GAS–LIQUID CHROMATOGRAPHY OF TERPENES

PART II. THE DEHYDRATION PRODUCTS OF α-TERPINEOL[1]

E. VON RUDLOFF

ABSTRACT

The complex mixture of terpenes obtained on dehydrating α-terpineol with aqueous oxalic acid was almost completely separated by gas–liquid chromatography (GLC), using rapeseed oil as a new liquid phase. Terpinolene, dipentene, α- and γ-terpinene, $\Delta^{2,4(8)}$-*p*-menthadiene, and 1,8-cineole were identified as the major reaction products; three minor and seven trace constituents were also detected. One of the minor components was *p*-cymene, one an oxide, and the third an unidentified hydrocarbon. The yield of these components after different reaction times was determined by GLC. The initial dehydration gives terpinolene and dipentene in the ratio of approximately 2:1. Terpinolene is isomerized to α- and γ-terpinene, $\Delta^{2,4(8)}$-*p*-menthadiene, and the unidentified hydrocarbon, but not to dipentene. 1,8-Cineole and the other oxide are formed in a reversible reaction. Dehydration of α-terpineol with several other acidic reagents yielded mixtures of products similar to that obtained with aqueous oxalic acid. With acetic acid or acetic anhydride, however, dipentene was formed preferentially and this reaction appears to proceed via the derived acetate.

INTRODUCTION

The first comprehensive study of the dehydration of α-terpineol (I) with acidic reagents was carried out by Wallach *et al.* (1, 2), who fractionated the steam-volatile reaction products by distillation and identified some of the constituents by conversion to known derivatives. In this manner terpinolene (II), dipentene (III), α-terpinene (IV), γ-terpinene (V), and 1,8-cineole (VI) were obtained by use of aqueous oxalic, sulphuric, or phosphoric acids. Mild conditions favored the formation of terpinolene, whereas longer reaction times gave higher yields of α-terpinene. In the reaction with fused potassium hydrogen sulphate only dipentene was identified. Reaction with acetic acid containing 2% sulphuric acid caused much resinification, whereas that with aqueous formic acid resulted in little dehydration. Flawitzky (3) found that when optically active α-terpineol was heated in a sealed tube with excess acetic anhydride, large amounts of limonene (optically active III) were formed. Baeyer (4) used the reaction with aqueous oxalic acid for the preparation of terpinolene (very short reaction time) and α-terpinene, but it is doubtful whether the pure hydrocarbons can be obtained in this manner (5). Using the same reaction for the preparation of α-terpinene, Alder and Rickert (6) reported the presence of an unidentified diene, which they thought to be possibly a seven-membered ring compound. O'Connor and Goldblatt (7), in a study of the spectral properties of terpene hydrocarbons, reported the preparation of α- and γ-terpinene and $\Delta^{2,4(8)}$-*p*-menthadiene (VII) and $\Delta^{3,8(9)}$-*p*-menthadiene (VIII) by dehydration of α-terpineol

followed by high-efficiency fractional distillation of the reaction products, but did not give experimental details for these preparations. Terpinolene was obtained by Petrů (8) in the reaction between α-terpineol and phthalic anhydride, also using short reaction times.

The products obtained in the above reactions thus appear to be rather complex mixtures of *p*-menthadienes and 1,8-cineole and it is doubtful whether all constituents have been identified. The mixtures have a boiling range from about 173–183° C, and it is very difficult to obtain pure components by fractional distillation, even when high-efficiency columns are used. It is possible that azeotropes are formed (9), and in 1891 Wallach himself (10) wrote: "experience has shown that it is especially difficult to determine the presence of other terpenes (*p*-menthadienes) when these are admixed with α-terpinene". Obviously, different analytical techniques are required for the analysis of such mixtures and gas–liquid chromatography (GLC) appears to be the ideal tool at the present time.

GAS–LIQUID CHROMATOGRAPHIC SEPARATION

Previously (11), the mixture obtained in the reaction of α-terpineol with aqueous oxalic acid was used by the author as one of the test mixtures in a study of some of the general aspects of the separation of terpenoid compounds by means of GLC. Using 6-ft×1/4-in. diameter columns with Craig polyesters, polyethylene glycol, polyphenyl ether, or squalene as liquid phase, it was shown that the mixture was composed of at least seven compounds, but the degree of separation obtained with these columns was insufficient to allow quantitative calculations or qualitative separations for preparative purposes. The investigation was therefore continued in order to find conditions which would permit a satisfactory analysis of this mixture and thus facilitate the study of the dehydration reaction itself.

There are several ways by which the chromatographic separations can be improved (12). Increasing the column length is limited by the dimensions of the apparatus and eventually by excessive retention times. The use of thinner diameter columns and smaller samples (less than the 1 to 20 μl commonly used) may also lead to increased efficiency, but requires an exceedingly sensitive detector. A third means of improving the degree of separation is by selecting a more efficient liquid phase. Of the liquid phases used for the separation of terpene hydrocarbons as described in the literature of the past year (9, 13–16), none gave better results for the mixture under consideration than were already obtained previously. In Part I (11) it was shown that squalene was a useful liquid phase and a 12-ft column did indeed give almost complete separation. However, this material is subject to fairly rapid deterioration and cannot be used above 100–120° C for any length of time. It may be reasoned that aliphatic olefins of greater stability and larger molecular weight may give equal or better results. Such compounds are readily available in the form of the triglycerides of vegetable oils, with the added advantage that a wide choice in the degree of unsaturation is available. The additional polarity due to the ester groups would be favorable in this instance, since the polyester columns partially separated peak C into two components whilst the squalene column did not (11). Superior separations were, in fact, obtained when rapeseed or olive oil were used as liquid phase. Oils having a higher degree of unsaturation, e.g. linseed or sunflower seed oil, were not as efficient, a finding which indicates that triolein itself may be very suitable as liquid phase. Columns containing rapeseed or olive oil gave reproducible results during 2 to 3 months of continuous or intermittent use at 120° C or lower, provided they were kept under helium or nitrogen at all times.

A 13-ft rapeseed oil column at 90° C was found to give almost complete separation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the components of the above mixture of terpenes with reasonable retention times. This allowed the near quantitative determination (±2 to 3%) of the nine components found to be present in the *p*-menthadiene range. Trace components (less than 0.5–1%) were also present in the camphene – *p*-menthene range (three peaks) and in the range between the *p*-menthadienes and unreacted α-terpineol (four peaks). This column, together with 12-ft polyester and polyethylene glycol and 6-ft polyphenyl ether columns, was used to determine the composition of the steam-volatile products obtained in the dehydration of α-terpineol.

EXPERIMENTAL

The gas-chromatographic equipment and procedures were those described previously (11). All columns were made up with the liquid phase on Chromosorb W (60–80 mesh) in the ratio of 1:6 (by weight). The retention times, measured from the time of injection to the initial emergence of a peak, of various terpenes on the columns used are shown in Table I. The percentage composition of a particular mixture was determined by the

area under the curves. Test runs with a synthetic mixture of pure limonene, 1,8-cineole, and α-terpineol gave values within ±1.5% of the weight composition, provided the peaks did not tail. When tailing took place, as with α-terpineol on some columns, the calculated values were low by 2–3%. Duplicate runs on the same column agreed within 0.5%, but differed on different columns by as much as 3%. Preparative runs (10 to 50 mg) were carried out either on the analytical 1/4-in. diameter columns, or on a combination of a 3-ft×3/8-in. diameter silicone grease column used ahead of a 6-ft×1/4-in. polyphenyl ether column. Samples were collected with the detector current off (11), and the purity of the fractions collected was determined by injecting 1- to 3-μl aliquots into the analytical columns. At no time was there any evidence of decomposition or rearrangement of any of the components isolated. Individual components were identified by infrared and ultraviolet spectra, by retention times, and, where possible, by conversion

For personal use only.

to known crystalline derivatives by standard techniques (5, 17) or as indicated. Melting points were determined on a Leitz hot-stage microscope. Infrared and ultraviolet spectra were recorded on Perkin–Elmer Model 21 infrared and Warren Electronic Inc. Spectracord spectrophotometers, respectively, using the film or potassium bromide disk method for the former instrument.

Commercial *dl*-α-terpineol was purified by fractional distillation through a Podbielniak 8-mm diameter spinning band column until GLC analysis showed less than 1% impurities to be present. Thus purified it had n_D^{20} 1.4829 (lit. (17) 1.4813, 1.4832) and gave the phenylurethane, m.p. 112–113° C (lit. (2, 5) m.p. 113° C), in good yield. α-Terpinyl acetate was prepared by refluxing α-terpineol with excess acetic anhydride in the presence of sodium acetate for 4 to 5 hours and was purified by fractional distillation; n_D^{20} 1.4666 (lit. (17) 1.4689).

Small-Scale Dehydration Experiments

α-Terpineol (1.0 g), oxalic acid (hydrate, 4.0 g), and water (5.0 ml) were placed in a 25-ml flask which had two necks with ground-glass joints. A small reflux condenser was attached to one of the joints whilst the other one was tightly stoppered. The mixture was brought to boil and refluxed for the required length of time. The reflux condenser was then changed to the horizontal position and the mixture was steam-distilled for 20 to 30 minutes. The distillate was collected in an ice-cooled flask and, after distillation was complete, the condenser was rinsed with a small amount of ether. The steam-volatile terpenes were recovered by extraction with small amounts of ether, the ethereal solution was washed with bicarbonate solution, then with water, and was dried over anhydrous sodium sulphate. The dried solution was quantitatively transferred to a weighed 25-ml flask having a long neck, and the ether was evaporated on a water bath at 80–90° C. In blank test runs with pure limonene the recovery was 94–98% with 3–5% ether remaining. Calculation of yields and percentage composition were, therefore, based on a 96% recovery. On this basis the yields were 98–100% of theory for reaction up to 8 hours. After that losses due to resinification became marked; for example, after 12 hours, the recovery was only 76% of theory.

In experiments using other dehydrating agents the same procedure was followed. The amounts of reagent used and reaction times are shown in Tables II and III.

Isolation and Identification of Individual Components

Terpinolene (Peak No. 9)

Oxalic acid (hydrate, 160 g) and water (200 ml) were brought to boil in a 500-ml flask which was equipped with a condenser, a dropping funnel, and an inlet tube. Steam was passed through the boiling solution and α-terpineol (40 g) was added dropwise (4), the steam distillate being collected in an ice-cooled flask. After the addition was complete, the mixture was steam-distilled for a further hour. The terpene mixture was recovered as described above. The crude product (38 g) was analyzed by GLC and then fractionally distilled through the spinning band column. The fractions collected were analyzed by GLC. The ninth (3.1 g), b.p. 92.5° at 41 mm Hg pressure, was found to contain better than 90% of peak 9 and had n_D^{20} 1.4914 (lit. (7) 1.4888). The infrared spectrum resembled that reported for terpinolene (7). The ultraviolet absorption was weak and devoid of any characteristic band due to conjugation. The fraction gave in good yield a crystalline bromide, m.p. 112–115° C, recrystallized from ether–methanol, m.p. 115.0–115.8° C (lit. (2) m.p. 116° C). Found: C, 26.48%; H, 3.68%; Br, 70.24%. Calculated for $C_{10}H_{16}Br_4$: C, 26.34%; H, 3.54%; Br, 70.12%. The derived tetrol was prepared as follows: terpinolene (126 mg) was added to an ice-cold solution of tertiary butanol (10 ml) and water (10 ml)

*At room temperature.

containing potassium hydroxide (0.1 g). To this was added with vigorous stirring and further cooling finely powdered potassium permanganate (0.4 g) in small aliquots. The initial permanganate color changed to black-purple, then to a dark green, and finally to a muddy brown. After complete addition and stirring for a further 10 minutes, the precipitated manganese dioxide was filtered off and the pH of the filtrate was brought to about 7 by leading in carbon dioxide. The solution was evaporated to dryness and extracted with ethanol:2-butanone (1:1 v/v). The mixture of solvents was evaporated and the residual material (192 mg) was taken up in a small volume of ethyl acetate or 2-butanone. The tetrol crystallized very slowly on keeping the solution at 0–2° C for several weeks. Recrystallization from these solvents was also very slow. Whilst the yield of crude tetrol was very good, that of crystalline material, m.p. 148–150° C (lit. (17) m.p. 149–150° C), was poor. Found: C, 58.71%; H, 9.78%. Calculated for $C_{10}H_{20}O_4$: C, 58.80%; H, 9.87%.

An aliquot of fraction 9 was purified by preparative GLC, 10 runs giving 100 mg of almost pure (99.2%) peak 9. It formed the terpinolene bromide in excellent yield and the derived tetrol more readily than the impure fraction.

Dipentene (Peak No. 5)

The first five fractions obtained in the above fractional distillation showed a high content of peak 5. These fractions were combined and redistilled to give a middle fraction containing about 80% of peak 5. This was further purified by preparative GLC, giving 98% pure peak 5. Its infrared spectrum corresponded to that of dipentene (7) and both the derived tetrabromide, m.p. 125.0–126.0° C (lit. (2, 17) m.p. 124–126° C) and tetrol, m.p. 191.5–192° C, were obtained in excellent yield. Found for the bromide: C, 26.52%; H, 3.67%; Br, 70.07% and for the tetrol: C, 58.66%; H, 9.84%.

α-Terpinene (Peak No. 3)

α-Terpineol (40 g) was refluxed with a mixture of oxalic acid (hydrate, 160 g) and water (200 ml) for 12 hours. The mixture was steam-distilled and the crude hydrocarbon mixture (29 g) recovered as above. Fractions 2 to 4 in the fractional distillation at 36 mm had a boiling point of 77–80° C and GLC analysis showed a high content of peak 3, with minor amounts of peaks 2, 4, 5, and 6 being present. Preparative GLC gave peak 3 in 95–96% purity, n_D^{20} 1.4792 (lit. (7) 1.4778). Its infrared and ultraviolet spectra corresponded to those of α-terpinene (7). No solid bromide was obtained nor did the permanganate oxidation give a derived tetrol. However, the acidified oxidation mixture on extraction with 2-butanone gave a good yield of α,δ-dihydroxy-α-methyl-δ-isopropyl adipic acid, m.p. 187–188° C (lit. (17, 18) m.p. 188–189° C). Found: C, 51.43%; H, 8.10%; neutral equivalent 115.5. Calculated for $C_{10}H_{18}O_6$: C, 51.27%; H, 7.75%; neutral equivalent 117.12. The compound melts with loss of water and forms the dilactone, m.p. 71–73° C, readily (18). The terpene gave the crystalline nitrosite, m.p. 155.5–156.5° C (lit. (2, 17) m.p. 155° C), in good yield.

γ-Terpinene (Peak No. 7)

Fractions 5 to 7 in the above fractional distillation had a boiling point of 80.5–84.5° C and showed a high content of peak 7. This was purified by GLC, when practically pure peak 7 was obtained; n_D^{20} 1.4748 (lit. (7) 1.4747). Its infrared spectrum was similar to that of γ-terpinene (7). The derived tetrol, m.p. 235–237° C (lit. (18) m.p. 237° C), was obtained in good yield. Found: C, 58.69%; H, 9.81%. This material also gave a crystalline nitrosochloride, m.p. 110–111° C, in fair yield.

$\Delta^{2,4(8)}$-p-Menthadiene (Peak No. 10)

The last two fractions in the above fractional distillation contained mainly peak 10

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

as well as some terpinolene (peak 9). Purification by GLC proved difficult, since these two peaks were not completely resolved. However, a small amount of peak 10, n_D^{20} 1.5030 (lit. (7) 1.5030), was obtained about 92–95% pure. The infrared and ultraviolet spectra (λ_{max} 243 mμ) corresponded to those of $\Delta^{2,4(8)}$-*p*-menthadiene (7). A nitrosite, m.p. 152–155° C, was obtained in poor yield. Pines and Eschinazi (19) report a melting point of 153–155° C for the β-nitrosite and melting points of 110°, 140–150° C for the α-nitrosite.

Oxides (Peaks Nos. 2 and 4) and p-Cymene (Peak 6)

An aliquot of the terpenoid mixture obtained in the preparation of terpinolene was oxidized exhaustively with cold, aqueous potassium permanganate. The unoxidized terpenes were recovered by extraction with ether. The dried ethereal solution was carefully evaporated and the residual material was analyzed by GLC. Peaks 2, 4, and 6 only were recorded, the major component being peak 4. The latter was isolated 95–96% pure by preparative GLC, and its infrared spectrum and retention times agreed with those of 1,8-cineole. This fraction formed the resorcinol adduct, m.p. 80–85° C (17), in fair yield. Peak 2 was not obtained pure in sufficient amount to allow positive identification. Its infrared spectrum resembled that of 1,8-cineole.

Peak 6 was also obtained only impure. However, its retention times and the ultraviolet spectrum were similar to those of *p*-cymene. Since only the other two oxides are the impurities present, there is little doubt that peak 6 corresponds to *p*-cymene.

Camphene (Peak No. 1)

The retention times of peak 1 on different columns agreed with those of camphene. α-Terpineol (40 g) was dissolved in 90% ethanol (160 ml) containing sulphuric acid (40 ml) and the mixture was refluxed for 1 hour. The steam-volatile terpenes (22 g) were recovered as before and fractionally distilled. The first fraction, b.p. 64–68° C at 20 mm pressure, contained about 80% of peak 1 and crystallized on seeding with camphene. The crystals were filtered off and recrystallized from ethanol–water, m.p. 47.5–49° C, undepressed in admixture with synthetic camphene.

Peak No. 8

This fraction was obtained only in very small amounts which were insufficient for characterization. Its spectral properties were similar to those of $\Delta^{3,8(9)}$-*p*-menthadiene (7).

RESULTS AND DISCUSSION

The amount of unreacted α-terpineol (I) and the percentage yield of the products formed in the reaction with aqueous oxalic acid after reaction times of 1/2 to 12 hours are shown in Figs. 1(*a*) and 1(*b*). Maximum yields of terpinolene (II), 1,8-cineole (VI), and oxide 1 were obtained within 1 to 3 hours and then diminished rapidly (Fig. 1(*a*)). The maximum yield of dipentene (III) was reached very quickly, decreasing only slowly after 4 to 6 hours. α-Terpinene (IV), γ-terpinene (V), $\Delta^{2,4(8)}$-*p*-menthadiene (VII), *p*-cymene, and peak 8 reached their maximum concentrations only after 8 hours, all but VII decreasing from then on. When pure II was treated under the same conditions for 6 hours, only IV, V, VII, and peak 8 were obtained (in approximately the same ratio); less than 1% of III was recorded. Thus, the four *p*-menthadienes, IV, V, VII, and peak 8, are clearly isomerization products of terpinolene. Pure limonene, under the same conditions, did not yield any isomerization or hydration products but resinified somewhat, explaining the loss of III as the reaction proceeds. Under similar conditions 1,8-cineole (VI) gave a product having the same chromatographic spectrum as was obtained for the reaction product obtained from α-terpineol (I) itself, 2–3% of I also being recorded. It

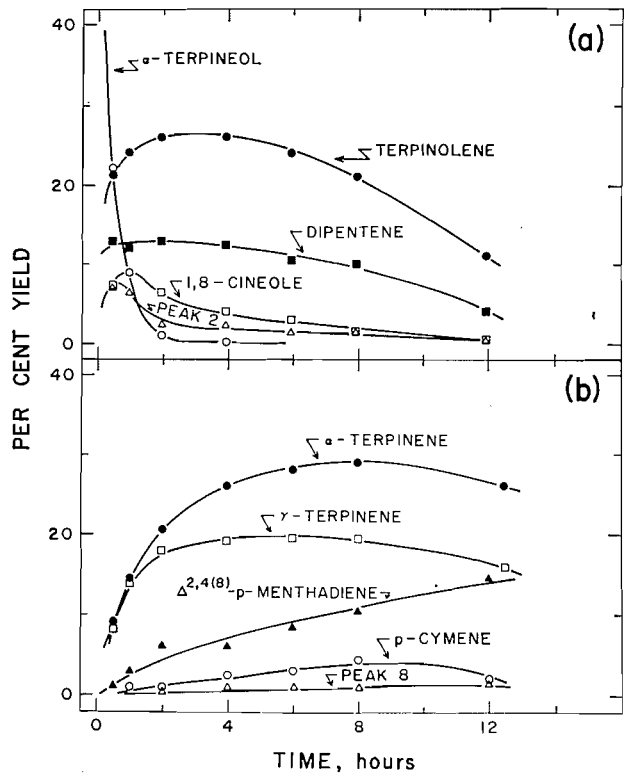

FIG. 1. Yields of individual components in the reaction of α-terpineol with aqueous oxalic acid: (*a*) initial products, (*b*) isomerization products.

can be concluded, therefore, that VI and I are in equilibrium with one another under these conditions. The similarity of the shape of the curves obtained for oxide 1 (peak 2) and VI (Fig. 1(*a*)) suggests that oxide 1 is formed in a similar reversible reaction. This could only be possible if this oxide is 2,8-cineole (dihydropinol), a finding which is further strengthened by the fact that its retention time is in good agreement with that expected for dihydropinol (as deduced from boiling points).

Thus, the reaction of α-terpineol with aqueous oxalic acid appears to proceed as follows:

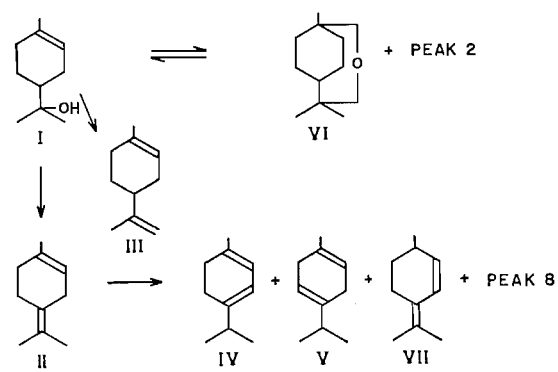

FIG. 2.

Semmler (20) has shown that alcoholic sulphuric acid isomerizes α-terpinene (IV) to V and II. Thus it is possible that these *p*-menthadienes are in a state of equilibrium under acid conditions. The above findings clearly show why it has been impossible to obtain II, IV, and V in a pure state when prepared under acidic reaction conditions.

The preferential formation of terpinolene (maximum yield about twice that of dipentene) is contrary to what would be expected from the postulate put forward by Brown *et al.* (21), according to which the exo-double bond should be formed in smaller amounts than the isopropenyl derivative. These authors quote Flawitzky (3) as having obtained limonene from I by dehydration with alcoholic sulphuric acid and use this as further evidence that tertiary alcohols of this type resist formation of an exo-double bond. Actually, Flawitzky used the alcoholic sulphuric acid to hydrate α-pinene (turpentine) to give I and the latter was then heated in a sealed tube with excess acetic anhydride to give appreciable amounts of limonene besides α-terpinyl acetate. As will be shown below, this reaction appears to be a deacetoxylation rather than a dehydration and proceeds via a different mechanism. Moreover, Brown *et al.* do not refer to the much more comprehensive studies of Wallach (1, 2), which clearly show that the exo-double bond, as in II, may be formed in substantial amounts in the acid-catalyzed dehydration. It is thus doubtful whether the olefin formation from compounds of the α-terpineol type can be included in the generalization put forward by Brown *et al.* Also, the isomerization of terpinolene does not proceed entirely according to this postulate, the exo-isomer VII being a major product besides the two endo-isomers IV and V. In a later communication, Brown (22) points out that their postulate has been misinterpreted by some workers by not considering the stability of the double bonds in cyclohexanes in conjunction with the corresponding cyclopentane derivatives. However, in the first paper, Brown *et al.* discuss the dehydration of α-terpineol and related compounds without any reference to the corresponding cyclopentanols. Recently (23), it has been shown that the whole question of the relative stabilities of methylene cycloalkanes and 1-methyl cycloalkenes is subject to some controversy.

In view of the above discrepancies, the work of Wallach and Flawitzky was repeated and the reaction with other acidic dehydrating agents was also investigated. The steam-volatile reaction products were analyzed by GLC as before and the results obtained are summarized in Table II. In the reaction with aqueous sulphuric and phosphoric acids, the reaction products had the same qualitative chromatographic spectra as that obtained with aqueous oxalic acid, confirming in essence Wallach's findings. When α-terpineol was dissolved in twice its volume of acetone and added dropwise to boiling aqueous sulphuric acid through which steam was passed (24), the steam-volatile product differed little from that obtained in the short-time reaction with aqueous oxalic acid, except that oxide 1 was produced in somewhat larger amounts and two additional peaks (11 and 13) became more prominent. Treatment with 90% ethanol – sulphuric acid (4:1 v/v) also gave a product of similar composition containing, however, a new major compound (peak 1) identified as camphene. Fused anhydrous potassium hydrogen sulphate also gave results similar to those obtained with aqueous oxalic acid, oxide formation being somewhat suppressed. This is contrary to the results Wallach obtained with "sharply dried" potassium hydrogen sulphate (2). Therefore, hydrogen sulphate was fused until fuming became extensive (pyrosulphate formation), and this was used in excess. Under these conditions I reacted to give a high yield of the oxides and camphene, but only traces of III. Thus, Wallach's findings could not be confirmed in this instance. That water is not responsible for any difference in the reaction follows from the results obtained with

For personal use only.

phthalic anhydride. Here, anhydrous conditions again give a mixture similar to that obtained with aqueous acids.

The dehydration of α-terpineol with 50% aqueous acetic acid proceeds slowly (see Table II) and allows a better study of the early stages of the reaction. II and III are distinctly the first dehydration products and the yield of the former increases much faster than that of the latter as the reaction proceeds. Oxide formation and isomerization of II is slow, making the reaction well suited for the preparation of II and III, especially so since these two *p*-menthadienes can be separated by fractional distillation. The different results obtained with glacial acetic acid (or acetic anhydride) are noteworthy (see below).

Mosher (25) proposed for the acid-catalyzed isomerization of α-pinene (X) to the *p*-menthadienes rearrangement to the intermediate carbonium ion XI. Loss of a proton leads to terpinolene (II) and dipentene (III), and (via the carbonium ion XII) to α-terpinene (IV) and γ-terpinene (V) (Fig. 3). This mixture of *p*-menthadienes is very

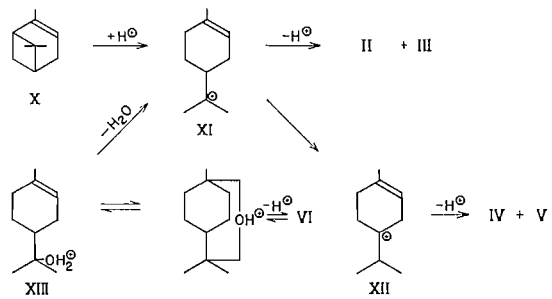

FIG. 3.

similar to that obtained in the acid-catalyzed dehydration of α-terpineol. Thus, it is likely that α-terpineol, in the protonated form (XIII), loses the elements of water to give the same intermediate carbonium ion XI. The present findings that terpinolene isomerizes readily to IV, V, and VII, but not to III, suggest that the ion XI rearranges rapidly and irreversibly to ion XII. The formation of VII, however, demands the presence of another intermediate ion. Cyclization of the protonated alcohol (XIII) and loss of a proton would lead to 1,8-cineole (VI) in a reversible reaction.

Refluxing I with excess acetic anhydride for 16 hours gave a yield of 50% α-terpinyl acetate, 32% III, and small amounts of *p*-menthadienes and oxides (see Table II), confirming, in essence, the findings of Flawitzky (3). The reaction with glacial acetic acid is similar, though the amount of α-terpineol which had reacted after 12 hours was only 30%. Since, in this reaction, I may be converted to the acetate first and this, on loss of the elements of acetic acid, could give III as the main elimination product, α-terpinyl acetate was treated in the same manner. Appreciable amounts of III, and smaller amounts of the other *p*-menthadienes, were formed (see Table III). Thus, it is possible that the preferential formation of III is due to deacetoxylation of the acetate rather than the dehydration of the parent alcohol.

Recently, Roček (26) has studied the kinetics of the dehydration of 1-methyl cyclohexanol as well as the deacetoxylation of the derived acetate, using acetic acid containing small amounts of sulphuric acid at room temperature. From the data obtained Roček concluded that both the dehydration and the deacetoxylation proceeds via the same intermediate carbonium ion and the rate-controlling step is given as the elimination of

For personal use only.

water from the protonated alcohol, or of acetic acid from the protonated ester. In the reaction of α-terpineol and its acetate with this reagent at room temperature or under reflux, appreciable amounts of camphene and the oxides, but only small amounts of the *p*-menthadienes, were obtained (see Tables II and III). The yield of steam-volatile products dropped markedly and a new peak (No. 15) in the α-terpineol range was recorded. Thus, with this reagent a third type of reaction was encountered in which the normal dehydration (or deacetoxylation) products did not survive the reaction, if these were formed at all. Similar results were also obtained when formic acid was used as dehydrating agent (Table II). Since this was no longer a normal dehydration reaction, it was not further investigated.

The presence of small amounts of *p*-cymene (peak No. 6) in most reaction products deserves some comment. Its formation in the acid-catalyzed dehydration of α-terpineol was already suspected by Wallach and Kerkhoff (2). Since the reaction conditions are not conducive to dehydrogenation, disproportionation of one or more of the *p*-menthadienes to *p*-cymene and *p*-menthenes may take place. This would account for the presence of the trace components in the *p*-menthene range.

CONCLUSIONS

The dehydration of α-terpineol with acidic reagents can occur in two different ways: (*a*) With aqueous acids, anhydrous potassium hydrogen sulphate, or phthalic anhydride, terpinolene is the major reaction product in the early stages of the reaction. About half as much dipentene and smaller amounts of 1,8-cineole and a second oxide, possibly 2,8-cineole, are also formed. As the reaction proceeds, terpinolene isomerizes to give mainly α-terpinene, somewhat less γ-terpinene and $\Delta^{2,4(8)}$-*p*-menthadiene, and a small amount of an unidentified terpene. Drastic conditions, or long reaction times, tend to cause resinification. The oxides are in equilibrium with α-terpineol and give the same reaction products on prolonged treatment. (*b*) With acetate-forming reagents, dipentene is formed preferentially. Apparently the acetate is an intermediate and subsequent loss of the elements of acetic acid favors the production of this *p*-menthadiene.

The present findings show that by proper choice of conditions the preferential formation of terpinolene, dipentene, α- and γ-terpinene, or $\Delta^{2,4(8)}$-*p*-menthadiene can be achieved. However, it is impossible to synthesize by this means any one of these *p*-menthadienes without concomitant formation of smaller amounts of several isomers. Only in very favorable instances can such mixtures be separated completely by fractional distillation. If very pure specimens of these *p*-menthadienes are required other sources must be sought, or the products obtained in the above reactions can be fractionated on a 0.01- to 0.1-g scale by preparative gas–liquid chromatography.

HYDROGEN ATOM ABSTRACTION BY ETHYL-d_5 RADICALS. PART II[1]

P. J. BODDY[2] AND E. W. R. STEACIE

ABSTRACT

Further experiments are reported on the hydrogen atom abstraction reactions of deuterated ethyl radicals produced by the photolysis of 3-pentanone-d_{10}.

The compounds studied include hydrogen, *n*-hexane, and cyclohexane. The activation energies for hydrogen atom abstraction relative to ethyl-d_5 recombination are respectively 11.3±0.5, 10.1±0.5, and 10.4±0.5 kcal/mole.

INTRODUCTION

Recently experimental data were reported for hydrogen atom abstraction from a series of typical alkanes by ethyl-d_5 radicals (1). This paper represents a continuation of that work in an effort to provide further points of comparison with the much investigated methyl radical reactions (2). The apparently arbitrary choice of compounds was dictated largely by what was possible analytically by conventional distillation and mass spectrometric techniques.

The photolysis of diethyl ketone is understood in some detail (3, 4). The mechanism is assumed to be similar for the deuterated species and is as follows (rate constants, of course, may be different):

$$(C_2D_5)_2CO \xrightarrow{h\nu} 2C_2D_5\cdot + CO \qquad [1]$$

$$2C_2D_5\cdot \rightarrow C_4D_{10} \qquad [2]$$

$$2C_2D_5\cdot \rightarrow C_2D_6 + C_2D_4 \qquad [3]$$

$$C_2D_5\cdot + (C_2D_5)_2CO \rightarrow C_2D_6 + C_2D_5COC_2D_4\cdot \qquad [4]$$

$$C_2D_5\cdot + C_2D_5COC_2D_4\cdot \rightarrow C_2D_5COC_4D_9 \qquad [5]$$

$$2C_2D_5COC_2D_4\cdot \rightarrow (C_2D_5COC_2D_4\cdot)_2 \qquad [6]$$

$$C_2D_5COC_2D_4\cdot \rightarrow C_2D_5\cdot + CO + C_2D_4 \qquad [7]$$

$$C_2D_5\cdot + RH \rightarrow C_2D_5H + R\cdot \qquad [8]$$

It can be shown that

$$\frac{k_8}{k_2^{1/2}} = \frac{R_{C_2D_5H}}{R_{C_4D_{10}}^{1/2}[RH]}$$

and

$$\frac{k_8}{k_4} = \frac{[\text{ketone}]}{[RH]} \cdot \frac{R_{C_2D_5H}}{R_{C_2D_6}},$$

where $R_{C_2D_5H}$ and $R_{C_2D_6}$ are the rates of formation of ethane-d_5 and ethane-d_6 from reactions [8] and [4]. Hence, the activation energy and frequency factor of reaction [8] may be determined relative to reactions [2] or [4] both of which are quantitatively understood (5, 1, 6, 7).

Difficulty arises due to the fact that the diethyl ketone is not completely deuterated. The sample used by us contained only a small percentage of the d_9-ketone, and the necessary corrections to the data, which have previously been described in detail (1), were made accordingly.

Another complication is due to the occurrence of reaction [7], which becomes considerable above 200° C. This may lead to errors in the estimation of C_2D_6 from reaction [4] since it is assumed that all of the C_2D_4 arises from reaction [3] and that this is equal to the C_2D_6 from the same source. In the absence of quantitative knowledge of reaction [7], it is difficult to estimate the magnitude of the error involved. In the present work only the hydrogen experiments extended much above this temperature and since the data gave a linear Arrhenius plot throughout the whole range, it is concluded that the error is not large in this case.

Some experiments were attempted with methane and benzene. With these compounds, as in the corresponding methyl radical reactions (2), the rate constants for hydrogen atom abstraction appear to be relatively small. This necessitates working at high RH: ketone ratios and elevated temperatures. Under these conditions reaction [7] becomes much more significant and the experiments were unsuccessful.

EXPERIMENTAL

The apparatus and experimental methods have been described previously (1).

n-Butane-d_{10} was collected as the fraction between −165° C and −125° C and its identity was checked by mass spectrometry. A correction was made for the *n*-butane-d_9 content which was found to be a constant fraction.

MATERIALS

The purity of the 3-pentanone-d_{10} was discussed previously (1).

n-Hexane and cyclohexane were Phillips Research Grade materials. They were degassed and stored under vacuum in blackened bulbs behind mercury cutoffs. Purities were in excess of 99.5%.

Hydrogen was purified before each experiment by passage through a heated palladium thimble.

RESULTS

The experimental data for the three compounds are presented in Tables I–III. The calculated values of $\log_{10}(k_8/k_4)$ are plotted in Fig. 1 as a function of $1/T$. The familiar departure from linearity at low temperatures (1, 4, 7) is apparent. The slopes and intercepts were calculated by the least squares method. Points lying on the dashed portion of the curves (lowest temperatures) were not included in the analysis. The results are summarized below. The values for $E_4-\frac{1}{2}E_2$ and $\log_{10}(A_4/A_2^{1/2})$ were determined previously (1) (the units throughout are molecules/ml, and seconds):

$$E_4-\tfrac{1}{2}E_2 = 9.0\pm0.5 \text{ kcal/mole},$$

$$\log_{10}\frac{A_4}{A_2^{1/2}} = \bar{8}.36\pm0.20.$$

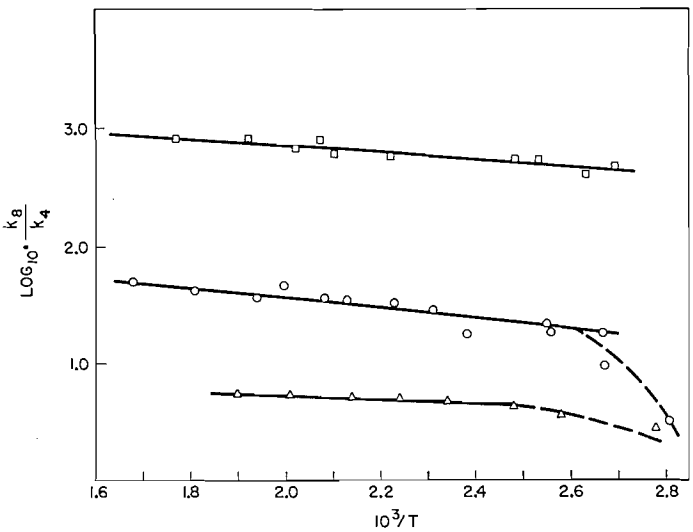

FIG. 1. $\log_{10}(k_8/k_4)$ as a function of $1/T$. Curves displaced up by number of units in parentheses. ○ H_2 (+2), △ n-C_6H_{14} (+1), □ cyclo-C_6H_{12} (+3).

For hydrogen

$$E_{8a}-E_4 = 2.3\pm0.2 \text{ kcal/mole},$$

$$\log_{10}\frac{A_{8a}}{A_4} = 0.56\pm0.086;$$

whence

$$E_{8a}-\tfrac{1}{2}E_2 = 11.3\pm0.5 \text{ kcal/mole},$$

$$\log_{10}\frac{A_{8a}}{A_2^{1/2}} = \bar{8}.92\pm0.2.$$

For n-hexane

$$E_{8b}-E_4 = 1.06\pm0.1 \text{ kcal/mole},$$

$$\log_{10}\frac{A_{8b}}{A_4} = 0.19\pm0.055;$$

therefore

$$E_{8b}-\tfrac{1}{2}E_2 = 10.1\pm0.5 \text{ kcal/mole},$$

$$\log_{10}\frac{A_{8b}}{A_2^{1/2}} = \bar{8}.55\pm0.2.$$

For cyclohexane

$$E_{8c}-E_4 = 1.4\pm0.14 \text{ kcal/mole},$$

$$\log_{10}\frac{A_{8c}}{A_4} = 0.47\pm0.07;$$

for the points to lie above the line by about 15% in $k_4/k_2^{1/2}$, but the slopes are not in disagreement and it appears there are no serious errors involved either in the chemical analyses or the methods used to compute the data.

DISCUSSION

The reaction between ethyl-d_0 radicals and molecular deuterium has been studied (8) and it was tentatively suggested that the activation energy for abstraction of a hydrogen atom from molecular hydrogen was 11.5±1 kcal/mole, in very good agreement with the value reported above.

If we write

$$C_2H_5 + D_2 \rightarrow C_2H_5D + D \qquad [8a]$$

$$2C_2H_5 \rightarrow C_4H_{10} \qquad [2a]$$

and

$$C_2D_5 + H_2 \rightarrow C_2D_5H + H \qquad [8]$$

$$2C_2D_5 \rightarrow C_4D_{10} \qquad [2]$$

$k_{8a}/k_{2a}^{1/2}$ may be calculated to be 1.0×10^{-13} at 182° C (4, 7). $k_8/k_2^{1/2}$ is 3.4×10^{-13} at the same temperature.

The ratio of these figures is quite close to that for the corresponding methyl radical reactions ($CD_3 + H_2$, $CH_3 + D_2$), which is 5.3 (9). The ratio is even closer to that for the reactions

$$\frac{CH_3+H_2}{CH_3+D_2} = 3.6 \qquad \text{at } 182° \text{ C} \qquad [9]$$

$$\frac{CD_3+H_2}{CD_3+D_2} = 3.7$$

and suggests that possibly ethyl-d_0 and ethyl-d_5 are more similar than the corresponding pair methyl-d_0 and methyl-d_3.

It is interesting to observe that, as compared with methyl, ethyl radicals seem to react relatively faster with hydrogen than with hydrocarbons at 182° C. Some rate constants (expressed in the same way as above) are:

$CH_3 + H_2$	12.6×10^{-13} (9)	$C_2D_5 + H_2$	4.3×10^{-13}
+ neo-C_5H_{12}	6.3 (2)	+ neo-C_5H_{12}	0.45 (1)
+ iso-C_4H_{10}	42 (2)	+ iso-C_4H_{10}	6.1 (1)

The reason for this is not understood.

The rate constant $(k_8/k_2^{1/2})_{182°C}$ for *n*-hexane is 5.7×10^{-13} (ml/molecule sec)$^{1/2}$. Correcting for the presence of the six primary hydrogen atoms (2) using the neopentane data (1), the rate constant per secondary hydrogen atom becomes 0.68×10^{-13}, in excellent agreement with the figure 0.70×10^{-13} obtained for *n*-butane (1). This may be compared with the figure for the reaction of ethyl-d_0 radicals with *n*-heptane (10), where $(k_8/k_2^{1/2})_{182°C}$ (our notation) is 10.7×10^{-13}: after correcting for the primary hydrogens using the ethyl-d_5 data, which should be approximately correct (the correction is very small in any case), the rate constant per secondary hydrogen atom becomes 1.05×10^{-13}. Thus, it appears that ethyl-d_0 is about 50% more reactive than ethyl-d_5. It is rather perplexing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

that an effect similar in magnitude but in the opposite direction is observed for the reaction of methyl-d_0 and -d_3 with H_2 and D_2 (9). A difference has been observed in the reaction of methyl radicals (-d_3 and -d_0) with neopentane amounting to about 15% and in the same direction that we observe, i.e., methyl-d_0 more reactive (11).

The rate constant for cyclohexane at 182° C is 7.2×10^{-13} (ml/molecule sec)$^{1/2}$ corresponding to a value of 0.6×10^{-13} per hydrogen atom. This agrees with the methyl radical results where cyclohexane was found to give a value typical of a secondary paraffinic hydrogen atom (2).

The authors wish to thank Mrs. R. H. Riem, who carried out the mass spectrometric analyses.

DEUTERATED ORGANIC COMPOUNDS

XXII. SYNTHESIS OF SOME DEUTERATED BENZENE DERIVATIVES[1]

R. N. RENAUD, D. KOVACHIC,[2] AND L. C. LEITCH

ABSTRACT

The deamination of certain aromatic amines in deuterohypophosphorous acid with sodium or isoamyl nitrite has been used to label aromatic compounds in a specific position with deuterium. Aniline 2,3-d_2 was synthesized by this method.

Exchange with deuterium sulphate has been extended to the deuteration of nitrotoluenes, bromotoluenes, and polychlorobenzenes.

Previous communications in this series (1, 2, 3) have dealt very largely with the synthesis of deuterated aliphatic compounds. Aromatic compounds were investigated only incidentally and then interest was centered on introducing deuterium into the side chain rather than into the nucleus. In this paper the deuteration of aromatic compounds will be formally discussed.

The total replacement of hydrogen by deuterium in the aromatic series is in general effected more readily than in aliphatic compounds. Some years ago one of us (4) showed that benzene-d_6 could be conveniently prepared by exchange with deuterium oxide at 100° C in the presence of platinum black. Others (5, 6, 7) have since reported that benzene derivatives such as benzoic acid or aniline and polynuclear hydrocarbons can be deuterated as well. In contrast, alkanes undergo exchange under these conditions only when deuterium gas is also present.

The exchange with deuterium oxide catalyzed by platinum black yields compounds completely deuterated in the ring. The method is therefore inapplicable for the preparation of compounds containing deuterium in specific positions. Several methods of obtaining such compounds have, however, been investigated in the past.

In early attempts to prepare deuterated benzenes, calcium salts of aromatic acids were decarboxylated in the presence of calcium deuteroxide. Morita and Titani (8) prepared benzene-d_1 by this method from anhydrous calcium benzoate. Later, Redlich and Stricks (9) obtained benzene-1,2-d_2 from calcium phthalate and Weldon and Wilson (10) synthesized benzene-1,3,5-d_3 from the calcium salt of mesitylene carboxylic acid. Finally, Erlenmeyer carried the method to its logical conclusion by preparing benzene-d_6 from calcium mellitate (11). The reaction was later reinvestigated by Best and Wilson (12), who showed that the isotopic purity of the products was low due to exchange under the drastic conditions employed.

Another method of obtaining deuterated benzenes is the hydrolysis of Grignard reagents with deuterium oxide or deuterium chloride. However, only one atom of deuterium can usually be introduced in this way. Redlich and Stricks (13) had prepared benzene-1,2-d_2 from 1,2-diiodobenzene in this manner but later work by Best and Wilson (12) showed the dimagnesium reagent from 1,4-dibromobenzene exchanged with ether presumably by a free radical mechanism to give benzene-1,4-d_2 of low isotopic purity. They circumvented this difficulty by introducing the deuterium in two stages, i.e. by two separate Grignard preparations and hydrolyses. In any event the application of Grignard

reagents to the problem of deuteration is severely restricted by the incompatibility of organometallic halides with several other functional groups such as nitro, carboxyl, amino, etc. Nevertheless, the Grignard synthesis is probably the best method of preparing benzene-d_1, the three deuterated toluenes, and perhaps other deuterated alkyl benzenes.

Deamination is a well-known method of replacing an amino group by hydrogen (14). It is usually carried out by heating the diazonium salt of the amine in ethanol. The mechanism of this reaction has recently been shown by deTar and Turetzky (15) to be a free radical process. It is not attractive for replacing an amino group by deuterium because ethyl alcohol labelled with deuterium on the methylene group is required. In the present work deamination in isopropyl alcohol was investigated since isopropyl-2-*d* alcohol, $CH_3CD(OH)CH_3$, is easily prepared from acetone and lithium aluminum deuteride. However, the yields obtained in the decomposition of the diazonium fluoborate in isopropyl alcohol were very poor and the method was abandoned in favor of deamination in hypophosphorous acid.

In conventional deamination with hypophosphorous acid (16) the amine is first diazotized in hydrochloric or sulphuric acid and the solution of the diazonium salt is treated with an excess of 50% hypophosphorous acid. Since preparation of diazonium salts in deuterium oxide as solvent is prohibitive on economic grounds, it was decided to deaminate some representative amines directly in 50% hypophosphorous acid solutions by addition of sodium nitrite. It was felt hypophosphorous acid would be strong enough to allow diazotization to take place. This was indeed found to be the case. Bromobenzene was obtained in 70% yield from 2-bromoaniline. A search of the literature revealed only one case of diazotization in H_3PO_2, Henry and Finnegan (17) having deaminated 5-aminotetrazole in 5% hypophosphorous acid. In the present work 2-bromo-3-methylaniline, 1-naphthylamine, and pentachloroaniline were similarly deaminated in 50% hypophosphorous acid.

The replacement of NH_2 by deuterium by the above method was an important step in a synthesis of aniline-2,3-d_2 which was required in connection with some work in N.M.R. spectroscopy (18). The most feasible route to this compound appeared to be the sequence of reactions shown below:

The preparation of the starting compound, 3-nitro-2-aminotoluene, has been reported in *Organic syntheses* (19). The amino group was replaced by bromine by a Sandmeyer reaction. The nitro group was successfully reduced to amino without simultaneous loss of bromine by reduction with activated iron powder in dioxane as described by Hazlett and Dornfeld (20). Deamination in hypophosphorous acid containing a low concentration of deuterium has been shown to be subject to a high deuterium isotope effect in favor of hydrogen (21). This meant that rigorous exclusion of exchangeable hydrogen was absolutely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

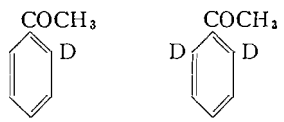
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

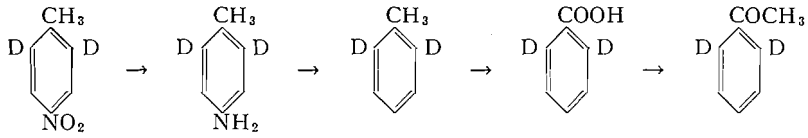


necessary to obtain a high concentration of deuterium in the product. Consequently, hypophosphorous acid was exchanged with deuterium oxide as described by Hammond and Grundemeier (22) until the hydrogen atom signal in the N.M.R. spectrum was absent. Similarly the hydrogen in the amino group of the amine was replaced by deuterium by several exchanges in slightly alkaline deuterium oxide. The 2-bromotoluene-3*d* isolated in 50% yield was 96 mole% C_7H_6BrD. The second deuterium atom was introduced via a Grignard synthesis. The deuterium content of the toluene-2,3-d_2 was 83 mole %. It was oxidized to benzoic-2,3-d_2 acid in aqueous alkaline permanganate without loss of deuterium. Aniline-2,3-d_2 was obtained from the acid via the acid chloride and the amide by the Hofmann degradation.

The benzene-1,2-d_2 prepared from the deuterated aniline by deamination analyzed 82.1% $C_6H_4D_2$ and 17.1% C_6H_5D. The slightly low content of deuterium may be due to a small loss of deuterium by exchange in each of the two reactions involving introduction of deuterium. In any event the compound was pure enough isotopically for the purpose. Deamination by means of deuterohypophosphorous acid thus offers a convenient means of replacing an amino group by deuterium in an aromatic compound. Another recent example of its use is the deamination of vicinal xylidine to 1,3-xylene-2-*d* by Fraser (23).

Yet another method of deuterating aromatic compounds is the action of deuterium chloride in the presence of anhydrous aluminum chloride. Klit and Langseth prepared benzene-d_6 by this method (24). The reaction is essentially an exchange catalyzed by the Lewis acid $DAlCl_4$. It probably cannot be used for deuterating in a specific position.

Important confirmation of an earlier prediction by Ingold, Raison, and Wilson (25) was obtained in 1936 when these authors observed a reasonably rapid exchange between benzene and 50 mole % deuterium sulphate in deuterium oxide at room temperature without any appreciable sulphonation. Several years later in continuation of their brilliant work on the spectroscopic investigation of the structure of benzene, Ingold, Wilson, and co-workers turned again to the exchange method to prepare benzene-d_6 and 1,4-dibromobenzene-d_4 (12). In deuterating bromobenzene by this method they were unable to avoid undue sulphonation. Apparently in this case the rates of sulphonation and exchange are very similar. A third deuterobenzene, the 1,3,5-d_3 isomer was prepared from aniline, in which exchange occurs under comparatively milder conditions than in benzene. It is sufficient to heat the hydrochloride in deuterium oxide for a day to establish equilibrium. Deuterium enters the ortho and para positions. After several such exchanges the deuterium in the amino group was washed out with ordinary water and the amine was deaminated to benzene-1,3,5-d_3. Since the paper by Best and Wilson (12) no appreciable use has been made of this reaction to deuterate aromatic compounds.



One of the aims of the present work was to extend the exchange method to a variety of substituted benzenes in order to obtain compounds of interest for infrared measurements. Two of these were acetophenone-2-*d* and acetophenone-2,6-d_2. The synthesis of 2-deuteroacetophenone was straightforward. It started with 2-bromotoluene, which was

converted to toluene-2-*d* by the Grignard reaction discussed above. The toluene-2-*d* was oxidized to benzoic-2-*d* acid without loss of the deuterium label by alkaline permanganate.

The deuterium was determined by combustion and estimation of the deuterium content of the water by infrared analysis. Acetophenone was prepared from benzoyl-2-*d* chloride and dimethyl cadmium as described by Cason (26).

For the synthesis of acetophenone-2,6-d_2 4-nitrotoluene was found to be a satisfactory starting material.

With 95% deuterium sulphate at 95° C, 4-nitrotoluene underwent exchange in the 2- and 6-positions without much sulphonation. After two exchanges the compound gave no signal in the N.M.R. corresponding to the 2,6-hydrogen atoms. The signal for the 3,5-hydrogen atoms occurs at lower field. The deuteronitrotoluene was reduced with tin and hydrochloric acid; deamination and oxidation took place with complete retention of the deuterium label. The other steps were the same as for the monodeutero compound. It is noteworthy that exchange occurs at the positions predicted by the orienting effects of the methyl and nitro substituents. It is also striking that exchange proceeds so smoothly when it is considered that toluene and nitrobenzene cannot be exchanged without considerable loss due to sulphonation. It has been found that 2- and 3-nitrotoluenes exchange readily with 95% D_2SO_4 to give 2-nitrotoluene-d_4 and 3-nitrotoluene-d_4. In these cases no selective deuteration occurs; all positions are affected by the substituents.

The bromotoluenes were next investigated. 4-Bromotoluene exchanged its ring protons readily in 95% D_2SO_4 at 80° C after 3 hours. Under these conditions 2-bromotoluene was sulphonated even at room temperature. However, 90% D_2SO_4 at room temperature brought about considerable exchange and little sulphonation in 24 hours. After three equilibrations with this acid the ring proton signals in the N.M.R. spectrum were no longer visible. 3-Bromotoluene sulphonated readily in 95% D_2SO_4 at room temperature. Exchanges with 80, 85, and 90% D_2SO_4 at room temperature were carried out without achieving any exchange. No change was apparent in the N.M.R. spectrum of the products.

In connection with a joint project with Lecomte (27) the synthesis of several polychlorodeuterobenzenes by exchange was investigated. 1,4-Dichlorobenzene was readily exchanged in 88 mole % D_2SO_4 as had been reported earlier by Best and Wilson (12) for the dibromo derivative. The more highly chlorinated benzenes such as the 1,3,5-trichloro, the 1,2,4,5-tetrachloro, and the pentachloro were expected to exchange under more drastic conditions due to the deactivating influence of the chlorine atoms. 1,3,5-Trichlorobenzene underwent exchange at 100° C but a temperature of 150° C was required to bring about exchange in the tetra- and penta-chlorobenzenes. Loss due to simultaneous sulphonation was, however, appreciable.

It appears that deuteration of ring protons follows the course to be expected from a consideration of the orienting effects of the substituents. The feasibility of exchange in any given case depends, however, upon the relative rates of sulphonation and exchange.

EXPERIMENTAL

Deamination of p-Nitrobenzenediazonium Fluoborate in Isopropyl Alcohol

p-Nitrobenzenediazonium fluoborate (4.0 g) prepared from *p*-nitroaniline as described by Starkey (28) was added to a suspension of 4.0 g of powdered anhydrous sodium acetate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

in 10 ml of isopropyl alcohol. Rapid evolution of nitrogen took place and the reaction mixture turned very dark. After the mixture had been standing for an hour the alcohol was removed under vacuum and the residue was taken up in pentane. The pentane solution was then washed with water and dried over a pellet of alkali. The residue which remained after the pentane was distilled off was transferred to a Späth bulb and distilled. Yield of nitrobenzene, 0.5 g (35%).

Deamination of 2-Bromoaniline in Hypophosphorous Acid

2-Bromoaniline (6.88 g, 0.04 mole) was treated, while being stirred, in a 100-ml three-necked round-bottomed flask with 25 ml of 50% hypophosphorous acid. The solution was heated to boiling and then cooled to −5° C. Sodium nitrite (3.0 g) was added in portions to the cold solution. Nitrogen was evolved after each addition of nitrite. The reaction mixture was stirred at 0° C for 3 hours and then poured on ice in a flask equipped for steam distillation. The distillate was taken up in ether, and the solution was dried over a pellet of alkali and then freed of solvent. The residue was purified by distillation on the vacuum line. Yield, 4.8 g (78%); $n_D^{24.5}$, 1.5521.

2-Amino-3-nitrotoluene

This compound was prepared as described in reference 19 in 53% yield.

2-Bromo-3-nitrotoluene

2-Amino-3-nitrotoluene (50 g, 0.3 mole) was dissolved in 160–175 ml of 48% hydrobromic acid heated on a hot plate. The solution was cooled to room temperature while 300 ml of water was slowly added. The solution was diazotized at −12° C with 30 g of sodium nitrite dissolved in 40 ml of water and filtered. The filtrate was added in portions to a solution of cuprous bromide prepared from 60 g of copper sulphate, 24 g of copper turnings, 400 ml of water, and a solution of 60 g of potassium bromide in 270 ml of 48% hydrobromic acid. The mixture was heated for ½ hour on the steam bath and then distilled in steam. Yield, 57 g (81%).

2-Bromo-3-aminotoluene

Activated iron was prepared by mixing 240 g of iron powder and 82 ml of 48% hydrobromic acid as described in reference 20. The mixture was evaporated nearly to dryness in a vacuum evaporator at 60° C. At this stage the mass of activated iron had broken up into small balls which were removed and pulverized in a mortar. Residual moisture was removed on the vacuum line but without further shaking on a water bath at 100° C.

The reduction was carried out using 20 g of 2-bromo-3-aminotoluene as described in the reference cited above except that dioxane was used instead of benzene. The reaction mixture from the reduction was steam-distilled to remove all the dioxane after addition of 80 ml of hydrobromic acid to convert the amine to the hydrobromide. The residue was basified with 35 g of sodium hydroxide in 70 ml of water and steam distillation continued to obtain the amine. The bromotoluidine was taken up in ether in the usual way. The yield of amine recovered from a distillation in a Späth bulb at 60° C under vacuum was 65–70%; n_D^{23}, 1.6034; n_D^{20}, 1.6050.

2-Bromo-3-amino-d_2-toluene

The amine (20.5 g, 0.11 mole) was stirred vigorously at 80° C for 8 hours with 25 ml of deuterium oxide containing one pellet of alkali. The exchanged amine was separated from the water in a separatory funnel and returned to the original flask for a second exchange. Two more exchanges were considered sufficient to replace all the amino hydrogen by deuterium. There was practically no loss during these operations.

For personal use only.

Deuterohypophosphorous Acid

Hypophosphorous acid was exchanged 10 times with deuterium oxide as described in reference 22 until the deuterium content as judged from the deuterium content of a sample of benzene-*d*, prepared by deamination of aniline-ND_2, was 95.91%.

2-Bromotoluene-3-d

To 20 g of 2-bromo-3-amino-d_2-toluene in a 250-ml round-bottomed flask with a side arm for a separatory funnel was added, while being cooled in ice water, 58 ml of 50% deuterohypophosphorous acid – deuterium oxide and finally 30 ml of additional deuterium oxide. To the mixture was added, very slowly, a solution of 8.0 g of sodium nitrite in 8 ml of deuterium oxide; during the addition, the temperature was still kept around 0° C, the mixture was stirred, and the rate of nitrogen evolution was observed. The reaction mixture was protected from moisture and kept in the refrigerator overnight. In the morning all the volatile material was distilled on the vacuum line into a Stock trap. The distillate was extracted with ether and the bromotoluene recovered in the vacuum line by distillation. Yield, 10 g (55%). Mass analysis: 93.9% C_7H_6DBr.

In a second run from 17.6 g of amine-d_2 there was obtained 9.4 g of 2-bromotoluene-3-d_1, n_D^{23} 1.5539. The boiling point was 181° C. Yield, 59%. 2-Bromotoluene has n_D^{23} 1.5540, b.p. 181° C. Mass analysis: 95.98% C_7H_6DBr, 4.0% C_7H_7Br.

Toluene-2,3-d_2

Magnesium (0.9 g) was placed in a 100-ml two-necked round-bottomed flask equipped with a separatory funnel and a reflux condenser. The apparatus was connected to a vacuum line flamed and pumped for 1 hour to remove traces of moisture. Dry air (freed of CO_2 by Ascarite) was introduced at the end. A few milliliters of ether dried over sodium wire was added to the magnesium followed by 5.7 g of 2-bromotoluene-3-*d* dissolved in 20 ml of anhydrous ether. Reaction started almost at once. After the solution was stirred for about 3 hours the ether was removed under reduced pressure. The residue was cooled in a bath of ice water and deuterium oxide (7.0 ml) was added dropwise. The toluene that was formed and ether were distilled into a Stock trap. The toluene was taken up in more ether, water was separated, and the ether solution was dried. The ether was removed on the vacuum line keeping the solution at −26° C. It was condensed in a trap cooled in dry ice and acetone at −78° C. During this operation the stopcocks are set so that a little ether distills slowly but continuously from the solution. When the pressure in the system has fallen to 1 mm the residue is virtually free of ether. Yield, 2.3 g (74%). Mass analysis:

	I	II
$C_7H_6D_2$	82.7%	80.1%
C_7H_7D	16.5%	17.8%
C_7H_8	0.6%	1.2%

Benzoic-2,3-d_2 Acid

Toluene-2,3-d_2 (4.5 g, 0.05 mole) and 400 ml of water were heated to boiling under a reflux condenser. Potassium permanganate (15.6 g, 0.1 mole) was added in portions over a period of 4 hours. After being heated under reflux for a further period of 4 hours the reaction mixture was filtered. The filtrate and washings were concentrated under reduced pressure to a volume of 50 ml. The solution was then acidified with concentrated hydrochloric acid (3.2 ml) and the white precipitate of benzoic-2,3-d_2 acid was filtered off and washed once with a little cold water. Yield, 4.3 g (73%); m.p. 123.4° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The use of a copper flask as described by Bigelow (29) did not lead to higher yields in test experiments.

Benzoyl-2,3-d_2 Chloride

Benzoic-2,3-d_2 acid (3.8 g, 0.03 mole) was heated under reflux with 4.6 g freshly distilled thionyl chloride for 2 hours. Hydrogen chloride and excess thionyl chloride were pumped off on the vacuum line and the residue was distilled into a Stock trap. Yield, 4.0 g (92%).

Benzamide-2,3-d_2

Benzoyl-2,3-d_2 chloride (4.0 g) was added slowly to 17.0 ml of concentrated ammonium hydroxide while the mixture was being stirred, and cooled in an ice bath. The solid was filtered and washed with cold water. Recrystallization from 17 ml of hot water gave 2.8 g of benzamide-2,3-d_2 (81%), m.p. 127–129° C.

Aniline-2,3-d_2

A solution of 4.2 g of potassium hydroxide in 50 ml of water in a 400-ml beaker was cooled to 0° C in an ice bath. Bromine (4.5 g) was added in one portion and the mixture was stirred until all the bromine had dissolved. Another solution of 6.0 g of potassium hydroxide in 10 ml of water was prepared. Finely powdered benzamide-2,3-d_2 (2.8 g, 0.02 mole) was added all at once to the potassium hypobromite, with vigorous stirring; at the same time there was added the concentrated solution of alkali prepared above. After 5 minutes all the solid had dissolved. The reaction mixture was transferred to a flask set for steam distillation and heated on the steam bath for 2 minutes. The oil which collected on the top was distilled over in a current of steam. The aniline-2,3-d_2 was taken up in ether, dried over alkali, filtered, and freed of solvent. The residue was distilled slowly into a trap in the vacuum line. Yield, 1.8 g (83%); n_D^{20}, 1.5844.

The deuterium content of the aniline was determined by deaminating it to benzene-1,2-d_2. The mass analysis of the latter was 82.1% $C_6H_4D_2$, 17.1% C_6H_5D, and 0.8% C_6H_6.

Deuterium Sulphate

Deuterium sulphate for exchange reactions was prepared by the modification described below of the procedure of Best and Wilson (12).

To a condenser with ground-glass joints set for downward distillation were connected a 1-liter Claisen flask and a receiver with a side arm to which was attached a drying tube filled with glass wool and phosphorus pentoxide. The other end of the drying tube was connected by means of rubber tubing to a filter flask with a controllable leak. No lubricant was used on any of the joints but they were covered with paraffin wax on the outside.

Stabilized sulphur trioxide (300 ml) purchased from Allied Chemical of Canada, Montreal, Quebec, under the name of "Sulfan B" was poured into the distilling flask and 100 g of 99.7% deuterium oxide was weighed into the tared receiver cooled in crushed ice. When the distilling flask was gently heated and slight suction from a glass aspirator pump was applied, sulphur trioxide distilled slowly into the water.

At the end of the distillation an aliquot of deuterium sulphate was removed and analyzed by titration against $N/10$ alkali. The concentration of deuterium sulphate was then adjusted as required by addition of the appropriate amount of deuterium oxide.

4-Nitrotoluene-2,6-d_2

A solution of 7.0 g (0.06 mole) of 4-nitrotoluene in 25 g of 94.81% deuterium sulphate was heated at 90° C for 24 hours. The reaction mixture was cooled, and poured onto

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

cracked ice. The oil was extracted with ether. The ether solution was washed with water, dried over calcium chloride, and freed of solvent. The exchanged 4-nitrotoluene (5.6 g) was equilibrated twice more with fresh quantities of deuterium sulphate.

The course of the exchange was followed by examining the N.M.R. spectrum of the compound. The normal compound shows two doublets spaced 25 c.p.s. apart and 200 c.p.s. lower than the methyl signal. In the exchanged compound the doublet at higher field and therefore corresponding to the 2,6-hydrogen atoms disappeared. The spectrum was essentially unchanged after the third exchange.

4-Nitrobenzoic-2,6-d_2 Acid

4-Nitrotoluene-2,6-d_2 (19.0 g, 0.015 mole) was oxidized with potassium permanganate as described by Bigelow (29) in a Pyrex rather than a copper flask. The yield of 4-nitrobenzoic-2,6-d_2 acid was 17.2 g (78%).

4-Aminobenzoic-2,6-d_2 Acid

The 4-nitro acid was reduced with tin and hydrochloric acid as described by Vogel (30). The yield was 71% of product, m.p. 186–186.5° C.

Benzoic-2,6-d_2 Acid

The amino acid was diazotized and deaminated as described by Kornblum (16). The yield from 10 g of amino acid was 4.9 g (55%), m.p. 121.5–122.0° C. Analysis by combustion gave a deuterium content of 1.96 atoms. All the reactions were therefore carried out without any appreciable loss of deuterium.

Benzoyl-2,6-d_2 Chloride

The chloride was prepared from thionyl chloride as described above for benzoic-2,3-d_2 acid.

Acetophenone-2,6-d_2

The acid chloride was converted into acetophenone exactly as described by Cason (26). The yield was 78% of product, n_D^{25} 1.5296, m.p. 17.5° C. For normal acetophenone, n_D^{25} is 1.5307.

3-Nitrotoluene-d_4

3-Nitrotoluene (6.0 g) was heated with 25 g of 97.3% deuterium sulphate for 24 hours at 75–80° C. The product was worked up as already described for the 4-nitro isomer. Recovery was 91%. Loss due to simultaneous sulphonation is therefore slight. After three exchanges there was no signal observed in the N.M.R. spectrum where the ring hydrogens occur in the light compound.

2-Nitrotoluene-d_4

Nuclear proton exchange was carried out under the same conditions as for the other two isomers. The N.M.R. spectrum indicated that exchange occurred in all positions as expected though more slowly than in the other isomers.

4-Bromotoluene-d_4

A mixture of 7.0 g of 4-bromotoluene (.04 mole) and 25 ml of 95.7% deuterium sulphate was stirred for 24 hours at room temperature. The exchanged 4-bromotoluene was isolated from the reaction mixture as described above. After two more exchanges the ring proton signals in the N.M.R. spectrum had disappeared while the signals due to the protons in the methyl group had their original intensity. All ring protons therefore exchange under these conditions. At 80° C the 4-bromotoluene was almost completely sulphonated after only 3 hours.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Non-exchange of 3-Bromotoluene

In 95.5% deuterium sulphate 3-bromotoluene is almost completely sulphonated after 3 hours at room temperature. Deuterium sulphate diluted with deuterium oxide to 80% acid did not sulphonate 3-bromotoluene at room temperature after 60 hours stirring but there was no change in the N.M.R. spectrum. Evidently no exchange had occurred. At room temperature 85% deuterium sulphate gave about 20% sulphonated product but again there was no evidence of exchange in the recovered 3-bromotoluene. In 90% deuterium sulphate at room temperature the amount of sulphonated product increased but there was still no evidence of exchange as judged from the N.M.R. spectrum. Apparently the rate of sulphonation in 3-bromotoluene is much more rapid than that of exchange.

2-Bromotoluene-d_4

The optimum condition for exchange was to stir 2-bromotoluene at room temperature with 90% deuterium sulphate for 24 hours. More concentrated acid or higher temperature both led to extensive sulphonation. After three exchanges the signal for the ring protons had completely disappeared from the N.M.R. spectrum while the methyl proton signal retained its original intensity.

Non-exchange in 1,2-Dimethyl-4-nitrobenzene

In 97% deuterium sulphate the compound gave only tar. In a second attempt to bring about proton exchange the compound was stirred at room temperature in 85% deuterium sulphate. At this concentration of acid there was 40% loss due to sulphonation but no change in the N.M.R. spectrum of the recovered nitro compound.

2-Chloronitrobenzene-3,5-d_2

2-Chloronitrobenzene (5.5 g) was heated at 70° C in 30 g of 95% deuterium sulphate for 30 hours. The product was isolated in the usual manner. There was hardly any loss due to sulphonation. After a second exchange the N.M.R. spectrum of the compound was measured. Some of the signals for the ring protons were considerably reduced. From a consideration of the orienting effects of the chlorine and nitro groups it would appear that deuteration occurred in the 3- and 5-positions.

p-Dichlorobenzene-d_4

p-Dichlorobenzene (5.0 g) was heated with 45 g of 95% deuterium sulphate at 105° C with stirring for 6 hours. The cold reaction mixture was poured onto cracked ice and the 1,4-dichlorobenzene was filtered off and washed with water. The product obtained after two more exchanges was recrystallized from ethyl alcohol. Yield, 2.5 g (50%); m.p. 54.5° C. The N.M.R. spectrum measured in cyclohexane gave no signal for benzene ring protons.

1,3,5-Trichlorobenzene-d_3

The conditions were essentially those employed to exchange the dichlorobenzene. Two exchanges were sufficient to cause the disappearance of the ring proton signal in the N.M.R. spectrum. The loss due to simultaneous sulphonation was again 50%.

1,2,4,5-Tetrachlorobenzene-d_2

1,2,4,5-Tetrachlorobenzene (5.0 g) and 45 g of 97% deuterium sulphate were heated for 12 hours in a sealed tube at 150° C. The exchanged product was isolated as described for 1,4-dichlorobenzene-d_4 above. After three exchanges 3.2 g of the tetrachloro compound were recovered. It was recrystallized from benzene, m.p. 141.5–142° C. The signal due to the ring protons in the N.M.R. spectrum had completely disappeared.

For personal use only.

Pentachlorobenzene

Pentachloronitrobenzene was reduced to pentachloroaniline in dioxane solution with activated iron and water as described above. An excellent yield of pentachloroaniline, m.p. 243–244° C, was obtained.

Pentachloroaniline was deaminated in 50% hypophosphorous acid in the presence of dioxane using isoamyl nitrite as the source of nitrous acid. One gram of the amine was dissolved in 15 ml of dioxane and 15 ml of 50% hypophosphorous acid. The stirred suspension was treated with 2 ml of isoamyl nitrite at room temperature. Nitrogen was slowly evolved for about 2 hours. The reaction mixture was poured into water and the solid filtered off. Recrystallization from ethyl alcohol gave 0.3 g of pentachlorobenzene, m.p. 84° C. The product was also purified by sublimation *in vacuo* from a bath at 70° C.

Pentachlorobenzene-d

The exchange was carried out with 97% deuterium sulphate as described for tetrachlorobenzene. Evidence of exchange having taken place was obtained from both N.M.R. and infrared spectra. The treatment with acid seemed to remove a small amount of impurity as the melting point of the exchanged product was raised to 86.5° C.

The compound was also prepared by deamination of pentachloroaniline in 50% deuterohypophosphorous acid but the pentachlorobenzene-*d* contained some of the normal compound (which probably arose from H in the amino group) and had to be enriched in deuterium by exchange with deuterium sulphate just the same.

ACKNOWLEDGMENTS

The authors wish to thank Mrs. R. H. Riem for several mass analyses, Mrs. M. A. Mackenzie for an analysis by combustion, and Mr. J. R. Nicholson for some N.M.R. spectra.

Thanks are also due to the Olin-Mathieson Chemical Corporation, Baltimore, Maryland, for the gift of a sample of pentachloronitrobenzene.

THE DONOR CHARACTERISTICS OF THE CARBONYL GROUP

II. THE EFFECT OF ANGULAR VARIATIONS AT THE CARBONYL GROUP[1]

DENYS COOK

ABSTRACT

The effect of variations in the angle X—C—X′ (in a typical carbonyl compound XX′C=O) on the carbonyl stretching frequency ($\nu_{C=O}$) is examined in the light of recently published empirical relations between $\nu_{C=O}$ and the ionization potential.

INTRODUCTION

In a recent paper dealing with the donor characteristics of the carbonyl group (1) empirical relationships were demonstrated between the carbonyl stretching frequency ($\nu_{C=O}$) and the ionization potential (IP). Two classes of compounds were noted: those having no group conjugated with the carbonyl group (A), and those with a group capable of such conjugation (B). The parameters of those molecules were expressed, respectively, by the equations

$$\nu_{C=O} = 49.35\ IP + 1249, \qquad [1a]$$

$$\nu_{C=O} = 29.20\ IP + 1409. \qquad [1b]$$

The variation of these parameters within each class was interpreted in terms of inductive and resonance effects due to the different groups attached to the carbonyl group.

The variation of IP with the carbonyl force constant $k_{C=O}$ was considered many years ago by Walsh (2). He pointed out the relationship between IP, $k_{C=O}$, and C=O bond length and a parameter defining the percentage of polarity of the C=O bond. Since that time many more IP's have been accurately measured though the number of determinations of force constants of C=O bonds is still relatively small.

Previously (1) no allowance was made for the effect of variations in angle XCX′ (α) (in the compound ) on $\nu_{C=O}$. This will now be considered.

VARIATION OF $\nu_{C=O}$ WITH α

The fact that $\nu_{C=O}$ increases on decreasing the size of a cycloalkanone ring has been known for some time (3). The phenomenon is not restricted to simple cyclic ketones, for similar compounds with heteroatoms in the ring show the same effect.

Figure 1 shows a graph of $\nu_{C=O}$ and α for a wide variety of cyclic carbonyl compounds, the data and source being listed in Table I. Points lying on the same curve in Fig. 1 are for compounds containing the same functional group, with different ring sizes depending on the number of —CH_2— groups contained therein. These lines do not have quite the same slope but get steeper from the bottom line to the top in a fairly smooth manner.

[1]*Manuscript received April 4, 1960.*
Contribution No. 27 from the Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario, Canada.

TABLE I

Compound	α(degrees)[a]	$\nu_{C=O}$(cm^{-1})	Solvent
1. δ-Valerolactone	120	1748[d]	CCl_4
2. γ-Butyrolactone	108	1783[d]	CCl_4
3. β-Propiolactone	94[b]	1841[d]	CCl_4
4. 5,6-Dihydro-α-pyrone	120	1743[e]	CCl_4
5. $\Delta^{\alpha\beta}$ Butenolide	108	1785[e]	CCl_4

13. Cyclohexenone	120	1686[k]	CCl_4
14. Cyclopentenone	108	1716[l]	?
15. 2-Piperidone	120	1671[h]	CCl_4
16. 2-Pyrrolidone	108	1700[h]	CCl_4

[a]Structural investigations have been made on only a few of the compounds in this table. For those without reference, reasonable estimates of α have been made depending on the size of the ring, and on the known structure of similar compounds. This results in 120° for six-membered rings, 108° for five-membered rings, and 94° for four-membered rings. Minor discrepancies in these angles will slightly affect the slope of the lines in Fig. 1, but will not alter the conclusions.

They all intersect fairly closely at one point, and a general equation has been developed which fits these lines quite closely. It has the form

$$[2] \qquad \nu_{C=O}^{120} = \frac{96(\nu_{C=O}-1439)}{(216-\alpha)}+1439$$

where α is in degrees and ν is in reciprocal centimeters. This equation then represents the variation of $\nu_{C=O}$ with α and should be valid whatever the nature of the group attached to the carbonyl group, for example $-CH_2-$, $-O-$, $-\overset{|}{N}-$, $-CH=CH-$, etc. These groups, because of differences in inductive capacity, or ability to conjugate with the carbonyl group alter the vertical displacement in Fig. 1.

An equation similar to [2] was recently derived by Halford (4), who showed how the secular determinant could be solved to define the dependence of $\nu_{C=O}$ on α. Over the range $\alpha = 80°$ to $\alpha = 130°$ the relation was virtually linear and was described by the equation

$$[3] \qquad \nu_{C=O} = 1278 + 68k_{C=O} - 2.2\alpha$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

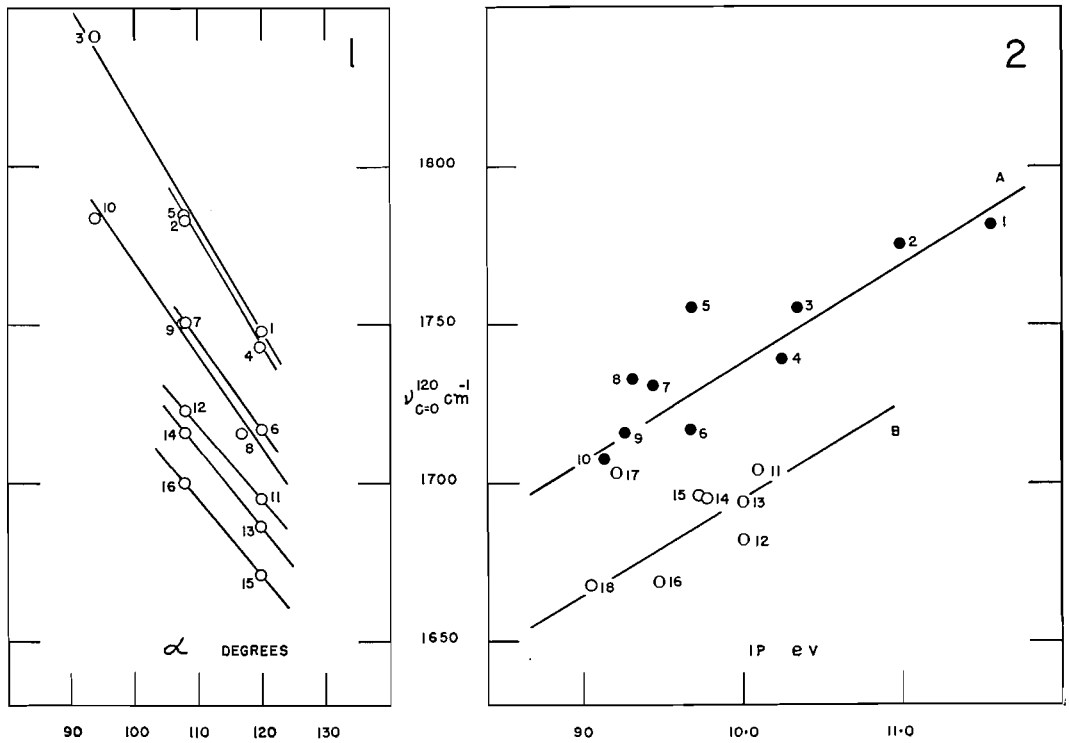

FIG. 1. Variation of $\nu^{120}_{C=O}$ with α for compounds listed in Table I.
FIG. 2. Variation of $\nu^{120}_{C=O}$ with IP for compounds listed in Table II.

where $k_{C=O}$ is the force constant of the carbonyl group in practical units. This equation rests on the assumptions that the masses X and X′ and the force constants of the C—X′ bonds are fixed.

The effect of altering α then seems to have a large effect on the value of $\nu_{C=O}$, but as Halford's results also show, little effect on $k_{C=O}$. What is applicable to ring compounds as just described should apply with no loss of validity to non-cyclic carbonyl compounds. In such compounds where $\alpha \neq 120°$ because of the dependence of $\nu_{C=O}$ on α, $\nu_{C=O}$ may be altered even though $k_{C=O}$ and therefore the IP and the carbon–oxygen bond distance do not alter greatly. Such alteration in $\nu_{C=O}$ would obscure the relationship between $\nu_{C=O}$ and IP as shown in reference 1. It is interesting therefore to adjust, by means of equation [2] the value of $\nu_{C=O}$ to what it would be if α were 120°. Such adjusted values are listed under the heading $\nu^{120}_{C=O}$ in Table II for many compounds where α is accurately known. The adjusted values are shown plotted against IP in Fig. 2.*

**Aldehydes have been excluded from this correlation. When the mass of a group attached to the carbonyl group is less than about 15 Halford (4) has shown that $\nu_{C=O}$ then becomes mass dependent and the phase relationships of vibrations of the carbonyl group may be altered. Aldehydes, therefore, represent an extreme case, where atypical carbonyl values may be expected. For the same reason formamides and formates have been excluded. The well-known anomaly of formates having lower frequencies than acetates, when the reverse would be expected, exemplifies this point.*

DISCUSSION

With a few exceptions the points in Fig. 2 define two straight lines separated by more than the experimental error. The upper line, curve A, is for non-conjugated compounds, the lower, curve B, for compounds with a conjugated carbonyl group. This behavior was noted in reference 1 but by taking into account angular variations the significant difference emerges that the lines in Fig. 2 are nearly parallel, being defined by the equations (derived by the method of least squares):

$$\nu_{C=O}^{120} = 30.57\ \text{IP} + 1432,$$

$$\nu_{C=O}^{120} = 30.07\ \text{IP} + 1394.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Adjusting these equations so that they have the same slope leads to

$$[4a] \qquad \nu^{120}_{C=O} = 30.50\ IP + 1433,$$

$$[4b] \qquad \nu^{120}_{C=O} = 30.50\ IP + 1390.$$

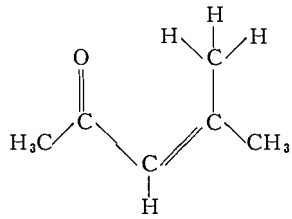
In the previous treatment (1) curves A and B converged at low $\nu_{C=O}$ values. The present case seems to be more satisfactory since it means that conjugation has approximately the same effect on the carbonyl frequency in all cases. The difference between the two lines at constant IP is about 43 cm^{-1}. This is a little larger than the difference in $\nu_{C=O}$ between non-conjugated and conjugated compounds, i.e. ~35 cm^{-1} (5), but a simple explanation is possible.

Consider the compounds in Table III, differing only in having a single or a double bond

TABLE III[a]

Compound	$\nu_{C=O}$	IP	$\Delta\nu_{C=O}$	ΔIP
$CH_3COCH_2CH_3$	1722	9.54	33	−0.17
$CH_3COCHCH_2$	1689	9.71		
$HCOCH_2CH_3$	1738	9.86	34	−0.24
$HCOCHCH_2$	1704	10.10		
$HOOCCH_2CH_3$	1758	10.27	37	−0.43
$HOOCCHCH_2$	1721	10.70		
$HCOCH_2CH_2CH_3$	1729	9.81	33	+0.08
$HCOCHCHCH_3$	1696	9.73		
		Average	34	−0.19

[a]Data from reference 1.

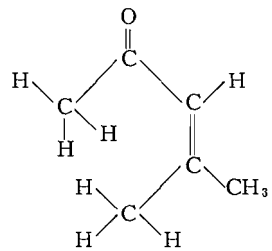


in the α position to the carbonyl group. The change from non-conjugated to conjugated compound decreases $\nu_{C=O}$ by 34 cm^{-1} but the IP increases by 0.19 ev. From equation [4] 0.19 ev corresponds to 6 cm^{-1}. The 35 cm^{-1} difference is therefore made up of two quantities of opposite sign, of approximate magnitudes 43 cm^{-1} and 6 cm^{-1}.

The conjugated molecules that have been considered here all have atomic skeletons that are planar so that there is no steric resistance to conjugation which would obscure the relation between IP and $\nu_{C=O}$. One compound which illustrates this point is benzophenone. By analogy with the known structure of substituted benzophenones, for example, 4,4′-dichlorobenzophenone (6) and 4,4′-dimethoxybenzophenone (7), in which the phenyl rings are about 38° out of the $\rangle C{=}O$ plane, there will be inhibited conjugation between the C=O group and the ring. For benzophenone $\nu_{C=O}$ = 1668 cm^{-1}. Assuming α = 125°, then $\nu^{120}_{C=O}$ = 1681 cm^{-1}. The IP is 9.00 ev and according to the equations [4*a*] and [4*b*] would require $\nu^{120}_{C=O}$ to be 1665 and 1708 cm^{-1} respectively. The actual value of $\nu^{120}_{C=O}$ lies in between these two values but nearer the conjugated value (curve B).

Two further molecules can be considered in detail, since they exemplify the arguments put forward here. The first is mesityl oxide, which when previously considered (1) did not lie on the appropriate curve B for a conjugated ketone, but was very close to curve A for non-conjugated compounds. Steric strain due to bulky methyl groups was invoked to account for the non-coplanarity of the double bonds and the consequent belief that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



the compound was properly placed on curve A. A more plausible explanation is now possible. The suggested model is planar and in the cis configuration I. This is in keeping with enhanced intensity of the C=C vibration at 1624 cm^{-1} (8) and dipole moment studies (9). The interference between the methyl group and the carbonyl oxygen is relieved

I

by decreasing (α) thus bending the carbonyl oxygen away from the methyl group. From a study of molecular models (Stuart-Briegleb) a decrease in α of about 12° would give ample clearance. Applying equation [2] again, $\Delta\nu$ would be 31 cm^{-1}. The effect of the change in angle then is to increase $\nu_{C=O}$ by 31 cm^{-1}. $\nu^{120}_{C=O}$ is therefore 1668 cm^{-1} and taking IP = 9.05 ev Fig. 2 shows that the point lies very close to curve B for conjugated molecules.

It is interesting to apply similar reasoning to the trans structure II. In this case the

II

interference is between the methyl groups. To relieve this situation α would have to increase and the value of $\nu_{C=O}$ would be lower than that corresponding to α = 120. In applying the correction therefore $\nu^{120}_{C=O}$ would be greater than 1697 cm^{-1}, and the point for mesityl oxide would be further from the curve than before.

The second molecule is tropone. Its carbonyl frequency is 1642 cm^{-1} (10). This value must be adjusted since it is for the pure liquid, which is well known to be invariably lower than that for a dilute solution in an inert solvent like CCl_4. The gas phase value is 1652 cm^{-1} (11). If a value of $\nu_{C=O}$ = 1647 cm^{-1} is assumed then $\nu^{120}_{C=O}$ now comes to 1669 cm^{-1}. Figure 2 shows how much more closely tropone approaches curve B than the unadjusted value.

The origin of the angle-dependent frequency shift has been made clear in some recent work by Overend and Scherer (12). After calculating the force constants of C=O bonds in carbonyl halides the surprising result was established that $k_{C=O}$ for COF_2 was little different from that of $COCl_2$, 12.85 and 12.61 md/Å respectively, while there was a difference of 101 cm^{-1} in $\nu_{C=O}$. On calculation of the relative displacement of the atoms in the normal vibrations of the carbonyl halides these authors found that as the C=O

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

bond stretched the carbon atom moved back into the two fluorine atoms. The C—F bonds were therefore compressed and the FCF angle increased. For COF_2 where k_{C-F} = 4.5 md/Å the resistance to these motions results in the greater frequency for COF_2 compared with $COCl_2$, where k_{C-Cl} = 2.0 md/Å.

Carbon–carbon single bonds have force constants of the order of 4 md/Å, quite comparable to the C—F bond. The C—O force constant is of similar magnitude. Consequently in the compounds discussed in this paper there will be an appreciable effect similar to that in the carbonyl halides. Moreover, it will be obvious that as the angle XCX′ decreases this effect will get larger since the movement of the C atom during a carbonyl stretching vibration will be more nearly along the line of the C—X atom.

A similar conclusion was reached by Bratŏz and Besaïnou (13). These authors started with a frequency value for an isolated carbonyl group then added increments depending on the type of group attached to the C=O group. The largest contributions arose from mechanical interaction between the carbon or oxygen atom next to the carbonyl group. This was shown to get larger as α became smaller, as has been shown above too.

No three-membered cyclic saturated ketone is known, unfortunately, so that it has not been possible to see, whether there is any point at which equation [2] breaks down. It has been shown that for propiolactone, the smallest ring compound for which both the IP and $\nu_{C=O}$ are known, a great improvement is achieved by use of equation [2] but that it is far from being a good correlation.* While no direct test of a three-membered cyclic ketone is possible due to lack of data, some approximations can be calculated for a substituted cyclopropenone recently synthesized. This is 2,3-diphenylcyclopropenone whose carbonyl frequency is 1852 cm^{-1} (14). Allowing about 40 cm^{-1} for the effect of conjugation and unsaturation the hypothetical cyclopropanone might have a frequency of 1892 cm^{-1}. Assuming α = 60°, $\nu^{120}_{C=O}$ is 1718 cm^{-1} in quite good agreement with saturated aliphatic ketones.

CONCLUSIONS

The present work goes some way toward an understanding of the large variations in carbonyl frequencies. From the results presented, however, it is apparent that there remain some unsatisfactory anomalies. Until, however, accurate force constants for a large number of molecules have been worked out, involving prodigious labor, methods such as the present one offer some hope of reducing the problem.

ACKNOWLEDGMENTS

I am grateful to Dr. J. Overend and Dr. J. R. Scherer for allowing me to see their paper before publication.

A PROTON MAGNETIC RESONANCE INVESTIGATION OF ROTATIONAL ISOMERISM IN 1,1,2,2-TETRACHLORO-1-FLUOROETHANE[1]

R. J. ABRAHAM[2] AND H. J. BERNSTEIN

ABSTRACT

The doublet separation in the proton resonance spectrum of the liquid was measured from −53 to 100° C. From the variation of the separation with temperature approximate values of the trans and gauche HF coupling constants were obtained. The values of $\Delta H \approx 400$ cal/mole and $\Delta S \approx 0$ are also consistent with the data.

Nuclear magnetic resonance has been used with some success in the investigation of problems concerned with rotation about single bonds (1, 2, 3). Data from other techniques, such as vibrational spectroscopic, for information regarding ΔH, the enthalpy difference of the rotamers, and the assumption that the entropy difference is negligible, has usually gone into the derivation of the coupling constants.

The purpose of this work was to investigate the simplest possible proton magnetic resonance spectrum, the spacing of which depends on the relative concentrations of the rotational isomers. $CFCl_2 \cdot CHCl_2$* is admirably suited for this since the proton magnetic resonance is a simple doublet. The doublet separation was measured with a Varian spectrometer at a radio frequency of 40 Mc/s as accurately as possible (to ±0.02 cycle/second) by the wiggle beat (4) method in a temperature-controlled (±1°) cell which has been previously described (5). The results are shown in Fig. 1 and Table I.

99.7	4.89	4.89	0.00

The molecule $CFCl_2 \cdot CHCl_2$ exists in three conformations, one in which H and F are trans oriented and a pair of mirror image gauche forms. If we denote the fraction of the trans form as p, that of each gauche form is $(1-p)/2$, and the total fraction of molecules in the gauche form is $1-p$, at any temperature

$$[1] \qquad \frac{p}{1-p} = \tfrac{1}{2}e^{-\Delta F/RT} = \tfrac{1}{2}e^{\Delta S/R} \cdot e^{-\Delta H/RT}$$

where the factor $\frac{1}{2}$ takes into account the two mirror image magnetically equivalent gauche forms. The observed spacing (i.e. coupling constant J in cycles/second) for this compound depends on the number average of the coupling constants in the trans (J_T) and gauche (J_G) forms (6) and is given by

$$[2] \qquad J = pJ_T + (1-p)J_G.$$

Eliminating p from [1] and [2] gives

$$J = J_T - \frac{J_T - J_G}{1 + \frac{1}{2}e^{\Delta S/R} \cdot e^{-\Delta H/RT}}.$$

In principle it is possible to evaluate the four unknowns in this equation (J_T, J_G, ΔS, ΔH). However, very much greater accuracy than ± 0.02 cycle/second in a measurement of J is required. A least squares solution attempt on the data of Table I turned out to be rather complicated due to the presence of the exponential function and did not give an acceptable result.* Various graphical methods were employed consisting chiefly of solving for J_T and J_G for different assumed values of ΔS and ΔH. It turns out that the following values of the parameters are consistent with the data of Table I:

$$J_G = 1.03 \text{ cycles/second},$$
$$J_T = 18.08 \text{ cycles/second},$$
$$\Delta S = 0,$$
$$\Delta H = 400 \text{ cal/mole}.$$

The values of J, calculated with the above, give the column of calculated J values in

**Because of the small available experimental range, the curve in Fig. 1 can be described within the experimental error by a three-parameter function. For this reason the least squares solution to determine all four parameters is not significant and when carried out leads to physically unacceptable results.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Table I. The value of $\Delta S = 0$ is not inconsistent with the very small entropy difference in the gas phase (7) for the rotamers of 1,2-dichloroethane. The fact that ΔH is positive shows that the gauche isomer is more stable than the trans isomer. This information and the value of $\Delta H = 400$ cal/mole are in agreement with the infrared studies on this molecule (8).

The values found for the coupling constants, entropy difference, and enthalpy difference are considered reliable to about 10%. Very much higher accuracy in the measurement of J, or a very much extended temperature range, would be required to improve on these numbers. There is no doubt, however, that J_T is considerably larger than J_G. This is analogous to the situation in substituted ethylenes (9) where the trans HF coupling constant is larger than the cis. Also, it is interesting to note that for the HH coupling constants in substituted ethanes (3), $J_T \gg J_G$. Presumably the same reasons (10) are valid for HF coupling constants that are invoked to explain the higher trans HH coupling constant.

AN INFRARED STUDY OF THE ADSORPTION OF BUTENES ON SURFACES OF POROUS VYCOR GLASS[1]

L. H. LITTLE,[2] H. E. KLAUSER,[3] AND C. H. AMBERG

ABSTRACT

The adsorption and reactions of the four butenes on porous Vycor glass at room temperature have been studied by infrared spectroscopy. Initial adsorption was rapid and was found to perturb the surface hydroxyl groups of the glass. In the case of the *n*-butenes rapid isomerization took place at room temperature. In addition to this the adsorbate spectra showed the occurrence of a slower reaction which led to an increase in saturated C—H groupings. C_8 and higher compounds were shown to have formed; on outgassing at room temperature small amounts of cracking products were collected. The polymerization of isobutene was particularly rapid. Experiments at low coverage ($\theta \sim 0.001$–0.002) gave identical initial spectra for the *n*-butenes. These were discussed in terms of possible models for butene adsorption. A reduction in the alumina and zirconia content of the glass by acid leaching resulted in decreased rates of isomerization and polymerization, suggesting that one or both of these oxides are at least partially responsible for the activity of the glass. A pure silica aerogel was almost completely inactive. Quantitative measurements of the spectra of several monoolefins in solution were made for comparison with the surface species, in particular with respect to their molar intensities of absorption.

INTRODUCTION

The adsorption of olefins on catalytically active surfaces is a prerequisite to subsequent isomerization, polymerization, and cracking reactions (1). For instance, in a recent publication MacIver, Zabor, and Emmett (2) discussed the chemisorption, followed by cracking and polymerization, of 1-butene and 1-octene on silica–alumina cracking catalysts; their data were consistent with the formation of carbonium ion intermediates. Few other studies of the adsorption of butenes or higher olefins on similar surfaces have appeared in the literature, probably because of the complexity of the resulting systems.

It was the object of the present investigation to study the adsorption of butenes on porous Vycor glass by infrared spectroscopy. The adsorbent was suitable owing to its high transmission in the region of 3.4 μ, where the bands due to C—H stretching modes in hydrocarbons occur. Moreover, it had a high surface area, so that even at low fractional coverages, sufficiently large quantities of adsorbed material remained in the sample to ensure good infrared sensitivity. An extensive review of infrared spectra of adsorbed molecules was given by Eischens and Pliskin (3).

EXPERIMENTAL

The samples of porous Vycor glass (Corning Glass, No. 7930) were generally in the form of plates 1 mm thick, 2 cm wide, and 5 cm long; 2-mm and 0.1-mm plates were used in some instances. They were cleaned by heating to 400° C in oxygen, cooled, weighed, and then transferred to the combined infrared and adsorption cell.

One of these cells consisted of a silica test tube of 1.5 mm wall thickness, 15 cm length, and 2.4 cm diameter. It was mounted in a vertical position with the infrared light beam passing through its walls. An infrared gas cell of 10-cm path length and fitted with sodium chloride windows was attached at the upper end of the silica tube through a

ground-glass joint. When required, this cell could be placed in the light beam. The whole assembly could be connected to a vacuum and gas-handling system. Another type of cell of 10-cm path length and 4 cm in diameter was wound with a heater along about 5 cm of its central section. Sodium chloride windows were attached at the ends by means of silicone resin (Dow Corning, No. 996); temperatures of at least 150° C could thus be tolerated at the windows. A flattened glass tube with just enough clearance for 2-mm Vycor plates was mounted to the cell in a vertical position. At its upper end there was provided a short piece of glass rod led horizontally into the cell through a ground-glass joint. Sample plates were suspended from it on a spun-glass thread; by rotating the rod they could be wound up and out of the infrared beam for the determination of vapor-phase spectra. A sketch of this cell is shown in Fig. 1.

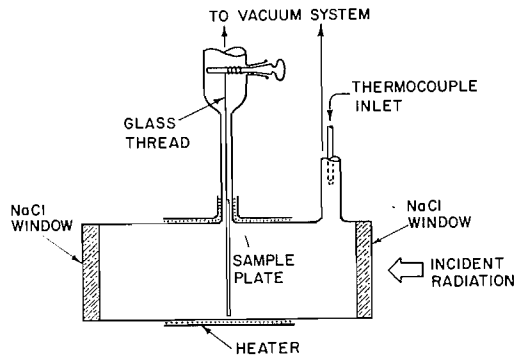

FIG. 1. Sketch of cell showing windlass arrangement for sample plate.

Samples were outgassed at 300° and cooled to room temperature, after which the background spectrum was recorded. The silica test tube transmitted in the same spectral region as the Vycor plates and thus did not interfere. After admission of gas to the sample the spectrum composed of background, adsorbate, and gas phase was recorded, as well as that of the gas phase alone. The latter was necessary to correct the adsorbate spectrum, where indicated, and was also useful for purposes of identifying reaction products. With the silica cell, corrections were usually not more than 10% of the absorption of the surface species; at low coverage they were completely negligible. All experiments were performed at room temperature.

The spectra were recorded on a Perkin–Elmer Model 21 spectrophotometer fitted with either a sodium chloride or a calcium fluoride prism, or alternately on a Beckman IR4 spectrophotometer with a lithium fluoride prism. All spectra reproduced in the diagrams are tracings from experimental records, while all data in the tables under the heading "Adsorbate" refer to the surface phase only. The time shown for each spectrum refers to time after gas admission.

The following spectral parameters were measured or computed for absorption bands of surface species: frequency ν cm^{-1}; optical density $D = \log_{10} J_0/J$, where J_0/J is the ratio of incident to transmitted radiant energy at a given frequency; extinction coefficient $\epsilon = D/cl$ mole^{-1} liter cm^{-1}, where c is the concentration of adsorbate in terms of moles of butene per liter of sample (external dimensions) and l is the total path length through the sample in centimeters; integral band intensity $I = \int D\, d\nu$ cm^{-1} and molar intensity $\bar{I} = I/cl$ mole^{-1} liter cm^{-2}. As long as c refers to actual butenes adsorbed on the glass

For personal use only.

surface, $\bar{I}$ represents the true value for butenes and is, within the experimental limits, an absolute intensity. However, when part or all of the butenes have polymerized, then $\bar{I}$ is a composite of all species present, expressed in molar concentrations of C_4. We have used these values for comparisons with pure butenes, or higher monoolefins similarly expressed in terms of C_4 concentrations (see Appendix).

Errors in the determination of $\bar{I}$ were $\pm 15\%$ at the worst, but usually somewhat better. Apart from errors inherent in the integrating procedure (Simpson's rule), the chief contributing factor was the uncertainty involved in constructing the background spectrum. This spectrum was subject to small changes from that originally measured on the pure adsorbent; these were due to (*a*) perturbation of the adsorbent by the adsorbate and (*b*) the occasional removal of the cell from the spectrometer and subsequent repositioning. Consistency between the three different prisms was about $\pm 5\%$. Errors in the volume adsorbed were usually less than $\pm 2\%$.

Neither extinction coefficients nor intensities were corrected for finite spectrometer resolving power, because of the overlapping nature of the bands. Bands above 3000 cm^{-1} were resolved graphically from the group of bands below for the purpose of determining their relative intensity. The errors involved, depending somewhat on the separation and intensities of the bands, were usually of the order of $\pm 10\%$, but in some cases higher.

The frequencies, indicated vertically in the figures, have uncertainties of ± 10 cm^{-1} for sodium chloride and ± 3 cm^{-1} for lithium fluoride optics. Spectral slit widths were, respectively, 18 cm^{-1} and 6 cm^{-1}. For some bands extinction coefficients were added in parentheses in the diagrams.

Supplementary analyses were undertaken by means of mass spectrometry and gas–liquid chromatography. Vapor-phase and weakly sorbed materials were collected by condensation into a liquid nitrogen trap. More severe stages of outgassing involved the additional use of a vacuum pump for periods of up to 20 hours and finally the application of heat to the sample.

A modified Vycor adsorbent was prepared by leaching the glass for 6 hours in boiling concentrated nitric acid and by carefully washing it. Spectrographic analyses showed that, of the chief constituents other than silica, boron had remained unchanged, while aluminum and zirconium, both present in approximately equal amounts, had decreased to about one-half their former value. Subsequent quantitative analysis showed B_2O_3 to have remained constant at 2.1% while R_2O_3 had decreased from 0.89% to 0.36%. The B.E.T. surface areas, determined with nitrogen at $-195°$ C, had changed from 165 m^2/g to 148 m^2/g.

The silica aerogel (Cab-O-Sil, Godfrey L. Cabot, Inc.) used had a surface area of 166 m^2/g. An infrared transparent plate was prepared from it by pressing at 40 tons/in^2.

The preparation of a sample of Vycor glass with black nickel oxide dispersed in its pores has been previously described (4).

RESULTS AND DISCUSSION

(i) Adsorption of n-Butenes on Porous Vycor Glass at $\theta \sim 0.1$

Rapid adsorption of *n*-butenes at an initial pressure of about 2 cm Hg occurred on a Vycor sample in the first 15- to 20-minute period; this was followed by a much slower uptake. Coverage in this series of experiments was of the order of 0.1 monolayer (see Section (*ii*)). In the early stages, adsorption of a predominant fraction of the surface molecules was of a physical nature (including interactions due to hydrogen bonding). This was inferred from the similarity between the initial spectra and the corresponding

spectra in carbon tetrachloride solution (Fig. 8). For example, the characteristic absorption bands associated with olefinic C—H stretching vibrations were clearly discernible in either case (1-butene: 3080 cm^{-1}, Fig. 2(*a*); 2-butenes: 3020 cm^{-1}, Figs. 2(*b*) and 2(*c*)). Moreover, the ratios of olefinic to total C—H band intensities (Table I) were approximately the same as the corresponding ones in carbon tetrachloride solution (Table VI). In addition to this the adsorbed molecules perturbed the surface hydroxyl groups of the glass with the result that the ν_{OH} band was broadened and displaced to lower frequencies; these changes are generally caused by hydrogen bonding (5) and may be attributable to the formation of such bonds involving surface hydroxyls and the

π-electrons of the adsorbed olefin (6). In the early stages of an experiment 70% of the adsorbed phase could be condensed into a liquid nitrogen trap within ~5 minutes; the condensate consisted of butenes only. By further outgassing it was possible to restore the surface hydroxyl band almost to its original shape.

Isomerization

Rapid double-bond isomerization of the *n*-butenes occurred on adsorption at room temperature. This is readily demonstrated by both the adsorbate and gas-phase spectra (Fig. 2). For instance, in the case of 1-butene (Fig. 2(*a*)), the band at 3080 cm^{-1} due to the asymmetric stretching mode of the $=CH_2$ group progressively decreased in intensity, while the =CH— band of the 2-butenes at 3020 cm^{-1} became stronger. At the same time the ratio of the olefinic to total C—H band intensity increased from the initial 8–10% of 1-butene to 14.5% (estimated from Table I and confirmed by subsequent runs), i.e. it approached the higher values of a predominantly cis–trans mixture (Table VI).

Two hours after admission of any one of the *n*-butenes the contour of the spectra of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the gas phase in contact with the surface showed these to consist largely of *trans*-2-butene by comparison with the spectra of the pure gases in Fig. 8. GLC analyses gave percentages of 3.5, 71.5, and 25.0 respectively for 1-butene, *trans*- and *cis*-2-butene both for the residual gas phase and for material removed from the sample by outgassing. The corresponding equilibrium values at 25° C calculated from the data of Rossini (7) are 2.42, 74.24, and 23.34%.

Polymerization and Cracking

After the isomerization process had reached equilibrium, the contour of the bands changed with further standing. The olefinic C—H band at 3020 cm^{-1} decreased, while the band at 2965 cm^{-1} due to saturated C—H groupings, increased in intensity. These results were consistent with a process of polymerization occurring on the surface, i.e. with a decrease in the number of double bonds per total number of bonds in the molecule. The process continued with standing and after 40 hours the intensity of the band at 3020 cm^{-1} had decreased from between 10 and 20% of the total to only 5% (for typical results, see *cis*-2-butene in Table I). This is approximately the value found for 2-octene in carbon tetrachloride solution (Table VI).

When the system was evacuated, unsaturated material, which was found to contain largely butenes, was removed and the intensity of the 3020 cm^{-1} band decreased to about 2–3% of the total intensity. This would indicate that the remaining material was composed of C_8 and possibly larger molecules. Along with the butenes, monoolefins with the following composition were identified in the condensate: C_3, C_5, C_6, C_7, C_8, and C_9.

In a further series of tests, the adsorbate was taken up in pentane, the resulting solution concentrated and analyzed by GLC on an Apiezon column. Various available pure monoolefins showed good linear correlation on a logarithmic elution time versus boiling point plot. On this basis a complex mixture of some 12 constituents boiling between 80° and 210° (C_6 to C_{12} region) was eluted.

By increasing the severity of outgassing after the condensation of what were largely butenes, the material removed from the surface contained a greater proportion of cracked and polymerized products. Intensity measurements of the residual adsorbate after outgassing for 1 hour at 50–150° C showed that 80–90% of the surface C—H groups had been removed. No bands due to unsaturated species were detectable. The bands at 2965, 2930, and 2870 cm^{-1} due to saturated C—H vibrations suggested a preponderance of methyl over methylene groups, i.e. branched rather than linear polymers. The ratio of the heights of these bands did not appear to change with outgassing (see Section (*vi*)).

(ii) Low-coverage Adsorption of n-Butenes, $\theta \sim 0.001$–0.002

In the spectra described above, the strong bands due to physically adsorbed material in the early stages of the adsorption process would almost certainly mask any bands due to a possible chemisorbed butene species and thus preclude its identification. After polymerization has set in, the intense bands of the polymeric surface species are again liable to interfere. It was thought that optimum conditions might be attained by working at low initial pressures. Small doses of butene were therefore admitted so that within 1–2 minutes the pressure had dropped to below 0.01 mm Hg. The initial measurements were made within 5–15 minutes after gas admission. Using the nitrogen area of 165 m^2/g and a molecular area for butenes of 31 $Å^2$ we estimate a coverage of 0.001–0.002 of a monolayer in these experiments (Fig. 3, Table II). Similarly, the coverage in the experiments described in the previous section was in the region of $\theta = 0.1$.

*Gas phase not observable. †Exact frequencies given in Fig. 3.

Because of the small amount of adsorbed material it was necessary to record the spectra through six plates, each 1 mm thick, in order to obtain bands of measurable intensity. The absorption and reflection from six plates of Vycor glass was itself appreciable in the spectral region being studied. Moreover, the spectrum of the samples was steeply sloping such as to make observation of weak bands superimposed upon this background very difficult. This was corrected by placing a similar but evacuated cell containing six 1-mm Vycor plates in the reference beam. Spectra were then recorded relative to this compensating cell. Figure 3(*a*) demonstrates the effect, and clearly emphasizes the necessity, of compensating for glass absorption in this case.

Within 5 minutes after admitting the *n*-butenes to the samples the spectra showed that the surface species were identical for the three *n*-butenes; presumably rapid isomerization had occurred on the surface. The band at 3020 cm^{-1} characteristic of the =CH— group was found in all three cases, i.e. it had replaced the $=CH_2$ band at 3080 cm^{-1} in the case of the 1-butene. Possible models for this surface species will be discussed below. The spectra for *cis*-2-butene are not reproduced in Fig. 3, since they differ in no way from the other two.

The molar intensities of absorption were well below the values for adsorbed butenes at the higher coverage of $\theta \sim 0.1$. It is interesting to note, though, that the fractional intensity of the band at 3020 cm^{-1} had remained in the same range as that found for $\theta \sim 0.1$ after the attainment of isomerization equilibrium.

The slow increase in total band intensity noticeable after a period of several days (Table II) was indicative of slow polymerization. The increase was particularly marked in the2965 cm^{-1} band; it was matched by an equally slow decrease of the 3020 cm^{-1} band. Furthermore the contours of the final spectra closely resembled those of the polymerized species found at $\theta \sim 0.1$ (Fig. 2).

(iii) Adsorption of Isobutene on Porous Vycor Glass

When sufficient isobutene for 0.03 monolayer coverage was admitted to the Vycor sample, adsorption was very rapid. Within 5 minutes the entire dose had adsorbed and no gas spectrum was detectable. The following observations confirm the view that a very fast polymerization process had occurred.

The spectrum of the surface species (Fig. 4) showed very intense absorption bands

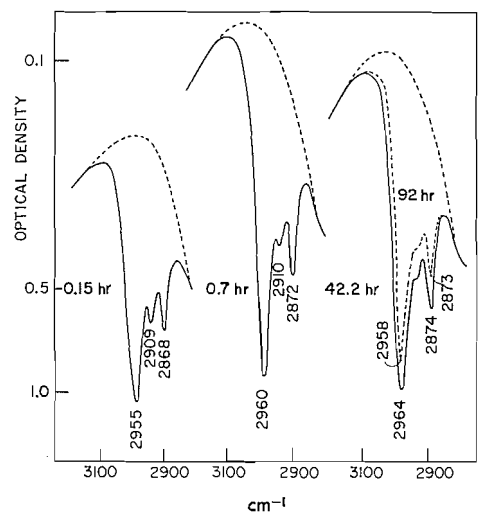

FIG. 4. Adsorption of isobutene on porous Vycor glass at $\theta \sim 0.03$. The broken line (92 hours) shows spectrum after outgassing. Optics: LiF.

of saturated hydrocarbon groups only. The frequencies and relative intensities of the bands at 2960 and 2870 cm^{-1} in the isobutene spectrum were the same as those in the spectrum of polymerized *n*-butenes (Fig. 2); in the former case the band at 3020 cm^{-1} due to unsaturated material was absent and the band at 2910 cm^{-1} was somewhat less resolved from that at 2960 cm^{-1}. The intensity of the 2910 cm^{-1} band in the isobutene spectrum decreased on standing, while the total intensity remained relatively unchanged.

On outgassing through a liquid nitrogen trap the intensity of the surface bands at 2960, 2910, and 2870 cm^{-1} decreased slightly, while their relative heights did not change. The gases thus condensed were shown to contain cracked and polymerized products similar to those found for the *n*-butenes.

The results of experiments at low coverage ($\theta = 0.002$) follow the same pattern as was found for the *n*-butenes. There was a significant decrease in molar intensity in going from $\theta = 0.03$ to 0.002 (Tables III and II), but the contours of the spectra were

identical (Figs. 4 and 3). The intensity of the 2910 cm^{-1} band again decreased. Eischens and Pliskin have assigned this band to tertiary C—H groups in surface molecules (3).

(iv) Adsorption of Butenes on Porous Glass Leached with Nitric Acid

Eight minutes after admitting 1-butene to a sample of the acid-leached glass to attain a coverage of $\theta \sim 0.1$, the spectrum (Fig. 5) was very similar to that of 1-butene in carbon tetrachloride solution (Fig. 8); the molar intensity of the surface material (Table IV) was in the same range as on the original glass (Table I), both being considerably less than the value in solution. Adsorption was rapid during the first 20 minutes, after which it slowed down markedly. In this respect adsorption proceeded likewise in a manner similar to that on unleached specimens. In contrast to this, however, the time to reach isomerization equilibrium had increased from approximately 1 to 50 hours. Appreciable isomerization had occurred already after 6 hours, the surface spectrum having changed to resemble that of *trans*-2-butene in solution (Fig. 8). Isomerization was similarly indicated by the gas-phase spectrum. After 4 days relatively little polymerization had occurred. This can be seen in Table IV, for instance, by the high fractional intensity of the 3020 cm^{-1} band. After the butenes had been removed by condensation,

weak bands remained, the contours of which (Fig. 5) were similar to those of the polymerized material remaining on unleached samples under comparable conditions (Fig. 2). The band intensities were, however, one order of magnitude less.

In a second experiment with 1-butene the effect of reducing the coverage to $\theta \sim 0.01$ was examined (Table IV, Fig. 6). The outstanding feature of the results was the shortening of the period within which the 3080 cm^{-1} band was replaced by that at 3020 cm^{-1}. While formerly the 3080 cm^{-1} band was still recognizable after 2 days, it had now completely disappeared after 40 minutes.

The adsorption of *trans*- and *cis*-2-butene was studied at $\theta \sim 0.1$ (Table IV); spectra (Fig. 7) were recorded at 20 and 40 minutes after gas admission, when isomerization was negligible. The molar intensities were again considerably less than the corresponding values in solution (Fig. 8). However, both ratios of olefinic to total C—H band intensities agreed remarkably well with the solution values.

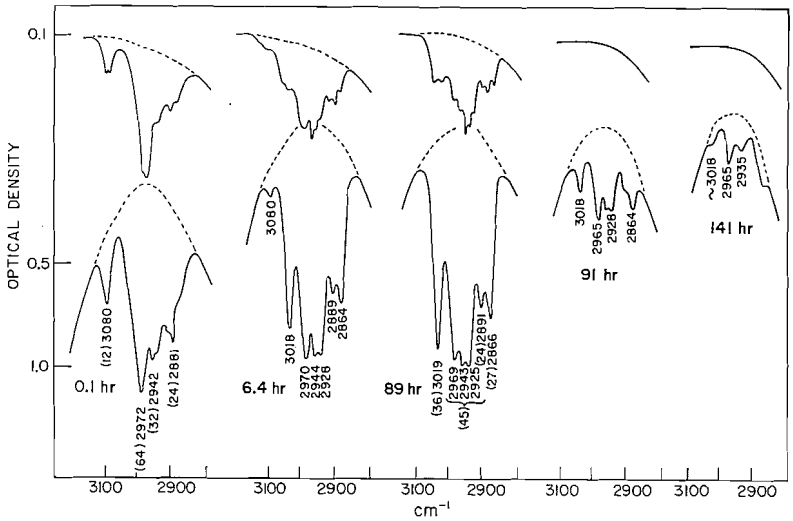

FIG. 5. Adsorption of 1-butene on acid-leached Vycor glass at $\theta \sim 0.1$. The upper spectra are those of the vapor phase. The last two spectra represent successive stages of outgassing. Optics: LiF.

Isobutene (Table IV) reacted far more rapidly than the *n*-butenes on the leached sample; as a result of this the gas uptake at a comparable initial pressure was greater. The fractional intensity of the 3080 cm^{-1} band even at 12 minutes after gas admission was about one-half the value in carbon tetrachloride solution (Table VI). It may be presumed from this that again considerable polymerization had taken place, although the rate of disappearance of the 3080 cm^{-1} band was far slower than with the unleached glass.

account for the marked decrease observed in the isomerization and polymerization rates.

In an effort to characterize more closely the source of these changes in activity, we attempted to observe the effect on the ν_{OH} band of the surface hydroxyl groups by the nitric acid leaching. This was not feasible with samples 1 mm thick, because they absorb completely all radiation between 3800 cm^{-1} and 3400 cm^{-1}. However, 0.1-mm samples transmit throughout this region and permit a complete study of the ν_{OH} band.

No significant change in the optical density and half-width of the ν_{OH} band after acid treatment was found.

Previous workers with Vycor glass (8) and similar materials (9) have discussed a second type of surface site, apart from the silanol group. This was tentatively ascribed to the Si–O–Si grouping or, more specifically, silicon atoms in the surface.

From the evidence presented in our case it is almost certain that the alumina (and probably also the zirconia) was involved in the adsorption and reaction of the butenes. If our examination of the change in the hydroxyl structure with leaching was sufficiently sensitive, then this would exclude a predominant role being played by surface hydroxyls in the activity changes discussed in the previous section. The metal or oxide sites would themselves form the adsorption centers or, possibly, act as proton acceptors for carbonium ions formed on neighboring surface hydroxyls. Removal of the centers would then result in decreased reaction rates at a given butene coverage. An extreme sample of this would be represented by the results of some experiments which we have conducted with a pure silica aerogel (Cab–O–Sil). The surface area of the silica was comparable to that of the Vycor glass. It had no R_2O_3 content, but an appreciable concentration of free surface hydroxyls. After standing in contact with butene for about 1 month, isomerization was barely perceptible; no polymeric species were detected.

On the other hand, the spectroscopic evidence regarding the ν_{OH} band is by no means unambiguous and the following picture would be equally consistent with the changes observed after leaching. If we accept a carbonium ion mechanism to be operative in the reactions (1), then adsorption on a surface hydroxyl (Si–OH or Al–OH) is a plausible first step towards subsequent proton transfer and carbonium ion formation. Of interest in this connection are the recent data of Scholze (10), who found that the content of free hydroxyls in alkali silicate glasses increased with Al_2O_3 content, although B_2O_3 showed the same effect to a high degree. However, our present data do not permit us to distinguish between these various possibilities.

It is instructive to estimate the concentration of "active sites" relative to initial butene coverage in the various experiments described. Such estimates must remain approximate inasmuch as we are ignorant not only of the exact nature of the sites, but also of their energy distributions. We shall confine ourselves therefore to estimating R_2O_3 concentrations in the surface.

Taking the R_2O_3 content (see Experimental Section) to be equally divided between alumina and zirconia, we arrive at a total (Al + Zr) concentration of 0.18 gram-atom/liter of Vycor. The density of the glass is 1.45 g/cc.* For a homogeneous dispersion of R_2O_3 we estimate about 15% or 0.027 gram-atom/liter to reside on the surface. This is by analogy with the silica surface-to-bulk ratio arrived at under the assumption of a 10 Å^2 area for repeat units of silica in the surface. After leaching, 40% of the original R_2O_3 remained in the glass, corresponding to a maximum of 0.011 gram-atom/liter in the surface, but probably very much less.

1-Butene is the most suitable of the *n*-butenes with which to follow the process of isomerization. Not only is almost all of it converted, but it is clearly recognizable down to low concentrations in butene mixtures, owing to the well-resolved band at 3080 cm^{-1}. In Table V we have grouped together data for the adsorption of 1-butene in the order

TABLE V

Correlation of 1-butene to (Al + Zr) ratio with activity and initial molar intensity

Mole ratio, 1-butene:(Al+Zr)	Glass	$\sim\theta$	3080 cm^{-1} band disappeared at $\sim$ hours	$\bar{I}_{initial}$, mole^{-1} l. cm^{-2}
15	Leached	0.1	50	5500
8	Original	0.1	1	5400
1	Leached	0.01	0.7	4900
0.06	Original	0.001	<0.1	3000–5000*

*Estimated from the identical spectra arising from *n*-butenes at low coverage.

of decreasing ratios of initial adsorbate to "active sites". These follow the same trend as the time it takes for isomerization to come to equilibrium. This correlation supports the view that the removal of R_2O_3 is the primary cause of the deactivation of the glass.

As a possible alternative to leaching out "active sites" we attempted to block them. (*a*) Unsupported nickel oxide is considered to be inactive as a butene isomerization catalyst below 400° (11). We found that when 1-butene was adsorbed on Vycor impregnated with ~2% nickel oxide, neither the isomerization nor the polymerization rates were significantly affected and the system behaved in every respect like that shown in

*Corning Glass, Specifications.

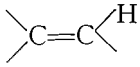
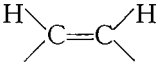
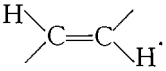
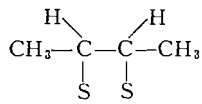
Fig. 2. Although this result is inconclusive, it throws additional light on the work of one of us (L.H.L.): Ethylene, which did not polymerize on Vycor alone, did so when nickel oxide was present, giving rise to a *trans*-2-butene spectrum (4). On continued standing, the butene polymerized further. We are now able to infer that it was the Vycor support rather than the nickel oxide which had catalyzed subsequent C_4 polymerization. (*b*) We performed a series of experiments involving several successive cycles of adsorption and partial desorption. This was done by admitting either a fresh dose of pure butene for each cycle, or else by readmitting the previously isomerized mixture. In no case were we able to detect inhibition of isomerization or polymerization activity due to polymer build-up on the surface. Since in all experiments the initial ratio of butene:(Al + Zr) was of the order of 10, our results tend to support the mechanism which involves the enhancement of surface hydroxyls by the R_2O_3 constituents. In other words the estimated ratio of 10 must be several times too small and far more extensive polymer coverage would be required for deactivation.







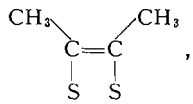
The last column in Table V shows the initial molar intensities for 1-butene. There is an apparent decrease with preponderance of "active sites" per mole of adsorbed butene, i.e. when the spectrum originates from an increasingly large fraction of strongly sorbed molecules in the adsorbed layer. This is in line with the lower values generally found in our case in the surface phase when compared with values in a solvent medium, but should nevertheless be regarded with caution because of the large probable error.



In this connection it is interesting to note that if the spectra in Fig. 3 ($\theta \sim 0.001$) are indeed those of predominantly *trans*-2-butene as was suggested by their contours, then the fractional intensities of the 3020 cm^{-1} band (Table II) are 30% lower than would be expected from the values in solution (Table VI). Barring the early onset of polymerization, which we consider unlikely, this indicates that the perturbation of the molecule by the surface was intensified about the double bond. Conversely, the agreement between the values in Table IV (leached glass, $\theta \sim 0.1$) and those in Table VI could be explained by the fact that the relevant surface spectra were chiefly determined by the large proportion of weakly sorbed butenes in the surface layer.

Within our limits of accuracy, extinction coefficients experienced the same fractional decrease from solution to surface as did the molar intensities, i.e. we could not observe any significant changes in band shape (compare corresponding numbers in parentheses in Figs. 5, 7, and 8). In most cases frequencies were not significantly different within the limits of error, although for *trans*-2-butene we have observed an apparently real shift in the olefinic stretching band from 3021 cm^{-1} in solution to 3019 and 3015 cm^{-1} at high and low surface coverages respectively. Small shifts of this type are commonly encountered in condensations from gaseous to liquid-type phases, as can be seen in Fig. 8, where the decrease from gas to solution for the butenes was in the range 7–9 cm^{-1}.

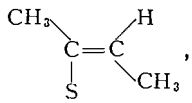
All the available evidence cited so far, as well as the probable short life of reaction intermediates (2), favors some type of physical adsorption to have been responsible for the observed spectra. However, we cannot entirely exclude the possibility that the spectra are those of a chemisorbed butene species, if not composites of both types. As discussed in Section (*ii*), the low-coverage spectra are the most suitable for examining this question. From these we may draw certain conclusions as to the possible structure of a spectrally predominant species.



(*a*) Since a band appeared at 3020 cm^{-1}, the species must contain one or more of the

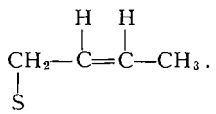
groups  ,  , or  . This would exclude adsorption by such mechanisms as

(I)



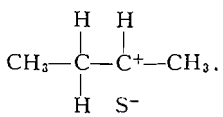
or

(II)



where S indicates a surface site.

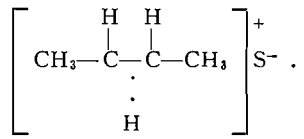
(*b*) The 10–12% intensity ratio of the 3020 cm^{-1} band would make a polymeric species unlikely (see Table VI). It would probably also exclude a structure such as



(III)

where only one H-atom is associated with the olefinic carbons (see 2-methyl-2-butene, Table VI). However, a species formed by the dissociation of hydrogen from an α-methyl group would be consistent with the observed spectra

(IV)



(*c*) The carbonium ion frequently postulated as the intermediate species in double-bond isomerization and polymerization reactions may be considered as existing in two stable forms (1). One of these is the σ-complex (12)

(V)

Only bands in the region of saturated C—H absorption might be expected from such a structure, i.e. it would not be consistent with the spectra in Fig. 3. However, evidence given below in connection with (VI) would suggest retention of some double-bond character in (V) as well. Exclusion of any species does not, of course, rule out participation in the processes under discussion, unobservable though it may be by spectroscopic means. The second form is the π-complex (12)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(VI)

Recently Powell and Sheppard (13) have determined the infrared spectra of a number of platinum and palladium complexes with ethylene. In their case weak bands in the C—H stretching region and frequencies similar to those of gaseous ethylene were observed. Earlier Chatt and Duncanson (14) had found that the olefinic character in the spectra of a number of metal–olefin π-complexes had been essentially preserved. We quote this work to show that a relatively stable π-complex with the surface might still be expected to give rise to absorption above 3000 cm^{-1} and would be compatible with the spectra in Fig. 3. A weaker type of interaction with surface hydroxyls, which also involves the π-electrons of the olefinic double bond and which can be regarded as hydrogen bonding, we have already discussed in Section (*i*). Presumably this latter type of bond would represent the first stage in carbonium ion formation.

(vi) Band Assignments for Adsorbed Species

In the past, bands at 2965 cm^{-1} and 2870 cm^{-1} have been assigned to vibrations of methyl groups and bands at 2930 cm^{-1} and 2850 cm^{-1} to vibrations of methylene groups for spectra of adsorbed molecules (3, 4), although Eischens and Pliskin (3) have commented on the uncertainties in making such assignments. They are made by analogy with spectra of normal liquid hydrocarbons (15) and are probably correct for large adsorbed molecules. On the other hand, for such molecules as *trans*-2-butene, the occurrence of bands at 2930 and 2850 cm^{-1} clearly cannot indicate the presence of methylene groups. The multiplicity of bands in the spectra of small unsaturated molecules arises *inter alia* from overtones of C—H deformation vibrations.

A further difficulty arises from the fact that large regions of the spectrum may be obscured by intense absorption bands of the adsorbent. Thus confirmation of a likely structure by observing bands in other spectral regions may not be possible, and structural conclusions have to depend on observations of a limited number of bands.

For assigning structures to adsorbed molecules we have confined ourselves to comparing the spectra with analogous ones in solution. The only exception to this has been the assignment of bands occurring at wave numbers higher than 3000 cm^{-1} to unsaturated groupings. This was substantiated by quantitative intensity measurements as well as by GC and mass spectrometric analyses after desorption of the materials responsible for those bands.

APPENDIX

As indicated in the preceding sections, spectral determinations of pure olefins have been made for purposes of comparison with surface species (Table VI, Figs. 8 and 9).

Butene solutions were analyzed by mass spectrometry immediately after the recording of a spectrum. Following this, the spectrum was re-recorded to check for possible evaporation losses.

All butenes used were Phillips Research Grade. Of the higher olefins, all were Phillips Research Grade, except for 2-octene and 2,4,4-trimethyl-2-pentene which were Phillips

OXIDATION OF WHEAT STARCH WITH ALKALINE HYPOCHLORITE[1]

A. A. EISENBRAUN[2] AND C. B. PURVES

ABSTRACT

The starch was oxidized with 5.5 base molar equivalents of 0.43 *M* calcium hypochlorite kept near pH 12 and 20°. The rate of oxidation was consistent with the occurrence of two first-order reactions differing in rate by a factor of 10, the more rapid of which consumed about 4 moles of hypochlorite for each $C_6H_{10}O_5$ unit actually oxidized. Oxalic acid (0.21 mole) and perhaps carbonic acid (⩾0.17 mole) were formed directly, but it was necessary to hydrolyze the product in order to liberate D-glucose (0.4 mole), glyoxylic acid (0.03 mole), D-erythronic acid (0.11 mole), mesotartaric acid (0.02 mole), D-tartaric acid (0.02 mole), L-tartaric acid (0.01 mole), D-glucuronic acid (0.004 mole), and probably tartronic acid (⩾0.03 mole).

The oxidation of various species of starch with alkaline hypochlorite, a process of industrial as well as academic interest, has been studied for many years. Reviews (1, 2) of the subject show that most of the early interest was attracted to the changes produced by various amounts of oxidant in such properties as viscosity and copper-reducing power, ease of retrogradation, and the adsorption of dyes. Degradation products were isolated and identified in only a very few instances. McKillican and Purves (3) more recently obtained evidence that hypochlorous acid near pH 4 oxidized wheat starch in the second and sixth positions of the glucose residues to yield in part 2-keto and uronic acid derivatives. Whistler and his collaborators (4, 5), employing corn amylose and amylopectin with hypochlorite kept at 25° and at various pH values between 3 and 13, dialyzed the products and showed that both the dialyzable and the non-dialyzable portions yielded D-glucose, glyoxylic acid, D-erythronic acid, and D-erythronolactone after hydrolysis with acid. Oxidations near pH 7 produced the maximum amount (about 0.3 mole) of glyoxylic acid. The present research provided additional information about the course of the reaction at pH 12 and 20°.

Preliminary experiments, employing 0.12 *M* and 0.06 *M* calcium hypochlorite with mole ratios per $C_6H_{10}O_5$ unit of 1:1 or 1:0.5, confirmed the observation (5) that such oxidations were exceedingly slow. Sodium hypochlorite yielded solutions from which it was more difficult to isolate the organic products. The use of a greater excess (mole ratio, 5.5:1) of a more concentrated (0.43 *M*) hypochlorite increased the speed of the oxidation to a convenient value, and had the additional advantage that the rate constant for the disappearance of hypochlorite would tend to follow the first-order kinetic equation. A semilogarithmic plot of the data (Fig. 1, plot A) became linear after about 76 hours and could be represented by the equation $\log 0.24/(0.24-b) = 2.2\times10^{-3}T$, where b was the concentration of hypochlorite consumed at time T, the units being moles, liters, and hours. Substitution of values of T between zero and 76 hours then yielded values of b from which, by difference from the observed values, the corresponding data b_1 for the initial, fast reaction could be calculated. These data (plot B) also fitted a first-order equation, $\log 0.19/(0.19-b_1) = 2.2\pm0.1\times10^{-2}\ T$.

The above calculations suggested that the oxidation of starch with hypochlorite at pH 12 consisted of a relatively rapid reaction consuming 2.34 moles of hypochlorite

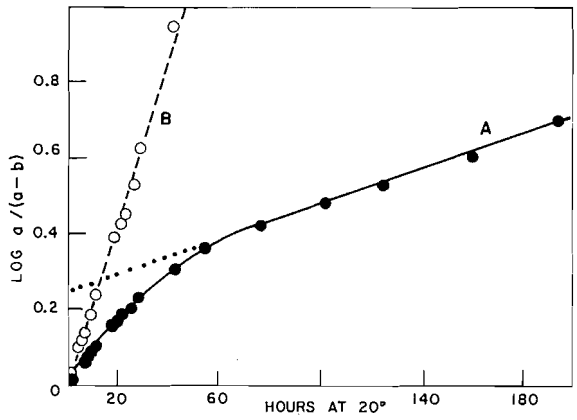

FIG. 1. Rate of oxidation of 0.183 base molar starch solution at pH 12 and 20° with 1.33 volumes of 0.756 *M* calcium hypochlorite. Ordinates, logarithm of initial to remaining concentration of hypochlorite. Plot A (full line), observed data; plot B, (broken line) calculated for initial rapid reaction.

per anhydroglucose unit, and a second reaction proceeding at about one-tenth the speed. Although at pH 12 aqueous calcium hypochlorite was in equilibrium with about 0.5% of undissociated hypochlorous acid (5), the two reaction rates could not be attributed to the independent action of these two species of oxidant, because any disequilibrium between them would be redressed almost instantaneously. The assumption that the anhydroglucose units of starch underwent a rapid initial oxidation followed by a much slower secondary oxidation seemed more plausible, but failed to explain why about two-fifths of these units remained unoxidized at the end of the initial reaction (see below). The three-fifths that reacted therefore reduced an average of about 4 moles of hypochlorite per glucose residue, or enough to oxidize the whole of this portion to the level of oxalic and erythronic acids. A more detailed kinetic study of this oxidation, employing different concentrations and mole ratios of hypochlorite, would be desirable.

The conditions noted in Fig. 1 were used in subsequent oxidations, but when 3.0 moles of calcium hypochlorite per anhydroglucose unit had been utilized acetone was added to convert the excess hypochlorite to chloroform. The liquors from the oxidation contained no organic substances of interest, and the crude insoluble products, ranging in weight from 143 to 225% of the original starch, contained 20 to 31.3% of calcium. An attempt to remove this calcium as the oxalate yielded the information that much was already present in that form, and another attempt at removal as the alcohol-soluble chloride showed that most of the organic acids liberated were also soluble in 70 to 90% ethanol at −10°.

Better results were obtained by adjusting an aqueous suspension of the calcium salts to pH 7 with dilute hydrochloric acid, removing those that failed to dissolve (fraction I, 37.5% by weight of the starch), and diluting the liquor with ethanol. In this way, any calcium hydroxide was eliminated as the soluble chloride, and the remaining calcium salts of the sugar acids were precipitated (fraction II, 87%). Calculations from the extensive analytical data showed that the free sugar acids from fraction I amounted to 22.5% of the starch, and those from fraction II to 62.5%; a further 3.7% was recovered as carbon dioxide present as calcium carbonate in the two fractions, but some or all of this amount might have been acquired adventitiously. Although hydrolyzates of the two fractions gave no chromatographic evidence of pentose sugars, the original sugar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

acids yielded 0.73% and 2.34%, respectively, of furfural. These amounts were therefore attributed to the presence of 3.5% and 11.9% of uronic anhydride (6). After inorganic carbon dioxide had been removed, the conventional uronic anhydride determination gave the values 6.9% and 17.4%, respectively. These values were rejected as being too high, because Daniels (7) recently showed that only a small proportion of the "uronic anhydride" carbon dioxide yielded by a hypochlorite oxycellulose-6-C^{14} originated from position 6, and that the determination could not be interpreted in such cases.

Preliminary experiments on the hydrolysis of the major fraction II with boiling *N* sulphuric acid showed that its copper-reducing power as glucose, originally 2.8%, increased to a nearly constant value of 46.4% within 3 hours; the carbon dioxide evolved in the same time corresponded to the destruction of 13% of "uronic anhydride". The latter observation suggested that the low final reduction reflected the presence of non-reducing constituents rather than that of acid-resistant aldobiuronic acids. After inorganic ions had been removed, the hydrolyzate was chromatographed with *n*-butanol – formic acid – water both on paper and on a cellulose column. The major fractions yielded four acidic compounds, of which three had the flow rates of glyoxylic, erythronic, and optically active tartaric acid. The column when subsequently eluted with water yielded 46% of a partly crystalline syrup consisting almost entirely of glucose, which was thoroughly identified. Even when the glucose was removed by a prior fermentation with yeast, the acidic products could not be obtained in a crystalline condition.

Khym and Doherty (8), however, separated glucuronic and galacturonic acids by adsorption on a column of anion-exchange resin followed by elution with 0.15 *M* acetic acid, the order of elution depending on the relative dissociation constants of the acids and the eluent. After preliminary experiments, the hydrolyzed acids from fraction II, freed from calcium and sulphate ions, were adsorbed on the anion-exchange resin, which failed to absorb the glucose. The column was then eluted exhaustively and in succession with 2 *N* acetic acid, *N* formic acid, and 0.5 *N* trifluoroacetic acid, the effluent being collected in 20-ml or 25-ml volumes which were examined by paper chromatography (Table I).

Although erythronic acid and erythronolactone were removed simultaneously from the column by 2 *N* acetic acid, they had different R_F values when chromatographed on paper; both were isolated as the crystalline lactone. Glucuronic acid, however, chromatographed on paper as a single chemical individual. As expected, crystalline glyoxylic acid, mesotartaric acid, and DL-tartaric acid were recovered in the order of their dissociation constants, reported as $10^4 K = 4.74$, 6.3, and 9.7, respectively (9, 10, 11). DL- and D-Tartaric acids had the same dissociation constant, and were therefore isolated from the ion-exchange column together; they were subsequently separated by fractional crystallization from water, in which the latter was about seven times more soluble than the former (12). Both were obtained with their correct melting points, the first being optically inactive and the second having its correct specific rotation of $-14°$ in water (*c*, 5.5%). The racemic acid was probably not an artifact, because an authentic sample of L-tartaric acid underwent no change in rotation when kept for 3 days in water buffered to pH 12 (as in the oxidation of the starch), or when boiled for 2.5 hours in *N* sulphuric acid (as in the hydrolysis of the oxidized starch). Prolonged attempts to isolate tartronic acid in the crystalline form, or as a crystalline derivative, failed.

The water-insoluble calcium salts comprising fraction I of the oxidized starch were next examined. Extraction with aqueous acetic acid left a residue of crude calcium oxalate. After calcium and a small amount of chloride ions had been removed from the

extract, evaporation left 13.6% of fraction I as a colorless glass containing the free sugar acids. Hydrolysis of the acids followed by paper chromatography revealed the presence of glucose and glyoxylic acid, together with non-reducing compounds with R_F values close to those of mesotartaric, L-tartaric, D-erythronic, and tartronic acids and of D-erythronolactone. The crude mixture amounted to only 5.1% of the starch, and was not separated quantitatively.

In Fig. 2, the total molar yield of each product was given the first time the substance was recorded; these yields were minimum estimates, with the exception of those for carbonic and tartronic acids, whose authenticity was doubtful. Together with the carbonic acid lost by decarboxylation during hydrolysis, they accounted for between 70 and 80% of the hypochlorite used in the oxidation. Only oxalic acid, and perhaps carbonic acid, occurred as such among the original, unhydrolyzed products, about 80% of which dialyzed through cellophane in aqueous solution and were therefore of no great molecular size. Nevertheless, paper chromatograms failed to reveal erythronic acid and lactone, glyoxylic, tartronic, and the tartaric acids in circumstances where their mobilities would have rendered them readily detectable. Since any ester groups would not have survived the alkalinity of the oxidation, the conclusion seemed inevitable that the acids remained attached to adjacent units of the oxystarch structure by glucosidic or acetal bonds until liberated by acid hydrolysis. Any speculation concerning the course of the oxidation had to take account of this circumstance.

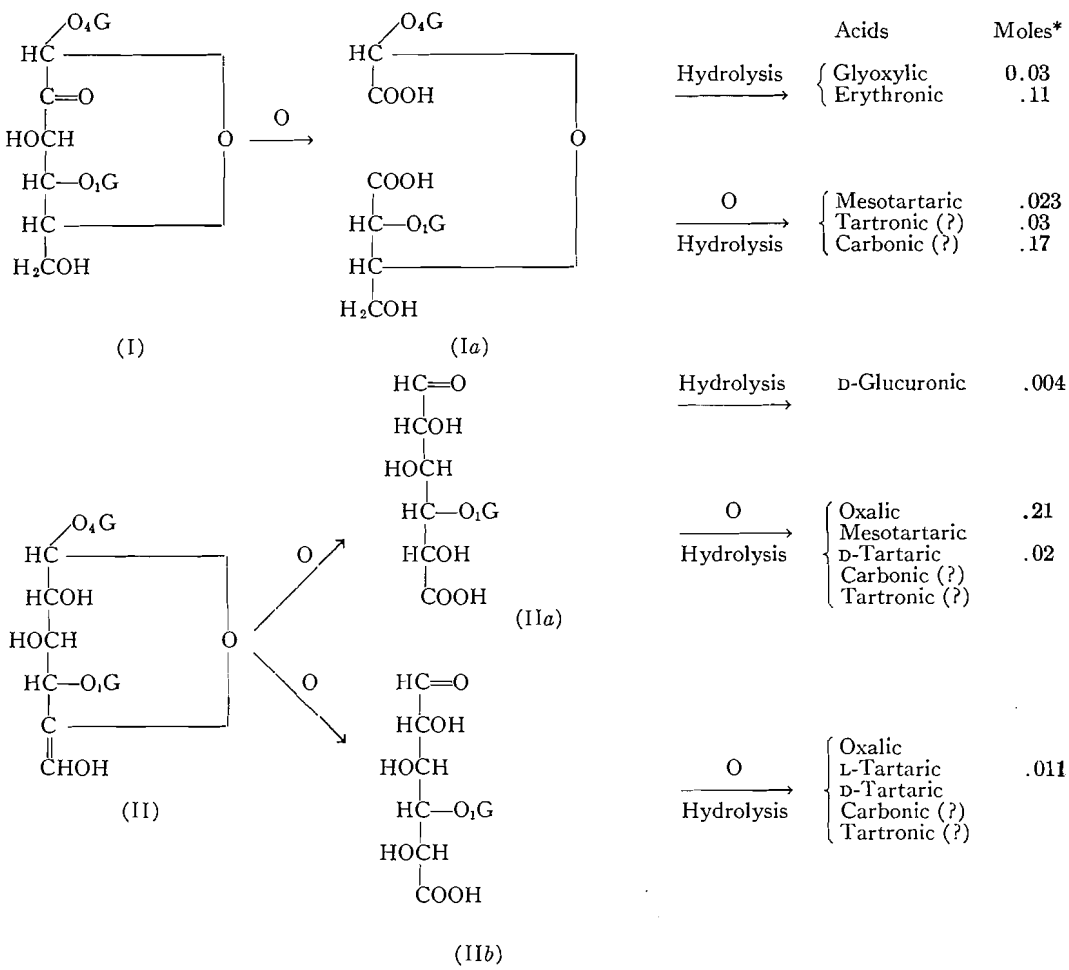

FIG. 2. Identified end products and postulated intermediates in oxidation of starch with calcium hypochlorite at pH 12. Adjacent anhydroglucose units, linked through fourth and first positions, denoted as $_4$G and $_1$G, respectively.

The relatively large yields of D-erythronic acid and lactone were readily explained by oxidation of an anhydroglucose unit in starch to the 2-keto structure I, followed by oxidative cleavage between the second and third positions to I*a*, as Whistler and his collaborators (4, 5) had already supposed. Further oxidation of I*a* would readily yield the precursors of mesotartaric and of tartronic acid. The other probable site of initial oxidation was the primary or sixth position of the anhydroglucose unit. It appeared necessary to assume that the enolic form of the 6-aldehyde structure II had at least a transitory existence, and yielded on further oxidation not only the D-glucuronic moiety II*a* but also the L-iduronic derivative II*b*, although only the former was isolated. Farley and Hixon (13) also isolated a small amount of glucuronic acid from a starch oxidized with 4 equivalents of bromine in neutral solution. By analogy with the easy cleavage of methyl-α-D-galactopyranuronoside and of pectic acid to free galacturonic acid by alkaline hypochlorite (14), the present oxidation at position 6 would lead to the collapse

**Per anhydroglucose unit in starch.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of the glycosidic linkage at position 1, as shown in structures II*a* and II*b*. Further oxidation in the 2,3-positions would yield more mesotartaric acid from II*a*, but L-tartaric acid from II*b*, the other product in each case probably being oxalic acid. If oxidation occurred in the 1,2- and 5,6-positions, the product in both cases would be D-tartaric acid and carbonic acid.

Höning and Ruziczka (15), who oxidized starch with barium hypobromite in 0.02 *N* barium hydroxide, found maltobionic, and perhaps gluconic acid, among the products. These two substances were not detected on the present occasion. Neither were saccharinic acids, which might have been formed by the action of alkali on reducing structures such as I and II (16). D-Glucaric acid (saccharic acid) was not found, although mucic acid was prominent among the oxidation products of pectic acid (14); there was no evidence of 5-carbon acids such as arabonic and trihydroxyglutaric. At least some of these negative results might have arisen from the limitations of the experimental methods used.

EXPERIMENTAL

Materials and Analytical Methods

Unless stated otherwise, all liquors were concentrated in a rotary evaporator at little more than room temperature, and analyses quoted were the mean of concordant duplicate or triplicate determinations. Specific rotations referred to the *D*-line of sodium and to 20°.

The commercial, unbleached wheat starch was simultaneously freed from fat and ash, and converted to the thin-boiling state, by being steeped for 5 days in changes of 97% acetic acid at room temperature (17). Periodate oxystarch, when reoxidized with bromine (18) and hydrolyzed, yielded brucine D-erythronate from which a solution of the free acid was prepared via the barium salt. Provided the brucine and barium salts were carefully purified, the D-erythronolactone crystallized when the solution was evaporated and the last traces of moisture were removed by distillation with toluene. Recrystallization from ethyl acetate yielded material with the correct (19) melting point, 102°, and specific rotation, −72.8°. This lactone, and also crystalline glyoxylic acid (20), were synthesized for reference purposes.

Solutions of reagent grade calcium hypochlorite were filtered through sintered glass and were standardized iodometrically or by the arsenite method. A blank, determined as 0.118 *M* by both methods, remained unchanged in titer for at least 44 hours at 20°, and conversion to chlorate was therefore negligible (5). The calcium content of the oxystarch was determined either as carbonate by incineration to constant weight at 475° to 525°, or as sulphate by incineration at 900° after treatment with sulphuric acid; precipitation as the oxalate and titration of the latter with 0.1 *N* potassium permanganate in dilute sulphuric acid (21) was also used. To determine inorganic chloride, an aqueous solution or suspension of the sample was acidified with pure, 6% nitric acid and was titrated potentiometrically with 0.1 *N* silver nitrate to an end point at 275 millivolts (22). Inorganic carbonate was estimated by decomposing a 1- to 2-g sample with 12% hydrochloric acid at 70° in an uronic acid apparatus (23) and weighing the carbon dioxide evolved; uronic anhydride carbon dioxide was then determined separately by boiling a similar still residue under reflux for 3 and 5 hours and extrapolating the data to zero time. Somogyi's method (24) was used to determine copper-reducing power, the reagents being standardized with pure glucose.

Salts were usually converted to the free acids by passing the aqueous solution through a column of the cation-exchange resin, "Amberlite IR-120", which was subsequently

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

eluted with water until the effluent became neutral. Aliquots of the effluents could then be examined by descending paper chromatography, the eluent being the organic phase of a water – *n*-butanol – 85% formic acid mixture (385:500:115) equilibrated by boiling under reflux for 1 hour (25). Since bromphenol blue in 95% ethanol (26) was almost always the spray, the chromatograms first had to be dried *in vacuo* at 110° for 8 hours to eliminate the last traces of formic acid. The other acids then gave well-defined yellow spots on a blue background. An acidic solution of *o*-aminodiphenyl (27) gave brown, purple, and yellow spots with glucose, D-glucuronic acid and its lactone, and with glyoxylic acid, respectively, while a spray of alkaline hydroxylamine followed by ferric chloride in 1% hydrochloric acid (28) gave clear brown spots with lactones.

Rate of Oxidation (Fig. 1)

The starch, 2.50 g with 10.7% moisture (13.7 mmoles), was dispersed in 12.5 ml of water and the mixture was gelatinized by the addition of 37.5 ml of boiling water. After immersion in a boiling water bath for 10 minutes, the solution was cooled to room temperature (20°), and mixed with 125 ml of water containing 75.6 mmoles of calcium hypochlorite and 1 g of powdered calcium hydroxide. The flask used was protected from light, the mixture was mechanically stirred, and the hydrogen ion concentration was kept at all times within the limits pH 12.1 to 11.6 by the addition of two 1-g portions of calcium hydroxide. Aliquots were removed at intervals and the amount of residual hypochlorite was determined iodometrically.

Larger-Scale Oxidation

A 225-g sample of the starch (7.2% moisture) was dissolved in 5 liters of water in the way described, and was oxidized with 10 liters of calcium hypochlorite kept near 20°. The concentrations of the starch per $C_6H_{10}O_5$ unit and of hypochlorite were 86 mmoles and 443 mmoles per liter, respectively. A total of 210 g of powdered calcium hydroxide was added during the oxidation to maintain the alkalinity between pH 11.8 and 12.1. After 2.98 moles of hypochlorite per anhydrohexose unit had been consumed, the reaction was stopped by the addition of 500 ml of acetone. The mixture was filtered and the insoluble material was repulped in 1000 ml of water.

The combined liquors were neutralized with carbon dioxide, the precipitated calcium carbonate was discarded, and the concentrated mother liquor was diluted with much ethanol. Crystalline calcium acetate monohydrate (from the acetone), contaminated with the chloride and carbonate, separated, but no salt derived from the oxidized starch could be found.

A slurry of the above, insoluble calcium salts in 2000 ml of fresh water was then neutralized to pH 7.0 by adding 300 ml of concentrated hydrochloric acid, neutralization being considered complete after the pH remained unchanged for 24 hours. The insoluble residue was recovered, slurried with 1000 ml of water in a Waring Blendor to reduce the particle size, extracted twice more with a total of 1100 ml of water, and dried in the air. Yield of fraction I, 78.2 g or 37.5% by weight of starch. All the neutral filtrates and washings from fraction I were combined, concentrated to 700 ml, and diluted with 2 volumes of ethanol to precipitate the water-soluble calcium salts of the oxystarch. This precipitation was repeated twice more to remove calcium chloride, and the product was dried in the air. All alcoholic liquors were combined, concentrated, and again diluted with ethanol to recover another 14 g of calcium salts. These salts were combined with the main crop to give 181.7 g (87%) of fraction II.

Found for fraction I: ash at 1200° (CaO), 32.4; Cl, 0.23; moisture, 8.1; furfural, 0.73;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

uronic anhydride, 6.9; inorganic CO_2, 5.5%. Samples, 0.139 g, 0.204 g, and 0.200 g, reduced 9.7 ml, 14.2 ml, and 14.1 ml, respectively, of acid potassium permanganate, the corresponding oxidation equivalent being 51.3, 51.3, and 51.9% of calcium oxalate monohydrate. When corrected for calcium chloride, calcium carbonate, and moisture, the calcium content of the product was 22.9%, giving a yield of 60.1% of fraction I (22.5% of the starch) as sugar acids of average equivalent weight 68.3.

Found for fraction II: ash (as $CaSO_4$), 37.3; Cl, 1.45; moisture, 11.9; furfural, 2.34; uronic anhydride, 17.3; inorganic CO_2, 1.84%. Correction for calcium carbonate, calcium chloride, and moisture gave Ca, 10.4% for the salts of the sugar acids, whose equivalent weight was 173 and whose yield was 73.6% of fraction II or 64% of the starch.

A solution of fraction II (2 g) in 15 ml of water was freed of cations and the effluent was diluted to 100 ml. One 20-ml aliquot of this acidic effluent, corresponding to 0.4 g of fraction II, yielded 0.282 g, or 70.5%, of sugar acids when dried *in vacuo* to constant weight. Two other aliquots were mixed with 0.1 *N* sodium hydroxide and were back-titrated after 16 hours to a phenolphthalein end point with 0.1 *N* hydrochloric acid; the aliquots neutralized 4.46, 4.52 milliequivalents per gram. Since 1 g of fraction II originally contained 0.41 milliequivalent of chloride, the value for the sugar acids was 4.08, corresponding to a neutralization equivalent of 705/4.08 or 173. Both this value and the yield were in good agreement with those calculated from the analytical data.

A 1.32-g sample of fraction II was freed from cations and the solution was dialyzed through collodion against two 4-liter volumes of 0.01 *N* hydrochloric acid for 36 hours, then against the same volumes of distilled water to remove the hydrochloric acid. Evaporation of the residual liquor yielded 0.153 g or 11.6% of non-dialyzable material, corresponding to 16% of the free sugar acids.

Products from Hydrolysis of Fraction II

A solution of fraction II, 0.598 g, in 20 ml of *N* sulphuric acid was boiled under reflux, aliquots being periodically removed and neutralized with sodium hydroxide. After 0, 0.25, 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, 6.6, and 8.6 hours the copper reduction as glucose (24) was 2.8, 11.0, 17.8, 26.0, 33.5, 35.9, 37.0, 38.7, 41.2, and 42%, respectively. Hydrolysis for 2.5 hours was judged sufficient in the subsequent work. A mixture of fraction II, 1.02 g, and 60 ml of *N* sulphuric acid, contained in the uronic acid apparatus (22), was freed from inorganic carbon dioxide by the passage of nitrogen for 1 hour, and was then boiled under reflux for 2.5 hours. Found: uronic anhydride, 9.4%, corresponding to the decomposition during hydrolysis of 13.1% of carboxyl groups in the sugar acids.

An aqueous solution of the fraction II from an earlier oxidation, 2 g, was decationized, evaporated almost to dryness, and redissolved in 40 ml of *N* sulphuric acid. After hydrolysis as just described, sulphate ion was precipitated by the exact amount of aqueous barium hydroxide, and the filtrate on evaporation yielded 1.86 g of a syrup. This syrup, 1.58 g, was chromatographed on a cellulose column. All acidic material was removed by the passage of 5500 ml of the butanol – formic acid – water mixture, and then the glucose was eluted with 5000 ml of water. Evaporation of the aqueous effluents left 0.675 g of a syrup (43% of the calcium-free material) which partly crystallized when stored *in vacuo* over solid sodium hydroxide. The phenylosazone (29) decomposed at 198–199°, or in the proper range for the glucose derivative. The corresponding osotriazole (30) had the melting point 195.5°, not depressed by admixture with authentic glucose phenylosotriazole, m.p. 195°.

Fifty grams of fraction II, suspended in water and mixed with 70 g of "Amberlite

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

IR-120", was put on the top of a column of the same resin and eluted with water. Evaporation of the effluent left 51 g of calcium-free, acidic syrup which was hydrolyzed, the hydrolyzate then being freed from sulphate ion by the addition of the exact amount of aqueous barium hydroxide. The filtrate and washings were concentrated to 1500 ml and passed through a 25 cm×3.5 cm column containing "Dowex 1-X-4" anion-exchange resin (free base) at a rate of 17 ml per minute. Paper chromatography of the effluent revealed no evidence of any sugar save glucose, and epimerization to other sugars had not occurred during the 90-minute exposure to the strongly basic resin (31). The resin with its adsorbed sugar acids, but no more than traces of glucose, was transferred without delay to the top of a 100×5.6 cm column containing the same resin in its acetate form. Elution of the column at once began with 2 *N* acetic acid at a flow rate of 1.5 ml to 3 ml per minute, and the effluent was collected in 25-ml or 20-ml fractions. Every 20th or 30th fraction was evaporated to 0.3 ml, and chromatographed on paper. When nothing more was extracted by the acetic acid, the eluent was changed to *N* formic acid, which was later replaced by 0.5 *N* trifluoroacetic acid, the total volume of effluents being more than 60 liters. Fractions shown by paper chromatography to contain the same compound or compounds were combined and concentrated to syrups. Of these syrups, those derived from the following sets of fractions (Table I) were examined.

Fractions 226–340

The corresponding syrup, 0.85 g, yielded several spots, revealed by the bromphenol blue spray, when chromatographed on paper for several days. When a solution was titrated with alkali to pH 7, the behavior was that of a lactone. Several attempts to obtain a crystalline acid or calcium salt from the syrup failed.

D-*Erythronolactone*

Fractions 376–510 yielded 4.83 g of a syrup which crystallized when nucleated with 2 mg of pure D-erythronolactone; 1.2 g of crystals melting at 85–95° separated. Recrystallization yielded 1 g of material whose neutralization equivalent, 117.4, melting point, 101–103°, and specific rotation, −72.9° (*c*, 4.57, water) agreed with accepted values (19, 32). A mixed melting point with an authentic sample was undepressed and the infrared spectra of both samples were identical.

D-*Glucuronic Acid*

The syrup, 0.322 g, from fractions 924–1105 was adsorbed on a microcolumn of "Dowex 1-X-4" anion-exchange resin (free base form), which was quickly eluted with water to remove any cations. Elution with 2 *N* acetic acid began immediately, and evaporation of the first 85 ml yielded 0.249 g of a syrup. Nucleation of this syrup with 0.3 mg of D-glucuronic acid caused the crystallization of 0.106 g of the crude material, which was isolated by pressing the partly crystalline mass between pads of filter paper. The material recovered from the paper was heated to convert it to the lactone, but the product could not be crystallized. The glucuronic acid, after recrystallization from aqueous ethanol, melted correctly at 154–155° and had the correct (33) equilibrium specific rotation in water, +35.6° (*c*, 2). The infrared spectrum was identical with that of pure D-glucuronic acid prepared from the crystalline lactone.

Glyoxylic Acid

Fractions 1301–1500 yielded 0.917 g of a syrup which when chromatographed on paper gave a yellow spot, R_F 0.61–0.70, with the *o*-aminodiphenyl spray, and a spot of R_F 0.66–0.74, with bromphenol blue. The behavior of authentic glyoxylic acid was

identical. The syrup gave 59% of the theoretical yield of yellow, crystalline, glyoxylic acid 2,4-dinitrophenylhydrazone melting with decomposition at 189–191°, in agreement with the recorded (4) value. Found: N, 22.1. Calc. for $C_8H_6N_4O_6$: N, 22.1%.

Mesotartaric Acid

The syrup, 1.226 g, from fractions 2176–2300 partly crystallized when nucleated with 0.3 mg of mesotartaric acid, and its R_F value, 0.61–0.70, when chromatographed on paper was identical with that observed for an authentic L-tartaric acid. Some of this syrup, 0.41 g, was neutralized to pH 8 with 0.345 *N* barium hydroxide, and 0.40 g of a crystalline barium salt separated. Found (after purification): Ba, 63.1%. Calc. for $BaC_4H_4O_6.H_2O$: Ba, 65.1; for $BaC_4H_4O_6.2H_2O$: Ba, 61.1%.

A portion, 0.206 g, of the above salt when deionized gave 0.100 g of the crystalline free acid which melted at 130–137°. These crystals were neutralized to pH 3.5 with 0.25 *N* potassium hydroxide; dilution of the liquor with 2 volumes of ethanol and the addition of 0.3 mg of monopotassium mesotartrate caused the crystallization of that substance. Yield, 0.082 g after purification by extraction with ethanol. Found: ash as carbonate, 36.5%. Calc. for $KC_4H_5O_6$: K_2CO_3, 36.7%. Upon recovery from this salt, the colorless crystals of the free acid were optically inactive and had the melting point, 139–140°, reported for pure mesotartaric acid (34).

DL- *and* D-*Tartaric Acid*

Fractions 2466–2600 yielded a mixture, of which 0.612 g crystallized and 0.48 g remained as syrup. After recrystallization from acetone, the crystals melted at 203–204° and their neutralization equivalent of 76.1 was close to that, 75, calculated for a tartaric acid. A 0.315-g sample of these crystals yielded 0.298 g of the white monopotassium salt which was then twice recrystallized from water. Found: ash as carbonate, 36.7%. Calc. for $KC_4H_5O_6$: K_2CO_3, 36.7%.

A part of this salt, 0.14 g, yielded 0.11 g of crystalline free acid melting with decomf position at 204° after recrystallization from tetrahydrofurane. The melting point o, DL-tartaric acid was 204–206° (35). As expected, the crystals were optically inactive and yielded a precipitate when an aqueous solution was diluted with a saturated aqueous solution of calcium sulphate. This test distinguished the racemic from the optically active forms of tartaric acid (36). The paper chromatographic flow rate of an aqueous solution of the crystals (Table I) was identical with that of authentic DL-tartaric acid, which was a streak of R_F 0.32–0.62 with reference to L-tartaric acid as standard.

Most of the syrup from the original crystallization, 0.41 g, was freed of any contaminating cations, and was converted as above to the monopotassium salt, a solution of which in 66% ethanol was seeded with a trace of monopotassium D-tartrate. The crystals which separated after 24 hours near 0°, 0.30 g, were washed in ethanol and twice recrystallized from hot water. Yield 0.29 g. Found: ash as carbonate, 36.9%. Calc. for $KC_4H_5O_6$: K_2CO_3, 36.7%. When a solution of this purified salt was freed from cations, the acidic effluent crystallized solidly; melting point, 168–170°, and specific rotation in water $-14.0\pm0.6°$ (*c*, 5.5). The melting point reported (35) for D-tartaric acid was 170°, and the specific rotation for *c*, 5.5, was calculated from Landolt's formula (37) as −14.3°. When chromatographed on paper, the flow rate of an aqueous solution of the crystals was identical with that of authentic L-tartaric acid.

Fractions 3516–3553

These fractions were evaporated to 15 ml, diluted with water, and evaporated several times to expel most of the trifluoroacetic acid. Continuous extraction of the final aqueous residue for a total of 17 hours with ether yielded 1.16 g of syrup, the first portion of which, 0.93 g, partly crystallized during isolation. An aqueous solution of these crystals, 0.21 g, was decolorized with absorbent carbon and was then evaporated over solid sodium hydroxide at 30-mm pressure. A control experiment showed that oxalic acid dihydrate was stable under these conditions, but became anhydrous when drying agents more powerful than sodium hydroxide were used. The residual, transparent crystals after recrystallization from hot water had the melting point, 100–101°, of oxalic acid dihydrate. A mixed melting point with an authentic sample was not depressed. A 16-mg sample reduced 9.74 ml of 0.026 *N* potassium permanganate, the value calculated for oxalic acid dihydrate being 9.73 ml.

The ether extract from which the oxalic acid had originally crystallized yielded 0.71 g of a syrup, 0.2 g of which was freed of any cations. When the concentrated, acidic effluent was neutralized with 0.044 *M* calcium hydroxide about 15 mg of calcium oxalate separated and was removed. Dilution of the concentrated filtrate with 2 volumes of ethanol precipitated 0.155 g of a calcium salt (A) and evaporation of the mother liquor yielded a further 0.087 g (B). Calcium salts (A) and (B) were separately freed from calcium ions and the acidic effluents were chromatographed on paper. At low concentrations the R_F values for authentic tartronic acid, acids A and B, were 0.30–0.34, 0.27–0.31, and 0.32–0.34, respectively; at higher concentrations the values were 0.30–0.47, 0.40–0.48, and 0.40–0.47. The similar variations in R_F with concentration made it probable, but failed to prove, that acids A and B consisted of tartronic acid. Acid A was adsorbed on a micro "Dowex-1-X-4" anion-exchange column, which was then eluted with *N* acetic acid before the product was recovered in 25% aqueous formic acid. The syrup from the effluent, however, failed to crystallize, either as such or when converted to the neutral potassium or calcium salts. Control experiments with authentic, crystalline tartronic acid showed that it was eluted readily from the above resin with formic acid, and readily yielded a crystalline potassium salt and a precipitate of calcium salt.

Examination of Fraction I

Five grams of the original, water-insoluble calcium salts was mechanically agitated for several hours in an excess of aqueous 5% acetic acid. The undissolved portion was re-extracted in the same way, was washed with water, and was dried. Yield 3.1 g or 62%. Found: ash as sulphate, 77.9%; or Ca, 22.9%. Calc. for $CaC_2O_4.H_2O$: Ca, 27.4%. A solution of this product in 40 ml of 20% hydrochloric acid was continuously extracted with ether for 14 hours, and evaporation of the extracts yielded 2.15 g of crude oxalic acid. Recrystallization from a little hot water left 2.08 g of the pure substance with the correct permanganate equivalent. The yield corresponded to 48.2% of calcium oxalate monohydrate in fraction I.

An acetic acid extract from another 5 g of fraction I was freed by an ion-exchange resin from calcium ions, and then from chloride ions by shaking with a slight excess of silver carbonate, the final filtrate being concentrated to dryness. A brittle glass remained; weight 0.67 g (5.1% of the starch) of which 69% passed through a cellophane membrane when dialyzed against water. A part of this glass was hydrolyzed and the sulphuric acid was precipitated as the barium salt. The filtrate when chromatographed on paper

yielded spots with R_F values corresponding to the substances noted in Table I, those for D-glucose, D-erythronic acid, and D-tartaric acid being most intense.

ACKNOWLEDGMENTS

The authors thank K. M. Gaver and the Ogilvie Flour Mills Company Limited for a gift of the purified wheat starch used. One of them (A.A.E.) also thanks the Gottesman Foundation of New York for the Fellowship held during the research. Analyses for inorganic carbonate, uronic acid, and pentosan were carried out in the Analytical Department of the Institute under the supervision of Mr. J. E. Tasman.

PHOTOOXIDATION OF AZOMETHANE

IV. THE ROLE OF FORMALDEHYDE[1]

M. SHAHIN[2] AND K. O. KUTSCHKE

ABSTRACT

The photooxidation of azomethane has been reinvestigated over a range of conversion extending to at least 7% at relatively high oxygen pressure and at 162° C. Kinetic and tracer (added $C^{13}H_2O$) studies support the view that the formaldehyde formed in the reaction can act as a source of the oxides of carbon. These were found to be enriched in C^{13} in the tracer work.

INTRODUCTION

One of the puzzling features of the mechanism of the photooxidation of azomethane (1) has been the nature of the product responsible for the self-inhibition (2, 3) of the reaction. Formaldehyde, nitrous oxide, and "excess nitrogen" (3) are produced at rates which decrease with the time of exposure. These products are thought (1, 3) to arise via the reactions

$$R + CH_3N_2CH_3 \rightarrow RH + CH_2{-}N_2CH_3, \quad [1]$$

$$CH_3N_2CH_2 + O_2 \rightarrow N_2O + CH_2O + CH_3, \quad [2]$$

$$\rightarrow N_2 + CH_2O + CH_3O, \quad [3]$$

where R is some radical in the system and [2] and [3] are written as over-all processes which might occur in stages. Provided methyl and methoxyl, or radical products of their reaction with oxygen, can function as R in [1], the elements of a chain reaction are present in the mechanism as appears to be required by the data (3).

It was recognized (2, 3) that when this chain was inhibited by some product, the inhibition mechanism must involve the production of carbon monoxide and, probably, of carbon dioxide. The mechanism suggested was a competition for the radicals R by the inhibiting substance, here designated by R'H.

$$R + R'H \rightarrow RH + R' \quad [4]$$

$$R' + O_2 \rightarrow CO + \text{other products} \quad [5]$$

$$\rightarrow CO_2 + \text{other products} \quad [6]$$

It is postulated that the "other products" do not propagate chains to any extent. Initially it was suggested that formaldehyde should be identified as R'H (2). While this suggestion led to a satisfactory qualitative explanation of the phenomenon, it was not compatible with later (3) quantitative data. Therefore another mechanism, which identified R'H with performic acid, was advanced.

The purpose of the present work was to obtain data confirming, or otherwise, the hypothesis that formaldehyde could not function as R'H. In addition to a purely kinetic approach, experiments were done in which formaldehyde-C^{13} was added to the reaction system. From a kinetic point of view the concentration of formaldehyde found at the end of an experiment, including that formed in the reaction, is indicative of whether or not formaldehyde was consumed in the reaction. If such consumption did indeed

[1]*Manuscript received August 2, 1960.*

occur, and if the mechanism of the consumption involves the inhibition mechanism [4], [5], and [6], the oxides of carbon found should be enriched in C^{13}.

EXPERIMENTAL

Apparatus

The vacuum apparatus, thermostatted air oven, and optical arrangements were essentially those used in an earlier investigation (3) with only minor modifications. The volume of the 5-cm diameter reaction cell was 180 cc, that of the complete reaction system, including the stirrer, 256 cc. All connecting tubing through which formaldehyde was required to pass could be heated to 140° C to prevent polymerization of that substance.

Materials

Azomethane (Merck of Canada, Montreal) was purified in the vacuum system in the usual manner (1, 2, 3). Gas chromatographic separation and estimation along with mass spectrometric identification of impurities revealed the presence in this sample of trimethyl hydrazine (<2%), methyl chloride (<0.1%), and methanol (<0.1%). The latter impurity was particularly objectionable in the experiments done at low conversions and, for these, it was removed by gas chromatography.

Oxygen was prepared by heating potassium permanganate and was separated from condensable impurities by passage through a trap at −196° C.

Formaldehyde-C^{13} (C^{13}/C^{12} = 20.4%) was obtained as required by heating a sample of enriched α-polyoxymethylene supplied by Dr. L. C. Leitch of these laboratories.

The trisodium salt of chromatropic acid (4,5-dihydroxy-2,7-naphthalene disulphonic acid, trisodium salt) used in the analysis of formaldehyde was prepared by titration of an aqueous solution (15%) of chromatropic acid disodium salt (Eastman Kodak) with a solution of sodium hydroxide (3%) to pH 7 as measured on a pH-meter. The salt was purified by fractional precipitation (3) and the beige-colored crystals were kept in dark bottles.

Procedure

Aside from minor details most operations in an experiment were done as described previously (3).

For the experiments with added formaldehyde-C^{13}, several break-seal bulbs, whose volumes were known, were filled from a manifold at one time using the filling technique developed earlier (3). The formaldehyde content of one bulb was determined and that of each of the others was calculated from the known volumes. Mixtures of azomethane, formaldehyde, and oxygen were prepared in the reaction system as described before (3).

Analysis of Products

After an exposure the products were condensed at −196° C in a U tube and the noncondensable gases (O_2, N_2, CO) were collected and analyzed over a hot mixture of copper and cupric oxide (1). Carbon dioxide and nitrous oxide were separated from a Le Roy still (4) at −160° C and analyzed by mass spectrometry. Small quantities of formaldehyde, methyl chloride (present as an impurity), and azomethane always appeared in this fraction and prevented accurate estimation of the major components. Some uncertainty is also introduced into the C^{13}/C^{12} ratio of the carbon dioxide because of the effects of these impurities.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Formaldehyde was separated from the remaining liquid products by a single passage through a Le Roy still held at −130° C and condensed onto a frozen solution of the trisodium salt of chromatropic acid held at −196° C. All connecting tubing accessible to the formaldehyde vapor was held at 140° C. Procedures developed earlier (3) were followed in detail for the remaining steps in this modification of the chromatropic acid method (5). The liquid products were collected and analyzed for methanol by gas chromatography in a column developed by Blake and Kutschke (6) (25% dinonyl phthalate and 5% glycerol on Fischer Columpak; 29° C; H_2 flow rate, 45 cc/min). Peak areas were compared with those of standard samples.

RESULTS

Table I gives the data from several experiments at 162° C. The conditions were maintained as closely as possible to the earlier work (3). Oxygen concentration was sufficiently high to suppress completely the formation of methane and ethane. The trend of the

yields with time is shown in Fig. 1 in which quantum yields of a product, defined as the ratio of the amount of a product formed per unit time to that of nitrogen formed in the absence of oxygen with otherwise identical conditions, are plotted as a function of conversion. The latter corresponds to D_1 of reference 2 and is calculated with the assumptions that (*a*) each molecule of azomethane which disappears gives rise to a molecule of nitrogen or of nitrous oxide, and that (*b*) the stirring was completely efficient. Aside from that of methanol and formaldehyde the general forms of the curves in Fig. 1 agree with those obtained earlier (2, 3).

Results from experiments with added formaldehyde-C^{13} are given in Table II. The amount of formaldehyde added corresponded to a concentration about twice as great as that found after long experiments without added formaldehyde. Figure 2 shows that the concentration of formaldehyde rapidly adjusts to that same, approximately steady,

concentration and thereafter remains unchanged. The yields of carbon monoxide obtained from experiments of low conversion were much greater in the presence of added formaldehyde than in its absence. This is shown in Fig. 3 as a plot of the absolute amounts of carbon monoxide formed at various times for the two sets of conditions. The slope of the curve (Fig. 3, open circles) obtained in the presence of formaldehyde becomes constant at about the degree of conversion at which the formaldehyde concentration reaches its approximately steady value (Fig. 2).

The last two columns of Table II present the data on the isotopic composition of the oxides of carbon found. There is little doubt that these compounds are enriched in C^{13}. Mixtures of formaldehyde-C^{13} and carbon monoxide were carried through the procedure of an experiment in the absence of ultraviolet illumination. On analysis no detectable enrichment was observed in the carbon monoxide.

DISCUSSION

This report is concerned only with the reaction at 162° C with conditions used in earlier investigations (1, 2, 3) and is confined largely to the discussion of the likelihood that formaldehyde can inhibit the reaction under these conditions. Moreover, the discussion is limited to the region of conversion greater than about 1%. At lower conversions, reproducible data are very difficult to obtain.

In an earlier communication (3) several arguments were offered to refute the hypothesis that formaldehyde could participate in the inhibition mechanism. These were of two types: kinetic, which discussed the shape of the yield vs. time curves, and isotopic, which involved the results of a photooxidation experiment done in the presence of formaldehyde enriched in oxygen-18.

In considering the kinetic arguments it must be borne in mind that, to a precision of about 10–15%, good agreement between this and the earlier study is found in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

yield vs. time curves of many of the products. This agreement is excellent in the curves for total nitrogen, carbon monoxide, nitrous oxide and, with somewhat less precision, for secondary nitrogen and carbon dioxide. Analogous curves for formaldehyde and methanol yields differ significantly.

The present data indicate quite definitely that formaldehyde concentration does indeed approach a stationary value with time. The earlier data, covering a somewhat smaller range of conversion, did not exhibit such a limit although the existence of such a limit is not incompatible with those data. For some reason as yet unknown the limiting concentration, or possible limiting concentration in the case of the earlier work, found in the two sets of data differ by a factor of about two as does the time (or conversion) required to attain that limit. The excellent agreement between the yields of other products, especially those of carbon monoxide, indicate that the two sets of data were taken under very similar conditions. The only possible explanations involve either an unknown systematic error in one or the other analytical techniques (which were virtually identical) or a difference in surface characteristics causing this specific effect. At present no choice is possible between these alternatives.

More extensive data are presented here concerning the effect of added formaldehyde on the yields of some products. In particular, Fig. 2 shows that formaldehyde is not inert in the system as was required by the mechanism suggested earlier (3).

That the consumption of formaldehyde is accompanied by the production of carbon monoxide is indicated by the enhanced rate of production of that product when excess formaldehyde is present initially (Fig. 3). After formaldehyde has been depleted to approximately its stationary value (i.e. about 0.5% conversion, Fig. 2), the yield–time curve for the formation of carbon monoxide is not inconsistent with a rate of production similar to that found in the absence of added formaldehyde (Fig. 3).

The C^{13} experiments (Table II) also indicate that carbon monoxide can be formed in this system from a formaldehyde intermediate. In addition it is clear that carbon dioxide also can arise from the same intermediate (values of the absolute yield of nitrous oxide and of carbon dioxide were not measured in these experiments). While these conclusions disagree with those reached on the basis of the O^{18} work reported earlier (3) the relative insensitivity of the present technique to errors caused by possible exchange over the hot copper oxide suggest that they are the more reliable. The value of the C^{13}/C^{12} ratio found in the oxides of carbon are lower than that of the added formaldehyde. This implies that some compound, presumably formaldehyde, which is produced in the system also acts as a precursor to the oxides of carbon.

It may be concluded from the present data that formaldehyde is not inert in this photooxidation system and that the oxides of carbon can be formed from the reactions of this compound.

If equations [5] and [6] represent the major sources of the oxides of carbon, then $R_{CO}/R_{CO_2} = k_5/k_6$. The data from 15 minutes to 55 minutes yield a value $k_5/k_6 = 3.7 \pm 0.1$, a value which is somewhat lower than that ($\sim$5) which can be deduced from similar data in the earlier work (3). A detailed mechanism has been suggested (7) for these reactions which involves the formation of HCO_3 radicals followed by isomerization to O=COOH and decomposition either to carbon monoxide and HO_2 radical or to carbon dioxide and an hydroxyl radical.

If, in addition to the assumption above, it is also valid to assume (*a*) that nitrous oxide and secondary nitrogen arise only from [2] and [3], and (*b*) that [2] and [3] represent the sole fates of $CH_2N_2CH_3$ radicals formed in [1], and [5] and [6] the sole fates of formyl

radicals formed in [4], then it follows that $(R_{CO}+R_{CO_2})[A]/\{(R_{N_2})_{secondary}+R_{N_2O}\}[F] = k_1/k_4$. Calculations based on the data of Table I give $k_1/k_4 = 212\pm10$ with no obvious trend with conversion. If A_1/A_4 is taken as unity approximately, this calculation indicates that $E_1 = E_4 = 4$–5 kcal/mole. Since it has not been established that the radical R in [1] and [4] is a single species (probably OH, HO_2, CH_3O, and CH_3O_2 enter into these reactions at various rates), the value calculated cannot be ascribed to a single reaction. However, it might be noted that the difference obtained is relatively large compared with the difference E_1-E_4 when R is a methyl radical. This latter difference has been reported as 2.2 kcal/mole (8).

Brief mention should be made at this point of the shape of the curve of the quantum yield of methanol as a function of conversion (Fig. 1). Analytical uncertainties are rather large in the low-conversion region and rigorous attention had to be paid to the purity of the reactants. The combination of these two factors renders the determination of quantum yields in this region highly imprecise. On the basis of the present data it is impossible to decide whether Φ_{CH_3OH} approaches unity or zero at these conversions (Fig. 1). While of obviously considerable significance, possible explanations of either extrapolation are closely associated with the mechanism of formation of methyl hydroperoxide recently found to be a product in this system (9). Detailed consideration of these points will be presented at a later time.

ACKNOWLEDGMENTS

The authors wish to thank Dr. E. W. R. Steacie for his interest and advice during the course of this work. They are also indebted to Mrs. R. H. Riem for the mass spectrometric analyses.

THE PREPARATION AND SOME PROPERTIES OF GERMANIUM DIFLUORIDE[1]

NEIL BARTLETT AND K. C. YU

ABSTRACT

Germanium difluoride can be prepared by the reduction of germanium tetrafluoride with germanium metal. It is a white solid, m.p. 110°, and is orthorhombic, $a = 8.30$, $b = 5.17$, $c = 4.67$ Å. It possesses strong reducing properties.

INTRODUCTION

Evidence for the existence of germanium difluoride was noted by Winkler (1), who heated potassium fluorogermanate in a stream of hydrogen and obtained a dark-colored mass, an aqueous extract of which yielded germanous sulphide with hydrogen sulphide. The only other description of a difluoride of germanium is that given by Dennis and Laubengayer (2) and it is their findings which are widely quoted. They characterized the fluoride as a white, sublimable, hygroscopic solid which disproportionated on heating. An aqueous solution of it possessed the reducing properties of divalent germanium but the identity of the solid was not established by analysis.

We have prepared material similar to the latter and have proved it to be germanium difluoride. Some of the physical and chemical properties of the compound have also been examined.

DISCUSSION AND RESULTS

Dennis and Laubengayer prepared the difluoride by passing the gaseous tetrafluoride, produced by the pyrolysis of barium hexafluorogermanate, over powdered germanium, above 100°. We repeated this procedure and undoubtedly germanium difluoride was formed, but on no occasion was a sufficiently large or pure sample secured for analysis. The difluoride prepared in this way could not be transferred by distillation nor by pouring of the melt, without extensive interaction with the glass and disproportionation. These difficulties were associated with the presence of impurities, including water and hydrogen fluoride, as was manifest from the etching of the glass apparatus and may account for the delay in substantiating the earlier reports of the difluoride.

When germanium tetrafluoride was used which had been prepared by the direct fluorination of germanium metal, under strictly anhydrous conditions, the reduction proceeded smoothly and extensively in the temperature range 150–300° and in this way gram samples of the compound could be prepared and transferred without decomposition.

The stoichiometry, GeF_2, was established by germanium and fluorine analysis and the divalency was confirmed by iodine titration.

The white solid, m.p. 110°, distills without decomposition *in vacuo* at temperatures slightly above the fusion point. At higher temperatures disproportionation begins, as indicated by the appearance of an orange-red solid together with the concurrent evolution of germanium tetrafluoride. With some samples the temperature of decomposition was above 160° but since the decomposition is evidently catalyzed by impurities it is possible that more thermally stable material than this can be made. As the temperature is raised the orange-red product becomes red-brown and finally black, the last being associated

[1]*Manuscript received August 18, 1960.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver, British Columbia.

with the presence of germanium metal. This behavior resembles that of germanium dichloride and it is probable that the orange-red intermediate is a polymeric subfluoride $(GeF)_x$, since a similar material $(GeCl)_x$ has been reported as arising from the thermal decomposition of the dichloride (3, 4).

In ordinary moist air the difluoride deliquesces and on prolonged exposure orange germanous hydroxide separates. A mild exothermic hydrolysis occurs with water and the hydroxide precipitates. The fluoride is, however, totally soluble in 48% hydrofluoric acid and this solution has reducing properties, silver being deposited in the cold from a silver nitrate solution. The fluoride also dissolves in ethanol and forms an etherate with diethyl ether, but is insoluble in carbon tetrachloride.

The reducing properties expected to be associated with divalent germanium have been illustrated in several reactions.

Selenium tetrafluoride is reduced to selenium by the difluoride, which is oxidized to the tetrafluoride. The germanium tetrafluoride combines with excess selenium tetrafluoride to give the crystalline solid, fluoroselenonium hexafluorogermanate. The sequence of reactions is

$$2GeF_2 + SeF_4 = 2GeF_4 + Se,$$
$$GeF_4 + 2SeF_4 = (SeF_4)_2GeF_4.$$

The latter material, which will be an acid in the solvent selenium tetrafluoride, is isostructural with the acids $(SeF_4)_2PtF_4$ and $(SeF_4)_2PdF_4$, prepared recently in this laboratory. Details of these and other fluoroselenonium compounds will be given in a forthcoming communication.

The α form of sulphur trioxide is reduced explosively by the difluoride, when the mixture is warmed, the reaction probably being

$$GeF_2 + SO_3 = GeOF_2 + SO_2.$$

Liquid chlorine combines rapidly with the difluoride to produce a mixture containing germanium tetrafluoride, germanium tetrachloride, and chlorofluorides of germanium. The failure to prepare pure germanium dichlorodifluoride is in agreement with the observation of Booth and Morris (5) that this compound changes to a mixture of the tetrafluoride and the tetrachloride. The reaction sequence is probably

$$GeF_2 + Cl_2 = GeF_2Cl_2,$$
$$3GeF_2Cl_2 = 2GeF_3Cl + GeCl_4,$$
$$4GeF_3Cl = 3GeF_4 + GeCl_4.$$

Iodine in ether solution reacts with the difluoride to give germanium tetraiodide,

$$2GeF_2 + 2I_2 = GeF_4 + GeI_4.$$

It would appear that germanium difluoride will be a useful reducing agent for the preparation of lower fluorides of the transition metals and certain aspects of this work are in hand.

Germanium difluoride, like its congeners arsenic trifluoride and selenium tetrafluoride, possesses a nonbonding valence electron pair. The steric effect of the nonbonding electron pair is evident in the molecular structure of both arsenic trifluoride (6) and selenium tetrafluoride (7). A similar steric influence is evidently responsible for the absence in the difluoride of the hexagonal (low quartz) and tetragonal (rutile) arrangements found (8, 9) in the two forms of germanium dioxide. These require, respectively, regular tetrahedral and octahedral co-ordination of the germanium atom. The X-ray powder pattern

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of the difluoride was indexed on the basis of an orthorhombic unit cell $a = 8.30$, $b = 5.17$, $c = 4.67$ Å. As there are no systematic absences of general *hkl* reflections the cell must be primitive. A density measurement shows that it contains four molecules.

