%. Trouvé: N, 10.70%.

Acide amino-1 cyclohexane carboxylique

On hydrolyse de façon analogue à la précédente, 50.46 g (0.3 mole) de 1,3-diazaspiro-[4.5]décanedione-2,4. L'acide amino-1 cyclohexane carboxylique obtenu est recristallisé avec de l'eau et de l'acétone. Rendement: 34.4 g (80%). Anal. Calc. pour $C_7H_{13}O_2N$: N, 9.77%. Trouvé: N, 9.80%.

Acide N-carbobenzoxy amino-1 cyclopentane carboxylique

On dissout 12.92 g (0.1 mole) de l'acide amino-1 cyclopentane carboxylique dans 25 ml (0.1 mole) d'hydroxyde de sodium 4 *N*. En agitant vigoureusement, dans un bain d'eau à 20°, on additionne simultanément, goutte-à-goutte, pendant 30 minutes, 27.5 ml (0.11 mole) d'hydroxyde de sodium 4 *N* et 22.8 ml (0.11 mole) d'une solution de chloroformate de benzyle dans le toluène et dont la concentration est de 8.3 g/10 ml. L'addition des réactifs étant terminée, on continue l'agitation pendant 30 minutes. On extrait avec 50 ml d'éther et on acidifie la fraction aqueuse refroidie avec 15 ml d'acide chlorhydrique concentré. On extrait ensuite le produit avec deux portions de 50 ml d'acétate d'éthyle qu'on sèche finalement sur du sulfate de magnésium anhydre. Après concentration de

For personal use only.

la solution, le produit cristallise au froid par addition d'un excès d'éther de pétrole. Rendement: 19.5 g (74.3%). Le produit recristallisé fond à 92–93°.* Anal. Calc. pour $C_{14}H_{17}O_4N$: N, 5.33%. Trouvé: N, 5.43%.

Acide N-carbobenzoxy amino-1 cyclohexane carboxylique

On traite 14.32 g (0.1 mole) d'acide amino-1 cyclohexane carboxylique par le chloroformate de benzyle tel que décrit précédemment. On obtient ainsi 20 g (72.2%) du dérivé N-carbobenzoxy de l'acide amino-1 cyclohexane carboxylique. P.f. 154–156°. Anal. Calc. pour $C_{15}H_{19}O_4N$: N, 5.06%. Trouvé: N, 5.07%.

N-Carbobenzoxy glycine

On condense 7.5 g (0.1 mole) de glycine avec le chloroformate de benzyle tel que décrit plus haut, mais dans un bain d'eau à 0°. Le dérivé N-carbobenzoxy de la glycine est précipité par l'acide chlorhydrique puis filtré et recristallisé avec du chloroforme. Rendement: 17 g (81.3%). P.f. 119–120° (litt. p.f. 120°) (14). Anal. Calc. pour $C_{10}H_{11}O_4N$: N, 6.70%. Trouvé: 6.80%.

N-Carbobenzoxy DL-*phénylalanine*

On traite comme précédemment 16.5 g (0.1 mole) de DL-phénylalanine. La réaction se fait dans un bain d'eau à 0°. Le dérivé N-carbobenzoxy de la DL-phénylalanine obtenu pèse 23 g (76.8%). P.f. 98°. Après recristallisation avec de l'éther et de l'éther de pétrole, le produit fond à 103° (litt. p.f. 103°) (14). Anal. Calc. pour $C_{17}H_{17}O_4N$: N, 4.68%. Trouvé: 4.60%.

3-Oxa-1-azaspiro[4.4]nonanedione-2,4

A 2.63 g (0.1 mole) de l'acide N-carbobenzoxy amino-1 cyclopentane carboxylique, on additionne 5 ml d'anhydride acétique et 1 ml de chlorure de thionyle. On maintient à l'ébullition pendant une minute. On évapore à sec sous vide, et on cristallise l'anhydride formé en dissolvant le résidu dans un peu d'acétate d'éthyle chaud, et en ajoutant un excès d'éther de pétrole. Rendement: 1.1 g (73.3%). Le produit recristallisé fond à 128–129° (p.f. litt. 128°) (7). Anal. Calc. pour $C_7H_9O_3N$: N, 9.00%. Trouvé: N, 9.01%.

3-Oxa-1-azaspiro[4.5]décanedione-2,4

On traite 2.77 g (0.1 mole) de l'acide N-carbobenzoxy amino-1 cyclohexane carboxylique par le chlorure de thionyle tel que décrit plus haut. On obtient ainsi 1.3 g (76.8%) de l'anhydride. P.f. 112° (litt. p.f. 114.8–115.2°) (7). Anal. Calc. pour $C_8H_{11}O_3N$: N, 8.26%. Trouvé: N, 8.32%.

Acide N-chloroacétyl-amino-1 cyclopentane carboxylique

On dissout 5.46 g (0.05 mole) d'acide amino-1 cyclopentane carboxylique dans 12.5 ml (0.05 mole) d'hydroxyde de sodium 4 *N*. On ajoute à froid, en agitant violemment, simultanément et par portions, pendant 20 minutes, 13.75 ml (0.055 mole) d'hydroxyde de sodium 4 *N* et 6.21 g de chlorure de chloroacétyle. L'addition des réactifs terminée, on continue l'agitation pendant 15 minutes, et on ajoute à froid 10 ml d'acide chlorhydrique concentré. Après 3 heures au froid, on filtre le dérivé chloroacétylé et on le recristallise avec de l'acétate d'éthyle et de l'éther de pétrole. Rendement: 6 g (73%). P.f. 160°. Anal. Calc. pour $C_8H_{12}O_3NCl$: N, 6.80%, Cl, 17.25%. Trouvé: N, 6.89%, Cl, 17.54%.

Les autres dérivés chloroacétylés sont préparés de façon analogue.

**Les points de fusion ne sont pas corrigés.*

Acide N-chloroacétyl-amino-1 cyclohexane carboxylique

On traite comme ci-haut 6.45 g (0.05 mole) d'acide amino-1 cyclohexane carboxylique par le chlorure de chloroacétyle. Le dérivé chloroacétylé obtenu pèse 8 g (72.8%). P.f. 206°. Anal. Calc. pour $C_9H_{14}O_3NCl$: N, 6.37%; Cl, 16.18%. Trouvé: N, 6.48%; Cl, 16.23%.

Glycyl-acide amino-1 cyclopentane carboxylique (IV)

A 100 ml d'ammoniaque concentrée, on ajoute 3 g (0.015 mole) d'acide N-chloroacétyl-amino-1 cyclopentane carboxylique. Après 3 jours à la température de la chambre tout est dissous, et on laisse continuer la réaction une journée de plus. On évapore ensuite à sec sous vide sur un bain-marie. Le résidu est dissous dans un minimum d'eau bouillante et on additionne un excès de méthanol. Le glycyl-acide amino-1 cyclopentane carboxylique cristallise à froid. Rendement: 2 g (71.7%). P.f. 271–275°. On recristallise avec de l'eau et du méthanol. P.f. 276–278°. Anal. Calc. pour $C_8H_{14}O_3N_2$: N, 15.05%. Trouvé: 15.10%.

Tous les autres dérivés chloroacétylés sont traités de façon analogue par l'ammoniaque.

Chlorhydrate du glycyl-acide amino-1 cyclopentane carboxylique

On dissout 3.72 g (0.02 mole) du glycyl-acide amino-1 cyclopentane carboxylique dans 25 ml d'eau. Après refroidissement dans la glace on additionne 22 ml (0.022 mole) d'acide chlorhydrique 1 *N*. Après quelques minutes, on évapore à sec sous vide et on recristallise deux fois le chlorhydrate avec de l'eau et de l'acétone. Rendement: 3.5 g (78.7%). P.f. 214–215° (litt. p.f. 216°) (5). Anal. Calc. pour $C_8H_{14}O_3N_2.HCl$: N, 12.52%. Trouvé: N, 12.65%.

Glycyl-acide amino-1 cyclohexane carboxylique (V)

On traite comme ci-haut, 2.2 g (0.01 mole) d'acide N-chloroacétyl-amino-1 cyclohexane carboxylique par 100 ml d'ammoniaque concentrée. On obtient ainsi 1.5 g (75%) de glycyl-acide amino-1 cyclohexane carboxylique. Après une recristallisation avec de l'eau et de l'éthanol, le produit se décompose à une température supérieure à 300°. Anal. Calc. pour $C_9H_{16}O_3N_2$: N, 14.01%. Trouvé: N, 14.00%.

N-Carbobenzoxy glycyl-acide amino-1 cyclopentane carboxylique

On traite 18.6 g (0.1 mole) du glycyl-acide amino-1 cyclopentane carboxylique par le chloroformate de benzyle tel que décrit plus haut. Le dérivé N-carbobenzoxy du glycyl-acide amino-1 cyclopentane carboxylique, précipité par l'addition d'acide chlorhydrique concentré, est filtré et recristallisé avec de l'eau contenant 25% d'éthanol. Rendement: 26 g (81.2%). P.f. 176°. Anal. Calc. pour $C_{16}H_{20}O_5N_2$: N, 8.74%. Trouvé: N, 8.60%.

N-Carbobenzoxy glycyl-acide amino-1 cyclohexane carboxylique

On condense 20 g (0.1 mole) du glycyl-acide amino-1 cyclohexane carboxylique avec le chloroformate de benzyle tel que décrit plus haut. Le dérivé N-carbobenzoxy du glycyl-acide amino-1 cyclohexane carboxylique est précipité à un pH de 5–6 par addition d'acide chlorhydrique dilué. Le produit est filtré et recristallisé avec un minimum d'eau contenant 25% d'éthanol. Rendement: 31 g (92.5%). P.f. 263°. Anal. Calc. pour $C_{17}H_{22}O_5N_2$: N, 8.37%. Trouvé: N, 8.30%.

p-Toluènesulfonate de l'ester benzylique de l'acide amino-1 cyclopentane carboxylique

On suspend 6.46 g (0.05 mole) d'acide amino-1 cyclopentane carboxylique et 10.46 g (0.055 mole) d'acide *p*-toluènesulfonique monohydraté dans 100 ml d'alcool benzylique et 150 ml de toluène. On laisse bouillir le mélange pendant une nuit, en recueillant l'eau formée au moyen d'un tube de Dean et Stark. Après refroidissement, on filtre une partie

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

de l'ester qui pèse 10 g, et on évapore le filtrat à sec sous vide et à une température ne dépassant pas 130°. On reprend le résidu à chaud avec un minimum de chloroforme et on cristallise à froid en présence d'un excès d'éther. On obtient ainsi le reste de l'ester qui pèse 9 g. Rendement: 19 g (92.7%). P.f. 180–186° C. Après trois recristallisations, on obtient le *p*-toluènesulfonate de l'ester benzylique de l'acide amino-1 cyclopentane carboxylique pur qui fond à 193–195°. Anal. Calc. pour $C_{13}H_{17}O_2N.p\text{-}CH_3C_6H_4SO_3H$: N, 3.58%. Trouvé: N, 3.58%.

Chlorhydrate de l'ester benzylique de l'acide amino-1-cyclopentane carboxylique

On suspend 16.38 g (0.04 mole) de *p*-toluènesulfonate de l'ester benzylique de l'acide amino-1 cyclopentane carboxylique dans 100 ml d'eau glacée et 50 ml de chloroforme. On agite fortement pendant 10 minutes en neutralisant avec un léger excès d'une solution 1 *M* de bicarbonate de sodium. On décante le chloroforme et on extrait de nouveau avec 50 ml de chloroforme. Après avoir séché les deux fractions de chloroforme réunies sur du sulfate de magnésium anhydre, on sature la solution d'acide chlorhydrique gazeux, on évapore à environ 50 ml, et le produit cristallise au froid par addition d'une excès d'éther. Rendement: 9.7 g (95%). P.f. 162°. On recristallise avec du dioxane et de l'éther. P.f. 163°. Anal. Calc. pour $C_{13}H_{17}O_2N.HCl$: N, 5.48%; Cl, 13.88%. Trouvé: N, 5.53%; Cl, 14.00%.

p-Toluènesulfonate de l'ester benzylique de l'acide amino-1 cyclohexane carboxylique

On traite comme précédemment 7.2 g (0.05 mole) d'acide amino-1 cyclohexane carboxylique. Après refroidissement du mélange, rien ne cristallise. Après évaporation à sec et cristallisation du résidu avec du chloroforme et de l'éther, on obtient 19 g (85%) de *p*-toluènesulfonate de l'ester benzylique de l'acide amino-1 cyclohexane carboxylique qui fond à 160–163°. Après deux recristallisations avec du chloroforme et de l'éther, le produit fond à 167–169°. Anal. Calc. pour $C_{14}H_{19}O_2N.p\text{-}CH_3C_6H_4SO_3H$: N, 3.46%. Trouvé: N, 3.33%.

Chlorhydrate de l'ester benzylique de l'acide amino-1 cyclohexane carboxylique

On traite comme précédemment 16.94 g (0.04 mole) de *p*-toluènesulfonate de l'ester benzylique de l'acide amino-1 cyclohexane carboxylique. Le chlorhydrate de l'ester benzylique de l'acide amino-1 cyclohexane carboxylique ainsi obtenu pèse 9.6 g (90%) et est recristallisé avec du dioxane et de l'éther. P.f. 211°. Anal. Calc. pour $C_{14}H_{19}O_2N.HCl$: N, 5.21%; Cl, 13.18%. Trouvé: N, 5.40%; Cl, 13.60%.

p-Toluènesulfonate de l'ester benzylique de la glycine

On estérifie de façon analogue aux expériences précédentes, 30 g (0.4 mole) de glycine en présence de 83.6 g (0.44 mole) d'acide *p*-toluènesulfonique monohydraté dans 200 ml d'alcool benzylique et 200 ml de benzène. L'estérification terminée, on ajoute 200 ml d'éther de pétrole et le *p*-toluènesulfonate de l'ester benzylique de la glycine cristallise à froid. Rendement: 140 g (98.5%). P.f. 128–130°. On recristallise le produit avec du chloroforme et de l'éther de pétrole. P.f. 134–135°. Anal. Calc. pour $C_9H_{11}O_2N.p\text{-}CH_3C_6H_4SO_3H$: N, 4.15%. Trouvé: 4.20%.

Chlorhydrate de l'ester benzylique de la glycine

Comme précédemment, on suspend 6.7 g (0.02 mole) de *p*-toluènesulfonate de l'ester benzylique de la glycine dans 75 ml de chloroforme en présence de 50 ml d'eau glacée. Le chlorhydrate de l'ester benzylique de la glycine ainsi obtenu pèse 4 g (99%) et est recristallisé avec du chloroforme contenant 25% d'éthanol. P.f. 139–140° (litt. p.f. 139–140°) (15). Anal. Calc. pour $C_9H_{11}O_2N.HCl$: N, 6.95%. Trouvé: N, 7.00%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

p-Toluènesulfonate de l'ester benzylique de la DL-*phénylalanine*

On estérifie comme ci-haut 33 g (0.2 mole) de DL-phénylalanine en présence de 41.8 g (0.22 mole) d'acide *p*-toluènesulfonique monohydraté, de 200 ml d'alcool benzylique et de 100 ml de benzène. L'estérification terminée, on refroidit et on ajoute 200 ml d'éther de pétrole. Le *p*-toluènesulfonate de l'ester benzylique de la DL-phénylalanine cristallise au froid. Rendement: 84.5 g (95%). P.f. 142–146°. Après une recristallisation avec du chloroforme et de l'éther de pétrole le produit fond à 145–146°. Anal. Calc. pour $C_{16}H_{17}O_2N.p\text{-}CH_3C_6H_4SO_3H$: N, 3.14%. Trouvé: N, 3.09%.