In view of the low melting point and the volatility of the compound it is probable that a pseudotetrahedral co-ordination of the germanium atom with three fluorine atoms and a nonbonding electron pair would be more likely than an approximate hexaco-ordination. A pseudotetrahedral arrangement would result in a selenium dioxide type of structure (10) with the pseudo tetrahedron sharing fluorine atoms to form chains. It is perhaps not without significance that the cell dimensions $a = 8.35$, $c = 5.05$ Å (10) of the tetragonal unit cell of selenium dioxide are very similar to two of the dimensions of the germanium difluoride unit cell.

EXPERIMENTAL

Apparatus and Techniques

Pyrex glass apparatus was used in the various experiments and when silica was incorporated it was joined to the glass by graded seals.

Progressive hydrolysis of the fluorides and etching of the apparatus was avoided by rigidly excluding water. All glassware was heated strongly under vacuum with a luminous flame and in those experiments conducted at atmospheric pressure, ingress of moisture was prevented by using U traps immersed in liquid oxygen.

The Preparation of Germanium Tetrafluoride

The tetrafluoride was made by the fluorination of germanium metal (arsenic content 0.05 p.p.m., as supplied by Johnson, Matthey & Co. Ltd.) contained in a shallow bed in a 12-mm clear silica tube joined to a train of collecting traps, each one of which was provided with a break seal. Fluorine, diluted with nitrogen, was passed and the combustion of the germanium, which burned with a blue-green flame, was initiated with the heat from a small flame.

Apart from germanium tetrafluoride, silicon tetrafluoride was also formed, the latter arising from interaction of fluorine with the container and both products were collected at liquid oxygen temperature. By allowing the traps to warm to about $-90°$, most of the silicon fluoride was removed in the nitrogen stream used to purge the apparatus of fluorine. Each trap was sealed under vacuum, after recooling to liquid oxygen temperature, and was kept at $-180°$ until required.

The Reduction of Germanium Tetrafluoride

The most satisfactory preparation of the difluoride used lump germanium metal of the same quality as that employed above. The pieces of metal were approximately 4–5 mm in diameter and were arranged along the bottom of a 12-mm glass tube, at each end of which was joined a pair of traps. A side arm, provided with a break seal to collect the product, was situated beyond the metal and the reduction was carried out with the tetrafluoride streaming over the metal towards the side arm. In this way the product collected in the neighborhood of the side arm and was readily melted into it.

Germanium tetrafluoride, from the storage break-seal bottles, was transferred under vacuum into the appropriate set of traps, whence it was slowly passed to the second set beyond the germanium metal and the collecting side arm. With the tetrafluoride passing in this direction, reduction was affected by heating the metal with a very small flame, to maintain the temperature in the range 150–300°. The difluoride collected on the cooler glass as a colorless liquid which rapidly crystallized. Unchanged tetrafluoride condensed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in the second set of traps, cooled in liquid nitrogen. When this transference was complete, the germanium was cooled and the tetrafluoride retransferred to the first set of traps, prior to continuation of the reduction of the gas. Since the reduction took place slowly, 10 or more passings of the tetrafluoride over the metal were usually necessary to make a 1- to 2-g sample.

Attempts to improve the speed and efficiency of the reduction were abandoned when it was found that finely powdered germanium metal transferred in the gas streams and contaminated the product, which disproportionated to or was reduced to an orange product, in the presence of the metal.

When germanium tetrafluoride was used, as prepared by the pyrolysis at 600–700°, of barium hexafluogermanate contained in a silica bulb joined to an apparatus similar to that described above, the germanium metal became inactive after the formation of only small quantities of difluoride. These samples disproportionated at lower temperatures than the more pure material and the evidence of etching indicated that hydrogen fluoride, presumably arising from impure barium fluorogermanate, was responsible for this behavior. Drying of the barium salt at 200° *in vacuo* did not overcome these difficulties.

The difluoride melted at 110° and could be distilled *in vacuo* at 130°. Disproportionation, indicated by gas evolution and the appearance of a solid orange phase, began in some samples above 160°, the color of the product changing to orange-red to red-brown to black, as the temperature rose to 200°. The decomposition temperature was, however, markedly dependent upon the purity of the material and one sample showed only slight decomposition at 180°.

Analysis: A 2-g sample of the fluoride was dissolved in a mixture of ammonium hydroxide and hydrogen peroxide, the solution being subsequently boiled to destroy excess of the latter. Aliquots were taken for fluorine and germanium estimation. Fluorine was determined as lead chlorofluoride in the fluosilicic acid, hydrofluoric acid distillate produced by distilling the solution with sulphuric acid at 132–138°. The purity of the lead chlorofluoride was checked by determination of chlorine as silver chloride. Germanium was estimated as magnesium orthogermanate (11). Found: Ge, 65.6; F, 34.8%. GeF_2 requires: Ge, 65.6; F, 34.4%. A second sample was dissolved in dilute sulphuric acid and was titrated against $N/10$ iodine solution. One mole required 1.92 equivalents of iodine.

X-Ray powder photograph.—A 0.5-mm Pyrex capillary was charged with the finely powdered difluoride, the dry-box technique being employed. Photographs were taken using a 14.32-cm camera and Cu-K_α radiation in conjunction with a nickel filter. See Table I for the X-ray data.

Behavior with Miscellaneous Solvents

Water.—The difluoride was instantly hydrolized in a mild exothermic reaction. The initial yellow precipitate of germanous hydroxide rapidly turned orange. The filtrate decolorized permanganate and precipitated silver from a nitrate solution.

48% Hydrofluoric acid.—The fluoride was completely soluble in the acid and the solution possessed the reducing properties of the aqueous extract.

Ethanol.—The fluoride dissolved readily in the anhydrous solvent.

Diethyl ether.—The fluoride dissolved in dry ether but a white solid crystallized slowly from this solution. Evaporation of the ether *in vacuo* led to the breakdown of this solid, leaving what appeared to be germanium difluoride. The etherate was not investigated further.

Carbon tetrachloride.—A small particle of the difluoride remained undissolved by approximately 20 cc of the tetrachloride.

The Determination of the Density of the Solid

A 2-ml-capacity density bottle, provided with a ground-glass cap, was loaded in a dry box. All weighings were made with the bottle and its contents at 23°. Carbon tetrachloride was employed as the displacement fluid. $d_{23°} = 3.7$ g/cc.

With four molecules per unit cell ($a = 5.17$, $b = 4.67$, $c = 8.30$ Å), $d_{calc} = 3.66$ g/cc.

The Reaction of Germanium Difluoride with Selenium Tetrafluoride

Selenium tetrafluoride prepared as described by Aynsley, Peacock, and Robinson (12) was transferred by vacuum distillation to a bulb at −180°, situated beneath an upturned break-seal bottle containing a sample of the difluoride. This sample was melted down on to the excess of selenium tetrafluoride. The difluoride dissolved in the selenium fluoride when the mixture was warmed to 20°. Green colloidal selenium was produced almost immediately and this rapidly transformed to red selenium. As the reaction proceeded a white solid also crystallized from the solution. When the reaction was judged to be complete the excess of selenium tetrafluoride was removed by vacuum distillation and a residue of red selenium and a white solid remained. The latter sublimed at ca. 100° (1 atm).

An X-ray powder photograph of the residual mixture was taken, in the manner described.

The Preparation of $(SeF_4)_2GeF_4$

An excess of germanium tetrafluoride was mixed with selenium tetrafluoride at atmospheric pressure. A white solid formed immediately. The excess of germanium tetrafluoride was removed under vacuum at 0°. This solid sublimed at ca. 100° (1 atm). An X-ray powder photograph of the solid was taken and the pattern was found to conform with the major pattern of the residue from the selenium tetrafluoride – germanium difluoride reaction.

Analysis: A weighed sample was dissolved in sodium carbonate solution and aliquots were analyzed for selenium, which was determined as the element by reduction with sulphurous acid in strong hydrochloric acid solution, and fluorine which was determined as previously described. Found: Se, 34.4; F, 51.0%. $(SeF_4)_2GeF_4$ requires: Se, 34.5; F, 49.7%.

Germanium Difluoride with α-Sulphur Trioxide

Liquid sulphur trioxide was prepared by the distillation of 60% oleum with phosphorus pentoxide, followed by a second distillation from phosphorus pentoxide. The apparatus used for this preparation was rigorously dried and ingress of moisture was prevented by three U traps, in series, at −180°. A sample of the trioxide was distilled under vacuum into a break-seal bottle cooled in ice.

A break-seal bottle (cooled in ice) containing a sample of germanium difluoride was opened and sulphur trioxide was distilled into it, under vacuum. The apparatus was opened to the air via a series of U traps immersed in liquid oxygen and the mixture was allowed to warm to room temperature. The difluoride did not dissolve noticeably in the liquid trioxide up to 25° and when the mixture was warmed there was an explosion which destroyed the containing bottle.

Germanium Difluoride with Chlorine

Chlorine was melted on to a 0.5-g sample of the difluoride. The immediate and vigorous reaction, which followed, was moderated by cooling with liquid oxygen. On completion of the reaction, excess chlorine was removed from the mixture under vacuum at −78° and a colorless liquid remained. A gas, which condensed to a white solid was removed with the chlorine. This solid resembled germanium tetrafluoride.

The colorless liquid which had a vapor pressure of 20 cm at 24° transferred rapidly and completely in a vacuum, at room temperature. Anal. Found: mol. wt., 197. Calc.: mol. wt. GeF_2Cl_2, 181.6; mol. wt. $GeFCl_3$, 198.1; $GeCl_4$, 214.6.

Infrared spectra of successive fractions of the vapor showed a strong absorption band at 740 cm^{-1}, indicative of Ge—F stretching. There was no band at 800 cm^{-1}, which is the location for a strong germanium tetrafluoride absorption band (13). A small peak at 1050 cm^{-1} showed silicon tetrafluoride (arising from fluoride attack on the glass apparatus) to be present in low concentration.

A gravimetric analysis for chlorine as silver chloride was made on the least volatile fraction of the liquid. Found: Cl, 60.8%. Calc. for $GeCl_4$: Cl, 66.4%; for $GeFCl_3$: Cl, 53.7%. Although both GeF_2Cl_2, b.p. −2.8° (5), and $GeFCl_3$, b.p. 37.5° (5), are probably present, it is not possible at this time to say which of the chlorofluorides predominates in the mixture with germanium tetrachloride.

Germanium Difluoride with Iodine

A solution of iodine in ether was added to a suspension of germanium difluoride in ether, until the iodine color persisted. Evaporation of the ether under vacuum left an

orange residue. This was washed with a small quantity of ether and was dried in a vacuum. It was identified as germanium tetraiodide, m.p. 146°, literature value 146° (14).

THE DECOMPOSITION OF METHANE IN THE NEGATIVE GLOW[1]

A. W. TICKNER

ABSTRACT

The decomposition of methane was studied in the negative glow of a d-c. discharge at pressures of 0.30 and 0.050 mm. The discharge tube was cooled by liquid or solid nitrogen.

The main products were ethane, ethylene, and acetylene in addition to hydrogen and a nonvolatile product which appeared mainly on the cathode as a solid having the formula $(CH)_n$. Smaller amounts of propane, propene, propyne, butane, butene, butadiene, and pentene were also found. Lowering the temperature of the discharge tube from −196° to −210° C greatly increased the amount of ethylene recovered.

The solid product is apparently transported to the cathode in the form of ions and may result from ionic polymerization of the acetylene. Acetylene is the volatile product formed closest to the cathode which suggests that it may also be formed by ionic processes. The formation of the remaining products is consistent with an excitation mechanism in which the C_2 products are formed first and the higher hydrocarbons are formed from them.

INTRODUCTION

The decomposition of methane in the glow discharge has been studied for many years; the early work is summarized in reference 1. More recently, Yeddanapalli (2) studied the decomposition of methane in a d-c. glow discharge using a discharge tube cooled in liquid air. He worked at pressures of a few millimeters and found that the products consisted of ethane, ethylene, and acetylene as well as hydrogen and a nonvolatile product having the formula $(CH_2)_n$. Wiener and Burton (3), using a d-c. glow discharge at atmospheric pressure, showed that under conditions of high conversion and relatively high temperature the only significant products were acetylene, hydrogen, and carbon. McCarthy (4) found that, in addition to acetylene, ethylene and ethane were obtained as products when the gas from a microwave discharge in methane was allowed to impinge directly on a wall cooled by liquid nitrogen.

The low-pressure d-c. glow discharge is suitable for investigations of this type because it permits studying the decomposition in a number of different discharge regions for which the electrical processes are reasonably well understood (5, 6). In addition, the vapor pressures of methane and its decomposition products are such that most of the products can be removed rapidly from the reaction by freezing them out on the discharge tube wall. There is thus the possibility of obtaining direct information about the primary products of the decomposition. This approach was used by Yeddanapalli (2), whose work, however, had two main weaknesses: (*a*) at the temperature of liquid air the vapor pressure of ethylene is sufficiently high that much of it would have remained in the gas phase, and (*b*) his method of analysis was such that the products were determined as acetylene and ethylene with the remainder assumed to be ethane. Any higher hydrocarbons which might have been formed would thus not have been detected.

The negative glow was chosen as a suitable region with which to begin a study of the decomposition of methane in the electric discharge. It was known to be a region of great chemical activity which could be to a considerable degree operated independently of other discharge regions. The experiments reported here were intended primarily to clarify the work of Yeddanapalli and to serve as a basis for a more detailed study of the discharge decomposition. In order to recover the first products more completely, temperatures lower than those in the earlier work have been used. The use of a direct pumping system

[1]*Manuscript received August 17, 1960.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 6063.

instead of the circulating system previously employed (2) enabled the experiments to be carried out at constant pressure and reduced the residence time in the discharge zone.

EXPERIMENTAL

The experiments were carried out in the apparatus shown diagrammatically in Fig. 1. It consisted of a jacketed discharge tube with a fixed cathode and an anode which could be moved by a rack and gear as shown. The discharge tube diameter of 3.4 cm was

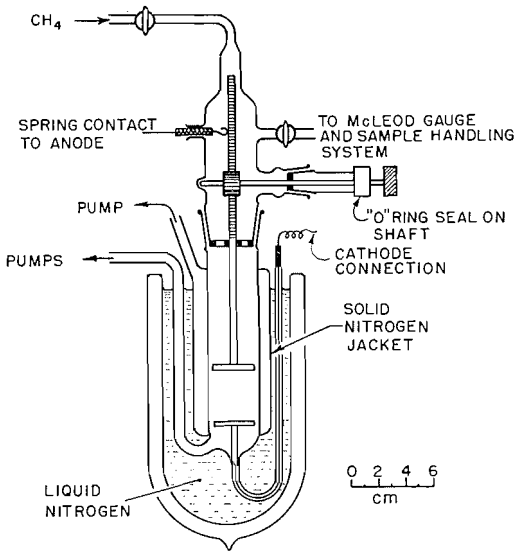

FIG. 1. Discharge tube.

chosen as a reasonable compromise between the requirements for efficient trapping of products (small diameter) and ideal glow discharge conditions (large diameter). The electrodes were 3.0 cm in diameter and were made of stainless steel. A mercury diffusion pump with a pumping speed of 10 liters per second and a forepump allowed the system to be evacuated to pressures of less than 10^{-5} mm of mercury. The residence time in the discharge zone with the electrodes placed to include the entire negative glow was 0.05 second for a discharge pressure of 0.3 mm and 0.5 second for a discharge pressure of 0.05 mm. Pressures were measured by a small McLeod gauge.

A variable voltage d-c. power supply having a ripple of less than 0.1 volt supplied power to the discharge through a 10,000-ohm series resistor. The discharge current was controlled manually.

The discharge tube was cooled by filling the jacket with liquid nitrogen and pumping on it until the nitrogen solidified. By controlling the pumping speed it was possible to maintain a constant pressure over the nitrogen in the jacket and thus to maintain a constant discharge tube wall temperature for a period of about 15 minutes. Temperatures down to $-220°$ C could be obtained in this way. The temperature of the discharge tube wall was determined by measuring the vapor pressure of methane corresponding to a given jacket pressure and comparing this with the vapor pressure of methane as given by Ziegler (7).

The methane used was Matheson C.P. grade; it was purified by fractional distillation

before admitting it to the storage reservoir. Its flow rate was controlled by a needle valve and it was admitted through a trap maintained at either the temperature of liquid nitrogen or the triple point of nitrogen depending upon the methane pressure being used. When necessary a correction was made for the small amount of ethane which was found to be present in blank runs.

The lengths of the negative glow and cathode dark space were determined by measuring the voltage drop across the discharge for various electrode spacings at constant discharge current (5). For the purpose of this work the length of the cathode dark space was taken as equal to the electrode spacing at which the voltage began to rise steeply when the anode was being moved towards the cathode. The anode end of the negative glow was taken as equal to the electrode spacing at which the voltage began to increase when the anode was being moved away from the cathode.

The experiments were performed by cooling the discharge tube to the required temperature, establishing the methane flow, and operating the discharge for a suitable period which in practice varied from 3 to 12 minutes. After the discharge was turned off, the discharge tube was pumped briefly to a low pressure, isolated, and warmed to room temperature. The volatile products were then transferred to a gas burette for measurement and analyzed on a mass spectrometer. The carbon content of the nonvolatile discharge product was determined by oxidizing it *in situ* with an oxygen discharge and measuring the carbon dioxide produced. The method has been described previously (8).

RESULTS

Preliminary experiments demonstrated that the amount of ethylene recovered at about 1% methane decomposition increased nearly 10-fold when the discharge tube temperature was lowered from that of liquid nitrogen (−196° C) to the triple point of nitrogen (−210° C). The amount of ethane recovered also increased by about one-third and some of the higher products, especially propene and butene, decreased in amount. Extrapolation of the existing vapor pressure data for ethylene and ethane (7) indicates that their vapor pressures are less than 10^{-6} mm at −210° C. Thus, the recovery of these products should be practically quantitative at this temperature, assuming equilibrium at the wall.

In several experiments at approximately 2% methane decomposition the gas downstream from the discharge was sampled and analyzed on a mass spectrometer. In each case the amount of hydrogen found agreed, within the accuracy of the analysis, with that calculated on the basis of the products formed.

The variation of the products with discharge current was studied in a series of experiments at a pressure of 0.30 mm, which is the vapor pressure of methane at −210° C. The electrode spacing used was 3.0 cm, equal to the length of the negative glow at this pressure. The results are shown in Fig. 2. The amount of methane decomposed was calculated from the composition of the products; the percentage decomposition was 0.5% for a current of 1 ma. Values shown for the nonvolatile product give its carbon content in gram-atoms. In these experiments the voltage drop across the discharge increased from 330 volts for a current of 1 ma to 390 volts for a current of 4.5 ma.

A pressure of 0.05 mm was chosen as a convenient one for most of the experiments. The choice of a lower pressure made control of the wall temperature less critical and reduced the number of collisions undergone by product molecules in diffusing to the cold wall. In addition, the increased lengths of the cathode dark space and the negative

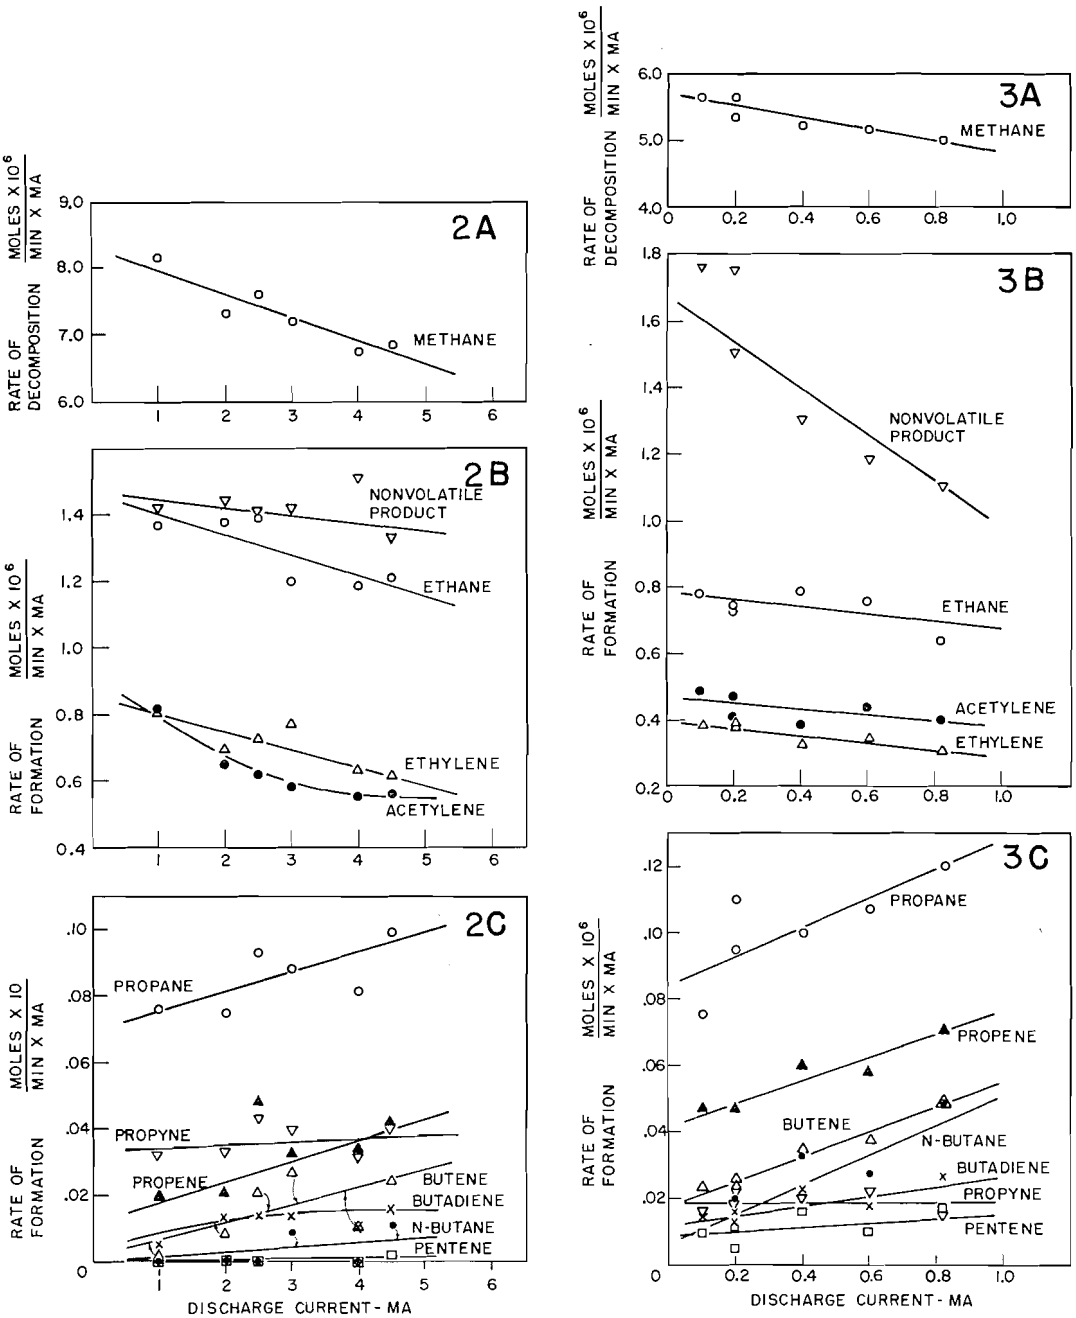

FIG. 2. Effect of discharge current on the decomposition of methane in the negative glow at −210° C. Methane pressure, 0.30 mm. Electrode spacing, 3.0 cm.

FIG. 3. Effect of discharge current on the decomposition of methane in the negative glow at 0.050-mm pressure. Electrode spacing, 10 cm. Temperature, −213° C.

glow made it easier to detect any variation in the products along the discharge. A wall temperature of about −213° C was used in experiments at this pressure.

The effect of discharge current on the rates of formation of the products at a pressure of 0.050 mm is shown in Fig. 3. An electrode spacing of 10 cm was used, corresponding to the length of the negative glow at this pressure. A discharge current of 0.10 ma corresponded to 0.6% decomposition of the methane. The discharge voltage increased from 385 volts for a current of 0.10 ma to 750 volts for a current of 0.82 ma.

Hydrogen was the only product whose effect on the reaction could be conveniently tested. Figure 4 gives the results of a series of experiments in which hydrogen was added to the methane to give mixtures having total hydrogen contents of up to 20 mole%. The hydrogen formed in the decomposition was taken into account in calculating the compositions of the mixtures.

The distribution of products along the negative glow was studied in another series of experiments in which the electrode spacing was varied. The results are shown in Fig. 5. As the anode was moved towards the cathode the negative glow was eliminated progressively from the anode end. This appeared to have little effect on the operation of the discharge until the edge of the cathode dark space was reached at an electrode spacing of about 1.8 cm. In order to make the experiments comparable over as wide a range as possible a discharge current of 0.50 ma was chosen; lower currents could not be maintained at the smallest electrode spacings used.

The nonvolatile product which formed in the discharge experiments was visible only as a solid deposit on the cathode. This deposit appeared to be a continuous film and interference colors showed it to be of uniform thickness over the area of the electrode covered. In one of the experiments at a pressure of 0.05 mm a flat Pyrex disk having a diameter of 4 mm and a thickness of 0.025 mm was placed on the surface of the cathode. Although a uniform and readily visible deposit was formed on the cathode all around the disk, and extending up to the edge of it, no deposit was visible on the disk itself. It appeared therefore that the deposit was formed only on that part of the cathode which was bombarded by incoming ions.

In order to obtain enough of the cathode deposit for a chemical analysis, several experiments were carried out in which the discharge was operated for periods of about 30 minutes at currents of 7 or 8 ma. The upper electrode was made the cathode in these experiments to facilitate the removal of the deposit. Two samples of about 2 mg each, obtained at the temperature of liquid nitrogen, gave analyses corresponding to $C_{1.00}H_{1.01}$ and $C_{1.00}H_{1.02}$. In another experiment the liquid nitrogen level was maintained about 1 cm below the cathode in order to reduce the possibility that a deposit of frozen product gases was contributing to the formation of the solid. Analysis of this sample gave a composition represented by $C_{1.00}H_{0.75}$. A further sample of the cathode deposit, prepared by operating the discharge at room temperature, was found to have the composition given by $C_{1.00}H_{0.70}$. Although the removal of the solid from the cathode was not quantitative the amount recovered accounted in every case for more than half the nonvolatile product calculated to be formed on the basis of the results in Fig. 2. It seems probable therefore that the cathode deposit accounts for nearly all of the nonvolatile product. The only evidence of any other accumulation of a nonvolatile product was the appearance of interference colors on the anode during these experiments. This may have indicated the formation there of much smaller quantities of another solid product.

It was not possible to determine from the mass spectra whether the product which appeared at $m/e = 42$ was propene or cyclopropane. This product was separated from the others by gas chromatography and shown to be propene.

DISCUSSION

The products obtained in this work were considerably more complex than those obtained by Yeddanapalli (2). This was due mainly to the improved analytical technique used. In addition, the increased recovery of ethylene at wall temperatures of $-210°$ C or lower indicates that the yield of ethylene found by Yeddanapalli was too low because much of it would not have been removed from the reaction at the temperature of liquid air. Instead of a polymer having the formula $(CH_2)_n$ as indicated by Yeddanapalli's results, the nonvolatile product was found to consist mostly of a solid of formula $(CH)_n$ which appeared on the cathode.

Yeddanapalli's conclusion that the rate of decomposition in the negative glow is proportional to the current and independent of the pressure holds only approximately for these experiments which extend into the abnormal discharge region. The electron efficiency in this work is defined as the number of methane molecules decomposed per electron charge carried by the current. In the experiments at 0.30-mm pressure (Fig. 2), for which the discharge is nearly normal, the electron efficiency decreases from 12.8 at 1.0 ma to 10.7 at 4.5 ma. At 0.050 mm where the discharge is more abnormal the electron efficiency decreases from 9.0 at 0.10 ma to 8.0 at 0.82 ma. These values are to be compared with the average value of 10 obtained by Yeddanapalli (2) at pressures ranging from 2 to 9 mm and discharge currents between 10 and 30 ma. It is evident that the electron efficiency for the negative glow plus the cathode dark space is approximately 10 over a fairly wide range of discharge conditions.

The products found in these experiments are very similar to those found by Manton and Tickner (9) in their study of the decomposition of methane by a beam of electrons. Since it is known that the electrons in the negative regions of a d-c. glow discharge possess beam properties and have energies similar to those used in the electron beam experiments, this suggests that the products of the negative glow are formed by a mechanism similar to the one which they proposed. The higher electron efficiencies obtained in the glow are accounted for by the many secondary electrons which acquire energy in the electric field, lose it in exciting gas molecules, and subsequently recombine with ions without contributing to the discharge current.

The work of Manton and Tickner indicated that the products were due mainly to excitation rather than to ionization and provided some evidence that the higher products were formed by the reaction of some species, such as excited methylene radicals, with the lower hydrocarbon products. The results obtained here are consistent with this mechanism. In the experiments at both 0.30 mm (Fig. 2) and 0.050 mm (Fig. 3) the yields of the C_2 products fall off with increasing current while the yields of the higher hydrocarbons increase. Also, lowering the discharge tube temperature from $-196°$ C to $-210°$ C while greatly increasing the recovery of ethylene resulted in a decrease in the amounts of propene and butene. Thus, there seems to be definite evidence that the higher hydrocarbons are formed at the expense of the C_2 products.

It has been suggested (10) that the addition of excited methylene to a double bond often results in the formation of an energy-rich cyclic compound which may then rearrange to an olefin. Since no cyclopropane is found among the discharge products there is no evidence of this kind that excited methylene is the active species.

The addition of hydrogen to the methane in concentrations up to 20 mole% appears to have little effect on the products. The small lowering of all yields as the concentration of hydrogen is increased is consistent with the explanation put forward by Yeddanapalli that hydrogen behaves as a diluent, absorbing some of the electrical energy. Since some

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

decomposition of the hydrogen into atoms would be expected, it seems probable that under our conditions of fast trapping the reactions of hydrogen atoms do not play an important part. It is possible, however, that the number of hydrogen atoms generated from the added hydrogen is small compared with the number formed in the methane decomposition and that for this reason the effect of the added hydrogen is not appreciable.

The results obtained by varying the distance between the electrodes (Fig. 5) indicate that the products are not formed uniformly throughout the negative glow. While it is possible that moving the anode into the glow may alter the mechanism it seems to be accepted (5) that the operation of a discharge is disturbed to a relatively small extent until the anode reaches the cathode edge of the glow. Judging by the observed current–voltage relationship this seems to hold true for these experiments. Thus, there appears to be good evidence that most of the acetylene, and possibly part of the ethylene, are formed either at the edge of the negative glow nearest the cathode or, perhaps, in the cathode dark space. The other products appear to be formed in the body of the glow although the results in Fig. 5 may indicate that the distribution is not the same for all of them.

It seems likely that the variation in the relative amounts of the various products along the glow is related to the variation in the electron energy distribution. At the cathode edge of the glow a relatively large number of electrons have sufficient energy to ionize but their number falls off rapidly with increasing distance from the cathode. In the interior of the glow, electrons of much lower energy predominate (5, 6). The fact that most of the acetylene is apparently formed in a region in which there are relatively large numbers of high-energy electrons appears to indicate that it depends on ionization for its formation. This would not be inconsistent with the findings of Manton and Tickner (9) because acetylene constituted a relatively small part of the total product on which their conclusions were based. The remaining products are formed in the interior of the glow where excitation processes are more important. Thus, with the possible exception of acetylene, the mechanism put forward by Manton and Tickner seems to offer a reasonable explanation of the products of the negative glow.

The conclusion that acetylene was the product formed nearest the cathode takes on interesting implications when related to the formation of the solid product. At the low temperatures and low currents used in these experiments a solid product having exactly the formula $(CH)_n$ formed in visible quantities only on the cathode. Since no deposit formed on an insulator covering part of the cathode surface it seems likely that the solid layer was formed by the incoming ions. This conclusion is consistent with the observation that the rate of formation of the nonvolatile product was affected little by changes in wall temperature, pressure, or electrode spacing as shown in Figs. 2 to 5. Experiments in which the cathode was kept above the liquid nitrogen level or in which the discharge was operated at room temperature indicate that the deposit did not originate in a layer of acetylene frozen out on the cathode surface. Instead, these experiments provide some evidence that at higher temperatures the cathode deposit loses hydrogen under ion bombardment. These considerations lead to the conclusion that the solid product on the cathode is an acetylene polymer similar to the cuprene formed in the high-energy irradiation of acetylene (11, 12). There is a considerable amount of evidence that the cuprene formed in these irradiation studies depends on ionization for its formation (12, 13, 14). It seems possible therefore that in the glow discharge acetylene formed near the cathode becomes ionized, either directly or by charge exchange, and then polymerizes in a series of ion–molecule reactions while on its way to the cathode.

The appearance of traces of an involatile product on the anode may indicate that small amounts of a polymer are also formed by another mechanism.

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Mr. R. L. Sander, who performed the mass spectrometric analyses, and to Mr. J. R. H. Seguin, who analyzed the solid product appearing on the cathode.

OXIDATION OF MANGANATE BY HYPOCHLORITE[1]

M. W. Lister and Y. Yoshino[2]

ABSTRACT

The oxidation of potassium manganate to potassium permanganate by potassium hypochlorite has been examined. The rate of the reaction is proportional to the square of the manganate concentration and the first power of the hypochlorite, and it is inversely proportional to the permanganate concentration and to the square of the hydroxide ion concentration. It seems probable that the reaction involves the intermediate formation of hypomanganate ions from a relatively fast disproportionation of manganate, followed by a slower oxidation by hypochlorite. The following mechanism is tentatively proposed:

$$MnO_4^{--} + H_2O \rightleftharpoons HMnO_4^- + OH^-$$

$$2HMnO_4^- \rightleftharpoons H_2MnO_4^- + MnO_4^-$$

$$H_2MnO_4^- + OCl^- \rightarrow MnO_4^- + Cl^- + H_2O.$$

Data on the over-all rate and effective activation energy (19.6 kcal/g-molecule) are given; but at present it is not possible to separate all the rate constants and equilibrium constants.

The present writers have examined in a recent paper (1) the mechanism of the oxidation of manganate by periodate ions. It was found that this reaction goes chiefly through the intermediate formation of hypomanganate ions, arising from the equilibrium

$$2MnO_4^{--} \rightleftharpoons MnO_4^{-3} + MnO_4^-.$$

The hypomanganate ions are then oxidized in a bimolecular reaction with periodate. The reaction of manganate with hypochlorite ions is at first sight a similar reaction. This reaction also takes place in alkaline solution, the over-all change being

$$2K_2MnO_4 + KOCl + H_2O \rightarrow 2KMnO_4 + KCl + 2KOH.$$

As with periodate, the hypochlorite ion changes by two oxidation steps, while the manganate ion changes by one; so a reaction in at least two steps, or else a termolecular reaction, seemed probable. With periodate ions a termolecular reaction is largely avoided by the two-stage reaction involving hypomanganate ions. The evidence which will be given below shows that a very similar mechanism operates with hypochlorite ions.

EXPERIMENTAL METHOD

Mixtures of potassium manganate, potassium hypochlorite, and potassium hydroxide of various concentrations were made up in aqueous solution. They were kept in a thermostat controlled to 0.1° C, and samples were taken at intervals for analysis. The reaction was followed by measuring the optical density of the solutions, mostly at 610 mμ, on a Beckmann DU spectrophotometer. This wave length is at the absorption maximum for manganate ions; the extinction coefficients used were the same as in the earlier paper (1). It was assumed that all the manganese was present either as manganate or permanganate ions. This was confirmed in several ways. Firstly the solutions showed no signs of precipitated manganese dioxide, which is the most probable alternative form for the manganese. Secondly, the total oxidizing normality of the solution (measured by adding potassium iodide and sulphuric acid, and titrating with sodium thiosulphate) was found not to change during a run. Thirdly, measurements were also made at 550 mμ, where the

[1]*Manuscript received August 25, 1960.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario.
[2]*College of General Education, University of Tokyo, Tokyo, Japan.*

permanganate ion has an absorption maximum; the concentrations of manganate and of permanganate, calculated from the measurements at the two wave lengths, were in good agreement.

Potassium manganate was made as described by Carrington and Symonds (2). Potassium hypochlorite was made by the usual method of passing chlorine into cold potassium hydroxide solution; hence the reaction mixtures always contained potassium chloride.

The initial concentrations in various runs are given in Table I. In most of these runs

the potassium hypochlorite was in sufficient excess so that it remained effectively constant throughout the run. The ionic strength was regulated at an initial value of 0.2 by addition of potassium nitrate. The ionic strength changed by an insignificant amount during any run.

RESULTS

The concentrations of manganate ions at various times were calculated for all runs. These concentrations will be presented in terms of the equation that they were found to fit, as described below. At first the usual equations for a monomolecular or a bimolecular mechanism were tried, but the results did not fit these simple equations. The rate of reaction was rapid at first, but slowed up very markedly with time; in fact in some runs the rate was not far from being proportional to the fourth power of the manganate concentration. This slowing up cannot be attributed to reversibility of the reaction, as the relevant standard electrode potentials (3) are

$$MnO_4^{--} \rightarrow MnO_4^{-} + e^{-}, \qquad E_0 = -0.564 \text{ volt};$$

$$Cl^{-} + 2\,OH^{-} \rightarrow OCl^{-} + H_2O + 2e^{-}, \qquad E_0 = -0.89 \text{ volt}.$$

Hence at equilibrium, for the conditions used, virtually all the manganese would be present as permanganate ions.

It was found, however, that the following mechanism gave an equation which fitted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the experimental results:

$$2MnO_4^{--} \rightleftharpoons MnO_4^{-3} + MnO_4^{-}, \quad \text{(i)}$$

$$MnO_4^{-3} + OCl^- + H_2O \rightarrow MnO_4^- + Cl^- + 2OH^-. \quad \text{(ii)}$$

The initial equilibrium in reaction (i) is assumed to be fast relative to reaction (ii), which determines the rate. If k_2 is the rate constant of the second reaction, then

$$\frac{d[MnO_4^{--}]}{dt} = -2k_2[MnO_4^{-3}] \,.\, [OCl^-]$$

as two manganate ions react to give one hypomanganate ion. If K is the equilibrium constant of reaction (i), and if the concentration of hypomanganate ion at any time is very small, then

$$[MnO_4^{-3}] = \frac{K.\,[MnO_4^{--}]^2}{[MnO_4^{-2}]_0 - [MnO_4^{-2}] + [MnO_4^-]_0}$$

where the subscript "0" indicates the initial concentration. If we substitute this in the rate equation, and allow for the fact that the potassium hypochlorite is also used up, integration of the rate equation gives

(A) $2K.k_2[OCl^-]_0(1-b/2)t = (1+w)(a-1) - [(1+wb/2)/(1-b/2)] \ln [a(1-b/2+b/2a)]$

where $a = [MnO_4^{--}]_0/[MnO_4^{--}]$,

$b = [MnO_4^{--}]_0/[OCl^-]_0$,

and $w = [MnO_4^-]_0/[MnO_4^{--}]_0$.

In most runs the initial hypochlorite concentration was so large that b can be taken to be negligibly small; equation (A) then reduces to

(B) $$2K.k_2[OCl^-]_0 t = (1+w)(a-1) - \ln a.$$

Equation (B) is accurate to within 1% for all runs except 5, 6, and 10, which were done with low hypochlorite ion concentrations, and even here the error in the calculated rate constants by using equation (B) would be about 5%. Equation (A) was used for these runs.

If this theory of the reaction mechanism is correct, then a plot of $[(1+w)(a-1)-\ln a]$ against time should be linear. These plots are shown in the figures, and do in fact give straight lines for all runs. Data for a typical run are:

Run 1; $w = 0$

Time, minutes	$[MnO_4^{--}]$, $\times 10^{-4}$ M	$[a-1-\ln a]$	Time, minutes	$[MnO_4^{--}]$, $\times 10^{-4}$ M	$[a-1-\ln a]$

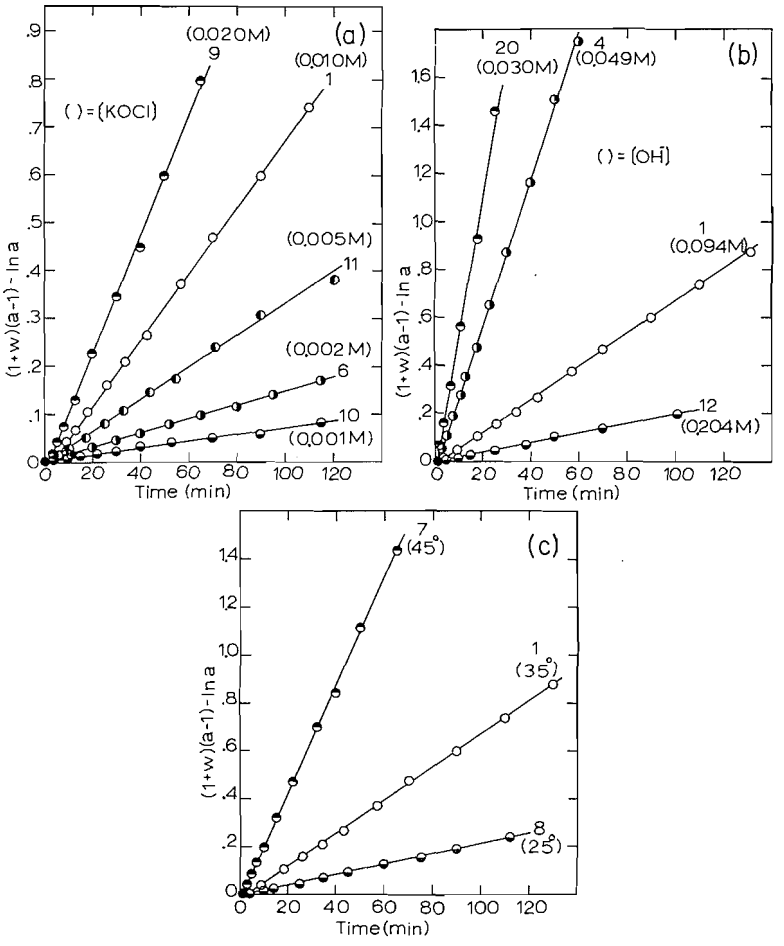

FIG. 1. Results showing agreement of experiment with equation (B). (*a*) Effect of hypochlorite concentration. (*b*) Effect of hydroxide concentration. (*c*) Effect of temperature.

In many runs there is a slight deviation from a straight line initially. This is partly due to the assumption that initially $[MnO_4^-]$ is zero, while in practice reaction (i) would inevitably provide a small quantity of permanganate. Once the reaction has started, errors due to this approximation will rapidly become negligible. However, this effect is in general not large enough to account for the observed deviation, which is presumably due to a trace of permanganate present as an impurity in the potassium manganate. Apart from the points obtained during the first few minutes of any run, the experimental points, plotted according to equation (B), always fell on a straight line.

A further argument in favor of the above mechanism is that addition of potassium permanganate does in fact slow down the reaction. This was found in runs 15, 16, 17, 18, and 19; and in addition, as will be seen later, the amount of the slowing down is close to that calculated from the proposed mechanism, so that equation (B) is still obeyed.

Equation (B) requires that $[(1+w)(a-1)-\ln a]$ plotted against time should give a straight line of slope $2k_2K.[OCl^-]_0$. The observed values of these slopes are given in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the last column of Table I, under the heading "Slope", and in what follows when a "slope" is mentioned it is this slope that is meant. It can be seen from Table I that the slope is proportional to $[OCl^-]_0$, as required. For instance the following runs were done at 35° C in approximately 0.1 *M* potassium hydroxide:

Run	Slope, $\times 10^{-3}$	$[OCl^-]_0$, $\times 10^{-4}$ *M*	Slope/$[OCl^-]_0$, $\times 10^{-1}$
1	6.8	100	6.8
2	6.9	100	6.9
3	7.5	100	7.5
6	1.47	20	7.35
9	11.9	200	5.95
10	0.70	10	7.0
11	3.5	50	7.0

It is also apparent that the rate is affected by the hydroxide ion concentration, and in fact it is approximately inversely proportional to the square of this concentration. Hence the quantity, slope.$[OH^-]^2/[OCl^-]_0$, should be constant, and this is seen to be at least approximately so for the following runs, all at 35° C:

Run	$[OH^-]$, *M*	Slope. $[OH^-]^2/[OCl^-]_0$, $\times 10^{-3}$	Run	$[OH^-]$, *M*	Slope. $[OH^-]^2/[OCl^-]_0$, $\times 10^{-3}$
1	0.094	6.0	12	0.024	8.2
2	0.106	7.75	13	0.029	4.9
3	0.099	7.35	14	0.098	5.2
4	0.049	7.2	15	0.100	9.1
5	0.049	8.9	16	0.103	8.2
6	0.103	7.8	17	0.0995	8.3
9	0.106	6.7	18	0.0995	8.8
10	0.102	7.3	19	0.099	9.3
11	0.102	7.3	20	0.030	5.7

There is some scatter in the results, with a slight decrease in the quantity, slope.$[OH^-]^2/[OCl^-]_0$, at low hydroxide ion concentrations. However, the general trend is clear; the average value of slope.$[OH^-]^2/[OCl^-]_0$ at 35° C is 7.45×10^{-3}. It will be seen that runs 15–19 with added potassium permanganate fall into line. The explanation of these results in terms of mechanism will be considered below, after noting the effect of temperature.

The runs at different temperatures give:

Run	Temp., °C	Slope.$[OH^-]^2/[OCl^-]_0$, $\times 10^{-3}$
8	25	2.53
Mean	35	7.45
7	45	20.3

These give a good straight line for the plot of log(slope.$[OH^-]^2/[OCl^-]_0$) against $1/T$, corresponding to an activation energy of 19.6 kcal/g-molecule.

Returning to a general consideration of the mechanism, the first point to note is that in the present reaction it is the second stage that is the slower, while in the oxidation by periodate it is the first stage; at least this is true for concentrations in the region of 10^{-4}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

to 10^{-3} M such as were used in these experiments. This is in agreement with the activation energies for it was found (1) that the activation energy of reaction (i) is 13.9 kcal/g-molecule, while the effective activation energy for the oxidation by potassium hypochlorite is 19.6 kcal/g-molecule. This, of course, is not a simple activation energy, since equation (B) shows that

$$\text{slope} \cdot [OH^-]^2/[OCl^-]_0 = 2K \cdot k_2[OH^-]^2$$

so that the 19.6 kcal/g-molecule should contain the heat of reaction (i) plus the activation energy of reaction (ii). Carrington and Symonds (2) give ΔH for reaction (i) as 5.5 kcal, which makes the activation energy for reaction (ii) only 14.1 kcal. However, these conclusions ignore the question of the effect of potassium hydroxide, which must now be considered.

Higher concentrations of potassium hydroxide retard the reaction. It is not at present possible to explain this in terms of mechanism with any certainty, since more than one mechanism could give the observed fact that the rate is inversely proportional to the square of the potassium hydroxide concentration. Presumably this dependence means that hydrolyzed species, such as hypochlorous acid or $HMnO_4^{-2}$ ions, are reacting in the rate-determining step; and that two hydrogen ions have combined with the hypomanganate or hypochlorite ions. These two hydrogen ions could go one each on the hypomanganate and hypochlorite ions, in which case the reaction would be

$$HOCl + HMnO_4^{-2} \rightarrow MnO_4^- + Cl^- + H_2O. \quad \text{(iii)}$$

Alternatively both hydrogen ions might be attached to the hypomanganate ion, when the reaction would be

$$OCl^- + H_2MnO_4^- \rightarrow MnO_4^- + Cl^- + H_2O. \quad \text{(iv)}$$

The hydrolysis constant of hypochlorite ions is 5.5×10^{-7} at 35° C (4). The hydrolysis constant of hypomanganate ions is unknown, but they are probably more easily hydrolyzed than manganate ions. It was found in the study of the reaction between manganate and periodate ions that the results could be explained if the second ionization constant of manganic acid is about 7×10^{-11}. Therefore it is probable that hypomanganate ions are more easily hydrolyzed than hypochlorite ions, and this would on the whole make reaction (iv) a little more probable. It is possible to suggest simple mechanisms for both reactions (iii) and (iv), in terms of either electron or hydrogen atom transfer, so that on this score there is nothing to choose between them.

XXII. PRIMARY DECOMPOSITION STEPS IN THE MERCURY-PHOTOSENSITIZED DECOMPOSITION OF METHANOL AND DIMETHYL ETHER[1]

R. F. POTTIE,[2] A. G. HARRISON,[3] AND F. P. LOSSING

ABSTRACT

The Hg $^3P_1$ photosensitized decomposition of methanol at low pressures proceeds mainly by a dissociation into CH_3O radicals and H atoms. No formation of CH_2OH radicals is observed. A subsidiary reaction to form CH_3 and OH may also be a primary step. Formation of CH_2OH radicals at higher pressures is attributed to an abstraction reaction of CH_3O with CH_3OH.

Two primary modes of dissociation are found to occur for dimethyl ether:

$$Hg\ ^3P_1 + CH_3OCH_3 \rightarrow CH_3OCH_2 + H + Hg\ ^1S_0,$$
$$\rightarrow CH_3O + CH_3 + Hg\ ^1S_0.$$

The relative probabilities of occurrence at low pressures are ~45% and ~50%, respectively. The possibility that the second reaction proceeds by formation of an excited molecule is discussed.

INTRODUCTION

The mercury-photosensitized decomposition of methanol has been examined in some detail by Phibbs and Darwent (1) over a pressure range from 30 to 100 mm Hg and from 25° C to 500° C. They found the products of the reaction below 400° to be almost entirely hydrogen and ethylene glycol, and concluded that the primary step was

$$Hg\ ^3P_1 + CH_3OH \rightarrow CH_2OH + H + Hg\ ^1S_0. \quad [1]$$

From experiments with CH_3OD, they concluded that the alternative primary reaction to form CH_3O did not occur,

$$Hg\ ^3P_1 + CH_3OH \rightarrow CH_3O + H + Hg\ ^1S_0. \quad [2]$$

At temperatures above 400° C CH_2O and CO were formed in addition, evidently by dissociation of the radical formed in the primary step.

The direct photolysis of methanol was recently investigated by Porter and Noyes (2) using λ 1800–2000. They found that two primary steps occurred:

$$CH_3OH + h\nu \rightarrow CH_2O + H_2, \quad [3]$$

$$CH_3OH + h\nu \rightarrow CH_3O + H. \quad [4]$$

Since it had been shown that CH_3O radicals abstract H atoms rapidly (3), they pointed out that formation of CH_3O radicals by [4] would be followed by an abstraction reaction,

$$CH_3O + CH_3OH \rightarrow CH_3OH + CH_2OH, \quad [5]$$

in which CH_2OH radicals would be produced. Using CD_3OH they found no formation of D_2 except at high conversions, and concluded that the evidence against a split into $CH_2OH + H$ in the direct photolysis was fairly strong.

It appeared, therefore, that a re-examination of the mercury-photosensitized reaction of methanol at low pressures under conditions where the occurrence of reaction [5] would be negligibly slow might provide further evidence as to the relative probabilities of the primary reactions [1] and [2].

[3]*National Research Council Postdoctorate Fellow 1957–59.*

The mercury-photosensitized decomposition of dimethyl ether has been examined by Marcus, Darwent, and Steacie (4), who found the main products at 25° C to be hydrogen and 1,2-dimethoxyethane, corresponding to the primary decomposition step,

$$Hg\ ^3P_1 + CH_3OCH_3 \rightarrow CH_3OCH_2 + H + Hg\ ^1S_0. \quad [6]$$

Subsequent reactions were

$$H + CH_3OCH_3 \rightarrow CH_3OCH_2 + H_2, \quad [7]$$

$$2CH_3OCH_2 \rightarrow (CH_3OCH_2)_2. \quad [8]$$

At 265° C products corresponding to the decomposition of the CH_3OCH_2 radical were found,

$$CH_3OCH_2 \rightarrow CH_3 + CH_2O. \quad [9]$$

They found no evidence for the formation of excited molecules in this reaction, and no evidence for a primary rupture of the C—O bond,

$$Hg\ ^3P_1 + CH_3OCH_3 \rightarrow CH_3O + CH_3 + Hg\ ^1S_0. \quad [10]$$

EXPERIMENTAL

The mercury-photosensitized reactions were examined using a fast-flow system coupled to a mass spectrometer, the apparatus and method of operation being the same as that employed earlier (5, 6). In this apparatus the reactant and mercury vapor at partial pressures of a few microns are carried in a stream of helium at 8 mm pressure through a tubular reactor which is strongly illuminated by a low-pressure lamp of high intensity. The reactor is maintained at 55° C. The residence time in the illuminated zone is about 0.001 second. Directly following the illuminated zone the reaction stream passes over a small orifice through which a portion flows directly into the ionization chamber of a mass spectrometer. The bulk of the stream passes into a fast-pumping system. As discussed earlier (6), the reaction conditions resemble those of flash photolysis, in as much as radical–radical reactions are greatly favored over radical–substrate reactions.

The sample of CD_3OH was obtained from Merck and Co., Montreal. The isotopic purity was greater than 99%.

RESULTS AND DISCUSSION

Methanol

In preliminary experiments on methanol, it was found that although products such as CH_2O, CO, CH_4, H_2, and methyl radicals could be easily detected, no increase in the 31 peak attributable to the CH_3O or CH_2OH radicals could be found. It was concluded therefore that the sensitivity of the mass spectrometer to radicals of this type was quite low, and that a distinction between reactions [1] and [2] could not be made by identifying by mass the radicals produced in the decomposition of CD_3OH:

$$Hg\ ^3P_1 + CD_3OH \rightarrow CD_2OH + D + Hg\ ^1S_0, \quad [1a]$$

$$\rightarrow CD_3O + H + Hg\ ^1S_0. \quad [2a]$$

An alternative means for identifying the radicals, which had earlier been found useful (7), was employed. The addition of a small partial pressure of $Hg(CH_3)_2$ to the reaction stream resulted, by the mercury-photosensitized decomposition of the dimethyl mercury, in the production of methyl radicals. The combination of these with radicals formed in the primary decomposition of the compound under examination then resulted in the formation of identifiable stable products. In the case of methanol it was advantageous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

to employ CD_3OH instead of CH_3OH, and to add CD_3 radicals by the use of $Hg(CD_3)_2$. Assuming that both primary steps [1*a*] and [2*a*] were occurring, the two combination reactions of CD_3 radicals would be

$$CD_3 + CD_2OH \rightarrow CD_3CD_2OH \text{ (parent mass 51)}, \quad [11]$$

$$CD_3 + CD_3O \rightarrow CD_3OCD_3 \text{ (parent mass 52)}. \quad [12]$$

Since ethanol and dimethyl ether have large parent peaks, the identification of the combination product by mass number was quite straightforward. As shown in Fig. 1,

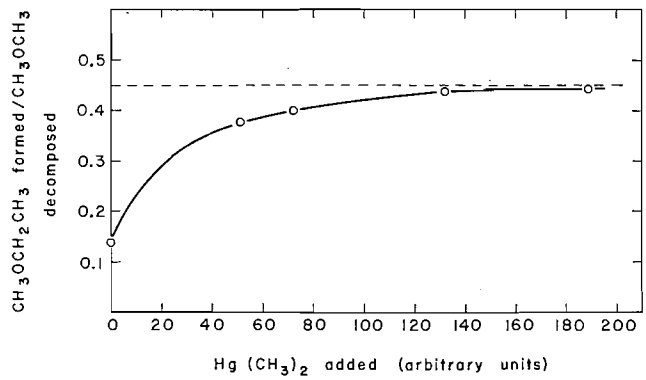

FIG. 1. Yield of $CH_3OCH_2CH_3$ formed by reaction of the CH_3OCH_2 radicals produced in primary decomposition of dimethyl ether with excess CH_3 radicals from added $Hg(CH_3)_2$.

only CD_3OCD_3 was produced in this experiment. (Additional confirmation for the identity of CD_3OCD_3 is provided by the ratio of peaks at mass 50 and 52 (2.00), which was the same as the corresponding ratio for mass 45/46 in CH_3OCH_3 (2.09).) After correction of the mass 51 peak height in the spectrum in Table I, the net CD_3CD_2OH peak is less than 1% of the CD_3OCD_3 peak. Since the parent peak sensitivity for dimethyl ether is about three times that for ethanol, it is evident that an upper limit for CD_3CD_2OH formation is 3% of the CD_3OCD_3 formation. Assuming that the rates of the combination reactions [11] and [12] are not greatly different, as seems reasonable, it seems clear that under the present experimental conditions the fraction of the primary reaction leading to the formation of CH_2OH radicals is less than 3%, and that the predominating mode of dissociation is to CH_3O and H. This is in agreement with the direct photolytic result of Porter and Noyes (2).

It is probable that the apparent contradiction between the present work and that of Phibbs and Darwent (1) concerning CH_2OH formation arises from the fact that the present work was carried out at very low partial pressures of methanol. This difference in conditions could affect the result in two ways. The first is the possibility that CH_3O formation results from dissociation of an excited molecule produced in a primary step,

$$Hg\ ^3P_1 + CH_3OH \rightarrow CH_3OH^* + Hg\ ^1S_0, \quad [13]$$

which is deactivated at high pressures, while CH_2OH results from direct removal of a H-atom by the excited mercury atom. This explanation is quite unsatisfactory, however. If one accepts the present result that reaction [1] has a cross section less than 3% of that for reaction [2], this explanation would require the quantum yield of H_2 (or other products) at high pressures to be less than 0.03. Since Phibbs and Darwent found the quantum yield of H_2 to be 0.43 under their conditions, this possibility can be ruled

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

out. To be consistent with this observation it would be necessary to postulate two excited states, one leading to the other by collision. Following reaction [13] one would require

$$CH_3OH^* \rightarrow CH_3O + H, \quad [14]$$

$$CH_3OH^* + M \rightarrow CH_3OH^{**} + M, \quad [15]$$

$$CH_3OH^{**} \rightarrow CH_2OH + H. \quad [16]$$

It seems more probable, however, that the apparent discrepancy arises from the rapid conversion of CH_3O into CH_2OH by reaction [5] as pointed out by Porter and Noyes (2). This reaction is exothermic by 7–8 kcal/mole (8), and at the pressures employed by Phibbs and Darwent it is quite possible that it would be much faster than the alternative reactions of CH_3O:

$$2CH_3O \rightarrow CH_3OOCH_3, \quad [17]$$

$$2CH_3O \rightarrow CH_2O + CH_3OH. \quad [18]$$

Reaction [17] appears in any case to be quite slow. No formation of dimethyl peroxide was observed by Wijnen (3) in the photolysis of methyl acetate. In an earlier paper of this series (6) the amount of dimethyl peroxide formed by [17] was found to be negligibly small under conditions favorable for its occurrence. In the present work it was not found in the experiments on CH_3OH and CH_3OCH_3, although CH_3O radicals were evidently present in good yields. A failure to detect dimethyl peroxide, as in Phibbs and Darwent's work, provides therefore no evidence for the absence of CH_3O. An analysis of the products from methanol photodecomposition is given in Table II. The reason

for the low carbon and oxygen material balances is not apparent, since there was no visible formation of polymeric deposits in the reactor. The presence of C_2H_6, CH_4, and CH_3, which cannot be derived from a primary split giving CH_3O, and the formation of H_2O which is evidently derived from OH radical, suggest the occurrence of a second primary decomposition,

$$Hg\ ^3P_1 + CH_3OH \rightarrow CH_3 + OH + Hg\ ^1S_0. \qquad [19]$$

The sum of products derived from CH_3, $2(C_2H_6) + (CH_4) + (CH_3OCH_3)$, is equal to 0.075 μ, in fair agreement with the yield of H_2O, which is 0.065 μ. Reaction [19] would therefore account for about 18% of the methanol decomposed. The possibility cannot be entirely ruled out that these products result in part from an atomic cracking reaction,

$$H + CH_3O \rightarrow CH_3OH^* \rightarrow CH_3 + OH. \qquad [20]$$

Dimethyl Ether

Although the present results confirm the occurrence of reaction [6] as an important primary mode of dissociation of dimethyl ether, they provide strong evidence that a primary dissociation by a C—O split, reaction [10], is equally important at low pressures. An analysis of the products of the mercury-photosensitized reaction at 55° C in the presence of 8 mm of helium is given in Table III. The combination products $(CH_3OCH_3)_2$,

TABLE III

C balance	94.8%		

$CH_3OCH_2OCH_3$, and $CH_3OCH_2CH_3$ were identified by comparison of the spectra with those of pure samples of these compounds examined in separate experiments. These three products were evidently formed from CH_3OCH_2 radicals by the combination reactions:

$$2CH_3OCH_2 \rightarrow (CH_3OCH_2)_2, \qquad [21]$$

$$CH_3OCH_2 + OCH_3 \rightarrow CH_3OCH_2OCH_3, \qquad [22]$$

$$CH_3OCH_2 + CH_3 \rightarrow CH_3OCH_2CH_3. \qquad [23]$$

Taken together the quantities of these three products correspond to 0.136 μ of CH_3OCH_2 radical, that is, 27.8% of the dimethyl ether decomposed. Since some CH_3OCH_2 radicals may decompose (see below), this figure is evidently a lower limit for their formation.

A more reliable estimate for the relative probability of reaction [6] was obtained by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

measuring the yield of $CH_3OCH_2CH_3$ in the presence of methyl radicals added to the reaction stream. It can be seen from Fig. 1 that this yield reached a limiting value of 0.45 in the presence of a large excess of methyl radicals. An almost identical limit was obtained for the yield of $CH_3OCH_2CD_3$ when CD_3 radicals were added (Fig. 2). This limit must correspond quite closely to the relative probability of reaction [6].

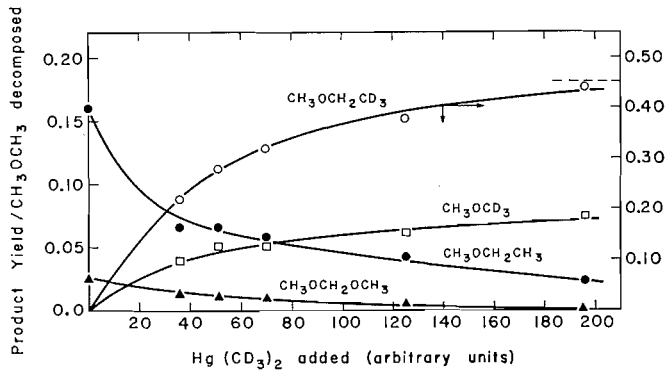

FIG. 2. Yields of products formed by radical interaction in the dimethyl ether decomposition in the presence of added CD_3 radicals.

The difference between the yield of 0.45 and the yield of 0.28 as a lower limit obtained from the data in Table III must represent CH_3OCH_2 radicals which are formed, but which, in the absence of excess CH_3 radicals, do not appear as dimeric products. Since the radical appears to be thermally stable at 55° C (4) it must disappear mainly by reaction with an excited mercury atom,

$$Hg^* + CH_3OCH_2 \rightarrow CH_3 + CH_2O + Hg. \quad [24]$$

The extent of this reaction is equivalent to 0.49 (0.45−0.28) = 0.084 μ of CH_3OCH_2 radical.

From the data in Table III the relative probability of the primary reaction [10] can be estimated in two ways: from products derived from CH_3, and from products derived from CH_3O.

(*a*) Reactions removing CH_3 radicals would be reaction [23], and the following:

$$2CH_3 \rightarrow C_2H_6, \quad [25]$$

$$CH_3 + OCH_3 \rightarrow CH_4 + CH_2O. \quad [26]$$

The total amount of products derived from CH_3 is then, from Table III,

$$(CH_3OCH_2CH_3) + 2(C_2H_6) + (CH_4) + (CH_3) = 0.327\ \mu.$$

To obtain the amount of CH_3 formed in reaction [10] one must subtract 0.084 μ of CH_3 produced by [24]. On this basis the relative probability of reaction [10] is 0.243 μ/0.49 μ = 0.49_6.

(*b*) Reactions removing CH_3O radicals would be [18], [22], [26], and the following:

$$Hg^* + CH_3O \rightarrow CH_2O + H + Hg, \quad [27]$$

$$H + CH_3O \rightarrow CH_2O + H_2. \quad [28]$$

The CO found was most probably formed from CH_2O by reaction with an excited

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

mercury atom, since this reaction has a large relative cross section (9). The quantity of products derived from CH_3O is therefore

$$(CH_3OCH_2OCH_3) + (CH_3OH) + (CH_2O) + (CO) - (CH_2O \text{ from } [24]) = 0.246\ \mu.$$

This corresponds to a relative probability of 0.50_2 for the primary reaction [10], in good agreement with the value obtained from the yield of methyl. Although these two estimates for reaction [10] are independent of one another, their close agreement arises from the near equality of the carbon and oxygen balances given in Table III.

These estimates should be regarded as only approximate, since some re-formation of dimethyl ether may occur by the following reactions:

$$CH_3OCH_2 + CH_3O \rightarrow CH_3OCH_3 + CH_2O, \quad [29]$$

$$CH_3OCH_2 + H \rightarrow CH_3OCH_3, \quad [30]$$

$$CH_3O + CH_3 \rightarrow CH_3OCH_3. \quad [31]$$

In the experiment in which a large excess of CD_3 radicals was added, the yield of CH_3OCD_3 amounted to only about 7% of the dimethyl ether decomposed, as shown in Fig. 2. When no methyl radicals were added as for the data in Table III, the extent of reaction [31] would be considerably less, certainly not more than 2–3%. Since the concentrations of CH_3OCH_2, CH_3O, and H were of the same order or less than CH_3, interference by reactions [29] and [30] would also be small. Moreover it should be noted that the same limit for CH_3OCH_2 production was reached by CH_3 addition and by CD_3 addition, even though in the latter experiment reaction [31] would not interfere with the measurement of the amount of CH_3OCH_3 decomposed. This also indicates that the limits of 0.45 and 0.50 for reactions [6] and [10] are not seriously in error as a result of interference by back reactions.

Some question may be raised as to whether some or all of the CH_3O formation observed at these low pressures results from an atomic cracking reaction rather than from a primary dissociation. The following series of reactions could be proposed to explain the formation of CH_3O at low pressures and its absence under the higher pressure conditions of Marcus, Darwent, and Steacie (4):

$$CH_3OCH_2 + H \rightarrow CH_3OCH_3^*, \quad [32]$$

$$CH_3OCH_3^* \rightarrow CH_3O + CH_3, \quad [33]$$

$$CH_3OCH_3^* + M \rightarrow CH_3OCH_3 + M. \quad [34]$$

The results given in Figs. 1 and 2 show, however, that this series of reactions does not play a significant role under the present conditions. As shown in Fig. 1, the addition of an excess of CH_3 radicals, which would suppress reaction [32], gives an upper limit of 0.45 for the relative probability of reaction [6], and not nearly unity as would be the case if reaction [6] were the only primary mode of decomposition. The yield of $CH_2OCH_2CD_3$ in Fig. 2 confirms this observation. Moreover, the yield of CH_3OCD_3 (Fig. 2) does not pass through a maximum and then decrease with increasing CD_3 addition as would be expected if reactions [32] and [33] were important under these conditions. It seems quite clear from these results that at low pressures CH_3O is formed in a primary decomposition step with a probability of about 0.50. The non-occurrence of this mode of dissociation at pressures in the 28- to 500-mm region (4) suggests that it may go by formation of an excited molecule,

$$Hg\ ^3P_1 + CH_3OCH_3 \rightarrow CH_3OCH_3^* + Hg\ ^1S_0, \quad [35]$$

followed by the dissociation and deactivation reactions [33] and [34]. Since the 8 mm

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of helium used in the present experiments would be completely ineffective in quenching excited molecules, the effective pressure is that of the ether itself, i.e. about 0.010 mm, and deactivation would be quite slow. Even in the experiments in which methyl radicals were added, the total partial pressure effective for deactivation was still well below 0.05 mm.

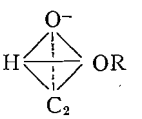
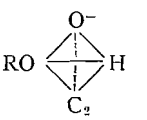
EXCEPTIONS TO HUDSON'S RULES OF ISOROTATION



THE NUCLEAR MAGNETIC RESONANCE SPECTRA OF ANOMERIC PYRIMIDINE 2-DEOXY-D-RIBONUCLEOSIDES[1]

R. U. LEMIEUX AND M. HOFFER



ABSTRACT

Nuclear magnetic resonance spectroscopy and optical rotatory dispersion measurements were used to correlate the configurations of anomeric pairs for the 1-(2-deoxy-D-ribofuranosyl) derivatives of 5-methyl- and 5-fluoro-uracil. The optical rotations of the anomers were found opposite to those expected on the basis of Hudson's rules of isorotation.

Hudson's rules of isorotation in their earliest form (1) in effect stated that for D-glycosides the more dextrorotatory (or less levorotatory) anomer is to be named α-D-. As evidence for the absolute configurations of glycopyranosides accumulated, it became evident that the rules correlate rotation and anomeric configuration (2). It has consequently become a widespread practice to assign absolute anomeric configurations on the basis of Hudson's rules and the assumption that the absolute configurations are those which follow.

α-D or β-L

β-D or α-L

The purpose of this communication is to report that the rules of isorotation are violated in every respect in the case of certain 2-deoxy-D-ribonucleosides. Thus, although the rules are well tested and are undoubtedly of value in assigning anomeric configurations to *O*-glycopyranosyl compounds, reserve is indicated in their application to the kinds of glycosides for which there exists no compelling empirical evidence (3).

Hoffer, Duschinsky, Fox, and Young (4) recently have reported syntheses of the anomeric pairs for the pyrimidine 2-deoxy-D-ribonucleosides I and II, and III and IV (see Fig. 3). The optical rotations for these compounds measured with the *D-line of sodium* are presented in Table I.

On the basis of the anomeric configurations assigned to the compounds in Table I, *except* for the anomers V and VI and the anomers I and II the rotations for these compounds when measured in dimethylformamide are opposite to those required by Hudson's rules. The assignments of configuration are those made by Hoffer and co-workers (4) on the basis of the fact that all the natural 2-deoxyribonucleosides possess the β-D-configuration (5) and the assumption that the anomers obtained in the greater yield, in their syntheses (4) from crystalline 3,5-di-*O*-*p*-toluyl-2-deoxy-D-ribofuranosyl chloride, are configurationally related.

Application of Hudson's rules to isomeric glycosyl compounds of course requires that the compounds differ only in the configuration of the anomeric center. Hoffer (6) has shown, in this respect, that methylation of compounds V and VI introduces a methyl

group in each case at position-3 of the pyrimidine ring. Thus, in view of the synthesis of V and VI from pure 3,5-di-*O*-*p*-toluyl-2-deoxy-D-ribofuranosyl chloride (4), there can be no doubt that I and II are truly anomeric. The ultraviolet absorption spectral data obtained with solutions of III and IV as well as I and II at varying pH also provided evidence for the anomeric relationship between the fluorides III and IV (6). As will be seen below, the nuclear magnetic resonance spectra and optical rotatory dispersion curves for these compounds confirm these conclusions.

Lemieux, Kullnig, Bernstein, and Schneider (7) have shown that the anomeric configurations of aldosides in principle often can be determined by proton magnetic resonance spectroscopy. The application usually requires detection of the fine structure for the signal of the anomeric hydrogen and a knowledge of the conformation of the compound. It is clear, however, that unless changes in the aglycon of a glycoside change the conformation of the sugar residue, then the fine structure of the signals for the protons of the sugar residue should not be altered appreciably. Also, the chemical shifts can be expected to be relatively constant. Certainly, when the fine structure and chemical shifts are substantially the same for the protons in the sugar portions of two glycosides differing only in the aglycon, the two compounds must possess the same anomeric configurations. Thus, proton magnetic resonance spectroscopy should be useful for classifying anomeric compounds even in the absence of a knowledge of their configurations.

The proton magnetic resonance spectra for the nucleosides listed in Table I are given in Figs. 1 and 2. The signals in the spectra can be readily assigned to the hydrogens in the compounds on the basis of the experience with related compounds (7, 8) but these assignments are not needed for the present purpose of grouping the compounds into two series of configurationally related substances—a feat which is not possible on the basis of optical rotations measured at the *D*-line of sodium only. However, as seen in Fig. 3, the optical rotatory dispersion curves for compounds I to IV clearly indicate the configurational relationships at the anomeric centers for these compounds. That is, it must

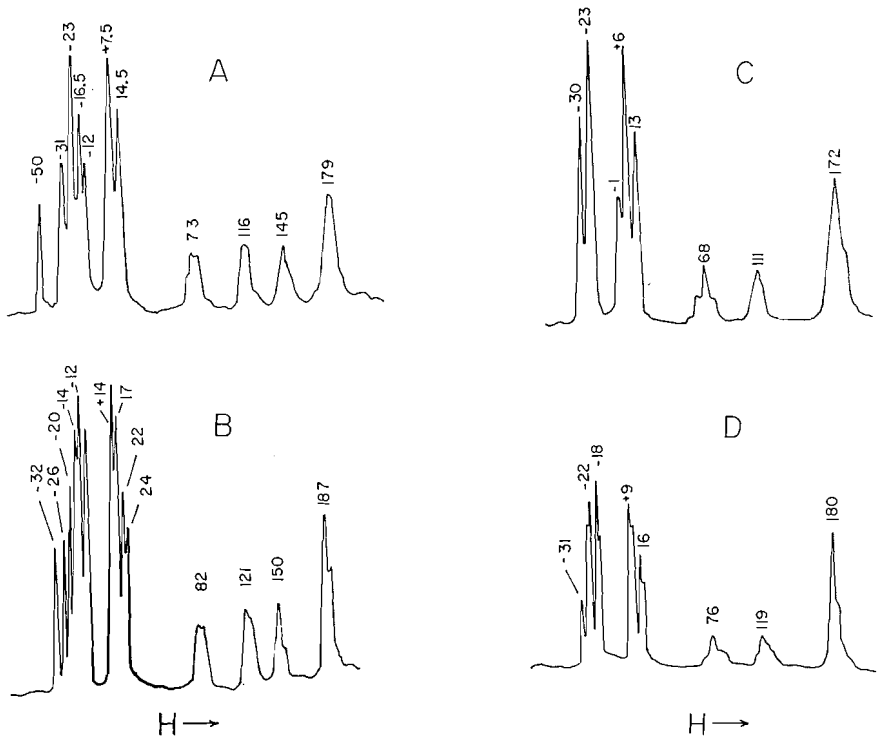

FIG. 2. The nuclear magnetic resonance spectra of anomeric glycofuranosides measured in dimethyl sulphoxide with a high-resolution Varian spectrometer operating at 60 Mc/sec. The positions of the signals are from chloroform used as an external standard. The signals at higher field were obscured by those of the solvent.

(A) 1-(Di-*O*-*p*-toluyl-2-deoxy-α-D-ribofuranosyl)-5-methyluracil (V).
(B) 1-(Di-*O*-*p*-toluyl-2-deoxy-α-D-ribofuranosyl)-5-fluorouracil (VII).
(C) 1-(Di-*O*-*p*-toluyl-2-deoxy-β-D-ribofuranosyl)-5-methyluracil (VI).
(D) 1-(Di-*O*-*p*-toluyl-2-deoxy-β-D-ribofuranosyl)-5-fluorouracil (VIII).

be expected (9) that for such closely related substances, the two compounds whose specific rotations follow similar trends with decreasing wavelength are configurationally related. These results show clearly that the anomalous rotations (from the viewpoint of Hudson's rules and the assigned configurations (4)) obtained with the *D*-line of sodium are not the result of a fortuitous crossing-over of the rotatory dispersion curves but, instead, that the anomalous rotations are a characteristic of the compounds at all the wavelengths used.

Thus, the nuclear magnetic resonance spectra and optical rotatory dispersion curves leave no doubt as to which of the compounds (I to IV) are configurationally related. The conclusion that the rotations of these compounds do not agree with predictions based on Hudson's rules of course requires unequivocal proof of the absolute configuration of at least one of the compounds. Michelson and Todd (5) have established the configuration of thymidine (I). As indicated above synthetic evidence already exists for the configurations and structures depicted in Fig. 3 for compounds II, III, and IV. It was also found possible to deduce the configurations and conformations of thymidine (I) and its anomer (II) from their nuclear magnetic spectra and the range of coupling constants calculated by Karplus (10) for two protons on neighboring saturated carbons. A detailed consideration of these matters is reserved for a separate report (11).

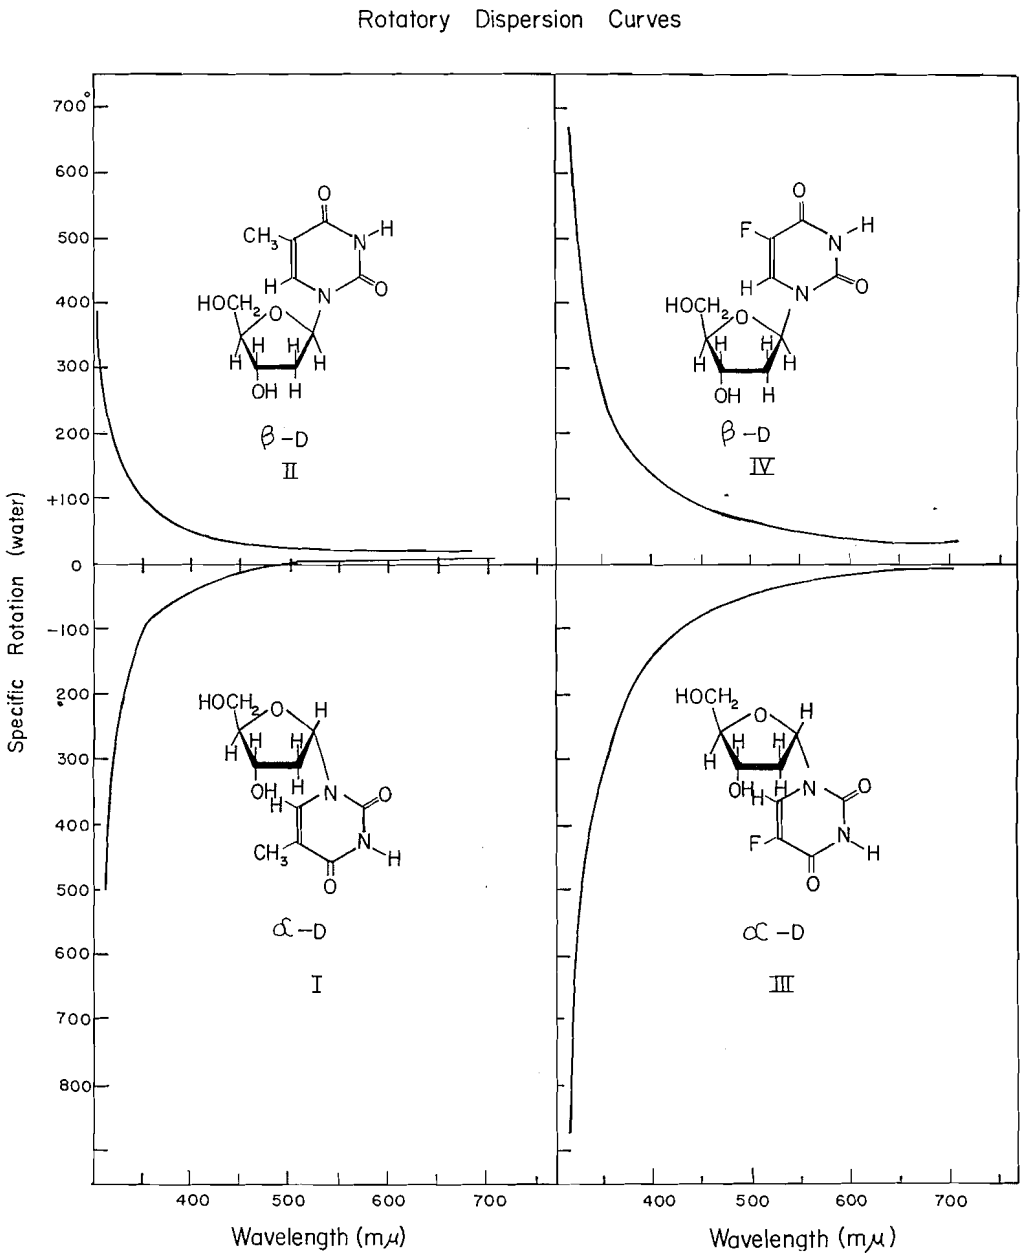

FIG. 3. Optical rotatory dispersion curves of the indicated compounds measured, using about 0.75% solutions in water, at 24–25°.

Fox (12) has already anticipated the failure of Hudson's rules of isorotation in the series of pyrimidine nucleosides. Evidence has been obtained (13) that the rotations of 2-deoxyglucopyranosides and 2-deoxyribopyranosides follow Hudson's rules. Indications that this may not have been the case was suggested by the rotations observed (14) for 2-deoxy-D-glucose tetraacetates. The so-called α-D- ($[\alpha]_D$ +12.3° (ethanol)) and β-D-compounds ($[\alpha]_D^{20}$ +30° (ethanol)) were found (13) to be both impure preparations of 2-deoxy-β-D-glucopyranose tetraacetate.

In conclusion, the configurations of thymidine (I) and its α-anomer (II) are opposite to those which would have been anticipated on the basis of Hudson's rules of isorotation and the rotations measured either in water or aqueous sodium hydroxide. The rotations of the compounds are, however, in accordance with Hudson's rules when measured in dimethylformamide as are the rotations of their di-*O*-toluyl derivatives V and VI, respectively, when measured either in pyridine or dimethylformamide. The substitution of the methyl group in the thymine residue by fluorine atom results in compounds, III and IV, whose rotations are opposite to those expected from Hudson's isorotation rules when measured either in water or dimethylformamide. Also, the rotations of the di-*O*-toluyl derivatives of III and IV (VII and VIII, respectively) are not in agreement with Hudson's rules when measured either in pyridine or dimethylformamide. Thus, it is evident that the precise meaning of the α- and β-designations which are used to describe carbohydrate structures needs revision. The convention, as was seen above, used in carbohydrate nomenclature which employs two different designations to represent each of the two absolute configurations for anomeric centers is unique in the field of organic chemistry. It seems reasonable in view of the above described exceptions to Hudson's rules of isorotation that serious consideration be given to a substitution of these rules of nomenclature by rules that are more compatible with the more widely accepted procedures for naming such structures.

ACKNOWLEDGMENTS

The authors are grateful to Mrs. A. Westland for technical assistance and the National Research Council of Canada for financial assistance in the operation and maintenance of the nuclear magnetic resonance spectrometer. Mr. J. A. Findlay, University of New Brunswick, made the optical rotatory dispersion measurements.

THE CONFIGURATION AND CONFORMATION OF THYMIDINE[1]

R. U. LEMIEUX

ABSTRACT

The nuclear magnetic resonance spectrum for the anomer of the naturally occurring deoxyribonucleoside thymidine allowed a conclusion as to its anomeric configuration through an interpretation of the fine structure observed in the signals for the H_1', H_2', and H_2'' atoms. Thus, indirect evidence for the configuration of thymidine was obtained. The nuclear magnetic resonance spectrum of thymidine suggests that the compound possesses considerable conformational purity when dissolved in water since an interpretation of the spectrum leads to the assignment of the plausible conformation wherein all of the large substituents on the furanose ring are in partially staggered orientations with the neighboring atoms.

The anomeric configuration of thymidine has been established beyond any reasonable doubt by Michelson and Todd (1). A purpose of this communication is to show that it is possible to arrive at the same conclusion by a consideration of the nuclear magnetic resonance spectra for thymidine and its α-anomer (2, 3). More important, the results of the present investigation allow conclusions as to the conformation of thymidine in aqueous solution.

It was not possible to establish the configuration of thymidine directly from its N.M.R. spectrum (see Fig. 1) since there proved to be little, if any, chemical shift between the 2-hydrogens (H_2' and H_2''). For this reason, the signal of the 1-hydrogen (H_1') was found to be in the form of a triplet, the spacing (7.0 ± 0.2 c.p.s.) of which reflects the

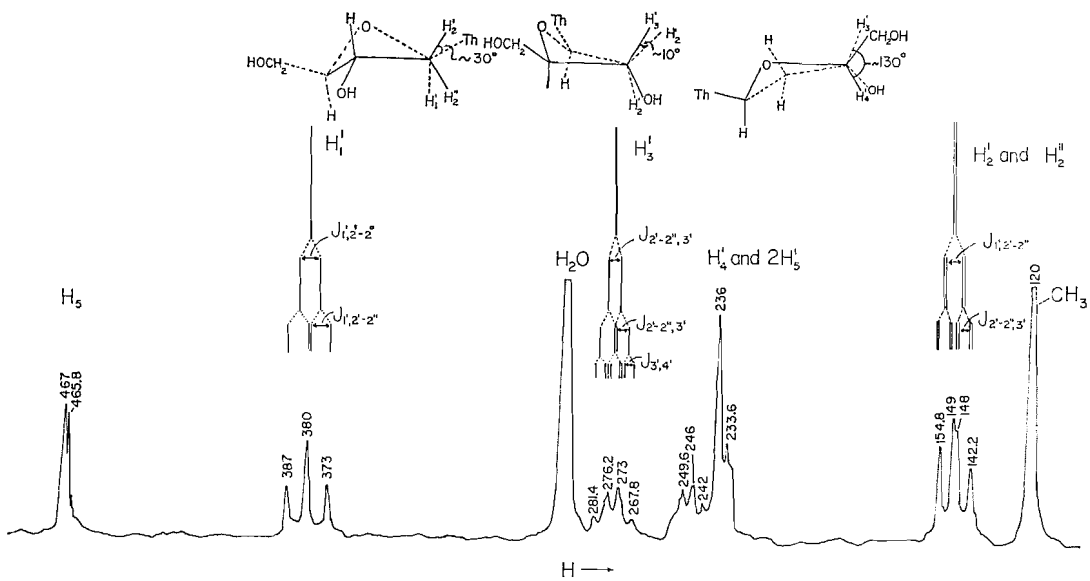

FIG. 1. The experimental and calculated nuclear magnetic resonance spectra of thymidine. The spectrum was measured using a 20% solution in deuterium oxide at 25° with a high-resolution spectrometer operating at 60 Mc/sec. The positions of the signals are from tetramethylsilane used as an external standard. The projection formulas represent the conformation for thymidine suggested by the spectrum. The projections are those obtained by viewing the molecular model first along the C_2 to C_1 bond with C_2 in front, secondly along the C_3 to C_2 bond with C_3 in front, and thirdly along the C_4 to C_3 bond with C_4 in front.

Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Canada.

average of the coupling with H_2' and H_2'' (4). The magnitude of the coupling requires that H_1' be coupled strongly ($J > 5$ c.p.s.) with H_2', since the coupling of H_1' with H_2'' should not be greater than 9. In view of the dependency of the coupling between neighboring hydrogens on their spatial arrangement relative to the bridging carbons (5, 6) and the fact that H_1' is coupled to an extent of less than 3 c.p.s. with H_2' in pyrimidine ribonucleosides (7), it is apparent that the pyrimidine deoxyribonucleosides and the pyrimidine ribonucleosides possess *different* conformations for the furanoside rings.

The N.M.R. spectrum for the anomer of thymidine (Fig. 2) which was recently

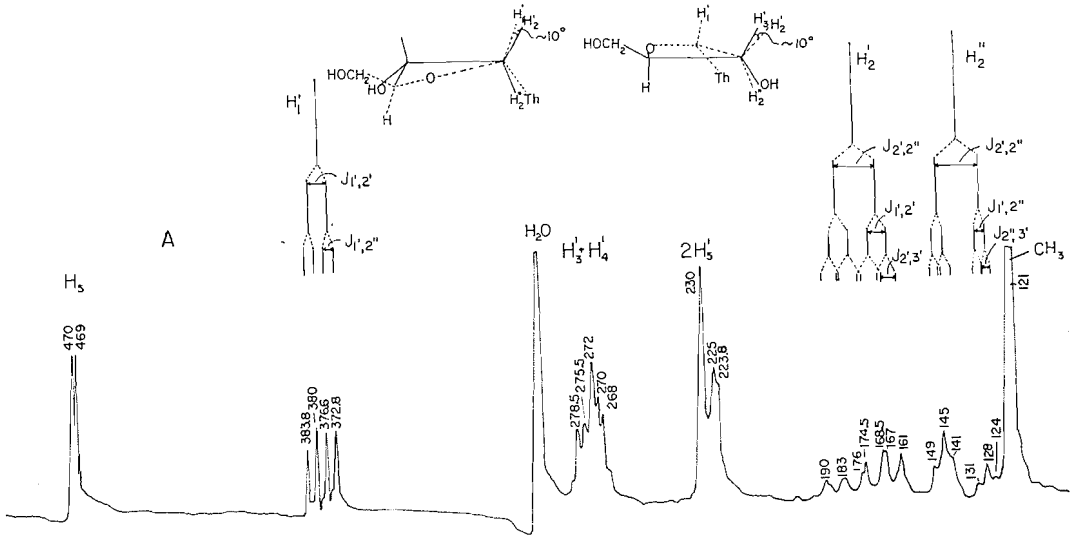

FIG. 2. The experimental and calculated nuclear magnetic resonance spectra of the α-anomer of thymidine. The spectrum was measured using a 20% solution in deuterium oxide at 25° with a high-resolution spectrometer operating at 60 Mc/sec. The positions of the signals are from tetramethylsilane used as an external standard. The projection formulas are to be interpreted as is indicated in Fig. 1 for the β-anomer and represent the conformation for the compound suggested by the spectrum.

synthesized by Hoffer and co-workers (3) provides evidence for its configuration and, consequently, an indirect proof for the configuration of thymidine. Also, the spectrum for thymidine (Fig. 1) allows a conclusion as to the conformation of the compound. The procedure used is based on two assumptions which must be recognized. First of all, the procedure requires the assumption that the compounds are conformationally pure under the conditions that their spectra were measured, namely, in a 20% solution in deuterium oxide at 25°. Secondly, it must be assumed that the variation in the coupling between neighboring hydrogens calculated by Karplus (6) exists for the type of structure under consideration with sufficient precision to warrant their application in this manner. It is noteworthy in this respect that the application does not require a high degree of precision. Consequently, it is felt unlikely that variations (in coupling versus projected angle) from the expected values should arise which would be sufficiently great as to be misleading. In view of these assumptions, the main justification for the approach, at this stage of the development of the nuclear magnetic resonance spectroscopy of carbohydrate structures, is the results obtained. Certainly, as will be seen in the interpretations that follow, wherever it was possible to anticipate a result the approach based on nuclear magnetic

resonance spectroscopy provided a confirmation of the expectation. Also, the conformation arrived at for thymidine is intrinsically attractive from the point of view of nonbonded interactions.

The signals for the 2-hydrogens of the anomer of thymidine (see Fig. 2) are chemically shifted by 37 c.p.s. and these (average) are shifted about 222 and 120 c.p.s. from the signals for H_1' and H_3'. Under these circumstances, the fine structures observed for signals of the H_1', H_2', and H_2'' atoms can be analyzed simply on the basis of first-order perturbation theory (8). The spacing of the quartet observed for the H_1' atom requires this proton to be coupled with the H_2' and H_2'' atoms by amounts of 7.2 ± 0.2 c.p.s. and 3.8 ± 0.2 c.p.s. The signal for one of the 2-hydrogens appears as two triplets separated by 17 c.p.s. This separation infers that the carbon valence angle for the 2-hydrogens is about 107° (9). The spacing for both these triplets is 4.0 ± 0.2 c.p.s. Therefore, the particular 2-hydrogen which is weakly coupled with H_1' is coupled to nearly the same extent with H_3'. The signal for the 2-hydrogen which occurs at lower field is *roughly* in the form of a broad quintet. This must be the 2-hydrogen which is strongly coupled, $J = 7.2\pm0.2$ c.p.s., with H_1'. The spacing of the quintet requires this 2-hydrogen also to be strongly coupled, $J = 7\pm0.5$ c.p.s., with H_3'. The knowledge of these coupling constants and the configuration of 2-deoxy-D-ribose together with the values calculated by Karplus (6, 7) for the dihedral angles the neighboring protons can be expected to define in order to provide the coupling observed allows the following deduction of the conformation of the synthetic anomer of thymidine. Precise atomic models of the conformational type described by Barton (10) were employed as a basis for these deductions.

For the H_3' atom to be coupled 4.0 ± 0.2 c.p.s. with a 2-hydrogen, it must define a dihedral angle of either 45 to 50° or 125 to 130° with the 2-hydrogen. If H_3' projected between H_2' and H_2'', then it would define dihedral angles of 45 to 50° and 70 to 75° with the 2-hydrogens. This situation would result in coupling constants of 3.6 ± 0.4 and 0.6 ± 0.4 c.p.s. and, therefore, can be eliminated as a possibility. If H_3' should be sufficiently axially oriented to define a dihedral angle of 45 to 50° with H_2' and if the compound possessed the β-D-configuration (1,3-*trans*-configuration) (2) then H_1' would necessarily project between the hydrogens at position 2 and define dihedral angles in the range 10 to 30° with H_2'' and, consequently, 90 to 110° with H_2'. Thus, H_1' would be coupled to the extents of 6 to 7.6 and -0.4 to 0.8 c.p.s. with the hydrogens at the 2-position, coupling constants which are not in agreement with those observed (7.2 ± 0.2 and 3.8 ± 0.2 c.p.s.). Consequently, the possibility that the compound exists in both this configuration and conformation can also be eliminated. In view of the fact that the configuration of a 2-deoxy-D-ribofuranoside does not allow a dihedral angle of 125–130° to be defined by H_3' and H_2', only one conformation remains possible on the assumption that the compound possesses the β-D-configuration; namely, the conformation which would have H_3' and H_2'' define a dihedral angle of 125–130°. In this conformation, H_1' would necessarily project between H_2' and H_2''. As was seen above for a similar situation, the coupling constants observed for H_1' and H_2' and for H_1' and H_2'' cannot be accounted for in this event. *Therefore, the anomer of thymidine cannot possess the* β-D-*configuration.* That the compound indeed possesses the α-D-configuration is supported not only by the fact that an interpretation of its spectrum is possible on the basis of this configuration but also by the fact that the interpretation places the compound in a favorable conformation.

As was seen above, the coupling constants observed for H_1' with the 2-hydrogens cannot be accounted for should H_1' project between H_2' and H_2''. Therefore, since the

anomer of thymidine has the α-D-configuration, should H_3' define the rather unlikely dihedral angle of 45 to 50° with H_2', H_1' would define a dihedral angle of 10 to 30° with H_2' and 130 to 150° with H_2''. On this basis the coupling constants for H_2' and H_2'' with H_3' would be 5.8 to 7.6 and 4.4 to 6.8 c.p.s., respectively. Although these coupling constants are reasonably close to those observed, the conformation they would imply is much less attractive than that which would have H_3' define a dihedral angle of only 5 to 10° with H_2' and, therefore, a dihedral angle of 125 to 130° with H_2''. On this basis, the coupling constants for H_3' with H_2' and H_2'' would be expected to be in the ranges 7.6 to 8.2 and 3.2 to 4.0 c.p.s., respectively, as compared with the observed values of 7 ± 0.5 and 4.0 ± 0.2 c.p.s. It would follow that H_1' would be similarly oriented relative to H_2' and H_2'', a condition which would meet the observed coupling constants of 7.2 ± 0.2 and 3.8 ± 0.2 found for H_1'. Therefore, the conformation of the anomer of thymidine (1-(2-deoxy-α-D-ribofuranosyl)-5-methyluracil) must be that represented in Fig. 2 in which none of the substituents about the furanoside ring are eclipsed with their neighbors. Jardetzky (7) has commented on this type of conformation in relation to the conformations of ribonucleosides. It is seen that H_2' and H_2'' are in "equatorial" and "axial" orientations, respectively. Therefore, it would be expected (5) that the signal for H_2' would be at lower field than that for H_2'', as is in fact the case. The first-approximation, theoretical spectrum for the compound is shown in Fig. 2. The resemblance of this spectrum to that actually determined should be noted.

The N.M.R. spectrum (see Fig. 1) of the natural 2-deoxyribonucleoside, thymidine, sheds considerable light on the conformation of this important biochemical. The average coupling of H_1' with the 2-hydrogens, 7.0 ± 0.2 c.p.s., requires that H_1' define dihedral angles of about 150° and 30° with H_2' and H_2'', respectively. The structure of the signal for H_2' and H_2'' requires that the average of the coupling constants of these protons with H_3' is about 5.8 c.p.s. The structure of the signal for H_3' supports this contention.

The signal in the form of a rough quartet at about 274.5 c.p.s. can be assigned to H_3'. The assignment can be made first of all on the basis that the spacing between the first and second lines of 5.2 c.p.s. is in close agreement with the coupling constant, 5.8 c.p.s., observed for the average of the coupling of the two hydrogens at the 2-position with H_3'. Secondly, the structure for the signal for the two hydrogens at position 5 at 236 c.p.s. clearly indicates that the signal for these hydrogens is not greatly chemically shifted from the signal for H_4'. However, the signal for H_3' cannot be a simple quartet but must be an octet in view of the coupling of H_3' with H_2', H_2'', and H_4'. As is indicated in Fig. 1, the structure of the signal can be reasonably accounted for as resulting from coupling interactions of 5.8 c.p.s. with each of the hydrogens at the 2-position and 3.2 c.p.s. with H_4'. On this basis, the conformation for thymidine which is best accommodated by the results is that depicted in Fig. 1. The geometrical and spectral features for thymidine and its α-anomer are summarized in Table I. The conformation implied by the spectrum for thymidine clearly possesses a favorable disposition of the groups about the furanoside ring. It is noteworthy that thymidine possesses a conformation for the furanoside ring which closely approximates the C_s conformation for cyclopentane (11) while the conformation of the α-anomer is closer to the so-called C_2 conformation for cyclopentane. It is also of interest to note that the substitution of H_2'' by a hydroxyl group to form a ribonucleoside would require a near eclipsing of the hydroxyl with the 3-hydroxyl. Consequently, it is not surprising that, as seen above, the conformation of the furanoside ring of thymidine is different to that of pyrimidine ribonucleosides. The general features of the N.M.R. spectrum of thymidine requires that it possess considerable conformational

H_2'', H_3'	130°	3.5	4.0

purity, a matter which is noteworthy in view of the role of deoxynucleosides as building units of the templates of living processes.

In conclusion, it is of interest to note that the present results provide further evidence of the fact that nuclear magnetic resonance spectroscopy can be an important tool for elucidation of the detailed structure of biochemicals in aqueous solution.

CHEMICAL EFFECTS OF THE (n,γ) ACTIVATION OF BROMINE IN THE ALKYL BROMIDES: THE HALOMETHANES[1]

W. E. HARRIS[2]

ABSTRACT

Techniques for studying the chemical effects accompanying the neutron irradiation of the halomethanes with a neutron flux of only 10^8 neutrons per square centimeter per second are described. Results are presented from the irradiation of mixtures of bromine with the four bromomethanes and carbon tetrachloride. The formation of organic products which occur as the result of "hot", "hot-spot diffusive", and "thermal" reactions are discussed. The amounts of products resulting from these three types of reactions are estimated. Observations with respect to the formation of bromoethanes are also discussed.

INTRODUCTION

When a sample containing bromine atoms is irradiated with thermal neutrons, the bromine isotopes of masses 79 and 81 are converted to radioactive bromine of masses 80 and 82 by the (n,γ) nuclear reaction. In this transformation, the nucleus emits from two to six gamma rays in cascade. The resulting recoil momentum gives the radiobromine sufficient energy to dissociate it from the parent molecule and bring about chemical reactions with the other molecules present.

If an organic bromide is irradiated some of the radioactive bromine is converted to an inorganic form (1) and some is retained in various organic forms. The predominant organic product is usually the parent molecule in which radiobromine has been substituted for the inactive bromine, but in addition, a wide variety of new organic compounds are formed. Conversely, it has been found that when a mixture of bromine and pentane (2) or carbon tetrachloride (3) are irradiated, some of the radiobromine is converted to an organic form by recoil labelling and some remains as inorganic bromine. Thus, when a mixture of bromine and an alkyl bromide is irradiated, the bromine atoms in the organic radiobromine compounds originate from both the alkyl bromide and the bromine. Thus it appears that the initial chemical form of the bromine is of secondary importance. Reviews of the many papers in this field have been published by Willard (4, 5).

Many studies (5) have been made with the haloalkanes to determine the fraction of radiohalogen appearing in organic combination, called the organic yield, under a variety of conditions. Experiments have also determined the nature of the new organic products. The organic yield of the irradiated sample has been classically determined by extraction with an aqueous solution of reducing agent and carrier salt and counting the radioactivity of the organic and aqueous layers separately. The organic compounds have frequently been determined by addition of carriers to the extracted organic phase followed by a fractional distillation to separate the components. Evans and Willard (6) have shown that gas chromatography can be applied to the direct separation of the organic products with or without the addition of carriers.

The present work describes the results of neutron irradiation of a wide range of bromomethane–bromine mixtures. The organic yields were determined by a new technique involving reaction of the inorganic radiobromine in the gas phase with solid potassium ferrocyanide (7), and the organic products were separated by gas chromatography.

EXPERIMENTAL

Sample Preparation

In order to attain the high purity required (8, 9) for a study of hot-atom reactions, samples were purified by gas chromatography prior to irradiation. About 0.5-ml samples of reagent grade bromoalkanes were purified with a column 2.5 meters long and 2.2 cm i.d. which contained a packing of Dow-Corning high-vacuum silicone grease on firebrick. The effluent was monitored with a thermal detector which was bypassed in favor of a condenser when the desired material was eluting from the column. A central fraction was condensed and collected in the irradiation vessel which consisted of a 0.5-ml bulb blown at the end of 4-mm soft-glass tubing. The samples were cooled with liquid air, evacuated, sealed, and immediately wrapped with black electrical pressure-sensitive tape to exclude light. When desired, a measured volume of either liquid bromine or its saturated vapor was transferred to the irradiation vessel prior to the collection of the bromoalkane.

Because of the low boiling point (3.6°) of bromomethane, samples of it required special handling. Before addition to the gas chromatographic column a sample was frozen in an ampoule with liquid air. This was opened and put into a chamber at the inlet to the column where the sample evaporated into the eluent gas stream. The condenser at the outlet of the column was cooled by a stream of air precooled with liquid nitrogen. The bromomethane was collected in ampoules cooled with Dry Ice.

Irradiation

The samples were irradiated at ambient temperature, about 25°, for 10 to 50 hours in a special facility (7) on the external face of the shielding of the Chalk River NRX reactor. The neutron flux of this position was slightly over 10^8 neutrons per square centimeter per second and a measurement of the gamma flux with a portable survey meter gave a maximum reading of 11 roentgens per hour. Thus the total gamma-ray dosage was considerably less than the value of 2×10^4 roentgens which has been shown to be the threshold value for gamma-ray effects (10).

Analysis for Radioactive Organic Products

The organic products of the reactions were separated by a programed temperature gas chromatography column, 2.5 meters long and 5 mm i.d., packed with Dow-Corning silicone grease on a crushed firebrick support. Helium was used as the eluent gas at 50 ml per minute. The irradiated sample was introduced into the column by first freezing it in liquid nitrogen, opening the ampoule, and immediately putting it into a small chamber at the entrance to the column. The column and accessories were arranged so that the sample came in contact with only the glass parts of the equipment. The amount of radioactivity associated with the samples was too low for convenient use of a recorder along with a radioactivity detector which monitored the continuous flow from the chromatographic column (6, 11). A method was therefore developed for concentrating the radiobromine in the effluent in a number of fractions through the use of a series of charcoal tubes put at the outlet of the chromatographic column. The charcoal tubes were cooled by a stream of air through a loose-fitting air condenser. To ensure retention of the low-boiling bromoalkanes with the continued flow of eluent gas, those tubes used to collect extremely volatile substances such as bromomethane were cooled with air which had passed through a coil immersed in liquid nitrogen. In the usual analysis a fraction was collected each minute and the radioactivity was determined by inserting the tube in a well attached to a thallium-activated sodium iodide scintillation crystal.

When the radioactivity of each sample was plotted as a function of time of elution, chromatograms such as in Fig. 1 were obtained. The identity of the activity associated

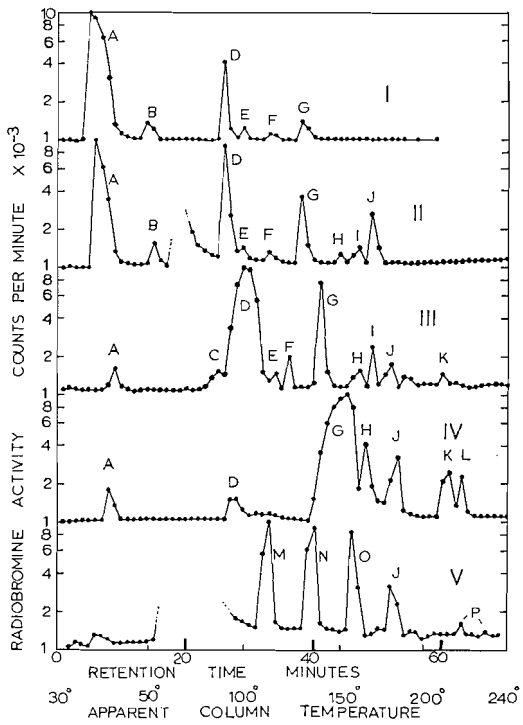

FIG. 1. Examples of chromatograms obtained from neutron-irradiated halomethanes: (I) pure monobromomethane; (II) monobromomethane with about 6 mole% bromine; (III) pure dibromomethane, (IV) pure tribromomethane; (V) tetrachloromethane with about 70 mole% bromine.

The peak assignments are as follows: (A) monobromomethane; (B) monobromoethane; (C) unidentified, probably unsaturated dibromoethane; (D) dibromomethane; (E) 1,1-dibromoethane; (F) 1,2-dibromoethane; (G) tribromomethane; (H) 1,1,1-tribromoethane; (I) 1,1,2-tribromoethane; (J) tetrabromomethane; (K) 1,1,1,2-tetrabromoethane; (L) 1,1,2,2-tetrabromoethane; (M) monobromotrichloromethane; (N) dibromodichloromethane; (O) tribromomonochloromethane; (P) bromochloroethanes.

with the various peaks was inferred in most instances by running macro amounts of known alkyl bromides through the column under the same conditions but using a thermal detector. In other cases, such as for the polybromoethanes, samples were not available and the identities of these have been presumed from boiling-point characteristics and position on the chromatogram (12).

It has been shown (13, 14) that similar results with respect to organic retention and organic products are obtained for both bromine 80 and 82. Therefore in these studies no attempt was made to distinguish between the radioactivity resulting from these two isotopes. In addition, since most of the organic radiobromine activity associated with a sample was determined during an interval of only a few minutes, corrections to a standard time to allow for decay generally amounted to less than 0.2% and were therefore negligible. With an irradiation of normally about 20 hours followed by analysis within a few hours the radioactivity in terms of counts per minute would be divided roughly equally beteeen the two isotopes.

Analysis for Organic Yield

Organic-yield measurements were made from separate irradiations using the absorption technique previously described (7) with an absorption tube as shown in Fig. 2. The

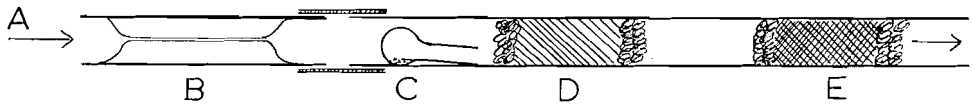

FIG. 2. Apparatus for organic-yield measurements. (A) Air 15 lb/in². (B) Thermometer capillary allowing about 50 to 100 ml/min air flow. (C) Irradiation vial with sample. (D) Potassium ferrocyanide, 50–100 mesh. (E) Charcoal about 100 mesh, cooled with Dry Ice while air was flowing.

inorganic bromine was retained by the potassium ferrocyanide and the organic compounds were retained by the charcoal. The organic retention was determined by cutting the tube and measuring the radioactivity associated with each part.

EXPERIMENTAL RESULTS

Organic Yield

Although they were not of primary interest, organic-yield measurements were made to enable one to make calculations of the distribution of the total radiobromine among the various organic products. In Fig. 3 are shown the organic-yield results obtained

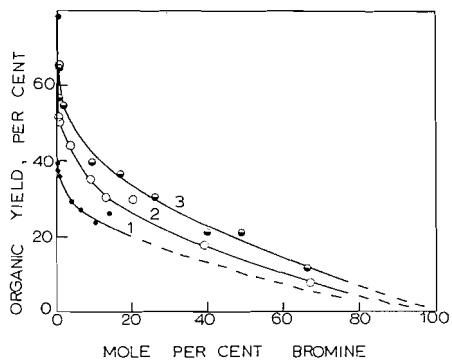

FIG. 3. Organic yield as a function of mole% of bromine: (1) ● monobromomethane; (2) ○ dibromomethane; (3) ◒ tribromomethane.

with the bromomethanes. These data indicate that the organic yield for pure bromomethanes was much higher than for pure monobromoethane or monobromopropane (8, 15). The organic yield for tribromomethane was comparable to that found previously (16). It is evident from these curves that sensitivity to the scavenging action of small amounts of bromine decreases in the order mono-, di-, and tri-bromomethane.

Distribution of Organic Products

Typical chromatograms obtained by the charcoal absorption tube technique for irradiated mono-, di-, and tri-bromomethanes and for a carbon tetrachloride–bromine mixture are shown in Fig. 1. It should be noted that the chromatographic peaks for the parent materials were not so sharp as the other peaks because samples of about 100 to 200 mg of the irradiated bromoalkane were used. This amount of sample caused flooding of the column. In the interests of uniformity, in Fig. 1, the original experimental results were recalculated to a background activity of about 1000 c.p.m. and to a highest peak of 10,000 c.p.m.

Detailed experimental results from irradiated bromomethanes are shown in Tables I and II. A considerable variety of organic products were obtained in each case. The number of products was not so numerous as was found for irradiated bromopropane (6) because, in the former case, the parent molecules contained only one carbon atom. Since the molecular weight of the largest molecules likely to have been formed in the irradiations would be low, the data of Tables I and II include results for all of the probable organic reaction products formed in appreciable amounts.

contrast, carbon tetrachloride when irradiated in the presence of bromine produced bromochloroethanes to a little less than 1% in addition to all the possible bromochloromethanes (Table III). This aspect of the study was not pursued.

DISCUSSION

It is noteworthy that the total yields of the bromoethanes from the mono-, di-, and tri-bromomethanes without bromine were 3.1, 6.2, and 10.3%. These results are reasonable when interpreted in light of the processes leading to the formation of the various products which have been described (4, 5, 8) in terms of a random fragmentation model. In this model the recoiling radiobromine atom and the atoms with which it collides are limited to a "hot spot". When the radiobromine has lost its excess energy it will be in this hot spot of a few hundred cubic Angstroms (17). In this thermalization region, there is a high local concentration of free radicals or ions formed by disruptive collisions during the thermalization of the bromine atom. The bromine atom may combine with one of these fragments during or after thermalization or it may diffuse into the surrounding medium before reaction. The above yields of bromoethanes therefore seem reasonable when it is realized that thermalization would occur in a smaller volume with the tribromomethane than with the monobromomethane. There would be a more efficient transfer of energy between the hot radiobromine atom and a highly brominated substrate due to there being a higher "concentration" of atoms of equivalent atomic mass. This more efficient confinement by tribromomethane would give a higher local concentration of the reactive fragments in the thermalization region than would monobromomethane. The higher concentration of reactive fragments would produce the larger proportions of bromoethanes observed since the formation of a bromoethane molecule requires that there be a collision between two one-carbon fragments.

To explain some of the chemical effects of nuclear transformations nine possible elementary reactions involving radiobromine have been discussed (8). On the basis of scavenger effects, the reactions have generally been described as either "hot" or "thermal" by Willard (4, 5). Those reactions involving a thermalized radiobromine atom after it has had an opportunity of undergoing thermal collisions are termed diffusive or thermal and the other reactions are termed hot. If a small amount of bromine scavenger is added to the irradiated substance, the radiobromine will probably exchange with the inactive bromine before it has opportunity to diffuse into the surrounding medium and react to give an organic product. Thus the products of thermal reactions are normally considered

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to be those that are readily scavenged. For instance, the percentage of radioactive monobromomethane was decreased from about 64% to 21% in going from 0% to 1 mole% bromine in monobromomethane irradiations. This dramatic decrease must be ascribed almost wholly to the elimination of thermal reactions. The reactions taking place in the radiobromine recoil zone or "hot spot" are relatively insensitive to the presence of scavenger and therefore are generally classed as hot. Hence products formed by these two kinds of reactions are distinguishable by how they are affected by the addition of scavenger.

In Tables I and II are shown data relating to the effect of the addition of bromine scavenger on the amounts of the various products formed. Detailed examination of these data shows that the irradiation products were formed by three classes of reactions instead of the two referred to above. Again, a thermal reaction, i.e. one that was eliminated by a small amount of bromine scavenger, was observed and this type of reaction appeared to be largely confined to the formation of the parent compound. Of the remaining products one group, formed by hot reactions, was insensitive to bromine concentration. In addition, there was a group of products which were gradually suppressed by very high bromine concentration. It is suggested that this last group be termed "hot-spot diffusive".

The hot reactions as considered here may roughly correspond to the "primary recombination" reaction discussed by Noyes (18) in connection with pairs of reactive fragments produced from a molecule. In a similar way, there is possible parallelism between hot-spot diffusive reactions and Noyes' "secondary recombination" reaction. In this connection, it should be pointed out that the hot reactions as discussed here are defined very broadly to include some reactions which are not conventionally thought of as being hot. Thus, the hot reactions of the present system could include, in addition to primary recombination in a "cage", the reactions involving hot replacement of a bromine atom by an energetic radiobromide atom and also reactions involving neutron activation of bromine in an alkyl bromide which fails to rupture the parent carbon–bromine bond. Evidence of the failure of the carbon–bromine bond to rupture in some cases has already been cited (19).

The amount of radioactive parent formed by thermal reactions was estimated from the decrease brought about by the addition of 1 to 2% of bromine to the pure bromomethane. To make a tentative assignment of the amounts of the organic radiobromide products formed by the hot and hot-spot diffusive reactions the data of Table I and II were corrected for the simple dilution effect of increasing amounts of bromine in the bromomethane–bromine mixtures. The formation of an organic radiobromine product in a system containing a hot radiobromine atom in an environment of bromomethane and bromine molecules would depend upon the chance that the atom would encounter a carbon-containing molecule or fragment. Therefore, it was most reasonable to normalize the data by multiplying the observed percentages of the total radiobromine in the various organic molecules by (100/mole% of bromomethane in the mixture). The organic products were divided into groups and, when the normalized data for the groups of products were plotted against the mole per cent of the bromine, in the manner shown in Fig. 4, sets of straight lines were obtained.[3] It can be seen that the results for one group of products were essentially independent of the amount of bromine in the mixture

[3]*An alternative set of graphs analogous to those of Fig. 4 were drawn involving atom per cent bromine and involving a normalization on the basis of the number of bromine atoms in the alkyl bromide. The use of those graphs led to virtually the same conclusions as those given in the text. For the reason given, it seemed best to normalize the organic radioactivity in terms of the carbon atoms present in the system.*

in the range from 100 to about 1 or 2 mole%. This group consisted of bromomethanes with more bromine than the parent molecule irradiated. Thus, for example, with irradiated dibromomethane this group consisted of tri- and tetra-bromomethane. A second group of products fell on a straight line which extrapolated to zero at the limit of 100 mole% bromine. This group comprised all of the other non-parent organic products. For example, with irradiated dibromomethane these consisted of monobromomethane and all of the bromoethanes. The parent materials formed a third set of straight lines which showed dependence on bromomethane concentration but extrapolated to a finite value at 100 mole% bromine.

The formation of a bromoethane molecule from bromomethane almost certainly must involve a collision of two one-carbon fragments. This implies a diffusive step following the formation of the appropriate one-carbon radicals or ions at the site of thermalization of the radiobromine atom. Since bromine would be an active competitor in reactions involving these fragments, its addition to the system would be expected to decrease the chance of reaction between two one-carbon fragments. Hence, the bromoethanes should be formed nearly exclusively in the hot-spot or thermalization zone. In order for the reaction to be significantly scavenged the concentration of scavenger would have to be comparable to the concentration of the reacting fragments in the reaction zone. The mole per cent of reactive fragments in the hot spot would be expected to be high and hence the bromine concentration must also be high to bring about a significant decrease in the extent of reaction leading to the formation of bromoethanes. It can be seen from Fig. 4B and Tables I and II that, although at 50 mole% bromine the fraction of these products was notably reduced, they could be considered to be completely scavenged only when the mole per cent of bromine approaches 100. Thus, these are hot-spot diffusive products. The chance of two fragments from bromomethane molecules colliding outside of the hot spot would be remote and hence the formation of bromoethanes by thermal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

reactions does not occur to an appreciable extent. The observation that traces of bromine had little effect on the proportions of those products bears out the contention that they were not formed outide the thermalization region. In this connection, it is noteworthy that the formation of bromoethanes from monobromomethane was even enhanced by a trace of bromine since 4.2% of bromoethanes was obtained with 0.066 mole% bromine while 3.1% was obtained when no bromine was present. This increase may have been due to an efficient scavenging of the hydrogen atoms or ions formed during thermalization. If hydrogen atoms or ions were scavenged more readily than the other fragments, there could be an increased formation of products resulting from recombinations of the remaining fragments, providing, of course, that the bromine concentrations were not too high. The hot-spot diffusive products discussed above appear to include the bromomethanes with less bromine that the parent molecule. Such products must be formed from an extensively fragmented bromomethane and radiobromine. For instance, to obtain radioactive monobromomethane from irradiated tribromomethane at least two and probably three carbon–bromine bonds must have been broken. It is not unreasonable to suppose that the one-carbon fragment and the radiobromine would have to diffuse together to form the product.

The products which persisted (Fig. 4A) in spite of large amounts of bromine must have been formed by hot processes (8) involving direct reaction of the recoiling radiobromine and a molecule or fragment in its environment. The extent of formation of products from this type of reaction should be independent of the concentration of the bromine scavenger after allowance is made for the dilution effect of the increasing amounts of bromine. It appears from these data that the hot products include all the bromomethanes with more bromine than the parent.

The lines in Fig. 4C suggest that in the presence of bromine the parent was formed by both hot and hot-spot diffusive reactions. It is proposed that the values obtained by extrapolation to 100 mole% of bromine are measures of the parent radiobromine-containing molecules formed by hot reactions. Similarly, radioactive parent formed in excess of this extrapolated value in the presence of a trace of bromine are measures of that formed by hot-spot diffusive recombination of radiobromine with an appropriate radical, ion, or molecule. As pointed out earlier, an estimate of the parent formed by thermal reactions was obtained from the effect of a small amount of bromine. It would thus appear that radioactive parent was formed by all three modes of reaction.

In Table IV are shown estimates made on the basis of the preceding discussion of the

distribution, according to the three types of reactions, of the products which made up the 78%, 65%, and 65% organic yield observed for mono-, di-, and tri-bromomethane (Tables I and II). It is interesting that the amount of parent formed by hot reactions was approximately in the ratio of 1 to 2 to 3 for mono-, di-, and tri-bromomethane. It would suggest that the chance of forming radioactive parent molecules by the types of hot reactions previously mentioned was directly proportional to the number of bromine atoms in the molecule.

PERFLUOROALKYL DERIVATIVES OF TIN

II. DIMETHYLTRIFLUOROMETHYLTIN CHLORIDE[1,2]

R. D. CHAMBERS, H. C. CLARK, AND C. J. WILLIS

ABSTRACT

A methyl group is cleaved by chlorine in preference to trifluoromethyl from trimethyltrifluoromethyltin and dimethyltrifluoromethyltin chloride; the significance of this is discussed in terms of the electronegativity of the trifluoromethyl group. The influence of trifluoromethyl on the acceptor properties of the tin atom in dimethyltrifluoromethyltin chloride has been illustrated by means of conductivity measurements. Nuclear magnetic resonance measurements of trimethyltrifluoromethyltin and dimethyltrifluoromethyltin chloride are also reported.

INTRODUCTION

Perfluoroalkyl derivatives of tin have been prepared recently by the reaction of hexamethylditin with perfluoroiodoalkanes (1, 2, 3),

$$Me_3Sn{-}SnMe_3 + R_FI \rightarrow Me_3SnR_F + Me_3SnI.$$

The reaction has since been shown to be applicable to other compounds containing metal–metal, or metalloid–metalloid, bonds and has led to the synthesis of new perfluoroalkyl compounds of arsenic (4) and phosphorus (5). Tin is the most electropositive element for which a stable trifluoromethyl derivative has been prepared, and the resultant compound has been shown to have interesting properties (1, 11). Because of this, and also because of the valuable synthetic properties of alkyltin halides, we have studied further the halogenation of trimethyltrifluoromethyltin.

EXPERIMENTAL

Preparation of Trimethyltrifluoromethyltin

Trimethyltrifluoromethyltin was prepared by irradiating, with ultraviolet light, a mixture of hexamethylditin and excess trifluoroiodomethane contained in a Carius tube. The details of this preparation have been described (1, 3).

Chlorination of Trimethyltrifluoromethyltin

Chlorine (2.68 g, 38 mmoles) was condensed into a Carius tube which contained a solution of trimethyltrifluoromethyltin (9.5 g, 41 mmoles) in chloroform (15 ml). The tube was sealed under vacuum and transferred to a cooling bath at −46°; the bath was allowed to warm to room temperature and after 2 days the reaction mixture had become colorless. Volatile material was removed under vacuum and, apart from chloroform, it consisted essentially of methyl chloride, together with small amounts of chlorotrifluoromethane and fluoroform. A white solid remained from which dimethyltrifluoromethyltin chloride (8 g, 77% yield), m.p. 46–47°, was sublimed *in vacuo* at 60–70°.

Chlorination of Dimethyltrifluoromethyltin Chloride

Chlorine (0.75 g, 10.6 mmoles) was condensed into a Carius tube which contained a solution of dimethyltrifluoromethyltin chloride (2.55 g, 10.1 mmoles) in carbon tetrachloride (15 ml). The color due to the chlorine did not appear to have diminished after 10 days and therefore the tube was warmed to 60° for 48 hours, during which time the

[1]*Manuscript received September 2, 1960.*

mixture had become colorless. The volatile material was distilled into a vacuum system and then fractionated. A fraction condensing at −195° (0.10 g) was shown by infrared examination to consist of chlorotrifluoromethane together with a small amount of fluoroform; the fraction condensing at −132° (0.44 g) consisted mainly of methyl chloride and a small amount of some unidentified material. A white solid (1 g) remained in the Carius tube; the solid was triturated with carbon tetrachloride and the mixture filtered. The filtrate was evaporated, leaving a solid (0.6 g) which melted at 103°. Dimethyltin dichloride melts at 106°; a mixed melting point gave no depression. The insoluble residue did not melt below 200°; it contained no chlorine and analyzed: C, 9.51; H, 1.57; F, 37.54. The infrared spectrum (Nujol mull) showed strong bands at 1150 and 1080 cm^{-1}, which are characteristic of C—F stretching modes for trifluoromethyl attached to tin (trimethyltrifluoromethyltin and dimethyltrifluoromethyltin chloride give almost identical absorption in this region (1)). A band at 800 (m) was present, which is characteristic of a tin–methyl rocking mode (1). Thus, from the analysis and infrared spectrum, the residue appears to contain methyl, trifluoromethyl, and fluoride in the ratio 1:1:2.

Conductometric Measurements

Measurements were carried out using a standard a-c. bridge. The cell used was fitted with a stopper to prevent evaporation of the solutions; and the cell constant was found to be 0.2958 by using a standard aqueous solution of potassium chloride, made up by weight.

Titration of Dimethyltrifluoromethyltin Chloride in Nitrobenzene with Pyridine

Nitrobenzene was purified by several distillations, and "Analar" grade pyridine was used. Additions of liquid to the cell were made by means of a weight pipette which incorporated a "Teflon" stopcock.

A solution of dimethyltrifluoromethyltin chloride (0.344 g) in nitrobenzene (60 g) was added to the cell. For the initial measurements a solution of pyridine (8 g) in nitrobenzene (50 g) was added from the weight pipette. Pure pyridine was used for the later measurements.

The titration of trimethyltin chloride (0.27 g) in nitrobenzene (59.63 g) was carried out in the same manner.

Dissociation Constant of Dimethyltrifluoromethyltin Chloride in Absolute Ethanol

Kraus and Callis (6) found that trimethyltin chloride behaved as a weak electrolyte in ethanol and that a dissociation constant could be determined. We have carried out the same procedure for dimethyltrifluoromethyltin chloride. The specific conductance of a solution of dimethyltrifluoromethyltin chloride in absolute ethanol was measured at various concentrations up to 1.50×10^{-2} moles per liter, and a graph was drawn of specific conductance as abscissa against the reciprocal of equivalent conductance as ordinate. If the "law of mass-action" can be applied, then the slope of the graph represents $(1/K_{diss}\Lambda_0^2)$ and the intercept with the ordinate represents $(1/\Lambda_0)$. The graph was a straight line up to a concentration of 0.59×10^{-2} mole per liter (showing that the "law of mass-action" can be applied in this case) with a slope 2.016×10^{5} and intercept with the ordinate 0.14, giving $K_{diss} = 9.73\times10^{-5}$ moles per liter at 25° (Table II).

Proton and Fluorine Resonance Spectra

The measurements were made at a fixed frequency of 40 Mc/sec on a Varian Model V-4300B high-resolution N.M.R. spectrometer. An internal standard (benzene) was used for the proton resonance, using carbon tetrachloride as solvent, and an external standard

(trifluoroacetic acid) was used for the fluorine resonance. The sample concentration used was 10–15%, and 2–5% benzene. A "side-banding" technique was used for these determinations.

DISCUSSION

The reaction of trimethyltrifluoromethyltin with an equimolar quantity of chlorine has previously been studied (1); a methyl group was easily removed at room temperature giving methyl chloride and dimethyltrifluoromethyltin chloride. This reaction has now been carried out in chloroform solution and improved yields have been obtained. Further chlorination of dimethyltrifluoromethyltin chloride in carbon tetrachloride, with an equimolar quantity of chlorine, was considerably more difficult and required heating to 60° for 2 days to complete the reaction. A complex mixture of volatile products was obtained which could not be completely separated by fractionation and was investigated spectroscopically. The two isolated fractions were methyl chloride, containing a small amount of some unidentified material, and trifluorochloromethane. Traces of fluoroform were also detected. The ratio of the weights of these two fractions, taken in conjunction with their infrared spectra, showed that the ratio of methyl chloride to trifluorochloromethane in the products was approximately 8:1.

The solid residue was separated by extraction with carbon tetrachloride into dimethyltin dichloride and a white intractable solid which was shown by analysis and its infrared spectrum to contain methyl, trifluoromethyl, and fluoride in the ratio, 1:1:2. It is clear,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

then, that preferential removal of a methyl group occurred, followed by rearrangement of the products. The formation of fluorides most likely takes place through the elimination of difluorocarbene from trifluoromethyl. The difluorocarbene eliminated might interact with some of the compounds present and greatly increase the complexity of the reaction mixture. Decomposition of trimethyltrifluoromethyltin and dimethyltrifluoromethyltin chloride has already been shown to occur in this way. A similar reaction of dimethyltrifluoromethyltin chloride with two equivalents of chlorine gave an equally complex mixture and no trifluoromethyltin trichloride could be isolated. The failure to isolate this compound may be due to its low thermal stability, which would be in accord with the much lower stability of dimethyltrifluoromethyltin chloride as compared with trimethyltrifluoromethyltin.

Thus, the tendency for a methyl group to be eliminated in preference to trifluoromethyl, at least in the first two stages of chlorination, has been illustrated. It has been shown by other workers (7) that the cleavage of organotin compounds by electrophilic reagents follows the empirical rule that the most electronegative group is preferentially eliminated and, on this basis, the cleavage of methyl in preference to trifluoromethyl is surprising. It has been shown (8) that the perfluorovinyl group is very easily cleaved by electrophilic reagents, and that it falls into the cleavage series of $CF_2{=}CF$, $C_6H_5 > CH_3 > CF_3$. It has been postulated (9) that such cleavage series may be explained in terms of electrophilic attack on the carbon atom with the highest electron density, and other workers (10) have suggested that, because of the inductive effect of the fluorine atoms, the carbon atom of the trifluoromethyl group is more electron deficient than the carbon atoms of the methyl groups in trimethyltrifluoromethyltin. This view does not take into account the ability of the trifluoromethyl group to behave as a separate electronegative entity, as illustrated by the removal of a trifluoromethyl group from trimethyltrifluoromethyltin by boron trifluoride (11). These compounds react under anhydrous conditions, in an inert solvent, with transfer of a trifluoromethyl anion to the boron trifluoride forming the very stable $[BF_3CF_3]^-$ ion. There is clearly a considerable difference in the behavior of the two electrophilic reagents, chlorine and boron trifluoride.

Lagowski (12) has concluded on the basis of thermochemical and infrared data that the value of the effective electronegativity of the trifluoromethyl group lies between those of fluorine and chlorine. Although other factors must also be involved, it is interesting then to note the similar behavior of the trifluoromethyl group and halogens in organotin compounds, with respect to cleavage reactions.

$$Me_3SnCF_3 + HCl\ (or\ Cl_2) \rightarrow Me_2CF_3SnCl + CH_4\ (or\ CH_3Cl)$$
$$Me_3SnCl + HCl\ (or\ Cl_2) \rightarrow Me_2SnCl_2 + CH_4\ (or\ CH_3Cl)$$
$$Me_3SnCF_3 + NaOH\ aq. \rightarrow Me_3SnOH + CF_3H$$
$$Me_3SnCl + NaOH\ aq. \rightarrow Me_3SnOH + HCl$$

It appears that as a result of its high electronegativity the trifluoromethyl group in trimethyltrifluoromethyltin is attached to the tin atom by a highly polarized bond, and, as such, differs from other organic groups which have been attached to a tin atom and placed in the cleavage series. The importance of this polarity in determining the properties of certain organotin compounds has recently been considered by Seyferth and Kahlen (13), who have discussed the properties of trimethyltin cyanide in terms of the highly polarized tin–carbon bond of the cyanide group.

In the cleavage of trimethyltrifluoromethyltin by electrophilic reagents, the relative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

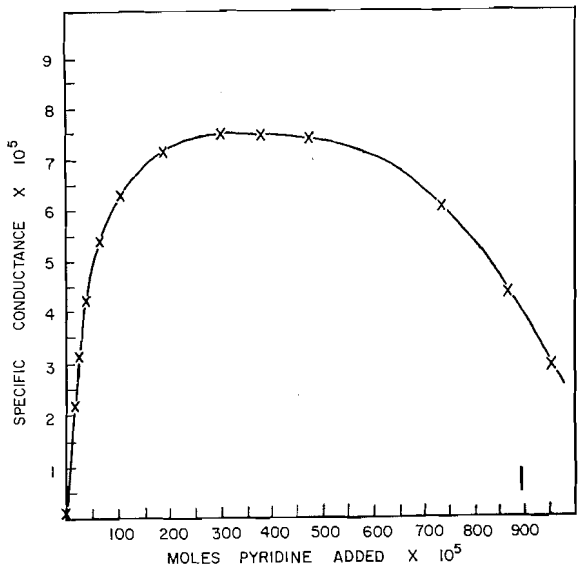
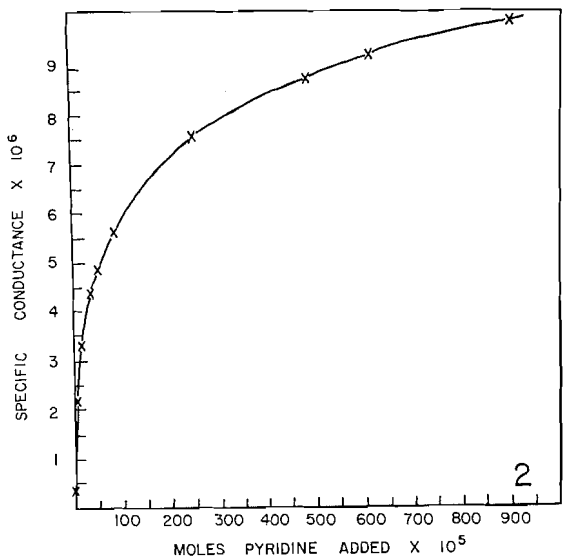
tin–carbon bond energies resulting from the polarized nature of the tin–trifluoromethyl bond may then be the controlling factors. Cleavage of a methyl in preference to a trifluoromethyl group on reaction with chlorine under non-polar conditions may result from the presence of this highly polarized bond which, by its influence on the tin–carbon bond energies, may make this elimination energetically favorable.

Trimethyltin chloride will react with pyridine and ammonia to form stable 1:1 co-ordination compounds, whereas dimethyltin dichloride adds on two donor molecules (14). It was our aim to prepare similar complex compounds using dimethyltrifluoromethyltin chloride, establish their constitution, and hence compare trifluoromethyl and chlorine with respect to their influence on the acceptor properties of an adjoining tin atom. We were not able to isolate complex salts, since direct reaction with pyridine gave a solid which did not contain trifluoromethyl. It was therefore necessary to use conductometric measurements in order to illustrate the acceptor properties of the tin atom in dimethyltrifluoromethyltin chloride.



It has been shown (15) that trimethyltin chloride is non-conducting in non-donor solvents and that addition of pyridine to a solution of trimethyltin chloride in nitrobenzene is accompanied by a rise in conductivity of the solution. Trimethyltrifluoromethyltin was found to be non-conducting in nitrobenzene and no significant rise in conductivity was observed with the addition of pyridine, indicating that there was little or no tendency to form a co-ordination compound which could yield ionic species. We have also compared the changes in conductivity of equimolar solutions of trimethyltin chloride and dimethyltrifluoromethyltin chloride in nitrobenzene (2.7×10^{2} moles of chloride per liter) with the addition of pyridine. Dimethyltrifluoromethyltin chloride was non-conducting in nitrobenzene but the conductivity rose very sharply with the addition of pyridine (Fig. 1) in an analogous manner to trimethyltin chloride (Fig. 2). The specific conductance of a 0.015 *M* solution of dimethyltrifluoromethyltin chloride in ethanol, which is a solvent of lower dielectric constant than nitrobenzene, was found to be 88.94×10^{-7} ohm^{-1} cm^{-1}. Thus, conducting species are formed, presumably due to co-ordination of pyridine to the tin atom in dimethyltrifluoromethyltin chloride. The resulting co-ordination complex appears to be a much stronger electrolyte than the corresponding complex between trimethyltin chloride and pyridine, since the conductivity of the dimethyltrifluoromethyltin chloride solution rises much more quickly than that of trimethyltin chloride (compare Fig. 1 and Fig. 2) for equivalent amounts of pyridine added during the first part of the experiment. The maximum values of specific conductance reached were 7.54×10^{-5} ohm^{-1} cm^{-1} for dimethyltrifluoromethyltin chloride, and 11.25×10^{-6} ohm^{-1} cm^{-1} for trimethyltin chloride.



A dissociation constant for the reaction

$$Me_2CF_3SnCl + EtOH \rightleftharpoons Me_2CF_3\overset{+}{S}nEtOH + Cl^-$$

was determined by the method used by Kraus and Callis (6) and found to be 9.7×10^{-5} moles per liter at 25° C (cf. 3.5×10^{-5} moles per liter at 25° C for trimethyltin chloride). The strong inductive effect of the trifluoromethyl group probably increases the acceptor properties of the tin atom, thus increasing the ionization of any co-ordination complex.

During the titration of dimethyltrifluoromethyltin chloride, after a concentration of 7.42×10^{-2} moles of pyridine per liter had been reached (Fig. 1) a further reaction occurred. The conductivity of the solution decreased and this was accompanied by the appearance of a precipitate in the cell; analysis and the infrared spectrum showed that this compound did not contain trifluoromethyl, and that it was identical with the uncharacterized

FIGS. 1 and 2.

compound obtained by direct reaction of pyridine and dimethyltrifluoromethyltin chloride. The nature of this secondary reaction was not investigated further.

We have attempted to extend the anionic transfer reaction with boron trifluoride, by adding trimethyltrifluoromethyltin to other acceptor molecules where the formation of complex ions is possible.

Preliminary experiments (16) have shown that compounds of the type $Me_3Sn[MCl_3X]$ (where M = Al or Ga, and X = halogen) can be prepared. However, reaction between aluminum trichloride or gallium trichloride and trimethyltrifluoromethyltin did not yield complex compounds of the form $Me_3Sn[MCl_3CF_3]$, (M = Al or Ga). Further

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

investigation of complex compounds involving trimethyltin and dimethyltin cations is proceeding.

Thus the reactions of trimethyltrifluoromethyltin with chlorine and with boron trifluoride demonstrate the "halogen-like" character of the trifluoromethyl group. The foregoing results show, however, that this analogy has several limitations, particularly under conditions where reaction with the trifluoromethyl groups leads to its decomposition.

Brown and Webster (17) have determined the changes in chemical shift in the proton resonance of a series of methyltin chlorides [Me_xSnCl_{4-x}] and have observed approximately equal increments for each methyl group replaced by chlorine, from tetramethyltin to methyltin trichloride. We have also observed this effect and have determined the proton and fluorine chemical shifts in trimethyltrifluoromethyltin and dimethyltrifluoromethyltin chloride. These results are shown in Table I and, since all shifts are to low field, an increase of shift corresponds to a decrease in the shielding. The increment of shift from tetramethyltin caused by the introduction of trifluoromethyl is not of the same order as the increment due to introduction of a halogen atom. This, however, cannot be taken as a comparison of the chemical similarity of trifluoromethyl and halogens since chemical shift appears to depend on so many factors other than electronegativity (18).

COCATALYSIS IN FRIEDEL–CRAFTS REACTIONS

IV. BORON FLUORIDE – METHANOL[1]

JOAN M. CLAYTON[2] AND A. M. EASTHAM

ABSTRACT

The kinetics of the isomerization of *cis*- and *trans*-2-butenes, catalyzed by methanol and boron fluoride mixtures, have been studied. The rate was found to be proportional to the concentrations of the boron fluoride – methanol complex and of free boron fluoride but independent of the butene concentration.

In previous papers (1, 2) we have reported the results of some experiments on the isomerization of *cis*- and *trans*-2-butenes in ethylene dichloride solution, using boron fluoride – water mixtures as catalyst. In order to interpret the results of those experiments it was necessary to estimate the position of the equilibrium between the mono- and di-hydrates of boron fluoride,

$$(BF_3.H_2O)^2 = (BF_3)(BF_3.2H_2O),$$

and this was done from measurements of the vapor pressure of boron fluoride over solutions of water in ethylene dichloride. From the resulting values for the concentrations of the hydrates it was concluded that the rate expression for the conversion of one butene isomer into the other was

$$d(\text{isomer}_B)/dt = k(BF_3)(BF_3.H_2O)(\text{isomer}_A).$$

The equilibrium constant obtained for the monohydrate–dihydrate reaction was at best an approximate one for, as its measurement was dependent upon small differences between large numbers, a considerable error was possible. With the catalyst system boron fluoride – methanol, however, this uncertainty can be largely avoided because the dialcoholate is very much less stable than the monoalcoholate and one may therefore assume that the concentration of the latter is approximately that of the added alcohol. Furthermore, the rates are much slower, and hence more easily measured, than those with water as cocatalyst, the catalyst mixtures are completely soluble over a wide range of concentrations, and the higher vapor pressure of the methanol permits more accurate dispensing of the cocatalyst. The present paper reports the results of some studies of the isomerization of the 2-butenes by boron fluoride – methanol mixtures.

EXPERIMENTAL

Materials were prepared and handled essentially as previously described. Methanol was dried with magnesium methoxide and measured as the vapor at pressures well below the saturation vapor pressure at room temperature.

Rates were measured in a reaction flask equipped with a manometer and having a total free space of about 215 ml. Ethylene dichloride (35 ml) was used as solvent and the temperature was controlled at 20° C by water circulating around the flask. Samples were removed as previously described and analyzed either by infrared spectroscopy or by gas chromatography. Isomerization of the trans isomer was followed by the appearance

[1]*Manuscript received July 14, 1960.*

Issued as N.R.C. No. 6056.
[2]*National Research Council Postdoctorate Fellow.*

of the cis peak in the infrared spectrum while that of the cis isomer was followed by the appearance of the trans peak in the chromatogram of a column prepared from 30 g silver nitrate dissolved in 30 ml glycerine, supported on 58 g Celite and packed into 16 feet of stainless steel tubing. The chromatographic method is suitable for mixtures containing up to about 75% of the trans isomer and is more accurate than the spectrographic method because it is not affected by traces of solvent. At low cis concentrations, however, the peaks for the two isomers overlap in the chromatogram and the infrared method gives the better results if a correction is made for the small absorption due to residual solvent.

The vapor pressure of boron fluoride over solutions of methanol in ethylene dichloride is shown in Fig. 1 and indicates clearly the essentially quantitative formation of the

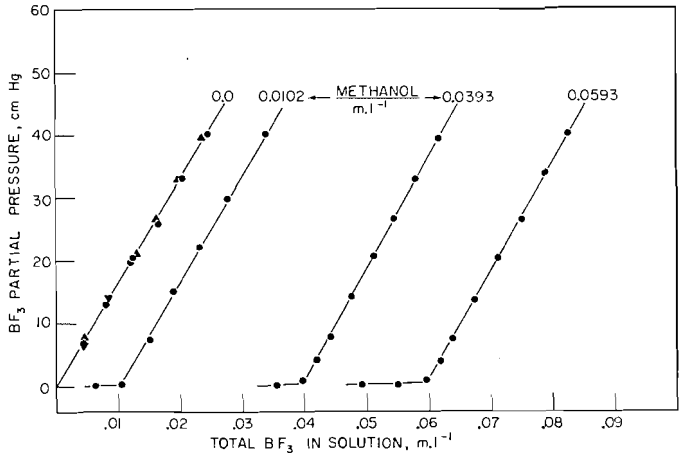

FIG. 1. The vapor pressure of boron fluoride over solutions of methanol in ethylene dichloride.

1:1 complex at all boron fluoride concentrations in excess of the methanol (compare the corresponding data for water (2)).

In this paper most concentrations have been expressed as moles per liter, calculated from the number of moles of reactant introduced into the reaction vessel divided by the volume of solvent. Concentrations expressed in this way give a reasonably accurate statement of the amount of dissolved material when the vapor pressure of the reactant is low, e.g. the methanol – boron fluoride complex, and are also quite accurate for the butenes since about 95% of the added olefin is in solution under the conditions of these experiments. In the case of boron fluoride, however, since about 80% of the free reagent is in the gas phase, the following terms, all based on the volume of solvent, have been used to define the concentrations:

$(BF_3)_{total}$ = the total BF_3 added to the system whether complexed, dissolved, or in the gas phase.

$(BF_3)_{free}$ = all uncomplexed BF_3 whether dissolved or in the gas phase.

$(BF_3)_{solution}$ = that part of the free BF_3 (about 20%) which is in solution.

RESULTS

In Fig. 2, the initial rates of isomerization of *trans*-2-butene are shown for a series of experiments in which the methanol concentration was varied at constant concentrations

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of butene and of total boron fluoride (1.0 mole $l.^{-1}$ and 6.0×10^{-3} moles $l.^{-1}$ respectively). It is evident that the variation in rate is essentially similar in type to that observed for cocatalysis by water (1), but the rates are much slower. Because of differences in temperature, in the free space of the reaction vessel, and perhaps in the kinetics, the relative rates for the two cocatalysts cannot be estimated accurately but for the conditions of this particular set of experiments, water appears to be about 50 times as effective as methanol.

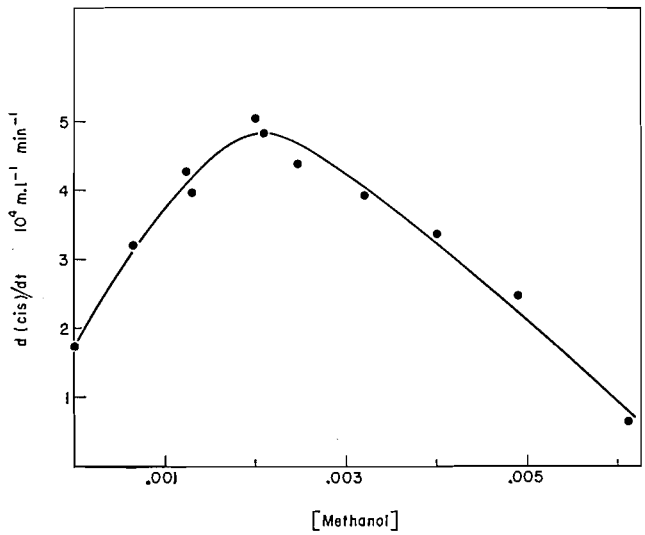

FIG. 2. The rate of isomerization of *trans*-2-butene at constant total boron fluoride concentration and varying methanol concentration.

The kinetics were examined in more detail by varying each of the three reactants in turn. For the experiments shown in Fig. 3(*a*) the initial *trans*-butene and methanol concentrations were fixed at 1.0 mole $l.^{-1}$ and 2.1×10^{-3} moles $l.^{-1}$, respectively, and the boron fluoride concentration was varied. For the experiments of Fig. 3(*b*) the *trans*-butene concentration was again 1.0 mole $l.^{-1}$ but the methanol concentration was varied and the boron fluoride adjusted to produce a constant 1.0×10^{-2} moles $l.^{-1}$ excess over the methanol. The dependence of the rate upon the concentrations of both free boron fluoride and the methanol – boron fluoride complex appears to be of the first order.

The dependence of the rate upon butene concentration is rather more difficult to determine, especially in the conversion of the trans to the cis isomer. In the previous work with water as cocatalyst, the limited evidence available suggested a first-order dependence on butene but the present results show clearly an order approaching zero (Table I). Furthermore the initial rates are almost identical when either isomer is used as starting material, indicating that the equilibrium is not determined primarily in the rate-controlling step. There is some indication in the experiments with *trans*-butene that the rates may not be entirely independent of the butene concentration but as the divergence is greatest where the experimental error is greatest we are inclined to believe that the data for the cis isomer are the more reliable.

The rate constants in the above table must be regarded as peculiar to the present

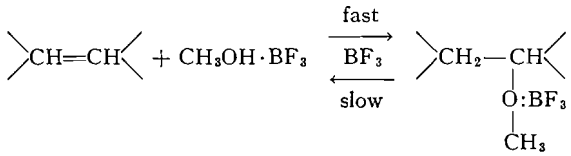
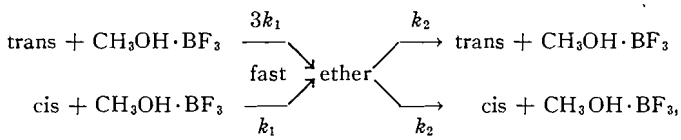
apparatus where about 80% of the free boron fluoride is in the gas phase. For purposes of comparison with other work, the value of k' in the expression



$$dx/dt = k'(CH_3OH \cdot BF_3)(BF_3)_{solution}$$

may be assigned the value 4.0×10^2 l. mole^{-1} min^{-1}.



Polymerization of the butene becomes important at high reactant concentrations and can be observed by the falling vapor pressure of the solutions. A few data gathered

throughout the course of this work suggest that the rate of polymerization is strongly dependent upon the concentrations of butene and of the methanol – boron fluoride complex but seemingly less dependent upon the concentration of free boron fluoride. The present evidence does not suggest that isomerization and polymerization are the parallel reactions one would expect if both were to occur through a common intermediate (e.g. a carbonium ion). This aspect of the problem is now under investigation.

The zero-order dependence of the isomerization upon butene concentration suggests either that butene reacts rapidly with catalyst to form a relatively stable intermediate, or else that the rate is controlled by some slow step not involving butene as for example a reaction between the two catalyst components. The only obvious stable intermediate would be the ether resulting from addition of methanol to the olefin (2-methoxy-butane), and indeed a reaction of the form

could account completely for all of the kinetic data reported here. If one assumes that equilibrium is determined entirely in the addition of the boron fluoride – methanol complex to the olefin and not in the regeneration of the olefin, that the equilibrium mixture contains only the cis and trans isomers in a 1:3 ratio, that steady-state conditions apply to the unreacted boron fluoride – methanol complex, and that all reactions are

catalyzed by free boron fluoride, then the following integrated rate expressions are obtained for the reactions:

$$\text{trans} \rightarrow \text{cis} \qquad k_{obs}t = \frac{3a}{8} \ln \frac{a}{a-4x} - \frac{x}{2},$$

$$\text{cis} \rightarrow \text{trans} \qquad k_{obs}t = \frac{3a}{8} \ln \frac{3a}{3a-4x} + \frac{x}{2}.$$

In these expressions a is the initial concentration of one isomer, x the concentration of the other formed in time t, and $k_{obs} = k_2\,(CH_3OH \cdot BF_3)_{initial}(BF_3)_{free}$. The values of k_{obs} obtained from these expressions hold very well over one or two half-lives of the reactions and agree reasonably well with the values obtained from initial rates (Table I).

However, although a treatment of this kind seems to account for these data, more recent experiments in this laboratory indicate that the isomerization cannot occur in this way. The addition and elimination of methanol do indeed occur under boron fluoride catalysis, but the rates seem to be too slow to explain the isomerization. It is possible that some other intermediate less stable than the ether is involved but it is difficult to conceive of one which would not be in equilibrium with free butene.

For personal use only.

If the reaction does not involve a stable intermediate then presumably some reaction of the catalyst system, as, for example,

$$CH_3OH \cdot BF_3 + BF_3 \rightleftarrows CH_3O(BF_3)_2^- + H^+,$$

must be rate controlling. A reaction of this kind would explain the need for free boron fluoride in the isomerization but we have been reluctant to postulate intermediates in which two boron fluoride molecules are attached to one oxygen atom because of the absence of any independent evidence for them. Their existence as transitory species is not, however, impossible. One of the difficulties with this approach is that it suggests the direct protonation of olefins to form carbonium ions and there is a growing body of evidence which suggests that, because of the high reactivity of such ions, their formation is not readily reversible (3) and hence cannot account for the rapid isomerization. A loosely bound proton–olefin complex such as a π-complex would, on the other hand, be reversible but probably would not disturb the olefin structure sufficiently to produce isomerization.

CONTRIBUTION À L'ÉTUDE DE LA RÉACTION DE VON RICHTER

I. SUR L'IDENTIFICATION DE QUELQUES PRODUITS ACIDES[1]

E. CULLEN[2] ET PH. L'ÉCUYER

RÉSUMÉ

La réaction de von Richter avec le *p*-chloronitrobenzène fournit, outre l'acide *m*-chlorobenzoïque attendu, un mélange de produits dont le 4,4′-dichloro-2,2′-dicarbamylazobenzène, le 3,8-dichloro-6-cétoquinazolo[1,2,2′,3′]indazol et l'acide 4,4′-dichloroazoxybenzène-2,2′-dicarboxylique. Ce dernier se transforme en la lactone de l'acide 5-chloro-2-[5-chloro-3-oxyindazyl-(2)]-benzoïque par sublimation.

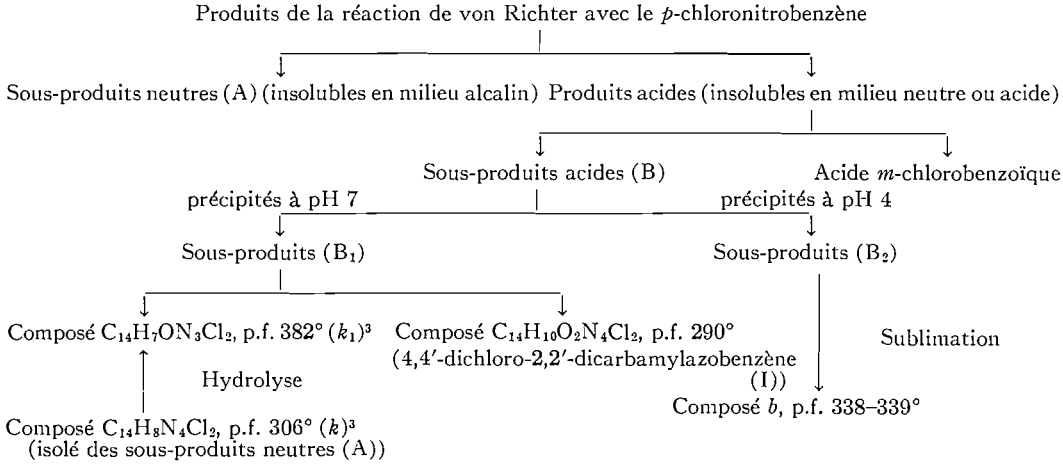
Avec le nitrobenzène, outre l'acide benzoïque, seul le 6-cétoquinazolo[1,2,2′,3′]indazol a été isolé.

Dans le but de déterminer la position des substituants dans les dérivés du nitrobenzène, von Richter (1, 2, 3) a fait réagir les dérivés nitrés du nitrobenzène avec le cyanure de potassium en solution alcoolique. Comme il obtenait des acides carboxyliques et que la réaction était invariablement accompagnée de la perte d'un groupe nitré, il supposa que le groupement nitrile substituait le groupe nitré et se transformait en groupement carboxylique. Toutefois, à la suite d'études de structures exécutées concurremment par Griess (4) et Korner (5), von Richter (6) dut admettre que le groupement nitrile se fixe en ortho de la fonction éliminée au lieu de déplacer directement le groupe nitré, ce qui a depuis été vérifié par Holleman (7) et tout récemment par Bunnett, Cormack et McKay (8). La transformation du *p*-bromonitrobenzène en acide *m*-bromobenzoïque peut servir d'exemple de cette réaction.

Sauf le travail de Holleman, la réaction est demeurée dans l'oubli jusqu'en 1950 alors que Bunnett et des collaborateurs (8, 9, 10) entreprirent d'en étudier la portée et le mécanisme. En plus de confirmer les résultats déjà obtenus par von Richter, ces chercheurs ont étendu le champ des observations antérieures. Ils ont, en particulier, montré qu'il est préférable de faire bouillir les réactifs dans l'alcool aqueux plutôt que de chauffer en tube scellé à 150°; car une température élevée favorise l'hydrolyse du cyanure (9, 11).

Cette réaction fournit, en plus de l'acide attendu, des produits neutres (insolubles en milieu alcalin) et des produits acides (insolubles en milieu neutre ou acide), dont les uns ou les autres prédominent suivant la nature des substituants dans le cycle du benzène (10).

I. RÉACTION AVEC LE *p*-CHLORONITROBENZÈNE (Tableau I)



Suivant les indications de Bunnett (9), nous avons isolé, à partir du *p*-chloronitrobenzène, 10% de produits neutres (A), 37% d'acide *m*-chlorobenzoïque et 12% d'autres produits acides (B). Nous avons réussi à obtenir proportionnellement plus d'acide *m*-chlorobenzoïque et de produits B en modifiant la façon de les isoler.

Une fois les produits A essorés, le filtrat est acidifié et les produits acides sont isolés et extraits à la ligroïne dans un Soxhlet. Seul l'acide *m*-chlorobenzoïque se dissout. Les produits B constituent le résidu. Ils peuvent être dissous dans de la soude diluée contenant un peu d'éthanol et séparés en deux groupes de composés: les premiers (B_1) précipitent à pH 7 et les seconds (B_2), à pH 4. Le même résultat est atteint, si les substances B_1

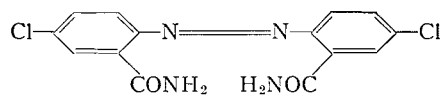
TABLEAU I



Produits de la réaction de von Richter avec le *p*-chloronitrobenzène

sont d'abord précipités dans le filtrat à pH 7, et ensuite les composés B_2 à pH 4. L'acide *m*-chlorobenzoïque est alors obtenu de ces derniers par extraction à la ligroïne.

Nature des produits B_1 et B_2

Du mélange de produits B_1 nous avons isolé deux substances. La première, $C_{14}H_7ON_3Cl_2$, fond à 382°. D'après un point de fusion mixte et les spectres infrarouges, elle s'est avérée identique à un composé (k_1) obtenu par l'hydrolyse d'une substance (*k*), p.f. 306°, qui appartient au groupe des produits neutres (A) de la réaction.[3] La seconde fond à 290° et a pour formule empirique $C_{14}H_{10}O_2N_4Cl_2$. Elle possède une fonction azoïque et un groupe amide. Nous sommes d'avis qu'elle est le 4,4′-dichloro-2,2′-dicarbamylazobenzène (I). Bunnett et Rauhut (12) ont récemment isolé une substance analogue, le 4,4′-diméthoxy-2,2′-dicarbamylazoxybenzène, à partir du *p*-nitroanisole.

(I)

Après avoir extrait l'acide *m*-chlorobenzoïque, nous avons sublimé, sous 12 mm de pression, le résidu des produits acides (B_2). Le sublimé, recueilli entre 180 et 350°, se dissout dans le β-éthoxyéthanol bouillant et fournit par cristallisation une substance (*b*) de point de fusion de 338–339°. Nous avons tenté de séparer le sublimé par sublimation fractionnée. Trois fractions ont été recueillies entre 180 et 210°, 210 et 290° et 290 et 350°. La troisième fraction contient la substance (*b*), qui est évidemment un produit de transformation, puisqu'elle n'est plus soluble dans la soude diluée. Quant aux fractions 1 et 2, il a été impossible de les purifier.

Identification du composé b (Tableau II)

D'après son analyse élémentaire, le composé *b*, p.f. 338–339°, possède la formule brute $C_{14}H_6O_2N_2Cl_2$. Il est insoluble dans les solvants organiques usuels ainsi que dans les

[3]*La description de ces deux substances, k et k_1, et de leurs analogues k′ et k_1′, paraîtra bientôt dans ce journal.*

alcalis et les acides dilués, mais soluble dans la potasse alcoolique et l'acide sulfurique concentré dans lequel il précipite par addition d'eau.

Nous nous sommes rendus compte que cette substance résulte d'une transformation de l'acide 4,4′-dichloroazoxybenzène-2,2′-dicarboxylique (II) qui se produit au cours de sa sublimation. Désirant vérifier comment cet acide se comporte, lorsqu'il est soumis aux conditions de la réaction de von Richter,[4] nous l'avons synthétisé suivant la méthode utilisée (13) pour préparer l'acide non-chloré III correspondant. Nous avons constaté que, lorsqu'il est sublimé, il se transforme en la substance *b*, comme le révèlant un point de fusion mixte et les spectres infrarouges (Fig. 1).

(II) X = Cl
(III) X = H

Au cours de cette transformation, l'acide perd une molécule d'eau et une molécule d'oxygène (équation 1, X = Cl).

$$C_{14}H_8O_5N_2X_2 \rightarrow C_{14}H_6O_2N_2X_2 + H_2O + O_2 \qquad [1]$$

X = H ou Cl

Les bandes dues à l'absorption des groupes carboxyliques à 3050–2550, à 1420 et 1300 cm^{-1} dans le spectre infrarouge de l'acide n'apparaissent pas dans celui du composé *b*, qui toutefois montre, à 1700 cm^{-1}, la bande due à la présence du groupe carbonyle.

[4]*Il ne change pas.*

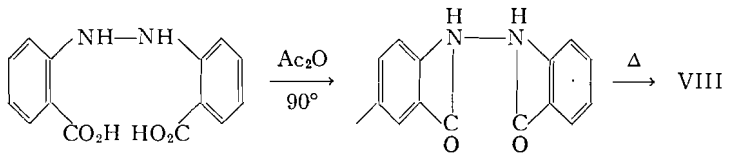
La substance *b* ne possède pas de fonction azoïque, azoxyque, nitrée, amine tertiaire ou amide secondaire. Elle donne le test des 1,2-dicétones, mais n'est pas oxydée par un mélange de peroxyde d'hydrogène et d'acide perchlorique et ne se condense pas avec l'*o*-phénylènediamine. Elle n'est réduite ni par l'étain ou le fer en milieu acide, ni par l'hydrogène et le palladium à la pression atmosphérique.

Par ébullition dans la soude alcoolique, le composé *b* se transforme en une substance blanche (b_1) qui est très soluble dans la soude diluée. Le spectre infrarouge de cette dernière présente les caractéristiques des dimères des acides carboxyliques (bande d'absorption due au groupement carbonyle à 1728 cm^{-1} et, dans la région de 3100–2400 cm^{-1}, une série de bandes attribuables aux groupes hydroxyles fortement associés par ponts hydrogène).

L'analyse centésimale et le poids moléculaire du produit de saponification b_1 correspondent à la formule brute $C_{14}H_8O_3N_2Cl_2$. Celle-ci ne diffère de celle de la substance *b* que par les éléments d'une molécule d'eau en plus. La substance b_1 est oxydée par l'acide nitrique en un produit jaune-orangé, $C_{14}H_8O_4N_2Cl_2$ (b_2), qui noircit vers 278–281° et fond à 308–310°. Sous l'action de la chaleur, elle perd une molécule d'eau et redonne la substance *b*. À ce stade-ci du travail, nous avons poursuivi cette étude de structure en utilisant l'acide azoxybenzène-2,2′-dicarboxylique (III) correspondant.

Cet acide non-chloré, $C_{14}H_{10}O_5N_2$, tel que prévu, se transforme facilement par sublimation (équation 1, X = H) en la substance $C_{14}H_8O_2N_2$ (b'), p.f. 292°, qui est l'analogue du composé *b*. Saponifiée par la soude alcoolique, la substance b' donne un composé blanc, $C_{14}H_{10}O_3N_2$ (b_1'), analogue au composé b_1. L'oxydation du composé b_1' à l'acide nitrique donne un produit orangé, $C_{14}H_{10}O_4N_2$ (b_2'), de point de fusion de 237°, analogue à la substance b_2 et identique à l'acide azobenzène-2,2′-dicarboxylique (IV) (14).

Carré (15, 16) a synthétisé ce dernier acide en oxydant l'acide 2-[3-oxy-indazyl-(2)]-benzoïque (VI), obtenu par la saponification de la lactone correspondante (VIII) (*a*). Or toutes les propriétés de la substance b' montrent qu'elle est identique à la lactone VIII (17). Par analogie, nous pouvons conclure que le composé *b* est la lactone de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque (IX).

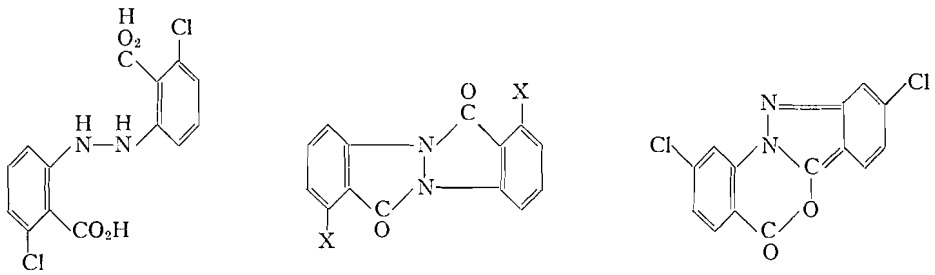


(VIII) X = H
(IX) X = Cl

(VI) X = H
(VII) X = Cl

(IV) X = H
(V) X = Cl

D'ailleurs, le produit b_1, qui provient de la saponification de la substance *b*, doit nécessairement être l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque (VII); car, le composé jaune-orangé (b_2) qu'il donne, lorsqu'il est oxydé par l'acide nitrique, est l'acide 4,4′-dichloroazobenzène-2,2′-dicarboxylique (V) de point de fusion de 308–310°. En effet, un point de fusion mixte et les spectres infrarouges ont montré que ce dernier acide est identique à l'acide que nous avons obtenu par synthèse, en réduisant l'acide 2-nitro-5-chlorobenzoïque par le zinc et la soude en l'acide 4,4′-dichlorohydrazobenzène-2,2′-dicarboxylique et oxydant celui-ci par l'acide nitrique.



Diverses opinions ont été émises concernant la structure de composés du genre de la lactone VIII. Celle-ci peut être obtenue par la déshydratation de l'acide hydrazobenzène-2,2′-dicarboxylique (X). D'après Heller (18), cette réaction se ferait par l'intermédiaire du bisanthranile (XI) (*b*).

(*b*)

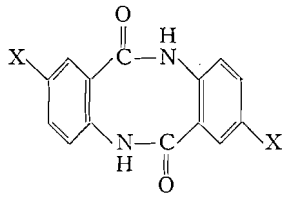
(X) (XI)

Reich et Merki (19) ont, par ailleurs, transformé le 2-nitro-6-chlorobenzaldéhyde en l'acide 3,3′-dichlorohydrazobenzène-2,2′-dicarboxylique (XII) et, celui-ci en une substance de point de fusion de 347–348°, insoluble dans les acides et les bases, à laquelle ils attribuent la structure dilactame XIII.

(XII) (XIII) X = Cl (XIV) X = H (XV)

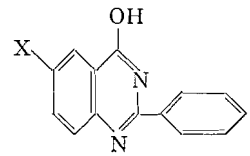
D'autre part, par déshydratation de l'acide 5,5′-dichlorohydrazobenzène-2,2′-dicarboxylique, Heller (18) a obtenu un isomère de la substance XIII, fondant à 335°, et lui attribue la structure XV.

Enfin, à la suite d'une étude des spectres infrarouges du bisanthranile XI de Heller et de la lactone VIII, Mosby (20) prétend qu'il faudrait attribuer au bisanthranile la structure lactone VIII et à la supposée lactone VIII, la structure dilactame XIV.



Nous sommes d'avis que la saponification des substances *b* et *b′* en acides 2-[3-oxy-indazyl-(2)]-benzoïques VII et VI justifie une structure lactone, mais non dilactame. En effet, l'obtention de ces acides VI et VII par la saponification des dilactames XIV et XIII ne pourrait s'expliquer que par une transformation facile des acides hydrazobenzène-2,2′-dicarboxyliques en acides 2-[3-oxy-indazyl-(2)]-benzoïques. Dans ce cas cette transformation devrait alors se produire en premier lieu au moment de la cyclisation au lieu de la transformation en dilactame.

Au cours de cette étude, nous avons voulu synthétiser la 2,9-dichlorophénomazine XVI. Selon Cooper et Partridge (21), l'anthranilate de méthyle se condense en présence de sodium métallique et de benzonitrile pour donner la phénomazine (XVII) et un peu de 4-hydroxy-2-phénylquinazoline (XVIII).



Le 5-chloroanthranilate de méthyle peut être préparé en chlorurant l'anthranilate de méthyle (22) ou en estérifiant l'acide 5-chloroanthranilique (23). Nous l'avons obtenu

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

en réduisant le 2-nitro-5-chlorobenzoate de méthyle par le fer activé. Le 5-chloro-anthranilate de méthyle se condense dans le xylène en présence de benzonitrile et de sodium métallique; mais nous n'avons isolé que de la 6-chloro-2-phényl-4-hydroxyquinazoline (XIX).

(XVI) X = Cl
(XVII) X = H

(XVIII) X = H
(XIX) X = Cl

II. Réaction avec le nitrobenzène

La réaction de von Richter avec le nitrobenzène a fourni de l'acide benzoïque et une substance, $C_{14}H_9ON_3$, fondant à 334–336°. D'après un point de fusion mixte et les spectres infrarouges, elle s'est avérée identique à un composé (k_1') obtenu par l'hydrolyse d'une substance (k'), p.f. 222–223°, qui est un produit neutre de la réaction.[3]

Partie expérimentale[5]

I. Réaction avec le *p*-chloronitrobenzène

En ce qui concerne la réaction proprement dite, le mode opératoire suivi est, à peu de variantes près, celui de Bunnett et ses collaborateurs (9). Une solution comprenant 1 partie de *p*-chloronitrobenzène et 4 parties de cyanure de potassium dans 10 parties (en volume) d'éthanol à 50% est bouillie à reflux pendant 48 heures. Le produit de la réaction est ensuite étendu à cinq fois son volume avec de l'eau et filtré. (Avant de filtrer, le mélange peut être soumis à une distillation à la vapeur d'eau. Celle-ci permet de récupérer environ 1% de la quantité initiale de *p*-chloronitrobenzène, qui est rapidement entraînée par la vapeur, et d'améliorer de 10% le rendement en acide *m*-chlorobenzoïque.) On obtient ainsi un solide neutre A jaune-verdâtre et un filtrat A.

(1) Isolement de l'acide m-chlorobenzoïque

L'acide *m*-chlorobenzoïque peut être extrait du filtrat A selon la méthode de Bunnett (8) ou suivant la modification suivante. Le filtrat A est acidifié à pH 4 et maintenu à 5° pendant au moins 12 heures. Les acides précipités sont alors filtrés et lavés à l'eau. Le filtrat et les eaux de lavage sont extraits au chloroforme et les extraits chloroformés épuisés à la soude 5%. La solution alcaline est chauffée pour en chasser les traces de chloroforme, puis est refroidie et acidifiée. Les acides ainsi précipités sont essorés, ajoutés aux acides déjà isolés, séchés sous pression réduite et extraits à la ligroïne (Eb = 65–110°) dans un Soxhlet. Seul l'acide *m*-chlorobenzoïque est extrait. L'extrait est ensuite évaporé à siccité. Le résidu, cristallisé dans le même solvant, fournit l'acide *m*-chlorobenzoïque (rendement 46% de la théorie) de point de fusion de 155–157°.

[5]*Les points de fusion (p.f.) ont été pris en tubes capillaires et ne sont pas corrigés. Les spectres infrarouges ont été déterminés au moyen d'un spectromètre Beckman IR4; les solides étaient mélangés à du bromure de potassium et pressés; seules les bandes servant à l'identification des composés sont indiquées; les valeurs en cm^{-1} correspondent au maximum d'absorption, sauf celles qui correspondent aux groupes hydroxyles des acides carboxyliques et qui montrent la région entière de l'absorption. Les microanalyses ont été effectuées par M. W. Manser, Zürich, Suisse.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(2) Isolement et identification d'autres produits

Du filtrat A, en plus de l'acide *m*-chlorobenzoïque, on peut isoler des produits (B) qui précipitent à différents pH.

(a) À pH 7

En ajoutant lentement au filtrat A, refroidi dans un bain glacé, de l'acide chlorhydrique 6 *N* jusqu'à ce que le pH devienne 5, puis la quantité de carbonate de sodium nécessaire pour le ramener à 7, des produits (B_1) (10 à 15% du poids de *m*-chloronitrobenzène de départ) précipitent et sont filtrés.

4,4'-Dichloro-2,2'-dicarbamylazobenzène (I) et 3,8-dichloro-6-cétoquinazolo[1,2,2',3']indazol (k_1).— Les produits B_1 (5.56 g), sublimés, sous 12 mm de mercure entre 180 et 350°, donnent un sublimé jaune-orangé (1.5 g). Lorsque celui-ci est sublimé de nouveau sous pression réduite, on recueille deux portions, l'une (0.386 g) au-dessous, et l'autre (0.919 g) au-dessus de 200°. Cette dernière peut être séparée en deux autres fractions par une troisième sublimation. Le composé qui constitue la première fraction est recueilli au-dessous de 220° et fond à 290°. D'après son analyse élémentaire et ses propriétés, il serait le 4,4'-dichloro-2,2'-dicarbamylazobenzène (I). Calculé pour $C_{14}H_{10}O_3N_2Cl_2$: C, 49.87%; H, 2.99%; N, 16.62%. Trouvé: C, 50.09%; H, 2.64%; N, 16.85%. Le produit de la deuxième fraction, recueilli entre 250 et 350°, cristallise dans la N,N-diméthylformamide en aiguilles de couleur jaune pâle et de point de fusion de 382°. Un point de fusion mixte de cette substance et du composé k_1 (le produit d'hydrolyse d'une substance *k* qui appartient aux produits neutres (A) de la réaction) n'est pas abaissé et les spectres infrarouges des deux sont identiques. Cette substance est le 3,8-dichloro-6-céto-quinazolo[1,2,2',3'] indazol.

(b) À pH 4

En portant à 4 le pH du filtrat obtenu en (*a*) et en procédant de la façon qui est décrite précédemment pour l'extraction de l'acide *m*-chlorobenzoïque à la ligroïne, d'autres produits acides (B_2) ont été isolés. Le résidu de l'extraction à la ligroïne (Eb = 65–110°) constitue ces produits.

Lactone de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque (IX) (b).—Tout comme les produits B_1, les produits B_2 (18–20% du poids de *p*-chloronitrobenzène de départ) n'ont pu être séparés que par sublimation. Trois températures ont été arbitrairement choisies pour recueillir trois fractions: (i) au-dessous de 200°, (ii) entre 210 et 240° et (iii) au-dessus de 250°. Il a été impossible de purifier les deux premières substances, soit par cristallisation, soit par sublimation. Le premier composé (i) fond à 205–210°. Calculé pour $C_{14}H_8O_7N_4Cl_2$: C, 39.54%; H, 4.27%; N, 13.18%. Trouvé: C, 39.70%; H, 4.15%; N, 13.03%. Le second fond à 280–290°. Calculé pour $C_{15}H_9O_3N_3Cl_2$: C, 51.45%; H, 2.59%; N, 12.00%. Trouvé: C, 51.88%; H, 2.53%; N, 11.60%. Quant à la troisième substance (iii), elle est la plus abondante des trois et correspond à la lactone de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque. Elle cristallise dans le β-éthoxyéthanol ou la 3-pentanone en paillettes lustrées de point de fusion 338–339°. Calculé pour $C_{14}H_6O_2N_2Cl_2$: C, 55.11%; H, 1.98%; N, 9,18%. Trouvé: C, 55.02%; H, 2.14%; N, 9.32%. L'acide 4,4'-dichloroazoxybenzène-2,2'-dicarboxylique (0.100 g), dont la synthèse apparaît plus loin, se sublime sous 12 mm de mercure, entre 250 et 350°, pour donner la lactone de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque (0.053 g) qui, après cristallisation dans le β-éthoxyéthanol, fond à 338°. Un point de fusion mixte d'un mélange de ce composé et de la substance (iii), décrite précédemment, n'est pas abaissé et les spectres infrarouges des deux sont identiques (Fig. 1). Calculé

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

pour $C_{14}H_6O_2N_2Cl_2$: C, 55.11%; H, 1.98%; O, 10.42%; N, 9.18%; Cl, 23.24%. Trouvé: C, 54.70%; H, 2.32%; O, 10.42%; N, 9.18%; Cl, 22.96%. Les essais de synthèse de l'acide 4,4′-dichloroazoxybenzène-2,2′-dicarboxylique à partir de l'acide 5-chloro-2-nitrobenzoïque (4.0 g) selon la méthode utilisée pour la préparation de l'acide 4,4′-diméthoxyazoxybenzène-2,2′-dicarboxylique (12) ou pour celle de l'acide azoxybenzène-2,2′-dicarboxylique (24) n'ont pas permis d'obtenir l'acide à l'état pur par la cristallisation des produits engendrés. Toutefois, en sublimant ces derniers sous 12 mm de mercure, on recueille, au-dessous de 200°, de l'acide 5-chloroanthranilique (p.f. 213–214°), et, entre 210 et 350°, un sublimé qui cristallise dans le β-éthoxyéthanol en paillettes lustrées de couleur jaune pâle et de point de fusion de 338–339°. Ce dernier est la lactone de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque (*b*) identique à la substance (iii). Calculé pour $C_{14}H_6O_2N_2Cl_2$: N, 9.18%. Trouvé: N, 9.11%.

Acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque (VII) (b_1).—De la lactone de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque (*b*) (0.030 g), dissoute dans 3 ml de soude 5 *N* et 3 ml d'éthanol, est chauffée à reflux pendant 2 heures. On dilue ensuite par l'eau à 25 ml et acidifie par l'acide chlorhydrique. L'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque précipite. Il cristallise dans l'acide acétique à 80% en lamelles blanches. Spectre infrarouge: —OH(—COOH), 2400–3400 cm^{-1}; =CO acide, 1730 cm^{-1}. Chauffé au-dessus de 100°, il redonne lentement la lactone de départ. Calculé pour $C_{14}H_8O_3N_2Cl_2$: C, 52.03%; H, 2.49%; N, 8.67%. Trouvé: C, 52.18%; H, 2.37%; N, 8.81%.

Acide 4,4′-dichloroazoxybenzène-2,2′-dicarboxylique (II).—Un mélange d'acide 2-nitro-5-chlorobenzoïque (5.0 g), d'hydroxyde de potassium (5.0 g) et d'éthanol (20 ml) est chauffé au bain-marie durant 2 heures et ensuite évaporé à siccité. Le résidu est dilué par l'eau, refroidi par addition de glace et acidifié par l'acide chlorhydrique. L'acide précipité est agité pendant environ 15 minutes avec 300 ml d'eau de baryte. On filtre, fait barboter un courant d'anhydride carbonique dans le filtrat pour précipiter l'excès de baryte et filtre de nouveau. En acidifiant le filtrat, l'acide 4,4′-dichloroazoxybenzène-2,2′-dicarboxylique (1.62 g, 36% de la théorie) précipite. Il cristallise dans l'acide acétique en courtes aiguilles de point de fusion de 272° (avec décomposition). Calculé pour $C_{14}H_8O_5N_2Cl_2$: C, 47.36%; H, 2.27%; N, 7.88%; Cl, 19.96%. Trouvé: C, 47.31%; H, 2.21%; N, 7.67%; Cl, 19.88%.

Acide 4,4′-dichloroazobenzène-2,2′-dicarboxylique (V) (b_2).—À une solution de 0.21 g de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque dans 30 ml de soude à 2%, on ajoute 30 ml d'acide nitrique concentré et chauffe au bain-marie pendant 2 heures. Après un repos de quelques minutes à la température ambiante, on filtre, lave à l'eau et sèche le précipité qui s'est formé. L'acide 4,4′-dichloroazobenzène-2,2′-dicarboxylique cristallise dans l'éthanol en fines aiguilles jaunes qui noircissent vers 278–280° et fondent à 308–310°. Calculé pour $C_{14}H_8O_4N_2Cl_2$: C, 49.57%; H, 2.38%; N, 8.26%. Trouvé: C, 49.46%; H, 2.59%; N, 8.55%. Un point de fusion mixte de cette substance et de l'acide obtenu par synthèse de la façon décrite ci-après n'est pas abaissé. Les spectres infrarouges de l'acide provenant des deux sources différentes sont de plus identiques.

On dissout 4.65 g d'acide 2-nitro-5-chlorobenzoïque dans 30 ml d'éthanol, ajoute à cette solution 6 ml de soude à 50% et chauffe au bain-marie. Sous agitation mécanique, on introduit ensuite peu à peu du zinc en poudre jusqu'à ce que la solution de rouge sombre passe au rouge pâle (environ 2 heures). Après un repos de quelques minutes, le mélange est filtré et le précipité d'oxyde de zinc ainsi que l'excès de zinc est lavé par de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

l'éthanol bouillant. Le filtrat est réuni à l'éthanol de lavage, dilué par un égal volume d'eau et acidifié par de l'acide chlorhydrique concentré. Le précipité jaune pâle, qui se forme, est essoré, lavé à l'eau et séché. On dissout ensuite ce solide (1.15 g) dans 280 ml d'acide acétique bouillant, ajoute 15 ml d'acide nitrique concentré à la solution et la fait bouillir à reflux pendant quelques minutes. À la température ambiante l'acide 4,4′-dichloroazobenzène-2,2′-dicarboxylique cristallise en aiguilles jaune-orangé. Après deux cristallisations dans l'acide acétique, il noircit vers 278–280° et fond à 308–310°. Calculé pour $C_{14}H_8O_4N_2Cl_2$: C, 49.57%; H, 2.38%; N, 8.26%. Trouvé: C, 49.31%; H, 2.51%; N, 8.42%.

4-Hydroxy-6-chloro-2-phénylquinazoline (XIX).—Le 5-chloro-2-nitrobenzoate de méthyle (12) est réduit en 5-chloroanthranilate de méthyle par le fer activé dans le benzène humide selon la méthode générale de Hazlet et Dornfeld (25) avec un rendement de 91%. On introduit ensuite, sous agitation mécanique, 5.0 g de 5-chloroanthranilate de méthyle et 4.2 g de benzonitrile dans un ballon muni d'un réfrigérant et contenant 1.2 g de sodium pulvérisé dans 125 ml de xylène anhydre. Une réaction exothermique s'amorce immédiatement. Une fois celle-ci atténuée (environ une demi-heure), on chauffe à reflux pendant 2 heures et on extrait ensuite à la soude 5 *N* le produit de la réaction. En acidifiant la solution alcaline, on obtient la 4-hydroxy-6-chloro-2-phénylquinazoline qui cristallise dans le xylène contenant un peu d'éthanol. Son point de fusion est de 292° et le rendement de 1.97 g (27% de la théorie). Calculé pour $C_{14}H_9ON_2Cl$: C, 65.41%; H, 3.54%; N, 10.94%. Trouvé: C, 65.00%; H, 3.53%; N, 10.90%.

Lactone de l'acide 2-[3-oxy-indazyl-(2)]-benzoïque (VIII) (b′).—L'acide azoxybenzène-2,2′-dicarboxylique se transforme par sublimation en la lactone de l'acide indazylbenzoïque. Sous 12 mm de mercure, lorsque la température du bain atteint 160°, l'acide ramollit, se gonfle et se solidifie de nouveau vers 200°. Il faut alors discontinuer l'opération et pulvériser la masse avant de continuer. Au-dessus de 280°, la sublimation se fait assez rapidement. À partir de 2.0 g de l'acide, on obtient 0.71 g de la lactone de l'acide 2-[3-oxy-indazyl-(2)]-benzoïque. Elle cristallise dans la 3-pentanone ou le β-éthoxy-éthanol en paillettes lustrées de couleur jaune pâle et fond à 292° (p.f. lit. 294° (16)). Calculé pour $C_{14}H_8O_2N_2$: C, 71.18%; H, 3.14%; N, 11.86%. Trouvé: C, 71.02%; H, 3.42%; N, 11.76%.

Acide 2-[3-oxy-indazyl-(2)]-benzoïque (VI) et acide azobenzène-2,2′-dicarboxylique (IV) (b_1′).—L'acide 2-[3-oxy-indazyl-(2)]-benzoïque est obtenu en faisant bouillir à reflux une suspension de 0.5 g de la lactone de l'acide 2-[3-oxy-indazyl-(2)]-benzoïque (obtenu précédemment par sublimation) dans 30 ml de soude 5 *N* et 30 ml d'éthanol. L'acide isolé (0.49 g) cristallise dans l'eau en lamelles blanches et fond à environ 285° après ramollissement vers 230° (p.f. lit. 230° (16)). De l'acide 2-[3-oxy-indazyl-(2)]-benzoïque (0.4 g) dissous dans la soude à 2% (40 ml) est oxydé par l'acide nitrique concentré (40 ml), comme il est décrit précédemment pour l'acide 4,4′-dichloroazobenzène-2,2′-dicarboxylique. L'acide azobenzène-2,2′-dicarboxylique obtenu cristallise dans l'eau et fond à 237° avec décomposition.

II. Réaction avec le nitrobenzène

Un mélange de 20.0 g de nitrobenzène, de 60.0 g de cyanure de potassium et de 200 ml de glycol à 90% est bouilli à reflux pendant 3 heures et abandonné à la température ambiante pendant 15 heures. En diluant avec de l'eau à environ 3000 ml, tout comme

dans le cas de la réaction avec le *p*-chloronitrobenzène, on obtient un solide neutre A′ jaune-verdâtre et un filtrat A′.

L'acide benzoïque (20% de la théorie) est extrait du filtrat A′ en procédant exactement tel que décrit précédemment pour l'acide *m*-chlorobenzoïque. Le résidu de l'extraction à la ligroïne (Eb = 65–110°) contient le produit acide B′.

Isolement et identification du produit acide B′

Le solide B′, obtenu précédemment après l'extraction de l'acide benzoïque à la ligroïne, ne se sublime qu'au-delà de 250°, sous 12 mm de mercure. Le sublimé ne correspond pas à la lactone de l'acide 2-[3-oxy-indazyl-(2)]-benzoïque, mais bien au 6-cétoquinazolo-[1,2,2′,3′]-indazol.[3] En effet, cristallisé dans l'acide acétique, il fond à 334–336°. Un point de fusion mixte de cette substance et du composé k_1' (le produit d'hydrolyse d'une substance k', un produit neutre de la réaction) n'est pas abaissé. Calculé pour $C_{14}H_9ON_3$: C, 71.48%; H, 3.85%; N, 17.86%. Trouvé: C, 71.39%; H, 4.14%; N, 17.78%.

REMERCIEMENTS

Nous remercions le Conseil national de Recherches du Canada, les firmes C.I.L. et Shell Oil, ainsi que l'Office de Recherches scientifiques de la Province de Québec pour des bourses d'études accordées à l'un de nous (E. C.).

CONTRIBUTION À L'ÉTUDE DE LA RÉACTION DE VON RICHTER

II. SUR L'IDENTIFICATION DE PRODUITS NEUTRES[1]

E. CULLEN[2] ET PH. L'ÉCUYER

RÉSUMÉ

La réaction de von Richter fournit, en plus de produits acides, des composés neutres. Avec le *p*-chloronitrobenzène, elle donne le 3,8-dichloro-6-iminoquinazolo[1,2,2′,3′]indazol et le 4,4′-dichloro-2-carbamylazoxybenzène, et avec le nitrobenzène, le 6-iminoquinazolo[1,2,2′,3′]-indazol.

La réaction de von Richter fournit, outre l'acide attendu, des produits neutres et des produits acides. Nous avons décrit précédemment (1) deux de ces derniers formés par la réduction du groupement nitré. Dans le présent mémoire nous décrivons trois produits neutres. Deux proviennent de la réaction avec le *p*-chloronitrobenzène et l'autre, de la réaction avec le nitrobenzène. En extrayant à la butanone les produits bruts neutres (A), essorés après la réaction avec le *p*-chloronitrobenzène, nous avons isolé trois substances, *k*, *m* et *n* (cette dernière en traces seulement), fondant respectivement à 306, 422 et 228–229°. L'extraction du filtrat (A) fournit même des traces d'un quatrième composé de point de fusion 164°.

La substance *k* est insoluble dans les bases et les acides dilués, mais se dissout dans l'acide sulfurique concentré. Elle est presque insoluble dans l'éther et peu soluble dans les autres solvants organiques usuels. En solution dans l'éthanol ou la butanone elle exhibe une forte fluorescence jaune-verdâtre. Son analyse élémentaire et la détermination de son poids moléculaire ont permis de déduire la formule empirique $C_{14}H_8N_4Cl_2$. Elle forme un chlorhydrate, $C_{14}H_8N_4Cl_2 \cdot HCl$, qui fond avec décomposition à 300–310°, et un dérivé acétylé, $C_{16}H_{10}ON_4Cl_2 \cdot \frac{1}{2}(CH_3CO)_2O$, de point de fusion de 260–261°.

Cette substance *k* est hydrolysée par l'acide chlorhydrique concentré en solution acétique et saponifiée par les bases inorganiques dans le glycol en libérant de l'ammoniac. Son produit d'hydrolyse (k_1) est insoluble dans les bases et les acides dilués, presque insoluble dans les solvants organiques, mais soluble à chaud dans les acides concentrés et la potasse alcoolique. Une fois sublimé, il fond à 378–380°. Son analyse centésimale correspond à la formule brute $C_{14}H_7ON_3Cl_2$. Il forme un sel de potassium $C_{14}H_6N_3Cl_2OK \cdot 2H_2O$, fondant à 420–422° (cristallisé dans l'eau), ou $C_{14}H_6N_3Cl_2OK \cdot H_2O$, de point de fusion 410° (cristallisé dans l'isopropanol), un sel de baryum, $(C_{14}H_6N_3Cl_2O)_2Ba \cdot 4H_2O$, et un éther méthylique, $C_{14}H_6N_3Cl_2OCH_3$, de point de fusion de 278–279°, mais pas de dérivé acétylé.

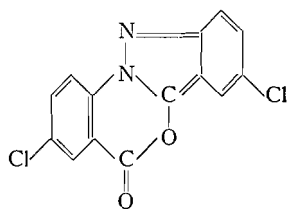
Les deux composés, *k* et k_1, donnent les tests des amines secondaires et des amides secondaires. Que le produit d'hydrolyse k_1 possède une fonction amide secondaire semble de plus confirmé par le fait qu'il forme une N-nitrozolactame dont l'hydrolyse donne le composé $C_{14}H_8O_3N_4Cl_2$ de point de fusion de 418–420°.

Le spectre infrarouge de la substance *k* indique une fonction imine (absorption à 3325 et 1650 cm^{-1}) et celui de la substance k_1, une fonction carbonyle (absorption à 1670 cm^{-1}), mais aucune vibration définie attribuable au groupe hydroxyle dans la région de 3500 cm^{-1}. Il est évident que c'est la fonction imine de la substance *k* qui est acétylée;

[1]*Manuscrit reçu le 21 septembre 1960.*
Contribution du Département de Chimie, Faculté des Sciences, Université Laval, Québec, Qué.
[2]*Bénéficiaire de bourses d'études accordées par le Conseil national de Recherches du Canada, les firmes C.I.L. et Shell Oil et l'Office de Recherches scientifiques de la Province de Québec.*

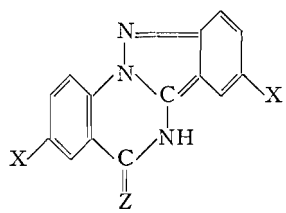
car, après l'élimination de cette fonction par hydrolyse, l'acétylation n'est plus possible.

La substance *k* n'est pas réduite par le fer activé, l'hydrogène en présence de palladium, ou l'hydrure de lithium et d'aluminium. Le composé *k* ou son dérivé acétylé est décomposé par l'acide chromique ou le permanganate neutre ou alcalin; mais il fournit, tout comme son produit d'hydrolyse k_1, des composés définis, lorsqu' ils sont traités par le peroxyde d'hydrogène à 95% et l'acide perchlorique en milieu acétique. Dans le premier cas, la substance obtenue fond à 252–254° et a la formule brute $C_{14}H_8O_2N_4Cl_2$. Dans le second, le composé formé, de point de fusion de 266°, a la formule empirique $C_{14}H_7O_3N_3Cl_2$.



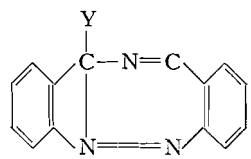
Ces deux produits d'oxydation, qui possèdent deux atomes d'oxygène de plus que les composés de départ, libèrent de l'iode dans une solution d'iodure de potassium à 10%. Ils se comportent comme des oxydes d'amines et seraient formés par l'oxydation de deux atomes d'azote tertiaire, laissant intactes la fonction amidine de la substance *k* et la fonction amide du composé k_1; car, ils peuvent encore réagir avec les nitrites.

Par analogie avec la lactone de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque (I) (1), nous suggérons la structure II pour la substance *k*, et la formule III pour son produit d'hydrolyse k_1.



Nous avons aussi isolé parmi les produits neutres de la réaction de von Richter avec le nitrobenzène une substance *k'*, $C_{14}H_{10}N_4$, de point de fusion de 222–223°, analogue à la substance *k*. Par hydrolyse elle fournit un composé k_1', $C_{14}H_9ON_3$, analogue au composé k_1.

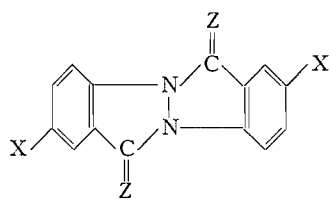
Ces deux substances, *k'* et k_1', sont relativement plus solubles dans les solvants organiques que leurs analogues chlorés, mais elles possèdent les mêmes propriétés chimiques et caractéristiques physiques. Ainsi, leurs solutions alcooliques montrent une forte fluorescence en lumière ultraviolette et les vibrations imine et carbonyle, qui apparaissent respectivement dans le spectre infrarouge des substances *k* et k_1, se retrouvent aussi dans celui des composés *k'* et k_1'. Nous suggérons les structures respectives IV et V pour ces substances *k'* et k_1'.



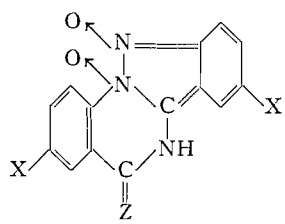
La substance *k'* semble identique à celle que Pinnow et Müller (2) ont isolée parmi les produits de la réduction de l'*o*-nitrobenzonitrile et qui, d'après eux, serait la diphénylaminopyrodiazoline (VI). Les deux ont le même point de fusion, donnent le même chlorhydrate, le même dérivé acétylé, le même dérivé benzoylé et le même produit d'hydrolyse (VII, d'après Pinnow et Müller).

(I)

(II) X = Cl; Z = NH
(III) X = Cl; Z = O
(IV) X = H; Z = NH
(V) X = H; Z = O

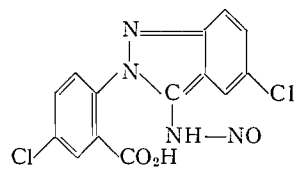


(VI) Y = NH_2
(VII) Y = OH



À notre avis, les structures VI et VII proposées par Pinnow et Müller sont inacceptables; les tests indiquent la présence d'une fonction amidine, mais non celle d'une fonction amine primaire dans la molécule de la substance *k'*. D'ailleurs, les spectres infrarouges des substances *k* et *k'* excluent la présence d'une fonction amine primaire et

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



ceux de leurs produits d'hydrolyse, k_1 et k_1', celle d'un groupe hydroxyle. Il semble aussi impossible d'attribuer la structure VIII à la substance k; car, si celle-ci possédait cette formule, elle aurait donné la dilactame correspondante IX, au lieu de la lactame que nous avons obtenue par hydrolyse. Nous proposons donc respectivement pour la substance k' et son produit d'hydrolyse k_1' les structures IV et V qui rendent bien compte de leurs spectres infrarouges et de leurs propriétés chimiques.

(VIII) X = Cl; Z = NH
(IX) X = Cl; Z = O

(X) X = Cl; Z = NH
(XI) X = Cl; Z = O

(XII)

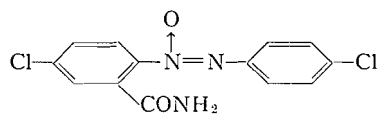
Les substances k et k' seraient donc le 3,8-dichloro-6-iminoquinazolo[1,2,2',3']indazol (II) et le 6-iminoquinazolo[1,2,2',3']indazol (IV), et leurs produits d'hydrolyse, k_1 et k_1', le 3,8-dichloro-6-cétoquinazolo[1,2,2',3']indazol (III), et le 6-cétoquinazolo[1,2,2',3']-indazol (V).

Ajoutons que le comportement des deux substances, k et k', vis-à-vis de l'oxydation et de la réduction ressemble à celui de l'indazol lui-même (3). C'est d'ailleurs aussi fort probablement à la présence du squelette de l'indazole qu'il faut attribuer la formation d'un produit rouge sous l'action de l'acide nitrique sur le composé d'hydrolyse k_1 (réaction de Knorr (4)). De plus, il est connu que la 2,4-dicétotétrahydroquinazoline se forme facilement par chauffage de l'acide *o*-uraminobenzoïque dans la soude concentrée (5), qu'elle se sublime à haute température et forme des sels de sodium hydratés tout comme le composé k_1.

Les structures X et XI semblent acceptables pour les produits d'oxydation, $C_{14}H_8O_2N_4Cl_2$ et $C_{14}H_7O_3N_3Cl_2$, de la substance k et de son produit d'hydrolyse k_1.

La substance $C_{14}H_8O_3N_4Cl_2$, qui est obtenue par nitrosation du produit d'hydrolyse k_1, pourrait avoir la structure XII, ce qui expliquerait sa solubilité dans la soude et ses caractéristiques d'amine secondaire. Son spectre infrarouge présente une forte vibration carbonyle à 1700 cm^{-1}, alors que la large bande entre 3200 et 2700 cm^{-1} du spectre du composé k_1 est absente. Ceci laisse entendre que l'hydrogène de la fonction amine est vraiment substitué.

Enfin, l'allure identique de la courbe d'absorption de la substance k' et de celle de la lactone de l'acide 5-chloro-2-[5-chloro-3-oxy-indazyl-(2)]-benzoïque (I) dans l'ultraviolet est conforme à la structure IV.



Il ne fait aucun doute que l'intermédiaire de la substance k est un produit de réduction du *p*-chloronitrobenzène, puisqu'une substance identique au produit non-chloré k' a été isolé par Pinnow et Müller (2) par réduction de l'*o*-nitrobenzonitrile. Toutefois, il est très peu probable que le nitrile soit un intermédiaire de la réaction de von Richter; car, après avoir fait bouillir pendant 20 heures une solution alcoolique de 2-nitro-5-chlorobenzonitrile dans les conditions de la réaction, nous n'avons pas obtenu le 3,8-dichloro-6-iminoquinazolo[1,2,2',3']indazol (II).

Nous avons alors voulu vérifier si la substance *k'* pouvait être produite par la transformation du 2,2'-dicyanohydrazobenzène; il est, en effet, connu que l'acide hydrazobenzène-2,2'-dicarboxylique peut être transformé en la lactone de l'acide 2-[3-oxyindazyl-(2)]-benzoïque (6). En conséquence, nous avons traité le 2,2'-dicyanoazoxybenzène dans les conditions de la réaction de von Richter, et nous avons obtenu, probablement par l'intermédiaire du composé hydrazoïque, le 6-iminoquinazolo[1,2,2',3']-indazol (IV), comme l'ont confirmé un point de fusion mixte et les spectres infrarouges.

Le composé *n*, p.f. 228–229°, a la formule brute $C_{13}H_9O_2N_3Cl_2$. Il est insoluble dans les acides et les alcalis dilués et très peu soluble dans l'éther. Il donne le test du groupe azoxyque et celui des amides. Son spectre infrarouge ne montre aucune vibration nitrile, mais des bandes d'absorption correspondant à la déformation de valence d'une fonction amide secondaire. D'autre part, la seule bande d'absorption de son spectre ultraviolet indiquerait la fonction azoxyque (7). Ces données font croire que la substance *n* est le 4,4'-dichloro-2-carbamylazoxybenzène (XIII).

(XIII)

PARTIE EXPÉRIMENTALE[3]

Trois substances, *k*, *m* et *n*, peuvent être isolées du mélange de produits neutres (A) qui sont essorés une fois la réaction de von Richter avec le *p*-chloronitrobenzène terminée (1).

$(C_{30}H_{20}O_2N_{10}Cl_4)_n$ *(m)*

Le résidu (environ 2%), obtenu après l'extraction du solide neutre (A) à la butanone dans un Soxhlet, cristallise dans la N,N-diméthylformamide en aiguilles jaunes de point de fusion de 422–423°. Calculé pour $(C_{30}H_{20}O_2N_{10}Cl_4)_n$: C, 51.65%; H, 2.90%; N, 20.17%; Cl, 20.02%. Trouvé: C, 51.45%; H, 2.84%; N, 19.79%; Cl, 20.00%. Spectre ultraviolet: max $\lambda m\mu$ 234 (ϵ 38,800); $\lambda m\mu$ 245 (ϵ 38,200); $\lambda m\mu$ 315 (ϵ 11,560); $\lambda m\mu$ 420 (ϵ 4,400). Les valeurs de ϵ sont calculées pour $n = 1$.

3,8-Dichloro-6-iminoquinazolo[1,2,2',3']indazol (k) (II)

L'extrait du solide (A) à la butanone est d'abord refroidi à 0°, puis porté à environ 50° et filtré, pour éliminer les dernières traces de la substance *m*. En refroidissant le filtrat, le 3,8-dichloro-6-iminoquinazolo[1,2,2',3']indazol (environ 60–70% du solide (A)) cristallise sous forme de lamelles lustrées et transparentes de couleur jaune-verdâtre. Après deux cristallisations dans la butanone la substance fond à 306°. Calculé pour $C_{14}H_8N_4Cl_2$: C, 55.46%; H, 2.66%; N, 18.48%. Trouvé: C, 55.27%; H, 2.42%; N, 18.32%. Dans l'isopropanol elle cristallise en longues aiguilles transparentes, p.f. 307°, qui contiennent une demi-molécule de solvant de cristallisation. Calculé pour $C_{14}H_8N_4Cl_2 \cdot \frac{1}{2}C_3H_8O$: C, 55.86%; H, 3.63%; N, 16.82%; Cl, 21.28%; O, 2.40%. Trouvé: C, 55.46%; H, 3.48%; N, 16.90%; Cl, 20.82%; O, 2.36%. Spectre infrarouge: 1650, 3325 (=NH), 3150 cm^{-1} (—NH— associé).

[3]*Les points de fusion (p.f.) ont été pris en tubes capillaires et ne sont pas corrigés. Les spectres ultraviolets ont été déterminés au moyen d'un spectromètre Beckman DU, en solution dans l'éthanol, et les spectres infrarouges, à l'aide d'un spectromètre Beckman IR-4; les solides étaient mélangés à du bromure de potassium et pressés; seules les bandes servant à l'identification des composés sont indiquées; les valeurs en cm^{-1} correspondent au maximum d'absorption, sauf celles qui correspondent au groupe* =CO—NH— *des amides secondaires qui montrent la région entière de l'absorption. Les microanalyses ont été effectuées par M. W. Manser, Zürich, Suisse.*

For personal use only.

La solution éthérée de l'indazol II traitée à l'acide chlorhydrique gazeux forme facilement un chlorhydrate blanc, qui jaunit rapidement et fond avec décomposition entre 300 et 310°. Calculé pour $C_{14}H_8N_4Cl_2 \cdot HCl$: Cl, 30.77%. Trouvé: Cl, 29.50%. Spectre infrarouge: 1662 (NH·HCl), 2440 à 3050 cm^{-1} (déplacement et élargissement) (8).

Le dérivé acétylé de l'indazol II est obtenu en faisant bouillir 50 mg de l'indazol dans 25 ml d'acide acétique, 0.5 ml de pyridine et 1 ml d'anhydride acétique et en cristallisant le produit dans l'acide acétique et ensuite le xylène. Il contient une demi-molécule d'anhydride acétique de cristallisation et fond à 260–261°. Calculé pour $C_{16}H_{10}ON_4Cl_2 \cdot \frac{1}{2}C_4H_6O_3$: C, 54.57%; H, 3.30%; N, 14.14%. Trouvé: C, 54.99%; H, 3.07%; N, 14.28%.

3,8-Dichloro-6-cétoquinazolo[1,2,2′,3′]indazol (k_1) (III)

On chauffe à reflux 0.522 g de 3,8-dichloro-6-iminoquinazolo[1,2,2′,3′]indazol et 1 g d'hydroxyde de potassium dans 20 ml de glycol. Durant l'ébullition il se dégage de l'ammoniac. La solution prend d'abord une teinte rouge et tourne rapidement au jaune-vert pâle. La réaction terminée, on refroidit la solution, la dilue par l'eau à environ 100 ml, l'acidifie à l'acide acétique ou chlorhydrique et l'abandonne à la température ambiante pendant 12 heures. On filtre ensuite le solide, le lave abondamment à l'eau et le sèche sous-vide. Le 3, 8-dichloro-6-cétoquinazolo[1,2,2′,3′]indazol (0.434 g) cristallise dans la N,N-diméthylformamide et fournit 0.315 g d'aiguilles jaunes de point de fusion de 382° qui contiennent une demi-molécule de solvant de cristallisation. Calculé pour $C_{14}H_7ON_3Cl_2 \cdot \frac{1}{2}HCON(CH_3)_2$: C, 54.81%; H, 2.82%; N, 14.43%; Cl, 20.88%. Trouvé: C, 55.13%; H, 2.79%; N, 13.99%; Cl, 21.10%.

Lorsqu'on purifie le produit brut par sublimation, on obtient, sous 12 mm de mercure entre 250 et 350°, un sublimé jaune pâle fondant à 378–380°. Calculé pour $C_{14}H_7ON_3Cl_2$: C, 55.28%; H, 2.32%; O, 5.26%; N, 13.82%; Cl, 23.32%. Trouvé: C, 55.18%; H, 2.28%; O, 5.60%; N, 13.85%; Cl, 23.22%. Spectre infrarouge: 1670 (=CO), 2400–3200 cm^{-1} (=CO—NH— associé).

Le sel de potassium s'obtient lorsqu'on fait bouillir du 3,8-dichloro-6-cétoquinazolo-[1,2,2′,3′]indazol (100 mg) dans la potasse à 10% (15 ml). Après une demi-heure d'ébullition, on ajoute prudemment la quantité d'eau chaude requise pour rendre la solution limpide et on la laisse refroidir à la température ambiante. Le sel cristallise en fines aiguilles de point de fusion de 420–422° avec deux molécules d'eau. Calculé pour $C_{14}H_6ON_3Cl_2K \cdot 2H_2O$: C, 44.57%; H, 2.67%; N, 11.14%; Cl, 18.80%. Trouvé: C, 43.92%; H, 2.51%; N, 10.71%; Cl, 18.95%. Dans l'isopropanol ou la N,N-diméthylformamide le sel de potassium cristallise en aiguilles jaune pâle de point de fusion 410°. Calculé pour $C_{14}H_6ON_3Cl_2K \cdot H_2O$: C, 46.67%; H, 2.24%; N, 11.66%. Trouvé: C, 46.89%; H, 2.53%; N, 11.47%.

Le sel de baryum s'obtient en additionnant de l'eau de baryte à une solution de sel de potassium. Le sel de baryum précipite. Il est filtré, lavé à l'eau et séché. Il noircit vers 340°, mais ne fond pas au-dessous de 500°. Calculé pour $Ba(C_{14}H_6ON_3Cl_2)_2 \cdot 4H_2O$: C, 41.22%; H, 2.47%; N, 10.30%. Trouvé: C, 40.91%; H, 2.30%; N, 10.03%.

Ether méthylique du 3,8-dichloro-6-cétoquinazolo[1,2,2′,3′]indazol

Le 3,8-dichloro-6-cétoquinazolo[1,2,2′,3′]indazol (50 mg) est bouilli à reflux pendant une demi-heure dans 50 ml de potasse à 10%. Le sel de potassium précipite à la température ambiante. Il est dissous par addition d'eau et, sous agitation, est traité par un excès de sulfate de méthyle (1 ml). Un solide jaune pâle précipite presque immédiatement. Après un séjour de 6 heures à la température ambiante, il est essoré, lavé, séché et cristallisé successivement dans l'acide acétique et le xylène. L'éther méthylique du 3,8-dichloro-6-cétoquinazolo[1,2,2′,3′]indazol apparaît sous la forme d'aiguilles microscopiques de

point de fusion de 278–279°. Calculé pour $C_{15}H_9ON_3Cl_2$: C, 56.62%; H, 2.85%; N, 13.20%. Trouvé: C, 57.02%; H, 2.94%; N, 13.05%.

5-Chloro-3-nitrosamino-2-[4-chloro-2-carboxyphényl-(2)]indazol (XII)

Le 3,8-dichloro-6-cétoquinazolo[1,2,2′,3′]indazol (0.140 g) est dissous dans l'acide sulfurique à 70% (en volume) et la solution, sous agitation, est refroidie à 5°. À la suspension du sulfate, on ajoute goutte à goutte, tout en maintenant la solution à 10°, 2 ml d'une solution de nitrite de sodium à 20%. On laisse séjourner le mélange dans le bain glacé durant 2 heures, on décompose ensuite l'excès de nitrite par addition d'urée et dilue finalement le tout par l'eau à 50 ml. On essore, lave et sèche le précipité (0.146 g). Cristallisé successivement dans la N,N-diméthylformamide et l'acide acétique, le 5-chloro-3-nitrosamino-2-[4-chloro-2-carboxyphényl-(2)]indazol forme des aiguilles jaunes de point de fusion de 418–420°. Calculé pour $C_{14}H_8O_3N_4Cl_2$: C, 47.88%; H, 2.30%; N, 15.96%. Trouvé: C, 48.18%; H, 1.97%; N, 15.81%. Spectre infrarouge: 1680 cm^{-1} (—COOH).

3,8-Dichloro-6-imino-11,12-dioxoquinazolo[1,2,2′,3′]indazol (X)

On dissout 0.536 g de 3,8-dichloro-6-iminoquinazolo[1,2,2′,3′]indazol dans 60 ml d'acide acétique glacial, et, tout en maintenant la température de la solution au-dessous de 20°, on ajoute 1.5 ml d'acide perchlorique à 60% et ensuite 1.5 ml de peroxyde d'hydrogène à 95%. On chauffe à reflux jusqu'à ce que soit disparue la coloration rouge qui apparaît au début de l'ébullition, ce qui exige environ une demi-heure. La solution est alors refroidie, diluée par l'eau à environ 175 ml et alcalinisée par la soude diluée. Le 3,8-dichloro-6-imino-11,12-dioxoquinazolo[1,2,2′,3′]indazol (0.134 g) jaune pâle précipite dès que le pH atteint la valeur de 3 à 4. Recristallisé deux fois dans le xylène, il se présente sous forme d'aiguilles crèmes de point de fusion de 252–254°. Calculé pour $C_{14}H_8O_2N_4Cl_2$: C, 50.14%; H, 2.40%; N, 16.72%. Trouvé: C, 50.16%; H, 2.45%; N, 16.44%.

3,8-Dichloro-6-céto-11,12-dioxoquinazolo[1,2,2′,3′]indazol (XI)

À une suspension de 0.310 g de 3,8-dichloro-6-cétoquinazolo[1,2,2′,3′]indazol dans 75 ml d'acide acétique, on ajoute à la température ambiante 1.5 ml d'acide perchlorique et 1.5 ml de peroxyde d'hydrogène à 95%. Après $1\frac{1}{2}$ heure d'ébullition à reflux, la solution est refroidie et diluée par l'eau. La solution colloïdale, qui apparaît d'abord, se coagule après quelque temps en un solide jaune (0.110 g). Celui-ci est essoré et sublimé entre 150 et 250° sous 12 mm de mercure. On recueille le 3,8-dichloro-6-céto-11,12-dioxoquinazolo[1,2,2′,3′]indazol qui fond à 250–252°, puis se solidifie et fond de nouveau à 266°. Calculé pour $C_{14}H_7O_3N_3Cl_2$: C, 49.87%; H, 2.39%; N, 12.46%. Trouvé: C, 49.97%; H, 2.42%; N, 12.29%.

4,4′-Dichloro-2-carbamylazoxybenzène (XIII)

En évaporant à siccité les filtrats provenant de la cristallisation du 3,8-dichloro-6-iminoquinazolo[1,2,2′,3′]indazol, la substance *k* décrite précédemment, et en cristallisant le résidu successivement dans divers solvants tels que l'acide acétique, l'éthanol et le 2-chloroéthanol, on parvient à isoler une troisième substance (*n*). Pour obtenir le 4,4′-dichloro-2-carbamylazoxybenzène à l'état pur, il faut le traiter à chaud par la soude alcoolique diluée, l'essorer, le laver à l'eau et le recristalliser dans l'acide acétique dans lequel il forme des aiguilles crèmes fondant à 228–229°. Calculé pour $C_{13}H_9O_2Cl_2$: C, 50.34%; H, 2.92%; N, 13.55%. Trouvé: C, 50.33%; H, 2.87%; N, 13.56%. Spectre ultraviolet: max $\lambda m\mu$ 335 (ϵ 20,800). Spectre infrarouge: 1680 (=CO), 3150 et 3400 cm^{-1} (—$CONH_2$).

For personal use only.

6-Iminoquinazolo[1,2,2′,3′]indazol (k′) (IV)

Le solide (A′), qui est obtenu à la suite de la réaction de von Richter avec le nitrobenzène (20 g) dans le glycol à 90% (200 ml) (1), cristallise dans l'éthanol en aiguilles (1.3 g) lustrées et transparentes de couleur jaune-verdâtre et de point de fusion de 222–223°. Toutefois, la plupart du temps, pour réussir à le purifier, il faut d'abord l'extraire à la butanone, évaporer l'extrait à siccité et cristalliser le résidu dans le même solvant. Calculé pour $C_{14}H_{10}N_4$: C, 71.77%; H, 4.30%; N, 23.92%. Trouvé: C, 71.72%; H, 4.41%; N, 23.78%. Spectre infrarouge: 1670 et 3310 (=NH), 3120 cm^{-1} (—NH—). Spectre ultraviolet: max $\lambda m\mu$ 236 (ϵ 56,800); $\lambda m\mu$ 300 (ϵ 18,800); $\lambda m\mu$ 375 (ϵ 9,500).

Le chlorhydrate du 6-iminoquinazolo[1,2,2′,3′]indazol s'obtient en dissolvant l'indazol IV dans l'acide chlorhydrique concentré à 60°. En laissant refroidir la solution à la température ambiante, le chlorhydrate cristallise. Il forme des cristaux jaunes de point de fusion de 279–280° (lit. 277° (2)).

Une solution de 2,2′-dicyanoazoxybenzène (1.0 g) et de cyanure de potassium (30.0 g) dans le glycol à 90% (100 ml) est bouillie à reflux pendant 3 heures, refroidie et diluée par l'eau (500 ml). Le précipité jaune-verdâtre (0.051 g), qui apparaît, est filtré, lavé, séché et extrait à la butanone. L'extrait est evaporé à siccité. Le résidu, cristallisé deux fois dans l'éthanol (noir animal), fournit des lamelles lustrées et transparentes de point de fusion de 221–222°. Un point de fusion mixte de cette substance et du 6-iminoquinazolo-[1,2,2′,3′]indazol obtenu précédemment n'est pas abaissé et les spectres infrarouges des deux composés sont identiques.

6-Cétoquinazolo[1,2,2′,3′]indazol (k_1′) (V)

Le 6-iminoquinazolo[1,2,2′,3′]indazol (0.500 g) est traité par l'hydroxyde de potassium dans le glycol (10 ml), comme il est décrit précédemment pour le 3,8-dichloro-6-céto-quinazolo[1,2,2′,3′]indazol. Le produit obtenu fournit par sublimation, à environ 280° sous 12 mm de mercure, un sublimé de 6-cétoquinazolo[1,2,2′,3′]indazol. Il cristallise dans l'acide acétique en aiguilles jaunes de point de fusion de 334–336°. Calculé pour $C_{14}H_9ON_3$: C, 71.48%; H, 3.85%; N, 17.86%. Trouvé: C, 71.55%; H, 3.85%; N, 17.94%. Spectre infrarouge: 1680 (=CO), 2500–3200 cm^{-1} (=C—NH— associé).

REMERCIEMENTS

THE KINETICS AND MECHANISM OF THE Cu^{++}-CATALYZED REDUCTION OF Cr^{VI} BY HYDROGEN IN AQUEOUS SOLUTIONS[1]

E. A. Hahn and E. Peters

ABSTRACT

The kinetics of the Cu^{++}-catalyzed reduction of Cr^{VI} by H_2 in aqueous perchlorate solutions have been investigated between 160° and 200° C. The mechanism proposed to account for the kinetics gives rise to a rate law of the form

$$\frac{-d[H_2]}{dt} = \frac{k_1[Cu^{++}][H_2]\{(k_2/k_{-1})[Cu^{++}]+(k_3/k_{-1})[Cr^{VI}]\}}{[H^+]+(k_2/k_{-1})[Cu^{++}]+(k_3/k_{-1})[Cr^{VI}]},$$

where

$$k_1 = 5.3\times10^{10}\exp(-25{,}800/RT) \text{ liter mole}^{-1}\text{ sec}^{-1},$$
$$k_2/k_{-1} = 2.5\pm0.7 \quad \text{and} \quad (k_3/k_{-1}) = 48\pm10.$$

As a consequence of these studies an important anomaly between the previously published rate law for dichromate reduction and a more recent kinetic study of the cupric-perchlorate-catalyzed hydrogen–oxygen recombination has been resolved.

INTRODUCTION

The reduction of dichromate by hydrogen in aqueous cupric perchlorate solutions has been described previously by Peters and Halpern (1), who observed simple second-order kinetics in the temperature range 80° to 140° C, the reaction being zero-order in dichromate, first-order in hydrogen, and first-order in cupric perchlorate. It was noted that perchloric acid additions above .025 M retarded the rate slightly, and subsequent studies (2) showed that this acid effect, at concentrations up to 1.00 M $HClO_4$, could be incorporated into the rate law to yield the expression

$$[1] \qquad \frac{-3d[Cr_2O_7^{=}]}{dt} = \frac{-d[H_2]}{dt} = \frac{k_1[H_2][Cu^{++}]^2}{[Cu^{++}]+(k_{-1}/k_2)[H^+]},$$

where k_1, k_{-1}, and k_2 are rate constants applicable to the slow steps of the following reaction sequence:

$$Cu^{++} + H_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} CuH^+ + H^+, \qquad [2a]$$

$$CuH^+ + Cu^{++} \xrightarrow{k_2} 2Cu^+ + H^+, \qquad [2b]$$

$$2Cu^+ + Cr_2O_7^{=} \xrightarrow{\text{fast}} 2Cu^{++} + \text{products}. \qquad [2c]$$

The rate law predicts a simple second-order reaction at low H^+ concentrations, as previously observed, and a more complex reaction approaching second-order dependence in copper at high acidities, which was later verified (2). Subsequently, it was observed that the initial reduction kinetics for copper precipitation from perchlorate solutions by hydrogen (3) followed the same law at temperatures up to 160° C. In this case a disproportionation process replaces step [2c] above, i.e.

$$2Cu^+ \xrightarrow{\text{fast}} Cu^{++} + Cu^0. \qquad [2d]$$

The object of the present investigation was to determine the effect of higher temperatures on the dichromate reaction, which had not been studied above 140° C, in order

[1]*Manuscript received September 8, 1960.*
Contribution from the Department of Mining and Metallurgy, University of British Columbia, Vancouver, British Columbia.

to learn more about the reaction mechanism and in particular the rate constants k_{-1} and k_2. Because of the very strong temperature effect, which doubled the reaction rate for approximately every 10° C increase in temperature, the cupric perchlorate concentrations were lowered substantially, while the initial dichromate levels were raised from those used in previous investigations in order to obtain reaction times long enough for good rate measurements.

EXPERIMENTAL

The experiments were conducted in the 1-gallon titanium-lined autoclave described in connection with earlier investigations (1, 2, 3, 4, 5), using a similar procedure. Silicon carbide, about 240 mesh, was packed between the titanium liner and the stainless steel autoclave to provide a heat transfer medium, to replace water which had been used previously, but which was unsatisfactory at higher temperatures. Glass wool was packed above the silicon carbide powder to prevent contamination of the solution. By this arrangement the temperature was controlled to within ±0.3° C with a Leeds and Northrup Micromax controller–recorder.

The exit tube from the sampling valve consisted of 3 feet of titanium tubing in the form of a coil which was water-cooled to eliminate flashing of the samples when they were drawn from the autoclave at temperatures up to 200° C.

All chemicals used were of reagent grade, supplied by Baker and Adamson Limited. Stock solutions were prepared with distilled water. Cupric perchlorate was prepared from perchloric acid and cupric oxide. Commercial hydrogen gas, supplied in cylinders by Canadian Liquid Air Company, was used without further purification.

Two and one-half liters of solution of the desired composition were placed in the titanium liner of the autoclave, which was then sealed, flushed with nitrogen, and heated to the desired temperature. Experiments were performed at temperatures of 160°, 180°, and 200° C. Hydrogen was introduced after the autoclave had been maintained at the reaction temperature for an appreciable amount of time. Samples of the solution were withdrawn at intervals both before and after the addition of hydrogen, and analyzed to determine the course of the reaction. Dichromate determinations were made spectrophotometrically at the 350 mμ absorption peak, using a Beckman DU spectrophotometer. Copper was determined electrolytically, and free acid was titrated with sodium tetraborate solutions.

RESULTS AND DISCUSSION

Early in this investigation it was observed that the plots depicting the reduction of dichromate by hydrogen in the presence of cupric perchlorate were not straight lines, as found at lower temperatures, lower dichromate levels, and higher copper concentrations, by previous investigators (1, 2). Typical rate plots, shown in Fig. 1, indicate that the rate is dichromate dependent, and the extent of this dependence increases as the acidity is increased.

Rate measurements were made from these plots by measuring slopes at various dichromate levels.*

On the assumption that the kinetics of this reaction obeyed a rate law that bears some

**To make rate measurements, the best smooth curve was drawn through the points with a flexible curved ruler, and tangents were drawn by the mirror-image method. The measurements have a maximum precision near the mid-point of the curve of about ±5%, with the precision falling off at both ends, because of the scatter of experimental points.*

For personal use only.

relation to equation 1, in spite of the partial dichromate dependence, the effect of varying the hydrogen ion concentration was studied. The reduction plots of one set of these experiments are presented in Fig. 1, and the inverse rates of these plots measured at several dichromate levels are shown in Fig. 2. The latter plots are seen to be straight lines, indicating that an inverse dependence of the rate on hydrogen ion concentration exists at all dichromate levels. In the same plot, the dichromate dependence appears to vanish at low hydrogen ion concentration.

A mechanism has been proposed that will account for all of these observations and involves a simple modification of mechanism [2]. The steps are:

$$Cu^{++} + H_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} CuH^+ + H^+, \qquad [3a]$$

$$CuH^+ + Cu^{++} \xrightarrow{k_2} 2Cu^+ + H^+, \qquad [3b]$$

$$CuH^+ + Cr^{VI} \xrightarrow{k_3} \text{intermediates} \xrightarrow{\text{fast}} Cu^{++} + \text{products}, \qquad [3c]$$

$$2Cu^+ + Cr^{VI} \xrightarrow{\text{fast}} 2Cu^{++} + \text{products}. \qquad [3d]$$

When this mechanism is subjected to the steady-state treatment in CuH^+, the following rate law is obtained:

$$[4] \qquad \frac{-3d[Cr_2O_7^{=}]}{dt} = \frac{-d[H_2]}{dt} = \frac{k_1[Cu^{++}][H_2]\{(k_2/k_{-1})[Cu^{++}]+(k_3/k_{-1})[Cr^{VI}]\}}{[H^+]+(k_2/k_{-1})[Cu^{++}]+(k_3/k_{-1})[Cr^{VI}]}.$$

The above expression can be inverted to give the function in H^+ that is plotted in Fig. 2. The intercept on this plot is seen to be

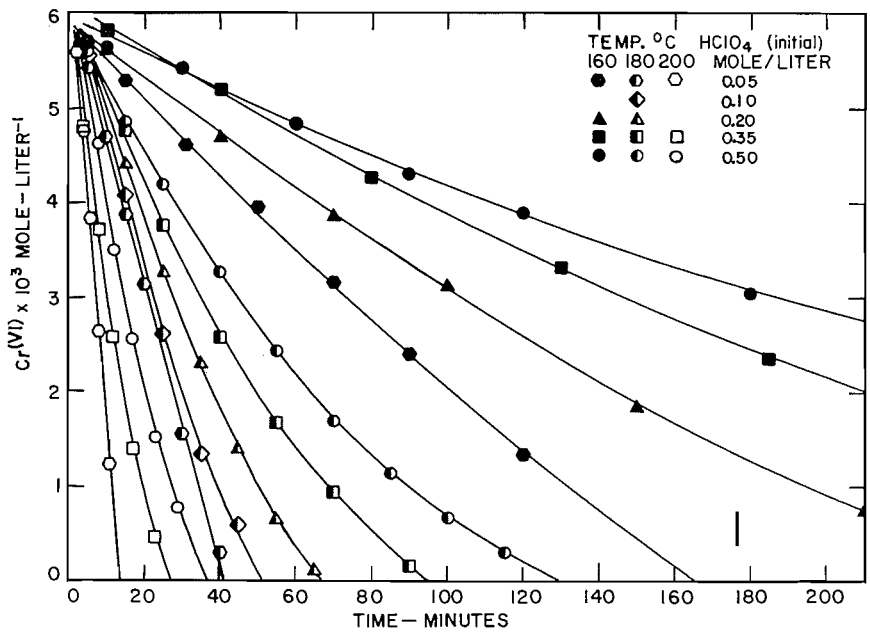
$$[5] \qquad I = \frac{1}{k_1[Cu^{++}][H_2]},$$

while the slope can be expressed as

$$[6] \qquad S = \frac{1}{k_1[Cu^{++}][H_2]\{(k_2/k_{-1})[Cu^{++}]+(k_3/k_{-1})[Cr^{VI}]\}}.$$

From equation 6, it is apparent that the reciprocals of the slopes in Fig. 2 should be linear in Cr^{VI}. This is demonstrated in Fig. 3, where the inverse slopes of the lines in Fig. 2, $1/S$, are plotted against Cr^{VI} for the three different temperatures. The equation representing these lines is obtained by inverting equation 6, i.e.,

$$[7] \qquad \frac{1}{S} = k_1[Cu^{++}][H_2]\{(k_2/k_{-1})[Cu^{++}]+(k_3/k_{-1})[Cr^{VI}]\}.$$



Thus it can be seen that the slopes of Fig. 3 represent the value of $k_1[Cu^{++}][H_2](k_3/k_{-1})$ and the intercepts represent the value $k_1[Cu^{++}][H_2](k_2/k_{-1})[Cu^{++}]$.

A further simplification can be obtained by dividing equation 7 through by $k_1[Cu^{++}][H_2]$ which is the value of the reaction rate extrapolated to zero hydrogen ion concentration, that is, the inverse intercept of Fig. 2, expressed by equation 5. The resulting expression is given by

$$[8] \qquad \frac{I}{S} = \frac{k_2}{k_{-1}}[Cu^{++}]+\frac{k_3}{k_{-1}}[Cr^{VI}].$$

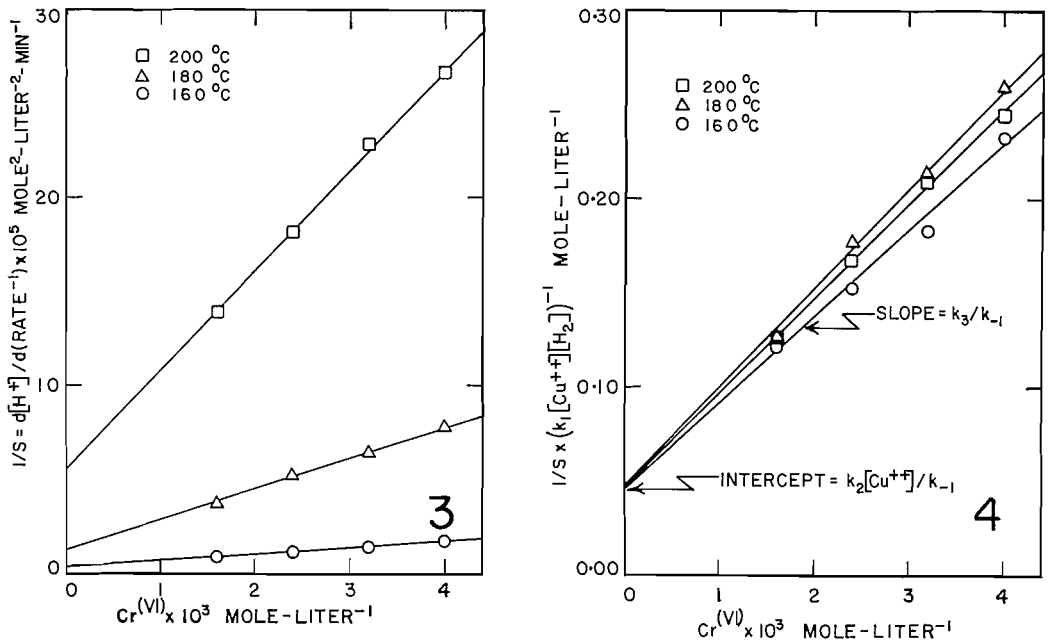

FIG. 3. Dependence of the function $d[H^+]/d(\text{rate}^{-1})$ on the dichromate level in solution.
FIG. 4. Dependence of the function $(d[H^+])/\{k_1[Cu^{++}][H_2]\times d(\text{rate}^{-1})\}$ on the dichromate level.

A plot of I/S vs. Cr^{VI} is given in Fig. 4, for the three temperatures that were studied. It can be seen that fairly straight lines are obtained and that the temperature dependence that appears so pronounced in Fig. 3 virtually disappears in Fig. 4. It can, therefore, be concluded that only k_1 is particularly temperature dependent and that k_2/k_{-1} and k_3/k_{-1} are relatively insensitive to temperatures in this region. Values of k_2/k_{-1} and k_3/k_{-1} that are obtained from the slopes and intercepts of Fig. 4 are listed in Table I, together with values of k_1 obtained from intercepts of Fig. 2.

TABLE I

Rate constants at various temperatures

200	$5.7\times10^{-2}\pm15\%$	$2.6\pm30\%$	$49\pm20\%$

*Obtained from intercepts in Fig. 2, using Cu^{++} = .02 mole/liter and new H_2 solubility data (6).
†Values at 110° C were obtained from reference 2.
‡Value of k_2/k_{-1} at 110° C is the reciprocal of the value for k_{-1}/k_2 (= 0.26) given in reference 2.

The temperature dependence of k_1 is depicted by means of an Arrhenius plot in Fig. 5. The activation energy of 25.8 kcal, obtained from the slope of this plot, is in excellent agreement with the value (26.6 kcal), obtained earlier (5). The rate constant k_1 is thus given by

[9] $$k_1 = 5.3\times10^{10}\exp(-25{,}800/RT) \text{ liter mole}^{-1}\text{ sec}^{-1}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

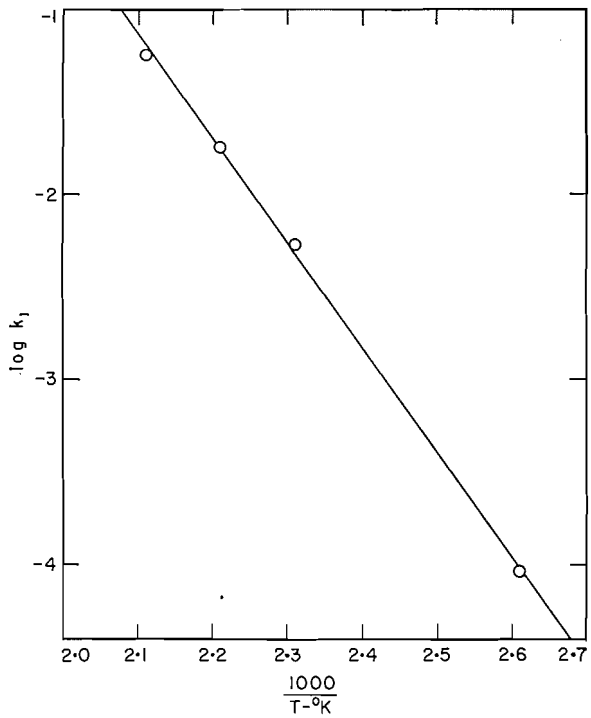

FIG. 5. Arrhenius plot of k_1: 0.02 M $Cu(ClO_4)_2$, 10 atm H_2.

The plots shown in Figs. 1–4 inclusive indicate that the data are consistent with the proposed mechanism [3], and the resulting rate law [4]. The data can be treated another way, by inverting equation 4 to obtain

$$[10] \qquad \frac{1}{R} = \frac{[H^+]}{R_0\{(k_2/k_{-1})[Cu^{++}]+(k_3/k_{-1})[Cr^{VI}]\}}+\frac{1}{R_0}$$

where R is the measured rate $= (-d[H_2])/dt$ and R_0 is the value of $k_1[Cu^{++}][H_2]$. Rearranging the above we obtain

$$[11] \qquad \frac{R[H^+]}{R_0-R} = \frac{k_2}{k_{-1}}[Cu^{++}]+\frac{k_3}{k_{-1}}[Cr^{VI}]$$

and a linear plot would be expected if the function $(R[H^+])/(R_0-R)$ were plotted against Cr^{VI}. The results of this type of a plot, using three of the 180° C experiments, are depicted in Fig. 6. There is a significant departure from linearity in both directions at higher Cr^{VI} levels. However, the rate measurements in this region are erratic because they are near the beginning of a run. The best results are obtained on this form of plot when using the highest acid experiments, since in this case the rate difference, R_0-R, is the largest value obtainable.

The significance of this reaction is that a process that is first-order in Cr^{VI} is competing with a forward reaction involving Cu^{++} and a back reaction involving H^+. The effects of these three species are interrelated through the three terms in the denominator of equation 4, and the dependence of the forward reaction on $[H^+]$, $[Cu^{++}]$, or $[Cr^{VI}]$ is a function of the relative values of these three terms. At low values of $[H^+]$ the equation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

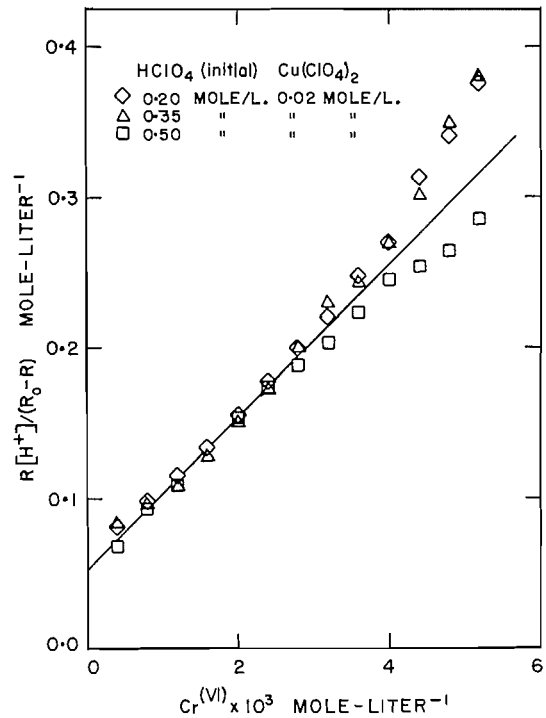

FIG. 6. Dependence of the function (rate$\times$[H$^+$])(k_1[Cu^{++}][H$_2$]$-$rate)$^{-1}$ on the dichromate level: 180° C.

reduces to a second-order reaction that is first-order in each of Cu^{++} and H$_2$. At high H$^+$ concentrations the reaction may be second-order in Cu^{++} and zero-order in Cr^{VI}, or first order in each of Cu^{++} and Cr^{VI}, depending on their relative concentrations.

Of interest here is a related reaction involving the recombination of hydrogen and oxygen in nuclear reactors, which is catalyzed by Cu^{++} ions. This reaction was studied in sulphate and in perchlorate solutions at temperatures in the 200° to 300° C range by McDuffie and co-workers (7). McDuffie found that at 250° C and in solutions containing up to .05 mole/liter free perchloric acid, the reaction was first-order in Cu^{++} and independent of acidity. He observed that this was inconsistent with the rate law expressed by equation 1 unless the value for k_{-1}/k_2 was far smaller than 0.26 as predicted by Peters and Halpern (1), because the value of [Cu^{++}] in McDuffie's work was very small, of the order of 0.002 mole/liter.

However, if oxygen, like Cr^{VI}, directly attacks the CuH$^+$ complex, the rate expression describing the oxygen–hydrogen recombination kinetics would resemble equation 4, with O$_2$ replacing Cr^{VI}. This mechanism would be written as follows:

$$Cu^{++} + H_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} CuH^+ + H^+, \qquad [12a]$$

$$CuH^+ + Cu^{++} \xrightarrow{k_2} 2Cu^+ + H^+, \qquad [12b]$$

$$CuH^+ + O_2 \xrightarrow{k_3'} \text{intermediates} \xrightarrow{\text{fast}} Cu^{++} + \text{products}, \qquad [12c]$$

$$2Cu^+ + O_2 \xrightarrow{\text{fast}} 2Cu^{++} + \text{products}. \qquad [12d]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The rate expression for this mechanism, obtained via the steady-state approximation in CuH^+, is

$$[13] \qquad \frac{-2d[O_2]}{dt} = \frac{-d[H_2]}{dt} = \frac{k_1[Cu^{++}][H_2]\{(k_2/k_{-1})[Cu^{++}]+(k_3'/k_{-1})[O_2]\}}{[H^+]+(k_2/k_{-1})[Cu^{++}]+(k_3'/k_{-1})[O_2]}.$$

The conditions under which McDuffie *et al.* examined the kinetics in perchlorate solutions were 250° C, .002 mole/liter Cu^{++}, up to .05 mole/liter H^+, and initial oxygen partial pressures of the order of 400 p.s.i. At this pressure, the application of known oxygen solubility data (8) yields a concentration of .076 mole/liter O_2.

Assuming the value of k_2/k_{-1} to be unchanged from the 200° C value of 2.6 the second term of the denominator of equation 13, $(k_2/k_{-1})[Cu^{++}]$, would have a value of .0052. The first denominator term $[H^+]$ would be .05 and, since McDuffie did not observe an acid dependence, this term must be small compared with the third term, $(k_3'/k_{-1})[O_2]$. This last term must have a value of at least 0.5 for the acid effect to be less than 10%. At .076 mole/liter O_2, this places the value of k_3'/k_{-1} at greater than 6.6. Such a large value is entirely reasonable in view of the large values of k_3/k_{-1} observed in the 160° to 200° C range in the present work when the oxidant is Cr^{VI} instead of O_2, even though there is no reason to assume that k_3' and k_3 must be equal.

A relatively surprising result of this study is that there is no significant temperature dependence of the rate constant ratios k_2/k_{-1} and k_3/k_{-1}. These ratios have not been determined with sufficient precision for accurate analysis, but it is clear that the activation energies of the three competing reactions involving the decomposition of CuH^+ do not differ by more than about 1.5 kcal/mole. This is not sufficient to account for the relatively large value of the rate constant ratio k_3/k_{-1}, which at a value of 48 would require an activation energy difference of 3.4 kcal in favor of the Cr^{VI} reaction, although it can account for the value of k_2/k_{-1}, which at 2.6 would require an activation energy difference of only 800 calories. It is therefore likely that activation entropy differences must be called upon to account completely for the differences in the rates by which CuH^+ is attacked by different oxidants.

CONCLUSIONS

The kinetics of dichromate reduction by hydrogen in aqueous cupric perchlorate solutions are more complex than previously noted (2) in that they show some dichromate dependence at low Cu^{++} and high Cr^{VI} levels. A mechanism involving the direct attack of the CuH^+ intermediate by both Cu^{++} and Cr^{VI}, followed by fast conversion of resulting intermediates to the stable final species, has been shown to be consistent with these results. The same form of attack of CuH^+ by O_2 in the hydrogen – oxygen recombination studies by McDuffie *et al.* (7) could account for the kinetics obtained by these workers who observed no acid dependence at 250° C in the cupric perchlorate system, such as would be expected if mechanism [2] is applied, where CuH^+ is attacked only by H^+ and Cu^{++}.

THE INFRARED AND THE NEAR-ULTRAVIOLET ABSORPTION SPECTRA OF POLYPHENYL DERIVATIVES OF THE ELEMENTS OF GROUPS IV*b* AND V*b*[1]

C. N. R. Rao,[2] J. Ramachandran,[3] and A. Balasubramanian

ABSTRACT

The near-ultraviolet absorption spectra of polyphenyl derivatives of the IV*b* and V*b* elements have been studied in detail. In the case of the triphenyl derivatives of the V*b* elements, the unshared *p*-electrons on the central atoms interact strongly with the π-orbitals of the benzene rings. When the central atoms do not possess unshared electrons as in the case of the derivatives of the IV*b* and the pentavalent V*b* elements, there appears to be no such resonance interaction. The Hammett reactivity constants of the para- and meta-trityl, triphenylsilyl, and triphenylgermanyl groups are estimated to be close to zero. However, the reactivity constant of the triphenylsilyl group in the para position of phenol is estimated to be about 0.30. The infrared spectra of the phenyl derivatives of the IV*b* and V*b* elements show smooth trends due to mass effects of the central atoms, in the C=C skeletal, C—H out-of-plane, and other vibrations. The absorption frequencies which are assigned to the phosphorus–phenyl and silicon–phenyl bonds in the literature do not appear to be unique for these linkages.

INTRODUCTION

The preliminary results on the infrared and the near-ultraviolet absorption spectra of some polyphenyl derivatives of the IV*b* and V*b* elements have been published earlier by Rao *et al.* (1). In this communication, the spectroscopy of these systems has been reported and discussed in detail. In the case of the V*b* elements, the spectra of derivatives in which the central atoms possess and do not possess unshared *p*-electrons (i.e. derivatives of the atoms in their "trivalent" and "pentavalent" states respectively) have been studied. The ultraviolet and the infrared spectra of substituted tetraphenylmethane, tetraphenylsilicane, and tetraphenylgermanium have also been investigated in order to be able to estimate the reactivity and resonance parameters of these groups.

EXPERIMENTAL

All the polyphenyl derivatives of the IV*b* and V*b* elements (mentioned in Table I) were commercially available and they were further purified before use. The trityl, triphenylsilyl, and triphenylgermanyl benzene derivatives with functional groups were prepared by the methods reported by Benkeser *et al.* (2, 3, 4).

The ultraviolet absorption spectra were recorded using a Cary Model 11 recording spectrophotometer and a Hilger spectrophotometer, H700. All the solvents were fractionated before use.

The infrared spectra were recorded using a Baird-Atomic spectrometer (Model KM 1) and a Perkin–Elmer (Model 21) spectrometer, both with NaCl optics. The samples were prepared as mulls in Nujol or as solutions in chloroform. The relative intensities of the peaks have been recorded as follows: S, strong; M, medium; and W, weak. The carbonyl frequencies reported in Table III are correct to within 5 cm^{-1}.

RESULTS AND DISCUSSION

All the triphenyl derivatives of the V*b* elements show fairly strong bands in their ultraviolet spectra (Table I). Triphenylamine exhibits two bands at 228 and 297 mμ. By analogy with the assignments in aniline,* the lower wavelength band is probably the

so-called "primary" benzenoid band or the *E*-band. The longer wavelength band at 297 mμ is the "secondary" band or the *B*-band. The other triphenyl derivatives of the V*b* elements (with the exception of triphenylbismuthine) show only one band in the near-ultraviolet region, which may be *tentatively* assigned to the *B*-band.†

The *B*-band of benzene ($\pi \rightarrow \pi^*$ transition around 260 mμ) shows vibrational fine structure. The absence of the vibrational structure in the *B*-bands of the triphenyl derivatives of the V*b* elements is probably due to the interaction of the non-bonded *p*-electrons on the central atoms with the π-orbitals of the benzene rings. Of course, one would imagine that the electrons are delocalized over the entire molecule (6). Further, there is a progressive increase in the *B*-band wavelength with the increase in the number of phenyl groups around the central atom. The *B*-bands of aniline, diphenylamine, and triphenylamine are found at 280, 285, and 297 mμ respectively. The phosphorus, arsenic, and antimony derivatives also show similar variations of the *B*-band. As Robertson and Matsen (5) have pointed out, the dissimilarity between the spectra of compounds $(C_6H_5)_2X$ and $(C_6H_5)XH$ is a measure of the resonance interaction of the phenyl groups and the central atom. In general, the results of the present investigation and the interpretations offered are in agreement with the earlier work (6, 7, 8).

Among the triphenyl derivatives of the V*b* elements, triphenylamine exhibits the *B*-band at the largest wavelength with the maximum intensity. This is understandable since nitrogen, being a first row element, will have greater tendency for double-bond formation. There is a marked decrease in the *B*-band wavelength and intensity, in the case of triphenylphosphine and a further decrease in triphenylarsine. In phosphorus, the 3*d*-shell is vacant, while in arsenic it is completely filled. While going from triphenylarsine to triphenylstibine and triphenylbismuthine, there is a progressive increase in the *B*-band wavelength (248, 256, and 280 mμ respectively). This is possibly due to the predominating influence of the decreasing ionization potential (9) of the central atom. Apparently, the similarity of the electronic structures of the inner shells in arsenic, antimony, and bismuth (all the three with filled *d*-shells) is responsible for exhibiting such a marked effect of the decreasing ionization potential on the absorption spectra. The importance of the

Aniline exhibits bands at 230 and 280 mμ. These have been labelled as "primary" and "secondary" bands by Doub and Vandenbelt (J. Am. Chem. Soc.* **69, *2714 (1947)); as E and B bands by Gillam and Stern (In Electronic absorption spectroscopy. Edward Arnold Ltd., London. 1957. p. 140).*

†Jaffe (6) makes a similar assignment. The discussion of the results will not be affected by any possible change in the assignment.

ionization potentials in determining bathochromic shifts has been pointed out earlier (10, 11). Triphenylbismuthine exhibits another band at 250 mμ which may represent the dissociation process.

The polyphenyl derivatives of the V*b* elements in their pentavalent state, in contrast to the triphenyl derivatives, show vibrational structure in their *B*-bands (Table I) similar to benzene itself. In Fig. 1, the spectra of triphenylstibine and triphenylstibonium-

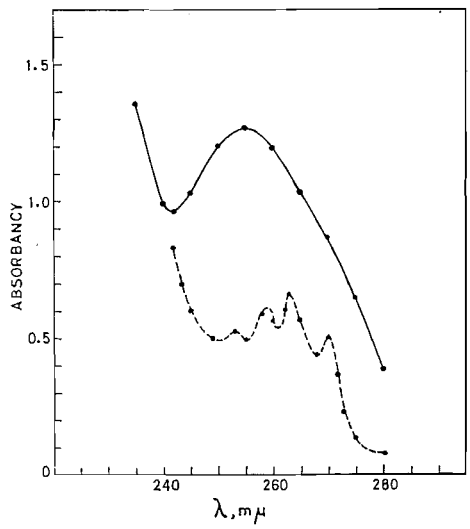

FIG. 1. Near-ultraviolet absorption spectra of triphenylstibine (——) and triphenylstiboniumdichloride (– – –) in ethanol.

dichloride are reproduced for purposes of comparison. The presence of the vibrational structure in the *B*-bands of these derivatives of V*b* elements indicate negligible or no resonance interaction of the central atoms with the π-orbitals of the benzene rings. This is understandable since the central atoms do not possess any unshared electrons. Further, *B*-band positions of these derivatives show little variation with the number of phenyl groups attached to the central atom, and the intensity seems to be directly proportional to the number of phenyl groups. The results with these derivatives agree well with the earlier work on similar systems (7, 8, 12) and the explanations offered are similar to those of Jaffe (6).

The ultraviolet spectra of the polyphenyl derivatives of the IV*b* elements (Table I) are very similar to the spectra of the derivatives of the V*b* elements in their pentavalent state. Here also, the *B*-bands show vibrational structure. The *B*-band position does not depend on the number of phenyl groups and the intensity contribution by a phenyl group is constant and additive. The results on the IV*b* derivatives reported here are similar to those of Milazzo (13) and Bowden and Braude (7) on derivatives of the type $C_6H_5MR_3$ (R = alkyl group).

Among the IV*b* derivatives, the silicon derivative seems to show a slightly larger bathochromic shift. Similarly, the phosphorus derivative seems to show a larger bathochromic shift among the V*b* pentavalent derivatives. These observations may possibly be taken as evidence for the "expansion of the valence shells" in these two second row elements. The formation of π-bonds by the second row elements, using 3*d* orbitals

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

appears to be quite general (14). Recently, reviews giving experimental evidence for d_π-orbitals in silicon (15) and phosphorus (16) have been published. The inductive effects of phosphorus and silicon will also be considerably different from those of the corresponding first row elements. But, it is more likely that resonance or π-orbital interaction is responsible for the bathochromic shifts in these phosphorus and silicon derivatives rather than inductive effects.

The ultraviolet spectrum of pentaphenylphosphorus is supposed to be very close to that of triphenylphosphine.* However, the ultraviolet spectrum of pentaphenylantimony shows vibrational fine structure. It is not possible, therefore, to explain Van Wazer's observation in a simple fashion. The possibility of some type of steric crowding in the case of pentaphenylphosphorus cannot be excluded. Such steric crowding will be less significant in the antimony derivative by virtue of the larger atomic volume of antimony compared with phosphorus.

The solvent effects on the ultraviolet spectra of some of the derivatives of the IV*b* and V*b* elements were studied. The spectra of tetraphenylmethane and tetraphenylphosphoniumbromide did not show any change with the solvents. The triphenyl derivatives of the V*b* elements showed very small solvent blue-shifts in polar solvents, although there is no possibility of $n \rightarrow \pi^*$ transitions (17) in these molecules.

All the ortho-, meta-, and para-substituted trityl, triphenylsilyl, and triphenylgermanyl benzene derivatives show vibrational structure in their *B*-bands. The absorption maxima of some of the derivatives are summarized in Table II. The para-carbonyl derivatives show fairly well-defined peaks due to the *E*-bands (at wavelengths lower than their *B*-bands), while the meta-carbonyl derivatives show only the vibrational structure of the *B*-bands (see Fig. 2). The *E*-band wavelengths in the para-carbonyl derivatives vary in the order, trityl > triphenylsilyl > triphenylgermanyl. These differences are, however, very small in magnitude. In any case, it appears fairly certain that all the

three groups do not interact strongly with the benzene nucleus in these derivatives. The resonance parameters, σ_R (18), for the three groups in these systems are estimated to be less than 0.10 by employing the λ_{max}–σ_R correlations of Rao (19, 20). This is in agreement with the Hammett reactivity constants, σ, proposed for the meta- and para-trityl (3), triphenylsilyl, and triphenylgermanyl (4) groups by Benkeser *et al.*

Benkeser *et al.* (4) have pointed out that silicon and germanium atoms are capable of valence shell expansion when conjugated with strong electron-donating groups like in phenols and anilines. The *B*-bands of *m*- and *p*-trityl phenols are similar to those of *m*- and *p*-triphenylsilyl phenols (Table II). However, in *p*-triphenylsilylphenol an additional band is observed at 237 mμ which may be the displaced *E*-band. The *E*-band of phenol itself is found to be at about 210 mμ. The bathochromic shift observed in the *E*-band of *p*-triphenylsilylphenol may then be interpreted as due to the resonance interaction of the *p*-triphenylsilyl group (20). If the assignment of the 237 mμ band as the *E*-band is correct, the Hammett σ-value of the *p*-triphenylsilyl group may be estimated employing the correlation of the *E*-band absorption maxima with the σ-constants of substituents proposed by Rao (20). The Hammett σ-value* thus estimated is about 0.30 ± 0.10. This is in agreement with the σ^--value of 0.31 proposed by Benkeser *et al.* (4).

The carbonyl stretching frequencies in some of the meta- and para-trityl, triphenylsilyl, and triphenylgermanyl derivatives are shown in Table III. It is seen that the carbonyl

stretching frequencies in these compounds do not vary considerably from those in the unsubstituted compounds. It has been shown (21, 22) that the carbonyl frequencies in *m*- and *p*-substituted benzene derivatives may be directly correlated with the reactivity constants of the substituents. The data in Table III therefore suggest that the Hammett σ-values for the meta- and para-trityl, triphenylsilyl, and triphenylgermanyl groups are close to zero. This is in agreement with the conclusions drawn earlier from the ultraviolet absorption spectra and the kinetic data of Benkeser *et al.* (3, 4).

The major frequencies in the infrared spectra of the polyphenyl derivatives of IV*b* and V*b* elements are summarized in Table IV. The C=C skeletal vibration around 1580 cm^{-1}, some of the C—H in-plane deformation vibrations and ring vibrations, and the C—H out-of-plane deformation vibration around 740 cm^{-1} show nice trends due to mass effects of the central atoms. Similar mass effects have been observed in the spectra of metal alkyls (23). Typical plots of the change in frequency, $\Delta\nu$ (compared with the

V*b* elements in their pentavalent state than in their trivalent state. Apparently, the resonance interaction involving the unshared electrons in the triphenyl derivatives is responsible for such a behavior.

The splitting reported earlier (1) in the C—H out-of-plane vibrations have been found to be mere solid state anomalies, since the splittings are not noticed in solution spectra. Daasch and Smith (24) have observed bands of moderate intensity in the regions 1450–1435 cm^{-1} and 1005–995 cm^{-1}, in compounds containing the phosphorus–phenyl linkages. Although the latter band has been suspected to arise from some activated ring vibration, the former band around 1440 cm^{-1} was suggested to be characteristic of the phosphorus–phenyl linkage (25). On the basis of literature data, Bellamy (25) has suggested that bands around 1429 and 1130–1090 cm^{-1} are characteristic of the silicon–phenyl linkage. A survey of the data in Table IV shows that bands are observed in all the above-mentioned regions in the spectra of several polyphenyl derivatives. It is therefore suggested that they may all be due to some activated ring vibrations. In the case of triphenylamine, however, definite assignment of the C—N linkage to the strong band at 1337 cm^{-1} is possible.

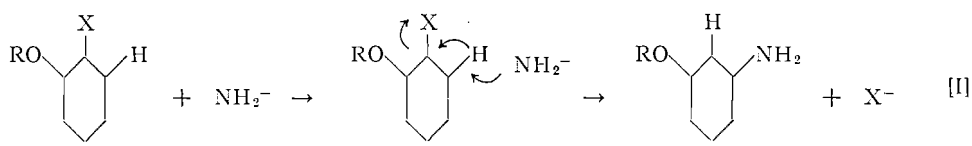
HYDROGEN ISOTOPE EFFECT IN THE AMINATION OF CHLOROBENZENE BY SODAMIDE[1]

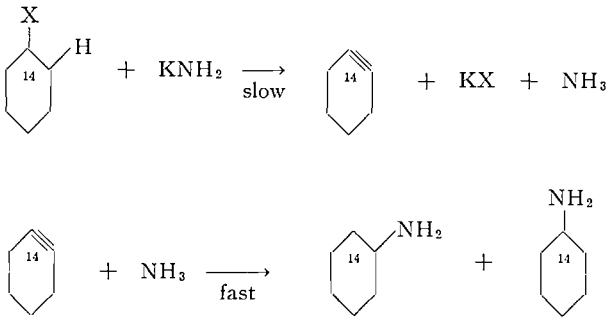
G. E. Dunn, Peter J. Krueger,[2] and Walter Rodewald



ABSTRACT

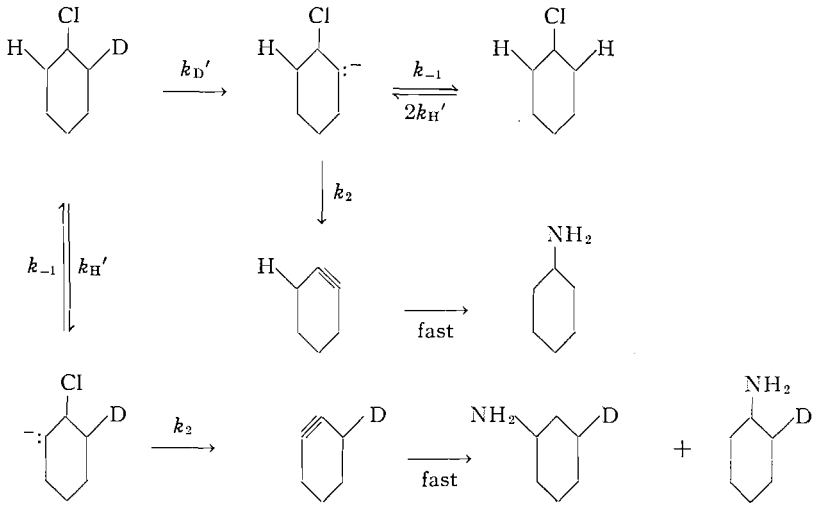
Mixtures of chlorobenzene and chlorobenzene-2-^{2}H have been subjected to partial amination by sodamide in liquid ammonia and both the unreacted starting material and the product aniline have been analyzed for deuterium. Deuterium in the aniline is distributed approximately equally between the ortho and meta positions. The results give strong support to the mechanism proposed by Roberts and co-workers in which the slow step is the formation of an intermediate, such as benzyne, which is symmetrical with respect to carbon atoms 1 and 2.

The amination of aromatic halides by alkali metal amides in liquid ammonia was discovered in 1936 by Bergstrom and co-workers (1), who were able to convert chloro-, bromo-, and iodo-benzene into aniline and a mixture of by-products containing diphenylamine, triphenylamine, and *p*-aminobiphenyl. Fluorobenzene did not react. In 1945 Gilman and Avakian reported that a number of ortho-halogenated ethers on treatment by Bergstrom's procedure gave meta-aminoethers (2) as illustrated by the equation



Bunnett and Zahler reviewed the reaction in 1951 (3) by which time aminations with rearrangement under the Bergstrom conditions had been observed with halogen substituents located ortho and para to ether, sulphide, sulphone, and trifluoromethyl groups. It had also been demonstrated, largely by Benkeser and co-workers (4), that the entering amide displaces a hydrogen atom ortho to the halogen atom. Bunnett and Zahler proposed a mechanism for the rearrangement in which attack by amide ion on carbon atom 2 of a halobenzene forces the migration of a hydride ion from carbon 2 to carbon 1 and the displacement of a halide ion by this hydride ion. The sequence of reactions in equation I below illustrates this mechanism.

[I]



In 1953 Roberts and co-workers (5) showed that rearrangement occurs even in unsubstituted halobenzenes by demonstrating that chlorobenzene-1-^{14}C with potassium amide in liquid ammonia gives aniline-1-^{14}C and aniline-2-^{14}C in almost equal amounts. The near equality of rearranged and unrearranged product suggested the participation of an intermediate symmetrical with respect to carbons 1 and 2. They considered the most likely intermediate to be benzyne, which would enter into the mechanism as shown in sequence II.

[2]*Holder of a National Research Council bursary, 1955–56.*

[II]

The existence of a symmetrical intermediate was further indicated when Roberts and co-workers (6) reported in 1956 that chlorobenzene-1-^{14}C, bromobenzene-1-^{14}C, and iodobenzene-1-^{14}C with potassium amide all give aniline-1-^{14}C and aniline-2-^{14}C in approximately equal quantities. They also studied the reaction of ortho-deuterated fluoro-, chloro-, and bromo-benzene by aminating mixtures of deuterated and undeuterated halobenzenes and comparing the percentage of deuterium before reaction with that after partial reaction. In deuterated bromobenzene the percentage of deuterium increased with the percentage of reaction indicating that the undeuterated material reacts faster, and the isotope effect, $i = k_H/k_D$, was found to be about 5.5. Fluorobenzene-2-^{2}H was found to exchange deuterium with the solvent very rapidly. Dilute solutions of chlorobenzene-2-^{2}H in chlorobenzene showed a small increase in deuterium content after partial reaction while concentrated solutions showed a decrease. This was taken to mean that chlorobenzene-2-^{2}H exchanges deuterium with the solvent at a rate comparable with the amination. On the basis of these and other observations the mechanism III was postulated for the amination and exchange of chlorobenzene-2-^{2}H.

[III]

Before the appearance of Roberts' second paper the authors had performed some experiments intended to distinguish between mechanisms I and II by finding out whether or not deuterium is lost from the aromatic ring when chlorobenzene-2-^{2}H is aminated by sodamide in liquid ammonia. Mechanism I predicts that chlorobenzene-2-^{2}H should

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

give aniline-^{2}H with the same total deuterium content, while mechanism II predicts aniline-^{2}H with a smaller deuterium content than the starting material. The results of these preliminary experiments are shown in Table I.

*Mean of three analyses ±maximum deviation.
†One analysis.
‡This material is probably a mixture of 2-, 2,4-, and 2,4,6-deuterated aniline but the analyses are calculated on the assumption that it is aniline-^{2}H.

Experiments 1 and 2, Table I, were intended to find out whether or not ring-deuterated aniline exchanges hydrogen isotopes with the reaction mixture or during recovery and purification. In experiment 1 a sample of aniline partially deuterated in the ortho and para positions was treated with sodamide in liquid ammonia and recovered by Bergstrom's method (1) which involves extraction of aniline from the reaction mixture with aqueous hydrochloric acid. It is seen that some deuterium was lost by this procedure. In experiment 2 the use of acid was avoided by extracting the reaction mixture with ether and recovering aniline by fractional distillation. The recovery of aniline was reduced by almost half but Table I shows that the loss of deuterium by this method was negligible.

A mixture of chlorobenzene and chlorobenzene-2-^{2}H was then treated with 1.7 times the equivalent quantity of sodamide in liquid ammonia and the aniline was recovered. Experiments 3, 4, and 5, Table I, show that the aniline produced contained about half the deuterium originally present in the starting material. This aniline was then brominated and the 2,4,6-tribromoaniline produced was analyzed for deuterium. Experiments 4 and 5, Table I, show that almost half the deuterium in the aniline was displaced by bromine so that a little more than half the deuterated aniline must have had its deuterium in the meta position.

These results were taken to favor mechanism II since it predicts a loss of deuterium and the formation of equal quantities of ortho- and meta-deuterated aniline. However, if the reaction did take place by mechanism II, the fact that half the deuterium was lost would lead to the surprising conclusion that protium and deuterium are lost at equal rates. A further test of this point was made by reacting a mixture of chlorobenzene and chlorobenzene-2-^{2}H with half the equivalent quantity of sodamide and recovering the unreacted chlorobenzene. The data from experiment 6, Table I, show that there was no change in the deuterium content of the chlorobenzene, which seemed to confirm that protium and deuterium react at equal rates.

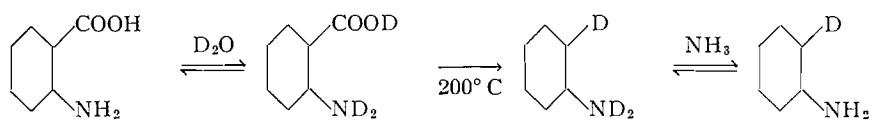
With the appearance of the second paper by Roberts and co-workers (6) it was evident

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

that our results could be accounted for by mechanism III in a very particular combination of circumstances. As the reaction proceeds, the usual isotope effect tends to increase the deuterium in the unreacted chlorobenzene and the product aniline, but exchange would tend to decrease it, so that a suitable combination of rate of amination, rate of exchange, initial concentration of deuterium, and percentage of reaction could result in a 50% loss of deuterium and no change in the deuterium content of the chlorobenzene. Since Roberts and co-workers did not measure the deuterium in their aniline and we did not measure the deuterium in our unreacted chlorobenzene it was not possible to determine whether or not the combination of factors necessary to fit our data to mechanism III actually existed. Since the fit of Roberts' own data to mechanism III was far from precise, it seemed worth while to repeat and extend our experiments to include in one set of reactions all the measurements necessary for a test of the mechanism.

EXPERIMENTAL



Chlorobenzene-2-^2H

Grignard reagent was prepared from 194 g of Eastman Kodak white label *o*-chloroiodobenzene (0.814 mole) in a flame-dried flask under an atmosphere of dry nitrogen. Acid titration of the solution indicated 90–97% yields. In the preliminary experiments the Grignard was decomposed by adding 1.63 g of deuterium oxide* (0.814 mole) very slowly with vigorous stirring. Gilman's color test I (7) was negative at the end of the addition. The solution was then washed with water and dried over anhydrous potassium carbonate. The product was recovered from the ether layer by fractionation through a 10-cm Vigreaux column. Yields ranged from 45% to 65%, b.p. 128–132° C at 742 mm, $n_D^{21.8} = 1.5261$. Deuterium analyses averaged about 80% chlorobenzene-2-^2H.

Since Roberts and co-workers reported the preparation of pure chlorobenzene-2-^2H (without stating the method of analysis) by decomposing *o*-chlorophenylmagnesium iodide with deuteroacetic acid, this method was tried. To the Grignard reagent prepared as described above was added 112.4 g (1.84 mole) of deuteroacetic acid slowly with vigorous stirring. At the end of the addition Gilman's color test I was negative (7). Water was added to dissolve the magnesium salts and the ether layer was separated. The ethereal solution was washed with sodium hydroxide to remove excess acetic acid, dried over anhydrous calcium sulphate, and distilled through an approximately 20-plate column. The yield of chlorobenzene was 49.6 g (53.8%), b.p. 130.0–130.5° C at 745 mm, $n_D^{25} = 1.5209$. This material analyzed 81.6% chlorobenzene-2-^2H. Two samples of deuteroacetic acid were used with identical results; one sample was prepared by hydrolyzing freshly distilled acetic anhydride with deuterium oxide, the other was obtained from Merck and was certified by the supplier to contain more than 98% deuteroacetic acid.

Deuterated Aniline

The preparation of aniline-2-^2H was attempted by the decarboxylation of deuterated anthranilic acid as shown in the following sequence of reactions.

Decarboxylation of aromatic acids with calcium deuteroxide at 500° C has been shown

**Obtained from the Commercial Products Division of Atomic Energy of Canada Ltd., and reported by the supplier to contain 99.83 atom% deuterium.*

to give a mixture of isomerically deuterated products (8), but it was thought that the mild conditions possible in the decarboxylation of anthranilic acid might permit success.

Thirty grams of anthranilic acid (0.219 mole) was dissolved in 70 ml of dioxane in a distilling flask and 6.6 g of deuterium oxide (0.330 mole) was added. After the solution had stood for 160 hours at room temperature the solvents were removed under vacuum. A condenser and receiver were attached to the distilling flask and the latter was heated in an oil bath at 200–210° C until no more aniline distilled over. This crude aniline was redistilled to give 16.2 g of product (85% yield), b.p. 179–183° C at 742 mm, $n_D^{21.8}$ = 1.5826. Deuterium analyses of the aniline obtained from two runs, A and B, gave the atom per cent deuterium in product A = 21.2±0.5% and in product B = 12.0±0.1%. (These analyses would correspond to an aniline-$^2H_3$ content of 49.4±1.2% in A and 27.9±0.2% in B.) In order to remove deuterium from the amino group of the aniline, it was twice dissolved in about 500 ml of liquid ammonia and allowed to stand until the ammonia had evaporated. Distillation gave aniline, b.p. 60–65° C at 2.5 mm, $n_D^{21.8}$ = 1.5834, in which the intensity of the NH stretching overtone at 1498 mμ matched that of ordinary aniline.* Analysis showed 12.1±0.3 at.% deuterium in A and 6.66±0.02 at.% in B. (This would correspond to an aniline-2-^2H content of 84.7±2.0% in A and 46.6±0.1% in B.)

These results show that the deuterated aniline obtained by decarboxylating partially deuterated anthranilic acid has a little more than half its deuterium in the ring instead of one-third as predicted for a statistical distribution, or less than one-third as would be expected if there were a normal isotope effect in the decarboxylation. This requires that the decarboxylation take place by a mechanism such that either deuterium migrates in preference to protium or deuterium enters more than one position in the ring. The latter possibility seems much the more likely, especially in view of the observation (8) that this actually happens with simple aromatic acids on decarboxylation with $Ca(OD)_2$. In order to find out how general the redistribution of deuterium is, some of the aniline from run B was converted to 2,4,6-tribromoaniline as described below. This tribromoaniline contained no deuterium so the most likely hypothesis is that decarboxylation gives a mixture of aniline-2-^2H, aniline-2,4-$^2H_2$, and aniline-2,4,6-$^2H_3$.

2,4,6-Tribromoaniline

To determine the fraction of deuterium in the meta position of the deuterated aniline obtained by decarboxylation or by amination the sample in question was brominated and the 2,4,6-tribromoaniline was analyzed for deuterium. This method has been used previously by Lauer and Errede (9). About 1.0–1.5 g of deuterated aniline was dissolved in 20 ml of water. The solution was cooled in ice and a solution of bromine in ethanol (25% by weight) was added from a burette until the first appearance of a permanent yellow tinge. The precipitate was filtered, washed with water, dissolved in alcohol, and reprecipitated by the addition of water. The material obtained in this way melted sharply at 118° C (uncorr.) and was analyzed for deuterium as described below.

Amination of Chlorobenzene-2-^2H

In the preliminary experiments the procedure of Bergstrom was used. Sodamide was prepared by the method of Vaughan, Vogt, and Nieuwland (10) from 5.2 g of sodium (0.226 g-atom) in about 600 ml of liquid ammonia. When the blue color of the metal solution had turned to the grey of sodamide, 15 g of chlorobenzene-2-^2H (0.133 mole)

**Spectral measurements were made on a Beckman spectrophotometer model DK-1.*

was added dropwise over a period of 20 minutes. After another 40 minutes, 11 g of ammonium chloride (0.202 mole) was added and the solvent was allowed to evaporate overnight. Ether was added to the residue and refluxed to drive off residual ammonia. The ether-insoluble salt was dissolved in water and the aniline was extracted from the aqueous layer with ether. The ether solution was dried over anhydrous potassium carbonate, and the aniline was recovered by repeated fractionations through a 10-cm Vigreaux column at 60–65° C at 20 mm. Purity of the aniline was checked by comparison of the intensity of the 1498 mμ peak with that of pure aniline. Yields of pure product averaged about 25% by this method of recovery. Bergstrom's method of acid extraction gave yields of 40% but could not be used because of the danger of exchange between the acid and ring hydrogen. Deuterium analyses on the product were carried out as described below.

In later experiments, where it was desired to isolate unreacted chlorobenzene as well as aniline, Roberts' procedure was used. The chlorobenzene-2-^{2}H in 150 ml of liquid ammonia was added to the sodamide solution over a period of 1 minute. Three minutes after the addition was complete the reaction was stopped by the addition of 20 g of ammonium nitrate (0.250 mole) dissolved in 100 ml of liquid ammonia. Anhydrous ether, 150 ml, was added to the reaction mixture and the ammonia was allowed to evaporate overnight. Then 200 ml of water was added and stirred for 10 minutes. The ether layer was separated and washed with water. The aqueous layer and washings were boiled to remove excess ammonia and ether, then analyzed for chloride by the Volhard method. The ethereal solution was dried over anhydrous calcium sulphate, then distilled. Fractionation through a 13-cm Vigreaux column gave aniline, b.p. 55–65° C at 4–5 mm, $n_D^{25} = 1.5836$, and chlorobenzene, b.p. 130.0–130.5° C at 754 mm, $n_D^{25} = 1.5207$. The initial separation of aniline and chlorobenzene was most convenient at reduced pressure but the final purification of chlorobenzene was done at atmospheric pressure in a 20-plate column. Each substance was shown to be free of the other by its infrared spectrum. Each was analyzed for deuterium as described below.

Deuterated Aniline under Amination Conditions

In order to determine whether or not aniline loses deuterium after it is produced in the reaction or during recovery, the first amination procedure was repeated exactly except that the deuterated aniline obtained from the decarboxylation of anthranilic acid was used instead of chlorobenzene. The results are shown as experiments 1 and 2, Table I.

Deuterium Analyses

The samples were burned in a standard macrocombustion apparatus using a Vycor tube and a plug of silver wire to trap halogens. The water of combustion was collected in a Dry Ice trap and treated with clean copper wire to remove halogens, or barium carbonate, to remove soluble oxides of nitrogen. It was then purified by the method of Keston, Rittenberg, and Schoenheimer (11) except that calcium oxide and potassium permanganate were used instead of potassium hydroxide and chromium trioxide. The density of the water of combustion was determined by the gradient density tube method described by Anfinsen (12). This gives the weight per cent, w, of deuterium oxide in the water of combustion. From this the atom per cent deuterium in the labelled positions of the molecule was calculated by the equation

$$\text{atom per cent deuterium in } n' \text{ positions} = (n/n') \cdot 900w/(1000-w),$$

where n' = number of labelled positions in the molecule and n = total number of hydrogen atoms in the unlabelled molecule.

In the case of chlorobenzene, combustion analyses were supplemented by spectrophotometric analyses using a Perkin–Elmer model 21 spectrophotometer. Measurements were made at 10.115 μ with slit width 160 μ and at 10.555 μ with slit width 248 μ. These correspond to spectral slit widths of 0.020 μ and 0.028 μ respectively. All measurements were made by the base-line technique in 0.025-mm cells. Mixtures of chlorobenzene and the 81.6% chlorobenzene-2-^{2}H described above gave linear Beer's law plots which were used to analyze the chlorobenzene obtained from the amination reactions. Table II shows the data for standard mixtures and Table III shows those for reaction products.

RESULTS AND DISCUSSION

Roberts and co-workers (6) derived a kinetic expression from mechanism III to account for the change in deuterium content of chlorobenzene during amination. It will be necessary to reproduce their derivation in order to extend it to cover the deuterium content of the aniline produced in the reaction.

If k_2 is large compared with k_H' and k_D', as seems likely, the rate of disappearance of deuterated chlorobenzene, D, is given by the expression

$$\frac{-d[D]}{dt} = (k_H'+k_D')[D][NH_2^-]-k_{-1}[\text{anion B}].$$

Application of the steady-state approximation to anion B gives

$$[\text{anion B}] = \frac{k_H'}{k_{-1}+k_2}[D][NH_2^-],$$

which converts the preceding expression to

$$\frac{-d[D]}{dt} = (k_H'+k_D')[D][NH_2^-]-\frac{k_{-1}k_H'}{k_{-1}+k_2}[D][NH_2^-].$$

By a similar process the rate of disappearance of chlorobenzene, H, is found to be

$$\frac{-d[H]}{dt} = 2k_H'[H][NH_2^-]-\frac{k_{-1}}{k_{-1}+k_2}(2k_H'[H][NH_2^-]+k_D'[D][NH_2^-]).$$

Letting the isotope effect, $k_H'/k_D' = i$, and the fraction of anion returning to starting material, $k_{-1}/(k_{-1}+k_2) = F$, division of one rate expression by the other gives

$$\frac{d[D]}{d[H]} = \frac{[i(1-F)+1][D]}{2i(1-F)[H]-F[D]}.$$

Integration of this expression yields

$$[1] \qquad \ln[D]\Bigg]_{[D]_0}^{[D]_t} + \frac{1+i-iF}{1-i+iF}\ln\left[(-1+i-iF)\frac{[H]}{[D]}-F\right]\Bigg]_{\frac{[H]_0}{[D]_0}}^{\frac{[H]_t}{[D]_t}} = 0.$$

Roberts' equation [1] can be more conveniently applied by setting the fraction of chlorobenzene deuterated at time $t = d$, and the fraction of starting material which has reacted at time $t = P$. Equation [1] then becomes

$$[2] \qquad \log\frac{d}{d_0}(1-P) = \frac{i(1-F)+1}{i(1-F)-1}\log\frac{(1/d)-1-[F/\{i(1-F)-1\}]}{(1/d_0)-1-[F/\{i(1-F)-1\}]}.$$

Equation [1] or [2] concerns only the change in concentration of deuterium in unreacted chlorobenzene. In order to calculate the aniline composition predicted by mechanism III it is necessary to extend the kinetic treatment as follows. Let A_D and A_H represent deuterated and undeuterated aniline, respectively,

$$\frac{d[A_D]}{dt} = k_2[B],$$

$$\frac{-d[D]}{dt} = (k_H'+k_D')[D][NH_2^-]-k_{-1}[B].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Dividing one rate by the other gives

$$\frac{-d[A_D]}{d[D]} = \frac{k_2[B]}{(k_H' + k_D')[D][NH_2^-] - k_{-1}[B]}.$$

Substituting the steady-state expression for B and introducing i and F, where appropriate, gives

$$\frac{-d[A_D]}{d[D]} = \frac{i(1-F)}{i(1-F)+1}.$$

Integrating with the condition that $[A_D] = 0$ when $[D] = [D]_0$ gives

$$[A_D] = \frac{i(1-F)}{i(1-F)+1}([D]_0 - [D]).$$

If it is assumed that $([A_D]+[A_H])/([D]_0+[H]_0) = P$ and that $([D]+[H])/([D]_0+[H]_0) = 1-P$ the above expression becomes

$$\frac{[A_D]}{[A_D]+[A_H]} = \frac{1}{P}\frac{i(1-F)}{i(1-F)+1}\frac{[D]_0}{[D]_0+[H]_0} - (1-P)\frac{[D]}{[D]+[H]}.$$

This expression is simplified by letting the fraction of aniline which is deuterated $= a$, and the fraction of chlorobenzene which is deuterated $= d$, which gives

[3] $$a = \frac{i(1-F)}{i(1-F)+1}\frac{d_0 - d(1-P)}{P}.$$

Equations [2] and [3] were used to calculate a and d according to mechanism III and the results are compared with the experimental results in Table IV. The F values shown in Table IV were calculated from equation [2] using Roberts' value of $i = 5.7$. The constancy of F through four different runs is strong support for the Roberts' mechanism of concurrent amination and exchange. The average value of 0.864 ± 0.020 is much more precise than the 0.56 ± 0.20 reported by Roberts and co-workers (6). The different magnitudes of F in the two investigations may be due to some difference in experimental conditions, such as the fact that potassium amide was used in one case and sodamide in the other, or it may be the result of a difference in the method of analyzing chlorobenzene for deuterium. A spectrophotometric method was used in both cases and the standard sample on which all the analyses rest was prepared in the same way in both investigations. In our case the standard sample analyzed 81.6% chlorobenzene-2-^{2}H by combustion, while in Roberts' case the standard sample was reported to be 100% chlorobenzene-2-^{2}H without mention of the method of analysis. If the two standard samples are assumed to be both about 80% deuterated then the two ranges of F values overlap, although the precision of the set by Roberts and co-workers is not improved.

The a values in Table IV were calculated from equation [3] using $i = 5.7$ and the calculated values of F. Comparison of the calculated and observed values of a shows that the former is lower by about 10% in each case. Although the a values calculated for Roberts' mechanism are low, they parallel the observed values so closely as to leave little room for doubt that the mechanism is essentially correct.

The 10% discrepancy is probably due largely to the method of determining P by measuring the moles of chloride ion produced. Bergstrom and co-workers (1) showed

that the aniline produced by amination of chlorobenzene is always accompanied by by-products, among which they identified diphenylamine, triphenylamine, and *p*-aminobiphenyl. They suggested that these are formed from aniline as illustrated in the following equations:

$$C_6H_5NH_2 + NaNH_2 \rightleftarrows C_6H_5NHNa + NH_3,$$

$$C_6H_5NHNa + C_6H_5Cl \rightarrow (C_6H_5)_2NH + NaCl.$$

It is seen that these side reactions produce chloride ion while consuming both chlorobenzene and aniline in a manner not included in the Roberts' mechanism. Since the side reactions should consume ring-deuterated and undeuterated reactants at equal specific rates, they will not alter the mole fraction of deuterated chlorobenzene, d, or aniline, a, but they will make the apparent percentage of reaction, $100P$, too large. Insertion of the experimental values of a, d, d_0, and $i = 5.7$ into equations [2] and [3] give calculated P values of 0.646, 0.647, and 0.648 in runs 2, 3, and 4, Table IV, respectively. While the precision of the calculated P values among runs is probably largely fortuitous, they show that a reasonable amount of side reaction of the type proposed by Bergstrom could account for the low calculated a values. A more attractive mechanism for the formation of by-products within the Roberts' mechanism would be the following:

but the effect on a would be the same as that suggested for the Bergstrom mechanism.

In summary, our data and the predictions of Roberts' mechanism of concurrent amination and exchange are in excellent agreement on the deuterium content of partially reacted chlorobenzene, on the ortho-to-meta ratio of the deuterated aniline produced, and in reasonable agreement on the total deuterium content of the aniline. There can be little doubt that the mechanism is essentially correct.

A referee has pointed out that the excess of aniline-3-^{2}H over aniline-2-^{2}H (56% and 54% of the former in experiments 4 and 5, Table I) suggests a secondary isotope effect on the rates of addition of ammonia to benzyne-2-^{2}H. Roberts and co-workers (13) have observed that inductive electron withdrawal by the substituent in a 2-substituted benzyne favors the formation of 3-substituted addition products. This would indicate that deuterium has a $-I$ effect, as has been suggested by Shiner on other grounds (14). The agreement of our data with Shiner's prediction is interesting, but we doubt whether the accuracy of the analysis warrants a definite conclusion.

ACKNOWLEDGMENTS

The authors wish to thank Dr. H. R. Coish for suggestions regarding the mathematical derivations, Miss A. Hetherington and Dr. B. L. Funt for assistance with the Bendix G-15 computer, and the National Research Council of Canada for a grant in aid of this research.

THE STRUCTURE OF THE "GUM ASAFOETIDA" POLYSACCHARIDE[1]

J. K. N. JONES AND G. H. S. THOMAS[2]

ABSTRACT

The polysaccharide from gum asafoetida contains D-galactose, L-arabinose, L-rhamnose, 4-*O*-methyl-D-glucuronic acid, and D-glucuronic acid. It is a highly branched polymer which contains a backbone of D-galactopyranose residues which are very probably mainly 1,3-β-linked.

The side chains consist of residues of L-arabinofuranose, D-galactopyranose, D-glucuronic acid, and its 4-*O*-methyl ether.

INTRODUCTION

Oleogum resins such as asafoetida (1), frankincense (2), and myrrh (3) consist in the main of a mixture of polysaccharide and aromatic substances. The impure carbohydrate portion remains when the crude gum is extracted with a solvent such as methanol. It may be purified by pouring its clarified aqueous solution into alcohol. Application of the above procedure to gum asafoetida gave the neutral salt (equiv. wt. 1500) of the polysaccharide as a white powder, readily soluble in cold water to form a conducting solution, which possessed a negative optical rotation (−48°). All attempts to fractionate it were unsuccessful and it was concluded that the polysaccharide was homogeneous. Acidic hydrolysis yielded a mixture of sugars which were characterized as D-galactose, L-arabinose, L-rhamnose, and D-glucuronic acid together with its 4-*O*-methyl derivative and were present in the approximate proportions 5:3:trace:1. Somewhat different figures (14.2%, 26.5%, 1.7%, 17.1% respectively) were obtained by Bézanger-Beauquesne and Chosson (4).

When the polysaccharide was partially broken down by acid, small amounts of two neutral disaccharides and larger amounts of two aldobiouronic acids were isolated. The neutral oligosaccharides were not obtained crystalline; they yielded D-galactose only on hydrolysis and were tentatively characterized by their rates of movement on chromatograms and by the infrared absorption spectra of their acetates (5) as 6-*O*-β-D-galactopyranosyl-D-galactose (6) and the 3-*O*-β-D-galactopyranosyl-D-galactose. Both the acidic disaccharides give D-galactose on hydrolysis, that which moved faster on the chromatogram also yielded 4-*O*-methyl-D-glucuronic acid, which was characterized as the amide of 4-*O*-methyl methyl-α-D-glucuronoside (7). The slower-moving aldobiouronic acid yielded D-glucuronic acid on hydrolysis. Both, after methylation, reduction with lithium aluminum hydride, and further methylation, followed by hydrolysis, gave 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3,4-tri-*O*-methyl-D-galactose and were therefore identified because of their low positive rotations as 6-*O*-(β-D-glucopyranosyluronic acid)-D-galactose (8) and as 6-*O*-(4-*O*-methyl-β-D-glucopyranosyluronic acid)-D-galactose (9). When the acidic, ash-free, polysaccharide was dissolved in water and the solution heated autohydrolysis occurred with the liberation of L-arabinose and L-rhamnose together with traces of D-galactose and oligosaccharides, leaving a degraded gum which contained D-galactose, D-glucuronic acid, and its 4-*O*-methyl derivatives, and traces (ca. 5%) of L-arabinose. Hydrolysis of the gum with 0.1 *N* hydrochloric acid at 100° for 17 hours

failed to remove all the L-arabinose residues. The degraded gum at this stage contained a galactose-to-arabinose ratio of approximately 15 to 1. It is possible therefore that some of the pentose residues were in the pyranose form.

Methylation experiments showed that both the original polysaccharide and the degraded polysaccharide were of the branched chain type. The methylated sugars isolated were identified as 2,3,5-tri-*O*-methyl-L-arabinose, 2,3,4,6-tetra-, 2,4,6-tri-, 2,4-di-, and 2-*O*-methyl-D-galactose and 2,3,4-tri-*O*-methyl-D-glucuronic acid. The 2-*O*-methyl-D-galactose derivative was not encountered in the products of hydrolysis of the degraded gum. An L-rhamnose derivative and an L-arabinose (?) derivative remain to be identified in the products of hydrolysis of the undegraded gum. The amounts of sugars were determined by the hypoiodite method of Hirst, Hough, and Jones (10) and were found to be present in the following approximate molecular proportions in the methylated original polysaccharide: 2,3,5-tri-*O*-methyl-L-arabinose plus 2,3,4,6-tetra-*O*-methyl-D-galactose (end groups), (3 + tr. parts); dimethyl-L-arabinose (?) (small); 2,4,6-tri- (2 parts), 2,4-di- (2 parts), and 2-mono-*O*-methyl-D-galactose (1 part); and 2,3,4-tri-*O*-methyl-D-glucuronic acid (1 part). The methylated degraded gum gave the neutral sugars 2,3,5-tri-*O*-methyl-L-arabinose; 2,3,4,6-tetra-*O*-methyl-, 2,4,6-tri-*O*-methyl-, 2,4-di-*O*-methyl-D-galactose; and 2,3,4-tri-*O*-methyl-D-glucuronic acid in the approximate proportion of 1:2:9:6:5. An aqueous solution of the gum was oxidized with sodium metaperiodate solution (cf. 10*a*) and yielded 0.11 mole of formic acid with the consumption of 0.65 mole of metaperiodate per sugar residue (calc. as $C_6H_{10}O_5$) in 30 hours. These figures show that for every sugar oxidized with the formation of formic acid, four other sugars were oxidized and that, in all, approximately half the sugar residues in the polysaccharide were destroyed by the reagent. This supposition is in fair agreement with the methylation results.

Some overoxidation of the polysaccharide would occur because of the presence of end groups of D-glucuronic acid but it is believed that this would not be great because (ca. 75% of) the D-glucuronic acid residues were substituted at C_4 by methoxyl groups which would prevent the formation of an easily overoxidized intermediate. It is assumed that formyl ester production was small.

The degraded gum consumed 0.83 mole of periodate with the production of 0.26 mole of formic acid (per $C_6H_{10}O_5$). Therefore, apparently approximately 75% of the polysaccharide was oxidized and a little over a quarter of the sugar residues were present as end groups which would yield formic acid. These results are not in good agreement with those obtained by the methylation procedure, which indicates that 33% of the polysaccharide should be oxidized and that approximately 20% of the sugars contain hydroxyl groups on each of three contiguous carbon atoms. The reason for the discrepancy is not clear but it may be due to an excess of consumption of metaperiodate at the reducing end of the polysaccharide or to "overoxidation".

The gum was degraded by first oxidizing it with sodium metaperiodate to a polyaldehyde as described above which was reduced with sodium borohydride to the polyalcohol. The product was then degraded by the action of cold dilute acid (Smith *et al.* (11), cf. 11*a*, 11*b*). The degraded polysaccharide was isolated when its solution was poured into ethanol. This material gave galactose and arabinose (ca. 5:1) only on complete hydrolysis. It had a slightly branched structure since on further periodate oxidation it yielded a small amount of formic (0.18 mole per $C_6H_{10}O_5$) and consumed some metaperiodate (0.34 mole per $C_6H_{10}O_5$). The alcohol-soluble fraction contained glycerol, ethylene glycol, and glycosides of arabinose and galactose which yielded these sugars on

acidic hydrolysis. The degraded gum when subjected to further degradation in similar fashion gave a galactan ($[\alpha]_D$ +31°) which was oxidized to a small extent by periodate (0.21 mole consumed per $C_6H_{10}O_5$) and produced traces (0.08 mole per $C_6H_{10}O_5$) of formic acid only on oxidation with metaperiodate.

These results indicate that the polysaccharide consisted of a main chain of mainly 1,3-linked-β-D-galactopyranose residues to which are attached D-galactopyranose, L-arabinofuranose, and L-arabinopyranose (?) residues. The mode of linkage of the last sugar was not identified. To the side chains are attached residues of D-glucuronic acid, its 4-*O*-methyl ether, L-rhamnose, and D-galactose (all in the pyranose form). It is not possible to give an unambiguous structure for gum asafoetida at this stage. The polysaccharide has a much smaller percentage of uronic acid residues than has that from frankincense (2) or that from myrrh (3).

EXPERIMENTAL

Paper chromatography was performed by the descending method on Whatman No. 1 paper. Small-scale qualitative separations were carried out by the method of Hirst, Hough, and Jones (12) on Whatman No. 3MM paper. Larger-scale separations were carried out by partition chromatography on cellulose columns using the method of Hough, Jones, and Wadman (13). Chromatographic separations were also conducted on charcoal columns (14) which consisted of a mixture (1:1 w/w) of activated charcoal (Darco C-60) and "Celite". Charcoal columns were eluted with water and/or ethanol.

The following solvent systems were used to separate the neutral sugars by paper chromatography (all v/v):

(A) butan-1-ol, ethanol, water (3:1:1);
(B) butan-1-ol, pyridine, water (10:3:3);
(C) benzene, ethanol, water (169:15:47).

Acidic solvents were used to separate uronic acids and their derivatives.

(D) ethyl acetate, acetic acid, water (9:2:2);
(E) ethyl acetate, acetic acid, formic acid, water (18:3:1:4).

The sugars were detected on paper chromatograms either by spraying them with a 1% solution of *p*-anisidine hydrochloride (15) in butan-1-ol followed by heating the chromatogram, or the chromatogram was sprayed with a 1% solution of silver nitrate in acetone followed by 2% ethanolic sodium hydroxide. The rates of movement of sugars are quoted relative to a standard sugar, e.g. R_{Rh} and R_G (relative to rhamnose, and 2,3,4,6-tetra-*O*-methyl-D-glucose). Paper electrophoresis was carried out in a borate buffer at pH 10 (16). Solutions were concentrated under reduced pressure at ca. 40° C or lower. Optical rotations were measured in water and at 26°±2° (unless otherwise stated).

Extraction of the Gum

The crude material consisted of the oleogum resin admixed with sand, bark, and organic debris. This material (707 g) was exhaustively extracted with hot methanol until a sample of the methanol extract gave no turbidity when poured into water. The residue was collected by centrifugation and extracted with water. The brownish-green extracts were concentrated to a volume of 150 ml and poured into ethanol (2 l.) to which hydrochloric acid (5 ml:10 *N*) had been added. The precipitate was collected (centrifuge), redissolved in ice-cold water (150 ml), and the precipitation procedure repeated twice more. The solid resulting was well washed with ethanol to remove hydrochloric acid, then with ether and was dried under reduced pressure. Yield, 120 g (17%).

For personal use only.

Attempted Fractionation of the Polysaccharide

The polysaccharide (20 g) was dissolved in water (1 liter) and ethanol (500-ml portions) was added with vigorous stirring. The polysaccharide was collected by centrifugation after each addition of ethanol. Four main fractions were obtained. Each fraction had $[\alpha]_D$ $-48°\pm2°$; equiv. wt., 1490 ± 10; and OMe, 1.6%. Each fraction gave on hydrolysis sugars which moved on paper chromatograms, at the rate of L-arabinose, D-galactose, and L-rhamnose plus 4-*O*-methyl-D-glucuronic acid.

Use of "Cetavlon" (17)

The polysaccharide (1 g) was dissolved in water (10 ml) and aqueous "Cetavlon" (20% w/v) was added until precipitation was complete. The precipitate was collected, dissolved in a minimum volume of aqueous sodium chloride (10% w/v), and the solution was poured into ethanol. The precipitate was dissolved in water and dialyzed against tap water until the solution was free from chloride (2 days). The dialyzate was concentrated and poured into two volumes of ethanol. The precipitate was collected, washed with ethanol and ether, and dried. Yield, 0.87 g.

The fraction which was not precipitated by "Cetavlon" was recovered when the solution was concentrated and poured into ethanol. The solid was dissolved in water, the solution dialyzed and recovered as described above. The product weighed 0.04 g. Both fractions had $[\alpha]_D$ $-48°\pm2°$ (*c*, 1.0) and equiv. wt. 1500 ± 10.

Preparation of Gum Acetate

The polysaccharide (5 g) was added, in small portions, to *N*,*N*-dimethylformamide (100 ml) at 30° C. After stirring for 1 hour the suspension had dissolved. Pyridine (90 ml) was then added portionwise during 30 minutes followed by acetic anhydride (32 ml) which was added in four equal portions during 4 hours. The solution was stirred for a further 5 hours at 32° C and then left at 20° C overnight. The solution was then poured with vigorous stirring into cold hydrochloric acid (1 liter; 2%) plus chopped ice (50 g). The precipitated cream-colored product was collected by filtration, washed well with hydrochloric acid (0.5%), and then with water (250 ml, ×5). The product (8 g) had $[\alpha]_D$ $-52°$ (*c*, 2.0 in $CHCl_3$). Found: $-COCH_3$, 42%.

The fractionation of this product by the method of Goodban and Owens (18) was attempted and yielded fractions with $[\alpha]_D$ $-46°\pm2°$ (*c*, 2.0 in $CHCl_3$) and $-COCH_3$, 41 ± 1%. No fractionation had been achieved.

Autohydrolysis of the Gum Polysaccharide

The gum (15 g) was obtained in an ash-free form by passing its aqueous solution through columns of ion-exchange material (Amberlite IR-120 and IR-4B). The acidic eluate was concentrated to a small volume and was precipitated by adding its solution to three volumes of ethanol. The precipitate was dissolved in water (750 ml) and the resulting viscous brown solution was heated under reflux on a steam bath.

At intervals samples were withdrawn and were analyzed chromatographically. The darkness of the solution prevented polarimetric observation being taken. L-Arabinose was the first reducing sugar to appear in the autohydrolyzate and no other sugar was detected until after 26 hours, when traces of D-galactose and L-rhamnose were liberated. The solution was then concentrated to a small volume (30 ml) and poured into ethanol with vigorous stirring. The precipitated degraded product was collected, washed with ethanol and acetone, and dried (yield 11 g, 73%). The supernatant solution from the precipitation was concentrated to a syrup which was dissolved in hot methanol and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

solution was filtered first through charcoal and then through celite. Concentration of this filtrate gave crystalline L-arabinose of melting point 160° C and $[\alpha]_D$ +105°.

Further Hydrolyses of the Degraded Polysaccharide

The degraded polysaccharide (5 g) was dissolved in formic acid solution (1%; 500 ml) and the solution was boiled under reflux for 10 hours. The solution was then evaporated to a syrup which was boiled with water and the solution was again evaporated to hydrolyze formyl esters. This process was repeated several times. Finally the residue was dissolved in water (50 ml) and the solution was poured into ethanol (2 l.) and the precipitate was collected. This product was washed well with ethanol and dried. It had $[\alpha]_D$ +2° (*c*, 1.0). The supernatant was concentrated to a syrup and examined chromatographically. It contained sugars which moved at the rate of galactose, arabinose, and rhamnose (solvent A and B) plus two neutral oligosaccharides and an aldobiouronic acid (solvent E).

The syrup was fractionated on a cellulose column (4×30 cm) using solvent D as the mobile phase and yielded fraction I: L-rhamnose, $[\alpha]_D$ +9° (*c*, 1.0), m.p. 91° C, identical with an authentic sample; fraction II: L-arabinose, $[\alpha]_D$ +100° (*c*, 1.0), m.p. 160° C, not depressed on admixture with an authentic sample; fraction III: D-galactose, $[\alpha]_D$ +81° (*c*, 1.0), m.p. 119° C, indistinguishable from an authentic specimen; fraction IV: had $R_{galactose}$ 0.61 and behaved like an aldobiouronic acid. It had $[\alpha]_D$ +1° (*c*, 1.0) and equiv. wt. 364 and after hydrolysis with 2 *N* sulphuric acid, yielded sugars which moved at the rates of 4-*O*-methyl-D-glucuronic acid and D-galactose. Fraction V was a neutral oligosaccharide which on hydrolysis with 2 *N* sulphuric acid yielded D-galactose only. Fraction VI was also a neutral oligosaccharide which on hydrolysis with 2 *N* sulphuric acid gave D-galactose only.

Characterization of Fractions V and VI

Their rates of movement on chromatograms indicated that both these substances were D-galactose-containing disaccharides. Their rates of movement on paper chromatograms in solvents A, B, D, and E and a comparison of their infrared spectra indicated that they were 3- and 6-*O*-β-D-galactopyranosyl-D-galactose. The corresponding acetates (amorphous) were prepared on the microscale by the method of White *et al.* (5) and their infrared absorption spectra were compared with authentic specimens and found to be identical. Neither disaccharide was obtained crystalline.

Large-scale Preparation of Aldobiouronic Acids

Insufficient quantity of fraction IV was available for characterization and a further quantity was prepared. The original polysaccharide (15 g) was dissolved in water (200 ml) and deionized by passing its solution down columns of ion-exchange resin (Amberlite IR-120).

The eluate was concentrated to a small volume (25 ml) and poured into ethanol (2 liters). The precipitate was collected (centrifuge), and washed with ethanol and acetone, and dried. The dried acidic polymer (8 g) was dissolved in sulphuric acid (800 ml, 2 *N*) and the solution was heated under reflux for 8 hours. Test experiments on small quantities of material had indicated that these conditions gave maximum yields of aldobiouronic acids. The solution was cooled, neutralized ($BaCO_3$), filtered and the filtrate was concentrated to a small volume and poured into ethanol (five volumes). The barium salts were collected, washed with alcohol, and dried. The ethanol solution on concentration gave a syrup which contained D-galactose, L-arabinose, and L-rhamnose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

The barium salts were dissolved in water, deionized (Amberlite IR-120 resin) and the solution was concentrated. The mixture of monosaccharides and oligosaccharides was separated on a squat charcoal – celite column by the method of Hough *et al.* (19). Elution with water removed the monosaccharides and elution with up to 30% aqueous ethanol displaced two aldobiouronic acids which were not separated from one another. Separation of these was achieved on sheets of Whatman 3MM paper using solvent E for development. The faster-moving component was identical with fraction IV (above) and was identified as 6-*O*-(4-*O*-methyl-D-glucopyranosyl uronic acid)-D-galactose. The slower-moving component was the corresponding unmethylated aldobiouronic acid.

Proof of Structure of the Aldobiouronic Acids

The acid (fraction IV, 200 mg) was dissolved in water (3 ml) and methylated with dimethyl sulphate (1.5 ml) and sodium hydroxide (30%; 3 ml) in the usual way. The partially methylated acid was isolated and methylated with Purdie's reagent (20). The resultant methylated ester glycoside (180 g) was dissolved in tetrahydrofuran (50 ml) and reduced by the dropwise addition with stirring of a solution of lithium aluminum hydride (600 ml) in tetrahydrofuran (25 ml).

After 24 hours, excess of lithium aluminum hydride was destroyed by the cautious addition first of ethyl acetate and then of water. The slurry was filtered and the filtrate was evaporated to a small volume which was continuously extracted with chloroform. Complete methylation of the disaccharide was achieved, by the gradual addition during 3 hours of dimethyl sulphate (3 ml) to a stirred solution of the syrup in tetrahydrofuran (15 ml) containing pulverized sodium hydroxide (26 g).

After 16 hours water was added to dissolve the solids and the mixture was heated to 80° to decompose dimethyl sulphate. The solution was neutralized, concentrated, and the residual solution exhaustively extracted with chloroform. Concentration of the extracts yielded the methylated neutral disaccharide (138 mg). Found: OMe, 54.2%. Calc. for $C_{20}H_{38}O_{11}$: OMe, 54.8%.

The methylated disaccharide (135 gm) was hydrolyzed by boiling its solution in formic acid (50%, 25 ml) for 6 hours, and after evaporation of the formic acid, with boiling hydrochloric acid (*N*; 25 ml), for 4 hours.

The hydrolyzate was neutralized (Ag_2CO_3), filtered, and the filtrate was evaporated to a syrup. Paper chromatography of the syrup indicated the presence of three sugars, the two major components were tentatively identified as 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3,4-tri-*O*-methyl-D-galactose. A third trace component of R_G 0.84 (solvent A) was not identified. The sugars were separated on 3MM paper and the two major fractions were identified in the usual way. The fast-moving component had $[\alpha]_D$ +80° (*c*, 1.0) and gave a crystalline *N*-phenylglycosylamine derivative on boiling its solution in ethanol with aniline. The product had a melting point of 116–117° C and $[\alpha]_D$ +205° (*c*, 1.0 in acetone). Its melting point was not depressed on admixture with authentic 2,3,4,6-tetra-*O*-methyl *N*-phenyl-D-glucosylamine.

The slow-moving syrup (R_G, 0.69 in solvent A) had $[\alpha]_D$ +96° (*c*, 1.0). On heating it in ethanol solution with aniline characteristic rhombic crystals of 2,3,4-tri-*O*-methyl-*N*-phenyl-D-galactosylamine were produced, $[\alpha]_D$ −50° → +46° (*c*, 1.0 in methanol), m.p. 169° C not depressed on admixture with an authentic specimen.

The second aldobiouronic acid contained no methoxyl residue and on hydrolysis with sulphuric acid (2 *N*) it yielded D-galactose, D-glucuronic acid, and D-glucurone (chromatographic evidence). It was methylated and then reduced with lithium aluminum

hydride as described above. The product was remethylated then hydrolyzed and yielded 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3,4-tri-*O*-methyl-D-galactose characterized as described above.

Quantitative Determination of Component Sugars Present in the Polysaccharide

The ash-free gum (40 g) was dissolved in *N* sulphuric acid (10 ml) and the solution was boiled under reflux for 10 hours. The solution was cooled, ribose (10 mg) was added, and the solution was then neutralized ($BaCO_3$) and filtered. The filtrate was concentrated to a syrup and the sugars were separated on Whatman 3MM paper. The position and quantity of sugars were determined by the method of Hirst, Hough, and Jones (10). Found: arabinose, 33%; rhamnose, 2%. Galactose was not determined.

Periodate Oxidation of the Undegraded Polysaccharide

The polysaccharide (100 mg) was dissolved in water (20 ml) and titrated to neutrality with sodium hydroxide (0.01 *N*) using screened methyl red as indicator. Sodium metaperiodate solution (5 ml; 0.3 *M*) was added and the solution was made up to 100 ml. A blank solution was prepared similarly. Oxidation was allowed to proceed in the dark at 20°. The periodate uptake was determined by the method of Willard and Greathouse (20) but using phosphate in place of borate and the formic acid production by the method of Halsall, Hirst, and Jones (21). Found: moles of metaperiodate consumed and moles of formic acid produced per $C_6H_{10}O_5$: 0.22, 0.08 (1 hour); 0.32, 0.08 (3 hours); 0.36, 0.10 (6 hours); 0.48, 0.11 (11 hours); 0.57, 0.11 (23 hours); 0.65, 0.11 (36 hours). Acidic hydrolysis of the periodate-oxidized polysaccharide yielded galactose only.

Periodate Oxidation of the Degraded Polysaccharide

The degraded polysaccharide (100 mg) was oxidized with sodium metaperiodate solution as described above. Found: (moles of metaperiodate consumed and moles of formic acid produced for $C_6H_{10}O_5$): 0.37, 0.15 (1 hour); 0.45, 0.15 (3 hours); 0.57, 0.15 (6 hours); 0.63, 0.16 (11 hours); 0.73, 0.19 (23 hours); 0.83, 0.26 (30 hours).

When the periodate-oxidized polysaccharide was recovered and hydrolyzed with dilute sulphuric acid galactose was the only sugar which could be detected chromatographically.

Periodate Oxidation and Degradation of the Gum. Stage I

The gum (16.2 g) was dissolved in water (100 ml) and oxidized with sodium metaperiodate (25 g) in water (150 ml) during 72 hours at 20° C with stirring. The solution was diluted with methanol (500 ml) and the precipitated salts were removed by filtration. The filtrate was evaporated to a small volume and sodium borohydride (6 g) in water (100 ml) was added to the solution. Sulphuric acid (2 *N*; 100 ml) was added and the mixture was left at 20° C for 18 hours. The solution was neutralized ($BaCO_3$), filtered, and the filtrate deionized with Amberlite resin 1R-120 (H). The filtrate was concentrated to 25 ml under reduced pressure and poured into ethanol. The precipitate was collected, dried, and weighed; yield, 4.5 g. This product (equiv. wt., 4300) was insoluble in water after it was dried. It contained galactose and arabinose in the approximate ratio of 5 to 1 (chromatographic evidence) and traces of acid. The alcoholic filtrate on concentration yielded a syrup (8 g) which contained glycerol, glycol, and glycosides, which on hydrolysis yielded galactose and arabinose in the approximate ratio of 1 to 1 (chromatographic evidence).

Periodate Oxidation of the Periodate-degraded Polysaccharide

The sample (20 mg) was oxidized in a volume of 100 ml by the addition of sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

metaperiodate solution (0.1 *M*, 5 ml) and water at 4° C in the dark. At intervals samples were withdrawn and the metaperiodate uptake and formic acid production were measured. Found: moles of metaperiodate consumed and moles of formic acid produced per 162 g polysaccharide: 0.27, 0.10 (4 hours); 0.3, 0.14 (6 hours); 0.36, 0.18 (24 hours); 0.40, 0.15 (48 hours); 0.42, 0.15 (72 hours); 0.44, 0.18 (96 hours).

Periodate Oxidation of the Gum. Stage II

The periodate-oxidized and periodate-degraded gum (3.5 g) was shaken with a solution of sodium metaperiodate (3 g) in water (50 ml) for 6 days at 20° C. The oxidized product was isolated from the clear solution as described above; the substance was reduced with a solution of sodium borohydride (3 g) in water (100 ml). After 24 hours, the solution was acidified with sulphuric acid (2 *N*, 100 ml) and kept at 20° C for a further 24 hours. The solution was then neutralized ($BaCO_3$), filtered, and the filtrate was deionized (Amberlite ion exchange resin, IR 120-H). The twice-degraded neutral polysaccharide (2 g) was isolated as described above. This material on hydrolysis yielded galactose only (chromatographic evidence) and had $[\alpha]_D$ $+31°\pm5°$ (*c*, 1.0). The alcohol-soluble material contained glycerol, glycol, and small quantities of galactose-containing glycosides.

Periodate Oxidation of the Gum. Stage III

The degraded gum (20 mg) was oxidized at a concentration of 20% with aqueous sodium metaperiodate (0.1 *M*, 5 ml) at 4° C in the dark. Found: moles of periodate consumed and moles of formic acid produced per $C_6H_{10}O_5$: 0.17, 0.08 (4 hours); 0.17, 0.08 (14 hours); 0.21, 0.08 (24 hours); 0.23, 0.10 (48 hours); 0.27, 0.12 (72 hours); 0.32, 0.11 (96 hours). Extrapolation to zero time gave an uptake of 0.21 mole of metaperiodate and a formation of 0.08 of formic acid per $C_6H_{10}O_5$.

Methylation of the Undegraded Polysaccharide

The acetylated polysaccharide (11 g) was dissolved in acetone (200 ml) and methylated with dimethyl sulphate and sodium hydroxide in the usual way. The product was dissolved in a mixture of methanol and methyl iodide and the solution was boiled under reflux; silver oxide was added portionwise to the solution. At the completion of the experiment (24 hours) the product was isolated in the usual way. Methylation was completed when the product was dissolved in dry tetrahydrofuran (200 ml), admixed with powdered sodium hydroxide (40 g), and dimethyl sulphate (13.5 ml) added with stirring at 20° C during 24 hours. The product (6 g) was isolated from the aqueous solution by extraction with chloroform, after the solution had been diluted with water, neutralized with dilute sulphuric acid, and dialyzed against tap water to remove salts, and concentrated. The methylated product had $[\alpha]_D$ $-76°$ (*c*, 1.0 in $CHCl_3$). Found: OMe, 40.5%. The product was fractionated by extracting it with mixtures of chloroform – light petroleum (b.p. 60–80° C). Two major products were isolated: (1) $[\alpha]_D$ $-75°$; OMe, 42%; and (2) $[\alpha]_D$ $-76°$ (*c*, 1.0 in $CHCl_3$); OMe, 42%. The fractions (1 g and 5 g, respectively) were combined and hydrolyzed as described below.

Hydrolysis of Methylated Gum

The methylated polysaccharide (5 g) was dissolved in formic acid (50%, 400 ml) and the solution was heated under reflux until the optical rotation reached a constant value (+35°). The solvent was removed and the syrupy residue was boiled with water and the solution concentrated. This process was repeated once more. The residue was dissolved in dilute sulphuric acid (2 *N*, 100 ml) and the solution was heated at 100° for 4 hours.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The cooled solution was then neutralized ($BaCO_3$), filtered, and the filtrate was concentrated to a syrup. The product was dissolved in water and the solution passed down columns of Amberlite ion exchange resins, IR-120 and IR-4B, and the effluent was concentrated to a syrup (4.28 g) which contained neutral sugars only. The acidic sugars (0.64 g) were recovered when the basic resin (IR-4B) was washed with 30% formic acid and the effluent was concentrated.

A quantitative determination of the sugars present in this mixture was made by the method of Hirst, Hough, Jones (10). Found: end group (3 parts); tri-*O*-methyl hexose (2 parts); di-*O*-methyl hexose (2 parts); mono-*O*-methyl hexose (1 part); and methylated uronic acid (end group) (1 part).

Characterization of the Methylated Neutral Sugars

The syrup (4.28 g) was separated on a cellulose column (50×4 cm) using light petroleum (b.p. 100–120° C):butan-1-ol (7:3) as the mobile phase. Six fractions were obtained: Fraction I had $[\alpha]_D$ −30° and OMe 47.2% and consisted chromatographically of one component only. A portion (100 mg) of the syrup was oxidized with bromine water in the usual way and the resulting lactone was dissolved in methanolic ammonia to yield crystalline 2,3,5-tri-*O*-methyl-L-arabonamide, m.p. and mixed m.p. 134° C, $[\alpha]_D$ −15° (*c*, 1.0). Fraction II was chromatographically pure and had $[\alpha]_D$ +108° and moved at the same rate as 2,3,4,6-tetra-*O*-methyl-D-galactose in solvent A, B, and C. Found: OMe, 51.9. Calc. for $C_{10}H_{20}O_6$: OMe, 52.5%. A portion of the syrup was boiled with ethanolic aniline and yielded 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-galactosylamine, m.p. 192° C, not depressed on admixture with an authentic specimen, $[\alpha]_D$ 40° (in acetone, equilibrium value). Fraction III was a mixture and was not characterized. Fraction IV moved chromatographically at the same rate as 2,4,6-tri-*O*-methyl-D-galactose and had OMe, 41.6% (calc. for $C_9H_{18}O_6$: OMe, 41.9%) and $[\alpha]_D$ 87°. The derived crystalline *N*-phenylglycosylamine derivative was identified as 2,4,6-tri-*O*-methyl-*N*-phenyl-D-galactosylamine, of m.p. 176°, not depressed by an authentic specimen. The infrared spectra of the derivative and of an authentic specimen were identical. Fraction V crystallized. It behaved chromatographically like 2,4-di-*O*-methyl-D-galactose in solvents A, B, and C. It had m.p. 102° C, not depressed on admixture with an authentic specimen and $[\alpha]_D$ +130° → 86° (constant 2 hours) (*c*, 1.0). The derived *N*-phenyl-D-galactosylamine had m.p. 215° C and was indistinguishable from an authentic specimen. Fraction VI was a syrup and had the properties of a mono-*O*-methyl hexose. (Found: OMe, 15.8%. Calc. for $C_7H_{14}O_6$: OMe, 16%). When nucleated with 2-*O*-methyl-D-galactose the syrup crystallized. The product had m.p. 148° C, not depressed on admixture with an authentic specimen and $[\alpha]_D$ +60° → 89° (2 hours constant) (*c*, 1.0). The derived *N*-phenyl-D-galactosylamine had m.p. 163° C and this product was indistinguishable from an authentic specimen.

Characterization of the Acidic Fraction

This syrupy material moved as one component (R_G 0.84) on a chromatogram (solvent E) and had $[\alpha]_D$ +40° (*c*, 1.0). Further hydrolysis with hot dilute acid did not liberate any neutral sugars. The syrup (250 mg) was dissolved in methanolic hydrogen chloride (2%; 20 ml) and boiled under reflux for 8 hours. The solution was then non-reducing to Fehling's solution. The solution was neutralized (Ag_2CO_3), filtered, and the filtrate was concentrated to a syrup. This was dissolved in dry tetrahydrofuran and the solution was added dropwise to a solution of lithium aluminum hydride (0.1 g) in tetrahydrofuran. After 24 hours the reduced product was isolated in the usual way and hydrolyzed with hot

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(92° C) dilute hydrochloric acid (2 *N*, 10 ml) for 6 hours. The resultant sugar had R_G 0.85 (solvent A) and was indistinguishable from 2,3,4-tri-*O*-methyl-D-glucose, $[\alpha]_D$ 65° (*c*, 1.0) (Found: OMe, 41.5%. Calc. for $C_9H_{18}O_6$: OMe, 41.9%). When the sugar was dissolved in ethanol containing aniline and the mixture heated under reflux for 5 hours 2,3,4-tri-*O*-methyl-*N*-phenyl-D-glucosylamine, m.p. and mixed m.p. 145° C, was produced.

Methylation of the Degraded Polysaccharide

The polysaccharide (5 g) was acetylated using the conditions described above for the acetylation of the original polysaccharide. The acetylated product (7 g) was methylated with sodium hydroxide and dimethyl sulphate in the usual manner and the methylated product was isolated. This material still contained hydroxyl groups (infrared spectrum) and methylation was therefore completed by the method of Kuhn *et al.* (22). The product (3 g) had OMe, 42.5%, and its infrared spectrum showed a trace of hydroxyl band.

Fractionation.—The acidic methylated degraded gum was treated with diazomethane and the neutral product was extracted with chloroform – light petroleum mixture (b.p. 100–120° C) of increasing chloroform concentration. Two main fractions were obtained which had $[\alpha]_D$ −50°±1° (*c*, 1.0, acetone); OMe, 44%; and equiv. wt., 940.

Hydrolysis of the Methylated Degraded Gum

The methylated degraded gum (2.9 g) was hydrolyzed with hot 50% aqueous formic acid as described for the hydrolysis of the original methylated polysaccharide. The sugars (2.9 g) were separated into neutral (2.2 g) and acidic (0.61 g) fractions on ion-exchange columns. A quantitative analysis of the mixture by the method of Hirst, Hough, and Jones (10) and by weighing the fractions eluted from the cellulose chromatographic columns (see below) gave an approximate ratio of end group:tri-*O*-methyl-hexose:di-*O*-methyl-hexose of 1:2:1(for fuller details see theoretical section).

Fractionation of Neutral Sugars

The neutral sugars (2.2 g) were fractionated on a cellulose column by the method of Hough, Jones, and Wadman (23). Six fractions were obtained. Fraction I (120 mg) had $[\alpha]_D$ −30° (*c*, 1.0) and was chromatographically identical in solvents A, B, and C with 2,3,5-tri-*O*-methyl-L-arabinose. Demethylation of a portion of the product with aqueous hydrobromic acid indicated the presence of arabinose only. A sample of the sugar was oxidized to the acid, the derived amide had a melting point of 134° C, $[\alpha]_D$ −15° (*c*, 1.0) and was indistinguishable from 2,3,5-tri-*O*-methyl-L-arabonamide. Fraction II (180 mg) was chromatographically pure and identical with 2,3,4,6-tetra-*O*-methyl-D-galactose. It had R_G 0.88 (solvent A) $[\alpha]_D$ +82° (*c*, 1.0) and the derived 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-galactosylamine had a melting point of 190–191° C, not depressed on admixture with an authentic specimen, and $[\alpha]_D$ +40° (*c*, 1.0 in acetone; equilibrium value). Fraction III (130 mg) was a mixture of 2,3,4,6-tetra-*O*-methyl-D-galactose (30 mg) and an unknown sugar (100 mg). Fraction IV (500 mg) was chromatographically pure and was identified as 2,4,6-tri-*O*-methyl-D-galactose with R_G 0.71 (solvent A), and $[\alpha]_D$ +87° (*c*, 1.0). The *N*-phenylglycosylamine derivative had a melting point of 171° C and $[\alpha]_D$ 40° (*c*, 1.0, acetone) and was indistinguishable by infrared spectroscopy from an authentic specimen. Fraction V (700 mg) was a mixture of 2,4,6-tri-*O*-methyl-D-galactose and of the 2,4-di-*O*-methyl derivative. Fraction VI (570 mg) had $[\alpha]_D$ +80° and crystallized. It was recrystallized from acetone and was identified as 2,4-di-*O*-methyl-D-galactose, m.p. 102° C, $[\alpha]_D$ +86° (*c*, 1.0), which was further characterized as the aniline derivative of melting point 215° C.

For personal use only.

Characterization of the Acidic Fraction

The acidic fraction (0.61) moved as one material on the chromatogram and had $[\alpha]_D$ +40° (*c*, 1.0). It was not affected by hot dilute hydrochloric acid and therefore did not contain any oligosaccharide derivatives. It was converted by boiling its solution in methanolic hydrogen chloride to the corresponding ester $\alpha+\beta$-glycoside. When this syrupy ester was dissolved in methanol and the solution was saturated with ammonia, the crystalline amides were produced. Recrystallization from ethanol–ether yielded pure 2,3,4-tri-*O*-methyl methyl α-D-glucuronamide, which had a melting point of 183° C and $[\alpha]_D$ +138° (*c*, 1.0) (7).

SHEAR DEPENDENCE IN THE VISCOMETRY OF HIGH POLYMER SOLUTIONS

A NEW VARIABLE-SHEAR CAPILLARY VISCOMETER[1]

L. H. CRAGG[2] AND H. VAN OENE[2]

ABSTRACT

The principles of capillary viscometry are reviewed, and design criteria for capillary viscometers to be used with non-Newtonian liquids are discussed. A description is given of a new type of variable-shear capillary viscometer—a modification of the Ubbelohde suspended-level viscometer—designed for measurements in the low-shear range. The instrument is rugged, convenient, and precise, and makes possible measurements at free fall over a 10-fold range of shear stress (or shear rate), a range that can easily be extended by use of two or more suitably modified instruments or by the application of external pressure. Experimental evidence is presented to show that proper choice of the dimensions of the instrument eliminates or minimizes most of the "effects" that limit the precision of measurements of relative viscosity (and related functions) of high polymer solutions in the range of low shear stresses.

A. INTRODUCTION

For many years now the measurement of viscosity has been a powerful and much-used procedure in the study of high polymer systems and particularly of polymers in dilute solutions. In most of these studies, capillary viscometers have been used, because they are relatively inexpensive and convenient. Many different types of capillary viscometers have been designed to meet special needs. One particularly convenient viscometer (1), a modification of the Ubbelohde instrument (2), makes possible dilution in the viscometer itself and so greatly facilitates obtaining the data necessary for the determination of intrinsic viscosities (limiting viscosity numbers).

The ordinary capillary viscometers (Ostwald, Cannon-Fenske, Ubbelohde, etc.), when used as they were meant to be used, provide measurements all made at the same (or very nearly the same) driving pressure. They were not designed for use with non-Newtonian liquids, with which measurements should be made at a number of different driving pressures. Until fairly recently this seldom mattered. Now, however, there is more and more interest in polymers whose solutions are non-Newtonian liquids. For these, the familiar instruments and the time-honored procedures are not satisfactory and, unless suitably modified, may yield completely spurious results.

Several capillary viscometers that have been designed for use with non-Newtonian systems have been described (3, 4, 5, 6, 7). These give good results at relatively large shear stresses, say in the range 5–20 dynes/cm^2. But most of them are not satisfactory for use at low stresses and hence cannot provide the data for a reliable extrapolation to zero shear stress. This is a serious inadequacy, for it is generally accepted that, in the study of polymers whose dilute solutions are non-Newtonian (polymers of very high molecular weight or with very stiff molecules), the quantity of greatest interest is the intrinsic viscosity at zero shear stress, a quantity that must be determined by extrapolation of data obtained at low shear stresses. That there is need for a rethinking of designs and procedures is evidenced by the fact that careful measurements with different variable-shear capillary viscometers have given results in the low-shear region that are

[1]*Manuscript received August 24, 1960.*
Contribution from the Department of Chemistry, McMaster University, Hamilton, Ontario, based on a thesis submitted by H. van Oene in October, 1958, in partial fulfillment of the degree M.Sc., and presented in part at 42nd Annual Conference of the Chemical Institute of Canada, Halifax, May 1959.
[2]*Present address: Department of Chemistry, University of Alberta, Edmonton, Alberta.*

at variance both with theory and with other experiments. Theory (8, 9) required a quadratic dependence on the shear stress to account for the fact that the viscosity of a liquid does not depend on the direction of the flow, that is, on the sign of the shear stress; and results obtained with Couette-type viscometers, which are intrinsically much better suited to shear-dependence studies, did in fact show this quadratic dependence (10), rather than a linear or exponential dependence indicated by results obtained with capillary viscometers (11, 12).

Since, in our judgment, existing variable-shear viscometers were either unsuited to, or inconvenient for, making precise, reliable measurements in the desirable range of low shear stresses, we have carefully reviewed the theoretical and experimental basis of capillary viscometry with a view to designing a suitable variable-shear capillary viscometer. As a result, we have developed a viscometer that has proved its worth during 3 years of use.

In this paper, we describe the new viscometer and discuss briefly the considerations which governed its design.

B. DESIGNING THE VISCOMETER

I. The Requirements

Ideally the viscometer should meet the following requirements:

(*a*) It should be rugged and compact.

(*b*) It should be simple and convenient to use. For example, it should not readily "clog"; it should be easy to load; it should permit dilution of the polymer solution in the instrument itself; and the flow times should not be excessively long.

(*c*) It should yield precise data. The flow times should not be too short, and the driving pressure should be reproducible and steady.

(*d*) It should make possible measurements at a number of different shear stresses in the low-stress range.

(*e*) Its dimensions should be such that the kinetic energy effect, the drainage effect, and the effects of surface tension will be negligible at all shear stresses (or at least can be readily corrected for).

II. The Poiseuille Equation and its Application

In designing an instrument to meet the requirements listed above, it is necessary to consider the Poiseuille equation (the basis of capillary viscometry) and reasons for deviations from it, and, in particular, the effects on these deviations of changes in concentration and in the shear stress.

The familiar form of the Poiseuille equation is

$$\eta = \frac{\pi R^4 p}{8VL} \cdot t \qquad [1]$$

where R is the radius of the capillary and L is its length (cm), V is the volume (cm^3) of liquid flowing through the capillary in time t (sec), and p is the driving pressure (dynes/cm^2). In a viscometer in which the liquid flows under its own head, $\bar{h}$ (cm), the driving pressure is related to the head by the equation $p = \bar{h}gd$, where d is the density of the liquid. Then

$$\eta = \frac{\pi R^4 \bar{h} g d}{8VL} \cdot t. \qquad [2]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In deriving this equation, certain assumptions are made.

(*a*) The flow is laminar.

(*b*) There is no slip at the wall of the capillary, that is, the velocity of flow at the wall is zero. (For stresses less than 10^2 dynes/cm^2 this assumption seems to be valid (39).)

(*c*) The liquid is incompressible.

(*d*) All the energy applied to the liquid is used to overcome viscous resistance and is dissipated as heat (none, for example, being used to start the liquid flowing (no "yield value"), or to overcome effects due to surface tension, or to impart kinetic energy to the liquid).

This last assumption is never strictly valid. There is always a "kinetic energy effect" more or less large. When allowance is made for this, the Poiseuille equation becomes

$$\eta = \frac{\pi R^4 \bar{h} g d}{8VL} \cdot t - \frac{mV}{8\pi L} d \cdot \frac{1}{t} \qquad [3]$$

where m is a semiempirical constant whose value depends on the shape of the capillary ends and on the velocity of flow (13, 14, 15). Because of this uncertainty in the value of m, the kinetic energy correction must be determined by calibration or, much better, made negligible by appropriate choice of the dimensional parameters. (It may easily be shown that the kinetic energy correction, expressed as a percentage correction, is proportional to R^4, $\bar{h}$, and $1/L^2$). If, then, the viscometer is appropriately designed, the simple Poiseuille equation [2] may be used in calculations.

In polymer-solution studies, the quantity desired is the viscosity ratio η/η_0 (the ratio of the solution viscosity to the solvent viscosity) rather than the viscosity of the solution. The assumption is usually made that $\eta/\eta_0 = t/t_0$. This assumption really involves four assumptions:

(*a*) that Poiseuille's equation [1] applies to both solution and solvent;

(*b*) that the kinetic energy correction is negligible;

(*c*) that the density ratio d/d_0 differs negligibly from unity; and

(*d*) that the quantity

$$\frac{\pi R^4 \bar{h} g}{8VL},$$

collectively called the apparatus constant A, is really a constant, R, $\bar{h}$, V, and L having the same value for different pure liquids and solutions.

The first of these assumptions is valid for Newtonian liquids; but if the solution is non-Newtonian, the equation applies only under conditions such that the deviations from Newtonian behavior are slight (16, 17).

The second assumption we have already discussed.

The error involved in making the third assumption can be calculated (18) or can be determined by density measurements (19).

But what of the fourth assumption, that the parameters R, $\bar{h}$, V, and L in the apparatus constant are truly constant? Let us consider each of these parameters in turn.

The Radius of the Capillary, R

The radius of the capillary may be altered in changing from solvent to solution if polymer is absorbed on the capillary wall. The effective radius R^* then would be

$$R^* = R - a$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where a is the thickness of the absorbed layer.[3] Öhrn (22) has obtained evidence of such a reduction in radius. It leads to an apparent viscosity ratio, η_r^*, that is greater than the true ratio, η_r. According to Öhrn

$$\eta_r = \eta_r^*\left(1-\frac{4a}{R}\right).$$

From this it follows that

$$[4] \qquad \frac{\eta_r-1}{c} = \frac{\eta_r^*-1}{c} - \frac{4a}{R}\cdot\frac{\eta_r^*}{c}$$

and that the "absorption" error, expressed as a percentage of the true reduced viscosity, amounts to

$$\frac{4a}{R}\cdot\frac{\eta_r^*}{(\eta_r^*-1)}\cdot 100.$$

Even at $\eta_r = 1.2$, the error in $(\eta_{sp})/c$ is still 1.2% assuming that the thickness of the absorbed layer is 1250 Å (which is about what Öhrn found it to be) and that the radius of the capillary is 0.0250 cm. Since the error in $(\eta_{sp})/c$ is larger the lower the concentration of the solution, the slope of the $(\eta_{sp})/c$ versus c line will be greater when corrected values of $(\eta_{sp})/c$ are plotted than when uncorrected values are plotted.[4] Hence the true value of $[\eta]$ will be smaller than that obtained if corrections are not made. This suggests that in the determination of $[\eta]$ by extrapolation, greater weight should be given to the points at higher concentrations than to those where η_r approaches 1.2. It is, however, worth mentioning that if the desorption of the polymer layer is slow (24), the error due to absorption will be smaller if the measurements are made with progressively more dilute solutions (as they are when dilution is made in the bulb of the viscometer) and if the flow time of solvent is measured after rather than before the flow times of the solutions are measured.

The Hydrostatic Head, $\bar{h}$

In any capillary viscometer, the hydrostatic head decreases during flow. Therefore a mean head must be used in calculations. What this mean head is depends upon the shape of the efflux bulb, and on whether the liquid flows out of the capillary into the air as in the Ubbelohde suspended-level viscometer or into another vessel, as in an Ostwald-type viscometer. In a Ubbelohde viscometer[5] in which the efflux bulb is spherical and in which there is negligible kinetic energy effect, the true mean head $\bar{h}$ for discharge into air is given by the expression (26)

$$[5] \qquad \bar{h} = \frac{4/3R_b}{2c-(c^2-1)\ln\frac{c+1}{c-1}}$$

[3]*Actually an apparent reduction in radius of this form may be due in part or whole to other effects such as the "size effect" encountered with suspensions of rigid particles (20) and the hydrodynamic repulsion by the wall which increases with the velocity of flow (21). Regardless of the cause, the observed apparent reduction in radius is of the order of magnitude of a particle radius.*

[4]*It may be shown (23) that the error in the slope, expressed as a percentage error, is equal to*

$$\frac{400a/R}{k'[\eta]^2c^2}.$$

For example, with our polystyrene fraction T_5, for which $[\eta] = 9.32$ dl/g and $k' = 0.31$ the percentage error would be 1.87% at a concentration, c, of 0.063 g per 100 ml (at which $\eta_r = 1.6$) and 7.2% at a concentration of 0.032 g per 100 ml (at which $\eta_r = 1.3$). To keep this error reasonably small, the measurements should be made at concentrations such that η_r is not less than about 1.5 (or else an absorption correction should be made).

[5]*The calculation of the mean head in an Ostwald-type viscometer is more complicated. It is discussed in a recent paper by Overbeek (25).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where R_b is the radius of the bulb and $c = h_m/R_b$ and h_m is the algebraic mean of the initial and final heads (provided that the fiducial marks are equidistant from the spherical bulb). After expansion of the logarithmic term this reduces to

$$\bar{h} = \frac{h_m}{1\ 0.200\ \frac{1}{c^2}\ 0.086\ \frac{1}{c^4}} \qquad [6a]$$

or, for all practicable heads,

$$\bar{h} = h_m. \qquad [6b]$$

Expression [5] is not strictly valid for non-Newtonian liquids (27). Nevertheless, the deviation from it is negligibly small, much smaller, say, than the error due to kinetic energy effect, even in a well-designed viscometer.

There is, however, an effect on the hydrostatic head which may not be negligible, namely, that due to *surface tension*. With organic solvents and their solutions the effect is very small in the usual capillary viscometers ($h \sim 10$ cm); but in viscometers with very low heads ($h < 3$ cm), and with the smaller bulb that must be used at these low heads to give a convenient flow time, the effect becomes very significant. Indeed with water and with aqueous solutions, it can amount to 30% or more of the mean head. Accordingly, a variable-shear viscometer for use at low shear stress should be so designed that surface tension effects are effectively eliminated or, failing that, can be corrected for with as little inconvenience as possible.

In various viscometers that have been designed for use at low shears, attempts have been made to eliminate the surface tension effect by having the effect of surface tension at the advancing meniscus exactly offset that at the receding (or falling) meniscus (see, for example, Sprokel's design for an Ostwald viscometer (28), Golub's work with a simple U-tube viscometer (11), and Signer and Berneis' work with an inclined capillary (5)). In all of these, however, one meniscus is advancing onto a dry surface and the other is receding from a wet surface. This gives rise to a hysteresis effect which manifests itself as an apparent yield value (29). This effect is the more serious the lower the hydrostatic head. In other words, it is most serious just where reliable data are most desired.

The viscometer in which the surface tension can best be coped with is the Ubbelohde, or suspended-level, viscometer. In this there is only one moving meniscus—the falling one. The other one is kept stationary and given a fixed radius of curvature, at the suspended level. The radius of curvature of the inverted surface can be selected so that surface tension exerts a downward pull at the suspended level that exactly counterbalances the upward pull at the falling meniscus. The required radius of curvature is calculated from the relation

$$R_0 = \frac{2\gamma}{d} \cdot \frac{1}{\langle h_\gamma \rangle} \qquad [7]$$

where γ is the surface tension and $\langle h_\gamma \rangle$ is the "volume average" capillary rise in the bulb and the tubing between the fiducial marks. Values of the quantity $\langle h_\gamma \rangle$ can be calculated (30, 13, 31) from the expression

$$\langle h_\gamma \rangle = \frac{\sum \langle h_1 \rangle_\gamma \Delta V_1}{\sum \Delta V_1} \qquad [8]$$

where $\Sigma \Delta V_1$ is the total volume of the bulb, including the volume of tubing between the marks.

Contrary to Ubbelohde's claim, a value of R_0 calculated for a given liquid does not apply for every other liquid; it applies only when that liquid, or another liquid for which the ratio γ/d has the same value, is used in the viscometer. Fortunately many of the common organic solvents do have nearly the same surface tension – density ratio, namely, about 30 dynes cm^2 g^{-1} (see Table I). Fortunately, too, a dilute polymer solution

TABLE I

Surface tension–density ratios (25° C)
(Data obtained from (32) and (33))

Solvent	γ, dynes/cm	d, g/cm^3	γ/d, dynes cm^2/g
Toluene	27.20	0.862	31.5
Benzene	27.47	0.874	31.4
Cyclohexane*	23.82	0.769	31.0
Methyl ethyl ketone	24.0	0.799	30.0
Acetone†	23.32	0.791	29.5
Carbon tetrachloride	26.15	1.58	16.5
Water	72.0	0.997	72.2

*At 30° C. †At 20° C.

in an organic solvent has very nearly the same value of the γ/d ratio as the solvent itself. So a viscometer designed for use with one organic solvent and its solutions is suitable for use with most others. It is *not*, however, suitable for use with water, for which $\gamma/d = 72.2$ dynes cm^2 g^{-1}, or for aqueous solutions.

The Efflux Volume, V

The actual volume of the efflux bulb does not necessarily equal the efflux volume V, the volume of liquid that passes through the capillary in flow. The true efflux volume will be the volume of the bulb (the volume between the fiducial marks) less the volume V_d of liquid left adhering to the walls. This volume, the *drainage correction* in the efflux volume, varies directly as the viscosity of the liquid and inversely as its flow time. It is, therefore, independent of the liquid *provided that the liquid flows under its own head* (34). Hence a drainage correction in the viscosity ratio (and derived functions) is not necessary if all measurements are made at free fall; it is necessary, however, if external pressures are used to vary the shear stress (27).

The Capillary Length, L

The effective length of the capillary L is not identical with the actual length of the capillary L_0, but is greater than it by the quantity nR, where R is the radius of the capillary and n is a parameter whose value is about 0.566. When a capillary of length L is divided into two sections, as in our viscometer, the end correction would be doubled, becoming $2nR$. The value of n may vary slightly with driving pressure, but in any event the end correction may be made negligible by making L large enough. (For viscoelastic liquids there is another "end correction" related to the "recoverable shear", S_R (35). Taking this into account, the total end correction in our viscometer amounts to $2(n+S_R/2)R$, where $S_R = 0$ for Newtonian liquids, $S_R \sim 1$ for most polymer solutions, and $S_R \sim 10$–100 for highly viscoelastic liquids such as molten polyethylene and aluminum soap solutions.)

III. The Design

The viscometer, Fig. 1, was designed taking all these factors into consideration. Some features of it need comment.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

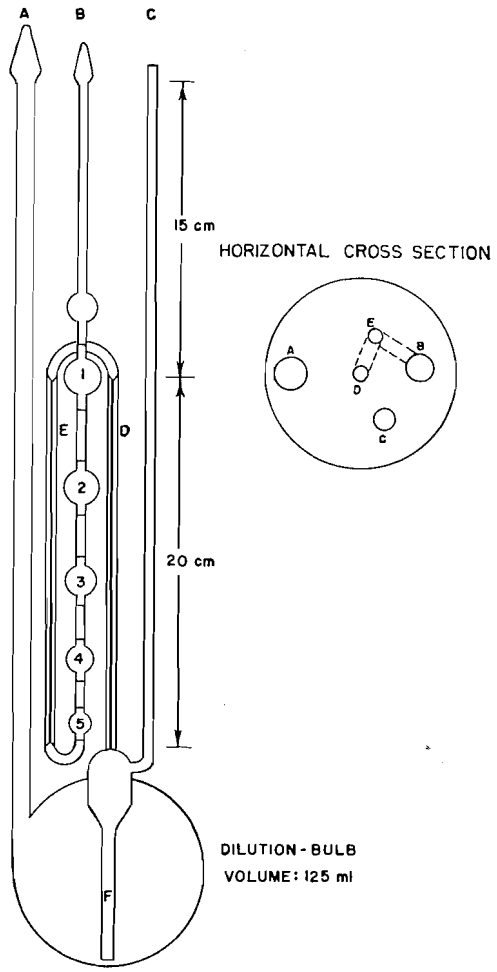

FIG. 1. Modified Ubbelohde variable-shear viscometer: (A) filling tube, O.D. 1 cm; (B) bulb system; (C) air inlet tube, O.D. 0.6 cm; (F) O.D. 0.6 cm, I.D. 0.4 cm (F almost touches the bottom of dilution bulb).

(*a*) The viscometer is provided with five efflux bulbs, each with its own pair of fiducial marks. With these can be achieved five different accurately reproducible mean heads, corresponding to shear stresses varying over a 10-fold range. Since the heads are built into the instrument, drainage corrections are unnecessary (so long as external pressure is not applied)

(*b*) The viscometer is of the Ubbelohde type, to facilitate elimination or correction of surface tension effects. The radius of curvature of the hemispherical suspended level is such that there is no surface tension effect at the lowest head when toluene is the solvent. (This means an overcorrection for the other bulbs, but the resulting negative corrections are very small in the next higher head and small even at the highest head. The *relative* error is always negligible with toluene as solvent and indeed with the other organic solvents of Table I for which $\gamma/d \approx 30$.)

(*c*) The viscometer is modified so that dilution of the solution can be accomplished without removing the solution from the instrument. This is possible because the position

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of the second meniscus is independent of the volume of liquid in the viscometer. Incidentally, this feature of the Ubbelohde also eliminates loading errors.

(*d*) Precision-bore capillary tubing is used, and with no bends in it, to ensure that liquid flow in the capillary will be truly laminar (at the driving pressures used).

(*e*) A lowest head of about 2 cm is achieved, in conjunction with the long length of capillary required to minimize the end effect and kinetic energy effect, by dividing the length of capillary tube into two lengths joined by a wider-bore U tube. With the two lengths of capillary disposed vertically, the whole instrument is compact and rugged.

IV. Dimensions of the Viscometer

The radius R and the length L of capillary tubing, the volumes of the bulbs, and the heights of the bulbs above the suspended level (which of course govern the heads) were chosen after balancing all relevant factors (see Table II). Two viscometers were designed

TABLE II

Considerations affecting the choice of dimensional parameters R, L, V, and h

Shear stress, dynes/cm²	Proportional to	R,	L^{-1},		h
Flow time, t	Proportional to	R^{-4},	L,	V,	h^{-1}
Kinetic energy effect (%)	Proportional to	R^{4},	L^{-2}		
Surface tension effect (%) (if not compensated for)	Proportional to			$V_b^{-1/3}$*,	h^{-1}
End effect (%)	Proportional to	R,	L^{-1}		
Absorption effect (%)	Proportional to	R^{-1}			

*For spherical bulbs of dry volume V_b.

to provide two different, and overlapping, shear-stress ranges.

The specifications for the two viscometers are listed in Tables III and IV. (The viscometers themselves, as fabricated by the master glassblower of Canadian Laboratory Supplies, Montreal, conformed very closely to these specifications.)

C. EVALUATION OF THE VISCOMETER

I. Experimental Tests

A simple and direct test is to compare measured flow-time ratios with kinematic viscosity ratios, for two different liquids. The Poiseuille equation [3] may be written in the form

$$[9] \qquad \nu = \frac{\pi R^4 \bar{h} g}{8VL} \cdot t - \frac{mV}{8\pi L} \frac{1}{t} = At - B\frac{1}{t}$$

where ν is the kinematic viscosity η/d. If the kinetic energy term is negligible, this reduces to

$$[10] \qquad \nu = \frac{\pi R^4 \bar{h} g}{8VL} \cdot t = At.$$

If A is constant, the ratio of flow time for two different liquids should be the ratio of their kinematic viscosities. Furthermore, if the two liquids are Newtonian, this ratio should be the same at all shear stresses.

Such a comparison was made for several pairs of liquids in two viscometers, IIA-1 and IIB-1, made to the specifications of Tables III and IV, respectively. The results of one comparison, using benzene[6] and toluene,[6] are given in Table V.

[6]*The solvents used in the experiments discussed in this paper were carefully purified in the manner already described (36).*

t_B/t_T	1.092	1.093	1.092	1.093	1.090	Av. 1.092

The constancy of the flow-time ratios, and the agreement with the kinematic viscosity ratio, indicate that both kinetic energy and surface tension effects are minor.

That the surface tension effect on t_r is negligible is indicated by the fact that the ratio has the same value at very low heads (bulb 5) as at heads 10 times greater (bulb 1).

This constancy, however, is not proof that the surface tension effect on h, and therefore on t, is negligible.

It may be shown that (with negligible kinetic energy effect)

$$\nu_r = t_r\left[1-\frac{1}{\bar{h}}(\langle h_\gamma\rangle_1-\langle h_\gamma\rangle_2) - \frac{1}{\bar{h}^2}(\langle h_\gamma\rangle_1\langle h_\gamma\rangle_2-\langle h_\gamma\rangle_2^2)\right]$$

where $\bar{h}$ is the mean head, $\langle h_\gamma\rangle_1$ is the correction in the head due to surface tension of liquid 1, and $\langle h_\gamma\rangle_2$ is the correction in the head due to surface tension of liquid 2. Since $\langle h_\gamma\rangle$ depends on γ/d, the surface tension – density ratio, it follows that (except for

hysteresis effects which are eliminated in an Ubbelohde-type viscometer) the surface tension effect in the *ratio* of the kinematic viscosities will be nil if the two liquids have the identical γ/d ratios, and will be negligible except when γ/d ratios differ appreciably.

This means that the effect of surface tension in t_r or η_r (or other relative functions like $(\eta_{sp})/c$ or $[\eta]$ can be neglected with most organic solvents and their solutions even when there is an appreciable surface tension effect in h. It does *not* mean, however, that *all* surface tension effects can be neglected. There can be a very significant effect on the shear stress. With non-Newtonian liquids, for example, the shear stress τ (or the shear rate D) is a very significant variable. It is calculated from the mean head $\bar{h}$. But a calculation of the mean head in flow from measured values of h_{initial} and h_{final} using equation [5] (or its simplified forms [6*a*] or [6*b*]) does not take into account the capillary rise in the bulb and, hence, yields a mean head which is in error (the relative error being greater the smaller $\bar{h}$ is). At low heads the percentage error in $\bar{h}$, and therefore in τ or D, can be very large. On the other hand, with a viscometer such as ours, the $\bar{h}$'s whose direct measurement would lead to greatest error, the small heads, can be determined indirectly. Since

$$\bar{h} = \frac{\eta}{d}\frac{8VL}{\pi R^4 g}\cdot\frac{1}{t},$$

measurements at the large values of $\bar{h}$ (when surface tension effects are negligible) with a liquid of known η/d, give a measure of $8L/g\pi R^4$ which, combined with measurements of V and t at the low heads, make it possible to calculate $\bar{h}$.

That the kinetic energy effects are small in these viscometers is also indicated by the constancy of the flow-time ratios. The kinetic energy effect on $t_{\text{benzene}}/t_{\text{toluene}}$ should be *relatively* larger in bulb 1 than in bulbs 5 or 4; but within the limits of error no difference in the ratio, as measured with bulb 1 and with bulbs 5 or 4, is detectable. But this is not surprising. If the percentage kinetic energy effect is small in a flow time, and we designed the viscometer to make it so, it will be much smaller still in a flow-time ratio. In other words, the test is not a very sensitive one.

A second and more sensitive test of the extent to which unwanted effects have been reduced involves the determination of the constants A and B in the modified viscosity equation [9]. These can be evaluated, as suggested by Higgins (37), from a plot of ν/t versus $1/t^2$; A is then the intercept and B is the slope constant. For this evaluation, we measured the flow times of benzene at 20° and 40° and toluene at 20°, 40°, and 60° C and we obtained the corresponding kinematic viscosities from Timmermans (32). Values of A and B obtained from the plots are given in Table VI.

TABLE VI

From the values of A and B, the percentage kinetic energy correction in the flow time, AB/ν^2, can be readily calculated. In Table VI are listed the corrections for benzene at 20° C. Considering the difficulty of fabricating an instrument like this exactly to specifications, these agree remarkably well with those calculated in Tables III and IV.

From our value of A and B and our measured values of t, we calculated kinematic viscosities of toluene at 20°, 40°, and 60°. These are given in Table VII.

TABLE VII

Kinematic viscosities of toluene at 20°, 40°, and 60° C (calculated as At and as $At-B/t$ (in c.s.t.))

	20° C		40° C		60° C	
Bulb	$\nu = At$	$\nu = At-B/t$	$\nu = At$	$\nu = At-B/t$	$\nu = At$	$\nu = At-B/t$
			Viscometer II-A-1

2	.680	.676	.552	.548	.464	.458
3	.689	.675	.549	.546	.463	.458
4	.677	.676	.546	.546	.460	.459
5	.673	.673	.540	.540	.455	.455
			Viscometer II-B-1			
1	.648	.674	.557	.545	.469	.454
2	.681	.674	.553	.544	.465	.454
3	.680	.674	.550	.543	.463	.454
4	.677	.673	.546	.541	.460	.454
5	.673	.673	.544	.543	.454	.454
Average		.674		.544		.456

From these data it is clear that the kinetic energy corrections are small but still significant, in the kinematic viscosities. In a flow-time ratio they would be very small. Even in a specific viscosity η_{sp} or intrinsic viscosity $[\eta]$ the corrections would, in the usual range $\eta_r = 1.1$–1.9, always be less than 1% and in the lower three bulbs less than 0.1%.

The kinematic viscosities measured at widely different heads are identical within experimental error. This fact is not, in itself, proof that the surface tension effects have been eliminated in these viscometers, for the apparatus constant A for each bulb was obtained by calibration. It is possible, however, to calculate from the calibration values of A the effective mean hydrostatic head corresponding to each bulb. If the surface tension effect has been eliminated, these effective mean heads should be the same as the mean heads calculated from measured initial and final heads ($\bar{h} = h_m$). The appropriate measurements and calculations were made, and the results for viscometer II-A-1 are assembled in Table VIII.

TABLE VIII

Comparison of mean heads calculated from apparatus constant A and from measured heads

The agreement between the measured mean head h_m and the calculated mean head $\bar{h}_{calib}$ is convincing evidence that the effect of surface tension on the mean head has been eliminated.

In summary, these and other similar calibration data show that the viscometers do indeed measure viscosities precisely, and over a wide range of shear stresses.

The measurements so far discussed have been made with pure solvents. Over the past 3 years, these, and other viscometers made to the same design, have been used in several different investigations, and all have proved to be very satisfactory both in routine measurements and for research purposes. They are easy to use and to clean and they are capable of giving precise data even at shear rates as low as 40 sec^{-1}.

The data obtained in these investigations will be given and discussed elsewhere. Here, it is probably sufficient to provide one example. Measurements were made with solutions, in toluene, of a polystyrene of very high molecular weight. For preparation of the solutions and purification of the solvent, see reference 36. The measurements were made at different concentrations to permit extrapolation to zero concentration at all the shear stresses obtainable at free fall in the two viscometers II-A-1 and II-B-1. The measured flow times for the solutions, which were markedly non-Newtonian, were used to calculate relative flow times (t/t_0) and from these relative viscosities (at the maximum shear stress τ_R, at the wall) were calculated according to the equation (38)

$$(\eta_r)_{\tau_R} = t_r[4/(3+d \log q_R/d \log \tau_R)].$$

From $(\eta_r)_{\tau_R}$ the corresponding values of reduced specific viscosity $(\eta_{sp}/c)_{\tau_R}$ were calculated and used to obtain the intrinsic viscosity at constant shear stress $[\eta]_{\tau_R}$. A typical plot of $(\eta_{sp}/c)_{\tau_R}$ vs. c and of $[\eta]_{\tau_R}$ vs. τ_R is given in Figs. 2 and 3.

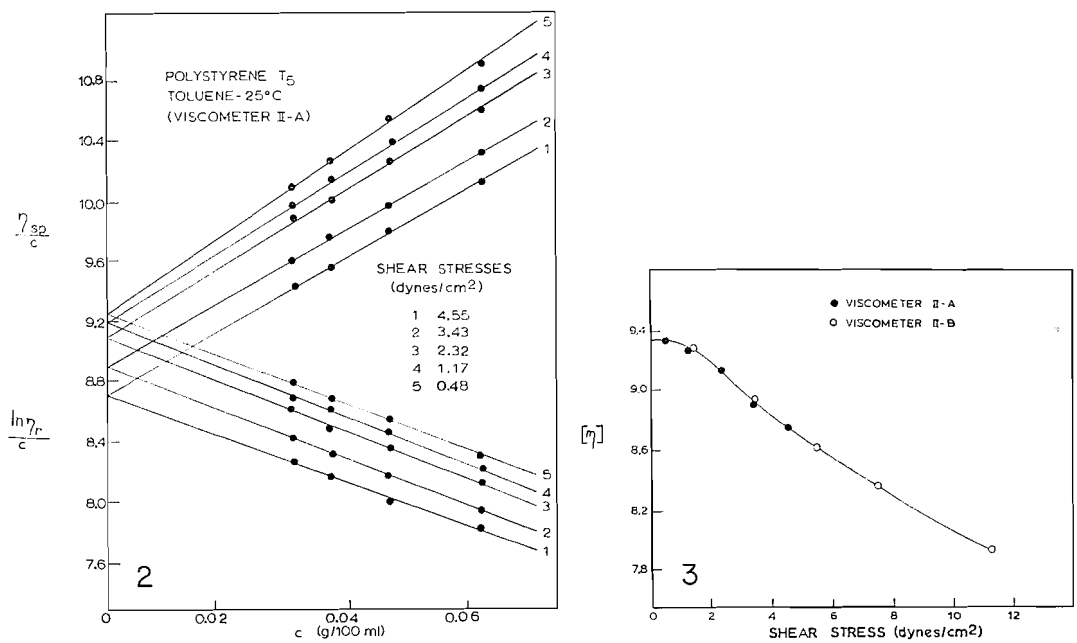

FIG. 2. A typical set of data obtained in the new variable-shear viscometer (reduced viscosities and inherent viscosities at five different shear stresses).

FIG. 3. Variation of intrinsic viscosity with shear stress for a polystyrene fraction of very high molecular weight, T_5. (Note the overlapping of the data obtained in the two different viscometers.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The points obtained with the two viscometers fall satisfactorily on the same curve. The curve exhibits the expected levelling off at low shear stresses, a feature that makes extrapolation to zero stress simple and safe.

It is worth stressing that this levelling off can be, and probably has been in some other investigations, obscured by effects of hysteresis and surface tension already mentioned. For example, even though surface tension effects may almost cancel out in η_r (and, therefore, in η_{sp}/c) they can still be significant in the shear stress τ (or the shear rate D), and being greater the lower the shear stress, they can be the cause of a spurious upcurve at very low shear stresses.

Our experience with these viscometers convinces us that they should be very useful both for determining whether or not a polymer–solvent system is non-Newtonian and for making measurements with it if it is. Further, the instruments are suitable both for making the low-shear measurements necessary for a reliable extrapolation to zero shear and for making determinations of viscosity functions at some arbitrary shear rate or shear stress.

THE ANALYSIS OF NUCLEAR MAGNETIC RESONANCE SPECTRA

V. THE ANALYSIS OF DECEPTIVELY SIMPLE SPECTRA[1]

R. J. ABRAHAM[2] AND H. J. BERNSTEIN

ABSTRACT

The analyses of the ABX, A_2X_2, and $ABXY$ types of spectra are discussed in detail under the conditions for which the observed spectra give less than the theoretical number of transitions. These conditions for which an observed spectrum is deceptively simple are derived from the general analyses, and experimental examples of such spectra are given.

The complete analyses of the more simple types of nuclear magnetic resonance spectra have been presented in the preceding papers of this series (1, 2, 3, 4). From these and other papers (8) it is seen that the problem of the analysis of any N.M.R. spectrum for which explicit energies and intensities can be formulated reduces to the problem of assigning the experimentally observed transitions. In some cases it is found that considerably fewer transitions are observed than one would expect from the theoretical spectra. This is due to the fact that some of the theoretical transitions nearly coalesce and others are very weak. In principle, higher resolution might reveal more lines but in practice many such spectra are encountered in which it is not possible to resolve the overlapping lines with presently available N.M.R. spectrometers. In these cases there may be more than one assignment and interpretation of the spectrum. In this paper some of the general analyses will be considered in detail for those cases for which this deceptively simple type of spectrum is obtained. In these cases it is found that the separation of the lines in each group of the spectrum becomes equal to the average of two or more of the coupling constants involved and explicit values for each of the coupling constants cannot be obtained from such spectra. The simplest system for which this type of spectrum can be obtained is the ABX system. This system will now be considered in some detail, as the behavior of the spectrum for more complex systems is very similar, although the calculations become more laborious.

The ABX System

The general ABX analysis has already been given by Bernstein, Pople, and Schneider (1). It is convenient to use the nomenclature of reference 1 with the additional definitions

$$L = \tfrac{1}{2}(J_{AX}-J_{BX}), \qquad \delta = \sigma_B-\sigma_A, \qquad [1]$$
$$N = \tfrac{1}{2}(J_{AX}+J_{BX}).$$

Parameters D and ϕ are then defined from

$$D_\pm \cos 2\phi_\pm = \tfrac{1}{2}\eta H_0\delta \pm (L/2), \qquad [1a]$$
$$D_\pm \sin 2\phi_\pm = \tfrac{1}{2}J_{AB}.$$

The transition energies and intensities for this system are given in terms of these quantities in Table I. This system in the general case gives the 12 transitions shown in Fig. 1(*a*)

8	A	$\frac{1}{2}\eta H_0(2-\sigma_A-\sigma_B)+\frac{1}{2}N+\frac{1}{2}J_{AB}+D_+$	$1-\sin 2\phi_+$
9	X	$\eta H_0(1-\sigma_X)-N$	1
10	X	$\eta H_0(1-\sigma_X)+D_+-D_-$	$\cos^2(\phi_+-\phi_-)$
11	X	$\eta H_0(1-\sigma_X)-D_++D_-$	$\cos^2(\phi_+-\phi_-)$
12	X	$\eta H_0(1-\sigma_X)+N$	1
13	Comb.	$\eta H_0(1+\sigma_X)$	0
14	Comb.	$\eta H_0(1-\sigma_X)-D_+-D_-$	$\sin^2(\phi_+-\phi_-)$
15	Comb.	$\eta H_0(1-\sigma_X)+D_++D_-$	$\sin^2(\phi_+-\phi_-)$

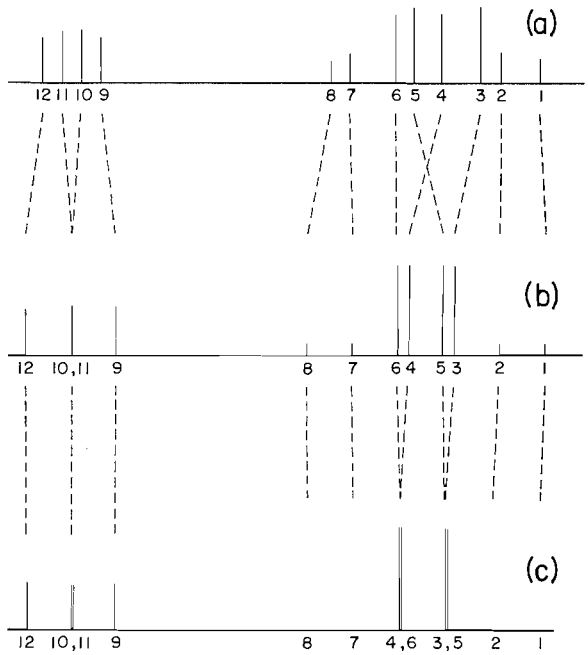

FIG. 1. Typical spectra of the ABX system when (*a*) δ_{AB} is large compared to J_{AB}, (*b*) δ_{AB} or $L = 0$, (*c*) $\delta_{AB} = 0$ and $L/J_{AB} \to 0$.

(ignoring the weak combination lines which are rarely observed). However, the number of observable transitions can be reduced in certain cases, down to a minimum of five lines (e.g. Fig. 1(*c*)). The conditions necessary for the 12-line spectrum to simplify to the 5-line one can be found from Table I. First consider the spectrum when the chemical shift difference between nuclei A and B (i.e. δ) equals zero. In this case from eqs. [1*a*]

$$D_+ = D_- = \tfrac{1}{2}\{J_{AB}{}^2+L^2\}^{\frac{1}{2}}$$

and

$$\sin 2\phi_\pm = \frac{J_{AB}}{2D_+} = \frac{J_{AB}}{2D_-} = \frac{J_{AB}}{2D}\,.$$

The X spectrum is now a triplet, transitions 10 and 11 having coalesced, but the AB portion will still be an 8-line spectrum (see Fig. 1(b)); thus the complete spectrum has 11 lines and the assignment is straightforward. A similar spectrum is obtained for the case when $L = 0$. However, by inspection of Table I, it can be seen that if $\delta = 0$, and also L is small compared with J_{AB}, i.e. $2D \rightarrow J_{AB}$ and $\sin 2\phi_{\pm} \rightarrow 1$, then the intensities of transitions 1, 2, 7, and 8 will approach zero and the strong transitions 3 and 5, and 4 and 6 will coalesce (see Fig. 1(c)). The X spectrum remains a triplet, thus the total spectrum will now consist of only five lines. Also the separation between transitions (3, 5) and (4, 6) and between transitions 9, (10, 11), and 12 is constant and equal to N, i.e. $\frac{1}{2}(J_{AX}+J_{BX})$.

The conditions necessary for the 12-line spectrum to degenerate to a simple 5-line spectrum can now be derived directly from Table I. For this to occur, the separations between lines 3 and 5, 4 and 6, and 10 and 11 must all be less than the half-height width of the component lines ($\Delta\nu_{\frac{1}{2}}$), and the intensities of lines 1, 2, 7, and 8 must all be less than a given fraction (i) of the total intensity. These two sets of conditions are covered by the limits

[2] $$(\eta H_0\delta+L)^2/2J_{AB} < \Delta\nu_{\frac{1}{2}}$$

and

[3] $$\frac{1}{2}\left(\frac{\eta H_0\delta+L}{J_{AB}}\right)^2 < i$$

where here $\eta H_0\delta$ and L refer to the absolute magnitudes of these quantities. If J_{AB} is less than $\Delta\nu_{\frac{1}{2}}/i$, eq. [3] is the more general case, if J_{AB} is greater than $\Delta\nu_{\frac{1}{2}}/i$, eq. [2] must be used. The quantities $\Delta\nu_{\frac{1}{2}}$ and i will be determined by the spectrometer used. For the Varian spectrometer operating at a radio frequency of 60 Mc/sec, the line width ($\Delta\nu_{\frac{1}{2}}$) is about 0.3 c.p.s. and the sensitivity is such that a small peak of 1/50th of the intensity of a neighboring strong line can be observed. If the strong peak is taken as one of the AB lines, then $i \approx 2/50$. Thus eq. [3] is used for J_{AB} less than 8 c.p.s., eq. [2] for J_{AB} greater than 8 c.p.s. However, for values of J_{AB} which are usually encountered (between 5 and 15 c.p.s.) the error involved in using eq. [2] only is not appreciable in view of the uncertainty in the measurement of i.

In any ABX system, when eq. [2] holds, the normal 12-line pattern degenerates to a simple 5-line spectrum in which the separation of the lines in the AB and X groups is equal to N i.e. the average of the two coupling constants J_{AX} and J_{BX}. The converse of this statement is equally important. This states that if an ABX system gives rise to a simple 5-line spectrum then the only constants that can be derived from the analysis of such a spectrum are the average values of J_{AX} and J_{BX}. It has been assumed previously (5) that if such a spectrum was obtained from an ABX system, then $J_{AX} = J_{BX}$ and $\delta = 0$. We see, however, that this is only one set of values which interprets the spectrum and in general only $J_{AX}/2$ and J_{BX} can be evaluated from the spacings.

The conditions for obtaining a 5-line spectrum in the 3-spin system ABX can be derived in an alternative manner. Consider the ABX system when L and δ are small compared to J_{AB}. In this case, the parameters $D_{\pm}$ in eq. [1a] can be written by neglecting higher powers of $(\eta H_0\delta\pm L)/J_{AB}$. This gives

$$D_{\pm} = \tfrac{1}{2}J_{AB}+\tfrac{1}{4}(\eta H_0\delta\pm L)^2/J_{AB}$$

and

$$\sin 2\phi_{\pm} = 1-\frac{1}{2}\left(\frac{\eta H_0\delta\pm L}{J_{AB}}\right)^2.$$

The energies and intensities in Table I can now be given directly in terms of $\eta H_0\delta$, L, and J_{AB} (Table II). The conditions necessary for the ABX system to give the 5-line

spectrum (eqs. [2] and [3]) are given by inspection of Table II. This table is of further use in the analysis of spectra in which transitions 4 and 6 may be resolved and some of the weaker lines can be observed (e.g. Fig. 1(b)), but in which L and δ are still small compared to J_{AB}.

The results obtained in this analysis may be conveniently expressed in terms of a correlation diagram. Figure 1 shows (a) a typical 12-line ABX pattern, (b) the 11-line spectrum obtained when δ or $L = 0$, and (c) the unresolved 5-line spectrum obtained when δ and L are small compared to J_{AB}.

The different types of ABX spectrum mentioned above can sometimes be obtained for the same compound, merely by altering the relative chemical shift δ by dissolving the compound in various solvents. Figure 2 shows the observed and calculated spectra for the ABX system of the ring protons of 2-furfurol in three different environments, i.e. for three different values of δ. Analysis of the spectrum 2c gives the following values for the coupling constants: $J_{AB} = 3.16$ c.p.s., $J_{AX} = 1.89$ c.p.s., and $J_{BX} = 0.91$ c.p.s. where A, B, and X represent protons 4, 3, and 5 respectively. In 2(a) $\delta \rightarrow 0$ thus the spectrum is the simple 5-line spectrum since eq. [2] is valid. In 2(b) $\delta = 1.83$ c.p.s. ($\sigma_B > \sigma_A$). This value is such that eq. [1] no longer holds, i.e. the spectrum is not a simple one, but L and δ are still small compared to J_{AB} thus the analysis of Table II can still be used and is in fact the most convenient method of analyzing the spectrum. In 2(c) $\delta = 4.13$ c.p.s. and thus the spectrum is the full 12-line pattern. The dotted lines are drawn between corresponding transitions. It can be seen that all the B transitions (1.2.3.4) move together as do all the A lines (5.6.7.8). The actual values of the ring coupling constants used in the calculations were obtained from the analysis of the spectrum of Fig. 2(c).

The spectrum of the ring protons of liquid furfurol at 40 Mc/sec has the simple 5-line pattern (5) and was interpreted previously (5) on the basis of L and $\delta = 0$. The value of δ for liquid furfurol at 60 Mc/sec = 1.83 c.p.s. (Fig. 2(b)). Thus the value of δ at

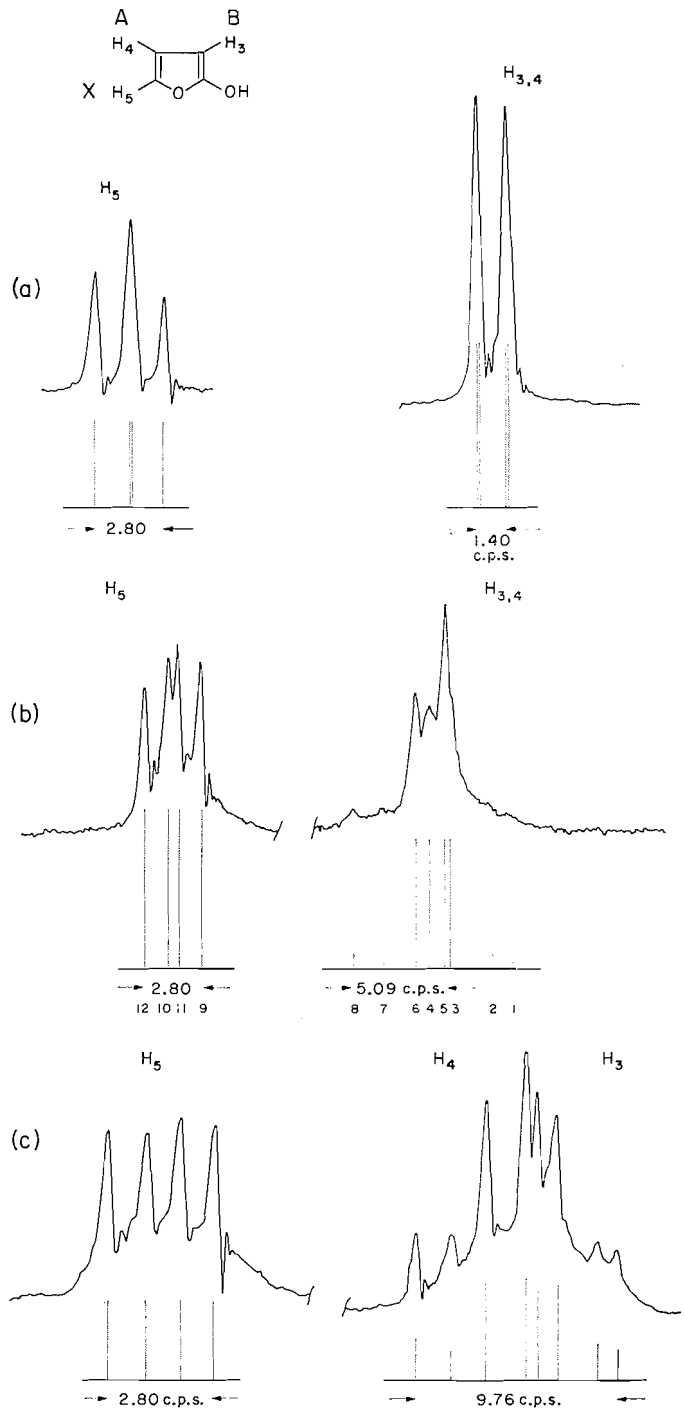

FIG. 2. Observed and calculated spectra of the ring protons of 2-furfurol at 60 Mc/sec: (*a*) in a 25% solution in benzene, (*b*) in the pure liquid, (*c*) in a 50% solution in dioxane.