Chlorhydrate de l'ester benzylique de la DL-*phénylalanine*

On neutralise comme précédemment 8.9 g (0.02 mole) de *p*-toluènesulfonate de l'ester benzylique de la DL-phénylalanine suspendus dans 75 ml de chloroforme et 50 ml d'eau glacée. On obtient finalement 5.5 g (94%) de chlorhydrate de l'ester benzylique de la DL-phénylalanine. P.f. 203–204°. On recristallise le produit deux fois avec de l'eau. P.f. 205–206° (litt. p.f. 196°) (8). Anal. Calc. pour $C_{16}H_{17}O_2N.HCl$: N, 4.80%. Trouvé: N, 4.88%.

Esters benzyliques libres des acides aminés

Pour effectuer les condensations par le N,N′-dicyclohexylcarbodiimide, les esters benzyliques qui sont synthétisés sous forme de chlorhydrates ou de *p*-toluènesulfonates doivent être obtenus à l'état libre. Le chlorhydrate ou le *p*-toluènesulfonate de l'ester benzylique est suspendu dans du chloroforme en présence de 25% en volume d'eau glacée. On additionne un excès d'une solution de bicarbonate de sodium 1 *M*. On agite fortement pendant 10 à 15 minutes et le chloroforme est décanté. On extrait de nouveau la solution aqueuse avec un peu de chloroforme qu'on décante ensuite. Après avoir séché les deux fractions de chloroforme réunies, sur du sulfate de magnésium anhydre, on évapore à sec sous vide. Les rendements moyens en esters libres sont de 90 à 99%.

N-Carbobenzoxy amino-1 cyclopentane carboxyl-glycinate de benzyle

On dissout dans 100 ml de chlorure de méthylène, 13.2 g (0.05 mole) de dérivé N-carbobenzoxy de l'acide amino-1 cyclopentane carboxylique et 9.08 g (0.055 mole) d'ester benzylique de la glycine. On additionne ensuite 11.4 g (0.055 mole) de N,N′-dicyclohexylcarbodiimide. Après 4 heures à la température de la chambre, on ajoute 5 ml d'acide acétique pour détruire l'excès de carbodiimide. Après 10 minutes, on filtre la N,N′-dicyclohexylurée formée qui pèse 12 g. On évapore le filtrat à sec sous vide et on reprend le résidu par un minimum d'acétate d'éthyle chaud. Le N-carbobenzoxy-amino-1-cyclopentane carboxyl-glycinate de benzyle cristallise à froid par addition d'un excès d'éther de pétrole. Rendement: 15 g (73.2%). P.f. 122–123°. Ce produit peut être hydrogéné directement sans être recristallisé. Après trois recristallisations avec de l'alcool et de l'éther de pétrole, le produit fond à 130–131°. Anal. Calc. pour $C_{23}H_{26}O_5N_2$: N, 6.83%. Trouvé: N, 6.83%. Les quatres condensations suivantes sont effectuées de façon analogue.

N-Carbobenzoxy DL-*phénylalanyl-amino-1 cyclopentane carboxylate de benzyle*

On dissout dans 50 ml de chlorure de méthylène, de façon analogue à la précédente, 8.98 g (0.03 mole) de dérivé N-carbobenzoxy de la DL-phénylalanine et 7.24 g (0.033 mole) d'ester benzylique de l'acide amino-1 cyclopentane carboxylique. On additionne ensuite 6.82 g (0.033 mole) de N,N′-dicyclohexylcarbodiimide. On obtient ainsi 12 g (80%) de N-carbobenzoxy DL-phénylalanyl-amino-1 cyclopentane carboxylate de benzyle. P.f. 107–110°. Ce produit peut être utilisé tel quel pour l'hydrogénation. Après deux recristallisations avec de l'alcool et de l'éther de pétrole, le produit fond à 123–124°. Anal. Calc. pour $C_{30}H_{32}O_5N_2$: N, 5.59%. Trouvé: 5.79%.

N-Carbobenzoxy DL-*phénylalanyl-amino-1 cyclohexane carboxylate de benzyle*

On dissout dans 40 ml de chlorure de méthylène, comme précédemment, 9.0 g (0.03 mole) de dérivé N-carbobenzoxy de la DL-phénylalanine et 7.7 g (0.033 mole) d'ester benzylique de l'acide amino-1 cyclohexane carboxylique. On additionne ensuite 6.82 g (0.033 mole) de N,N′-dicyclohexylcarbodiimide. On obtient ainsi 13 g (84.4%) de N-carbobenzoxy DL-phénylalanyl-amino-1 cyclohexane carboxylate de benzyle. P.f. 115–117°. On recristallise avec de l'alcool et de l'éther de pétrole. P.f. 117–118°. On peut hydrogéner subséquemment sans recristalliser. Anal. Calc. pour $C_{31}H_{34}O_5N_2$: N, 5.44%. Trouvé: N, 5.43%.

*Ester benzylique du N-carbobenzoxy amino-1 cyclohexane carboxyl-*DL-*phénylalanine*

On dissout comme ci-haut, dans 60 ml de chlorure de méthylène, 13.86 g (0.05 mole) de dérivé N-carbobenzoxy de l'acide amino-1 cyclohexane carboxylique et 14.05 g (0.055 mole) d'ester benzylique de la DL-phénylalanine. On additionne ensuite 16.85 g (0.056 mole) de N,N′-dicyclohexylcarbodiimide. On obtient ainsi 19.5 g (75.5%) d'ester benzylique du N-carbobenzoxy amino-1 cyclohexane carboxyl-DL-phénylalanine. P.f. 105–106°. Ce produit peut être hydrogéné tel quel. Après deux recristallisations avec de l'alcool et de l'éther de pétrole, le produit fond à 102–103°. Anal. Calc. pour $C_{31}H_{34}O_5N_2$: N, 5.44%. Trouvé: N, 5.44%.

*Ester benzylique du N-carbobenzoxy amino-1 cyclopentane carboxyl-*DL-*phénylalanine*

On dissout comme ci-haut, dans 200 ml de chlorure de méthylène, 13.2 g (0.05 mole) de dérivé N-carbobenzoxy de l'acide amino-1 cyclopentane carboxylique et 14.05 g (0.055 mole) d'ester benzylique de la DL-phénylalanine. On additionne ensuite 11.4 g (0.055 mole) de N,N′-dicyclohexylcarbodiimide. Après 4 heures à la température de la chambre, on filtre une partie de l'urée formée qui pèse 5 g. On additionne au filtrat 5 ml d'acide acétique et on évapore à sec sous vide. On reprend le résidu par 300 ml de dioxane à 50°. On filtre la solution. Il reste un résidu insoluble de 7 g constitué en grande partie du reste de l'urée. On évapore le filtrat jusqu'à un volume de 100 ml et le produit cristallise au froid par addition d'un excès d'éther de pétrole. Le rendement brût de l'ester benzylique du N-carbobenzoxy amino-1 cyclopentane carboxyl-DL-phénylalanine est de 21 g (84%). Ce produit fond à 154–157° et peut être utilisé tel quel pour l'hydrogénation. Après deux recristallisations avec de l'alcool additionné de 50% d'acide acétique, il fond à 165–166°. Anal. Calc. pour $C_{30}H_{32}O_5N_2$: N, 5.59%. Trouvé: 5.52%.

Amino-1 cyclopentane carboxyl-glycine (I)

On dissout 8.21 g (0.02 mole) de N-carbobenzoxy amino-1 cyclopentane-carboxyl-glycinate de benzyle dans 200 ml d'un mélange égal d'alcool et d'acide acétique bouillant. On refroidit à la température de la chambre et on additionne environ 0.1 g de palladium à 10% sur du carbone. On effectue ensuite l'hydrogénation pendant 6 heures sous une pression de départ de 30 livres. Après avoir filtré le catalyseur on évapore à sec sous vide. On reprend le résidu avec 20 ml d'acétate d'éthyle chaud. On laisse refroidir 15 minutes et on filtre le dipeptide insoluble. L'amino-1 cyclopentane carboxyl-glycine est recristallisé avec de l'eau et de l'acétone. P.f. 277°. Rendement: 3.5 g (94.5%). Anal. Calc. pour $C_8H_{14}O_3N_2$: N, 15.05%. Trouvé: 15.00%.

Pour les autres hydrogénations, on procède de façon analogue.

Chlorhydrate de l'amino-1 cyclopentane carboxyl-glycine

On dissout 2 g (0.017 mole) d'amino-1 cyclopentane carboxyl-glycine dans 20 ml d'eau bouillante. On refroidit dans la glace avant d'ajouter 17.4 ml (0.017 mole) d'acide chlorhydrique 1 *N*. On évapore à sec sous vide et après trois recristallisations avec de l'alcool

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

et de l'acétone on obtient un produit qui fond à 214–215° (p.f. litt. 200°) (5). Anal. Calc. pour $C_8H_{14}O_3N_2$.HCl: N, 12.52%; Cl, 15.75%. Trouvé: N, 12.38%; Cl, 15.70%.

DL-*Phénylalanyl-acide amino-1 cyclopentane carboxylique (VI)*

On dissout 10.01 g (0.02 mole) de N-carbobenzoxy DL-phénylalanyl-amino-1 cyclopentane carboxylate de benzyle dans 250 ml d'une solution chaude d'acide acétique à 25% dans l'éthanol. On refroidit à la température de la chambre et on fait l'hydrogénation comme précédemment. Le DL-phénylalanyl-acide amino-1 cyclopentane carboxylique est recristallisé avec de l'éthanol aqueux à 50%. Rendement: 5.0 g (90.4%). P.f. 270–272° (p.f. litt. 268–270°) (5). Anal. Calc. pour $C_{15}H_{20}O_3N_2$: N, 10.12%. Trouvé: 10.08%.

Amino-1 cyclohexane carboxyl-DL-*phénylalanine (III)*

On fait une hydrogénation comme ci-haut sur une solution contenant 10.29 g (0.02 mole) d'ester benzylique de N-carbobenzoxy amino-1 cyclohexane carboxyl-DL-phénylalanine. L'amino-1 cyclohexane carboxyl-DL-phénylalanine obtenu est recristallisé en le suspendant dans un peu d'eau chaude et en ajoutant à chaud de l'éthanol jusqu'à dissolution complète puis en portant au froid. Rendement: 5 g (86.2%). P.f. 286°. Après une recristallisation le produit fond à 292°. Anal. Calc. pour $C_{16}H_{22}O_3N_2$: N, 9.63%. Trouvé: 9.61%.

Amino-1 cyclopentane carboxyl-DL-*phénylalanine (II)*

On dissout 5 g (0.01 mole) de N-carbobenzoxy de l'ester benzylique de l'amino-1 cyclopentane carboxyl-DL-phénylalanine dans 200 ml d'un mélange égal d'éthanol et d'acide acétique bouillant. Avant que la solution ne refroidisse et que le produit de départ ne cristallise, on procède immédiatement à l'hydrogénation comme précédemment. L'amino-1 cyclopentane carboxyl-DL-phénylalanine ainsi obtenu est recristallisé en le suspendant dans 20 ml d'alcool bouillant et en additionnant de l'eau jusqu'à dissolution complète et en portant au froid. P.f. 272–273°. Rendement: 2 g (72.1%). Après recristallisation le peptide fond à 273°. Anal. Calc. pour $C_{15}H_{20}O_3N_2$: N, 10.13%. Trouvé: N, 10.14%.

Le produit est très insoluble dans l'eau et dans l'alcool, mais il se dissout dans un mélange des deux à chaud.

Chlorhydrate du DL-*phénylalanyl-acide amino-1 cyclohexane carboxylique (VII)*

Cette hydrogénation est analogue aux précédentes. On dissout 10.3 g (0.02 mole) de N-carbobenzoxy DL-phénylalanyl-amino-1 cyclohexane carboxylate de benzyle dans 100 ml d'alcool additionné de 25 ml d'acide acétique et de 10 ml d'acide chlorhydrique 3 *N*. L'hydrogénation terminée, on évapore le solvant à sec sous vide, après avoir filtré le catalyseur. Le résidu est traité par 20 ml d'acétone. Après 10 minutes on filtre le chlorhydrate du DL-phénylalanyl-acide amino-1 cyclohexane carboxylique insoluble qui pèse 5.0 g (77%). Le produit est recristallisé deux fois avec du méthanol et de l'éther. P.f. 281–282°. Anal. Calc. pour $C_{16}H_{22}O_3N_2$.HCl: N, 8.57%; Cl, 10.85%. Trouvé: N, 8.45%; Cl, 10.50%.

N-Chloroacétyl-amino-1 cyclopentane carboxyl-DL-*phénylalanine*

On dissout 2.76 g (0.01 mole) d'amino-1 cyclopentane carboxyl-DL-phénylalanine dans 50 ml d'éthanol aqueux (20%) bouillant. On refroidit vitement, et avant que le peptide ne cristallise on additionne 2.5 ml (0.01 mole) d'hydroxyde de sodium 4 *N*. On évapore à sec sous vide à une température ne dépassant pas 30° et on dissout le résidu dans un peu d'eau. On fait ensuite le Schotten-Baumann avec 2.75 ml (0.011 mole) d'hydroxyde

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

de sodium 4 *N* et 1.24 g (0.011 mole) de chlorure de chloroacétyle. Rendement: 2.5 g (71%). Le produit est recristallisé avec de l'alcool et de l'éther de pétrole. P.f. 189–191°. Anal. Calc. pour $C_{17}H_{21}O_4N_2Cl$: N, 7.94%; Cl, 10.05%. Trouvé: N, 7.85%; Cl, 10.21%.

*N-Chloroacétyl-amino-1 cyclohexane carboxyl-*DL*-phénylalanine*

On dissout 2.90 g (0.01 mole) d'amino-1 cyclohexane carboxyl-DL-phénylalanine dans 2.5 ml (0.01 mole) d'hydroxyde de sodium 4 *N*. Les réactifs additionnés sont les suivants: 2.75 ml (0.011 mole) d'hydroxyde de sodium 4 *N* et 1.24 g (0.011 mole) de chlorure de chloroacétyle. Rendement: 3 g (81.8%). Le dérivé chloroacétylé est recristallisé avec de l'alcool et de l'éther de pétrole. P.f. 172°. Anal. Calc. pour $C_{18}H_{23}O_4N_2Cl$: N, 7.64%; Cl, 9.72%. Trouvé: N, 7.75%; Cl, 10.00%.

*Glycyl-amino-1 cyclopentane carboxyl-*DL*-phénylalanine (VIII)*

On traite comme précédemment, 2.0 g (0.057 mole) de N-chloroacétyl-amino-1 cyclopentane carboxyl-DL-phénylalanine par 200 ml d'ammoniaque concentrée. On obtient alors 1.2 g (63.1%) de glycyl-amino-1 cyclopentane carboxyl-DL-phénylalanine qui fond à 243–244°. Anal. Calc. pour $C_{17}H_{23}O_4N_3$: N, 12.60%. Trouvé: 12.55%.