40 Mc/sec = 1.21 c.p.s. Using this value and the values given above for the coupling constants, the left-hand side of eq. [2] becomes 0.40 c.p.s. Since this was about the limit of resolution of the instrument when the spectrum was obtained, it is understandable that the simple spectrum was observed. A further example of an ABX system giving the 5-line spectrum is the ring spectrum of 2,6-dichloro-3-fluorobenzotrifluoride (6) in which the spacing in the triplet and doublet is 6.2 c.p.s. (6). From the above consideration $J_{\mathrm{HF_{ortho}}}+J_{\mathrm{HF_{meta}}} = 12.4$ c.p.s. Since the 5-line spectrum was obtained, eq. [2] gives

$$\frac{(J_{\mathrm{HF_{ortho}}} - J_{\mathrm{HF_{meta}}})^2}{2J_{AB}} < 0.3.$$

Assuming the spectrometer used was comparable to the Varian high-resolution instrument, and since J_{AB} is the spin coupling between adjacent protons in a benzene ring (ca. 8 c.p.s.), $J_{\mathrm{HF_{ortho}}}-J_{\mathrm{HF_{meta}}} \leqslant 2.2$, so that $J_{\mathrm{HF_{ortho}}} < 7.3$ and $J_{\mathrm{HF_{meta}}} > 5.1$ is the maximum information obtainable about the coupling constants from this spectrum. This example demonstrates that a 5-line spectrum can be obtained from a system in which the values of J_{AX} and J_{BX} are comparable to the value of J_{AB}.

Richards and Schaeffer also found very similar behavior in the spectra of some trisubstituted benzenes (7). In this case, ABC-type systems in which $\delta_B \approx \delta_C$ were found to give spectra which approximate to the AB_2 type, i.e. the spectrum has 5 lines characteristic of the AB_2 pattern, not the many transitions obtained in the general ABC case. This is analogous behavior to the case considered above, which is essentially an ABX system giving an A_2X spectrum. Richards and Schaeffer used, in the analyses of these ABB' systems, pseudosymmetric wave functions i.e. the wave functions for the AB_2 case were used and then two values of J_{AB} and J_{AB}' were introduced. This is an approximation and not a strictly rigorous treatment as some matrix elements were neglected. However, it is difficult to give a rigorous analysis in this case as the general ABC calculation does not give explicit values of the energies and intensities. The consequence of using pseudosymmetric wave functions in the ABX case is that only an 8-line spectrum (if the combination line is neglected) is obtained, 4 X lines and 4 AB lines. The weak transitions seen in the spectrum of Fig. 2(b), however, are to this approximation of zero intensity.

An equation analogous to eq. [2] can be written for these ABC systems, i.e. when

$$[4] \qquad \frac{\{\delta_{BC}+\frac{1}{2}(J_{AB}-J_{AC})\}^2}{2J_{BC}} < \Delta\nu_{\frac{1}{2}}$$

the ABC system may be expected to give a spectrum of the AB_2 type in which only the average of the coupling constants J_{AB} and J_{AC}, and the chemical shifts σ_B and σ_C, will be given explicitly. However, this equation has not been verified theoretically, though the experimental results of Richards and Schaeffer are not inconsistent with this statement.

The A_2X_2 Spectrum

The complete analysis for this system has already been given (2, 8) and is in a convenient form for the analysis of all possible types of spectra. Thus there is little value in formulating the complete energy level table under the conditions for which simple

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

spectra are obtained. However, the simple A_2X_2 spectrum of two triplet groups which is obtained under certain conditions has been widely misinterpreted and thus the conditions for the formation of this simple spectrum will be considered in detail.

The nomenclature of reference 2 will be used.

The A_2X_2 spectrum consists of two triplet groups when the separation between lines 10 and 11, and 6 and 7 is less than $\Delta\nu_{\frac{1}{2}}$ and the intensities of lines 5, 8, 9, and 12 are less than i. These conditions are covered by the equations

[5] $$(L^2/2M) < \Delta\delta_{\frac{1}{2}}$$

and

[6] $$(L^2/4M^2) < i$$

where

$$L = J-J',$$

$$M = J_A-J_X.$$

In this case the separation between the lines in each triplet group will be equal to $N/2$ i.e. $\frac{1}{2}(J+J')$.

As in the ABX case, eqs. [5] and [6] overlap, and again only eq. [5] will be considered.

As an example of the use of eq. [5], consider the spectrum of furan. This consists of two simple triplet groups and it has been widely interpreted (9, 10, 5, 6) as meaning that $J_{23}(J)$ and $J_{24}(J')$ are both equal to the line separation in the triplet groups, namely 1.3 c.p.s. (see Fig. 3 for the numbering of the protons). This is a possible interpretation

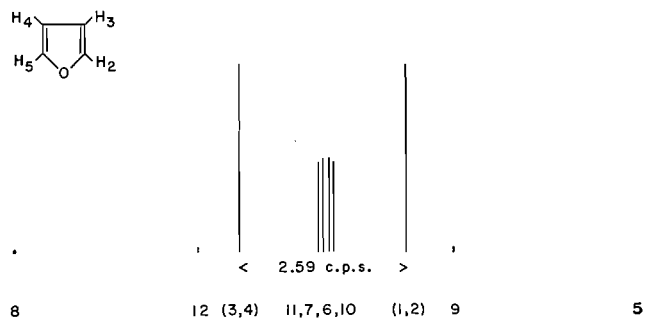

FIG. 3. The calculated spectrum of one of the triplet groups in furan.

of this spectrum. However, a more plausible interpretation can be obtained by considering the variation of coupling constants in the furan ring with substitution. It has been shown (11) that for a number of substituted furans the coupling constants are relatively insensitive to substitution and have the mean values $J_{23}(J) = 1.80$ c.p.s., $J_{24}(J') = 0.80$ c.p.s., $J_{25}(J_X) = 1.55$ c.p.s., and $J_{34}(J_A) = 3.53$ c.p.s. Using these values, eq. [5] holds and thus these coupling constants should explain the observed spectrum. In Fig. 3 the spectrum of furan, calculated with the above values of the coupling constants, is shown.

It is immediately apparent why the spectrum is observed as a simple triplet. The transitions labelled 5, 9, 8, and 12 are too weak to be observed and the spacings in the 11, 7, 6, 10 group are too small to be resolved. Strong support for this interpretation is the fact that the value of $J+J'$ obtained experimentally from the furan spectrum (2.6 c.p.s.) agrees exactly with the value obtained independently from the spectra of the substituted furans.

Similar types of simple spectra, which give, however, more information about the coupling constants involved, are the proton resonance spectra of the compounds $CF_2X—CH_2X$ where X is chlorine or bromine (12). These spectra have again essentially the triplet pattern but in these cases the center line is a doublet with a very small spacing. In these compounds J_{FF} is so much larger than J_{HH} that J_{HH} can be neglected and in this case the splitting of the central peak is equal to $L^2/2J_{FF}$. Once again, only the average value of $J+J'$ can be found explicitly from the observed spectrum, but if J_{FF} can be estimated e.g. by analogy with similar compounds, L can be calculated and thus both J and J' can be found. In the bromo compound the splitting of the central peak is well resolved (0.6 c.p.s.) but in the chloro compound the splitting (0.25 c.p.s.) can only be estimated by an analysis of the beats. Note that in this case eq. [5] holds (i.e. with a resolution of 0.3 c.p.s. only the main triplet structure would be observed) even though L has the quite large value of 10 c.p.s.* Using the formula given above gives the same results as Shoolery and Crawford for the chloro and iodo compounds, thus proving the validity of the approximation involved in neglecting J_{HH}, but the value for L obtained for the bromo compound is 14.5 c.p.s. Thus $J_T = 20$, and $J_C = 6$ c.p.s. respectively. The slight difference from the reported values is due to an arithmetical error (12). Here we have preferred $J_T > J_C$ in keeping with our unpublished results on the relative sizes of J_T and J_C in 1,1,2,2-tetrachloro-1-fluoroethane.†

The ABXY Spectrum

The ABX analysis considered earlier shows that a simple spectrum is obtained when J_{AB} is large compared to δ_{AB} and $J_{AX}-J_{BX}$. The same general statement is true for the A_2X_2 system remembering that in this case due to the symmetry of the system, the actual functions involved in the analysis are sums and differences of the coupling constants. By analogy, an $ABXY$ system will be expected to give a simple spectrum when J_{AB} and J_{XY} are large compared to δ_{AB}, δ_{XY} and terms like $J_{AX}-J_{BX}$.

The quantitative expression of this statement will now be derived. The transition energies and intensities for the $ABXY$ system cannot be derived explicitly in the general case as this involves solving a 4×4 determinant. However, in the case considered here, this 4×4 determinant can be solved explicitly and thus the energies and intensities can be written down completely.

This calculation follows the procedure laid down in reference 1. The basic functions, diagonal elements, and off-diagonal elements needed are given in Table III. Some off-diagonal elements, e.g. $\mathfrak{H}_{24}$ are not given as they are not involved in the calculation. These basic functions do not mix when (*a*) there is a difference in the total spin quantum number (this separation is shown by the full lines) and (*b*) there is an energy difference of the form $\delta_A-\delta_X$ (this is shown by the dotted lines in Table III).

**L is defined in reference 12 as $\frac{1}{2}(J+J')$ thus it has one-half the value of L used here.*

†Given at the Symposium on Molecular Spectra, Columbus, Ohio, June 1959.

$\mathcal{H}_{7,8} = \frac{1}{2}J_{XY}$, $\mathcal{H}_{7,9} = \frac{1}{2}J_{AB}$, $\mathcal{H}_{7,10} = 0$

$\mathcal{H}_{8,9} = 0$, $\mathcal{H}_{8,10} = \frac{1}{2}J_{AB}$

$\mathcal{H}_{9,10} = \frac{1}{2}J_{XY}$

$\mathcal{H}_{12,13} = \frac{1}{2}J_{AB}$, $\mathcal{H}_{14,15} = \frac{1}{2}J_{XY}$

*The + and − signs represent +1 and −1 respectively.

Thus to determine the energies and wave functions in this case four 2×2 determinants and one 4×4 determinant have to be solved.

The former can be solved explicitly. It is convenient to define the following constants.

$$L = \tfrac{1}{2}(J_{AX}-J_{AY}) \qquad R = \tfrac{1}{2}(J_{BX}+J_{BY})$$
$$T = \tfrac{1}{2}(J_{BX}-J_{BY}) \qquad M = \tfrac{1}{2}(J_{AB}-J_{XY})$$
$$N = \tfrac{1}{2}(J_{AX}+J_{AY}) \qquad K = \tfrac{1}{2}(J_{AB}+J_{XY})$$
$$\delta_{AB} = \nu_0(H_A-H_B) \qquad \delta_{XY} = \nu_0(H_X-H_Y)$$

and

$$C_\pm \cos 2\phi_\pm = \tfrac{1}{2}\delta_{XY} \pm \tfrac{1}{2}(L+T)$$
$$C_\pm \sin 2\phi_\pm = \tfrac{1}{2}J_{XY}$$
$$D_\pm \cos 2\phi_\pm = \tfrac{1}{2}\delta_{AB} \pm \tfrac{1}{2}(N-R)$$
$$D_\pm \sin 2\phi_\pm = \tfrac{1}{2}J_{AB}$$

The energy levels and wave functions for all the states except 7, 8, 9, and 10 can now be given in terms of these quantities (Table IV). These have been derived for the

*The numbers in parentheses refer to the spin functions given in Table III.

general $ABXY$ system. However, in order to solve the 4×4 secular determinant (eq. [7]), the case for which L, T, δ_{AB}, and δ_{XY} are small compared to J_{XY} and J_{AB}, must be considered.

$$[7]\qquad \begin{vmatrix} \frac{1}{2}(\delta_{AB}+\delta_{XY}-K+L-T)-E & \frac{1}{2}J_{XY} & \frac{1}{2}J_{AB} & 0 \\ \frac{1}{2}J_{XY} & \frac{1}{2}(\delta_{AB}-\delta_{XY}-K-L+T)-E & 0 & \frac{1}{2}J_{AB} \\ \frac{1}{2}J_{AB} & 0 & \frac{1}{2}(-\delta_{AB}+\delta_{XY}-K-L+T)-E & \frac{1}{2}J_{XY} \\ 0 & \frac{1}{2}J_{AB} & \frac{1}{2}J_{XY} & \frac{1}{2}(-\delta_{AB}-\delta_{XY}-K+L-T)-E \end{vmatrix} = 0$$

The difference of two small quantities, i.e. $\delta_{AB}-\delta_{XY}$ and $L-T$ in eq. [7], will be neglected. Thus, defining

$$F = -K-2E \qquad \text{and} \qquad \Delta = \delta_{AB}+\delta_{XY}$$

eq. [7] becomes

$$[8]\qquad \begin{vmatrix} \Delta+F & J_{XY} & J_{AB} & 0 \\ J_{XY} & F & 0 & J_{AB} \\ J_{AB} & 0 & F & J_{XY} \\ 0 & J_{AB} & J_{XY} & -\Delta+F \end{vmatrix} = 0$$

Expanding this determinant and reuniting in terms of M and K gives

$$F^4-4F^2[K^2+M^2+(\Delta^2/4)]+16M^2K^2 = 0.$$

Neglecting $(\Delta/2)^2$ with respect to $K^2 + M^2$ gives the roots

$$F = \pm 2K; \qquad \pm 2M$$

and thus the energies of the states 7′, 8′, 9′, and 10′.

The wave functions for these states are given by introducing these energy values successively in eq. [8] and solving the four simultaneous equations obtained using the normalizing condition for the coefficients of the basic functions, neglecting Δ^2 when it occurs. The complete wave functions and energies are given in Table IV. As we have included now (for states 7′, 8′, 9′, and 10′) the condition of L, T, δ_{AB}, and δ_{XY} being small compared to J_{AB} and J_{XY}, we will consider how the energies and intensities of the remaining states change when this condition holds before giving the transition energies and intensities. When this condition holds,

$$C_{\pm} = \tfrac{1}{2}J_{XY}\{1+\tfrac{1}{2}(\alpha_{\pm}/J_{XY})^2\},$$
$$D_{\pm} = \tfrac{1}{2}J_{AB}\{1+\tfrac{1}{2}(\beta_{\pm}/J_{AB})^2\},$$

and

$$(\cos\theta_{\pm}-\sin\theta_{\pm})^2 = \tfrac{1}{2}(\alpha_{\pm}/J_{XY})^2,$$
$$(\cos\phi_{\pm}-\sin\phi_{\pm})^2 = \tfrac{1}{2}(\beta_{\pm}/J_{AB})^2,$$
$$(\cos\theta_{\pm}+\sin\theta_{\pm})^2 = (\cos\phi_{\pm}+\sin\phi_{\pm})^2 = 2,$$

where

$$\alpha_{\pm} = \delta_{XY}\pm(L+T),$$
$$\beta_{\pm} = \delta_{AB}\pm(N-R).$$

The transition energies and intensities can be derived simply from Table IV. Including in these expressions the above equations gives the transition energies and relative intensities explicitly for the $ABXY$ system in the case considered. These are shown in Table V.

Table V is in the same form as Table II for the ABX case and the type of spectrum obtained when Table V is valid (the AB part is shown in Fig. 4(b)) is very similar in form to the AB part of the spectrum of Fig. 2(b). The spectrum of Fig. 4(b) approximates to that of a simple triplet group (Fig. 4(c)) and the conditions under which this simple spectrum is obtained can be derived in exactly the same manner as in the ABX case. The conditions under which an $ABXY$ system will give a simple spectrum of two triplet groups are

[9] $$\{\delta_{XY}+(L+T)\}^2/2J_{XY} < \Delta\nu_{\frac{1}{2}},$$

[10] $$\{\delta_{AB}+(N-R)\}^2/2J_{AB} < \Delta\nu_{\frac{1}{2}},$$

and

[11] $$\tfrac{1}{2}\{(\delta_{XY}+L+T)/J_{XY}\}^2 < i,$$
$$\tfrac{1}{2}\{(\delta_{AB}+N-R)/J_{AB}\}^2 < i,$$
$$\tfrac{1}{2}\{(\delta_{AB}+\delta_{XY})/2J_{AB}\}^2 < i,$$
$$\tfrac{1}{2}\{(\delta_{AB}+\delta_{XY})/2J_{XY}\}^2 < i,$$

and when these conditions hold, the spacing in the triplet groups is equal to $\frac{1}{2}(N+R)$.

These results may also be conveniently expressed in the form of a correlation diagram (Fig. 4). This gives the AB part of an $ABXY$ spectrum (the XY half will be very similar), and in this case, as the general $ABXY$ spectrum cannot be given explicitly, Fig. 4(a) gives the AB spectrum in the first-order approximation when δ_{AB} and δ_{XY} are large compared to the coupling constants. In Fig. 4(b), the spectrum is given when Table V

is valid, i.e. L, T, δ_{AB}, and δ_{XY} are small compared to J_{AB} and J_{XY}, but eqs. [9], [10], and [11] do not hold, and in Fig. 4(*c*) is shown the simple 3-line spectrum obtained when eqs. [9], [10], and [11] are valid. The actual values of the coupling constants J_{AB}, J_{XY}, J_{AX}, J_{AY}, J_{BX}, and J_{BY} used in Fig. 4 were 10, 12, 9.5, 8.5, 9.5, and 4.5 c.p.s., respectively, and the chemical shift values are $\delta_{AB} = 48$ c.p.s. in Fig. 4(*a*) (δ_{XY} is not involved in this case), $\delta_{AB} = 3$ c.p.s., and $\delta_{XY} = 4$ c.p.s. in Fig. 4(*b*), and $\delta_{AB} = \delta_{XY} = 0$ c.p.s. in Fig. 4(*c*).

The calculations in this section have given the quantitative condition necessary in order that the $ABXY$ system will give a simple spectrum, and it is seen that the assumption made in the beginning of this section, i.e. that the simple spectrum is obtained when J_{AB} and J_{XY} are large compared to terms like δ_{AB}, δ_{XY}, and $J_{AX}-J_{BX}$, which was obtained merely by inspection of the results for the ABX and A_2X_2 systems, is valid. In the next section, the results for the three systems considered are compared in order to obtain the general condition necessary for these simple spectra to be obtained.

The General Case

The conditions under which the ABX, A_2X_2, and $ABXY$ systems give these deceptively

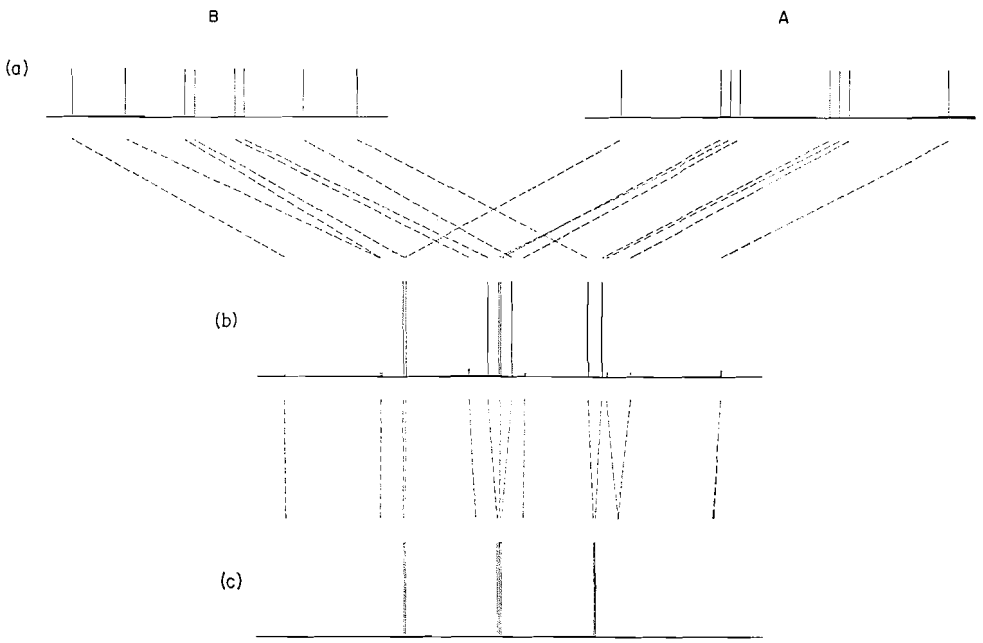

FIG. 4. Typical spectra of the AB part of the $ABXY$ system when (*a*) δ_{AB} and δ_{XY} are large compared to J_{AB} and J_{XY}; (*b*) J_{AB} and J_{XY} are large compared to δ_{AB}, δ_{XY}, L, and T; (*c*) equations [7] and [8] are valid.

simple spectra (eqs. [2], [5], [9], and [10]), can be compared most easily by rewriting these equations in terms of the actual coupling constants involved. These equations become

$$[2a] \qquad \{\delta_{AB}+\tfrac{1}{2}(J_{AX}-J_{BX})\}^2/2J_{AB} < \Delta\nu_{\frac{1}{2}},$$

$$[5a] \qquad (J-J')^2/2(J_A-J_X) < \Delta\nu_{\frac{1}{2}},$$

$$[9a] \qquad \{\delta_{XY}+\tfrac{1}{2}(J_{AX}-J_{AY}+J_{BX}-J_{BY})\}^2/2J_{XY} < \Delta\nu_{\frac{1}{2}},$$

$$[10a] \qquad \{\delta_{AB}+\tfrac{1}{2}(J_{AX}-J_{BX}+J_{AY}-J_{BY})\}^2/2J_{AB} < \Delta\nu_{\frac{1}{2}}.$$

It can be seen that eqs. [2*a*] and [10*a*] are equivalent, but the latter has extra terms involving the new nucleus Y which are of the same form as those involving X in eq. [2*a*]. This result shows that any general condition valid for the $ABXY$ case will also be valid for the ABX case merely by removing the terms in Y and also it indicates that one explicit condition for the $ABXYZ\ldots$ system to give a simple spectrum will be

$$[12] \qquad \{\delta_{AB}+\tfrac{1}{2}(J_{AX}-J_{BX}+J_{AY}-J_{BY}+J_{AZ}-J_{BZ}+\ldots)\}^2/J_{AB} < \Delta\nu_{\frac{1}{2}}.$$

The conditions necessary for the general system $ABC\ldots XYZ\ldots$ to give a simple spectrum cannot, however, be derived explicitly, but from the form of the equations above, the nature of these conditions may be given in a qualitative fashion, as follows. The system $ABC\ldots XYZ\ldots$ will be expected to give a simple spectrum when the terms of the type J_{AB}, J_{XY} are large compared to the chemical shift differences δ_{AB}, δ_{XY} plus terms of the form $J_{AX}-J_{AY}$, etc. and in this case the spectrum will be a simple first-order A_mX_n spectrum in which the separation of the lines in each group of the spectrum is given by the average of the coupling constants J_{AX}, J_{AY}, etc.

spacing of 0.64 c.p.s.* The observed proton spectrum of this compound is given in Fig. 5 and the triplet spacing of 0.55 c.p.s. agrees excellently with the predicted value.

The above result for benzene-d_1 may be extended to almost any monodeutero-substituted compound as in these compounds the proton–deuterium coupling constants will be much less that the proton–proton coupling constants. Thus in these compounds the general statement above will apply and therefore monodeuterium substitution in a molecule containing more than two hydrogen atoms will generally only give the average of all the proton–deuterium couplings which are present in the molecule.

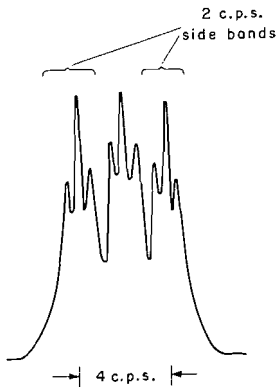

FIG. 5. The proton spectrum of liquid benzene-d_1 at 60 Mc/sec with a 2 c.p.s. side band.

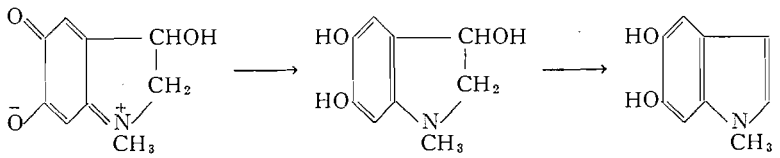
THE PREPARATION, PAPER CHROMATOGRAPHY, AND COLOR REACTIONS OF SEVERAL 5,6-DIHYDROXYINDOLES AND 5,6-DIACETOXYINDOLES[1]

R. A. HEACOCK, M. E. MAHON, AND B. D. SCOTT

ABSTRACT

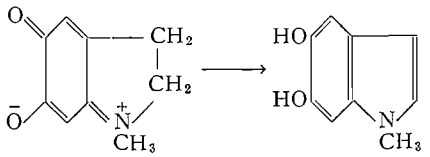
The paper chromatographic behavior of several 5,6-dihydroxyindoles has been studied. The colors given by nine dihydroxyindoles with 16 chromogenic reagents are reported. The R_f values of this group of compounds on Whatman No. 1 paper with 2% acetic acid in water or *n*-butanol/acetic acid/water (6:1:2) as running solvents have been determined. The 5,6-dihydroxyindoles can be chromatographed satisfactorily using Zaffaroni-type systems (i.e. formamide-treated paper and non-polar running solvents). Satisfactory R_f values can also be obtained for the 5,6-diacetoxyindoles on formamide-treated paper using a suitable non-polar mobile phase. The preparations of several new 5,6-dihydroxyindoles and 5,6-diacetoxyindoles are described and improved procedures for the syntheses of some known members of these groups are reported.



The importance of the 5,6-dihydroxindoles as intermediates in the production of the dark pigments known as melanins, in plants and animals, has been recognized for some time (for references see reviews by Lerner (1), Mason (2), and Thomas (3)), but it is only in relatively recent years that many of these highly reactive compounds have been obtained in pure crystalline form (see (3) and (4) for references). Although there has been a considerable volume of work carried out on the chromatography of the indoles in the past decade, there have been relatively few studies reported of the paper chromatographic behavior of the 5,6-dihydroxyindoles and their derivatives. In a study of the urine melanogens observed in cases of malignant melanoma of the liver, Leonhardi reported the R_f values of some 5,6-dihydroxyindole derivatives (e.g. *O*-acetyl, *O*-methyl, *O*-sulphatoxy, etc.) in several different solvent systems. These compounds were employed as models for the urinary melanogens which were considered by Leonhardi to be 5,6-dihydroxyindole derivatives (5). During an investigation into the metabolism of β-(3,4-dihydroxyphenyl)-alanine in albino rats Pellerin and D'Iorio obtained a product with a R_f of 0.85 in a *n*-butanol/acetic acid/water system which they suggested was possibly 5,6-dihydroxyindole (6).

One of the main difficulties encountered in carrying out paper chromatographic studies with the 5,6-dihydroxyindoles is the ease with which they undergo destructive oxidation to melanitic pigments, especially under alkaline conditions; consequently basic solvent systems, including the isopropanol/aqueous ammonia systems widely favored for indole chromatography, are quite useless with this group of indole derivatives. In an investigation of the reduction of adrenochrome with various reducing agents, carried out in these laboratories (7, 8, 9), we have made extensive use of paper chromatographic procedures in the examination of the reaction products. Many of the products encountered in this program were either 5,6-dihydroxyindoles or their derivatives, and one of the most satisfactory systems for the study of these reaction mixtures was found to be 2% acetic acid in water using chromatographic paper that had been extensively prewashed with the running solvent, prior to use. The possible use of *n*-butanol/acetic acid/water (6:1:2) as the running solvent was also considered but it gave somewhat less satisfactory results than 2% acetic acid. In parallel studies on the relatively unstable aminochromes derived

[1]*Manuscript received August 8, 1960.*
Contribution from the Psychiatric Research Unit, University Hospital, Saskatoon, Saskatchewan. This investigation was supported by grants from the Government of Saskatchewan, the Department of National Health and Welfare (Ottawa), and the Rockefeller Foundation.



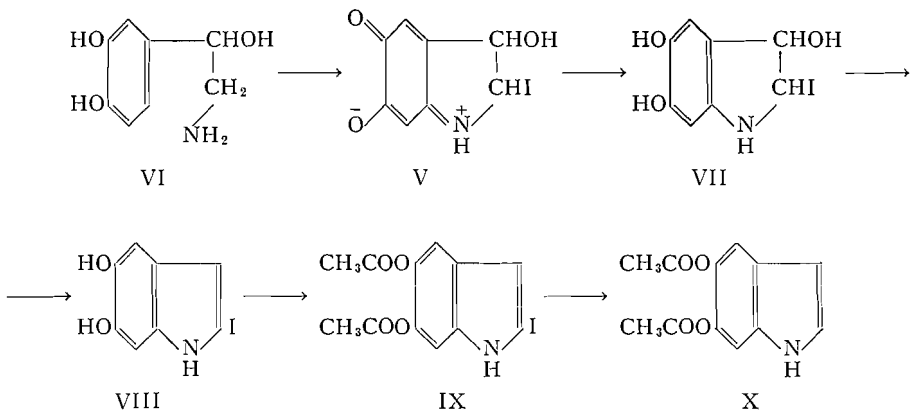
from "DOPA", dopamine and noradrenaline, Bouchilloux and Kodja utilized paper chromatographic and paper electrophoretic procedures to investigate both the spontaneous transformations these compounds undergo in aqueous solution and their behavior with reducing agents, using distilled water and *n*-butanol/acetic acid/water as running solvents (10, 11, 12). These authors stress the need to work with well-washed paper to ensure that all traces of sulphites, which can form addition compounds with the 5,6-dihydroxyindoles and the aminochromes have been removed from the chromatographic paper before use.

5,6-Dihydroxyindoles can arise from the aminochromes in at least two ways. If the aminochrome is of the type with a 3-hydroxyl group, reduction leads initially to the formation of an unstable leuco compound, which immediately loses water to form the 5,6-dihydroxyindole (e.g. adrenochrome (I) would be initially reduced to "leuco-adrenochrome" (II) which apparently only has a transient existence and loses water forming 5,6-dihydroxy-*N*-methylindole (III) (see (4) for references)). However, the aminochromes

I II III

with no 3-hydroxyl substituent undergo an internal oxidation–reduction reaction with considerable ease resulting in the formation of a 5,6-dihydroxyindole. This reaction is catalyzed by OH^- and Zn^{++} ions, but will also occur spontaneously even in the solid state (e.g. epinochrome (IV) readily rearranges to 5,6-dihydroxy-*N*-methylindole (III)). (See (4) for references.)

IV III



The 5,6-dihydroxyindoles used in this investigation were, with the exception of 5,6-dihydroxyindole itself (which was prepared by the method of Beer *et al.* (13)), prepared by the reduction of the corresponding aminochrome. 5,6-Dihydroxy-*N*-methylindole had previously been obtained in about 30% yield from either the hydrogenation of, or the sodium hydrosulphite reduction of, adrenochrome, adrenolutin being obtained as a by-product in each case (14). It was observed, as a result of a preliminary paper chromatographic examination of the reduction mixtures obtained from adrenochrome with a variety of reducing agents, that sodium hydrosulphite always gave the sodium bisulphite addition compound of adrenochrome and smaller amounts of a second water-soluble indole as well as 5,6-dihydroxy-*N*-methylindole (8). However, chromatograms of the zinc and 2% acetic acid, hydrogen sulphide, or sodium borohydride reduction products of adrenochrome showed 5,6-dihydroxy-*N*-methylindole as a very intense spot and only one other relatively weak spot due to an unidentified by-product in each case (8). Contamination of the product with sulphur was a serious disadvantage which was encountered during the use of hydrogen sulphide as the reducing agent for a preparative procedure,

For personal use only.

but either zinc and 2% acetic acid or sodium borohydride have proved very satisfactory for the preparation of 5,6-dihydroxy-*N*-methylindole and yields of up to ca. 70% have been obtained from adrenochrome. Attempts to prepare crystalline *N*-ethyl-5,6-dihydroxyindole or 5,6-dihydroxy-*N*-isopropylindole by adaptation of the procedures used for the preparation of 5,6-dihydroxy-*N*-methylindole have, as yet, been unsuccessful, the products being obtained as colorless gums. However, crystalline diacetyl derivatives have been prepared from both the dihydroxy compounds. Ethereal solutions of *N*-ethyl-5,6-dihydroxyindole and 5,6-dihydroxy-*N*-isopropylindole (suitable for examination of their paper chromatographic behavior) can be obtained easily by ether extraction of the products obtained from the reduction of *N*-ethylnoradrenochrome and *N*-isopropylnoradrenochrome respectively. (The reduction can be conveniently carried out with zinc and 2% acetic acid, sodium borohydride, or sodium hydrosulphite.) A simple method has been developed for the preparation of the diacetyl derivatives of 5,6-dihydroxy-*N*-methylindole, *N*-ethyl-5,6-dihydroxyindole, and 5,6-dihydroxy-*N*-isopropylindole, directly from the corresponding catecholamine. The catecholamine is oxidized with silver oxide; the resulting aminochrome solution reduced with zinc and dilute acetic acid (or sodium borohydride) and the crude *N*-alkyl-5,6-dihydroxyindole solution acetylated directly with acetic anhydride in aqueous alkali.

The preparation of 2-iodonoradrenochrome (V) by the oxidation of noradrenaline (VI) with potassium iodate had been reported by Bu'Lock and Harley-Mason but only a relatively low yield of crystalline product was obtained after discarding much tarry material (15). In view of the success of the dilute solution technique, first described by Sobotka and Austin for the preparation of 2-iodoadrenochrome (16) and subsequently used for the preparation of the *N*-ethyl and *N*-isopropyl analogues (17), an attempt was made to prepare 2-iodonoradrenochrome (V) this way. Although a deep-violet solution was obtained, no precipitation of the desired aminochrome occurred, even on standing at 0° for 24 hours, presumably due to its higher water solubility. However, the deep-violet color of the solution was rapidly discharged by the addition of excess ascorbic acid and

VIII IX X

5,6-dihydroxy-2-iodoindole (VIII) could be extracted from the reaction mixture with ether; VIII had presumably arisen from the spontaneous dehydration of the initial "leuco" derivative, 2,3-dihydro-3,5,6-trihydroxy-2-iodoindole (VII). In fact, there are several other water-soluble indoles produced in this reaction; this will be discussed in more detail in a later publication (18). 5,6-Diacetoxy-2-iodoindole (IX) could be obtained

from the dihydroxy compound (VIII) by acetylation with acetic anhydride and pyridine. 5,6-Diacetoxyindole (X) was obtained by the deiodination of 5,6-diacetoxy-2-iodoindole with zinc and acetic acid using the procedure described by Bu'Lock and Harley-Mason for the deiodination of several 5,6-di- and 3,5,6-triacetoxyiodoindoles (15). 5,6-Dihydroxy-2-iodo-*N*-methylindole was obtained in crystalline form from 2-iodoadrenochrome by reduction with sodium hydrosulphite (cf. 19) (acetylation with acetic anhydride in pyridine readily gave 5,6-diacetoxy-2-iodo-*N*-methylindole (19)). Reduction of the *N*-ethyl and *N*-isopropyl analogues with sodium hydrosulphite gave *N*-ethyl-5,6-dihydroxy-2-iodoindole and 5,6-dihydroxy-2-iodo-*N*-isopropylindole, respectively; as yet, both of these substances have only been obtained as amorphous solids, but their crystalline diacetyl derivatives have been described (17).

The 5,6-dihydroxyindoles can be very easily detected by color reactions; these highly reactive compounds possess the indole ring system and consequently give colors with the conventional indole reagents such as Ehrlich's reagent, cinnamaldehyde, *p*-dimethylaminocinnamaldehyde, the Hopkins-Cole reagent, and terephthalaldehyde. They also contain phenolic hydroxyl groups and give colored products with many phenol-detecting reagents such as diazotized *p*-nitroaniline, Gibb's reagent, ferric chloride, and Folin and Ciocalteu's reagent. The 5,6-dihydroxyindoles are also catechol derivatives and have strong reducing properties and will reduce such reagents as ammoniacal silver nitrate and ferric chloride/potassium ferricyanide; the 5,6-dihdroxyindoles undergo air oxidation with extreme ease, under alkaline conditions, and spraying with dilute aqueous alkali or even exposing the papers to ammonia fumes converts the compound into a dark insoluble melanin-like pigment. The colors obtained with several chromogenic reagents are given in Table I. In the 5,6-diacetoxyindoles the catechol function is blocked and consequently these compounds are not so readily oxidized as the free hydroxy compounds, nevertheless, they do give colors with most of the usual indole and phenol reagents. The results obtained with several chromogenic reagents are given in Table III.

In view of the success attending the use of 2% acetic acid in water, on acid-washed paper, as a medium for preliminary paper chromatographic studies of the crude reaction mixtures, containing several 5,6-dihydroxyindoles and their derivatives, obtained by reduction of the aminochromes (cf. 7, 8, 9, 19), the R_f values of several standard 5,6-dihydroxyindoles on acid-washed Whatman No. 1 paper, using 2% acetic acid as running solvent, were determined both by the descending and circular techniques (the results are given in Table II). It will be seen that, in general, the R_f values obtained by the circular procedure are somewhat higher than those obtained by the descending method. *n*-Butanol /acetic acid/water solvent mixtures have also been employed for paper chromatographic investigations in this field (7, 10, 11, 12) and consequently the R_f values of several 5,6-dihydroxyindoles were determined in *n*-butanol/acetic acid/water (6:1:2). The results are given in Table II.

Acetic acid (2%) cannot be used satisfactorily as a running solvent for the paper chromatography of the 5,6-diacetoxyindoles owing to their low water solubility; *n*-butanol /acetic acid/water systems are of little value either since the diacetoxy compounds run almost to the solvent front in this solvent. A method for studying the paper chromatographic behavior of steroids was introduced about 10 years ago (20, 21) which used a highly polar stationary phase (e.g. paper treated with formamide or propylene glycol) and a non-polar mobile phase (e.g. cyclohexane, benzene, chloroform, etc.); this type of system has subsequently been widely used for the chromatographic separation of the ergot alkaloids (22, 23, 24). This technique has now been extended successfully to include

For personal use only.

the 5,6-diacetoxyindoles which can be easily separated on formamide-treated paper (the "pH" of the formamide was adjusted to 5 by the cautious addition of 98% formic acid prior to impregnation of the paper) using non-polar running solvents, such as: light petroleum, cyclohexane, benzene/light petroleum (1:9), carbon tetrachloride, etc. Benzene gave satisfactory R_f's with the 5,6-diacetoxyindoles not alkylated on the nitrogen atom; however, the *N*-alkyl derivatives ran almost to the solvent front. The results obtained are given in Table V. It was possible to utilize this general procedure for a study of the paper chromatography of the 5,6-dihydroxyindoles, although it was necessary to use a slightly more polar mobile phase: i.e. benzene/chloroform (1:1), chloroform, benzene/ethyl acetate (3:1), chloroform/ethyl acetate (4:1), and dichloromethane. With these solvent systems satisfactory R_f values could be obtained for all the dihydroxy compounds studied; the results obtained are given in Table IV. The "pH" of the formamide was adjusted to 5, prior to impregnation of the paper, in all cases, since air oxidation of the 5,6-dihydroxyindoles was slower, under weakly acid, than neutral or alkaline conditions. Some experiments were carried out with the "pH" of the formamide adjusted to 7 or 9 before treatment of the paper, but in both cases, particularly the latter, considerable dark streaking behind the 5,6-dihydroxyindole spots was observed, presumably due to melanin formation. Changing the "pH" of the stationary phase also alters the R_f's of the compounds but only relatively few runs were carried out and will not be reported here. Throughout these investigations involving the use of formamide-treated paper it was desirable to saturate the mobile phase with formamide; however, with the chlorinated solvents, particularly dichloromethane it was found that it was better, in practice, to add slightly less than the amount of formamide required to saturate the solvent so as to ensure that the formamide remains in solution during the running of the chromatograms. If the solvents become cloudy due to separation of free formamide, inconsistent and unsatisfactory results are obtained. Gröger used the formamide/dichloromethane system to separate the Clavin group of ergot alkaloids and stressed that the mobile phase must not be allowed to become cloudy during the development of the chromatograms (25). During the course of these investigations the authors became aware of a paper by Prochazka *et al.* on the paper chromatography of indoles in general and the R_f's of several indoles on formamide-treated paper with cyclohexane, benzene, and chloroform as the mobile phases were reported (26); however, no 5,6-dihydroxyindoles or 5,6-diacetoxyindoles were included in the group of substances studied.

EXPERIMENTAL

Chemical

(I) *5,6-Dihydroxyindoles*

(*A*) *5,6-Dihydroxyindole*

5,6-Dihydroxyindole was prepared by the method of Beer, Clarke, Khorana, and Robertson (13).

(*B*) *5,6-Dihydroxy-N-methylindole*

(i) *From adrenochrome.*—(*a*) A solution of adrenochrome (1.0 g) in water (100 ml) was added slowly, with stirring, to a solution of sodium borohydride (0.3 g) in water (25 ml); the red color of the adrenochrome solution was instantly discharged and a pale yellow solution obtained. After decomposition of excess reducing agent by the cautious dropwise addition of 2 *N* sulphuric acid, the reaction mixture was extracted with peroxide-free ether (4×100 ml). The combined, dried (Na_2SO_4) extracts were concentrated to small

bulk, under nitrogen, below 30°; dry benzene (100 ml) was added and the remaining ether distilled off. (It was found that if the original ethereal solution was evaporated to dryness, the residue would not completely redissolve in benzene.) The product was adsorbed on a silica gel* column (10×2.4 cm); elution of the column with benzene (150 ml) and benzene /ethyl acetate (95:5) (300 ml) gave white solids (the solvent having been removed *in vacuo*, under nitrogen, below 30°), which on recrystallization from light petroleum (b.p. 100–120°) gave 5,6-dihydroxy-*N*-methylindole (0.68 g) as colorless needles (m.p. 134–135°). (Found: C, 66.14; H, 5.58. $C_9H_9NO_2$ requires C, 66.25; H, 5.56%.) The melting point of this substance is quoted in the literature as 136° (14) and 133° (27).† (*b*) Zinc dust (40.0 g) was added, with vigorous stirring, to a solution of adrenochrome (1.0 g) in 2% acetic acid (200 ml). The red color of the solution was rapidly discharged and stirring was maintained for a further 4 to 5 minutes. The reaction mixture was filtered (suction) and both the residue and filtrate repeatedly extracted with peroxide-free ether. The combined, dried (Na_2SO_4) ethereal extracts were concentrated and the product worked up and purified chromatographically as described above (see Subsection i(*a*) above). 5,6-Dihydroxy-*N*-methylindole (0.35 g) was obtained in colorless needles (m.p. 133–134°).

(ii) *From adrenaline.*—Silver oxide (10 g) was added to a well-stirred solution of adrenaline bitartrate (2.5 g) in water (50 ml). The reaction mixture was vigorously stirred, with external cooling, for a further 3 minutes after which time the resulting deep-red suspension was filtered (with suction) through a Dowex-1(Cl^-) resin bed (3.5×1.5 cm‡) directly into a vigorously stirred solution of sodium borohydride (0.6 g) in water (25 ml). (It was necessary to add a few drops of peroxide-free ether from time to time to control the vigorous frothing that occurred.) Sulphuric acid (2 *N*) was added dropwise to decompose the excess sodium borohydride and the solution was immediately extracted with peroxide-free ether (4×125 ml). The combined, dried (Na_2SO_4) extracts were concentrated and the products were worked up and purified chromatographically, as described in Subsection i(*a*) above, to give 5,6-dihydroxy-*N*-methylindole in colorless needles (0.37 g), m.p. 133–134°.

(*C*) *N-Ethyl-5,6-dihydroxyindole*

N-Ethyl-5,6-dihydroxyindole was prepared in solution in peroxide-free ether. As yet, *N*-ethyl-5,6-dihydroxyindole has only been obtained as a yellow gum, however, a crystalline diacetyl derivative has been prepared (see Section II(*C*)). Sodium hydrosulphite (50 mg) was added to a solution of *N*-ethylnoradrenochrome (20 mg, prepared by the method of Heacock and Scott (17)) in water (10 ml); the red color of the solution was rapidly discharged and the reaction mixture extracted with peroxide-free ether (2×4 ml). The dried (Na_2SO_4) ethereal extract containing the *N*-ethyl-5,6-dihydroxyindole (concentration, ca. 1 mg/ml) was used directly for the chromatographic studies.

(*D*) *5,6-Dihydroxy-N-isopropylindole*

5,6-Dihydroxy-*N*-isopropylindole was prepared in solution in peroxide-free ether (at a concentration of ca. 1 mg/ml) from *N*-isopropylnoradrenochrome (17) in an analogous manner to the method described above for the preparation of the *N*-ethyl derivative. As in the case of the *N*-ethyl analogue, 5,6-dihydroxy-*N*-isopropylindole has, as yet, only

**In this and subsequent experiments described in this paper the chromatographic silica gel used was obtained from L. Light & Co. (200/300 mesh size).*

†In this case the substance was prepared by the rearrangement of epinochrome.

‡The resin (200/400 mesh size) was purified by extensive washing with: (a) 2 N hydrochloric acid and (b) water until neutral to litmus. This procedure was used for the preparation of the resin beds described throughout this paper.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

been obtained as a yellow gum, but a crystalline diacetyl derivative has been prepared (see Section II(*D*)).

(*E*) *5,6-Dihydroxy-2-iodoindole*

Potassium iodate (3.2 g) was added to a solution of noradrenaline hydrochloride (2.0 g) in water (1600 ml) and the reaction mixture was stirred at room temperature for 2 hours. An excess of solid ascorbic acid was added (until the deep-violet color of the solution was discharged) and the reaction mixture extracted with peroxide-free ether (5×200 ml). Dry benzene (250 ml) was added to the dried (Na_2SO_4) ethereal extract and the ether was removed *in vacuo*, under nitrogen (bath temperature below 30°); the final traces of ether were removed by the addition of further small quantities of dry benzene and removal of them *in vacuo*. (If the ether extract was concentrated to dryness without the prior addition of benzene, the dark residue obtained was only partially soluble in benzene.) The crude product (obtained in solution in benzene by the method described above) gave 5,6-dihydroxy-2-iodoindole (1.1 g), m.p. 108–108.5° (with decomposition), in pale yellow needles after chromatographic purification on a silica gel column (7×2.4 cm) (adsorption from benzene – light petroleum (b.p. 80–100°) (1:1) and elution with this solvent and benzene). (Found: C, 35.05; H, 2.21; I, 45.93. $C_8H_6NO_2I$ requires C, 34.94; H, 2.20; I, 46.14%.) This product was relatively unstable and decomposed to a black vitreous substance on standing 4 weeks at room temperature.

(*F*) *5,6-Dihydroxy-2-iodo-N-methylindole*

5,6-Dihydroxy-2-iodo-*N*-methylindole was prepared in the manner described by Heacock and Scott (19).

(*G*) *N-Ethyl-5,6-dihydroxy-2-iodoindole*

N-Ethyl-5,6-dihydroxy-2-iodoindole was prepared in solution in peroxide-free ether; although, as yet, *N*-ethyl-5,6-dihydroxy-2-iodoindole has only been obtained as a brownish-yellow amorphous solid, a crystalline diacetyl derivative has been described (17). Sodium hydrosulphite (60 mg) was added to a stirred suspension of *N*-ethyl-2-iodonoradrenochrome (30 mg, prepared by the method of Heacock and Scott (17)) in water (10 ml). After being stirred for ca. 2 minutes the cloudy yellow suspension was filtered from residual solid material and the filtrate was extracted with peroxide-free ether (4×4 ml). The dried (Na_2SO_4) ethereal extract containing the *N*-ethyl-5,6-dihydroxy-2-iodoindole (concentration, ca. 1 mg/ml) was used directly for the chromatographic studies.

(*H*) *5,6-Dihydroxy-2-iodo-N-isopropylindole*

5,6-Dihydroxy-2-iodo-*N*-isopropylindole was prepared in peroxide-free ether solution (from 2-iodo-*N*-isopropylnoradrenochrome (17)) at a concentration of ca. 1 mg/ml in an analogous manner to that described above for the *N*-ethyl derivative. As yet, 5,6-dihydroxy-2-iodo-*N*-isopropylindole has only been obtained as a greenish-brown amorphous solid but a crystalline diacetyl derivative has been described (17).

(*I*) *2-Bromo-5,6-dihydroxy-N-methylindole*

2-Bromo-5,6-dihydroxy-*N*-methylindole was prepared by the method described by Harley-Mason (14).

(II) *5,6-Diacetoxyindoles*

(*A*) *5,6-Diacetoxyindole*

Zinc powder (6.0 g) was added portionwise, during a period of 15 minutes, to a solution of 5,6-diacetoxy-2-iodoindole (0.9 g, prepared by the method described below (Section II

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(*E*)) in glacial acetic acid (12 ml). The reaction mixture was filtered and the residual zinc was washed with glacial acetic acid (3×5 ml); the combined filtrate and washings were poured into ice water. The aqueous reaction mixture was extracted with peroxide-free ether (5×150 ml) and the ethereal extract washed free of acetic acid with saturated aqueous sodium bicarbonate. Concentration (*in vacuo*), of the dried (Na_2SO_4) ethereal extract, gave a red-brown gum, which by chromatographic purification on a short silica gel column using benzene as eluent and recrystallization from light petroleum (b.p. 80–100°) gave 5,6-diacetoxyindole in colorless needles (0.1 g), m.p. 139–140°. (Found: C, 61.77; H, 4.71. $C_{12}H_{11}NO_4$ requires C, 61.80; H, 4.75%.) Beer *et al.* (13), who prepared this compound by a different route report a melting point of 130–133°.

(*B*) *5,6-Diacetoxy-N-methylindole*

(i) Adrenaline (1.6 g) was suspended in water (50 ml) and concentrated hydrochloric acid was added dropwise until a clear solution was obtained. Silver oxide (8 g) was added to the stirred solution, and the stirring continued for a further 3 minutes. The reaction mixture was filtered (with suction) through a Dowex-1 (Cl^-) resin bed (1.5×2.5 cm) directly into a stirred solution of sodium borohydride (0.6 g) in water (25 ml). (The addition of a few drops of peroxide-free ether was necessary at this stage to control the vigorous frothing that occurred.) The excess reducing agent was decomposed by the addition of glacial acetic acid (3 ml). A rapid stream of nitrogen was passed through the stirred solution, cooled to ca. 10–15°, and 40% aqueous sodium hydroxide (10 ml) was added, followed directly by acetic anhydride (5 ml). After being stirred at room temperature for 30 minutes (the cooling bath was removed after 5 minutes), the reaction mixture was extracted with peroxide-free ether (5×100 ml). The combined ethereal extracts were washed with 5% aqueous sodium bicarbonate (2×100 ml) and water (100 ml), dried (Na_2SO_4), and concentrated to dryness (*in vacuo*, below 40°). The product, a greenish-brown gum, was dissolved in benzene – light petroleum (b.p. 80–100°) (1:1) and adsorbed on a silica gel column (12.5×2.4 cm). Elution of the column with the same solvent (100 ml) gave a small quantity of a pale-yellow gum which was discarded; further elution with benzene (400 ml) gave a white solid which on recrystallization from light petroleum (b.p. 80–100°) gave 5,6-diacetoxy-*N*-methylindole (0.69 g), m.p. 109–110°. (Found: C, 63.10; H, 5.24; N, 5.56. $C_{13}H_{13}NO_4$ requires C, 63.15; H, 5.30; N, 5.66%.) This melting point is somewhat higher than those previously quoted in the literature: 101–102° (27), 101° (28), and 104–105° (14). (The product obtained above did not depress the melting point of a sample prepared by direct acetylation of crystalline 5,6-dihydroxy-*N*-methylindole with acetic anhydride in pyridine.)

(ii) Adrenaline (1.6 g) was suspended in water (40 ml) and concentrated hydrochloric acid added dropwise until a clear solution was obtained. Silver oxide (8.0 g) was added to the stirred solution and the stirring continued for 3 minutes and the reaction mixture was filtered through a Dowex-1 (Cl^-) resin bed (1.5×2.5 cm). Glacial acetic acid (2 ml) was added to the vigorously stirred filtrate followed by zinc powder (40.0 g), which caused a rapid discharge of the red color. The product was filtered; the zinc residue was washed with acetone (3×5 ml), and the washings were added to the filtrate. The solution of crude 5,6-dihydroxy-*N*-methylindole so obtained was acetylated directly and the products worked up and purified chromatographically by the methods described above (Subsection *B*(i)) giving 5,6-diacetoxy-*N*-methylindole (0.42 g), m.p. 109.5–110.5°.

(*C*) *5,6-Diacetoxy-N-ethylindole*

N-Ethylnoradrenaline (1.6 g) was suspended in water (40 ml) and concentrated

hydrochloric acid was added dropwise until a clear solution was obtained; silver oxide (8.0 g) was added to the stirred solution and stirring continued for 3 minutes; the product was filtered through a Dowex-1 (Cl^-) resin bed (1.5×2.5 cm) and glacial acetic acid (2 ml), followed by zinc powder (40 g), added to the stirred filtrate. The reaction mixture was filtered; the residual zinc was washed with acetone (3×5 ml); and the washings were added to the filtrate. A rapid stream of nitrogen was passed through the stirred filtrate, cooled to ca. 10–15°, and 40% sodium hydroxide (10 ml) was added, followed directly by acetic anhydride (5 ml). After stirring at room temperature for 30 minutes (the cooling bath was removed after about 5 minutes), the reaction mixture was extracted with peroxide-free ether (5×100 ml). The combined ethereal extracts were washed with 5% aqueous sodium bicarbonate (2×100 ml) and water (100 ml). Concentration, *in vacuo*, below 40°, of the dried (Na_2SO_4) extract, afforded a greenish-brown gum which was dissolved in benzene – light petroleum (b.p. 80–100°) (1:1) and adsorbed on a silica gel column (12.5×2.4 cm). Elution of the column with this solvent (100 ml) gave a trace of gum which was rejected; further elution with benzene (500 ml) gave a white crystalline solid which yielded 5,6-diacetoxy-*N*-ethylindole (0.5 g), m.p. 107–108.5°, on recrystallization from light petroleum (b.p. 80–100°). (Found: C, 64.52; H, 5.78; N, 5.14. $C_{14}H_{15}NO_4$ requires C, 64.37; H, 5.79; N, 5.36%.)

(*D*) *5,6-Diacetoxy-N-isopropylindole*

(i) Silver oxide (16 g) was added to a solution of *N*-isopropylnoradrenaline hydrochloride (4 g) in water (80 ml) and the suspension vigorously stirred for 2 to 3 minutes. The reaction mixture was filtered through a Dowex-1 (Cl^-) resin bed (2.5×1.5 cm) directly into a cooled stirred solution of sodium borohydride (0.75 g) in water (20 ml). (Excessive foaming at this stage was controlled by the addition of small quantities of peroxide-free ether.) The reaction mixture was acidified with glacial acetic acid (3 ml), and a rapid stream of nitrogen passed through the solution, cooled to ca. 10–15°. Aqueous sodium hydroxide (40%, 20 ml) was added, followed directly by acetic anhydride (10 ml). After being stirred at room temperature for 30 minutes (the cooling bath was removed after 5 minutes), the reaction mixture was extracted with peroxide-free ether (5×100 ml); the combined ethereal extracts were washed with 5% aqueous sodium bicarbonate (2×50 ml) and water (100 ml), dried (Na_2SO_4), and concentrated to dryness *in vacuo*, below 40°. The product was dissolved in benzene – light petroleum (b.p. 80–100°) (1:1) and adsorbed on a silica gel column (12.5×2.4 cm). Elution of the column with this solvent (150 ml) gave only traces of gums which were rejected, further elution with benzene (450 ml) gave a white solid, which on recrystallization from benzene – light petroleum (b.p. 80–100°), gave 5,6-diacetoxy-*N*-isopropylindole as colorless prisms (0.5 g), m.p. 90.5–91°. (Found: C, 65.60; H, 6.15; N, 4.94. $C_{15}H_{17}NO_4$ requires C, 65.43; H, 6.23; N, 5.09%.)

(ii) A solution of *N*-isopropylnoradrenochrome (from 2 g of *N*-isopropylnoradrenaline sulphate) in water (40 ml) prepared by the method described above was acidified with glacial acetic acid (5 ml) and reduced with zinc powder (40 g). The reaction product was acetylated directly with acetic anhydride (5 ml) in the presence of 40% aqueous sodium hydroxide (10 ml) by the method previously described. The product was extracted and purified chromatographically by the above method and 5,6-diacetoxy-*N*-isopropylnoradrenochrome was obtained in colorless elongated prisms (0.75 g), m.p. 89.5–90.5°.

(*E*) *5,6-Diacetoxy-2-iodoindole*

An ethereal solution of crude 5,6-dihydroxy-2-iodoindole was prepared by the method

described in Section I(*E*). A mixture of acetic anhydride (15 ml) and dry* pyridine (15 ml) was added and the ether removed *in vacuo*, under nitrogen (bath temperature below 40°). The residual acetylation mixture was allowed to stand overnight at room temperature, after which time it was poured, with stirring, into an ice-water mixture. A brown oil separated, which did not solidify. The product was extracted with peroxide-free ether (5×150 ml) and the ethereal extract washed free of acetic acid with saturated aqueous sodium bicarbonate. Concentration of the dried (Na_2SO_4) ethereal extract gave a brownish residue which was dissolved in a mixture of benzene and light petroleum (b.p. 80–100°) (1:1) and purified chromatographically on a short silica gel column, the same solvent being used for elution. 5,6-Diacetoxy-2-iodoindole (1.1 g), m.p. 125–126.5°, was obtained in fluffy white needles. (Found: C, 40.02; H, 2.77; I, 35.30. $C_{12}H_{10}NO_4I$ requires C, 40.15; H, 2.81; I, 35.35%.)

(*F*) *5,6-Diacetoxy-N-methyl-2-iodoindole*

5,6-Diacetoxy-*N*-methyl-2-iodoindole was prepared by the method of Heacock and Scott (19).

(*G*) *5,6-Diacetoxy-N-ethyl-2-iodoindole*

5,6-Diacetoxy-*N*-ethyl-2-iodoindole was prepared in the manner described by Heacock and Scott (17).

(*H*) *5,6-Diacetoxy-2-iodo-N-isopropylindole*

5,6-Diacetoxy-2-iodo-*N*-isopropylindole was prepared in the manner described by Heacock and Scott (17).

Chromogenic Reagents

(*a*) *Ehrlich's reagent.*—*p*-Dimethylaminobenzaldehyde (1 g) was dissolved in a mixture of concentrated hydrochloric acid (30 ml) and ethanol (30 ml) and the solution was diluted to 100 ml with water.

(*b*) *Cinnamaldehyde solution* (cf. Sen and Leopold (29)).—Cinnamaldehyde (5 ml) was dissolved in a mixture of ethanol (95 ml) and concentrated hydrochloric acid (5 ml).

(*c*) *p-Dimethylaminocinnamaldehyde solution* (cf. Harley-Mason and Archer (30)).—*p*-Dimethylaminocinnamaldehyde (2 g) was dissolved in 6 *N* hydrochloric acid (100 ml) and ethanol (100 ml). The stock solution (10 ml) was diluted with ethanol (40 ml) prior to use.

(*d*) *Hopkins-Cole reagent* (cf. Benedict (31)).—A saturated aqueous solution of oxalic acid (250 ml) was added slowly to a cooled suspension of magnesium filings (10 g) in sufficient water to just cover the metal. After addition of the acid the flask was vigorously shaken for a few minutes and the solution filtered. The filtrate was stabilized by the addition of a little glacial acetic acid and diluted to 1000 ml with water.

(*e*) *Acidic oxidizing reagent* (cf. Jepson (32), p. 125).—Freshly prepared saturated potassium persulphate solution (1 ml†) was mixed with concentrated hydrochloric acid (10 ml) and acetone (40 ml), and the solution used immediately.

(*f*) *Salkowski reagent* (cf. Sen and Leopold (29)).—Ferric chloride (0.5 *M*, 2 ml) was added to 5% perchloric acid (100 ml).

(*g*) *Terephthalaldehyde solution* (cf. Curzon and Giltrow (33)).—Terephthalaldehyde (0.2 g) was dissolved in a mixture of acetone (90 ml) and acetic acid (10 ml). After being

**Distilled from phosphorus pentoxide.*

†This quantity of potassium persulphate solution is greater than that used by Jepson and gives more intense colors in the cases studied. The use of the stronger reagent was suggested to the authors by Dr. F. Wightman of Carleton University, Ottawa.

sprayed with this solution the chromatograms were sprayed with 2% concentrated hydrochloric acid in acetone.

(*h*) *Nitrose reagent* (cf. Jepson (32), p. 127).—Sodium nitrite (1 ml of a 5% aqueous solution) was added to a solution of concentrated nitric acid (5 ml) in acetone (45 ml) and the mixture was used directly.

(*i*) *Formaldehyde/hydrochloric acid* (cf. Prochazka *et al.* (26)).—Aqueous formaldehyde solution (10 ml of a 30 to 40% solution) was mixed with concentrated hydrochloric acid (10 ml) and water (20 ml). In order to develop the colors, the chromatograms were warmed to 90–95° after spraying.

(*j*) *Xanthydrol reagent* (cf. Dickmann and Crockett (34)).—Xanthydrol (0.2 g) was dissolved in ethanol (90 ml) and concentrated hydrochloric acid (10 ml).

(*k*) *Gibb's reagent.*—*N*-2,6-Trichloro-*p*-quinoneimine (2 g) was dissolved in ethanol (100 ml).

(*l*) *Diazotized p-nitroaniline* (cf. Bray *et al.* (35)).—A *p*-nitroaniline solution (25 ml) of a 0.3% solution in 8% (w/v) hydrochloric acid was diazotized with sodium nitrite solution (1.5 ml of a 5% solution) immediately prior to use. (The second spraying with aqueous alkali was omitted.)

(*m*) *Folin and Ciocalteu's reagent.*—This solution was available commercially (B. D. H.) and was diluted with two volumes of water prior to use.

(*n*) *Sodium molybdate/hydrochloric acid* (cf. Coulson and Evans (36)).—Sodium molybdate solution (10%, 20 ml) was diluted with 0.5 *N* hydrochloric acid (10 ml).

(*o*) *Ferric chloride/potassium ferricyanide reagent* (as described by Heacock *et al.* (37)).—Ferric chloride (3%, 5 ml) and potassium ferricyanide (3%, 5 ml) were mixed immediately prior to use and the solution was diluted to 100 ml with water. In order to prevent discoloration of the papers after spraying with this reagent, they were subsequently washed with (*a*) water, (*b*) 2 *N* hydrochloric acid, and (*c*) water.

(*p*) *Ferric chloride solution.*—Ferric chloride (3 g) was dissolved in water (100 ml) containing a few drops of hydrochloric acid.

(*q*) *Ammoniacal silver nitrate.*—Ammonia solution (5 *N*) was added dropwise to 0.1 *N* aqueous silver nitrate, until the precipitate which initially formed just redissolved.

Chromatographic Procedure (5,6-Dihydroxyindoles)

(*A*) *Descending*

1. Paper.—Whatman No. 1 paper was washed with 2% acetic acid for 48 hours and dried prior to use.

2. Solvents.—S_1, 2% acetic acid in water; S_2, *n*-butanol:glacial acetic acid:water (6:1:2).

3. Detection.—All the chromogenic reagents mentioned above give colors with the 5,6-dihydroxyindoles (see Table I). Satisfactory color intensities were obtained with spots derived from 10 to 25 μg of the compounds. The unhalogenated 5,6-dihydroxyindoles also show a definite light blue to mauve fluorescence in ultraviolet light.

(*B*) *Circular*

1. Paper.—(*a*) Whatman No. 1 paper, slotted disks (diameter = 26.5 cm*); (*b*) disks (diameter = 26.5 cm) of Whatman 3MM paper were dipped into a 30% solution of reagent grade formamide ("pH" = 5)† in acetone, removed, blotted dry, and allowed to dry in air for 20 minutes.

**As supplied by the Shandon Scientific Company Ltd.*
†The "pH" of the formamide was adjusted to 5 by the careful dropwise addition of 98% formic acid.

CHARACTERISTIC VIBRATIONS OF THE SULPHURYL GROUP[1]

E. A. ROBINSON

ABSTRACT

A compilation of the S—O symmetric and asymmetric stretching frequencies is given for a large number of compounds containing an —SO_2— group. It is shown that a linear relationship between $\nu_{SO_2(sym)}$ and $\nu_{SO_2(asym)}$ is valid for a large number of sulphuryl and polysulphuryl compounds and that the actual frequencies depend in a systematic manner on the electronegativities of the attached groups. These relationships have proved very useful in assigning and in some cases reassigning the S—O bands in the infrared and Raman spectra of a number of sulphuryl compounds. It is pointed out that there is a relationship between the SO_2 frequencies of some sulphonic acids and their acid strengths.

The calculation of values for group electronegativities from the vibration frequencies of the P═O and SO_2 groups is discussed.

For a variety of organic compounds including sulphones, sulphonyl chlorides, covalent sulphates, sulphonamides, sulphonic acid esters, and sulphonates, the sulphur–oxygen symmetrical and antisymmetrical stretching frequencies obtained from infrared and Raman spectra have been characterized. A compilation of these frequencies has been given by Bellamy (1).

In 1957 Bellamy and Williams (2) pointed out that any change in the symmetric frequency, $\nu_{SO_2(sym)}$, is accompanied by a proportional change in the asymmetric frequency, $\nu_{SO_2(asym)}$. They plotted $\nu_{SO_2(sym)}$ against $\nu_{SO_2(asym)}$ for 29 compounds taken from the work of Haszeldine and Kidd (3, 4), Barnard, Fabian, and Koch (5), and of Baxter, Cymerman-Craig, and Willis (6) and obtained a good straight line. They pointed out that since the —SO_2— stretching frequencies are essentially free from mass and coupling effects such a correlation is expected and that the exact positions of $\nu_{SO_2(sym)}$ and $\nu_{SO_2(asym)}$ depend on the nature of the substituents attached to the sulphuryl group. It is expected that the more electronegative the groups that are attached the stronger the S═O bonds will be and hence the higher the vibrational frequencies.

In recent years symmetric and asymmetric vibrations for sulphuryl groups in a large number of compounds including several inorganic compounds have been reported. Data for different compounds are reported in Table I and are plotted in Fig. 1. It is clear that the symmetrical and asymmetrical S—O vibrations for compounds of the type X_2SO_2, $XYSO_2$, (including $X(OH)SO_2$), for ions such as XSO_3^- and SO_4^{--} (although strictly speaking the S—O vibrations in these cases should not be described in this manner), and for more complex compounds containing —SO_2— as part of a ring or chain, all fit the linear relationship of Bellamy and Williams (2) reasonably well.

When the —SO_2— group is bonded to two alkyl groups $\nu_{SO_2(sym)}$ comes in the narrow range 1136 to 1145 cm^{-1}, whereas for two aryl groups, or for one alkyl group and one aryl group this frequency is in the range 1150 to 1160 cm^{-1}. In all cases $\nu_{SO_2(asym)}$ is in the range 1312 to 1334 cm^{-1}. When an alkyl or an aryl group is replaced by the more electronegative —NH_2 group (e.g. in the sulphonamides), a slight shift of $\nu_{SO_2(sym)}$ and a corresponding shift of $\nu_{SO_2(asym)}$ to higher frequencies is noted; $\nu_{SO_2(sym)}$ is in the range 1152 to 1169 cm^{-1} and $\nu_{SO_2(asym)}$ in the range 1336 to 1358 cm^{-1}. Similarly on replacing the —NH_2 group by oxygen (e.g. in the sulphonic acid esters), further shifts of the S—O bands to yet higher frequencies are observed. In general, replacement of groups attached

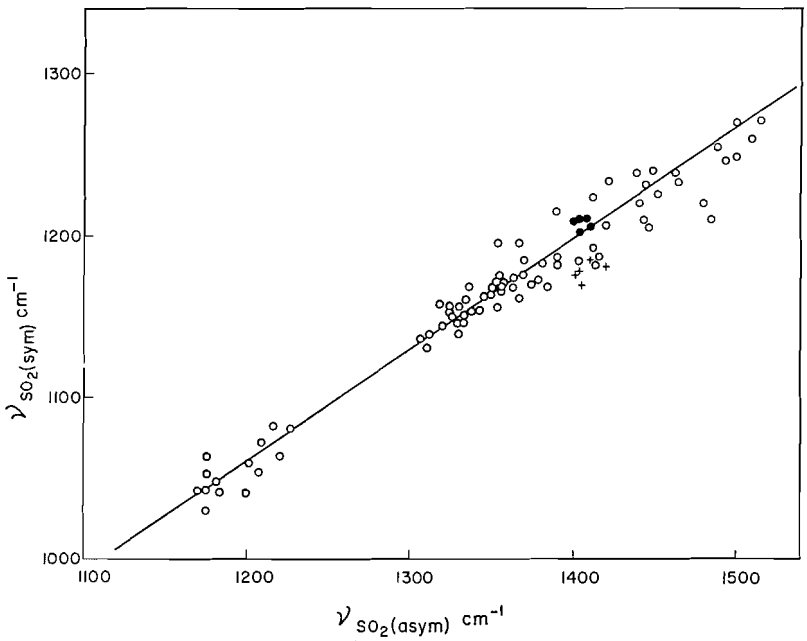

FIG. 1. Correlation of symmetric and asymmetric S—O stretching frequencies.

to the sulphuryl group by groups having a greater effective electronegativity leads to a shift in the S—O stretch to higher frequency (Table II).

The shift of the SO_2 stretching frequencies to higher values as the electronegativities of the attached groups increase indicates increasing strength of the S=O bonds which

may be reasonably attributed at least partly to increased double-bond character. The more electronegative are the groups X and Y in $XYSO_2$ the less important are contributions from structures such as $XYS^{+}\!\!<\!\!\begin{matrix}O^{-}\\O\end{matrix}$ compared with the double-bonded structure $XYS\!\!<\!\!\begin{matrix}O\\O\end{matrix}$.

An example of how the above correlation of $\nu_{SO_2(sym)}$ with $\nu_{SO_2(asym)}$ and of both of these frequencies with the effect of the attached groups may be used is afforded by the sulphonyl fluorides. Bands at 1177, 1180, 1178, 1169, and 1184 cm^{-1}, respectively, for methane, benzene, *o*-toluene, *m*-toluene, and *p*-toluene sulphonyl fluorides, have been assigned previously to the symmetrical stretch by Ham and Hambly (7). We suggest, however, that bands at 1210, 1205, 1209, 1203, and 1205 cm^{-1}, respectively, assigned by the above workers to a vibration of the SO_2F group should be reassigned to the S—O symmetrical stretch. This vibration has a frequency in the range 1170 to 1180 cm^{-1} in the corresponding chlorides and it is reasonable to expect a shift from this value to a higher value on substituting fluorine for chlorine, e.g. on passing from SO_2Cl_2 to SO_2F_2 the S—O symmetrical stretch shifts from 1180 to 1269 cm^{-1}. Moreover the reassigned frequencies fit the straight line rather better (points indicated ● on Fig. 1) than the original assignments (indicated by + on Fig. 1).

Figure 1 also shows that for anions, XSO_3^-, the S—O bands come at much lower frequencies than for any neutral molecule. This is consistent with the smaller double-bond character of the S—O bonds in these species. The effect of the X substituent, although much reduced, is also apparent in these anions, e.g. $\nu_{SO_2(sym)}$ for FSO_3^- is at 1080 cm^{-1} while this vibration has the frequency 1054 cm^{-1} for $ClSO_3^-$ and 1040 cm^{-1} for HSO_4^-. The straight-line relationship between the two S—O frequencies is not so good for some of these anions possibly due to inaccuracies in the frequencies resulting from the difficulty of resolving bands in some of the spectra.

Another example of the use of the above correlation in structure determination is afforded by the observation of two bands assigned to the S—O stretches, at 1030 and 1240 cm^{-1} in the spectrum of *p*-toluenesulphonic acid monohydrate. It is immediately clear from Fig. 1 that these bands are characteristic of the *p*-toluene sulphonate ion and not the parent acid so that the compound is actually the salt $H_3O^+ \cdot CH_3 \cdot C_6H_4 \cdot SO_3^-$. Again Haszeldine and Kidd (4) report the S—O bands for CF_3SO_3H at 1030 and 1176 cm^{-1} but from Fig. 1 it seems that they should be assigned not to the acid but to its anion $CF_3 \cdot SO_3^-$.

The $—SO_2—$ group frequencies in the molecule XSO_3H can be related to its strength as an acid. A similar correlation of the —OH stretching frequency in carboxylic acids with their strengths has been pointed out by Goulden (8) and the change in the carbonyl stretching frequency has been used similarly (9). The frequencies of the $—SO_2—$ symmetrical stretch in the sulphonic acids appears to increase with increasing acid strength as is shown in Table III. Disulphuric acid, $H_2S_2O_7$, is a moderately weak acid of the sulphuric acid system (10). Fluorsulphuric and chlorsulphuric acids are very weak acids in sulphuric acid (11) while *p*-toluene sulphonic and benzene sulphonic acids behave as weak bases of the sulphuric acid system (12) and are presumably therefore weaker acids than sulphuric acid. Comparison of CF_3SO_2Cl ($\nu_{SO_2(sym)}$ = 1239, $\nu_{SO_2(asym)}$ = 1439 cm^{-1}) with SO_2Cl_2 ($\nu_{SO_2(sym)}$ = 1182, $\nu_{SO_2(asym)}$ = 1414 cm^{-1}) would suggest that the SO_2 frequencies in CF_3SO_3H would be higher than in $ClSO_3H$ and it might be predicted therefore that CF_3SO_3H would be a stronger acid than $ClSO_3H$. Unfortunately the

TABLE III

Correlation of $\nu_{SO_2(sym)}$ with the acid dissociation constants of sulphonic acids in sulphuric acid

	SO_2(sym) (cm^{-1})	K_a, moles kg^{-1} (25° C)
Disulphuric acid	1240	0.014
Fluorsulphuric acid	1230	0.002
Chlorsulphuric acid	1209	0.001
Sulphuric acid	1195	—
Benzenesulphonic acid	1182	Base
p-Toluenesulphonic acid	1170	Base

ionization of CF_3SO_3H in sulphuric acid has not been studied. It can also be predicted from a comparison of the SO_2 frequencies of CF_3SO_2F at 1239 and 1463 cm^{-1} and those of FSO_2F (1269 cm^{-1}, 1501 cm^{-1}) that CF_3SO_3H would be a weaker acid than FSO_3H. Thus the following is probably the order of the strengths of these sulphonic acids,

$$H_2S_2O_7 > FSO_3H > CF_3SO_3H > ClSO_3H > H_2SO_4 > MeSO_3H.$$

A similar effect of electronegative substituents on the characteristic frequency of a group has been observed in other cases, e.g. for phosphoryl compounds (13) and for carbonyl compounds (14), and attempts have been made to devise quantitative relationships between the vibrational frequency of a group and the effective electronegativities of the attached substituents.

Bell and co-workers assumed that the P=O frequency in phosphoryl compounds is directly related to the sum of the effective electronegativities of the groups X, Y, Z, in the molecule (XYZ)P=O ($\Sigma\psi = \psi_X+\psi_Y+\psi_Z$). By assuming the Pauling values (4.0, 3.0, and 2.8) for the electronegativities of fluorine, chlorine, and bromine, respectively, they were able to obtain a correlation between the Raman shifts of the P=O group and the sum of the electronegativities of the halogens attached to it. The weakness of the method is that it assumes that the effect of the halogen is to be entirely attributed to its changing the effective electronegativity of the phosphorus atom and ignores any possible effects due to double-bond formation with the halogen which may be particularly important for fluorine. Generally the P—F bond distance is found to be considerably less than the sum of the covalent radii (41), and this has been attributed (15) to partial double-bond formation between fluorine and phosphorus. We find that if we consider first only the phosphoryl compounds not containing fluorine and correlate the P=O stretching frequency (Table IV) with the sum of the Pauling electronegativities in these compounds (Fig. 2), then a good straight line can be drawn which has a different slope

TABLE IV

Values of the P—O stretching frequency in phosphoryl halides (XYZ). P=O*

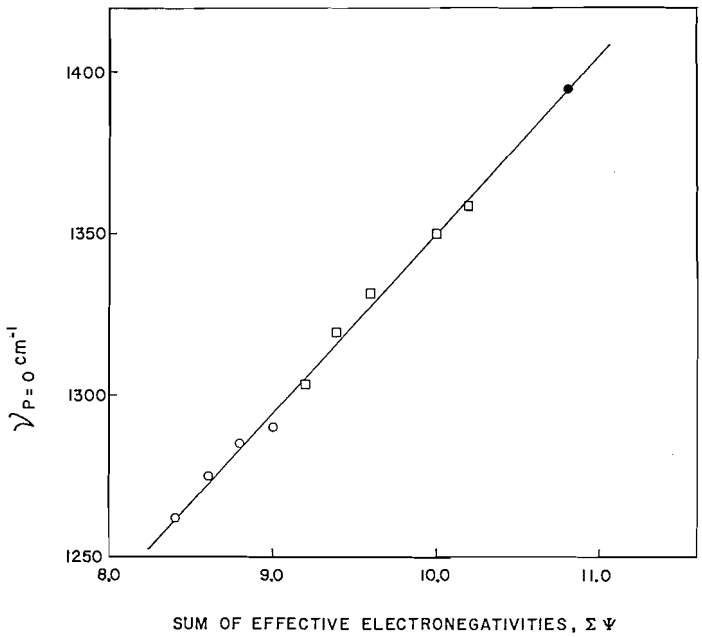

FIG. 2. Correlation of P—O stretching frequency with $\Sigma\psi$. ○ chloro, bromo, and chloro–bromo compounds; ● POF_3; □ chloro–fluoro and bromo–fluoro compounds and POFClBr.

from the line proposed by Bell and co-workers (13). The correlation is probably justified for chloro and bromo phosphorus compounds, since the phosphorus halogen bond lengths are nearer to the sum of the covalent radii (41), indicating that the bonds are probably near to single. On the basis of the new straight line we find that a value of 3.6 is required for the effective electronegativity of fluorine in order for the P=O frequency in POF_3 to fall on the straight line (Fig. 2). This can be attributed to the fact that double bonding between fluorine and phosphorus reduces the extent of P—O double bonding and thus apparently reduces the effective electronegativity of fluorine. The value 3.6 seems to be appropriate for all phosphoryl compounds since if we use this value for fluorine and the Pauling values for chlorine and bromine, then the present straight line is also found to hold for all mixed halogen–fluorine phosphoryl compounds (Fig. 2).

It is clear from the above discussion that evaluation of electronegativities for groups is complicated by the probable occurrence of double bonding. Nevertheless the order of electronegativities of groups can probably be established from the spectra. For phosphoryl compounds the order

$$F > CF_3 > OAr \simeq OR > CN > Cl > Br > SR > Ar > R \simeq NH_2$$

is obtained.

The multiplicity of P—F bonds implied by the low apparent electronegativity of fluorine and the short bond lengths is consistent with the P—F symmetrical stretching frequency in fluorphosphorus compounds. For the PF_6^- ion the P—F distance is apparently single (1.73 Å) and the P—F stretching frequency is at 741 cm^{-1} whereas in other P—F compounds where the P—F distance is abnormally short this particular vibration is at a much higher frequency (820 to 940 cm^{-1}), implying a strengthening of the bond. In PF_6^- the outer shell contains six electron pairs and P—F double-bond

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

formation presumably cannot occur whereas in the other compounds considered the valency shell contains less than six electron pairs making partial double-bond formation very probable (16). A similar effect has been recognized (15), in the case of bonds of fluorine with silicon. For example, in SiF_4 the Si—F bond length is 1.54 Å and the Si—F stretching frequency is at 800 cm^{-1} while in SiF_6^{--} the bond length is 1.71 Å and the stretching frequency is at 656 cm^{-1}.

In view of the obvious defects in the calculations of effective electronegativities by the method of Bell and co-workers and because few reference compounds are available no attempt has been made to evaluate the electronegativities of groups attached to the SO_2 group in sulphuryl compounds. However, the order of electronegativities is probably

$$F > OF > CF_3 > OR \simeq OH > Cl \simeq CCl_3 > SR \simeq NH_2 > Ar > R,$$

which is very similar to the order found for these groups attached to the phosphoryl group.

Recently Lagowski (38) using the S—O frequencies for the compounds SO_2F_2, SO_2Cl_2, CF_3SO_2F, and CF_3SO_2Cl has deduced that the effective electronegativity of the CF_3 group is between those of fluorine and chlorine and the effect of substituted alkyl and aryl substituents on ν_s and ν_{as} has been discussed by Momose *et al.* (39).

Difficulties with regard to S—F double bonding are to be expected. Thus in SF_6 where no double bonding between sulphur and fluorine is expected the S—F stretching frequency is at 775 cm^{-1}, but in most other fluorosulphur compounds this vibration has a higher frequency in the range 820 to 850 cm^{-1} which could be attributed to partial double-bond character of the S—F bonds.

NOTES

STUDIES ON THE CRYSTALS SEPARATING FROM AQUEOUS LITHIUM NITRATE SOLUTION

G. ARAVAMUDAN* AND S. RAMASESHAN

Systematic studies (1, 2, 3, 4) on lithium nitrate–water systems have established the existence of $LiNO_3.3H_2O$. In fact Campbell and Bailey (3*c*) have not only isolated this salt but have succeeded in recording its X-ray powder diagram. During the course of some investigations on $LiNO_3$–H_2O systems in this Institute (5) very good single crystals of $LiNO_3.3H_2O$ were obtained. This note reports the determination of its space group as well as some morphological studies of anhydrous $LiNO_3$ crystals separating from aqueous solution at various temperatures.

When an aqueous $LiNO_3$ solution corresponding to the composition of the trihydrate (56.11% $LiNO_3$ by weight) is cooled to $-5°$ C spontaneous crystallization occurs with the deposition of a mass of $LiNO_3.3H_2O$ crystals. If one of these tiny crystals is used to inoculate a more dilute solution (50% $LiNO_3$) and the temperature maintained constant (say at 25° C), extremely well defined euhedral crystals, sometimes as large as 6 cm × 2 cm × 1.5 cm, could be grown during the course of 2 days.

The crystals appeared to belong to the orthorhombic system and the peculiar distribution of the faces suggested a hemimorphic form lacking a center of symmetry (point group *mm*2). The *a* and *b* faces were well developed while the *c* face (perpendicular to the axis of elongation) could be recognized only in rare cases. Two prominent faces which made respectively 28° and 46° with the *b* face were later identified as the (110) and (120) planes. These angles were measured with a contact goniometer because of the inherent difficulty of mounting these excessively hygroscopic, low-melting crystals on a two-circle goniometer.

Using a few flawless crystals the density was determined by the flotation method (bromoform + xylene mixture) to be 1.55.

Rotation and Weissenberg photographs about the *c* axis were taken with a single crystal enclosed in a Lindemann glass tube. The crystal belongs to the orthorhombic symmetry with unit cell dimensions $a = 6.82$ Å, $b = 12.78$ Å, and $c = 6.05$ Å. The observed density gave four molecules in the unit cell.

From *hk*0, *hk*1, and *hk*2 Weissenberg photographs it was found that the constraining condition for the appearance of *hkl* reflections was $h+k = 2n$, while that for the *h*0*l* reflections was ($h = 2n$), $l = 2n$. All the other reflections like *hk*0, 0*kl*, *h*00, 0*k*0, and 00*l* were also governed by these two conditions. The only space groups consistent with these conditions are (6):

centrosymmetric space group — $Cmcm$—D_{2h}^{17} (No. 63)

or

non-centrosymmetric space groups — $Cmc2$—C_{2v}^{16} (No. 40)

$Cmc2_1$—C_{2v}^{12} (No. 36).

**Present address: Department of Chemistry, Indian Institute of Technology, Madras, S. India.*

If any weight could be given to the cursory morphological examination mentioned earlier, the crystal should belong to one of the latter two non-centrosymmetric space groups. The crystal structure analysis of this substance is in progress.

A powder photograph of $LiNO_3.3H_2O$ was taken using a 9-cm Unicam powder camera. Since the specimen diameter was nearly 0.6 mm, high resolution could not be attained. Table I gives an approximate visual estimate of the intensity of each line, its spacing,

its index, and spacing computed from the Weissenberg data as also the values reported by Campbell and Bailey. The present measurements are accurate to 1% only.

The work of Campbell and his co-workers has definitely disproved the existence of lithium nitrate hemihydrate ($LiNO_3.\frac{1}{2}H_2O$) which Donnan and Burt (1) reported. According to these authors the anhydrous salt separating at higher temperatures (70 to 90° C) had a different crystal form from the "hemihydrate" crystals which they claimed were formed in their experiments at about 40° C. However, this suggested that the morphological study of crystals grown from concentrated aqueous solution by evaporation or by cooling at various temperatures from 0° C to 90° C would be of interest. These crystals were most carefully examined optically and goniometrically. A simple plastic attachment was made to the Unicam two-circle goniometer to completely prevent moist air from coming in contact with the hygroscopic crystals. Although the measurement of the angles were necessarily inaccurate (due to the intervening thin plastic cover) there was no doubt from the stereographic projections that all the crystals obtained were definitely the anhydrous rhombohedral $LiNO_3$. The crystals, however,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

exhibited a profusion of faces and forms, the most prominent being $c(0001)$, $m(10\bar{1}0)$, $r(10\bar{1}1)$, $0(02\bar{2}1)$, $e(01\bar{1}2)$, and $v(21\bar{3}1)$. Measurement of the rhombohedral angle gave a value 72° 30′ well in agreement with that computed from X-ray data (7) (72° 42′) for anhydrous $LiNO_3$.

It is perhaps worth while mentioning that it was impossible to separate out the trihydrate crystals from concentrated solutions of lithium nitrate even at temperatures as low as 0° C. Neither do these crystals form on the slow removal of water from saturated solution above −5° C. This is due to the strong tendency of $LiNO_3.3H_2O$ to supercool and it is precisely for this reason that seeding of the solution has to be resorted to for preparing the trihydrate crystals at ambient temperature (25° C).

The authors wish to thank Professor K. R. Krishnaswamy and Professor R. S. Krishnan for their kind interest in this work.

THE FLUORINE MAGNETIC RESONANCE IN THE IONS $[BF_4]^-$ AND $[BF_3CF_3]^-$

R. D. Chambers, H. C. Clark, L. W. Reeves, and C. J. Willis

Three of the authors have recently reported the new $[BF_3—CF_3]^-$ anion (1), the first compound with a perfluoroalkyl–boron bond. The present note presents the nuclear magnetic resonance data at 40 Mc for this ion and the $[BF_4]^-$ ion in aqueous solution. The resonance signals were referred to an external capillary containing CF_3COOH. No corrections for diamagnetic susceptibility differences in a cylindrical tube have been employed because the magnitude of the chemical shifts observed is so large (2, 3).

At the left of the figure are shown F^{19} magnetic resonance spectra of the CF_3 region of the $[CF_3BF_3]^-$ ion (I) and the peak due to trifluoroacetic acid (II). Peak III, which is shifted +77.3 p.p.m. to high field, is the F^{19} resonance of the BF_3 region of the ion. The correspondence of these chemical shifts to the boron–fluorine and the carbon–fluorine electronegativity differences and the equal intensity is satisfactory proof of the formulation of the ion (4, 5). At the right of the figure the spectrum of the $[BF_4]^-$ ion is shown from a concentrated aqueous solution of the sodium salt. Chemical shifts are indicated above the respective spectrum.

The spectra all show a quartette with some underlying structure which is not resolved.

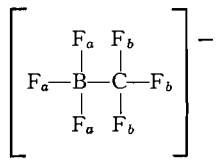
THE FLUORINE MAGNETIC RESONANCE IN THE IONS $[BF_4]^-$ AND $[BF_3CF_3]^-$

R. D. Chambers, H. C. Clark, L. W. Reeves, and C. J. Willis



Three of the authors have recently reported the new $[BF_3—CF_3]^-$ anion (1), the first compound with a perfluoroalkyl–boron bond. The present note presents the nuclear magnetic resonance data at 40 Mc for this ion and the $[BF_4]^-$ ion in aqueous solution. The resonance signals were referred to an external capillary containing CF_3COOH. No corrections for diamagnetic susceptibility differences in a cylindrical tube have been employed because the magnitude of the chemical shifts observed is so large (2, 3).

At the left of the figure are shown F^{19} magnetic resonance spectra of the CF_3 region of the $[CF_3BF_3]^-$ ion (I) and the peak due to trifluoroacetic acid (II). Peak III, which is shifted +77.3 p.p.m. to high field, is the F^{19} resonance of the BF_3 region of the ion. The correspondence of these chemical shifts to the boron–fluorine and the carbon–fluorine electronegativity differences and the equal intensity is satisfactory proof of the formulation of the ion (4, 5). At the right of the figure the spectrum of the $[BF_4]^-$ ion is shown from a concentrated aqueous solution of the sodium salt. Chemical shifts are indicated above the respective spectrum.

The spectra all show a quartette with some underlying structure which is not resolved.

This quartette arises from indirect spin–spin interaction between the 81.2% abundant B^{11} isotope and F^{19}. It is to be noted that the individual multiplets are much narrower in the $[BF_4]^-$ ion because the tetrahedral symmetry minimizes the electric field gradients at the boron nucleus (6, 7, 8).

The spectrum of the $[BF_3—CF_3]^-$ ion should reflect the following coupling constants $J_{B^{11}-F_a{}^{19}}$, $J_{B^{11}-F_b{}^{19}}$, and $J_{F_a{}^{19}-F_b{}^{19}}$ from

The values obtained are $J_{B^{11}-F_b{}^{19}} = 34$ c.p.s., $J_{B^{11}-F_a{}^{19}} = 39.0$ c.p.s., and $J_{F_a{}^{19}-F_b{}^{19}}$ is not resolved. The value of $J_{B^{11}-F_a{}^{19}}$ is similar to that observed in BF_3 (6). In the $[BF_4]^-$ ion $J_{B^{11}-F^{19}}$ is only 4.8 c.p.s.

The spectrum for the $[BF_4]^-$ shows that no other species such as $[BF_3(OH)]^-$ is present in any appreciable amount, in agreement with the observations of Wamser (9) that the degree of hydrolysis of $[BF_4]^-$ in concentrated solutions is very small. It has already been found that the $[CF_3BF_3]^-$ ion is not appreciably hydrolyzed in aqueous solution (1) and the simple N.M.R. spectrum found is therefore to be expected, in the absence of species such as $[CF_3BF_2OH]^-$.

REARRANGEMENT IN THE REACTION BETWEEN THIONYL CHLORIDE AND 3-METHYL-2-BUTANOL

C. C. Lee and A. J. Finlayson

Nucleophilic displacements which occur with retention of configuration have been designated S_Ni reactions (1). The most extensively studied reaction of this type is that between thionyl chloride and secondary alcohols. Recent work in this field has led to the conclusion that S_Ni reactions possess considerable ionic characteristics, with carbonium ions or ion-pairs suggested as intermediates (2–5). Rearrangements typical of intermediate carbonium ions have been observed by Cram (2) for the reaction of thionyl chloride with the stereoisomers of 3-phenyl-2-butanol, 2-phenyl-3-pentanol, and 3-phenyl-2-pentanol. The present communication reports the formation of a rearranged product from the reaction between thionyl chloride and 3-methyl-2-butanol.

3-Methyl-2-butanol was added dropwise, with stirring, to a 100% excess of purified thionyl chloride at −35° C. Stirring was continued for 2 hours at −35° C. The hydrogen chloride produced was pumped off at about 25 mm pressure. The reaction mixture was then allowed to stand at room temperature for 1.5 hours before the excess thionyl chloride was distilled at 29–31° C at 25–30 mm. The resulting chlorosulphite was decomposed by heating at 40–50° C for 1.5 hours. Evolution of sulphur dioxide was noted during the decomposition. On raising the temperature, the crude product distilled. The distillate was washed with water and with dilute sodium carbonate solution until the washing remained basic. The washed product was dissolved in ether and dried over phosphorus pentoxide. After removal of the solvent, the residue was distilled to give about 20% yields of alkyl chloride, b.p. 84–85° C (lit. (6*a*) for *t*-amyl chloride, b.p. 86° C), which gave an immediate precipitate with alcoholic silver nitrate at room temperature. The infrared absorption spectrum of this product showed all the absorption peaks as known *t*-amyl chloride together with an extra, weak and broad band in the 1725 to 1750 cm^{-1} region. These results appear to indicate that the reaction product may be *t*-amyl chloride contaminated with a small amount of unknown impurity.

To confirm the identity of the reaction product as chiefly *t*-amyl chloride, it was converted to the Grignard reagent followed by reaction with carbon dioxide to give dimethylethylacetic acid (7, 8) with an over-all yield of 35%. The low yield was to be expected since it is difficult to prepare Grignard reagents from *t*-alkyl halides. The dimethylethylacetic acid was identified by conversion to the *p*-phenylphenacyl ester, which melted alone and on admixture with an authentic sample at 84° C (lit. (6*b*) m.p. 86.5° C). Considering these results, it is reasonable to conclude that *t*-amyl chloride was obtained from the reaction of thionyl chloride with 3-methyl-2-butanol. A 1,2-hydride shift must have occurred in the reaction. A similar type of 1,2-shift has been noted in the reaction of thionyl chloride with 2-butanol-1-C^{14}, resulting in the formation of some 2-butyl-4-C^{14} chloride.* The rearrangement in the labelled 2-butyl system was found to occur during the S_Ni reaction itself and did not arise during the process of purification or degradation. With these findings in mind, it appears safe to conclude that the *t*-amyl chloride obtained in the present study actually resulted from rearrangement during the reaction between thionyl chloride and 3-methyl-2-butanol. Rearrangements resulting from 1,2-shifts in the 3-methyl-2-butyl system have also been noted in carbonium ion-type reactions

SYNTHESIS OF α-POLYOXYMETHYLENE-C^{13} AND α-POLYOXYMETHYLENE-O^{18}*

R. N. RENAUD AND L. C. LEITCH

Several methods of preparing formaldehyde labelled with C^{14} have been proposed (3). In all these syntheses the aldehyde is obtained as an aqueous solution. An earlier paper on the synthesis of deuterated formaldehyde by one of us (1) indicated the difficulty of obtaining polymeric formaldehyde from such solutions. Nevertheless, according to Jones and Skraba (2), evaporation of an aqueous solution obtained by hydrolysis of chloromethyl-C^{14} acetate leaves a residue of dry formaldehyde-C^{14} polymer. In our experience only traces of polymer were ever obtained under these conditions. Consequently, polyoxymethylene-C^{13} was prepared from chloromethyl-C^{13} acetate by a modification of the procedure employed in making deuterated polymeric formaldehyde. When a solution of chloromethyl-C^{13} acetate in benzene is heated with the calculated amount of water the ester is slowly hydrolyzed to formaldehyde-C^{13}, which is deposited as α-polyoxymethylene of melting point 168–170° C on the wall of the condenser in 77% yield.

The chloromethyl-C^{13} acetate was prepared by chlorinating methyl-C^{13} acetate by means of sulphuryl chloride and a trace of peroxide instead of elemental chlorine as described by Jones and Skraba (2). In this way formation of the dichloroester is almost entirely suppressed. The methyl-C^{13} acetate was prepared by heating methyl-C^{13} iodide and silver acetate in a sealed tube.

Polyoxymethylene labelled with O^{18} was prepared by heating the normal compound with water containing approximately 20% excess O^{18} and a trace of sulphuric acid. The product isolated from the reaction analyzed 9% CH_2O^{18}. Hydrolysis of chloromethyl acetate with H_2O^{18} gave polyoxymethylene, which contained only 2.7% CH_2O^{18}.

R. N. RENAUD AND L. C. LEITCH

Several methods of preparing formaldehyde labelled with C^{14} have been proposed (3). In all these syntheses the aldehyde is obtained as an aqueous solution. An earlier paper on the synthesis of deuterated formaldehyde by one of us (1) indicated the difficulty of obtaining polymeric formaldehyde from such solutions. Nevertheless, according to Jones and Skraba (2), evaporation of an aqueous solution obtained by hydrolysis of chloromethyl-C^{14} acetate leaves a residue of dry formaldehyde-C^{14} polymer. In our experience only traces of polymer were ever obtained under these conditions. Consequently, polyoxymethylene-C^{13} was prepared from chloromethyl-C^{13} acetate by a modification of the procedure employed in making deuterated polymeric formaldehyde. When a solution of chloromethyl-C^{13} acetate in benzene is heated with the calculated amount of water the ester is slowly hydrolyzed to formaldehyde-C^{13}, which is deposited as α-polyoxymethylene of melting point 168–170° C on the wall of the condenser in 77% yield.

The chloromethyl-C^{13} acetate was prepared by chlorinating methyl-C^{13} acetate by means of sulphuryl chloride and a trace of peroxide instead of elemental chlorine as described by Jones and Skraba (2). In this way formation of the dichloroester is almost entirely suppressed. The methyl-C^{13} acetate was prepared by heating methyl-C^{13} iodide and silver acetate in a sealed tube.

Polyoxymethylene labelled with O^{18} was prepared by heating the normal compound with water containing approximately 20% excess O^{18} and a trace of sulphuric acid. The product isolated from the reaction analyzed 9% CH_2O^{18}. Hydrolysis of chloromethyl acetate with H_2O^{18} gave polyoxymethylene, which contained only 2.7% CH_2O^{18}.

EXPERIMENTAL

Methyl-C^{13} Acetate

Silver acetate (21.0 g, 0.125 mole) was placed in a high-pressure glass tube which was constricted near the top to facilitate sealing later and attached to the vacuum line. The salt was dried at 80° for 4 hours by continuous pumping. Methyl-C^{13} iodide (14.3 g, 0.1 mole) containing 24% excess C^{13} was distilled into the tube of silver acetate, which was then sealed off at the constriction. The tube was heated in a rocking furnace for 24 hours at 90–100° C. It was then cooled in dry ice, opened, and attached to the vacuum line. Volatile products were distilled from the silver iodide into another trap on the vacuum line. Yield, 7.6 g (theoretical amount). Fractional distillation in a small column packed with glass helices gave 6.4 g of methyl-C^{13} acetate, b.p. 56.2–56.4° C. Yield, 84%.

Chloromethyl-C^{13} Acetate

Methyl-C^{13} acetate (6.4 g, 0.08 mole) and 0.15 g of dibenzoyl peroxide were placed in a small flask with a side arm carrying a separatory funnel. The neck of the flask was surmounted by a condenser and a spiral trap cooled to −78° in dry ice and acetone. A drying tube filled with Drierite was attached to the open end of the trap. Freshly distilled sulphuryl chloride (13 g, 0.1 mole) was added very slowly to the methyl-C^{13} acetate, which was heated just below its boiling point. The progress of the reaction was followed by observing the volume of liquid in the trap. It took 2 days to complete the reaction. When the reaction mixture is heated too rapidly free chlorine begins to appear in the trap. The rate of the reaction is considerably reduced by traces of methyl iodide, which acts as a peroxide inhibitor.

The reaction mixture was placed on the vacuum line, freed of dissolved hydrogen chloride and sulphur dioxide, and distilled into another trap on the line. The distillate obtained was fractionated in a column packed with glass helices to give 5.2 g of product, b.p. 114° C (70% of the theoretical amount).

Polyoxymethylene-C^{13}

Chloromethyl-C^{13} acetate (5.2 g, 0.05 mole) in 10 ml of benzene was added all at once to a mixture of 20 ml of benzene, 0.9 ml of water, and one drop of concentrated sulphuric acid in a 50-ml three-necked round-bottomed flask equipped with a thermometer, an inlet tube for passing in nitrogen, a stirring bar, and a reflux condenser. A Stock trap cooled to −78° in dry ice and acetone was connected to the condenser. The reaction mixture was gradually heated to 65–70° C while a slow current of nitrogen was passed through it. Rapid stirring is required to keep the water suspended in the benzene. After 7 hours' heating and stirring, white polymeric material began to appear on the wall of the condenser. After another 8 hours the flask was removed from the condenser and replaced by a plug. Liquid in the condenser was pumped away and the hard white solid scraped off. It was washed with a little absolute ether and dried. Yield, 0.3 g. By replacing the flask with the reaction mixture and resuming heating and stirring for another 10 hours, more polymer was obtained. The total yield of product isolated was finally 1.1 g (77% of the theoretical). This product melted at 169–171° C and analyzed 24% excess C^{13} by mass spectrometry. There was 1% of an unknown impurity of mass 61.

Polyoxymethylene-O^{18}

A mixture of 0.5 g of polyoxymethylene, 20 ml of benzene, 5.5 ml of water containing 20% excess O^{18}, and a drop of concentrated sulphuric acid was heated for 24 hours in a sealed tube at 80° C. The contents of the tube were then transferred to the apparatus

used to prepare the C^{13}-labelled compound and heated as described in that preparation. A small amount of polymer, m.p. 145–150° C, which contained 9.5% CH_2O^{18} was isolated.

Hydrolysis of chloromethyl acetate with H_2O^{18} and a trace of sulphuric acid under the conditions used to prepare polyoxymethylene-C^{13} gave a polymer which contained only 2.73% CH_2O^{18}. This is what would have been expected from our knowledge of the hydrolysis of esters in H_2O^{18}. The presence of the small amount of CH_2O^{18} is due to exchange.

ACKNOWLEDGMENT

We wish to thank Mrs. R. H. Riem for several mass spectrometric analyses of the polyoxymethylene.

INFLUENCE OF pH AND TEMPERATURE ON MYOSIN INACTIVATION[1]

GÉRARD E. PELLETIER[2] AND LUDOVIC OUELLET[3]

ABSTRACT

The inactivation of myosin adenosine triphosphatase activity was studied in 0.6 *M* potassium chloride solution at pH ranging from 7.0 to 10.6 and for 5° C to 40° C. The inactivation is a first-order process with respect to time and 0.6th order with respect to the concentration of protein. The rate of inactivation is independent of the pH for pH 7.0 to pH 8.5 at 35° C and increases rapidly with pH at higher pH. At 12° C, close to pH 10.4, the rate is inversely proportional to the 4.5th power of the hydrogen ion concentration. The energies of activation are 56 kcal mole^{-1} at pH 8.0 and 58 kcal mole^{-1} at pH 10.5. A discussion of the data stresses the importance of structural changes and indicates a possible role for the electrostatic charge in the inactivation process.

INTRODUCTION

The enzymatic activity of myosin, a muscular protein and an adenosine triphosphatase, increases with pH up to pH 9.3 at 25° C (1). The rapid decrease in activity at a higher pH was attributed by Blum (2) to enzyme inactivation. A maximum in enzymatic activity is not obtained. This work on myosin inactivation was necessitated to define the region of pH in which the kinetics of the adenosine triphosphatase activity of protein could be studied at different temperatures.

In a previous preliminary study (3), the inactivation was shown to be a first-order process with a high energy of activation. Adenosine triphosphate (ATP) decreases the rate of inactivation at pH 7.0. Mommaerts and Green (4) have reported on the stability of myosin on storage and noted that the myosin solutions are more stable at higher protein concentrations. The influence of calcium ions was also indicated. Poglasov and his collaborators (5) have suggested that heat denaturation occurs along with a decrease in the number of free sulphydryl groups. Yasui and his group (6, 7) have found that the rate of inactivation is pH independent from pH 5.7 to pH 8.9 and that the energy of activation is 57 kcal mole^{-1}. Protection by pyrophosphate was also reported by these authors.

EXPERIMENTAL

Reagents

Rabbit muscle myosin of the Weber-Edsall type (8) was used throughout these experiments. Protein concentrations were determined by a micro-Kjehldahl nitrogen determination method (9). The myosin had on the average a specific activity of 5.1×10^{-6} moles of ATP hydrolyzed per second per gram of protein, in 0.6 *M* potassium chloride,

[1]*Manuscript received October 24, 1960.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Ontario. Part of the work was done at l'Université Laval, Quebec, Que.

0.01 *M* calcium chloride, and 0.1 *M* THAM, at pH 7.5, at 25° C. Myosin preparations were stored in 0.6 *M* potassium chloride at 4° C and their activity was checked periodically.

The disodium salt of adenosine triphosphate (Pabst Laboratories, Milwaukee, Wisconsin) was used throughout these experiments.

Potassium chloride, sodium chloride, calcium chloride, trichloroacetic acid, potassium carbonate (anhydrous), and potassium bicarbonate were certified reagents. Tris(hydroxymethyl)aminomethane (THAM) was a purified reagent. Glycine and acetic acid were of the reagent grade. All solutions were made in glass-distilled water.

All reactions were carried out in buffered solutions containing 0.6 mole per liter of potassium chloride and 0.1 mole per liter of a suitable buffer. For pH values ranging from 7.5 to 9.0, a solution of THAM (pK_a 8.5 at 25° C) and acetic acid was used as buffer. Glycine (pK_a 10.3 at 0° C) – sodium hydroxide was used at higher pH's. These buffers were adjusted to the required pH at each temperature by addition of concentrated solutions of acetic acid or sodium hydroxide, pH values being read off a Beckman pH meter, model GS, equipped with shielded exterior electrodes (Beckman No. 1440). No salt-effect correction was applied.

Procedure

Activity Determination

The activity of the enzyme was determined by allowing a solution of myosin to catalyze the hydrolysis of ATP in the presence of 0.012 *M* calcium ions, the number of moles of inorganic phosphate produced per liter per second at pH 8.5 and 12° C taken as a measure of the enzyme activity. A 5-ml sample of a myosin solution whose activity was to be measured was pipetted into 20 ml of a THAM buffer containing 0.012 mole per liter of calcium chloride, incubated in a constant-temperature bath at 12° C and adjusted at pH 8.5. The resultant concentrations were such that the concentration of ATP was much greater than K_m, the Michaelis constant. The hydrolysis reaction was followed by pipetting at measured intervals of time 5-ml samples of the reaction mixture into 3 ml of a 20% solution of trichloroacetic acid, filtering the precipitated myosin, and determining phosphate concentrations in the filtrate by the Fiske and SubbaRow method (10) using a Beckman DU spectrophotometer. A plot of phosphate concentration against time gave a straight line, the slope of which was proportional to the activity of the enzyme.

Inactivation Rates

The inactivation of myosin was studied by incubating a solution of the enzyme in a buffer at the required temperature and pH and following its activity as a function of time. A flask containing 95 ml of a buffer, THAM or glycine, was placed in a constant-temperature bath and the pH of the solution was adjusted to the required value. Five milliliters of a stock solution of myosin was added and the resulting mixture thoroughly mixed by swirling of the flask. At measured intervals of time 5-ml samples were withdrawn and pipetted into a flask containing 20 ml of a THAM buffer at pH 8.5 and 12° C, and containing 0.012 mole of calcium chloride per liter.

The activity of each sample was then measured as described previously by reaction with ATP. Results presented later in the investigation show that under these conditions of pH and temperature no appreciable inactivation occurs. The above THAM buffer therefore served the dual purpose of stopping the inactivation rate and acting as a medium for activity determinations.

The logarithms of the myosin activity were then plotted against the time that the enzyme was exposed under the conditions of pH and temperature studied and the half-life was determined from these graphs. The inactivation rate constant (k_D) was calculated from the half-life of the enzyme.

RESULTS AND DISCUSSION

Order of the Reaction

As suggested by Letort (11) a distinction should be made for complex reactions between the order with respect to time and that with respect to concentration. This can readily be accomplished experimentally by applying van't Hoff's differential method to data for a single-rate determination to obtain the order with respect to time, and by applying the same method to the initial conditions of rate and concentration for a series of individual reactions to obtain the order with respect to concentration.

Figure 1 represents typical results obtained when the percentage of the initial myosin

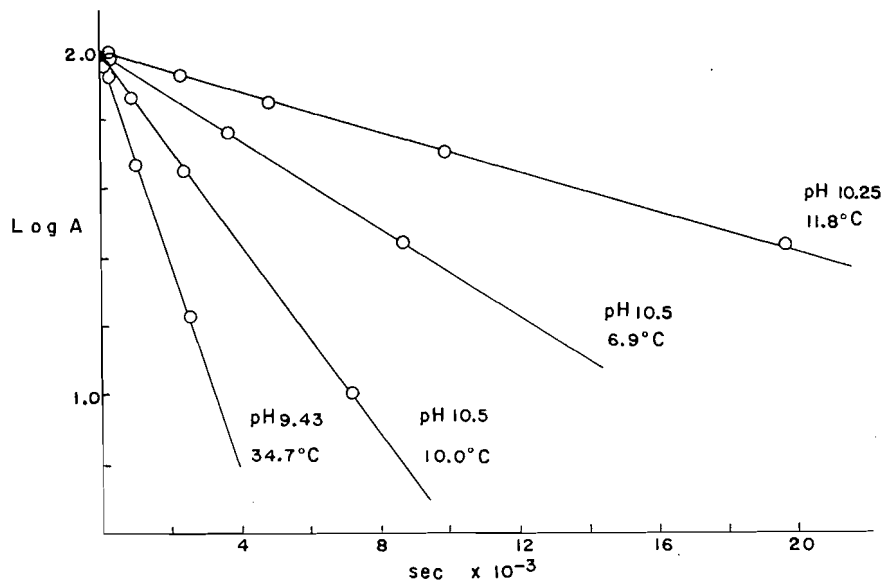

FIG. 1. Logarithms of the activity of myosin, in percentage of initial activity, as a function of time under different conditions.

activity, which is proportional to the percentage of the initial myosin concentration, was plotted against the time that the myosin was exposed to the indicated conditions of temperature and pH, at a protein concentration of 0.6 gram per liter. The straight lines obtained indicate adherence to first-order kinetics with respect to time. In some cases (e.g. curve *b*) reactions were followed to over 90% completion without departure from linearity in the log activity versus time plot. In similar experiments Yasui *et al.* (6, 7) have observed a drift towards second-order kinetics as the reaction proceeds. This difference in behavior could be attributed to slightly different myosin preparations or to the fact that Yasui *et al.* used a THAM–maleate buffer whereas we used a THAM–acetate buffer.

The order with respect to concentration is, however, more complex. Figure 2 shows the results obtained when the logarithms of the initial inactivation rates were plotted

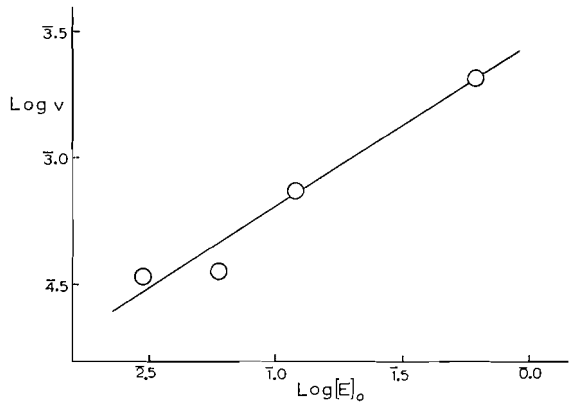

FIG. 2. Determination of the order of the inactivation reaction of myosin with respect to concentration; V is in arbitrary units and $[E]_0$, the initial concentration of myosin is in grams per liter.

against the logarithms of the initial concentrations for a series of inactivation reaction at pH 10.5 and 12.6° C over a 20-fold range of enzyme concentrations extending from 0.03 gram per liter to 0.6 gram per liter. The slope of the curve obtained is less than unity, giving a fractional order with respect to concentration, of about 0.6 to 0.7. Although most investigations on protein denaturation include only the order with respect to time, which is usually one, departure from first-order kinetics with respect to concentration (and even with respect to time) is not unfamiliar. Orders of less than one with respect to concentration have been reported in particular for the denaturation of tobacco mosaic virus (12) and potato β-amylase (13). Protection by a substance present in the protein preparation could explain the above behavior. Such a scheme has been proposed by Lauffer to explain his results on tobacco mosaic virus (12).

Influence of Calcium Chloride

In the presence of 0.005 M calcium chloride at 11.8° C at pH 10.5 the half-life of myosin was found to be 2.7×10^3 sec while it is 1.2×10^3 sec at the same protein concentration (0.6 gram per liter) under identical conditions in the absence of added calcium chloride. This would suggest an interaction between calcium ions and an area of the protein sensitive to inactivation.

Influence of pH

In common with other denaturation processes the rate of inactivation of myosin was found to be markedly dependent on the hydrogen ion concentration. Figure 3 shows the dependence of the logarithm of the first-order inactivation constant k_D of myosin on the pH of the solution at 34.7° C at a protein concentration of 0.6 gram per liter. As previously shown by Yasui (6, 7) the inactivation rate is practically independent of pH from pH 7.5 to pH 8.5. Above pH 8.5, however, the inactivation rate increases sharply with pH. Points on the curve between pH 9.2 and pH 9.64 give a straight line of slope 1.35. Above pH 10, myosin is inactivated so rapidly that rates are difficult to measure at 35° C. Accordingly, above this pH, inactivation was studied at a lower temperature. Figure 4 shows the results obtained at 11.8° C from pH 10.25 to pH 10.62. The slope of the curve obtained has a value of approximately 4.5.

For personal use only.

Influence of Temperature

The variation of the rate of inactivation of myosin with temperature follows the usual Arrhenius law. Figure 5 gives the usual plot of log k_D versus $1/T$. The energy of

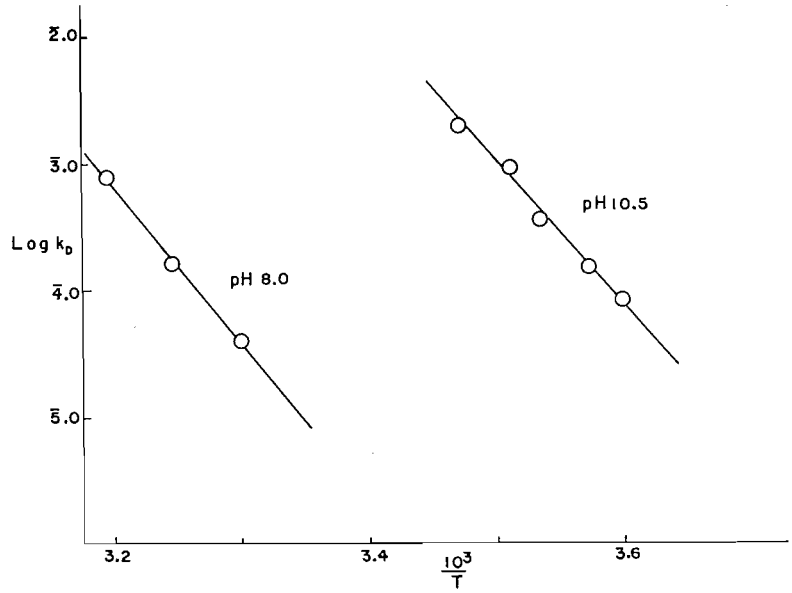

FIG. 5. Influence of temperature on the inactivation rate of myosin.

activation is 56 kcal mole^{-1} at pH 8.0 and 58 kcal mole^{-1} at pH 10.5. The data at pH 8.0 were obtained from 30 to 40° C and those at 10.5 from 5 to 15° C. Using the well-known Eyring's relation, the entropies of activation are calculated to be 107 cal deg^{-1} mole^{-1} at pH 8.0 and 137 cal deg^{-1} mole^{-1} at pH 10.5. These large energies and entropies of activation are normal for enzyme inactivation and protein denaturation. For myosin, Yasui *et al.* (7) have reported an energy of activation of 57 kcal mole^{-1} at pH 7.5, a value in line with ours.

The discussion of the effects of hydrogen ion concentration and temperature should refer to the classical work of Levy and Benaglia (14). The basic hypothesis is made that the protein exists in different ionic states, dependent on the pH, and that each species has a different inactivation rate constant.

The fact that the order increases monotonously at almost five with respect to hydroxyl ion concentration would indicate that the lowest pK of ionization is larger than 10. The fractional order would suggest that a plot of $1/k_D[H^+]^4$ vs. $[H^+]$ might yield the ionization constant. However, pH measurements are not accurate enough to justify such operations.

The energy of activation of 56 kcal mole^{-1} comes within 10 kcal of the accepted value (67 kcal) for the S—S bond (15). Although the idea of the breaking of a single bond to form the active complex is attractive, it is difficult to imagine that the breaking of a cystine bridge should involve such a large entropy change in the activated state. The breaking of several low-energy bonds, possibly accompanied by dehydration, might correspond to the structural changes usually mentioned in connection with this phenomenon. It would require, for example, the breaking of a large number of hydrogen bonds to lower the energy of activation to a reasonable value. These could be expressed as a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

series of equilibrium constants and would participate in the thermodynamics of formation of the activated complex as long as the concentration of the species is small compared with the total concentration of the enzyme. We believe that such structural changes are important in the case of myosin. This could be accompanied by considerable dehydration as advanced by Klotz (16).

At higher pH, the dependence of the rate on hydrogen ion concentration forces us to consider the proton dissociation. As the proteinic groups ionizing in alkaline solutions (SH, OH, phenol, NH_3^+) have heats of ionization from 6 to 13 kcal mole^{-1} (17), four to five of these could explain a major part if not all of the energy of activation of 58 kcal mole^{-1}.

A group with a pK of ionization higher than 10 has a standard free energy of ionization larger than 13 kcal mole^{-1}. This value, combined with the above heats of ionization, leads to a negative entropy of ionization, which is in line with the reported values (18, 19).

If the reference state for myosin is taken as the five times ionized species, rather than the non-ionized species, the energy of activation is drastically reduced but the entropy of activation is increased. A plausible interpretation would then involve structural changes possibly similar to those postulated at lower pH. Structural changes possibly pertaining to inactivation at high pH have been described by Blum (2).

It is also possible that the ionization of specific groups is less important than the charge on the enzyme. A comparison between the curve in Fig. 3 and the curve representing the charge on the protein as a function of pH, as published by Mihalyi (20), has led to the relation plotted in Fig. 6. The rather good straight line obtained when

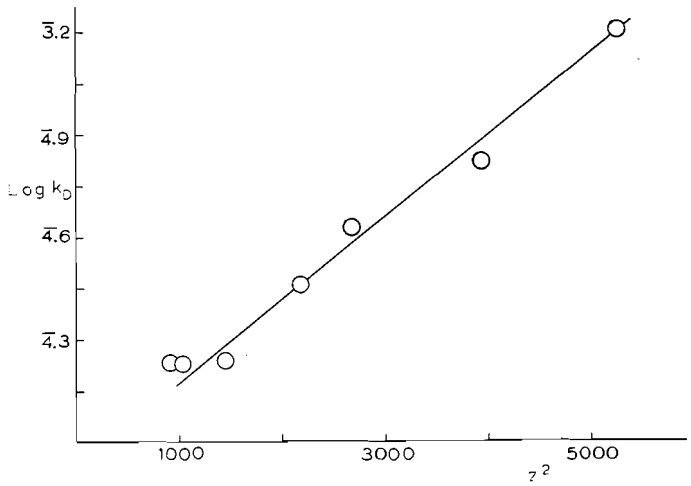

FIG. 6. Plot of log k_D as a function of the square of the charge on myosin, Z^2; k_D at 34.7° C (Fig. 4), Z is read off a figure representing titration data obtained by Mihalyi (20) at 38° C.

the logarithm of k_D is plotted against the square of the charge would indicate that the stability of the protein far from its isoionic point depends on its charge. Of course, the energy of activation should then be calculated for conditions involving the same charge on the protein molecule. With the present data, this is not possible.

CONCLUSION

As with all protein denaturation processes, the inactivation of myosin is complex and it is difficult to suggest a simple mechanism that would account for all the experimental

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

data. The order of the reaction with respect to concentration can be readily explained on the basis of protection but temperature and hydrogen ion concentration effects cannot be rationalized by a simple explanation. At low pH's where the rate is pH independent, it seems that structural changes and (or) dehydration are the main factors. At high pH's, however, dissociation most certainly occurs on inactivation. Dissociation in this region can account for the high energies of activation observed but cannot explain the high entropies of activation obtained. In fact, dissociation would most probably increase to a considerable extent the already high entropy terms. Considerable structural changes and (or) extensive dehydration of the protein would therefore seem to be required to account for the data. If the active center is a small area, the considerable amount of structural changes or the large amount of dehydration necessary to account for the thermodynamic values obtained suggest that the process measured in these experiments is not merely the inactivation of the active center but the denaturation of the protein as a whole, leading to a loss of enzymatic activity. The influence of pH could also be interpreted as a purely electrostatic effect.

With regards to the investigation on the influence of hydrogen ion concentration the following practical remarks can be made on the stability of myosin ATPase at high pH's. The data show that at pH 10.5 the half-life of myosin is approximately 42,000 seconds at 0° C, 8000 at 5° C, and 2000 seconds at 10° C. At pH 10.7 the pH dependence is such that these figures must be divided by a factor of 8. As a normal kinetic run for the measurement of the rate of hydrolysis of ATP takes about 200 seconds, data obtained above pH 10.7 would not be reliable except in the vicinity of 0° C. At pH 10.5, the upper limit of temperature would be 5° C, while that at pH 10.3, 10° C would be a maximum value. Above these limits, any decrease in activity could be attributed to enzyme inactivation unless there is a definite protection by the substrate.

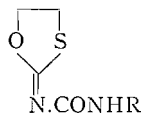
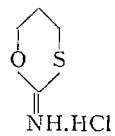
THE REARRANGEMENT OF 2-IMINO-1,3-OXATHIANE[1]

MARCEL MENARD, AVERIL M. WRIGLEY, AND FRANCIS L. CHUBB



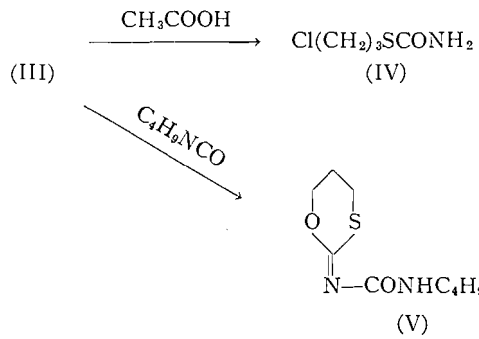
ABSTRACT

2-Imino-1,3-oxathiolane, in the free state, evolves cyanic acid spontaneously and gives rise to ethylene sulphide. This rearrangement is characteristic of all substituted 2-imino-1,3-oxathiolanes. It has now been found that rearrangement of the next higher homologue, 2-imino-1,3-oxathiane, does not give the anticipated trimethylene sulphide but only tris-3-mercaptopropyl cyanurate. The mechanism of this rearrangement is discussed.



Wagner-Jauregg and Haring (1) have reported the synthesis and reactions of a series of 2-imino-1,3-oxathiolane hydrochlorides (I) and N-carbamyl-2-imino-1,3-oxathiolanes (II). Several of the last-mentioned compounds possessed hypoglycemic activity. They also prepared 2-imino-1,3-oxathiane (III) by the action of thiocyanic acid on trimethylene oxide. The work herein reported, which describes the preparation of some new derivatives of III, was undertaken in the hope of obtaining some new hypoglycemic compounds.

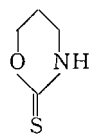
(I)



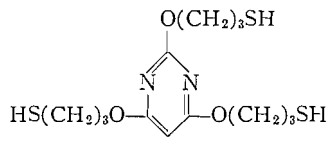
(II)

(III)

3-Hydroxypropyl thiocyanate was obtained in 55% yield from the corresponding chloroalcohol. Cyclization with hydrogen chloride in ether solution at 0° afforded a good yield of a water-soluble hydrochloride which was found to be identical with the 2-imino-1,3-oxathiane (III) described by Wagner-Jauregg and Haring. On standing, or upon heating for a few minutes with glacial acetic acid, III was transformed into a water-insoluble chlorine-containing compound. This rearrangement is similar to that of I which is rapidly converted to 2-chloroethylthiol carbamate in boiling acetic acid. The infrared spectrum and analytical data showed that this compound was the analogous 3-chloropropylthiol carbamate (IV). IV was also obtained by the action of hydrogen chloride on 3-hydroxypropyl thiocyanate at room temperature. The reaction of *n*-butyl isocyanate with III in aqueous dioxane yielded the expected N-(butylcarbamyl)-2-imino-1,3-oxathiane (V).



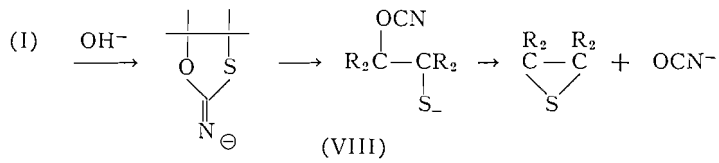
(V)



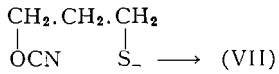
[1]*Manuscript received October 4, 1960.*
Contribution from the Department of Organic Chemical Research, Frank W. Horner Limited, Montreal, Que.

The reaction of III with potassium cyanate afforded none of the expected N-carbamyl derivative, analogous to II, but a crystalline compound having the same empirical formula as the free 2-imino-1,3-oxathiane. It was found that the compound was also obtained by the action of 1 mole of carbonate or hydroxide on III, which suggested that it was a rearrangement product. Infrared data showed the presence of the —SH, —C=N—, and —C—O—C— groups in the molecule. Of the possible rearrangement products tetrahydro-1,3-oxazine-2-thione (VI) seemed the most probable, since rearrangement of III to VI could be expected to take place through ring opening and recyclization (2). But synthesis of VI by two unequivocal methods (3, 4) gave a compound different from the rearrangement product. Acid or basic hydrolysis of the rearrangement product yielded cyanuric acid and in the case of acid hydrolysis, an elastic sulphur-containing polymer. An elastic polymer was again obtained when the rearrangement product was oxidized with hydrogen peroxide, indicating that more than one thiol group may have been present in the molecule.

Finally attempted desulphurization with lead nitrate was unsuccessful, but desulphurization with Raney nickel yielded a solid melting at 30–33°, which was shown to be tris-*n*-propyl cyanurate. This established the structure of the rearrangement product as tris-mercaptopropyl cyanurate (VII).



(VI)



(VII)

That 2-imino-1,3-oxathiolanes are intermediates in the conversion of ethylene oxides to episulphides has been shown by Van Tamelen (5) and Price and Kirk (6). The mechanism of the conversion of 2-imino-1,3-oxathiolanes to episulphides as proposed by Van Tamelen is shown below. The abnormal behavior of 2-imino-1,3-oxathiane, compared with the corresponding oxathiolanes, can be easily understood in terms of this mechanism. Once the ring has opened to form the mercaptoalkyl cyanate (VIII) two reactions are possible. Alkyl cyanates are unstable substances which normally trimerize to cyanurates. However, another competing reaction is the backside attack of the sulphur atom on the adjacent carbon to form an episulphide. In the case of the mercaptoethyl cyanate the trans conformation of the intermediate is energetically favored and steric conditions for the S_N2 displacement of the cyanate ion by sulphur are favorable. Hence formation of the episulphide is expected to predominate. This is in accord with the results of Van Tamelen (5) and Price and Kirk (6), who have isolated good yields of episulphides by the treatment of 2-imino-1,3-oxathiolanes with base. In the case of the mercaptopropyl intermediate (IX) the steric requirements for the formation of the four-membered sulphide ring are not so easily fulfilled as is shown by the slow rate of formation of trimethylene oxides as compared with ethylene oxides (7). The trimerization reaction might be expected to be faster in this case, and this is confirmed by formation of VII from III in 80% yield.

EXPERIMENTAL

Melting points are uncorrected. Microanalyses were performed by E. Thommen, Thannerstrasse 45, Basel, Switzerland.

3-Hydroxypropyl Thiocyanate

To a boiling solution of 130 g (1.3 moles) of potassium thiocyanate in 340 ml of 95% ethanol, 94.5 g (1 mole) of 3-chloropropanol was slowly added. After the mixture was stirred and refluxed for 4 hours it was allowed to stand overnight. Following the evaporation of about 250 ml of ethanol on the steam cone 500 ml of water was added and the solution was extracted with 3×150 ml ether. The combined organic layers were washed with water, dried, and concentrated. Distillation of the residue yielded 64.5 g (55%) of 3-hydroxypropyl thiocyanate, boiling at 140–150° under a pressure of 25 mm. No analysis is reported for this compound since it is unstable like the corresponding 2-hydroxyethyl thiocyanate (6).

2-Imino-1,3-oxathiane Hydrochloride

An excess of dry hydrogen chloride was passed through a solution of 41 g of 3-hydroxypropyl thiocyanate in 200 ml of anhydrous ether at 0° in an ice bath. After standing for 1 hour the crystalline hydrochloride was filtered and washed with ether. A yield of 47 g (87%), m.p. 88° (lit. m.p. 81.5–83°), was obtained.

3-Chloropropylthiol Carbamate

(a) From 3-hydroxypropyl thiocyanate.—An excess of dry hydrogen chloride was passed through 21 g of 3-hydroxypropyl thiocyanate at room temperature. The solid was broken up, suspended in ether, and treated again with dry hydrogen chloride. Filtration of the solid and recrystallization from water gave 19.2 g (70%) of colorless plates melting at 101–102°. Anal. Calculated for C_4H_8ONSCl: C, 31.27; H, 5.25; N, 9.12%. Found: C, 31.63; H, 5.26; N, 9.07, 9.27%. Infrared spectrum: maxima at 3580, 3475 cm^{-1} (N—H), and 1700, 1590 cm^{-1} (amide I and II).

(b) From 2-imino-1,3-oxathiane hydrochloride.—A mixture of 5 g of 2-imino-1,3-oxathiane hydrochloride and 25 ml of glacial acetic acid was stirred and heated on the steam bath for 1 hour. Water was added to the cooled solution and the crystalline thiolcarbamate was filtered and recrystallized from water to give 2.9 g (58%) of colorless plates melting at 101–102°, not depressed on admixture with a sample prepared according to (*a*).

N-(Butylcarbamyl)-2-imino-1,3-oxathiane

2-Imino-1,3-oxathiane hydrochloride (2 g) and butyl isocyanate (1.3 g) were slurried in 10 ml of dioxane. Anhydrous sodium carbonate (1 g) was added and the mixture was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

stirred and heated to 60° but with no reaction. After the addition of 10 ml of water, heat was evolved and an oil separated. Stirring was continued for 15 minutes, a further 20 ml of water was added, and the mixture was extracted with ether (3×10 ml). The combined organic layers were washed with water, dried, and concentrated. Repeated recrystallization of the residue from ethyl acetate – petroleum ether gave 1.7 g (60%) of a white powder melting at 91–92°. Anal. Calculated for $C_9H_{16}O_2N_2S$: C, 49.59; H, 7.46; N, 12.95%. Found: C, 49.96; H, 7.56; N, 13.80%.

Tris-3-mercaptopropyl Cyanurate

An aqueous solution of 1 equivalent of either potassium cyanate, potassium acetate, or sodium carbonate was added all at once to a freshly prepared solution of 1 equivalent of 2-imino-1,3-oxathiane hydrochloride in water. An exothermic reaction took place and a white precipitate soon appeared. After standing for 1 hour the solid was filtered and recrystallized from 95% ethanol to give a 75% yield of colorless needles melting at 97°. A slow titration of 2-imino-1,3-oxathiane hydrochloride in the cold with 1 *N* sodium hydroxide yielded the same compound. Anal. Calculated for $C_{12}H_{21}O_3N_3S_3$: C, 41.00; H, 6.02; N, 11.95%. Found: C, 40.93; H, 5.96; N, 11.90, 12.06%. Infrared spectrum: maxima at 2550 cm^{-1} (SH), 1580 (—C=N—), and 1145 cm^{-1} (—C—O—C—).

Hydrolysis of tris-3-Mercaptopropyl Cyanurate

(a) Alkaline.—The mercaptopropyl cyanurate (0.5 g) was refluxed for 2 hours with 20 ml of a 20% sodium hydroxide solution. On cooling a colorless solid was obtained which was filtered, washed with dilute hydrochloric acid, and recrystallized from water to give 0.15 g of cyanuric acid.

(b) Acidic.—The cyanurate (0.5 g) was refluxed for 2 hours with 20 ml of a 30% sulphuric acid solution. On cooling, colorless needles of cyanuric acid were obtained. A sulphur-containing polymer was formed on the wall of the condenser.

Desulphurization of tris-Mercaptopropyl Cyanurate

A mixture of 2 g of tris-mercaptopropyl cyanurate, 100 ml of 95% ethanol, and 15 g of Raney nickel was stirred and refluxed for 2 hours. Filtration of the catalyst, removal of the solvent, and distillation of the residue furnished 0.2 g (13%) of a colorless liquid, $b.p._{10}$ 180°, which solidified in ice to give colorless crystals melting at 30–33°. A mixed melting point determination and a comparison of infrared spectra have shown this compound to be identical with tris-*n*-propyl cyanurate (8).

Tetrahydro-1,3-oxazine-2-thione

(*a*) Carbon disulphide (20 ml) was added in small portions to a solution of 24.2 g of propanolamine in 50 ml of methanol cooled in an ice bath. With the temperature kept at 0°, a methanolic solution of iodine (15%) was added slowly from a burette until a faint permanent yellow color was obtained. The white solid, which had precipitated, was filtered, washed several times with methanol, and slurried in 150 ml of water. The slurry was then gradually heated to boiling over a period of 1 hour. The resulting solution was acidified with dilute sulphuric acid, cooled, filtered to remove suspended sulphur, saturated with sodium chloride, and extracted many times with small portions of ethyl acetate. Concentration of the ethyl acetate solution yielded 5 g (13%) of a white powder, m.p. 125–126°. Recrystallization of this solid from ethanol afforded 3.2 g of colorless needles melting at 125–126°. Anal. Calculated for C_4H_7ONS: C, 41.00; H, 6.02; N, 11.96; S, 27.37%. Found: C, 41.18; H, 6.07; N, 11.72; S, 27.00%.

(*b*) A solution of 12.3 g of propanolamine and 11 g of potassium hydroxide in 100 ml of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

water, kept at 0° in an ice bath, was stirred vigorously for 5 minutes with a solution of 13 g of carbon disulphide in 80 ml of dioxane; 5.5 g of potassium hydroxide in 100 ml of water was added followed by a solution of 55 g of lead nitrate in 300 ml of water. The suspension was stirred at 60° for ½ hour and the precipitated lead sulphide was filtered and washed with hot water. Concentration of the filtrates under reduced pressure left a dark residue which was extracted twice with 350 ml of boiling benzene. Evaporation of the benzene extracts afforded 13.2 g (70%) of crude product which, upon recrystallization from ethanol, yielded 11 g of colorless needles melting at 125–126° and giving no melting point depression with a sample prepared according to (*a*).

THE OXIDATION OF DI-*tertiary*-BUTYL PEROXIDE[1]

A. R. BLAKE[2] AND K. O. KUTSCHKE

ABSTRACT

The oxidation of di-*t*-butyl peroxide has been investigated in a static system at low conversion at 124° C with sufficient oxygen present to suppress completely the formation of methane and ethane. The decomposition of the *t*-butoxy radical is unaffected by the presence of oxygen. A major product of the oxidation is formaldehyde whose yield rapidly approaches a stationary value. It is postulated that the major source of formaldehyde is the decomposition of methyl peroxy radicals, which may also abstract hydrogen from formaldehyde to form methyl hydroperoxide, and that this competition leads to the stationary concentration of formaldehyde actually observed. Methyl hydroperoxide was demonstrated to be unstable in the system and the predominant decomposition product was methanol, a compound also found in high yields in the oxidation. Experiments with added formaldehyde-C^{13} showed that formaldehyde can be converted to carbon monoxide in the system and indicated that formaldehyde was a likely precursor to the carbon monoxide found in the oxidation.

INTRODUCTION

The pyrolysis of di-*t*-butyl peroxide (DTBP) provides a particularly convenient source of methyl radicals because of the high activation energy (1) required for the abstraction of hydrogen from that compound. Raley *et al.* (2) used this method to study the oxidation of methyl radicals but their reactions were carried to large conversions. The experiments reported by Bose (3) were also done at high conversion. The present study was undertaken to extend this work to lower (<5%) conversions and to investigate the effect of conversion on the rates of production of the major products. The role of formaldehyde as a hydrogen donor in the photooxidation of azomethane has been investigated previously in this laboratory (4, 5, 6). Experiments are reported in which formaldehyde-C^{13} was added to the reactants in the present system to investigate this point further.

EXPERIMENTAL

Most of the apparatus was the same as that described in a previous communication (1). A reaction was started by expanding a mixture of oxygen and DTBP from a preheater held at 80° C, where pressures could be measured on a quartz spiral gauge, to the Pyrex reaction vessel (volume, 550 ml) the temperature of which could be held to within 0.1° C.

Analyses were made for carbon monoxide, acetone, methanol, and formaldehyde; the yields of methane and ethane were vanishingly small. Formaldehyde, oxygen, and carbon monoxide were separated from the liquid products (acetone, methanol, and unreacted DTBP) by passage through a trap held at −130° C. Formaldehyde was condensed in a second trap at −196° C and the permanent gases were transferred to a tube containing a mixture of copper and cupric oxide where the carbon monoxide was oxidized at 270° C. The liquid products were analyzed by gas chromatography on a 10-ft column containing 25% dinonyl phthalate and 5% glycerol on Fisher Columpak (30–60 mesh). With a hydrogen flow rate of 45 ml/minute at 29° C appearance times of 28, 56, 77, and 121 minutes were observed for acetone, methanol, *t*-butanol (present as an impurity), and DTBP, respectively.

Considerable difficulty has been encountered in the past in the analysis of small amounts (less than 10 μmoles) of formaldehyde in the presence of large amounts (several hundred micromoles) of unchanged reactant. The analytical procedure used for this analysis will, therefore, be reported in some detail. Part of the analytical system is shown in Fig. 1.

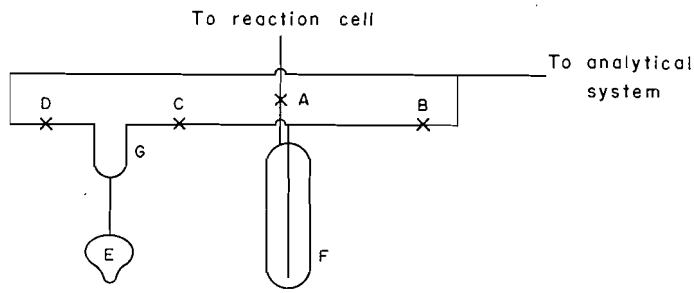

FIG. 1. Part of the apparatus used for the separation of formaldehyde. A, metal valve; B, C, and D, mercury cutoffs.

To stop a reaction, valve A (Hoke type 413 situated within the thermostat) was opened with B closed and D and C open. Liquid products were collected in trap F at $-130°$ C and formaldehyde was collected in the U-tube G at $-196°$ C. The permanent gases were transferred to the rest of the analytical system at this time. Liquid products were removed from F with C and D closed. All of the apparatus between A, B, and D was then heated to 150° C to volatilize any polymerized formaldehyde and the monomeric material was collected in bulb E at $-196°$ C which had been charged previously with 7.5 ml concentrated H_2SO_4 and 2 ml of chromotropic acid solution (7) (0.6 g disodium salt of chromotropic acid in 25 ml water). Bulb E was sealed off, heated for 30 minutes, and the colored solution which resulted diluted to 50 ml. The optical density of the solution at 570 mμ was measured and the formaldehyde yield estimated by comparison with a calibration curve.

DTBP was purified as described previously (1); a residual of about 0.1% *t*-butanol could not be removed. Oxygen was prepared by heating potassium permanganate *in vacuo*. Formaldehyde was obtained by heating α-polyoxymethylene containing 20.6% C^{13}; the polymer was provided by Dr. L. C. Leitch of these laboratories. A sample of methyl hydroperoxide was also supplied by Dr. Leitch.

RESULTS

Products of the oxidation of DTBP at 124° C are shown in Table I. Traces of isobutylene oxide were also formed and the presence of this compound hampered the mass spectrometric estimation of carbon dioxide since a cracking pattern for the former was not available. Consequently data for the yields of carbon dioxide are not recorded.

The formation of acetone was virtually unaffected by the addition of oxygen. Rate constants, k_1, for the pyrolysis of DTBP calculated from the acetone formed in the experiments in Table I are in excellent agreement with the value 0.105×10^{-4} sec^{-1} which had been obtained at the same temperature in the absence of oxygen (1).

The variation of the yields of the various products with time of reaction are shown in Fig. 2. The high yields of formaldehyde relative to those of methanol in the early stages

of the reaction are particularly striking; after 1000 seconds of reaction, $[CH_2O]/[CH_3OH] = 4$. As the reaction proceeds this ratio decreases markedly because of an increase in the rate of formation of methanol and a decrease in that of formaldehyde. It is evident that the yield of the latter approaches a stationary value at about 15 μmoles, which corresponds to 2.7×10^{-8} mole/ml. This point is emphasized by the single experiment at 34% conversion; if a carbon balance of 0.91 is assumed for that experiment, the formaldehyde yield corresponds to 3×10^{-8} mole/ml. In agreement with the data of Raley *et al.* (2),

the present results indicate that methanol and carbon monoxide are indeed the major products found in this system at high conversions.

Material balances based on acetone are also given in Table I. For the calculation of the carbon balance it was assumed that $CO_2/CO = 0.25$ as has been obtained recently in the photooxidation of azomethane (6). Uncertainties in this assumption will have only a small effect on the carbon balance. From the balances shown in Table I it would appear that all the major carbon-containing compounds were determined and that the only product likely to have been missed was, as indicated by the low hydrogen balance, water. No attempt was made to measure this product.

The addition of formaldehyde-C^{13} to the system caused a marked increase in the rate of formation of carbon monoxide in the early stages of the reaction. The enhanced rate was independent of time over the region studied and its value is similar to that approached by the rate of formation of carbon monoxide in the absence of added formaldehyde, Fig. 3. Mass spectrometric analysis of the carbon dioxide recovered from the copper/cupric oxide after oxidation of the carbon monoxide indicated enrichment in C^{13} (Table II).

DISCUSSION

The agreement between the rate constant for DTBP calculated from the rate of acetone formation in the presence of oxygen (Table I) and the known rate constant at the same temperature is strong evidence that the rate of formation of methyl radicals by [1] and [2] is unaffected by the presence of oxygen. Raley *et al.* came to the same conclusion (2).

$$(CH_3)_3COOC(CH_3)_3 \rightarrow 2(CH_3)_3CO \quad [1]$$

$$(CH_3)_3CO \rightarrow CH_3 + CH_3COCH_3 \quad [2]$$

The experiment of shortest duration in Table I indicates an enhanced rate of formation of acetone ($k_1 = 0.120 \times 10^{-4}$ sec^{-1}) at this conversion. This in turn suggests the possibility of radical attack on the peroxide followed by decomposition of the resulting free radical to *t*-butoxy radical and isobutylene oxide giving the elements of a chain reaction. Much more data is required at very low conversion before any definite conclusion can be drawn in this respect.

The material balances shown in Table I suggest that no important product containing carbon has been omitted in the analytical scheme. Carbon dioxide was not determined quantitatively but was identified by mass spectrometry and a rough estimate of its yield on this basis agreed with the ratio $CO/CO_2 \sim 4$ used in computing the material balance. The latter ratio was found in a recent reinvestigation of the photooxidation of azomethane (6), where it was proposed that these two products arise by a mechanism identical with that to be suggested below. The hydrogen balance indicates that relatively large quantities of hydrogen are unaccounted for; a relatively large yield of water, which was not estimated, could account for the decrement. Little can be said in this regard until reliable techniques are devised for the recovery of water from the system and for the determination of that compound in the mixture of liquid products.

It is important to note the trend with time (or conversion) of the yields of the various products. At very low conversions it would appear that formaldehyde is the only product; the hydrogen balance suggests that water is also formed in good yield. As formaldehyde builds up in the system carbon monoxide and methanol begin to appear. Even after 1000 seconds of reaction (about 1% conversion based on acetone formed) the ratio formaldehyde/methanol is as great as four. Thus one of the mechanisms suggested by Bell *et al.* (8) for the oxidation of methyl radicals, viz.,

$$CH_3 + O_2 \rightarrow CH_3O_2$$

$$2CH_3O_2 \rightarrow 2CH_3O + O_2$$

$$2CH_3O \rightarrow CH_3OH + CH_2O$$

cannot operate in the present system since it requires that the ratio formaldehyde/methanol be no greater than unity. If abstraction reactions of methoxy radicals leading to methanol are considered, the ratio is expected to be even less.

The association of methyl radicals with oxygen has been demonstrated to require a third body (9, 10, 11), and some evidence has been presented (10) which suggests that there are two modes of dissociation of the methyl peroxy radical formed initially.

$$CH_3 + O_2 \rightarrow CH_3O_2^* \quad [3]$$

$$CH_3O_2^* \rightarrow CH_3 + O_2 \quad [4]$$

$$CH_3O_2^* \rightarrow CH_2O + OH \quad [5]$$

$$CH_3O_2^* + M \rightarrow CH_3O_2 + M \quad [6]$$

Considering the relatively low total pressure used in these experiments it is not unreasonable to suggest that the present conditions would tend to favor [4] and [5] at the expense of [6]. This is especially so if it could be demonstrated that DTBP were not an efficient third body, M.

For these reasons it is proposed that reactions [1] to [5] describe the main features of the reaction in its early stages. Presumably the fate of hydroxyl radicals is reaction with DTBP to form water. The radical $CH_2(CH_3)_2COOC(CH_3)_3$ formed by that abstraction might decompose to isobutylene oxide and a *t*-butoxy radical so that, taken with [2], [3], and [5], the elements of a chain are present. It was pointed out above that the presence of a short chain in this region of conversion is not incompatible with the acetone yield observed.

As the reaction proceeds and formaldehyde accumulates in the system, reactions of methyl peroxy radicals with this substance become possible.

$$CH_3O_2^* + CH_2O \rightarrow CH_3O_2H + HCO \quad [7]$$

$$HCO + O_2 \rightarrow CO + HO_2 \quad [8]$$

$$\rightarrow CO_2 + OH \quad [9]$$

Reaction [7] inhibits the possible chain and its operation over a range of conversion will lead to the observed steady state in formaldehyde concentration and the formation of new products, methyl hydroperoxide and the oxides of carbon.

The former product has not been observed in the present system. However, it was demonstrated that a synthetic sample of methyl hydroperoxide (30 μmoles) introduced into the reaction vessel for 2000 seconds at 124° C was recorded by the analytical method as methanol along with small quantities of formaldehyde. Even when the sample was taken from the reaction cell to the mass spectrometer without an intervening chromatographic separation, no peak at *m/e* 48, which was prominent from the original material, was observed. It is not clear whether the decomposition was homogeneous, was catalyzed by the metal and glass surfaces, or was induced by mercury vapor. The observation is similar to that made by Cvetanović *et al.* (12, 13), who observed that ethyl hydroperoxide, after being mixed with liquid mercury, was converted, almost quantitatively, to ethanol, with only small amounts of acetaldehyde being formed. It is not in harmony with the observations of Hanst and Calvert (14), who found methyl hydroperoxide to be stable up to 200° C in their system.

Therefore it is proposed that reaction [7] is an important fate of the methyl peroxy radical formed in [6]. This should not be taken to imply that the radical must in all systems be in a vibrationally excited form, as the asterisk indicates, in order to undergo reaction [7]. As discussed above, however, it is felt that, in this system, a large fraction of these radicals are indeed in a high vibrational level.

The experiments with added formaldehyde-C^{13} were devised to test the suggestion that formaldehyde could act as the precursor to carbon monoxide in this system. Since the amount of formaldehyde added approximated closely to the steady-state concentration of that product, it was expected that the rate of formation of carbon monoxide should also be nearly that corresponding to the later stages of the reaction in the absence of added formaldehyde. The yields of carbon monoxide shown in Table II and Fig. 3 are fully in agreement with that prediction. The isotopic composition of the carbon monoxide (Table II) also shows that formaldehyde is an efficient source of carbon monoxide in this system. A similar conclusion was reached by an application of the same technique to the photooxidation of azomethane (6).

One further point should be mentioned. The mechanism proposed, if complete, requires that $[CH_3O_2H(=CH_3OH)]-[CO]-[CO_2]$ vanish for all conditions. Figure 2 shows that the data are not quite in agreement with this prediction since the function shows a slow but steady rise with conversion. This can be explained if it is assumed that, as it becomes more concentrated in the system, acetone can compete with formaldehyde in a reaction analogous to [7]. The data for the experiment of greatest duration also suggest that acetone is not completely inert in the system as indicated by the very low value of k_1 calculated from the acetone yield. Depletion of DTBP at this long time is not sufficient to account for the low yield of acetone in this experiment.

ACKNOWLEDGMENTS

The authors wish to thank Dr. E. W. R. Steacie for his continued interest in this work, Dr. M. Shahin for many helpful discussions, and Mrs. R. H. Riem for the mass spectrometric analyses.

RATES OF DECARBOXYLATION OF SUBSTITUTED ANTHRANILIC ACIDS IN NITROBENZENE SOLUTION[1]

G. E. Dunn and Russell Prysiazniuk

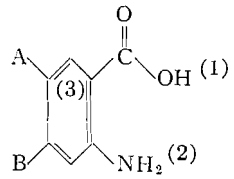
ABSTRACT

The synthesis of a series of meta- and para-substituted anthranilic acids is reported with their rates of decarboxylation in nitrobenzene solution at 210.5° C. The reaction is second order with respect to anthranilic acid. The rate is increased by electron-releasing substituents and decreased by deuterium in the functional groups. The relative rates are interpreted by means of the Hammett equation and its extensions and it is concluded that the rate-determining step involves attack by proton from one anthranilic acid molecule on carbon 1 of a second molecule.

Previous investigations of anthranilic acid decarboxylation have shown that the reaction is first order in boiling aqueous solution but catalyzed by mineral acids (1, 2). The aqueous-acid-catalyzed reaction was considered to involve attack by a proton from the mineral acid on carbon 1 of the aromatic ring (2) and therefore to belong to the class of S_E2 aromatic displacement reactions (3). Decarboxylation in the melt, however, must involve shift of a proton to the ring from one of the functional groups of anthranilic acid itself. Several possibilities for such a proton transfer are available: it may occur in the neutral acid or the zwitterion, it may involve the carboxyl group or the amino group, and it may be intermolecular or intramolecular. The present investigation is an attempt to decide among these various possibilities.

In order to determine whether the reaction is intermolecular or intramolecular it is desirable to know the order of the reaction. In the melt the reaction has been reported to be first order (2, 4) but this is not very informative since the composition of the reaction mixture changes during the decarboxylation from pure anthranilic acid to pure aniline. Since aniline could serve as proton donor it might take over the role of a second molecule of anthranilic acid in an intermolecular reaction. An aprotic solvent would be preferable and it must be a high-boiling one since the temperature required for thermal decarboxylation is around 200° C. We have had some success with 1-methylnaphthalene as solvent but nitrobenzene proved to be more satisfactory since it is a better solvent for acids. In both these solvents the reaction is second order with respect to anthranilic acid and the reaction is therefore probably intermolecular.

In an intermolecular reaction there are several possibilities for the rate-determining step. It may involve (*a*) hydrogen–oxygen bond breaking, (*b*) hydrogen–nitrogen bond breaking, (*c*) hydrogen–carbon bond making, or (*d*) carbon–carbon bond breaking. Stevens, Pepper, and Lounsbury have eliminated possibility (*d*) by showing that there is no carbon isotope effect in the decarboxylation of anthranilic acid either in aqueous solution or in the melt (2). The three remaining possibilities may be distinguished by the site of the rate-determining step: in (*a*) it is the carboxyl group, in (*b*) it is the amino group, and in (*c*) it is carbon 1 of the ring. We have attempted to decide among the possibilities by application of the Hammett equation to the rates of decarboxylation of substituted anthranilic acids.



[1]*Manuscript received September 26, 1960.*
Contribution from the Chemistry Department of the University of Manitoba, Winnipeg, Manitoba. Presented in part, at the 42nd annual conference of the Canadian Institute of Chemistry, Halifax, May 1, 1959.

Hammett has shown (5) that the effect of substituents on the reactivity of a side chain in *m*- and *p*-substituted benzene derivatives can be expressed by the equation

$$\log k/k_0 = \rho\sigma$$

where k and k_0 are the rates or equilibrium constants for the reactions of the substituted and unsubstituted derivatives, respectively, ρ is a constant characteristic of the reaction, and σ is a constant characteristic of the substituent. The treatment has been extended by Brown and co-workers (6) to cover electrophilic aromatic substitution, in which the reaction site is on the ring instead of the side chain, by means of a new set of constants, σ^+. In a molecule where there are two or more possible reaction sites a substituent which is meta to one site may be para to the other so that its influence on the reactivity of the molecule will be different depending on the location of the reaction site. Jaffe has shown (7, 8) that in favorable circumstances this difference can be used to determine the location of the reaction site.

In anthranilic acid the three likely reaction sites may be numbered as shown below.

The influence of a substituent at A or B on reactivity at sites 1, 2, and 3 will be given by equations 1, 2, and 3, respectively,

[1] site 1: $\log k/k_0 = \rho_1\sigma_1$

[2] site 2: $\log k/k_0 = \rho_2\sigma_2$

[3] site 3: $\log k/k_0 = \rho_3\sigma_3$

where σ_1 is Hammett's σ for carboxylic acid reactions, σ_2 is Hammett's σ for amines and phenols, and σ_3 is Brown's σ^+. Of course, any two or all three reaction sites may be involved in the rate-determining step and the most general case is represented by equation 4,

[4] all sites: $\log k/k_0 = \rho_1\sigma_1+\rho_2\sigma_2+\rho_3\sigma_3$.

The nature of the reaction site may then be determined by finding which of equations 1–4 best fits the rates of decarboxylation of a series of substituted anthranilic acids. It should be noted that σ_1 differs most from σ_2 for substituents capable of strong mesomeric electron withdrawal while σ_1 differs most from σ_3 for substituents capable of strong mesomeric electron release. Therefore, substituents of both these types should be included in the series.

EXPERIMENTAL

Nitrobenzene and 1-methylnaphthalene were commercial products. They were fractionated through a 14-in. Vigreaux column, collecting the fractions boiling at 210–210.5° C at 745 mm and 240–241° C at 744 mm, respectively, and stored over anhydrous sodium sulphate and sodium wire, respectively. Anthranilic, 5-chloroanthranilic, N-methylanthranilic, N-phenylanthranilic, and *p*-aminobenzoic acids were commercial products recrystallized to constant melting point. The remaining acids were synthesized as de-

scribed below. Melting points were determined with a Hershberg melting point apparatus (9) using Anschütz thermometers calibrated against a U.S. Bureau of Standards platinum resistance thermometer.

4-Bromoanthranilic Acid

o-Acetotoluidide was prepared by the method of Berkenheim and Livshits (10). *o*-Toluidine, 100 ml (0.93 mole), was refluxed with 102 ml of acetic anhydride (1.00 mole) in 200 ml of benzene for 1 hour. The benzene was distilled off and the residue was poured over ice. The crude product was recrystallized from benzene and 106 g of *o*-acetotoluidide (70% yield), m.p. 110–111° C, was obtained.

o-Acetotoluidide was brominated by an adaptation of the method of Wheeler (11). Thirty grams of *o*-acetotoluidide (0.20 mole) in 300 ml of glacial acetic acid at 15–16° C was treated with 10.5 ml of bromine (0.20 mole). After 1 hour the solution was poured into cold water and the hydrobromide was collected.

The salt was decomposed by boiling in 1 liter of water for 1 hour. The hot filtrate yielded most of the product and repeated extraction of the residue yielded the balance. Thirty-seven grams (84% yield) of 2-methyl-5-bromoacetanilide, m.p. 158–159° C, was obtained.

This material was oxidized by the method of Justoni, Ternizzi, and Pirola (12). Seven grams of 2-methyl-5-bromoacetanilide (0.030 mole) was suspended in 3.5 liters of water at 85° C and 10 g of magnesium sulphate and 15 g of potassium permanganate were added. The solution was allowed to remain at 80° C overnight. After being cooled, the manganese dioxide was filtered out and the product was precipitated by acidification with hydrochloric acid. Recrystallization from hot water gave 5.5 g 4-bromoacetoanthranilic acid (65% yield), m.p. 214–215° C. Hydrolysis of this acetyl derivative was accomplished by boiling 5.5 g (0.022 mole) with 50 ml of 1:1 sulphuric acid for 1 hour. Diluting and neutralizing the solution gave 4 g of 4-bromoanthranilic acid, m.p. 217–218° C, after two recrystallizations from dilute ethanol.

5-Bromoanthranilic Acid

This compound was prepared by brominating anthranilic acid by Wheeler's method (11) as described above for *o*-acetotoluidide. A 65% yield of 5-bromoanthranilic acid, m.p. 215–217° C, was obtained after two recrystallizations from dilute ethanol.

4-Nitroanthranilic Acid

This compound was prepared by the method of Hillers, Lokenbacks, and Majs (13). Sixty grams of *o*-acetotoluidide dissolved in 400 ml of concentrated sulphuric acid was nitrated for 4 hours at −5° C with 40 ml of concentrated nitric acid in 120 ml of concentrated sulphuric acid. The acid solution when poured over ice yielded 35 g (45%) of 2-methyl-5-nitroacetanilide, m.p. 135–140° C. Several crystallizations from hot water raised the melting point to 149–150° C. The purified product was oxidized by treating 10 g (0.051 mole) in 3 liters of water at 95° C with 25 g of potassium permanganate and 12 g magnesium sulphate and allowing the solution to stand at about 90° C overnight. Seven grams of the corresponding acid was obtained (61% yield) with a melting point of 215–216° C after recrystallization from water. Heating 10 g (0.044 mole) of this material in 30 ml of alcohol and 120 ml of concentrated hydrochloric acid for 2 hours gave 7.5 g (90% yield) of 4-nitroanthranilic acid. After several recrystallizations from water it melted at 262–264° C with decomposition. 4-Nitroanthranilic acid with identical properties was also prepared from 2-methyl-5-nitroaniline as described below for 5-nitroanthranilic acid.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

5-Nitroanthranilic Acid

This compound was prepared by a modification of the method of Iguchi (14). Fifty grams of 2-methyl-4-nitroaniline (0.33 mole) was acetylated by refluxing with 138 g of acetic anhydride (1.35 mole) for 2 hours. Excess acetic anhydride was destroyed by boiling the solution with water whereupon 44 g (70% yield) of 2-methyl-4-nitroacetanilide, m.p. 198–200° C, precipitated. This was oxidized and hydrolyzed as described under 4-nitroanthranilic acid, to give 5-nitroanthranilic acid, m.p. 268–269° C with decomposition.

4-Chloroanthranilic Acid

A modification of the method of Cohn (15) was used. 2-Methyl-5-chloroaniline was acetylated by dissolving 2.5 g (0.18 mole) in 100 ml of boiling glacial acetic acid, adding 75 ml of acetic anhydride (0.67 mole), and refluxing for 15 minutes. A yield of 27 g (91%) of 2-methyl-5-chloroacetanilide, m.p. 131–132° C, was obtained on diluting the solution with water. This was oxidized and hydrolyzed as described above to give 4-chloroanthranilic acid, m.p. 234–235° C, after recrystallization from dilute alcohol.

5-Methylanthranilic Acid

m-Toluic acid was nitrated by the method of Giacolone and Russo (16). Twenty grams of potassium nitrate (0.20 mole) in 120 ml of concentrated sulphuric acid was added cautiously to 20 g of *m*-toluic acid dissolved in 120 ml of concentrated sulphuric acid at 0° C. The mixture was poured on ice and a mixture of 2-nitro-3-methylbenzoic acid and 2-nitro-5-methylbenzoic acid precipitated. The latter was extracted from the mixture with hot water, yielding 13 g (36%) of 2-nitro-5-methylbenzoic acid, m.p. 131–132° C. This nitro acid was reduced by the method of Wheeler and Hoffman (17). Four grams (0.022 mole) was dissolved in 100 ml of concentrated ammonium hydroxide and 50 g of ferrous sulphate heptahydrate (0.17 mole) in 200 ml of water was added. The solution was brought to a boil and after it was cooled the inorganic salts were filtered out. Acidification and cooling the solution yielded 3 g of 5-methylanthranilic acid (90% yield). It melted at 175–177° C after recrystallization from dilute alcohol.

4-Aminoanthranilic Acid

This compound was prepared by reduction of 4-nitroanthranilic acid by the method of Wheeler and Hoffman (17) described above. It gave a 40% yield of 4-aminoanthranilic acid, m.p. 134–136° C, after recrystallization from dilute alcohol.

N-Acetylanthranilic Acid

This compound, m.p. 184–185° C, was prepared in 80% yield by acetylation of anthranilic acid in boiling acetic anhydride.

Anthranilic Acid-$^2H_3$

Anthranilic acid, 23 g, was exchanged four times with heavy water by dissolving it in 54 ml of purified dioxane and 5 g of deuterium oxide. The solvents were removed under reduced pressure and the acid was dried at 85° C in a vacuum oven at 15-mm pressure. This material analyzed 78.5±.08 at. % anthranilic acid-$^2H_3$ by the method previously described (18).

Rate Measurements

The rates of decarboxylation were measured by absorption of the evolved carbon dioxide on ascarite which was weighed at regular intervals. The apparatus is shown in Fig. 1. The thermostat was a 1-liter two-necked flask heated by an electric mantle. In

this flask diphenyl ether was refluxed so that the vapors bathed the reaction vessel (*a*) which was a 25-ml test-tube-shaped vessel made from a 34/45 standard taper male joint. A gas inlet tube (*b*) extended to the bottom of the reaction vessel and a stream of dry carbon-dioxide-free nitrogen passing through this tube swept the evolved carbon dioxide through a condenser (*c*), an *n*-butyl phthalate bubbler (*d*), a sulphuric acid bubbler (*e*), a U tube of anhydrous calcium sulphate (*f*), into the ascarite weighing bottle (*h*) which was protected from the atmosphere by a tube (*i*) containing calcium sulphate and ascarite. A second ascarite weighing bottle could be interchanged with (*h*) by means of the three-way stopcock (*g*).

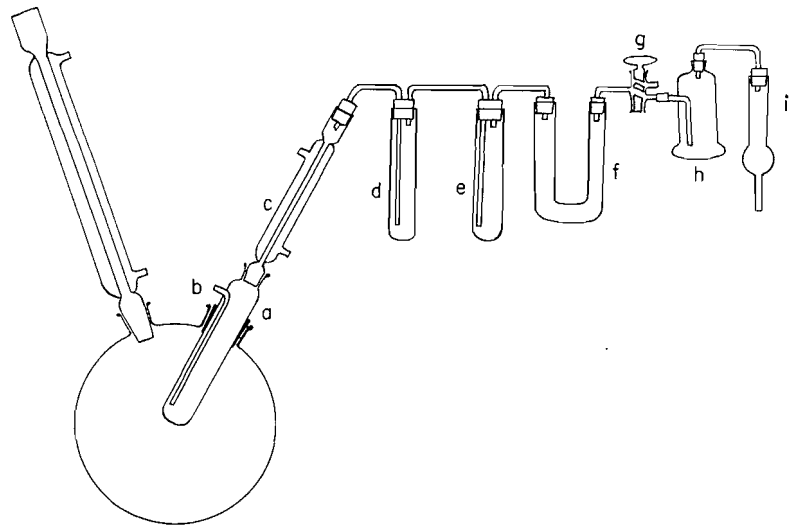

FIG. 1. Apparatus for decarboxylation.

About 10 ml of nitrobenzene was placed in the reaction vessel and the nitrogen flow was adjusted to a suitable rate. Since diphenyl ether has a higher boiling point (259° C) than nitrobenzene (210.5° C) or 1-methylnaphthalene (242° C) the solvent boiled gently in the reaction vessel. Attempts to operate at thermostat temperatures below the boiling point of the solvent gave poor temperature control because the sweeping nitrogen cools the solvent and fluctuations in its rate of flow cause temperature fluctuations and difficulty in reproducing temperatures between runs. An iron–constantan thermocouple introduced into the reaction vessel through the condenser showed that temperature variations during a run in refluxing solvent did not exceed 0.2° C. Temperature variation between runs varied as much as 0.5° C because of different solute concentrations and the high boiling-point-elevation constant of nitrobenzene. When the system had come to equilibrium a pellet of about 0.4 g of the acid to be decarboxylated was dropped into the reaction vessel. The refluxing solvent dissolved it quickly and the evolved carbon dioxide was weighed in the ascarite weighing bottles at intervals.

Rate constants were calculated from the slopes of plots of $1/(a-x)$ against time, where $a-x$ = initial moles of anthranilic acid less moles of carbon dioxide at time t all divided by the volume of the solution corrected to 210.5° C by means of the coefficient of cubic expansion of nitrobenzene. Data from a typical run are shown in Fig. 2. Rate constants for the various anthranilic acids in nitrobenzene are shown in Table I and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

those for the three acids which could be dissolved in 1-methylnaphthalene are shown in Table II. The rates for 4-aminoanthranilic acid were so large that enough points for a plot could not be obtained so the rate was calculated from the observed half lives in seven runs. The variation of the observed half lives for this acid and anthranilic acid itself confirm the second order shown in Fig. 2.

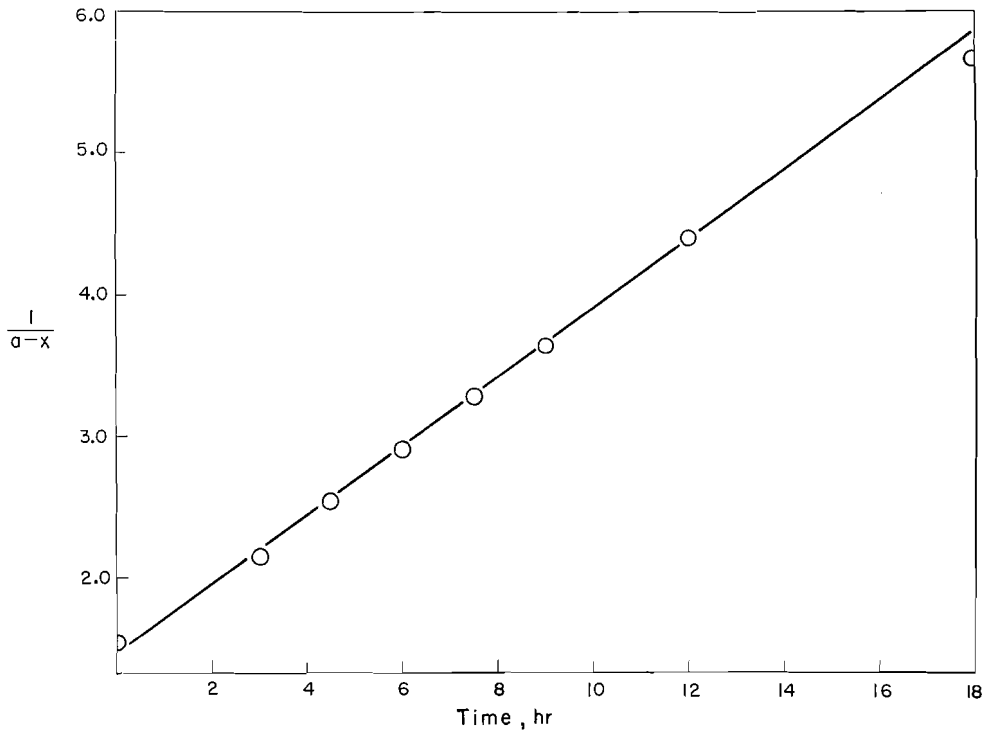

FIG. 2. Anthranilic acid in nitrobenzene at 210.5° C.

In order to obtain the rate constant for pure anthranilic acid-$^2H_3$ from the apparent constant for partly deuterated anthranilic acid the following calculations were made:

$$\frac{d[CO_2]}{dt} = k'([A_H]+[A_D])^2$$

where A_H = anthranilic acid, A_D = anthranilic acid-$^2H_3$, and k' is the apparent rate constant for partially deuterated acid. The apparent rate can also be written

$$\frac{d[CO_2]}{dt} = k_H[A_H]^2+k_H[A_H][A_D]+k_D[A_H][A_D]+k_D[A_D]^2$$

so that

$$k'([A_H]+[A_D])^2 = ([A_H]+[A_D])(k_H[A_H]+k_D[A_D])$$

and

$$k'([A_H]+[A_D]) = k_H[A_H]+k_D[A_D].$$

Substituting $k_H = (6.17\pm.17)\times10^{-5}$, $k' = (3.14\pm.22)\times10^{-5}$, $[A_H] = 0.215\pm.001$, and $[A_D] = 0.785\pm.001$ gives $k_D = (2.32\pm.34)\times10^{-5}$. This makes the isotope effect, $k_H/k_D = 2.66\pm.46$.

DISCUSSION

The data of Fig. 2 and Tables I, II, and III show that the decarboxylation of anthranilic acids is second order with respect to the acid in both nitrobenzene and 1-methylnapththalene. The second-order kinetics shows that there are two molecules of anthranilic acid in the transition state or some step preceding it and so suggests that the proton transfer is intermolecular. It is possible that anthranilic acid forms a dimer in solution and that proton transfer could be intramolecular within this dimer, although extensive dimerization in boiling nitrobenzene seems unlikely.

Rates were measured in boiling solutions so that rates in the two solvents are not directly comparable. In 1-methylnaphthalene at 242° C the rate is about 2.5 times that in nitrobenzene at 210° C so that rates in the two solvents at the same temperature can not be very different. Since nitrobenzene is a considerably more polar solvent than 1-methylnaphthalene (ϵ_{25} = 35 and 2.7 respectively) the small difference in rates suggests that the polarity of the transition state is not greatly different from that of the reactant.

Anthranilic acid is seen to decarboxylate 2 to 3 times faster than functionally deuterated anthranilic acid so that proton transfer must be involved in the rate-determining step or some step preceding it. It is obvious from Table I that electron-releasing groups accelerate the decarboxylation and this must account for the fact that anthranilic and *p*-aminobenzoic acids decarboxylate while benzoic acid does not. The increased rates with N-methyl- and N-phenyl-anthranilic acids and the decreased rate with N-acetylanthranilic acids are in agreement with this interpretation of the role of the *o*-amino group. These observations show that decarboxylation must take place from the neutral acid rather than the zwitterion since protonation of the amino group would destroy its electron-releasing properties. If reaction takes place from the neutral molecule, proton donation must come from the carboxyl group and electron-releasing substituents should hinder, not help, the donation. This rules out site 1 as the only reaction center but leaves the possibility that more than one site is involved in the transition state, with the substituent effect at site 1 outweighed by that at the others.

In Figs. 3, 4, and 5 the data of Table I are plotted according to equations 1, 2, and 3, respectively. It is seen that the fit to a single straight line is not good in any of the three. Table III shows the results of a standard statistical analysis (19), of the fit of the data to a linear equation $Y = a+bX$, where $Y = \log k/k_0$, $X = \sigma$, $b = \rho$, s_E is the standard error in the estimate of Y, s_b is the standard error in b, r is the linear correlation coefficient in equations 1–3 or the multiple correlation coefficient in equation 4, and F is the variance ratio (19). Comparison of columns b and s_b show that equations 1 and 3 fit the data much better than 2 and 4. Column F makes the comparison quantitative, and shows (19) b ($= \rho$) different from zero at the 99% confidence level for equations 1 and 3, at the 95% confidence level for equation 2, and at no significant level for equation 4. Evidently site 1 or site 3 is of predominant importance in the transition state and the negative sign of ρ requires that it be site 3, as has been indicated previously. Jaffe has shown (8) that in order to distinguish between one site or two by means of substituent effects it is necessary that the σ's for the substituents referred to the two sites have a correlation coefficient less than 0.9. The substituents used in the present investigation have the following correlation coefficients: $r_{12} = 0.817, r_{23} = 0.702, r_{13} = 0.974$. Evidently the Jaffe treatment of our data can rule out participation by site 2 in the transition state, but not joint participation by sites 1 and 3. The conclusion is, then, that site 3 is of predominant importance in the transition state with less important contributions from site 1.

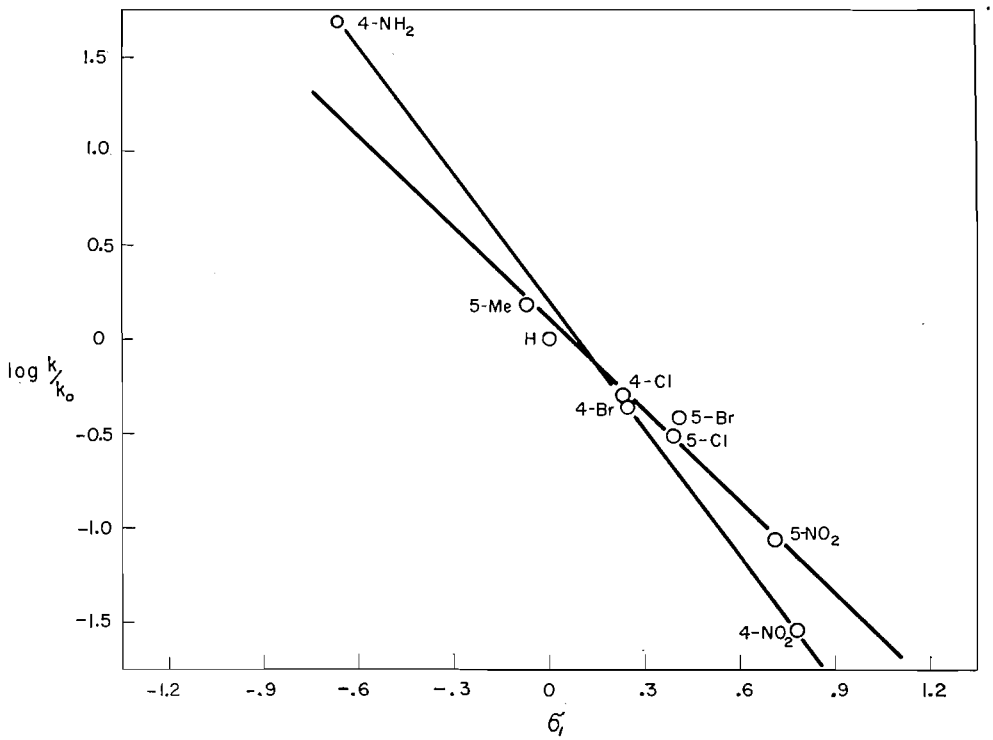

FIG. 3. Equations 1, 5, and 6.

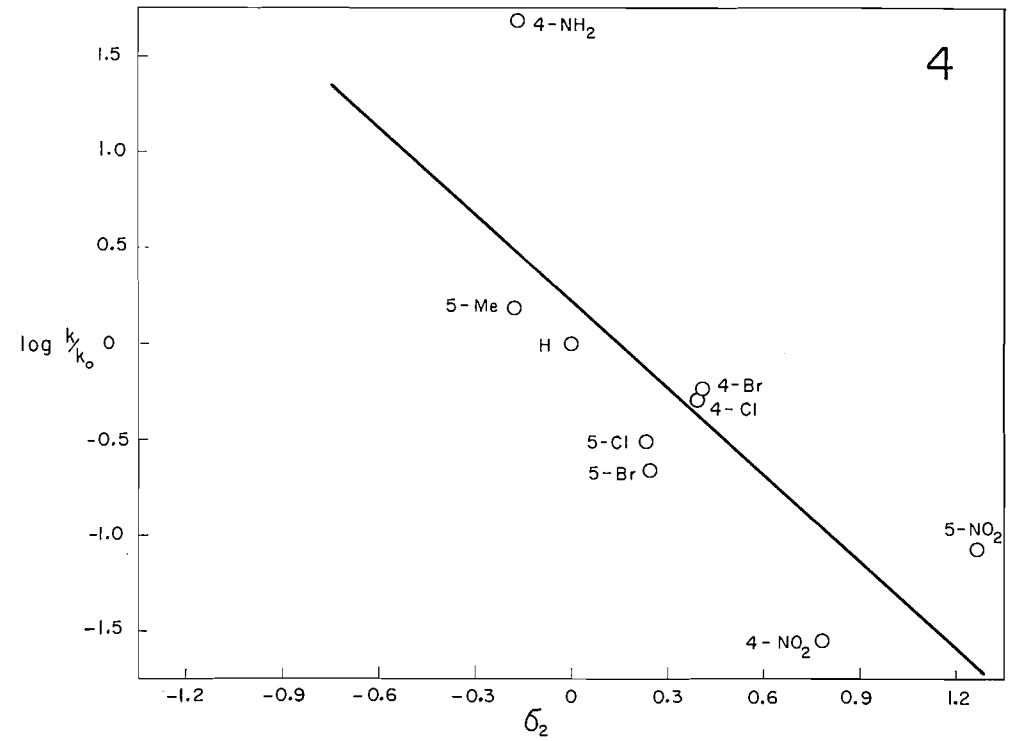
TABLE III

Relationship between rates and substituents constants



Equation	a	b	s_b	s_E	r	F
1	0.191	−2.04	0.134	0.163	0.985	23.9
2	0.221	−1.50	0.488	0.628	0.759	9.5
3	−0.070	−1.45	0.109	0.189	0.985	23.7
4	0.023	−1.45 (b_1)	1.166	0.177	0.988	1.6
		−0.08 (b_2)	0.353			
		−0.48 (b_3)	0.672			
5	0.195	−2.26	0.035	0.036	0.999	1500
6	0.110	−1.60	0.143	0.079	0.986	141

Although the data do not fit any of the four equations well, it is remarkable that in Fig. 1 the points for 4-substituents fall on one line and those for 5-substituents fall on another. The line for 4-substituents is represented by equation 5 and that for 5-substituents by equation 6 in Table III and it is seen that the fit to the separate equations is much better than to any one of the preceding four equations. It will be noted that ρ_4 (b, equation 5, Table III) is numerically larger than ρ_5 (b, equation 6, Table III) which suggests that in anthranilic acid decarboxylation the electron density at the reaction site is more sensitive to resonance effects from substituents than it is in ionization of benzoic acid, the standard reaction from which Hammett's σ's are determined. This agrees with site 3 as the principal reaction center since site 1 is equivalent to that in the standard reaction.

Similar splits between meta and para substituent effects are well known in the reactions

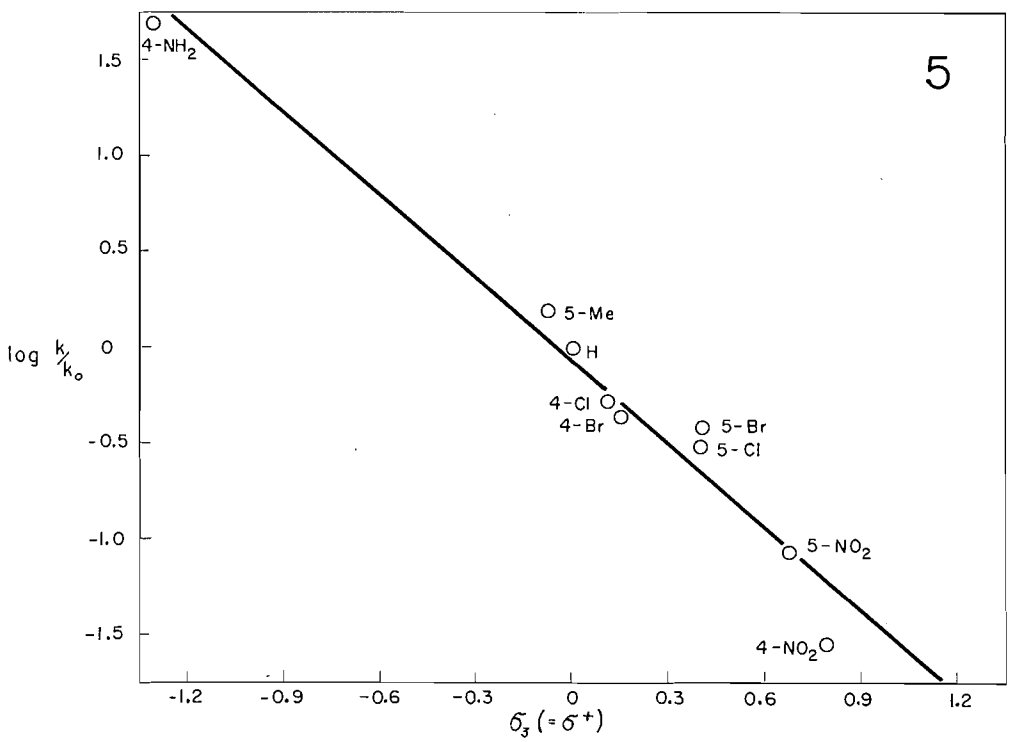

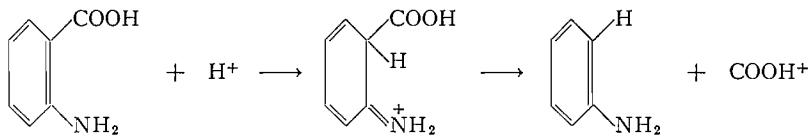

FIG. 4. Equation 2.
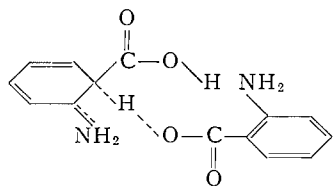
FIG. 5. Equation 3.



of amines and phenols on the one hand and in substitution reactions on aromatic and benzyl compounds on the other. The former case led Hammett to assign separate $+\sigma$'s for the reactions of amines and phenols (5), but new $-\sigma$'s were not necessary since mesomeric increase of electron density on amines and phenols is limited by the lack of low-energy orbitals on oxygen and nitrogen to receive it. In aromatic and benzyl substitutions, on the other hand, the increased efficiency of substituents with $-\sigma$'s led Brown to the establishment of separate values, $-\sigma^+$, for these cases. Thus far, $+\sigma^+$'s have not been found to be significantly different from Hammett's $+\sigma$'s, presumably because in the transition states of such reactions the reaction center bears a large positive charge and so is incapable of mesomeric electron release.

In anthranilic acid decarboxylation para substituents seem to be more effective for *both* electron release and electron attraction than in the standard reaction, which would require that the reaction center in the transition state of decarboxylation be capable of either accepting or releasing electrons. This would be the case at site 3 only if the ring carbon still has a π electron available for conjugation; that is, if either the new bond or the old is weak. By analogy with the accepted mechanism of aromatic substitution, an intermediate may be postulated in decarboxylation, as shown below.

In the usual aromatic substitution reactions the large magnitude of ρ and the absence of a hydrogen isotope effect show that the transition state resembles the intermediate, but in decarboxylation the preceding arguments suggest that the transition state must be closer to reactant or product than is the case in the usual aromatic substitutions. Stevens' observation (2) that there is no carbon isotope effect in the decarboxylation shows that the transition state can not lie between intermediate and product.

The deuterium isotope effect in decarboxylation shows that a proton is involved in the reaction site but its small magnitude, $k_H/k_D = 2$–3 suggests that the O—H bond is weakened but not broken in the transition state. This is consistent, too, with the small importance of acid strength on the rate as indicated by the negative value of ρ. The small magnitude of ρ compared to that in most aromatic substitutions (6) confirms that charge at the reaction site is small (20), as does the small solvent effect mentioned previously. Taken together these considerations indicate a transition state something like that represented by the formula

in which the O—H bond is weakened but not yet broken and the C—H bond is only partially formed. The role of the left-hand amino group in stabilizing the transition state is obvious and the proximity of the right-hand amino group to the leaving carboxyl group

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

suggests that the transfer of a proton to the ring may be accompanied or immediately followed by transfer of a second proton from the departing carbon dioxide molecule to the right-hand amino group. The previously noted unimportance of the amino group in the rate-determining step requires that this second proton transfer have a low activation energy, as is usually observed for proton transfer O to N. The right-hand molecule, in catalyzing the decarboxylation, would be converted from a neutral molecule to a zwitterion, like the bifunctional catalysts described by Swain (21). Such a bifunctional catalysis should provide a relatively low-energy route for proton transfer in a solvent of low dielectric constant, especially since the zwitterion could revert to neutral molecule intramolecularly. This interpretation agrees with the observation that *p*-aminobenzoic acid decarboxylates at only one-fifth the rate of anthranilic acid.

In summary, then, we conclude that decarboxylation takes place in the neutral molecule, not the zwitterion, that proton transfer is intermolecular, that the rate-determining step involves proton attack on the ring carbon, and that in the transition state the carbon–hydrogen bond is just beginning to be formed. It is possible that catalysis by the second anthranilic acid molecule is bifunctional in character.

ACKNOWLEDGMENT

CHALKOGENIDES OF THE TRANSITION ELEMENTS

II. EXISTENCE OF THE π PHASE IN THE M_9S_8 SECTION OF THE SYSTEM Fe–Co–Ni–S[1,2]

OSVALD KNOP AND MOHAMMAD ANWAR IBRAHIM

ABSTRACT

The face-centered cubic phase π(Fe,Co,Ni,S) has been shown to exist, at room temperature, within wide composition limits in or close to the M_9S_8 section of the quaternary system Fe–Co–Ni–S. The M:S ratio of the binary phase π(Co,S) is 9:8 with very narrow homogeneity ranges on both sides of Co_9S_8, but in π(Fe,Co,Ni,S) the ratio is somewhat higher and appears to increase with decreasing cobalt content. Stoichiometric Co_9S_8 probably contains a small number of vacancies in both sublattices. It is quite likely that the sulphur sublattice is nearly fully occupied and that departures from stoichiometry are caused by the varying degree of occupancy of the metal sublattice.

The crystal structure, which was proposed for Co_9S_8 and for the mineral pentlandite by Lindqvist *et al.*, has been confirmed for these two substances and for π(Fe,Co,Ni,S) in general by X-ray and neutron powder diffraction. The present evidence does not support the crystal structure suggested for natural pentlandite by Eliseev; Eliseev's model does not, in fact, account for the diffraction data of any of the substances examined in this work.

Replacement of cobalt in π(Co,S) by iron or nickel or both results in an expansion of the unit cell, the maximum increase in $a(\pi)$ amounting to about 3%. Cobalt in π(Co,S) cannot be replaced completely by iron or by nickel in samples prepared by dry synthesis, but if the substitution is simultaneous, the π structure will be preserved over a considerable range of compositions even on total replacement. The stability limits of π(Fe,Ni,S) have been found somewhat wider than those stated by Lundqvist.

In π phases with the compositions Co_8MS_8 the metal atoms can conceivably be present in ordered sublattices. This possibility was explored by neutron diffraction in slowly cooled Co_8NiS_8. Unlike in spinels, where nickel shows a strong preference for octahedral co-ordination, the cobalt and nickel atoms were found to be distributed at random.

INTRODUCTION

Nature of the π Phase

The first definite evidence for the existence of phases containing less than 50 at.% sulphur in the system cobalt–sulphur was presented in 1908 by Friedrich (1), who investigated the system by thermal analysis. He concluded that three such phases existed in the system and ascribed them the formulae Co_4S_3, Co_5S_4, and Co_6S_5, the latter two, however, only tentatively. The first of these sulphides was investigated by X-ray diffraction by Cagliotti and Roberti (2). They found that the sulphide had face-centered cubic symmetry and that its powder pattern resembled that of the mineral bornite. Since the formula of bornite was then thought to be Cu_3FeS_3, Cagliotti and Roberti concluded by analogy that Co_4S_3 was the stoichiometric composition of the phase.

Hülsmann and Weibke (3) reinvestigated the system in 1936. They confirmed the existence of the face-centered cubic sulphide but found by microscopic examination that a sulphide of the gross composition Co_4S_3 was not homogeneous. They considered the formula Co_6S_5 to be more consistent with the experimental facts.

A detailed study of this phase was undertaken in 1936 by Lindqvist, Lundqvist, and Westgren (4, abbreviated in the following to LLW). The space group of the sulphide was shown to be O_h^5—$Fm3m$, and from its experimental density it was inferred that there were four Co_9S_8 formula units per unit cell. The 36 cobalt atoms were distributed over two sets of equivalent lattice sites, one containing 32, and the other 4, atoms. Similarly the 32 sulphur atoms were split up into a set of 8 and a set of 24 atoms. The agreement between the calculated and the visually estimated powder-pattern intensities

was satisfactory. The correctness of the proposed formula Co_9S_8 was thus supported by a crystal-structure argument.

The crystal structure of the mineral pentlandite was discussed in the same paper. Although pentlandite is one of the most important nickel minerals, its formula remained uncertain for a long time. Alsén (5) proposed for it a crystal structure based on the space group O_h^5—*Fm3m*, taking the number of atoms per unit cell as 64. This would correspond with the LLW structure of Co_9S_8 containing only the 32 metal atoms, so that the corresponding formula would be (Fe,Ni)S. The agreement between the calculated and observed intensities was rather good, but there were certain discrepancies. These Alsén attributed to slight errors in his choice of the atomic parameters, which, incidentally, were the same as those proposed later by LLW for Co_9S_8. However, LLW considered pentlandite to be isostructural with Co_9S_8, so that the incomplete agreement between Alsén's calculated and observed intensities was, in their view, due to an incorrect formula, i.e., to the additional four metal atoms per unit cell of pentlandite. The formula of the mineral would then be $(Fe,Ni)_9S_8$, in complete analogy with Co_9S_8. The LLW structure proposed for these two substances was later incorporated as the structure type $D8_9$ in the *Strukturbericht* (7).

LLW prepared two artificial pentlandites, $Fe_{4.5}Ni_{4.5}S_8$ and $Fe_6Ni_3S_8$. The powder patterns of these two samples contained the lines of the Co_9S_8 pattern and, in addition, faint lines of a pyrrhotite phase. No explanation was advanced for the presence of the pyrrhotite lines.

The investigation of the system Co–S was repeated by a number of workers, all of whom presented evidence in support of the existence of a cubic phase at or near Co_9S_8. Lundqvist and Westgren (8) did not observe any changes in the lattice constant of Co_9S_8 on annealing and quenching from 200, 500, 650, and 800° C, regardless of whether cobalt or CoS was also present. They concluded that Co_9S_8 in their experiments had a sharp, constant composition. In an investigation of the $CoS_{1.05}$–$Fe_{12}S_{13}$ section of the system Co–Fe–S, Curlook and Pidgeon (9) prepared a number of Co–S samples with compositions in the vicinity of Co_9S_8. They reported that the sample containing 32 wt.% sulphur was essentially cubic but small amounts of a hexagonal phase were detected by X-ray spectrometer analysis. From this and from the previous finding (4) that a sample with 31.6 wt.% sulphur had contained free cobalt, they concluded that the composition of the cubic sulphide would be better expressed by the formula $Co_{15}S_{13}$.

Rosenqvist (10) measured the sulphur pressures and the H_2S/H_2 equilibria in the systems Co–S, Fe–S, and Ni–S between 400 and 1200° C. He confirmed that the phase Co_9S_8 was stable up to about 835° C and that it had only a very narrow homogeneity range. He also suggested that Co_9S_8 and pentlandite, being isostructural, were stabilized primarily by the electron/atom ratio. Stubbles (11) reinvestigated the stoichiometry of the sulphide between 585 and 800° C by the same method. He came to the conclusion that, while at higher temperatures there was a homogeneity range representable by the formula $Co_{9+x}S_8$ with x between -0.013 and $+0.031$, the limiting composition of the phase in equilibrium with cobalt remained slightly higher in cobalt than the stoichiometric as the temperature was decreased, though the limiting sulphur content was probably still above 47.05 at.% sulphur. The limiting composition of the phase saturated with sulphur could not be determined from Stubbles's data, as it was not possible to predict the trend of his sulphur-pressure curves for temperatures below 585° C.

Lundqvist (12) later extended his structural investigations to the system Fe–Ni–S. The expected narrowness of the homogeneity range of $(Fe,Ni)_9S_8$ with respect to the

M:S ratio seemed to be confirmed by the fact that he did not observe any variation in the lattice constant with the sulphur content of the samples. Varying the Ni:Fe ratio did affect the lattice constant, however, and from this variation Lundqvist established the stability limits of the synthetic pentlandite phase below 200° C as 0.42±2 and 0.58±2 Fe/(Fe+Ni). The sulphur content of the phase was stated to be invariably 47.0 at.% sulphur, irrespective of the total sulphur content of the samples or of the quenching temperature.

Lundqvist referred to the synthetic pentlandite phase as the π phase. Since the letter π has not been used to designate any other well-defined type of alloy phases and no confusion is likely to arise, it is proposed that the term π phase be reserved for phases of the $D8_9$ type regardless of their stoichiometry. The introduction of this notation in preference to definite formulae seems desirable, as there are indications (see above) that the formula M_9S_8 may not be a correct representation of the composition of the two π phases, π(Co,S) and π(Fe,Ni,S). Furthermore, phases of this type have recently been claimed to exist in systems other than Co–S and Fe–Ni–S (13, 14), so that compounds of this and of related types may be more numerous than hitherto supposed.

Literature references to the composition and properties of natural pentlandite are numerous and often contradictory. Since a structural investigation of the mineral will be the subject of another paper in this series (15) a review of the pertinent facts will be found there.

Crystal Structures Proposed for the π Phase

The crystal structures proposed for Co_9S_8 and for pentlandite by LLW are identical except for the nature of the metal atoms. The space group is O_h^5—$Fm3m$, with four formula units M_9S_8 per unit cell. The atoms are distributed over the lattice sites as follows (6):

32 M in 32(f): xxx etc. ($x_M = 1/8$),
4 M in 4(b): 1/2 1/2 1/2 etc.,
24 S in 24(e): $x00$ etc. ($x_S = 1/4$),
8 S in 8(c): 1/4 1/4 1/4 etc.

The 32 metal atoms occupy expanded tetrahedral interstices in a face-centered cubic lattice of sulphur atoms, while the remaining 4 atoms are in octahedrally co-ordinated positions. The sulphur atoms in 24(e) have the co-ordination number five, and those in 8(c) are four-co-ordinated. The metal atoms, which in Co_9S_8 are simply cobalt atoms with either four or six nearest sulphur neighbors, are in pentlandite distributed statistically over the two sets of sites.

With the above choice of x_M and x_S the co-ordination tetrahedra and octahedra of the metal atoms are regular. Their edge length is $a\sqrt{2}/4$, and the M–S distances are $a\sqrt{3}/8$ and $a/4$, respectively. The co-ordination tetrahedra of the 8 sulphur atoms are identical with those of the metal atoms. The metal atoms surrounding the five-co-ordinated sulphur are at the corners of a square pyramid with a base edge of $a/4$ and a height of $3a/8$. The distance of the sulphur atom from the apex is $a/4$, the other four metal atoms being equidistant and at $a\sqrt{3}/8$.

Eliseev (16) suggested in a recent study of the composition and crystal structure of natural pentlandite that the structure of the mineral differed from the LLW structure by the positions of the octahedrally co-ordinated metal atoms. From his drawing of the proposed structure it appears that he placed the four metal atoms in 4(a):000 etc. Since the LLW structure can be thought of as a regular array of antifluorite-type unit cells

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

alternating with face-centered unit cubes containing a single metal atom in the center, Eliseev's structure would differ from this arrangement by concentrating all the metal atoms in the antifluorite-type cells, leaving the alternate cubes empty (Fig. 1).

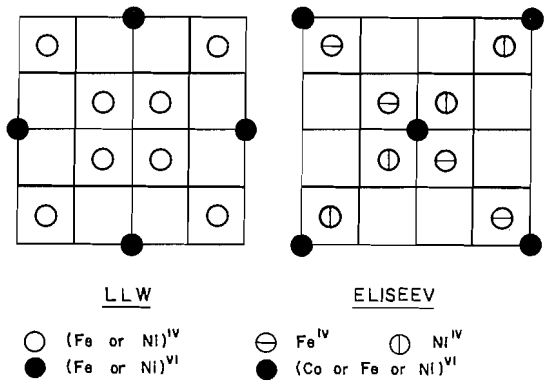

FIG. 1. Schematic representation of the differences between the two crystal structures proposed for pentlandite. The unit-cell contents between $z = -1/4$ and $1/4$ are projected on the 001 plane. The origin of Eliseev's structure is shifted by 1/4, 1/4, 1/4 to match the LLW structure. Sulphur atoms, which would appear at the intersections of the 1/4-co-ordinates, are omitted.

The iron and nickel atoms occupying $32(f)$ in Eliseev's structure were assumed to be present in the ratio 1:1 and completely ordered. Excess iron, or nickel, or cobalt sometimes present in small amounts in natural pentlandite would be located in $4(a)$, thereby balancing the over-all composition. The ordered arrangement of the metal atoms would be expected to lower the observable symmetry of the unit cell, as there is no 16-fold position in O_h^5—$Fm3m$ and the only 8-fold position has been utilized by the sulphur atoms. Eliseev believed to have evidence in support of his modified pentlandite structure in the doubling of certain lines in the powder photographs of the mineral and in the broadening of many "single" lines, as, for instance, 440. He stated that the doublets were often strong and that they all could be indexed on the basis of the same unit cell. The doubling was observed not only in powder but also in rotation photographs. The splitting of the pentlandite lines was said to be similar to that observed by Micheev (17) with mineral diarsenides of iron and nickel. Micheev had shown that the line splitting was due to a lowering of the crystal symmetry with a simultaneous preservation of the general character of the structure.

The M_9S_8 Section of the System Fe–Co–Ni–S

The composition triangle of this section is defined by the three compositions Fe_9S_8, Co_9S_8, and Ni_9S_8. Of these only Co_9S_8 can be obtained readily as a homogeneous phase by dry synthesis from the elements.

Ni_9S_8 has been reported by Peyronel and Pacilli (18) to consist, below 400° C, of a mixture of millerite and a phase of unknown structure with an approximate formula Ni_7S_6 (N). N gave the poorest diffraction lines of all the Ni–S phases studied by these authors. Its powder pattern, which was obtained with unfiltered FeK radiation in a 57.3-mm camera, contained a large number of lines and differed from that of π(Co,S). From this it was concluded that N had a low symmetry.* Presumably the same phase was

**The statement attributed in reference 19 to Peyronel and Pacilli that N possessed a monoclinic symmetry does not appear in reference 18. It is probably due to a translator's error in the abstract of reference 18 in Chem. Zbl. 1943 I, 1457, which Lundqvist used instead of the original paper not available to him at the time.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

observed later by Lundqvist (19, 12), though he never succeeded in obtaining it in the pure state. These observations are in agreement with our own experience with this phase and with the analogous phase in the system Ni–Se (20). Lundqvist also stated that almost all the strongest lines of N were close to, and possibly split up from, the strongest lines of the π-phase pattern, and he advanced the suggestion that N may have a degenerate π structure. On the other hand, Sokolova (21), who reinvestigated the Ni–S system between 30 and 50 at.% sulphur by a number of methods, denied the existence of Ni_7S_6, but reported a homogeneous phase with a composition Ni_9S_8. She claimed to have shown by X-ray diffraction that a sample of the appropriate composition consisted, on annealing at 200° C (and presumably also at 380° C), of the pure phase. She also obtained a local minimum in the electrical conductivity vs. composition curve close to Ni_9S_8.* The available evidence concerning the identity and formula of the intermediate phase is thus quite conflicting. One cannot, of course, exclude the possibility of existence of more than one low-temperature phase between Ni_3S_2 and NiS, nor can much reliance be placed in the above interpretations of diffraction patterns of inferior quality. Leaving aside the exact nature of this phase, we shall refer to it in the following simply as N.

No iron sulphide higher in iron than FeS has ever been mentioned to exist in preparations obtained by dry synthesis or by degradation of higher iron sulphides. However, a cubic sulphide was reported quite recently (14) to form on the surface of mild steel exposed to wet hydrogen sulphide. The sulphide was first noticed as a corrosion product of steel in the sour crude wells of Kansas and was given the name kansite. Its X-ray powder pattern was reported to be compatible with a face-centered cubic lattice with $a = 10.1 \pm 0.05$ Å. On this and some analytical evidence it was suggested that the sulphide had the formula Fe_9S_8 and that it was isostructural with Co_9S_8.

Although a number of studies of the three ternary systems, Fe–Ni–S, Fe–Co–S, and Co–Ni–S, are available (22, 23, 24, 12, 25, 26, 27, 9, 28), structural data concerning the M_9S_8 sections are scanty. Curlook and Pidgeon (9) reported the existence of a cubic phase in alloys containing 0–32 wt.% $Fe_{12}S_{13}$ in the section $CoS_{1.05}$–$Fe_{12}S_{13}$. The phase was detected by powder photography in alloys containing up to 30 wt. % and in polished sections of alloys containing up to 32 wt.% $Fe_{12}S_{13}$. Its lattice parameter was stated to increase by only 0.008 Å over the composition range 0–30 wt.% $Fe_{12}S_{13}$, which was taken as an indication that the cubic phase contained very little iron.

The only ternary system investigated in detail by X-ray diffraction was Fe–Ni–S (12). Lundqvist established the saturation limits of the homogeneous π phase in the $(Fe,Ni)_9S_8$ section (see above) as well as the nature of the phases coexisting with π in the adjacent phase spaces below 200° C. This and other available evidence points to the existence of a ternary π phase over a considerable region of the M_9S_8 plane.

Purpose of this Investigation

The state of our knowledge of the π phase that can be obtained by collating the available data may be summarized as follows.

A ternary π phase exists in the system Fe–Co–Ni–S over an appreciable composition range. Arguments based on the crystal structure proposed for Co_9S_8 by LLW lead to the formula $(Fe,Co,Ni)_9S_8$, but there is evidence that the metal content of the phase

**The experimental evidence presented in Sokolova's paper in support of the formula Ni_9S_8 is not entirely convincing. There are no details of the X-ray investigation, and nothing is said about the diffraction pattern of the phase. The position of the conductivity vs. composition minimum seems to favor the formula Ni_7S_6 at least as well as Ni_9S_8, as far as can be judged from Fig. 3 of the original paper. The constitution diagram of Fig. 1 of her paper does not obey the phase rule along the line e–s–t–d.*

may be higher than would correspond to an M:S ratio of 9/8. The homogeneity range with respect to the sulphur content of the phase is probably narrow. Since Co_9S_8 and natural pentlandite, $(Fe,Ni)_9S_8$, had been reported by LLW to be isostructural, Rosenqvist proposed that the π phase is stabilized by the electron/atom ratio, the electron stabilization being similar to that encountered in the Hume–Rothery and related phases. On the other hand, Eliseev suggested that the LLW structure for Co_9S_8, though similar, does not apply to natural pentlandite and that the correct structure of the mineral is a modified version of the LLW structure. His argument was based on the observation, which he claimed to have made, that the diffraction symmetry of pentlandite was lower than that of Co_9S_8.

Since Co_9S_8 and natural pentlandite are the only two substances listed in the *Strukturbericht* and elsewhere as belonging to the $D8_9$ type, Eliseev's statement is of sufficient importance to merit a re-examination of the structural evidence, and this was one of the aims of this study. A number of comments apropos of the two postulated structures can, however, be made immediately. When examining the evidence presented in support of the modified structure, attention should be drawn to the fact that Eliseev seems to have used unfiltered FeK radiation and a powder camera of 66-mm diameter. The reproduction of a powder photograph of pentlandite on page 57 of Eliseev's paper, intended to demonstrate the line splitting, is hardly of a quality suitable for examining the nature of the reported doublets. Since LLW found their focusing-camera photographs of Co_9S_8 and natural pentlandite to be identical (except for a lineshift due to different values of a), evidence for the correctness of Eliseev's pentlandite structure would also be evidence against the LLW structure proposed for the cobalt sulphide. Interchanging the occupancy of 4(a) and 4(b) would produce observable changes in the line intensities for the two substances, but this point is not discussed in Eliseev's paper at all. The atomic arrangement in Eliseev's structure is not very probable on entropy grounds, and there are certain symmetry arguments against symmetry degeneration brought about by the ordering. It is not known if Eliseev's modification would apply to synthetic pentlandite. There may be significant differences between the natural and the synthetic material whose possible existence must be kept in mind.

Regardless of which of the two structures is correct in any given case, there exists a possibility of ordering of the metal atoms in homogeneous π phases containing two kind of metal atoms in the ratio 1:8. That such preferential arrangement is likely to be expected with certain elements is well known from the crystallography of spinel-type compounds. No π phase of such composition had been reported in the literature prior to this work (cf. 29). If ordered homogeneous π phases of compositions Co_8FeS_8 and Co_8NiS_8 can be obtained, the ordering would be difficult to detect because of the close similarity of the X-ray atomic scattering amplitudes of the three metals and the unfavorable ratio of the two metals in such phases. The segregation of the iron or nickel metals into octahedral sites could, however, be demonstrated by neutron diffraction.

Rosenqvist's suggestion that the π phase may be 3d-electron stabilized is worth while examining. The phase has a certain amount of metallic character, but the reported existence of Fe_9S_8 (14) and the possibly close relationship of π and N (19, 12) throw some doubt on such stabilization. A preliminary to a more detailed study of this point would be the knowledge of the limits of existence of the π phase at room temperature in the M_9S_8 section of the Fe–Co–Ni–S system. To obtain this information by X-ray techniques is the main purpose of this work. The stoichiometry of the π phase and the correctness of representing its composition by the formula M_9S_8 will also be examined.

EXPERIMENTAL

Materials

Sulphur, Sublimed Merck, USP, was distilled four times *in vacuo* and kept in tightly closed containers. Carbonyl iron powder, G. A. and F. Grade L, of average particle size 20 microns was used throughout. The supplied analysis of the powder was 99.6–99.9% Fe, 0.01–0.06% C, 0.10–0.30% O, 0–0.005% N. The powder was reduced with purified hydrogen before use. Spectrographic analysis of the reduced powder gave 0.03% Ni; cobalt was not detected.

The bulk of the nickel used in the investigation consisted of carbonyl nickel shot kindly donated by the International Nickel Company of Canada, Limited. The supplied analysis read 99.9% Ni, 0.008% Cu, 0.025% Fe, 0.04% C, 0.01% S. The shot was cleaned in acid immediately before use and was in most cases degassed by heating *in vacuo*. Since it was impractical to use the shot where small amounts of nickel were required, a quantity of nickel powder was obtained by reduction of nickel oxide with purified hydrogen. The oxide was prepared by calcining nickelous nitrate hexahydrate low in cobalt (Baker and Adamson Reagent Special). The supplied lot analysis of the nitrate, expressed as maximum limits of impurities, was as follows: insoluble, 0.005%; 0.002% SO_4; 0.001% Fe; 0.002% Co; 0.005% Cu; 0.005% Pb; 0.001% Cl; 0.05% NH_3; alkalies and earths, 0.10%; total impurities, 0.17%. Spectrographic analysis of the metal powder gave 0.002% Fe and 0.002% Co.

Nickel shot caused difficulties in the quartz glass reaction tubes during the initial heating. As the nickel beads grew in size, owing to the formation of the less dense sulphide, the tubes cracked on a number of occasions. In addition, the pellets were too large for convenient handling when filling the reaction tubes. A large amount of Ni_3S_2 was therefore prepared separately and crushed to 100 mesh for use instead of the shot.

Purified cobalt powder low in nickel (Fisher Scientific No. C-363) was reduced with hydrogen before use. Spectrographic analysis of the reduced powder, which was carried out only after most of the samples had been prepared, revealed the presence of 0.3% iron and 0.4% nickel. The purity was thus much inferior to what had been expected, so that the iron and nickel contents of the cobalt powder must be taken into account when stating the compositions of the samples. However, the Fe:Ni ratio was sufficiently close to one for all the sample compositions to be shifted by small amounts in the same direction, namely almost parallel with the constant-ratio line Co_9S_8–$Fe_{4.5}Ni_{4.5}S_8$ of the composition triangle. The shift would be largest for Co_9S_8 and it would decrease in proportion to the cobalt content of the samples. Samples with no cobalt would not be affected, while the true composition of No. 1 (see Table I) would be $Fe_{0.027}Co_{8.937}Ni_{0.036}S_8$ rather than Co_9S_8. The deviation from the intended composition is quite small and one finds that the change in a produced by the impurities can be expected to affect only the fourth decimal (see Results and Discussion). Since the accuracy of the lattice constant of Co_9S_8 is of some importance, especially in view of the discrepancies in the reported values, four additional samples (Nos. 46, 47, 48, 49) were prepared from Johnson Matthey spectrographic-purity cobalt sponge. The sponge was freshly reduced before use. A small variation in the sulphur content was introduced to establish if there was any change in a arising from the possible existence of a narrow homogeneity range. However, the a values of these samples were all within the error limits of the value 9.929 ± 2 Å obtained for No. 1. The lattice constant of π(Co,S) is thus indeed quite insensitive to the presence of small amounts of iron and nickel, so that the lattice constants obtained with samples

prepared with the impure cobalt powder remained unaffected within the accuracy limits of this work.

The lattice constants of the reduced iron, cobalt, and nickel powders were 2.8659±5 Å; 2.506 and 4.078 Å; and 3.5237±1 Å, respectively. The lattice constants of Ni_3S_2 were 5.743 and 7.154 Å, c/a = 1.246. All these values were in good agreement with the literature values (30, 31).

Preparation of Samples

In order to keep the number of samples at a minimum the sample compositions were chosen in such a way that they would fall on constant-percentage or constant-ratio lines of the composition triangle Fe_9S_8–Co_9S_8–Ni_9S_8 (Fig. 2 and Table I). The total

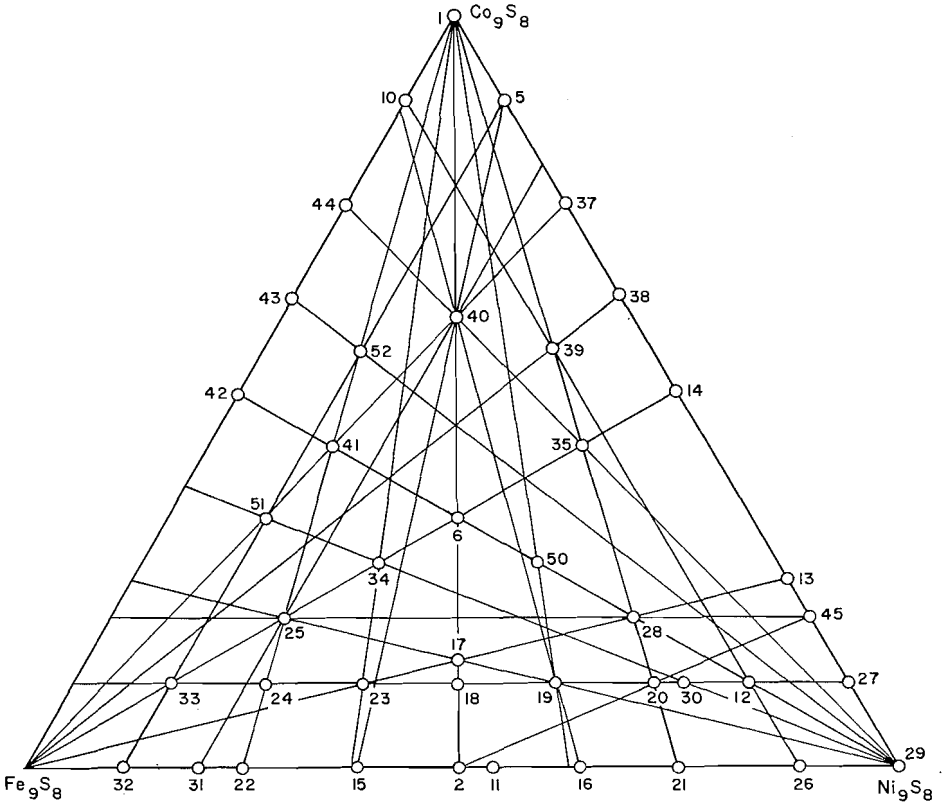

FIG. 2. Compositions of the synthetic samples.

amount of each sample was not less than 10 grams. Carefully weighed quantities of the elements were transferred quantitatively into clean degassed tubes of transparent silica. The tubes were evacuated to 10^{-5}–10^{-6} mm Hg, sealed off, and transferred into a deep horizontal tubular furnace with a steep temperature gradient and the hot zone at about 700° C. The strongly exothermic reaction between the fine metal powders and the free sulphur required extra care and some skill in initiating the reaction (29). When all the sulphur had reacted the tube was pushed completely into the hot zone and left there for about half an hour to ensure complete conversion of the metal, as otherwise the malleable metal particles would cause difficulties in subsequent handling. On cooling the tube was opened carefully, the sample removed, inspected for glass chips, and crushed to pass 100 mesh. The thoroughly mixed powder was again transferred into a transparent silica tube, which was then evacuated, sealed, and transferred into a vertical tubular furnace for homogenization. This procedure was repeated to ensure equalization of composition both by mechanical mixing and by diffusion.

The progress of homogenization was determined from powder photographs and from the internal consistency of the lattice constants. Wherever necessary a third homogenization was carried out. The samples were kept at the annealing temperature, which was usually in the vicinity of 800° C, up to 120 hours (29). Absence of reliable information on the phase equilibria in the system Fe–Co–Ni–S made the choice of the upper temperature limit for subsolidus annealing uncertain. It seems that the solidus must be somewhere in the vicinity of 820° C for most compositions of interest.

The strong shrinkage on homogenization indicated good consolidation of the initially loose powder. The sintered ingots were so compact that they had to be crushed in a hardened-steel mortar before grinding. The shrinkage was particularly appreciable for samples low in cobalt.*

The annealed samples were allowed to cool slowly in the furnace at a cooling rate of not less than 70° C/hour. The silica glass in contact with samples rich in cobalt devitrified to a white milky surface layer. The thickness of the layer varied with the length of contact and with the maximum temperature to which the tube had been exposed. The powder photographs of the devitrified product showed it to be ordinary crystalline quartz. Only in a few instances, where the samples were kept at temperatures over 810° C for long periods of time, was there a slight blue or purplish coloration of the silica in contact with the sulphide.

The color of the sintered powders varied from grey to pale yellow, depending on the composition. Samples rich in iron tended to be grey, those rich in nickel were pale yellow. Massive cobalt-rich alloys were greyish-white. All the alloys were brittle.

X-Ray Diffraction Technique

Powder diffraction photographs of the samples were taken in Straumanis-type cameras of 114.6- and 57.3-mm diameter. Filtered and unfiltered FeK and CrK radiations were employed throughout except for the nickel samples, where CuK radiation was used. The following wavelengths were used in the calculations: CrK_{α_1}, 2.28962 Å; CrK_{α_2}, 2.29352 Å; FeK_{α_1}, 1.93597 Å; FeK_{α_2}, 1.93991 Å; CuK_{α_1}, 1.54050 Å; CuK_{α_2}, 1.54434 Å. Care was taken to avoid disproportionation in the preparation of the fiber-mounted specimens. Nelson–Riley extrapolation was used in the lattice-constant determinations, utilizing reflections with θ at least 30° and fitting the straight lines by least squares.

Although some samples gave very good patterns with sharp lines even at high Bragg angles, the quality of most of the high-angle lines was only fair. The diffuseness of these lines could not be improved appreciably by annealing the 325-mesh powders below 400° C for 2 or 3 days. The improvement was not great enough to warrant the time and effort spent in the long annealing process. Samples near the Ni_9S_8 corner were the most troublesome (Nos. 12, 13, 26, 27, 29, 45). Their photographs contained many fine and diffuse interfering lines which made accurate measurement impossible.† Almost equally troublesome were the compositions near Fe_9S_8, the only difference being that the interfering lines were fewer (Nos. 32, 33, 42). The lines of the π phase in some of these photographs were, however, still distinguishable and could be measured. Thus for composition Nos. 13, 26, 32, 33, and 42 the lattice constants of the equilibrium π phase

**It is not certain whether the strong shrinkage of the samples low in cobalt, or with no cobalt at all, was caused by higher surface mobilities of iron and nickel atoms or by solidus temperatures lower than in the system* Co–S. *In the latter case the annealing temperature might have been above the solidus and the consolidation could have been aided by small amounts of a liquid phase.*

†The same difficulty was encountered by Lundqvist (19) in his study of the system Ni–S, *and in our laboratory with nickel selenides of similar compositions.*

could still be evaluated. The values of a obtained from these films were, of course, of lower accuracy, although a check using a $\sin^2\theta(844)$ vs. a graph showed that the discrepancies were not serious.

Either FeK or CrK radiation was used, except for Nos. 13, 27, 29, and 36, where photographs were taken with both radiations. The CrK photographs were obtained to increase the resolution, which was inadequate with FeK radiation.

Diffraction lines not belonging to the π-phase pattern were frequently present in the photographs. Except for the above samples the foreign lines did not interfere with the measurement of the π-phase lines.

The relative intensities were obtained by planimetering the diffraction peaks on diffractometer charts taken with filtered FeK radiation.

Neutron-Diffraction Study

The lead-crystal neutron spectrometer installed at the NRU reactor of the Atomic Energy of Canada, Ltd., in Chalk River was used to obtain the neutron powder diffraction patterns of Co_9S_8 and Co_8NiS_8. These samples were prepared in sufficiently large quantities especially for this purpose.* Co_9S_8 was kept at 750° C for 6 days and then cooled in the furnace which was controlled to give an average cooling rate of 38°/hour. The Co_8NiS_8 sample was kept at 810° C for 4 days. It was then brought to 445° C at an average rate of 2°/hour. Below this temperature it was allowed to cool at the natural cooling rate of the furnace.

The 200-mesh powders were sandwiched between two pieces of aluminum foil 0.005 in. thick in a circular aluminum specimen holder of 4-in. diameter. The thickness of the powder sandwich was 1/8 inch. Transmission half-angling scans were made in 1/4° (2θ) steps. The neutron beam of an effective wavelength of 1.910 Å was contaminated by about 8% of second-order neutrons of 0.955 Å wavelength. The amount of interference due to the second-order reflections was determined by making each run twice, once with a Norton No. 0′ blank disk and then with a Norton No. 3 samarium oxide disk, which reduced the second-order intensities to about one-third. Even so, however, the composite effect of the background and of the reduced second-order peaks did not permit evaluation of the intensities of weak first-order reflections.

The integrated intensities were obtained by planimetering the diffraction maxima.

Density Measurement

Densities of the samples were determined with pyknometers of 25- and 50-ml capacity using degassed paraffin oil (Stanolax) as displacement liquid. About 4 g of 100- or 200-mesh powder was placed in the dry, weighed pyknometer. The pyknometer was transferred to a vacuum desiccator, evacuated, and filled with the degassed oil without breaking the vacuum. The filled pyknometers were brought to 25±0.02° C before inserting the stoppers. Three separate determinations were made for each powder filling.

The average of four calibration runs with C.P. KCl was 1.9826±14 g/cm³, which is only 0.08% lower than the usually quoted density, 1.984 g/cm³, and 0.2% lower than the value of 1.9867 g/cm³ based on $a(25°\text{ C}) = 6.2929$ Å (32) and $N = 6.0235\times10^{23}$.

**The cobalt used was 99.55% electrolytic cobalt donated by the International Nickel Company of Canada, Ltd.; it contained 0.4% nickel. Correction for the nickel content was made when preparing Co_8NiS_8. The small discrepancies in $a(\pi)$ of the neutron-diffraction specimens in Table I are probably due to the varying impurity content of the cobalt metal.*

RESULTS AND DISCUSSION

The Lattice Constants and Existence Limits of π(Fe,Co,Ni,S) *in the* M_9S_8 *Section*

The results of the lattice-constant determinations are listed together with the sample compositions and densities in Table I.

Figure 3 shows the variation of $a(\pi)$ with composition as well as the limits within

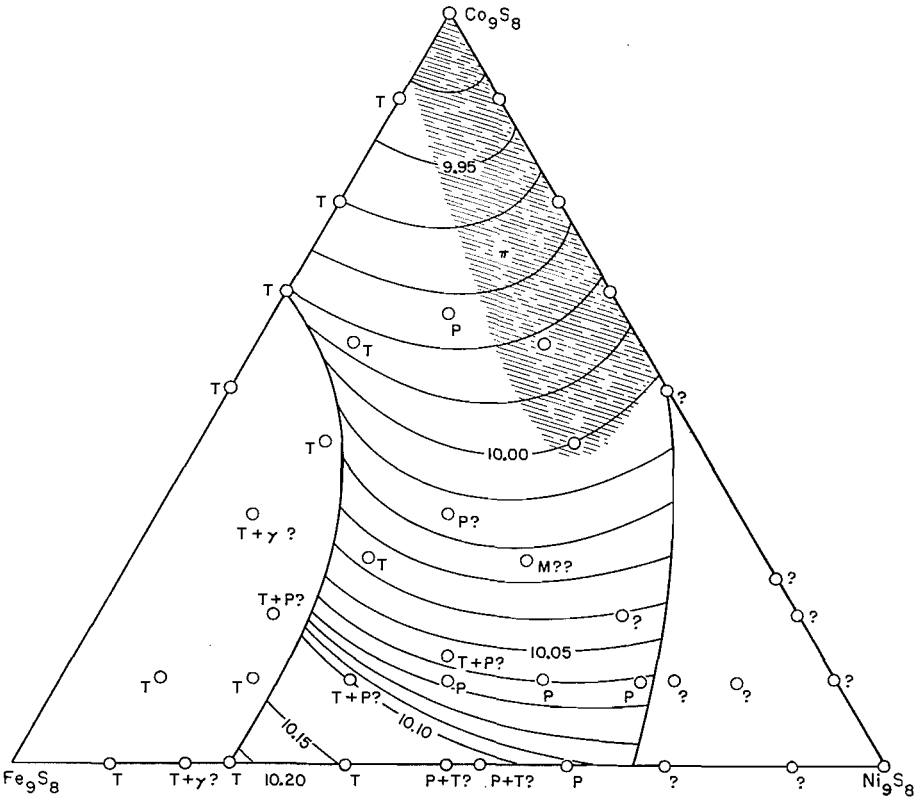

FIG. 3. Limits of existence of π in the M_9S_8 section. Shaded area: pure π. Area within curved boundaries: quasihomogeneous π field. For abbreviations, see text.

which π(Fe,Co,Ni,S) occurs in the M_9S_8 section of the quaternary system at room temperature. Only the samples within the shaded area gave diffraction patterns of the π phase free from foreign lines. All the other samples contained admixtures of other phases in varying amounts. The phase boundaries of the homogeneous π field were estimated from the variation of $a(\pi)$ along the constant-percentage and constant-ratio lines. It is evident that the M_9S_8 plane cuts through the π space of the Fe–Co–Ni–S composition tetrahedron at most only in the region indicated by the shaded area.* Outside this region lines of troilite (T), pyrrhotite (P), and millerite (M) began to appear in the diffraction patterns. This would indicate that the thin π-space slab drops below the M_9S_8 plane towards the Fe–Co–Ni side of the tetrahedron. Assuming that the samples were reasonably near their equilibrium states, the saturated π phases must have con-

**The reliability of the boundary determination depends, of course, on the sensitivity of detection of the admixed phases by powder photography. No effort was made to ascertain the sensitivity limits, but it is estimated that admixture of as little as 1–2 mole% of γ and 5 mole% or less of the other phases can be detected.*

For personal use only.

tained less sulphur than would correspond to the formula $(Fe,Co,Ni)_9S_8$. This finding is in agreement with the presence of faint P lines in the powder patterns of the two artificial pentlandites prepared by LLW, $Fe_{4.5}Ni_{4.5}S_8$ and $Fe_6Ni_3S_8$ (cf. Introduction).

To judge by the relative intensities of the foreign lines the M_9S_8 plane must be quite close to the sulphur-saturation boundary surface of the π space. Furthermore, the thickness of the π slab cannot be appreciable (4, 12, 11). The tentative isoparametric contour lines in the quasihomogeneous π field refer, except for the shaded area, to sulphur-saturated π in equilibrium with the admixed phases rather than to homogeneous π of compositions identical with the gross sample compositions. They must, however, very nearly coincide with the appropriate contour lines in the boundary surface of the π space, the displacement caused by the projection of the two-phase tie lines being quite small.

The saturation limits of $\pi(Fe,Ni,S)$ were estimated from the discontinuities in the $a(\pi)$ vs. composition curves as $Fe_{6.8}Ni_{2.2}S_8$ and $Fe_{2.6}Ni_{6.4}S_8$, the lattice constants of the saturated phases being 10.210 ± 3 Å and 10.087 ± 5 Å, respectively. The homogeneity region of $\pi(Fe,Ni,S)$ at room temperature is thus wider than stated by Lundqvist, whose values would correspond to the formulae $Fe_{5.22\pm18}Ni_{3.78\pm18}S_8$ and $Fe_{3.78\pm18}Ni_{5.22\pm18}S_8$. Lundqvist's lattice constants for these limiting compositions were 10.195 and 10.095 Å,* respectively, the former value having probably been arrived at from $a(\pi)$ in $Fe_6Ni_3S_8$ (4).†

Immediately outside the boundaries of the quasihomogeneous π region of the M_9S_8 section there are three-phase sections through the adjacent room-temperature phase spaces. On the iron side the coexisting phases are γ-Fe, T, and π of equilibrium composition. On the nickel side π coexists with M and N. Since the sulphur-saturation boundary of the π space clears the M_9S_8 plane on approaching the Fe_9S_8–Ni_9S_8 base line, small amounts of the *B8* phase (P) will coexist with π in samples outside the shaded (homogeneous) area. P will also appear in small amounts as a third phase with π and T, and with π and M, respectively, outside the boundaries of the quasihomogeneous region.

Except very near the iron and nickel corners of the composition triangle of Fig. 3 the amounts of phases admixed with π were small. The relative weakness of the foreign lines in the π diffraction pattern did not permit an evaluation of the composition dependence of the unit-cell dimensions of the P phase, although the positions of the 100, 101, and 102 lines of the P pattern in samples within the quasihomogeneous π region seemed to vary somewhat with composition. In fact, the faintness of the strongest foreign lines in some films made it difficult to distinguish between the T and P phases. Thus there is some uncertainty as to whether the second phase in sample Nos. 15, 23, 34, and 52 was T or P. A further factor complicating the identification is our lack of knowledge concerning the stability and metastability of the nickel-saturated troilite.

In the nickel corner the circumstances are even less favorable for an adequate phase analysis. The phases in equilibrium are π, M, and N (or, more correctly, $\pi+P+M$, $\pi+M$, and $\pi+N+M$). According to reference 12 M seems to have little ability to substitute iron for nickel, and one would think that the millerite pattern would be easily recognizable in the photographs. However, as Lundqvist (19) observed in the system Ni–S for compositions near N, the diffraction patterns were rather indistinct and difficult to measure with confidence. The composite patterns of samples in the

**The values 10.175 and 10.075 of reference 12, though quoted in Ångström units, were really in kX, as were all the lattice constants in references 4, 8, 9, 12, and probably also in reference 2.*

†The value of 9.91 Å originally quoted for this composition in reference 4 was a misprint. It was corrected o 10.175 in reference 12 (cf. preceding footnote).

nickel corner thus hardly encourage attempts to clarify the phase relationships further than indicated in Fig. 3. This matter may be resolved later, when more information is available on the pertinent portion of the system Ni–S.

The agreement between the present values of $a(\pi)$ and those reported previously for π(Co,S) and $Fe_{4.5}Ni_{4.5}S_8$ is quite good, provided that the latter are converted to Ångström units wherever this seems warranted (cf. footnotes 4 and 5 of Table I). For π(Co,S) the available values are 9.924±7 Å (3), 9.927 Å (4, 8), 9.924±6 Å (9), and 9.93 Å (2). These values compare favorably with our values 9.929±2 Å for No. 1 and 9.9279±5 Å for No. 46. For $Fe_{4.5}Ni_{4.5}S_8$ (No. 2) the present value of 10.115±2 Å agrees well with the value reported in reference 4, 10.11 Å.

Only after the experimental work on this paper had been terminated the results of Stubbles' redetermination of a for π(Co,S) came to our attention (11). The powder photographs of his carefully equilibrated specimens were taken with filtered CoK radiation in a 19-cm Bradley-Jay type camera. The reported lattice constants of his two quenched samples, $Co_{9.032}S_8$ (S_{F5}) and $Co_{8.989}S_8$ (S_{F8}), were 9.9282±4 Å and 9.9264±4 Å, respectively. Both values fit well into our series of four samples prepared from spectrographic-purity cobalt (Nos. 48, 47, 46, and 49), although the uncertainty in our values is higher. Stubbles regarded the slight difference in a as significant and indicative of a narrow homogeneity range of the phase. This point will be considered in the next section.

Substitution of cobalt by iron or nickel in π(Co,S) causes an expansion of the unit cell. This is true for iron and nickel separately as well as for simultaneous substitution at different Fe:Ni ratios. Iron is capable of replacing cobalt to the extent of about 37.5% and with a corresponding increase in a of 0.049 Å. The variation of a with the iron content is, within the limits of our accuracy, practically linear. The nickel substitution in π(Co,S) does not cause a second phase to appear up to about 50%, the corresponding lattice expansion amounting to 0.076 Å. The variation of a is almost linear.

Although homogeneous π(Co,Fe,S) and π(Co,Ni,S) are confined to the above limits, cobalt in π(Co,S) can be replaced completely and the π phase preserved if Fe and Ni are introduced simultaneously. For the Fe:Ni ratio equal to unity the lattice constant increases on complete replacement by 0.188 Å, i.e., less than 2%. For Fe:Ni ratios greater than 1, a increases to its limiting value, 10.210±3 Å, whereas for smaller ratios it decreases to the limit of 10.087±5 Å. The saturation limit on the nickel side cannot be determined accurately since the a vs. composition curve flattens out. The relationship between a and the Fe:Ni ratio, which is of some importance for the mineralogy of natural pentlandite, will be dealt with more fully in reference 15.

The existence of π(Fe,Co,Ni,S) within wide Fe:Co:Ni limits on both sides of the Co_9S_8–$Fe_{4.5}Ni_{4.5}S_8$ in or near the M_9S_8 plane satisfies the phenomenological requirement of an essentially constant 3d-electron content per unit cell which underlies Rosenqvist's suggestion that the π phase might be electron-stabilized. In fact, the boundaries of the quasihomogeneous π field coincide roughly with the 6.5 and the 7.5 3d-electron-per-atom contour lines of the M_9S_8 section. Whether or not it is meaningful to speak of such stabilization can be shown only by demonstrating that a homogeneous π(Fe,S) or a homogeneous π(Ni,S) or both exist. If satisfactory evidence of the existence of such phases is obtained, the above suggestion cannot hold, and in any case the requirement of a constant 3d-electron concentration per unit cell ought to be reformulated in more fundamental terms.

Though the relationship between natural pentlandite and the synthetic π(Fe,Co,Ni,S) phase will be discussed more fully in reference 15, it is of interest to note that the formula

$Fe_4^{IV}Ni_4^{IV}(Co,Ni,Fe)_{0-1}^{VI}S_8$, proposed for the mineral by Eliseev, has been invalidated by the recent discovery of natural pentlandites containing up to 70% Co/(Fe+Co+Ni) (33).

Crystal Structure and Composition of π(Fe,Co,Ni,S)

Intensities of the powder diffraction lines of Co_9S_8 were calculated for FeK radiation using both the LLW model and the structure proposed by Eliseev for natural pentlandite. The parameter of the cobalt atom was taken as 1/8 and that of sulphur as 1/4. Neutral atomic form factors (34) were used in the calculation. For comparison, the form factors of Co^{2+} (estimated) and S^{2-} were also used up to 222. The slightly different I_{calc} values based on the ionic form factors are listed in Table II in parentheses. Temperature and absorption factors were not included in the calculations. The calculated values were compared with integrated intensities obtained by planimetering the diffractometer peaks of Co_9S_8 (average of four samples, Nos. 846, 847, 848, and 849), $Fe_{4.5}Ni_{4.5}S_8$ (No. 2), and Sudbury pentlandite (SI AU).

As may be seen in Table II, the agreement between I_{obs} (Co_9S_8) and the intensities calculated for the LLW structure is, on the whole, good. It is even slightly improved by using the ionic form factors for the first few reflections. The adopted parameters

must thus be very nearly correct. A small adjustment might result in further improvement, but the powder intensities were not considered sufficiently reliable to warrant such treatment.* In view of the relatively high proportion of multiple reflections no attempt has been made to calculate the customary reliability index. The interatomic distances calculated from the above parameters are Co^{IV}–S, 2.150 Å, and Co^{VI}–S, 2.482 Å.

Since the atomic form factors of iron and nickel are very similar to the form factor of cobalt, $Fe_{4.5}Ni_{4.5}S_8$ should yield, according to LLW, the same diffraction intensities as Co_9S_8, and this should also be true of natural pentlandite. That this is indeed the case may be seen in the table, but it is possible that the small discrepancies are not entirely accidental.

I_{calc} values for Eliseev's structure model for pentlandite also are shown in Table II. The interchange of the four metal atoms in 4(*b*) of the LLW structure with 4(*a*) of Eliseev's structure affects only those reflections for which all three indices are odd. Inspection of the table shows that Eliseev's model does not apply to any of the three substances examined. The essential correctness of the LLW structure of π is thus substantiated.

The homogeneity range of π(Co,S) is difficult to establish with confidence. Stubbles' equilibrium data (11) leave no doubt about its narrowness at temperatures above 600° C. At room temperature its width can be expected to be even less. An estimate has been attempted by plotting Stubbles' and our own $a(\pi)$ values for samples on both sides of Co_9S_8 against at.% sulphur (Fig. 4). The consistency of the two sets of points is

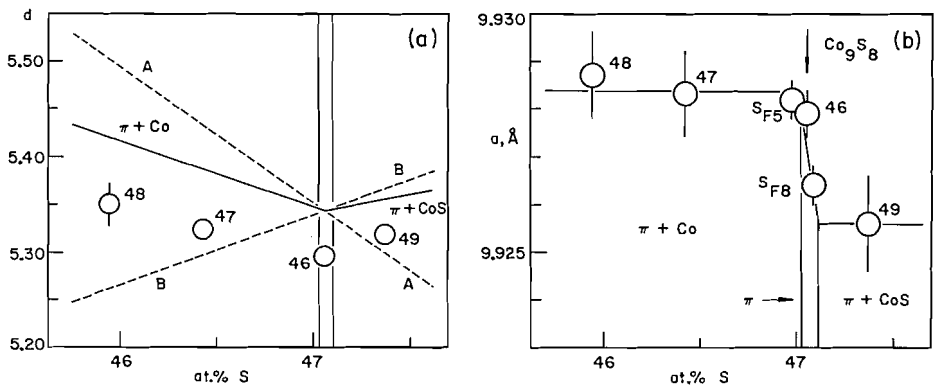

FIG. 4. (*a*) Densities of Co–S samples in the vicinity of Co_9S_8: A, density of π(Co,S) assuming full occupancy of the S sites; B, density of π(Co,S) assuming full occupancy of the Co sites. (*b*) Variation of $a(\pi)$ with composition in the vicinity of Co_9S_8. Vertical lines indicate precision of individual determinations.

surprisingly good. The homogeneity boundaries would appear to be at ca. 47.04 ($Co_{9.006}S_8$) and 47.11 at.% sulphur ($Co_{8.987}S_8$). These limits are wider than the equilibrium data would suggest (cf. Introduction), but considering the uncertainties in drawing the lines of Fig. 4, the agreement must be viewed as reasonable.

The lattice constant of π(Co,S) saturated with sulphur is estimated to be 9.9256±10 Å and that of the cobalt-saturated phase, 9.9284±10 Å. This corresponds to a decrease of *a* by about 0.003 Å for an increase of 0.07 at.% sulphur.

**Geller (35) obtained recently a value of 0.126 for x_{Co} from limited single-crystal data for Co_9S_8, while x_S did not yield to refinement. Since $x_{Co} \neq 1/8$ necessitates a distortion of the co-ordination polyhedra, a full-scale three-dimensional refinement of the structure would be desirable.*

For personal use only.

The measured densities (Table I and Fig. 4) are too few to be of any value for an estimate of the width of the homogeneity region. They are all consistently lower, by roughly the same amount, than the densities calculated from the X-ray density of Co_9S_8 for mixtures of Co_9S_8+Co and Co_9S_8+CoS. As can be seen from the graph, taking into account the width of the homogeneity region would make relatively little difference to the positions of the lines calculated for the mixtures, regardless of whether full occupancy of the available sulphur sites or that of the cobalt sites required by the LLW model is postulated for the structure of nonstoichiometric π(Co,S). The discrepancy between the densities can be explained by assuming that stoichiometric Co_9S_8 is intrinsically defective and that 0.86% atoms of each kind are missing. This amounts to 0.310 cobalt vacancies and 0.275 sulphur vacancies per unit cell, the corresponding formula of the stoichiometric phase being $Co_{8.924}S_{7.932}$.

The existence of Schottky defects in stoichiometric binary oxides and chalkogenides has been demonstrated a number of times. Among the classical examples is stoichiometric CrS, which was shown to contain about 8% vacancies in each sublattice (36), and stoichiometric δ-TiO, in which the concentration of vacancy pairs is even higher, amounting to about 15% (37). Intrinsically defective phases of this type are usually 1:1 compounds but in principle there is no reason why a phase whose ideal composition is well defined by its crystal symmetry could not behave in a similar manner.

The assumption of vacancies in the sulphur sublattice is not consistent with the very low mobility of sulphur in Co_9S_8. Stubbles determined the self-diffusion coefficient of sulphur in π(Co,S) of varying stoichiometry at 800° C and found that the anion mobility was extremely low even along grain boundaries. From this he concluded that the sulphur sublattice contained few imperfections. The mobility of cobalt, on the other hand, is quite high; the self-diffusion coefficient of cobalt in Co_9S_8 at 800° C is about 10^4 larger than the self-diffusion coefficient of Fe in Fe_3O_4 at the same temperature. This Stubbles attributed to the possibility of migration of the cobalt atoms between unoccupied octahedral sites in the structure. In stoichiometric Co_9S_8 this diffusion mechanism would presuppose an intrinsically disordered occupancy of the cobalt sublattice with some cobalt atoms in octahedral sites other than 4(*b*). These would also be the sites occupied by the excess cobalt atoms in phases with nonstoichiometric compositions $Co_{9+x}S_8$, and the same diffusion mechanism would operate. In $Co_{9-x}S_8$ there is the additional possibility of migration between 4(*b*) and the other octahedral positions. According to this model the general formula of π(Co,S) would be $Co_{9\pm x}S_{8-y}$, where $y \ll x$. Since $|x|_{max}$ reported in reference 11 was 0.031, the above value of $y = 0.068$ estimated from density data for stoichiometric Co_9S_8, is certainly not of the right order of magnitude. On the other hand, the reliability of even very careful density determinations on powders is admittedly somewhat open to question, and the true densities may be higher than stated in Table I (the uncertainty quoted there refers to precision, not accuracy).

As for the high self-diffusion mobility of cobalt, vacancies in the cobalt sublattice of stoichiometric Co_9S_8 would facilitate migration of the metal atoms and satisfy the condition of intrinsic disorder equally well as the displaced atoms postulated by Stubbles. Since tetrahedral as well as octahedral sites would be unoccupied, the differences in the potential (and activation) energies associated with the different types of sites (and jumps) would have to be considered when proposing a self-diffusion mechanism on the assumption of a structure deficient in both sublattices. It is, of course, possible for the structure of stoichiometric Co_9S_8 to conform with the formula $Co_{9(1-\delta)}S_{8(1-\delta)}$ and yet contain some of the cobalt atoms in interstitial, octahedrally co-ordinated positions,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

though it cannot be determined from the densities whether this is the case. The X-ray diffraction intensities are too insensitive to be of use for small values of δ.

Evidence presented in the preceding section shows that in π(Fe,Co,Ni,S) the M:S ratio was not exactly 9:8 but higher. Of the several possibilities to account for the excess metal the most likely one seems the arrangement proposed by Stubbles for $Co_{9+z}S_8$, though not necessarily with the sulphur sites fully occupied. The correctness of this contention cannot, however, be supported from density measurements, as the observed densities do not refer to homogeneous π but to π-containing admixtures of other phases. Densities and relative amounts of the admixed phases have not been determined, since the gross compositions of the samples were restricted to the M_9S_8 section.

Neutron-Diffraction Study of Co_8NiS_8 *and the Possibility of Existence of an Ordered* π *Phase*

It seemed worth while to investigate whether in the stoichiometrically favorable samples Co_8FeS_8 and Co_8NiS_8 the Fe and Ni atoms would segregate into the octahedral sites with cobalt remaining in the tetrahedral positions. Since nickel appeared to enter the π structure more readily than iron, Co_8NiS_8 rather than Co_8FeS_8 was the composition selected for a neutron-diffraction study.

The coherent neutron scattering amplitudes of iron, cobalt, and nickel are, in 10^{-12} cm, 0.96, 0.28, and 1.03 respectively (38). The appreciable difference between the scattering amplitudes of iron and nickel on the one hand and that of cobalt on the other makes it possible to distinguish between the two extreme cases of distribution of metal atoms, i.e., between the completely random arrangement and complete segregation.

All the neutron-diffraction maxima appearing in the experimentally accessible angular region 7.5–40.5° (θ) in the powder patterns of slowly cooled Co_9S_8 and Co_8NiS_8 were accounted for on the basis of the chemical unit cell of π. The relative diffraction intensities of the more prominent maxima are listed in Table III. These figures provide, at the

same time, information concerning the degree of order in Co_8NiS_8 and a correctness test for the two proposed structure models of the phase. From the intensity values normalized to I_{440} (upper half of Table III) one finds that a comparison of I_{obs} and I_{calc} of Co_9S_8 favors the LLW model. This provides an independent confirmation of a similar conclusion based on the X-ray diffraction data. For Co_8NiS_8 the best agreement is obtained for the random LLW structure.

Since interference from the second-order maxima could not be eliminated completely even with a samarium oxide filter, it may be argued that the agreement between I_{obs} and I_{calc} is to some extent fortuitous. This objection is removed if one considers that the integrated diffraction maxima from atomic planes of Co_9S_8 and Co_8NiS_8 with identical indices are of the same order of magnitude. Consequently in the ratios $I(Co_8NiS_8)/I(Co_9S_8)$ the effect of the second-order maxima will be very substantially reduced and the comparison will be more accurate and reliable, provided only that the diffraction peaks are reasonably strong. This is indeed the case (lower half of Table III). Comparison of the observed intensity ratios with those calculated for four different models confirms the conclusion made in the preceding paragraph, but unfortunately the uniqueness of choice between the LLW and Eliseev's models with statistical distribution is reduced. There is, however, no doubt that the Co_8NiS_8 sample had a randomized structure.

That ordered Co_8MS_8 phases of this type exist has been shown in cases with M other than nickel (39). The failure of Co_8NiS_8 to form an ordered phase must then be due to the lack of preference of nickel for octahedral co-ordination, though the ordered phase $Co_8^{IV}Ni^{VI}S_8$ might still be obtainable by even longer annealing at a more favorable (as yet unknown) temperature. In this respect Co_8NiS_8 differs from the oxidic spinels, in which divalent nickel has been shown to favor octahedral positions (cf., for instance, references 40, 41, and 42). The metal distribution in the somewhat related sulphocobaltite $NiCo_2S_4$ (43) is not yet known, but for the corresponding cobaltites McClure (41) has predicted that $FeCo_2O_4$ and Co_3O_4 should be normal spinels, whereas $NiCo_2O_4$ should be of the inverse type.

We have not been able to corroborate Eliseev's contention that the O_h^5—$Fm3m$ symmetry is lowered in natural pentlandite by an ordering of the iron and nickel atoms in $32(f)$, but the possibility of such an arrangement cannot be ruled out, since the symmetry degeneration caused by the ordering may be virtually undetectable (see 15 for a more detailed discussion).

Some idea of the tendency of nickel and iron to form ordered sublattices in $4(b)$ might be obtained from a comparison of the self-diffusion coefficients of nickel and iron in Co_8NiS_8 and Co_8FeS_8 (or its nearest homogeneous equivalent) with those of cobalt in Co_9S_8 over a range of temperatures. A similar investigation of the variation of the mobility of cobalt with composition along the line Co_9S_8–$Fe_{4.5}Ni_{4.5}S_8$ might also be useful as an extension of Stubbles' work.

Further Observations

Our diffraction data are not adequate to demonstrate the exact shape of the cobalt and sulphur co-ordination polyhedra in the π structure. Before the parameters x_{Co} and x_S are known with sufficient accuracy, reliable values for the interatomic distances in π(Co,S) cannot be obtained, nor can conclusions be made from the co-ordination stereochemistry of the atoms about their orbital configurations.

In π(Fe,Co,Ni,S) there is an additional complication arising from the possibility of existence of ordered sublattices at certain compositions. For example, in Co_8NiS_8 with the cobalt and nickel atoms distributed statistically over the tetrahedral and octahedral sites, x_{Co} and x_{Ni} might have somewhat different values, so that only average values of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the M–S distances could be obtained from $a(\pi)$. The same holds a fortiori for compositions that preclude ordered arrangements.

As for the increase of $a(\pi)$ on replacing cobalt in Co_9S_8 severally by iron and nickel, one would not expect to find that both kinds of atoms expand the lattice. Lotgering (43) reported a similar situation for the spinel-type cobaltites $Fe_{0.99}Co_{2.01}S_4$, Co_3O_4, and $NiCo_2O_4$, whose lattice parameters were 8.254, 8.092, and 8.121 Å, respectively. He did not succeed in preparing the sulphocobaltite $FeCo_2S_4$, but the lattice constants of Co_3S_4 and $NiCo_2S_4$, 9.416 and 9.392 Å, respectively, show the reverse trend on going from cobalt to nickel. The interatomic distances "M^{2+}–X" in the chalkogenides of the 3d-series do show a minimum at cobalt for octahedrally co-ordinated M (44), but with a ratio of 8:1 of tetrahedral to octahedral sites in π attempts to rationalize the situation seem, in the absence of more detailed information on the distribution of the metal atoms in the nonionic Co_8FeS_8 and in the sulphospinels, premature. The increasing departure of π(Co,S) from the stoichiometric formula on progressive replacement of the cobalt with iron and nickel, and the possibility of some of the metal atoms being accommodated interstitially, may be partly responsible for the variation of $a(\pi)$ with composition and should be considered in addition to the effect of the interatomic distances.

ACKNOWLEDGMENTS

The authors would like to express their gratitude to the following persons and agencies: Colombo Plan Administration, Ottawa, for a scholarship awarded to one of them (M.A.I.); Nova Scotia Research Foundation for providing the salary of a student assistant for two summers; Mr. Muntaz Ali and Miss Judith Osyany for assistance with the experimental work; Dr. L. Castelliz for evaluation of a number of X-ray diffraction photographs; Dr. B. N. Brockhouse, Atomic Energy of Canada Ltd., Chalk River, Ontario, for permission to use his neutron spectrometer; Dr. J. R. Stubbles, Department of Metallurgy, University of Manchester, for loan of his unpublished Ph.D. Thesis; and Mr. S. Bender, Application Laboratory, Philips Electronic Instruments, Mount Vernon, N.Y., for obtaining some of the diffractometer charts.

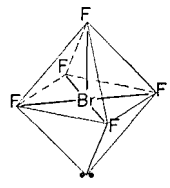
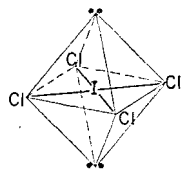
BOND LENGTHS AND BOND ANGLES IN OCTAHEDRAL, TRIGONAL-BIPYRAMIDAL, AND RELATED MOLECULES OF THE NON-TRANSITION ELEMENTS[1]

R. J. GILLESPIE



ABSTRACT

The stereochemistry of molecules in which there are five or six pairs of electrons in the valency shell of a central atom is discussed in terms of the repulsions that exist between pairs of electrons in the valency shell as a consequence of the operation of the Pauli exclusion principle. An explanation is given for the difference in lengths of the axial and equatorial bonds in molecules such as PCl_5 and ClF_3 whose structures are based on the trigonal-bipyramidal arrangement of five valency-shell electron pairs. The fact that in molecules with a central atom with a valency shell of six electron pairs, one of which is a lone pair and which have the structure of a square pyramid, the central atom always lies below rather than in, or above, the base of the square pyramid, is also accounted for.



The stereochemistry of an atom in a molecule is determined by the total number of electron pairs, including both lone pairs and bonding pairs, in its valency shell (1). The operation of the Pauli exclusion principle which keeps electrons of the same spin as far apart as possible determines the arrangement of these electron pairs and this in turn determines the stereochemistry (2, 3). For non-transition elements, five and six pairs of valency-shell electrons adopt the trigonal-bipyramidal and octahedral arrangements respectively (1, 3). If we denote a central atom by A, a ligand by X, and an unshared pair of electrons by E then AX_6 molecules are octahedral (e.g., SF_6(I)), AX_5E molecules are square pyramidal (e.g., BrF_5(II)), AX_4E_2 molecules are square planar (e.g., ICl_4^-(III)), AX_5 molecules are trigonal-bipyramidal (e.g., PCl_5(IV)), AX_4E molecules have the structure of $TeCl_4$(V), and AX_3E_2 molecules are T-shaped (e.g., ClF_3(VI)). In these molecules the bond angles are only equal to the "ideal" values of 120° and 90°

and the covalent radius of the central atom is only the same for all the bonds if all the electron pairs are strictly equivalent to each other. In many of these molecules the valency-shell electron pairs are not all equivalent even when all the ligands are the same and therefore deviations of the bond angles from the ideal values and differences in bond lengths are to be expected. These deviations from ideal structures which have been briefly considered in a previous publication (3) are discussed in detail in this paper.

AX_5, AX_4E, AND AX_3E_2 MOLECULES

Bond Lengths

It is a special feature of the trigonal-bipyramidal arrangement of five electron pairs that the positions occupied by the electron pairs are not all equivalent to each other in contrast to the completely equivalent positions of all the electron pairs in the tetrahedral, octahedral, and square antiprism arrangements of four, six, and eight electron pairs respectively. In the trigonal bipyramid the two axial positions are not equivalent to the three equatorial positions (*a* and *e*, respectively, in IV). An electron pair in an *a* position has three nearest neighbors at an angle of 90° and one further away at 180° while an electron pair in an *e* position has two nearest neighbors at an angle of 90° and two further away at 120°.

The Pauli repulsion forces which determine the arrangement of the electron pairs are of such a nature that they are very small when the orbitals of the two electron pairs do not overlap to an appreciable extent but they increase very considerably as the interelectron distance is reduced and the orbitals begin to overlap appreciably, i.e., they may be approximately represented as a function of some large inverse power of the distance (3). Thus, when considering the resultant magnitude of the repulsions between sets of electron pairs the repulsions between nearest neighbors are much more important than those between electron pairs that are further apart, and, to a first approximation, all repulsions except those between nearest neighbors may be neglected. In the trigonal-bipyramidal arrangement of five electron pairs the two axial pairs each have three equatorial pairs at an angle of 90° as nearest neighbors while the equatorial pairs each have only two axial pairs at 90° as nearest neighbors. Hence the total repulsion exerted on the axial pairs is greater than that exerted on the equatorial pairs. This means that a trigonal-bipyramidal arrangement with the electron pairs all at the same distance from the nucleus will not be the true equilibrium arrangement but the distances of the electron pairs from the nucleus will adjust themselves so as to equalize the repulsions between any pair of electrons. Evidently this will result in the axial electron pairs being at a greater distance from the nucleus than the equatorial pairs. Therefore the lengths of bonds to identical ligands in the axial and equatorial positions will not be the same (as is necessarily the case for bonds to four, six, and eight identical ligands in the tetrahedral, octahedral, and square antiprism arrangements, respectively), but the axial bonds will be longer than the equatorial bonds. More generally, to take account of cases where the ligands are not all identical, we can say that the covalent radius of the central atom will be greater in the axial than in the equatorial direction.

When one or more of the electron pairs is a lone pair another factor must be considered. Bonding pairs which are under the influence of two nuclei occupy more restricted "thinner" orbitals than lone pairs which are under the influence of only one nucleus and occupy less restricted "fatter" orbitals (3). These larger lone-pair orbitals overlap more than the smaller bonding orbitals and consequently lone-pair electrons repel other lone-pair or bonding electrons more strongly than bonding electrons repel each other.

Thus in AX_4E and AX_3E_2 molecules where there are one or two lone pairs in equatorial positions the greater repulsions exerted by the lone pairs will reinforce the difference in the lengths of axial and equatorial bonds discussed above.

Covalent radii for phosphorus, tin, selenium, tellurium, chlorine, bromine, and iodine in AX_5, AX_4E, and AX_3E_2 molecules have been calculated from the experimental bond distances by subtracting the covalent radii (4) of the ligand atoms and the values are given in Table I. It may be seen that for all 13 molecules whose bond lengths have been

determined with sufficient accuracy the axial radius of the central atom is greater than its equatorial radius by 0.1 to 0.2 Å.

The five electron pairs are of course not strictly localized at the corners of the trigonal bipyramid. These are simply the positions at which they are most probably to be found and they may be regarded as effectively occupying all the space in the valency shell, each pair occupying an orbital which is directed towards one of the corners of the trigonal bipyramid; these are essentially the sp^3d orbitals of valence-bond theory. Just as the five positions for the electron pairs are not equivalent to each other so the five sp^3d orbitals are similarly not equivalent. It has been shown by making certain assumptions concerning the effective atomic numbers of the atoms involved that maximum overlap of an orbital of the ligand atom with an equatorial orbital of the central atom occurs at a slightly smaller internuclear distance than for an axial orbital (10) and therefore the axial bonds are expected to be slightly longer than the equatorial bonds. This is an alternative explanation to that given above but it involves some arbitrary assumptions and is in a sense less fundamental. Although the hybrid orbitals that it uses are a convenient way of describing the electron arrangement this arrangement is essentially determined by the operation of the Pauli exclusion principle. McCullough and Marsh (11) have suggested that s orbitals of the next highest quantum shell (e.g. 6s rather than 5s for tellurium) contribute to the hybrid orbitals involved in the axial bonds. Such orbitals may indeed make a small contribution to the actual bonding orbitals but this is not a satisfactory *explanation* of the anomalous length of the axial bonds but only a convenient approximate *description* of the bond orbitals.

The difference in bond lengths in ClF_3 has been attributed to double bonding between the equatorial fluorine atom and the chlorine, but no explanation was given for why double bonding occurs with the equatorial and not the axial fluorine atoms (12). Moreover, such a special explanation is not necessary in view of the fact that this molecule has a five electron pair valency shell in which we have seen that axial single bonds will be longer than equatorial single bonds to the same ligands.

Bond Angles

For AX_5 molecules with five identical ligands or with three identical equatorial and two identical axial ligands, as in PF_3Cl_2, all the bond angles would be expected, and are found, to be equal to either 90° or 120°. In all other cases where there are two or more different ligands small deviations from the 90° and 120° bond angles would be expected, but no bond angles have been determined for such molecules.

For AX_4E molecules the extra repulsion exerted by the lone pair would be expected, in addition to lengthening the axial bonds as explained above, to decrease the angles between all the bonds. It may be seen from Table II that the angle between equatorial

bonds is in every case reduced to a value considerably less than 120°. The angle between the two axial bonds differs only slightly from the value of 180°. It has been pointed out previously (13) that for second and subsequent row elements repulsions between valency-shell electron pairs do not become of appreciable magnitude until they make angles of approximately 90° with each other at the nucleus. It is reasonable then that the greatest distortion should occur in the angle between the equatorial bonds which is 120° in the ideal case as the repulsion between these electron pairs is small. The axial bond electrons make an ideal angle of 90° with the equatorial bond electrons, and any reduction in the angle between the axial bonds necessitates a simultaneous reduction in the angle that they make with the equatorial bonds. Such a decrease in this angle will be strongly opposed by the strong electron-pair repulsions which come into play at an angle of approximately 90°. In the case of $(CH_3)_2TeCl_2$ (VIII) the Cl—Te—Cl angle is slightly less than 180°, i.e., the Te—Cl bonds are bent slightly towards the Te—C bonds and away from the lone pair, as would be expected. In all other cases where a deviation from the ideal angle of 180° has been recorded the angle between the axial bond is slightly greater than 180°, i.e., the axial bonds are bent slightly away from the equatorial

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

bonds and towards the lone pair, e.g., $(C_6H_5)_2TeBr_2$ (VIII). This is not in accordance with the prediction made above but it may be noted that in all these cases the equatorial

(VII)

(VIII)

ligands are phenyl, or substituted phenyl, groups and there may be additional repulsions between the bulky phenyl groups and the axial ligands and, moreover, the lone pair on the central atom might be expected to be conjugated with, and partially delocalized into, the aromatic rings which will reduce its repulsive effect on the bond electron pairs. The increased electron density in such partial double bonds between the tellurium and the benzene rings would increase the repulsions between these bonds and the axial bonds and this would also tend to decrease the angle between the axial bonds.

For AX_3E_2 molecules the extra repulsions exerted by the two lone pairs in the equatorial positions cause the axial bonds to lengthen as discussed above and the angles between the axial and equatorial bonds to be slightly smaller than 90° as shown by the examples in Table II.

AX_6, AX_5E, AND AX_4E_2 MOLECULES

In octahedral AX_6 molecules all the bonds to identical ligands will be the same length, i.e., the radius of the central atom will be the same in all directions. For AX_5E molecules which have a square pyramidal shape the extra repulsion exerted by the lone pair would be expected to cause the neighboring four bonds, i.e., those at the base of the square pyramid to be slightly longer than the fifth bond to the apex. Experimental evidence on molecules of this type is scanty (5). The four square-planar bonds are longer than the single bond to the apex in $SbCl_5^{2-}$ but they appear to be shorter in SbF_5^{2-}. The extra repulsion exerted by the lone pair would also be expected to decrease the angles between the bonds to slightly less than 90° giving a molecule in which the central atom is slightly below the base of the square pyramid. It has been recently pointed out by Grednic and Scavnicar (14) that this type of structure is observed in the following substances which all contain five-co-ordinated tervalent antimony with a square pyramidal configuration: K_2SbF_5, $KSbF_4$, $FeSb_2S_4$, $HgSb_4F_8$, $PbAgSbS_3$, Sb_2S_3. The same structure is also found for BrF_5 (15). In each case the central atom is found to be 0.1–0.3 Å below the base of the square pyramid. No example is known where the central atom in an AX_5E molecule is either in, or above, the base of the square pyramid formed by the five ligands.

Molecules of the type AX_4E_2 (e.g., ICl_4^- and BrF_4^-) are expected, and are found, to be square planar with equal bond angles and bond lengths (5, 16).

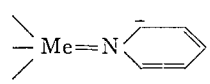
π-BONDING IN INORGANIC COMPOUNDS

II. THE TRANSMISSION OF ELECTRONIC EFFECTS THROUGH SQUARE-PLANAR COMPLEXES[1, 2]

A. D. WESTLAND AND L. WESTLAND

ABSTRACT



Measurement of the transmission of electronic effects through square-planar complexes of platinum has provided evidence of double bonding to halogen and nitro ligands. The nuclear magnetic resonance chemical shift of the β-protons in pyridine ligands serves as an indicator of electron drift in the complexes. Justification is thus provided for the assumed mechanism of the trans effect involving π-bonding. The observations are in accord with the assumption that the increase in trans-directing powers with atomic number of the halogen is due to an increasing tendency to accept *d*-electrons from the central atom.

Chatt, Duncanson, and Venanzi have sought to explain the trans-directing power of certain ligands in substitution reactions involving complex compounds by making use of a model involving the donation of *d*-electrons (1). Their explanation rests upon an examination of N—H stretching frequencies of amines situated trans to various ligands. It was argued that since the frequencies showed no correlation with trans-directing power the effect could not be due to a weakening of the metal – amine bond as a result of the inductive influence of ligands at the antipode of the molecule. These experiments were actually inconclusive, however, for if the trans effect operates as postulated by Grinberg (2) it does not depend simply upon the strength of the bond to the group being replaced but rather upon its strength *relative* to that of a similar bond in the cis direction. In a subsequent publication (3), Chatt and co-workers examined the infrared spectra of some complexes having cis configuration, as well as others having trans configuration, but this time they found no need to postulate the existence of π-bonds in their compounds.

A number of authors have questioned the generality of the theory of π-bonding (4, 5, 6). In fact it appears that the only evidence cited in support of the theory which is not circumstantial in character is that of Reeves (7), who found by means of a broad-line N.M.R. investigation of dichlorodiethylene-μ,μ'-dichlorodiplatinum(II) that the ethylene ligand is not free to rotate. Thus π-bonding to olefins seems clearly established. The present authors, in seeking evidence of such bonding to the *d*-orbitals of halogen atoms have examined the electron drift in the cis and trans forms of square-planar complexes of platinum(II) and a description of this investigation follows.

DISCUSSION AND RESULTS

The stability of complexes containing pyridine, α,α'-dipyridyl, *o*-phenanthroline, etc. may be variously accounted for as being due to (i) the mesomeric effect involving a partial double bond from the central atom to the nitrogen atom:

or (ii) an unusually large interaction energy resulting from a high polarization. Condition (i) would give rise to a π-electron drift toward the ligand as well as a σ-electron drift

[1]*Manuscript received May 30, 1960.*
Contribution from the Department of Chemistry, University of Ottawa, Ottawa, Ontario.
[2]*Part I: Can. J. Chem.* **38**, *1300 (1960).*

away, whereas condition (ii) would involve only a drift away from the ligand. It therefore seemed promising to examine the high-resolution N.M.R. spectra of complexes containing pyridine.

If the bonding in *trans*-dipyridinedichloroplatinum(II) and *trans*-dipyridinedichloropalladium(II) is solely of σ-type, the stronger bonding of the former compound should stem from a greater polarization of the ligands. A comparison of the spectra of these two compounds failed to detect any significant difference in chemical shifts, however (see Table I). It is assumed that the chemical shift of the β-proton in pyridine com-

TABLE I

Chemical shifts of the pyridine β-hydrogen atoms in metal complexes (Values are given in cycles per second at 60 megacycles with respect to 0.6 mole% uncomplexed pyridine in dimethylsulphoxide)

Compound	I cis form	II trans form	Difference (II − I)

[Pd py_2Br_2]		−5.8	
[Pd py_2I_2]		−4.8	

plexes relative to uncomplexed pyridine is a measure of the net inductive effect to which the ligand is subject.* If, on the other hand, the greater stability of the platinum compound is due at least in part to stronger double bonding, the π-electron drift would tend to compensate for the change in σ-bond polarity. The result is thus suggestive of π-bonding.

The examination of N.M.R. spectra of dipyridine – platinum complexes in cis and trans configurations revealed direct evidence that ligands which possess vacant *d*-type orbitals do indeed draw electrons away from the central atom as well as form a σ-bond with it. This supports the theory of Chatt, Duncanson, and Venanzi (1) that a large trans effect is due to π-bonding of the ligand responsible, with a consequent diminution of the *d*-orbital electron density on the opposite side of the molecule.

Figure 2 illustrates the conceived nature of the electron drift. Solid lines to the ligands represent σ-bonds and dotted lines represent π-bonds. It will be noted that if the acido group, X, forms π-bonds, the *d*-electrons of the platinum atom are subjected to a "pull" from all four directions. This condition would lead to bonding of various strengths and bond orders. This is indicated qualitatively in the figure by the relative densities of the dots. The distinction between cis and trans configurations can be rationalized following Chatt, Duncanson, and Venanzi. Two ligands trans to each other along the *x*-axis must both draw their *d*-electrons from the d_{xy} and d_{xz} orbitals. If a group be in the cis position, it draws its electrons from the d_{xy} and the d_{yz} orbitals. Because there is a competition for the *d*-electrons, a strongly bonding ligand in the *x*-direction will weaken the π-bond to a ligand in trans position more than that to one in the cis position. The groups X,

**The β-proton is the best choice for comparison because its chemical shift should be relatively independent of changes in the resonance of the ring due to complexing and it should be less subject to field effects than the α-shift. The spectra revealed very little or no changes in resonance in all the complexes studied in any case. A comparison of typical spectra is shown in Fig. 1.*

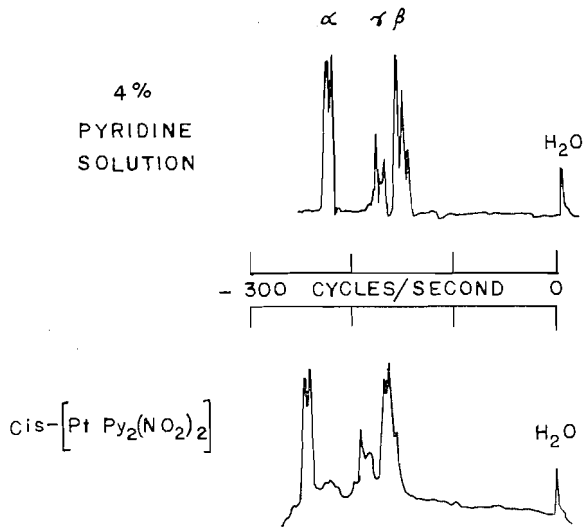

FIG. 1. Comparison of the spectra of free and complexed pyridine in dimethylsulphoxide solution.

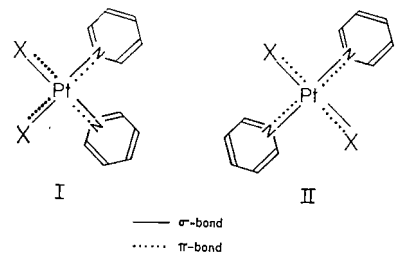

FIG. 2. Relative strengths of the π-bonds in *cis*- and *trans*-[Pt py_2X_2].

in Fig. 2, are considered more strongly π-bonding than pyridine. Thus we have shown the π-bonds to pyridine as being weaker in I than in II. It must be remembered that the σ-bonds will likewise differ somewhat in strength in the two configurations respectively. Therefore, in interpreting the nuclear magnetic resonance spectra of these complexes, account must be taken of inductive effects due to both *d*-acceptor character and electronegativity differences.

The chemical shift of the β-protons in a series of corresponding cis and trans isomers relative to that in uncomplexed pyridine and the differences between these values are given in Table I. The compounds are listed downwards in order of increasing trans-directing power of the "X" ligands (1). The difference column shows a gradual increase from a negative value at [Pt $py_2(NH_3)_2]Cl_2$ to the most positive value at [Pt py_2I_2] but there is a reversal in trend at [Pt $py_2(NO_2)_2$]. These results cannot be explained on the basis of the electron-donating power of the ligands alone. In what follows, the correctness of the π-bonding theory will be assumed and the chemical shifts rationalized accordingly.

Consider the compound [Pt $py_2(NH_3)_2]Cl_2$ in which there is little or no π-bonding to the NH_3 groups. The relatively large electron-donor character of ammonia will give rise to a smaller shift to lower magnetic field strength when ammonia is trans to pyridine, i.e. in the cis isomer, than would be the case when the other pyridine is in the trans

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

position assuming that operation of inductive effects through a straight angle is more pronounced than that through a right angle. Moreover, the diamagnetic effect of "ring current" in rotating pyridine rings would also have the effect of shifting the resonance in the cis compound to higher field relative to the trans compound. The negative entry in the difference column of the table is therefore plausible. The difference value for [Pt py_2Cl_2] is still negative even though in this case the chlorine atom has a stronger trans influence than pyridine. The inductive effect through the σ-bonds therefore still predominates over any electron drift in the opposite direction due to π-bonding.

As the trans influence of the various halogens increases with atomic number, the effect of π-bonding appears in the chemical shifts of the cis isomers becoming greater than those of the trans forms. If it were not for the decreasing electronegativity of the halogen atoms, as is evidenced by the decreasing shifts down the series of trans isomers, we might have obtained an even more pronounced trend among the difference values. Thus the near constancy of the chemical shifts in the cis halo compounds indicates an approximate compensation of the increasing double-bond character and decreasing electronegativity in this configuration.

The nitro group has a large trans-directing power but in the isomers of [Pt $py_2(NO_2)_2$] it provides chemical shifts giving a large negative difference value, viz. −8.0. This is not really anomalous when one reasons as follows. The nitro group is negative and the nitrogen atom is almost as strongly electronegative as chlorine. Neglecting *d*-electron drift for the moment, we should expect the chemical shift of *trans*-[Pt $py_2(NO_2)_2$] to be slightly more positive than −6.5, the value for *trans*-[Pt py_2Cl_2]. The value is actually −16.0, however, which is plausible if one considers the influence of π-bonding and mesomerism of the nitro group. The nitrogen atom is much smaller than chlorine so that it would be expected to exert a greater inductive effect through the σ-bonds, in fact about as much as in [Pt $py_2(NH_3)_2$]Cl_2 which provides a difference value of ca. −10.5. The difference value for the nitro compound is less than this which is qualitatively what is expected from the influence of π-bonding.

Because the differences in chemical shift are very small it might be argued that they are caused by field or solvent influences. Thus the trend in the different values among the various halogen complexes, which is due principally to the trend among the trans-isomers, might be ascribed to an increasing field effect with increase in atomic number of the halogen atoms. However, the chemical shift along the analogous series of trans-complexes of palladium exhibits only a slight trend to higher field strength. Since the palladium analogues have nearly the same molecular dimensions as the platinum compounds, the difference in behavior must be due to a difference in the character of the metal atoms.

The same experiment shows that the trend in chemical shift of the platinum compounds is not due simply to a direct solvent interaction with the ring protons. Nevertheless, because of the highly polar nature of the solvents which it was found necessary to use, the question of solvent influence is nevertheless a serious one.* In order to investigate the influence of the solvent, the following control experiment was carried out.

Trans-pyridinetri-*n*-propylphosphinedihaloplatinum compounds were found to be soluble in solvents of low polarity as well as in dimethylsulphoxide and they should be closely analogous to *trans*-dipyridine complexes. Chemical shifts relative to that of the chloro compound in carbon tetrachloride are given in Table II for three compounds in

**The authors are indebted to the referee for emphasizing this point.*

TABLE II

Influence of solvent on the chemical shift
(Values are expressed in cycles per second with respect to [Pt py(PPr_3)Cl_2] in CCl_4)

	Solvent					
Compound	CCl_4	Difference	$(CH_3)_2SO$	Difference	$(CH_3)_2CO$	Difference
[Pt py(PPr_3)Cl_2]	0.0	2.3	+13.2	1.9	+53.6	2.4
[Pt py(PPr_3)Br_2]	+2.3	0.0	+15.1	0.4	+56.0	0.0
[Pt py(PPr_3)I_2]	+2.3		+15.5		+56.0	

each of three solvents. Although there is a large solvent effect, the difference columns show that it is essentially the same for all three compounds. We assume that the dipyridine compounds are not more affected by field and solvent influences.

EXPERIMENTAL

The nuclear magnetic resonance spectra were obtained with a Varian Associates 60 megacycle spectrometer, Model V 4302, adjusted for high resolution. Spectra were calibrated with respect to an external water standard (1% protons in D_2O) by means of a Hewlett – Packard side-band oscillator, which, in turn, was calibrated with a Hewlett – Packard electronic counter. The temperature of the resonant system was constant to $\pm 0.5°$ C. Each of the values of chemical shift reported is the mean of 8 to 14 determinations on a single sample and was calculated simply on the basis of the positions of the sharpest peaks in the β-proton resonance. This procedure appeared to be justified for there were no apparent differences in coupling among the several spectra obtained. The chemical shifts of the dipyridine complexes are expressed relative to 0.6 mole% pyridine in dimethylsulphoxide. Bulk diamagnetic susceptibility corrections were carried out following the method of Pople, Schneider, and Bernstein (8).

Because of the low solubilities of the dipyridine salts, 0.3 mole% solutions were used for N.M.R. examinations. The chloride salts were dissolved in D_2O and the remaining compounds in dimethylsulphoxide. Ten per cent (w/v) solutions of the tri-*n*-propylphosphine complexes in dimethylsulphoxide, acetone, and carbon tetrachloride were employed for the investigation of solvent effect. The chemical shifts were corrected for bulk diamagnetic susceptibility of the media.

Debye – Scherrer diffraction patterns showed that all of the compounds could be recrystallized unchanged from their respective solvents.

Preparations

Trans-dipyridinedihalopalladium, *cis*- and *trans*-dipyridinedichloroplatinum, *cis*- and *trans*-dipyridinediammineplatinum monohydrate, and *cis*- and *trans*-dipyridinedinitroplatinum were prepared by existing procedures (9, 10, 11, 12). Carbon, hydrogen, platinum, and palladium analyses agreed well with the calculated compositions.

Cis-dipyridinedibromoplatinum

Finely powdered *cis*-dipyridinedichloroplatinum (200 mg) was suspended in a gently boiling solution containing 10 ml water, 15 ml acetone, and 2 g KBr. After 60 minutes the solid was separated by filtration and washed successively with hot water and methanol. The yellow color of the product was slightly more intense than that of the chloro analogue. The X-ray diffraction pattern revealed a homogeneous product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

having a crystal lattice isomorphous with, but slightly larger than, that of the chloro compound. Anal. Calc. for [Pt py_2Br_2]: C, 23.6; H, 1.96; Pt, 38.1. Found: C, 23.7; H, 1.96; Pt, 38.6.

Trans-dipyridinedibromoplatinum

The preparation was similar to that described for the cis compound starting, however, with *trans*-dipyridinedichloroplatinum. The color of the product was slightly deeper than that of the cis analogue. The X-ray diffraction pattern showed the product to be homogeneous and isomorphous with, but distinct from the starting material. Anal. Calc.: *vide supra*. Found: C, 23.9; H, 2.11; Pt, 38.6.

Cis-dipyridinediiodoplatinum

This was prepared in a manner similar to that of the bromo compound except that the product was easily soluble in the reaction mixture and had to be isolated by evaporation. The product consisted of well-formed orange crystallites which were more readily dissolved by organic solvents than the other halogen analogues. Anal. Calc. for [Pt py_2I_2]: C, 19.9; H, 1.66; Pt, 32.2. Found: C. 20.3; H, 1.70; Pt, 32.3.

Trans-dipyridinediiodoplatinum

Starting from *trans*-dipyridinedichloroplatinum, the same procedure was used as in the case of the cis compound except that 100 ml instead of 15 ml of acetone were used in preparing the reaction solvent. The product was again orange in color and well crystallized. Anal. Calc.: *vide supra*. Found: C, 19.7; H, 1.73; Pt, 31.4.

Trans-pyridinetri-n-propylphosphinedichloroplatinum

This was prepared by a procedure analogous to that used by Chatt (13) to prepare *trans-p*-toluidine-tri-*n*-propylphosphinedichloroplatinum except that pyridine was used in place of *p*-toluidine. The product recrystallized from ethanol was bright yellow. Anal. Calc. for [Pt $(C_3H_7)_3P$ py Cl_2]: C, 33.3; H, 5.18; Pt, 38.6. Found: C, 33.7; H, 5.28; Pt, 38.9.

Trans-pyridinetri-n-propylphosphinedibromoplatinum

The method of preparation was the same as that used for the chloro analogue except that dibromobis-(tri-*n*-propylphosphine)-μ,μ'-dibromodiplatinum was used. This latter compound was prepared as described by Chatt (14). The product was golden yellow in color. Anal. Calc. for [$Pt(C_3H_7)_3P$ py Br_2]: C, 28.3; H, 4.41; Pt, 32.8. Found: C, 28.0; H, 4.34; Pt, 29.6.

Trans-pyridinetri-n-propylphosphinediiodoplatinum

This also was prepared in a similar manner using diiodobis-(tri-*n*-propylphosphine)-μ,μ'-diiododiplatinum (14). The product was yellow-orange. Anal. Calc. for [$Pt(C_3H_7)_3$-Ppy I_2]: C, 24.4; H, 3.81; Pt, 28.3. Found: C, 24.5; H, 3.78; Pt, 28.8.

SOME PROPERTIES OF PURE POLYOXYETHYLENEGLYCOL ETHERS IN SOLUTION[1]

A. F. Sirianni and B. A. Gingras

ABSTRACT

Solution properties of a series of hexaoxyethyleneglycol ethers having 8 to 16 carbon atoms in a paraffin chain along with a number of diethers were assessed in ethanol at 48 and 60° C. The molecular weights at infinite dilution indicated that the compounds are unassociated. Solvation effects were observed for the monoethers having 14 or more carbon atoms in the hydrophobic portion of the molecule, but were absent for those molecules containing 12 carbon atoms or less. The apparent micellar weights suggested that association did not proceed beyond a dimer for most of the hexaoxyethyleneglycol compounds. The diethers obeyed Raoult's law up to the critical micelle concentration while different apparent association patterns were observed beyond this concentration.

INTRODUCTION

The molecular weight, critical micelle concentration (cmc) and apparent association patterns of surface-active materials in solution have been determined by means of vapor pressure depression using various means for its measurement. Data have been obtained in this way by McBain *et al.* (1) using thermistors and aqueous solutions of alkyl – aryl sulphonates, by Kitahara (2) on dodecyl-ammonium-benzoate, -caprylate, and -butyrate in cyclohexane and by Debye (3) with a series of α-glycerides in a variety of nonaqueous solvents.

Additional information concerning the micellar weight and critical micelle concentration of nonionic detergents, based on ethylene oxide, has been obtained from light scattering measurements in aqueous (4) and in benzene solutions (5). Recently, ultracentrifugal measurements on aqueous systems have been employed (6). Large differences between weight-average (Mw) and number-average (Mn) molecular weight exist. Debye (7) pointed out that small amounts of impurities enhance light scattering leading to anomalous micellar sizes. Low molecular weight impurities decrease the number-average molecular weight, thus widening the gap between these two methods of measurement. Becher *et al.* (8) presented some evidence that nonequilibrium solutions containing an appreciable concentration of micelles may be present below the critical micelle concentration.

The present investigation was undertaken in an effort to assess the colligative properties of some pure nonionic detergents by vapor pressure depression measurements, utilizing the difference in vapor pressure between pure solvent and solutions for a series of chemically well-defined polyoxyethyleneglycol ethers. Their physical properties and method of preparations were given by Gingras and Bayley (9, 10). The compounds examined were mono- and di-ethers of hexaoxyethyleneglycol, covering a molecular weight range from 390 to 730. Some other pure compounds of different ethylene oxide content were also studied. A list of the various compounds is given below:

I. Monoethers containing six ethylene oxide units:

$$R—O—(CH_2CH_2O)_6H;\quad R = n\text{-}C_8H_{17},\ n\text{-}C_{12}H_{25},\ n\text{-}C_{14}H_{29},\ n\text{-}C_{16}H_{33}.$$

II. Monoether containing seven ethylene oxide units:

$$p\text{-iso-}C_8H_{17}—C_6H_4—O(CH_2CH_2O)_7H.$$

[1]*Manuscript received October 4, 1960.*
Contribution from the Division of Applied Chemistry, National Research Council, Ottawa, Canada. Issued as N.R.C. No. 6115.

III. Diethers containing six ethylene oxide units:

$$R—O(CH_2CH_2O)_6R \qquad R = n\text{-}C_{12}H_{25} \text{ and } n\text{-}C_{18}H_{33}.$$

IV. Diether containing two ethylene oxide units:

$$n\text{-}C_{18}H_{37}O(CH_2CH_2O)_2C_{18}H_{37}.$$

V. Diether derivative of *n*-butane:

$$p\text{-iso-}C_8H_{17}—C_6H_4—O(CH_2)_4O—C_6H_4—C_8H_{17}\text{-}p\text{-iso}.$$

The preparation and physical properties of the latter two substances, which have not been reported before, are described in the experimental part.

The diethers are not soluble in water. Monoethers become less hydrophilic with increase in the number of carbon atoms in the paraffin chain, with decreasing ethylene oxide content and with increased temperature. In order to compare the behavior of the mono- with the di-ethers it was found desirable to carry out the measurements in an hydroxylated dissociating solvent of reasonably high dielectric constant. Ethanol was used for this purpose. It has been reported that in the case of some ionic detergents, micelles form in alcohol with the same value of the cmc as in water (11). This is not the case with the nonionic detergents since they lack the electrical forces necessary to impede aggregation (12) and the cmc is expected to be solvent dependent.

While most of the vapor pressure measurements were made on alcohol solutions at 48° C a few determinations have been made at 60° C and some measurements were conducted in water and in benzene at other temperatures in order to extend the data and compare them with other published results.

EXPERIMENTAL

The experimental technique and the apparatus used to carry out the differential vapor pressure measurements have been described in detail elsewhere (13). About 0.3 to 6 mg of material is weighed from the bulk sample into 4-mm i.d. pyrex tube previously fire-polished and steamed to remove any possible extraneous soluble impurities. The sample is washed to the bottom of the cell with about 0.4 to 0.6 ml of a solution of distilled alcohol and benzene. After evaporation of the solvents, the glass tube is sealed on the apparatus and evacuated to a pressure of about 10^{-5} mm Hg. Care is taken, however, to maintain the viscous liquids at 0° C with an ice-water bath to prevent loss of solute by evaporation during the evacuation process. Solutions of different concentrations are made by adding various amounts of alcohol, usually between the limits of 20 to 90 mg. With several weighed portions of solute it is possible to cover a reasonably wide range of concentrations. The system is arranged in such a manner that the solvent can be recycled after each determination. Solutions reach equilibrium within several hours after each filling. Readings of the vapor pressure depressions are taken at intervals of 1 to 2 hours. The null point of the apparatus is measured at the end of each determination.

Preparation of 1,4-Bis(p-isooctylphenoxy) Butane (V)

p-Isooctylphenol (1,1,3,3-tetramethylbutyl phenol) (41.2 g, 0.2 mole) was added to a solution of sodium (2.3 g, 0.1 g-atom) in MeOH (150 ml). When the solution was completed, 1,4-dibromobutane (21.6 g, 0.1 mole) was added and the resulting mixture was refluxed for 3 hours, after which it was neutral to litmus paper. The solid that crystallized on cooling was collected by filtration and was recrystallized from a mixture of MeOH–*n*-hexane, 1:1. The product obtained had m.p. 100° C, yield 30 g, 74%. Calculated for $C_{32}H_{50}O_2$, M.W. 466: C, 82.4; H, 10.7%. Found: C, 82.29; H, 10.62%.

Preparation of Di-(n-octadecyl) Ethyleneglycol Ether

Potassium (7.8 g, 0.2 g-atom) was added to diethyleneglycol (10.6 g, 0.1 mole) at 60° C, in an atmosphere of nitrogen. *n*-Hexane (ca. 50 ml) was added to keep the mixture in suspension for better stirring. After 0.5 hour, all the potassium had reacted and octadecyl chloride (57.8 g, 0.2 mole) was added slowly. The temperature was kept at 60° C and the slurry was stirred for 2 days. Then the mixture was heated to 180° C for 1 hour while a heavy precipitate was formed. After cooling, acetone (200 ml) was added and the precipitate, collected by filtration, was washed with water to remove the potassium chloride, and dried. The product was crystallized from benzene and recrystallized from ethanol; m.p. 90° C, 24 g, 40%. Calculated for $C_{40}H_{82}O_3$, M.W. 610: C, 78.6; H, 13.45%. Found: C, 78.88; H, 13.51%.

RESULTS AND DISCUSSION

The variation of the apparent molecular weight with solute concentration for a number of hexaoxyethyleneglycols having a terminal hydroxyl group etherified with a hydrocarbon chain of 8 to 16 carbon atoms, is shown in Fig. 1. The molecular weights at finite concentrations were calculated by means of Raoult's law. Curves 1, 2, 3, and 4 represent the data obtained for the monoethers (I). Curve 5 was obtained with heptaoxyethyleneglycol mono-*p*-isooctylphenyl ether (II).

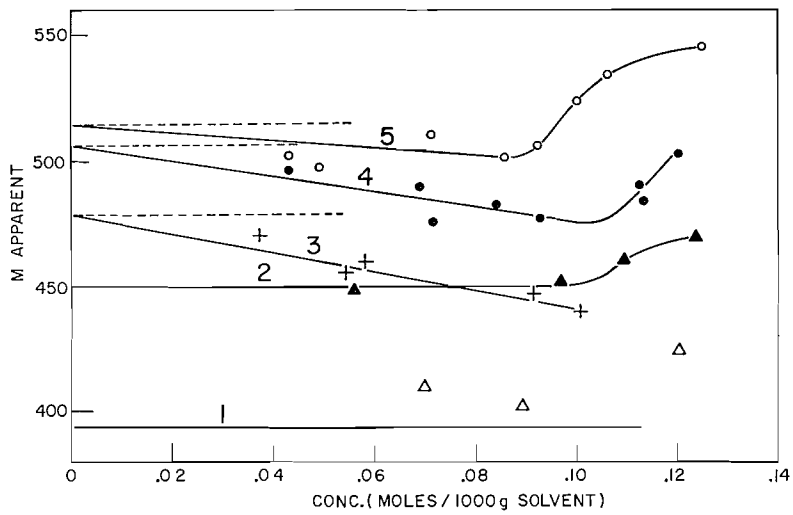

FIG. 1. Apparent molecular weight versus solute concentration for a series of hexaoxyethyleneglycol monoethers in alcohol at 48° C.

Curve 1, type I $C_8H_{17}(E.O)_6H$; heavy line drawn independent of concentration denotes the theoretical molecular weight of the compound.
Curve 2, type I $C_{12}H_{25}O(E.O)_6H$.
Curve 3, type I $C_{14}H_{29}O(E.O)_6H$. The broken line corresponds to the theoretical molecular weight of the compounds.
Curve 4, type I $C_{16}H_{33}O(E.O)_6H$.
Curve 5, type II *p*-iso-$C_8H_{17}C_6H_4O(E.O)_7H$.

The apparent molecular weight of the monoether (I, R = $C_{16}H_{33}$, curve 4) decreases with increasing concentration up to about 0.1 molal followed by a rapid increase at higher concentrations. The monoether (I, R = $C_{14}H_{29}$, curve 3) behaves in a similar way over the concentration range studied. The solutions of ether (I, R = $C_{12}H_{25}$, curve 2) behaves in an ideal fashion up to the cmc with evidence of solute association beyond 0.1 molal.

The observed molecular weights for the ether (I, R = C_8H_{17}, curve 1) are about 3–5% higher than the theoretical value, below 0.1 molal which should be well below the cmc. The concentration at which the solute associates is similar for all of the compounds of the type I. Compound II (curve 5) behaves similarly to compound (I) having the same number of carbon atoms in the hydrocarbon chain. The cmc is somewhat lower however, and the apparent molecular weight rises more steeply with increased concentration.

While the reason for the unusual change in solution properties in going from C_{12} to C_{14} and C_{16} compounds of type I, is not too clear, it may be related to the influence of the free primary hydroxyl groups and the length of the hydrocarbon adduct.

The behavior is similar to that of a typical polymeric system when a "good" solvent is employed. The monoether II, which possesses a short hydrocarbon chain, is probably reasonably well balanced in its solvophilic – solvophobic properties, and a smaller amount of solute – solvent interaction occurs. No interaction was observed with a hydrocarbon chain of 12 carbon atoms or less. Solvation of the lyophilic portion of the molecule could cause the observed effect provided the degree of solvation increased with effective increase in the concentration of the lyophobic part of the solute molecule. The slopes of the curves for the monoethers containing 14 and 16 carbon atoms in the chain may not be drawn sufficiently steeply. Owing to the difficulty of obtaining reliable data at the very low concentrations these have been extrapolated to the theoretical value at zero concentration. Actually in this regard the solution may be ideal and a point of inflection reached when the concentration of hydrocarbon is sufficient to increase the solvation of the nonhydrocarbon portion of the solute molecule.

The apparent molecular weight appears to decrease in a rather orderly fashion with solute concentration. The effect was sufficiently pronounced that curve 2 actually crossed curve 3 at a concentration of about 0.75 molal. An error of the order of 8% at 0.1 molal would be required to account for this effect and this is 4 times the error of reproducibility of individual determinations.

It is interesting to note that anomalies have also been observed with surface tension measurements of aqueous solutions of similar homologous series of polyoxyethyleneglycol ethers (14). Lange (14) observed that surface tension lowering increases regularly for a C_{12} monoether, but the sharp bend at the cmc disappeared for the C_{14} surfactant. The curves relating surface tension with solute concentration for the two compounds crossed.

The anomalous behavior of the monoethers was not found with diethers having hydrocarbon chains of similar lengths. Raoult's law was closely followed up to cmc, association of solute then occurred, particularly for the systems of low oxygen content. These results are recorded graphically by Fig. 2. The solid lines represent the theoretical molecular weight of the compounds below the cmc. Curves 1 and 2 represent the behavior of the diether (V) at 48 and 60° C respectively. In this case the hydrophilic oxygens are spaced 4 carbon atoms apart and an enormous change in cmc occurred with increased temperature. After the early stages of association, the apparent molecular weight increases virtually linearly with concentration. Although not shown in the graph, this system was followed up to about 0.5 molal. Owing to the increasing magnitude of the association factors with concentration, it is suggested that micelles of higher order than dimers are being formed. As the temperature was raised to 60° C the cmc appeared to be appreciably higher. Higher concentrations gave vapor pressure depressions beyond the calibrated range of the instrument.

Curve 3 was obtained with a sample of pure di-(*n*-octadecyl) ethyleneglycol ether

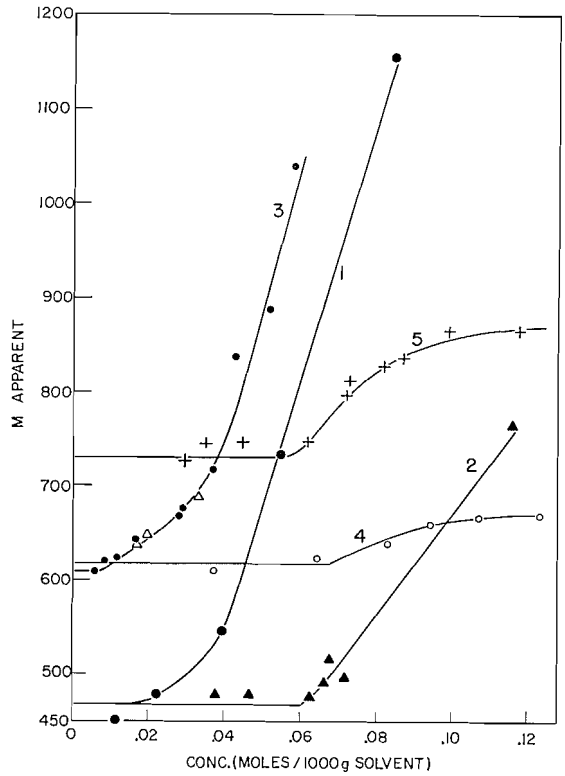

FIG. 2. Apparent molecular weight versus solute concentration for a series of diethers at 48° C. The heavy lines drawn independent of concentration correspond to the theoretical molecular weight of the compounds.

Curve 1, type V *p*-iso-$C_8H_{17}C_6H_4O(CH_2)_4OC_6H_4.C_8H_{17}$-*p*-iso.
Curve 2, same compound at 60° C.
Curve 3, type IV $C_{18}H_{37}O(CH_2CH_2O)_2C_{18}H_{37}$. Filled triangles at 60° C.
Curve 4, type III $C_{12}H_{25}O(CH_2CH_2O)_6C_{12}H_{25}$.
Curve 5, type III $C_{16}H_{33}O(CH_2CH_2O)_6C_{16}H_{33}$.

(IV). Measurements were carried out at 48° C (filled circles) and a few more at 60° C (triangles). The cmc is low and little affected by temperature. The apparent molecular weight rises almost linearly with concentration.

Curves 4 and 5 illustrate the behavior of the diethers (III, R = *n*-$C_{12}H_{25}$ and *n*-$C_{16}H_{33}$). In sharp contrast to the behavior of the corresponding monoethers, these compounds obeyed Raoult's law up to the cmc. In both cases, the apparent molecular weight reaches an almost constant value after the initial stages of association suggesting that aggregation does not proceed beyond an equilibrium mixture of monomers and dimers. A similar phenomenon has been observed for trichloroacetanilide in benzene by Davis and Thomas (15). A particular association pattern was not ascribed for their system beyond the dimerization stage.

The apparent association factors, f, described as the ratio of observed, M_a, to theoretical molecular weight, M_0, are obviously of the same order of magnitude for both diethers at 0.115 molal. The percentage association is higher with the C_{16} compound by approximately a factor of 4, however.

Table I contains a summary of the results illustrated by Figs. 1 and 2.

Since a large number of experimental points would be necessary to trace accurately the position of the cmc from the M_a vs. N graphs at the incipient state of micellization, a closer approximation may be made by the following relation due to Kitahara (2):

$$N_a = N[(f-1)/f],$$

N_a = associated solute molality,

N = total solute molality,

f = association factor = M_a/M_0.

Values for N_a are calculated at finite concentration and plotted as a function of N. A straight line joining these points when extrapolated to $N_a = 0$, gives an average value for the cmc in molality units. These values and those obtained from the M_a vs. N plots are summarized in Table I.

The fraction of the monomer associated is calculated according to the following relation, without making any assumption as to the degree of aggregation.

$$X = (M_a - M_0)/M_a \qquad \text{(cf. Davy and Sidgwick (16)).}$$

The total mean molal concentration of all species

$$= \bar{N} = N(M_0/M_a) \qquad \text{(cf. Davies and Thomas (15)).}$$

The weight of the micelle Mm is obtained from the following relation, which assumes that a certain number of molecules remain in solution as monomers and the remainder associate to form larger aggregates:

$$Mm = \left(\frac{1}{x}\right)M_a - \left(\frac{1-x}{x}\right)M_0.$$

Our experimental results, which were obtained with rigorously dry pure solvent necessary to establish vapor pressure equilibrium quickly, indicate that aggregation occurs in alcohol. The behavior of systems containing six ethylene oxide units suggests that the micellar solution is composed of an equilibrium mixture of monomer and dimer at 48° C and that, in fact, the micelles present have an aggregation number of two. Continuous association occurs for diethyleneglycol octadecyl diether (IV) after the cmc is reached. The cmc, however, increases very little with rising temperature. In comparison, the aromatic diether (V) is quite temperature sensitive, since an appreciable rise in cmc occurred on increasing the temperature from 48° to 60° C.

The general behavior of the hexaoxyethyleneglycol ethers indicates that alcohol is a good solvent for these systems. The solvophilic – solvophobic balance of these compounds appears to inhibit the formation of large clusters of monomers. The results reported by Becher (5) from light-scattering measurements of benzene solutions of pure $C_{12}H_{25}O(CH_2CH_2O)_2H$ and $C_{13}H_{27}O(CH_2CH_2O)_6H$ indicated that benzene is a better solvent for the 2-ethylene oxide compound than for the 6-ethylene oxide monoether since a smaller micellar weight was obtained. Alcohol works in the reverse fashion, probably due to the inversion of the portion of the molecule responsible for the screening effect in going from an hydroxylated to a hydrocarbon solvent.

A few determinations in benzene at 30° C with the monoethers (I, R = *n*-$C_{12}H_{25}$, and *n*-$C_{14}H_{29}$) indicated that the apparent molecular weights were virtually independent of concentration from about 0.013 to 0.07 molal within ±2% in all cases. The association factors of the order 1.22 for I(C_{12}) and 1.14 for I(C_{14}) suggests that the systems consisted of monomers and dimers only. The cmc, which occurred at 0.0045 and 0.005 moles/1000 grams of solvent for I(C_{12}) and I(C_{14}) respectively, is in reasonably good agreement with other published results (5). The micellar weights obtained from light scattering at 25° C by Becher (5) with hexaoxyethylene *n*-tridecanol are about a factor of 50 higher than those found here from vapor pressure lowering measurements at 30° C. This ratio is unexpectedly high for these compounds, which differ only by plus or minus one carbon atom in the hydrophobic portion of the molecule, and the C_{13} compound used by Becher. However, large differences in micellar weights obtained by light-scattering and vapor pressure measurements have been noted with α-glycerides by Debye (3). Such differences may be due to heterogeneity of sizes or more likely to the kinetic mobility of a portion of the molecules forming the clusters, which may be sufficient to allow them to act as independent units in the vapor pressure lowering without affecting the amounts of scattered light.

A sample of pure *n*-decyl hexaoxyethyleneglycol monoether was examined in water in the vicinity of the cloud point (9). The solutions were made up at concentrations above the expected cmc. Ultracentrifugal measurements on a variety of commercial nonionic detergents showed that micellar weights should not vary with concentration (6). The results given in Table II suggest, however, that the micellar weight does increase

TABLE II

Behavior of $C_{10}H_{21}O(CH_2CH_2O)_6H$ in water

Temp. (° C)	Molal conc. (*N*)	App. M_a	Micellar mol. wt. (*Mm*)	Aggregate number (*n*)
50	0.0399	4615	5,000	12
56	0.0399	5270	5,650	13.4
63	0.0493	9600	10,000	24

with rising temperature in aqueous solutions, and this is in qualitative agreement with previous work (17).

The behavior of these compounds and a number of commercial nonionic detergents is now being examined in other solvents.

ACKNOWLEDGMENT

The authors wish to thank Dr. I. E. Puddington for his interest and for the many stimulating discussions concerning this work.

ORGANOGERMANIUM COMPOUNDS

PART I. THE INTERACTION OF HEXAMETHYLDIGERMOXANE AND TRIMETHYLMETHOXYGERMANE WITH BORON TRIFLUORIDE[1]

J. E. GRIFFITHS[2] AND M. ONYSZCHUK

ABSTRACT

Boron trifluoride does not form a stable adduct with hexamethyldigermoxane. Instead, cleavage of the Ge—O—Ge linkage occurs with quantitative formation of trimethylfluorogermane and boron trioxide. Trimethylmethoxygermane and boron trifluoride form a 1:1 addition compound which sublimes without decomposition. Dative d_π–p_π bonding, if present in the Ge—O linkage of trimethylmethoxygermane, does not appear to affect appreciably the electron-donor activity of the oxygen atom toward boron trifluoride. The preparation and some properties of CH_3GeH_2Br, CH_3GeHCl_2, $(CH_3)_3GeCl$, $(CH_3)_3GeF$, $[(CH_3)_3Ge]_2O$, and $(CH_3)_3GeOCH_3$ are described.

Boron trifluoride and organic ethers form 1:1 adducts of the type, R_2O,BF_3, which are so stable that they can be distilled without decomposition (1). Methyldisiloxanes, on the other hand, do not give stable addition compounds with boron trifluoride (2). Instead, cleavage of the Si—O—Si linkage occurs at −78° in two stages:

$$(CH_3SiH_2)_2O + BF_3 = CH_3SiH_2OBF_2 + CH_3SiH_2F,$$

$$3CH_3SiH_2OBF_2 = 3CH_3SiH_2F + BF_3 + B_2O_3,$$

and the methylsiloxyboron difluoride formed in the first step is too unstable to be isolated. The experiments described in this paper were made to examine the interaction of boron trifluoride with the Ge—O—Ge and Ge—O—C linkages in hexamethyldigermoxane and trimethylmethoxygermane respectively.

Preparation of Germyl Ethers

Hexamethyldigermoxane, a new compound, was prepared in 61% yield by the interaction of gaseous trimethylchlorogermane with dry silver carbonate:

$$2(CH_3)_3GeCl + Ag_2CO_3 \rightarrow [(CH_3)_3Ge]_2O + CO_2 + 2AgCl.$$

The same compound was probably obtained in the hydrolysis of trimethylbromogermane (3) and trimethylchlorogermane (4), but it was not identified in these reactions. Hexaethyldigermoxane, the only simple digermoxane reported previously, has been prepared in 97% yield by hydrolysis of triethylbromogermane with aqueous potassium hydroxide (5).

By reaction with anhydrous sodium methoxide, trimethylbromogermane was converted into trimethylmethoxygermane in 98% yield, according to the reaction:

$$(CH_3)_3GeBr + NaOCH_3 \rightarrow (CH_3)_3GeOCH_3 + NaBr.$$

Trimethylmethoxygermane had been obtained previously in 56% yield by the reaction of impure trimethyliodogermane with sodium methoxide in methanol (6).

We tried to prepare a partially methylated digermoxane, such as 1,1′-dimethyldigermoxane, $(CH_3GeH_2)_2O$, by the interaction of a methylhalogenogermane with silver carbonate. While preparing methylchlorogermane, CH_3GeH_2Cl, by the interaction of

methylgermane with hydrogen chloride in the presence of aluminum trichloride, we found that methyldichlorogermane, CH_3GeHCl_2, was formed instead. Using hydrogen bromide and aluminum tribromide, however, methylgermane was converted in 53% yield into methylbromogermane, CH_3GeH_2Br. This new compound did not react with dry silver carbonate to give the expected 1,1′-dimethyldigermoxane; carbon dioxide, and an unidentified, non-volatile, transparent, viscous liquid were obtained instead. Evidently an initial reaction producing the digermoxane was followed by a rapid change of the digermoxane into complex methylgermoxane polymers.

An attempt to prepare the mixed ether methylmethoxygermane, $CH_3GeH_2OCH_3$, was equally unsuccessful. The reaction at $-80°$ of methylbromogermane with sodium methylate produced a volatile substance which was mainly methylmethoxygermane, and which decomposed slowly into methanol and an unidentified white, non-volatile solid. The latter was probably a polymer of the type $(CH_3GeH)_x$ formed by decomposition of methylmethoxygermane, as represented by:

$$xCH_3GeH_2OCH_3 \rightarrow xCH_3OH + (CH_3GeH)_x.$$

The amount of methanol recovered was roughly in agreement with this reaction.

The conclusion that germyl ethers with Ge—H bonds are unstable is also supported by the observation that digermoxane, $(GeH_3)_2O$, cannot be obtained either by hydrolysis of chlorogermane (7) or by reaction of chlorogermane with silver carbonate (8). Moreover, the anticipated 1,1′-di-*n*-butyldigermoxane was not formed by hydrolysis of *n*-butylchlorogermane (9). The apparent instability of such germyl ethers is in marked contrast with the stable silyl ethers containing Si—H bonds (10, 11).

Reaction of Trimethylmethoxygermane with Boron Trifluoride

Trimethylmethoxygermane and boron trifluoride formed a white solid 1:1 adduct which melted in the range 41 to 46°, and which sublimed at 25° without decomposition. It formed a transparent jelly when heated at 235° for 16 hours.

The formation of this adduct shows that the electron-donor activity of the oxygen atom is not appreciably less in germyl ethers than it is in alkyl ethers. This result is surprising, since one might expect that the electron-donor power would be reduced by d_π–p_π dative bonding from oxygen to germanium, similar to that in the Si—O bond (10). This so-called back co-ordination of electrons from oxygen to silicon in disiloxane and the methyldisiloxanes accounts for the unexpectedly large Si—O—Si bond angle, and also for the apparent lack of donor activity in these compounds (10). Theoretical considerations indicate that the amount of d_π–p_π bonding should be approximately independent of the size of the atom having the *d*-orbitals (12). Since silicon and germanium have similar covalent radii, 1.17 and 1.22 Å respectively (13), the extent of π-bonding to germanium and silicon should be roughly the same. Some experimental data on the dissociation constants of para-substituted benzoic acids with general formula p-$R_3M \cdot C_6H_4 \cdot CO_2H$, where M = C, Si, Ge, and Sn, and R = CH_3 and C_2H_5, provide strong evidence that dative π-bonding occurs between the benzene ring and Si, Ge, or Sn, approximately to the same degree in all three cases (14). Moreover, Hammett sigma values for the *meta*- and *para*-triphenylsilyl and -triphenylgermyl groups also show that the amount of partial double bonding between the benzene ring and silicon or germanium is almost identical (15). On the other hand, measurements of hydrogen bonding in triphenylhydroxyl compounds of the type $(C_6H_5)_3MOH$, where M = C, Si, Ge, Sn, and Pb, indicate that π-bonding from oxygen to M atoms is strong in $(C_6H_5)_3SiOH$, weaker in $(C_6H_5)_3GeOH$, and negligible in the other three compounds (16). Our results indicate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

that dative d_π–p_π bonding, if it occurs in the Ge—O bond of trimethylmethoxygermane, does not appreciably alter the electron-donor activity of the oxygen atom toward boron trifluoride, since trimethylmethoxygermane and boron trifluoride form a stable 1:1 adduct.

Reaction of Hexamethyldigermoxane with Boron Trifluoride

Hexamethyldigermoxane and boron trifluoride did not yield a stable 1:1 adduct, but cleavage of Ge—O bonds occurred at 25° with quantitative formation of trimethylfluorogermane and boron trioxide, as given by the stoichiometric equation:

$$3[(CH_3)_3Ge]_2O + 2BF_3 = 6(CH_3)_3GeF + B_2O_3.$$

This reaction provides a new and more convenient method for the preparation of trimethylfluorogermane, previously obtained in 71% yield from the reaction of tetramethylgermane with liquid hydrogen fluoride in copper apparatus (17).

While the 1:1 adduct could not be isolated and there was no dissociation into original reactants, the possibility of its formation at low temperatures could not be excluded, since its decomposition at −80° made it impossible to detect and identify the adduct. The mechanism of this decomposition, as outlined below, might involve four-center cyclic transition states of the type proposed for the analogous interaction of boron trichloride and tribromide with alkyl ethers (18) and disiloxanes (19) respectively.

$$(CH_3)_3Ge\cdots O(F)\cdots BF_2\text{—}Ge(CH_3)_3 \longrightarrow (CH_3)_3GeF + (CH_3)_3GeOBF_2,$$

$$(CH_3)_3Ge\cdots O(F)\cdots BF \longrightarrow (CH_3)_3GeF + BOF,$$

$$3BOF \longrightarrow B_2O_3 + BF_3.$$

Although trimethylgermoxyboron difluoride and boron oxyfluoride could not be isolated, they were identified with the white solid which decomposed slowly at 20° into boron trifluoride, boron trioxide, and additional trimethylfluorogermane. Boron oxyfluoride exists below −140° as a cyclic trimer called trifluoroboroxine and decomposes rapidly at higher temperatures into boron trifluoride and boron trioxide (20). The yields of trimethylfluorogermane and boron trioxide for the over-all decomposition were quantitatively in agreement with the stoichiometric equation.

The failure of hexamethyldigermoxane to form a stable adduct with boron trifluoride does not necessarily imply a lack of electron-donor activity at the oxygen atom in the Ge—O—Ge linkage, since bond cleavage concealed possible adduct formation. This is in sharp contrast with the trimethylmethoxygermane – boron trifluoride system in which the absence of bond cleavage apparently allowed the isolation of the 1:1 adduct. Since bond polarities and inductive and steric effects determine the stabilities of co-ordination compounds of boron trifluoride (1), it is necessary to obtain information about their relative importance in germyl ether – boron trifluoride adducts. Experiments planned to give this information are now in progress and the results will be reported later.

EXPERIMENTAL

Apparatus

A Pyrex glass high-vacuum apparatus of the conventional type was used to manipulate volatile substances. Ground-glass joints and stopcocks were lubricated with Apiezon N grease. Vapor pressures were measured with a null-point glass spoon gauge. Molecular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

weights (M) were obtained by the direct weight method. The Stock magnetic plunger apparatus was used for the determination of melting points (21). Temperatures below $-20°$ were measured with calibrated copper – constantan thermocouples in conjunction with a sensitive potentiometer. A column of the type described by Le Roy (22) was used for fractional distillations and condensations in the range -196 to $-20°$.

Materials

Methylgermane was obtained from reaction of methyl iodide with germylsodium as described by Teal and Kraus (23). Found: M, 90.5, v.p. 24.5 mm at $-99.7°$, yield, 51%. Calc. for CH_3GeH_3: M, 90.6. Although methylgermane had been characterized previously by its boiling point, melting point, and analysis (23), its vapor pressure – temperature relationship has not yet been reported. We found that vapor pressures, listed in Table I, of a tensiometrically pure sample are expressed in the range -114 to $-43°$ by the equation $\log_{10} p(\text{mm}) = 6.266-(850/T)$, which gives an extrapolated boiling point of $-22.2\pm0.5°$ (lit. (23), $-23.0°$), a heat of vaporization of 3965 cal mole^{-1}, and a Trouton constant of 15.9. The melting point was $-153.7\pm0.3°$ (lit. (23), $-158.0°$).

Tetramethylgermane was prepared by reaction of dimethylzinc with germanium tetrachloride (24). Found: M, 132.4, v.p. 139.1 mm at 0°, yield, 67%. Calc. for $Ge(CH_3)_4$: M, 132.6, v.p. 139.3 mm at 0°.

Trimethylbromogermane was obtained by reaction of bromine with tetramethylgermane (25). Found: M, 198.0, yield, 95%, v.p. 5.6 mm at 0°. Calc. for $(CH_3)_3GeBr$: M, 197.5, v.p. 5.6 mm at 0°.

Commercial boron trifluoride was used only after it had been distilled and its vapor pressure and molecular weight had been checked.

Preparation of Methylbromogermane

Methylgermane (3.08 mmole) and hydrogen bromide (3.08 mmole) were condensed in a vessel the walls of which had first been coated with anhydrous aluminum tribromide. After the mixture was heated at 100° for 4 hours, the hydrogen formed in the reaction was pumped away through a trap held at $-196°$, which retained condensable gases. Unreacted methylgermane and hydrogen bromide were removed together by three distillations at $-96°$, leaving tensiometrically pure methylbromogermane. Found: Br, 47.0%; M, 169.7, v.p. 26.8 mm at 0°, yield, 53%. Calc. for CH_3GeH_2Br: Br, 47.11%; M, 169.6.

Methylbromogermane had vapor pressures (0 to 60°) given by the equation $\log_{10} p(\text{mm}) = 7.800-(1740/T)$, which gives an extrapolated boiling point of $80.5\pm0.5°$, a latent heat of vaporization of 7960 cal mole^{-1}, and a Trouton constant of 22.5. A list of the measured vapor pressures is given in Table II. The melting point was $-89.2\pm0.2°$.

Preparation of Methyldichlorogermane

A bulb (5 l.) previously coated with anhydrous aluminum trichloride was charged with methylgermane (1.46 mmole) and hydrogen chloride (1.12 mmole) and heated for 4 hours at 100°. Hydrogen was pumped off. Unreacted methylgermane and hydrogen chloride were removed by distillation in the range -130 to $-92°$. Methyldichlorogermane was separated from the residue by several distillations at $-45.2°$. Found: Cl, 43.1%; M, 160.3, v.p. 25.8 mm at 20°. Calc. for CH_3GeHCl_2: Cl, 43.41%; M, 159.6. Vapor pressures of methyldichlorogermane, which are listed in Table III, obey the equation $\log_{10} p(\text{mm}) = 7.551-(1800/T)$, giving an extrapolated boiling point of $112.2\pm0.5°$, a latent heat of vaporization of 8250 cal mole^{-1}, and a Trouton constant of 21.4. The melting point was found to be $-63.1\pm0.1°$.

Reaction of Methylbromogermane with Silver Carbonate

Methylbromogermane (1.42 mmole) was slowly passed through a glass wool – silver carbonate (2.0 g) plug which turned black during the process. Hydrogen (0.3 mmole) was pumped away through a trap cooled with liquid air which retained condensable vapors. These were distilled at −96° to separate carbon dioxide (2.15 mmole. Found: M, 47.5. Calc. for CO_2: M, 44.0) from the residue. Redistillation of the residue at −45.2° gave a distillate which was mainly unreacted methylbromogermane (0.14 mmole. Found: M, 155.5. Calc. for CH_3GeH_2Br: M, 169.5) and a residue which was a clear viscous liquid with undetectable vapor pressure at room temperature. It was not identified.

Reaction of Methylbromogermane with Sodium Methylate

Methylbromogermane (1.94 mmole) and dry sodium methylate kept at −80° for 30 minutes gave on distillation at −80° a fraction (1.83 mmole. Found: M, 107.4) which was probably methylmethoxygermane (Calc.: M, 120.6) contaminated with methanol (Calc.: M, 32.0). Redistillation of this fraction at −65° and again at 20° yielded only methanol (1.63 mmole. Found: M, 38.1. Calc. for CH_3OH: M, 32.0) and an unidentified, non-volatile white solid residue.

Preparation of Trimethylchlorogermane

Tetramethylgermane (2.27 mmole) and hydrogen chloride (2.15 mmole) were condensed in a reaction bulb which had previously been charged with aluminum trichloride. The mixture was warmed to room temperature and, after 1 hour, methane was pumped off. Condensable vapors were separated into three fractions by distillation through a series of traps held at −80, −130, and −196°. Hydrogen chloride (0.66 mmole) was condensed in the trap maintained at −196°, while tetramethylgermane (0.14 mmole) collected in the trap held at −130°. The fraction retained at −80° was trimethylchlorogermane. Found: M, 153.1, yield 33%. Calc. for $(CH_3)_3GeCl$: M, 153.1.

Vapor pressures of trimethylchlorogermane (0 to 68°) are expressed by the equation $\log_{10} p(\text{mm}) = 7.665-(1795/T)$, which gives an extrapolated boiling point of 102.0±0.5°, a latent heat of vaporization of 8210 cal mole^{-1}, and a Trouton constant of 21.9. Vapor pressures are listed in Table IV. Rochow (4) reported the boiling points of dimethyldichlorogermane and trimethylchlorogermane as 124° and 115° respectively. Since he obtained trimethylchlorogermane by distillation from a mixture rich in dimethyldichlorogermane, his trimethylchlorogermane fraction was probably contaminated with a small amount of the dichloro compound resulting in a higher boiling point than we obtained by extrapolation of vapor pressure data.

Reaction of Trimethylchlorogermane with Silver Carbonate

Silver carbonate (1 g) and trimethylchlorogermane (1.17 mmole) were kept together for 3 hours at room temperature with frequent shaking. Distillation at −80° yielded a distillate of carbon dioxide (0.86 mmole. Found: M, 44.6. Calc. for CO_2: M, 44.0) and a residue of impure hexamethyldigermoxane. Unreacted trimethylchlorogermane was separated from hexamethyldigermoxane by several distillations at −22.9° leaving a residue of tensiometrically pure hexamethyldigermoxane. Found: M, 250, v.p. 5.7 mm at 18.2°, yield, 60.5%. Calc. for $[(CH_3)_3Ge]_2O$: M, 251.2. Vapor pressure measurements in the range of 18.2 to 72.4°, listed in Table V, determine the equation $\log_{10} p(\text{mm}) = 8.580-(2290/T)$, which indicates an extrapolated boiling point of 129°, a latent heat of vaporization of 10,540 cal mole^{-1}, and a Trouton constant of 26.0. The compound melted sharply at −61.1±0.1°.

Reaction of Trimethylbromogermane with Sodium Methylate

Trimethylbromogermane (8.05 mmole) was condensed on excess sodium methylate which had first been dried at 90° for 5 hours in vacuum. After the reaction mixture had been kept at −22.9° for 90 minutes, volatile products were distilled out and treated with freshly cut sodium to remove methanol impurities. Trimethylmethoxygermane was then distilled through a trap maintained at −45.2° to remove any hexamethyldigermane formed during the treatment with sodium. Found: M, 147.0, yield, 98%. Calc. for $(CH_3)_3GeOCH_3$: M, 148.6. Vapor pressures, measured in the range 0 to 61.9° and listed in Table VI, obey the equation $\log_{10} p(\text{mm}) = 7.531-(1695/T)$, which gives an extrapolated boiling point of 91.1±0.5°, a latent heat of vaporization of 7750 cal mole^{-1}, and a Trouton constant of 21.2. The melting point was −102.2±0.3°. The boiling point determined here from vapor pressure data is 4.1° higher than that previously reported for a sample obtained by distillation of trimethylmethoxygermane from a methanolic solution (6). Since it is difficult to remove the last traces of methanol from trimethylmethoxygermane by vacuum distillation, 91.1° appears to be a more reliable value for the boiling point.

Reaction of Hexamethyldigermoxane with Boron Trifluoride

Hexamethyldigermoxane (0.672 mmole) and boron trifluoride (0.448 mmole) in a 3:2 mole ratio were maintained at −80° for 12 hours. Only three-quarters of the boron trifluoride was consumed at this temperature. The product was a white solid. On warming to 20°, consumption of boron trifluoride was complete and, after 4 hours, the white solid decomposed into a volatile substance and an involatile white solid. The volatile fraction was pure trimethylfluorogermane (1.31 mmole. Found: M, 136.4, v.p. 83.5 mm at 22.2°. Calc. for $(CH_3)_3GeF$: M, 136.6). The involatile residue of boron trioxide was titrated, in the presence of mannitol, with sodium hydroxide to the phenolphthalein end point. Calculations based on the stoichiometric equation, $3[(CH_3)_3Ge]_2O + 2BF_3 = 6(CH_3)_3GeF + B_2O_3$, indicated that boron trioxide and trimethylfluorogermane were formed in 97.5 and 97.6% yield, respectively, thus proving the composition of hexamethyldigermoxane.

Vapor pressures of liquid trimethylfluorogermane in the range 12.7 to 71.9°, listed in Table VII, are expressed by the equation $\log_{10} p(\text{mm}) = 7.655-(1695/T)$, which gives an extrapolated boiling point of 81.1±0.5°, a latent heat of vaporization of 7750 cal mole^{-1}, and a Trouton constant of 21.8. A boiling point of 77–78° at 755 mm had previously been reported for this compound (17). Sublimation pressures of trimethylfluorogermane in the range −23 to 9°, given in Table VIII, are expressed by the equation $\log_{10} p(\text{mm}) = 9.028-(2083/T)$, which indicates a latent heat of vaporization of 9550 cal mole^{-1}. The latent heat of fusion was 1800 cal mole^{-1} and the melting point was 1.9±0.4°.

Reaction of Trimethylmethoxygermane with Boron Trifluoride

Trimethylmethoxygermane (0.307 mmole) and boron trifluoride (0.307 mmole) gave a white solid when left overnight at room temperature. This adduct was sublimed at 25° without decomposition. Saturation vapor pressures in the range 16.5 to 33.0°, listed in Table IX, are expressed by the equation $\log_{10} p(\text{mm}) = 10.790-(3105/T)$. At about 41° large positive deviations from the sublimation pressure equation began to occur. On cooling to less than 41°, sublimation pressures again followed the sublimation pressure plot. The adduct melted in the range 41 to 46°.

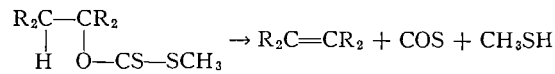
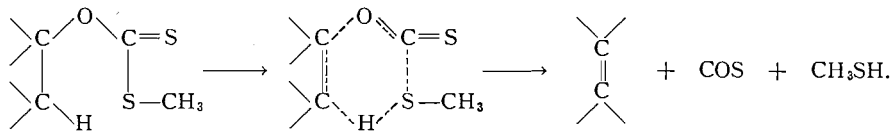
A KINETIC ISOTOPE EFFECT STUDY OF THE TSCHUGAEFF REACTION[1]



RICHARD F. W. BADER[2] AND A. N. BOURNS

ABSTRACT

Three different kinetic isotope effects have been measured in the thermal decomposition of S-methyl-*trans*-2-methyl-1-indanyl xanthate: the S^{32}/S^{34} effect for the thio-ether sulphur atom, the S^{32}/S^{34} effect for the thion sulphur, and the C^{12}/C^{13} effect for the carbonyl carbon. The results of these measurements provide strong support for a two-step mechanism, in which the rate-determining step is the removal through a cyclic transition state of the cis beta hydrogen atom by the thion sulphur atom.

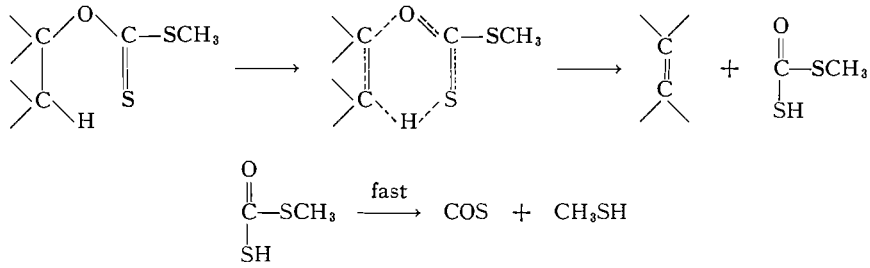


INTRODUCTION

The pyrolytic decomposition of a xanthate ester to yield an alkene, carbonyl sulphide, and a mercaptan

is named the Tschugaeff reaction in honor of its discoverer (1). It belongs to that class of reactions known as pyrolytic cis eliminations, a class which also includes the thermal decomposition of such compounds as esters, amine oxides, and organic chlorides. The steric course of the reaction was first established by Hückel, Tappe, and Legutke (2), who, from a study of the products obtained from the thermal decomposition of the xanthates derived from *l*-menthol, *d*-neomenthol, and the isomeric decalols, discovered the then surprising fact that a cis beta hydrogen is preferentially removed in the elimination process. Subsequent studies by Cram (3), Alexander and Mudrak (4, 5, 6), Barton (7), and Bordwell and Landis (8) have provided ample confirmation of the steric course of the reaction. Recently, DePuy and King (9) have summarized this and other work on the Tschugaeff reaction in a review dealing with pyrolytic cis elimination processes.

As with other cis eliminations, the Tschugaeff reaction is found to be unimolecular and to possess a negative entropy of activation (10, 11). These observations, including the cis behavior, are accommodated by mechanisms which involve a cyclic transition state, such as were first postulated by Hückel *et al.* (2) and by Stevens and Richmond (12). The mechanisms proposed by these two groups of investigators, however, differed in the assignment of the sulphur atom, which was considered to play the role of the nucleophilic agent in the hydrogen abstraction. Hückel *et al.* assigned this role to the thio-ether sulphur atom and pictured the reaction as a one-step process proceeding through a six-membered cyclic transition state as follows:



MECHANISM I

This mechanism for xanthate decomposition, which in subsequent discussion will be referred to as mechanism I, has been cited by Barton (7), Ingold (13), and Bartlett (14).

[1]*Manuscript received November 4, 1960.*
Contribution from the Burke Chemical Laboratories, Department of Chemistry, McMaster University, Hamilton, Ontario. Presented at the XIVth International Congress of Pure and Applied Chemistry, Zürich, 1955.
[2]*Present address: Department of Chemistry, University of Ottawa, Ottawa, Ontario.*

In contrast to Hückel's proposal, Stevens and Richmond (12) cast the thion sulphur atom in the role of hydrogen abstractor. This choice also provides for the formation of a six-membered cyclic transition state. The decomposition of this transition state, however, does not lead directly to all of the observed products. Rather, it results in the initial formation of the alkene and an unstable xanthic acid, the latter being expected to dissociate in a subsequent fast step to carbonyl sulphide and mercaptan.

MECHANISM II

Cram (3) also favored this mechanism, which shall be termed mechanism II, on the grounds that resonance structures for the xanthate grouping place more negative charge on the thion than on the thio-ether sulphur atom. He further maintained that the ester group would present steric problems not to be encountered with the thion sulphur atom. Alexander and Mudrak (4) held essentially similar views. The two possible mechanisms thus exhibit a fundamental difference not only in the functions assigned to the sulphur atoms but also in the manner in which the activated complexes revert to products.[3]

Classical methods, such as steric and kinetic studies have led to a general formulation of the reaction mechanism, but they afford no obvious method for differentiating between the two mechanisms, I and II. There is, however, a more subtle method of gaining an insight into the properties of a transition state molecule. This method is dependent upon the measurement of kinetic isotope effects. The object of this paper is to decide between the two proposed mechanisms for the Tschugaeff reaction by offering evidence obtained from such measurements.

Two isotopic species will exhibit a difference in their relative rates of reaction whenever their bonding energy undergoes a change in or before that step of the reaction which determines the over-all rate. Since the changes in bonding predicted for the thion and thio-ether sulphur atoms are very different in the two mechanisms, a knowledge of the isotopic fractionation incurred by these atoms will permit the assigning of definite roles to each in the rate-determining step. In addition, the mechanisms involve quite different bonding changes for the carbonyl (xanthate) carbon atom, and, therefore, information regarding its isotopic fractionation should also prove helpful in distinguishing between the two possibilities.

It is possible to make predictions concerning the magnitude of the isotope effects to be expected for each mechanism by use of the familiar Bigeleisen equation which relates the kinetic isotope effect to isotopic mass and vibrational frequencies (17):

[3]*Tarbell and Harnish (15) have proposed a mechanism based on an initial isomerization of the xanthate ester to a dithiolcarbonate. This mechanism, aside from being difficult to reconcile with the known steric results for the Tschugaeff reaction, may be completely discounted by the observations of Salomaa (16) that the dithiolcarbonates are much more stable than the corresponding xanthate esters.*

$$k_1/k_2 = (m_2^{\ddagger}/m_1^{\ddagger})^{\frac{1}{2}}\left[1+\sum_{i}^{3n-6} G(u_i)\Delta u_i+\sum_{i}^{3n'-6} G(u_i^{\ddagger})\Delta u_i^{\ddagger}\right]$$

where k is the rate constant, $m^{\ddagger}$ is the effective mass of the transition state in the direction of the reaction co-ordinate, $G(u_i)$ is a free energy function defined by Bigeleisen and Mayer (18), $3n-6$ is the number of vibrational modes of the molecule, and Δu_i is equal to $(\nu_1-\nu_2)h/kT$. The subscripts 1 and 2 refer to light and heavy isotopic molecules, respectively.

A common procedure used in calculating, from vibrational frequency data, the free energy (square bracket) term of this equation for a bond-rupture process, is to assume a model for the transition state in which the bond in question is completely broken and the vibrational frequencies of all other bonds are unchanged (19). On this basis, if the reaction is one involving the rupture of a single bond associated with the isotopic atom, the summation for the transition state is zero and that of the initial state may be readily calculated from the vibrational stretching frequency of the isotopic bond. For a reaction in which the main covalency change involving the isotopic atom is the conversion of a double to a single bond, the initial state and transition state summations may be evaluated from a knowledge of the double and single bond vibrational stretching frequencies, respectively. This method of approximation is crude, but it can be justified on the basis that the calculations are readily made, and what is of greater importance, the results in general have been found to give surprisingly good agreement with experimental data (19).

By application of this method and by reference to known examples, the following predictions have been made concerning the direction and magnitude of the isotope effects to be expected for each mechanism of xanthate decomposition.[4] Since a compound of natural isotopic abundance was used in the experimental study, these predictions refer to S^{32}/S^{34} and C^{12}/C^{13} rate ratios.

A. Thio-ether Sulphur

Mechanism I.—The bond between the thio-ether sulphur atom and the carbonyl carbon atom is broken in the rate-determining step. Using the Slater theorem (19, 20) for the evaluation of the effective mass term and a vibrational stretching frequency of 650 cm^{-1} (21) for the C—S bond, an isotope effect $(k_{32}/k_{34}-1)$ of 1.2% is calculated for reaction at 78° C.

Mechanism II.—The bond between the thio-ether sulphur atom and the carbon atom undergoes no significant change in the rate-determining step. A zero isotope effect, therefore, would be predicted, or, if there is some C—S bond weakening in the transition state leading to the xanthic acid, an effect of a few tenths of one per cent at the most.

B. Thion Sulphur

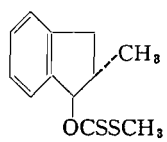
Mechanism I.—The carbon–sulphur double bond is not appreciably altered in the rate-determining step, with the result that the isotope effect should be small or zero.

Mechanism II.—The carbon–sulphur double bond becomes a carbon–sulphur single bond. Using C—S (single bond) as a model for the transition state, and vibrational stretching frequencies of 1150 cm^{-1} and 650 cm^{-1} (21) for double and single bonds of

[4]*In addition, a number of fairly detailed calculations were performed to give more substance to the predicted isotope effects. These calculations involved the determination of the normal frequencies and their isotopic shifts for simplified models which approximated the xanthate portion of the molecule for the initial state and the two possible transition states. The isotope effects were then calculated from the frequencies and the effective masses thus obtained by substitution in the Bigeleisen equation. This more refined treatment gives results which are in close agreement with those obtained by the more approximate method.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

sulphur to carbon, respectively, one obtains a free energy term of 1.007 at 78° C. The effective mass term, however, will be very small since the rate-determining step does not lead to a separation of the sulphur atom, but only to a lengthening of its bond to carbon. The isotope effect for the thion sulphur atom would be expected to be between 0.7 and 1.0%.



C. Carbonyl Carbon

Mechanism I.—A carbon–sulphur single bond is broken in the rate-determining step. Treatment of the reaction as simply the dissociation of a C—S diatomic molecule into its constituent atoms leads to the prediction of a carbon-13 isotope effect of 3 to 4% at 78° C. That the isotope effects found in the somewhat analogous reaction of decarboxylation fall within this range (19) lends support to this prediction.

Mechanism II.—In the rate-determining step no bond involving isotopic carbon is completely broken, but rather a carbon–sulphur double bond becomes a single bond and a carbon – oxygen single bond becomes a double bond. If these two processes occur to about the same extent in the transition state, the free energy summations for the initial and transition state terms might be expected to effectively cancel each other. Since there is no separation of atoms, the effective mass term should also be small. The net result then will be a very small or zero isotope effect for the carbonyl carbon.

RESULTS AND DISCUSSION

The compound employed in this investigation was S-methyl-*trans*-2-methyl-1-indanyl xanthate (I), the pyrolytic decomposition of which had been previously investigated by Alexander *et al.* (6). This compound was chosen for the following reasons: it possesses but one hydrogen atom on a beta carbon; the configuration is such that cis elimination only can occur; it is a solid readily purified by recrystallization; its decomposition proceeds with better than 80% yield of the gaseous products.

I

The observed isotope effects for each of the two sulphur atoms and for the carbonyl carbon are given in Table I, together with a summary of the effects predicted for the two mechanisms.

It is seen from Table I that the experimental results are incompatible with the predictions of mechanism I. The absence of any isotope effect whatsoever for the xanthate carbon atom and a very small one for the thio-ether sulphur atom proves conclusively that the bond between these two atoms is not severed in the rate-determining step, as would be required by this mechanism. Furthermore, mechanism I allows for only a very small isotope effect for the thion sulphur atom, and can in no manner account for the 9/10% actually observed. The experimental results are, however, in excellent agreement with the predictions of mechanism II. The zero isotope effect for the xanthate carbon is entirely compatible with this mechanism in which there is concurrent partial π bond formation and rupture in the transition state of the rate-determining step. The 9/10% isotope effect for the thion sulphur atom is also in accord with mechanism II. Though this is a relatively small effect, it does show that the bonding of this atom is altered

significantly in the rate-determining step. The 2/10% isotope effect observed for the thio-ether sulphur atom is explicable only if it is assumed to be undergoing no significant change in bond energy or type in the rate-determining step. This is the case in mechanism II.

From this comparison it is concluded that a mechanism is operative in the Tschugaeff reaction which follows the major steps outlined for mechanism II, i.e., the reaction proceeds via a two-step mechanism wherein the thion sulphur atom abstracts the cis beta hydrogen atom resulting in the formation of an unstable xanthic acid intermediate. This is analogous to the mechanism which is currently accepted for the thermal decomposition of carboxylic acid esters (9).

The absence of an isotope effect for the carbonyl carbon atom provides a further insight into the more detailed aspects of the reaction. O'Connor and Nace (11), in order to account for the decreased thermal stability of cholesteryl xanthates with increased electronegativity of R— in the xanthate group, —O—C(=S)—SR, had pictured the oxygen atom as forming a π-bond with the carbonyl carbon atom during the rate-determining step. The more electronegative the xanthate group, the larger the induced positive charge on the carbon atom and hence the greater the driving force due to the partial π bond formation. Some recent work by Salomaa (16) has demonstrated the importance of this particular driving force in pyrolytic ester decompositions. He investigated the thermal properties of compounds of types II to VI:

which are respectively, the xanthate ester, the dithiolcarbonate, the carbonate ester, the thio ester, and the thio carbonate ester. Compounds of types II and VI possess the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

system —O—C=S, which is capable of providing driving force (···O···C···S···) for the reaction and only these compounds are found to be thermally unstable. Compounds of the types III, IV, and V contain the ester grouping —S—C=O or —O—C=O, and their reaction, therefore, must give rise to a transition state in which there has been either an increase in the bonding of the carbonyl carbon to sulphur at the expense of its bonding to oxygen, which would be energetically unfavorable, or a change in bonding from one oxygen atom to another, which would involve only a very small free energy change. Salomaa found that these compounds remain unchanged on distillation, which is in accord with these considerations.

The absence of an isotope effect for the carbonyl carbon shows clearly that this partial π-bond driving force is indeed present. A calculation has shown that if there were no concurrent π bond formation of the oxygen with the carbonyl carbon, the isotope effect for this carbon atom would be of the order of 1%. A lower value can only arise as a consequence of participation of oxygen in π bond formation; and the fact that the observed isotope effect in the present study is zero, within the limits of measurement, strongly suggest that the two bond changes involving carbon are nearly balanced. In other reaction systems this need not be the case, and it should be possible to relate the change in the observed isotope effect with a change in driving force as, for example, the ester grouping is made more electronegative.

EXPERIMENTAL

The synthetic work entailed the preparation of the ketone 2-methyl-1-indanone, which under proper conditions could be hydrogenated to yield only the trans form of the alcohol, 2-methyl-1-indanol. The 2-methyl-1-indanone was prepared according to the procedure given by Alexander and Mudrak (6) and also by an alternative method reported by Fuson and Burckhalter (22). Of the two synthetic procedures, the latter method was found to give the purer product and the higher over-all yield, namely 50%, as compared to 30%. The procedure of Alexander and Mudrak (6) was used for the stereospecific hydrogenation over copper chromite of the ketone to *trans*-2-methyl-1-indanol, as was also his method for the conversion of the alcohol to the xanthate ester. The carbon disulphide employed in the synthesis contained carbon and sulphur of natural isotopic abundance. S^{34} is found in natural sulphur to the extent of 4.2% and C^{13} occurs naturally to the extent of 0.7%. Both of these abundances are quite sufficient for precise mass spectrometric analysis.

Since it was necessary to measure the isotopic fractionation of the thion and thio-ether sulphur atoms and also of the carbonyl carbon atom, a method for their quantitative separation and recovery was required. The products of the decomposition of the xanthate ester (I) are 2-methyl-1-indene, methyl mercaptan, and carbonyl sulphide. The alkene is a high-boiling compound and remains in the reaction flask. Carbonyl sulphide and methyl mercaptan are both gases at room temperature and may be rapidly removed from the reaction mixture with a stream of inert gas. The thio-ether sulphur atom is found in the methyl mercaptan, and the thion sulphur and the carbonyl carbon atoms in the carbonyl sulphide.

The separation of the two gaseous products (and thus of the two forms of sulphur) was based on the fact that carbonyl sulphide is unaffected by cold, fuming nitric acid (23), whereas methyl mercaptan is very rapidly oxidized to non-volatile methanesulphonic acid.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The gaseous product consisting of methyl mercaptan and carbonyl sulphide was swept into the fuming nitric acid trap, A, in Fig. 1, by a stream of purified nitrogen gas. After

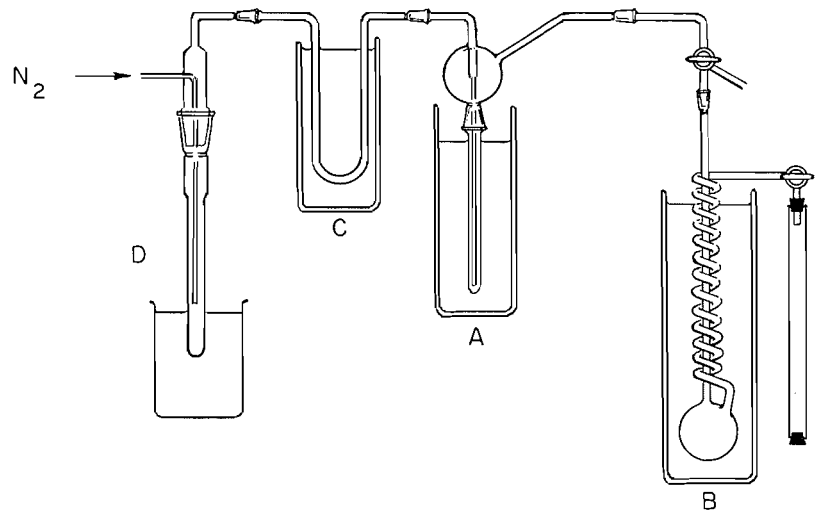

FIG. 1. Apparatus for total decompositions.

the completion of the experiment the tube and bubbler of trap A were sealed in a Carius tube and heated for 24 hours in a furnace maintained at 260 to 270° C. This treatment oxidized all of the methanesulphonic acid to sulphate ion, carbon dioxide, and water. The sulphate ion was then precipitated as barium sulphate according to the procedure outlined by Kolthoff and Sandell (24), after the excess nitrate ion was first removed by three successive evaporations in the presence of hydrochloride acid. The carbonyl sulphide was swept unreacted through the fuming nitric acid and collected in trap B, which was immersed in liquid air and contained lead hydroxide and excess base. Subsequent warming of the closed, isolated trap converted the carbonyl sulphide into lead sulphide and lead carbonate. The latter was decomposed by the addition of acetic acid and the evolved carbon dioxide precipitated as barium carbonate according to the procedure outlined by Calvin *et al.* (25). The thio-ether and thion sulphur atoms of the xanthate ester were thus recovered as barium sulphate and lead sulphide, respectively, while the barium carbonate contained the carbonyl carbon.

The quantitativeness of the separation of the two gaseous compounds and of the recovery of the three resulting products was established using pure samples of methyl mercaptan and carbonyl sulphide. In the experiments using carbonyl sulphide alone, no sulphur in any form was detected in the fuming nitric acid trap, and recovery of sulphur as lead sulphide was better than 98%. With synthetic mixtures of the two gases, yields of lead sulphide ranged from 96 to 101%, of barium sulphate 96 to 103%, and of barium carbonate 100 to 102%.

In the final stages of the procedure the three solid products, barium sulphate, lead sulphide, and barium carbonate, were converted to gaseous products suitable for mass spectrometer analysis, namely, sulphur dioxide and carbon dioxide. The barium sulphate was reduced to hydrogen sulphide by treatment with a solution containing hydriodic acid, concentrated hydrochloric acid, and hypophosphorous acid. The hydrogen sulphide was precipitated as cadmium sulphide and then converted to silver sulphide. This silver

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

sulphide, as well as the lead sulphide formed from carbonyl sulphide, was burned in a stream of purified oxygen to sulphur dioxide, which was purified and collected using high-vacuum techniques. These procedures for the conversion of metal sulphates and sulphides to sulphur dioxide have been previously described by Thode and his co-workers (26) and have been shown to involve no significant isotopic fractionation. Barium carbonate was treated with concentrated sulphuric acid in a high-vacuum system and the resulting carbon dioxide purified and collected. Yields of purified carbon dioxide were shown to be better than 98%.

An isotope effect is conveniently determined by intercomparison of the isotopic ratio for the atom in question in the original reactant and in the product formed from some small measured extent of reaction. In the present investigation the isotopic ratios in the reactant were determined by allowing the reaction of a sample of the xanthate to proceed to completion, separating the products, converting them to sulphur dioxide and carbon dioxide, and analyzing the gases mass spectrometrically. These ratios were then combined with corresponding ratios obtained for the products of a partial reaction and the isotope effects were calculated using an expression derived by Stevens and Attree (27) which takes into account the extent of reaction.

Total Decompositions

The total decompositions were carried out in the manner described below, employing the apparatus shown in Fig. 1. On the day previous to which an experiment was performed, the xanthate ester was repeatedly recrystallized until it exhibited a constant melting point. The material was then stored overnight in a vacuum desiccator containing phosphorus pentoxide. A small portion of the xanthate ester, in the neighborhood of 1 millimole, was accurately weighed and placed in the decomposition tube D. Before traps A and B, charged as previously described, were attached to the line, tubes D and C were flushed for 1 hour with purified nitrogen gas. A dry ice – acetone bath was placed around trap C, an ice-water bath around trap A, and a liquid-air bath around trap B. Without interruption of the nitrogen gas flow an oil bath, heated to a temperature of 103° C, was placed around tube D at such a height that the liquid level of the bath was slightly higher than that of the solid inside tube D. The temperature of the bath was maintained at approximately 100° C, resulting in the rapid melting of the xanthate and in the evolution of gaseous products. The methyl mercaptan condensed in the U tube C, where it was visible as a clear, colorless liquid. At no time did any of the 2-methyl-1-indene distill into tube C. One-half hour after the initial application of heat, the dry ice – acetone bath was slowly lowered from around trap C; and when a total of $1\frac{1}{2}$ hours had elasped, the heating was discontinued. The nitrogen sweep was continued for $\frac{1}{2}$ hour more, after which time traps A and B were removed from the line and their contents treated as previously described.

The work of Alexander and Mudrak (6) had indicated that the pyrolysis of S-methyl-*trans*-2-methyl-1-indanyl xanthate produced approximately 80% of the theoretical amount of gaseous products, a figure arrived at by measuring the volume of the evolved carbonyl sulphide and methyl mercaptan. Trial runs using the procedure outlined above gave results slightly higher than those reported by Alexander and Mudrak. Table III lists the results of three such runs. The percentage yield of the methyl mercaptan is expressed in terms of the recovered barium sulphate, and the carbonyl sulphide is similarly expressed in terms of the recovered lead sulphide and barium carbonate.

Although the yields of products are less than quantitative, the isotopic ratios obtained for thio-ether sulphur and for carbonyl carbon should not differ significantly from the

ratios in the original reactant, since these atoms undergo little or no isotopic fractionation in the pyrolytic reaction. The thion sulphur atom is, however, isotopically fractionated, and the failure to achieve complete conversion to carbonyl sulphide in the "total" decompositions might conceivably give a product whose S^{32}/S^{34} ratio is slightly higher than that in the original reactant. This would mean that the true isotope for this atom would be somewhat higher than that obtained by the intercomparison of ratios for the partial and "total" reaction products. In this event, mechanism II would be even more strongly indicated.

Partial Decompositions

Since the partial decompositions required only short heating periods, varying from 2 to 3 minutes, there was a possibility that some of the carbonyl sulphide and methyl mercaptan would remain dissolved in the unchanged reactant and the 2-methyl-1-indene. To circumvent this difficulty, the partial decompositions were performed in an evacuated system and the products collected in a liquid-air trap, thus insuring the complete and rapid removal of the gaseous products from the melt. A pair of total and partial decompositions were always carried out on the same day.

The apparatus employed for the partial decompositions is shown in Fig. 2. A weighed amount of the xanthate ester, of the order of 20 mmoles, was placed in the bulb of flask E, which was attached to a U tube F, provided with two stopcocks. The other arm of the U tube was connected to a high-vacuum system. Stopcocks S_5 and S_6 were both opened and the system was evacuated to a pressure of 10^{-5} mm of mercury or less. Tube F was then immersed in a liquid-air bath, stopcock S_6 was closed, and an oil bath

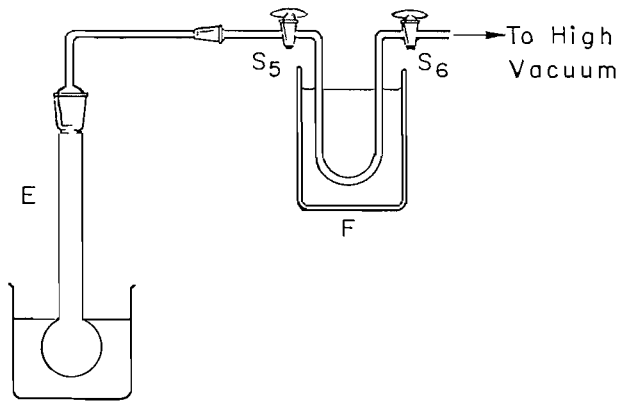

FIG. 2. Apparatus for partial decompositions.

at 70° C was raised to cover the bulb of tube E.[5] The solid in tube E melted rapidly and the temperature was then quickly raised to the desired value of 75 to 80° C. The reaction was allowed to proceed to only a small extent, usually 3 to 10% of completion. The oil bath was removed and the contents of the bulb were allowed to cool. Stopcock S_5 was then closed, tube F detached from E and the vacuum line, and, while still immersed in liquid air, connected to traps A and B. (Tube F has thus replaced D and C in Fig. 1.) With stopcocks S_5 and S_6 closed, a dry ice – acetone slurry was substituted for the liquid-air bath. Stopcock S_5 was then slowly opened to admit a stream of purified nitrogen gas. When the pressure within the tube had reached atmospheric, stopcock S_6 was opened and the nitrogen gas allowed to flow through the remainder of the apparatus. Tube F was kept immersed in the dry ice – acetone bath for $\frac{1}{2}$ hour, after which time the slurry was removed and the flushing with nitrogen continued for another $1\frac{1}{2}$ hours. The line was then dismantled and the contents of traps A and B were treated as previously described.

Mass Spectrometry

The relative abundances of the sulphur and carbon isotopes were measured using a 180°, directional focusing mass spectrometer of the Nier type equipped with an automatic recorder. The S^{32}/S^{34} ratios were obtained from the mass 64/mass 66 ion current ratios after applying a suitable correction for the contribution to mass 66 of the molecular species $S^{32}O^{16}O^{18}$ (28). Similarly, the C^{12}/C^{13} ratios were obtained from 44/45 ion current ratios with a correction being made for the contribution of $C^{12}O^{16}O^{17}$ to mass 45 (29). All of the mass spectrometer ratios reported have a precision of 0.1% or better.

The experimental data pertaining to the total decompositions (TD) and the partial decompositions (PD) are listed in Table III.

ACKNOWLEDGMENTS

Grateful acknowledgment is made to the National Research Council for financial support of this work and to the Ontario Research Foundation for the award of a fellowship to R. F. W. B. We are indebted also to Dr. W. H. Fleming for performing the mass spectrometric analyses.

[5]*By first melting the xanthate ester at a temperature lower than that actually employed for the decompositions, it was possible to obtain a homogeneous reaction at the higher temperature while incurring only a minor amount of decomposition during the melting process.*

PHASE TRANSITIONS IN SOME ANHYDROUS POTASSIUM SOAPS[1]

R. F. GRANT[2] AND B. A. DUNELL

ABSTRACT

The proton magnetic resonance absorption of the anhydrous potassium soaps of palmitic, myristic, lauric, and capric acids has been studied. Pronounced changes in the proton magnetic resonance line widths correspond to known phase transitions in these soaps.

INTRODUCTION

The anhydrous potassium soaps of long-chain fatty acids pass through several reversible phase transitions before melting (1, 2). Since the nature of some of these transitions is not well understood, their investigation by the broad-line nuclear magnetic resonance (n.m.r.) technique was undertaken. In a previous study, the proton magnetic resonance absorption in anhydrous potassium stearate was discussed in some detail and two phase transitions were identified (3). The work reported here is the continuation of this earlier investigation to the proton magnetic resonance absorption in the anhydrous potassium soaps of palmitic, myristic, lauric, and capric acids.

METHOD AND RESULTS

These soaps were made from Eastman Kodak white label grade acids which had been purified by a low-temperature crystallization technique (4). The method used in preparing the potassium soap sample (3) and the details of the nuclear magnetic resonance spectrometer (5) have been previously described. The variation of the proton magnetic resonance line width of potassium palmitate, C_{16}, myristate, C_{14}, laurate, C_{12}, and potassium caprate, C_{10}, is shown in Fig. 1. The line width is taken as the separation in gauss of the points of maximum and minimum slope of the proton magnetic resonance absorption line.

With the exception of potassium caprate, all the potassium soaps investigated show a relatively small change in line width between $-180°$ C and 20° C. They all exhibit a comparatively abrupt change in line width over a short temperature range, which falls between 50° C and 75° C. The line widths decrease somewhat gradually again as the temperature is raised above this range, and the line-width-vs.-temperature curve levels off above 130° C in the case of potassium laurate and caprate. Finally, at higher temperatures there is an abrupt change where the line width decreases from a value between 3 and 5 gauss, to a value which seems to be governed by the inhomogeneity of the magnetic field over the sample.

DISCUSSION

In potassium stearate it has been shown that molecular motion is probably confined to torsional oscillation of small amplitude at temperatures below about 20° C (3). However, this motion about the longitudinal axes of the paraffin chains increases considerably as the temperature is raised through the crystal-structure transition which is known to occur at some temperature between 50° C and 80° C in most potassium soaps (6). At temperatures above the crystal-structure transition the oscillation or twisting of the

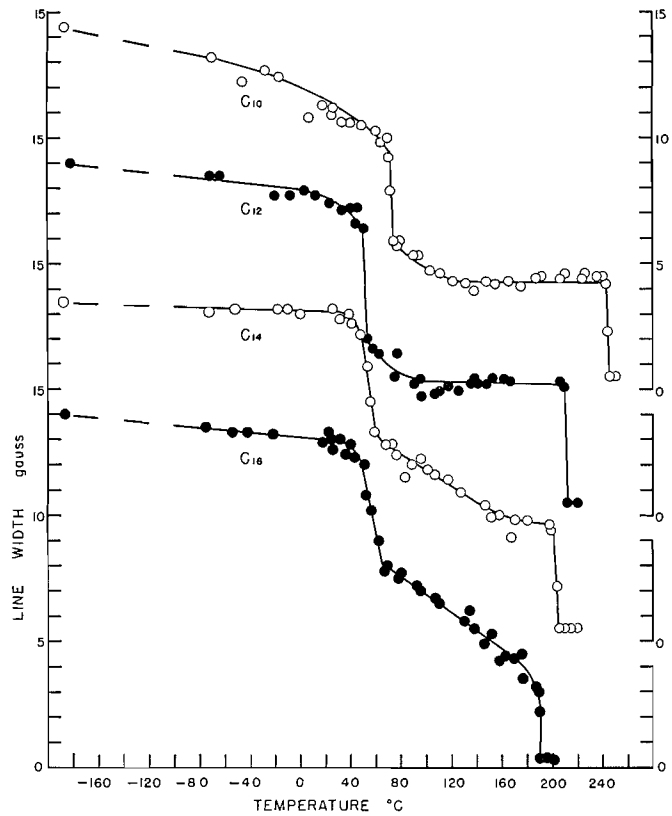

FIG. 1. Line width versus temperature for potassium caprate (C_{10}), potassium laurate (C_{12}), potassium myristate (C_{14}), and potassium palmitate (C_{16}).

paraffin chains appears to increase in violence until abruptly, at a higher temperature phase transition, motion of the paraffin chains is unrestricted except for the probable constraint that the polar chain ends remain in lattice array. These changes in motion are indicated by changes in line width and second moment, the final phase transition being indicated by the abrupt narrowing of the line to the limits of the spectrometer resolution (3). The line-width changes of the potassium soaps studied here parallel those changes observed in potassium stearate, and it is assumed that the same sequence of molecular motion occurs in each of these soaps.

The temperatures of the crystal-phase transitions in the potassium soaps from the stearate to caprate are given in Table I. For the n.m.r. case, these temperatures are those

at which the abrupt line narrowing is completed, and it can be seen that the n.m.r. transition temperatures agree reasonably well with the crystal transition temperatures obtained by calorimetric (2) and X-ray (6) methods. The only significant disagreement is for potassium stearate between the microscopic study and the other two methods.

The temperature at which the n.m.r. line becomes very narrow is given for each potassium soap in Table II, and is compared with the temperature of the nearest significant transition found calorimetrically (2) and with transition temperatures found by

other methods. The agreement is not close, particularly for potassium palmitate. The abrupt narrowing of the line width to less than half a gauss suggests that this transition is similar in nature to the supercurd-to-subwaxy transition in sodium soaps (3). In the sodium soaps, however, the supercurd-to-subwaxy transition temperatures are almost independent of chain length and show no trend to higher or lower values with changing length of chain (7), whereas this transition temperature increases gradually with decreasing chain length in the potassium soaps. It is probably reasonable to attribute this rise in transition temperature to increased effectiveness of the polar ends of the molecules in maintaining a firm lattice as the ratio of polar ends to CH_2 groups increases with decreasing size of hydrocarbon chain. The levelling off of line width with increasing temperature at temperatures below the transition indicates that a limiting extent of motion is reached in the shorter-chain soaps (C_{14} and shorter) at temperatures appreciably below the temperature which allows very extensive motion of the hydrocarbon chains. As one goes from C_{18} to C_{10} the temperature of levelling off is lower and the maximum amount of motion is less (as indicated by greater line width), both phenomena indicating the increasing effectiveness of the polar end groups in binding the lattice more tightly as the hydrocarbon chain gets shorter.

At temperatures below the crystal transition temperature, on the other hand, the shorter hydrocarbon chains can move, within the limits to which any motion is possible, more freely than the longer chains. Such behavior is indicated by the greater decrease in line width of the shorter-chain soaps as the crystal transition temperature is approached from below, and is consistent with the view of low-temperature molecular motion in these salts suggested in an earlier paper (3). The hydrocarbon chains are believed to be capable of torsional oscillation of amplitude increasing from the fixed polar ends to the terminal CH_3 group. The constraints on the motion of the hydrocarbon chain alone are smaller for the shorter chains.

Although clear indication of phase transitions at temperatures falling between the crystal transition temperature and 170° C have been obtained from calorimetric and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

microscopic studies of potassium soaps (1, 2), no corresponding n.m.r. transitions have been observed. Such behavior is consistent with the fact that the n.m.r. line is narrowed by reorientations which are of low frequency compared with frequencies required to produce a thermodynamic effect. The fact that n.m.r. and thermal transitions do not necessarily coincide at one temperature was discussed by Gutowsky and Pake (12), and in the light of their discussion it is suggested that the transitions occurring between approximately 90° and 160° C are non-co-operative. A dilatometric anomaly has been reported for potassium palmitate at 130° C (1). It is, however, only a "small inflection" in the specific-volume-vs.-temperature curve, a fact which would not contradict the interpretation given here for the n.m.r. results.

ORGANIC DEUTERIUM COMPOUNDS

XXIII. SYNTHESIS OF DEUTERATED OLEFINS[1]

D. KOVACHIC[2] AND L. C. LEITCH

ABSTRACT

The synthesis of some deuterated ethylenes, propylenes, butenes, and pentenes is described. Homolytic addition of hydrogen bromide and deuterium bromide to allene and some deutero-allenes was investigated and found to give 2-bromopropylene and deutero-2-bromopropylenes rather than the 3-bromo isomers. The preparation of 3-bromopentadeuteropropene by the allylic bromination of hexadeuteropropene is described. Bromotrichloromethane and 1,3-butadiene gave, under homolytic conditions, *trans*-5,5,5-trichloro-1-bromo-2-pentene, which was debrominated to a mixture of 5,5,5-trichloropentenes. The latter was then dechlorinated to 1-pentene, which contained some 2-pentenes. Hexadeuterobutadiene reacted similarly to give the corresponding deuterated compounds.

Two previous communications in this series dealt with the synthesis of deuterated alkanes (1) and diolefins (2). This paper describes the synthesis of several deuterated olefins embracing compounds from C_2 to C_5. Some of these are now reported for the first time while others have been obtained by a shorter route or in higher isotopic purity than previously.

Synthetic methods have been reported for four of the six possible deuterated ethylenes. Tetradeuteroethylene was prepared by partial reduction of dideuteroacetylene over palladium (3) or by the debromination of 1,2-dibromotetradeuteroethane (4, 5). *cis*- and *trans*-Dideuteroethylene were obtained by the reduction of dideuteroacetylene with zinc and hydrochloric acid (6) and chromous chloride respectively (7). 1,1-Dideuteroethylene was formed in 37% yield during the electrolysis of α-deuterated propionic acid (8). A mixture of all three mono-, di-, and tri-deuteroethylenes was obtained when ethylene was exchanged with deuterium oxide at 150° over a nickel catalyst (9). Finally an outline showing the preparation of several deuteroethylenes from acetylene or dideuteroacetylene and deuterium bromide has appeared in a review by de Hemptinne (10).

Three of the possible deuteroethylenes have now been prepared more conveniently and in better yield by the sequence shown below:

$$CH_2{=}CHCl \xrightarrow[h\nu]{DBr} CH_2BrCHDCl \xrightarrow{Zn} CH_2{=}CHD$$

$$CH_2{=}CDCl \xrightarrow[h\nu]{DBr} CH_2BrCD_2Cl \xrightarrow{Zn} CH_2{=}CD_2$$

$$CH_2{=}CDBr \xrightarrow[h\nu]{HBr} CD_2BrCHDCl \xrightarrow{Zn} CD_2{=}CHD$$

The vinyl bromide deuterated on the carbon atom bearing the chlorine was reported by us in a previous paper (11). Trideuterovinyl bromide was obtained by treating 1,2-dibromotetradeuteroethane with alkali.

Only a few deuterated propenes have been reported up to now. In the course of their studies on the mechanism of electrolysis of fatty acids, Schanzer and Clusius (12) reported

[1]*Manuscript received August 19, 1960.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada. Presented at the 136th meeting of the American Chemical Society, Atlantic City, N.J., September 1959.

the formation of 2-deutero-1-propene from the deuterated isobutyric acid $(CH_3)_2CDCO_2D$, 3,3,3-trideutero-1-propene from butyric acid labelled on the terminal carbon atom, $CD_3CH_2CH_2COOH$, and 1,1-dideutero-1-propene from butyric acid labelled in the α-methylene group, $CH_3CH_2CD_2CO_2H$. *cis*-1-Deutero-1-propene was obtained by the reduction of 1-deutero-1-propyne (6). 3-Deuteropropene was prepared by the dechlorination of 3-chloropropene with zinc and acetic deuteroacid (13). According to McNesby, 3,3,3-trideuteropropene is formed in significant amount in the reaction between trideuteromethyl radicals and 1-butene at 325° (14).

Investigation of the addition of hydrogen and deuterium bromides to allene and tetradeuteroallene opened a route to a large number of deuteropropenes. Addition was found to take place in accordance with Markovnikov's rule to give mainly 2-bromopropene even under homolytic conditions, viz. in the presence of dibenzoyl peroxide or under ultraviolet illumination. Only very small amounts of the isomeric 3-bromopropene were found in the products. This result is unexpected in view of Haszeldine's (15) observation that trifluoromethyl iodide adds to allene homolytically to give $CF_3CI{=}CH_2$. However, theoretical considerations indicate 2-bromopropene may be expected since its formation involves the intermediate $\dot{C}H_2CBr{=}CH_2$ radical, which would be more stable than the alternative $CH_2Br\dot{C}{=}CH_2$ radical required for the formation of 3-bromopropene. While this result disrupted a projected route to deuterated allylbromide, it opened the way to the wide diversity of deuterated propenes shown in Table I. The

synthesis of these compounds was vastly facilitated by the discovery of a method of preparing 1,3-dideuteroallene and tetradeuteroallene in one step which was reported recently by one of us (2).

The only deuterated butene reported is a trideuterobutene which is formed by terminal addition of CD_3 radicals to 1-butene (14). Hexadeutero-2-butene was prepared in the present work from hexadeuterobutadiene by addition of deuterium iodide followed by deiodination of the iodobutene with zinc dust and deuterium oxide. 4,4,4-Trideutero-1-butene, $CD_3CH_2CH{=}CH_2$, was prepared by addition of bromotrichloromethane to allyl chloride as described by Kharasch (16, 17) followed by dehalogenation of the bromochlorobutane formed by treatment with zinc dust and deuterium oxide. Synthesis

of the inversely deuterated 1-butene, $CH_3CD_2CD{=}CD_2$, by this route involved first the preparation of deuterated allyl bromide. Unsuccessful attempts to add deuterium bromide to allene were delineated above. Consequently, other routes to this intermediate were investigated.

In one of the earliest reports of allylic bromination, a dibromopropylene was obtained from propylene and N-bromoacetamide (18). Several attempts were made in the present work to brominate propylene to 3-bromopropene by means of N-bromosuccinimide. However, as no conditions could be found which gave a yield higher than 10%, this approach was abandoned.

An alternative method is the vapor-phase halogenation of propylene. Whereas there are several references to patents on this reaction very few papers have appeared on the subject. Actually the only reference to bromination is in a paper by Groll and Hearne (19), who reported the preparation of 3-bromopropene in 65% yields or more, based on bromine, by employing a high ratio of propylene to bromine. Yields based on propene consumed are, however, only 25–30%. Nevertheless this appeared to be the most practical way of preparing deuterated allyl bromide. 1,1,2,3,3-Pentadeutero-1-butene was synthesized from deuterated allyl bromide and methyl magnesium bromide.

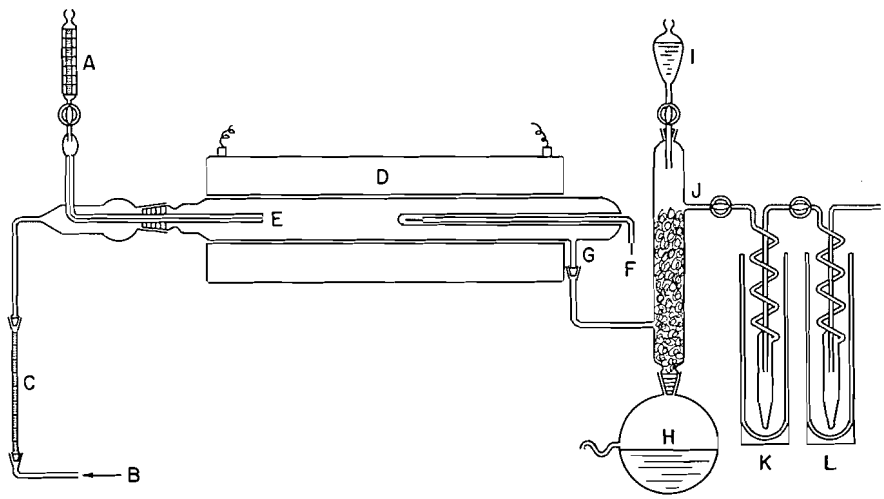

FIG. 1. Apparatus for preparation of 3-bromo-pentadeuteropropene.

Of the possible deuterated pentenes only 1,1,1,3-tetradeutero-2-pentene, $CD_3CH{=}CDCH_2CH_3$, has been reported (20). The facile preparation of hexadeuterobutadiene from hexachlorobutadiene (2) makes it an attractive starting material for the synthesis of several deuteropentenes. One of these, C_5D_{10}, gives on reduction completely deuterated *n*-pentane, which is a useful solvent for N.M.R. investigations.

According to Kharasch (17), the homolytic addition of bromotrichloromethane to butadiene produces a mixture of bromotrichloropentenes, presumably $CCl_3CH_2CHBrCH{=}CH_2$ and $CCl_3CH_2CH{=}CHCH_2Br$, which are reported to boil about 10° apart. In the present work the main product isolated was a compound, b.p. 88 to 90° under 6 mm. Its index of refraction was identical with that of one of the isomers reported by Kharasch. Attempts to oxidize the pentene to a trichloroacid with permanganate gave an inseparable mixture of acids. A capillary film of the compound gave the infrared spectrum shown in Fig. 2*a*. Absorption is consistent with a *trans*-ethylenic compound. The strong band

at 967 cm^{-1} usually assigned to the C—H out-of-plane bending vibration of the *trans*-ethylenic structure is present. On the other hand the band in the 1640 cm^{-1} region due to C=C stretching in vinyl compounds is absent. Furthermore, there are no bands in the 995–985 cm^{-1} and 910–905 cm^{-1} regions characteristic of C—H out-of-plane bending vibrations in vinyl compounds. The compound is therefore *trans*-5,5,5-trichloro-1-bromo-2-pentene. The two bands at 765 cm^{-1} and 700 cm^{-1} are attributed to the C—Cl vibration in the trichloromethyl group. The strong band at 1205 cm^{-1} could not be positively identified. From a comparison with the spectrum of the deuterated chlorobromopentene (Fig. 2*b*) prepared in the same manner from hexadeuterobutadiene it was possible to assign several bands of medium to low intensity to —C—C— skeletal vibrations. Absorption at 937, 1025, 1065, 1083, and 1140 cm^{-1} is probably of this type.

Owing to the enhanced activity of the bromine atom in the allylic position it was found possible to dehalogenate the halide selectively to a trichloropentene. Oxidation of the latter gave formic acid and a trichlorobutyric acid identical with 4,4,4-trichlorobutyric acid prepared by Bruson (21) by a different method. Apparently the trichloropentene was predominantly the 1-isomer, $CCl_3CH_2CH_2CH{=}CH_2$. An examination of the infrared spectrum of the compound confirmed this structure (Fig. 3*a*). A band of medium intensity now appears at 1650 cm^{-1} and two other strong bands characteristic of a vinyl grouping appear at 990 and 910 cm^{-1}. However, the band at 967 cm^{-1} attributed to *trans*-ethylenic compounds persists. The compound therefore contains some of the 2-pentene. It seems that an allylic rearrangement of the bromine atom has taken place during the dehalogenation.

Complete dehalogenation of the compound gave an olefin whose infrared spectrum indicated it was a mixture of the 1- and 2-pentenes (Fig. 3*b*). From the intensity of the bands in the 1640 cm^{-1} and 1000–900 cm^{-1} regions it appears to contain mainly 1-pentene. The presence of a slight peak at 967 cm^{-1} indicates the presence also of the 2-isomer.

By dehalogenating in the appropriate medium it is obviously possible to prepare pentenes deuterated only in the methyl group or only in the rest of the chain, namely $CD_3CH_2CH_2CH{=}CH_2$ or $CH_3CD_2CD_2CD{=}CD_2$. From earlier unpublished studies in this laboratory on catalytic reduction with deuterium it should be possible to reduce these compounds to labelled pentanes without concomitant exchange.