*Glycyl-amino-1 cyclohexane carboxyl-*DL*-phénylalanine (IX)*

On ajoute 2.5 g (0.0068 mole) de N-chloroacétyl-amino-1 cyclohexane carboxyl-DL-phénylalanine à 200 ml d'ammoniaque concentrée, comme précédemment. On obtient 2.0 g (84%) de glycyl-amino-1 cyclohexane carboxyl-DL-phénylalanine. On recristallise le tripeptide avec de l'eau et de l'éthanol. Le produit prend un aspect vitreux à environ 155°, commence à se décomposer à 200° et fond à 202–204°. Anal. Calc. pour $C_{18}H_{25}O_4N_3$: N, 12.10%. Trouvé: 11.92%.

1,4-Diazaspiro [4.5]décanedione-2,5 (X)

On traite 8.0 g (0.043 mole) de glycyl-acide amino-1 cyclopentane carboxylique à 180° et sous un vide de 0.03–0.04 mm pendant 6 heures, dans une fiole conique à succion de 1000 ml. On dissout le produit dans 100 ml d'eau bouillante et on traite par environ 0.5 g de noir animal. La solution purifiée est ensuite évaporée à environ 60 ml. La dicétopipérazine cristallise au froid. Rendement: 6.0 g (81%). P.f. 275–277° (p.f. litt. 275–280°) (5). Anal. Calc. pour $C_8H_{12}O_2N_2$: C, 57.12%; H, 7.20%; N, 16.67%. Trouvé: C, 57.39%; H, 7.23%; N, 16.65%.

1,4-Diazaspiro[4.5]décanedione-2,5 (X)

On traite 8.0 g (0.043 mole) d'amino-1 cyclopentane carboxyl-glycine à 180° et sous un vide de 0.03–0.04 mm pendant 6 heures, dans une fiole conique à succion de 1000 ml. On décante le produit non sublimé, constitué du peptide non cyclisé, et on dissout le produit sublimé sur les parois dans 25 ml d'eau bouillante. On traite par un peu de noir animal et on évapore la solution purifiée à environ 10 ml. La dicétopipérazine cristallise à froid. Rendement: 1 g (13.5%). P.f. 276–277° (p.f. litt. 275–280°) (5). Anal. Calc. pour $C_8H_{12}O_2N_2$: C, 57.12%; H, 7.20%; N, 16.67%. Trouvé: C, 57.33%; H, 7.29%; N, 16.58%.

Hydrolyse du 1,4-diazaspiro[4.5]décanedione-2,5

On laisse bouillir à reflux pendant 48 heures 0.3 g (0.0018 mole) de 1,4-diazaspiro[4.5]-décanedione-2,5 en présence de 30 ml d'acide chlorhydrique 1 *N*. On prélève un aliquot de 1 ml à différents intervalles de temps, et on identifie par chromatographie les produits d'hydrolyse de ces différents échantillons. Les acides aminés et les peptides soumis à la chromatographie l'ont toujours été sous forme de chlorhydrates.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Le chromatogramme illustré par la figure 1 montre que la dicétopipérazine s'hydrolyse rapidement et qu'après 20 minutes, un lien peptidique est ouvert complètement. Mais après 10 minutes les deux peptides (I) et (IV) formés commencent à s'hydrolyser très lentement et ce n'est qu'après 48 heures qu'ils disparaissent complètement. Le système de solvants utilisé est le suivant: *n*-butanol (225), acide acétique (75) et eau (25). Les deux peptides ayant des R_f à peu près identiques dans ce système de solvants, on doit, pour les séparer convenablement, utiliser d'autres solvants. Dans un mélange de *s*-collidine (1 partie), de lutidine-2,4 (85%) (1 partie) et d'eau (2 parties), le glycyl-acide amino-1 cyclopentane carboxylique (IV) a un R_f de 0.22 et l'amino-1 cyclopentane carboxyl-glycine a un R_f de 0.35.

Cette dernière chromatographie n'est utilisée que pour l'aliquot de 5 minutes, identifiant ainsi les deux peptides et prouvant que l'hydrolyse coupe de façon non spécifique une des deux liaisons de la dicétopipérazine. Il ne semble pas que la formation d'un peptide soit favorisée plus que l'autre.

REMERCIEMENTS

Les auteurs sont très reconnaissants envers le Conseil National de Recherches pour une bourse accordée à l'un d'eux (P.T.), et envers l'Institut National du Cancer pour aide financière. Ils remercient de plus le Dr Léo Marion, directeur de la division de chimie du Conseil National de Recherches à Ottawa, pour l'analyse aux rayons-X de deux échantillons.

THE RADIO-FREQUENCY DIELECTRIC DISPERSION IN SOLID ETHYL STEARATE[1]

D. W. DAVIDSON

ABSTRACT

The dielectric properties of solid ethyl stearate were studied between −100° and the melting point at frequencies between 100 cycles/sec and 80 Mc/sec. The circular-arc locus lying within this frequency range in the β (tilted) form consists of a time-dependent and a time-independent part. It is more likely to arise from rotational disorder of tilted molecules than from regions of vertically stacked molecules. The width of the relaxation-time distribution function appears to decrease somewhat more rapidly with increasing temperature than would be expected for a temperature-independent distribution of heights of rotational-energy barriers.

In spite of the common occurrence of dielectric-relaxation effects in the solid forms of polar derivatives of long-chained aliphatic compounds (1) there remains considerable doubt about their origin. One such compound is ethyl stearate, for which a number of experimental studies (2–4) have been published. In the most recent report (4), the radio-frequency dispersion in the β form of ethyl stearate has been attributed to the presence of metastable regions of vertically stacked molecules.

The present report gives some recent results which bear on this question.

EXPERIMENTAL METHODS

Two samples of ethyl stearate were used: one (EK) was the Eastman Kodak White Label product, the other (PRL) a purified product provided by Dr. Burton M. Craig of the Prairie Regional Laboratory. Melting points determined by the capillary-tube method were 31.9 and 30.0° for the β and α forms of the EK sample and 33.1 and 30.7° for the corresponding forms of the PRL sample. The latter are in close agreement with the values of Smith (33.3 and 30.9°, respectively) (5).

Measurements were made at frequencies between 0.1 and 800 kc/sec with a capacitance bridge, and at frequencies between 80 and 80,000 kc/sec by the voltage-resonance method of Hartshorn and Ward (6). Measurements were made to below −100° with the bridge and to −35° with the Hartshorn–Ward apparatus. In the latter the micrometer head containing the sample was enclosed in a Lucite box through which cold air was circulated.

All solid samples were prepared by cooling the melts in the dielectric cells. For examination at low temperatures the samples were rapidly cooled so as to "freeze-in" a sufficient number of defects to ensure sufficient dispersion for accurate measurement.

RESULTS

In Fig. 1 the dielectric constant of the EK sample is plotted vs. temperature for two separate cycles, starting from the liquid, at cooling and heating rates of ca. 3° per hour. In the first cycle freezing into the α phase ($\epsilon = \sim 2.95$) was followed by conversion into the β phase, which was complete at 20°. The shape of the curve in the $\alpha \rightarrow \beta$ transformation region depends on the rate of cooling and on the purity of the sample, the transformation being more rapid for the PRL than for the EK sample. In the second

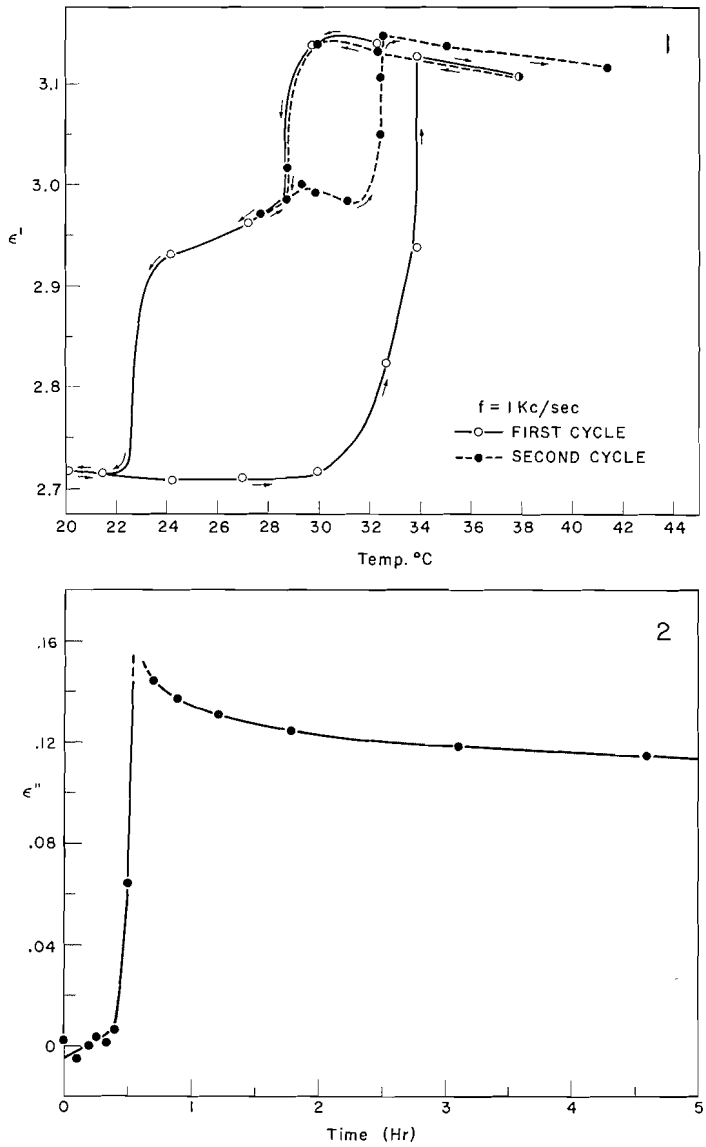

FIG. 1. Phase changes in ethyl stearate.
FIG. 2. Time dependence of ϵ'' at 15 Mc/sec and 24°, following freezing.

cycle the α form was melted before an appreciable amount of the β form had been formed. It is apparent that the melting point of the α form is lower by about 2° than that of the β form.

Figure 2 shows the dependence on time of the dielectric loss of the PRL sample at 24°, measured at a frequency near that of the loss maximum of the β form. The zero of time was taken at the first appearance of solid (α form) in the melt. At 24°, conversion to the β form starts within 30 minutes of freezing and is thereafter rapidly completed.

Typical complex plane loci for the PRL sample are illustrated in Fig. 3. Except for an upward turn at low frequencies (particularly marked for these rapidly cooled samples),

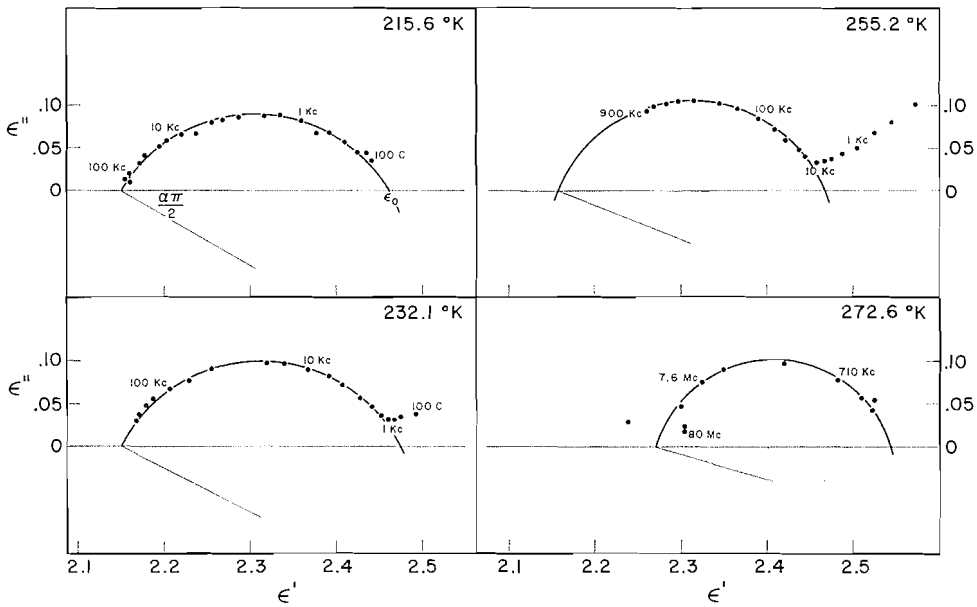

FIG. 3. Cole–Cole plots for β-phase ethyl stearate.

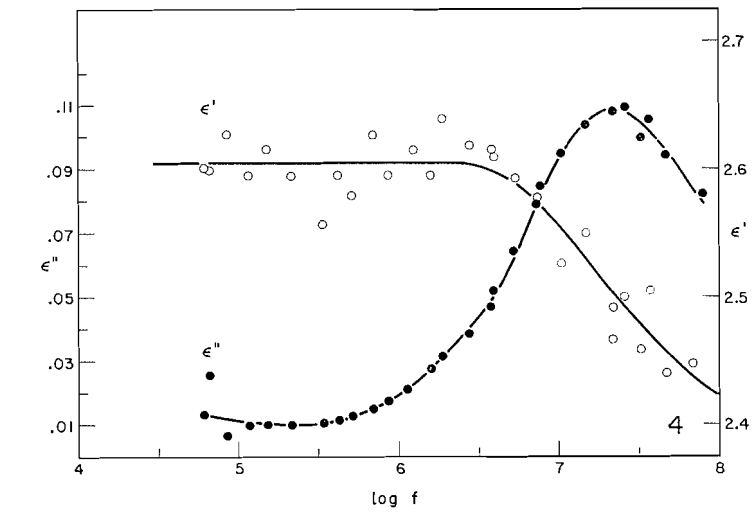
these loci are circular arcs, with centers below the real axis. Data obtained with the resonance device (like those shown at 272.6° K) give more uncertain arcs than bridge data. This arises primarily from the inaccuracy of the ϵ' values, as may be seen from the results shown in Fig. 4. Analysis of the resonance results was based on ϵ'' values alone.

Typical dielectric parameters are listed in Table I. For the bridge measurements,

TABLE I

Dielectric parameters of ethyl stearate (PRL sample)



Phase	T (°K)	τ_0 (sec)	ϵ_0	$\Delta\epsilon$	α	ϵ''_{max}	Method
β	204.7	3.29×10^{-4}	2.517	.326	.37	.084	Bridge
	215.6	7.04×10^{-5}	2.461	.312	.34	.088	
	226.9	1.47×10^{-5}	2.469	.326	.31$_5$	.095	
	244.6	1.85×10^{-5}	2.486	.330	.29	.102	
	255.2	5.04×10^{-7}	2.467	.311	.25	.104	
	272.6	7.58×10^{-8}	~2.50	.27	~.21	.097	Resonance
	297.2	7.40×10^{-9}	~2.50*	.27*	~.12	.109*

Liquid	301.4 (supercooled)		3.106				
	312.0		3.031				

*Sixteen hours after freezing.

ϵ_0 and ϵ_1 were the low- and high-frequency intercepts of the circular arcs with $\epsilon'' = 0$, and $\Delta\epsilon = \epsilon_0 - \epsilon_1$. The most probable relaxation time τ_0 and the distribution parameter α were determined from plots of $\log v/u$ vs. $\log f$, where $v^2 = (\epsilon_0-\epsilon')^2+(\epsilon'')^2$ and $u^2 = (\epsilon'-\epsilon_1)^2+(\epsilon'')^2$. For Cole–Cole arcs (7), $\log v/u = (1-\alpha)(\log f+\log 2\pi\tau_0)$. Figure 5 shows such a plot of the data at 215.6° K.

For the resonance data, $\Delta\epsilon$ was determined from the area of the ϵ'' vs. $\log f$ plot (8) and α from $\tan(1-\alpha)\pi/4 = 2\epsilon''_{max}/\Delta\epsilon$ (7).

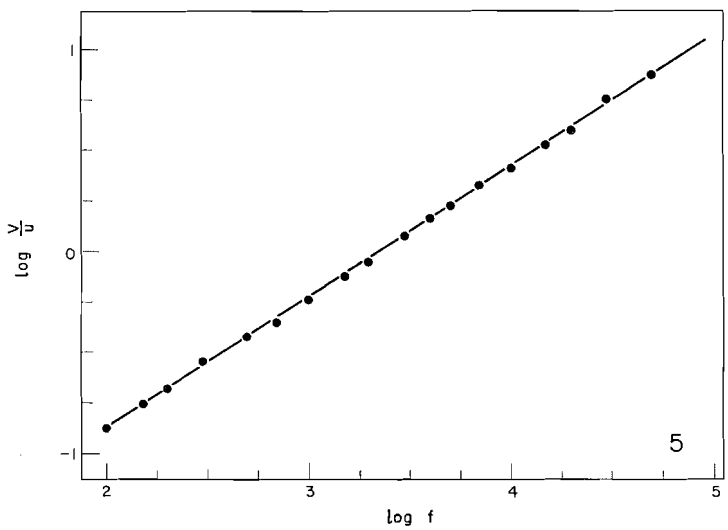

FIG. 4. β-Phase ethyl stearate at 24°.
FIG. 5. Method of determining τ_0 and α from bridge data.

The results given for bridge measurements in Table I refer to the same solid sample; no dependence on time was observed at these temperatures. The amplitude, but not the frequency characteristics, of the dispersion–absorption region varied considerably with the thermal history of the sample. At room temperature the magnitude of the dispersion decreased slowly with time, as is shown by the decay of the loss in Fig. 6. The decay was approximately exponential, with a time constant of some 24 hours. After several days the loss had fallen to about one half of its initial value and no further reduction was apparent.

The linear dependence of log τ_0 on $1/T$ (Fig. 7) formally gives an activation energy of 13.7 kcal/mole, in agreement with the value 13 kcal/mole reported by Dryden and Dasgupta (3) from measurements in the vicinity of room temperature and with the 12.7 kcal/mole value obtained by Broadhurst and Fitzgerald (4) for temperatures between ca. −80 and −30°.

DISCUSSION

Variation of Width of the Distribution Function of Relaxation Times with Temperature

Broadhurst and Fitzgerald reported (4) a value of 0.39 for the distribution parameter α, a value obtained from measurements at $-65°$ (private communication from Professor Fitzgerald). As is evident from Fig. 8, our results indicate that α decreases rapidly with

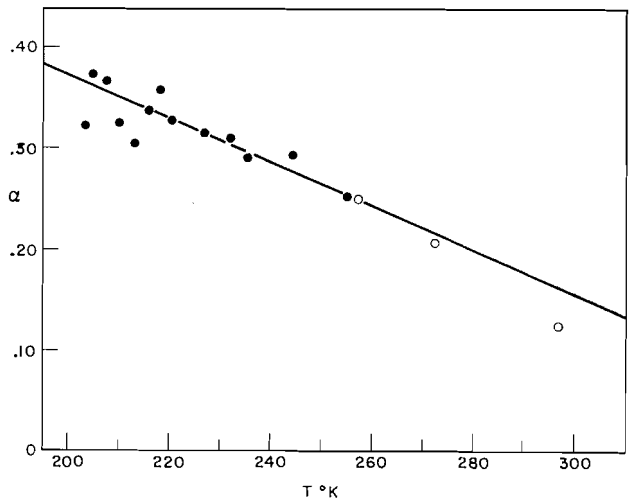

FIG. 8. Variation of α with temperature: ● bridge, ○ resonance measurements.

increasing temperature. Such a trend is to be expected from the presence of a finite distribution in heights of the energy barriers to orientation of dipoles. It is of interest to attempt to estimate quantitatively the temperature-dependence of α in such a case.

The distribution function (7) for relaxation times $G(s)ds$, where $s = \ln_e(\tau/\tau_0)$, may be replaced by a distribution in barrier heights B, where B is related to the relaxation time by $\tau/\tau_0 = \exp(B/T)$:

$$H(B)dB = \frac{\sin \alpha\pi}{2\pi T[\cosh (1-\alpha)B/T - \cos \alpha\pi]}\, dB.$$

If the distribution of barrier heights does not depend on temperature, the integral

$$\int_{-\infty}^{B} H(B)dB = 0.5 + \frac{1}{(1-\alpha)\pi} \tan^{-1}\left[\tanh \frac{(1-\alpha)B}{2T} \tan \frac{(1-\alpha)\pi}{2}\right]$$

is independent of temperature. If α is known at some temperature, α may then be computed for some other temperature for various assumed values of B. The value so obtained is found to be somewhat dependent on B, which implies that the assumption of a temperature-independent distribution of barrier heights is not strictly compatible with maintenance of the circular-arc locus as the temperature is changed. However, the variation of α with B is small for B's which contribute appreciably to the relaxation behavior.

It is evident from Table II that over-all values of α of 0.31 at 250° and 0.265 at 300° K lead to approximately the same integral distribution in B as that given by the experimental value of α (0.38) at 200° K. The experimental values of α (Fig. 8) decrease somewhat more rapidly than these "predicted" values. This suggests that the breadth of the barrier distribution function decreases as the temperature is raised.

TABLE II

Integrated distribution function $I(B) = \int_{-\infty}^{B} H(B)dB$

For positive values of B, $I(B) = 1 - I(-B)$.

It is worth noting that the range of barrier heights corresponding to the distribution of relaxation times is small in comparison with the actual magnitude of the barriers. Thus at 200° K half the relaxation occurs across barrier heights which lie within $BR = \pm 0.5$ kcal/mole of the 14 kcal/mole value of the most probable barrier height given by the energy of activation.

The variations with temperature of bridge values of $\Delta\epsilon$ and ϵ''_{max} for the same rapidly cooled sample are shown in Fig. 9. The fall in ϵ''_{max} with decreasing temperature, observed

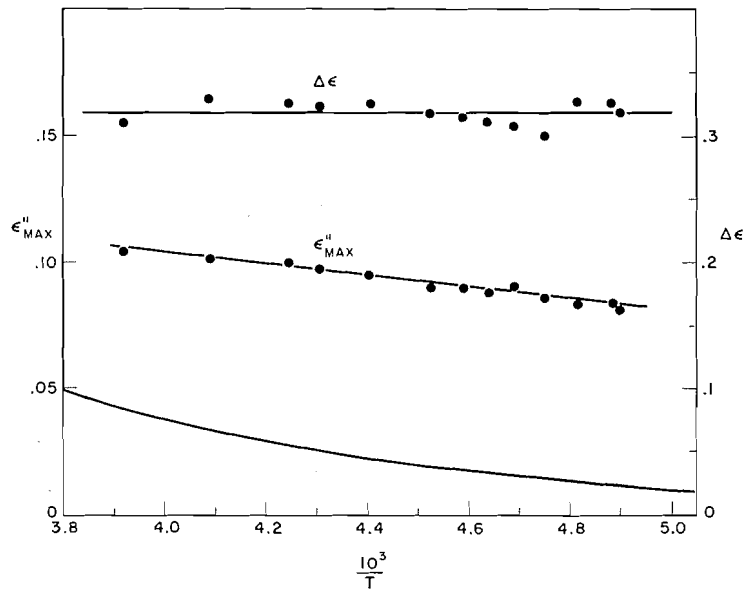

FIG. 9. Variations of ϵ''_{max} and $\Delta\epsilon$ with temperature.

also by Broadhurst and Fitzgerald, reflects the increase in α, since $\Delta\epsilon$ is approximately constant.

Origin of the Dispersion

There can be little doubt that the dispersion and absorption effects observed at radio frequencies are related to defects in the crystal structure. The amplitude of these effects, but neither the most probable relaxation time nor the width of the distribution of relaxation times, depends appreciably on the thermal history of the sample. Measurements in the vicinity of room temperature indicate that the amplitude of absorption ultimately

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

reaches a steady value, rather than falling to zero. This suggests that in general the absorption is the sum of two terms, one arising from the presence of defects intrinsic in the sample at the temperature of measurement, and the second from the presence of defects in excess of the "equilibrium" number by an amount which depends on the thermal history. At low temperatures the rate of disappearance of excess defects is so slow that they are effectively "frozen-in". The loss observed is then considerably higher than that corresponding to the "equilibrium" number of defects. In Fig. 9 the lowest curve is an extrapolation from higher temperatures of the equation for the equilibrium value of ϵ''_{max} reported by Dryden and Dasgupta (3). For a sample maintained several days at room temperature, however, our ϵ''_{max} agreed with the equilibrium value given by their equation (0.08) (but not with the value shown in their Fig. 1).

It is apparent that the dispersion cannot arise from the presence of regions of vertically stacked molecules of the type originally produced on freezing of the sample, since the latter phase shows no dispersion in this frequency range. The possibility has been considered (4) that a second vertical form may be responsible for the dispersion. This suggestion is not supported by a number of factors:

(1) The X-ray photographs of freshly frozen samples show (9) a single long spacing which is quite rapidly replaced completely by a second, somewhat shorter, long spacing. The size of the contribution of the dispersion to the static dielectric constant (0.2 to 0.4 or more at room temperature) is an appreciable fraction of the contribution of the rotating dipoles in the liquid state (0.8 to 0.9, extrapolated to room temperature). This seems to indicate that an appreciable fraction (of the order of one third) of the molecules in the β phase at room temperature are capable of contributing to the polarization, despite the X-ray evidence for the absence of a vertical form. This does not necessarily imply that, according to the model of vertical packing, about one third of the molecules need exhibit vertical packing, since one defect might affect the ability of several molecules to orient. However, the case in which the effective defect population is least, that of single, or small groups of, defect molecules, is precisely the case which is least attractive thermodynamically for defects which consist of molecules whose long axes are considerably inclined to the long axes of neighboring molecules.

(2) It appears unlikely that parts of the sample can remain indefinitely frozen into a vertical structure, when a good part of the dispersion disappears at a finite rate.

(3) Broadhurst and Fitzgerald (4) found that the dispersion shown by the solidified form of a 10% solution of ethyl stearate in heneicosane was similar to that shown by pure ester, except for the magnitude of the dispersion, which was only about 10% as great. These workers have inferred, since heneicosane exists only in vertical modifications, that ethyl stearate in the solid solution occurs in a vertical form. However, the effect of the ester on the crystal form of the hydrocarbon is not known. Moreover, one should have expected the dispersion, per ethyl stearate molecule, to be much greater in the solution (where all the molecules are vertically packed) than in the pure ester (where groups of vertically packed molecules constitute defects in a tilted form).

Perhaps the most satisfactory model is one which takes the defects to consist of molecules whose carbon chains lie in planes which make appreciable angles with the planes of neighboring molecules, that is, which have been considerably rotated about their long axes from their most stable positions. Positions of relative stability would occur at angles of rotation determined by the crystalline field but separated from coplanarity with neighboring molecules by a high rotational barrier. Dryden and Meakins (1) suggest that positions of relative stability exist for angles of rotation of about 90°.

For personal use only.

Considerable uncertainty about the nature of the dispersion process remains. A vertical-type defect is not definitely excluded. It is possible that a detailed X-ray or wide-band nuclear magnetic resonance study would prove useful.

Interfacial polarization in the microcrystalline solid is probably responsible for the low-frequency effects (see Fig. 3), which seem to depend even more on rate of cooling than does the radio-frequency dispersion.

ACKNOWLEDGMENTS

The author is indebted to Dr. Burton M. Craig of the Prairie Regional Laboratory, Saskatoon, for a sample of ethyl stearate and to Professor E. R. Fitzgerald for helpful correspondence.

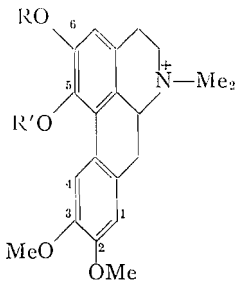
A NEW QUATERNARY APORPHINE FROM FAGARA TINGUASSOIBA HOEHNE[1]

N. V. RIGGS,[2] L. ANTONACCIO,[3] AND LÉO MARION

ABSTRACT

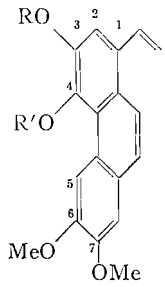
An alkaloid isolated as picrate from *Fagara tinguassoiba* gives rise on methylation to a derivative of glaucine. It has been shown to be the 6-hydroxy-2,3,5-trimethoxy-N,N-dimethylaporphinium ion.



An extract of the bark of the Brazilian plant, *Fagara tinguassoiba* Hoehne, has yielded an alkaloid which has been isolated as a picrate. We have been able to investigate the structure of this alkaloid and are now reporting our results.

Passage of a solution of the crude picrate through a strong base ion-exchange resin gave a water-soluble base, $C_{21}H_{27}O_5N$, converted by hydriodic or hydrochloric acid into the corresponding halide, $C_{21}H_{26}O_4NX$, containing three methoxyl groups. The ultraviolet absorption spectra of the base and chloride in the absence of added alkali were nearly identical and resembled closely that of glaucine. The presence in the chloride of the fourth oxygen atom as a phenolic hydroxyl group was suggested by the large displacement to longer wavelength in its spectrum on addition of alkali; in agreement, a monoacetate was formed on gentle acetylation. The alkaloid was apparently a phenolic quaternary aporphine, probably oxygenated in positions 2, 3, 5, and 6, since oxygenation in positions 3, 4, 5, and 6 leads to light absorption of much lower intensity in the vicinity of 300 mμ than that observed in the present case (1, 2).

N-Methylisocorydine, a quaternary representative of the latter oxygenation class, has been isolated from *Fagara coca* (3), and from Australian *Zanthoxylum* species (4, 5), but its picrate has a much higher melting point, and its chloride a much greater optical rotation than the melting point and rotation of the corresponding derivatives of the *F. tinguassoiba* alkaloid. Confirmation of the suggested oxygenation pattern in the present case was obtained by O-methylation of the iodide to give a product which by m.p., mixed m.p., infrared spectra, and X-ray powder diagrams proved identical with N-methylglaucinium (I*a*) iodide. Two-stage Hofmann degradation of the O-methylated chloride gave 3,4,6,7-tetramethoxy-1-vinylphenanthrene (II*a*) (but see Experimental section).



The phenolic hydroxyl group of the parent substance was not in position 5, since the product of O-ethylation of the phenolic quaternary iodide differed from O-ethyl-N-methylglaucentrinium (I*b*) iodide (6). A generous sample of the latter was kindly provided by Dr. R. H. F. Manske, but unfortunately the so-far unknown vinyl derivative II*b* of the two-stage Hofmann degradation polymerized during evaporation of its ethereal solution so that it could not be compared with the ethoxytrimethoxyvinylphenanthrene

obtained from our alkaloid.[4] This last degradation product from our alkaloid was, however, different from the known 6-ethoxy-3,4,7-trimethoxy- and 7-ethoxy-3,4,6-trimethoxy-1-vinylphenanthrene (7). It was oxidized to an acid which must be 3-ethoxy-4,6,7-trimethoxyphenanthrene carboxylic acid. Elimination of trimethylamine in the second stage of the Hofmann degradation incidentally showed the presence of an N,N-dimethyl group in the parent alkaloid; it is difficult to understand why exhaustive Herzig–Meyer analysis of the phenolic quaternary chloride gave a value close to that for only one N-methyl group, whereas a value close to the theoretical for two N-methyl groups was obtained with N-methylisocorydinium chloride (3).