EXPERIMENTAL

Hydrogen Bromide

The apparatus consisted of a magnetic stirring bar in a 250-ml round-bottomed flask equipped with a separatory funnel and reflux condenser to which were connected a U tube containing moist phosphorus and a spiral trap of 25-ml capacity cooled to −78° in dry ice and acetone. A drying tube filled with Drierite was attached to the outlet of the spiral trap. Hydrogen bromide was generated by adding 10.0 ml (31.2 g) of bromine dropwise over a period of 2 hours to a stirred, boiling suspension of 7.0 g of red phosphorus and 6.0 ml of water in 150 ml of carbon tetrachloride. The yield of anhydrous hydrogen bromide was 16.0 ml (34.0 g), i.e. nearly quantitative.

Deuterium Bromide

To ensure a product of high deuterium content it is essential to employ dry carbon tetrachloride and dry bromine. The phosphorus must also be freed of traces of phosphoric acid by stirring it with 10% aqueous sodium hydroxide, filtering the suspension, and drying the product in a vacuum desiccator. The yield of deuterium bromide was quantitative.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Hydrogen (or Deuterium) Iodide

In this case water (6.0 ml) or deuterium oxide was added dropwise to a suspension of 7 g of phosphorus in a solution of 50 g of iodine in 150 ml of carbon tetrachloride.

1-Bromo-2-chloro-2-deuteroethane, $CH_2BrCHDCl$

The addition of deuterium bromide to vinyl chloride was carried out in a 500-ml round-bottomed quartz flask connected by a "cold finger" condenser to a vacuum line fitted with the necessary stopcocks and traps. After the apparatus was evacuated, vinyl chloride (5.5 ml) was condensed from a cylinder into a graduated tube and distilled into the quartz flask by placing chips of dry ice in the condenser. While the quartz flask was irradiated with light from a Hanovia lamp, deuterium bromide from another trap was distilled in small fractions into the quartz flask where it reacted rapidly to form the bromochloroethane. When addition was complete as indicated by the manometer, the excess deuterium bromide was distilled off into the exhaust trap and the product purified by distillation in a Vigreux column. The yield of pure bromochloroethane, b.p. 105–105.5°, n_D^{20} 1.4896 was 14.5 g (90% of the theoretical amount).

1-Bromo-2-chloro-2,2-dideuteroethane, CH_2BrCD_2Cl

Deuterium bromide (6.0 ml; 18.0 g) reacted in the same manner with 1-chloro-1-deuteroethene (11.0 g) prepared as described in reference 11. The yield of product, b.p. 105°, n_D^{25} 1.4862 was 13.7 ml (22.7 g, 72% of the theoretical amount).

Trideuterovinyl Bromide, $CD_2{=}CDBr$

To 17.0 g of pulverized potassium hydroxide in a 250-ml round-bottomed flask equipped with a heating mantle, a separatory funnel, and an air-cooled condenser leading to a spiral trap cooled in dry ice and acetone, there was added 27.0 g of 1,2-dibromo-tetradeuteroethane dropwise during heating of the alkali. Reaction was immediate. Trideuterovinyl bromide in the apparatus at the end of the reaction was swept into the spiral trap by a current of nitrogen. The yield of product was 6.3 ml (11.3 g) measured at −78° (73% of the theoretical amount).

1,2-Dibromo-1,1,2-trideuteroethane, $CD_2BrCHDBr$

The addition of hydrogen bromide to the vinyl bromide was carried out as already described above. The yield of product, n_D^{21} 1.5370, from 11.3 ml of trideuterovinyl bromide and 8.2 g of hydrogen bromide was 8.1 ml (17.9 g) i.e. nearly quantitative. For normal 1,2-dibromoethane, n_D^{20} is 1.5380.

Monodeuteroethylene

The dehalogenation of 1-bromo-2-chloro-2-deuteroethane was carried out as described previously with zinc dust in dioxane (4). The yield of monodeuteroethylene was nearly quantitative. Mass analysis, 96.0% C_2H_3D.

1,1-Dideuteroethylene

1-Bromo-2-chloro-2,2-dideuteroethane was dehalogenated as reported previously (4) in nearly quantitative yield. Mass analysis, 97.4 mole% C_2H_2D.

Trideuteroethylene

1,2-Dibromo-1,1,2-trideuteroethane was dehalogenated as reported previously (4) in nearly quantitative yield. Mass analysis, 70% C_2D_3H, 11.8% $C_2H_2D_2$, 9.4% C_2H_3D.

The low deuterium content was due to the presence of CH_2BrCD_2Br in the dibromoethane employed to prepare the vinyl compound.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Propadiene-1,3

1,2-Dibromo-2-propene was debrominated with zinc dust in ethanol as described in reference 4.

Tetradeutero-1,3-propadiene

Hexachloropropene was dehalogenated with zinc dust in dioxane – deuterium oxide as described in reference 2.

Addition of Hydrogen Bromide to Propadiene

The preparation of 2-bromopropene and 1,2-dibromopropane to be described is typical of all the addition reactions carried out in this work between hydrogen or deuterium bromide and propadiene or deuteropropadiene. To facilitate manipulation all transfers of gases were made in an evacuated system.

Propadiene (7.0 g; 0.18 mole) was condensed from a gas holder or distilled from a trap into a 500-ml round-bottomed quartz flask attached to the end of the vacuum line by means of a cold finger condenser. The flask was immersed in a bath of dry ice and acetone at −78°. On irradiation of the flask with ultraviolet light at room temperature, reaction with hydrogen bromide was rapid as indicated by the rise in the manometer.

The product was placed in a separatory funnel immersed in ice-cold water and washed with aqueous sodium bicarbonate. Distillation in a Vigreux column gave mainly 2-bromopropene, b.p. 47.5–48.5°. Yield: 10.5 g (50%). The temperature then rose rapidly to the boiling point of 1,2-dibromopropane. The amount of 3-bromopropene formed was apparently very small.

Addition of two moles of hydrogen bromide in this manner gave nearly quantitative yields of 1,2-dibromopropane.

By varying the order of addition of hydrogen and deuterium bromide the deuterated 2-bromopropenes and 1,2-dibromopropanes shown in Table I were readily obtained. The series of compounds obtainable from 1,3-dideuteropropadiene, CHD=C=CHD, also shown in the table was not actually prepared in this work but the same procedure obviously applies.

Debromination of the 1,2-Dibromopropanes

The deuterated propylenes I to VII in Table I were prepared by dehalogenation of the halides with zinc dust in ethanol essentially as described in reference 4.

The purity of the compounds was determined by mass analysis and found to be of the order of 97%.

1-Iodo-4-deutero-2-butene, $CH_2ICH{=}CHCH_2D$

This halide was prepared by the addition of deuterium iodide to butadiene in the apparatus used to prepare the deuterated bromopropenes. Butadiene (21.0 ml; 12.6 g; 0.23 mole) was condensed from a cylinder attached to the vacuum line into a graduated trap to measure its volume at −25°, and distilled from there into a 500-ml round-bottomed flask connected at the end of the line by a cold finger condenser. To the frozen butadiene was added 0.5 to 0.75 ml of deuterium iodide condensed in a trap on the line. When the mixture melted rapid reaction occurred. The butadiene was frozen again and more deuterium iodide was introduced until a total of 12 ml had been added. When the temperature of the mixture rose much above −78° some iodine was liberated. The iodobutene was distilled into a trap from the reaction flask. The yield was 28.0 g (75%). Owing to the intense lachrymatory action of the compound the index of refraction was not determined.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

1,4-Dideutero-2-butene, $CH_2DCH{=}CHCH_2D$

In a 250-ml three-necked round-bottomed flask fitted with a separatory funnel, thermometer, and reflux condenser to which was connected a spiral trap cooled to −78° in dry ice and acetone, 28 g of 1-iodo-2-deutero-2-butene was added slowly to a stirred suspension of 20.0 g of zinc dust in a boiling solution of 5.5 g of deuterium oxide in 150 ml of anhydrous dioxane. The yield of liquid butene in the trap amounted to 5.4 g measured at −78° (60% of the theoretical). Mass analysis gave ambiguous results but by analogy with the analyses of octadeuterobutene given below the deuterium content of the butene was about 97%.

Dechlorination of 1,4-dichloro-2-butene regenerates butadiene instead of giving 2-butene. It is therefore impossible to prepare dideuterobutene by this method.

1-Iodo-heptadeutero-2-butene, $CD_2ICD{=}CDCD_3$

This compound was prepared by addition of deuterium iodide to hexadeuterobutadiene as described above. The hexadeuterobutadiene was prepared from hexachlorobutadiene as described in reference 2. From 9.2 ml of the liquid diene and 5.0 ml of liquid deuterium iodide there was obtained 8.6 g (48%) of iodobutene, n_D^{22} 1.5239.

By addition of hydrogen iodide to hexadeuterobutadiene, 1-iodo-1,1,2,3,4,4-hexadeutero-2-butene would result.

Octadeutero-2-butene

1-Iodo-2-heptadeuterobutene was deiodinated as described above with zinc dust and deuterium oxide. Yield: 55%. Mass analysis: 73 mole% C_4D_8 and 26% C_4D_7H or 97 atom%.

Deiodination with zinc dust in water would of course lead to $CD_2HCD{=}CDCD_3$.

4,4,4-Trideutero-1-butene, $CD_3CH_2CH{=}CH_2$

This deuterobutene was prepared by the dehalogenation of 1,1,1,4-tetrachloro-3-bromobutane. The latter was synthesized from allyl chloride and bromotrichloromethane by the method of Kharasch, Reinmuth, and Urry (16).

To a mixture of 20 g of zinc dust, 40 ml of anhydrous dioxane and 5.0 ml of deuterium oxide in a 100-ml round-bottomed flask fitted with a reflux condenser to which was attached a trap cooled to −78° in dry ice and acetone, there was added with stirring and heating 5.0 ml (9.0 g) of 1,1,1,4-tetrachloro-3-bromobutane. After 5 hours' heating under reflux, 3.2 ml (90%) of butene had condensed in the trap. The vapor pressure of several fractions collected at −30° was constant.

3-Bromopropene, $CH_2BrCH{=}CH_2$, *and 3-Bromopentadeuteropropene*, $CD_2BrCD{=}CD_2$

(a) By Bromination of Propylene with N-Bromosuccinimide

In a pressure bottle ordinarily used for low-pressure hydrogenations 150 ml of methylene chloride, 17.4 g (0.1 mole) of N-bromosuccinimide, and 2.0 g of dibenzoylperoxide were heated under three atmospheres of propylene. The bottle was wrapped in glass heating tape and heated to 90°. After 3 hours' heating and shaking the reaction mixture was worked up. Methylene chloride was distilled off in a Vigreux column and the residue fractionated on the vacuum line; the index of refraction of the residue, n_D^{25} 1.4360, was only slightly higher than that of pure methylene chloride (lit. n_D^{20} 1.4320).

When carbon tetrachloride was used instead of methylene chloride propylene reacted preferentially with it under the influence of peroxide to give what appeared to be the tetrachlorobutane, $CCl_3CH_2CHClCH_3$. From the excess CCl_4 removed by distillation a small amount of the isothiourea picrate of 3-bromopropene, m.p. 153° (lit. 155°), was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

obtained by means of thiourea and picric acid. The yield was, however, very low. In any event the use of carbon tetrachloride as a solvent is not practical because it boils very close to 3-bromopropene.

An experiment was carried out with propylene, peroxide, and N-bromosuccinimide in a sealed tube heated to 100° C. After 3 hours' heating the solid had melted and turned dark. A product was isolated which had b.p. 131°, n_D^{25} 1.5160, the physical constants of 1,2-dibromoethane. At this stage further experiments with N-bromosuccinimide were abandoned.

(b) By Bromination of Propylene at 350°

The bromination of propene and hexadeuteropropene was carried out in the apparatus illustrated in Fig. 1. The reactor was made from a piece of glass tubing about 1 m long and 2.5 mm in diameter. Hexadeuteropropene was introduced at B from a gasholder and metered in the flowmeter C. Bromine was added at a constant rate from funnel A through a needle valve and capillary E. J was a scrubbing tower 12 in. high and 1 in. in diameter filled with glass beads. Water was added through funnel I to wash the effluent gases free of deuterium bromide. The washings were collected with a portion of the product in H. Unreacted deuteropropene, which was always used in excess to reduce additive bromination, was condensed along with the deutero-3-bromopropene in the spiral traps K and L, which were cooled in dry ice and acetone to −78°.

At the start of a run the furnace D was heated to 350–375°, the temperature being measured by means of the thermocouple F inserted in the well. Hexadeuteropropene (9.0 l.) and bromine (10.0 ml; 0.19 mole) were added at such a rate that a run was completed in $1\frac{1}{4}$ to $1\frac{1}{2}$ hours. The actual rate was determined by making several trial runs with ordinary propene. The apparatus was flushed with nitrogen at the end. The dark oily liquid in H was drawn off through the capillary and fractionated on the vacuum line. About 1.5 ml of deuterated-3-bromopropene were distilled off leaving a residue of undetermined composition which was probably a mixture of polybrominated compounds. Unreacted deuteropropene was redistilled at −40°, from the traps K and L back into the gas holder to be reused. Residual deuterated 3-bromopropene in traps K and L was combined with the product recovered from the oil and fractionated on the vacuum line. The yield of 3-bromopentadeuteropropene was generally 8.5 to 10.0 g per run. The product from several runs was combined and fractionated in a column with a whirling band. The fraction, b.p. 66.5°, was collected. An infrared spectrum of this material measured in the vapor phase showed only traces of absorption in the C—H stretching region of the spectrum.

Although the yield was only 25–30% per run and the synthesis has disadvantages from other points of view, it appears to be the only practical way to obtain deuterated 3-bromopropene at present.

1,1,2,3,3-Pentadeutero-1-butene, $CD_2{=}CDCD_2CH_3$

Methylmagnesium bromide was prepared in the usual manner from 1.2 g of magnesium turnings and 7.1 g of methyl iodide in 25 ml of *n*-dibutyl ether. After attaching a spiral trap cooled to −78° in dry ice and acetone to the reflux condenser, 3-bromopentadeuteropropene (6.0 g; 0.05 mole) was added slowly to the Grignard reagent. Residual butene in the apparatus at the end was flushed out by a slow stream of nitrogen. The deuterated butene was freed of traces of ether by distillation on the vacuum line from a bath at −30°. The yield was 1.5 ml (50% of the theoretical). Mass analysis, 84 mole% $C_4D_5H_3$ and 12.8 mole% $C_4D_4H_4$ or 90.4 atom%.

5,5,5-Trichloro-1-bromo-2-pentene, $CCl_3CH_2CH{=}CHCH_2Br$

Redistilled bromotrichloromethane (150 ml) was placed in a 500-ml quartz flask attached through a cold finger condenser to the vacuum line. The system was evacuated and butadiene from a cylinder was condensed in a trap on the line until the volume of liquid was 30 ml. When dry ice was placed in the finger of the condenser the butadiene distilled into the bromotrichloromethane. The quartz flask was irradiated with ultraviolet light for 5 to 6 hours. Excess halomethane was distilled off into a trap on the vacuum line. The residue was distilled under reduced pressure through a Vigreux column at a reflux ratio of 10:1. After a small fraction (4.0 ml) was collected at 84–97° at 8 mm pressure, the product came over at 97–98° at 8 mm. Yield: 89.5 g, n_D^{26} 1.5320, n_D^{20} 1.5351. Kharasch (16) gives n_D^{20} 1.5349 for a fraction, b.p. 84° at 1.5 mm.

The absorption bands in the infrared spectrum of the compound confirm the structure of a trans-substituted olefin (Fig. 2*a*). It would seem that only very small amounts, if any, of the isomeric halopentene are formed by 1,2-addition.

5,5,5-Trichloro-1-pentene, $CH_2{=}CHCH_2CH_2CCl_3$

The selective dehalogenation of the bromotrichloropentene was carried out by adding zinc dust in portions to a stirred solution of the halide (23.5 g; 0.15 mole) in 25 ml of methanol kept at room temperature by immersion in a water bath. After 4 hours' stirring the reaction mixture was filtered with suction from excess zinc and the filtrate was poured into water. Acetic acid was added to dissolve basic zinc salts and the oil was taken up in ether. After the solution was dried over potassium carbonate, the ether was distilled off. The residue was distilled under reduced pressure in a Vigreux column at a reflux ratio of 10 to 1. After collecting the main faction at 64–65° at 40 mm the boiling point rose rapidly to 100°, and then to the boiling point of bromotrichloropentene. The yield of product was 6.1 g (60% based on the recovered halide), n_D^{28} 1.4648. Anal: Calc. for $C_5H_7Cl_3$: Cl, 61.38%. Found: Cl, 61.10%.

A second run starting with 65 g of bromotrichloropentene gave 17.0 g of product, b.p. 78–80° at 90 mm, n_D^{27} 1.4650.

The infrared absorption spectrum of the compound indicates it is predominantly trichloro-1-pentene (Fig. 3*a*).

4,4,4-Trichlorobutyric Acid, $CCl_3CH_2CH_2COOH$

The trichloropentene (3.7 g) was added to a stirred solution of 5% aqueous potassium permanganate. Further amounts of permanganate solution were added until no further decolorization took place; a total of 250 ml of oxidizing agent was required. The manganese dioxide was filtered off and the filtrate was evaporated to dryness. The residue was acidified with 6 *N* H_2SO_4 and extracted several times with ether. Distillation of the ether left a residue which was dried by pumping off volatile material into a trap on the vacuum line. With aqueous silver nitrate the material in the trap gave a thick white precipitate which rapidly decomposed to metallic silver. This behavior is characteristic of silver formate; indeed sodium formate gave the same unstable precipitate with silver nitrate. Since formic acid is only produced in the oxidation of olefins of the type $R{-}CH{=}CH_2$, a strong presumption exists that there is a terminal double bond in the trichloropentene.

The residue obtained after pumping off the formic acid was recrystallized from pentene after decolorizing the solution with Norite. On cooling, white crystals separated which melted at 49–50°. Recrystallization from water gave an acid, m.p. 53–54°; 0.686 g of this product required 3.3 ml of *N*/10 alkali for neutralization. Neutralization equivalent:

208. The calculated neutralization equivalent for $C_4H_5O_2Cl_3$, H_2O is 209.5. Bruson (21) reported that 4,4,4-trichlorobutyric acid prepared from acrylonitrile melts at 55°. The second oxidation product of trichloropentene is therefore 4,4,4-trichlorobutyric acid. The trichloropentene must evidently be very largely the 1-butene. Since the yields on oxidation are far from quantitative one cannot say with certainty there is none of the 2-isomer.

1-Pentene

trans-5,5,5-Trichloro-1-bromo-2-pentene (6.0 g; 0.025 mole) was added dropwise to a stirred suspension of zinc dust (10.0 g) in acetic acid (30 ml) in a flask attached to a vacuum line through a reflux condenser. Evolved gas was collected in a trap cooled with dry ice and acetone to −78° C. The halide reacted vigorously; stirring was continued for an hour after addition of the halide had been completed. The liquid in the trap was fractionated on the vacuum line and yielded 1.6 ml (65%, measured at 0°) of liquid which was predominantly 1-pentene but also contained some of the 2-isomer.

5,5,5-Trichloro-1-bromo-hexadeutero-2-pentene, $CCl_3CD_2CD{=}CDCD_2Br$

Hexadeuterobutadiene was prepared from hexachlorobutadiene as described in reference 2. From 7.9 g of butadiene, 30.7 g (93%) of addition product, n_D^{20} 1.5330, were obtained.

Decadeutero-1-pentene

The halide was dehalogenated as described for the normal compound using a solution of 6.6 g of deuterium oxide in 35 ml of anhydrous dioxane (previously distilled over sodium) instead of acetic acid. The yields were similar. An N.M.R. spectrum showed no signals for hydrogen. The compound is therefore useful as a solvent for substances to be examined by N.M.R.

From the dioxane solution there was obtained in addition to the deuteropentene a small amount (0.1 ml) of by-product with a vapor pressure of only 3 mm at room temperature and an index of refraction 1.4470. This is thought to be a decadiene produced by doubling of the C_5 chain.

ACKNOWLEDGMENTS

We wish to thank Dr. J. E. Francis for preparing monodeuteroethylene and Dr. F. P. Lossing for a number of mass analyses.

A WATER-SOLUBLE GALACTOMANNAN FROM COCONUT (COCOS NUCIFERA)

PART I. METHYLATION STUDIES[1]

C. V. N. Rao, D. Choudhury, and P. Bagchi

ABSTRACT

A water-soluble polysaccharide isolated from the kernel of coconut (*Cocos nucifera*) had $[\alpha]_D$ −85° and contained D-galactose (1 mole) and D-mannose (2 moles). Methylation and hydrolysis yielded 2,3,4,6-tetra-*O*-methyl-D-mannose (0.51 mole); 2,3,4,6-tetra-*O*-methyl-D-galactose (0.5 mole); 2,3,6-tri-*O*-methyl-D-mannose (5.52 moles); 2,3,6-tri-*O*-methyl-D-galactose (1.51 moles); and a di-*O*-methyl-D-galactose (1 mole). These data agree with those of periodate oxidation. The structural significance of these results is discussed.

The kernel of coconut (*Cocos nucifera*), a tree which is generally found in coastal regions of India and south-east Asia is a popular food. The kernel is soft when the fruit is young and becomes hard when old. Although much work has been done on the oil (1) extracted from the kernel, copra (2), the liquid (3) within the shell, and other parts of the fruit such as the coir (4) etc., the polysaccharide in the kernel does not appear to have been investigated.

This paper deals with the studies on the polysaccharide precipitated from the aqueous extract of the kernel with ethanol. Hydrolysis of the polysaccharide $[\alpha]_D^{29}$ −85° (in 4% sodium hydroxide solution) gave D-galactose and D-mannose in the proportion 1:2 as revealed by chromatographic analysis (5). Traces of arabinose were also formed. Purification of the polysaccharide via the copper complex (6) removed the arabinose-containing impurities as well as traces of uronides, and hydrolysis showed that the galactose: mannose ratio was the same as before.

The galactomannan was methylated first by methyl sulphate and sodium hydroxide and then by Purdie's method. The resulting methylated galactomannan, which showed no hydroxyl band at 3500–3600 cm^{-1} in I.R. spectrum, was light yellow in color and had $[\alpha]_D^{25}$ +25° in chloroform. After methanolysis of the methylated polysaccharide and hydrolysis of the methyl glycosides the mixture of methylated sugars was resolved on a cellulose column (7) using butanone–water azeotrope (8) as eluant.

From the results of the column chromatography the mixture was found to consist of 2,3,4,6-tetra-*O*-methyl-D-mannose (0.51 mole), 2,3,4,6-tetra-*O*-methyl-D-galactose (0.5 mole), 2,3,6-tri-*O*-methyl-D-mannose (5.52 moles), 2,3,6-tri-*O*-methyl-D-galactose (1.51 moles), and a di-*O*-methyl-galactose (1 mole). The proportions of the above sugars were determined in a separate experiment using alkaline hypoiodite method (9). It will be evident from the above results that the proportion of tetra-:tri-:di-*O*-methyl sugars is as 1:7:1 indicating that the polysaccharide possesses a highly branched structure and that the average repeating unit consists of about 9 hexose residues.

The two tetra-*O*-methyl sugars were separated on filter papers. The 2,3,4,6-tetra-*O*-methyl-D-mannose obtained as sirup after elution and evaporation, having $[\alpha]_D^{30}$ +3° in water, was characterized as *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-mannosylamine, m.p. and mixed m.p. 142°, $[\alpha]_D^{30}$ −8°. The 2,3,4,6-tetra-*O*-methyl-D-galactose ($[\alpha]_D^{30}$ +110°

[1]*Manuscript received September 29, 1960.*
Contribution from the Department of Macromolecules, Indian Association for the Cultivation of Science, Calcutta 32, India.

in water) was characterized as its anilide, m.p. and mixed m.p. 187–188°, $[\alpha]_D^{31}$ −40° in acetone.

The 2,3,6-tri-*O*-methyl-D-mannose obtained as a sirup ($[\alpha]_D^{30}$ −9° in water) was characterized through its crystalline 1,4-di-*p*-nitrobenzoate whereas the 2,3,6-tri-*O*-methyl-D-galactose having specific rotation +89° (in water) was identified as the corresponding gamma lactone.

The dimethyl sugar fraction on demethylation was found to contain only galactose and was chromatographically homogeneous. No anilide could be prepared and its $R_{rhamnose}$ value (10) in paper chromatography differed from those of the known isomers. From these results it is tentatively assumed that the dimethyl sugar is 3,6-di-*O*-methyl galactose.

The identification of the hydrolysis products of the methylated polysaccharide enables the general structural features of the polysaccharide to be deduced. The demonstration of the presence of the 2,3,4,6-tetra-*O*-methyl derivatives of D-galactose and D-mannose shows that the terminal non-reducing ends in the polysaccharide consist of pyranose units of D-galactose and D-mannose in equal proportions.

The characterization of the 2,3,6-tri-*O*-methyl derivatives of the D-galactose and D-mannose indicates that the components arise from 1 → 4 linked residues of D-galactose and D-mannose of the pyranose type.

The unidentified di-*O*-methyl derivative of D-galactose shows that the branching in the molecule occurs at certain of the units of D-galactose in the main chain. If the methylated galactose derivative is 3,6-di-*O*-methyl-D-galactose then branching could occur at either C_2 or C_4. The ratio of the number of non-reducing terminal groups to branching units is about 1:1 as required by theory.

The methylation data indicating a ratio of terminal to non-terminal units of 1:8 is supported by the finding that during periodate oxidation 1 molar proportion of formic acid is liberated for every 8 hexose units and that the periodate consumption is 1.03 moles per hexose unit. The periodate-oxidized polysaccharide, on reduction and hydrolysis gave glycerol, erythritol, threitol, and D-galactose in a molar ratio of 1:6.8:1.9:0.9. These compounds were characterized as crystalline derivatives and the amounts obtained were in reasonable agreement with the amounts of *O*-methyl ethers arising from the same structural units. Thus the glycerol represented non-reducing terminal units (1.01 moles from methylation); threitol arose from 1 → 4 linked D-galactose units (1.51 moles by methylation); erythritol came from 1 → 4 linked D-mannose units (5.52 moles by methylation); and D-galactose must have represented branch points (1.0 mole by methylation). Demonstration of the presence of D-galactose in the hydrolysis product of periodate-oxidized galactomannan definitely shows that the branch units are not linked through C_6 of galactose moiety. The implication of this fact is that the di-*O*-methyl sugar mentioned previously is in all probability 3,6-di-*O*-methyl-D-galactose. More definite evidence in favor of its structure will be supplied in a subsequent communication.

The polysaccharide, whose methylated derivative has a moleculer weight of 1.25×10^5, as determined by light scattering, appears to be linked largely by β-linkage since the polysaccharide displays a negative specific rotation.

The constitutional studies of the galactomannans have shown that all of them possess a 1 → 4 linked D-mannopyranose backbone and to C_6 of certain of these mannose units are attached side chains terminated by D-galactose units (10*a*). The galactomannan from coconut kernel differs from these in having 1 → 4 linked D-galactose units and with branches being located on D-galactose rather than D-mannose residues.

EXPERIMENTAL

Methods

The following solvents were used for partition chromatography:

(A) ethyl acetate:pyridine:water (8:2:1),
(B) *n*-butanol:acetic acid:water (4:1:5), upper layer,
(C) *n*-butanol:pyridine:benzene:water (5:3:1:3), upper layer,
(D) *n*-butanol:ethanol:water (40:11:19),
(E) butanone–water azeotrope,
(F) *n*-butanol:ethanol:water (4:1:5), upper layer.

Spray reagents were:

(*a*) saturated solution of aniline oxalate (11),
(*b*) aniline phthalate in *n*-butanol saturated with water,
(*c*) 3% solution of *p*-anisidine hydrochloride in *n*-butanol, and
(*d*) ammoniacal silver nitrate.

Unless otherwise stated all evaporations were carried out *in vacuo* at 30–40°. All the optical rotations given are at equilibrium.

Isolation and Purification of the Polysaccharide

The kernel of the green coconut obtained from the market was peeled. The outer hard brown layer, which was found to contain large amounts of lignin, was carefully removed. The white kernel was sliced and macerated in a high speed "Kenmix 55" blender for 5 minutes in ethanol. The resulting mass was kept under ethanol for 2 hours, filtered, and freed from alcohol by squeezing. This was dried over a water bath at 60°. The material gave a positive test for the presence of nitrogen. The oil in the material was removed by Soxhlet extraction for 24 hours with a mixture of benzene and ethanol (2:1). The dried material gave a negative test for nitrogen.

The crude material (100 g) was soaked with 2 liters of water in a round-bottomed flask for 2 hours. The flask was then heated on a water bath for 5 hours at 90° with stirring. The slurry obtained was kept overnight and squeezed through fine cloth. The extraction was repeated for the second time, but heated for 2 hours only. The combined extracts were passed through Sharples super centrifuge (at a speed of 25,000 to 30,000 r.p.m.) for clarification. It was then acidified to pH 4 to 5 with acetic acid and added to twice its volume of 95% ethanol dropwise, when the polysaccharide precipitated in the form of long fibers. The polysaccharide was separated by filtration of the mixture through a fine cloth and was kept overnight under absolute alcohol. It was triturated four times with absolute alcohol, washed with ether, and finally dried *in vacuo* at 40°. The yield was 7 g; ash 0.35%, lignin (12, p. 369 (after Klason's method)) 0.7%, pentosan (12, p. 381 (A. W. Schorger's method)) 1.68%, uronic acid (12, p. 391 (uronic acid estimation)) 2.14%, methoxyl 0.46%; $[\alpha]_D^{29}$ −85° in 4% sodium hydroxide solution (*c*, 1); intrinsic viscosity, 1.13 (dl/g) in 4% sodium hydroxide solution. D-Galactose, D-mannose, and traces of L-arabinose were detected by paper chromatography using solvents A, B, and C, after hydrolysis. The amounts of D-galactose and D-mannose were determined by separating the hydrolyzate on a paper chromatogram, using solvent A, followed by elution in the usual way and estimation by the periodate method (5). The ratio of D-galactose to D-mannose was found to be 1:2, L-arabinose being present in insignificant amount.

The crude polysaccharide was purified by complexing with Fehling's solution (6).

The polysaccharide (10 g) was dissolved in 4% sodium hydroxide (500 ml) in an atmosphere of nitrogen and freshly prepared Fehling's solution (250 ml) was added. The

precipitate was removed by centrifuging, washed with water, and stirred with 0.5 *N* hydrochloric acid (700 ml) at 0° for 4 hours. The resulting solution was poured into ethanol (1400 ml) and the precipitate was washed with 0.1 *N* hydrochloric acid in a mixture of acetone and water (6:4). The material was finally dried after washing with methanol. The copper complex purification step was repeated once again. Yield 6 g; $[\alpha]_D^{29}$ −89° 4% sodium hydroxide solution. Hydrolysis of the polysaccharide as before gave a mixture of D-galactose (1 part) and D-mannose (2 parts). L-Arabinose and uronic acid were not present.

Hydrolysis and Identification of D-*Galactose and* D-*Mannose*

The polysaccharide (2 g) was kept with 72% sulphuric acid (13, 14), (25°) overnight and made up to a normal solution with respect to sulphuric acid by cautious dilution (to avoid reprecipitation) with water. The solution was heated for 10 hours in boiling water bath, when the hydrolysis, which was followed iodometrically (15), was found to be complete.

The solution was neutralized with barium carbonate, filtered, and passed through Amberlite IR-120 (H)* and Amberlite IR-45 (OH).* After concentration the sirup containing 200 mg of the hydrolyzate was spread on Whatman No. 3 MM filter paper over a length of 12 cm. The mixture was separated by solvent A. The strips corresponding to D-galactose and D-mannose were eluted with water (20 ml). The eluents were evaporated to yield sirups.

D-Galactose $[\alpha]_D^{30}$ +80° in water (*c*, 1),
D-mannose $[\alpha]_D^{30}$ +14° in water (*c*, 1).

The D-galactose and D-mannose components were each treated with *p*-nitroaniline in acidified methanol (16). The galactose components afforded *N*-*p*-nitrophenyl-D-galactosylamine, m.p. and mixed m.p. 217–218°, $[\alpha]_D^{29}$ −247° in dry pyridine (*c*, 0.5), lit. −248° (16), and D-mannose component gave *N*-*p*-nitrophenyl-D-mannosylamine, m.p. and mixed m.p. 217–218°, $[\alpha]_D^{29}$ −326° in dry pyridine (*c*, 1), lit. −325° (16).

Methylation of Galactomannan

The galactomannan (5 g) was methylated according to the method adopted by Adams (17). The product (2.75 g) was treated with silver oxide and methyl iodide in the usual manner to give the methylated polysaccharide (2.24 g), $[\alpha]_D^{29}$ +25° in chloroform (*c*, 1). (Anal. Calc. for $C_9H_{16}O_5$: OCH_3, 44.7. Found: OCH_3, 43.7.) The methylated polysaccharide showed no hydroxyl absorption band in the infrared. Intrinsic viscosity 0.36 (dl/g) in chloroform.

The molecular weight of the methylated galactomannan was determined by the light-scattering method using a Brice-phoenix photometer (Model OM 1000 A) using semi-octagonal cells. The concentration used was over a range of $(1–4)\times10^{-3}$ g/ml. The molecular weight was found to be 1.25×10^5 calculated by the dissymmetry method (18).

Methanolysis and Hydrolysis of the Methylated Galactomannan

A solution of methylated galactomannan (0.5 g) in 5% methanolic hydrogen chloride (40 ml) was refluxed till the rotation reached a constant value (16 hours). The solution was evaporated to a sirup under reduced pressure, *N* hydrochloric acid (40 ml) was added, and the mixture was refluxed for 14 hours when the rotation reached a constant value. The solution was cooled, neutralized with silver carbonate, and filtered. The resulting solution was deionized by passage through Amberlite IR-120 (H) and Amberlite IR-45 (OH). The solution was evaporated to a thin sirup.

Upon paper chromatographic analysis of the mixture using solvent D and a saturated solution of aniline oxalate in water as spray reagent the following spots were identified:

Spot No.	R_G	
1	.96	2,3,4,6-tetra-*O*-methyl-D-mannose,
2	.91	2,3,4,6-tetra-*O*-methyl-D-galactose,
3	.82	2,3,6-tri-*O*-methyl-D-mannose,
4	.74	2,3,6-tri-*O*-methyl-D-galactose,
5	.53	di-*O*-methyl-D-galactose.

(R_G values are with reference to 2,3,4,6-tetra-*O*-methyl-D-glucose.)

Separation of Mixture of Methylated Sugars by Column Chromatography

The mixture of methylated sugars (ca. 300 mg) was separated on a cellulose column (7) using solvent E (8). The results are given below.

TABLE I

Tube No.	Yield (mg)	Methoxyl (%)	Components
14 and 15	31.2	52.5	2,3,4,6-Tetra-*O*-methyl-D-mannose and 2,3,4,6-tetra-*O*-methyl-D-galactose
16	69.2	41.2	2,3,6-Tri-*O*-methyl-D-mannose
17	80.7	41.6	2,3,6-Tri-*O*-methyl-D-mannose and 2,3,6-tri-*O*-methyl-D-galactose
18 and 19	35.1	41.9	2,3,6-Tri-*O*-methyl-D-galactose
21 and 24	30.1	29.7	Di-*O*-methyl-D-galactose

Identification of 2,3,4,6-Tetra-O-methyl-D-mannose and 2,3,4,6-Tetra-O-methyl-D-galactose

A part of the sirup (5 mg) obtained from test tubes 14 and 15 was demethylated (19) by heating with 48% hydrobromic acid. The resulting sirup obtained after the usual treatment, on paper chromatographic analysis using solvent A, gave spots corresponding to those for D-mannose and D-galactose along with spots for partially methylated sugars. The mixture of sugars, when examined chromatographically using solvent E, gave spots having R_F values corresponding to those of 2,3,4,6-tetra-*O*-methyl-D-mannose and 2,3,4,6-tetra-*O*-methyl-D-galactose. The remaining sirup was separated on Whatman No. 3 MM paper using solvent E. The zones corresponding to the two tetramethyl sugars were eluted and evaporated.

The 2,3,4,6-tetra-*O*-methyl-D-mannose component, having $[\alpha]_D^{30}$ +3° in water (*c*, 0.5), lit. +1.2° (20), +2.4° (21) was characterized by converting it to the anilide, m.p. and mixed m.p. 143–144°, lit. 142–143° (22), 144–145° (23); $[\alpha]_D^{30}$ −38° in acetone (*c*, 0.5), lit. −38.9° (22). The 2,3,4,6-tetra-*O*-methyl-D-galactose, obtained as a sirup having $[\alpha]_D^{30}$ +110° in water (*c*, 0.5), lit. +109.5° (24), was converted into *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-galactosylamine in the usual way, m.p. and mixed m.p. 187–189°, lit. 186–188° (25), 188–190° (26), 192° (27); $[\alpha]_D^{31}$ +40° in acetone (*c*, 0.5), lit. +39° (26), +40.7° (27).

Identification of 2,3,6-Tri-O-methyl-D-mannose

The 2,3,6-tri-*O*-methyl-D-mannose component (69.2 mg) from test tube 16, which was chromatographically pure, had $[\alpha]_D^{30}$ −9° in water (*c*, 1), lit. −13° (28), −10° (29). It afforded 2,3,6-tri-*O*-methyl-D-mannose-1,4-di-*p*-nitrobenzoate (30), m.p. and mixed m.p. 189–190°, lit. −191° (28); $[\alpha]_D^{30}$ −35° in chloroform (*c*, 1), lit. −33° (30).

Identification of 2,3,6-Tri-O-methyl-D-galactose

The 2,3,6-tri-*O*-methyl-D-galactose component from test tubes 18 and 19, which was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

found to be chromatographically pure, having $[\alpha]_D^{30}$ +89° in water (*c*, 1), lit. +87° (31), +78° (32), +80° (33), was obtained as sirup. It was converted to 2,3,6-tri-*O*-methyl-D-galactonolactone, m.p. and mixed m.p. 97–98°, lit. 99° (31), 101° (35), 97–98° (34); $[\alpha]_D^{30}$ −28° in water (*c*, 1), lit. −28° (31), −21.3° (34).

*Examination of the Mixture of 2,3,6-Tri-O-methyl-*D*-mannose and 2,3,6-Tri-O-methyl-*D*-galactose*

The sirup obtained from test tube 17 (80.7 mg) on demethylation in the above manner gave D-galactose and D-mannose together with partially methylated sugars when examined chromatographically using solvent A. On paper chromatographic separation of the same sirup using solvent E, two spots were detected corresponding to 2,3,6-tri-*O*-methyl-D mannose and 2,3,6-tri-*O*-methyl-D-galactose.

Identification of Di-O-methyl-sugar

The sirup (30.1 mg) obtained from test tubes 21–24, having specific rotation −55° in water (*c*, 1) was chromatographically homogeneous and gave on demethylation in the usual way, only D-galactose. No anilide could be prepared. R_{rhamnose} value (10) (1.30) in solvent D does not correspond to any known di-*O*-methyl-D-galactose (2,4; 2,6; 3,4; 4,6).

Quantitative Estimation of Methyl Sugars

A small quantity of the mixture of methylated sugars (ca. 10 mg) was separated by paper chromatography using solvent E. The zones corresponding to each methyl sugar were eluted and estimated by alkaline hypoiodite method (9). The molar ratio of various methyl sugars determined in duplicate experiments were as follows:

2,3,4,6-tetra-*O*-methyl-D-mannose : 2,3,4,6-tetra-*O*-methyl-D-galactose : 2,3,6-tri-*O*-methyl-D-mannose : 2,3,6-tri-*O*-methyl-D-galactose : di-*O*-methyl galactose is as 0.51:0.5:5.52:1.51:1.

Periodate Oxidation

The polysaccharide (94.8 mg) was treated with 0.1 *N* sodium metaperiodate (100 ml) and the reaction was carried out in dark at 25°. The liberated formic acid and the periodate consumed in the reaction were estimated in the usual way (36). After 37 hours the liberation of formic acid became constant, corresponding to 7.86 hexose residues per 1 mole of formic acid and after 44 hours the periodate uptake became constant corresponding to 1.03 moles of periodate per hexose residue.

Reduction of the Periodate-Oxidized Galactomannan

The periodate-oxidized galactomannan was neutralized with barium hydroxide and filtered and to the clean solution (150 ml) sodium borohydride (200 mg) was added. The reduction was allowed to proceed for $3\frac{1}{2}$ hours at room temperature. The resulting solution was treated in the usual way and the sirup obtained was examined chromatographically using solvent F and spray reagent D. Four spots corresponding to erythritol, threitol, glycerol, and D-galactose were detected.

The above mixture was separated on Whatman No. 3 MM filter paper using solvent F. The zones corresponding to glycerol, erythritol, threitol, and galactose were eluted separately and evaporated to sirups. Glycerol and erythritol were characterized through their crystalline tri- and tetra-tosyl derivatives respectively. Tri-*O*-tosyl-glycerol, m.p. and mixed m.p. 102–104°, lit. 103–104° (37). Tetra-*O*-tosyl-erythritol, m.p. and mixed m.p. 164–165°, lit. 165–166° (37). Threitol was characterized as dibenzylidine threitol, m.p. 219–221°, lit. 221–223° (38). The galactose was identified by observing its optical rotation $[\alpha]_D^{30}$ +80.0° in water (*c*, 0.5).

Quantitative Estimation of D-*Galactose and Polyhydric Alcohols*

The mixture was separated quantitatively by paper chromatography. D-Galactose was estimated by phenol – sulphuric acid method (39) and the polyhydric alcohols by oxidation with periodate followed by the determination of formaldehyde with chromotroptic acid (40). The ratio of the components of the hydrolyzate is glycerol (1 mole), galactose (0.9 mole), erythritol (6.8 moles), threitol (1.9 moles).

CONTRIBUTION À L'ÉTUDE DE LA RÉACTION DE VON RICHTER

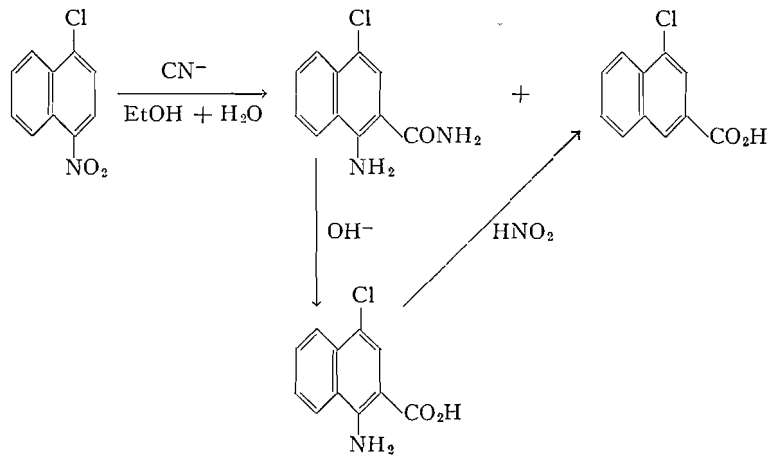
III. SUR LA RÉACTION AVEC DIVERS NITRONAPHTALÈNES[1]

E. CULLEN[2] ET PH. L'ÉCUYER

RÉSUMÉ

Dans la réaction de von Richter avec les dérivés du naphtalène, le rendement des acides naphtoïques formés est nettement inférieur à celui des acides benzoïques obtenus dans la série du benzène. Par contre, des aminoamides se trouvent parmi les produits de la réaction et, lorsque celle-ci est exécutée dans des conditions bien définies avec le 1-nitronaphtalène ou le 1-chloro-4-nitronaphtalène, deux substances, $C_{22}H_{16}O_3N_4$ et $C_{22}H_{14}O_3N_4Cl_2$, peuvent être isolées. Ces dernières pourraient être des intermédiaires de la réaction, puisqu'elles se transforment respectivement en acides 2-naphtoïque et 4-chloro-2-naphtoïque, lorsqu'elles sont traitées selon les conditions de la réaction de von Richter.

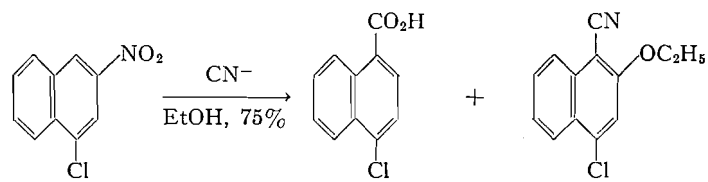
Au cours de travaux précédents (1, 2) nous avons établi la structure de quelques composés neutres et acides qui sont isolés parmi les produits de la réaction de von Richter avec le nitrobenzène ou le *p*-chloronitrobenzène. Lorsque cette réaction est exécutée à partir de dérivés nitrés du naphtalène, l'acide naphtoïque qui se forme est difficile à purifier directement (3). Nous y sommes aisément parvenus, en extrayant au benzène les produits acides dans un Soxhlet, en évaporant l'extrait à siccité et en cristallisant ensuite l'acide dans le xylène.



En variant les conditions expérimentales de la réaction avec le 1-chloro- ou le 1-bromo-4-nitronaphtalène, nous avons vérifié que les meilleurs résultats s'obtiennent dans l'alcool à 75 au lieu de 48% et avec le cyanure de sodium plutôt qu'avec le cyanure de potassium (Tableau I). La réaction est plus rapide avec les nitronaphtalènes qu'avec les nitrobenzènes.

Après la réaction avec le 1-chloro-4-nitronaphtalène, outre l'acide 4-chloro-2-naphtoïque de p.f. 241° (4), nous avons recueilli une substance fondant à 235–236°, qui, d'après son analyse élémentaire et son poids moléculaire, possède la formule empirique $C_{11}H_9ON_2Cl$. Cette substance traitée à l'ébullition par la potasse dans le glycol dégage de l'ammoniac et forme un sel. L'acide $C_{11}H_8O_2NCl$, qui en est obtenu par neutralisation de ce sel, cristallise dans le xylène et fond à 252°. Cet acide contient une fonction amine primaire qui peut être éliminée par diazotation pour donner naissance à l'acide 4-chloro-2-naphtoïque. La substance de p.f. 235–236° est donc la 4-chloro-1-amino-2-naphtamide (*a*).

Nous avons obtenu de la même façon, à partir du 1-bromo-4-nitronaphtalène, la 4-bromo-1-amino-2-naphtamide de p.f. 226°, et l'acide 4-bromo-2-naphtoïque fondant à 245–246°.



Avec le 1-nitronaphtalène nous avons isolé l'acide 2-naphtoïque et une amide de formule brute $C_{11}H_{10}ON_2$, fondant à 192–193°. Celle-ci est la 1-amino-2-naphtamide, puisque par hydrolyse nous en avons obtenu l'acide 1-amino-2-naphtoïque de p.f. 202–205° (5). Avec le 5-bromo-1-nitronaphtalène nous avons recueilli un peu d'acide 5-bromo-2-naphtoïque de p.f. 249–250° (6), et une amide, $C_{11}H_9ON_2Br$, de p.f. 246°, qui ne peut être que la 1-amino-5-bromo-2-naphtamide.

(*a*)

Après la réaction avec le 1-chloro-3-nitronaphtalène, nous n'avons pas décelé la présence d'acide 1-chloro-2-naphtoïque dans le mélange de produits obtenus. Nous n'avons recueilli qu'un peu d'acide 4-chloro-1-naphtoïque et une substance, $C_{13}H_{10}ONCl$, fondant à 103–104° (33% de la théorie). Ce composé doit être le 2-éthoxy-4-chloro-1-naphtonitrile (*b*); car il est reconnu que, au cours de la réduction de dérivés nitrés du benzène en milieu alcoolique, le groupement alcoxyle peut occasionnellement (7) substituer un groupe nitré. D'autre part, le groupe nitrile doit entrer en position 4 du 1-chloro-3-nitronaphtalène plutôt qu'au sommet 2, parce que la localisation de la double liaison aux positions 2,3 exige 15 kcal/mole de plus qu'en 1,2 (8) et que l'acide 1-chloro-2-naphtoïque ne se forme pas au cours de la réaction.

(*b*)

La réaction du 1-chloro- ou du 1-bromo-2-nitronaphtalène avec les cyanures alcalins dans l'éthanol aqueux n'a fourni que 14% de produits acides et aucun produit neutre. Même après avoir été bouilli à reflux pendant 48 heures, 50% du matériel de départ n'a pas encore réagi. Quant au produit acide obtenu, il s'agit du 2-nitronaphtol.

Durant l'ébullition à reflux d'une solution de 1-chloro-4-nitronaphtalène et de cyanure de potassium dans l'éthanol à 48%, il se forme un précipité verdâtre (*r*) (environ 10% du produit de départ). Celui-ci n'apparaît pas lorsque la réaction est exécutée dans l'alcool à 75%, et le rendement de l'acide 4-chloro-2-naphtoïque est alors deux fois plus élevé (Tableau I).

Une substance non-chlorée analogue (*r'*) prend aussi naissance, lorsqu'une solution de 1-nitronaphtalène et de cyanure de potassium dans l'éthanol à 75% est gardée pendant un mois à une température variant de 5 à 25°. Il semble que l'emploi d'éthanol dont la concentration est supérieure à 50% ou une élévation de la température de réaction favorise la transformation de ces substances et empêche de les isoler.

TABLEAU I

Réaction de 1-halo-4-nitronaphtalènes avec le cyanure de potassium ou de sodium dans divers solvants

4-Nitronaphtalène	Solvant	Cyanure	Temps (heures)	Produits %		
					Acides	
				Neutres	Bruts	4-Halo-2-naphtoïque
1-Chloro-	Éthanol 48%	KCN	48	50	31	3.5
"	Éthanol 48%	KCN	2	50	34	3.5
"	Éthanol 99%	KCN	4	—	9	Traces
"	Éthanol 75%	KCN	4	66	35	6.0
"	Éthanol 75%	NaCN	4	64	42	7.6
"	Éthanol 48%	NaCN	4	—	31	5.7
"	Glycol 70%	KCN	5	—	20	Traces
"	Glycol 90%	KCN	4	—	50	0.0
"	Dioxane 50%	KCN	4	—	31	4.0
1-Bromo-	Éthanol 48%	KCN	4	63	26	3.4
"	Éthanol 75%	KCN	4	—	33	5.0
"	Éthanol 75%	NaCN	4	73	27	7.0

Ces composés *r* et *r'* sont insolubles dans les bases et les acides dilués, presque insolubles dans les solvants organiques usuels, mais solubles à chaud dans la potassse alcoolique. En solution dans l'acide sulfurique concentré ils donnent une forte coloration bleue. L'analyse centésimale du premier (*r*), p.f. 308°, correspond à la formule empirique $C_{22}H_{14}O_3N_4Cl_2$; celle du second (*r'*), p.f. 266°, à la formule brute $C_{22}H_{16}O_3N_4$.

Le spectre infrarouge de la substance *r* suggère qu'elle possède une fonction amide primaire (bandes d'absorption à 3410, 3220 et 1655 cm^{-1}). Ces substances pourraient être respectivement le 4,4'-dichloro-2,2'-dicarbamylazoxynaphtalène (I) et le 2,2'-dicarbamylazoxynaphtalène (II). Elles sont probablement des intermédiaires de la réaction. En effet, en solution dans le glycol, elles sont saponifiées par l'hydroxyde de potassium en dégageant de l'ammoniac, et se transforment respectivement en l'acide 4-chloro-2-naphtoïque et l'acide 2-naphtoïque. Nous tentons présentement d'éclaircir ce point.

I X = Cl
II X = H

DISCUSSION DES RÉSULTATS

De tous les dérivés nitrés du naphtalène qui ont été essayés, le 2-nitronaphtalène est celui qui, dans les conditions de la réaction de von Richter, donne le plus fort pourcentage d'acide, soit 14% (3) et, dans ce cas, seul l'acide 1-naphtoïque est obtenu. Il y a deux positions ortho libres auxquelles l'ion cyanure peut se fixer, mais la localisation d'une double liaison en position 2,3 du naphtalène exige 15 kcal/mole de plus qu'en 1,2 (8).

Pour le 1-nitro- et le 2-nitro-naphtalène, on peut présumer que la réactivité ne dépend que de la polarisabilité du sommet attaqué. Avec le 1-nitronaphtalène, l'activation par le groupe nitré est utilisée, en partie du moins, pour neutraliser le supplément d'énergie de polarisation que requiert le sommet 2 par rapport au sommet 1, soit environ 3 kcal/mole (9). L'effet ortho, dû au voisinage de l'hydrogène péri et du groupement nitré,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

empêche, sans doute par défaut de coplanéité, la transmission totale des effets électroniques du noyau vers la position 2 (10).

Il est à noter que, grâce à l'activation d'un atome d'halogène en position para du groupe nitré, le rendement de l'acide naphtoïque augmente considérablement. Il est de 8% dans le cas de l'acide 4-chloro-2-nitronaphtoïque obtenu à partir du 4-chloro-1-nitronaphtalène, alors qu'il n'est que de 1% pour l'acide 5-bromo-2-naphtoïque produit par le 5-bromo-1-nitronaphtalène dans lequel l'effet de l'atome de brome ne peut se faire sentir en position 2.

La réaction avec le 2-nitro-1-chloronaphtalène confirme la résistance du sommet 3 à l'attaque des réactifs et il est à propos de faire ici un rapprochement avec le 2-naphtol. On sait, en effet, que les réactions de ce dernier (par exemple, le couplage avec les diazoïques) intéressent toujours le sommet 1 et non la position 3 et que, parallèlement au cas précédent, l'occupation de la position 1 conduit, s'il y a réaction, à l'élimination du groupe substituant à ce sommet.

Enfin, en ce qui concerne la réaction avec le 1-chloro-3-nitronaphtalène, on constate une désactivation importante par l'atome de chlore, son effet électromère neutralisant celui du groupe nitré. Pour les mêmes raisons que précédemment, il faut rejeter la possibilité que l'ion cyanure se fixe en position 2 et, par conséquent, que se forment le 1-chloro-3-éthoxy-2-naphtonitrile et l'acide 1-chloro-2-naphtoïque.

Dans les réactions avec les nitronaphtalènes, les faibles rendements en acides naphtoïques ne semblent pas attribuables à la difficulté que l'ion cyanure éprouve à se fixer au noyau du naphtalène, mais plutôt à une modification des étapes subséquentes. En effet, nous avons observé que même si l'on abaisse le pH de la solution en y faisant passer un courant d'anhydride carbonique durant la réaction du 1-chloro-4-nitronaphtalène, le groupe nitrile se fixe quand même; mais, alors que le rendement de la 4-chloro-1-amino-2-naphtamide s'accroît du double (14%), celui de l'acide naphtoïque devient nul.

PARTIE EXPÉRIMENTALE[3]

Le 1-chloro- et le 1-bromo-4-nitronaphtalène, le 1-chloro- et le 1-bromo-2-nitronaphtalène ainsi que le 2-chloro-1-nitronaphtalène ont été préparés selon Hodgson et Walker (11). Ces composés cristallisent beaucoup mieux dans la ligroine (Eb = 65–110°) que dans l'éthanol tel que suggéré.

Le 1,8-dinitro-4-chloronaphtalène a été préparé selon Bassilios (12), le 1-nitro-5-bromonaphtalène selon McLeish et Campbell (13), le 1-chloro-3-nitronaphtalène, selon Hodgson et Elliott (14), la 8-nitro-1-naphtylamine selon Hodgson et Davey (15), la 1-nitro-2-naphtylamine selon Saunders et Hamilton (16), la 4- et la 2-nitro-1-naphtylamine selon Hodgson et Walker (17), le 1-nitronaphtalène selon Berkebile et Fries (18) et, finalement, le 2-nitronaphtalène par désamination de la 2-nitro-1-naphtylamine d'après la méthode générale de Hodgson et Walker (11).

Avec le 1-chloro-4-nitronaphtalène

Un mélange de 1-chloro-4-nitronaphtalène (2.0 g), de cyanure de sodium (8.0 g) et d'éthanol à 75% (100 ml) est chauffé à reflux durant 4 heures et ensuite versé dans 300 ml d'eau. On essore la suspension et recueille 0.98 g d'un produit neutre brun-verdâtre et

[3]*Les points de fusion (p.f.) ont été pris en tubes capillaires et ne sont pas corrigés. Les spectres infrarouges ont été déterminés au moyen d'un spectromètre Beckman IR-4; le solide était mélangé à du bromure de potassium et pressé; seules les bandes servant à l'identification du composé sont indiquées; les valeurs en cm^{-1} correspondent au maximum d'absorption. Les microanalyses ont été effectuées par M. W. Manser, Zürich, Suisse.*

For personal use only.

un filtrat. En épuisant le filtrat à l'éther, on peut obtenir une quantité additionnelle (0.30 g) du produit neutre, ce qui donne en tout 1.28 g.

Acide 4-chloro-2-naphtoïque

Le filtrat est d'abord chauffé pour en chasser les dernières traces d'éther, puis refroidi et acidifié par addition d'acide chlorhydrique. Les acides précipités (0.837 g) sont essorés et extraits au benzène dans un Soxhlet. L'extrait est traité avec un peu de noir animal, filtré et évaporé à siccité. Le résidu, cristallisé dans le xylène, fournit 0.152 g (7.6% de la théorie) d'acide 4-chloro-2-naphtoïque de p.f. 241°. Recristallisé dans l'acide acétique et ensuite le xylène, l'acide fond à 244° (p.f. lit. 241° (14)).

4-Chloro-1-amino-2-naphtamide

Le produit neutre (1.28 g) est extrait au benzène dans un Soxhlet et l'extrait évaporé à siccité. Cristallisé successivement dans le xylène et l'acide acétique à 95% (noir animal), le résidu donne la 4-chloro-1-amino-2-naphtamide (0.12 g) sous forme d'aiguilles crèmes de p.f. 235–236°. Recristallisée dans le xylène, elle fond à 236–237°. Calculé pour $C_{11}H_9ON_2Cl$: C, 60.32%; H, 4.32%; N, 12.67%. Trouvé: C, 59.87%; H, 4.11%; N, 12.70%.

Acide 4-chloro-1-amino-2-naphtoïque

De la 4-chloro-1-amino-2-naphtamide (0.227 g) et de l'hydroxyde de potassium (1.0 g) sont dissous dans le glycol (20 ml) et chauffés à reflux pendant $2\frac{1}{2}$ heures. La solution jaune pâle est ensuite refroidie, diluée par l'eau et acidifiée. L'acide 4-chloro-1-amino-2-naphtoïque filtré et séché cristallise dans le xylène en aiguilles crèmes de p.f. 250°. Calculé pour $C_{11}H_8O_2NCl$: C, 59.60%; H, 3.64%; N, 6.32%. Trouvé: C, 59.45%; H, 3.60%; N, 6.12%.

Cet acide (0.290 g) donne, par désamination suivant la méthode générale de Hodgson (11), l'acide 4-chloro-2-naphtoïque (0.113 g) qui cristallise dans le xylène en aiguilles de p.f. 242°. Le point de fusion mixte de cet acide et de l'acide isolé après la réaction de von Richter avec le 1-chloro-4-nitronaphtalène n'est pas abaissé et les spectres infrarouges des deux échantillons sont superposables.

Composé $C_{22}H_{14}O_3N_4Cl_2$ (r)

Lorsque la réaction de von Richter avec le 1-chloro-4-nitronaphtalène (2.0 g) est effectuée dans l'alcool à 48 au lieu de 75%, il se forme durant l'ébullition à reflux un précipité vert (*r*) (0.20 g) qui est recueilli en filtrant à chaud. Le filtrat, traité comme précédemment, donne 5% de 4-chloro-1-amino-2-naphtamide mais seulement 3% d'acide 4-chloro-2-naphtoïque.

Le produit vert (*r*) est insoluble dans les bases et les acides dilués et la plupart des solvants organiques. Il cristallise dans un mélange de N,N-diméthylformamide et de xylène (4:1) (noir animal) en minuscules aiguilles jaune-verdâtre de p.f. 308°. Calculé pour $C_{22}H_{14}O_3N_4Cl_2$: C, 58.29%; H, 3.11%; N, 12.36%. Trouvé: C, 58.34%; H, 3.19%; N, 12.33%. Les résultats de cette analyse correspondent exactement à la formule du 4,4′-dichloro-2,2′-dicarbamylazoxynaphtalène, mais les tests ne confirment ni la présence du groupe azoïque, ni celle du groupement azoxyque. Spectre infrarouge: 1655, 3220 et 3410 cm^{-1} (—$CONH_2$).

Ce composé (0.50 g) en solution dans le glycol est saponifié par l'hydroxyde de potassium (1.5 g) en faisant bouillir à reflux pendant 3 heures. Le dégagement d'ammoniac terminé, le produit de la réaction est refroidi et acidifié et l'acide (0.20 g) essoré. Celui-ci cristallise dans le xylène (noir animal) en aiguilles crèmes fondant à 241°. Un point de fusion mixte de cet acide avec l'acide 4-chloro-2-naphtoïque authentique n'est pas abaissé. Les spectres infrarouges des deux sont identiques.

Avec le 1-bromo-4-nitronaphtalène ou le 5-bromo-1-nitronaphtalène

En opérant dans l'alcool à 75%, comme il est décrit précédemment pour le 1-chloro-4-nitronaphtalène, on obtient avec le 1-bromo-4-nitronaphtalène un acide A et une amide B, et avec le 5-bromo-1-nitronaphtalène, un acide 1A et une amide 1B.

Acide 4-bromo-2-naphtoïque

L'acide A est extrait au benzène dans un Soxhlet, l'extrait évaporé à siccité et le résidu sublimé à 250° sous 12 mm de mercure. L'acide 4-bromo-2-naphtoïque (0.142 g) (7.1% de la théorie) ainsi obtenu, cristallise dans le benzène en aiguilles crèmes de p.f. 245–246°. Calculé pour $C_{11}H_7O_2Br$: C, 52.62%; H, 2.81%; Br, 31.83%. Trouvé: C, 52.74%; H, 2.81%; Br, 30.95%.

4-Bromo-1-amino-2-naphtamide

L'amide B (1.20 g) est extraite au xylène dans un Soxhlet, l'extrait évaporé à siccité et le résidu cristallisé successivement dans l'acide acétique et le toluène. La 4-bromo-1-amino-2-naphtamide (environ 6% de la théorie) cristallise en aiguilles de p.f. 226°. Calculé pour $C_{11}H_9ON_2Br$: C, 49.80%; H, 3.40%; N, 10.60%. Trouvé: C, 49.67%; H, 3.55%; N, 10.48%.

Acide 5-bromo-2-naphtoïque

L'acide 1A est extrait au tétrachlorure de carbone dans un Soxhlet et l'extrait évaporé à siccité. Le résidu cristallisé dans le toluène (noir animal) fournit l'acide 5-bromo-2-naphtoïque en aiguilles jaunes pâles, de p.f. 249–250° (p.f. lit. 248–250° (10)).

1-Amino-5-bromo-2-naphtamide

L'amide 1B est extraite au xylène dans un Soxhlet et l'extrait est traité au noir animal, concentré et refroidi. La 1-amino-5-bromo-2-naphtamide précipitée, est filtrée et cristallisée dans l'acide acétique. On en obtient 0.234 g (7.0% de la théorie) sous forme d'aillures jaunes pâles de p.f. 246°. Calculé pour $C_{11}H_9ON_2Br$: C, 49.80%; H, 3.40%; N, 10.60%. Trouvé: C, 49.92%; H, 3.49%; N, 11.55%.

Avec le 1-chloro-3-nitronaphtalène

La réaction est effectuée comme précédemment dans 20 ml d'éthanol à 75% à partir de 0.512 g de 1-chloro-3-nitronaphtalène et 2.0 g de cyanure de sodium. La solution est ensuite diluée par l'eau à 100 ml. Il précipite alors un produit neutre jaune-orangé qui est essoré (0.44 g). Le filtrat est acidifié et fournit 0.050 g d'acide.

2-Éthoxy-4-chloro-1-naphtonitrile

Le produit neutre se sublime entre 90 et 200° sous 12 mm de mercure. Le sublimé cristallise dans l'éthanol en aiguilles de couleur jaune-orangé de p.f. 103–104°. C'est le 2-éthoxy-4-chloro-1-naphtonitrile (0.103 g; 18% de la théorie). Calculé pour $C_{13}H_{10}ONCl$: C, 67.39%; H, 4.35%; N, 6.05%. Trouvé: C, 67.30%; H, 4.50%; N, 6.12%.

Acide 4-chloro-1-naphtoïque

Le produit acide est sublimé sous 12 mm de mercure entre 120 et 160°. On recueille l'acide 1-chloro-4-naphtoïque qui, cristallisé dans l'acide acétique, puis dans le benzène, fond à 224° (p.f. lit. 223–224° (19)).

Avec le 1-nitronaphtalène

Après avoir fait bouillir à reflux une solution de 1-nitronaphtalène (5.0 g) et de cyanure de sodium (15 g) dans de l'éthanol à 50% (200 ml), on obtient, en extrayant à l'éther

le mélange de la réaction dans un extracteur liquide – liquide, une amide dans la phase éthérée et un produit acide dans la phase aqueuse. En acidifiant cette dernière, la majeure partie des acides (2.05 g) précipite. Une quantité supplémentaire d'acide (0.167 g) peut être obtenue en procédant comme il a déjà été décrit précédemment pour la réaction avec le *p*-chloronitrobenzène (1).

Acide 2-naphtoïque

Le produit acide (2.24 g) est extrait à la ligroïne (Eb = 65–110°) et l'extrait bouilli avec un peu de noir animal, filtré et concentré. L'acide 2-naphtoïque (0.108 g) cristallise en aiguilles de p.f. 184–185° (p.f. lit. 185° (20)).

1-Amino-2-naphtamide

L'extrait éthéré est évaporé au bain-marie et le résidu dilué par l'eau et acidifié par l'acide acétique. Le précipité est essoré, séché, extrait au benzène et traité au noir animal. Après deux cristallisations dans le benzène, la 1-amino-2-naphtamide (0.124 g; 2.3% de la théorie) apparaît sous forme d'aiguilles lustrées de teinte jaune pâle, fondant à 193–194°. Calculé pour $C_{11}H_{10}ON_2$: C, 70.96%; H, 5.41%; N, 15.05%. Trouvé: C, 71.08%; H, 5.29%; N, 14.96%.

Acide 1-amino-2-naphtoïque

La 1-amino-2-naphtamide (0.097 g) est hydrolysée par l'hydroxyde de potassium (0.50 g) dans le glycol (5 ml) en acide 1-amino-2-naphtoïque qui cristallise dans l'acide acétique en aiguilles crèmes de p.f. 205° (p.f. lit. 202–205° (5)).

Composé $C_{22}H_{16}O_3N_4$ (r')

Lorsqu'une solution de 1-nitronaphtalène (10.0 g) et de cyanure de potassium dans l'éthanol à 75% (100 ml) séjourne alternativement à la température ambiante pendant 24 heures et au réfrigérateur à 5° pendant une semaine durant une période d'un mois, il se forme un solide qui cristallise dans un mélange de N,N-diméthylformamide et de xylène (3:1) en aiguilles jaune-verdâtre de p.f. 266°. Calculé pour $C_{22}H_{16}O_3N_4$: C, 68.74%; H, 4.20%; N, 14.58%. Trouvé: C, 68.88%; H, 4.24%; N, 14.61%. Les résultats de l'analyse centésimale correspondant à la formule du 2,2'-dicarbamylazoxynaphtalène; mais ni la présence du groupe azoïque, ni celle du groupement azoxyque, n'a pu être vérifiée.

Cette substance saponifié par l'hydroxyde de potassium dans le glycol perd de l'ammoniac et donne l'acide 2-naphtoïque dont le point de fusion (185°), après deux cristallisations dans la ligroïne (Eb = 65–110°), n'est pas abaissé lorsque l'acide est mélangé à un échantillon d'acide 2-naphtoïque authentique.

Avec le 2-nitro-1-bromonaphtalène ou le 2-nitro-1-chloronaphtalène

2-Nitro-1-naphtol

Le produit qui est obtenu en faisant bouillir (24 heures) du 2-nitro-1-bromonaphtalène (4.7 g) et du cyanure de sodium (15 g) dans l'éthanol à 50% est versé dans 500 ml d'eau. Le solide est essoré et cristallisé dans le 1,1-diméthyléthanol; c'est du 2-nitro-1-bromonaphtalène (60%) qui n'a pas réagi. En acidifiant le filtrat, le 2-nitro-1-naphtol est isolé. Cristallisé successivement dans la ligroïne (Eb = 65–110°) et l'alcool, il forme des lamelles jaunes de p.f. 129° (p.f. lit. 128° (21)). Calculé pour $C_{10}H_7O_3N$: C, 63.49%; H, 3.73%; N, 7.41%. Trouvé: C, 63.64%; H, 3.89%; N, 7.58%.

Le 2-nitro-1-chloronaphtalène fournit aussi le même naphtol.

Avec le chloro-4-nitronaphtalène dans une atmosphère d'anhydride carbonique

La réaction de von Richter avec le 1-chloro-4-nitronaphtalène (1.0 g) en solution dans l'alcool à 75% (50 ml) dont le pH est maintenu constant par un courant d'anhydride carbonique, ne donne pas de produit acide. Quant au produit neutre, sublimé entre 150 et 250° sous 12 mm de mercure, il donne 0.15 g d'une substance jaune, qui cristallise dans le xylène en aiguilles de p.f. 235° et est identique à la 4-chloro-1-amino-2-naphtamide, comme le montre le point de fusion mixte avec un échantillon de l'amide authentique.

NOTES

IMPROVEMENTS IN THE ACIDOLYSIS PROCEDURE FOR LIGNIN ISOLATION AND IN THE PROCEDURE FOR THE ANALYSIS OF LIGNIN OXIDATION PRODUCTS

J. M. Pepper and M. Siddiqueullah*

Improvements in the Acidolysis Procedure for Lignin Isolation

The acidolysis of wood meal, whereby an only moderately modified lignin fraction may be obtained in good yields in a short time, has proved of value in lignin research (1, 2). Recently some modifications have resulted in a simpler extraction procedure with resultant improved yields of lignin. Previously, after the initial acid-catalyzed dissolution of lignin into the dioxane–water (9:1) solvent medium, the procedure was to neutralize the acid with sodium bicarbonate, and then to obtain the lignin by first concentrating this solution and then precipitating the concentrate together with the bicarbonate sludge into a 1% sodium sulphate solution. Subsequent extensive washings, with water, of the precipitated lignin, gave rise to stable suspensions which would not clear even on prolonged centrifugation. Since large volumes of water were required to remove all the inorganic contaminants, an appreciable amount of lignin was lost in the discarded washings.

It has now been observed that the lignin may be recovered without the use of either sodium bicarbonate or sodium sulphate. After acidolysis, the acidic extract was concentrated under reduced pressure and the lignin in the concentrate was precipitated into a large excess of vigorously stirred water. The lignin settled readily in a coagulated state leaving a clear mother liquor. In subsequent water washing of the recovered lignin there was little tendency for a colloidal suspension to be formed. Indeed with fewer ions to be removed less washing was required.

No significant difference could be detected in the analyses of lignin samples isolated from the same pre-extracted aspen wood meal under conditions of 0.2 *N* initial hydrogen chloride concentration and 0.5-hour extraction time, but using the two methods of purification. The color, infrared absorption spectra, methoxyl content, and percentage phenolic aldehydes obtained by alkaline nitrobenzene oxidation were very similar. This modified technique has been used successfully for the isolation of a lignin fraction from several woody plants and cereal straws.

Modifications in the Analytical Procedure for the Alkaline Nitrobenzene Oxidation Products of Lignin

The widely adopted procedure of Stone and Blundell (3) for the quantitative estimation of the phenolic aldehydes, vanillin, syringaldehyde, and *p*-hydroxybenzaldehyde resulting from the alkaline nitrobenzene oxidation of lignin has certain limitations. The oxidation mixture is not homogeneous and the presence of small oily droplets of nitrobenzene and its reduction products makes it difficult to pipette accurately the small aliquot sample of the aqueous phase that is required for spotting on the chromatographic paper. To overcome this difficulty, as well as to eliminate the step involving acidification of the paper using boiling acetic acid, it has been found preferable to use the following modification. The alkaline reaction products were extracted continuously with ether to

**Colombo Plan Fellow in Canada, 1957–1960.*

remove excess nitrobenzene and its reduction products, then acidified, and further extracted with ether to remove the required lignin oxidation products. Solvent exchange with ethanol gave an alcoholic solution from which an aliquot was readily taken for the subsequent chromatographic separations.

In the original publication (3) no mention was made of the need for proper equilibration of the chromatographic paper prior to use. Experience has shown that for best results this is an important consideration. It is recommended that all papers be equilibrated over water in a closed vessel, preferably for at least 2 days, and that during the charging of the samples much care be exercised to maintain this equilibrium.

EXCHANGE REACTIONS BETWEEN ZINC AND ITS IONS[1]

J. E. SANDOR[2]

ABSTRACT

The exchange reaction between zinc metal and zinc ions in solution has been studied by means of radioactive zinc-65. Polycrystalline zinc and bicrystals of zinc were used under conditions where the radioactive material was incorporated either in the solid or the liquid phase. Strain-free clean surfaces were obtained and autoradiographs taken.

The results of the experiments using bicrystals were interpreted on the basis that a local cell action sets up an electrochemical potential between liquid and solid at the beginning of the reaction. Exchange was found to take place in both directions, but the reaction did not follow a simple logarithmic law.

INTRODUCTION

The extensive use of radioisotopes has made possible the study of many exchange reactions. In 1915, Hevesy (1) showed that in the system $Pb^{++}/Pb(NO_3)_2$ a deep exchange takes place in a very short period of time, i.e. more than one monolayer exchanges, and this was found later to happen in other metals, too. Various mechanisms have been suggested for such exchange reactions, but no conclusive explanation has yet been put forward. In the general case one expects more or less rapid exchange in the surface layer, followed by slow penetration to the interior of the metal at a speed controlled by the diffusion coefficient and orientation of the crystals.

The heterogeneous exchange reaction between zinc and its ions has been studied by Rollin (2) in zinc dust, by Gaudin and Vincent (3), Haenney and Mivelaz (4), Matsura (5), and King and Evans (6), in both zinc dust and zinc foil; and Bushmanov and Vozdvizhenky (7) in zinc single crystals. There are considerable variations in the results obtained by the different authors in this field, due to the fact that some factors, such as surface preparation, oxidation, corrosion, are not always fully considered.

In this investigation, zinc metal was dipped in different solutions of zinc salt to show that the exchange reaction $Zn^0_{metal} \rightleftarrows Zn^{++}_{sol}$ takes place in both directions. This was done by labeling either the metal or the zinc solution with radioactive zinc-65, and following the change in activity for different times of immersion. The influence of oxide or hydroxide on the exchange was also investigated. Finally, the exchange reaction between zinc bicrystals and carrier-free solutions of Zn^{65} was studied.

The following factors were considered of importance in this study: (1) preparing undistorted zinc surfaces; (2) working in an oxygen-free atmosphere; (3) minimizing of corrosion and adsorption. It is known that zinc is a soft metal, easily worked, and that the depth of distorted metal after mechanical polishing may commonly extend to at

[1]*Manuscript received May 13, 1960.*
Contribution from the Mineral Sciences Division, Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada.

least 20 times the penetration of the deepest scratch (8). For silver, Tingley, Henderson, and Coffin (9) have shown definitely that the exchange reaction is notably different with different surface preparation techniques.

Zinc is a chemically reactive metal, easily oxidized, and considerable corrosion can take place in solution in the presence of oxygen as a result of electrochemical action.

EXPERIMENTAL DETAILS

Materials

Zinc metal.—Zinc metal, 99.999% purity, was cast in an argon atmosphere in rods of 1.56-cm diameter. Disks of 0.62-cm thickness and 1.56-cm diameter were cut by means of a lathe, annealed 12 hours at 350° C and mounted in Lucite in such a way that only one face was used in the experiments.

Active metal.—From the same 99.999% Zn rods as before, a number of disks of 1.56-cm diameter were cold-rolled to 0.78-mm thickness, cut in strips of 2.5-cm length, annealed for 24 hours at 350° C, and sent to Chalk River, Ont., for irradiation. The specific activity after irradiation was 5.1 mc/g. These samples were checked for purity with a 100-channel pulse height analyzer, to see if there was any unwanted activity not resulting from Zn^{65}.

Carrier-free zinc.—Carrier-free zinc was used in some experiments. Obtained from Nuclear Science and Engineering Corporation (Pittsburgh), it had an activity of 0.8 mc and a specific concentration of 1.1 mc/ml.

Preparation of Samples

The polycrystalline samples were mechanically polished with emery papers, and on microcloth laps using Al_2O_3 suspensions. They were finally etched with a cold solution of equal parts of HNO_3, C_2H_5OH, and H_2O_2. When the underlying structure of the zinc became visible under a microscope and no twins appeared (10), it was considered that an undistorted surface was obtained.

To avoid oxidation of the samples after etching and rinsing, the samples were immediately immersed in the exchange solution. Solutions of active and inactive deaerated $Zn(NO_3)_2$ were used. The molarities were 10^{-1} and 10^{-2} and the pH varied between 5.2 and 6.2. The active solutions had a specific activity of 0.4 mc/g. The solutions were thoroughly deaerated.

After polishing the polycrystalline metal samples, they were introduced into a dry box, in which the etching and exchange were carried out in an inert atmosphere of argon. The apparatus was set up so that the exchange process of six samples could be observed simultaneously in the same solution. This solution was kept in a thermostat at $25° \pm 0.5°$ C. The periods of immersion were varied between 1 hour and 1 week.

Bicrystals were grown from seeds provided by Dr. F. Weinberg; the bicrystals were annealed, strongly etched to remove the worked and recrystallized material, and, finally electropolished by using an orthophosphoric acid – ethanol solution (1:1). Carrier-free deaerated zinc solutions of pH 6 were used. Argon was bubbled continuously and the samples were immersed for short periods of time, ranging from a few seconds to a few minutes. The samples were then rinsed with water, washed with alcohol, and dried, and an autoradiograph was taken with No-Screen X-ray film. Different exposure times—depending on the activity of the samples—were tried, ranging from 8 to 64 hours.

For the purpose of studying the influence of oxidation on the exchange, one sample was pretreated for 24 hours in an air-free 10^{-2} *M* $Zn(NO_3)_2$ solution; this led to formation of a $Zn(OH)_2$ film. Then half of the sample was etched and the other half was left with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the hydroxide. Again, care was taken, during the rinsing of the samples, to avoid activities resulting from contamination only and not from exchange itself.

Some 99.999% Zn irradiated samples were immersed for short periods in a glass immersion cell, which had argon bubbling continuously through the solutions. The volume of solution was 100 ml, and fresh portions were used for each immersion period. Aliquots were taken out and counted for 30 minutes in a well-type scintillation counter.

To ensure radiochemical purity, solution samples were checked for possible contamination with the gamma-ray spectrometer. Samples had to be rinsed carefully, in order to remove all traces of the etching solution prior to the exchange experiment.

Activity measurements.—The activity measurements were done with a 3-in. well-type NaI(Tl) scintillation counter, mounted on a 6655 RCA photomultiplier. For measuring the metal activity, the samples were mounted in 1-in. diameter Lucite mounts which fitted exactly the well of the counter.

RESULTS

1. *Active Solution – Inactive Metal*

It has been shown by MacKay (11), and others, that any homogeneous exchange reaction can be described by the following type of equation:

$$[1] \qquad -\log(1-F) = kt,$$

where F is the fraction exchanged, k is a constant, and t is the exchange time. For a heterogeneous reaction, this type of equation holds only as long as the reacting mixture remains chemically unchanged, and if the isotopic distribution is uniform in each phase during the course of the reaction.

The results of the experiments done so far indicate that the activity increase (or exchanged fraction) varies exponentially with time (Figs. 1 and 2), but not in accordance

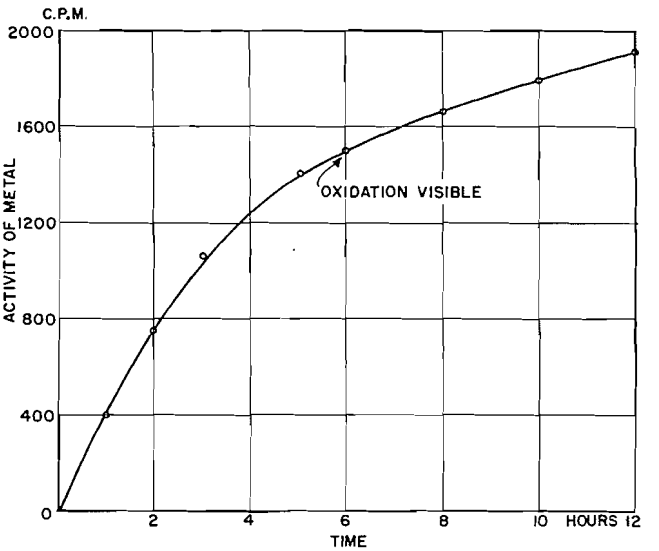

FIG. 2. Exchange between inactive metal and active 10^{-2} M $Zn(NO_3)_2$ solution.

with equation [1]. In Figs. 3 and 4 the logarithm of the exchanged fraction F is plotted as a function of time of immersion and it is seen that the slope is not constant.* At the

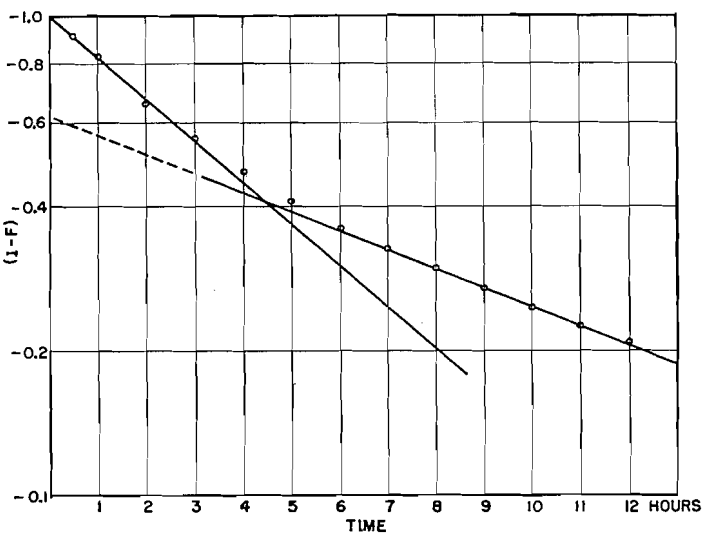

FIG. 3. Fraction exchanged as function of time. Plotted from results of Fig. 1.

same time it was observed that some visible film, presumably $Zn(OH)_2$, was formed during the second stage of the reaction marked in Figs. 1 and 2. The onset of this film

*$F = A_t/A_\infty$, *where* A_t *is activity of sample at time* t *and* A_∞ *is activity when apparent equilibrium is approached.*

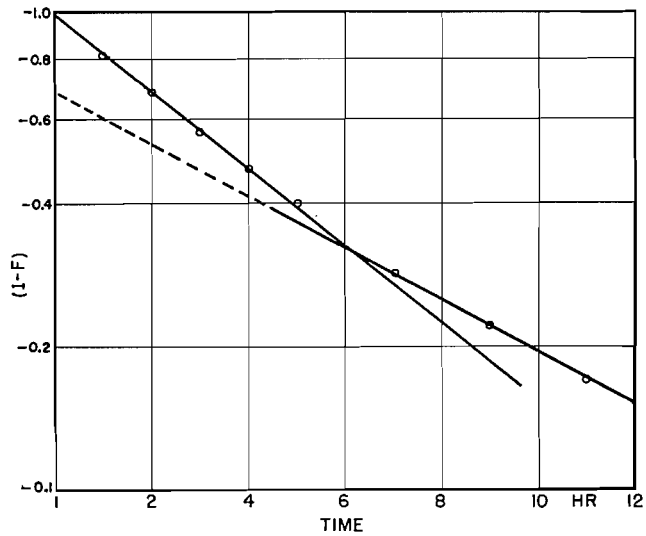

FIG. 4. Fraction exchanged as function of time. Plotted from results of Fig. 2.

formation can not be accurately determined. It was found that apparent exchange equilibrium was approached after 48 hours. Experiments with one week of immersion showed considerable scatter of results.

2. Active Metal – Inactive Solution

When the metal was immersed in acidulated water at pH 4.8, continuous dissolution was observed. No continuous increase in activity took place at pH 5.2 and 6.2; the aliquots taken had an activity slightly higher than the background. The same happened when a sample was pretreated for 24 hours in 10^{-2} *M* $Zn(NO_3)_2$ solution. When the exchange was done for 1 to 6 seconds, wide scattering was obtained giving unreliable results.

During the last set of experiments, when the exchange time was 1 to 6 minutes, it was found that a rapid exchange takes place: in 6 minutes, 20 apparent layers of atoms took part in the exchange. The samples were etched before each immersion. The curve presented in Fig. 5 was obtained when the samples were etched only at the beginning. No difference was observed between tests at pH 5.2 and tests at pH 6.2.

3. Bicrystal Experiments

The autoradiographs of three bicrystal samples shown in Fig. 6 showed a preferential exchange in one of their crystal faces. At the same time it was observed that the difference in activity acquired by each crystal soon disappeared and that after 30 seconds an even distribution of activity was obtained. (Figure 6*a* corresponds to 10-second, 6*b* to 20-second, and 6*c* to 30-second immersion.)

Preferential exchange was shown also by a bicrystal that was markedly twinned (Fig. 7). A sample pretreated for 24 hours and half-etched showed much higher activity in the oxide layer than in the etched layer, but in this latter area a clear difference could be seen in comparing the exchange between each grain (Fig. 8). Other autoradiographs showed that there is a difference in activity between worked and unworked areas, as had been reported for silver and other metals (9).

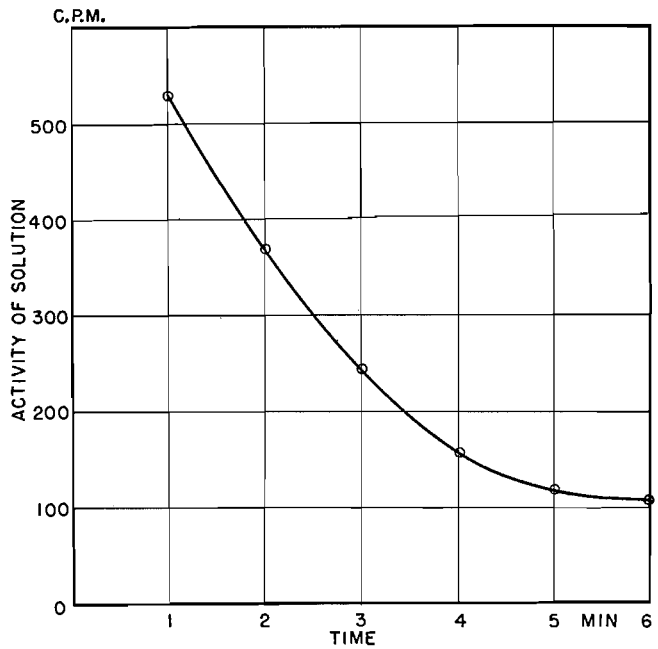

FIG. 5. Exchange between active metal and inactive $Zn(NO_3)_2$ solution.

DISCUSSION AND CONCLUSIONS

Heterogeneous exchange between atoms from a work-free zinc surface and atoms from a zinc solution was observed under conditions that minimized adsorption, corrosion, and oxidation. It could not be fully ascertained that an oxide-free surface was obtained, even if the immersion followed immediately after the etching or if the work was done under argon. (The etchants used are generally oxidizing agents.) It was observed that hydroxide formation took place even in the absence of O_2.

According to the definition of an exchange reaction (12), for a given system the rate of the reaction is independent of the nature of the compound tagged by the indicator; so, if $A^* \xrightarrow{k_1} B$ and $B^* \xrightarrow{k_2} A$; then $k_1 = k_2$. The results of these experiments show that an exchange takes place with deaerated 10^{-1} or 10^{-2} M $Zn(NO_3)_2$ solution at pH 5.2 or 6.2 in both directions. It could not be proved that $k_1 = k_2$, because in these experiments the rate of transfer of active zinc of one phase to the other is measured and not the exchange rate alone.

It has also been seen that the results of the $Zn^*_{sol} \rightarrow Zn_{metal}$ reactions do not fit a simple equation of the form $-\log(1-F) = kt$, because the reaction is controlled by either a recrystallization or a self-diffusion process. It would fit an exponential function of two terms, as Matsura (5) found, of the general form:

$$[2] \qquad F = 1-[A_r \exp(-k_r t)+A_s \exp(-k_s t)],$$

where F = fraction exchanged, A_r, A_s, k_r, k_s = constants.

It is concluded, from the experimental results available so far, that the exchange of zinc cannot be presented simply as a diffusion process or a recrystallization-controlled process, in spite of the fact that fast exchange has been obtained in the $Zn^*_{metal} \rightarrow Zn_{sol}$ reaction. More information is needed about the adsorption properties of zinc ions on

zinc metal. Some work has been done by Matsura with zinc dust, but he did not take into consideration either the surface oxidation or the preparation of the samples.

In the present work a deep exchange has been found between the active metal and the inactive solution in a relatively short period of time. The same effect has been found in silver (13) and it has been explained as caused by a disordered layer of atoms close to the surface giving rise to a very fast diffusion process near the surface of the solid. The surface reaction is not a simple one. In addition to exchange with surface atoms, there always takes place an exchange resulting from local cell action, as postulated by Hevesy (1). It is the author's suggestion that the rapid exchange noticed at the beginning of the experiments is due mainly to this type of mechanism, i.e., one crystal face behaves as an anodic area and the other as a cathodic.

It has been known for some time that the different crystallographic faces of a metal have different electrochemical and physical properties, and hence different electrode potentials, dissolution and oxidation rates, and adsorption. Preferential adsorption may take place, but is relatively unimportant here, since the solutions were very dilute and the immersion periods were very short.

The experiment performed with a half-oxidized and half-etched sample showed that the oxide layer picked up much more activity than did the etched one. This would indicate that the preferential exchange could be caused by preferential oxidation (possibly by the same electrochemical corrosion mechanism as mentioned before). The fact that the activities were soon evened out in the samples indicated that a very small "exchange current" flowed between the two "electrodes". In support of this idea, the recent work of Bushmanov and Vozdvizhenky (7) shows that different crystal faces of zinc single crystals that are connected together act as a galvanocouple. They also found that the different faces exchange at different rates. Alternatively the difference in exchange and adsorption can be ascribed to the difference in surface free energy associated with the different atom densities along the lattice planes involved.

It should be pointed out that in the carrier-free solutions the concentration of the tracer is so low that the products formed may not be the same as those formed at ordinary concentrations, because of rate effects, equilibrium shifts, etc. In some respects this is an advantage, because with so low a concentration no spurious precipitations can happen, since the solubility product cannot be exceeded.

While there is strong evidence that an exchange reaction is involved as a first step in the pickup of activity, this reaction is likely accompanied by other processes, e.g. corrosion and oxidation.

There are considerable variations in the exchange processes described in the literature, mainly because of difficulties in obtaining reproducible, clean metallic surfaces that correspond in composition and structure to the bulk of the metal. It is believed that the surfaces used in this work were of a cleanness comparable with or better than those used in published experiments, but the difference in surface conditions obtained make direct comparisons of results difficult. Even in the case where an oxide-free surface is obtained it is always covered by a thin layer of gases and vapors. Holm and Meissner (14) in their work on platinum had to heat platinum wires for hours at 1100° C in a perpetually evacuated glass vessel, the walls of which were cooled with liquid hydrogen, to obtain a thoroughly degassed surface.

Another problem that has to be solved is to obtain an exact knowledge of the "true" area of the sample, as compared with the geometric area, because in exchange experiments the results are generally expressed in "number of exchanged atom layers". Several methods

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

are available to determine the surface roughness of metals and some general information is available about the average height of the "hills" and "valleys" in a metallic surface (15); this magnitude is of the following order:

in steel, lapped or polished	—	2 to 25×10^{-6} cm,
die-cast	—	40 to 400×10^{-6} cm,
ground	—	50 to 250×10^{-6} cm,
turned, shaped	—	300 to 600×10^{-6} cm.

There are no similar figures for zinc, but since it is a very soft metal and flows very easily during the polishing operations, comparable figures may differ from those for steel by as much as a factor of 10.

The results can be summarized as follows:

1. The zinc exchange reaction takes place with work-free surfaces in deaerated 10^{-1} and 10^{-2} M $Zn(NO_3)_2$ solutions at pH 5.2. to 6.2 and it takes place in both directions.

2. The reaction $Zn^{++}{}_{sol} \rightarrow Zn^{0}{}_{metal}$ can be described by a relation of the form

$$F = 1-[A_r \exp(-k_r t)+A_s \exp(-k_s t)],$$

rather than by a single exponential function.

3. Fast exchange has been found in the reaction $Zn^{0}{}_{metal} \rightarrow Zn^{++}{}_{sol}$, indicating that adsorption was low compared with exchange under the conditions of the experiments.

4. ZnO and $Zn(OH)_2$ are formed in the metallic samples, preventing the exchange from continuing. $Zn(OH)_2$ is formed even in the absence of air.

5. Preferential exchange on certain crystal faces has been found to take place in zinc bicrystals.

6. It is suggested that the deep-exchange mechanism involved in the short periods is a local cell action, one crystal behaving as an anode and the other as a cathode.

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Dr. G. G. Eichholz for his help during all this work, to Dr. F. Weinberg and Mr. I. I. Tingley for many helpful discussions, to J. R. Barkley for some experimental help, and to many members of the Physics and Radiotracer Section of the Mineral Sciences Division, Mines Branch, for their advice and assistance. This work was done during the tenure of a National Research Council of Canada postdoctorate fellowship at the Mines Branch of the Department of Mines and Technical Surveys, Ottawa. This paper is published by permission of the Director of the Mines Branch, Department of Mines and Technical Surveys.

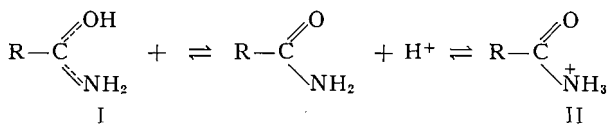
PROTONATION OF THE AMIDE GROUP

II. DICYCLOHEXYLUREA-O^{18} [1]

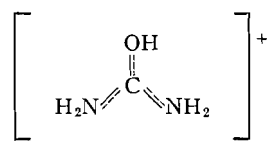


ROSS STEWART AND L. J. MUENSTER

ABSTRACT

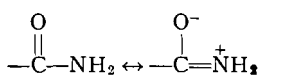
Dicyclohexylurea-O^{18} containing 78% oxygen-18 has been prepared. The amide I and II bands in this molecule are located at 1611 and 1575 cm^{-1} respectively compared to 1628 and 1575 cm^{-1} in ordinary dicyclohexylurea (KBr disk). Thus the amide I band (carbonyl stretching) undergoes the expected shift to lower frequency on isotopic substitution. The *p*-toluenesulphonate salt of dicyclohexylurea has been prepared and been found to have a band at 1669 cm^{-1} commonly attributed to carbonyl stretching in amide salts. This band, however, undergoes no isotopic shift and is clearly not due to a carbonyl stretching motion. This result casts doubt on the infrared evidence supporting N-protonation of amides.

INTRODUCTION



In the previous paper in this series the evidence both for N-protonation and for O-protonation of amides was reviewed (1). In that paper we reported the basicity of a series of benzamides and pointed out that this evidence lent some support to the charge-localized structure II (N-protonated form) for the amide conjugate acid rather than the resonance-stabilized structure I (O-protonated form).

I II



This situation is in contrast to that of the carboxyl group where the resonance-stabilized form appears almost certainly to be the more stable (2).

The principal evidence favoring O-protonation is provided by N.M.R. spectroscopy (2*a*, 2*b*). The principal evidence favoring N-protonation is provided by infrared spectroscopy, viz., the observed shift of the carbonyl stretching band to higher frequencies when amides are converted to their salts (3, 4, 5, 6). Thus the carbonyl stretching frequency in propionamide at 1660 cm^{-1} is replaced by a band at 1710 cm^{-1} in the hydrobromide (6). Urea, more than ordinary amides, would be expected to undergo O-protonation because of the very favorable resonance possibilities in the conjugate acid, III. Urea salts, however, in particular the well-known urea nitrate, are reported to

III

have infrared spectra which include a carbonyl stretching band (3, 4). This band is at higher frequency in agreement with the idea that N-protonation would produce more double bond character in the carbonyl group by eliminating resonance of the following type.

[1]*Manuscript received October 6, 1960.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver, B.C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

This evidence in favor of N-protonation is difficult to controvert if it can be proved that the bands in question are, in fact, due to carbonyl stretching motions. The purpose of this research was to check the identity of this band in an amide salt by the use of oxygen-18. Halmann and Pinchas have studied the infrared spectra of benzophenone labelled with oxygen-18 (76%) in the carbonyl group (7). They found the only significant difference in the spectra of benzophenone and benzophenone-O^{18} was in the carbonyl stretching region; benzophenone absorbs at 1664 cm^{-1}, benzophenone-O^{18} at 1635 cm^{-1} in carbon tetrachloride. This shift of 29 cm^{-1} to shorter frequency on isotopic substitution is similar to that observed by Braude and Turner (8) for the shift (30 cm^{-1}) of the carbonyl band in cinnamyl *p*-nitrobenzoate on isotopic substitution. More recently Pinchas, Samuel, and Weiss-Broday have prepared benzamide-O^{18} and have made a thorough study of its infrared spectrum (9). They found that the carbonyl band, amide I, shifts by 24 cm^{-1} (in carbon tetrachloride), the N—H bonding, amide II, by 10 cm^{-1} (in chloroform).

We attempted to prepare urea labelled in the carbonyl group but had little success with controlled hydration of cyanamide using stoichiometric amounts of water. We have turned therefore, to dicyclohexylurea, which can be readily prepared by the hydration of dicyclohexylcarbodiimide. This proved to be a very satisfactory alternative.

Dicyclohexylurea-O^{18} was prepared from dicyclohexylcarbodiimide according to the following equations.

$$C_6H_{11}N{=}C{=}NC_6H_{11} + D_2O^{18} \rightarrow C_6H_{11}NDC(=O^{18})NDC_6H_{11} \xrightarrow{EtOH} C_6H_{11}NHC(=O^{18})NHC_6H_{11}$$

The para toluenesulphonate salt can have either structure IV or V.

$$C_6H_{11}NHC(=O)NHC_6H_{11} + C_7H_8SO_3H \rightleftharpoons \left[C_6H_{11}NH{=}C(OH){-}NHC_6H_{11}\right]^+ C_7H_8SO_3^-$$

IV

$$C_6H_{11}\overset{+}{N}H_2C(=O)NHC_6H_{11} \quad C_7H_8SO_3^-$$

V

EXPERIMENTAL

Apparatus and Reagents

Infrared spectra were recorded with a Perkin–Elmer Model 21 instrument equipped with sodium chloride optics using potassium bromide pellets. Since it is known that the latter can sometimes give spurious results (10) the spectra of dicyclohexylurea-O^{16} and -O^{18} and their *p*-toluenesulphonate salts were also recorded in Nujol mulls. The spectra were virtually identical in the two media. The mass spectrometric work was done on a Metropolitan-Vickers mass spectrometer, type 45/1.

The D_2O^{18} (91% O^{18}, 1.1% O^{17}) was obtained from The Weizmann Institute of Science, Israel.

N,N'-Dicyclohexylurea-O^{18}

To 15 ml of dioxane (purified and dried with sodium metal) contained in a 50-ml beaker was added 2.34 g (0.0114 mole) of dicyclohexylcarbodiimide. The beaker was placed in an ice-water bath and 0.25 g (0.0114 mole) of D_2O^{18} was pipetted into the solution. Dry hydrochloric acid gas was bubbled through the mixture via a capillary

for $1\frac{1}{2}$ minutes. The resulting white precipitate was filtered at the pump, washed with a little dioxane, and dried in a vacuum desiccator. The crude product weighed 1.66 g or 64% of the theoretical yield.

To obtain a deuterium-free sample, 300 mg of the crude product was dissolved in 5 ml of boiling absolute ethanol. On cooling of the solution to room temperature, colorless, broad needles separated out which melted at 237–238° (uncorr.).

The percentage of O^{18} contained in the compound was determined according to the method by Rittenberg and Ponticorvo (11). The oxygen-18 content of the carbon dioxide was measured by scanning the masses from 44 to 48. The average value obtained from five determinations was 78.3% O^{18}, though the precision was rather low (standard deviation of the mean: ±2.3%).

N,N'-Dicyclohexylurea-O^{18} p-Toluenesulphonate

N,N'-Dicyclohexylurea-O^{18} (0.50 g, 0.0021 mole) and *p*-toluenesulphonic acid (0.38 g, 0.0021 mole) were added to 2 ml of dry dioxane and refluxed for 10 minutes. On cooling to room temperature colorless, small needles separated out. After several recrystallizations from thiophene-free dry benzene 0.33 g (39% of the theory) of the *p*-toluenesulphonate was obtained which melted at 154–155° (corr.). Calc. for $C_{20}H_{32}N_2SO_3O^{18}$: C, 60.24; H, 8.10; N, 7.03; O, 16.56; S, 8.04. Found: C, 60.33; H, 8.02; N, 6.91; O, 16.23; S, 8.02.

When this salt was crystallized from absolute ethanol it reverted to dicyclohexylurea with no loss of isotopic oxygen. This was shown to be so by a comparison of infrared spectra.

Urea p-Toluenesulphonate

Urea (3.0 g, 0.05 mole), *p*-toluenesulphonic acid (10.7 g, 0.06 mole), and 100 ml of dry dioxane were heated to boiling. The voluminous white precipitate which formed was filtered and washed with ice-cold water and ether. After one recrystallization from water the yield was 8.9 g (77%). During three subsequent recrystallizations from water the melting point remained constant at 181–183° (corr.). Calc. for $C_8H_{12}N_2O_4S$: C, 41.37; H, 5.21; N, 12.05; S, 13.80%. Found: C, 41.36; H, 5.14; N, 12.02; S, 13.61%.

The melting point of this compound is near that reported for the covalent compound, *p*-toluenesulphonylurea (m.p., 191–2° (12)) and its resistance to hydrolysis during crystallization from water is also compatible with the latter structure. The analytical data together with the following facts show the compound to be the salt: (*a*) titration with standard base gives the correct neutral equivalent, (*b*) passage of a solution of the compound through a strongly acid cation-exchange column (Nalco HCR-W) produces *p*-toluenesulphuric acid.

RESULTS AND DISCUSSION

The infrared spectra of dicyclohexylurea, dicyclohexylurea-*d*-O^{18}, and dicyclohexylurea-O^{18} are shown in Fig. 1. The spectra of the *p*-toluenesulphonates of dicyclohexylurea and dicyclohexylurea-O^{18} are shown in Fig. 2.

Dicyclohexylurea

The infrared spectrum of this compound (Fig. 1) is similar to those of other substituted ureas and to that of urea itself (13, 14, 15, 16). The amide I band (carbonyl stretching) is at 1628 cm^{-1} and the amide II band (17, 18) is at 1575 cm^{-1}. In addition a third band is present in dicyclohexylurea at 1539 cm^{-1} which is also present (1550 cm^{-1}) in monocyclohexylurea (14). The "amide band" locations are listed in Table I.

Dicyclohexylurea-d-O^{18}

The percentage deuterium in this compound is unknown. However, the considerably greater intensity of the N—H stretching band at 3343 cm^{-1} than the N—D stretching band at about 2480 cm^{-1} indicates that there is probably more protium than deuterium present. The amide II band at 1575 cm^{-1} is broadened and five new peaks at 2480, 1480, 1425, 988, and 795 cm^{-1} appear in the spectrum of the partly deuterated compound.

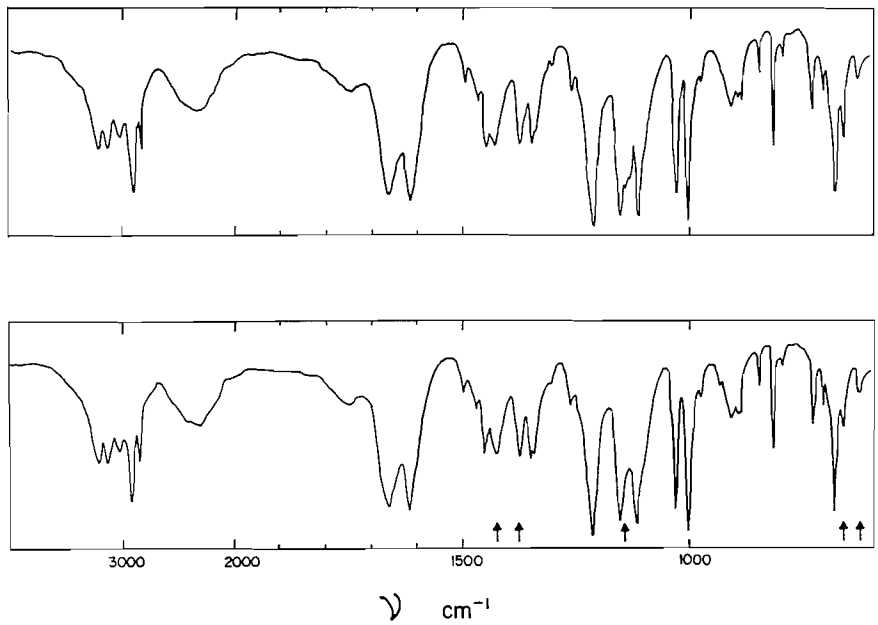

FIG. 2. The infrared spectra of dicyclohexylurea *p*-toluenesulphonate (upper) and dicyclohexylurea-O^{18} *p*-toluenesulphonate (lower).

Dicyclohexylurea-O^{18}

The principal feature of interest in this system is the shift of the amide I band on isotopic substitution. This band, which is generally attributed to carbonyl stretching, shows the isotopic shift to lower frequency expected for such a band. The shift of 17 cm^{-1} (1628 to 1611 cm^{-1} in KBr) is smaller than the corresponding shift observed for benzophenone (29 cm^{-1} in CCl_4) (7), and for benzamide (24 cm^{-1} in CCl_4) (9). (The magnitude of the isotopic shift appears to depend on the medium since Pinchas *et al.* (9) observed that it was considerably less in chloroform than in carbon tetrachloride.) The smaller shift in the present case may be due to a contribution from the C—N stretching vibration to the amide I band as suggested by Myazawa *et al.* (18). (See, however, ref. 9.)

The amide II band at 1575 cm^{-1} undergoes no isotopic shift at all. The third band in this region, the one at 1539 cm^{-1} in ordinary dicyclohexylurea undergoes a small isotopic shift and appears at 1533 cm^{-1} in the oxygen-18 compound. Table II lists the bands in the amide which undergo oxygen isotopic shifts of 3 cm^{-1} or more.

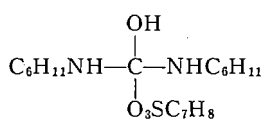
resulting in a set of moderately sharp bands above 3000 cm^{-1} and a very broad absorption in the 2400–2600 cm^{-1} region. These changes in the N—H absorption and the absence of an O—H stretching band contributed to the rejection by Davies and Hopkins (3) and Spinner (4) of the idea of O-protonation in urea nitrate.

In the carbonyl stretching region between 1600 and 1700 cm^{-1} there are two bands in both urea nitrate and dicyclohexylurea *p*-toluenesulphonate. These are located at 1705 and 1675 cm^{-1} in the former (Davies and Hopkins (3) report 1708 and 1670 cm^{-1}) and at 1669 and 1620 cm^{-1} in the latter. The 1670 band in urea nitrate has been assigned by Davies and Hopkins to carbonyl absorption and the shift from 1610 cm^{-1} in urea attributed to the increase in carbonyl bond order as a result of N-protonation (3). Other investigators have assigned carbonyl stretching in urea to the band in the 1680 cm^{-1} region (15, 16). If one of these bands in the spectrum of the salt of dicyclohexylurea is in fact due to carbonyl stretching an isotopic shift should be observed in the oxygen-18 compound.



Dicyclohexylurea-O^{18} p-Toluenesulphonate

Figure 2 shows the spectrum of this compound and Table II lists those peaks which undergo an isotopic shift of 3 cm^{-1} or more. The largest of these is the shift of the 1437 peak which moves 10 cm^{-1} to lower frequency. Particularly significant is the fact that the peak at 1669 cm^{-1} is in virtually the same place in the oxygen-18 compound. An average of several runs gave the peak locations as 1669 and 1668 cm^{-1} in the isotopically unsubstituted and substituted compounds respectively. One can therefore conclude that this band in dicyclohexylurea *p*-toluenesulphonate is not, in fact, caused by a carbonyl stretching motion and its location at higher frequency than the amide I band in dicyclohexylurea *does not* constitute support for the idea of N-protonation of amides.

The infrared evidence, in fact, supports the idea of O-protonation of urea-type compounds. (It is true that an O—H stretching band cannot be detected in the infrared (14) but this band may be shifted and masked by the broad N—H absorption. Furthermore, hydrogen stretching bands are sometimes of very low intensity in organic cations (19).) The isotopic shift in dicyclohexylurea *p*-toluenesulphonate (Table II) from 1437 cm^{-1} to 1427 cm^{-1} probably corresponds to O—H bending (20) and the isotopic shift from 1135 cm^{-1} to 1129 cm^{-1} can also be explained on the basis of O-protonation since C—OH stretching vibrations are usually found in this region. The first band in the carbonyl region of the urea and dicyclohexylurea *p*-toluenesulphonates may be due to N—H bending increased in frequency by strong inner hydrogen bonding with the tosylate oxygen atoms. (We are grateful to Dr. S. Pinchas for drawing our attention to some of these points.)

Ionic Character

We have considered the possibility that the *p*-toluenesulphonate of dicyclohexylurea might be a covalent compound of some such structure as the following.

Although this is unlikely in view of the high stability of the *p*-toluenesulphonate ion we attempted to prepare other salts of this compound. Our attempts to prepare the perchlorate, hydrochloride, and nitrate were unsuccessful, however.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

We turned then to a comparison of the infrared spectra of other *p*-toluenesulphonates, both covalent and ionic, with that of the compound in question. Table III lists the

principal absorption bands below 1200 cm^{-1} of the following *p*-toluenesulphonates:

(*a*) the dicyclohexylurea compound,
(*b*) the sodium, potassium, and ammonium salts (ionic),
(*c*) the methyl ester (covalent).

A comparison of the absorption bands shows a very close correspondence between the bands in the ionic sulphonates (except for the band at 1156 cm^{-1}) and those in the dicyclohexylurea compound whereas the bands in the covalent methyl ester are missing in the latter. We conclude that dicyclohexylurea *p*-toluenesulphonate is an ionic compound.

The similarity between dicyclohexylurea *p*-toluenesulphonate and urea nitrate can be seen by a comparison of the infrared spectra of these compounds and those of other salts of urea. We have prepared the *p*-toluenesulphonates and perchlorates of urea and it can be seen from the absorption data in Table IV that the peaks of these compounds

TABLE IV

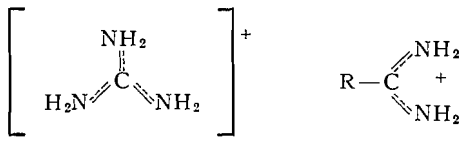
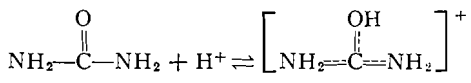
in the carbonyl stretching region correspond closely to those of the well-studied salt, urea nitrate, indicating that the character (presumably ionic) of these two compounds is the same. If one then examines the spectrum of one of these, urea *p*-toluenesulphonate,



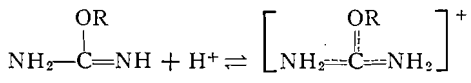
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in the region below 1250 cm^{-1} where the tosylate group absorption occurs, one can see (Table III) that the peaks correspond fairly closely to those of dicyclohexylurea *p*-toluenesulphonate and sodium, potassium, and ammonium *p*-toluenesulphonates.



Thus both urea nitrate and dicyclohexylurea *p*-toluenesulphonate appear to be ionic compounds. Both show an amide I band at higher frequency than in the neutral compounds. This evidence does not support N-protonation, however, since this band, at least in the one case, does not correspond to carbonyl stretching. One cannot, of course, conclude that the band assigned to carbonyl stretching in the salts of ordinary amides is misassigned but the present work shows that caution should be used in making the assignment. We intend to conduct a similar investigation to the present one using ordinary amides.

Amidine Protonation



It should be made clear that the uncertainty with regard to the structure of the amide cation does not apply to the guanidinium ion, or amidinium ions in general, where the following resonance-stabilized structures are unquestionably the stable ones.

It seems clear, however, that the high basicity of amidines is due as much to decreased resonance in the neutral molecules (compared to urea and ordinary amides) as it is to increased resonance in the ions. Indeed, the fact that O-alkyl ureas are about 10^{10} times as basic as urea (21, 22) must be attributed almost entirely to the difference in resonance energies of the neutral molecules VI and VIII, since it is highly improbable that ions VII and IX have very different resonance energies. (The equilibrium between N- and O-protonated forms of urea does not affect this argument.)

STEROIDS

V. PYRIDINIUM BETAINES OF 2-α-BROMOCHOLESTAN-3-ONE[1,2]

G. FRANGATOS[3] AND A. TAURINS

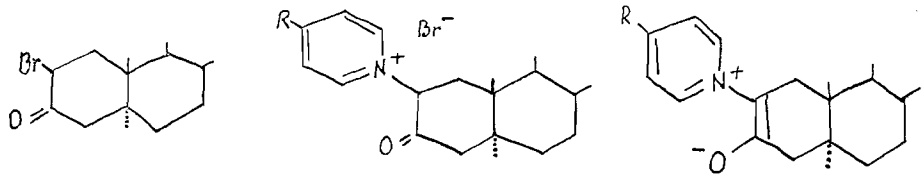
ABSTRACT

2-α-Bromocholestan-3-one reacts with pyridine, and 3- and 4-methylpyridines to give the 1-[2-(3-oxocholestanyl)]pyridinium bromides which, on dehydrobromination with bases, form the betaines of 1-[2-(3-oxocholestanyl)]pyridinium hydroxides.

DISCUSSION

The treatment of α-bromo ketones with pyridine and its homologues leads to the elimination of hydrogen bromide from the α-bromo ketone and to the formation of a double bond in α,β-position to the carbonyl group. On several occasions it has been observed that intermediate adducts are formed in the reaction of steroidal α-bromo ketones and pyridine bases. In some instances differences in opinion exist regarding the structure of the intermediates. Thus two entirely different structural formulae II and III have been proposed by Ruzicka (1), and Inhoffen (2), respectively, for the product of the reaction between 2-α-bromocholestan-3-one (I) (3) and pyridine.

In an attempt to establish which of the structures was correct, the present work was undertaken. If the formula set forth by Ruzicka is correct, then elimination of a molecule of hydrogen bromide from II (a pyridinium bromide) should result in the formation of a pyridinium enol betaine (IV) (4,5). Elimination of hydrogen bromide from III (a hydrobromide of a 4-substituted pyridine), on the other hand, should produce a 4-substituted pyridine base. With this in mind, hydrogen bromide was eliminated from the reaction product of pyridine and 2-α-bromocholestan-3-one (I), and isolation of the reaction product attempted. When a solution of the product in chloroform was treated with solid anhydrous potassium carbonate, a deep-red oil was isolated which resisted all attempts of crystallization and exhibited a pronounced tendency to form thin films. It was sensitive to heat and decomposed gradually on exposure to light. Elementary analysis indicated the presence of nitrogen but not of bromine. Upon treatment with hydrogen bromide, the product afforded the starting material. When an aqueous solution of perchloric acid was added to the oil, the corresponding colorless perchlorate was formed readily.



These experimental facts supported the assumption that the reaction product of pyridine and the bromo ketone (I) was the pyridinium salt (II) which formed the betaine of 1-[2-(3-hydroxy-2-cholestanyl)]pyridinium hydroxide (IV) upon elimination of a molecule of hydrogen bromide.

In other attempts to obtain the betaine (IV), the pyridinium bromide (II) was suspended in water or ethanol and treated with aqueous solutions of inorganic bases. Piperidine, morpholine, and guanidine carbonate reacted similarly, and in all cases hydrogen bromide was eliminated. However, the betaine (IV) was always obtained as an amorphous material. Finally, the betaine of 1-[2-(3-hydroxy-2-cholestanyl)] pyridinium hydroxide (IV) was obtained in crystalline form, when the dehydrobromination of the

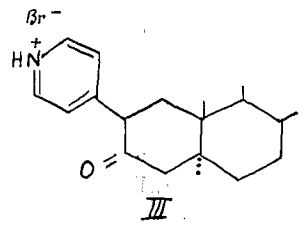
pyridinium bromide (II) was carried out in the three-component system ethanol – water – dimethylamine. The ultraviolet spectrum of the betaine showed three absorption maxima at 245, 304, and 430 mμ. The similarity in pattern of the spectrum of IV and of the betaines obtained from methylpyridines and 2-bromo-1,3-indandione by Frangatos and Taurins (5) provided further proof that IV was a typical pyridinium betaine.



On the basis of the assumptions made by Inhoffen (2), the addition product of pyridine and 2-α-bromocholestan-3-one (I) should be a 4-substituted pyridine hydrobromide. If this is correct, then 4-methylpyridine should not react with the bromo ketone (I). It was found, however, that the reaction of 4-methylpyridine with I proceeded smoothly to give the salt, 1-[2-(3-oxocholestanyl)]4-methylpyridinium bromide (V). The dehydrobromination of V was achieved in chloroform solution using anhydrous potassium carbonate. The product, the betaine of 1-[2-(3-hydroxy-2-cholestanyl)]4-methylpyridinium hydroxide (VI), was an amorphous, dark-red solid. In sunlight, it gradually decomposed, and on

III

I

VII

VIII

IX

treatment with acids, colorless solids, the pyridinium salts, were formed. Elementary analysis and the ultraviolet absorption spectrum of VI were in agreement with the assignment of a betaine structure to this compound. 3-Methylpyridine reacted similarly and the betaine of 1-[2-(3-hydroxy-2-cholestanyl)]3-methylpyridinium hydroxide was obtained as a dark-red powder which could not be crystallized.

The reaction of the bromo ketone (I) with 2-methylpyridine did not afford the corresponding pyridinium bromide. Instead 2-methylpyridine hydrobromide was isolated from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the reaction mixture indicating that dehydrobromination of the bromo ketone (I) had occurred. Dehydrobromination could proceed directly or through the formation of the intermediate salt, 1-[2-(3-oxocholestanyl)]2-methylpyridinium bromide. However, by analogy with the reactions of pyridine, and 3- and 4-methylpyridines and the bromo ketone (I), the formation of the salt would seem improbable since it would interfere with the elimination of hydrogen bromide. This assumption was confirmed experimentally by taking samples from the reaction mixture at different times, and treating them with alkali. No change in color was observed. If 1-[2-(3-oxocholestanyl)]2-methylpyridinium bromide had been present in the reaction mixture, it should have undergone a dehydrobromination and formed the corresponding betaine. This process would have been accompanied by a change in color. It was presumed that dehydrobromination of the bromo ketone (I) yielded a mixture of compounds (VII, VIII, IX), similar to those isolated by Jacobsen (6) from the reaction of I with 2,4,6-trimethylpyridine.

EXPERIMENTAL

The melting points below 225° were determined in a Thiele–Dennis melting-point tube containing sulphuric acid. Those above 225° were determined in a melting-point block constructed according to the specifications of Fieser (7). All melting points are uncorrected. Pyridine and methylpyridines were dried and purified. The analyses were carried out by Schwarzkopf in Woodside, N.Y. The ultraviolet absorption spectra were measured by means of a Beckman recording spectrophotometer Model DK1.

1-[2-(3-Oxocholestanyl)]pyridinium Bromide (II)

A solution of 2-α-bromocholestan-3-one (I) (7 g, 0.015 mole) in pyridine (34 ml) was heated, in a nitrogen atmosphere, to the reflux temperature. After 10 minutes, a solid material separated rapidly. When the reaction mixture had been refluxed for 2 hours, it was allowed to cool to room temperature. The solid material was filtered off, washed thoroughly with three 25-ml portions of petroleum ether (b.p. 60–90°), and dried. Recrystallization from ethanol provided 1-[2-(3-oxocholestanyl)]pyridinium bromide (II) (6.2 g), m.p. 310° (decomposed); lit. (1) m.p. 310° (decomp.); λ_{max}^{EtOH} 261 mμ (log ε 3.5).

1-[2-(3-Hydroxy-2-cholestanyl)]pyridinium Hydroxide, Betaine (IV)

1-[2-(3-Oxocholestanyl)]pyridinium bromide (II) (0.54 g, 0.001 mole) was suspended in alcohol (3 ml), and stirred in a nitrogen atmosphere at the reflux temperature, while a 25% aqueous solution of dimethylamine was added dropwise. Gradually the solid material passed into solution. The addition of dimethylamine was continued until the yellow solution had become turbid. As the reaction mixture cooled very slowly to room temperature, fine yellow needles separated from the solution. Recrystallization from alcohol and aqueous 25% dimethylamine in a nitrogen atmosphere gave the betaine of 1-[2-(3-hydroxy-2-cholestanyl)] pyridinium hydroxide (IV) (0.029 g), m.p. 169° (decomp.); λ_{max}^{EtOH} 245, 304, 430 mμ (log ε 3.8, 3.0, 3.7). An analytical sample was dried *in vacuo* over phosphorus pentoxide at 34° for 72 hours in the dark. Anal. Calcd. for $C_{32}H_{49}NO$: N, 3.02. Found: N, 3.19%.

1-[2-(3-Oxocholestanyl)]4-methylpyridinium Bromide (V)

A solution of 2-α-bromocholestan-3-one (I) (4.65 g, 0.01 mole) in 4-methylpyridine (15 ml) was refluxed for 4 hours; the reaction mixture was allowed to cool to room temperature. The solid precipitate was collected, washed with petroleum ether, and dried. Recrystallization from hot acetic acid gave 1-[2-(3-oxocholestanyl)]4-methylpyridinium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

bromide (V) (3.7 g) in shining colorless prisms, m.p. 316° (decomp.); λ_{max}^{EtOH} 225, 257.5 mμ (log ε 4.0, 3.6). Anal. Calcd. for $C_{33}H_{52}BrNO$: C, 70.95; H, 9.36; N, 2.5. Found: C, 71.35; H, 9.57; N, 2.75%.

1-[2-(3-Hydroxy-2-cholestanyl)]4-methylpyridinium Hydroxide, Betaine (VI)

The pyridinium bromide (V) (0.28 g, 0.005 mole) was added to a stirred suspension of anhydrous potassium carbonate (1 g) in chloroform (10 ml). The mixture became orange immediately, and deepened in color as the reaction proceeded. The reaction mixture was refluxed gently for 5 minutes in a nitrogen stream. Then it was cooled to 0°, filtered, and washed with two 5-ml portions of chloroform. The washings and filtrate were combined and evaporated to dryness. The residue was dried *in vacuo* at 34° for 72 hours, and in this way the betaine (VI) (0.19 g) was obtained. The substance softened above 100° but had an indefinite melting point. λ_{max}^{EtOH} 248, 308, 431 mμ. Anal. Calcd. for $C_{33}H_{51}NO$: N, 2.93. Found: N, 2.92%.

1-[2-(3-Oxocholestanyl)]3-methylpyridinium Bromide

This substance was prepared in a manner analogous to that used for the preparation of compounds (II) and (IV). Colorless plates (from a 2:3 acetic acid – water mixture), m.p. 314° (decomp.).

1-[2-(3-Hydroxy-2-cholestanyl)]3-methylpyridinium Hydroxide, Betaine

This betaine was obtained in a manner analogous to that employed for the preparation of compounds (IV) and (VI). Yellow needles (from chloroform); the substance softened at 128°, but did not melt at a definite temperature. λ_{max}^{EtOH} 255, 314, 432 mμ (log ε 3.2, 3.2, 3.0). Anal. Calcd. for $C_{33}H_{51}NO$: N, 2.93; Found: N, 2.74%.

Reaction of 2-α-Bromocholestan-3-one (I) with 2-Methylpyridine

A mixture of 2-methylpyridine (10 ml) and I (2.33 g, 0.005 mole) was refluxed, in a nitrogen atmosphere, for 5 hours. No precipitate was formed at any time during the reflux period. Several samples were taken by means of a micropipette at different times; no pronounced change in color was observed when those samples were added to dilute alkaline solutions. The excess 2-methylpyridine was removed from the reaction mixture in a stream of nitrogen under reduced pressure. A white substance, sublimed from the residue at 125–130° under 2 mm pressure, was characterized as 2-methylpyridine hydrobromide.

INFRARED SPECTRA – STRUCTURE CORRELATIONS OF N-SUBSTITUTED TRIFLUOROACETAMIDINES[1]

JOHN C. GRIVAS[2] AND ALFRED TAURINS

ABSTRACT

A correlation between the infrared spectra and the structure of some N-mono- and N-disubstituted trifluoroacetamidines is presented. It was found that there was a considerable similarity between the infrared spectra of trifluoroacetamidines and those of the corresponding trichloroacetamidines. Additional information of the existence of these amidines in the imino form, CF_3—C(=NH)NHR, was provided by the infrared study of N,N-dideuterioamidines.

INTRODUCTION

In a previous communication (1) the evidence for the existence of N-alkyl- and N-aryltrichloroacetamidines in the form I was presented.

(I) $CCl_3C(=NH)NHR$ (R = alkyl, aryl)

Prevoršek (2) in a study of the infrared spectra of N-substituted benzamidines (II*a* and II*b*) concluded that when R′ was an alkyl group (ethyl) the benzamidines existed in the form II*a*, but when R′ was an aryl group (phenyl) the amidine had the structure II*b*.

$C_6H_5C(=NH)NHR'$ (II*a*) $\qquad$ $C_6H_5C(NH_2)=NR'$ (II*b*)

The infrared spectrum of alkyl-substituted amidines II*a* showed a very strong "amidine II" band at 1560 cm^{-1} which was displaced in solution. In the spectra of deuterated amidines (II*a*) this band was not present but a new band appeared at 1400 cm^{-1}. There was no "amidine II" band for the aryl-substituted benzamidines (II*b*) between 1580–1500 cm^{-1} since such displacement of the band observed did not occur on deuteration and was not also sensitive to the breaking of hydrogen bonds on dilution. Therefore the structure II*b* of aryl-substituted benzamidines was accepted. Prevoršek (2) also found that the observed $\nu_{sym}(NH)$ vibrations were in good agreement with those calculated by the Bellamy equation (3):

$$\nu_{sym}(NH) = 345.5 + 0.876\nu_{asym}.$$

EXPERIMENTAL

The trifluoroacetamidines used in this infrared study were prepared by known methods (4) or by procedures outlined in the previous paper (6). The deuterioamidines were synthesized from nitriles and N,N-deuterioamines according to the following reaction scheme:

$$R{-}C{\equiv}N + R'ND_2 \rightarrow R{-}C(=ND){-}NDR'.$$

(R = Cl_3C—, F_3C—)
(R′ = CH_3, C_6H_5)

The infrared spectra were recorded on a Perkin–Elmer Model 21 spectrometer equipped with a sodium chloride prism. The solid substances were investigated in potassium bromide pellets or in Nujol mulls. Liquid substances were examined in a thin layer between two sodium chloride plates. Amidines were also studied by infrared in tetrachloroethylene solutions (10 mg in 1 ml of the solvent), and sodium chloride cells 1 mm thick were used.

N-Methyl-α,α,α-trifluoroacetamidine-d_2

Trifluoroacetonitrile (0.04 mole) was condensed in a Pyrex tube (20×700 mm) previously flushed with nitrogen. The lower part of the tube, 30 cm in length, was immersed in a dry ice – acetone mixture. Methylamine-d_2 (2 ml) was then allowed to condense through a long glass tube leading to about 5 cm above the bottom of the Pyrex tube. The top of the last tube was closed with a well-fitting rubber stopper carrying two short tubes, 4 and 0.5 mm in diameter. The two tubes allowed the slow circulation of dry nitrogen through the upper part of the Pyrex tube during the whole operation, thus preventing the condensation of atmospheric moisture in the reaction mixture. Finally the stream of nitrogen was stopped, and the tube was quickly sealed and left at room temperature for 4 hours. The mixture was then transferred quickly to a semimicro distillation apparatus and distilled at reduced pressure in a nitrogen atmosphere to give a colorless amidine, b.p. 39–40°/15 mm (yield 80%).

N-Methyl-α,α,α-trichloroacetamidine-d_2

For the synthesis of this compound the same method was used. Equimolar amounts of trichloroacetonitrile and methylamine-d_2 were allowed to react in a sealed tube and were then distilled at reduced pressure in nitrogen atmosphere. B.p. 50–52°/15 mm.

N-Phenyl-α,α,α-trichloroacetamidine-d_2

Aniline-d_2 (1 g) and an excess of trichloroacetonitrile were mixed and left in a tightly closed sublimation apparatus at room temperature for 5 days. The excess of the nitrile was then eliminated in vacuum and the remainder sublimed at 1 mm pressure. The first portion was discarded and the sublimation continued until pure amidine-d_2, was collected. All the operations were conducted in a dry nitrogen atmosphere.

RESULTS AND DISCUSSION

Table I summarizes the positions of absorption maxima (cm^{-1}) in the infrared spectra of N-substituted trifluoroacetamidines. As was expected, the infrared spectra of these compounds showed a considerable similarity to those of the corresponding N-substituted trichloroacetamidines, except the bands produced by C—F and C—Cl respectively.

I. Region 4000–1800 cm^{-1}

The spectra of trifluoroacetamidine, CF_3—C(=NH)NH_2 (III), and trichloroacetamidine, CCl_3—C(=NH)NH_2 (IV) showed three absorption peaks in dilute tetrachloroethylene solutions. These peaks corresponded to the asymmetric and symmetric stretching vibrations of the primary amino group ($\nu(NH_2)$) and the stretching vibration of the imino group (ν(=N—H)). They were in agreement with the spectrum of perfluorobutyramidine, C_2F_7C(=NH)NH_2 (5).

This proves that the $\nu(NH_2)_{sym}$ and ν(=NH) absorption bands do not overlap in the spectrogram and this circumstance may be used in deciding which of the two tautomeric forms of the N-substituted trifluoroacetamidines is present.

Assuming that the validity of the Bellamy equation holds in N-substituted trifluoroacetamidines having the structure (V*b*), the difference, $\Delta\nu = \nu_{sym\ calc} - \nu_{sym\ obs}$, was calculated. Although these values were obtained using a NaCl prism possessing a low

resolving power in the high-frequency region and so cannot be considered very accurate, they were in the range of 17–35 cm^{-1}, much larger than the standard deviation of 4.8 cm^{-1} reported for 64 primary amines examined. Such evidence favored the structure (V*a*) for both the N-alkyl and N-aryl series of trifluoroacetamidines, although the value of the deviation decreased in passing from the first to the second series. N-substituted trichloroacetamidines behaved in a similar way.

$CF_3—C(=NH)—NH—R$ (V*a*) $\qquad$ $CF_3—C(NH_2)=N—R$ (V*b*)

N-substituted trifluoroacetamidines, $CF_3—C(=NH)NHR$, showed strong association in the liquid and solid phase except the N-dialkyl compounds, which presented only one inflection on the sharp $\nu(=NH)$ band in the condensed phase. Thus, in the spectra of the solid and liquid amidines, more than two bands were found, and in some cases it was difficult to distinguish between the free and bonded NH stretching frequencies. Dilution in tetrachloroethylene resulted in two sharp peaks only. For example, four strong bands were present in the spectrum of N-benzyl-α,α,α-trifluoroacetamidine and were still persistent near 3475, 3340, 3270, and 3200 cm^{-1} at 1.3 *M* concentration in tetrachloroethylene. Upon further dilution they were replaced by a sharp band, $\nu(\rangle NH)$, of medium intensity at 3465 cm^{-1} and a weak one, $\nu(=NH)$, at 3360 cm^{-1}.

In N-monosubstituted amidines (V*a*) there are two hydrogen atoms which might be involved in hydrogen bonding. Theoretical considerations demonstrate that amino hydrogen bears a partial positive charge owing to resonance and is more acidic than the imino hydrogen (=N—H).

II. Region 1800–1000 cm^{-1}

(a) The $\nu(C=N)$ Absorption

This easily recognizable frequency appeared as a very strong band at 1615–1690 cm^{-1} in all the spectra examined. Upon dilution it was slightly displaced to the higher frequencies as was expected for a $\nu(C=N)$ vibration. The $\nu(C=N)$ absorption bands in the N-aryl-, N-alkyl-, and N-dialkyl-trifluoroacetamidines followed exactly the same pattern as those of the trichloroamidines (1) and provided evidence for the existence of the N-substituted trihaloacetamidines in the imino form (V*a*).

A comparison of the $\nu(C=N)$ vibration of the following amidines in dilute tetrachloroethylene solutions showed the occurrence of this mode at the same frequency:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$Cl_3C—\underset{\underset{NH}{\|}}{C}—NH_2$: 1670 cm^{-1}; $Cl_3C—\underset{\underset{NH}{\|}}{C}—NHAr$: 1667–1672 cm^{-1};

$F_3C—\underset{\underset{NH}{\|}}{C}—NH_2$: 1690 cm^{-1}; $F_3C—\underset{\underset{NH}{\|}}{C}—NHAr$: 1690 cm^{-1}.

This behavior may not be a pure coincidence but may indicate that the presence of the aryl groups does not influence the resonance within the amidine system, whereas substitution by one or two alkyl radicals in the amino group does increase the contribution of the ionic structures of the resonance hybrid. This results in the progressive displacement of the C=N stretching vibration towards the lower frequencies which has its lowest value in the case of N-dialkyl-substituted amidines.

(*b*) *The "Amidine II" Band, δ(N—H)*

This infrared absorption appeared as a medium to strong band in the spectra of four N-alkyltrifluoroacetamidines (see Table I). It was absent from the spectra of the N-dialkyl compounds and was displaced to the higher frequencies (10–20 cm^{-1}) when association occurred. Nevertheless, it was not found in the spectrum of the solid N-benzyl-α,α,α-trifluoroacetamidine but appeared as usual (at 1530–1517 cm^{-1}) when solutions of this substance were studied. The δ(N—H) band was also identified when the spectrum of the melted N-benzyl-α,α,α-trifluoroacetamidine was taken but vanished when the melt was left to resolidify, this being done several times with the same result. Since the melting point of the compound was low (51°), decomposition by heating was not likely to occur and the spectrum of the solidified melt was exactly the same as that of the original substance in Nujol mull or in potassium bromide pellet. This behavior, which presents an example unique in the literature, could only be attributed to changes in the crystal lattice.

A strong absorption band with two well-separated peaks at 1607 and 1582 cm^{-1} appeared in the spectrum of the solid N-phenyl-α,α,α-trifluoroacetamidine but was replaced by only one very strong band at 1582 cm^{-1} upon dilution. The 1607 cm^{-1} band was taken as evidence for the "amidine II" vibration which had been displaced and therefore coincided with the aromatic ring absorption.

The assignment of the "amidine II" band to the 1570–1590 cm^{-1} absorption in N-aryl-trifluoro- and -trichloro-acetamidines was supported by the study of the infrared spectrum of the deuterated N-phenyl-α,α,α-trichloroacetamidine, $Cl_3C—C(=ND)NHC_6H_5$. The 1580 cm^{-1} band of the ordinary N-phenyl-α,α,α-trichloroacetamidine could not be observed in the deuterated analogue. A similar phenomenon was also noted with the deuterated N-methyl-α,α,α-trifluoro- and N-methyl-α,α,α-trichloro-acetamidine. In this case, changes in the infrared spectra occurred in the low-frequency region, indicating that coupled (mixed) rather than pure vibrations were present in this type of molecule.

(*c*) *The ν(C—N) Frequencies*

The very strong absorption bands of the F_3C-group varying in number from two to five even for the simplest molecules occurred in the same region (1100 to 1250 cm^{-1}) as the ν(C—N) vibrations and produced complicated infrared spectra. However, the $\nu(C_{ar}—N)$ frequency could be related to a very strong absorption at 1407 cm^{-1} in the N-phenyl-α,α,α-trifluoroacetamidine. This was clearly understood, since it was the only strong band between 1125 and 1480 cm^{-1}, and it was not present in the spectrum of trifluoroacetamidine and did not change on deuteration. The existence of a strong

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

absorption near 1080 cm^{-1} in the spectra of N-dialkyl amidines could be attributed to a $\nu(C_{alk}—N)$ mode in these N-dialkyl compounds, since this band was absent in the case of the N-monoalkyl compounds.

THE REACTION OF ALKYL IODIDES WITH IODO-ARSINES IN THE PRESENCE OF MERCURY[1]

M. M. Baig and W. R. Cullen

ABSTRACT

The reaction of alkyl iodides with iodo-arsines in the presence of mercury generally gives arsonium derivatives of triiodomercury (II). Thus tetramethylarsonium triiodomercury (II) is obtained from the reactions of methyl iodide with the compounds $(CH_3)_{3-n}AsI_n$ (n = 1, 2, 3). Phenyl-iodo-arsines give the new compounds $C_6H_5AsR_3HgI_3$ and $(C_6H_5)_2AsR_2HgI_3$ (R = CH_3 or C_2H_5) from similar reactions. However, the reaction of iododimethylarsine with ethyl iodide gives the 1:1 arsine complex $(CH_3)_2AsC_2H_5.HgI_2$. The compounds $(C_2H_5)_4AsI$ and $(C_2H_5)_4AsHgI_3$ were reinvestigated, and used to prepare the compound $((C_2H_5)_4As)_2HgI_4$.

DISCUSSION AND RESULTS

The reaction of alkyl- and aryl- iodo-arsines with perfluoroalkyl iodides in the presence of excess mercury has been found to yield alkyl- or aryl- perfluoroalkyl-arsines (1, 2). In the present investigation the reactions of alkyl iodides with iodo-arsines in the presence of mercury have been studied. Apart from one reaction, the main products are compounds which in the past have been named as arsonium derivatives of triiodomercury (II) (3, 4). Similar derivatives are known for other elements which form -onium compounds and there is good evidence that some of these mercuri-iodides are ionic in solution and that one of the ions is HgI_3^- (4, 5). However, solid state structural studies are clearly necessary.

The reactions involving alkyl iodides, mercury, and iodo-arsines, which were investigated, are shown in Table I and the new compounds prepared in this way are listed in Table II.

TABLE I

Reactants	Time of reaction	Products	Yields*
$AsI_3+Hg+CH_3I$	10 days	$(CH_3)_4AsHgI_3$	32%

$(CH_3)_2AsI+Hg+C_2H_5I$	5 days	$(CH_3)_2AsC_2H_5.HgI_2$	37%

*Yields are based on the iodo-arsine added (ca. 10 g).
†Estimated because of difficulty in separating the two compounds.

Like the other arsonium mercuri-iodides the new compounds are low-melting yellow solids, easily soluble in hot acetone and alcohol. The reaction between ethyl iodide, mercury, and iododimethylarsine, however, gives as a main product the 1:1 complex of mercuric iodide and ethyldimethylarsine. The molecular weight of this substance in camphor indicates that it is predominantly in the form of a monomer instead of the

expected halogen-bridged dimer (6), and consequently could contain 3-co-ordinate mercury. A similar situation is found in certain 1:1 tertiary phosphine mercuric iodide complexes (7). The arsine complex seems to decompose slowly and cannot be repurified by fractional crystallization. The alkyl-mercury iodides isolated from the reactions involving aryl-iodo-arsines are probably produced by the side reaction

$$RI + Hg \rightarrow RHgI.$$

Such reactions are well known for alkyl iodides and would be catalyzed by any free iodine present in the iodo-arsines (8).

The rate of reaction of alkyl iodides with the aryl-iodo-arsines in the presence of mercury seems to be slower when there are two iodine atoms on the arsenic. Similar behavior is found when these arsines are reacted in the same way with trifluoroiodomethane (2). The reaction of methyl iodide with arsenic triiodide and mercury is slower than with the substituted iodo-arsines, though it appears that methyl iodide reacts more easily in such reactions than does trifluoroiodomethane (1, 2). The latter compound does not react with arsenic triiodide and mercury (9). Antimony triiodide also reacts with methyl iodide in the presence of mercury but not with trifluoroiodomethane (10).

The most probable mechanism for the formation of the arsonium mercuri-iodides appears to be firstly, the formation of an arsine mercuric iodide complex (most likely 1:1), followed by the addition of alkyl iodide to give the final product: for example

$$(CH_3)_2AsI + Hg + CH_3I \rightarrow (CH_3)_3As.HgI_2,$$
$$(CH_3)_3As.HgI_2 + CH_3I \rightarrow (CH_3)_4AsHgI_3.$$

This route is supported by the isolation in one instance of the 1:1 arsine mercuric iodide complex, by the result that 2:1 arsine mercuric iodide complexes add on alkyl halides to give arsonium derivatives of tetraiodomercury (II) (7), and by the result that only aryl- and alkyl-perfluoroalkyl-arsines are isolated when perfluoroalkyl iodides are used in similar reactions (1, 2). Unfortunately the reactions so far studied give little indication as to which of the many possible mechanisms is the operative one in the formation of the perfluoroalkyl-arsine or the arsine mercuric iodide complex.

Two other arsonium mercuri-iodides have been studied in the present investigation, these are tetraethylarsonium triiodomercury (II) and bis(tetraethylarsonium) tetraiodomercury (II). The latter, a new compound, is a pale yellow crystalline substance, m.p. 238°. The triiodomercury (II) derivative is the usual low-melting yellow solid (m.p. 117°). Their preparation and relationship can be shown as follows.

$$(C_2H_5)_4AsI + HgI_2 \text{ (excess)} \xrightarrow[EtOH]{\text{cold}} (C_2H_5)_4AsHgI_3$$

$$(C_2H_5)_4AsI \text{ (excess)} \downarrow \text{EtOH, hot}$$

$$(C_2H_5)_4AsI \text{ (excess)} + HgI_2 \xrightarrow[EtOH]{\text{hot}} ((C_2H_5)_4As)_2HgI_4$$

For personal use only.

The anomalously low melting point of tetraethylarsonium iodide (160° (decomp.) (11)) is now found to be incorrect. The compound prepared and characterized in this investigation decomposed at 307°, a more reasonable figure in view of the value of 326° (decomp.) for tetramethylarsonium iodide (12). The low melting points of other tetraalkylarsonium compounds are probably also incorrect.

The infrared spectra of these arsonium derivatives have been measured. These are in the main complex and further work is in progress in an attempt to correlate these spectra with those of other arsenic compounds.

EXPERIMENTAL

Preparation of the Arsonium Derivatives of Triiodomercury (II)

The alkyl- and aryl- iodo-arsines were prepared as previously described (1, 2), the arsenic triiodide was prepared using the procedure in *Inorganic syntheses* (13).

The reactions shown in Table I were carried out at room temperature in sealed tubes (250-ml capacity) in the absence of air and light. The reaction mixtures were shaken continuously to ensure the exposure of a clean mercury surface to the solution of the iodo-arsine in the alkyl iodide. A large excess of mercury (ca. 200 g) and alkyl iodide (ca. 60 g) was used: the amount of iodo-arsine was 10 g. The reaction mixture was worked up by extracting the contents of the tubes with acetone and separating the soluble components by fractional crystallization from this solvent. Final purification was achieved by repeated crystallization from alcohol. The by-products of alkyl-mercury halides produced in the reactions of the aryl-iodo-arsines were identified in each case by analysis. Anal.: Methylmercury iodide: found: C, 3.52; H, 0.93; Hg, 57.9; I, 36.8%; mol. wt. 319; m.p. 147°. CH_3HgI requires: C, 3.50; H, 0.87; Hg, 58.6; I, 37.0%; mol. wt. 343; m.p. 152° (8). Ethylmercury iodide: found: C, 6.83; H, 1.41; Hg, 55.5; I, 35.7%; mol. wt. 340; m.p. 187°. C_2H_5HgI requires: C, 6.72; H, 1.40; Hg, 56.3; I, 35.6%; mol. wt. 357; m.p. 186° (8).

In the reaction producing dimethyldiphenylarsonium triiodomercury (II) a small fraction was isolated which contained an impurity melting at 122°. Infrared spectra and X-ray powder photographs were used in order to establish the impurity as methylmercury iodide or the complex $(C_6H_5)_2AsCH_3.HgI_2$ which was prepared for the purpose of comparison (m.p.: found, 117°; lit. value, 116° (14)). However, no definite conclusions could be reached from either the spectra or the powder photographs. The tetramethylarsonium compound was identified by its melting point, found: m.p. 189°; lit. value, 185° (11), and by the identity of its infrared spectrum with that of a sample produced from tetramethylarsonium iodide and mercuric iodide (11).

No unchanged iodo-arsine was recovered from these reactions.

Reaction of Iododimethylarsine with Ethyl Iodide in the Presence of Mercury

The iodo-arsine (7.1 g), ethyl iodide (50 g), and mercury (200 g) in a sealed tube (250 ml) which was not evacuated, were shaken at room temperature for 5 days. The contents of the tube were extracted with acetone. The solution was diluted by an equal volume of alcohol and a yellow precipitate appeared. This was soluble on warming, and on cooling 6 g of the mercuric iodide complex of ethyldimethylarsine were obtained (see Table II for analysis results). The complex was recrystallized from the mixed solvent, m.p. 111°. On the addition of more ethanol to the combined mother liquors a pale red liquid separated which was insoluble in boiling ethanol but crystallized on standing to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

pale yellow needles. This solid phase seemed to contain more than one compound and was not further characterized.

The arsine mercuric iodide complex was unstable as after 2 months the melting point changed from 111° to 100–110° and repurification could not be achieved by fractional crystallization. One of the larger fractions, m.p. 105–108°, analyzed as follows: found: Hg, 30.9; I, 41.1%. Calc. for $C_4H_{11}AsHgI_2$: Hg, 34.1; I, 43.2%.

Preparation of Tetraethylarsonium Iodide

Triethylarsine was prepared by a Grignard reaction using arsenic trichloride and ethyl bromide: the product distilled at 138–139° in a nitrogen atmosphere (15). When excess ethyl iodide was added to the arsine at room temperature a colorless solution was obtained which slowly deposited a white solid. After 2 days the solid was filtered off and purified by dissolving it in ethanol and reprecipitating by adding a large volume of ether. The product was identified as tetraethylarsonium iodide. Anal.: found: C, 30.3; H, 6.44; I, 39.3%. $C_8H_{20}AsI$ requires: C, 30.2; H, 6.39; I, 39.9%. The compound decomposed at 307° without melting (lit. value, 160° (decomp.) (11)).

Preparation of Tetraethylarsonium Triiodomercury (II) and Bis(tetraethylarsonium) Tetraiodomercury (II)

When a solution of tetraethylarsonium iodide in ethanol was added to a stirred solution of excess mercuric iodide in ethanol at room temperature, a yellow precipitate was obtained. This solid was washed with ethanol and was identified as tetraethylarsonium triiodomercury (II). Anal.: found: C, 12.4; H, 2.78; Hg, 25.8; I, 48.9%; mol. wt. 731; m.p. 117°. $C_8H_{20}AsHgI_3$ requires: C, 12.4; H, 2.59; Hg, 26.0; I, 49.3%; mol. wt. 773; m.p. 112° (11). When hot arsonium iodide and excess mercuric iodide solutions were mixed a yellow precipitate was obtained, m.p. 87–90°, containing two phases which could not be separated by fractional crystallization. However, the infrared spectrum of this mixture indicated that it was mainly the arsonium triiodomercury (II) derivative. When a hot solution of excess tetraethylarsonium iodide in ethanol was added to a hot solution of mercuric iodide in ethanol, a pale yellow precipitate was obtained. This was filtered, washed with alcohol, recrystallized, and identified as bis(tetraethylarsonium) tetraiodomercury (II). Anal.: found: C, 18.0; H, 3.66; Hg, 18.2; I, 46.2%; m.p. 238°. Calc. for $C_{16}H_{40}AsHgI_4$: C, 17.5; H, 3.66; Hg, 18.4; I, 46.4%. The same compound was produced when a solution of tetraethylarsonium triiodomercury (II) (0.5 g) in a minimum volume of hot ethanol was added to a solution of excess tetraethylarsonium iodide (1 g) in hot ethanol (5 ml). The bis(tetraethylarsonium) tetraiodomercury (II) which was precipitated was identified by its melting point of 236–238° and by its infrared absorption spectrum.

THE COMPLEX DIELECTRIC CONSTANT AT LOW MICROWAVE FREQUENCIES OF ETHYL CHLORIDE ADSORBED ON POROUS VYCOR GLASS[1]

J. D. McCowan[2] and R. McIntosh

ABSTRACT

The complex dielectric constant of the system Vycor glass – ethyl chloride has been measured at three temperatures in the range +11° C to −33° C and in the frequency range between 500 Mc sec^{-1} and 4000 Mc sec^{-1} by the use of a coaxial line. The real and imaginary parts of the dielectric constant of the adsorbate have also been evaluated. Appreciable loss in the adsorbed matter is found for small quantities adsorbed, and loss is again detected at the highest frequencies and lowest temperatures for the matter held in multilayers or condensed in capillaries. The frequency range and accuracy of measurement were not sufficient to classify the type of loss curve, but other evidence suggests that the loss for the first quantities adsorbed will turn out to be that for rotational oscillators. In general earlier observations of this system are confirmed and extended.

INTRODUCTION

In a series of papers from this and other laboratories, the apparent dielectric constants have been reported of polar and non-polar substances adsorbed on porous adsorbents. There is agreement among several of the investigators (1, 2, 3, 4, 5, 6, 7) that there are at least two linear sections of the primary data of either dielectric constant or capacitance change as a function of quantity adsorbed. Channen and McIntosh (5) have stressed the need to understand the experimental observation that the second linear region has a lower slope than the first, even for non-polar butane. As this is found only with porous adsorbents, Petrie and McIntosh (7) suggested that the internal field in which the matter is located changes suddenly at some critical quantity of adsorbate, and that this change is due to the location of the molecules in relation to the internal structure of the solid. In the case of polar adsorbates it is possible that explanations in terms of the value of the orientational polarization might be possible. Thus, molecules adsorbed initially with large apparent polarization, might, in the later stages of adsorption, be followed by molecules which are rotational oscillators with a lesser average dipole moment in the field. Although such concepts are unable to provide an explanation of the behavior of normal butane, nevertheless, since it is possible that adsorbates show specific differences of properties, any evidence concerning the dipolar character of adsorbates would be of value. To this end techniques have been developed to permit examination of adsorbates from 20° C to −183° C over a frequency range 3000 cycles sec^{-1} to 4 Mc sec^{-1} and from 10° C to −40° C in the frequency range 500 Mc sec^{-1} to 4000 Mc sec^{-1}. A description of the devices used for the high frequency experiments and the results found for ethyl chloride on porous Vycor glass are given in this paper. The reproducibility of results has proved excellent although the variation from one frequency to another has caused disappointment, and seems to be due to the coaxial line itself. Before describing the experimental assembly and reporting the results, it is useful to state what experimental findings can be (at least qualitatively) interpreted in elucidating the nature of the adsorbed phase.

(1) A negative temperature coefficient of dielectric constant, from experience gained with bulk matter, signifies an assembly of molecules free to align themselves in the field, or of dipolar molecules with several possible orientations relative to the field, as discussed by Frohlich (8). Such systems, if of normal liquid density, would be expected to possess a fairly large value of the dielectric constant, approximately that of the liquid state.

(2) Alternatively, experiment might reveal a negligible temperature coefficient of the dielectric constant of the adsorbate. This as Kurbatov (9), and Benson, Channen, and McIntosh (10) have stated, suggests that the adsorbate consists of an assembly of rotational oscillators. For these the orientational polarization, and hence the dielectric constant of the assembly, might be small.

(3) If the adsorbate exists in thick liquid-like layers, dispersion might be expected in the frequency and temperature ranges normal to the liquid state.

(4) Lastly, in the first adsorbed layer, dispersion of rotational oscillators, which would presumably be the nature of the adsorbed molecules, might not be found until very high frequencies. An estimate of the frequency was attempted by Benson, Channen, and McIntosh (10) for a simple molecule like hydrogen chloride adsorbed on a sodium chloride surface. The frequency at which dispersion occurs would depend, of course, upon the molecular structure of the adsorbate and the surface.

In the results given below, the real and imaginary parts of the dielectric constant of the total system, and of the adsorbate, are given. The tedious calculations necessary to obtain the adsorbate properties were based upon the extended Böttcher treatment which has been discussed in earlier papers (5, 7), and allowance had to be made for the lossy character of the substrate itself. The omission of the values of the real part of the dielectric constant for the total system and the fact that the properties of the adsorbate were not computed by Waldman (11) has much reduced the significance of that work. The findings of the present investigation may be briefly summarized as follows:

1. The measurement of the real and imaginary parts of the dielectric of both the adsorbent and a polar adsorbate has been successfully achieved over a temperature range $+11°$ to $-33°$ C and a frequency range 500 Mc sec^{-1} to 4000 Mc sec^{-1} by means of a coaxial line system. The reproducibility of any given measurement was finally established as better than $\pm 0.2\%$ over the 40 degree temperature range studied, but random variations with frequency amounted to $\pm 2\%$. This variation appears to be inherent in the line used, not in the method employed, nor in the procedures of amplification.

2. The existence of losses in the adsorbed dielectric has been established for the first time in this temperature range. Moreover, the losses of the adsorbate alone have been evaluated, and, as might be anticipated from the knowledge that the measurable loss of the total dielectric is caused by a comparatively small amount of adsorbate, the loss in the adsorbate is substantial.

3. The pronounced losses are found for the adsorbate in equilibrium with low relative pressures, and little loss is to be observed for the adsorbate in the multilayer or capillary condensed material, although a slight loss is observed at the lowest temperature and highest frequencies.

4. The existence of loss permits the occurrence of a positive temperature coefficient of the real part of the dielectric constant. Earlier work with the same adsorbent–adsorbate system (7) has shown a negligible temperature coefficient of the dielectric constant when measuring frequencies that were too low to create losses were employed. Since a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

negligible temperature coefficient suggests rotational oscillators, the loss detected appears to be for an oscillatory or resonant type of motion.

5. No evidence of hysteresis in the dielectric constant was obtained, as found by Thorp (12) for several systems, and more recently by Fiat (13). The lack of hysteresis confirms the statement by Petrie and McIntosh (7) published without supporting evidence. A graph of their results, which were obtained with greater precision than the present data, is included below.

EXPERIMENTAL

The equipment used for the preparation of the materials and to obtain adsorption data was relatively simple and described in detail elsewhere (14, 15, 16). Hoke type 413 metal valves were used throughout the measuring system to ensure that no mercury or stopcock grease could distill into the cell.

Small equilibrium pressures were measured by condensing the gas from a large known volume to a small volume in which the pressure was measured. From a knowledge of all the volumes in the system, equilibrium pressures and amount adsorbed were calculated.

The dielectric measurements were carried out by setting up a standing electromagnetic wave for which the node positions and voltage standing wave ratio were dependent on the complex dielectric constant of the adsorbate–adsorbent system.

The cell is shown in Fig. 1. The two coaxial cylinders which channel the microwave were of 0.007-inch wall German silver tubing. Their dimensions, and those of the tapers leading to the UG30C/U adapter, were chosen to present an impedance of 50.0 ohms to the microwave. The adapter formed a vacuum seal and, together with the gasketed plate behind the shorting plate, permitted evacuation of the sample chamber and the admission of known quantities of gas. The evacuation and admission were accomplished through a copper tube leading to the small chamber behind the short and through a pinhole in the outer conductor.

Around this whole structure, a brass cylinder was attached which could be sealed by a gasket at its open end. The Genitron 21, used to control the temperature of the sample, was circulated through this chamber. Details of the temperature control may be found elsewhere (17).

Temperature was measured by calibrated copper–constantan thermocouples inserted in the wells shown in the diagram. They showed a temperature gradient of 0.3° C and fluctuation of ± 0.2 C° for a temperature of $+11$° C and a gradient of 1.5 C° and long term fluctuations of ± 1 C° at -33° C.

The porous Vycor glass, brand number 7930, was ground to make a sliding fit with both conductors. In the final assembly, care was taken to have it adjacent to the short. Both ends were planar and orthogonal to the axis.

Preparation of the Vycor involved gentle heating, first in a succession of 30% nitric acid solutions and then in distilled-water baths. It was then sealed in the final assembly and the water pumped off gently over 2 days. The glass was then heated to 65° C and pumping continued for 1 day more. An ultimate vacuum of 10^{-6} mm Hg was obtained.

Three signal generators, covering a range from 200 to 4000 Mc sec^{-1}, could be connected, in turn, to two General Radio LBA slotted lines in series. Connections between a generator and the first line, called the reference line, and between the reference line and the second or signal line, were made by RG21/U attenuating cable. This reduced reflection into the generator. The signal line was attached directly to the cell. In this slotted line, the standing wave pattern was studied by means of a travelling carriage

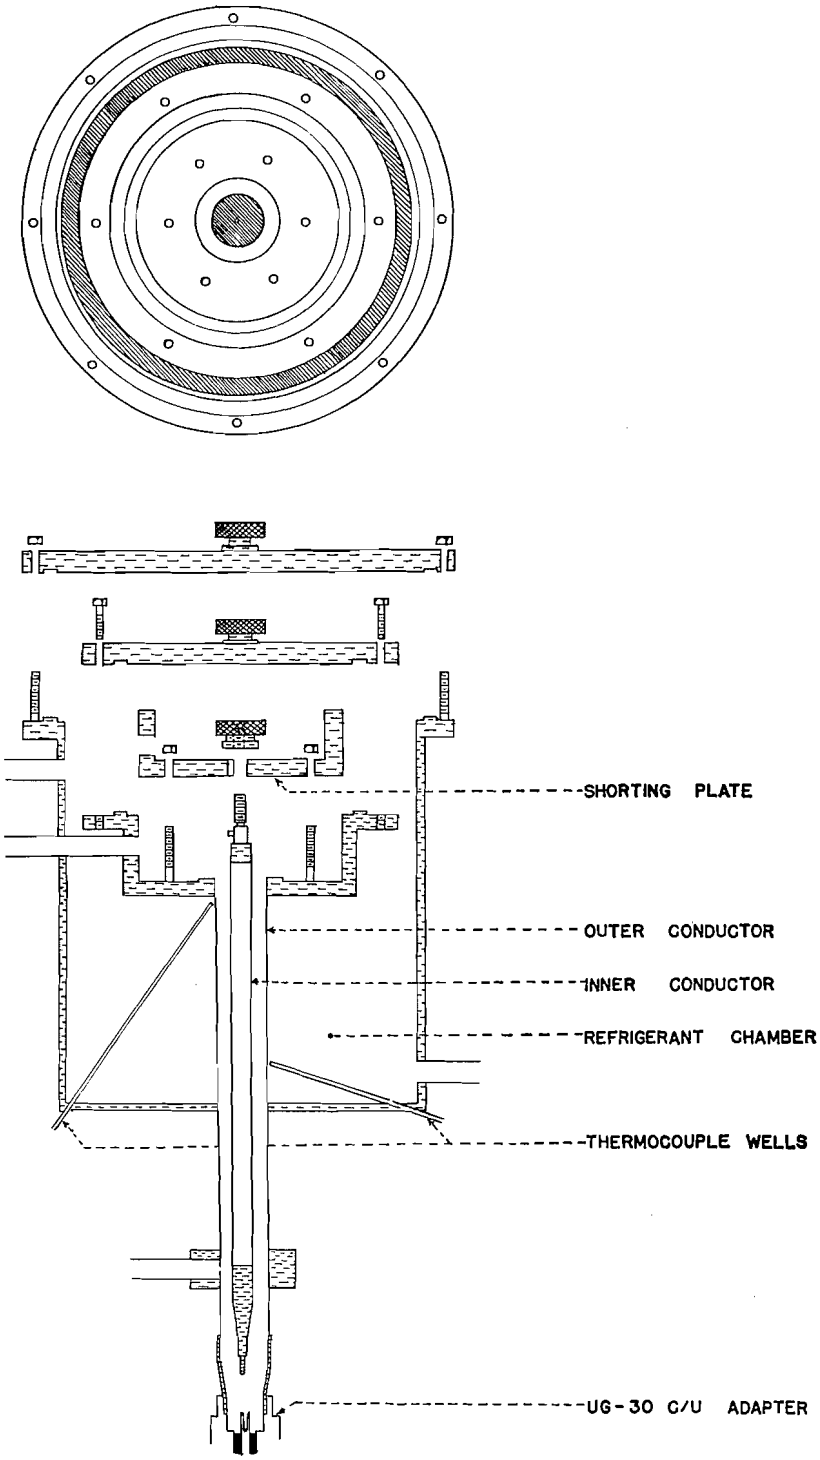

FIG. 1. Side cross-sectional and end views of coaxial cell assembly.

containing a probe and a 1N21B crystal diode. The output of this diode showed no detectable departure from square law response in the voltage range studied. The carriage was moved by the rotation of a threaded bar running the length of the slotted section. Motion of the carriage could be estimated to 0.002 cm.

The line nearer the signal source was not fitted with the worm drive device and was used to produce a reference voltage.

The d-c. outputs of the crystal diodes were fed into two identical d-c. amplifiers each with amplifications of 10^2, 3×10^2, and 10^3. The amplifiers were of a negative feedback type employing the action of a light beam reflected from a galvanometer on two photocells in series. Separate power supplies must be used for the two amplifiers. Oscillations in the output occur if several resistors are not kept within fairly narrow tolerances (15).

Precautions were taken to ensure that ground potential was the same throughout the d-c. system. Small contact potentials were eliminated from input switches by the use of Leeds and Northrup type 31-3 switches but it was found impossible to eliminate them from the spring type General Radio connectors of the slotted lines.

The output of the reference amplifier was applied to the input of a General Radio decade voltage divider. The divided output was fed, through a switch, to one terminal of a galvanometer. The output of the signal amplifier was applied to the other terminal. For a null reading of the galvanometer, the voltage divider box read the exact ratio of the signal amplifier output to the reference amplifier output. A block diagram is shown in Fig. 2. The signal was measured as a ratio, rather than in absolute terms, to eliminate

the effects of both the short and comparatively long term variations in the source voltage from the signal generator.

In practice, this ratio, K, differed from the ratio of the crystal voltages, k, by about 1% due to the zero errors arising from the spring contacts. These small voltages of less than 3 microvolts were measured for every minimum as was the total output of the reference amplifier, V. If x and y are the residual voltages of the signal and reference amplifiers respectively for no microwave signal, then

$$k = \frac{A_s S + x}{A_r R + y}$$

and

$$K = \frac{S}{R} = \frac{A_r}{A_s}\left[k + \frac{ky}{V-y} - \frac{x}{V-y}\right]$$

where A_s and A_r are the amplifications, and S and R the magnitudes of the crystal voltages for the signal and reference lines respectively.

The probe carriage had a range of travel of about 45 cm and, for each determination, the two minima furthest apart within this range were studied. Voltage readings were recorded every 0.025 cm or, in the case of broad minima, every 0.050 or 0.100 cm, in the region of the minimum. Care was taken to extend these readings beyond the points of twice minimal voltage.

CALCULATIONS

Von Hippel (18) shows that

$$\frac{\tanh \gamma_2 d}{\gamma_2 d} = \frac{-j\lambda_1}{2\pi d} \frac{\frac{E_{min}}{E_{max}} - j \tan \frac{2\pi X_0}{\lambda_1}}{1 - j \frac{E_{min}}{E_{max}} \tan \frac{2\pi X_0}{\lambda_1}} \equiv Ce^{j\zeta}$$

where γ_2 is the propagation factor of medium 2, the adsorbate–adsorbent system; d is the sample length; λ_1 is the wavelength of the radiation in the slotted section; E_{min}/E_{max} is the inverse voltage–standing wave ratio; and X_0 is the position of the first minimum from the surface of the sample. X is defined as positive in the direction of the incident wave and has its origin at the interface of the sample. The short, then, occurs at $x = d$.

If $\gamma_2 d = Te^{j\tau}$, then, once C and ζ are known, T and τ can be evaluated either by charts (19, 20, 21) as was done in the present work or by a series approximation of the function $\tanh Te^{j\tau}/Te^{j\tau}$. Hence

$$\frac{\epsilon^*}{\epsilon_s} = \frac{\gamma_2^2}{\gamma_s^2} = \frac{\lambda_1^2}{(2\pi d)^2} (T_e{}^{j\tau})^2.$$

ϵ^* is the complex dielectric constant of medium 2, and ϵ_s is the dielectric constant of free space.

An examination of the above formulae shows that, depending entirely on the magnitudes of the primary data, great variations in the accuracy of the calculated values can occur. This fact has its source in two stages of the calculation.

One is the nature of equation for $Ce^{j\zeta}$. It will be seen that, if X_0 is very small or very near $-(\lambda_1/2)$, the term $\tan(2\pi X_0/\lambda_1)$, cannot be evaluated with great accuracy, even although the precision and accuracy of the primary data remain unchanged. Similarly,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

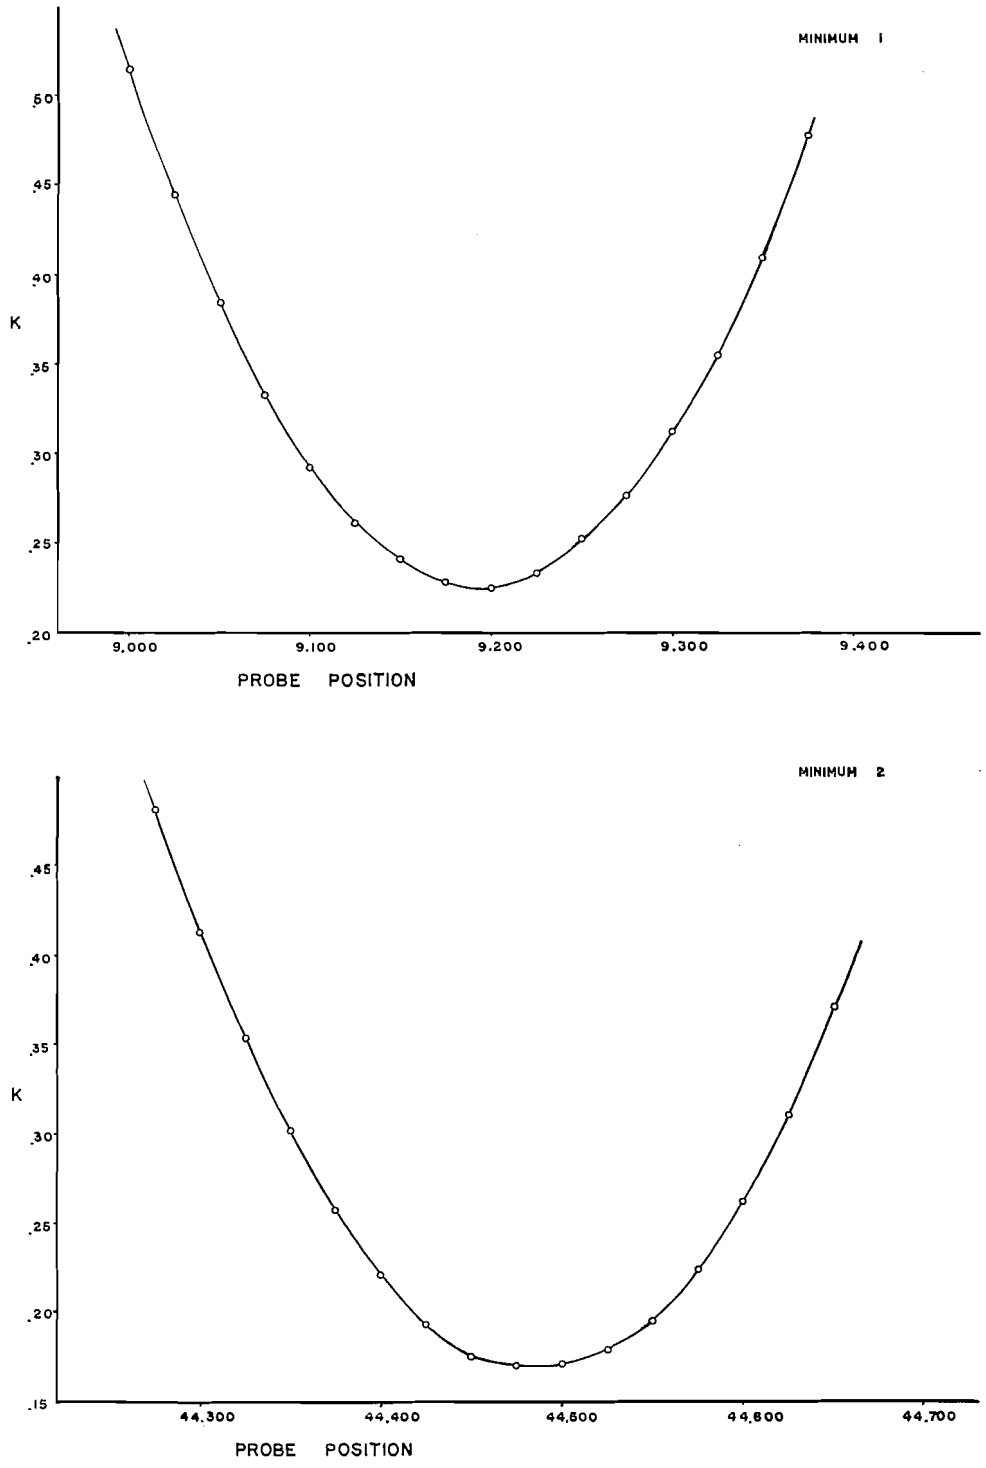

FIG. 3. Plots of K against probe position for measurements of 1280 Mc sec^{-1}, 339.8 cc of ethyl chloride adsorbed, and $-33.2°$ C.

when X_0 is approximately equal to $-(\lambda_1/4)$, $\tan 2\pi X_0/\lambda_1$ varies very rapidly with X_0 and the accuracy of Ce^{jr} becomes much less than that of the primary data.

It is the nature of these measurements that, as ϵ' increases, all else remaining equal, X_0 decreases from $-\lambda_1/2$ to 0 in cycles. Hence it was inevitable in the course of these measurements that, for a fixed sample length, certain regions of interest were not capable of accurate analysis. This was true, for example, at 1600 megacycles for comparatively low dielectric values and at 1280 megacycles for comparatively high dielectric values, despite the fine primary data, an example of which is shown in Fig. 3.

The other source of variation in the magnitude of the error is the $T-\tau$ chart. In each $T-\tau$ chart are areas of curvature and skew which make linear interpolation between the plotted lines very approximate. Other areas are nearly Cartesian in their regularity and can be read to four significant figures with ease. It is suggested that the programing of a computer to solve equation for γ_2 by a series approximation would be an improvement.

Care was taken to apply corrections to ΔX for attenuation in the line and its fittings (22), for asymmetry (22), and for deviations of the wave form, at low standing wave ratios, from the assumed form (18, 19, 20, 23) by which E_{min}/E_{max} was evaluated from the width of the curve at twice minimal voltage.

RESULTS

For small admission of gas, a fixed amount of gas was put in the cell system and the temperature varied. For large admissions, the temperature was kept constant while known amounts of gas were admitted to the system. This procedure was adopted in the multilayer since it was one of the purposes of this research to determine if hysteresis existed in the dielectric data corresponding to the hysteresis in the adsorption data. The latter method proved very satisfactory, although slightly slower, and is recommended. Isotherms for the three temperatures studied are shown in Fig. 4.

For each isotherm, dielectric constants were obtained at from six to nine chosen frequencies for eight or nine adsorptions. A disappointing error between frequencies was observed, which hindered accurate assessment of the dependence of ϵ' or ϵ'' on frequency.

For glass alone, no variations of ϵ' or ϵ'' with temperature could be observed. Average values of the dielectric constants, with their average deviations, are shown in Table I.

TABLE I

Dielectric constants of Vycor glass. Average, for each frequency, of data obtained at three temperatures at which isotherms were studied

Plots of ϵ' and ϵ'' against volume adsorbed were made. Examples are shown in Figs. 5 and 6. It will be seen that the plots of ϵ' against volume adsorbed consist of two linear portions. The second section, beginning between 100 and 150 cc adsorbed, always has a lower slope than the first. This is in agreement with results obtained by McIntosh, Rideal, and Snelgrove (3) and Petrie and McIntosh (7).

Straight lines are fitted to the data by the least-squares method, different lines being fitted above and below 125 cc. Since the values of ϵ_0' for glass were the means of three determinations, the additional constraint was put on the first section that it pass through this point. The values of the slopes, calculated by this method are shown in Table II.

TABLE II

Slopes of plots of ϵ' against volume adsorbed

Temperature (°C)	Frequency (Mc sec^{-1})						
	530	640	1020	1280	1600	2000	3200
+11.2	.00464	.00445	.00541	.00437	.00552	.00420	.00426
−17.9	.00464	.00408	.00482	.00414	.00480	.00392	.00368
−32.9	.00438	.00386	.00469	.00394	.00446	.00357	.00329

Values of the dielectric constant of the adsorbed phase were calculated using the extension of Böttcher's treatment (3, 5). This was done for two representative points in each straight line portion. (See below.)

In calculating the adsorbate dielectric constant, the volume fraction of pore space was taken as 0.370 (24). The density of the ethyl chloride was taken to be that of the liquid at the appropriate temperature (25). Calculated values are shown in Table III.

Since the expressions arising in the extended Böttcher treatment are complicated when both the solid adsorbent and adsorbate exhibit loss, a statement concerning the method of solution and the necessary equations will be given.

The usual expression of the extended treatment, when the dielectric constant of the gas phase is taken as 1.0, is

$$[1] \qquad \frac{\epsilon+2}{3}-\frac{3\epsilon}{2\epsilon+1}\,\delta_3=\frac{\epsilon_0-1}{4\pi C_1}+\frac{\epsilon-\epsilon_0}{4\pi C_2};$$

ϵ is the dielectric constant of the composite system, ϵ_0 of the porous glass, δ_3 the volume fraction of free space, C_1 and C_2 the volume average polarizability of the glass and adsorbate, respectively. It must be remembered in the general case that ϵ, ϵ_0, C_1, and C_2 are complex quantities. On making these terms complex and equating real and imaginary quantities, one obtains

$$[2] \qquad \frac{\epsilon'+2}{3}-3\delta_3\left[\frac{2(\epsilon')^2+\epsilon'+2\epsilon''^2}{(2\epsilon'+1)^2+(2\epsilon'')^2}\right]=\frac{\epsilon_0'C_1'-C_1'+\epsilon_0''C_1''}{4\pi(C_1'^2+C_1''^2)}+\frac{(\epsilon_1'-\epsilon_0')C_2'+(\epsilon''-\epsilon_0'')C_2''}{4\pi(C_2'^2+C_2''^2)}$$

$$[3] \qquad -\frac{\epsilon''}{3}+3\delta_3\left[\frac{\epsilon''}{(2\epsilon'+1)^2+(2\epsilon'')^2}\right]=\frac{C_1''(\epsilon_0'-1)-C_1'\epsilon_0''}{4\pi(C_1'^2+C_1''^2)}+\frac{(\epsilon'-\epsilon_0')C_2''+(\epsilon_0''-\epsilon'')C_2'}{4\pi(C_2'^2+C_2''^2)}.$$

Calling the left-hand sides of equations [2] and [3] L_1 and L_2, respectively, and the first term of the right-hand side of each of equations [2] and [3], A_1 and A_2, respectively, it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

follows that

$$[4] \qquad \frac{L_1-A_1}{L_2-A_2} = \frac{C_2'(\epsilon'-\epsilon_0')+C_2''(\epsilon''-\epsilon_0'')}{C_2''(\epsilon'-\epsilon_0')+C_2'(\epsilon_0''-\epsilon'')}$$

and therefore that

$$[5] \qquad C_2'' = \frac{(\epsilon_0''-\epsilon'')(L_1-A_1)-(\epsilon'-\epsilon_0')(L_2-A_2)}{(\epsilon''-\epsilon_0'')(L_2-A_2)-(\epsilon'-\epsilon_0')(L_1-A_1)}\, C_2' = XC_2'.$$

Substitution in [2] for C_2'' yields

$$L_1 = A_1+\frac{1}{4\pi C_2'}\,\frac{(\epsilon'-\epsilon_0')+(\epsilon''-\epsilon_0'')X}{1+X^2}.$$

A plot of L_1 versus the coefficient of $1/(4\pi C_2')$ gives the value of C_2', C_2'' follows from equation [5]. Once these two quantities are known the values of ϵ_2' and ϵ_2'' may be obtained by equating the real and imaginary parts of the equation

$$[6] \qquad \frac{4}{3}\,\pi(C_2'-jC_2'') = \frac{\epsilon_2'-1-j\epsilon_2''}{\epsilon_2'+2-j\epsilon_2''}$$

and solving for ϵ_2' and ϵ_2''.

DISCUSSION

In spite of the scatter of results as a function of frequency, the reality of certain findings appears definite. Thus, for quantities of gas adsorbed below about 140 cc, a slight positive temperature coefficient of ϵ_2' and large values of ϵ_2'' are found. These facts are sufficient to establish the existence of dispersion in the adsorbate for coverages which suggest the formation and the filling of the first layer. Since, as was suggested in the introduction, a zero or negligible temperature coefficient implies rotational oscillators it is not improbable that when the loss curve is adequately established, it will turn out to have a form associated with resonance absorption.

The values of ϵ_2'' are much higher for 40 cc adsorbed than for 100 cc adsorbed although ϵ'' for the total system is higher at 100 cc. This indicates that the new material in the adsorbed phase contributes less to the loss. The same observation is even more marked for higher adsorptions.

The absolute values of ϵ_2' and ϵ_2'' are, of course, subject to the uncertainties which have been pointed out in earlier papers (5).

In the present instance the value of ϵ_2' is quite close to that of bulk liquid for adsorption below 140 cc, and this must mean that the amplitude of the oscillations of the adsorbed molecules is large. This, in turn, implies that the frequency of rotational oscillations need not be very great. Assuming, then, that the adsorbed molecules do behave as rotational oscillators and that the evidence of a loss maximum at a frequency in the order of a few thousand megacycles per second may be accepted, the two findings are not mutually inconsistent. Where estimates have been attempted to ascertain the natural frequency of such a mode of motion for an adsorbed molecule (10), a much simpler molecule and surface were assumed, and the frequency was much higher than observed here.

According to Figs. 5 and 6 the value of ϵ' of the total system and that of ϵ'' change in a different manner with volume adsorbed once about 140 cc of gas has been adsorbed. The anomaly of low values of ϵ_2' which results from these primary data even when there is no evidence of dispersion has already been emphasized in earlier publications (5). As the calculated value of ϵ_2' is appreciably greater than could be accounted for by distortion polarization alone, a situation which is not found in the case of normal butane, it is again possible that rotational oscillations of smaller amplitude than for the first adsorbed matter could account for the result. In the present instance, however, the variation of ϵ_2'' with amount adsorbed is much less than for the initially adsorbed matter. Moreover, the effect of temperature on the loss, as the plots of ϵ'' show, is much less than for the first section of the data. The matter does not behave, however, as bulk liquid, since the temperature coefficient of ϵ_2' is negligible. Moreover, the beginning of absorption in the multilayer region is evident only at the highest frequencies used and for the highest adsorptions where the material might be expected to approximate most closely to the liquid structure. Calculations for the absorption peak for liquid ethyl chloride (26) based on the equation of Debye (27) and Powles (28) show that the peak for the liquid should occur between 7000 and 10,000 Mc sec^{-1} at $-30°$ C. Between 140 and 400 cc adsorbed, there is little evidence of loss. It would seem, then, that the adsorbate, particularly at the beginning of the multilayer region, does not have liquid properties. It is thus shown that the lower absolute value of ϵ_2' is not wholly caused by whatever factor brings about the low value of dielectric constant in butane.

Although it is true that absolute values of ϵ_2' differ to some extent from values reported by Petrie, Channen, and McIntosh (16) for rutile as the substrate, and by Petrie and

McIntosh (7) for powdered Vycor glass and silica gel as the adsorbent, the general measure of agreement is good. All work has shown higher dielectric constants for the first matter adsorbed than for the second on porous adsorbents, and the temperature coefficients are small or zero, except for the situation described here of a positive temperature coefficient in a region where dispersion is clearly apparent.

Comment upon the existence of hysteresis in the dielectric curves as claimed by Thorp (12) and more recently by Fiat (13) is difficult. No evidence in support of their claims appears in this work or in that done by Petrie (see Fig. 7). Thorp's claim to relate

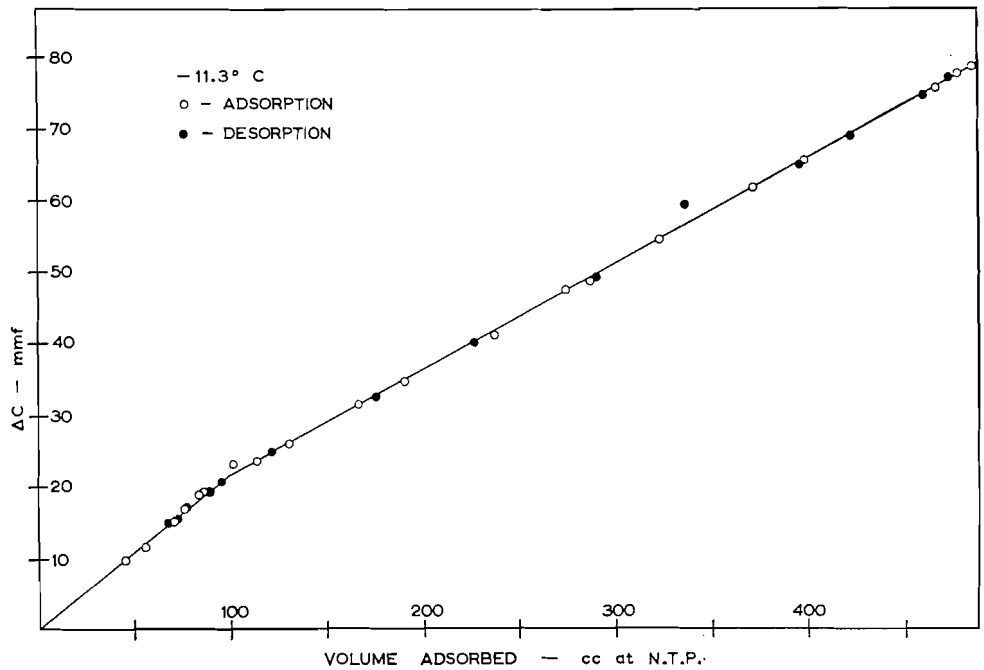

FIG. 7. Variation of capacity with volume adsorbed at −11.3° C, 3.70 Mc sec^{-1}, and 7.053 g of Vycor glass granules.

the variations of type of hysteresis to pore-size distribution appears unwarranted in view of the doubt that pore-size distributions may be assessed even qualitatively from the shape of isotherms and the Kelvin theory (29). On the other hand, gel systems like Vycor glass, activated carbon, etc. are known to shrink and swell due to the presence of adsorbate (24, 30, 31), and such movement may cause changes of packing in powders. Additionally, very long time lags occur before the establishment of apparent equilibrium, and possibly these are involved. In any event, some difference of experimental procedure of the several investigators seems to be the cause of the discordant results, because the gel systems employed appear very similar in terms of the type of adsorption isotherm which they exhibit.

THE ALUMINUM REDUCTION OF MAGNESIUM OXIDE

I. THE VAPOR PRESSURE OF MAGNESIUM OVER THE SYSTEM Al–MgO[1]

K. GRJOTHEIM, O. HERSTAD, AND J. M. TOGURI

ABSTRACT

The equilibrium vapor pressure of magnesium over the reaction between magnesium oxide and aluminum was measured by means of the transportation method. In the temperature range 850–1150° C the results can be expressed by the equation $\log P_{\text{mm of Hg}} = -9617/T + 8.93$. From X-ray diffraction analysis this reaction proceeds according to the equilibrium

$$4MgO(s)+2Al(l) = MgAl_2O_4(s)+3Mg(g).$$

INTRODUCTION

Very little information exists in the literature on the reaction between solid magnesium oxide and metallic aluminum. On the assumption that this reaction proceeds according to equation [I],

$$3MgO + 2Al = Al_2O_3 + 3Mg, \qquad [I]$$

Treadwell (1) has calculated the equilibrium vapor pressure of magnesium over this reaction. His calculations showed that at 1470° C the equilibrium pressure of magnesium is 7.6 mm of Hg.

Later Beljajew (2) has reported that the equilibrium pressure of magnesium over reaction [I] is 1 atm at 1300° C.

From the available thermodynamic data (3) the present authors have calculated the pressure of magnesium over reaction [I] to be 98 mm of Hg at 1300° C.

Since this discrepancy exists, it was the purpose of the present investigation to examine the reaction between solid magnesium oxide and metallic aluminum. The logical approach to the study of reactions of this type, involving components in the vapor, is the measurement of the equilibrium vapor pressure associated with the reaction, and to identify the end products of the reaction in order to establish the reaction scheme.

EXPERIMENTAL

The experimental method adopted to measure the equilibrium vapor pressure of magnesium was the transportation method, since the expected vapor pressure range was 10^{-2}–10^{2} mm of Hg over the desired temperature range. This method of measuring vapor pressure has proved to be successful for a number of similar reactions (4, 5). It is a dynamic method, in which the magnesium vapor in equilibrium with the solid components is carried away by a stream of inert gas flowing at a constant velocity. The amount of magnesium vapor transported is determined by condensing the vapor in a suitable condenser. The vapor pressure is then proportional to the mass of entrained vapor divided by the total volume of gas leaving the equilibration zone.

The important feature of the transportation method is the geometry of the apparatus. It must be designed to insure saturation of the carrier gas over a range of flow rates where the diffusion errors are negligible, and where the measured pressure is independent of flow rate.

The furnace utilized for this purpose is shown in Fig. 1. It is a Kanthal A wire-wound electrical furnace similar to that described in detail by Motzfeldt (6). With this furnace an uniform temperature zone was obtained readily to within ±1.5° C, along the middle 15 cm of the furnace for temperatures of 800–1200° C.

An inconel tube (76% Ni, 15% Cr, and 9% Fe) of 3.2-cm I.D. was used as the reaction tube, since it was found to be chemically inert against the reactants and products of the reaction concerned, below 1150° C.

The charge is placed between two inconel perforated spacers, as shown in Fig. 1. These spacers not only keep the charge in place but also aid in packing the charge together, thus contributing towards the saturation of the carrier gas.

A steel condenser filled with washed steel wool is placed near the outlet of the reaction tube. This serves to condense and collect completely the evolved magnesium gas.

The carrier gas utilized throughout this investigation was S-argon gas obtained from Norsk Hydro, the analysis given was 99.94%. The impurities CO_2 and H_2O were removed by passing the argon through an Ascarite and a Dehydrite tower respectively. The hydrogen was obtained from Norsk Surstof og Vandstoffabrik A/S (99.7%) and was similarly purified.

The gas flow rate was measured using a calibrated rotameter and the total volume was determined by means of a calibrated gas meter.

A Pt–Pt 10% Rh thermocouple was placed into the charge, as shown in Fig. 1, to measure the temperature in conjunction with a precision Tinsley potentiometer with a mirror Lange-galvanometer.

PREPARATION OF CHARGE

The magnesium oxide and aluminum powder used throughout this investigation was obtained from Merck, Germany. The magnesium oxide was of pro analysis grade and the analysis of the aluminum was 99.9%.

Before use, the MgO was dried at 1000° C for 12 hours. The MgO and aluminum was then mixed and ground in a ball mill. The powdered mixture was pressed into briquettes at 500 kg/cm². The size of the briquettes were 2.0 cm in diameter by 1.5 cm in height.

These briquettes were broken into pieces of approximately 5 mm and packed into the reaction tube. Approximately 120 g of charge was used. The reactants prepared in this manner gave rise to a large sample surface area to reaction tube volume ratio and thus a condition which is favorable for insuring saturation of the carrier gas.

The experiment was started by moving the furnace, which is 100° C higher than the required temperature, along the reaction tube to a position such that the sample was located in the uniform temperature zone. During this period a stream of argon was passed from the opposite end until the required temperature was obtained, a period of approximately 5 to 10 minutes. When the temperature was reached the flow of argon was reversed and zero time was observed.

RESULTS AND DISCUSSION

(A) Effect of Flow Rate on the Apparent Vapor Pressure

A number of experiments were carried out to determine the effect of the flow rate of the carrier gas on the measured vapor pressure. In Fig. 2 results are shown for such experiments carried out at 998° C. In the case of argon as the carrier gas, the flow rate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

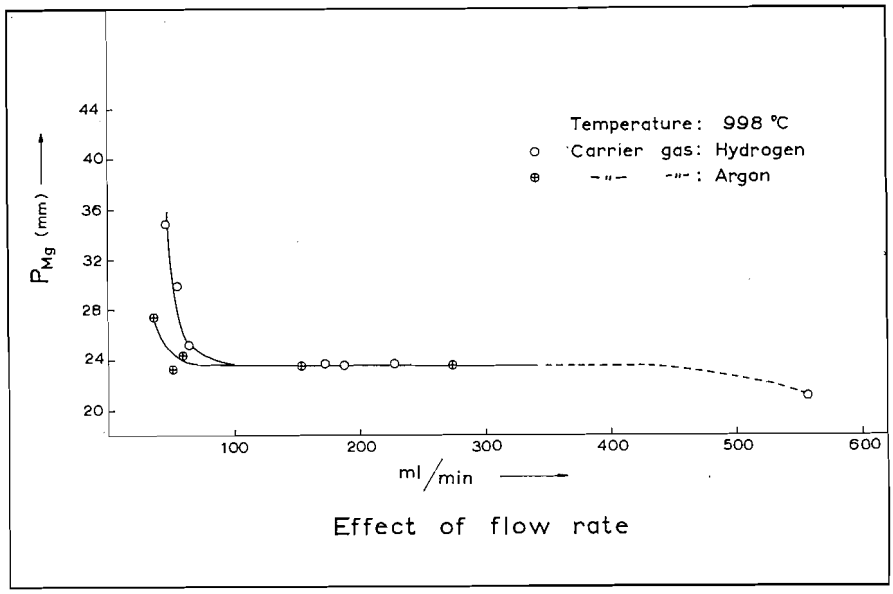

FIG. 2. Effect of flow rate using hydrogen and argon as carrier gas.

was varied from 37 to 274 ml/minute. For flow rates exceeding 100 ml/minute, there appears a plateau where the vapor pressure is independent of the flow rate. At lower flow rates, the resulting pressure, that is the mass of magnesium collected per unit volume, is much higher. This indicates that in addition to the equilibrium concentration of the vapor in the carrier gas, there is movement of vapor due to thermal diffusion and self-diffusion. This feature has been analyzed by Lepore and Van Wazer (7).

The existence of a relatively large region where the pressure is independent of the flow rate insured saturation of the carrier gas as well as a satisfactory design of the apparatus.

(B) Effect of Carrier Gas on the Vapor Pressure

To insure that the pressure measurements were independent of the nature of the carrier gas, hydrogen was also utilized as the entrainment gas. The results are shown in Fig. 2, at a temperature of 998° C. The flow rate was varied from 43 to 557 ml/minute. In the range from 100–350 ml/minute the vapor pressure is independent of the flow rate and is identical to that observed with argon. However, as expected the pressure increases very rapidly at low flow rates. At 43 ml/minute a 50% increase in pressure was observed.

These experiments showed that the measured pressure is independent of the nature of the carrier gas in the region of the plateau.

(C) Vapor Pressure Measurements over the Reaction

Measurements of the equilibrium vapor pressures of magnesium were carried out over the temperature range 870 to 1141° C. The results are shown in Fig. 3 and tabulated in Table I.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

TABLE I

Experimental vapor pressure of magnesium

Temp. (° C)	Pressure (mm of Hg)
870	3.55
921	7.56
959	13.3
998	23.6
1072	56.0
1106	89.0
1115	100.1
1117	102.5
1141	143.2

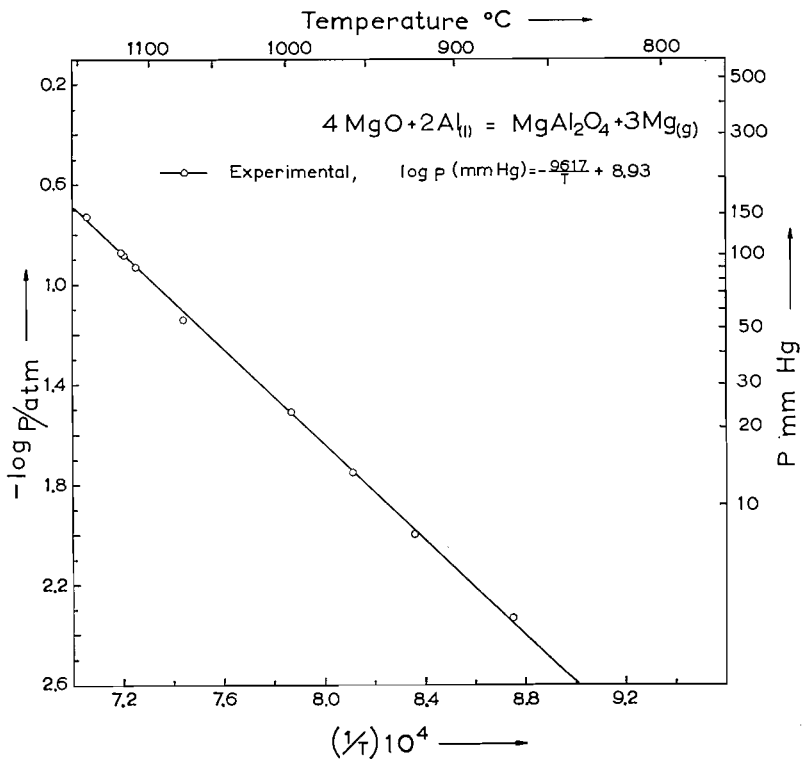

FIG. 3. Log P_{atm} of Mg versus $1/T°$ K.

In the temperature range investigated the data may be represented as a straight line and fitted to the equation,

$$\log P_{\text{mm of Hg}} = -(9617/T)+8.93,$$

where P is pressure in mm of Hg and T the absolute temperature.

(D) Analysis of the Reaction Product

The observed vapor pressure of magnesium in this investigation is in the same order of magnitude as that given by Beljajew (2) for reaction [I]. However, because the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

measured and calculated vapor pressure is so vastly different for this reaction, the reaction product was determined by X-ray diffraction analysis.

It was found that the product is not Al_2O_3 but consisted of the spinel $MgAl_2O_4$ as shown in Fig. 4, and as compared to the ASTM Index (8). When the unreacted MgO and Al were removed by washing the reaction product in 0.5 *M* HCl acid, the resulting X-ray analysis showed only the spinel $MgAl_2O_4$. Chemical analysis of the product also confirmed the formation of the spinel.

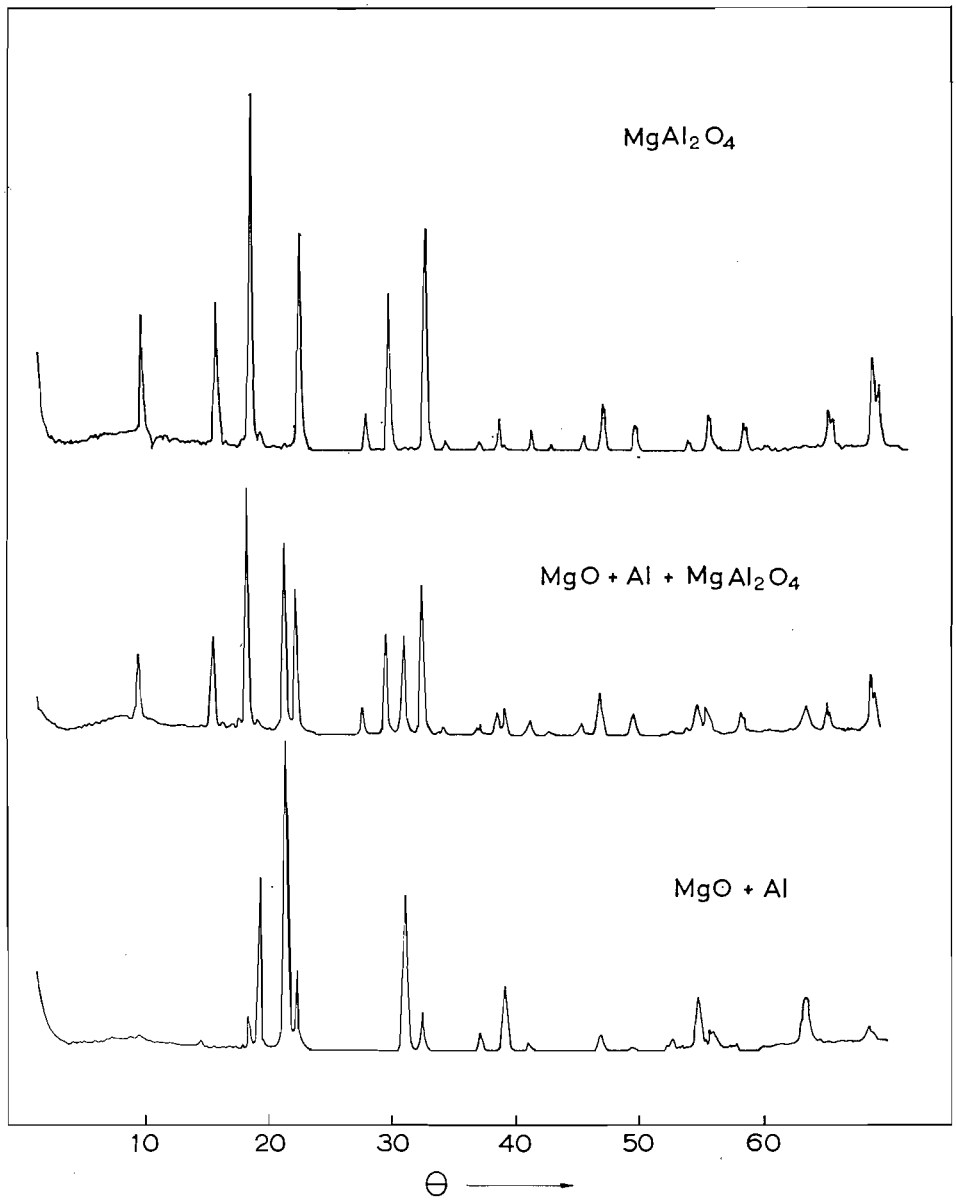

FIG. 4. X-Ray diffraction patterns obtained on using Cu target and Ni filter. The bottom shows the diffraction pattern of the reactants, the middle the residue. The top figure shows the pattern obtained after washing the residue with 0.5 *M* HCl acid, and indicates only $MgAl_2O_4$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The reaction can therefore be represented by the equation

$$4MgO(s)+2Al(l) = MgAl_2O_4(s)+3Mg(g). \quad [II]$$

Upon altering the ratio of MgO/Al from 2/1 to 3/2 the measured vapor pressures were found to be identical.

(E) Thermodynamic Considerations

In the reaction concerned, aluminum appears as a liquid, and thus some solution of magnesium would be expected. For this reason the unreacted aluminum balls were collected from the reaction products and analyzed. In a few experiments small beads of aluminum were placed between the charge and condenser, in the uniform temperature zone, and these were also analyzed. The results at four temperatures are shown in Table II.

TABLE II

Analysis of magnesium in aluminum

Temp. (° C)	Mole% of Mg in aluminum	Activity of magnesium	
		From analysis of aluminum	From pressure measurements
870	3.7±5%	0.037	0.048
921	5.9±5%	0.059	0.056
959	6.0±5%	0.060	0.066
998	10.4±5%	0.104	0.079

Assuming ideality, the activity of magnesium has been calculated from the analysis. This is found to be in good agreement with the activity derived from the measured pressure, as shown in Table II.

Thus it was assumed that within the limits of the error of the analysis, aluminum formed an ideal solution with magnesium at the temperature at which the investigation was carried out.

In order to derive the thermodynamic functions of the spinel $MgAl_2O_4$, the equilibrium constant of the reaction was calculated for each temperature investigated, on the assumption that aluminum formed an ideal solution with magnesium. The phase diagram for the system MgO–$MgAl_2O_4$ (9) shows no solid solubility thus the activity of the oxides are assumed to equal unity. A "Σ-plot" has been carried out using the specific heat functions recommended by Kelley (10). The derived functions are shown in Table III for the over-all reaction.

TABLE III

Thermodynamic functions for the reaction $4MgO(s) + 2Al(l) = MgAl_2O_4(s)+3Mg(g)$ where $a_{Al} = 1$ (in the temperature range 932–1423° K)

$$\Delta C_p = -3.01-0.56\times10^{-3}T-3.86\times10^{5}T^{-2}$$
$$\Delta H^0_T = 137{,}400-3.01T-0.28\times10^{-3}T^2+3.86\times10^{5}T^{-1}$$
$$\Delta G^0_T = 137{,}400+6.93T\log T+0.28\times10^{-3}T^2+1.93\times10^{5}T^{-1}-109.74T$$
$$\Delta H^0_{1280°K} = 133{,}400 \text{ cal}$$
$$\Delta G^0_{1280°K} = 25{,}100 \text{ cal}$$
$$\Delta S^0_{1280°K} = 84.61 \text{ e.u.}$$

NOTE: It must be emphasized that these functions are also subjected to the inaccuracies of the C_p values obtained from the literature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Combining the experimental data with the data on MgO and Al_2O_3 given by Kubaschewski and Evans (3), one obtains for reaction [III]

$$MgO + Al_2O_3 = MgAl_2O_4 \qquad [III]$$

the following data, $\Delta H^0_{298° K} = +1.1$ kcal, $\Delta G^0_{298° K} = -1.9$ kcal, and $\Delta S^0_{298° K} = 10.1$ e.u. The positive heat and the unreasonable large value of the entropy can be accounted for by the assumptions made with respect to the solubility of MgO in $MgAl_2O_4$ and the ideality of the Al–Mg system as well as the uncertainty of the existing literature data which is accumulated in the above type of calculation.

CONCLUSIONS

The reaction between solid magnesium oxide and metallic aluminum was found to proceed according to the equation

$$4MgO(s) + 2Al(l) = MgAl_2O_4(s) + 3Mg(g).$$

The solid reaction product is the spinel $MgAl_2O_4$ and not Al_2O_3 as reported by previous investigators.

The equilibrium pressure of magnesium over this reaction, in the temperature range 850–1150° C, can be represented by the equation,

$$\log P_{\text{mm of Hg}} = -(9617/T) + 8.93$$

as determined by means of the transportation method.

ACKNOWLEDGMENTS

This investigation, one of the series on the reduction of magnesium compounds, has been carried out under a research grant from ELEKTROKEMISKS FORSKNINGSFOND, for which the authors are grateful. One of the authors (J.M.T.) is indebted to the National Research Council of Canada for financial support in a form of a Postdoctorate Overseas Fellowship.

THE CRYSTAL SPECTRUM OF PERYLENE[1]

ROBIN M. HOCHSTRASSER

ABSTRACT

The electronic absorption spectrum of crystalline perylene has been examined in the spectral region 3000–4700 Å. The lowest energy electronic state of perylene has a large oscillator strength and the crystal spectrum deviates considerably from that calculated from a weak coupling (Davydov) model.

The sublimation flakes were examined at room temperature and at the temperature of boiling nitrogen. The lowest energy crystal state was polarized along the crystallographic a-axis (B_u) and the factor group splitting of lowest vibrational envelope of the electronic band was 800 cm^{-1}. The whole spectrum was more intense along the a- than along the b-axis of the crystal. These results are consistent with the notion that the crystal spectrum is derived from dipole-induced dipole interactions between molecular B_{2u} levels of perylene and neighboring unexcited molecules. This assignment of the lowest excited level of perylene is in agreement with theory.

The molecular vibrational structure is severely altered in the crystal and the observed crystal shift is much smaller than that predicted by the Davydov theory.

INTRODUCTION

It is now well established that the Davydov theory of the energy states of molecular crystals (1) can predict to a fair degree of accuracy the main features of the electronic absorption spectra of crystals. The theory has been most often applied to crystals of aromatic hydrocarbons such as naphthalene (2), anthracene (3), and phenanthrene (4).

With the exception of the 2500 Å system of anthracene the Davydov splittings that have been measured are usually from 10 cm^{-1} to 500 cm^{-1}, the actual value depending on the oscillator strength of the transition involved. In the intense short wavelength system of anthracene the splitting is much greater than this (ca. 15,400 cm^{-1}) (5) although in this case detailed examination of the structure is difficult because of the awkward spectral location of the bands.

Perylene has an intense absorption in the visible region and it is the purpose of this paper to present measurements of the polarized absorption spectra of single crystals of perylene and to compare these with the above-mentioned theory.

THE CRYSTAL STRUCTURE OF PERYLENE

Perylene is monoclinic prismatic (6). There are 4 molecules per unit cell occupying the general positions in the space group $C_{2h}^5(P2_1/a)$. The unit cell dimensions are as follows: $a = 11.35$, $b = 10.87$, $c = 10.31$ Å, $\beta = 100.8°$.

The angles which the molecular axes L (long) and M (short) make with the crystal axes a and b are denoted by χ and ψ. The calculated values of these angles along with the oriented gas ratios for absorption intensity along the a and b crystallographic axes for light incident perpendicular to the ab (001) face of the crystal are given in Table I.

TABLE I

The orientation of the molecules in the crystal and the oriented gas ratios

The Energy Levels of the Crystal

It is assumed that the allowed $^1(\pi\pi^*)$ electronic states of perylene are polarized in the molecular plane. In this event the lowest energy molecular singlet level will have the symmetry B_{2u} (short axis polarized) or B_{3u} (long axis polarized). The site symmetry in the crystal is lower than the D_{2h} symmetry of the molecule and each of the molecular levels will split into two allowed crystal states. The polarizations and relative energies of these states—the A_u and B_u representations in the space group C_{2h}^5—can be calculated if the oscillator strength of the molecular transition and the dipole interaction integral summations are known (5). Table II gives the intermolecular interaction integrals within the dipole–dipole approximation. Only the sums over non-translationally equivalent molecules are given; p runs over molecules related by the operation C_2^b (twofold screw along the b-axis) and q runs over molecules related by σ^{ac} (glide reflection in the ac-plane). The geometry factors used were calculated to convergence by Craig and Walmsley (7).

Figure 1 illustrates the type of splitting expected for B_{2u} and B_{3u} molecular levels. In the former case the splitting is 196 cm^{-1} $(Å)^{-2}$ with the B_u (a axis polarized) crystal state at lowest energy. For B_{3u} levels the lowest crystal state is also B_u and the splitting is 2592 cm^{-1} $(Å)^{-2}$. The shift of the crystal spectrum relative to that in solution was calculated from the data of Craig and Walmsley (7) and the results are included in Fig. 1. The B_{2u} and B_{3u} molecular levels are thus predicted to show widely different properties when these crystal interactions are taken into account.

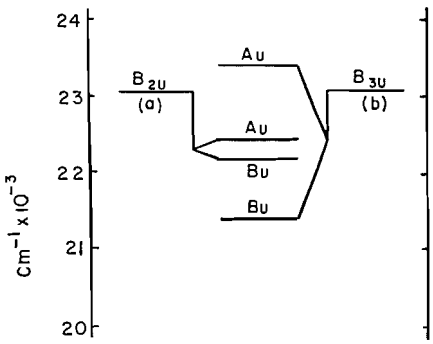

FIG. 1. The predicted arrangement of absorption bands of the perylene crystal for transitions to B_{2u} and B_{3u} molecular levels. Calculated for a dipole length of 1 Å.

EXPERIMENTAL

The perylene was purified further by recrystallization followed by sublimation *in vacuo*. Large rectangular plates were obtained when perylene was sublimed just below its melting point in an atmosphere of carbon dioxide. This was the only method whereby very thin crystals of this substance could be grown. Recrystallization from solution or the melt, sublimation *in vacuo*, and recrystallization between quartz disks all proved unsuccessful techniques in this case. The pure crystals were golden yellow. The thin crystals were pleochroic and exhibited symmetrical extinction under the polarizing microscope. A detailed examination of the isogyre patterns and the order of the interference colors indicated that the plates were basal sections with 001 as the most fully developed face. The b-axis was found to run parallel to the bisector of the slightly obtuse corner of the approximate rectangle. The optic plane of the crystal, containing the

For personal use only.

a-axis, was normal to the exposed surface and bisected the acute-angled edge. Visual observations of the pleochroism indicated that the crystal absorbed most strongly when the electric vector of the light was made to vibrate parallel to the a-crystallographic axis.

The light source was a voltage-stabilized, air-cooled tungsten lamp. The spectrometer has been described previously. For the measurements at 77° K a metal cell was constructed with a copper holder in the nitrogen-free optical path. This cell has been described previously (8). The crystals were mounted over a pinhole by employing their own adhesive properties to metal or quartz. The analyzer was a Wollaston prism. In the low temperature experiments the polarized absorption spectra were obtained by spectrographic examination of each of the beams from the prism. For the experiments at room temperature the crystal was rotated relative to the prism and the optical system was not otherwise disturbed.

The f-number used in this work was determined by integration of the absorption spectrum of perylene in ethanol solution. A value of 5.4 ± 0.3 was obtained. The f-numbers of the vibronic components of the spectrum were obtained from the estimated areas of the individual vibronic bands of the spectrum in ethanol.

The Absorption Spectra

Figure 2 shows the absorption spectrum of a perylene crystal at room temperature. The relative intensities and exact spectral location of the bands were extremely sensitive to the crystal orientation. Figure 3 shows the spectrum of a thicker crystal at room temperature. The bands were much sharper at 77° K but even at this temperature (see Figs. 4 and 5) the details of the spectra were considerably altered by rotating the crystal through only fractions of a degree. This was understandable if the long axis of the molecule was active. This axis makes angles of 83.3° and 89.2° with the a- and b-crystallographic axes and very slight misorientations of the crystal would result in drastic changes of the expected oriented gas ratio of absorption intensities.

Table III shows the band positions measured in both crystal polarizations. The b-

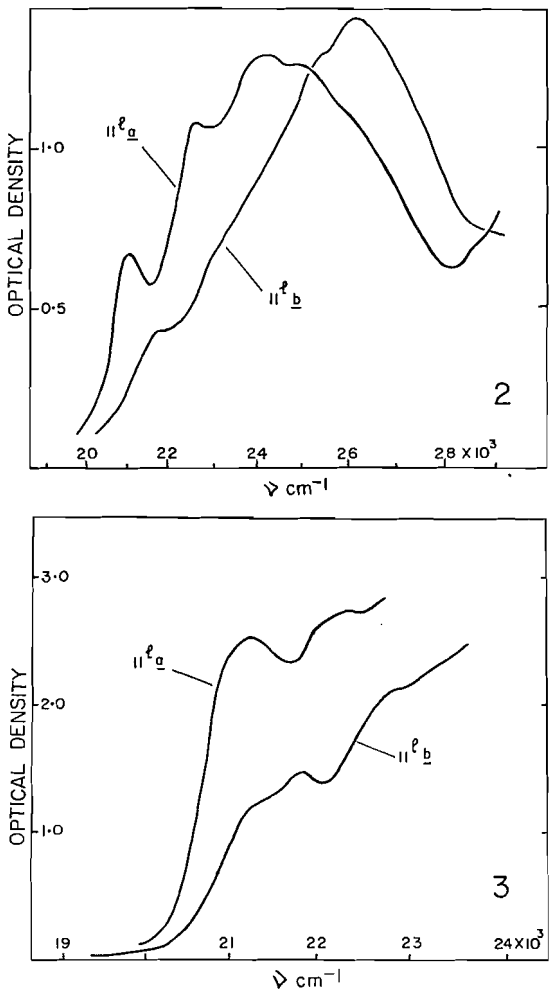
polarized spectra were particularly difficult to interpret owing to the extreme weakness of some of the ill-resolved bands. The values which are quoted on Table III were seldom all observed with one crystal. It is for this reason that four representative spectra are shown.

Only a very broad, weak fluorescence emission was detected and the present experimental technique was not sensitive enough to enable a detailed study to be made. In this regard perylene resembles pyrene (9), a molecule that has also a similar crystal structure (6).



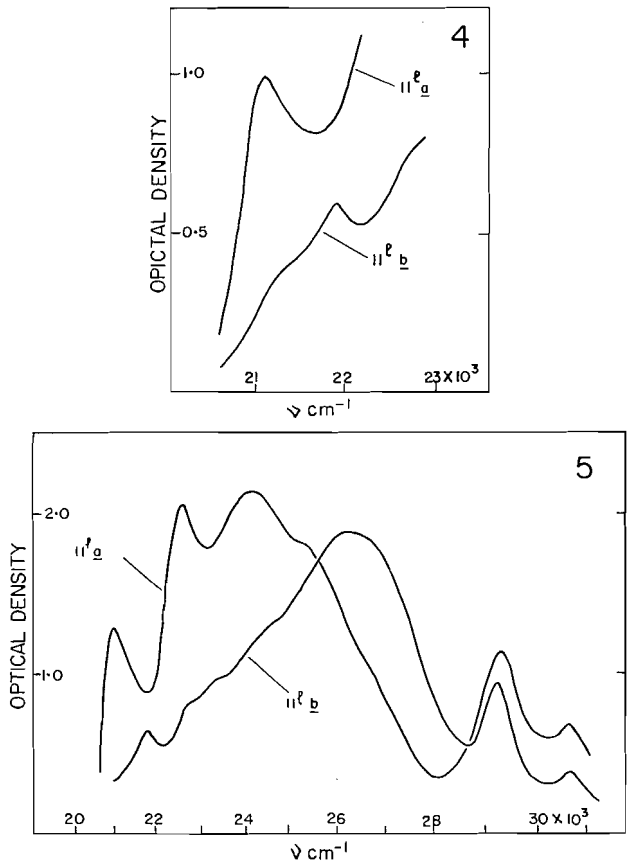


FIG. 2. Polarized absorption spectrum of perylene at room temperature.
FIG. 3. Polarized absorption spectrum of a thick perylene sublimation flake at room temperature.

DISCUSSION

The electronic levels of perylene have not yet received much theoretical attention. Platt (10) has predicted the polarizations of the transitions in this molecule using the simple free electron box model. The three lowest energy singlet states were calculated to have the same polarization properties; namely, they were all long axis polarized states thus belonging to the representation B_{2u} of the D_{2h} point group. A straightforward L.C.A.O.–A.S.M.O. calculation using Hückel orbitals yields the result that the lowest two excited molecular levels should have different symmetry. These two levels are predicted to lie at 19.8 kK (B_{2u}), and 28.4 kK (B_{3u}) respectively (1 kK ≡ 1000 cm^{-1}). A further intense level is expected at 42.4 kK with B_{3u} symmetry. These results are in fair agreement with the solution spectrum (11), which exhibits four separable absorptions in this spectral region. These were assigned on the basis of analogy, band structure, and intensity by Clar (11) as follows: 22.75 kK (p, B_{2u}); 29.60 kK (α, B_{3u}); 34.32 kK (β, B_{2u}); 39.86 (β, B_{3u}).

FIGS. 4 and 5. Polarized absorption spectrum of the perylene crystal at 77° K.

These predictions were substantiated by the results of Williams (11), who has shown that the lowest molecular level of perylene is polarized at right angles to the level at 39.86 kK.

In summary, it may be expected that absorption to the lowest excited singlet state of perylene will be intense and that the next lowest excited level will be active along the short molecular axis of the molecule (B_{3u}).

Figure 6 shows the observed energy scheme for the perylene crystal. A comparison with Fig. 1 clearly indicates that it is the B_{2u} molecular level from which the crystal spectrum is derived. The observed splittings are one order of magnitude too small to be accounted for by interactions between dipoles directed along the short molecular axes.

The over-all intensity of absorption in the *a*-polarized spectrum is greater than in the *b*-spectrum. This observation is in agreement with the predictions in Table I. The polarization ratios, however, were not expected to correlate with the oriented gas ratios in view of the large splitting. The poor agreement between theory and experiment in regard to polarization ratio is probably concerned with the near coincidence of the long molecular axis with the C′-crystallographic axis thus making it difficult to measure this quantity. In any case, the measured quantity in this work was the optical density ratio. This ratio may only be equal to the polarization ratio if the bands have similar shapes and have

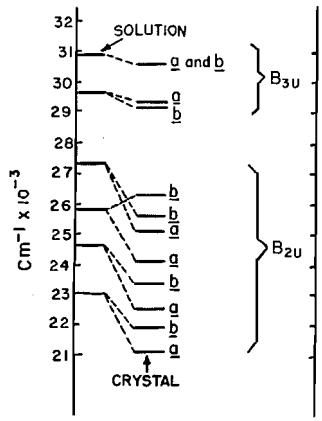

FIG. 6. Comparison of the observed data for perylene in solution and in the crystalline state.

nearly equal frequencies of maximum absorption. Clearly these conditions are not satisfied.

The absorption spectra show four bands in the region 20,000–28,000 cm^{-1}. The relationship between the *a*- and *b*-polarized spectra is apparent for the two lowest energy bands in each polarization (see Table III) but there may be some ambiguity regarding the

remaining bands. The frequency intervals other than that between the two lowest energy maxima do not correspond to a regularly spaced vibrational structure. Nor do the wave numbers between the centers of gravity of the pairs of A_u and B_u states follow any regular pattern. It is expected from the Davydov theory that in the crystal each molecular vibronic state will be split by an amount which depends on the strength of that separate oscillator. Accordingly Table IV gives the experimental *f*-numbers for the four principal vibronic levels of the perylene molecule. The *f*-numbers for the crystal vibronic levels could not be calculated as neither the crystal thickness nor the reflection corrections were known accurately.

*The values in this column refer to the centers of gravity of the pairs of *a*- and *b*-polarized bands which are shown in Fig. 6.

The Coupling Process

The coupling energy of the molecular vibronic forces in the perylene crystal by resonance force interaction is extremely large. The magnitude of the splitting is determined by the crystal geometry and the dipole strength of the crystal under study. It is therefore of interest to examine the applicability of the Davydov model, which was intended to treat only weakly coupled systems. Simpson and Peterson (13) have defined criteria in the form of inequalities which should distinguish one type of coupling from another. Clearly perylene falls into the class of strong to intermediate coupling as the band widths and interaction energies are of the same order of magnitude. The zeroth level splitting of 780 cm^{-1} was in fair agreement with the calculated value of 1098 cm^{-1}. This appears to imply that the Davydov theory is useful even in strongly coupled situations. On the other hand the higher vibronic levels, with the vibrational quantum number of the upper state greater than one, appear to split apart much more than is predicted by the Davydov theory. This suggests that it is the introduction of strong vibrational–electronic coupling which causes the deviations from the simple picture.

If the oscillator strength for a single vibronic transition is f_v then the total oscillator strength of the electronic transition is given by $\sum f_v$. The energy of interaction (splitting) between vibronic states with electronic symmetry B_{2u} is given by θm_v^2 where θ is the appropriate geometry factor and m_v is the dipole length corresponding to f_v. Thus the total interaction energy ΔE is

$$\Delta E = e^2\theta\sum m_v^2 = e^2\sum(\theta m_v^2).$$

The calculated value of ΔE, which is the sum of the splittings in the second last column of Table IV, was found to be 3987 cm^{-1}. Experimentally observed was a total interaction energy of 4290 cm^{-1}, which is in excellent agreement with that calculated within the dipole–dipole approximation.

Thus it is safe to conclude that the lack of agreement between theory and experiment for the individual vibronic transitions did not arise because of the use of a dipole–dipole approximation. Instead it appeared that a drastic redistribution of intensity compared to that in solution had occurred.

The Spectrum at Higher Energies

Above 28,000 cm^{-1} there appears to commence a new electronic transition. This transition is weaker than the first transition and virtually no splitting was observed. In solution there is a weak band at 29,600 cm^{-1}, which Clar assigned as the α'-band. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

absorption in this region is then expected to be due to the excitation of a state belonging to the $^1B_{3u}$ representation of the D_{2h} point group. This band appears to be much stronger in the crystal than in solution. Neither the small splitting nor the polarization ratio would fit with the assignment of the bands as absorption to a short axis polarized level. This region of the crystal spectrum was experimentally difficult to study and some reflection data is needed before the intensity may be measured more accurately.

A more complete account of the absorption spectrum of perylene sublimation flakes, including calculations of the band intensities and the emission spectrum at liquid helium temperature is in preparation.

THE EFFECT OF INTRAMOLECULAR TWISTING ON THE EMISSION SPECTRA OF HINDERED AROMATIC MOLECULES

PART I. 1,1′-BINAPHTHYL[1]

ROBIN M. HOCHSTRASSER

ABSTRACT

The fluorescence spectrum of 1,1′-binaphthyl has been examined in solution, in rigid glass, and in the crystal. It is found that in rigid media the spectral location of the emission is very sensitive to temperature. At 300° K the band is broad and structureless with a maximum at 26,700 cm^{-1} and a zero–zero band at about 30,200 cm^{-1} with very low intensity. The same is true at 273° K and 195° K. At temperatures below 157° K structure starts to appear until at 77° K the center of gravity of the emission is around 29,000 cm^{-1} and the 0–0 band at 31,270 cm^{-1} is quite clear and strong. Even at 77° K there is apparent a broad, but now weak band at 27,260 cm^{-1}. In the crystal the spectrum is broad and structureless at 300° K with a maximum emission intensity at 26,300 cm^{-1}. On lowering the temperature to about 142° K the intensity is built up on the high energy side of this band until eventually a new peak at 27,850 cm^{-1} becomes apparent at 77° K.

These results are interpreted on the basis of unsymmetrical potential energy variations with angle of twist which permit two origins for the fluorescence spectra of double molecules of this type.

INTRODUCTION

Aromatic molecules which consist of two identical planar aromatic systems joined through a single carbon–carbon bond may exhibit ultraviolet spectra which are either very different from or virtually identical with the known spectrum of one half of the molecule. If the rings are coplanar then resonance interaction is strong and the spectrum of the double molecule is vastly different from that of the isolated chromophores. If the molecular planes are perpendicular, the systems are essentially non-interacting, within a π-electron approximation, and the double-molecule spectrum does not appear different from that of one ring of the system. Perhaps the most extensively studied group of compounds in this regard are the biphenyls (1).

The binaphthyls were studied by Friedel and Orchin (2) and the ultraviolet spectra in solution at room temperature indicated that resonance interaction was at a minimum for 1,1′-binaphthyl whose spectrum was quite similar to that of naphthalene. 2,2′-Binaphthyl on the other hand exhibited a spectrum which extended much further to the red than did that of naphthalene, and in this case the steric inhibition of resonance was presumed to be at a minimum.

Unfortunately the spectra of these materials at room temperature are characteristically broad, and exact spectral comparisons are out of the question. The same is true of the luminescence spectra (phosphorescence and fluorescence) so that from such spectra little can be explained of the exact spectral shifts or of the true degree of interaction between the ring systems.

In this work a detailed study has been made of the low temperature absorption spectrum of 1,1′-binaphthyl and of the fluorescence and phosphorescence spectra of this compound at a variety of temperatures and in various rigid media.

EXPERIMENTAL

The low temperature absorption spectra were taken on a Cary 14 recording spectrophotometer. The low temperature cell has been previously described (3). Extinction coefficients were calculated after corrections for contraction on cooling from 300° K to 77° K.

The fluorescence and phosphorescence spectra were excited by one of the mercury 3131 Å group of lines from a G.E. AH6 arc. A good monochromatic source was obtained by using a high aperture Bausch and Lomb grating monochromater with the entrance and exit slits at 1 mm in conjunction with the mercury arc. The parallel beam from the monochromater was directed onto the sample, which was contained in a quartz test tube, itself immersed in an unsilvered quartz Dewar flask. When the coolant was transparent to 3130 Å an immersed region of the solution was irradiated, otherwise the region just above the coolant surface was used.

The emission was focused on the slit of a medium Hilger quartz spectrograph. In order to obtain comparative fluorescence and phosphorescence curves the emission was recorded automatically. The travelling photomultiplier (R.C.A. 1P28) photocurrent was amplified by a Keithley (200B) vacuum tube micromicroammeter.

The solvents used were E.P.A. (ether, 5 parts; isopentane, 5 parts; ethyl alcohol, 2 parts); ethyl alcohol, which forms a slightly strained but nevertheless useful rigid glass at liquid nitrogen temperature; *n*-heptane, which when freshly distilled forms transparent crystals at 77° K; glycerol, which is virtually transparent to 3131-Å radiation (log I_0/I 0.12 in 1-cm path) and forms a rigid glass over the range 273° K–150° K. Dextrose and *n*-hexadecane were also used as solvents.

The following were employed as coolants: boiling nitrogen (77° K); *n*-pentane (142° K); diethyl ether (157° K); solid carbon dioxide (195° K); and melting ice (273° K).

RESULTS

Figure 1 shows the absorption spectrum of 1,1′-binaphthyl in ethyl alcohol at 300° K and in E.P.A. at 77° K. Only the long wavelength region is shown in the figure. Figure 2 shows the total emission spectra of naphthalene and 1-1′-binaphthyl in alcohol at 77° K. These spectra emphasize the similarity of vibrational structure in each tracing. The intensity scale in Fig. 2 was chosen such that the area under each of the fluorescence curves was comparable.

Figure 3 shows the fluorescence spectra of 1,1′-binaphthyl in glycerol at 273° K and 142° K; the fluorescence of 1,1′-binaphthyl in alcohol at 77° K is also shown in Fig. 3. Again, the curves were adjusted until they had similar areas on the drawn scale.

The 0–0 band of the lowest energy transition was measured at room temperature in ethyl alcohol and in the same solvent at 77° K. The crossing point of the broad high temperature absorption and emission curves was taken as the 0–0 band energy in this case. At low temperatures the mirror relationship between the long wavelength absorption and the fluorescence permitted accurate measurement of the 0–0 band energy. Table I

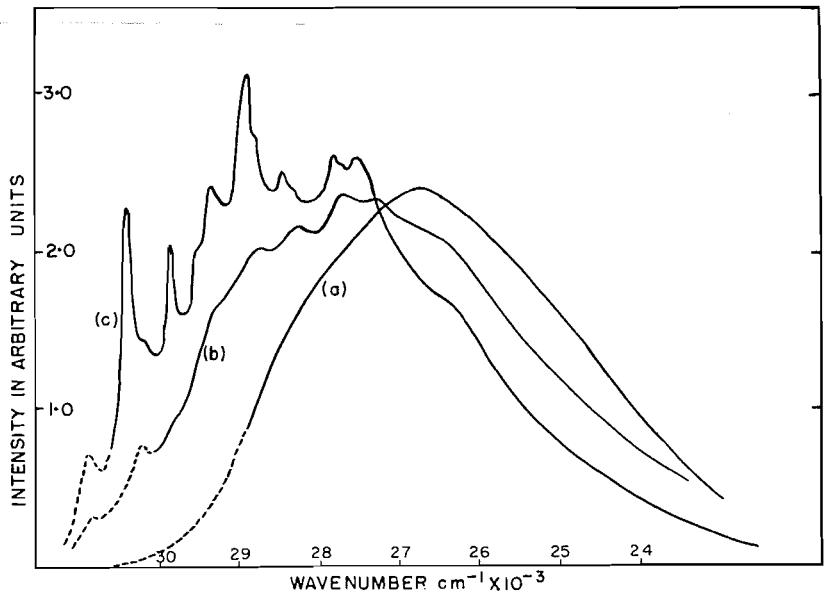

FIG. 3. The effect of temperature on the fluorescence spectrum of 1,1′-binaphthyl. (*a*) Glycerol, 273° K. (*b*) Glycerol, 142° K. (*c*) Ethyl alcohol, 77° K. The regions where very slight corrections for reabsorption of fluorescence may be necessary are covered by dashed curves.

summarizes these measurements. In all the experiments described so far the concentration of 1,1′-binaphthyl (10^{-4} *M*) and the optical arrangement, as far as possible, were uniformly maintained. When necessary, proper corrections were made for reabsorption of the fluorescence emission. The spectral response of the photomultiplier was not linear over the whole spectral range of phosphorescence plus fluorescence. However, the naphthalene spectra were so similar to those of the double molecule that accurate comparisons could be made without a complete spectral response curve. The phosphorescence emission spectra of naphthalene and 1,1′-binaphthyl were similarly located in the spectrum so that they also could be compared without a detailed knowledge of the spectral response curve.

The following is a summary of the experimental results including a few observations which may not be clear from the foregoing figures and description.

(1) The 0–0 band position was different at 300° K to that at 77° K. However, the error on the former measurement was large (see Table I).

(2) The center of gravity of the fluorescence band lay at $27{,}370 \pm 80$ cm^{-1} at 300° K, 273° K, or 194.7° K; the band was then broad and devoid of vibrational structure. At 77° K and 142° K vibrational structure was evident and the center of gravity of the spectrum was around 29,000 cm^{-1}.

(3) No radical changes were effected in the spectra at any temperature by altering the medium. This is clear from Table II. There were, however, marked changes in the phosphorescence – fluorescence yield ratios which will be discussed in a later paper.

(4) The 0–0 band of 1,1′-binaphthyl in alcohol was found to lie only 460 cm^{-1} to lower energies than that of the corresponding transition in naphthalene.

(5) Apart from the more subtle changes in the relative intensities of some vibrational bands in the low temperature fluorescence spectra, there was a shoulder at 27,260 cm^{-1}

in all of the liquid nitrogen temperature spectra. There is no such shoulder in the naphthalene spectrum. The emission in this region was thus at about the same energy as the emission maximum of the higher temperature spectra.

(6) A similar set of phenomena have been observed for 1-phenylnaphthalene and to a lesser extent for biphenyl and 2,2′-binaphthyl. These results are being prepared for publication.

The Fluorescence Spectrum of the Crystal

The crystal emission was broad and structureless at 300° K with a peak at 26,300 cm^{-1}. At 77° K a little structure appeared at the high energy side of the band but the band maximum was shifted to 27,850 cm^{-1}. This blue shift amounted to 1550 cm^{-1} and was comparable to the shift of the center of gravity of the rigid glass fluorescence over the same temperature range. These spectra, which are shown in Fig. 4, were from randomly oriented crystals and they were not corrected for reabsorption of fluorescence. The spectra were taken under conditions which would minimize the reabsorption, i.e. front face illumination, and this correction probably becomes important at about 29,000 cm^{-1}. The third spectrum of Fig. 4 is of the crystal fluorescence at 194.7° K and the fourth was taken with the crystals at 157° K. From these spectra it was apparent that the 26,300 cm^{-1} band was not actually shifting to the blue with decreasing temperature but rather the intensity of the emission in this region was dropping as the intensity in the 27,850 cm^{-1} region was increasing.

The crystal spectra, solution spectra, and the fluorescence spectra in rigid glasses and their variations with temperature strongly indicate that emission is arising from two origins in the molecule of 1,1′-binaphthyl and that the *lower* energy level is favored at room temperature.

Vibrational Analysis of the Fluorescence in Alcohol

Table III compares the spectra of naphthalene and 1,1′-binaphthyl. It is quite clear from this analysis that the naphthalene state from which the emission occurs and the ground state at this same instant are not much affected by the presence of another α-naphthyl group. Thus at low temperatures the molecule behaves like two virtually non-interacting naphthalene molecules. Clearly there is no naphthalene analogue for the

shoulder of medium intensity which appeared at 27,260 cm^{-1}. The analysis is based on the more complete findings of Bolotnikova (4), who studied naphthalene in pentane at 77° K.

Of the more subtle differences between the spectrum of 1,1′-binaphthyl and naphthalene is the large change in the frequency of the b_{1g} vibration (495 cm^{-1} in naphthalene ground state), which is lowered to 360±20 cm^{-1} in 1,1-binaphthyl. It has been suggested that this vibration is one of those responsible for the appearance of short axis polarized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

absorption in the spectrum of the lowest energy $B_{2u} \leftarrow A_{1g}$ (long axis polarized) transition in naphthalene (4). If this in fact is the case, vibrations of this symmetry would be more modified in the double molecule than the totally symmetric ones because at interplanar angles around 90° the dipole–dipole interaction – vibronic coupling between the rings can only be significant for short axis polarized levels. In future experiments at higher resolution these discrepancies may be cleared up.

DISCUSSION

Firstly it is of interest to discuss the results in terms of known models. Jaffé and Orchin (5) have recently proposed a model to explain the wavelength shifts and intensity variations in hindered stilbenes. In this model the potential energy curves for the upper and lower states have double minima. These arise after the superimposition of a rotation barrier on the usual resonance potential versus angle of twist curve. The barrier is assumed small compared to the resonance stabilization at zero twist, and because the resonance interaction is not the same in both states it follows that the equilibrium angle of twist is not the same in the upper and lower states. The 1,1′ bond is most likely shorter in the upper state so the ground and excited state rotation barriers may not be identical.

If such a model is accepted for 1,1′-binaphthyl then the fluorescence spectrum would not be expected to alter markedly with temperature. Certainly the center of gravity of the emission would remain at the same energy at all temperatures in view of the Franck–Condon principle. Besides this, the experiments show that the spectral location of the bulk of the emission intensity red shifts as the temperature is raised, which would imply that the ground state potential curves were steeper than those of the upper state. This is contradictory to an increase of resonance interaction in the upper state. Even the postulate that emission may occur from highly excited twisting modes does not explain the observed phenomena on this model.

The Probable Configuration of 1,1′-Binaphthyl

In the trans planar configuration the 2–8′ and 8–2′ repulsions must be very great. In this configuration (see Fig. 5(*a*)) the molecule could be likened to 3,4-benzphenanthrene, which is known to be distorted from the planar configuration (6). In the cis planar configuration the interactions are akin to those in biphenyl (for the 2–2′ positions) and

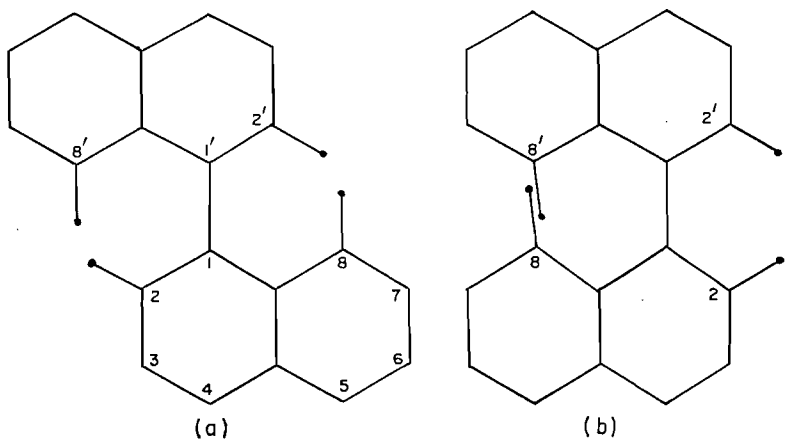

FIG. 5. 1,1′-Binaphthyl: (*a*) Trans-planar, (*b*) Cis-planar. C—H bands were drawn to terminate at the hydrogen nucleus in each case.

For personal use only.

3,4-5,6-dibenzphenanthrene (for the 8–8′ positions). Certainly in the latter there is a large repulsion as dibenzphenanthrene is non-planar (7). The repulsions in 1,1′-binaphthyl will be smaller than those of the above analogies as the 1–1′ bond is presumably longer than for the condensed hydrocarbons.

Calculation has shown that when the H—H and C—C repulsions are minimized, i.e. the molecule is rotated about 1–1′ until each H—H and C—C distance is maximized and as near as possible equalized, then the most stable configuration on this basis is with the rings inclined to cis with an angle of 78° between the ring planes. Trotter (8) has recently determined the configuration from X-ray data at room temperature; the cis configuration was confirmed and the angle was 72°. The angle of twist was measured from 0° at the cis planar configuration.

It was also clear, both from the above discussion of the polynuclear hydrocarbon analogues and from geometrical calculations, that the energy required to reduce the angle by any given amount from 78° is much greater than the energy required to increase the angle by the same amount. This implies that the repulsion energy versus angle of twist curve will be *much steeper on the low angle (or cis) side of the equilibrium situation* than on the high angle (or trans) side.

The 1,1′-binaphthyl-5,5′-dicarboxylic acid has been resolved into optically active isomers at room temperature (9). This indicates that the rotation barrier is extremely large both at the trans and cis planar configurations.

The Resonance Energy of Interaction between Rings

There is some confusion regarding the resonance interaction between the two naphthalene units. On the one hand Magnus and Becker (10) have found an experimental resonance energy of 174.4 kcal for 1,1′-binaphthyl. From this they concluded that the molecule was planar. This result is at variance with conclusions from the optical activity of the 5,5′-dicarboxylic acid and the X-ray data, both of which indicate a severely twisted molecule. The ultraviolet absorption spectrum does not differ considerably from that of naphthalene, nor does the low temperature fluorescence spectrum; these results indicate that neither in the ground nor the excited state are the two rings strongly interacting. The broadness of the absorption spectrum in solution is most likely caused by librations about the equilibrium angle rather than by a permanent, strong, resonance force interaction.

The assumption will be held here that the resonance stabilization energy in the ground state is small in comparison to the van der Waals repulsive energy in either of the planar situations. In biphenyl the experimental resonance interaction energy is about 6 kcal/mole (2080 cm^{-1}) in the gas phase where the interplanar angle is probably near 45°. Thus the planar form should be stabilized by at least 12 kcal/mole.

After electronic excitation it is likely that the 1–1′ bond will be shortened because of the redistribution of charge at the 1 and 1′ carbon atoms. The resonance interactions in the excited state will therefore be greater than in the ground state.

The Potential Curves for the Ground and Excited States

Figure 6 shows the approximate variation of van der Waals repulsion energy with the interplanar angle. The curve is drawn steeper to the cis side in accordance with the above discussion. The dotted curve in Fig. 6 indicates the variation of the resonance interaction energy with interplanar angle and the extent of this variation is assumed to be larger in the excited state.

The van der Waals repulsive curves are drawn approximately in order that the ground

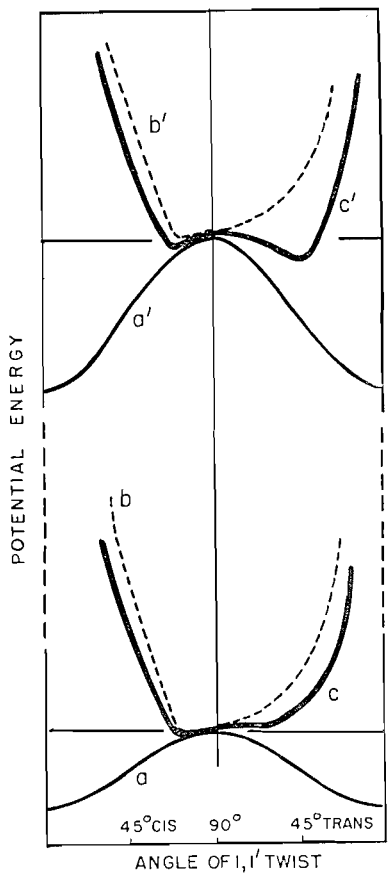

FIG. 6. The potential curves of the ground and excited states of a sterically hindered double molecule. Dashed curve: the non-uniform van der Waals repulsive energy. Thin line curve: resonance interaction. Thick line curve: resultant variation of potential with angle of twist.

NOTE: *The resonance interaction potential may not, in the general case, be symmetric about* $\theta = 90°$. *However, this is probably the case for molecules such as biphenyl, 1-phenylnaphthalene, and 2,2'-binaphthyl for which comparable experimental data has been collected. Therefore the particular case of 1,1'-binaphthyl, where the resonance interaction is greatest in the trans planar configuration and non-zero when the interplanar angle is 90° is avoided in this more general diagram. The curves on Fig. 7, on the other hand, refer specifically to 1,1'-binaphthyl. The resonance interaction energy discussed above is taken to be the potential energy of interaction of two dipoles (dipole-induced dipole) each of which is directed along the long axis and in the plane of one half of the molecule.*

state minimum occurs when there is about 72° between the ring planes. The same curves have been drawn in the upper state although in fact the repulsive forces in the upper state may be considerably altered. The equilibrium angle may also be different in the excited state but in the absence of detailed information on this point the minimum at 72° is drawn for both the ground and excited states. It is not thought that these assumptions will seriously affect the ensuing discussion.

In Fig. 6 the curve of the upper state has two potential minima while the ground state curve has only one. The trans-side minimum in the upper curve is probably lower than the cis-side minimum and it is certainly broader. This implies that molecules in this configuration are flapping with greater amplitude than molecules with the same thermal energy in the cis configuration.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

It should be emphasized that potential energy curves of this type will arise even if the molecule under consideration does not have the trans and cis planar configurations. All that is required is that the equilibrium configuration is different from 90°. This condition may also be satisfied in phenylnaphthalene. For this molecule the 2 and 6 phenyl positions are subject to different repulsion energies at the planar position. Phenylnaphthalene would therefore be at least less planar than biphenyl on the basis of atom – atom repulsion energy.

The Fluorescence Spectra

It is proposed that there are two fluorescence origins in double molecules of this type. The origins arise because of the asymmetry of the potential energy in relation to angle of twist. Figure 7 shows one arrangement of ground and excited state potential curves

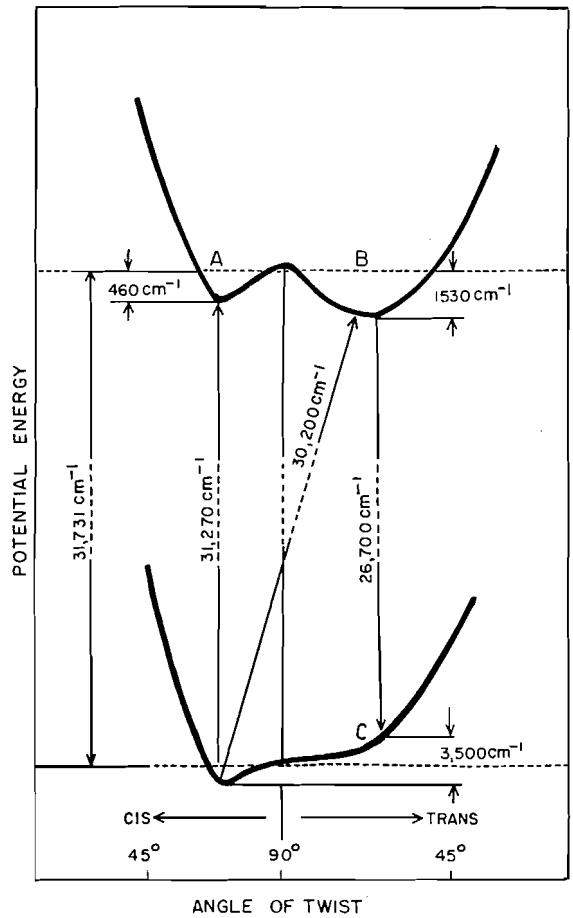

FIG. 7. The potential energy versus angle of twist relationships for 1,1′-binaphthyl: a model which accounts for the emission spectrum.

which may account for all the observed features of the fluorescence spectra of 1,1′-binaphthyl. It has been shown in the foregoing that curves of this type can arise from a combination of van der Waals and resonance forces which have slightly dissimilar angular variations in the ground and excited electronic states.

The difference in energy between the zero-point vibrational levels in the minima A and B is given by the difference in 0–0 band frequencies at 77° K and 300° K, that is 1050 cm^{-1}. This is necessarily approximate due to the uncertainty in the measurement at 300° K. The upper limit to the depth of minimum A is given to a first approximation by the difference in 0–0 band energies of naphthalene and 1,1′-binaphthyl at 77° K, that is 480 cm^{-1}. Thus the depth of the potential minimum B is approximately the sum of these two derived quantities (1050 + 480) cm^{-1} yielding 1530 cm^{-1}. The energy difference between the configuration represented by C in Fig. 7 and the zeroth vibrational level in the ground state is then 3500 cm^{-1} assuming vertical transitions (31,730–26,700–1,530 cm^{-1}).

At temperatures below room temperature virtually all molecules have a cis-inclined configuration and this configuration must be maintained immediately after light absorption in accordance with the Franck–Condon principle. Thus newly formed excited molecules have A-type configurations with an excess of vibrational energy. Within an extremely short time after this, the excited molecule will be vibrationally deactivated while retaining the cis configuration. This will arise because the twisting frequency should be small and hence the twisting time large (10^{-11}–10^{-12} seconds) in comparison to the time of vibrational deactivation (10^{-13} seconds). At a short time after light absorption the excited molecules will be in thermal equilibrium with the surrounding medium and the configuration A will be preferred. The potential barrier between A and B then determines the number of excited molecules which will remain in state A.

The height of this potential barrier is, however, not the only factor which will determine the relative yields of emission from state A and state B. It is unlikely that the rates of fluorescence emission will be the same in each of these states. Although the natural radiative lifetimes between the excited states and the ground state may be about equal in each configuration, any difference in the form of the potential minima, which describe the amplitude of any particular twisting mode, will alter the actual lifetimes of emission from these levels. Due to the different ring orientations in each minimum the internal conversion processes which bring about non-radiative transitions to the ground electronic state will not necessarily be identical for type A and B situations.

The following situations are envisaged after light absorption: (*a*) At 300° K—the thermal energy ($kT \doteqdot 200$ cm^{-1}) is comparable to the barrier height (<480 cm^{-1}) and the rate of emission from state A is considerably slower than from state B. Thus nearly all the radiatively lost energy originates from state B where the barrier height (1530 cm^{-1}) is large in comparison to kT. (*b*) At 77° K—the thermal energy ($kT \doteqdot 48$ cm^{-1}) is now small in comparison with the barrier height. Thus only about 5% of the emission will originate from state B (for a barrier of 480 cm^{-1}). (*c*) At intermediate temperatures both states will emit to some degree. The critical temperature appeared to be about 130° K ($2kT \doteqdot 140$ cm^{-1}), which may mean that the barrier height was overestimated by spectral measurements.

On the basis of the model presented here the experimental value of the zero–zero band energy at 300° K must lose significance. Instead the measured value is an upper limit of the actual value of the difference in energy between the zeroth level of the ground state and the zero-point vibrational level of the type B potential energy situation of Fig. 7. This stipulation is necessary because of the impossibility of knowing the exact form of the absorption to state B at the higher temperatures. The curve (*c*) in Fig. 1 is almost certainly composed of absorption to both A and B. In this event the zero (ground state) to zero (state B) energy can only be at lower energy than the measured value.

In conclusion, and in conjecture, it may be possible to say which of the potential curves has the greatest amplitude for the low frequency twist. The configuration which occupies the greatest volume (i.e. the trans) would probably exchange vibrational energy most rapidly with the surrounding medium. Thus the internal conversion from this to the ground level might be greater than for the cis configuration. This would imply that the curves A and B should be interchanged such that A is at lowest energy while B becomes shallow and flat-bottomed. The phosphorescence results do indicate that intersystem crossing is more favorable from the emitting level in 1,1′-binaphthyl than from the lowest singlet state of naphthalene (see Fig. 2). This problem will be treated more fully in Part II of this series.

CONCLUSIONS

Still many questions remain to be answered in regard to the effect of intramolecular twisting on the spectra of molecules of this type. Similar studies to the above on biphenyl, stilbene, 1-phenylnaphthalene, and 2,2′-binaphthyl and on the phosphorescence spectra of these materials are in preparation for publication. It is believed that much detailed information, some of this previously unforeseen, may be extracted from a study of the luminescence of such compounds.

It is not inconceivable that two emission origins A and B could arise for some other reason than has been presented here. The upper state of naphthalene would certainly be split into two double-molecule states of different polarization and radiative lifetime (11). It is also conceivable that one of these states is preferred over the other only at certain interplanar angles. Polarized fluorescence measurements will help to clear up these points. Preliminary calculations within a dipole–dipole approximation have, however, strengthened the present interpretation. The resonance interactions between the rings in the excited state at the cis, 90°, and trans configurations are in the respective ratios 0:1:5. These calculations indicate that the resonance interaction potential also varies in a non-uniform manner with angle of twist. The inclusion of this refinement in Fig. 7 would pull the minimum B down even further below A.

THE INFRARED FREQUENCIES AND INTENSITIES OF THE HYDROXYL BAND IN ORTHO-SUBSTITUTED PHENOLS[1]

K. U. INGOLD AND D. R. TAYLOR[2]

ABSTRACT

The infrared frequencies, intensities, and half-band widths of the fundamental stretching vibration of the hydroxyl group have been measured for a large number of ortho-alkyl phenols. It has been found that phenols containing a single ortho-alkyl substituent exist as cis and trans isomers in unequal amounts, the trans isomer being the more abundant. The difference in free energy between the two isomers in dilute solution in carbon tetrachloride at 24° C has been measured for ortho-cresol, 2,3-dimethyl phenol, and several ortho-*tert*-alkyl phenols.

INTRODUCTION

The fundamental frequencies of the hydroxyl group in *o*-alkyl-substituted phenols have been reported for a rather limited range of alkyl substituents by a number of workers (1, 2, 3, 4), but, with the exception of 2,6-di-*t*-butyl-4-substituted phenols (5), there has been no systematic study of the effect of these substituents on band intensities. The present work describes a comprehensive examination of both the frequencies and the intensities over a large range of *o*-alkyl substituents.

The O—H vibrational frequency, in carbon tetrachloride solution, of 2,6-di-*t*-butyl phenol is 36 cm^{-1} higher than phenol (5) and since the O—H band is coplanar with the ring in both cases (5) it should therefore be possible to observe two bands in the spectra of *o*-*t*-butyl phenol, and perhaps in other *o*-*t*-alkyl phenols as well. The two bands would correspond to geometrical isomers i.e. cis and trans structures in which the O—H group points towards the alkyl substituent and away from it, respectively. These two bands were, in fact, observed in all *o*-*t*-alkyl phenols, and while this work was being prepared for publication Goddu (6) reported finding two bands in *o*-*t*-butyl phenols and in 2-*t*-butyl-6-methyl phenols.

The possibility of detecting geometrical isomerism in non-tertiary-alkyl-*o*-substituted phenols was also examined.

EXPERIMENTAL

A Beckman I. R. 4 spectrophotometer with lithium fluoride optics was used to measure the O—H bands, the frequencies being calibrated by the standard absorption lines of water vapor. The effective slit width was about 4 cm^{-1}. Carbon tetrachloride was employed as the solvent and solution concentrations (C) were in the range 0.01 to 0.002 molar. Three cells of thickness (l), 1, 5, and 10 mm were used. Throughout this paper the term "intensity" (A) refers to the ratio, for the substituted phenol to phenol, of the apparent integrated absorption intensities, i.e. the band areas, and numerical values of A are given relative to the intensity of phenol. The band areas were obtained from the product of the half-band width ($\Delta\nu_{\frac{1}{2}}$) and the molecular extinction coefficient ($E_{max} = (1/Cl) \log_{10} (I_0/I)\nu_{max}$) (7).

Many of the phenols employed were commercial products which were purified by recrystallization or distillation before use. The purity of the liquid samples was checked

[1]*Manuscript received November 1, 1960.*

by gas chromatography and some of the phenols were purified on a preparatory column. The phenols 2-*t*-amyl-4-methyl; 2,6-di-*t*-amyl-4-methyl (8); 2-*t*-*t*-octyl-4-methyl (m.p. 50–51.2°) (9);* 2,6-di-*t*-*t*-octyl-4-methyl (m.p. 53.2–54.2°) (9); 2-triethylmethyl-4-methyl (m.p. 43–44°); and 2,6-di-triethylmethyl-4-methyl (m.p. 44°) were obtained by alkylation of *p*-cresol with the appropriate olefin by the method of Stillson, Sawyer, and Hunt (8). The hindered (2,6-substituted) and partially hindered (2-substituted) *p*-cresols were separated by adsorption chromatography on alumina. The yield of the last two hindered phenols was only 5 or 10%. 2-*t*-Butyl-5,6-dimethyl phenol (m.p. 52–53°) was obtained by alkylation of 2,3-dimethyl phenol with the theoretical amount of isobutylene. 2,6-Di-*t*-*t*-octyl-4-formyl phenol (white needles, m.p. 157–158°) was prepared in 25% yield from the 4-methyl derivative by oxidation with bromine (10). The main product of this reaction is a yellow crystalline material m.p. 124° C, the infrared spectrum of which suggests a para-quinolide structure (11). Since it appears to contain an equimolar quantity of HBr the analysis suggests it is 4-bromo-4-methyl-2,6-di-*t*-*t*-octyl-cyclohexadiene-2,5-one-1, hydrobromide. Analysis: Found C, 56.4; H, 8.15; Br, 32.6. Calculated for $C_{23}H_{40}OBr_2$: C, 56.1; H, 8.19; Br, 32.4.

2-*t*-*t*-Octyl-4-methyl-6-*t*-butyl phenol (m.p. 33–34°) was prepared by butylating 2-*t*-*t*-octyl-4-methyl phenol.

We are indebted to the Eastman Kodak Co. for gifts of the following phenols: 2,4,6-tri-*sec*-butyl; 2,4-di-*n*-amyl; 2,4,6-tri-*n*-amyl; 2-*n*-decyl-4-methyl; and 2-*sec*-dodecyl-4-methyl.

RESULTS

It has been shown previously (5) that the frequencies of the O—H band maxima (ν_m) for 4-substituted phenols and for 4-substituted-2,6-di-*t*-butyl phenols can be correlated by a Hammett $\rho\sigma$ relation. Two parallel straight lines were obtained whose slopes (ρ) were both -13.7 cm^{-1}. The intensities of the two groups of substituted phenols relative to phenol and to 2,6-di-*t*-butyl phenol respectively can be represented on a Hammett plot by a single straight line whose slope equals 0.37 (5). The measured values of ν_m and of the intensity relative to phenol (A) for the phenols studied here have therefore been compared with the values calculated from the Hammett equation to show up any departures from the predicted values. $\Delta\nu_m$ represents the difference between the measured and calculated values of ν_m and ΔA represents the difference between the measured and calculated values of A. It has been assumed in the calculations that the σ constant for an ortho substituent is the same as that for a para substituent (12). The σ values for the *t*-*t*-octyl and triethylmethyl groups have been assumed to be -0.19 and -0.18 respectively for structural reasons. All results are averages of at least two experiments.

The frequencies of single bands and of the main band in those phenols which show a double band are probably relatively correct to within 1 cm^{-1}.† Relative intensities should be correct to within about ± 0.05. The absolute intensity of phenol obtained by graphical integration over the absorption band using $\log_{10}(I_0/I)$ and applying Ramsey's correction for the wing absorption (7) has been redetermined to be 5.30 (1×10^4 mole^{-1} liter cm^{-2}). If the band is measured only to the flat wings of the curve (13) the intensity is 4.35 in the same units. These values are in good agreement with other recent estimates (13).

The results obtained with those phenols which were substituted with at least one *t*-alkyl group in an ortho position are given in Table I. The symmetrically substituted

*The *t*-*t*-octyl group is* $(CH_3)_3CCH_2(CH_3)_2C$—.

†*Frequencies given in reference 5 were low by 2 or 3 cm^{-1} owing to an error in the spectrometer calibration.*

For personal use only.

phenols show only a single band but the asymmetrically substituted compounds show a complex band which consists of a main band at approximately the same frequency as phenol and a smaller, incompletely resolved band at a frequency approximately that of the 2,6-di-*t*-alkyl phenol. The value of ν_m for the side band is probably correct only to 2 or 3 cm^{-1}, owing to the difficulty of separating the contribution from the main band. Typical spectra are shown in Fig. 1. Table I also includes the ratio of the intensities of the two bands (denoted by $A(\text{trans})/A(\text{cis})$).

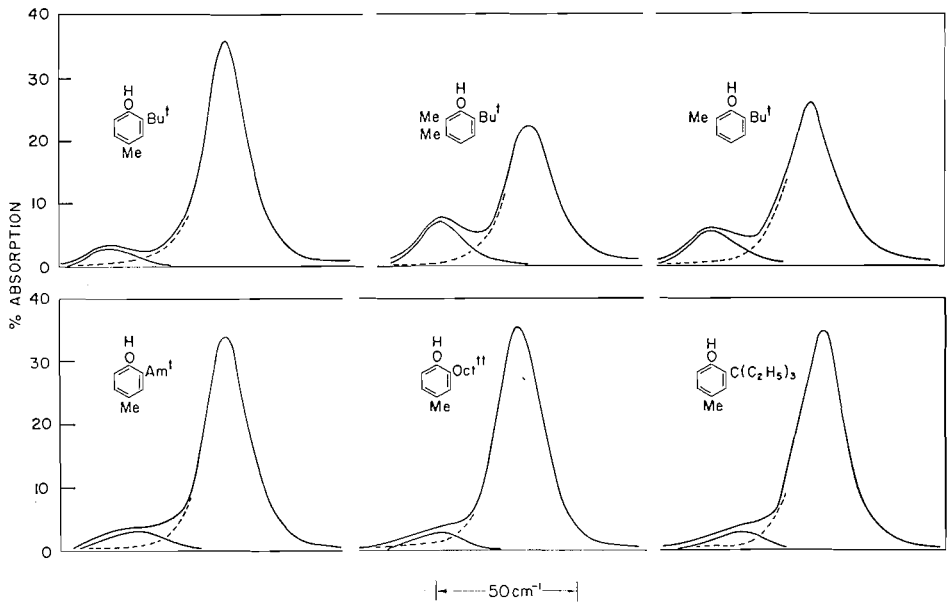

FIG. 1. The fundamental O—H vibration bands of ortho-*tert*-alkyl phenols.

The results obtained with phenols which do not contain an ortho-*t*-alkyl substituent are given in Table II.

DISCUSSION

The increases in frequency observed with 2,6-di-*t*-alkyl phenols compared with phenol are too large to be explained by the polar contributions of the *t*-alkyl groups. It has been shown previously (5) that the increase associated with 2,6-di-*t*-butyl phenols cannot be attributed to the twisting of the O—H bond out of the plane of the benzene ring. Similar evidence that the O—H bond is coplanar with the ring, or at least is nearly coplanar, has now been extended to 2,6-di-*t*-*t*-octyl phenols.

The fundamental stretching frequency of the C=O group in substituted benzaldehydes has been shown to follow a Hammett $\rho\sigma$ relation (14). If the O—H group is coplanar in 2,6-di-*t*-alkyl-4-formyl phenols the effective σ will be the sum of $\sigma_{para}(OH) = -0.36$ plus σ_{meta} for two *t*-alkyl groups $= 2\times -0.12$, i.e. -0.60. The shift in C=O frequency from benzaldehyde to *p*-hydroxybenzaldehyde and to 2,6-di-*t*-alkyl-4-formyl phenol should therefore be in the ratio 0.36:0.60, i.e., 3:5. If, however, the O—H bond is twisted away from the plane by the *t*-alkyl groups its effective σ will be increased i.e. become more

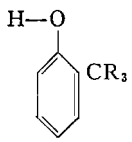
Although the OH group is coplanar in the presence of strong electron-attracting groups such as CHO this does not necessarily imply that it is also coplanar when the 4-substituent is electron releasing (e.g. CH_3). However, the differences in frequency between the hydroxyl groups of the 4-methyl and 4-formyl derivatives of phenol, 2,6-di-*t*-butyl phenol, and 2,6-di-*t*-*t*-octyl phenol are 16.5 (5), 17, and 18.5 cm^{-1} respectively compared with a calculated difference of 17.5 cm^{-1}.* That is, within the limits of experimental error the plots of ν_m against σ for these three classes of phenols are parallel (5) and therefore the OH group has the same orientation, independent of the 4-substituent, in all cases.

The intensities of the hindered phenols give further confirmation that they are true phenols and not "pseudo" phenols containing a non-planar hydroxyl group. The intensity of phenol is two or three times as great as the intensities of alcohols (13, 16), and, therefore, since the hindered phenols have even higher intensities than phenol, they must be true phenols. Moreover, the ratio of the intensities of the 4-formyl to 4-methyl derivatives of phenol; 2,6-di-*t*-butyl phenol; and 2,6-di-*t*-*t*-octyl phenol are 1.66 (5), 1.51, and 1.44



**An interesting difference between the OH bands of 2,6-di-t-butyl and 2,6-di-t-t-octyl phenols is that their half-band widths appear to change in opposite directions with a change in σ (Table I) (5).*

respectively, compared with a calculated ratio of 1.48, again suggesting that the structure of the phenols is independent of the 4-substituent.

Although the results quoted above strongly suggest that the OH group is coplanar with the ring, the accuracy of the experiments does not preclude the possibility that it is slightly twisted away from the plane. Both the resonance energy and the charge density at the carbon atom para to the resonance-inhibited group vary approximately as $\cos^2\theta$ (15, 17, 18) where θ is the angle of twist. That is, the resonance energy and charge density fall off rather slowly for small values of θ and therefore we could not detect small angles of twist in our experiments.

The conclusion that the OH group is in the plane, or at least close to it, makes the interpretation of the results obtained with single ortho-*t*-alkyl substituents comparatively straightforward. The results given in Table I and Fig. 1 clearly demonstrate the presence of two forms of *o*-*t*-alkyl phenols, as was predicted. Since the frequencies of the two bands are fairly close the one to the frequency of phenol, and the other to that of the corresponding 2,6-di-*t*-alkyl phenol, it is logical to suppose that the two forms represent geometrical isomers. The more intense band at the lower frequency will correspond to the trans isomer (T) and the less intense band at the higher frequency to the cis isomer (C).

(T)

(C)

Geometrical isomerism has been reported previously (19, 20) for *o*-substituted phenols in which the substituent can form an intramolecular hydrogen bond with the phenolic hydrogen (e.g. *o*-chlorophenol). This isomerism, which was deduced from infrared spectra, arises from the attraction of the phenolic hydrogen towards the *o*-substituent since the main band occurs at a much lower frequency than in phenol and the minor band occurs near the phenol frequency. In other words, the cis form is the most stable, whereas in *o*-*t*-alkyl phenols it is the trans form that is more stable. This suggests the presence of a steric repulsion between the phenolic hydrogen and the *t*-alkyl group, as might be expected.

Substitution of a methyl group in the 6-position increases the proportion of the isomer cis to the *t*-alkyl group. Substitution of a second methyl at the 5-position increases the proportion of the cis isomer even further, presumably because of its "buttressing" action on the methyl in the 6-position.

It should be pointed out that the occurrence of two bands does not necessarily imply that they correspond to geometrical isomers, since the low intensity band could conceivably be due to Fermi resonance (21) as has been postulated for hydroxy compounds containing the $—CH_2OH$ group (13). This possibility can, however, be discarded since the intensity of the subsidiary (cis) band decreases slightly as the two bands get closer together on going from *o*-*t*-butyl to *o*-*t*-amyl phenol, which is contrary to what would be expected from Fermi resonance. The results obtained with 2-*t*-butyl-6-methyl phenols and with 2-*t*-butyl-5,6-dimethyl phenol would also be difficult to explain on this basis. Furthermore, the spectra of structurally similar phenols e.g. *p*-*t*-butyl phenol, 2,6-diethyl phenol, 2,6-di-isopropyl phenol, etc. do not show any subsidiary bands.

The difference in free energy (ΔG) between the two isomers can be calculated from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

ratio of the intensities of the trans to cis bands in an *o*-*t*-alkyl phenol. This energy difference should be independent of the presence or absence of a 4-substituent, since any change in resonance energy produced by a 4-substituent will presumably alter the depths of the two coplanar potential minima by the same amount. However, the measured ratio of the intensities should be corrected for the fact that when the O—H group is cis to the *t*-alkyl group, as it must be in 2,6-di-*t*-alkyl phenols, the intensity is higher than phenol, whereas when it is trans to the substituent the intensity probably approximately follows the Hammett equation (5) and will be lower than phenol. For example, the average calculated cis intensity for 2-*t*-butyl phenol (1.09) is obtained from the intensities of 2,6-di-*t*-butyl phenol (1.02), and 2,6-di-*t*-butyl-4-methyl phenol (0.95) by applying corrections for the polar effects of an *o*-*t*-butyl group ($-(-0.20\times0.37)$) and for the effect of an *o*-*t*-butyl group and a *p*-methyl group ($-(-0.20-0.17)\times0.37$). The calculated trans intensity is based on phenol (1.00) less the effect of an *o*-*t*-butyl group i.e. 0.93. For 2-*t*-butyl-6-methyl phenol the calculated intensity cis to the *t*-butyl group is based on the calculated cis intensity of *o*-*t*-butyl phenol corrected for the polar effect of the 6-methyl group, and the calculated trans intensity is based in the same way on the measured intensities of 2,6-dimethyl and 2,4,6-trimethyl phenol. The measured trans to cis intensity ratio must be multiplied by the calculated cis to trans intensity ratio in order to obtain the true relative amounts of the two isomers. Table III gives the steps in the calculations

of the percentage of cis and trans isomers and the difference in free energy (ΔG) in kcal/mole between the two isomers in dilute solution in carbon tetrachloride at 24° C. ΔG is obtained in calories from the relation

$$\log_{10}\frac{[\text{trans}]}{[\text{cis}]} = \frac{\Delta G}{2.3RT}.$$

The measured trans/cis ratio for 2-*t*-butyl and 2-*t*-amyl have been taken from the values found for their 4-methyl derivatives; and for 2-*t*-butyl-6-methyl the ratio obtained with this phenol has been used. This was done since these compounds were known to be very pure and since the measurements were repeated at least six times, including once on a high-resolution Perkin–Elmer prism-grating spectrometer, model 112 G. Average values of the ratio for the other phenols of these types are in quite good agreement with the values chosen. The measured trans/cis ratio for 2-*t*-butyl and 2-*t*-butyl-6-methyl phenols are in good agreement with the values of Goddu (6), although our frequencies are from 3 to 8 cm^{-1} higher than the values he reported, the differences being most pronounced for 2,6-di-*t*-butyl phenols and for the cis isomers of various *o*-*t*-butyl phenols.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

The percentages of the cis isomers given in Table III show, as would be expected, that the cis isomer decreases as the size of the *t*-alkyl substituent is increased, but is increased by substitution of a methyl at the 6-position or by two methyls at the 5- and 6-positions.

The values of ΔG obtained for 2-*t*-butyl-6-methyl phenol and for 2-*t*-butyl-5,6-dimethyl phenol can be combined with the value for 2-*t*-butyl phenol to give the differences in free energy between the cis and trans isomers of *o*-cresol and 2,3-dimethyl phenol. These values are also included in Table III. It was also possible to obtain a rough estimate of ΔG for the two forms of 2-*t*-*t*-octyl-4-methyl-6-*t*-butyl phenol. The OH band of this compound is asymmetric and from the degree of asymmetry observed on the prism-grating instrument ΔG was estimated to be 0.17 kcal/mole. The intensity of the band was also compared with the intensity of the combined band of mixtures of different proportions of 2,6-di-*t*-*t*-octyl-4-methyl phenol and 2,6-di-*t*-butyl-4-methyl phenol. A value of ΔG of 0.30 kcal/mole was obtained in this way. These values are in reasonably good agreement with the value of 0.14 kcal/mole obtained by difference from 2-*t*-*t*-octyl and 2-*t*-butyl phenol.

The ratio of the intensities of the cis to trans isomers of *o*-chlorophenol is about 50:1 in carbon tetrachloride at room temperature (22, 23), corresponding to $\Delta G \sim 2.3$ kcal/mole. We have found that for 2-chloro-6-methyl phenol this ratio increases to $\geqslant 100{:}1$ ($\Delta G \geqslant 2.7$ kcal/mole). The two values of ΔG can be combined to obtain ΔG for *o*-cresol $\geqslant 0.4$ kcal/mole, in reasonable agreement with the value given in Table III.

The results given in Table II show that a single non-tertiary alkyl group substituted in the ortho position gives a measured increase in frequency and decrease in intensity in good agreement with the values calculated from the Hammett equation (5). However, the results given in Table III show that these phenols must exist as cis–trans isomers in unequal amounts. The only direct evidence for this is that the half-band widths ($\Delta\nu_{\frac{1}{2}}$) are definitely greater for these *o*-alkyl phenols than for phenol or for the corresponding 2,6-dialkyl phenols. This suggests the presence of two unresolved bands, particularly since the half-band widths would be expected to decrease below the value for phenol with alkyl substitution (5) (see also results for 3-methyl, 4-methyl, and 3,4,5-trimethyl phenol in Table II). Failure to resolve these bands is not surprising since the band maxima would appear to be less than 10 cm^{-1} apart in general and even the prism-grating spectrometer would not resolve the two bands of 2-*t*-*t*-octyl-4-methyl-6-*t*-butyl phenol where a separation of about 15 cm^{-1} is expected.

The positive values of $\Delta\nu_m$ observed with the 2,6-dialkyl phenols in Table II (and which are also encountered with 2,6-di-*t*-alkyl phenols) suggest a steric interaction between these non-tertiary alkyl groups and the hydroxyl group. On the other hand, the values of ΔA are negative for these phenols, whereas positive values were obtained with the 2,6-di-*t*-alkyl phenols. This shows that the intensities cannot be simply related to the extent of steric interference by the alkyl groups. However, for the phenols listed in Table II the values of $\Delta\nu_m$ and ΔA both tend to increase with the expected increase in steric interaction (see 2,6-dimethyl; 2,3,6-trimethyl; 2,3,4,6-tetramethyl; 2,3,5,6-tetramethyl; and pentamethyl phenol). This result cannot be due to any saturation of the electronic effects produced by the increasing number of substituents (5) since this would cause both $\Delta\nu_m$ and ΔA to decrease. The magnitude of these differences may, however, have been reduced because of saturation effects; somewhat larger values would smooth out the curves in Fig. 2 (see below).

In Fig. 2 values of $\Delta\nu_m$ and ΔA for 2,6-dialkyl phenols have been plotted against the values of ΔG obtained from the *o*-alkyl phenols. There is no direct justification for this

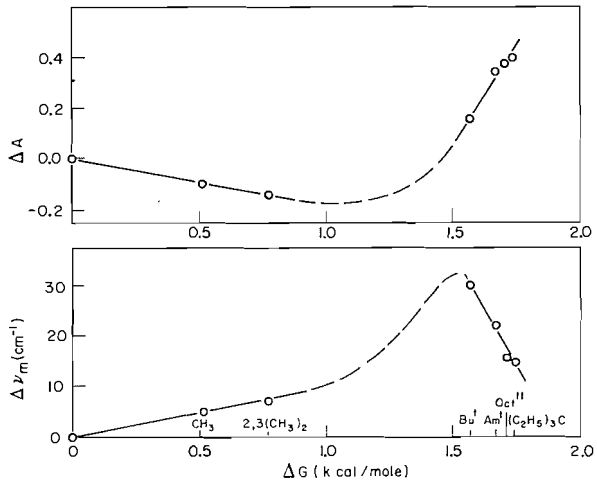

FIG. 2. Differences between measured and calculated frequencies, and intensities, of 2,6-dialkyl phenols plotted against ΔG.

procedure, but it is obvious that the values of ν_m and A for these phenols must be related in some way to the steric interaction of the alkyl groups with the hydroxyl group, and that this is measured approximately by ΔG. Both plots apparently show a discontinuity between the methyl phenols and the *t*-alkyl phenols, the curves going through a maximum or minimum. This shows that ortho-alkyl groups have two different effects on the hydroxyl, the magnitude of the two effects varying with the size of the alkyl groups.

A possible explanation of these results is that mild steric interaction between the alkyl and hydroxyl groups narrows the potential-energy well of the stretching mode of the O—H bond; this will increase the vibration frequency and decrease its amplitude and hence decrease the intensity. Stronger steric repulsions will begin to separate the proton from the electrons of the O—H bond since the repulsion is exerted primarily on the electrons of the phenolic hydrogen and only through them on the proton itself. This will tend to polarize the bond (i.e. $\overset{\delta-}{O}—\overset{\delta+}{H}$) and increase the intensity, and at the same time will weaken the internal force constant and so decrease the frequency. Incidentally the values of ΔG do not increase with the size of the *t*-alkyl substituent as rapidly as might be expected, which may be because the energy is minimized by an increase in the $C—\hat{O}—H$ angle. This forcing of the phenolic hydrogen away from its equilibrium position, as the substituents become larger than *t*-butyl, would also tend to decrease the O—H bond strength and hence ν_m.

The frequencies of the trans isomers of *o*-*t*-alkyl phenols, which are appreciably below their calculated values, are obviously much more readily influenced by the alkyl substituent than are the intensities (cf. small values of ΔA for these phenols in Table I); i.e. the intensities, but not the frequencies, follow the usual Hammett $\rho\sigma$ relations. The low frequencies observed must mean that an *o*-*t*-alkyl substituent has an effect on the hydroxyl group even when the latter is pointing away from it. This effect might be due to a more rigid geometry in the trans isomer compared to phenol (5). An alternative explanation that appears to be more consistent with the results is that *t*-alkyl groups exert van der Waals attraction on the lone pairs of electrons on the oxygen. This withdrawal of electrons from the oxygen would be transmitted to the O—H bond, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

frequency of which would be decreased. This suggestion helps to explain why $\Delta\nu_m$ is higher for the cis isomer of *o*-*t*-alkyl phenols than for the corresponding 2,6-di-*t*-alkyl phenol. In the cis isomer the only effect on the hydroxyl is one of steric repulsion, whereas in di-*t*-alkyl phenols there is also the attraction of the oxygen's electrons by the second *t*-alkyl group, which will decrease the frequency. The same effect may also be operating in ortho halophenols since the frequency, in carbon tetrachloride solution, of the trans isomer decreases by 5 cm^{-1} on increasing the size of the substituent from bromine to iodine, whereas the corresponding decrease for these two para-substituted phenols is only 1 cm^{-1} (22, 23).

An *o*-methyl or 2,3-dimethyl group has no effect, other than the calculated polar effect, on the frequency of the trans isomer (Table II). Therefore in 2-*t*-butyl-6-methyl and in 2-*t*-butyl-5,6-dimethyl phenol $\Delta\nu_m$ for the cis (to *t*-butyl) isomer has about the same value as for 2-*t*-butyl phenols (Table I). On the other hand, $\Delta\nu_m$ values for the trans (to *t*-butyl) isomers of these phenols are below $\Delta\nu_m$ values for 2,6-dimethyl and 2,3,5,6-tetramethyl phenol because of the influence of the *t*-butyl group. Non-tertiary alkyl groups in the ortho position apparently, therefore, only affect the hydroxyl group when it points towards them.

The barrier to rotation of the hydroxyl group in 2,4,6-tri-*t*-butyl phenol has been estimated from dielectric measurements to be 2.8 kcal/mole (24). The rotational barrier in this compound will be lower than in phenol owing to steric repulsion by the *t*-butyl groups ($\sim$1.6 kcal/mole) and also, perhaps, to a decrease in the resonance interaction between the hydroxyl and the ring because of the polar effects of the alkyl substituents. The barrier in phenol is, therefore, $\geqslant$4.4 kcal/mole.

ACKNOWLEDGMENTS

The authors are indebted to Dr. R. N. Jones for the spectra on the prism-grating spectrometer, and to Dr. D. Davidson and Dr. I. E. Puddington for several helpful discussions.

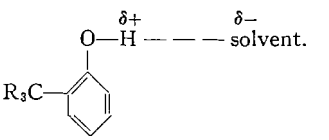
THE EFFECT OF SOLVENT AND TEMPERATURE ON THE CIS–TRANS ISOMERISM OF ORTHO-*tert*-ALKYL PHENOLS[1]

K. U. INGOLD AND D. R. TAYLOR[2]



ABSTRACT

The effects of different solvents and of a change of temperature on the infrared band due to the fundamental hydroxyl stretching vibration in several 2,6-di-*t*-alkyl phenols and in the corresponding ortho-*t*-alkyl phenols have been examined. The conclusion that the two bands observed in ortho-*t*-alkyl phenols represent cis and trans isomers has been confirmed. The differences in enthalpy and entropy between the two isomers have been measured for six different phenols.

INTRODUCTION

The conclusions reached in the previous paper (1) as to the nature of the two hydroxyl stretching bands observed in *o-t*-alkyl phenols has been confirmed by an examination of the effects of different solvents and of changes in temperature on the ratios of the intensities of the two bands.

It was predicted, on the basis that the two bands represent cis and trans isomers, that an increase in the polarity or polarizability of the solvent would decrease the percentage of the cis isomer owing to the increased stability of structures of the type

It was also predicted that the trans/cis intensity ratio should decrease with increasing temperature. Both the predictions have been experimentally verified.

EXPERIMENTAL

The spectrometer and slit conditions have been described previously (1). The high-temperature cell consisted simply of a 5-mm cavity cell enclosed by an electrically heated glass tube, the ends of which were sealed by NaCl windows. Hexachloro-1,3-butadiene (HXB) was used as the solvent because of its high boiling point and because frequencies and intensities in this solvent are closely similar to their values in carbon tetrachloride. The concentration of the solute phenol was 0.005 *M*.

RESULTS

Bellamy and Williams (2) have shown that the effect of various solvents on the frequency of the O—H band (ν_m) of 2,6-di-*t*-butyl-4-methyl phenol is quite different from the solvent effect on phenol and on 2,6-dialkyl phenols in which the substituents are not tertiary alkyl groups. Their results have been confirmed with a limited number of solvents for phenol and 2,6-di-*t*-butyl-4-methyl phenol and the measurements have been extended to other 2,6-di-*t*-alkyl-4-methyl phenols. Pentamethyl phenol was also

examined in order to discover whether this phenol behaved like the 2,6-di-tertiary or non-tertiary alkyl phenols. The frequencies (ν_m cm^{-1}) are given in Table I, which also includes intensities relative to phenol in carbon tetrachloride (A) and half-band widths ($\Delta\nu_{\frac{1}{2}}$ cm^{-1}). Intensities were obtained from the product of $\Delta\nu_{\frac{1}{2}}$ and the molecular extinction coefficient (1), they are probably not very accurate as they are based only on a single measurement in each case. Results are also included in Table I for the effect of solvent on the cis and trans bands of 2-*t*-butyl-4-methyl phenol.

*See text.

For the work at different temperatures it was necessary to examine not only the *o*-*t*-alkyl phenols, but also the corresponding dialkyl phenols and an unhindered phenol in order to find out whether the correction for the intrinsic differences in intensity between cis and trans isomers varied with temperature. 4-*t*-Butyl phenol was used in place of phenol because of its lower volatility—the presence of a para-substituent would not be expected to affect the results.

The intensities of symmetrically substituted phenols in HXB relative to phenol in HXB at room temperature (i.e. A_{HXB}) decrease linearly with increasing temperature within the accuracy of the measurements (Fig. 1). The points plotted in this figure have not been corrected for expansion of the solvent nor for changes in the path length. Over

the temperature range studied the former effect will cause values of A_{HXB} to decrease by about 10%. The percentage absorptions ($\log(I_0/I)_{max}$) of the bands decreased (3, 4) and their half-band widths increased as the temperature was raised. In contrast to a previous report (3) ν_m was found to increase regularly with temperature. The values of ν_m and $\Delta\nu_{\frac{1}{2}}$ at room temperature are given in Table I except for 4-*t*-butyl phenol ($\nu_m = 3610.5\ cm^{-1}$, $A = 0.94$, $\Delta\nu_{\frac{1}{2}} = 22.5\ cm^{-1}$) and 2,3,5,6-tetramethyl phenol ($\nu_m = 3626\ cm^{-1}$, $A = 0.64$, $\Delta\nu_{\frac{1}{2}} = 21.5\ cm^{-1}$). The increases in ν_m and $\Delta\nu_{\frac{1}{2}}$ in cm^{-1} on raising the temperature from 24° to 150° C are respectively: 4-*t*-butyl 7.5 and 3; 2,3,5,6-tetramethyl 4 and 2; 2,6-di-*t*-butyl-4-methyl 2.5 and 5.5; 2,6-di-*t*-amyl-4-methyl 2 and 4; 2,6-di-*t*-*t*-octyl-4-methyl 1.5 and 3; 2,6-di-triethylmethyl-4-methyl phenol 1.5 and 3.5.

Table II shows the effect of temperature on *o*-*t*-alkyl phenols. The temperatures are only approximately (±5° C) those at which the measurements were made, in order to simplify the Table. ν_m values for cis isomers are less accurate than for the trans isomers (1). The increases in ν_m and $\Delta\nu_{\frac{1}{2}}$ appear to follow the same relations as were observed with the symmetrically substituted phenols, i.e. ν_m and $\Delta\nu_{\frac{1}{2}}$ increase by about 6 cm^{-1} and 3 cm^{-1} respectively in the range 24° to 150° C for the trans band and by about 2.5 cm^{-1} and 3 cm^{-1} respectively for the cis band. However, the plots of A_{HXB} against temperature for trans isomers have much steeper slopes than are observed with the symmetrically substituted phenols, presumably because of the relative increase in the amount of cis isomers as the temperature rises. These plots appear, in general, to be slightly convex towards the temperature axis. As the temperature is raised it becomes increasingly difficult to separate the cis band since not only are both bands smeared out owing to the increase in $\Delta\nu_{\frac{1}{2}}$, but also the two band maxima move slightly closer together.

The parallel straight lines shown in Fig. 1 for symmetrically substituted phenols indicate that the correction factors for the intrinsic differences in intensity between cis and trans isomers are independent of temperature. The intensities of substituted phenols relative to phenol when plotted against Hammett σ constants are independent of solvent for a small range of solvent types (5). This means that ρ is independent of solvent and therefore the correction factors in HXB can be readily obtained (1). These factors are

given in Table III; they are only slightly different from the values calculated in carbon tetrachloride (1). The measured ratios A(trans)/A(cis), which will, of course, be independent of solvent expansion etc., were multiplied by these factors to give the true concentration ratios of the two isomers at each temperature. The logarithms of the true concentration ratios have been plotted against $1/T$ (°K) in Fig. 2, since the relation

$$\log_{10}\frac{[\text{trans}]}{[\text{cis}]} = \frac{\Delta G}{2.3\,RT} = \frac{\Delta H}{2.3\,RT} - \frac{\Delta S}{2.3\,R}$$

should be obeyed. That is, the slopes of the lines in Fig. 2 give ΔH, the enthalpy difference between the cis and trans isomers, and the intercepts give ΔS, the entropy difference. These results, as well as values of ΔG obtained at room temperatures in carbon tetrachloride (1) are given in Table III.

TABLE III

Enthalpy difference between cis and trans isomers of *o*-*t*-alkyl phenols

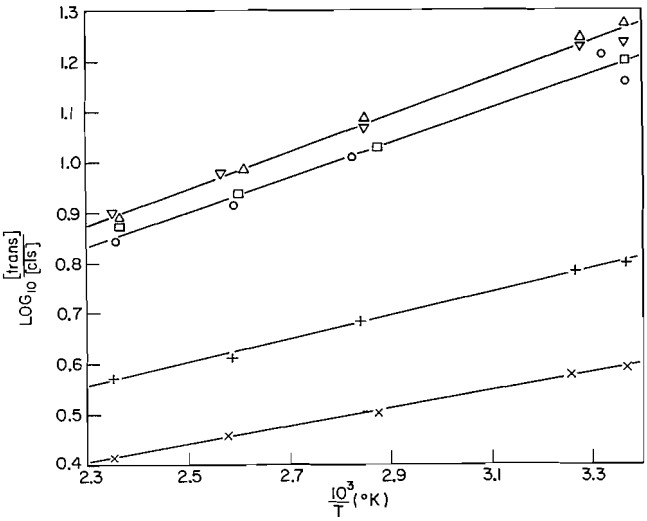

FIG. 2. Effect of temperature on $\log_{10}$[trans]/[cis] for ortho-alkyl phenols. Key: 2-*t*-butyl-5,6-dimethyl ×; 2-*t*-butyl-6-methyl +; 2-*t*-butyl-4-methyl ○; 2-*t*-amyl-4-methyl □; 2-*t*-*t*-octyl-4-methyl △; 2-triethyl-methyl-4-methyl phenol ▽.

plots of 2-*t*-butyl-4-methyl and 2-*t*-amyl-4-methyl phenol and between 2-*t*-*t*-octyl-4-methyl and 2-triethylmethyl-4-methyl phenol, a single line has therefore been drawn through each pair.

Although a small positive intercept is obtained in each case, it may well be due to an overestimation of the correction factors. Moreover, the intercepts are sufficiently small that the data for each phenol could be fitted almost equally well by straight lines passing through the origin. That is, ΔS is certainly small in each case and is very probably zero.

DISCUSSION

Bellamy and Williams (2) have shown that the changes in ν_m for phenol and 2,6-dialkyl phenols on passing from one solvent to another are due to local association effects, which occur even in non-polar solvents. By comparing ν_m for 2,6-dimethyl, -diethyl, and -diisopropyl phenol in different solvents with ν_m for phenol, these workers concluded that there is no significant steric hindrance to solvent effects in these phenols, the small effects observed being ascribed to the polar effects of the alkyl substituents. The results given in the previous paper (1) suggest that two *o*-methyl groups backed up by *m*-methyl groups may exert a greater effect on the hydroxyl group than is exerted by, for example, two *o*-isopropyl groups. For this reason it was considered of interest to study the effect of solvents on ν_m for pentamethyl phenol to see whether any steric hindrance to solvent effects could be observed. The results obtained (Table I) are not significantly different from the results reported for dialkyl phenols (2), the small differences that are observed are very likely due to the increased polar effect of five methyl substituents. Therefore, on the basis of Bellamy and Williams' work it could be concluded that steric hindrance to solvent effects does not occur in pentamethyl phenol. However, the changes in $\Delta\nu_{\frac{1}{2}}$ (which were not reported by Bellamy and Williams) of pentamethyl phenol compared to phenol do suggest some small steric effects are present, and therefore small effects may also have been operating in the dialkyl phenols they studied.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

For 2,6-di-*t*-butyl-4-methyl phenol, however, Bellamy and Williams have shown that there is a very noticeable steric hindrance to the approach of solvent molecules. Our results confirm this, and also show that this hindrance increases with increasing size of the alkyl substituents, as would be expected. The comparatively small changes in A and $\Delta\nu_{\frac{1}{2}}$ for 2,6-di-*t*-alkyl phenols compared with phenol or pentamethyl phenol can also be ascribed to a steric hindrance of solvent effects.

The results obtained with 2-*t*-butyl-4-methyl phenol are in agreement with theory. That is, in terms of changes in ν_m, A, and $\Delta\nu_{\frac{1}{2}}$ the trans band behaves similarly to phenol and the cis band similarly to 2,6-di-*t*-butyl-4-methyl phenol, although the cis band does not appear to be quite as highly protected from solvent effects as is the band in the di-*t*-butyl phenol.

As the polarizability or polarity of the solvent increases the two band maxima move further apart, but the resolution of the two bands becomes more difficult owing to the increase in half-band widths. The values obtained for $A(\text{trans})/A(\text{cis})$ with 2-*t*-butyl-4-methyl phenol in the different solvents are given in Table I. In nitromethane no separate cis band was observed. A maximum value was estimated for this band from the value of $\Delta\nu_{\frac{1}{2}}$ for 2,6-di-*t*-butyl-4-methyl phenol and the maximum contribution to $\log(I_0/I)$ at the expected ν_m that could be due to the cis band. The trend in the ratio of $A(\text{trans})/A(\text{cis})$ overemphasizes the true increase in the percentage of the trans isomer since the solvent effect on this isomer will be greater than on the cis isomer, (cf. effect of solvent on A for phenol and 2,6-di-*t*-butyl-4-methyl phenol in Table I). However, even after this effect is approximately allowed for (i.e. [trans]/[cis] in Table I), the results still show the predicted increase in the concentration of the trans isomer with increasing solvent interaction. The results also show that even in carbon tetrachloride the percentage of trans isomer is greater than would be present in the vapor phase at the same temperature. A similar result has been observed with the isomers of *o*-halophenols by Rossmy, Lüttke, and Mecke (6). These workers, found, for example, that the trans isomer of *o*-iodophenol is stabilized by solvent interaction in carbon tetrachloride by about 1.4 kcal/mole with respect to the gaseous state. The values of ΔG and ΔH recorded in Table III must, therefore, be larger than they would be in the vapor state.

The increase in ν_m with temperature is probably related to the decreasing density of the solvent. That is, as the temperature is raised the solvent molecules are, on average, further removed from the solute molecules and therefore their influence will decrease and ν_m will increase. The smaller effect of temperature on ν_m for di-*t*-alkyl phenols compared with non-hindered phenols is to be expected since the effect of the solvent even at room temperature is greatly reduced by the shielding afforded to the OH group by the *t*-alkyl substituents.

As was mentioned above, ΔS values given in Table III are zero within the limits of experimental error, which suggests equal, a priori, probability for the two isomers and supports isomerization of the cis–trans type with the OH group coplanar in both isomers. If the O—H bond were twisted out of the plane in 2,6-di-*t*-alkyl phenols and also, therefore, in the cis isomer of *o*-*t*-alkyl phenols there would be two equivalent cis isomers and the a priori probability for this isomer would be twice that of the trans. Since ΔS is close to zero there is good agreement between ΔH and ΔG for the different phenols.

All the results obtained in this work support our original interpretation that the two infrared OH bands observed in *o*-*t*-alkyl phenols represent cis and trans isomers, the latter being thermodynamically more stable.

PHOTOCHEMICAL SYNTHESES

I. THE REACTION OF ALDEHYDES AND KETONES WITH CYCLOALKENES[1]

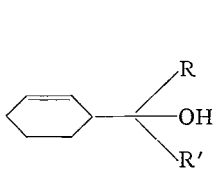
P. DE MAYO,[2] J. B. STOTHERS,[2] AND W. TEMPLETON

ABSTRACT

The irradiation of dialkyl ketones in cyclohexene leads to the formation of cyclohexenyldialkylcarbinols. The use of aldehydes leads to the formation of the corresponding secondary alcohols, but the reaction is more complex because of concomitant Kharasch addition which can, however, be suppressed. The mechanism of the alcohol formation has been elucidated by the use of an optically active substrate, carvomenthene, and has been shown to involve the intermediacy of a cyclohexenyl radical. The structure and genesis of a biscarbinol by-product is discussed.

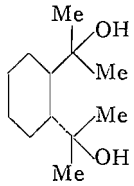
It was first observed by Bowen and Horton (1) that the irradiation of acetone in cyclohexane gave, in poor yield, an alcohol which was presumed to be cyclohexyldimethylcarbinol. More recent investigations (2) confirmed this, but the yield (12%) was not such as to render the reaction preparatively a very useful one.

It seemed probable that if the reaction proceeded by initial hydrogen atom abstraction by the photoactivated carbonyl compound, then any functional group designed to stabilize that radical should render the reaction more facile; and indeed there were indications in the literature (see, for instance, refs. 3, 4, 5) that in related transformations this was so.



A simple function that would fulfill the requirements was the ethylenic linkage and to this end the symmetrical hydrocarbon cyclohexene was selected. Irradiation at room temperature of a solution of acetone in this hydrocarbon until no carbonyl band could be detected in the infrared gave, after removal of excess hydrocarbon and distillation from a polymeric residue, a colorless oil. This could be separated by gas–liquid chromatography into an alcohol, shown to be the desired carbinol, and 3,3′-bicyclohexenyl. The latter was characterized as the known two tetrabromides (6).

The alcohol showed bands in the infrared at 3322 (hydroxyl), 1378 and 1368 (geminal dimethyl), and 733 cm^{-1} (cis disubstituted ethylene) in accordance with structure (I, R = R′ = Me), and had the required analysis. It was characterized as the 3,5-dinitrobenzoate, and an authentic specimen of the alcohol was synthesized from cyclohexene-3-carboxylic acid by esterification (diazomethane) and Grignard reaction with methyl magnesium iodide. The alcohol so obtained and the derived 3,5-dinitrobenzoate were identical in every respect with the corresponding photoproducts.



Under similar conditions the carbinols (I, R = R′ = Et) and (I, R = R′ = Pr) were obtained employing diethyl and dipropyl ketone respectively.

When the cyclohexene–acetone irradiation was performed at reflux temperature there was isolated in poor yield an additional substance, a saturated alcohol, which was readily characterized as a crystalline 3,5-dinitrobenzoate. The analysis indicated the condensation of two molecules of acetone with one of cyclohexene. The absence of unsaturation suggested structure (II) and comparison with an authentic specimen (see Experimental) confirmed this.

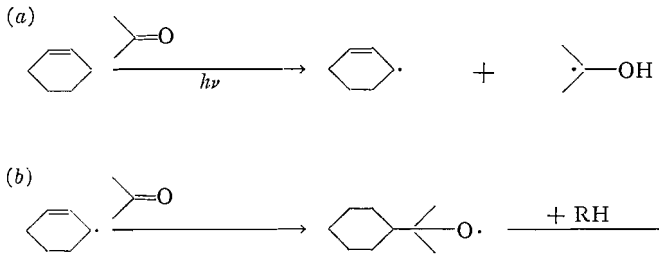
(I)

(II)



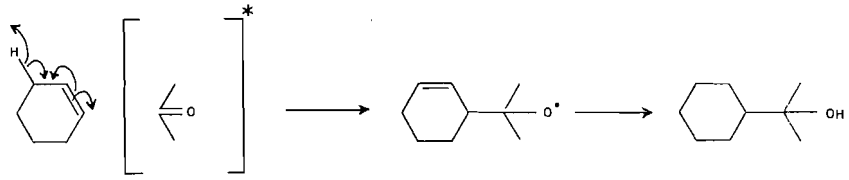
(III)

The formation of this interesting substance appears to be without photochemical parallel. Its genesis would not appear to involve, as expected, cyclohexenyl or, more probably, substituted cyclohexyl radicals, because when no attempt was made to exclude oxygen in the irradiation the formation of (I) was *totally suppressed*, all the cyclohexenyl radicals being trapped by the excess oxygen as cyclohexene hydroperoxide. The latter was characterized by conversion to cyclohexenone 2,4-dinitrophenylhydrazone. The yield of (II) remained, however, unaffected.

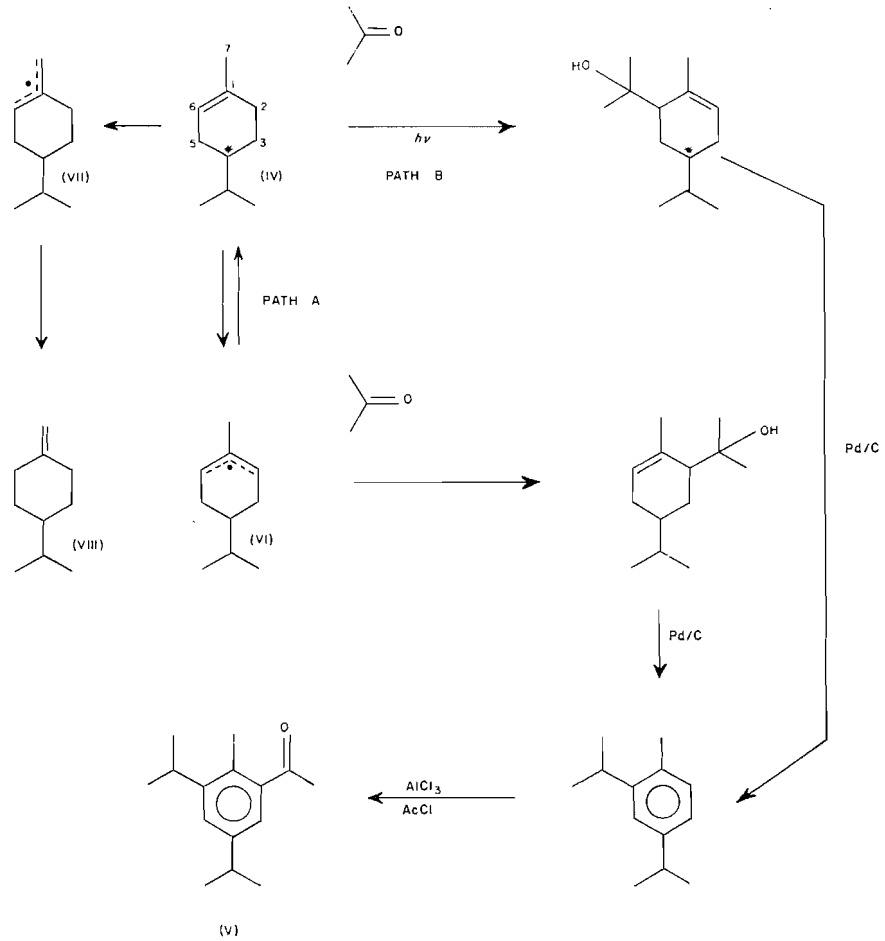
If such radicals are to be excluded a 'molecular' reaction must be presumed: one such reaction, known to occur with more-substituted ethylenes, is oxetane formation (7, 8). In the present case the oxide (III), not, however, isolated, would be the product. Bimolecular homolytic substitution at the cyclohexyl terminus of the oxide ring could then lead to (II). Radical displacements on carbon are rare, but are known to occur (cf. ref. 9). This possibility is being further investigated.

It has been the tacit assumption that the alcohols of type I were produced by the following steps:

Mechanism A



Evidence for step (*a*) lies in the formation of cyclohexene hydroperoxide in the presence of air, and in the formation of 3,3′-bicyclohexenyl as an important by-product. Although it is possible that in step (*b*) the cyclohexenyl radical may react with some other species than acetone in the ground state the assumption appears unnecessary since it is known (10) that chemically generated cyclohexyl radicals will add to carbonyl compounds in such a manner.



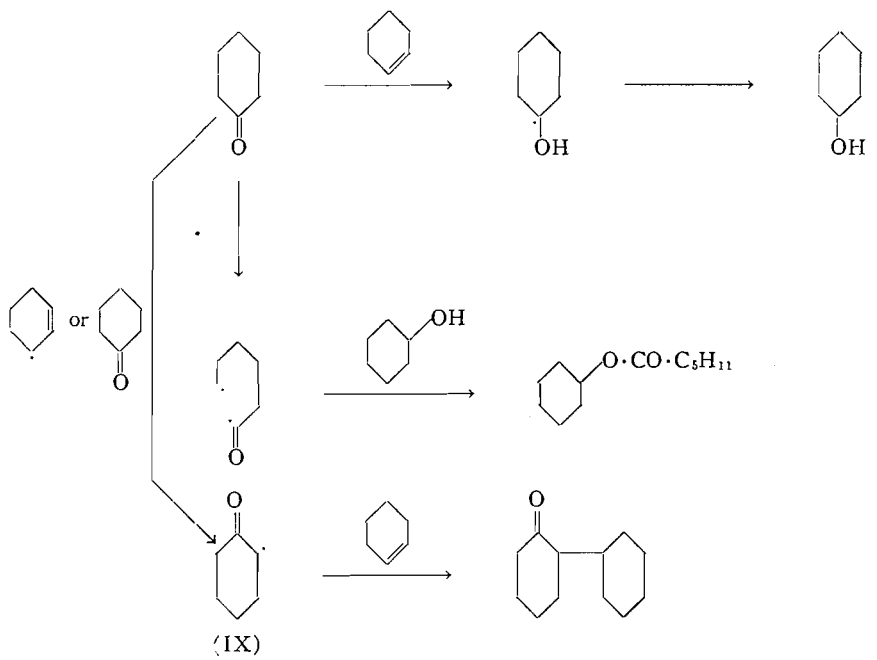
Nevertheless, although the evidence for step (*a*) is good it did not follow that the alcohol (I) was necessarily derived from a species produced in it. An alternative process, involving attack on the π-electrons of the cycloalkene appeared admissible, and such a mechanism has been proposed in radical substitutions in dienes and trienes (see, for instance, refs. 11, 12). This mechanism, in the present case, may be represented as follows:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Mechanism B

A distinction between these two mechanisms was arrived at in the following manner. (+)-Carvomenthene (IV), prepared by the hydrogenation of limonene, was irradiated in admixture with acetone. The alcoholic fraction, a mixture of stereoisomers, was completely racemized. The gross structure of the product was established by dehydrogenation and acylation to (V) characterized as the known 2,4-dinitrophenylhydrazone. The racemization of the active center during the photoreaction implies the intermediacy of the symmetrical allylic radical (VI), and supported mechanism A.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



A possible criticism of the foregoing conclusions might rest on the fact that the zero rotation may have been a fortuitous combination of positive and negative rotations in stereoisomers. Since the separation of these isomers appeared difficult an alternative approach was sought.

It appeared possible that the radical (VI) might compete with the photoactivated ketone for allylic hydrogen abstraction in (IV), thus regenerating (inactive) carvomenthene on one hand and a new, equivalent, radical on the other. If this occurred, racemization could precede (apparent) reaction. In the event, interruption of the reaction before completion and recovery of carvomenthene by gas–liquid chromatography gave material which was approximately 30% racemized thus providing compelling evidence for the intermediacy of (VI). Carvomenthene, in the absence of acetone, was unaffected under the irradiation conditions.

By gas–liquid chromatography, also, a small amount of *p*-menth-1,7-ene (VIII) (13) was also isolated during the same experiment. This hydrocarbon is evidently formed by allylic hydrogen abstraction at the (alternative) primary (C_7) position, and provides further general support for the present thesis.

The irradiation of cyclohexanone in cyclohexene led to entirely different results. No alcohol of the required type was isolated, but instead, in addition to the 3,3′-bicyclohexenyl, two further liquid substances were obtained by chromatography of the total volatile product on alumina.

The first of these was readily identified as cyclohexyl *n*-caproate by hydrolysis to its components, each being characterized by a solid derivative. Evidently the cyclohexanol (or equivalent) derives from the hydrogen-abstraction step, but the cyclohexene is, however, apparently too bulky a molecule to allow of backside attack of the cyclohexenyl radical on the cyclohexanone carbonyl. Such reaction is presumably controlled by the 1,3-axial hydrogen interactions in the transition state. Under these circumstances, and

(IX)

For personal use only.

in the presence of cyclohexanol, the slower solvolytic fission may then take place. Such fission in cyclic ketones is unexceptional (14).

The resistance of the cyclohexanone carbonyl to attack by the cyclohexenyl radical is also demonstrated by the nature of the second product. This substance showed a single carbonyl band in the infrared at 1715 cm^{-1}, whilst the empirical formula indicated it to be a 1:1 adduct of cyclohexanone and cyclohexene. The presumption that it was cyclohexyl cyclohexanone was justified by comparision of the ketone and its 2,4-dinitrophenylhydrazone with authentic specimens. The cyclohexenyl radical or, perhaps, activated ketone has, therefore, abstracted an α-hydrogen atom to give (IX), which has then added to a further molecule of cyclohexene. These observations parallel those of Kharasch, Kuderna, and Nudenberg, who noted the addition of cyclohexanone to oct-1-ene (15).

The irradiation of cyclohexene with aldehydes led to similar results. Propionaldehyde for instance gave (I, R = Et, R′ = H), characterized as the 3,5-dinitrobenzoate, and identified by comparison with an authentic specimen.[3] The latter was prepared by reaction of cyclohexene-3-carbonyl chloride with dimethyl cadmium followed by lithium aluminum hydride reduction. The expected product of Kharasch addition (16) was also obtained.

In the case of acetaldehyde it was found, because of the volatility of the substance, more convenient to work in a closed system. Here, again, the desired alcohol (I, R = Me, R′ = H) was obtained, together with the Kharasch addition product methylcyclohexyl ketone.

The 60 Mc N.M.R. spectra of the alcohol and its 3,5-dinitrobenzoate were obtained in CCl_4 solution (ca. 15%). The characteristic peaks observed (in p.p.m. from tetramethylsilane)[4] were as follows: alcohol: CH_3 group, 1.14 (doublet, J = 6 c.p.s.); OH, 2.9 (concentration-dependent); H on carbon bonded to oxygen, a multiplet centered at 3.6, and olefinic Hs, 5.7 (a multiplet); the 3,5-dinitrobenzoate: CH_3 group, 1.5 (doublet, J = 7 c.p.s.); H on carbon bonded to oxygen, 5.3 (center of multiplet); olefinic Hs, 5.8 (center of multiplet), and aromatic Hs, 9.1–9.4. The areas of the last three bands were in the ratio 1:2:3. These assignments are entirely compatible with the proposed structure. This is most clearly demonstrated in the paramagnetic shift of the methine hydrogen on carbon bonded to oxygen from 3.6 to 5.3 on esterification.

Since the Kharasch addition is a chain reaction (24) involving most probably the following steps:

(i) $R\cdot CHO \rightarrow \dot{R} + \dot{C}HO,$

(ii) $R\cdot + RCHO \rightarrow RH + R\dot{C}O,$

(iii) $R\dot{C}O + R_2C{=}CR_2 \rightarrow RCOR_2C{-}\dot{C}R_2,$

(iv) $RCOR_2C{-}\dot{C}R_2 + RCHO \rightarrow RCOR_2C{-}CHR_2 + R\dot{C}O$ etc.;

its perpetuation ((step ii)+(step iv)) should be favored by a high ratio of aldehyde to cyclohexene. On the other hand the process leading to the alcohol should require that the concentration of hydrocarbon be high so that hydrogen atom abstraction by the photoactivated aldehyde may compete with homolysis (step i). In the event, when the concentration (w/v) of acetaldehyde in cyclohexene was decreased from 20% to 2% the ratio of ketone to alcohol changed from about 1:1 to 1:9.

[3]*The alcohols from the aldehydes may possibly be mixtures of diastereoisomers. These did not resolve on the silicone column used. The synthetic specimens, also possibly diastereoisomers, were indistinguishable from these in chromatographic behavior as in other respects.*

[4]*For τ values (25) these figures should be subtracted from 10.*

EXPERIMENTAL

Materials were reagent grade and were dried over magnesium sulphate and distilled before use. Cyclohexene was purified by shaking with aqueous ferrous sulphate, dried, and distilled. Before use it was filtered through a short column of alumina. Gas–liquid chromatography was conducted on a silicone–celite column at 175°. Unless otherwise specified irradiations were carried out under dry oxygen-free nitrogen in a quartz immersion apparatus (8*b*), the light source being a 125-watt Compton mercury arc lamp or a Hanovia 85-watt AH-8, both of which had the outer envelope removed. The yields recorded are based on carbonyl compound employed (*not* that consumed) and are in no way optimum values. Light petroleum was b.p. 60–80°.

Irradiations

Acetone–Cyclohexene (i)

A solution of acetone (50 g) in cyclohexene (275 ml) was irradiated at approximately 20° for 100 hours. After evaporation of the solvents the residue was distilled *in vacuo* to give a colorless oil (70 g). Gas–liquid chromatography of a portion (0.65 g) gave two fractions. The first cyclohex-2-enyl dimethylcarbinol (0.34 g; 30%) had b.p. 82°/30° mm, n_D^{21} 1.4740. Calc. for $C_9H_{16}O$: C, 77.09; H, 11.50%. Found: C, 77.02; H, 11.82%. The 3,5-dinitrobenzoate crystallized from chloroform–methanol, and had m.p. 121–124°. Calc. for $C_{16}H_{18}O_6N_2$, 0.5 CH_3OH: C, 56.55; H, 5.75; N, 8.00. Found: C, 56.94; H, 5.38; N, 8.07%. The substance was identical in every respect with an authentic synthetic specimen (see below).

The second fraction 3,3′-bicyclohexenyl (0.28 g) had b.p. 167–170/130 mm, n_D^{24} 1.5050, λ_{max} 190 mμ (ϵ 14,300) expected for two cis disubstituted ethylenes,[5] ν_{max} 701 cm^{-1}. Bromination in carbon tetrachloride gave a crystalline mixture of bromides from which, by fractional crystallization from chloroform, the two tetrabromides of 3,3′-bicyclohexenyl, m.p. 158–160° and 191.5–192.5°, were obtained. These were identical in every respect with specimens of the same melting point prepared by the method of Farmer and Michael (6).

Acetone–Cyclohexene (ii)

Irradiation at reflux temperature, in a quartz vessel over a 500-watt Hanovia lamp, of a solution of acetone (25 g) in cyclohexene (225 ml) for 38 hours gave, after evaporation of the solvent and distillation, an oil (27 g). Gas–liquid chromatography revealed the presence of a further substance in addition to the 3,3′-bicyclohexenyl and the alcohol (I, R = R′ = Me). This component was obtained as a concentrate by fractional distillation (b.p. 133–138°/150 mm) and was converted into the 3,5-dinitrobenzoate, m.p. (from methanol) 112–115°. Calc. for $C_{26}H_{28}O_{12}N_4$: C, 53.06; H, 4.80; N, 9.52%. Found: C, 53.26; H, 4.45; N, 9.95%. It was identical in every respect with an authentic synthetic specimen of *trans*-1,2-di(2′-hydroxy-2′-propyl) cyclohexane prepared as described below. The corresponding alcohols had identical retention times on the silicone column.

Acetone–Cyclohexene (iii)

A solution of acetone (16 g) in cylohexene (200 ml) was irradiated at room temperature for 40 hours in the presence of excess oxygen. By fractional distillation an oil (2.5 g) b.p. 119–130°/140 mm was isolated. Gas–liquid chromatography showed the presence of two substances in approximately equal amounts. One was identified as *trans*-1,2-di(2′-hydroxy-2′-propyl) cyclohexane by retention time and conversion to the 3,5-dinitrobenzoate, m.p. and mixed m.p. 111–113°. The second substance cyclohex-2-ene

[5]*We are indebted to Dr. D. Turner (Imperial College) for the determination of this spectrum between 170 and 200 mμ.*

hydroperoxide was isolated by chromatography of the distillate (2 g) on silica gel (100 g). Elution with benzene–ether (1:1) gave a fraction (600 mg) which was optically transparent in the ultraviolet, gave a strong starch–iodide reaction, and had ν_{max} 3365 and 702 cm^{-1}. On treatment with 6 *N* sulphuric acid a maximum appeared in the ultraviolet at 228 mμ and rose to ϵ 8000. To convert the hydroperoxide into the α,β-unsaturated ketone 2,4-dinitrophenylhydrazone it was mixed with reagent hydrochloride at room temperature in dioxan–water and left to stand overnight; its melting point and mixed m.p. 163° were identical with those of an authentic specimen of cyclohexenone 2,4-dinitrophenylhydrazone.

Acetone – Diethyl Ketone

A solution of diethyl ketone (40.8 g) in cyclohexene (300 ml) was irradiated at room temperature for 138 hours. Fractional distillation of the product then gave a colorless oil (28 g). Chromatography of a portion (5 g) on alumina (Brockman Grade 3, 200 g) gave (eluted with light petroleum) 3,3′-bicyclohexenyl (3.5 g) identified by retention time and infrared spectrum. Elution with 4:1 benzene–ether then gave 3-cyclohex-2′-enylpentan-3-ol, b.p. 140°/50 mm, n_D^{23} 1.4823. Calc. for $C_{11}H_{20}O$: C, 78.51; H, 11.98%. Found: C, 78.25; H, 11.76%. The retention time and infrared spectrum were identical with those of an authentic specimen (see below).

Acetone - Dipropyl Ketone

A solution of di-*n*-propyl ketone (40 g) in cyclohexene (300 ml) was irradiated at room temperature for 72 hours. Fractional distillation yielded an oil (67 g) a sample of which (5 g) was chromatographed on alumina (Brockman Grade 3, 200 g). Elution with light petroleum gave 3,3′-bicyclohexenyl (4.0 g) identified as previously. Elution with ether – benzene (1:9) gave a mixture from which, by gas–liquid chromatography, the required alcohol could be isolated. It had n_D^{23} 1.4790. Calc. for $C_{13}H_{24}O$: C, 79.53; H, 12.32%. Found: C, 78.77; H, 12.27%. It was identical in infrared spectrum, retention time, and refractive index with a specimen prepared by an unambiguous route as described below.

Acetone – (+)-Carvomenthene (i)

A solution of acetone (80 g) in carvomenthene (270 g) ($[\alpha]_D$ +76°) (17) was irradiated at room temperature for 290 hours. Fractional distillation gave a crude product (41 g) which on gas–liquid chromatography gave an oil, $[\alpha]_D$ ±0°, ν_{max} 3434. Calc. for $C_{13}H_{24}O$: C, 79.53; H, 12.32%. Found: C, 79.43; H, 12.17%.

The crude alcohol (1.7 g) was refluxed with palladized charcoal (10%, 0.4 g) for 4 hours. The hydrocarbon (100 mg) was then acetylated in the manner described by Pines (23), and converted to the known 2,4-dinitrophenylhydrazone in the usual manner. The product, crystallized from chloroform–ethanol, had m.p. 161–165° undepressed on admixture with an authentic specimen of the same melting point (23).

Acetone – (+)-Carvomenthene (ii)

A solution of carvomenthene ($[\alpha]_D$+105°; 3.1 g) in acetone (60 ml) was irradiated at room temperature for 45 hours during which time the rotation of the solution fell from 102° to 43°. Distillation gave an oil b.p. 65–115°/14 mm. Gas–liquid chromatography then afforded carvomenthene ($[\alpha]_D$ +74° (*c*, 0.43)) identical in all respects except rotation with the starting material. A substance with lower retention time than carvomenthene was isolated and shown to be *p*-menth-1,7-ene. It had maxima in the infrared at 6.08 (s), 9.35, 9.62, 9.85, 10.07, 10.22, 11.07, and 11.26 (s) μ, and n_D^{25} 1.4578. The literature records (13) maxima in the infrared at 6.08 (s), 9.37, 9.62, 9.85, 10.07, 10.22, 11.07, 11.26 (s) μ and n_D^{25} 1.4575.

Carvomenthene was unaffected under the irradiation conditions in the absence of acetone.

Cyclohexanone–Cyclohexene

A solution of cyclohexanone (25 g) in cyclohexene (100 ml) was irradiated at reflux temperature over a 500-watt Hanovia lamp for 40 hours. Distillation then gave a colorless oil (15 g) b.p. 72–197°/25 mm. A portion (5 g) of the oil was chromatographed on alumina (Brockman Grade 5, 200 g). Three fractions were obtained. Fraction (i) (1 g) eluted with light petroleum had b.p. 108–109°/18 mm, n_D^{24} 1.5062, and was identical in every respect with 3,3′-bicyclohexenyl. Fraction (ii) (1.3 g) also eluted with light petroleum had b.p. 125°/7 mm, n_D^{24} 1.4513. Calc. for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18%. Found: C, 72.68; H, 10.98%. The substance was identified as cyclohexyl *n*-caproate by hydrolysis, the caproic acid being characterized as the *p*-bromophenacyl ester (m.p. and mixed m.p. 70–71°) and the cyclohexanol as the 3,5-dinitrobenzoate (m.p. and mixed m.p. 109–111°). Fraction (iii) (1.5 g) eluted with benzene–light petroleum (1:4) had b.p. 145–146°/20 mm, n_D^{23} 1.4970, ν_{max} 1715 cm^{-1}. It gave an orange 2,4-dinitrophenylhydrazone, m.p. 172–5° from ethanol–chloroform. Calc. for $C_{18}H_{24}O_4N_4$: N, 15.55%. Found: N, 15.56%. It was undepressed in melting point on admixture with the 2,4-dinitrophenylhydrazone of cyclohexyl cyclohexanone prepared by the method of Hückel *et al.* (18), and the infrared spectra in chloroform solution were superposable.

The same substances were produced by irradiation at room temperature in similar yields.

Propionaldehyde–Cyclohexene

A solution of propionaldehyde (40 g) in cyclohexene (200 ml) was irradiated at reflux temperature over a 500-watt Hanovia lamp for 24 hours. Distillation gave a colorless oil (25 g). A portion of the oil (5 g) was chromatographed on alumina (Brockman Grade 5, 175 g) to give three fractions. Fraction (i) (650 mg), eluted with light petroleum, was identified, as previously, as 3,3′-bicyclohexenyl. Fraction (ii), also eluted with light petroleum, had b.p. 71–73°/15 mm, n_D^{25} 1.4547, ν_{max} 1709 cm^{-1}. It gave a 2,4-dinitrophenylhydrazone, m.p. 149–151° (from benzene). Calc. for $C_{15}H_{20}O_4N_4$: C, 56.24; H, 6.29; N, 17.49%. Found: C, 56.46; H, 6.40; N, 17.43%. This, and its derivative, were identical in every respect with a specimen of ethylcyclohexyl ketone and its 2,4-dinitrophenylhydrazone prepared by the method of Morris and Lusth (19). Fraction (iii) (1.05 g), eluted with benzene–ether (19:1) had b.p. 87–88°/11 mm, n_D^{25} 1.4772. It gave a 3,5-dinitrobenzoate, m.p. 74–8°. Calc. for $C_{16}H_{16}O_6N_2$: C, 57.48; H, 5.43; N, 8.38%. Found: C, 57.65; H, 5.50; N, 8.22%. It was identical with the derivative of 1-cyclohex-2′-enylpropan-1-ol from the alcohol prepared by an unambiguous route prepared as described below.

The same products, with a somewhat lower yield of ketone, were obtained by irradiation at room temperature.

Acetaldehyde–Cyclohexene

A solution of acetaldehyde (10.2 g) in cyclohexene (50 ml) in a sealed quartz tube was irradiated for 65 hours with an AH-8 lamp, the tube being cooled in a current of air. The crude oil, b.p. 60–120°/14 mm (4.9 g), on gas–liquid chromatography gave three main components. The last (retention time 110 minutes) was shown, as in previous cases, to be 3,3′-bicyclohexenyl. The first (retention time 32 minutes) had n_D^{25} 1.4498 and gave a semicarbazone m.p. 172.5–173.5° undepressed on admixture with the semicarbazone of methylcyclohexyl ketone of the same melting point. The infrared spectrum of the first component and that of a methylcyclohexyl ketone were superposable.

The second component (retention time 45 minutes) was most readily isolated in larger amounts by heating, under reflux, of the crude distillate (2.4 g) with Girards 'T' reagent

(3.3 g) in 95% ethanol (15 ml) containing acetic acid (0.5 ml) for 12 hours. Isolation of the non-ketonic material (1.6 g) followed by chromatography on alumina (Brockman Grade 1, 50 g) gave, on elution with benzene–ether (3:1) 1-cyclohex-2′-enylethan-1-ol, n_D^{21} 1.4798, b.p. 88–90°/13 mm. Calc. for $C_8H_{14}O$: C, 76.14; H, 11.18%. Found: C, 75.21; H, 11.59%. The substance was identical in infrared spectrum with that of the alcohol prepared by an unambiguous route described below. The substance gave a 3,5-dinitrobenzoate, m.p. 75.5–76.5° (from light petroleum). Calc. for $C_{15}H_{16}O_6N_2$: C, 56.25; H, 5.04; N, 8.75%. Found: C, 55.76; H, 5.07; N, 8.59%.

Under these conditions the yields of alcohol and ketone were approximately 6%. A similar irradiation employing a more dilute solution of acetaldehyde (1.2 g) in cyclohexene (55 ml) gave the same products, but whereas the yield of ketone was essentially unchanged, the yield of alcohol was now 38%.

2-Cyclohex-2′-enylpropan-2-ol, 3,5-Dinitrobenzoate

Cyclohexene-3-carboxylic acid (20) (2 g) was esterified with excess diazomethane. After evaporation of the excess diazomethane the ester in ether (50 ml) was added to a solution of methyl magnesium iodide (from methyl iodide (5 g) and magnesium (0.8 g)) and the mixture stirred for 1 hour. Isolation of the neutral material gave 2-cyclohex-2-enylpropan-2-ol (2 g) (identical in retention time with the photochemical product), which was converted directly into the 3,5-dinitrobenzoate. Crystallized from chloroform – light petroleum this had m.p. 122–125°.

trans-1,2-Di(2′-hydroxy-2′-propyl)cyclohexane, 3,5-Dinitrobenzoate

trans-Cyclohexan-1,2-dicarboxylic acid (21) (3 g) was esterified with excess diazomethane, the excess diazomethane reagent removed by evaporation, and the ester in ether (50 ml) added to methyl magnesium iodide prepared from methyl iodide (213 g) and magnesium (45 g) in ether (1l.) and the mixture refluxed for 150 hours. Isolation of the neutral material in the usual way gave an oil (2 g). A portion (1.5 g) of the oil was converted into the 3,5-dinitrobenzoate by the method of Brewster and Ciotti (22). Chromatography of the product on silica gel (100 g) gave on elution with benzene–ether (9:1) and crystallization from methanol and from ethyl acetate – light petroleum the bis 3,5-dinitrobenzoate, m.p. 110–112.5°, undepressed on admixture with the 3,5-dinitrobenzoate of the product obtained by irradiation.

4-Cyclohex-2′-enylheptan-4-ol and 3-Cyclohex-2′-enylpentan-3-ol

Methyl cyclohexene-3-carboxylate (2.15 g) was added to the Grignard reagent prepared from *n*-propyl iodide (18.5 g) and magnesium (2.4 g) in dry ether (100 ml). After 1-hour stirring the neutral material was isolated in the usual way, and purified by gas–liquid chromatography. Its retention time on the silicone column, its refractive index, and its infrared spectrum were identical with those of the photochemical product.

3-Cyclohex-2′-enylpentan-3-ol, n_D^{23} 1.4800, was prepared in a similar manner. It was identical in retention time and infrared spectrum with the photochemical product.

1-Cyclohex-2′-enylpropan-1-ol

A solution of cyclohexane-3-carboxylic acid (2 g) and oxalyl chloride (3 g) in dry benzene (15 ml) was allowed to stand at room temperature for 2 days after which solvent and excess oxalyl chloride were removed *in vacuo*. The acid chloride was added to cadmium diethyl (from anhydrous cadmium chloride (6.25 g), ethyl bromide (15 g), and magnesium (1.75 g)) at 10° and the mixture stirred for 2 hours and allowed to stand at room temperature for 16 hours. Decomposition of the complex with water, and isolation of the

For personal use only.

neutral material gave an oil which was filtered through a column of silica gel in light petroleum – benzene (4:1) to remove alcoholic impurities. The crude unconjugated ($\epsilon_{230} < 600$) ketone (1.8 g) in ether (50 ml) was then added to a solution of lithium aluminum hydride in ether (100 ml) at 0°. After 1 hour the mixture was decomposed with ethyl acetate and the neutral material isolated in the usual way. The alcohol had the same retention time as the photochemical product on the silicone column, and gave a 3,5-dinitrobenzoate m.p. 65–78° undepressed on admixture with the derivative of the photochemical product and having identical infrared spectrum. However, although the column used in the gas–liquid chromatography showed a single peak it is probable in view of the diffuse melting point of the derivative that the product is a mixture of diastereoisomers.

1-Cyclohex-2-enylethan-1-ol was prepared in a precisely analogous fashion. The product had ν_{max} in the infrared at 3580, 3380, and 722 cm^{-1} and n_D^{25} 1.4806. It was identical in retention time with the photochemical product.

ACKNOWLEDGMENTS

The authors wish to thank the British Petroleum Company for support (for W. T.) and the Imperial Oil Ltd., of Canada for generous financial support. The authors are indebted to Professor D. H. R. Barton for his interest and for many discussions.

KINETICS AND THERMODYNAMICS OF THE CRYSTAL STRUCTURE TRANSFORMATION OF SPECTROSCOPICALLY PURE ANATASE TO RUTILE[1]

C. N. R. RAO[2]

ABSTRACT

The transformation of spectroscopically pure anatase to rutile was first investigated by Czanderna, Rao, and Honig. But it was not possible, then, to provide the mechanism on a molecular scale because of the lack of very accurate kinetic data. The kinetics and thermodynamics of the transformation have now been carefully investigated.

EXPERIMENTAL

The preparation of the spectroscopically pure anatase and the procedure adopted in the kinetic studies and in the X-ray analysis of the samples have been described earlier (1). The accuracy of the analytical method is found to be rather poor at anatase concentrations of less than 5% or greater than 95%. In order to obtain reliable kinetic data for fitting them into the order plots, the proportion of anatase was always seen to be within these limits. The temperature fluctuation in a run was within 5°. The purity of the sample is the most important requisite in this study since impurities are known to affect the transformation markedly (2, 3).

The differential thermal analysis of the anatase (preheated to 250° C) was carried out using a high sensitivity (0.25–0.5 cal) apparatus similar to that described by Pask and Warner (4). A sufficiently fast and constant heating rate of 12.5 deg min^{-1} was employed since the peaks corresponding to crystal structure transformations are usually small.

RESULTS AND DISCUSSION

The kinetic results at different temperatures are shown in Fig. 1(*a*). In Fig. 1(*b*), the data are plotted for the first-order equation. The data follow the first-order law fairly well. The first-order rate constants at different temperatures are summarized in Table I.

TABLE I

Temperature, °C	Rate constant, hr^{-1} $k\times10^2$
625	2.9_9
643	6.2_2
684	36.9_0
698	76.7_0

The reaction rate constants in Table I follow the Arrhenius equation closely (Fig. 2). The energy of activation is about 80±10 kcal per mole. The frequency factor is about 4×10^{14} sec^{-1}, which is surprisingly of the same order as expected for the first-order gas or solution reactions. The entropy of activation calculated from Eyring's theory is about 27 e.u. at 643° C.

The kinetic data of this investigation give a value of 610±10° C for the infinite-time

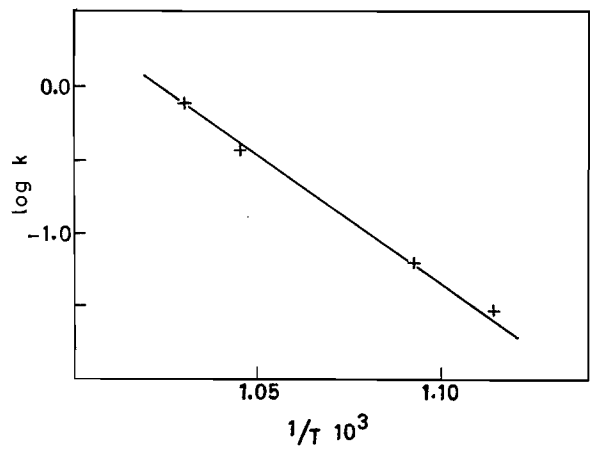

FIG. 2. Arrhenius plot.

temperature. That is, below 610° C, the transformation is immeasurably slow. This is in agreement with the value reported earlier (1).

The differential thermal analysis of the anatase showed a small exothermic peak starting around 630° C corresponding to the transformation to rutile. It was confirmed by X-ray analysis that the transformation was complete after the exothermic peak. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

temperature of 630° C corresponds excellently with the infinite-time temperature mentioned earlier.

The heat of the transformation, ΔH, was estimated by comparing the area of the exothermic peak with the α–β inversion peak of a known amount of quartz. The ΔH thus estimated was only -100 ± 50 cal per mole.

An interpretation of the data on the kinetics of this solid-state transformation may be obtained by drawing an analogy with the thermal decomposition of solids (1, 5). However, a more refined and satisfactory theoretical treatment has been possible, by the application of the order–disorder theory (6). The details of the theory will be discussed elsewhere (7). From the theory it can be shown that the ratio of the propagation rate constant to the nucleation rate constant is small. Also, the observed energy of activation seems to represent mainly the activation energy for the production of the nucleation sites.

ACKNOWLEDGMENT

The author's thanks are due to Prof. M. R. A. Rao for his keen interest.

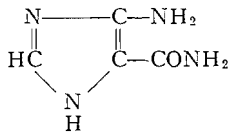
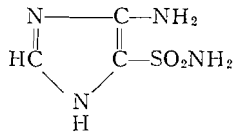
NITRO- AND AMINO-IMIDAZOLESULPHONAMIDES[1]



M. H. Fisher, W. H. Nicholson, and R. S. Stuart

ABSTRACT

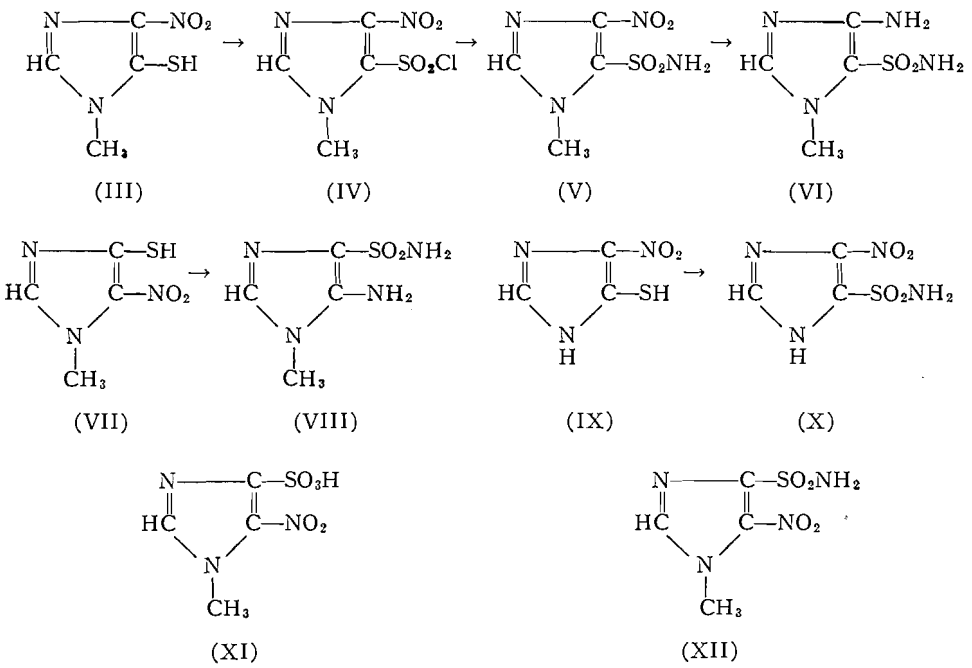


Several 4(5)-nitro- and 4(5)-amino-5(4)-sulphamylimidazoles have been synthesized as potential antagonists to 4(5)amino-5(4)-carbamylimidazole.

INTRODUCTION

There has recently been considerable interest in the role of 4(5)-amino-5(4)-carbamylimidazole (I) and related compounds in the biosynthesis of purines (1, 2, 3, 4). However, the preparation of imidazole analogues as potential antagonists has not been widely investigated (5). In this work compounds related to 4(5)-amino-5(4)-sulphamylimidazole (II) were synthesized for biological testing.[2]

(I)



(II)

A number of unsuccessful attempts to prepare compounds of this type have been reported, e.g. chlorination of imidazole sulphonic acids, chlorosulphonation of nitro- or acylamino-imidazoles, amination of bromo-imidazoles, and conversion of imidazolethiols to sulphenamides followed by oxidation (5, 6, 7). 4(5)-Bromo-5(4)-sulphamylimidazole was prepared by chlorosulphonation of 4(5)-bromoimidazole (5), but it failed to react with ammonia.

The most attractive approach was the oxidative chlorination of the thiols, a general method described by Sprague and Johnson (8) and later used for the preparation of 2-sulphamylimidazoles (9, 10). 5-Mercapto-1-methyl-4-nitroimidazole (III) (5) was converted to the sulphonyl chloride (IV) by oxidative chlorination in dilute hydrochloric acid. The sulphonyl chloride with concentrated aqueous ammonia yielded 1-methyl-4-nitro-5-sulphamylimidazole (V). Catalytic reduction of this compound gave 4-amino-1-methyl-5-sulphamylimidazole (VI). In a similar manner 5-amino-1-methyl-4-sulphamylimidazole (VIII) was obtained from 1-methyl-4-mercapto-5-nitroimidazole (VII). 4(5)-Mercapto-5(4)-nitroimidazole (IX) (5) was converted to 4(5)-nitro-5(4)-sulphamylimidazole (X) but attempted catalytic reduction caused gross decomposition.

[1]*Manuscript received November 29, 1960.*
Contribution from the Research Department, Merck and Co. Ltd., Montreal, Que.
[2]*The compounds are being screened for anticancer activity at the Sloan-Kettering Institute for Cancer Research.*

(III) (IV) (V) (VI)

(VII) (VIII) (IX) (X)

(XI) (XII)

The oxidative chlorination of the 4-thiol (VII) yielded variable products. The desired sulphonyl chloride was obtained when the reaction temperature was maintained below 40° and the rate of addition of chlorine carefully controlled. Too rapid addition of chlorine at 20° or above resulted in the formation of 1-methyl-5-nitroimidazole-4-sulphonic acid (XI). Best results were obtained when the chlorine was added rapidly at 0° until the bright yellow starting material became white. The preparation was further complicated because the sulphonamide (XII) was isolated in two forms melting at 149° and 159°. Catalytic reduction of either form yielded the same amine. The oxidative chlorination of the other thiols (III) and (IX) gave good yields of the sulphonyl chlorides at 20°–30° and 0° respectively.

There was a pronounced difference in stability between the amines. 4(5)-Amino-5(4)-sulphamylimidazole was so unstable that it was neither isolated as the base nor a salt. 4-Amino-1-methyl-5-sulphamylimidazole (VI) was an unstable base and formed a moderately stable hydrochloride. 5-Amino-1-methyl-4-sulphamylimidazole (VIII) was stable either as the base or as the hydrochloride.

EXPERIMENTAL

1-Methyl-4-mercapto-5-nitroimidazole (VII)

4-Chloro-1-methyl-5-nitroimidazole (11) (10 g) was suspended in a warm solution of water (67 ml) and concentrated ammonia (33 ml). Hydrogen sulphide gas was passed into the stirred mixture until a clear, dark red solution was obtained (20 minutes). The ammonium salt of the product crystallized on standing (9 g), m.p. 139°–140°. Recrystallization by the addition of three volumes of isopropanol to a solution in a minimum volume of water yielded dark orange needles, m.p. 140°–141°. Found: C, 27.4; H, 4.5; N, 31.1; S, 18.3. Calc. for $C_4H_8N_4O_2S$: C, 27.3; H, 4.5; N, 31.8; S, 18.2%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

4(5)-Nitro-5(4)-sulphamylimidazole (X)

The ammonium salt of 4(5)-mercapto-5(4)-nitroimidazole (5) (1 g) was suspended in 1 *N* hydrochloric acid (10 ml) and cooled in an ice bath. Chlorine gas was passed into the stirred mixture until the suspended solids became buff colored (35 minutes). The sulphonyl chloride produced (m.p. 180°–183°) was collected, washed with a little ice water, and dissolved in concentrated ammonia (10 ml). After 15 minutes the excess of ammonia was evaporated *in vacuo* and the residual solution was acidified with hydrochloric acid. The sulphonamide, which precipitated, was collected and crystallized from water as jagged white needles (0.4 g), m.p. 261°–262°. Found: C, 18.8; H, 2.1; N, 29.3; S, 16.9. Calc. for $C_3H_4N_4O_4S$: C, 18.8; H, 2.1; N, 29.2; S, 16.7%.

1-Methyl-5-nitro-4-sulphamylimidazole (XII)

The ammonium salt of 4-mercapto-1-methyl-5-nitroimidazole (VII) (5.0 g) treated in a similar manner yielded the sulphonyl chloride (m.p. 104°), which was converted into the sulphonamide (3 g), m.p. 158°–159°. Found: C, 23.3; H, 2.9; N, 27.5; S, 15.7. Calc. for $C_4H_6N_4O_4S$: C, 23.3; H, 2.9; N, 27.2; S, 15.5%. The product was also isolated in another form, m.p. 149°–150°. Found: C, 23.4; H, 3.0; N, 26.6; S, 15.5%.

From a similar experiment in which the temperature was allowed to reach 50° there was isolated the ammonium salt of *1-methyl-5-nitroimidazole-4-sulphonic acid (XI)* m.p. 260°–265° (decomp.). Found: C, 21.4; H, 3.5; N, 25.0; S, 14.4. Calc. for $C_4H_8N_4O_5S$: C, 21.4; H, 3.6; N, 25.0; S, 14.3%. Acidification of a solution of the ammonium salt in water precipitated the acid m.p. 299°–300°. Found: C, 23.3; H, 2.4; N, 20.0; S, 15.5. Calc. for $C_4H_5N_3O_5S$: C, 23.2; H, 2.4; N, 20.3; S, 15.5%.

1-Methl-4-nitro-5-sulphamylimidazole (V)

The ammonium salt of 5-mercapto-1-methyl-4-nitroimidazole (5) (22 g) by similar oxidative chlorination at 20°–30° yielded the sulphonyl chloride (m.p. 106°–107°), which was converted into the sulphonamide (16.5 g), m.p. 176°–177°. Found: C, 23.4; H, 3.0; N, 27.0; S, 15.3. Calc. for $C_4H_6N_4O_4S$: C, 23.3; H, 2.9; N, 27.2; S, 15.5%. The acetyl derivative was prepared by refluxing the sulphonamide for 1 hour in an excess of acetic anhydride. Crystallization from water yielded white needles m.p. 219°–220° (decomp.). Found: C, 29.0; H, 3.3; N, 22.7. Calc. for $C_6H_8N_4O_5S$: C, 29.0; H, 3.2; N, 22.6%.

4-Amino-1-methyl-5-sulphamylimidazole (VI)

A suspension of 1-methyl-4-nitro-5-sulphamylimidazole (5 g) and Adams' platinum catalyst (0.1 g) in dry ethanol (250 ml) was hydrogenated at room temperature and atmospheric pressure. The theoretical volume of hydrogen was absorbed in 1 hour and a white solid was precipitated. The solid and the catalyst were collected, washed with ether, and suspended in ethanol (125 ml). Concentrated hydrochloric acid (5 ml) was added, the amine was dissolved, and the catalyst was filtered off immediately with the aid of filtercel. The hydrochloride salt of the product crystallized on standing as cream needles (1.9 g), m.p. 180° (decomp.), with sintering at 140°–150°. Found: C, 20.6; H, 4.0; Cl, 15.6; N, 23.9; S, 14.0. Calc. for $C_4H_8N_4O_2S,HCl,H_2O$: C, 20.8; H, 4.8; Cl, 15.4; N, 24.3; S, 13.9%. Attempts to obtain the base were unsuccessful and the hydrochloride salt itself darkened and finally decomposed on long standing.

5-Amino-1-methyl-4-sulphamylimidazole (VIII)

Catalytic reduction of 1-methyl-5-nitro-4-sulphamylimidazole (5 g) in a similar manner yielded the hydrochloride salt of the product as white needles (4.2 g), m.p. 185°–187°

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(decomp.). Found: C, 22.6; H, 4.2; N, 26.3; S, 15.4. Calc. for $C_4H_8N_4O_2S$, HCl: C, 22.6; H, 4.2; N, 26.3; S, 15.0%.

An aqueous solution of the hydrochloride salt on addition of an excess of ammonia precipitated the base as white needles m.p. 208°–210° (decomp.).

Reduction of 4(5)-nitro-5(4)-sulphamylimidazole (X)

Catalytic reduction of 4(5)-nitro-5(4)-sulphamylimidazole with Adams' platinum catalyst was attempted in both dry ethanol and in a mixture of glacial acetic acid and acetic anhydride. In each case the solution became dark brown as hydrogen was absorbed. No crystalline products were isolated.

Infrared Spectra

The infrared spectrum of each of the compounds reported was examined. The nitroimidazole sulphonamides showed bands in the regions of 1540 and 1350 cm^{-1} characteristic of the nitro-group and bands in the regions of 1300 and 1175 cm^{-1} characteristic of the sulphonamide group. Reduction of the nitro-compounds caused a disappearance of the bands in the regions of 1540 and 1350 cm^{-1}. The spectra of the aminoimidazole sulphonamides showed two bands in the regions of 3385 and 3315 cm^{-1} characteristic of primary amine stretching absorptions and a band in the region of 1660 cm^{-1} characteristic of primary amine deformation vibrations. The bands in the regions of 1300 and 1175 cm^{-1} characteristic of sulphonamides were still evident.

The determination and interpretation of the infrared spectra was carried out by Professor A. Taurins, Department of Chemistry, McGill University.

N.M.R. SPECTRA OF SOME α–β UNSATURATED ESTERS[1]

ROBERT R. FRASER AND DONALD E. MCGREER

ABSTRACT

The results of analysis of methyl citraconate and mesaconate, methyl *cis*- and *trans*-crotonate, and methyl *cis*- and *trans*-2-pentenoate are reported. A previously reported analysis of the crotonates by first-order perturbation theory gave significantly different values for the 1,3 coupling constants. The discrepancy in results, which is due to the importance of second-order effects, emphasizes the need for caution in applying the first-order method. From values of 1,3 coupling constants reported here and elsewhere it is concluded that there is no simple relation between the magnitude of 1,3 coupling constants and geometrical configuration of the interacting nuclei.

Much attention has been devoted recently to the N.M.R. spectra of substituted propenes and butenes (1–7). Two aspects of the spectra have received special attention. The first is the magnitude of the 1,3 coupling constants.* Whipple *et al.* have reported 1,3 coupling to be consistently greater in the trans 2-substituted propenes ($J_{1,3\ cis}$) than in the cis isomers (2) ($J_{1,3\ trans}$). In tiglic and angelic acids and their methyl esters the opposite was found (1). Subsequently Jackman and Wiley (4) provided evidence which gave a different assignment to the protons of α-methacrolein from that of Whipple *et al.* and thus provided another case where $J_{1,3\ trans}$ was greater than $J_{1,3\ cis}$. The second aspect was the basis of Jackman's studies. He presented compelling evidence for the use of chemical shifts to assign configuration to α–β unsaturated esters. Among the compounds which he has studied were the methyl esters of mesaconic, citraconic, and *cis*- and *trans*-crotonic acids. We have examined these same four esters in addition to the methyl esters of *cis*- and *trans*-2-pentenoic acid. The more exact method of analysis employed in our case has provided some results of particular interest in this field.

Methyl Mesaconate and Methyl Citraconate

The olefinic and C-methyl protons in these esters comprise an AX_3 system. Analysis of such a system can be made by first-order perturbation theory. The complete results are listed in Table I. All coupling constants in this paper are reported with an estimated accuracy of ±0.05 cycle/sec as the standard deviation of each measurement was $\leqslant 0.05$ cycle/sec. The coupling constants in Table I are in agreement with those of Jackman and Wiley, who found values of 1.60±0.07 for each isomer. All chemical shift measurements are reported as τ values (8).

TABLE I

Compound	Coupling constants		Chemical shifts		
	$J_{1,3\ cis}$	$J_{1,3\ trans}$	β-H	β-CH_3	$COOCH_3$
Methyl mesaconate	—	1.56	3.32	7.75	6.22, 6.27
Methyl citraconate	1.64	—	4.23	7.97	6.28, 6.32

[1]*Manuscript received October 17, 1960.*

**The term 1,3 coupling constant is used to denote the energy of interaction between protons separated by three carbon atoms.*

Methyl cis-Crotonate and Methyl trans-Crotonate

The results of analysis by first-order perturbation theory and also by the ABX_3 treatment of Waugh and Fessenden (9) are given in Table II. The relative signs of the coupling constants in these compounds could not be conclusively established from the observed spectra. It was therefore assumed that $J_{1,3}$ has the opposite sign to $J_{1,2}$ and $J_{2,3}$. Both experimental evidence (9, 10, 11, 17) and theoretical calculations (6) on relative signs in olefinic compounds justify this assumption.

The spectrum of the olefinic and β-methyl protons of cis methyl crotonate is shown in Fig. 1 and illustrates the nearly first-order appearance of this spectrum. The slight

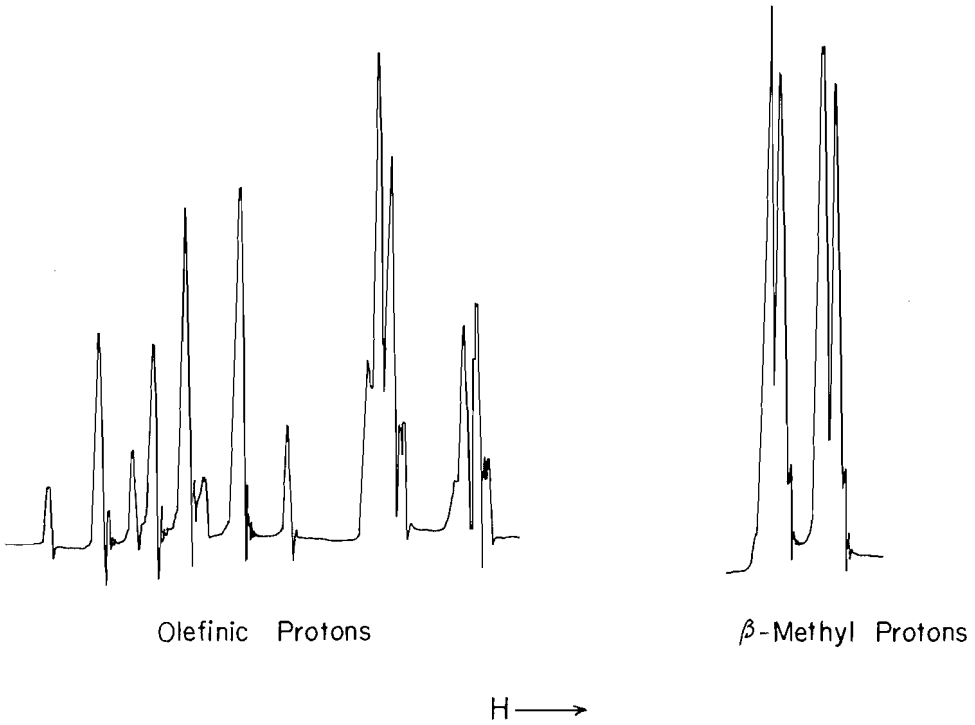

FIG. 1.

skewing of intensities is the only obvious indication of the mixing of proton spin states. Nevertheless, the observed splitting of the methyl group and the average of the three splittings in the weakly split quartets are 0.25 cycle/sec less than the actual interaction energy, $J_{1,3}$. While this error is usually, although not always, small in the determination of large coupling constants, it becomes important when dealing with the weaker long-range interactions. This effect, which was underestimated by one of us (R.R.F.) in the spectra of tiglic and angelic acids (1), emphasizes the need for caution in assuming first-order calculations to be applicable. Unfortunately exact analysis of the tiglic and angelic acids, which are A_3B_3X systems, is too tedious to warrant exact solution. Therefore the previously reported results for the coupling constants in tiglic and angelic acid and their esters must be considered as approximate. The results of first-order analysis of the crotonates agree with those of Jackman and Wiley. However, we found the values for the olefinic protons to be 0.15 p.p.m. to higher field.

Methyl cis-2-Pentenoate and Methyl trans-2-Pentenoate

The spectra of the pentenoates are further complicated by the presence of an extra methylene group. Analysis of the olefinic absorption was carried out by treating the olefinic and methylene protons as an ABX_2 system whose solution has been reported in detail by Mortimer (12). Again it was assumed that the sign of $J_{1,3}$ was opposite to that of the other coupling constants. By employing the ABX_2 method we have neglected two factors. First, the effect of the methyl group will be important if it is not sufficiently separated from the methylene protons. In the trans isomer, where this effect is greater, the J/δ ratio for the methyl–methylene interaction is <0.1 and therefore can be neglected. The possibility that the ABC_2 treatment should be employed was eliminated since the calculated second-order perturbation theory corrections (12), which were of the order of 0.02 cycle/sec, were negligible. The results are given in Table III.

DISCUSSION

It has been suggested that geometrical configuration might be the predominant factor in determining the relative magnitudes of $J_{1,3\ cis}$ and $J_{1,3\ trans}$ (1). It can be seen that in the three pairs of isomeric esters studied $J_{1,3\ trans}$ is equal to, greater than, and less than $J_{1,3\ cis}$. Furthermore Jackman and Wiley have found that in the 2-substituted propenes $J_{1,3\ cis} > J_{1,3\ trans}$ in all compounds except methacrolein whereas there was little or no difference in the magnitude of 1,3 couplings in five 1-substituted isobutenes (4). Since Whipple, Goldstein, and Mandell (2) had earlier made an assignment to the olefinic protons of methacrolein in opposition to Jackman and Wiley's rule we examined the effect of changing solvent on the spectrum of methacrolein* in order to confirm one assignment or the other. It was found that both olefinic protons were shifted by 0.88 p.p.m. to higher field in changing from cyclohexane to benzene, whereas the methyl shift was +0.56 p.p.m. Thus this method is not applicable to the assignment of proton structure in α-methacrolein and Jackman's assignment has been accepted.

From the work herein and that of Whipple *et al.* and Jackman and Wiley it is therefore clear that the geometrical configuration about the double bond will not determine the relative magnitude of 1,3 coupling constants. This does not mean that geometry is unimportant. Whipple, Goldstein, and McClure have shown that the coupling constants in 2,3-dihalopropenes vary with solvent composition (3) and have attributed this observation in a reasonable way to changes in geometry which result from a change in the population of conformations with change in solvent polarity.

EXPERIMENTAL

The spectra were obtained with a Varian V-4302 N.M.R. spectrometer at a frequency of 60 Mc/sec. Each measurement reported is the average of at least five determinations. Spectra for determination of coupling constants and chemical shifts were made on 40% (wt.:vol.) solutions in carbon tetrachloride. τ values were obtained from the spectra of 10% solutions in carbon tetrachloride containing 1% tetramethylsilane as internal reference. No difference in chemical shift at the two concentrations was observed.

The preparation of methyl *cis-* and *trans*-crotonate and methyl *cis-* and *trans*-2-pentenoate has been reported elsewhere (13, 14). Methyl citraconate and methyl mesaconate were prepared by conversion of itaconic acid to citraconic and mesaconic acids (15), followed by esterification to the known esters (16).

**Their assignment rested on the assumption that the preferential solvent shift of one olefinic proton and the methyl protons was approximately the same if the two were cis. This was applied to 2-chloropropene from which $J_{1,3\ cis}$ was found to be greater than $J_{1,3\ trans}$. From this observation assignments in other structures were made on the basis of the relative magnitudes of $J_{1,3\ cis}$ and $J_{1,3\ trans}$.*

SPECTROPHOTOMETRIC STUDY OF THE REACTION BETWEEN IRON (III) AND KOJIC ACID[1]

W. A. E. McBryde[2] and G. F. Atkinson[3]

ABSTRACT

A method introduced by Vareille enables calculation of formation constants of colored metallic complexes in solution by making appropriate deductions from the presence of isobestic points in the spectra of suitably chosen solutions. The rationale of this method is derived rigorously, and its application extended to include cases where three complexes are present together in certain regions of pH. These principles are applied to derive for the ferric kojates the following formation constants, at 25° C and ionic strength 0.5: $\log K_1 = 10.16$, $\log K_2 = 8.29$, $\log K_3 = 6.90$. The relationship between pH and pL for the experimental conditions is calculated, thereby enabling the estimation of the distribution of the metal among the several species in each solution and the absorption spectrum of each complex.

INTRODUCTION

Vareille (1) has derived and applied a method for obtaining formation constants of metallic complexes which consists in measuring the absorption spectra of solutions of fixed total concentration of metal, $[M]_T$, and ligand, $[L]_T$, and of various pH's; and then in locating, if they are present, isobestic points at which three or more of the spectral curves intersect at a single wavelength. This author interprets the presence of such isobestic points as evidence of the metal being distributed in solution between not more than two species in the ranges of pH in which the isobestic points are found. If the identity of these particular species can be established, it is possible, as Vareille has shown, to deduce the equilibrium constants governing their interconversion. In the first part of this communication we offer a generalized discussion of the principle of the method, showing in particular the conditions necessary or desirable for its application. From this discussion it will be seen that the systems of complexes to which the method may be applied are limited to those which possess a moderately large spread in magnitudes of the successive formation constants. The three systems examined by Vareille are ideal in this respect; but in this paper it is shown that the method may be extended to sets of complexes with less favorable spacing of formation constants.

PRINCIPLE OF THE METHOD

Many of the experimental methods for deriving the formation constants of the successive complexes formed by a metallic ion and a ligand molecule or ion depend on finding corresponding values of $\bar{n}$, the degree of complex formation, and [L], the molar concentration of free ligand. These are related to the formation constants of the several complexes by Bjerrum's formation function:

$$[1] \qquad \bar{n} = \frac{\sum_1^N n\beta_n[L]^n}{1+\sum_1^N \beta_n[L]^n}.$$

[1]*Manuscript received November 1, 1960.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ont., and (in part) University of Waterloo, Waterloo, Ont.
[2]*Present address: Department of Chemistry, University of Waterloo, Waterloo, Ontario.*
[3]*Present address: Department of Chemistry, University of Western Ontario, London, Ontario.*

In this,

β_n is a cumulative formation constant $= K_1K_2 \ldots K_n$

$$= \prod_1^n K_n.$$

K_n is the equilibrium constant for the reaction

$$ML_{n-1} + L = ML_n.$$

Following common practice, charges on individual species are omitted. The so-called equilibrium constants discussed in this paper are, with the exception of hydrogen ion, based on concentrations of the reacting species; they are therefore "formal" or "conditional" constants, applying in theory only to the medium in which they have been determined.

A plot of $\bar{n}$ vs. pL ($= -\log [L]$) yields the formation curve for the system of complexes. From experimentally determined formation curves it is possible to extract the individual formation constants by various numerical methods. The shape of the formation curve depends on the relative magnitudes of the several K's. Two distinct possibilities occur, and these are illustrated in Fig. 1, showing formation curves calculated by means of equation 1 and the appropriate formation constants for (*a*) the ferric 5-sulphosalicylates (one of the systems examined by Vareille), and (*b*) the ferric 5-sulpho-oxinates. The wide spacing in the constants for case (*a*) results in regions of pL in which each complex, ML, ML_2, and ML_3, has exclusive existence; and these correspond to the plateaux in this formation curve. Where the constants are not so widely spaced, as with case (*b*), the formation curve contains no plateau, and often shows only one point of inflection. For case (*b*) one may calculate that the quantity

$$[2] \qquad \alpha_n = \frac{[ML_n]}{[M]_T} = \frac{\beta_n[L]^n}{1+\beta_n[L]^n}$$

falls considerably short of the value unity for $n = 1$ or 2, so that the metal can never exclusively be in the form of ML or ML_2. This difference is illustrated for the same two sets of complexes in Fig. 2. Examination of these plots shows that, in case (*a*) only, as pL changes one complex gives way to another in such a way that no more than two species at a time make up practically the entire total concentration of metal.

For any system of metallic complexes with $\bar{n}_{max} = 3$, such as the foregoing two examples, and such as commonly occurs with many of the bi- and ter-valent transition metals of co-ordination number 6 when coupled with bifunctional ligands to form chelate complexes, the solution may contain, in addition to free and protonated ligand, the following species containing metal: M, ML, ML_2, and ML_3. It might also contain protonated metallic species, e.g. MHL, or polynuclear species, e.g. M_2L_2; but these will be assumed absent for this description. By introducing the assumption that, at the wavelengths under consideration, the ligand or any protonated form of it absorbs no significant amount of radiation, we may write for the molar extinction coefficient of the solution, ϵ_M, calculated from the total concentration of metal,

$$[3] \qquad \epsilon_M = \epsilon_0\alpha_0 + \epsilon_1\alpha_1 + \epsilon_2\alpha_2 + \epsilon_3\alpha_3$$

$$[4] \qquad = \frac{\epsilon_0 + \epsilon_1\beta_1[L] + \epsilon_2\beta_2[L]^2 + \epsilon_3\beta_3[L]^3}{1+\beta_1[L]+\beta_2[L]^2+\beta_3[L]^3}$$

in which α is defined by equation 2.

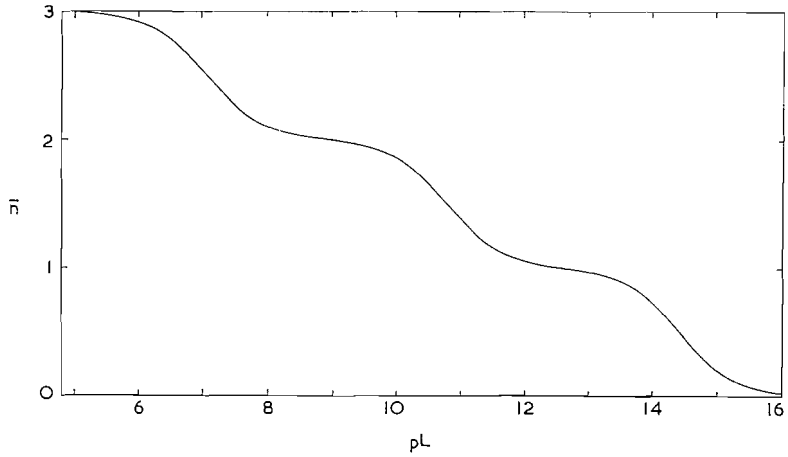

FIG. 1(*a*). Formation curve for the ferric sulphosalicylates.
$\log K_1 = 14.42$ $\log K_2 = 10.76$ $\log K_3 = 7.06$

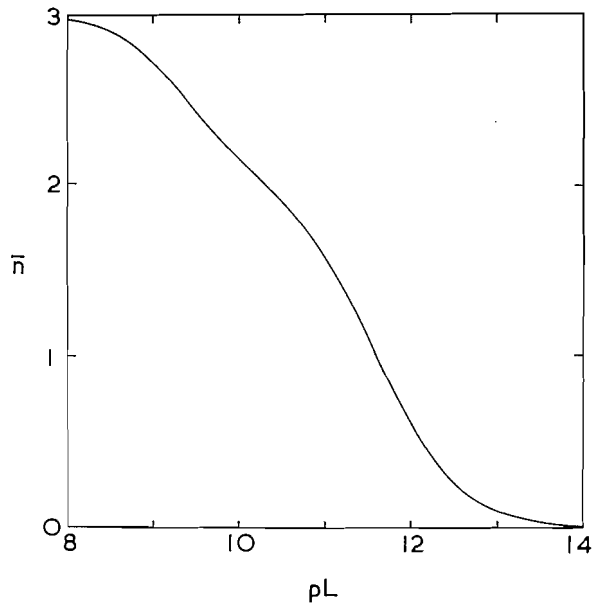

FIG. 1(*b*). Formation curve for the ferric sulpho-oxinates.
$\log K_1 = 12.0$ $\log K_2 = 11.2$ $\log K_3 = 9.4$

If the spectra of a series of solutions of these complexes differing only in pL reveal one or more isobestic points, then, at the wavelengths at which these points occur, plots of ϵ_M vs. pL will show horizontal regions which, in the discussion following, we may refer to as isobestic regions. We may derive an expression for the value of $d\epsilon_M/d\text{pL}$, and inquire into the conditions that will give this expression the value zero. Differentiating equation 4 with respect to [L], and simplifying, we get:

$$\frac{d\epsilon_M}{d[L]} = \{(\epsilon_1-\epsilon_0)\beta_1+2(\epsilon_2-\epsilon_0)\beta_2[L]+3(\epsilon_3-\epsilon_0)\beta_3[L]^2+(\epsilon_2-\epsilon_1)\beta_1\beta_2[L]^2 +2(\epsilon_3-\epsilon_1)\beta_1\beta_3[L]^3+(\epsilon_3-\epsilon_2)\beta_2\beta_3[L]^4\}(1+\beta_1[L]+\beta_2[L]^2+\beta_3[L]^3)^{-2}.$$

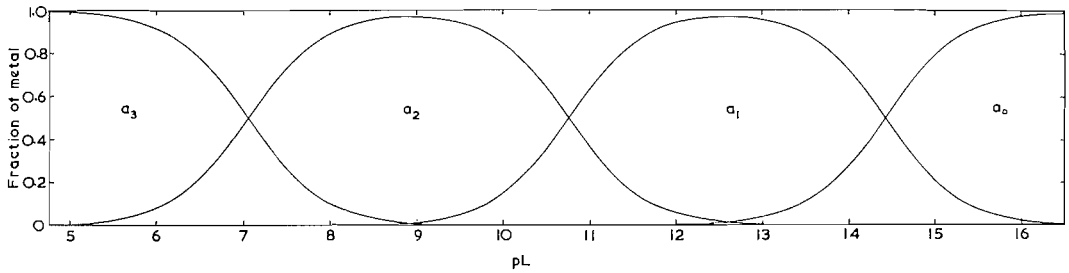

FIG. 2(*a*). Distribution of metal among simple and complex species: iron (III) + 5-sulphosalicylic acid.

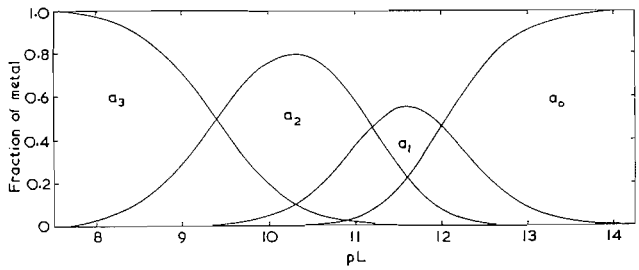

FIG. 2(*b*). Distribution of metal among simple and complex species: iron (III) + 8-hydroxyquinoline-5-sulphonic acid.

Multiplying both sides by [L], and applying equation 2, this becomes

$$[5] \qquad -0.4343\frac{d\epsilon_M}{d\mathrm{pL}} = (\epsilon_1-\epsilon_0)\alpha_0\alpha_1+2(\epsilon_2-\epsilon_0)\alpha_0\alpha_2+3(\epsilon_3-\epsilon_0)\alpha_0\alpha_3 + (\epsilon_2-\epsilon_1)\alpha_1\alpha_2+2(\epsilon_3-\epsilon_1)\alpha_1\alpha_3+(\epsilon_3-\epsilon_2)\alpha_2\alpha_3.$$

The expression on the right side of this equation will be zero if any one of the values of α becomes unity, since then the other three must be zero. This corresponds to the fact that ϵ_M will not change with pL as long as all the metal is present as a single constituent in solution. The same expression will be zero given the concurrence of any of the following pairs of relationships:

[6*a*]	$\epsilon_0 = \epsilon_1$	and	$\alpha_0+\alpha_1 \sim 1$
[6*b*]	$\epsilon_1 = \epsilon_2$	and	$\alpha_1+\alpha_2 \sim 1$
[6*c*]	$\epsilon_2 = \epsilon_3$	and	$\alpha_2+\alpha_3 \sim 1$
[7*a*]	$\epsilon_0 = \epsilon_1 = \epsilon_2$	and	$\alpha_0+\alpha_1+\alpha_2 \sim 1$
[7*b*]	$\epsilon_1 = \epsilon_2 = \epsilon_3$	and	$\alpha_1+\alpha_2+\alpha_3 \sim 1$

These are the conditions necessary for the generation of isobestic points in a series of absorption spectra of solutions differing only in pL.

The left-hand equations in 6 and 7 depend on wavelength only, and imply that each metallic species must obey Beer's law. The right-hand equations in each pair are independent of wavelength, but do depend on pL. From Fig. 2 it is seen that the relationships given by the right-hand members of the pairs of equations 6*a*, *b*, *c* are actually found for the ferric sulphosalicylates over practically the entire range of pL depicted. However, for the ferric sulpho-oxinates the same conditions are found only within comparatively narrow ranges of pL, especially that corresponding to equation 6*b*. Instead, for these complexes, the relationships of equations 7*a*, *b* are seen to obtain over most of the range of pL shown.

One may reasonably expect that any two adjacent members of a series of metallic complexes will have absorption spectra that intersect at some wavelength (see, for example, Fig. 6); that is, at some particular wavelength $\epsilon_n = \epsilon_{n+1}$. For as many such intersections as occur there will be corresponding isobestic points in a group of spectral curves for solutions differing only in pL, provided that the spacing of formation constants insures adherence to the relationships given by the right-hand members of equations 6*a*, *b*, *c* over moderate ranges of pL. For isobestic points to occur in a system of complexes having a distribution of species such as that shown in Fig. 2(*b*) is possible only within the narrow regions of pL in which equations 6*a*, *b*, *c* are valid. Where only equations 7*a*, *b* apply, the occurrence of isobestic points would require that three ionic species of differing complexity have the same molar extinction coefficient (not zero) at one wavelength; this possibility cannot be ruled out, but it seems to be exceedingly improbable.

In the systems of ferric complexes studied by Vareille, as well as in that considered in this paper, $\epsilon_0 \sim 0$ at the wavelengths under consideration, so that equation 6*a* does not apply and only two isobestic points are observed. All three sets of complexes in Vareille's work possess formation constants widely enough spaced so that the individual species are distributed as shown in Fig. 2(*a*). Thus as $\bar{n}$ increases the species ML essentially disappears from the solution before ML_3 forms in appreciable concentration. Also, the isobestic region for $\epsilon_1 = \epsilon_2$ ends at about the same pL (actually pH, but see below) as that for $\epsilon_2 = \epsilon_3$ begins; at this pL the metal is present almost exclusively as ML_2. At some wavelength (λ_{12}) $\epsilon_1 = \epsilon_2$; and a plot of ϵ_M vs. pL will show a horizontal region in which $\epsilon_M = \epsilon_1 = \epsilon_2$, and also, at lower pL, a horizontal region in which $\epsilon_M = \epsilon_3$. Between these horizontal regions there will be a skew-shaped curve in which $\epsilon_M = \epsilon_2\alpha_2 + \epsilon_3\alpha_3$. For the value of $\epsilon_M = \frac{1}{2}(\epsilon_2 + \epsilon_3)$ the corresponding value of pL = log K_3. Similarly at another wavelength (λ_{23}) $\epsilon_2 = \epsilon_3$; and when ϵ_M is plotted against pL two horizontal regions are noted, one in which $\epsilon_M = \epsilon_1$ and the other where $\epsilon_M = \epsilon_2 = \epsilon_3$. Between these horizontal regions $\epsilon_M = \epsilon_1\alpha_1 + \epsilon_2\alpha_2$, and the value of pL corresponding to $\epsilon_M = \frac{1}{2}(\epsilon_1 + \epsilon_2)$ is the value of log K_2. The identity between pL and log K in these two instances is based on the assumption that the logarithmic term in

$$\log K_n = \mathrm{pL} + \log \frac{[ML_n]}{[ML_{n-1}]}$$

is zero when $\epsilon_M = \frac{1}{2}(\epsilon_n + \epsilon_{n-1})$. However, this assumption is only valid if $\alpha_n + \alpha_{n-1} \sim 1$, that is, if the solution contains the metal in no more than two complex species in the region of pL in which ϵ_M is changing. It is evident, then, that Vareille's procedure for obtaining K_2 or K_3 cannot be applied without modification to sets of complexes in which the several species are distributed as portrayed in Fig. 2(*b*). Before introducing a proposal for dealing with such systems of complexes we must comment on the relationship between pL and pH in these solutions.