The quaternary alkaloid isolated as picrate from *F. tinguassoiba* is therefore the 6-hydroxy-2,3,5-trimethoxy-N,N-dimethylaporphinium (Ic) ion.

EXPERIMENTAL

All melting points were taken on a hot-stage under a microscope. The ultraviolet absorption spectra were determined in 95% ethanol on a Carey Model 11 recording spectrophotometer. Infrared absorption spectra were measured on a Perkin–Elmer double-beam Model 21 spectrophotometer equipped with sodium chloride optics, and in Nujol mulls. Except as otherwise noted, samples for analysis were dried in a vacuum at 100° for up to 20 hours.

Isolation of the Alkaloid

The ground bark of *F. tinguassoiba* Hoehne (2K) was extracted with ethanol, the extract evaporated to a small bulk, acidified to Congo red with hydrochloric acid, and washed with ether. The residual viscous solution left after extraction with ether was diluted with water, alkalized with sodium hydroxide, and extracted with chloroform. The aqueous alkaline solution was acidified with hydrochloric acid and treated with mercuric chloride. The precipitated complex was filtered, and the regenerated base isolated as the crystalline picrate, wt. 55.3 g. The picrate was recrystallized from a large volume of ethanol from which it separated as yellow needles, m.p. 118–124°, which

[4]*Some polymerization of the vinylphenanthrene from authentic glaucine methiodide also occurred, but none was observed when Hofmann degradation of the O-alkylated chlorides was carried through to the vinylphenanthrenes without purification of the intermediates; some occurred, however, when purified O-ethylated iodide was degraded. It is possible that polymerization, perhaps initiated by traces of peroxide in the ether used for extraction, is inhibited by phenolic material that escapes alkylation and is extracted in trace amounts from the alkaline solutions.*

browned and became sticky on being dried at 100°. For analysis the picrate was dried at 56° at 0.5 mm for 20 hours. Found: C, 55.51; H, 5.39; N, 8.92. Calc. for $C_{21}H_{26}O_4N.C_6H_2O_7N_3.C_2H_5OH$: C, 55.25; H, 5.46; N, 8.89%. This product or the original picrate formed prisms from aqueous acetone, m.p. 146–151°. Found (after drying at 80° at 0.5 mm for 20 hours): C, 55.29; H, 5.06; N, 9.30. Calc. for $C_{21}H_{26}O_4N.C_6H_2O_7N_3$: C, 55.47; H, 4.83; N, 9.59%. N-Methylisocorydinium picrate has m.p. 202–204° (3).

6-Hydroxy-2,3,5-trimethoxy-N,N-dimethylaporphinium (Ic) Hydroxide

A solution of the picrate (2 g) in a mixture of acetone (80 ml) and methanol (20 ml) was passed down a column of Amberlite IRA 400 (OH) (16 g), the deep red band formed extending nearly to the bottom of the column. The darkening eluate was rapidly evaporated to dryness at 60° under reduced pressure. The crystalline residue was readily soluble in water, methanol, or ethanol. Addition of several volumes of acetone to the ethanolic solution caused separation of long needles which were promptly filtered, washed with acetone, and dried overnight in a vacuum desiccator over potassium hydroxide pellets and concentrated sulphuric acid. The dried product melted at ca. 120° (decomp.). Found: C, 67.03; H, 7.53; N, 3.62. Calc. for $C_{21}H_{27}O_5N$: C, 67.54; H, 7.23; N, 3.75%. Ultraviolet spectrum: λ_{max} 228 mμ, log ε 4.57; λ_{max} 270 mμ (sh), log ε 4.00; λ_{max} 281 mμ, log ε 4.10; λ_{max} 307 mμ, log ε 4.18; λ_{max} 321 mμ (sh), log ε 4.04. The base darkened on being kept, and discolored rapidly in ethanol solution. If the eluate from the column, or a suspension of the product in acetone were kept for several hours, the mixture became dark brown, presumably owing to condensation of the acetone in the presence of the strong quaternary base, and little or no crystalline product could be obtained. The sparing solubility of the picrate in any other of the common volatile solvents required the use of acetone containing some water or methanol on the ion-exchange column. (No exchange occurred with acetone alone as solvent.) Satisfactory results were obtained as described in the following sections.

6-Hydroxy-2,3,5-trimethoxy-N,N-dimethylaporphinium (Ic) Iodide

The eluate from the column was run directly into a slight excess of hydriodic acid diluted with methanol. The brownish eluate was evaporated to a gum which crystallized on treatment with warm methanol and ether. Recrystallization from acetone–methanol–ether gave buff-colored leaves, m.p. 226–229° (decomp.). Found: C, 52.04; H, 5.54; I, 26.40; OCH_3, 18.61. Calc. for $C_{21}H_{26}O_4NI$: C, 52.17; H, 5.42; I, 26.25; $3OCH_3$, 19.26%.

6-Hydroxy-2,3,5-trimethoxy-N,N-dimethylaporphinium (Ic) Chloride

The eluate from the column was run directly into a slight excess of hydrochloric acid. The eluate remained practically colorless for several hours. Evaporation to dryness as above and recrystallization of the residue from methanol–acetone gave the chloride as long colorless needles, m.p. 215–219° (decomp.), $[\alpha]_D^{25}$ +30.2° (*c*, 2.16 in water). Found: C, 63.73; H, 6.95; OCH_3, 23.59; (N).CH_3, 3.57. Calc. for $C_{21}H_{26}O_4NCl$: C, 64.35; H, 6.69; $3OCH_3$, 23.74; 1(N).CH_3, 3.83%. Ultraviolet absorption (in neutral 95% ethanol): λ_{max} 228 mμ, log ε 4.60; λ_{max} 271 mμ (sh), log ε 4.02; λ_{max} 281 mμ, log ε 4.12; λ_{max} 307 mμ, log ε 4.21; λ_{max} 321 mμ (sh), log ε 4.06. (In 0.3 *N* sodium hydroxide in 95% ethanol): very strong below 230 mμ, λ_{max} 250 mμ (sh), log ε 4.40; λ_{max} 265–270 mμ (sh), log ε 4.29; λ_{max} 347 mμ, log ε 4.19.

N-Methylisocorydinium chloride has m.p. 217–218° (decomp.) on slow heating, and $[\alpha]_D^{30}$ +169° (*c*, 0.22 in water) (3).

6-Acetoxy-2,3,5-trimethoxy-N,N-dimethylaporphinium (Id) Chloride

A sample (128 mg) of the above product was warmed with acetic anhydride (2 ml) and pyridine (0.25 ml) for 1 hour. Evaporation to dryness on the steam bath under reduced pressure, and recrystallization of the residue from methanol–acetone–ether gave small prisms, m.p. 234–238°. Found: C, 63.47; H, 6.39. Calc. for $C_{23}H_{28}O_5NCl$: C, 63.66; H, 6.54%.

2,3,5,6-Tetramethoxy-N,N-dimethylaporphinium (Ia) Iodide

A solution of the iodide of I*c* in ice-cold methanol was treated with an excess of ethereal diazomethane for 24 hours, gas evolution ceasing after 6 hours. More ethereal diazomethane was added and after 24 hours the yellow mixture was evaporated under reduced pressure to a brown gum. Treatment with methanol and ether gave a heavy brown oil, and nearly colorless needles appeared in the supernatant liquor. Recrystallization from methanol–ether gave needles softening in the range 200–210° then melting sharply at 216–217° to a dark brown liquid. Glaucine methiodide (prepared from an authentic sample of glaucine provided by Dr. R. H. F. Manske) and a mixture of the two specimens behaved identically on the hot-stage. Debye–Scherer diagrams of the two were identical and the infrared absorption spectra in Nujol mulls of glaucine methiodide and the product were superimposable.

3,4,6,7-Tetramethoxy-1-vinylphenanthrene (IIa)

A solution of the chloride of I*c* (1.00 g) in ice-cold methanol (20 ml) was treated with an excess of ethereal diazomethane (from 3.0 g N-nitrosomethylurea). After 18 hours the reaction mixture was evaporated to a syrup which was dissolved in methanol (10 ml) and heated on the steam bath with 10% aqueous sodium hydroxide (10 ml) for 1 hour in an open flask. The cooled aqueous residue was extracted with ether, heated again for 1 hour, and after being cooled extracted once more with ether. The combined ether extract on evaporation yielded a resinous methine base (380 mg) which was converted to the methiodide and treated as above with aqueous methanolic sodium hydroxide. The product (234 mg) formed plates, m.p. 141–143°, from methanol. Found: C, 73.94; H, 5.98. Calc. for $C_{20}H_{20}O_4$: C, 73.98; H, 6.22%. It was apparently identical (mixed m.p. and infrared spectrum) with a sample of 3,4,6,7-tetramethoxy-1-vinylphenanthrene (II*a*) obtained by similar two-stage Hofmann degradation of N-methylglaucinium iodide, but the Debye–Scherer diagrams of the two were not identical. The latter result may arise from a difference in crystal form, but repeated attempts to purify the reference sample by chromatography and recrystallization have given material contaminated by a persistent flocculent impurity, possibly polymerized compound. The product from the new alkaloid was oxidized by potassium permanganate in acetone solution to a carboxylic acid, m.p. 207–215°, after crystallization from aqueous methanol, and m.p. 220–223°, after recrystallization from benzene–hexane.

Barger and Silberschmidt (8) report for 3,4,6,7-tetramethoxy-1-vinylphenanthrene, m.p. 142°, and for the corresponding 1-carboxylic acid recrystallized from aqueous acetone or benzene–ligroin, m.p. 215°. The small quantity of our product did not crystallize well from aqueous acetone.

6-Ethoxy-2,3,5-trimethoxy-N,N-dimethylaporphinium (Ie) Iodide

A solution of the iodide of I*c* (1.00 g) in ice-cold ethanol (50 ml) was treated with an excess of ethereal diazoethane (from 1.5 g N-nitrosoethylurea) for 24 hours. The same quantity of ethereal diazoethane was then added and after 24 hours the mixture was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

evaporated to dryness under reduced pressure. Twice crystallized from methanol–ether the residue formed colorless silky needles, m.p. 216–220° (decomp.), readily soluble in chloroform. Found: C, 54.10; H, 6.04; I, 24.71; OR (calc. as OCH_3), 23.94. Calc. for $C_{23}H_{30}O_4NI$: C, 54.04; H, 5.91; I, 24.81; 4×OR (calc. as OCH_3), 24.27%.

The product was different from O-ethyl-N-methylglaucentrinium (I*b*) iodide. Part of a sample of the latter provided by Dr. R. H. F. Manske was twice recrystallized from methanol–ether, and formed prisms, m.p. 205–207°, and was sparingly soluble in chloroform. It was also obtained in needles having a Debye–Scherer diagram identical with that of the prisms, and different from that of the above product.

3-Ethoxy-4,6,7-trimethoxy-1-vinylphenanthrene (IIc)

The iodide of I*e* was degraded with aqueous methanolic sodium hydroxide in two stages as in the preparation of 3,4,6,7-tetramethoxy-1-vinylphenanthrene (II*a*) to give some amorphous material, sparingly soluble in ether, together with a product extracted by ether and forming plates, m.p. 106–108°, from methanol. Similar degradation of the syrupy product of ethylation with ethereal diazomethane of the chloride of I*c* gave little amorphous material. The main product was extracted by ether. The extract was washed thoroughly with aqueous sodium hydroxide, dried, and chromatographed on basic alumina. The eluate yielded leaves, m.p. 106–108°, undepressed in admixture with the above vinyl derivative obtained from the iodide. Found: C, 73.92; H, 6.36; OR (calc. as OCH_3), 36.32. Calc. for $C_{21}H_{22}O_4$: C, 74.53; H, 6.56; 4×OR (calc. as OCH_3), 36.68%.

6-Ethoxy-3,4,7-trimethoxy-1-vinylphenanthrene has m.p. 141°, and 7-ethoxy-3,4,6-trimethoxy-1-vinylphenanthrene has m.p. 142°; these melting points are depressed on admixture of the compounds with one another or with 3,4,6,7-tetramethoxy-1-vinylphenanthrene, m.p. 142° (7).

The vapors of the second stage of the degradation were collected in methanolic picric acid. Evaporation of the solution to dryness and crystallization of the residue from ethyl acetate – ether gave yellow needles, m.p. 214–216°. (The recorded melting point for trimethylamine picrate is 216°.)

Similar degradation of O-ethyl-N-methylglaucentrinium (I*b*) iodide gave a product which at first crystallized on evaporation of its ethereal solution. Addition of a later extract and evaporation left an amorphous product which failed to crystallize from methanol and reduced potassium permanganate very slowly in acetone solution; a crystalline acidic product was not obtained from the oxidation mixture.

3-Ethoxy-4,6,7-trimethoxyphenanthrene-1-carboxylic Acid

The vinylphenanthrene (II*c*) (210 mg) in pure acetone (20 ml) at room temperature was oxidized with a saturated solution of potassium permanganate in pure acetone, added in portions (1 ml) until the color persisted for 30 minutes. The acidic product was obtained by addition of water and sulphur dioxide, evaporation of the acetone, and extraction into ether. The extract was washed with aqueous sodium hydrogen carbonate, dried, and chromatographed on silica. The eluate on evaporation left a residue which crystallized from a large volume of aqueous acetone as fawn needles, m.p. 196–198°. Found: C, 67.47; H, 5.49; OR (calc. as OCH_3), 34.75. Calc. for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66; 4×OR (calc. as OCH_3), 34.82%. Prismatic needles of the same melting point, but retaining tenaciously a trace of orange coloring matter, were obtained from more concentrated solutions in aqueous acetone, and gels formed when solutions in hot benzene were cooled, with or without addition of hexane.

For personal use only.

7-Ethoxy-3,4,6-trimethoxyphenanthrene-1-carboxylic acid has m.p. 213° (unsharp) when crystallized from acetone (7), or m.p. 222–223° when crystallized from benzene (9).

ACKNOWLEDGMENTS

We wish to thank Dr. R. H. F. Manske, Dominion Rubber Company, Guelph, Ontario, for providing generous samples of O-ethyl-N-methylglaucentrinium iodide and glaucine for comparison or degradation to reference compounds. Our indebtedness is also acknowledged to Dr. M. Przybylska for preparing the Debye–Scherer diagrams, to Mr. R. Lauzon for the infrared spectra, and Mr. M. Lesage for the ultraviolet spectra.

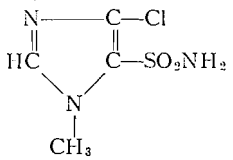
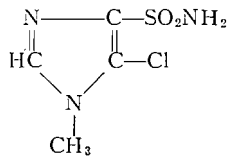
IMIDAZOLE SULPHONAMIDES AND RELATED COMPOUNDS[1]

M. H. Fisher, W. H. Nicholson, and R. S. Stuart



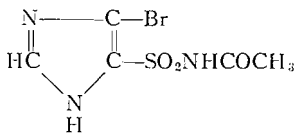
ABSTRACT

The preparations of a number of imidazole sulphonamides and related compounds are described.



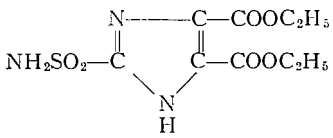
INTRODUCTION

The interest in heterocyclic sulphonamides as diuretic agents (1) prompted us to prepare a number of imidazole sulphonamides and related compounds for investigation. The syntheses of those compounds which have not been previously reported are described in this communication.

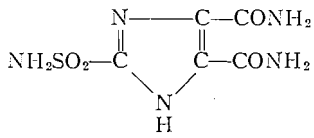


4-Chloro-1-methylimidazole (2) and 5-chloro-1-methylimidazole (3) were chlorosulphonated with chlorosulphonic acid and the sulphonyl chlorides were converted into the sulphonamides (I) and (II) with concentrated ammonia. 4(5)-Bromo-5(4)-sulphamylimidazole (4) was converted into the acetylsulphonamide (III) with acetic anhydride, in the usual way.

(I)

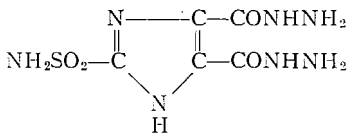


(II)



(III)

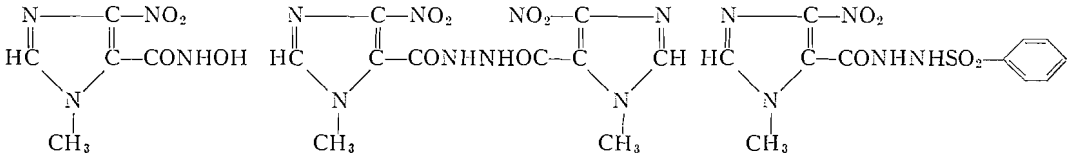
The halo compounds could not be converted into amines by treatment with alcoholic ammonia at an elevated temperature in a sealed tube. Bennett and Baker (4) showed similar inertness of the bromine atom in 4(5)-bromo-5(4)-sulphamylimidazole.



4,5-Bis(ethoxycarbonyl)-2-mercaptoimidazole (5) was converted into the sulphonyl chloride by oxidative chlorination in dilute hydrochloric acid. A brief treatment with concentrated ammonia gave the sulphonamide (IV). This ester on standing in concentrated ammonia or hydrazine for several hours was converted into the diamide (V) and the dihydrazide (VI).

(IV)

(V)



(VI)

Attempted conversion of the diamide into a xanthine with alkaline hypobromite (6) was unsuccessful. The dihydrazide with dilute hydrochloric acid gave a substance of undetermined structure rather than the expected dihydroxypyridazine (7).

The acid chloride of 5-carboxy-1-methyl-4-nitroimidazole (8) with hydroxylamine gave the expected hydroxamic acid (VII). However, with hydrazine under a variety of

conditions only the 1,2-disubstituted hydrazine (VIII) could be isolated. Reaction with benzenesulphonylhydrazine gave the normal benzenesulphonylhydrazide (IX).

(VII) (VIII) (IX)

4(5)-Ethoxycarbonyl-2-methylimidazole (9) refluxed with hydrazine in methanol gave the hydrazide (X).

(X)

EXPERIMENTAL

4-Chloro-1-methyl-5-sulphamylimidazole (I)

4-Chloro-1-methylimidazole (8 g) dissolved in chlorosulphonic acid (48 ml) was refluxed for 2 hours. The solution was cooled and poured on to ice. The sulphonyl chloride was collected, washed with a little water, and dissolved in concentrated ammonia. After 15 minutes the excess of ammonia was evaporated and the solution was acidified with hydrochloric acid. The product was collected and crystallized from water as white needles (2.1 g), m.p. 164–165°. Found: C, 24.5; H, 3.22; N, 21.4; S, 16.4. Calc. for $C_4H_6ClN_3O_2S$: C, 24.6; H, 3.07; N, 21.5; S, 16.4%.

5-Chloro-1-methyl-4-sulphamylimidazole (II)

This compound was prepared from 5-chloro-1-methylimidazole (12 g) in a similar manner. Recrystallization from water gave white needles (5.4 g), m.p. 188–189°. Found: C, 24.9; H, 3.24; N, 21.3; Calc. for $C_4H_6ClN_3O_2S$: C, 24.6; H, 3.07; N, 21.5%.

4(5)-Acetylsulphamyl-5(4)-bromoimidazole (III)

4(5)-Bromo-5(4)-sulphamylimidazole (5 g) and acetic anhydride (50 ml) were refluxed for 1 hour and then cooled. The solid which crystallized was collected and recrystallized from water as white needles (2.4 g) m.p. 247–248°. Found: C, 22.3; H, 2.3; N, 15.4; S, 11.9. Calc. for $C_5H_6BrN_3O_3S$: C, 22.4; H, 2.2; N, 15.7; S, 12.0%.

4,5-Bis(ethoxycarbonyl)-2-sulphamylimidazole (IV)

4,5-Bis(ethoxycarbonyl)-2-mercaptoimidazole (1 g) was suspended in 2 *N* hydrochloric acid (10 ml) and cooled in an ice bath. Chlorine gas was passed gently through the solution for 25 minutes. The sulphonyl chloride was collected, washed with a little water, and dissolved in concentrated ammonia (10 ml). After 10 minutes the excess of ammonia was evaporated and the solution was acidified with hydrochloric acid. The product was collected and crystallized from water as white needles (0.65 g), m.p. 235–236°. Found: C, 37.4; H, 4.47; N, 14.4; S, 11.1. Calc. for $C_9H_{13}N_3O_6S$: C, 37.1; H, 4.96; N, 14.4; S, 11.0%.

4,5-Dicarbamyl-2-sulphamylimidazole (V)

4,5-Bis(ethoxycarbonyl)-2-sulphamylimidazole (0.4 g) was dissolved in concentrated ammonia (10 ml) and allowed to stand at room temperature for 3 days. The excess of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

ammonia was evaporated and the solution was acidified with hydrochloric acid. The product was collected and crystallized from a large volume (100 ml) of water as white needles (0.2 g), m.p. >300°. Found: C, 25.5; H, 3.05; N, 29.6; S, 13.9. Calc. for $C_5H_7N_5O_4S$: C, 25.8; H, 3.01; N, 30.1; S, 13.8%.

4,5-Bis(hydrazinocarbonyl)-2-sulphamylimidazole (VI)

4,5-Bis(ethoxycarbonyl)-2-sulphamylimidazole (2.5 g) was dissolved in 30% hydrazine (50 ml) and allowed to stand at room temperature for 1 day. The solution was evaporated almost to dryness then diluted with water and acidified with glacial acetic acid. The product was collected and crystallized from water as small white needles (1.5 g), m.p. >300°. Found: C, 23.0; H, 3.45; N, 37.5; S, 12.3. Calc. for $C_5H_9N_7O_4S$: C, 22.8; H, 3.42; N, 37.2; S, 12.2%.

1-Methyl-4-nitroimidazole-5-hydroxamic acid (VII)

The acid chloride of 5-carboxy-1-methyl-4-nitroimidazole (11 g) dissolved in chloroform (25 ml) was added dropwise with stirring at 0–5° to a solution of hydroxylamine hydrochloride (5 g) and sodium hydroxide (9 g) in water (50 ml). The dark red solution was acidified at 0° with hydrochloric acid. The product which precipitated was collected and crystallized from "cellosolve" as white needles (3.5 g), m.p. 200° (sintered), 308° (decomp.). Found: C, 32.5; H, 3.31; N, 30.6; Calc. for $C_5H_6N_4O_4$: C, 32.3; H, 3.23; N, 30.2%.

1,2-Bis(1-methyl-4-nitro-5-imidazolylcarbonyl)-hydrazine (VIII)

The acid chloride of 5-carboxy-1-methyl-4-nitroimidazole (18 g) dissolved in chloroform (180 ml) was added dropwise, with stirring and cooling, to a solution of 95% hydrazine (7 ml) in chloroform (180 ml). After 30 minutes the orange product was collected, dissolved in water, and acidified with hydrochloric acid yielding white needles (10 g), m.p. 308°. Found: C, 36.1; H, 3.46; N, 33.6; Calc. for $C_{10}H_{10}N_8O_6$: C, 35.6; H, 2.96; N, 33.2%.

1-Methyl-4-nitro-5-phenylsulphonylhydrazinocarbonylimidazole (IX)

The acid chloride of 5-carboxy-1-methyl-4-nitroimidazole (11.1 g) dissolved in benzene (30 ml) was added dropwise, with stirring, to phenylsulphonylhydrazine (10 g) in pyridine (25 ml). After 10 minutes the solution was poured into an excess of ice-cold dilute hydrochloric acid to precipitate the product (10.5 g). Recrystallization from "cellosolve" gave small white needles, m.p. 248° (decomp.). Found: C, 40.7; H, 3.45; N, 21.4. Calc. for $C_{11}H_{11}N_5O_6S$: C, 40.6; H, 3.38; N, 21.5%.

4(5)-Hydrazinocarbonyl-2-methylimidazole (X)

4(5)-Ethoxycarbonyl-2-methylimidazole (0.7 g) was dissolved in a mixture of 85% hydrazine hydrate (5 ml) and methanol (5 ml) and refluxed for 1 hour. The solution was evaporated to dryness and the residue crystallized from methanol to give white needles (0.4 g), m.p. 210°. Found: C, 43.5; H, 5.70; N, 39.9. Calc. for $C_5H_8N_4O$: C, 42.9; H, 5.71; N, 40.0%.

The Reaction of 4,5-Dicarbamyl-2-sulphamylimidazole with Alkaline Hypobromite

4(5)-Dicarbamyl-2-sulphamylimidazole (1.17 g) was dissolved in a solution of bromine (1.6 g) and 10% sodium hydroxide (28 ml) at 0°. After 1 hour at 0° the solution was acidified with glacial acetic acid and the precipitate was collected. After several crystallizations from water the product was obtained as pale buff needles (0.15 g), m.p. >300°. Found: C, 20.6; H, 2.58; N, 24.8; S, 11.3; residue, 14.23%.

The Reaction of 4,5-Bis(hydrazinocarbonyl)-2-sulphamylimidazole with Hydrochloric Acid

4,5-Bis(hydrazinocarbonyl)-2-sulphamylimidazole (1.5 g) dissolved in 2 *N* hydrochloric acid (15 ml) was heated for 6 hours on a steam bath. The solid (0.7 g) which precipitated during the reaction was collected and purified by dissolution in dilute sodium hydroxide and precipitation with hydrochloric acid, as white needles, m.p. >300°. Found: C, 30.8; H, 2.55; N, 31.1; S, 5.29%.

THE CONVERSION OF α-KETO ACIDS AND OF α-KETO ACID OXIMES TO NITRILES IN AQUEOUS SOLUTION[1]

A. Ahmad and Ian D. Spenser

ABSTRACT

The conversion of α-oximino acids (anti HO— —COOH) to nitriles in aqueous solution is shown to be a general reaction. α-Keto acids are converted to nitriles in excellent yield in aqueous solution in the presence of hydroxylamine. Oxidation of α-oximino acids yields hydroxamic acids.

Recently we reported the facile conversion of indolyl-3-pyruvic acid oxime to indolyl-3-acetonitrile in aqueous solution at moderate temperature, and put forward the hypothesis that this reaction forms the missing link in the biosynthesis of this nitrile (1).

We have now extended our study to other α-keto acid oximes, all of which gave the lower nitrile and carbon dioxide on warming in dilute aqueous and also in dilute hydrochloric acid solution. A summary of the results obtained with 10 representative α-keto acid oximes is presented in Table I. In each case 25 mg acid was suspended in 10 ml water and refluxed 25 minutes under nitrogen. The system was protected from atmospheric carbon dioxide and the CO_2 generated in the reaction was collected quantitatively as $BaCO_3$. At the same time nitrile was isolated and identified by its infrared absorption. A similar series of experiments with 0.1 *M* HCl as the solvent gave substantially identical results. The rate of the reaction is lowered with rise in pH (1) and markedly affected by temperature. Thus α-oximinopropionic acid was stable at pH 4 below 45°, whereas at 55° it gave CO_2 corresponding to 79% decarboxylation in 6 hours.

The conversion $R—C(=NOH)COOH \rightarrow RCN+CO_2+H_2O$ thus constitutes a general reaction of α-keto acid oximes, and a general route to nitriles.

The general nature of the reaction in aqueous solution is further indicated by widely scattered observations of different authors. These are summarized in Table II. The general instability of α-oximino acids in aqueous solution at room temperature was also observed in the course of conductivity measurements (2).

In dilute mineral acid solution a similar conversion takes place, whose generality was recorded, without experimental evidence, by Waters (3, 4), who refers to a paper by Bouveault and Locquin (5). Table II presents a summary of reported instances of this reaction. It has also been found that under normal conditions of oxime formation indolyl-3-glyoxylic acid did not yield the corresponding oxime but 3-cyanoindole (6, 7), and that 2,6-dimethoxyphenylthiopyruvic acid gave a mixture of oximino acid and nitrile (8).

α-Oximino acids are stable in alkaline solution (3, 4); they may be obtained in good yields by alkaline hydrolysis of α-oximino esters (e.g. 9, 10) or amides (11).

No systematic experimental study of the reaction of α-oximino acids in aqueous solution has been reported, nor has it been used for the synthesis of nitriles.

Under anhydrous conditions this route of synthesis has been applied to prepare ring-substituted phenylacetonitriles from the corresponding phenylpyruvic acid oximes, either by pyrolysis (12) or in the manner of the Beckmann rearrangement, in acetic anhydride solution (13). The limitation to arylacetonitriles is surprising, since there is

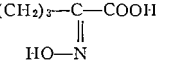
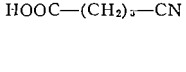
overwhelming evidence in the early literature that both reaction conditions are of general applicability (14): Table II lists the α-keto acid oximes which have been shown to yield the lower nitrile on warming with acetic anhydride. Yet only one nitrile other than an arylacetonitrile appears to have been prepared in this manner (8). Evidence regarding the generality of the pyrolytic decomposition is similarly dispersed throughout the literature: Most α-oximino acids described are reported to decompose at their melting point with evolution of gas, which was recognized as CO_2 in some instances while in others the second product of pyrolysis was identified as the nitrile (Table II).

It would appear that the pyrolytic decomposition and the decomposition under Beckmann conditions, as well as the decomposition in aqueous solution, are general reactions.





A further general property of α-oximino acids may be gleaned from the literature: A number of them have been reported to decompose to nitrile and CO_2 in aqueous solution

more readily in the presence of hydroxylamine hydrochloride (15). This led us to investigate whether nitrile could be prepared by direct treatment of α-keto acid with hydroxylamine, without isolation of the intermediate oximino acid, according to the reaction

$$R{-}\underset{\underset{O}{\|}}{C}{-}COOH + NH_2OH \rightarrow R{-}\underset{\underset{HO{-}N}{\|}}{C}{-}COOH \xrightarrow{H^+} R{-}CN + CO_2 + H_2O.$$

Each of eight α-keto acids was refluxed under nitrogen with one equivalent hydroxylamine hydrochloride in aqueous solution, and in every case an almost quantitative yield of the corresponding nitrile was obtained. The results are summarized in Table III.

*Values in parentheses are in moles.

α-Keto acids alone did not decarboxylate when refluxed in aqueous or 0.1 *M* HCl solution. The only acid amongst those tested which did not undergo conversion to nitrile under these conditions was 2,4,6-trimethylphenylglyoxylic acid. Di-ortho-substituted phenyl ketones do not form carbonyl derivatives under normal reaction conditions (16) and this failure serves as further indication for the required intermediary formation of oxime in the conversion to nitrile. Oxalacetic acid gave a mixture of cyanoacetic acid and, by further decarboxylation of the latter, acetonitrile. α-Ketoglutaric acid gave a quantitative yield of succinic acid, presumably by hydrolysis of the primary product, β-cyanopropionic acid.

The facile conversion to nitriles of α-keto acid oximes explains the finding (4) that standard methods for the hydrolysis of oximes fail in the case of α-oximino acids. α-Keto acid esters have been regenerated from their oximes by treatment with 85% formic acid and lead chamber crystals (5, 17), and α-keto acids from α-oximino acids by hydrolysis with concentrated HCl in the presence of formaldehyde (14, but cf. 18), but hydrolysis by dilute acid does not yield α-keto acid and hydroxylamine (4).

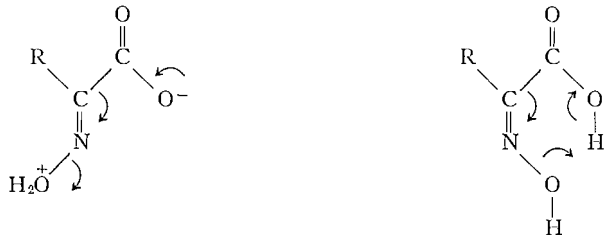
In view of this failure it is somewhat surprising that a method for the detection and estimation of oxime nitrogen, based on preliminary hydrolysis to hydroxylamine, has been repeatedly thought applicable to α-oximino acids (19, 20, 21). The procedure (19) and its modifications consists of the supposed acid hydrolysis of α-oximino acids to hydroxylamine, and detection of the latter (22) by oxidation to nitrite and treatment with sulphanilic acid and α-naphthylamine (Gries' reagent) to form an azo dye which may be estimated colorimetrically. In spite of the finding that very poor recoveries were obtained with α-oximino acids (21, 23) this procedure has been used in attempts to establish the occurrence of such compounds in living tissues. Evidence so obtained would appear to be questionable.

In another method of estimation of α-oximino acids (24), which gave almost quantitative results, acid hydrolysis was omitted. Instead the keto acid oxime was oxidized in alkaline solution with iodine, yielding nitrite ion, which was estimated as before. The tacit assumption was made that alkaline hydrolysis precedes oxidation in this case. In fact the reaction takes an entirely different course:

When α-oximino acids (R—C(=NOH)—COOH) were treated with hydrogen peroxide at pH 6 oxidative decarboxylation took place and the corresponding hydroxamic acids (R—CO—NHOH) were shown to be present in the reaction mixture. They were identified by paper chromatography (cf. 25, 26). The following α-keto acid oximes gave hydroxamates in this way: pyruvic, α-ketobutyric, oxalacetic, α-ketoglutaric, phenylglyoxylic (syn and anti), phenylpyruvic, *p*-methoxyphenylpyruvic, and 3-indolylpyruvic acid oximes. The pH of the reaction mixture was critical: below pH 4.0 and above pH 6.5, hydroxamic acids could not be detected; even under optimal conditions (pH 6.2) attempts to isolate the products have so far been successful in one case only (phenylacethydroxamic acid from phenylpyruvic acid oxime) in very poor yield.

This failure may be due either to the further oxidation of hydroxamic acid to nitrite ion (26, 27), or to a Lossen rearrangement of the hydroxamic acids to yield isocyanate which decomposes further (28).

Oxidation of α-oximino acids with iodine does not stop at the hydroxamic acid stage. The —NHOH moiety of hydroxamic acids is quantitatively converted to nitrite under these conditions (26, 27).



The steps in the estimation of α-oximino acids by means of iodine oxidation are thus as follows:

$$\mathrm{R{-}\underset{\underset{\mathrm{HO{-}N}}{\|}}{C}{-}COOH} \xrightarrow[-CO_2]{[O]} \mathrm{R{-}\underset{\underset{\mathrm{HO{-}N}}{\|}}{C}{-}OH} \rightleftharpoons \mathrm{R{-}CO{-}NHOH} \xrightarrow{[O]} NO_2^-.$$

The mechanism of the oxidative decarboxylation of α-oximino acids to hydroxamic acids, analogous to that proposed for the oxidative decarboxylation of α-amino acids (29), will be discussed in a separate communication.

Two types of mechanism for the conversion of α-oximino acids to nitriles may be considered, and have been discussed in connection with the failure of indolyl-3-glyoxylic

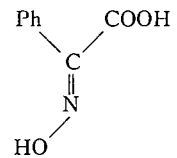
acid to yield oxime (7). The first, a concerted trans elimination, requires an anti (HO— —COOH) stereochemistry; the second, a concerted cyclic elimination, demands the syn (HO— —COOH) configuration of the α-oximino acids.

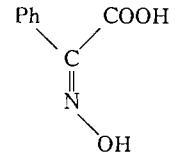
Initial decarboxylation to yield aldoxime, or initial hydrolysis to yield α-keto acid as intermediates in the reaction, may be excluded, since both aldoximes and α-keto acids are stable under conditions when the corresponding α-oximino acids yield nitrile.

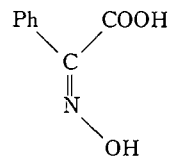
Few pairs of geometrical isomers of α-oximino acids are well authenticated: Hantzsch and his collaborators isolated and studied the isomers of phenylglyoxylic acid oxime (15), of oxalacetic acid oxime (30), of dioximinosuccinic acid (31, 32), and of dioximinopropionic acid (33, 34). Isomers have also been reported, mostly on the basis of melting point differences, of oximinoacetic acid (35, 36), α-oximinoglutaric acid (37, 38), $NH{=}C(NH_2){-}C(=NOH)COOH$ (39), furan-2-pyruvic acid oxime (40), *p*-methoxyphenylpyruvic acid oxime (41, 42), and phenylpyruvic acid oxime (e.g., 14, 42).

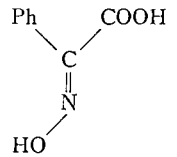
We have prepared the two isomers of phenylglyoxylic acid oxime (15) and of oxalacetic acid oxime (30). One of the latter, however, was exceedingly unstable so that a pure sample could not be obtained. We failed to isolate more than one isomer of α-ketoglutaric acid oxime (38), of phenyl- (14, 42), and of *p*-methoxyphenylpyruvic acid oxime[2] (41, 42).

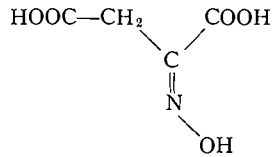
The only experimental attempt to assign configurations to the stereoisomers of α-oximino acids was that of Hantzsch and his collaborators (15, 30, 31, 33, cf. 43). By analogy with their work on benzaldoximes, they made their configurational assignment of the isomers of phenylglyoxylic acid oxime on the basis of the behavior of the O-acetyl derivatives on hydrolysis (44): The oxime (α-oxime) whose acetate on treatment with carbonate at 0° reverted to the oxime was assigned the anti (HO— —COOH) configuration, whereas the oxime (β-oxime), whose acetate under similar conditions gave nitrile, was assigned the syn (HO— —COOH) configuration. Since these assignments were based on the assumption of a cis elimination of the elements of acetic acid, an assumption which was proved erroneous by later experimental work (45), it is necessary to revise Hantzsch's assignments of the stereochemistry of phenylglyoxylic acid oximes (Table IV).

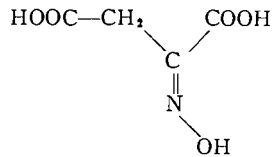


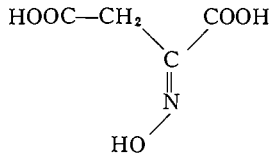


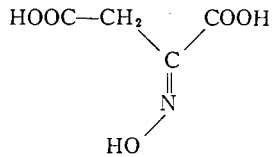


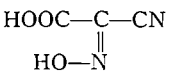


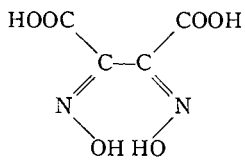


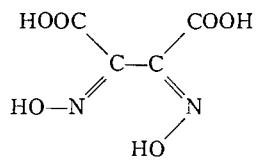












The decomposition of α-oximino acids in acetic anhydride is a special case of the "second-order" Beckmann rearrangement of α-oximinocarbonyl compounds (46), i.e.,

[2]*Dr. R. A. McIvor informs us that further work on his compounds (42) indicates that the phenylpyruvic acid oxime, decomp. 206°, was a molecular complex of the acid and its sodium salt, from which phenylpyruvic acid oxime, decomp. 166–167°, was obtained by high-vacuum sublimation; and that the isomer, decomp. 155°, had reducing properties and probably contained the hydroxylammonium salt of phenylpyruvic acid oxime. This also gave phenylpyruvic acid oxime, decomp. 166–167°, on sublimation at 10^{-3} mm. The isomer of p-methoxyphenylpyruvic acid oxime, decomp. 199°, gave p-methoxyphenylpyruvic acid oxime, decomp. 159°, on recrystallization from water and was a molecular complex of p-methoxyphenylpyruvic acid and its sodium salt. The "unknown compound", melting at 147.5–148° (decomp.), which had reducing properties, was shown to be the hydroxylammonium salt of p-methoxyphenylpyruvic acid oxime.*

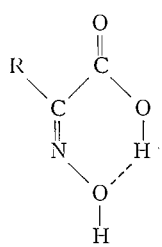
a trans fragmentation reaction requiring the anti (HO— —COOH) configuration (47), and stereochemical assignments must be made accordingly (Table IV).

Hantzsch (15) was able to convert phenylglyoxylic acid oxime, decomp. 127°, (α), into the β-isomer, decomp. 145°, at room temperature in aqueous solution. We observed a similar isomerization, accompanied by some decomposition to benzonitrile, when the low-melting oxime was distilled at 10^{-3} mm, just below its melting point. An attempt to prepare a pure specimen of the low-melting isomer of oxalacetic acid oxime (30) failed, since the crude product which gave a strong blue color with $FeCl_3$ (30), obtained by hydrolysis of diethyl oxalacetate oxime, was unstable at room temperature.

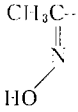
The isomer, decomp. 127°, of phenylglyoxylic acid oxime, decomposed much less readily to benzonitrile, on refluxing in aqueous solution, than the isomer, decomp. 145° (Table I). Since the former isomerizes slowly to the latter at room temperature in aqueous solution (15), it is probable that such a transformation preceded the decarboxylation of the isomer, decomp. 127°. Similarly, the isomer, decomp. 125°, of oxalacetic acid oxime yields cyanoacetic acid less readily in aqueous solution than the isomer, decomp. 88°. In both cases the isomer to which an anti (HO— —COOH) configuration is now assigned on the basis of the reactivity of the O-acetyl derivatives, undergoes elimination of CO_2 and water more readily than the corresponding syn isomer.

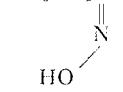


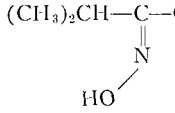
This leads us to favor a mechanism involving concerted trans elimination for the reaction in aqueous solution in the two cases where both syn and anti isomers are known, and prompts us to assign an anti (HO— —COOH) configuration to those α-oximino acids of which only one isomer has been described, which readily undergoes conversion to nitrile in aqueous solution (Table I).

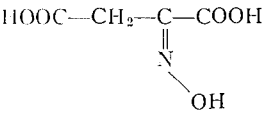
The zwitterion form

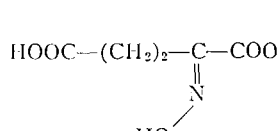
would be most favorable for concerted trans elimination. The observations that α-oximino acids may be recovered unchanged from concentrated sulphuric (15, 30, 48, 49) and hydrochloric acid (50), that they are stable in alkaline solution (4), and that in one instance (1) the reaction in aqueous solution has been shown to have a pH optimum at pH 2, tend to support the zwitterion form as the reacting species in a concerted trans elimination.

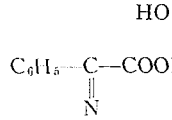


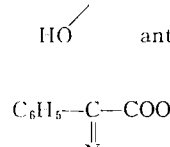


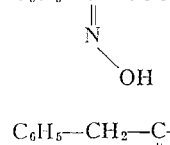


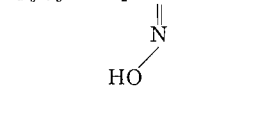


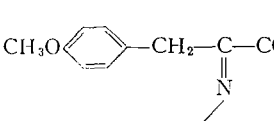












The pyrolytic decomposition is more likely to take place by a concerted cyclic mechanism (cf. 51) demanding the syn form of the α-oximino acid. Such a course of reaction would be favored by intramolecular hydrogen bonding, e.g.,

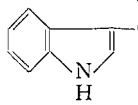
Infrared data (Table V) show up similarities between anti (HO— —COOH) phenylglyoxylic acid oxime and those oximes of which only one isomer is known. The syn (HO— —COOH) isomers of phenylglyoxylic acid oxime and of oxalacetic acid oxime showed similarities in absorption, and their infrared curves differed in certain respects from those of all other α-oximino acids examined.

The —OH stretching frequency, found at 3210 cm^{-1} in all anti oximes, was displaced in the two syn isomers (3250, 3280 cm^{-1} respectively for phenylglyoxylic and oxalacetic acid oxime). This is in accord with the assignment of Palm and Werbin (52). The band near 1300 cm^{-1}, assigned to —OH deformation, was present in all compounds between 1280 and 1300 cm^{-1}, except in the two dicarboxylic acids, where it was displaced to higher wave numbers (1325 and 1375 cm^{-1} respectively). The N—OH stretching vibration of oximes is associated with bands near 920 cm^{-1} (52). The two syn (HO— —COOH) compounds showed strong absorption in this region (940 and 930 cm^{-1} for phenylglyoxylic and oxalacetic acid oxime, respectively), whereas the anti (HO— —COOH) isomers showed bands of weaker intensity. All the compounds examined showed one or more strong bands between 1000 and 1085 cm^{-1}. In general all oximino acids show the band due to C=N vibration at 1620–1650 cm^{-1}. This band was masked by broad carbonyl absorption in the dicarboxylic acids. All monocarboxylic anti oximino acids showed carbonyl absorption at 1690 cm^{-1}. In syn-phenylglyoxylic acid oxime this band was split, appearing at 1660 cm^{-1} and 1712 cm^{-1}. The dicarboxylic acids absorbed at 1670 and 1720 cm^{-1}.

Hantzsch (53) attempted to confirm his configurational assignment on the basis of conductivity measurements. The significance of these results has, however, been called into question (2, 54). Table VI summarizes the pK_a values of the α-oximino acids we have determined, together with those recalculated from reports in the early literature. Configurational assignments have also been made, using as a criterion differences in the readiness of the isomers of α-oximino acids to complex with metal ions (55). It is reported that complexing takes place through the oxime-N and not through the oxime-O, and that anti (HO— —COOH) oximino acids react readily with Cu^{++} and Ca^{++}, whereas the syn (HO— —COOH) isomers do so slowly, presumably only after isomerization.



The general methods of synthesis of α-oximino acids have been listed (56). The compounds have been prepared from α-keto acids (e.g. 57) or α-thioketo acids (e.g. 14, 41, 42) by treatment with hydroxylamine, or from α-oximino esters by alkaline hydrolysis (e.g. 9, 10, 58). A more versatile method of preparation is by nitrosation, under a variety of conditions, of β-keto esters (9, 10, 48, 49, 58, 59, 60) or lactones (61), substituted malonic esters (62, 56), tetronic acids (63), phenylacetonitriles (64), or phenylacetic acid esters (65), followed by acid or alkaline hydrolysis of the resulting α-nitroso derivatives, with deacylation or decarboxylation respectively in the first two cases, and rearrangement to the α-oximino acid. Nitrosation of substituted malonic acids has also been used (66, 56). α-Oximino esters are obtained by treatment of α-halo esters (67) or α-nitro esters (68) with sodium nitrite. The mechanism of these two reactions has been elucidated (68).

Two other methods of preparation, whose route is puzzling, have been used: Treatment of α-halo acids with hydroxylamine (69) gave α-oximino acids, as did hydrolysis of α-hydroxylaminonitriles (11), i.e., of the addition products of aldoximes and HCN. The chemistry of these two reactions has now been clarified and will be discussed in a separate communication.

EXPERIMENTAL

α-Oximino Acids

α-Oximino acids were prepared by well-established methods, either from suitably substituted β-keto or malonic esters or malonic acids, by nitrosation with freshly prepared butyl nitrite (82), or from the α-keto acid and hydroxylamine. Details are given only when modifications of reported methods were used.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

α-Oximinopropionic Acid (Pyruvic Acid Oxime) (cf. 57)

A solution of hydroxylamine hydrochloride (3.50 g, 0.05 mole) in 15 ml water containing 4.20 g (0.05 mole) $NaHCO_3$ was cooled to 5° and poured, with cooling and stirring, into a cooled solution of pyruvic acid (4.40 g, 0.05 mole) in 30 ml water containing 4.20 g (0.05 mole) $NaHCO_3$. After standing 24 hours at room temperature the mixture was extracted with ether, cooled to 5°, carefully acidified with 3 *M* HCl, and repeatedly extracted with ether. The dried (Na_2SO_4) ether extract was evaporated at room temperature, yielding α-oximinopropionic acid, melting at 175–176° (decomp.); neutralization equivalent: found, 103; calculated, 103; pK_a, 3.38. Reported melting point 177° (decomp.) (9), 180–181° (decomp.) (54).

α-Oximinobutyric Acid (α-Ketobutyric Acid Oxime)

α-Oximinobutyric acid (α-ketobutyric acid oxime) was prepared by nitrosation of diethyl ethyl malonate with butyl nitrite under alkaline conditions (56) in 60% yield. After sublimation at 140° and 1.10^{-3} mm the product melted at 154–155° (decomp.); neutralization equivalent: found, 116; calculated, 117; pK_a, 3.20. Reported melting point 154° (decomp.) (69), 169–170° (decomp.) (59).

α-Oximino-β-methylbutyric Acid (α-Ketoisovaleric Acid Oxime)

α-Oximino-β-methylbutyric acid (α-ketoisovaleric acid oxime) was prepared from ethyl α-isopropylacetoacetate (83) by alkaline nitrosation. The ester (3.44 g, 0.02 mole) was dissolved in dry ethanol (15 ml) containing sodium metal (0.46 g, 0.02 mole). The solution was cooled to 5°, butyl nitrite (3.10 g, 0.03 mole) was added dropwise with stirring over 10 minutes, stirring was continued 20 minutes at 5° and then 30 minutes at room temperature. Ethanol was distilled off at room temperature, the residue mixed with crushed ice, acidified with 3 *M* H_2SO_4, and extracted with ether. The ether layer was extracted with 10% NaOH solution, the alkaline solution heated 15 minutes on the steam bath, cooled to 0°, acidified with dilute H_2SO_4, and repeatedly extracted with ether. The ether extract was dried (Na_2SO_4) and concentrated, yielding α-oximino-β-methylbutyric acid (1.78 g, 68%) as a white crystalline solid, melting point 150° (decomp.), after sublimation at 135° and 1.10^{-3} mm; neutralization equivalent: found, 130; calculated, 131; pK_a, 3.05. Reported melting point 163–165° (decomp.) (84), 171–172° (decomp.) (59), 151.5° (decomp.) (2).

α-Oximinosuccinic Acid (Oxalacetic Acid Oxime)

(*a*) syn (HO— α-COOH). This isomer was prepared by nitrosation of ethane-1,1,2-tricarboxylic acid (85). Butyl nitrite (1.03 g, 0.01 mole) was added to a solution of the tricarboxylic acid (1.62 g, 0.01 mole) in ether (30 ml) at 0°. A stream of dry HCl gas was passed through the solution for 10 minutes and the reaction mixture then evaporated. The residual oil was crystallized from chloroform – ethyl acetate, yielding 0.44 g (30%) syn (HO— α-COOH)-oximinosuccinic acid, melting at 126–127° (decomp.). Neutralization equivalent: found, 70; calculated, 73.5; pK_a, 2.90, 4.55. Reported melting point 125° (decomp.) (30), 126° (decomp.) (60). After 12 months at 5° a solid sample of this isomer had partially decomposed to cyanoacetic acid. Alkaline nitrosation of the triethyl ester failed to give the desired product. Treatment of oxalacetic acid with methanolic hydroxylamine at 0° yielded a product contaminated with hydroxylammonium salt.

(*b*) anti (HO— α-COOH) (cf. 30, 38). Sodium diethyl oxalacetate (10.5 g, 0.05 mole) in 50 ml methanol was treated with 3.5 g hydroxylamine hydrochloride (0.05 mole) in 30 ml methanol. The mixture was stirred at 40° for 1 hour, then rapidly cooled to 0° and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

precipitated sodium chloride filtered off. The filtrate was evaporated at room temperature when an oily colorless liquid was obtained which was extracted into ether and dried (Na_2SO_4). The oily liquid, obtained by evaporation of the ethereal solution, which gave a sharp infrared peak at 1630 cm^{-1} (C=N), was dissolved in 15 ml methanol and treated with 10% NaOH to adjust the pH to 10.5. The solution was warmed for 30 minutes on the steam bath with occasional shaking, cooled to 0°, and acidified (pH 2) with 4 *M* HCl. The white solid which separated on acidification was rapidly filtered with cooling, washed with a little cold water, and dried *in vacuo* over caustic soda. After 24 hours the product was washed with dry ether to remove any unreacted oxalacetic acid, as well as any cyanoacetic acid, yielding impure anti (HO— α-COOH) α-oximinosuccinic acid, melting with violent decomposition at 71° (yield 4.59 g, 61.2%). Attempts to purify this isomer at room temperature led to extensive decomposition. Reported melting point 88° (30).

α-Oximinoglutaric Acid (α-Ketoglutaric Acid Oxime)

α-Oximinoglutaric acid (α-ketoglutaric acid oxime) was obtained from triethyl propane-1,1,3-tricarboxylate (86) by alkaline nitrosation. The triethyl ester (6.50 g, 0.025 mole) was dissolved in sodium ethoxide solution (0.575 g sodium metal (0.025 mole) in 40 ml dry ethanol); the solution was cooled to 10° and a solution of *n*-butyl nitrite (2.86 g, 0.0275 mole) in 15 ml dry ethanol was added dropwise with stirring over 15 minutes. The reaction mixture was stirred for another 30 minutes and concentrated at room temperature. Crushed ice was added to the brown viscous residue and the mixture acidified with 3 *M* H_2SO_4. The solution was extracted with ether, the ether layer washed with a little water, extracted with 15 ml 10% NaOH, and the alkaline extract warmed on the steam bath for 15 minutes. On completion of the saponification the solution was cooled to 0°, acidified with 3 *M* H_2SO_4, and the product extracted into ether. The ether extract was washed with water, dried (Na_2SO_4), and concentrated, yielding a brown residue which was taken up in dry ether. On addition of petroleum ether (30–40°) α-oximinoglutaric acid (1.21 g, 30%), melting at 151–152° (decomp.), crystallized. Neutralization equivalent: found, 81; calculated, 80.5; pK_a, 3.25, 4.95. Reported melting point 152° (decomp.) (72, 37), 156° (decomp.) (38), 140° (decomp.) (71, 38).

This oximino acid was also obtained in 13% yield from propane-1,3,3-tricarboxylic acid (87) by acid nitrosation. Treatment of α-ketoglutaric acid with methanolic hydroxylamine (cf. 38) gave the oximino acid contaminated with hydroxylammonium salt, accounting for the low melting point (140°) of the product.

α-Oximinophenylacetic Acid (Phenylglyoxylic Acid Oxime)

(*a*) syn (HO— —COOH) (cf. 15). Cooled solutions of phenylglyoxylic acid (1.50 g, 0.01 mole) in 30 ml water containing 0.84 g $NaHCO_3$ (0.01 mole) and of hydroxylamine hydrochloride (0.70 g, 0.01 mole) in 10 ml water containing 0.84 g $NaHCO_3$ (0.01 mole) were mixed at 5° and shaken 24 hours at room temperature. The mixture was extracted with ether, cooled, and acidified with dilute H_2SO_4, and the product extracted into ether. The dried (Na_2SO_4) ether extract was concentrated at room temperature and the solid residue washed with dry benzene to remove unreacted phenylglyoxylic acid. The product (1.353 g, 82%) melted at 130–131° (decomp.); neutralization equivalent: found, 161; calculated, 165; pK_a, 2.27. Reported melting point 127° (decomp.) (15).

(*b*) anti (HO— —COOH) (cf. 15). The syn isomer, decomp. 130–131° (0.15 g), was dissolved in 5 ml water and the solution allowed to stand 24 hours at room temperature and then at 5°, when the anti isomer crystallized (0.043 g, 26%). It melted at 144–145° with decomposition; neutralization equivalent: found, 160; calculated, 165; pK_a, 2.82.

Sublimation of the syn isomer at 120° and 2.10^{-3} mm gave the anti isomer in 90% yield, together with a small amount of benzonitrile. Reported melting point 145° (decomp.) (15).

α-Oximino-β-phenylpropionic Acid (Phenylpyruvic Acid Oxime)

α-Oximino-β-phenylpropionic acid (phenylpyruvic acid oxime) was obtained by nitrosation, under acidic conditions, of benzylmalonic acid (56) in 85% yield. Recrystallization from hot water was unsatisfactory due to decomposition to phenylacetonitrile. Sublimation at 145° and 10^{-3} mm gave the product, melting at 166–167° (decomp.), neutralization equivalent: found, 175; calculated, 179; pK_a, 3.90. Reported melting point: 159–160° (decomp.) (88), 167° (decomp.) (63).

α-Oximino-β-(p-methoxyphenyl)-propionic Acid (p-Methoxyphenylpyruvic Acid Oxime)

α-Oximino-β-(*p*-methoxyphenyl)-propionic acid (*p*-methoxyphenylpyruvic acid oxime), decomp. 156–157°, neutralization equivalent: found, 209; calculated, 209; pK_a, 3.85; was supplied by Dr. R. A. McIvor,[3] who prepared it from his sample, melting at 199° (42), by recrystallization from water. Reported melting point 159° (decomp.) (41).

α-Oximino-β-(3-indolyl)-propionic Acid (Indolyl-3-pyruvic Acid Oxime)

α-Oximino-β-(3-indolyl)-propionic acid (indolyl-3-pyruvic acid oxime), melting at 157° (decomp.), neutralization equivalent: found, 218; calculated, 218; pK_a, 3.40; was obtained from indolyl-3-pyruvic acid (7) and also by alkaline nitrosation of ethyl α-acetyl-β-(3-indolyl)-propionate (89). Reported melting point 155° (decomp.) (89), 158° (decomp.) (7).

Conversion of α-Oximino Acids to Nitriles

The α-oximino acid (25 mg) was suspended in 10 ml water in a 25-ml two-necked flask, supplied with condenser and gas inlet. Nitrogen was passed first through a $Ba(OH)_2$ trap and then through the reaction mixture; CO_2 was collected in a trap containing saturated $Ba(OH)_2$ solution and the reaction train was linked to a further baryta trap. All experiments were carried out at reflux temperature over 25 minutes. Barium carbonate was collected, washed with water, and methanol, and dried to constant weight. The reaction mixture was worked up for nitrile either by ether extraction or, in the case of non-volatile nitriles, by evaporation. Nitriles were purified by distillation and identified by comparison of their infrared absorption curves with those of authentic specimens. Results are summarized in Table I. In several cases the experiments were repeated with larger quantities to make isolation of nitrile possible.

Oxidation of α-Oximino Acids to Hydroxamic Acids

The α-oximino acid (1 mg) was dissolved in phthalate buffer (pH 6.2) (1 ml). One drop of 15% H_2O_2 was added and the solution kept at 90° for 20–30 minutes, when solvent had almost completely evaporated. The residue was cooled and dissolved in methanol (1 ml), and a sample of this solution was chromatographed (Whatman No. 1, butanol – acetic acid – water, 4:1:5 (25)). After development, the chromatogram was sprayed with 5% $FeCl_3$ in methanol, followed by 2% aqueous HCl. Hydroxamic acids appeared as wine-red spots.

α-Keto Acids

Pyruvic, α-ketobutyric, oxalacetic, and α-ketoglutaric acid were commercial samples. Phenylglyoxylic acid (90), indolyl-3-glyoxylic acid (7), phenylpyruvic acid (91), and

[3]*See footnote 2.*

indolyl-3-pyruvic acid (92) were prepared by established methods. Mesitylglyoxylic acid was prepared by oxidation of 2,4,6-trimethylacetophenone with alkaline potassium permanganate (93), interrupting the oxidation at the keto-acid stage. The solution was then acidified with 1.5 *M* H_2SO_4 and the product extracted into ether. Drying and evaporation yielded mesitylglyoxylic acid (48% yield), melting point 116–117°. Reported melting point 115–116.5° (94).

Conversion of α-Keto Acids to Nitriles

Equivalent amounts of α-keto acid and hydroxylamine hydrochloride in aqueous solution were refluxed for 1–1.5 hours. When CO_2 evolution was complete, the nitriles were isolated as before, either by ether extraction or by evaporation of the reaction mixture. Results are summarized in Table III.

Nitriles

Authentic specimens of nitriles were either redistilled commercial specimens (acetonitrile, propionitrile, isobutyronitrile, cyanoacetic acid, benzonitrile, and phenylacetonitrile) or were prepared by established methods (*p*-methoxyphenylacetonitrile (95), indolyl-3-cyanide (7), indolyl-3-acetonitrile (1)).

ACKNOWLEDGMENTS

We are indebted to Dr. R. A. McIvor, Defence Research Board, Ottawa, for samples of phenyl- and *p*-methoxyphenylpyruvic acid oxime, and for permission to quote his unpublished results.

Financial assistance by the National Research Council of Canada and by the Ontario Research Foundation is gratefully acknowledged. One of us (A. A.) wishes to thank the Colombo Plan authorities for financial support and the Pakistan Council of Scientific and Industrial Research for the award of a scholarship.