The majority of the ligands whose attachment to metallic ions is of interest are bases, i.e. proton acceptors, in aqueous solution. Accordingly there is frequently competition between metallic ions and protons for combination with a given ligand. We may derive a relationship between pL and pH in solutions of such complex species, provided we know the relevant equilibrium constants, by the following general equation:

$$[8] \qquad [L]_T = [L]\left(1 + \frac{[H]}{K_I} + \frac{[H]^2}{K_I K_{II}} \ldots .\right) + \bar{n}[M]_T.$$

(The acid dissociation constants, in order of increasing degree of protonation, are K_I, K_{II}, etc.) Corresponding values of pL and pH for a given $[M]_T$ and $[L]_T$ have been

calculated for solutions of the ferric kojates, and are shown graphically in Fig. 5. For purposes of the present discussion it is sufficient to remark that, for fixed total concentrations of metal and ligand, there must be curves similar in shape to those of Fig. 2 showing the relationship between pH and the fractions of metal in the various species. Experimentally pH is usually more readily measured than pL, and any observed shift of absorption spectra then considered as a function of pH. The occurrence of isobestic points among such spectra will result in horizontal regions in a plot of ϵ_M vs. pH. It is in this form that Vareille's data and ours are shown.

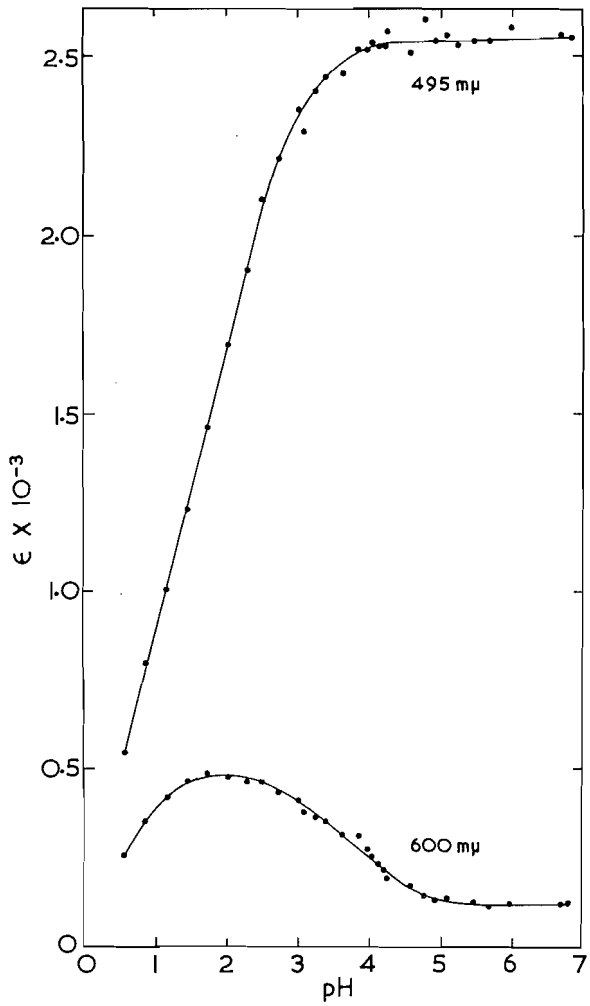

FIG. 3. Vareille curves, showing variation of molar extinction coefficient at isobestic wavelengths with pH.

Considering now the results of our experiments with the ferric kojates, we have confirmed the occurrence of isobestic points, first shown in the spectra published by Moss and Mellon (4), at 495 mμ and at 600 mμ. We have also confirmed, by the method of continuous variations, Moss and Mellon's finding that the complex formed at the highest pH is ML_3; we have assumed, by analogy with a great many other sets of ferric complexes, that with decreasing pH the species present are ML_2 and ML. We show in Fig. 3 our values of ϵ_M at the isobestic wavelengths plotted against pH. From the horizontal regions in these curves we may deduce as follows:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(i) above pH 5.2 only one species is present: $[M]_T = [ML_3]$; and at 600 mμ $\epsilon_3 = 120$ M^{-1} cm^{-1}.

(ii) between pH 4.0 and 5.2 $[M]_T = [ML_2]+[ML_3]$; and at 495 mμ $\epsilon_2 = \epsilon_3 = 2540$.

(iii) between pH 1.45 and 2.50 $[M]_T = [ML]+[ML_2]$; and at 600 mμ $\epsilon_1 = \epsilon_2 = 470$.

The absence of any isobestic region between pH 2.50 and 3.85 indicates that in this region $[M]_T = [ML]+[ML_2]+[ML_3]$. This is a difference from the cases investigated by Vareille, and presumably indicates a distribution of species similar to that shown in Fig. 2(*b*).

The consequence of the foregoing is that, for calculating equilibrium constants, we could not assume as Vareille had done that, at the mid-points of the curved portions of these plots, $[ML_3] = [ML_2]$ or $[ML_2] = [ML]$. Instead, we were obliged to estimate our formation constants by a series of successive approximations; the rapid convergence of the values for the constants with each cycle of approximations encouraged the belief that our extension of Vareille's procedure was valid.

The experimental data permitted calculation, not of the formation constants of the complexes, but of the equilibrium constants for the reaction

$$ML_{n-1}+HL = ML_n+H \qquad (n = 1, 2, 3)$$

and we designate these constants as $\mathscr{K}_n$. The method of evaluating these is now shown in detail.

Evaluation of $\mathscr{K}_3$

At pH 3.73 the value of ϵ_M at 600 mμ $= 295 = \frac{1}{2}(\epsilon_2+\epsilon_3)$. At this pH the solution may contain ML, ML_2, and ML_3, but since $\epsilon_1 = \epsilon_2$ we may put

[9] $$[ML_3] = [ML_2]+[ML] = [ML_2]\left(1+\frac{[H]}{\mathscr{K}_2[HL]}\right)$$

[10] $$[HL] = \frac{[HL]_T-\bar{n}[M]_T}{1+K_a/[H]} \sim [HL]_T-\bar{n}[M]_T$$

[11] $$\bar{n} = \frac{5+\dfrac{4[H]}{\mathscr{K}_2[HL]}}{2+\dfrac{2[H]}{\mathscr{K}_2[HL]}}$$

[12] $$\mathscr{K}_3 = \left(1+\frac{[H]}{\mathscr{K}_2[HL]}\right)\left(\frac{[H]}{[HL]_T-\bar{n}[M]_T}\right).$$

The value of $\mathscr{K}_3$ thus depends on the value of $\mathscr{K}_2$ obtained by the method described below. A cycle of approximations is introduced to find the best values of $\bar{n}$ and [HL]. This is begun by putting $\bar{n} = 2.5$ into equation 10, and the consequent value of [HL] into equation 11. When these values became constant, $\mathscr{K}_3$ was calculated by equation 12.

Evaluation of $\mathscr{K}_2$

For this purpose Vareille found the pH at which $\epsilon_M = \frac{1}{2}(\epsilon_1+\epsilon_2)$, and at which $[ML] = [ML_2]$. Our data give no direct indication of ϵ_1, so that we have had to estimate this quantity in order to calculate $\mathscr{K}_2$. Subsequently, with the aid of this value of $\mathscr{K}_2$, we were able to refine our estimate of ϵ_1. This cycle of approximations was repeated until constant values were obtained.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The lower limit of the isobestic region at 600 mμ, corresponding to $\epsilon_1 = \epsilon_2$ and $\alpha_1+\alpha_2=1$, occurs at pH 1.45. If, at this pH, α_1 became nearly unity we should have observed some horizontal region in the plot of ϵ_M vs. pH at 495 mμ; it was, in fact, from just such a horizontal that Vareille took his value of ϵ_1. We must assume for our solutions that, at and below pH 1.45, some ML_2 remains in solution. For all solutions below pH 2.5 we may write $\epsilon_M = \epsilon_1\alpha_1+\epsilon_2\alpha_2$, and for 495 mμ this becomes

$$\epsilon_1 = \frac{\epsilon_M - 2540\alpha_2}{\alpha_1}. \qquad [13]$$

The following data apply to the solutions of low pH.

pH	ϵ_M (600 mμ)	ϵ_M (495 mμ)	$\alpha_1+\alpha_2$
1.45	463	1230	1
0.57	254	545	0.548
0.86	350	794	0.758

Somewhat arbitrarily, in order to make an estimate of $\mathcal{K}_2$, we put ϵ_1 at 495 mμ = 1100 as a trial value.

Now, while at pH 1.45 $(\alpha_1+\alpha_2) = 1$, at any pH below this $(\alpha_1+\alpha_2) < 1$; and its value is given by the ratio of ϵ_M at this pH to ϵ_M at pH 1.45 measured at 600 mμ. In this way we get the values in the last column of the above table. But $\alpha_1+\alpha_2 = \alpha_1\{1+(\mathcal{K}_2[HL]/[H])\}$, and $[ML]+[ML_2] = (\alpha_1+\alpha_2)[M]_T = [ML]\{1+\mathcal{K}_2[HL]/[H]\}$. The conservation equation for L is

$$[HL]_T = [L] + [HL] + [ML] + 2[ML_2] + 3[ML_3] \qquad [14]$$

in which, for these solutions, the first and last terms on the right-hand side are relatively negligible. Hence we put

$$\begin{aligned}[HL] &= [HL]_T - [ML] - 2[ML_2] \\ &= [HL]_T - [ML] - 2([M]_T - [M] - [ML]) \\ &= [HL]_T + [ML] - 2[M]_T + 2[M].\end{aligned} \qquad [15]$$

The first estimate of [HL] was made by temporarily assuming $[ML_2] = 0$, and assigning [ML] the value calculated for $([ML]+[ML_2])$. Subsequent estimates were made using trial values of $\mathcal{K}_2$, since

$$[ML] = \frac{[ML]+[ML_2]}{1+\mathcal{K}_2([HL]/[H])}. \qquad [16]$$

The calculations quickly showed that the trial value of ϵ_1 had been too high, causing the first estimate of $\mathcal{K}_2$ to be too low.

The validity of this method of calculating $\mathcal{K}_2$ rests upon the inference from the isobestic region at 600 mμ that, at the pH at which $\epsilon_M = \frac{1}{2}(\epsilon_1+\epsilon_2)$, the metal in solution is present in only the two species, ML and ML_2.

Evaluation of $\mathcal{K}_1$

Once a steady value for [HL] in the solutions of pH 0.57 and 0.86 had been obtained from equations 15 and 16, and for [ML] from equation 16, the quantities in the expression for $\mathcal{K}_1$ could all be evaluated. In this way two estimates of this constant were obtained.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

A third estimate, from the solution at pH 1.16, was not considered as reliable since, in this solution, the quantity [M] is obtained as a difference of two similar magnitudes.

The foregoing development of the principles underlying this method of obtaining formation constants of metal complexes does not support Vareille's claim that points of inflection on a plot of λ_{max} vs. pH will indicate values of pH at which two metallic species are present in equal concentrations.

We may summarize the conditions and assumptions required by this method:

(i) Each metallic complex must have distinctively different absorption spectra, and different also from the simple metallic ion. The spectral curves of each adjacent species must cross at some wavelength in order that an isobestic point may be generated.

(ii) The ligand and its protonated forms must show negligible absorption in the range of wavelengths considered.

(iii) Beer's law must be obeyed by all the metallic species.

(iv) Protonated or polynuclear species must not form to any appreciable extent.

(v) The formation constants sought must be widely enough separated that regions of pH (or pL) shall occur in which the metal is distributed between only two of the possible species at a time. In the method as originally described by Vareille it is a requirement that at some pH practically all of the metal should be present as a single one of the various possible species.

(vi) Since the mass law must be applied, at least in part, to concentrations, measurements should be made in solutions of constant and preferably moderately high ionic strength.

EXPERIMENTAL

Reagents

Kojic acid of purity suitable for this investigation was not found commercially. The available material, consisting of one lot purchased from Matheson, Coleman, and Bell, and a second generously contributed by Charles Pfizer and Co., was purified as follows. The crude acid was recrystallized once from a minimum of hot water. The resulting yellow, crystalline mass was then subjected to two, or in some cases three, extractions with warm ether in a modified Soxhlet apparatus. White needlelike crystals accumulated in the pot, and were from time to time removed by filtration, washed with ether, and air-dried. Product of acceptable purity was dead-white, with m.p. 152–3° C (uncorrected), and neutralization equivalent 142. Aqueous solutions of this material retained full potency in reaction with ferric salts for at least a week, and showed no darkening on standing. Off-white crystals obtained after one, or in some cases two, extractions gave drifting pH values when titrated in aqueous solutions with alkali (see below), and the aqueous solutions became yellow on standing.

The following solutions were prepared from analytical reagent grade chemicals (except for chloracetic acid), and standardized as noted:

Ferric nitrate, 2×10^{-3} $M+8\times10^{-3}$ M in HNO_3, standardized gravimetrically as Fe_2O_3,

Sodium hydroxide, 0.25 M, carbonate-free, standardized titrimetrically with potassium hydrogen phthalate,

Potassium nitrate, 1.25 M, by direct weighing,

Acetic acid, 0.25 M, standardized titrimetrically with 0.25 M alkali,

Chloracetic acid, 0.25 M, prepared from Eastman White Label reagent, passed through a $\frac{1}{2}\times24$ in. column of Dowex-50 in the hydrogen form, then standardized titrimetrically with 0.25 M alkali,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Hexamethylenetetramine, 0.25 *M*, by direct weighing,
Nitric acid, 0.50 *M*, standardized titrimetrically with 0.25 *M* alkali,
Potassium tetroxalate, 0.05 *M*, standard for pH 1.67 (25° C),
Potassium hydrogen phthalate, 0.05 *M*, standard for pH 4.00,
Sodium tetraborate decahydrate, 0.05 *M*, standard for pH 9.18,
Radiometer buffer, diluted 1 to 25 from concentrate, standard for pH 6.50.

Apparatus

Optical densities of solutions were measured with a Beckman Model DU spectrophotometer in matched Corex-glass cells of 1-cm path length. The cell compartment was enclosed by thermospacers through which water thermostatted at 25.0° C was circulated.

Measurements of pH were made with commercially available glass and calomel electrodes fitted to either a Beckman Model G or a Radiometer Model 22 meter. The meter assembly was standardized by the buffer solution of pH closest to the range being examined, and the response of the glass electrode was routinely checked by one or two other buffer solutions; this calibration was repeated hourly during periods while pH measurements were being made.

Ionization Constant of Kojic Acid

Aqueous solutions containing accurately weighed portions of purified acid dissolved in known amounts of freshly boiled and cooled doubly distilled water were titrated with standard alkali. The pH was observed throughout the titration, and from 10 points on the titration curve (between 15% and 85% neutralization) values of pK_a calculated by means of the Henderson equation. The end point in the titration was also determined, and a neutralization equivalent for the acid calculated. To examine the influence of ionic strength on the value of pK_a, weighed portions of potassium nitrate were introduced into most of the solutions prior to titration. The ionic strength obviously varies throughout the titration; the value recorded is based on the amount of salts present when the acid is half neutralized.

It was found that substantial drifting toward lower pH values occurred during titration of any sample of the kojic acid that was not pure white, and that in such titrations the solution became somewhat amber as the sample became alkaline. The cause of this observation is not known.

Spectral Curves

A considerable number of solutions were prepared containing fixed amounts of ferric nitrate and kojic acid, various amounts of acid, alkali, or buffers, as noted below, to give a distribution of pH values from 0.57 to 6.82, and a sufficient amount of potassium nitrate to give a final ionic strength of 0.5. These solutions were all made up to known volume and allowed to stand at room temperature (23 to 26° C) for 1 hour. The optical density of each was then measured at intervals of 10 mμ from 350 mμ to 700 mμ. Immediately after the spectrum of each solution was obtained, its pH was measured.

Regulation of pH in these solutions was secured by the addition of the following reagents:

pH 0.57 to 3.01: varying amounts of HNO_3,
2.03 to 3.40: 0.10 *M* $CH_2ClCOOH$ + varying amounts of NaOH,
3.20 to 5.73: 0.10 *M* CH_3COOH + varying amounts of NaOH,
3.09 to 3.62: varying small amounts of NaOH,
3.85 to 6.82: 0.10 *M* hexamine + varying amounts of HNO_3.

Continuous Variations

A series of 12 solutions was prepared from a (different) standard iron solution and a kojic acid solution in various proportions adjusted so that the total molarity of these remained constant. In our experiments $[M]_T+[HL]_T = 0.001$, and of this molarity the fraction of iron varied from 0.03 to 0.58. Each solution was buffered by the addition of a fixed amount of sodium acetate and varying amounts of nitric acid to a pH of 5.1 ± 0.2, and contained sufficient potassium nitrate to make the total ionic strength 0.5. The optical density of each solution was measured, and the values plotted against "mole fraction" of iron in the solution.

RESULTS AND DISCUSSION

Ionization Constant of Kojic Acid

Table I gives the values of pK_a found at the various ionic strengths investigated. Graphical extrapolation to zero ionic strength suggests a value of 7.88 for pK_a and this may provisionally be taken as the thermodynamic constant. The variation in pK_a with ionic strength may be largely accounted for by the variation in activity coefficient of the kojate ion, the magnitude of which, from the above measurements, appears to be comparable to those of other univalent ions. Okáč (5) has reported the value 7.75 for this constant.

As all solutions of the ferric kojates studied absorptiometrically were prepared to be of ionic strength 0.5, the value 7.73 was taken for pK_a when calculating their formation constants.

TABLE I

Ionization constant of kojic acid

Ionic strength	pK_a
0.03	7.83 ± 0.007
0.23	7.77 ± 0.005
0.53	7.73 ± 0.005
1.03	7.81 ± 0.007

Isobestic Points and Vareille Curves

Moss and Mellon (4) have given spectra for solutions containing fixed concentrations of iron (III) and kojic acid but differing in pH, and these show isobestic points at 495 mμ and 600 mμ. The spectra of our solutions that do not contain acetate or chloroacetate confirm theirs, including the same isobestic points. In Fig. 3 we show our values of ϵ_M at these two wavelengths for all these solutions. The interpretation of the various regions of these curves has been discussed previously.

Composition of Highest Complex

In the absence of acetate the spectra of the ferric kojate solutions was not altered by increasing the pH above 5. We assume that at and above this pH the maximum co-ordination of kojate ion has occurred. The experiment applying the method of continuous variations (6) showed maximum optical density when the "mole fraction" of iron in the prepared solutions was 0.25. This shows that the complex of maximum co-ordination is ML_3, as is the case with many other phenolic reagents capable of chelation to the metal. The same observation has been recorded by Moss and Mellon (4).

Formation Constants of Complexes

The method of deriving the equilibrium constants, $\mathscr{K}_n$, from the data of Fig. 3 has been described previously. For all these solutions $[M]_T = 2.05\times10^{-4}$ and $[L]_T = 15.00\times10^{-4}$ M. The first calculation was that of $\mathscr{K}_2$, based on the initial assumption that ϵ_1 (495 mμ) = 1100. The successive estimates were:

ϵ_1 (495 mμ)	Mid-point pH	$\mathscr{K}_2$
1100 (assumed)	2.18	5.53
964	2.10	6.65
946	2.09	6.82
946	2.09	6.82

The estimation of $\mathscr{K}_1$ and ϵ_1 was based on the following data:

Points	[H]	[ML] + [ML$_2$]	[M]	[HL]
1	2.70×10^{-1}	1.12×10^{-4}	0.93×10^{-4}	12.76×10^{-4} + [ML]
2	1.38×10^{-1}	1.55×10^{-4}	0.50×10^{-4}	11.90×10^{-4} + [ML]

Refinement in the value of ϵ_1 resulted from changes in the value of [ML], which in turn depended on the value assigned to $\mathscr{K}_2$. The successive values obtained in these calculations were:

Point 1				Point 2			
α_1	α_2	ϵ_1	$\mathscr{K}_1$	α_1	α_2	ϵ_1	$\mathscr{K}_1$
0.534	0.014	954	229	0.719	0.039	973	304
0.530	0.018	942	227	0.712	0.046	951	301
0.530	0.018	942	227	0.711	0.047	950	301

The average value of $\mathscr{K}_1$ was taken as 264.

The solution of equations 10 and 11, beginning with the trial value $\bar{n} = 2.5$, led to steady values at pH 3.73 of $[HL] = 9.90\times10^{-4}$ and $\bar{n} = 2.49$. Putting these values, and the final value of $\mathscr{K}_2 = 6.82$, into equation 12, gave $\mathscr{K}_1 = 0.191$.

To transform these equilibrium constants into formation constants, as more commonly are reported for metallic complexes we employ the relationship:

$$\log K_n = \log \mathscr{K}_n + pK_a.$$

From this the following values were obtained: $\log K_1 = 10.16$, $\log K_2 = 8.29$, and $\log K_3 = 6.90$. Previous values determined for these constants are assembled in Table II, with the present values for comparison.

TABLE II

Formation constants for ferric kojate complexes

The values of Okáč, Sommer, and Rády, which differ signally from the other two, were obtained by the method of continuous variations. Various authors, especially Woldbye (8), have criticized the application of this method to the measurement of formation constants whenever the possibility arises of one complex passing gradually into the next as the ligand concentration is gradually increased. From the formation curve of the ferric kojates, calculated from our constants with equation 1, shown as Fig. 4, it is apparent that such will be the case with these complexes.

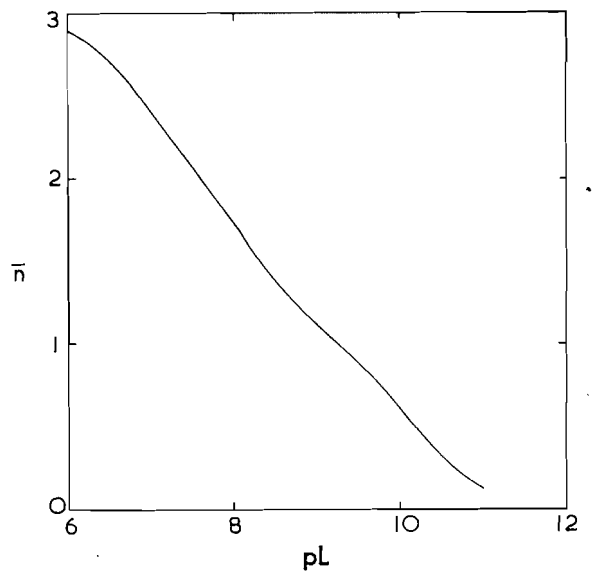

FIG. 4. Formation curve for the ferric kojates calculated from formation constants derived from this investigation.

In order to test the consistency between the conclusions drawn from Fig. 3 and the implications of the formation curve, we have calculated the relationship between pH and pL for our experimental solutions. For each value of pL at which a point on the formation curve was calculated, a value of pH was also obtained by means of equation 17

$$[17] \qquad 1 + \frac{[H]}{K_a} = \frac{[L]_T - \bar{n}[M]_T}{[L]}.$$

The results of these calculations are summarized in Table III, and shown graphically in Figs. 4 and 5.

Spectra of Single Complex Species

Since the spectra of a number of solutions of the ferric kojate complexes were available, and since the knowledge of the formation constants of these makes possible a calculation of their individual concentrations in the various solutions prepared, we undertook to extract from our data values of the molar extinction coefficients of the individual complexes. For these solutions, whose pH had been measured, a value of pL could be secured from Fig. 5, and with this, values of $\bar{n}$, α_0, α_1, etc. calculated. In the solution of highest pH, $\alpha_3 = 1$, and values of ϵ_3 were immediately available. In the solution of lowest pH the principal absorbing species was ML, but $\alpha_2 \sim 0.01$, so that a small contribution

from ML_2 was included in the observed spectrum. A first estimate of ϵ_1 was made from the spectrum of this solution, neglecting the contribution of ϵ_2. Later, when a value of ϵ_2 had been extracted, a second, modified estimate of ϵ_1 was calculated with equation 3.

The estimate of ϵ_2 was, in this case, based on the spectrum of a solution of pH 2.52, for which we calculate $\alpha_0 = 0.004$, $\alpha_1 = 0.394$, $\alpha_2 = 0.569$, and $\alpha_3 = 0.033$. Values of ϵ_2 were calculated from the expression

$$\epsilon_2 = \frac{\epsilon_M - 0.394\epsilon_1 - 0.033\epsilon_3}{0.569}$$

using in turn the raw and improved estimates of ϵ_1 as described previously.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The results are shown plotted as Fig. 6. It is recognized that the values of ϵ obtained in this way are not very accurate, since their calculation involves taking differences of experimental numbers. The spectra show, with increase in ligand number of the complexes, a hypsochromic shift in λ_{max}, and a roughly proportionate increase in ϵ_{max}, typical of numerous other complexes formed by ferric iron with phenolic chelating agents.

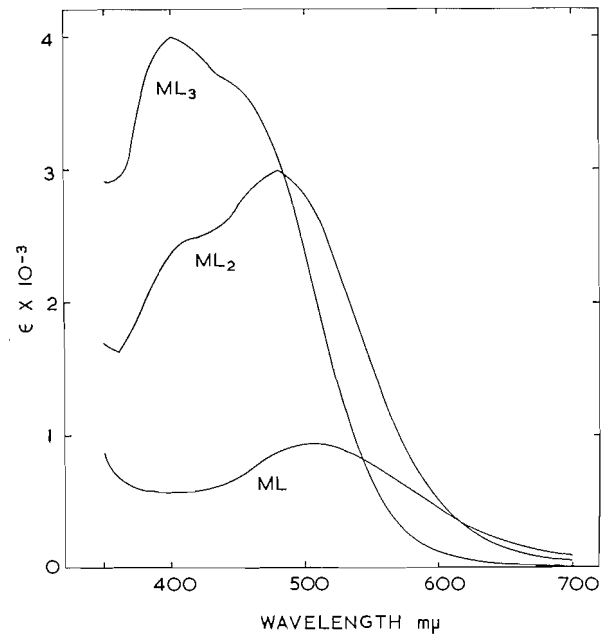

FIG. 6. Spectra of individual species for system iron (III) – kojic acid.

Effect of Acetate and Chloracetate

To prepare solutions of stabilized pH for spectral measurements it was planned to use buffering mixtures of acetic acid or chloracetic acid and sodium hydroxide. The use of acetate buffers is implied in the preparation of the solutions whose spectra had previously been examined by Moss and Mellon. The spectra of our solutions prepared with these buffering agents failed to give sharply defined isobestic points, and plots of ϵ_M vs. pH failed to give the expected horizontal regions. The effect observed is illustrated in Fig. 7, in which our experimental points at 495 mμ are shown together with the Vareille curve ultimately obtained for solutions not containing acetate or chloracetate (cf. Fig. 3). A similar drop in ϵ_M with increasing pH is observed with each set of solutions containing either acetate or chloracetate. This is attributed to a competition between acetate or chloracetate and the kojate ion for co-ordination to the metallic ion. As the concentration of the anion of either buffering acid increases with increase in pH, ferric acetate or chloracetate forms at the expense of the colored kojate. The fact that the experiments for continuous variations indicated a fairly robust 3:1 complex in the presence of a moderate concentration of acetate appears to rule out the likelihood of the formation of stable mixed acetate – kojate complexes.

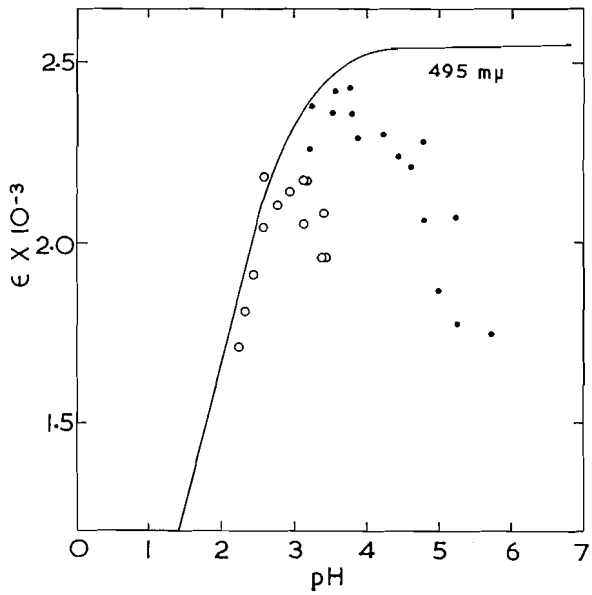

FIG. 7. Influence of acetate and chloracetate on formation of ferric kojates. The solid line shows the Vareille curve at 495 mμ taken from Fig. 3. Open circles show experimental observations for solutions buffered with chloracetic acid and alkali; solid circles refer to similar solutions buffered with acetic acid and alkali.

Implications of Results

Apart from any theoretical significance that may be attached to a knowledge of the formation constants and spectra of the three ferric kojate complexes, this study has certain practical consequences in analytical chemistry. Kojic acid has been proposed as a colorimetric reagent and as an indicator for complexometric titrations for iron (III). This work has revealed the superior stability of solutions of the highly purified reagent. It has demonstrated the significance of control of pH and of excess reagent necessary to insure that the solutions prepared for photometric measurement should have the same degree of complex formation. Finally, it has disclosed the deleterious effect of acetate in preventing complete formation of the colored complexes, and demonstrated that hexamine is a preferable buffering agent.

ACKNOWLEDGMENT

The authors gratefully acknowledge financial assistance from the National Research Council for this investigation. One author (G. F. A.) was holder of a Union Carbide Research Fellowship in 1958–59, for which thanks are hereby expressed.

THE COMPLEX DIELECTRIC CONSTANT OF SOLUTIONS OF TRIMETHYLPENTANE AND NITROBENZENE NEAR THE CONSOLUTE TEMPERATURE[1]

B. D. RIPLEY[2] AND R. MCINTOSH

ABSTRACT

The complex dielectric constants of three compositions of trimethylpentane and nitrobenzene have been measured as a function of temperature for a range near the consolute temperature. The frequency employed was 3300 Mc/sec. The experimental procedure involved the study of the standing wave established in a coaxial line. The chemical systems showed maxima in both the real and imaginary parts of the complex dielectric constant at temperatures above those at which phase separation occurs. The finding of Semenchenko and Azimov is thus confirmed. A discussion of the validity of applying thermodynamic formulae to dielectrics showing loss is given and some qualitative remarks are offered concerning the change of the systems as they are cooled. These remarks are based upon the effect of the applied field upon the entropy of the solutions.

INTRODUCTION

The properties of one-component systems at the critical temperature and of multicomponent systems at the consolute temperature are unusual, and have been frequently studied. Classical thermodynamics suffices to predict much of the behavior, such as the approach of c_p to an infinite value for a one-component system at the critical temperature (1). In the case of such systems the existence of turbidity, the occurrence of marked density gradients due to the extreme value of compressibility (2, 3), and the persistence of liquid-like properties above the temperature of the disappearance of the meniscus have been remarked frequently. Partially miscible liquid systems also show turbidity (4) and other interesting properties near the consolute temperature. Semenchenko and his associates have studied such properties as the viscosity (5), the specific heat (6), and the dielectric constant (7) for systems above the temperature at which phase separation occurs.

In all cases maxima of the physical properties were observed at a temperature between 0.5 and 1.5° C above that of the formation of layers. The magnitudes of the maxima were dependent upon composition and were greatest in each system for the composition corresponding to the consolute temperature. Semenchenko and Azimov (7) investigated the dielectric constant for low frequencies at which the liquids show no loss. Semenchenko (8, 9) has explained the occurrence of the maximum on the basis of the Gibbs' criteria for the existence of critical phases (10). Very briefly, the development follows the course outlined below.

The condition of a system of fixed mass, existing in one phase, is determined by the variables S, entropy, V, volume, and D, the dielectric displacement, which are taken as the independent variables. T, temperature, p, pressure, and E, electric field intensity are taken as dependent variables. The variations of these as a function of the independent variables may be written.

$$dT = \left(\frac{\partial T}{\partial S}\right)_{m,V,D} dS + \left(\frac{\partial T}{\partial V}\right)_{m,S,D} dV + \left(\frac{\partial T}{\partial D}\right)_{m,S,V} dD,$$

$$dp = \left(\frac{\partial p}{\partial S}\right)_{m,V,D} dS + \left(\frac{\partial p}{\partial V}\right)_{m,S,D} dV + \left(\frac{\partial p}{\partial D}\right)_{m,S,V} dD,$$

$$dE = \left(\frac{\partial E}{\partial S}\right)_{m,V,D} dS + \left(\frac{\partial E}{\partial V}\right)_{m,S,D} dV + \left(\frac{\partial E}{\partial D}\right)_{m,S,V} dD.$$

The restriction of constant mass assures variations of the properties of the phase.

Keeping T and p constant also, the value of $(\partial E/\partial D)_{m,p,T}$ is determined and is given by

$$\begin{vmatrix} \left(\frac{\partial T}{\partial S}\right)_{m,V,D} & \left(\frac{\partial T}{\partial V}\right)_{m,S,D} & \left(\frac{\partial T}{\partial D}\right)_{m,V,S} \\ \left(\frac{\partial p}{\partial S}\right)_{m,V,D} & \left(\frac{\partial p}{\partial V}\right)_{m,S,D} & \left(\frac{\partial p}{\partial D}\right)_{m,V,S} \\ \left(\frac{\partial E}{\partial S}\right)_{m,V,D} & \left(\frac{\partial E}{\partial V}\right)_{m,S,D} & \left(\frac{\partial E}{\partial D}\right)_{m,V,S} \end{vmatrix}$$

divided by

$$\begin{vmatrix} \left(\frac{\partial T}{\partial S}\right)_{m,V,D} & \left(\frac{\partial T}{\partial V}\right)_{m,S,D} \\ \left(\frac{\partial p}{\partial S}\right)_{m,V,D} & \left(\frac{\partial p}{\partial V}\right)_{m,S,D} \end{vmatrix}.$$

The numerator can be shown by a general argument to become zero at the critical condition, since a system in that condition is at the limit of stability for continuous changes (10). Thus $(\partial E/\partial D)_{m,p,T} = 1/\epsilon = 0$ at the consolute temperature and composition. Since E is neither a maximum nor a minimum, it follows that $(\partial^2 E/\partial D^2)_{m,p,T} = 0$. Since the phase is stable, the necessary condition is that $(\partial E/\partial D)_{m,p,T} \geqslant 0$. Semenchenko (11) gives the conditions for what he calls false critical points as $(\partial E/\partial D)_{m,p,T} > 0$, $(\partial^2 E/\partial D^2)_{m,p,T} > 0$ and predicts finite values of the maximum.

For time-dependent electrical fields and dielectrics showing power absorption, careful consideration must be given to the validity of applying thermodynamic arguments. It would appear, however, on the basis of the discussion concerning entropy which is given later, that the prediction of a maximum of the real part of the complex dielectric constant can still be made.

The present work is therefore largely a repetition of Semenchenko's (7, 11), except that the imaginary part of the dielectric constant has also been measured and the second component is 2,2,4-trimethylpentane instead of octane. A discussion of the validity of thermodynamic treatments for lossy systems is offered, as well as a description of a convenient and precise system of measuring the parts of the complex dielectric constants of such liquid systems.

EXPERIMENTAL

The dielectric cell is shown in Fig. 1. The outer conductor was German silver tubing 13/128 in. thick; the inner conductor was the same metal 6/1000 in. thick down to the region marked E, which had a copper plug 3/8 in. in diameter and $3\frac{3}{16}$ in. in length

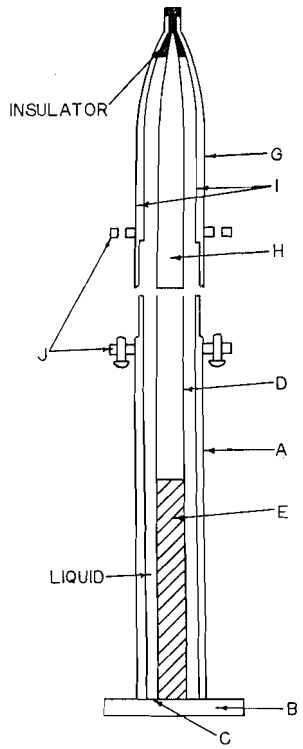

FIG. 1. Schematic representation of the experimental cell.

soldered inside the central conductor. The shorting plate was brass. The cell was designed in this way to provide good thermal conductivity to the fluid of the thermostat, but to reduce heat transfer to the air above the thermostat through the connector at the top of the cell. The cell was $6\frac{3}{16}$ in. long and 1 in. in diameter. A Caro UG-32U adaptor was used to make the connection between the cell and slotted line. The adaptor was designed so that no discontinuity occurred along either the inner or outer conductor surfaces. As indicated in the diagram, the adaptor was held to the cell by screws passing through plates, and these plates formed a tight fit to prevent evaporation of the liquids or absorption of water by them from the air. The oil thermostat was electrically heated and its temperature controlled by means of an adjustable mercury thermoregulator and a relay system. Temperatures were readily controlled to $\pm 0.01°$ C over a period of several hours, and because of the period of heating and cooling, the temperature of the liquid in the cell was more closely constant than this.

The coaxial line used was a Hewlett Packard model 805A, mounted vertically above the cell. In series with the line was a length of RG-21/U attenuating cable to reduce reflections to the generator. The generators were FXR L771B and S771B oscillators designed to work into a 50-ohm load. The generators were fitted with a series N, UG 107B/U tee adaptor providing connection from one side to the slotted line, and from the other, again through attenuating cable, to an FXR crystal mount. Connectors in both lines were series N, UG-18C/U plugs. Rectification of the r.-f. voltage was achieved by means of 1N21B crystals which were tested and found to provide square-law response in the range of voltages used.

The signal from the crystal of the slotted line was applied to one terminal of a Leeds

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

For personal use only.

and Northrup mirror galvanometer of 0.05 μv/mm sensitivity mounted on a vibration-free table. The signal of the crystal in the FXR mount was sent to a voltage-dividing Muirhead resistance box of 10,000 ohms. The output of this box was sent through variable resistors, in series (which served as protective resistances for the galvanometer) to the other terminal of the galvanometer. Very careful shielding of all elements in the circuit was necessary, and an efficient ground connection had to be provided.

The purpose of comparing the rectified signal from the slotted line with a signal from a reference source fed by the same oscillator was to compensate for both long and short term fluctuations of the amplitude of the signal generator. The same technique was used by McCowan and McIntosh (12), but in the present instance no amplification was employed. As the signal is read as a fraction of the oscillator output at the time of measurement, and as both P_x and $P_{\min}$ are so recorded, (where P_x is the output at position x), the ratio between them is immediately given. Power is here considered to be measured because of the square-law response of the detector.

The data obtained were those necessary for the application of the equation given in Von Hippel (13, p. 68)

$$\frac{\tanh \gamma_2 d}{\gamma_2 d} = \frac{-j\lambda_1}{2\pi d} \frac{\frac{E_{\min}}{E_{\max}} - \frac{j \tan 2\pi X_0}{\lambda_1}}{1 - j\frac{E_{\min}}{E_{\max}} \frac{\tan 2\pi X_0}{\lambda_1}}$$

where λ_1 is the wavelength of the signal in the guide, d the depth of liquid in the cell, $E_{\min}$ and $E_{\max}$ the magnitudes of the standing wave at a node and at maximum amplitude, and X_0 the distance of the first minimum from the short. The position of the short as experienced by the electric wave had, of course, to be determined initially with no liquid in the cell. This was done relative to the scale readings of the line by determining the distance between successive minima and considering the electrical short position to be at the distance given by the smallest integral number of nodes required to approximate to the geometrical distance of the short from the scale. The average for three frequencies was 39.318 ± 0.004 whereas the corresponding geometrical distance was 33.9 cm. It should be noted also that attenuation along the line proved negligible as the amplitude of the minimum was constant along the line.

Although it would have been feasible to measure the ratio $P_{\min}/P_{\max}$ directly, this was not done because the crystal response departed somewhat from the square-law response near the maximum. The distance $\Delta X/2$ between the position of the minimum and the position for twice the amplitude of the minimum was measured and employed in the formula $E_{\min}/E_{\max} = \pi\Delta X/\lambda_1$ (13, p. 67). The small errors arising from this practice are discussed by Purcell (14) but could not influence the qualitative nature of the results given below. A matter giving rise to some error of unknown and variable extent was the use of the charts in Von Hippel (13, p. 88 *et seq.*) to evaluate $\tanh \gamma_2 d/\gamma_2 d$. This error arose in interpolating, but is again too small to affect the results seriously. Finally, to ensure good performance, the liquid level was changed to give the best depth of liquid for any particular frequency, that is $\lambda_1/4$, where λ_1 is the wavelength. Densities of the liquid compositions at the limits of the temperature range were measured, and the height of liquid at any intermediate temperature computed using the density obtained by linear interpolation between the extreme values.

The 2,2,4-trimethylpentane was British Drug Houses spectroscopic Grade, Laboratory Reagent. The nitrobenzene was B.D.H. Microanalytical Reagent, Organic Standard. Both

substances were stored over "Drierite" and transferred to the cell by the pressure of dry air.

RESULTS

Three experiments using nitrobenzene at 30.0° C were carried out using a variety of frequencies and the frequency of maximum loss established for pure nitrobenzene as 3300 Mc/sec. The average of the values is plotted in Fig. 2.

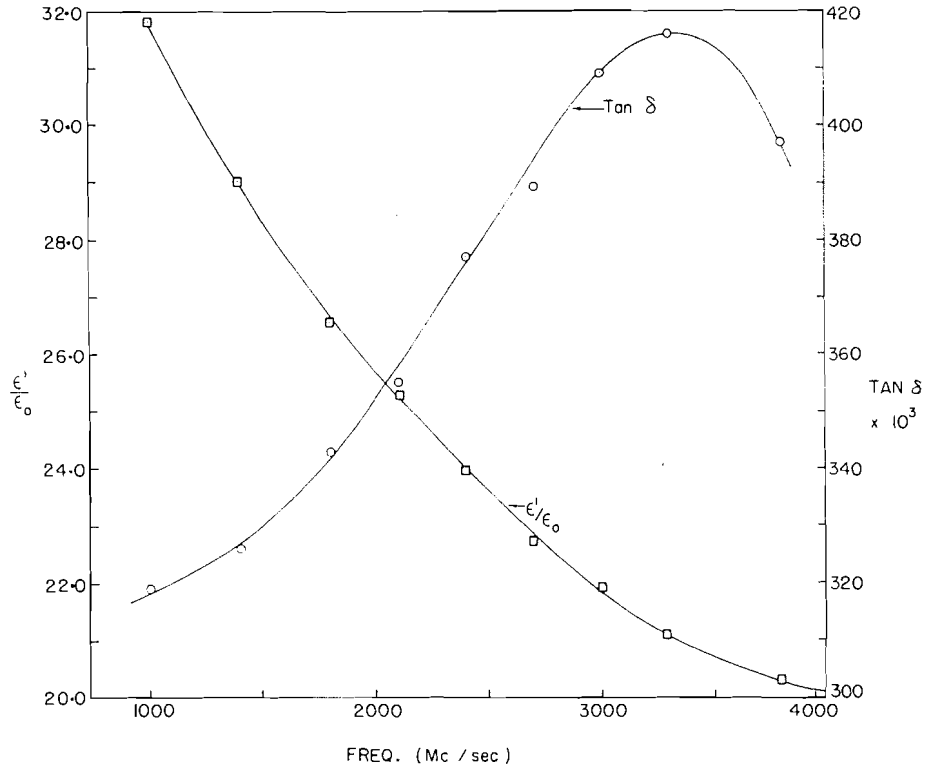

FIG. 2. The values of the real part of the dielectric constant and of tan δ of pure nitrobenzene as a function of frequency at 30.0° C.

Three two-component systems were also studied. These were nitrobenzene and trimethylpentane and the concentrations were 25.4%, 48.2%, and 77.1% nitrobenzene, respectively. The frequency used was 3300 Mc/sec. Table I shows the temperatures at

TABLE I

Temperatures of pronounced turbidity and of separation of phases

System	Temperature of turbidity, °C	Temperature of separation of phases, °C
I	22.6–22.7	21.0–21.1
II	29.6–29.7	27.6–27.7
III	23.1–23.2	21.4–21.5

which turbidity became marked and the temperatures at which phase separation occurred. For each of these three systems three series of determinations of complex dielectric constant versus temperature were carried out. The mean deviation never exceeded 0.3% and was usually 0.15% or less for the real part, with error up to 1% in tan δ. The averages of the real and imaginary parts of the complex dielectric constant are plotted as ϵ'/ϵ^0 (i.e. relative to vacuum) and as tan δ in Figs. 3, 4, and 5. It is clear from these plots that

both ϵ' and ϵ'' show maxima at the temperatures where turbidity becomes apparent. The magnitude of the maximum is greatest for the system corresponding most closely to the composition of the system at the consolute condition. The consolute temperature for this system is 30.38° C (15) and the consolute composition was estimated by us as 56% nitrobenzene. The maxima of $\hat{\epsilon}$ confirm findings by Semenchenko and Azimov (7, 11).

DISCUSSION

Fröhlich (16) shows that the entropy per unit volume of a dielectric in a static field may be written

$$S = S_0 + \frac{1}{8\pi}\frac{\partial \epsilon}{\partial T}E^2,$$

where S_0 is the entropy of the dielectric at the particular temperature but with no field applied. If $\partial\epsilon/\partial T < 0$, the effect of the field is to reduce the entropy, and if $\partial\epsilon/\partial T > 0$, the effect of the field is to increase it. Fröhlich states that the treatment of the general case of time-dependent fields is complex and does not discuss it further. On the basis of the following considerations it appears that a very similar relation should be valid for time-dependent fields and dielectrics which absorb power.

In the case of lossy dielectrics an irreversible process is occurring due to the absorption of the power, namely the extraction of energy from the field at some temperature $T+\delta T$ and its elimination to the thermostat at T. The value of the energy absorbed per second is given by the imaginary part of $1/t\int_0^t \hat{E}\cdot d\hat{D}$. The real part of the expression represents energy stored by the dielectric and returned to the field twice during each cycle. In spite of the irreversible process and the generation of entropy, the condition of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

dielectric is specified by its temperature, assumed to be T, and by the time-average value of its polarization, which is a function of the value of the applied field at fixed frequency. We may thus consider the dielectric to exchange energy with its surroundings and to be maintained at constant volume, when, analogously with the equation given by Fröhlich (16), one may write $dU = TdS + (1/4\pi)$ r.p. $\overline{\hat{E} \cdot d\hat{D}}$, where S is a function of T and the real part of the applied field, and $\hat{D}$ is a function of temperature only at fixed frequency. The bar designates the time-average value and r.p. is the real part of the expression. Since $\hat{D} = \epsilon\hat{E}$ (magnitudes are employed since the vectors are parallel),

$$d\hat{D} = \epsilon d\hat{E} + \hat{E} d\hat{\epsilon}.$$

On substitution in the differential equation for energy, and using $\hat{E}^2$ as the variable

$$dU = \left(T\frac{\partial S}{\partial T} + \frac{1}{4\pi}\text{r.p.}\,\overline{\hat{E}^2\frac{\partial\hat{\epsilon}}{\partial T}}\right)dT + \left(T\frac{\partial S}{\partial \bar{\hat{E}}^2} + \frac{1}{8\pi}\text{r.p.}\,\hat{\epsilon}\right)\overline{d\hat{E}^2}.$$

Since,

$$\frac{\partial}{\partial \bar{\hat{E}}_2}\left(T\frac{\partial S}{\partial T} + \frac{1}{4\pi}\text{r.p.}\,\overline{\hat{E}^2\frac{\partial\hat{\epsilon}}{\partial T}}\right) = \frac{\partial}{\partial T}\left(T\frac{\partial S}{\partial \bar{\hat{E}}^2} + \frac{1}{8\pi}\text{r.p.}\,\hat{\epsilon}\right)$$

on integration, with $\hat{\epsilon}$ independent of $\hat{E}^2$, and on evaluation of the time average of the complex field, one obtains

$$S = S_0 + \frac{1}{16\pi}E_0^2\frac{\partial\epsilon'}{\partial T}$$

where E_0 is the maximum amplitude of the field. As in the static case, the system loses entropy or gains entropy in the presence of the field depending upon the sign of $\partial\epsilon'/\partial T$.

DISCUSSION OF EXPERIMENTAL RESULTS

Semenchenko (8, 9) has pointed out that the prediction of a maximum of the dielectric constant of one-phase systems at the condition of the limit of stability with respect to continuous changes is inherent in the general criteria established by Gibbs (10). He has obtained experimental confirmation of this prediction (7, 11). Using frequencies of measurement from 1000 to 3300 Mc/sec and the system nitrobenzene–trimethylpentane, we have confirmed Semenchenko's finding and have shown also that ϵ'' shows a maximum at the same temperature within the limits of experimental error. Analogous concepts to those of cybotactic groups (17) and regional orientation (18) which have been used to distinguish the liquid from the gaseous state of aggregation may also be employed to permit qualitative descriptions of the transition between single-phase and two-phase systems of several components. In the present instance, if the conclusion is correct that lossy dielectrics in alternating fields are amenable to discussion in terms of the usual thermodynamic treatment, then the maximum of the dielectric constant as a function of temperature permits the following qualitative description of the behavior of the system.

As the temperature is reduced towards the temperature of the maximum, association of the molecules into some type of structure is occurring. That this association is not complete is evident from the fact that the entropy of the system may be further reduced by the application of a field. At temperatures lower than that of the maximum, however, the reaction has occurred to a sufficient extent that application of a field will increase

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the entropy, presumably by the destruction of structures which exist when no field permeates the sample. As the value of $\partial\epsilon'/\partial T$ remains constant or increases slightly with diminishing temperature, the application of a field remains effective in destroying order down to the temperature at which separation into phases occurs. As the existence of discrete phases suggests an increasing stability of ordered regions within the fluid as temperature is lowered, and as the effectiveness of the field persists, it is suggested that the amount of ordered matter increases with lowered temperature.

The range of frequency investigated was not sufficiently broad for us to learn much about the nature of the loss in the system. Pure nitrobenzene does not reveal a loss curve of the Debye type. The three solutions of nitrobenzene can only be discussed on the basis of their behavior as a function of temperature. The diminishing values of ϵ'' on both sides of the temperature of maximum ϵ' could be reconciled with the hypothesis of a smaller amount of ordered matter, but the likelihood of this being correct for lower temperatures is small in view of the remarks made earlier. Moreover, a wider distribution of relaxation times or the variation of loss with temperature even for a fixed amount of a single type of molecular aggregate could also explain the experimental facts. The last possibility follows from the knowledge that even for systems of a single relaxation time, the loss curve goes through a maximum for a given frequency as temperature is varied. It therefore seems clear that a much more thorough examination of these systems using a wide range of measuring frequencies would be required to increase the present understanding of their behavior.

INFRARED SPECTRA OF GASES CHEMISORBED ON ZINC OXIDE

I. CO AND CO_2[1]

J. H. TAYLOR[2] AND C. H. AMBERG

ABSTRACT

The infrared spectra of CO and CO_2 adsorbed on zinc oxide have been observed in the region 2–9 μ. The results show that CO does not exist as such on the surface at 155° C, but is immediately oxidized to CO_2. There is no evidence for carbonate formation in the adsorption of CO, the spectra corresponding to structures of the carboxylate type. A band is observed at 2174 cm^{-1} for CO at 25° C which may correspond to dipole interaction or to an oxidation step.

INTRODUCTION

Previous work (1–5) on the chemisorption of CO on surfaces of zinc oxide has shown that there are two distinct types: one, a weak reversible adsorption occurring at room temperature with a negligible activation energy, the other a stronger adsorption occurring at higher temperature with an activation energy of 5 to 16 kcal/mole (4), in which the CO can be removed only as CO_2. It was thought that the infrared method might give information on the nature of the adsorbed species.

EXPERIMENTAL

The zinc oxide was prepared by the precipitation of either the carbonate from nitrate solution, with subsequent decomposition at 350°, or the oxalate from acetate solution, the oxalate being decomposed by heating at 400° C in air. The oxide was pressed at 40 tons/sq. in. into plates containing about 100 mg/sq. cm, which had a B.E.T. nitrogen area of 25–30 sq. m/g and transmitted approximately 50% of the incident infrared radiation before outgassing. These plates were mounted in a cell similar to that described by Little, Klauser, and Amberg (6). This cell with a path length of 11.0 cm was fitted with a winding device which enabled the sample to be removed from the beam and the background spectrum to be run. A matched cell containing gas at a pressure equal to that in the sample cell was placed in the reference beam. In all experiments the pressure of CO and CO_2 was 20 mm Hg. The instrument was a Beckman IR-4 double beam spectrometer used with sodium chloride optics.

RESULTS

Figure 1 (*a*, *b*, *c*) shows a sequence of spectra taken as the sample was outgassed. It was found that the transmission slowly decreased until after pumping at 320° C for several hours, the sample became completely opaque. The transmission could be entirely restored, as shown in Fig. 1*d*, by heating for 5 minutes at 350° C under 1 cm oxygen, cooling to room temperature, and pumping to 10^{-5} mm Hg. All the spectra reported here were taken from samples pretreated in this manner.

Figure 2 shows the spectra of CO and CO_2 adsorbed on zinc oxide, with the zinc oxide spectrum subtracted.

The CO at 25° C shows a sharp band at 2174 cm^{-1} and a weaker one at 1333 cm^{-1}, which were formed immediately upon admission of the gas (Fig. 2*a*). On standing, the

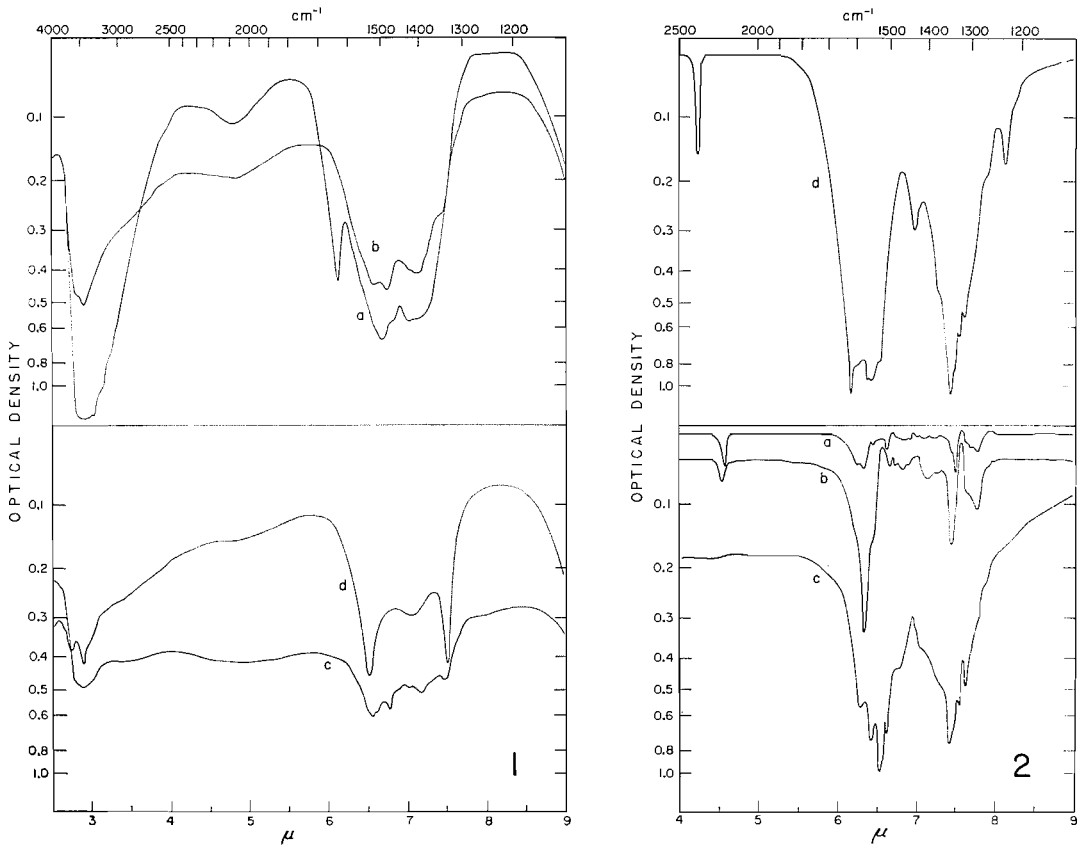

FIG. 1. Spectrum of zinc oxide on outgassing: (*a*) in air, (*b*) 3 hours at 150° C, (*c*) 18 hours at 150° C, (*d*) 18 hours at 320° C and treatment with 1 cm O_2 at 350° C. Spectra run at 25° C.

FIG. 2. Spectra of adsorbed gases with the zinc oxide spectrum subtracted: (*a*) CO at 25° C initially, (*b*) CO at 25° C after 24 hours, (*c*) CO at 155° C after 3 hours, (*d*) CO_2 at 25° C after 0.5 hour.

peak at 2174 cm^{-1} shifted slightly to a higher frequency, usually about 2198 cm^{-1}, and decreased in intensity. At the same time, three strong maxima appeared at 1575, 1342, and 1287 cm^{-1} and a slow increase in the background absorption was observed (Fig. 2*b*). The band at 2174 cm^{-1} disappeared as soon as evacuation was commenced, but those at 1575, 1342, and 1287 cm^{-1} were removed only by prolonged pumping at 320°.

Figure 2*c* is the spectrum obtained by admitting CO to zinc oxide at 155° C. In this case there was no peak at 2174 cm^{-1}, but the growth of the spectrum and increase in background absorption was much more rapid than in the cold. After some time at 155° C, a small peak at 2198 cm^{-1} was observed in some cases.

The adsorption of CO_2 at 25° was very rapid, and as can be seen from Fig. 2*d* the structure is somewhat complex. On opening of the system to the pumps the band at 2364 cm^{-1} was immediately removed, and that at 1618 cm^{-1} shifted to 1600 cm^{-1}. The bands at 1600, 1431, and 1230 cm^{-1} decreased quite rapidly in intensity and were almost entirely removed after 3 hours pumping at 25° C. The rest of the spectrum was removed only by several hours outgassing at 320° C.

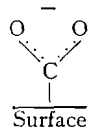
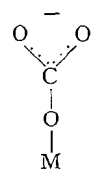
DISCUSSION



The spectrum shown in Fig. 1*a* corresponds to those we have obtained from mulls of basic zinc carbonate, and it is thought that in the presence of atmospheric water and CO_2, a surface carbonate was formed. This was decomposed on outgassing and simultaneously a steady decrease in the transmission of the sample occurred (Fig. 1, *b*, *c*). The latter phenomenon has been observed in previous work (7, 8, 9) and is generally ascribed to absorption by electrons in the conduction band. These may be produced by an increase in non-stoichiometry caused by loss of oxygen or the introduction of excess zinc. This readily explains why oxygen treatment restored the transmission since adsorbed oxygen atoms or molecules are known to act as electron traps. As the outgassing proceeded, three bands appeared at 1527, 1389, and 1333 cm^{-1}, those at 1527 and 1333 cm^{-1} in particular being apparently enhanced by the oxygen treatment (Fig. 1*d*). These peaks are unlikely to be due to nitrate impurity, as has been suggested by Matsushita and Nakata (7), as the same structure was obtained for samples prepared from the carbonate or the oxalate. The spectrum resembles that described by these authors, but a close correlation is not to be expected in view of the very different samples under investigation. The possibility that the two strong bands at 1527 and 1333 cm^{-1} arise from carboxylate residues can probably be discounted on the grounds that a sample outgassed at 570° C for 19 hours, and treated with oxygen as described above, still showed these two bands together with a third which appeared at 1350 cm^{-1}. In the unlikely event that CO_2^- surface impurities would remain stable under these conditions one would have to presume that the kinetic experiments which we are attempting to elucidate were similarly performed on samples containing the carboxylate group. We are at present unable to make definite assignments for the bands in question, but since they do not appear in the spectra of single crystals of zinc oxide, we believe that they may be associated with the defect structure of our material. During the adsorption of CO and CO_2 the two bands were apparently unchanged.

In the course of the outgassing treatment the physically adsorbed water was removed, but as can be seen from Fig. 1 a small concentration of hydroxyl groups remained. During the adsorption these bands were unperturbed and apparently took no part in the reaction.



In the spectrum of CO at 25° (Fig. 2*a*) the peak at 2174 cm^{-1} appears similar to that observed at 2193 cm^{-1} (4.56 μ) by Eischens and Pliskin (10) in the oxidation of CO over NiO. They attributed this frequency to the asymmetric vibration of a structure of the type Ni—O⁻—C⁺≡O but failed to find any absorption in the 6- or 7-μ region corresponding to the symmetric vibration. In the present work, a band is observed at 1333 cm^{-1} (7.5 μ) which would be at the limit of their working range with Cabosil-supported samples and which may be considered a confirmation of their assignment. However, for symmetric and asymmetric vibrations to occur, the two bonds should be of similar order, which is not compatible with the observed fact that the peak at 2174 cm^{-1} is easily removed by pumping at room temperature. It would appear more likely that the interaction is of a weak dipolar nature, rather than a covalent one as suggested by Eischens. Since the small dipole in CO is $^-C{\equiv}O^+$, structures in which the oxygen is interacting with the negatively charged surface cannot be neglected. (For a discussion of oxygen chemisorption on zinc oxide surfaces and the resulting negatively charged surface species, see, for instance, Stone (11, 12) and Terenin and Solonitzin (8).) In a separate experiment, the gas desorbed after CO had been adsorbed on zinc

oxide for 10 minutes was examined mass spectrometrically. It was found to contain very little CO_2 (10^{-5} of the gas adsorbed), which favors the second interpretation.

The two principal regions of absorption at 1560 and 1330 cm^{-1} are close to the maxima shown by carboxylate ions such as formate and oxalate, and probably correspond to structures of the type:

The fact that a number of peaks is observed in each of these two regions may be because adsorption is occurring at different sites, giving species of essentially the same geometrical structure, but with a variety of surface-adsorbate bond strengths. Bicarbonates have been shown (13) to have a band between 1610 and 1630 cm^{-1} and another in the 1390–1410 cm^{-1} region. Eischens has observed bands at 1640 and 1390 cm^{-1} (6.1 and 7.2 μ) in the adsorption of CO_2 on NiO (10), which he attributes to structures of the type:

Although in our case CO_2 gave a band at 1618 cm^{-1} (6.18 μ) no absorption was found in the region 1430–1350 cm^{-1} (7.0–7.4 μ). However, it is difficult to assess how closely the spectra of structures of this type might be expected to resemble that of the bicarbonate ion and our failure to observe a band in the latter region does not necessarily rule out the existence of such structures. Apart from the bands at 2364, 1618, 1431, and 1230 cm^{-1}, all of which are strongly influenced by the removal of the ambient gas, the spectrum of CO_2 at 25° C corresponds very closely to that of CO at 155° C. This indicates that at 155°, CO does not exist on the surface, but is immediately oxidized to CO_2.

No absorption was observed in the region 1820–2080 cm^{-1}, which is normally associated with the C—O stretching mode in metallic carbonyls, nor was there any evidence for $\rangle C{=}O$ which might arise from bridged structures in which the carbon monoxide was adsorbed at dual sites. Carbonates normally give rise to strong absorption in the 7 μ region. Thus the band at 1431 cm^{-1} in the adsorbed CO_2 spectrum may be due to zinc carbonate, while the absence of bands in this region in either of the CO spectra would indicate that in these cases no carbonate was formed.

In order to assess the validity of a comparison between our results and those reported in the literature, the following facts should be taken into consideration: (*a*) The general qualitative aspects are the same in all cases, comprising fast room-temperature chemisorption which is reversible, and a slow chemisorption step above about 150°. (*b*) Kubokawa (5) has shown that oxygen pretreatment has no effect on either of the CO chemisorption steps, and he has concluded that CO chemisorption is independent of the

electronic state of the zinc oxide. However, it should be noted that his initial outgassing temperature (500°) was higher than ours, thus possibly giving rise to a higher Zn:O ratio in the bulk lattice. Also his outgassing temperature after exposure to oxygen (260°) would leave a smaller fraction of adsorbed oxygen on the surface. Our need for high surface areas coupled with infrared transparency has precluded duplication of this author's conditions. Although we do not at present believe the uncertainty arising out of this to be a serious one, it is hoped that work in progress may throw more light on this question.

HIGH-TEMPERATURE STUDIES OF METALLURGICAL PROCESSES

PART I. THE THERMAL REDUCTION OF MAGNESIUM OXIDE WITH SILICON[1]

J. M. TOGURI[2] AND L. M. PIDGEON[3]

ABSTRACT

The rate of reaction (*a*) has been studied over the temperature range 1140–1460° C, by following the loss in weight of the reactants in high vacuum.

$$4MgO_{(s)} + Si_{(s)} = 2Mg_{(g)} + Mg_2SiO_{4(s)} \qquad (a)$$

The loss in weight of the reactants was found to be greater than that which can be accounted for by the above reaction. The excess weight loss was found to be due to a brownish, glassy deposit which appeared outside the reaction zone. This material was analyzed by X-ray diffraction and found to be an intimate mixture of Mg_2SiO_4 and Si. Experiments conducted showed that both of these materials are not appreciably volatile at 1350° C. This transfer of silicon and silicate is postulated to occur by the formation of gaseous SiO formed from the reaction mixture. Based on this assumption a possible mechanism for this reaction is postulated.

INTRODUCTION

The reduction of alkaline earth oxides by means of silicon proceeds theoretically according to the equation,

$$2MO_{(s)} + Si_{(s)} = SiO_{2\,(s)} + 2M_{(g)}. \qquad (I)$$

The reaction is reversible and generally proceeds from right to left at low temperatures with emission of heat and from left to right only at high temperatures with the absorption of heat. However, this simple equation is not followed and a secondary reaction always occurs in which the resulting silica combines with a certain amount of unreacted alkaline earth oxide, forming a silicate. Hence, when a theoretical reaction mixture is used according to reaction (I), only 1 mole of oxide is reduced from 2 moles of metal oxide and 1 mole of silicon and 1 mole of metal is formed, and $\frac{1}{2}$ mole silicon remains unused. In order to attain complete utilization of the reducing agent, it is necessary to have twice the amount of oxide as shown in equation (II).

$$4MO_{(s)} + Si_{(s)} = 2MO\cdot SiO_{2\,(s)} + 2M_{(g)}. \qquad (II)$$

In general, the reaction ceases when a dibasic silicate $2MO\cdot SiO_2$ has been formed. Jander (1) has shown that in a system of alkaline earth oxide – silica, the dibasic silicate is preferably formed.

Consequently, in the case of MgO, the reaction follows equation (II) where Mg replaces M.

This method of reduction of alkaline earth oxides by reducing agents producing a volatile metal and non-volatile oxide was known as early as 1878 (2). Schneider and Hesse (3) have studied this particular equilibrium, measuring the equilibrium pressure of magnesium using the transportation method with hydrogen as a carrier gas. From X-ray diffraction studies they identified the solid product as Mg_2SiO_4.

This reaction, however, has been found to be not as simple as is shown in equation (II). And, in order to have a better understanding of this reaction, it was investigated as a preliminary to the study of the calcined dolomite – silicon reaction.

EXPERIMENTAL PROCEDURES

The experimental method adopted for the determination of the reaction rate was to measure the weight loss of a briquetted mixture of reactants. By holding constant the particle size of the reactants and size and shape of the briquettes, the effect of rate-controlling factors could be determined.

The apparatus used in this investigation was described in detail in a previous paper (4). Briefly, it consists of a high-temperature vacuum furnace incorporating a thermobalance. The thermobalance was constructed from a helical wire spring such that continuous measurements of weight changes could be observed.

Finely powdered magnesium oxide of C.P. grade was used for all experiments. The silicon used was in the form of ferrosilicon, 200 mesh, the analysis of which was 96.7% Si. Briquettes of the reaction mixture were made in a 1-in. diameter mold at a pressure of 1500 p.s.i.

The reaction mixture contained 82% magnesium oxide and 18% ferrosilicon. This corresponds to a MgO:Si ratio of 3.33:1 or an excess of Si according to equation (II).

Three briquettes each weighing 10 g were placed in a graphite retort (Fig. 1) which was suspended in the furnace chamber from the helical wire spring. With this spring balance a weight change of 0.020 ± 0.005 g could be observed.

Blank runs using only MgO briquettes, prepared in the same manner as the reaction mixture, showed negligible weight losses due to reactions with the graphite retort over the temperature range 1100–1440° C. Thus, the weight loss of the briquetted reaction mixture was assumed to be due to the reaction between MgO and Si only. It is interesting

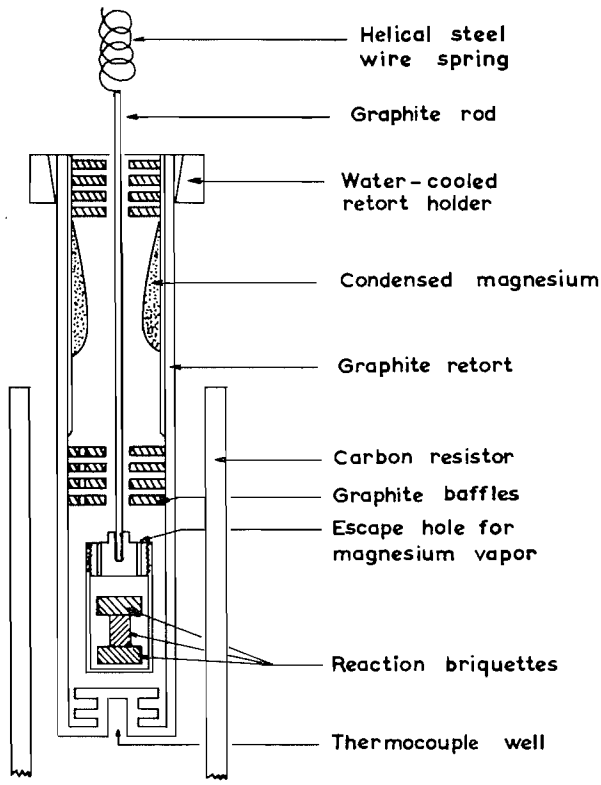

FIG. 1. Diagram of graphite retort.

to note that Kroll and Schlecten (5) found that, under high vacuum, carbon begins to react with MgO at a temperature of 1350° C. This value is lower by approximately 90° C than that determined above. This is to be expected, however, since Kroll and Schlecten used an intimate mixture of MgO and carbon, while in the present investigation a solid briquette of MgO was simply placed on the top of a surface of solid graphite.

The samples were in all cases heated to 750° C for 10 minutes, in order to effect degassing. After degassing, the length of the helical spring was measured by a cathetometer and the temperature of the furnace was increased to the required value. The time for reaching the operating temperature varied from 2 to 5 minutes. Loss in weight of the sample was then measured at constant intervals of time. During the experiments the vacuum of the system was maintained at a pressure of approximately one micron.

The bulk of the magnesium which evolved was successfully condensed as a dense deposit on the water-cooled walls of the condenser. There was no evidence of magnesium condensing on the graphite rod which supports the retort.

RESULTS AND DISCUSSION

The experimental results of this investigation are shown in Fig. 2 and Fig. 3. In Fig. 2

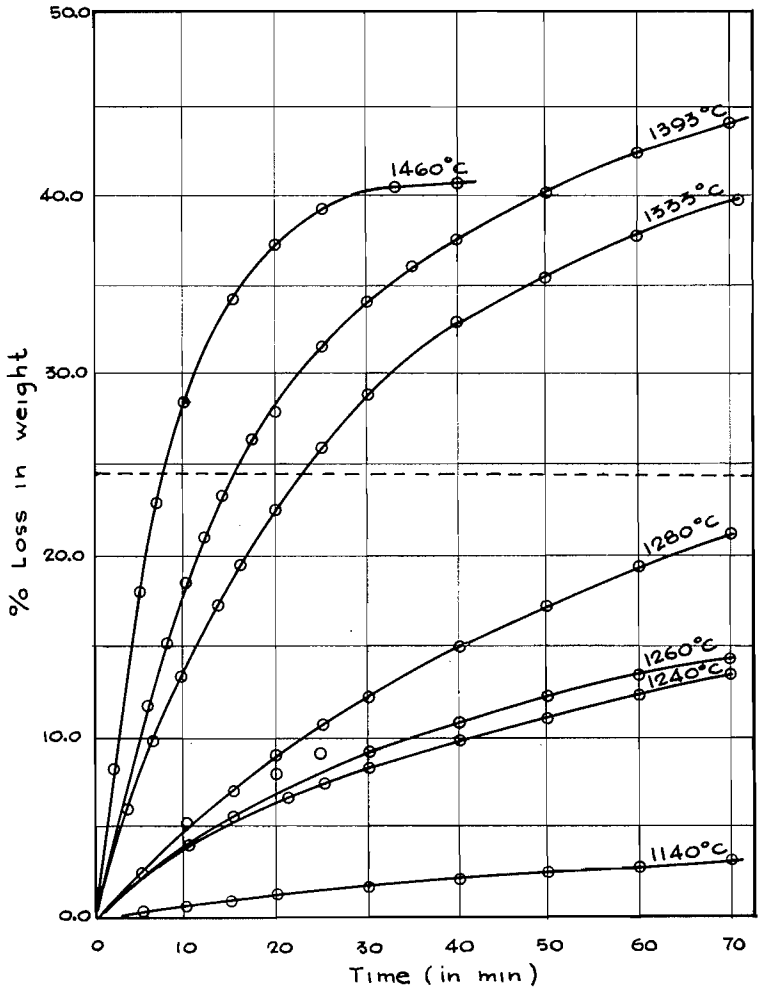

FIG. 2. Rate of reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

the percentage loss in weight of the reactant is plotted against time in minutes, while in Fig. 3 the percentage loss in weight of the reactant is plotted against temperature at

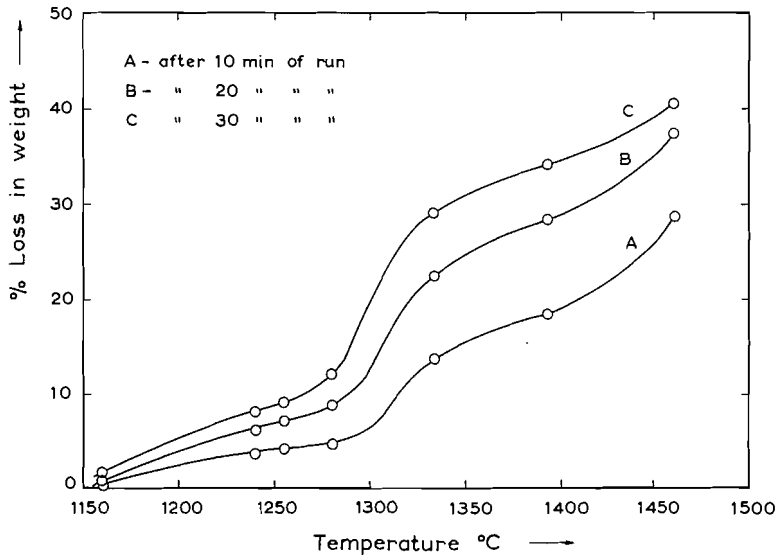

FIG. 3. Effect of temperature at constant time.

various constant times. A horizontal line is drawn through Fig. 2 to represent the maximum theoretical loss in weight, based on the magnesium evolution expected if MgO completely reacted according to equation (II).

The results at 1460° C show a tendency to level off after 25 minutes at temperature. This can be explained by the formation of liquid silicon at 1420° C which tends to agglomerate and thereby decrease the effective reaction surface.

Figure 3 shows a sharp change in the curve at about 1300° C. This suggests that another reaction involving a loss in weight becomes significant at this temperature.

After each experiment, the condenser containing the magnesium was weighed and it was found that the weight loss of the retort was always greater than the magnesium collected. Observation of the reaction retort after all experiments above 1280° C revealed a hard, glassy, brownish condensate on the baffles and condenser, the weight of which corresponded to the excess loss in weight.

On X-ray diffraction analysis, this material was found to be an intimate mixture of Mg_2SiO_4 and Si (compared with the A.S.T.M. Index), as shown in Fig. 4. The volatility of Mg_2SiO_4 and Si was independently investigated by heating each to a temperature of 1350° C. No measurable loss in weight could be observed after 1 hour of heating. The vapor pressure of silicon at 1350° C is approximately 10^{-3} mm of Hg (6). Thus, it was concluded that Mg_2SiO_4 and Si are not volatile at this temperature.

The presence of Mg_2SiO_4 and Si in the regions away from the reactor can be explained by the formation of gaseous silicon monoxide. It is known that when SiO_2 is heated with C, Si, and SiC or by the reduction of various silicates *in vacuo*, a brown distillate corresponding to the composition of SiO is produced. Zintl (7, 8) has suggested using solid SiO as a reducing agent for removing silica from siliceous compounds, or for reducing alkaline earth oxides according to the equation

$$3MO + SiO = M_2SiO_4 + M. \qquad (III)$$

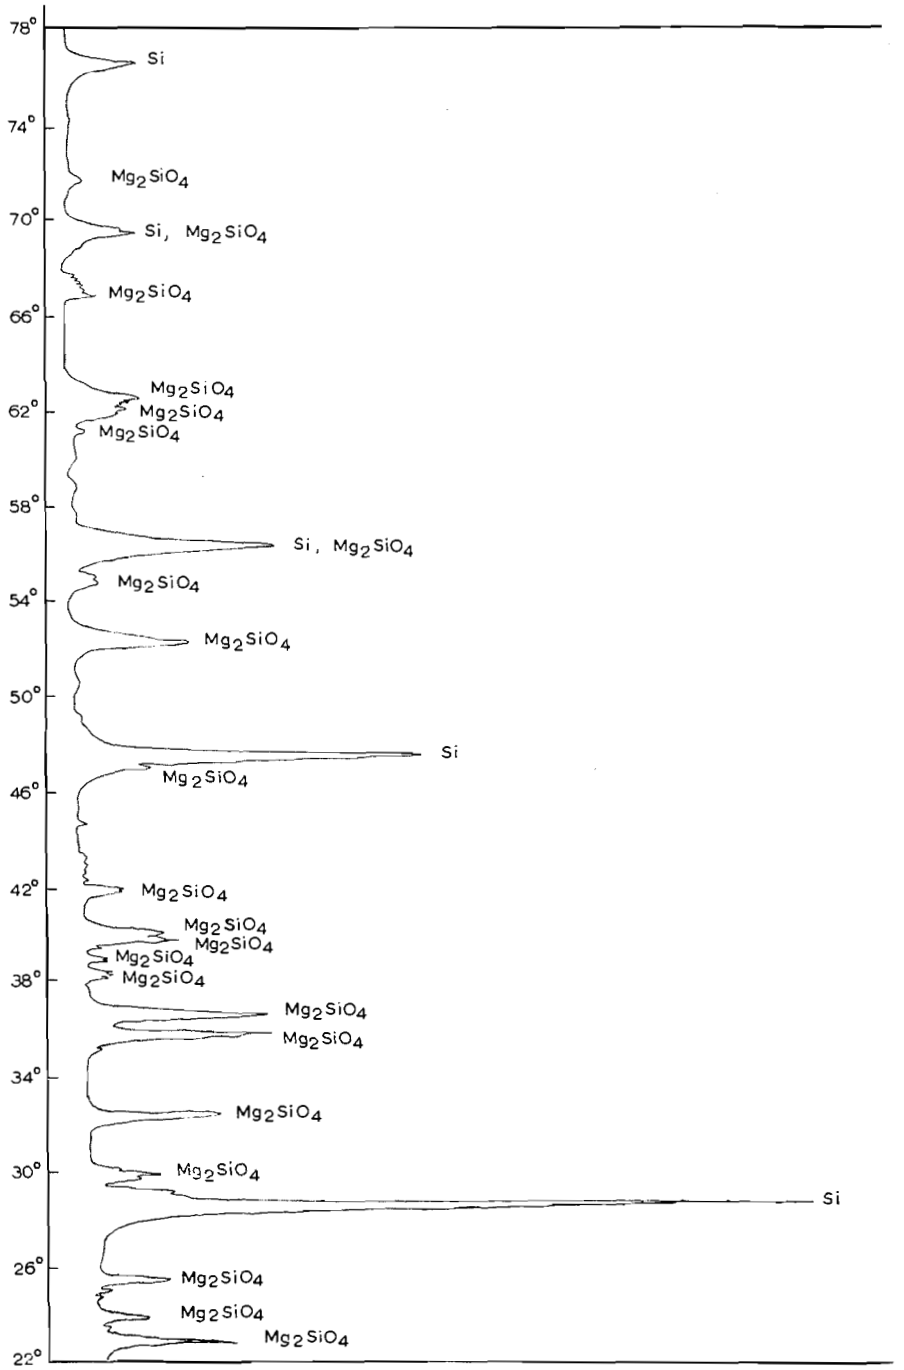

FIG. 4. X-Ray of brown condensate.

However, Brewer *et al.* (9, 10) reported in their extensive review of the literature on silicon monoxide that SiO solid appeared to be thermodynamically unstable at all temperatures, and that it disproportionated readily to Si and SiO_2. Spectrographic

TABLE I

The free-energy change for reactions under consideration

Eq. No.	Reaction	$\Delta G°$1550° K	Equilibrium pressure in mm Hg
IV	$MgO + Si = Mg + SiO$	47.8 kcal/mole Si	$P_{SiO} = 3.26\times10^{-1}$
V	$(4n+1)MgO+(1+n)Si = nMg_2SiO_4 + (1+2n)Mg + SiO$	44.9 kcal/mole Si	$P_{SiO} = 2.27\times10^{-1}$
VII	$2SiO + 2MgO = Mg_2SiO_4 + Si$	−27.0 kcal/mole MgO	$P_{SiO} = 1.18\times10^{-1}$

investigations have established unequivocally the existence of gaseous SiO. Kubaschewski and Evans (15) have recently summarized the thermodynamic data on gaseous SiO and their suggested value has been used in this discussion.

Of the number of reactions from which SiO can be formed, from a system containing MgO, Si, Mg_2SiO_4, and Mg gas, the most likely one according to thermodynamic calculations is

$$MgO + Si = Mg_{(g)} + SiO_{(g)}, \qquad (IV)$$

$$\Delta G°_{1550° K} = 47.8 \text{ kcal/mole Si.}$$

The over-all reaction can then be expressed by equation (V)

$$(4n + 1)MgO + (1 + n)Si = nMg_2SiO_4 + (1 + 2n)Mg_{(g)} + SiO_{(g)}, \qquad (V)$$

$$\Delta G°_{1550° K} = 44.9 \text{ kcal/mole Si when } n = 1.$$

The mole ratio of MgO:Si in equation (II) is 4:1, whereas in equation (V), assuming $n = 1$, the ratio is 2.5:1. The experimental ratio was 3.33:1. Therefore, according to equation (II) the reaction mixture should have an excess of silicon while according to equation (V) the reaction mixture should have an excess of magnesium oxide.

That the reaction between MgO and Si proceeds by equation (V) is substantiated by X-ray diffraction analysis of the residue. The diffraction patterns obtained in all experiments below 1280° C showed MgO, Mg_2SiO_4, and Si, while those above 1280° C showed only MgO and Mg_2SiO_4 even though excess Si was added to the reaction mixture according to equation (II). Since the residue shows in effect excess MgO, the formation of SiO cannot be due to the presence of excess silicon which might have continued its reducing action after most of the magnesium oxide had been removed from the system.

Reaction (V) would also explain the discrepancy in the weight loss of the reactants and the weight of the magnesium collected. The silicon monoxide gas that leaves the reaction zone disproportionates on reaching the cooler sections of the retort. The disproportionated product reacts with the magnesium gas coming from the reaction mixture as follows:

$$2SiO \rightarrow SiO_2 + Si,$$

$$2Mg + 2SiO_2 \rightarrow MgSiO_4 + Si,$$

the over-all reaction being represented by equation (VI).

$$4SiO + 2Mg = 3Si + Mg_2SiO_4. \qquad (VI)$$

The calculated equilibrium pressure of SiO above reaction (V) is 3.25×10^{-1} mm of Hg at 1300° C. The pressure of the system is of the order of 10^{-2} mm. Therefore one would expect the gaseous SiO to distill readily from the reactor. The discontinuity in the rate curve (Fig. 3) corresponds to the temperature at which the SiO distillation becomes significant.

Possible Reaction Mechanism

Although the present investigation does not permit a complete evaluation of the mechanism, a possible mechanism for the reaction between magnesium oxide and silicon, which accounts for the observed facts, may be expressed by the following equations. The initial reaction that occurs is that represented by equation (IV). The SiO that forms reacts with MgO according to

$$2SiO + 2MgO = Mg_2SiO_4 + Si, \qquad (VII)$$

$$\Delta G^\circ_{1550^\circ K} = -27.0 \text{ kcal/mole MgO.}$$

The calculated P_{SiO} over reactions (IV) and (VII) are 3.26×10^{-1} mm and 1.18×10^{-1} mm of Hg respectively at 1550° K. P_{SiO} must therefore be 1.18×10^{-1} mm of Hg before reaction (VII) will proceed. It is possible that the pressure of SiO is sufficient inside a reacting briquette for reaction (VII) to occur even though the residual pressure of the system is approximately 10^{-2} mm of Hg. At higher temperatures, however, SiO must be evolved faster by reaction (IV) than it can be removed by reaction (VII), thus resulting in distillation of SiO.

The reaction thus proceeds by a solid–solid and solid–gas mechanism. In both reactions (IV) and (VII), the silicons presumably occupy the magnesium sites in the oxide lattice, forming the orthosilicate. As this orthosilicate layer builds up around the silicon, diffusion of the oxygen anion outward to the silicon or diffusion of silicon to the magnesium oxide is necessary. Jander (1, 11) has indicated the rapidity at which alkaline earth oxides diffuse through the orthosilicate structure and this fact may also account for the diffusion process in the present reaction. According to equation (VII) any SiO molecules that react with MgO produce free silicon, which can act as a nucleus for further reaction. This phenomenon would decrease the diffusion path discussed above and may contribute in part to the explanation for the rapidity of this reaction.

The formation of Mg_2Si has been suggested as an intermediate in the reaction between magnesium oxide and silicon (12, 13). The phase diagram of the Mg–Si system shows only one-compound formation, Mg_2Si, with no solid solubility (14). In the present investigation Mg_2Si was heated to 1100° C in vacuum and complete dissociation according to equation (VIII) was observed on X-ray analysis.

$$Mg_2Si = 2Mg_{(g)} + Si. \qquad (VIII)$$

Furthermore when Si was replaced by Mg_2Si in the MgO–Si reaction, no difference in the rate was observed. X-Ray analysis of the residue from the MgO–Si reaction at various stages of the reaction showed no presence of magnesium silicides.

CONCLUSION

In the reaction between magnesium oxide and silicon, gaseous SiO is produced as well as magnesium. The reaction can be expressed by the equation

$$(4n + 1)MgO_{(s)} + (1 + n)Si_{(s)} = nMg_2SiO_{4\,(s)} + (1 + 2n)Mg_{(g)} + SiO_{(g)}.$$

The pressure of SiO appears to be appreciable above 1300° C.

A solid–solid, and solid–gas mechanism involving SiO is postulated for this reaction. An intermediate formation of Mg_2Si appears to be unlikely.

STEROIDS

I. 12β-METHYL-12a-HYDROXYPROGESTERONE[1]

GEORGE JUST AND R. NAGARAJAN

ABSTRACT

Lithium aluminum hydride reduction of 3α,12α-diacetoxypregnan-20-one (I*a*) gives as the major product pregnane-3α,12α,20β-triol (III), whereas the reduction of the corresponding dihydroxypregnanone I affords mainly the epimeric 3α,12α,20α-triol II. Triol III was transformed to 12β-methyl-12α-hydroxyprogesterone (VIII).

As part of a continuing study of the chemistry of steroids bearing functional groups in ring C, and of the interaction between substituents located at positions 12 and in the side-chain (1, 2), the preparation of 12-methyl-12-hydroxypregnane derivatives such as VI and VII was undertaken.

Engel and Huculak (3) have recently described the preparation of 3α,20β-dihydroxypregnan-12-one bis-methyl succinate (V*b*) through the sequence I*a* → III → III*b* → V*b*. This ketone V*b* appeared to us a useful intermediate for the introduction of a 12-methyl substituent.

Lithium aluminum hydride reduction of 3α,12α-diacetoxypregnan-20-one (I*a*) gave pregnane-3α,12α,20β-triol (III) and a small amount of material which Engel and Huculak (3) had tentatively formulated as pregnane-3α,12α,20α-triol (II). Chromic acid oxidation of this material to pregnane-3,12,20-trione (IV) confirmed this assignment of structure. In accordance to the findings of Sarett (4, see also refs. 3 and 5), the difference of increment of molecular rotation due to the acetylation of the 20β- and the 20α-hydroxy group was of the order of 200°.

Surprisingly, lithium aluminum hydride reduction of 3α,12α-dihydroxypregnan-20-one (I) gave as the major product pregnane-3α,12α,20α-triol (II). A more detailed study of the reduction revealed that the yield of the epimeric triols II and III depended on the solvent and on the nature of the functional group attached at position 12. The results are summarized in Table I.

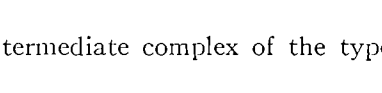

TABLE I

Starting material	Solvent	%II(20α-OH)	%III(20β-OH)
1. Diol I	Tetrahydrofuran	58.5	27.0
2. Diol I	Diethyl ether	65.8	10.2
3. Diacetate I*a*	Tetrahydrofuran	9.2	69.7*
4. Diacetate I*a*	Tetrahydrofuran	5.8	81 (3)
5. Diacetate I*a*	Diethyl ether	37	46.8

*No attempt was made in this case to obtain the maximum yield.

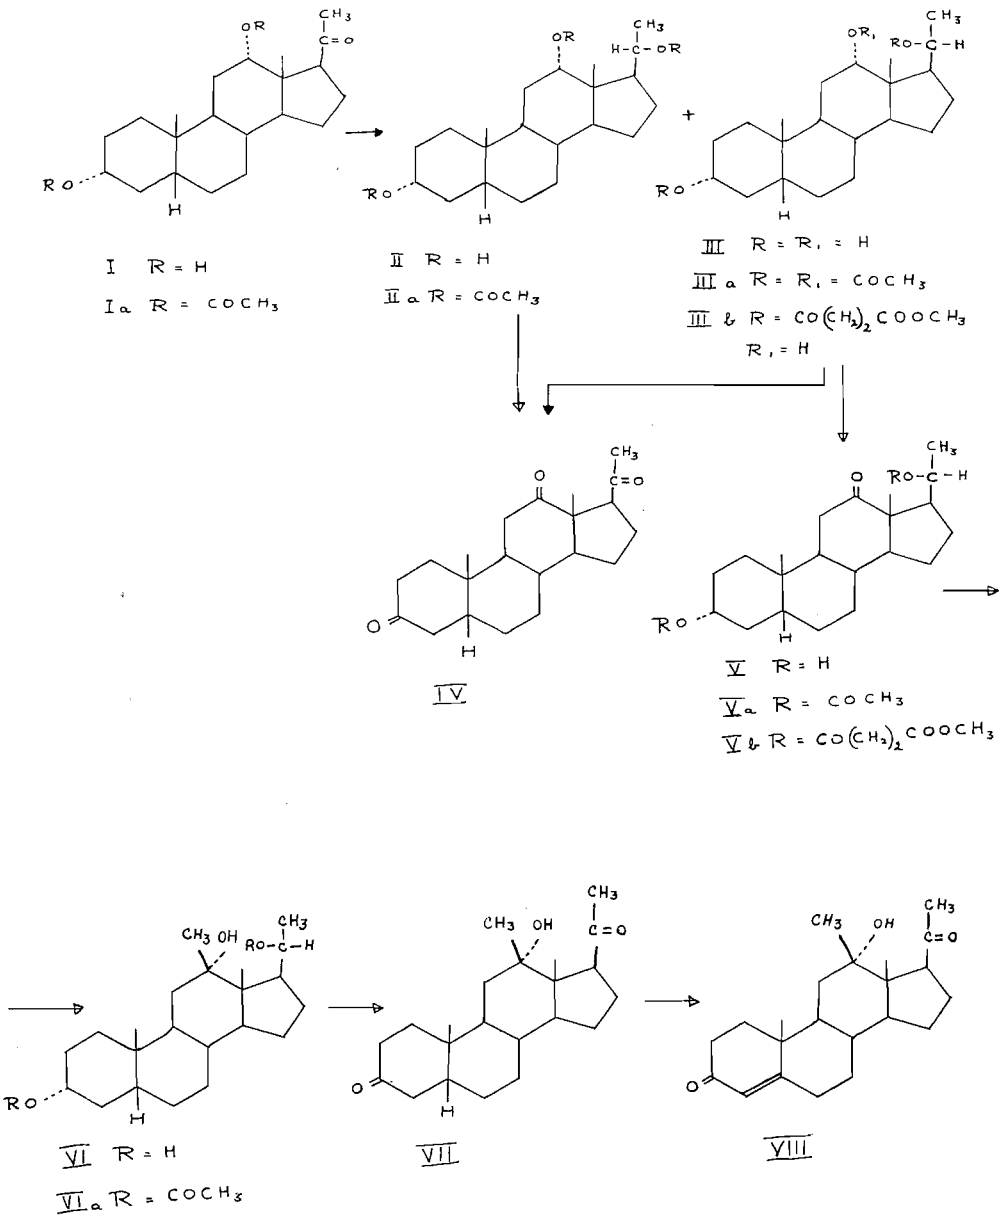
The reduction of the 20-keto diacetate I*a* to the 20β-triol III proceeds according to Cram's rule of steric control of asymmetric induction (6). The stereochemistry of the reduction of the 20-keto diol I to the 20α-triol II can be readily explained, if one assumes

[1]*Manuscript received November 7, 1960.*
Contribution from the Department of Chemistry, McGill University, Montreal, Que. This paper forms a part of the Ph.D. thesis of R. Nagarajan, to be presented to the Faculty of Graduate Studies, McGill University.

the formation of an intermediate complex of the type  . The carbonyl group is then reduced by another hydride molecule. Sicher *et al.* (7) have postulated a similar complex to explain why dehydrochloramphenicol and its *O*-acetate form threo- and erythro-chloramphenicol, respectively, upon Meerwein-Ponndorf reduction.

The co-ordination of the aluminum hydride alcoholate by the carbonyl group is competing with solvation by ether and tetrahydrofuran (8). As tetrahydrofuran is more basic than ether (9), one would expect less co-ordination of the 20-carbonyl oxygen in the lithium aluminum hydride reduction in tetrahydrofuran, and hence more 20β-alcohol III would be formed in that solvent. This hypothesis is confirmed by experimental evidence (Table I, columns 1 and 2).

An explanation of the solvent effect in the reduction of the diacetoxy ketone I*a* would follow similar lines. The only assumption which would have to be made is that the 20-keto group is reduced at a similar rate as the 12-acetate group. Reduction of keto diol I with a fivefold excess of sodium borohydride indicated the hindered nature of the 20-carbonyl group, since even after 20 hours it was not complete, as evident from infrared measurements. This experiment does lend some weight to the assumption made, without, however, proving it.



A co-ordination complex involving aluminum hydride would also account for the conversion of 17α-hydroxypregnan-20-ones by the action of lithium aluminum hydride to a mixture of 20β- and 20α-dihydroxypregnane derivatives, in which the latter predominated (5).

Succinylation of triol III to the succinate III*b* (3), followed by oxidation, afforded the 12-keto disuccinate V*b* (3). Prolonged treatment of the ketone V*b* with methyl magnesium iodide in diethyl ether led to a reaction mixture containing sizable amounts of starting material. The keto disuccinate V*b* was therefore hydrolyzed with methanolic potassium hydroxide to the dihydroxy ketone V, which was converted to the corresponding diacetate V*a*. Treatment of the 12-keto diacetate V*a* with excess ethereal methyl magnesium iodide for 20 hours gave a 73% yield of the desired 12β-methylpregnane-3α,12α,20β-triol VI. Triol VI formed a diacetate VI*a*, and was easily oxidized to 12β-methyl-12α-hydroxypregnane-3,20-dione (VII), thus establishing the tertiary nature of the 12-hydroxy group. The assignment of configuration of the 12-methyl group will be substantiated in a following paper. It is in disagreement with the assignment of configuration made by Levine and Wall (10) and Bladon and McMeekin (11), who transformed hecogenin to "12α-methyl-12β-hydroxy tigogenin".

Because of the considerable interest in steroid hormone analogues containing alkyl and other substituents in the steroid nucleus (see, e.g. 10, 11, 12), we decided to transform 12β-methyl-12α-hydroxypregnane-3,20-dione (VII) into the closely related 12β-methyl-12α-hydroxyprogesterone (VIII). This was readily achieved by bromination in position 4, followed by dehydrobromination (13). The progesterone analogue thus obtained did not exhibit any notable progestational, androgenic, diuretic, hypotensive, or anabolic properties.[2]

EXPERIMENTAL[3, 4, 5, 6]

Reduction of 3α,12α-Diacetoxypregnan-20-one (Ia) in Ether

A solution of the diacetate I*a* (14) (30.0 g, 0.0717 mole, m.p. 122–123°) in absolute ether (500 ml) was added with stirring to a solution of lithium aluminum hydride (33 g) in absolute ether (1500 ml). The reaction mixture was heated under reflux for 1 hour and

[3]*All the melting points were corrected.*
[4]*Only the best yields were reported.*
[5]*The commercially available aluminum oxide (Woelm) was used.*
[6]*The microanalyses were carried out by Dr. Alfred Bernhardt, Germany.*

left at room temperature overnight. The excess lithium aluminum hydride was destroyed by adding ethyl acetate (175 ml) and then 2 *N* sulphuric acid (450 ml). The solvents were removed by distillation and the reaction mixture extracted with chloroform. The chloroform layer was washed with 5% sodium bicarbonate solution, water, saturated sodium chloride solution, and dried over magnesium sulphate.

Repeated crystallizations from chloroform gave the 20α-alcohol II (8.902 g, 37.0%), m.p. 225–226°, $[\alpha]_D^{29}$ 46° (*c* 0.59 in $CHCl_3$). The substance was slightly hygroscopic. Crystallization from acetone did not change the melting point. Calcd. for $C_{21}H_{36}O_3$: C 74.98%, H 10.78%. Found: C 74.94%, H 10.66%.

Crystallization of the mother liquors from acetone gave the 20β-alcohol III (3) (11.260 g, 46.8%), m.p. 236–238°, $[\alpha]_D^{29}$ 34° (*c* 0.78 in $CHCl_3$).

Calcd. for $C_{21}H_{36}O_3$: C 74.98, H 10.78%. Found: C 74.84, H 10.61%.

Reduction of 3α,12α-Dihydroxypregnan-20-one (I) in Ether

A solution of the diol I (14) (1.414 g, 0.00423 mole, m.p. 168–172°; crude product obtained by alkaline hydrolysis of the diacetate I*a*) in absolute ether (200 ml) was added with stirring to a solution of lithium aluminum hydride (1.5 g) in absolute ether (100 ml). The reaction mixture was worked up as described above. The yields of 20α-alcohol II, m.p. 225–226°, and of 20β-alcohol III, m.p. 236–238°, were 65.5% and 10.5% respectively. The alcohols were identified by mixed melting point and comparison of I.R. spectra.

Reduction of 3α,12α-Dihydroxypregnan-20-one (I) in Tetrahydrofuran

A solution of the diol I (2.635 g, 0.00789 mole, m.p. 168–172°, crude product obtained by alkaline hydrolysis of the diacetate I*a*) in absolute tetrahydrofuran (200 ml) was added dropwise, with stirring, to a solution of lithium aluminum hydride (3.0 g) in absolute tetrahydrofuran (250 ml). The reaction mixture was worked up as described above. The yields of the 20α-alcohol II, m.p. 225–226°, and of 20β-alcohol III, m.p. 236–238°, were 58.5% and 27.2% respectively. The identity of the alcohols was confirmed by mixed melting point and superimposability of I.R. spectra.

Reduction of 3α,12α-Diacetoxypregnan-20-one (Ia) in Tetrahydrofuran (3)

A solution of the diacetate I*a* (30.9 g, 0.0739 mole, m.p. 122–123°) in absolute tetrahydrofuran (200 ml) was reduced with lithium aluminum hydride (36 g) in 1500 ml of absolute tetrahydrofuran (3). Chloroform extraction afforded 21.1 g (85% yield) of the crude product. Separation of the triols, as described above, afforded 2.40 g of the 20α-triol II (m.p. 221–224°, 9.5% yield), and 17.3 g of the 20β-triol III (m.p. 231–233°, 69.7% yield).

3α,12α,20α-Triacetoxypregnane (IIa)

Triol II (130 mg, m.p. 225–226°) was heated under reflux for 1 hour in pyridine (3 ml) and acetic anhydride (1 ml). The reaction mixture was worked up as usual and afforded, on crystallization from ether–hexane, the triacetate II*a*, m.p. 147–148°, $[\alpha]_D^{28}$ 95° (*c* 0.73 in $CHCl_3$).

Calcd. for $C_{27}H_{42}O_6$: C 70.09%, H 9.15%. Found: C 70.27%, H 9.20%.

3α,12α,20β-Triacetoxypregnane (IIIa)

Triol III (130 mg, m.p. 236–38°) was treated as described above. Crystallization of the crude product from ether–hexane yielded the triacetate III*a* (3), m.p. 201–202°, $[\alpha]_D^{28}$ 127° (*c* 0.81 in $CHCl_3$). The melting point was not depressed upon admixture with an authentic sample[7] and the I.R. spectra were identical.

Pregnane-3,12,20-trione (IV)

In parallel runs, a solution of triol II and of triol III (300 mg) in acetic acid (15 ml) was treated with a solution of chromium trioxide (300 mg) in 3 ml of 90% acetic acid at room temperature for 20 hours. Extraction and crystallization gave in each case an 80–90% yield of IV (15), m.p. 203–205°. The identity of the samples in both cases was confirmed by mixed melting point and superimposability of I.R. spectra.

3α,12α,20β-Trihydroxypregnane 3α,20β-bis-Methyl Succinate (IIIb)

To a solution of the triol III (4.38 g) in pyridine (40 ml), succinic anhydride (10.2 g) was added. The reaction mixture was heated at 90° on a water bath for 4 hours, and left overnight at room temperature. It was diluted with ice-cold water (1500 ml) and left for 1 hour. The solution was extracted with ether, washed with 2 *N* sulphuric acid, and twice with water. The ethereal extract was dried over magnesium sulphate. Upon evaporation of the solvent to 250 ml, 4.054 g of the bis-hemisuccinate, m.p. 188–189°, crystallized.

Crystallization of mother liquors from acetone–hexane afforded 2.192 g, m.p. 188–189°.

Recrystallization for analysis raised the m.p. to 190–191° (m.p. 182–184° (3)).

Calcd. for $C_{29}H_{44}O_9$: C 64.91%, H 8.26%. Found: C 64.79%, H 8.35%.

A solution of the bis-hemisuccinate (6.152 g) in ether (1500 ml) was methylated with an excess of diazomethane in ether. One crystallization from ether–hexane afforded 5.855 g of III*b* (3), m.p. 96–97°, $[\alpha]_D^{29}$ 67° (*c* 0.97 in $CHCl_3$). Crystallization of the mother liquors gave 0.257 g of III*b*, m.p. 94–95° (yield 84%).

3α,20β-Dihydroxypregnan-12-one bis-Methyl Succinate (Vb)

Oxidation with chromium trioxide in acetic acid of the bis-methyl succinate III*b* (6.025 g) afforded 5.971 g of the keto bis-methyl succinate V*b* (3), m.p. 112–113°, $[\alpha]_D^{29}$ 110° (*c* 0.91 in $CHCl_3$).

3α,20β-Dihydroxypregnan-12-one (V)

To a solution of the keto bis-methyl succinate V*b* (10.0 g) in methanol (700 ml) and water (100 ml) was added potassium carbonate (12.5 g) and the mixture was refluxed for 17 hours. The major part of the methanol was distilled off *in vacuo*. The reaction mixture was worked up as usual and on crystallization from acetone–hexane, 2.868 g of the hydroxy ketone V, m.p. 221–222°, was obtained. The I.R. spectrum of the mother liquors showed that the hydrolysis was not complete. The mother liquors were further hydrolyzed with 5% methanolic potassium hydroxide for 8 hours at reflux temperature and worked up as usual. Crystallization from acetone–hexane afforded 3.044 g of the hydroxy ketone V, m.p. 220–222° (yield 96%).

A portion of the hydroxy ketone V was crystallized twice from acetone–hexane for analysis, m.p. 222–223°, $[\alpha]_D^{29}$ 131° (*c* 0.95 in $CHCl_3$).

Calcd. for $C_{21}H_{34}O_3$: C 75.41, H 10.24. Found: C 75.20, H 10.06.

3α,20β-Diacetoxypregnan-12-one (Va)

A solution of the hydroxy ketone V (400 mg) in pyridine (10 ml) and acetic anhydride (10 ml) was kept in a water bath at 90° overnight. Ether extraction gave 511 mg of crude product. One crystallization from ether–hexane yielded 416 mg of the ketone V*a*, m.p. 136–137°. Crystallization of mother liquors afforded 53 mg of V*a*, m.p. 135–136° (yield 93%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A portion of ketone V*a* was crystallized twice from ether–hexane for analysis, m.p. 136–137°, $[\alpha]_D^{29}$ 179° (*c* 1.09 in $CHCl_3$).

Calcd. for $C_{35}H_{28}O_5$: C 71.73, H 9.15. Found: C 71.91, H 9.25.

12β-Methyl-3α,12α,20β-trihydroxypregnane (VI)

To 200 ml of an ethereal solution of methyl magnesium iodide (from 270 mg of magnesium and 0.7 ml of methyl iodide) was added with stirring 575 mg of the ketone V*a*, dissolved in 200 ml of absolute ether. The reaction mixture was refluxed for 20 hours. A solution of ammonium chloride (10 g) in water (200 ml) was added to the reaction mixture. It was then extracted with ether and the organic solution washed with water until neutral. The ethereal extract was dried over magnesium sulphate. On evaporating the major part of the ether, crystals of the triol VI (110 mg, m.p. 213–214°) were obtained. Crystallization of mother liquors afforded 98 mg of the triol VI, m.p. 210–213°.

Recrystallizations from aqueous methanol and methanol raised the m.p. to 213–215°, $[\alpha]_D^{29}$ 39° (*c* 0.88 in $CHCl_3$).

Calcd. for $C_{22}H_{38}O_3$: C, 75.37, H 10.92. Found: C 75.21, H 10.92.

The mother liquors were acetylated and the resulting oil (435 mg) chromatographed on alumina (4.5% water). The hexane–benzene (4:1) fractions consisted mainly of the unreacted ketone. Hexane–benzene (1:1) fractions were collected and on crystallization from hexane gave 73 mg of the diacetate VI*a*, m.p. 119–121°. The mother liquors on crystallization from hexane afforded 15 mg of the diacetate VI*a*, m.p. 119–121°.

A portion of the diacetate VI*a* was crystallized twice from hexane for analysis, m.p. 122–124°, $[\alpha]_D^{29}$ 78° (*c* 1.01 in $CHCl_3$).

Calcd. for $C_{26}H_{42}O_5$: C 71.86, H 9.74. Found: C 71.66, H 9.99.

The mother liquors of the hexane–benzene (1:1) fractions and the remainder of the fractions of the chromatogram afforded upon alkaline hydrolysis and crystallization from ether–hexane 71 mg of the triol VI, m.p. 208–210° (yield 73%).

12β-Methyl-12α-hydroxypregnane-3,20-dione (VII)

Chromium trioxide (490 mg) in 90% acetic acid (5 ml) was added with stirring to a solution of the triol VI (750 mg) in acetic acid (50 ml) and left at room temperature overnight. Ether extraction afforded 723 mg of the crude hydroxy ketone VII, m.p. 184–186°. One crystallization from acetone–hexane gave 663 mg of the hydroxy ketone VII, m.p. 187–188°. Crystallization of mother liquors afforded 15 mg of VII, m.p. 186–187° (yield 92%).

A portion of the hydroxy ketone VII was crystallized twice from acetone–hexane for analysis, m.p. 187–188°, $[\alpha]_D^{29}$ 102°, (*c* 1.05 in $CHCl_3$).

Calcd. for $C_{22}H_{34}O_3$: C 76.25, H 9.89. Found: C 76.10, H 9.87.

12β-Methyl-12α-hydroxyprogesterone (VIII)

A solution of bromine (141 mg) in acetic acid (9.4 ml) was added to a solution of the hydroxy ketone VII (300 mg) in acetic acid (10 ml) with stirring. After 5 minutes, the reaction mixture was poured into ice-water (500 ml), and extracted with ether. The organic layer was washed with water and dried. There was obtained 395 mg of an oil which resisted crystallization.

The crude bromo ketone was dehydrobrominated according to the method of McGuckin and Kendall (13). The crude product (240 mg of oil) on crystallization from ether–hexane afforded 125 mg of the progesterone derivative VIII, m.p. 140–150°. Repeated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

crystallizations gave 97 mg of analytically pure VIII, m.p. 152–153°, $[\alpha]_D^{29}$ 182° (*c* 1.01 in $CHCl_3$), λ_{max}^{EtOH} 239 mμ, (ε 17500), $\nu_{max}^{CCl_4}$ 1710 cm^{-1} (20-ketone), 1680 cm^{-1}, 1620 cm^{-1} (Δ^4-3-ketone).

Calcd. for $C_{22}H_{32}O_3$: C 76.68, H 9.37. Found: C 76.40, H 9.40.

THE DEMETHYLATION OF SUGARS WITH HYDROGEN PEROXIDE[1]

B. FRASER-REID, J. K. N. JONES, AND M. B. PERRY

ABSTRACT

Demethylation of methylated sugars can be achieved using hydrogen peroxide and ferrous iron (Fenton's reagent). The reaction is not specific and further oxidation of the sugar also occurs. The preparation of 3,4-di-*O*-methyl-D-mannose from the corresponding mannitol derivative is described. Mono-*O*-methyl derivatives of D-mannose and of D-mannitol as well as D-mannose and D-mannitol were also produced. The course of the demethylation of 2,3,4,6-tetra-*O*-methyl methyl α-D-glucoside by Fenton's reagent has been examined.

Hydrolysis of methylated yeast mannan yields 3,4-di-*O*-methyl-D-mannose as a major component of the methylated sugars (1, 2). No simple method is available for the synthesis of this sugar but Aspinall and Zweifel (3) have shown how it may be obtained from D-mannose by a rather long and involved route.

As early as 1894, Fenton (4) showed that ferrous iron had a specific influence on the oxidation of hydroxyl-containing compounds by hydrogen peroxide and other oxidizing agents. He showed, for example, that it was possible to convert various polyhydric alcohols into the corresponding aldoses (5). This method suggested itself to us as convenient for the conversion of 3,4-di-*O*-methyl-D-mannitol to 3,4-di-*O*-methyl-D-mannose, the starting material being readily available from 1,2-5,6-di-*O*-isopropylidene-D-mannitol. An attraction of this scheme is the symmetry of the dimethyl mannitol, which ensures that only one aldohexose would be produced regardless of which end of the molecule was oxidized.

It was surprising, therefore, to find that, when 3,4-di-*O*-methyl-D-mannitol was oxidized by Fenton's reagent in ice-cold solution and the resulting solution analyzed chromatographically, sugars corresponding to mannitol, mannose, and their mono-*O*-methyl and di-*O*-methyl derivatives were detected, as well as methylated pentoses and uronic acids. Repetition of this experiment under a variety of conditions confirmed these observations.

Because of the strangeness of these findings we investigated the action of the reagent on a fully methylated sugar. It was observed that 2,3,4,6-tetra-*O*-methyl methyl α-D-glucoside was demethylated to yield among other products D-glucose and the possible mono-, di-, tri-, and tetra-*O*-methyl-D-glucoses. Our analyses of the mixture of monomethyl glucoses so obtained indicate that the methoxyl groups on carbons 2 and 4 are most strongly attacked, those on carbon 6 next strongly, and those on carbon 3 least strongly attacked.

Saunders (6) has shown that, under the catalytic influence of the enzyme ferriperoxidase, hydrogen peroxide will oxidize *p*-anisidine to 2-amino-5-*p*-anisidino benzoquinone di-*p*-methoxyphenylimine with elimination of one methoxyl group. But as far as we are aware the observations described above are the first in which the elimination of methoxyl groups by oxidation from sugar residues has been described.

It is well established that the ferrous–peroxide system produces hydroxyl radicals and the reaction sequence first formulated by the Haber–Weiss theory (7) was later confirmed and expanded by Evans (8). Waters *et al.* (9, 10) have shown that the kinetics of the system is consistent with the thesis that the oxidizing species is the free radical. Grinstead

[1]*Manuscript received November 23, 1960.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario.

(11, 12) has suggested how they may attack various substrates and Waters (9, 10) has postulated that the radical attacks primary hydroxyl groups as follows (scheme A).

$$RCH_2OH + OH\cdot \rightarrow R\dot{C}HOH + H_2O$$
$$R\dot{C}HOH + HO{-}{-}OH \rightarrow \cdot OH + RCH(OH)_2$$
$$R\dot{C}HOH + OH\cdot \rightarrow RCH(OH)_2$$
$$RCH(OH)_2 \rightarrow RCHO + H_2O$$

SCHEME A

This scheme explains the oxidation of hexitol to hexose. The latter may then be further oxidized to a hexonic acid, and if oxidized further a pentose may arise by oxidative decarboxylation, a well-known reaction in carbohydrate chemistry.

We suggest that the hydroxyl free radical is also the demethylating species and that the scheme operates as follows (scheme B).

1. $R\cdot OCH_3 + OH\cdot \rightarrow RC\cdot OH_2\cdot + H_2O$
2. $ROCH_2\cdot + HO{-}{-}OH \rightarrow ROCH_2OH + OH\cdot$
3. $ROCH_2\cdot + OH\cdot \rightarrow ROCH_2OH$
4. $ROCH_2OH \rightarrow ROH + HCHO$

SCHEME B

Cleavage of the $R{-}{-}OCH_3$ bond seems unlikely because (*a*) this would involve the more complex radical abstraction of $-{-}OCH_3$ and (*b*) some inversion of configuration at the reaction center might be expected, especially in view of the absence of steric hindrance in the zigzag form of the hexitol in solution. No products resulting from such an inversion have been detected. The electronegativity of the hydroxyl radical should render it capable of such hydrogen abstraction (cf. ref. 13). Quantitative experiments with 2,3,4,6-tetra-*O*-methyl methyl-α-D-glucoside indicated that the reducing power of the reaction mixture, after acidic hydrolysis, was increased only by 27% of the theoretical value. This indicated that the glucosidic methoxyl group was attacked to the extent of 73%. In neutral solution demethylation proceeds only to a limited extent.

If the hydroxyl radical is engaged in both oxidation and demethylation then some competition for the radical to be involved in either of the processes (schemes A and B) is to be expected. Tables I and II record the conditions and results of experiments. In these tables the relative order of intensity of sugars as detected chromatographically is given in the form 1 > 2 > 3, etc. The reaction was initially exothermic and was accompanied by a considerable evolution of carbon dioxide. The solution rapidly became acidic

TABLE I

*Free, mono-, and di-methyl.
†As percentage from available primary alcohol.

(pH 6 → pH 1) (cf. ref. 14). From the percentage of reducing groups produced it is clear that much of the hexitol is converted into reducing sugars and then further oxidized to aldonic acids. Osones were not detected, nor was formaldehyde. The latter was presumably further oxidized to carbon dioxide. After completion of the reaction, the solution in certain cases (see Experimental Section) was neutralized and deionized and the products separated chromatographically. It is clear that in the absence of ferrous sulphate no demethylation occurs and that a decrease in the concentration of ferrous sulphate or in the temperature of the reaction mixture results in less demethylation. High concentration of hydrogen peroxide and high temperatures favor the formation of pentoses and non-reducing acidic materials.

We have also investigated the fate of anisole when subjected to Fenton's reagent at 0–3° C. The reaction is only very slightly exothermic and an immediate dirty-green color is produced on the addition of peroxide. At least four phenolic products have been obtained, one being identified (by paper chromatography) as guaiacol. Infrared analyses indicate that very little of the methoxyl group is removed. Thus it appears that the aromatic nucleus is much more readily attacked than is the methoxyl group.

The removal of the methyl group from a methoxyl group by hydroxyl radicals is of biochemical interest because a similar mechanism may be operative in some organisms.

EXPERIMENTAL

The following solvent systems were used to separate sugars on paper chromatograms: (i) butan-1-ol, ethanol, water (3:1:1) and (ii) butan-1-ol, pyridine, water (10:3:3) (all vol/vol). Reducing sugars were detected with (*a*) the *p*-anisidine hydrochloride spray (15) and components with adjacent hydroxyls (reducing and non-reducing) were detected with (*b*) 0.1 *M* sodium periodate followed after about 5 minutes with the *p*-anisidine spray (cf. ref. 16).

Phenols were separated by reverse phase chromatography on paper (Whatman No. 1) previously impregnated with 10% tetrahydro naphthalene in methanol and allowed to dry in air. The irrigant was water:methanol (8:2) and the phenols on the air-dried chromatogram were sprayed with a solution of sulphanilic acid followed immediately after with 20% sodium bicarbonate solution (17).

Paper electrophoresis was performed on Whatman 3mm paper saturated with borate buffer pH 10 at ca. 1500 volts for 1–1½ hours (18, 19).

Deionizations were effected by passing the solution down columns of Amberlite IR120 (H^+ form) followed by passage through Duolite A4 (OH^- form). All solutions were concentrated under diminished pressure below 50° C.

For personal use only.

Melting points and mixed melting points were determined simultaneously on a standard Fischer-Johns block and the values quoted are uncorrected. Optical rotations were determined in water ($C = 1$).

Chromatographic fractionations were effected by placing the syrup on a cellulose column in the usual manner (20). The columns were irrigated with butan-1-ol, light petroleum mixture (4:1) to remove tri-*O*- and higher methylated sugars; butan-1-ol – water mixture (95:5) was used to remove the lower methylated and free sugars. In every case the combined fractions were concentrated to a syrup which was purified by deionization and by refluxing their solutions in methanol with decolorizing charcoal.

PART I

Preparation of 3,4-Di-O-methyl-D-mannitol

3,4-Di-*O*-methyl-D-mannitol (m.p. 145–147° C) was prepared by methylation (Kuhn's method (21,22)) of 1,2–5,6-di-*O*-isopropylidene-D-mannitol, the latter being prepared from D-mannitol (23).

Oxidation of 3,4,Di-O-methyl-D-mannitol

To a solution of dimethyl mannitol (15 g) in water (100 ml) ferrous sulphate (45 g) was added with stirring. When solution was complete hydrogen peroxide (75 ml, 15%) was added gradually during 1½ hours and the temperature of the solution was maintained between 20–25° C by use of an ice-water bath. After the addition the reaction mixture was kept with stirring at room temperature for an additional 2 hours. The solution was neutralized and the precipitate was removed by filtration and the light-green-colored filtrate deionized. The solution was concentrated to give a syrup (9.5 g) which was fractionated on a cellulose column.

Fraction I gave a syrup which chromatographed as a single spot corresponding to authentic 3,4-di-*O*-methyl-D-mannose. This was crystallized from ethanol–ether. The crystals so deposited melted between 90–95° C and were possibly a mixture of the hydrated and anhydrous forms. The mixture was redissolved in dry acetone–ether and after about 6 weeks spherically shaped crystals had deposited, m.p. 77–79° C, mixed m.p. 78–81° C, $[\alpha]_D^{20} = 16.6°$ (initial) $\rightarrow 8°$ (after 24 hours, constant value) (cf. Aspinall and Zwiefel (3)).

Fraction II was identified as unchanged 3,4-di-*O*-methyl-D-mannitol.

Fraction III was identified chromatographically as a mixture of mono-*O*-methyl-D-mannoses. The purified syrup was dissolved in water (100 ml) (solution A) and the solution was used for further experiments.

Preparation and Analysis of Monomethyl Mannosides

The above solution (20 ml corresponding to 65 mg of syrup) was removed and evaporated to a syrup which was converted to the glycosides in the usual manner (see glycosidation of monomethyl glucoses below). The syrupy glycosides were purified by twice extracting them under reflux with ethanol, and once with water in the presence of decolorizing charcoal. The product was dried at 50° C (P_2O_5) to a constant weight (40.9 mg). This syrup was dissolved in water, diluted to 50 ml and periodate oxidation studies were conducted on 40 ml (≡ 32.7 mg) of the solution so prepared (31, 32). (See experimental on monomethyl glucose below.) After 35 hours the periodate uptake had a constant value of 0.41 mole, and the formic acid liberation was negligible (0.01 mole). These results indicate that approximately 40% of the monomethyl mannose is present as the 4-*O*-methyl isomer.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The oxidized solution was deionized and the deionized solution hydrolyzed with 2 *N* sulphuric acid. The hydrolyzate was neutralized with barium carbonate, filtered, deionized, and analyzed qualitatively by paper electrophoresis using authentic 3-*O*-methyl-D-mannose as standard. The presence of this isomer was clearly indicated.

Reduction of Monomethyl Mannose

Potassium borohydride (0.2 g) was added to solution A (30 ml) and the mixture was left at room temperature overnight, after which it gave a negative reaction to Fehling's solution. The solution was neutralized by adding Amberlite resin IR120 (H^+ form), filtered, and the filtrate was evaporated to dryness. The boric acid was removed by repeated codistillation with methanol. The resulting product was twice crystallized from ethanol, and then dried at 65° C to give white crystals; m.p. 133–134° C; $[\alpha]_D^{25} = +18°$, in good agreement with Hudson's constants for 3(4)-*O*-methyl-D-mannitol (24). Thus both sugars give one product upon reduction and this indicates conclusively that the two components are 3-*O*-, and 4-*O*-monomethyl-D-mannoses.

Fraction IV was monomethyl mannitol. The clear syrup was crystallized from ethanol. The dried crystals melted at 131–133° C and when mixed with the reduced monomethyl mannose above melted at 131–133° C. This fraction therefore contains only one component, which was identified as 3-*O*-monomethyl-D-mannitol (equivalent to the 4-*O*-methyl isomer).

Fraction V was identified as D-mannose. To the syrup obtained after purification 0.23 g phenylhydrazine reagent (6 ml) (1 g phenylhydrazine hydrochloride, 2.4 g sodium acetate, 0.6 ml acetic acid, and 25 ml water) was added. An almost immediate precipitate of D-mannose phenylhydrazone formed. The crystals were removed and recrystallized from ethanol. They had m.p. 190–191° C, mixed m.p. 191–192° C.

Fraction VI was identified as D-mannitol. The purified syrup was crystallized from methanol; m.p. 166–168° C, mixed m.p. 165–168° C.

PART II

Preparation of 2,3,4,6-Tetra-O-methyl Methyl-α-D-glucoside

Tetramethyl methyl glucoside was prepared by a Kuhn (21, 22) type methylation of reagent grade methyl-α-D-glucoside. The product had a refractive index of 1.4449 at 20° C [the accepted value is 1.4454 (25)].

Oxidation of 2,3,4,6-Tetra-O-methyl Methyl-α-D-glucoside

The glucoside (6 g) was dissolved in water (30 ml) and ferrous sulphate (36.6 g) was added with stirring. Hydrogen peroxide (50 ml, 15%) was added cautiously with stirring and the temperature was maintained between 20–25° C. After 18 hours at room temperature the mixture was neutralized with barium carbonate. The solution was filtered and the pale green filtrate was made 2 *N* with respect to sulphuric acid and the solution was boiled under reflux for 3½ hours. The cooled solution was neutralized (barium carbonate), filtered, and deionized and the solution evaporated to a syrup (0.992 g). A second oxidation was carried out using the same quantities of reagents but a smaller quantity of hydrogen peroxide.

The combined syrups (2.55 g) were fractionated on a cellulose column.

Fraction I was identified by paper chromatography as 2,3,4,6-tetra-*O*-methyl-D-glucose (260 mg). A partial crystallization occurred overnight. The crystals were removed and converted to the *N*-phenyl glucosylamine by the method of Wolfrom (26). The product had m.p. 133–135° C; mixed m.p. 132–135° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Fraction II (tri-*O*-methyl-D-glucoses) yielded a syrup (274 mg) which was a mixture. It was made up to a known volume (solution A) in water.

Detection of 2,3,4-Tri-O-methyl-D-glucose

A portion of solution A equivalent to ca. 20 mg of sugars was evaporated to a syrup which was then dissolved in phosphate buffer (10 ml, pH 7.4). The solution was then saturated with sodium periodate and left overnight at room temperature (solution B). To the oxidized solution (5 ml) excess inositol was added to destroy excess of periodate and acetyl acetone (3 ml) added. Within 1 minute a strong fluorescence developed indicative of the presence of formaldehyde (27). A blank of water treated similarly failed to show any fluorescence even when viewed under ultraviolet light.

Bell has shown (28) that 2,3,4-tri-*O*-methyl-D-glucose is attacked by periodate with non-quantitative liberation of formaldehyde. The presence of 2,3,4-tri-*O*-methyl-D-glucose is therefore established.

Detection of 3,4,6-Tri-O-methyl-D-glucose

The remainder of solution B (5 ml) was deionized and studied by paper chromatography in solvent systems (i) and (ii). A spot running evenly with 2,3,5-tri-*O*-methyl-D-arabinose indicated the presence of the latter in the periodate-oxidized material. This therefore confirms the presence of 3,4,6-tri-*O*-methyl-D-glucose as one of the components in the mixture.

The residue of tri-*O*-methyl-D-glucoses which had not been attacked by periodate was examined on the chromatogram and presumably contained the 2,3,6- and the 2,4,6-isomers since no color developed when the oxidized sample was treated with the triphenyl tetrazolium chloride spray (29, 30) (see Experimental Section on 3,4-di-*O*-methyl-D-glucose).

Fraction III contained di-*O*-methyl-D-glucoses.

Detection of 2,3- and 4,6-Di-O-methyl-D-glucoses

The syrup obtained (340 mg) was compared with authentic specimens of dimethyl glucose isomers by means of chromatograms run in solvent systems (i) and (ii) for 65 hours (*p*-anisidine spray). A major spot was revealed; but immediately ahead of it and immediately behind it, two distinct components were identifiable as 2,3- and 4,6-di-*O*-methyl-D-glucose respectively. The syrup (ca. 100 mg) was separated on paper in solvent system (i) and strips corresponding to the "major spot" removed and extracted with water, the extract now being evaporated to give a syrup (syrup B). Attempts to induce crystallization from ethanol, ethyl acetate, isopropyl acetate, and methanol were all unavailing.

Detection of 3,4- and 3,6-Di-O-methyl-D-glucoses

An electrophoretic analysis on a portion of syrup B against authentic samples of 3,4- and 4,6-di-*O*-methyl-D-glucoses revealed four components:

(i) a trace of a sugar which moved at the speed of the 4,6-isomer;

(ii) a large percentage of a sugar which corresponded with the 3,4-isomer;

(iii) a fast-moving constituent;

(iv) material which had remained on the base line.

A second electrophoretogram similarly prepared but developed with triphenyl tetrazolium chloride showed characteristic red coloration indicating free adjacent hydroxyls at carbons 1 and 2 (29, 30) and corresponding to (i), (ii), and (iii) above. Component (iii) was therefore probably the 3,6-di-*O*-methyl isomer.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Detection of 2,4-Di-O-methyl-D-glucose

A portion of syrup B was oxidized overnight at room temperature with sodium periodate solution. It was then deionized and the solution was chromatographed and showed residual sugar to be present. 2,4-Di-*O*-methyl-D-glucose is the only isomer in syrup B which is not oxidized by periodate and is therefore probably present in the mixture. The 2,6-di-*O*-methyl isomer was the only one not positively identified.

Fraction IV contained mono-*O*-methyl glucoses.

Preparation of Glucosides

A portion of the syrup obtained (250 mg) was converted to the glucosides by refluxing it with 5% methanolic hydrogen chloride for 18 hours. After neutralization with dry silver carbonate and removal of the precipitate by filtration, the methanolic solution was saturated with hydrogen sulphide, and the precipitated silver sulphide was filtered off through Celite. The filtrate, after decolorizing with charcoal, was evaporated to give a semicrystalline mass which was dried *in vacuo* over phosphorus pentoxide to a constant weight of 78 mg. It had a negative reaction to Fehling's solution.

The syrupy glucosides were made up to a volume of 25 ml with water. Of this, 10 ml (equivalent to 31.2 mg) was removed and 10 ml 0.1 *M* sodium periodate was added and the whole diluted to 100 ml. A blank of water was similarly prepared. Aliquots (5 ml) were removed at various time intervals and analyzed for periodate uptake by the method of Neumuller and Vasseur (31) and for formic acid liberation by that of Andrews *et al.* (32). The 3-*O*-methyl isomer is the only one which will survive attack (if all are pyranosides). (See Table III and Fig. 1.)

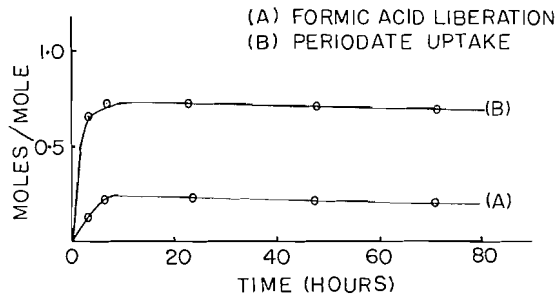

FIG. 1.

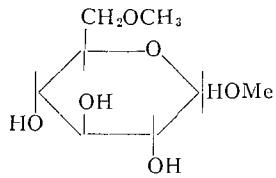
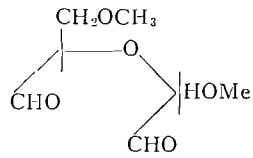
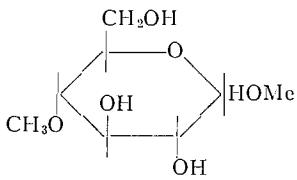
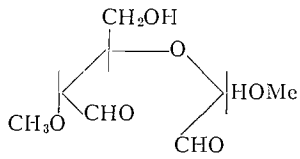
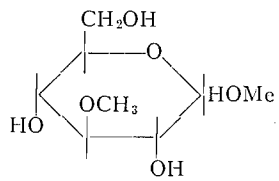
6-O-Monomethyl-D-glucose.—The molar production of formic acid is equivalent to the molar concentration of this isomer. This value is seen to be 0.23 mole, i.e. 23% of the mixture is present as 6-*O*-methyl-D-glucose.

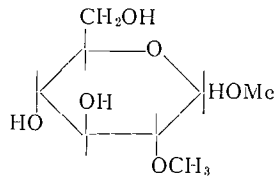


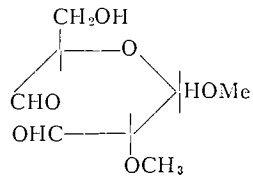












4- and 2-O-Methyl-D-glucose.—The total periodate consumption (0.68 mole) minus the molar concentration of the 6-*O*-methyl isomer (0.23 mole) gives the molar concentrations of both the 4- and 2-*O*-methyl isomers. Hence these two are present to the extent of 45% in the mixture.

3-Mono-O-methyl-D-mannose.—The remaining 32% of the mixture must be the 3-mono-*O*-methyl isomer.

Fraction V was identified as free glucose. The semicrystalline syrup (20 mg) obtained was dissolved in methanol (1 ml) and *p*-nitroaniline (20 mg) was added. The mixture was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

TABLE III

Possible constituents	Oxidation products	IO_4' uptake (moles)	HCOOH liberation (moles)
		2	1
		1	0
	No reaction	0	0
		1	0

transferred to a bulb blown in glass tubing (3 mm in diameter), one drop of 13% methanolic hydrogen chloride was added, the tube was sealed and heated at 70° C for 20 minutes. After the mixture had been allowed to stand in the cold overnight, crystals of D-glucose-*N*-*p*-nitrophenylglucosylamine separated, m.p. 179–181° C, mixed m.p. 179–182° C.

Oxidation of Anisole.—Ferrous sulphate (2 g) was dissolved in water (15 ml) and reagent grade anisole (5 ml) added and the mixture was cooled to 0° C. Hydrogen peroxide (15 ml, 15%) was then added during 45 minutes and the whole was allowed to stand for 1½ hours (at 0° C), after which excess sodium arsenite was added to reduce excess peroxide. A copious green precipitate was removed by centrifugation during 1 hour at 0° C, and the green supernatant liquid was saturated with sodium chloride and repeatedly extracted with chloroform. The orange-colored chloroform phase was washed with (*a*) 5% sodium bicarbonate solution, then (*b*) with 5% sodium hydroxide solution, and finally evaporated to dryness, to give a residue (i) smelling strongly of anisole. Both the sodium bicarbonate and sodium hydroxide washings were then neutralized with dilute hydrochloric acid, and each extracted with chloroform, and the extracts were evaporated to dryness to give two residues (ii) and (iii) respectively. When chromatographed, (i)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and (ii) showed only traces of phenols which had escaped extraction, but at least four components were recognized in (iii), one being identifiable as guaiacol, and another as hydroquinone.

ACKNOWLEDGMENTS

The authors wish to thank Mr. C. R. Willis for undertaking the experimental work leading to the results shown in Tables I and II. One of us (B.F.-R.) is grateful to Queen's University for a Reuben Wells Leonard Foundation Fellowship and to the National Research Council for a grant, which made this work possible.

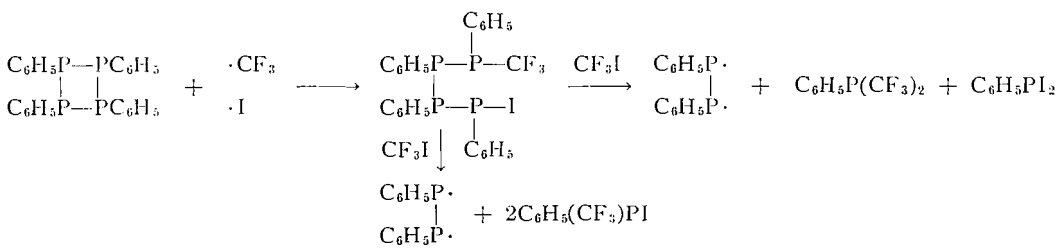
CHEMISTRY OF THE TRIFLUOROMETHYL GROUP

PART III. PHENYLBISTRIFLUOROMETHYLPHOSPHINE AND RELATED COMPOUNDS[1]

M. A. A. Beg and H. C. Clark

ABSTRACT

The reaction of trifluoroiodomethane with tetraphenylcyclotetraphosphine leads to the formation of phenylbistrifluoromethylphosphine and phenyltrifluoromethyliodophosphine. The mechanism of the reaction is discussed and the physical and chemical properties of these compounds are reported. Bromine reacts with phenylbistrifluoromethylphosphine to form phenylbistrifluoromethyldibromophosphorane which is hydrolyzed to phenyltrifluoromethylphosphinic acid, $C_6H_5(CF_3)P(O)OH$.



INTRODUCTION

In previous papers in this series, the donor properties of methyl-trifluoromethyl-phosphines were studied by the investigation of their ability to form complexes with boron trifluoride and platinum (II) chloride (1), and with a series of nickel (II) salts (2). Since much is known of the corresponding complexes of aryl phosphines, it seemed worthwhile to study the donor properties of aryl-trifluoromethyl-phosphines. Unlike the methyl-trifluoromethyl-phosphines which have been known for some time (3, 4, 5), the phenyl-trifluoromethyl-phosphines had not been previously reported, although their arsine analogues had been prepared (6). We now report the preparation of phenylbistrifluoromethylphosphine.

DISCUSSION AND RESULTS

Phenylbistrifluoromethylphosphine has been prepared by the reaction of trifluoroiodomethane with tetraphenylcyclotetraphosphine, the properties of which have been reported by other workers (7, 8, 9). The reaction was performed at 185°, above the melting point of the tetraphosphine, and the other reaction products, besides phenylbistrifluoromethylphosphine, are phenyltrifluoromethyliodophosphine, which is a very involatile reddish brown liquid, and small amounts of fluoroform and hexafluoroethane.

The mechanism of this reaction, involving the interaction of a perfluoroiodoalkane with a four-membered phosphorus ring is of some interest. A free-radical mechanism involving fission of phosphorus–phosphorus bonds by the attack of CF_3 radicals seems probable. This is supported by the fact that the reaction will occur thermally or on ultraviolet irradiation of the tetraphosphine with trifluoroiodomethane. Since the simultaneous breaking of four P—P bonds is unlikely, the following reaction scheme may be suggested.

$$2C_6H_5(CF_3)PI \rightleftharpoons C_6H_5P(CF_3)_2 + C_6H_5PI_2.$$

[1]*Manuscript received December 5, 1960.*

This scheme is supported by the observation that the reaction products contain phenylbistrifluoromethylphosphine and phenyltrifluoromethyliodophosphine in an approximately 2:1 ratio, and also by the results of a separate experiment which indicated extensive disproportionation of the iodophosphine at 200° as indicated above.

Phenylbistrifluoromethylphosphine is a colorless liquid boiling at 148–150°; it is stable at 200° and prolonged heating to 300° causes only partial decomposition. It is not hydrolyzed by acids, but reacts very slowly with water at 100° and much more rapidly with aqueous sodium hydroxide at 80°. The hydrolysis products are fluoroform and either phenylphosphonous acid $C_6H_5PO_2H_{27}$, or its sodium salt.

Phenylbistrifluoromethylphosphine does not react with iodine at room temperature, but at 185° the trifluoromethyl groups are cleaved as trifluoroiodomethane. There is no evidence of the formation of the diiodophosphorane, $C_6H_5(CF_3)_2PI_2$. However, the phosphine reacted vigorously with bromine at room temperature to form phenylbistrifluoromethyldibromophosphorane. This is in agreement with the usual decrease in stability for dichloro-, dibromo-, and diiodo-phosphoranes. Phenylbistrifluoromethyldibromophosphorane is readily hydrolyzed by water losing only one of the two trifluoromethyl groups per molecule as fluoroform and producing phenyltrifluoromethylphosphinic acid, $C_6H_5(CF_3)P(O)OH$.

Phenyltrifluoromethyliodophosphine is a reactive liquid which is readily hydrolyzed. Whereas alkaline hydrolysis produced fluoroform and the sodium phenylphosphonate, treatment with water gives phenyltrifluoromethylphosphine and phenyltrifluoromethylphosphinic acid, $C_6H_5(CF_3)P(O)OH$.

The production of phenyltrifluoromethylphosphinic acid from the aqueous hydrolysis of phenylbistrifluoromethyldibromophosphorane provides an interesting link between the trifluoromethyl- and aryl-phosphorus compounds. Whereas hydrolysis of triaryldichlorophosphoranes yields phosphine oxides (10), hydrolysis of tristrifluoromethyldichlorophosphorane (11) gives bistrifluoromethylphosphinic acid and one equivalent of fluoroform.

$$(CF_3)_3PCl_2 \xrightarrow{H_2O} [(CF_3)_3P(OH)_2] \rightarrow (CF_3)_2P(O)OH + CF_3H$$

The hydrolysis of phenylbistrifluoromethyldibromophosphorane shows that the intermediate compound $C_6H_5(CF_3)_2P(OH)_2$ is unstable.

$$C_6H_5(CF_3)_2PBr_2 \xrightarrow{H_2O} [C_6H_5(CF_3)_2P(OH)_2] \rightarrow C_6H_5(CF_3)P(O)OH + CF_3H$$

The trifluoromethyl groups behave in the same way as in the hydrolysis of tristrifluoromethyldichlorophosphorane and the phenyl group shows its customary resistance to hydrolytic attack.

The formation of phenyltrifluoromethylphosphinic acid from the hydrolysis of phenyltrifluoromethyliodophosphine is consistent with the general reactions of halophosphines (12). The spontaneous oxidation–reduction of the apparently unstable hydrolysis product leads to the production of phenyltrifluoromethylphosphine and phenyltrifluoromethylphosphinic acid.

$$2C_6H_5(CF_3)PI \xrightarrow{H_2O} [2C_6H_5(CF_3)POH] \rightarrow C_6H_5(CF_3)PH + C_6H_5(CF_3)P(O)OH$$

The infrared spectra of these phenyl-trifluoromethylphosphorus compounds show the expected features. Absorption associated with the strong carbon–fluorine stretching vibrations occurred in the 1100–1200 cm^{-1} region. However, it is of interest to notice

that the spectrum of silver phenyltrifluoromethylphosphinate, $C_6H_5(CF_3)P(O)OAg$, showed absorption at 1225 cm^{-1} corresponding to the P:O vibration. This absorption occurs in the same region for the aryl and alkyl phosphinic acids $R_2P(O)OH$, which are weak acids. For the strong acid, trifluoromethylphosphonic acid, this vibration is shifted to the higher frequency of 1300 cm^{-1} (13, 14). This might suggest that phenyltrifluoromethylphosphinic acid is a fairly weak acid.

EXPERIMENTAL

The preparations of the starting materials were carried out in a nitrogen atmosphere. Reactions with trifluoroiodomethane were carried out in sealed evacuated Pyrex tubes and the products and reactants were manipulated by standard vacuum techniques, out of contact with air and moisture.

Preparation of Tetraphenylcyclotetraphosphine

Phenyldichlorophosphine was obtained by the method of Buchner and Lockhart (15). The preparation of phenylphosphine by the Michaelis method (16, 17) is very cumbersome and gives a low yield. A much easier method (9, 18) is by reduction of phenyldichlorophosphine with lithium aluminum hydride. Phenyldichlorophosphine (18.8 g) dissolved in 100 ml diethyl ether was added cautiously to a well-stirred suspension of lithium aluminum hydride (3 g) in 100 ml ether. The reaction was vigorous and cooling was necessary. After the addition of phenyldichlorophosphine had been completed, the mixture was refluxed for 30 minutes and 5 ml of water were added dropwise. After being refluxed for an hour, the mixture was distilled and the resulting phenylphosphine, distilling at 160°, was dried over calcium chloride (yield 55%).

The preparation of tetraphenylcyclotetraphosphine by the Michaelis' method (19) is not convenient and the compound was prepared by adding phenylphosphine (11 g) in 50 ml ether to a well-stirred solution of phenyldichlorophosphine (18 g) in 50 ml ether. The solution gradually turned yellow but solid was not immediately deposited. After the addition was complete, the solution was refluxed for 3 hours during which time a white solid was deposited. The ether solution was decanted and the remaining solid was washed and dried. The yield of tetraphenylcyclotetraphosphine (m.p. 149–50°) was 90%.

Reaction of Tetraphenylcyclotetraphosphine with Trifluoroiodomethane

Tetraphenylcyclotetraphosphine (1.0 g) was sealed with trifluoroiodomethane (2.025 g) and left at room temperature for 24 hours. The solid phosphine was insoluble in trifluoroiodomethane. No reaction occurred at 70° C over 24 hours, nor at 150° C for 12 hours, but on heating at 185° C for 12 hours a dark-red involatile liquid was obtained and 0.558 g of unreacted trifluoroiodomethane was recovered. The dark-red liquid was shaken with mercury and the remaining liquid extracted with ether. After removal of the ether, a liquid (0.45 g) of low volatility was obtained and identified as phenylbistrifluoromethylphosphine (Found: C, 39.35%; H, 2.10%; F, 45.40%; P, 12.30%. Calculated for $C_8H_5F_6P$: C, 39.03%; H, 2.03%; F, 46.36%; P, 12.60%).

Phenylbistrifluoromethylphosphine is a colorless oily liquid whose odor is not as obnoxious as those of other phosphines. It boils at 148–150° and its vapor pressure is given by the equation $\log p_{mm} = 7.5606 - (1985/T)$, whence the latent heat of vaporization is 9054 cal $mole^{-1}$ and the Trouton's constant is 21.37. It is stable in air and does not react with water up to 100° C. It does not react with silver iodide, a solution of silver iodide in potassium iodide, or with carbon disulphide.

Two separate experiments were performed to investigate the mechanism of the above reaction and to characterize the other reaction products.

(1) Tetraphenylcyclotetraphosphine (2 g) was sealed with trifluoroiodomethane (5 g) in a Pyrex tube and was irradiated with ultraviolet radiation from a 200-watt U.V. lamp. The reaction was slow (possibly because of the heterogeneous phases), but after 15 days phenylbistrifluoromethylphosphine (0.899 g) and unreacted trifluoroiodomethane (2.192 g) were obtained. The rest of the product was a thick reddish syrup which showed strong absorption in the I.R. between 8–9 μ, characteristic of C—F stretching frequencies. This was not identified.

(2) Tetraphenylcyclotetraphosphine (7.5 g) was sealed with 18 g trifluoroiodomethane and heated at 185° C for 12 hours. A volatile mixture of hexafluoroethane and fluoroform (0.022 g), and 5.5 g of unreacted trifluoroiodomethane were recovered. The remaining liquid was subjected to fractional distillation under 20 mm pressure. Two fractions were obtained, one boiling at 62–65° (4.9 g) and the other boiling at 112–116° (3.8 g). A thick liquid which solidified on standing remained in the distillation flask. This showed strong absorption in the I.R., corresponding to the C—F stretching frequencies. Another experiment to identify this completely involatile liquid showed that it contained some iodides, including phosphorus triiodide. When treated with a large excess of trifluoroiodomethane and mercury, some pure phenylbistrifluoromethyl phosphine was obtained, but the main product was a very viscous pale-yellow liquid, presumably polymeric.

The liquid distilling at 62–65° was identified as phenylbistrifluoromethylphosphine and the fraction distilling at 112–114° was identified as phenyltrifluoromethyliodophosphine. (Found: I, 41.2%. Calculated for $C_7H_5F_3PI$: I, 41.78%.)

Reactions of Phenylbistrifluoromethylphosphine

(a) Hydrolysis

Phenylbistrifluoromethylphosphine (0.277 g) was sealed with water (1.28 g). There was no reaction at room temperature and the reactants formed two separate layers. After heating at 80° for 24 hours, only a trace of fluoroform was obtained, while after 36 hours at 110°, 0.038 g fluoroform was evolved. Traces of benzene were also identified spectroscopically. There remained a white crystalline solid which melted at 69° and was identified as phenylphosphonous acid.

Phenylbistrifluoromethylphosphine (0.273 g) was sealed with 5 ml of 20% aqueous sodium hydroxide solution. The reaction was slow at room temperature with the evolution of fluoroform. The tube was heated to 80° for 24 hours. The production of 0.149 g fluoroform (mol. wt. obtained 70.0, calculated 70.0) showed that the hydrolysis was 96.4% complete (CF_3 obtained as CF_3H: 54.8%; calculated for $C_6H_5P(CF_3)$: 56.1%). The solid obtained on evaporation of the solution was identified spectroscopically as the sodium salt of phenylphosphonous acid.

Phenylbistrifluoromethylphosphine (0.372 g) and 36 *N* hydrochloric acid (2 g) were sealed. There was no reaction at room temperature and the reactants formed separate layers. There was no reaction at 80° for 24 hours and at 110° for 48 hours. The tube was finally heated to 185° for 120 hours. At the end of this period the amount of fluoroform evolved was only 0.0022 g and the phosphine was recovered almost quantitatively.

(b) Reaction with Halogens

(1) Iodine.—Phenylbistrifluoromethylphosphine (0.389 g) and iodine (1.163 g) did not react at room temperature, nor after heating at 150° for 24 hours. The mixture was finally heated to 185° for 48 hours. The products obtained, were fluoroform (0.032 g),

trifluoroiodomethane (0.481 g), (mol. wt. 194, calculated 196), benzene (0.055 g), and traces of unreacted phosphine. The conversion into fluoroform and trifluoroiodomethane accounted for 91.5% of the trifluoromethyl group. The formation of fluoroform and benzene may be due to the presence of small traces of moisture on the iodine which is not removed even on extensive drying. The solid left in the tube, after pumping off the volatiles, contained phosphorus triiodide and no phenyltrifluoromethyliodophosphine.

(2) Bromine.—Phenylbistrifluoromethylphosphine (0.6965 g) and bromine (0.450 g) were combined. The ensuing vigorous reaction was controlled by performing the experiment in carbon tetrachloride solution and pumping off the volatiles after the reaction was complete. This was marked by the persistence of the bromine color. The reaction gave an orange-yellow solid which was very reactive towards moisture and was identified as phenylbistrifluoromethyldibromophosphorane (Found: Br, 38.93%. Calculated for $C_8H_5F_6PBr_2$: Br, 39.41%). On reacting the dibromophosphorane with water, one equivalent of CF_3 was lost and a white solid was left. The dibromophosphorane (0.324 g) was sealed with water (1.0 g) and left at room temperature overnight. Fluoroform (0.060 g) was evolved corresponding to a loss of one equivalent of CF_3 per mole (Found: CF_3, 18.4%. Calculated for $C_8H_5F_6PBr_2$:CF_3, 34.5%). A white solid was obtained by pumping off the liquids, recrystallizing the residue from water, and finally drying over phosphorus pentoxide. The solid was identified spectroscopically as phenyltrifluoromethylphosphinic acid, $C_6H_5(CF_3)P(O)OH$. The acid melted at 84–86°. The silver salt of the acid was obtained as needle-shaped crystals by treating the aqueous solution of the acid with silver oxide. The same salt could also be obtained from the reaction mixture of phenylbistrifluoromethyldibromophosphorane and water which had stood overnight and had lost one equivalent of CF_3. The silver salt $C_6H_5(CF_3)P(O)OAg$ (Found: Ag, 33.81%. Calculated for $C_7H_5F_3PO_2Ag$: Ag, 34.06%) melted at 294–96° and was very sensitive to light.

(c) Pyrolysis of the Phosphine

Phenylbistrifluoromethylphosphine (1.058 g) was heated to 210° for 48 hours; 1.004 g of the phosphine and traces of fluoroform and silicon tetrafluoride (identified spectroscopically) were obtained. Phosphine (0.639 g) was heated to 300° for 48 hours. The tube walls were etched but the phosphine was not all pyrolyzed: 0.48 g was recovered unchanged. The other volatile materials were fluoroform, silicon tetrafluoride, and some benzene trifluoride.

Reactions of Phenyltrifluoromethyliodophosphine

Phenyltrifluoromethyliodophosphine is a reddish-brown liquid which boils at 112–114° at 20 mm. It fumes in air and reacts slowly with water. The solution obtained by absorption of water is highly acidic. It disproportionates on heating.

(a) Hydrolysis

Phenyltrifluoromethyliodophosphine (0.334 g) was treated with 5 ml of 20% sodium hydroxide. There was immediate reaction at room temperature. The tube was heated to 100° for 15 hours. Fluoroform (0.0694 g) (mol. wt. found 69.8, calculated 70.0) was evolved (CF_3 found, 20.75%; calculated for $C_7H_5F_3PI$, 23.03%). The hydrolysis was only 90% complete. The residue contained a hygroscopic sodium salt whose I.R. spectrum corresponded with that of sodium phenylphosphonate.

Phenyltrifluoromethyliodophosphine (0.334 g) was treated with 0.125 g water and left in a sealed tube overnight. When water and other liquids were removed, a white solid was left. The melting point was 84–86° and in all respects the compound was similar to

that obtained from the hydrolysis of phenylbistrifluoromethyldibromophosphorane. The silver salt was also prepared by reacting more of the iodophosphine with water and precipitating the iodide as silver iodide. The solution was concentrated *in vacuo* and the solid dried over P_2O_5. The silver salt was identified analytically (Found: Ag, 33.80%. Calculated: Ag, 34.06%) by its melting point of 294–96°, and also spectroscopically.

The above treatment of the iodophosphine also gave a small amount of a liquid whose I.R. spectrum showed the presence of P—H, P—C_6H_5, and P—CF_3 bonds. The hydrolysis with water therefore appears to give some phenyltrifluoromethylphosphine.

(b) Reaction with Trifluoroiodomethane

The iodophosphine (2.347 g) was heated with trifluoroiodomethane (2.299 g) at 200° for 12 hours. Trifluoroiodomethane (2.210 g, 96.1%) was recovered and the main products of reaction, presumably from the disproportionation of the iodophosphine, were phenylbistrifluoromethylphosphine (0.617 g), phosphorus triiodide, and benzene. Some of the unreacted iodophosphine was also identified among the products.

(c) Reactions with Trifluoroiodomethane and Mercury

The iodophosphine (2.8 g) and trifluoroiodomethane (10 g), with 54 g mercury, were sealed in a tube and shaken for 24 hours. Trifluoroiodomethane (8.9 g) was recovered and phenylbistrifluoromethylphosphine (1.5 g) was obtained. The loss of 1.1 g of trifluoroiodomethane indicated that the reaction $C_6H_5PCF_3I + CF_3I \xrightarrow{Hg} C_6H_5(CF_3)_2P$ had occurred. Besides the phosphine, some polymers were also obtained as mentioned earlier.

Pyrolysis of phenyltrifluoromethylphosphine iodide: The iodophosphine (2.003 g) was heated in a sealed tube to 220° for 12 hours. Fluoroform (0.02 g) and trifluoroiodomethane (0.06 g) were obtained as the volatile products and there remained phenylbistrifluoromethylphosphine, benzene, phosphorus triiodide, and some unreacted phenyltrifluoromethyl iodophosphine.

The I.R. spectra were taken on a Perkin–Elmer model 21 double-beam instrument with rock salt optics. Liquid films were used for liquids and KBr pellets for solids. The following absorption bands were noted for the compounds mentioned.

DIELECTRIC RELAXATION IN LIQUIDS

I. THE REPRESENTATION OF RELAXATION BEHAVIOR[1]

D. W. DAVIDSON

ABSTRACT

Methods are described for the determination from experimental data of the parameters used in the skewed-arc representation in the complex dielectric constant plane of dielectric relaxation in liquids. Graphs give the frequency dependence of the real and imaginary parts of the dielectric constant predicted by the skewed-arc equation. Evidence, which includes an analysis of published data and of some new data, is presented for the frequent occurrence of this type of relaxation behavior in liquids. The resolution of the effects of different relaxation processes is discussed.

The recent defect-diffusion model of Glarum is found to lead, under some conditions, to complex dielectric constant loci which are practically indistinguishable from skewed-arc loci over much of the frequency range of dispersion. It predicts departures from skewed-arc behavior at relatively high frequencies which are possibly related to experimentally observed departures.

It is concluded that skewed-arc characteristics arise from the presence of co-operative relaxation processes, possibly aided by the diffusion of disordered regions, in which the individual mechanisms of relaxation cannot be resolved by application of the superposition principle.

I. INTRODUCTION

The question of the accuracy with which empirical representations fit the experimental dielectric relaxation data is of considerable importance in the development of adequate models of liquid relaxation. In a recent publication of the National Bureau of Standards (1), Buckley and Maryott have collected dielectric dispersion and absorption data for some 193 compounds in the liquid state, as found in the literature to the end of 1956. The dielectric behavior of many of these compounds has been represented analytically, either in terms of the simple Debye equation involving only a single relaxation time and a semicircular locus in the complex dielectric constant plane, or in terms of the equation due to Cole and Cole which is an arc of a circle in the complex plane and involves a logarithmically symmetrical distribution of relaxation times about a most probable value. Among the liquids whose relaxation parameters are tabulated by Buckley and Maryott, two (glycerol and 1,2-propanediol) were described by a third representation, the skewed-arc locus proposed by Cole and Davidson which corresponds to an asymmetrical distribution of relaxation times.

More recently, however, comparatively accurate data for a considerable number of other liquids have been fitted to this third representation. These include most of the liquids originally cited by Cole and Cole (2) as evidence for their symmetrical circular arc description in the complex dielectric constant plane. Moreover, many other liquids have been characterized by Cole–Cole parameters (1) on the basis of rather inaccurate and incomplete relaxation data. This is particularly true for measurements in the experimentally difficult frequency range above 100 Mc/sec. In fact, unlike many solids, no liquid seems to have a principal dispersion region appreciably broader than that given by the Debye equation for which the adequacy of the Cole–Cole representation has been established.

It is the purpose of the present paper to consider the application of the Cole–Davidson equation in some detail. Methods of analyzing experimental results are discussed and

Issued as N.R.C. No. 6128.

applied to data in the literature as well as to some new data. In subsequent papers the results of studies of other liquids will be presented.

II. THE DEBYE EQUATION

According to the classical Debye equation (3) the complex dielectric constant $\epsilon(i\omega) = \epsilon' - i\epsilon''$ is given by

$$\epsilon(i\omega) - \epsilon_1 = (\epsilon_0 - \epsilon_1)/(1 + i\omega\tau) \quad [1]$$

in which ϵ_0 and ϵ_1 are the values of the dielectric constant on the low- and high-frequency sides of the dispersion region, ω is the angular frequency, and τ the (single) relaxation time. This equation appears to be applicable (4) to the cases of relaxation of polar molecules in dilute solution in non-polar solvents, at least when the solute molecules are large in comparison with those of the solvent. Individual polar molecules are then in similar environments and a single relaxation time for rotation is adequate.

The Debye equation also describes the principal dielectric dispersion of water, at least to a high level of approximation (5), and of a large number of undiluted monohydroxy alcohols, within the accuracy of the measurements (6). In these liquids hydrogen bonding between molecules leads to a regularity of environment which may again account for the presence of only one relaxation time, although there is evidence (see VI(*b*) below) that here relaxation occurs by a co-operative process involving a large number of molecules.

Between these two extremes, a large number—probably the majority—of polar liquids show broader dielectric dispersion and absorption than can be attributed to a single relaxation time. There has been tendency to treat such departures from Debye behavior in terms of the symmetrical Cole–Cole locus (1), a procedure which has been reasonably successful in some cases. However, the data generally seem inadequate to show preference for this representation over other possible representations, in particular over that to be discussed in subsequent paragraphs.

III. THE SKEWED-ARC REPRESENTATION

The equation of the skewed-arc locus

$$\epsilon(i\omega) - \epsilon_1 = (\epsilon_0 - \epsilon_1)/(1 + i\omega\tau_0)^\beta \quad [2]$$

in which β is a positive parameter no greater than unity, was originally used (7) to represent, within the experimental accuracy, the relaxation behavior of glycerol and 1,2-propanediol and, subsequently, 1,3-propanediol (8). More recently, it has been successfully applied to accurate bridge data obtained for a variety of chemically dissimilar liquids (see IV below).

Methods of Applying the Equation to Extensive Data

The complex locus given by equation [2] is illustrated in Fig. 1. The imaginary part of the complex dielectric constant is plotted against the real part. It is an asymmetrical locus which resembles a semicircle on the low-frequency side and approaches asymptotically a line making an angle of $\beta\pi/2$ with the real axis on the high-frequency side. This behavior is apparent from an examination of the real and imaginary parts of equation [2]:

$$\frac{\epsilon' - \epsilon_1}{\epsilon_0 - \epsilon_1} = (\cos\phi)^\beta \cos\beta\phi \quad [3]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and

$$[4] \qquad \frac{\epsilon''}{\epsilon_0 - \epsilon_1} = (\cos \phi)^\beta \sin \beta\phi,$$

where ϕ is the principal value of $\tan^{-1} \omega\tau_0$. The ratio of these is

$$[5] \qquad \frac{\epsilon''}{\epsilon' - \epsilon_1} = \tan \beta\phi.$$

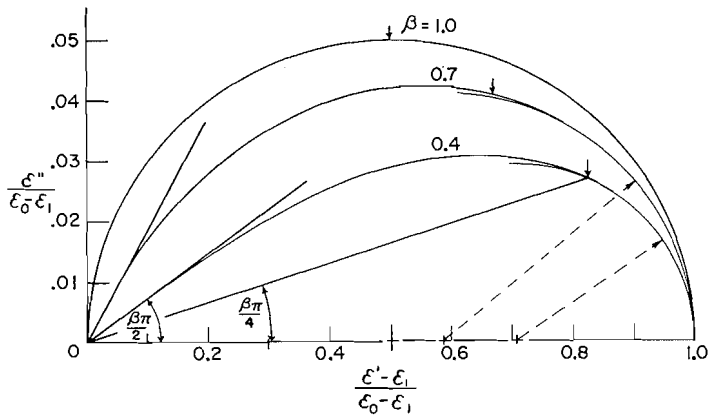

FIG. 1. Skewed-arc loci on the complex dielectric constant plane. Arrows indicate frequencies at which $\omega = 1/\tau_0$, broken lines the radii of circular arcs which coincide with the loci at low frequencies.

When an experimental locus has the characteristic shape of Fig. 1 the appropriate value of β may be obtained from the limiting slope at high frequencies. Since, for $\omega = 1/\tau_0$, $\epsilon''/(\epsilon' - \epsilon_1) = \tan \beta\pi/4$, τ_0 may be obtained as the reciprocal of the estimated radian frequency at which the bisector of the limiting angle cuts the locus. A more accurate method of evaluating the relaxation time τ_0, which is not dependent merely upon a few experimental points at values of ω in the vicinity of $1/\tau_0$, is to plot $\tan\{\tan^{-1}[\epsilon''/(\epsilon' - \epsilon_1)]/\beta\} = \omega\tau_0$ versus frequency, whence τ_0 may be evaluated from the frequency for which this function is unity. This also serves as a check of how well the data fit the predicted straight-line relationship. The plot is best made logarithmic in view of the large frequency range over which dispersion takes place. However, the validity of equation [5] is not a sufficient condition for the validity of equations [3] and [4]. Moreover, in many cases only one of ϵ' or ϵ'' (often only ϵ'') is accurately measured. Figures 2 and 3 show the individual variation of ϵ' and ϵ'' with frequency for a number of values of β and may be used to facilitate direct comparison with experiment.

Analysis of Less Extensive Data

The above methods for checking the agreement between experiment and the skewed-arc locus are applicable only when data are available for a considerable range of frequencies which includes the dispersion region. In cases where the data are less complete it is sometimes possible to use less straightforward methods. This may sometimes be done for data available at only a limited number of fixed frequencies provided that they are obtained over a considerable interval of temperature.

An aggregate complex locus may be drawn by plotting $\epsilon''/(\epsilon_0-\epsilon_1)$ versus $(\epsilon'-\epsilon_1)/(\epsilon_0-\epsilon_1)$ for data obtained at different temperatures. This method requires evaluation of ϵ_0 at the required temperatures by extrapolation of high temperature values and of ϵ_1 by extrapolation from low temperatures. Provided that β is not strongly temperature dependent (the evidence is that it increases slightly with increasing temperature), equation [2] requires that the points fall on a common skewed locus, from which β may

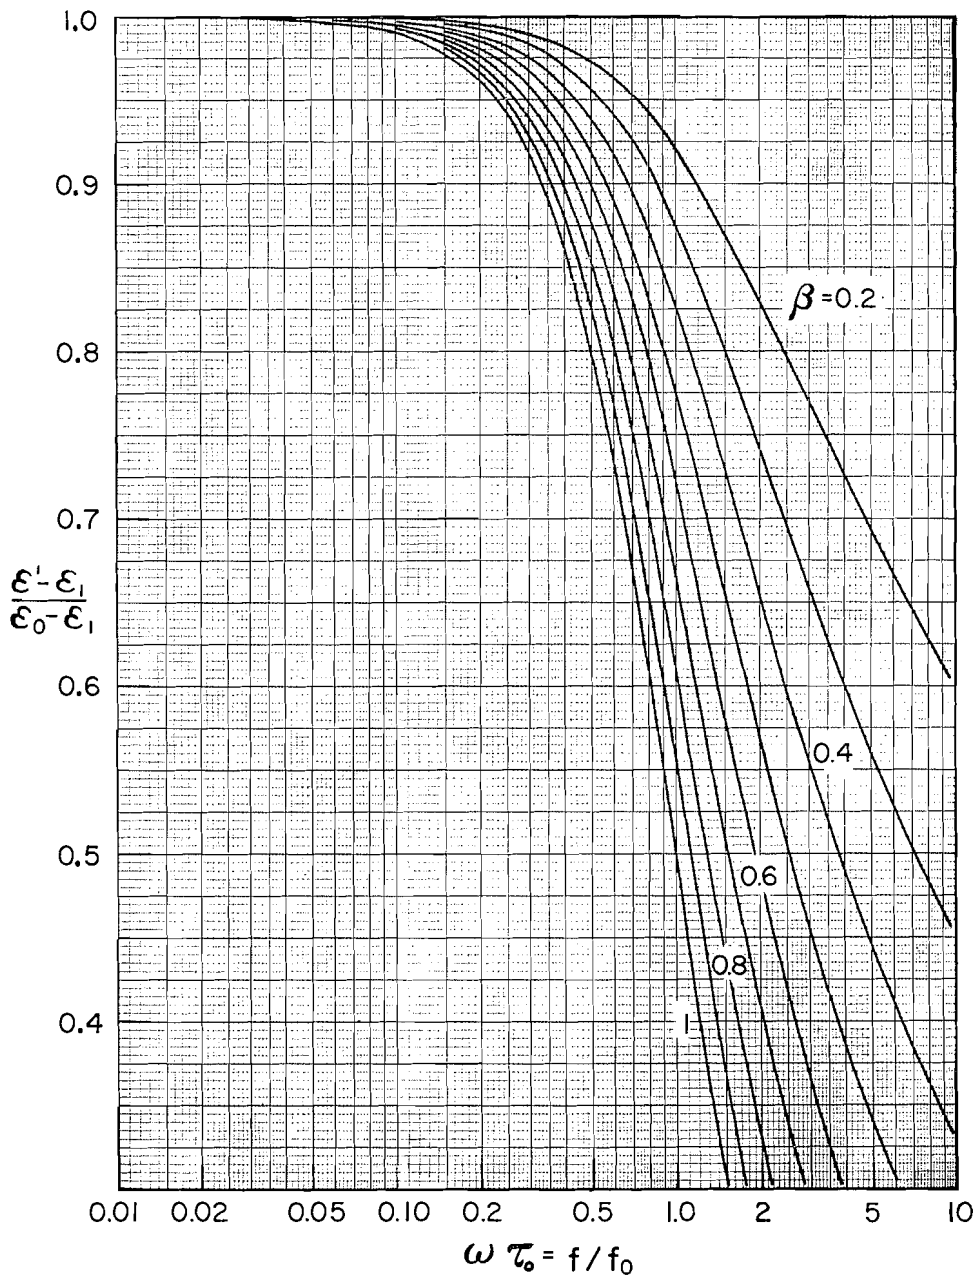

FIG. 2(*a*). Variation of ϵ' with frequency for skewed-arc behavior.

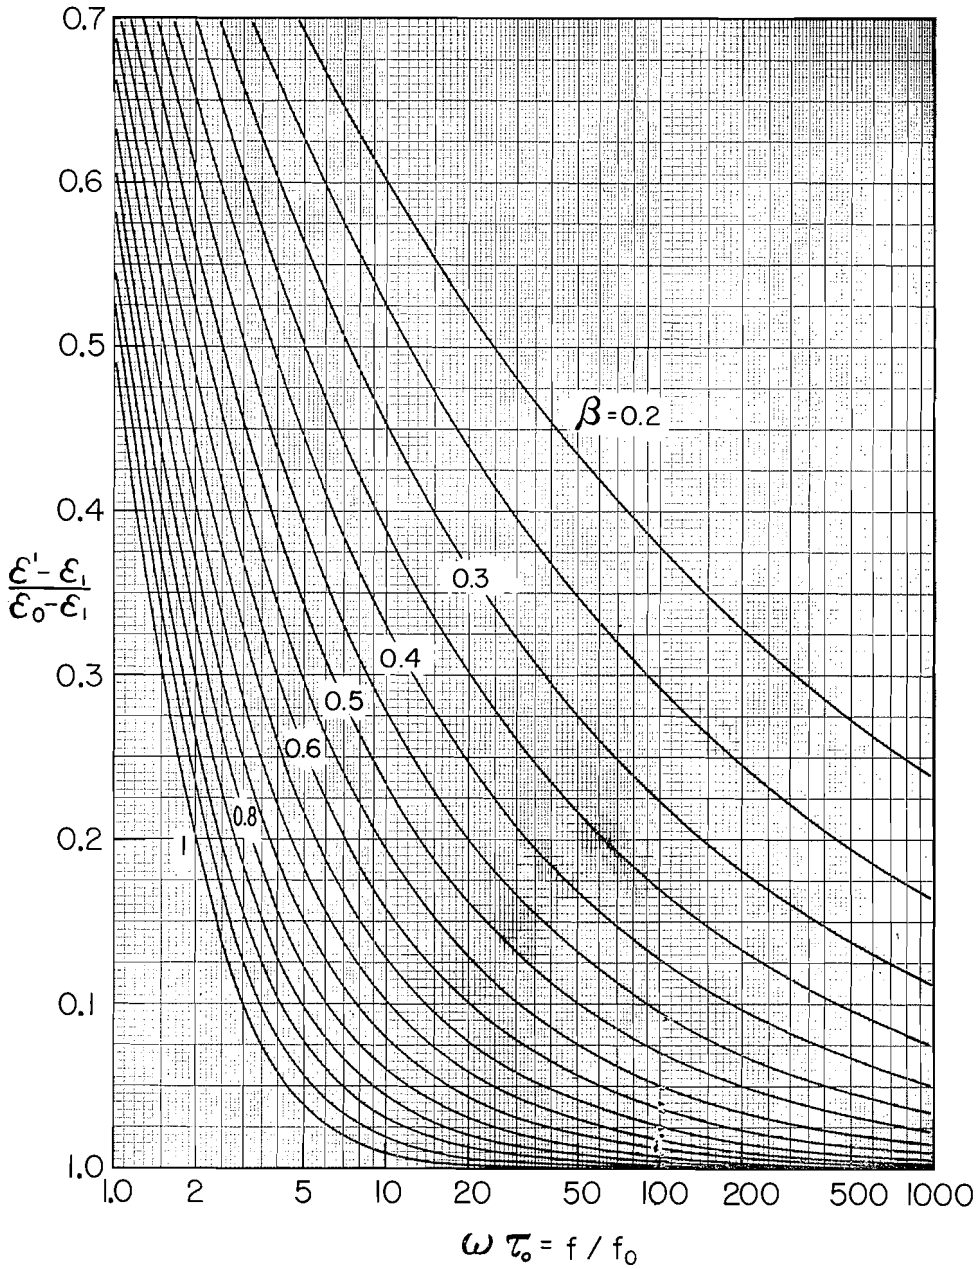

FIG. 2(*b*). Variation of ϵ' with frequency for skewed-arc behavior.

be determined. A value of τ_0 may then be obtained for each frequency of measurement at the estimated temperature at which the locus for that frequency is intercepted by the bisector of the limiting angle. A more complete analysis is possible if some reasonable assumption may be made about the variation of τ_0 with temperature. For example, τ_0 is sometimes proportional to the viscosity η, especially for viscous liquids (7, 9, 10), or, with more justification (11), to η/T.

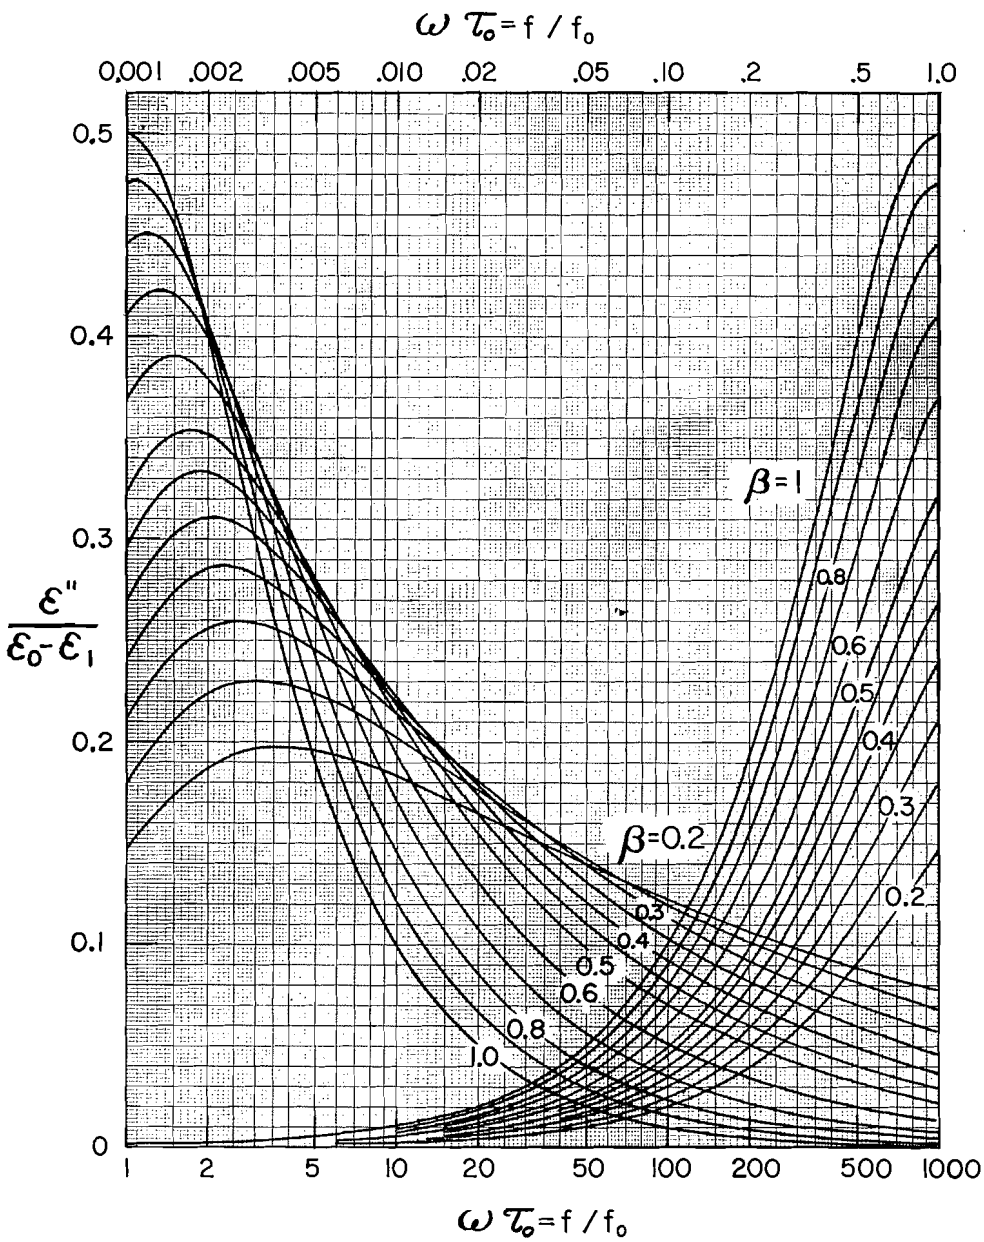

FIG. 3. Variation of ϵ'' with frequency for skewed-arc behavior.

An alternative method may be applied to data obtained at a fixed frequency over an adequate temperature range. The maximum in a plot of $\epsilon''/(\epsilon_0-\epsilon_1)$ versus temperature occurs at a temperature (T_0) such that the value of τ_0 is related to the fixed frequency of measurement $\omega_t/2\pi$ by

$$[6] \qquad \omega_t\tau_0 = \tan\frac{\pi}{2(1+\beta)} \qquad (\text{at } T_0).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

At the same temperature (T_0) equations [3] and [4] become

$$[7] \qquad \frac{\epsilon' - \epsilon_1}{\epsilon_0 - \epsilon_1} = \left[\cos \frac{\pi}{2(1+\beta)}\right]^{1+\beta} \tan \frac{\pi}{2(1+\beta)} \qquad (\text{at } T_0),$$

and

$$[8] \qquad \frac{\epsilon''}{\epsilon_0 - \epsilon_1} = \left[\cos \frac{\pi}{2(1+\beta)}\right]^{1+\beta} \qquad (\text{at } T_0).$$

The variations of these functions with β are shown in Fig. 4. The simplest method of

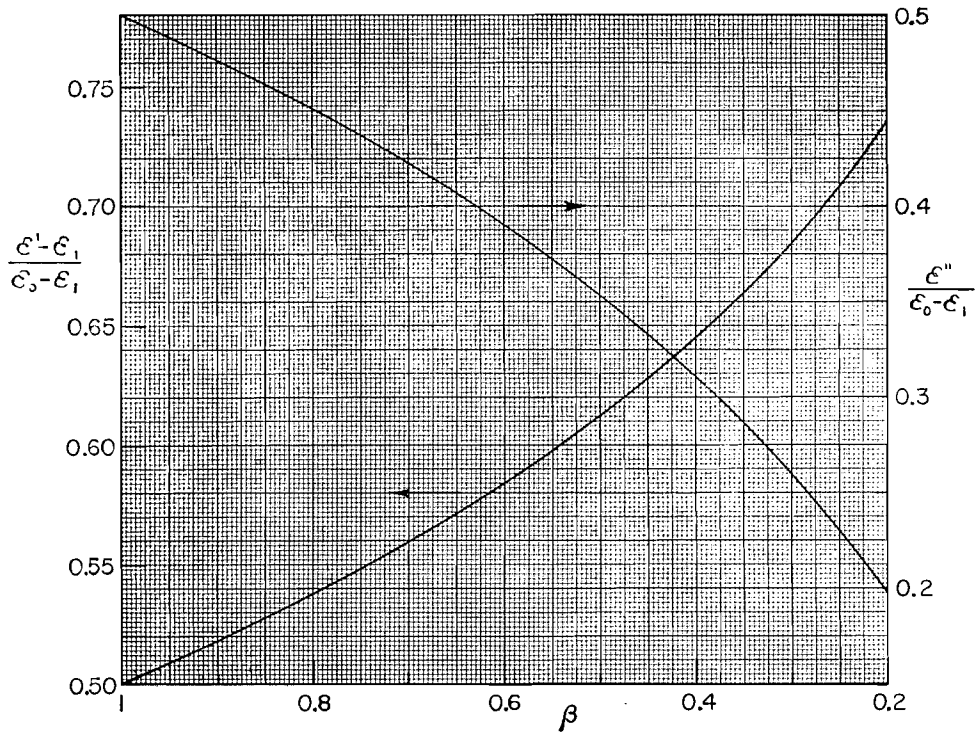

FIG. 4. Variation of reduced ϵ' and ϵ'' with β under conditions of maximum loss.

estimating β and τ_0 is from

$$[9] \qquad \frac{\epsilon' - \epsilon_1}{\epsilon''} = \omega_f \tau_0 = \tan \frac{\pi}{2(1+\beta)} \qquad (\text{at } T_0).$$

Determination of β and τ_0 from values of ϵ' and ϵ'' for a fixed frequency at the temperature of maximum loss, however, is meaningful only if there is some reason to believe that the behavior is of the skewed-arc type. This may be tested by considering the data at other temperatures. In one approach that has proved useful, the temperature dependence of the relaxation time τ_0 is assumed to be given by

$$[10] \qquad \tau_0 = Ae^{B/T}$$

over a narrow temperature range about T_0 and β is considered constant over this same temperature range. Suppose that two temperatures T_1 and T_2 are defined by $1/T_1$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$= 1/T_0 - \Delta$ and $1/T_2 = 1/T_0 + \Delta$. Δ may be chosen, for example, to make ϵ'' of the order of $\epsilon_{max}''/2$. The values of $\epsilon''/(\epsilon' - \epsilon_1)$ at T_1 and T_2, according to equation [5], are then

$$\tan \beta[\tan^{-1}(\omega_f \tau_0^0 e^{-B\Delta})] \quad \text{and} \quad \tan \beta[\tan^{-1}(\omega_f \tau_0^0 e^{B\Delta})],$$

respectively, in which τ_0^0 is the value of τ_0 at T_0. τ_0^0 and β are assumed to have been determined by the method of the previous paragraph. A necessary condition for the skewed-arc locus is that for some value of $B\Delta$ a pair of $\epsilon''/(\epsilon' - \epsilon_1)$ values can be computed which agree, within the experimental uncertainty, with the measured values at T_1 and T_2. Such pairs of values are given, for different values of β and $B\Delta$, in Fig. 5. If the data warrant it, the value of B so obtained may be used to calculate the dependence of ϵ' and ϵ'' on temperature, with the help of Figs. 2 and 3.

Under similar assumptions, the Cole–Cole symmetrical-arc locus gives rise to values of ϵ'' which are symmetrical in $1/T$ about the temperature of maximum loss and $\epsilon' - \epsilon_1$ at T_1 is equal to $\epsilon_0 - \epsilon'$ at T_2.

Transient Measurements

At temperatures sufficiently low that polarization takes place too slowly to follow the changing phase of a low-frequency voltage, transient methods may be substituted for bridge methods. In these the charging or discharging current is measured as a function of time following application or removal of a suitable voltage.

TABLE I

Applied voltage	Transient current $I(t)$, $t \geqslant 0$, for: Debye locus	Skewed-arc locus
$V(t) = 0, \quad t < 0$ $= V_0, \quad t \geqslant 0$	(1) $V_0C_0\left[\epsilon_1\delta_0+\frac{\epsilon_0-\epsilon_1}{\tau}e^{-t/\tau}\right]$	(2) $V_0C_0\left[\epsilon_1\delta_0+\frac{\epsilon_0-\epsilon_1}{\tau_0\Gamma(\beta)}\left(\frac{t}{\tau_0}\right)^{\beta-1}e^{-t/\tau_0}\right]$
$V(t) = 0, \quad t < 0$ $= at, \quad t \geqslant 0$	(3) $aC_0\left[\epsilon_1+(\epsilon_0-\epsilon_1)(1-e^{-t/\tau})\right]$	(4) $aC_0\left[\epsilon_1+(\epsilon_0-\epsilon_1)\frac{\Gamma t/\tau_0(\beta)}{\Gamma(\beta)}\right]$

Table I summarizes the transient currents which follow the application of step and ramp voltage pulses to dielectrics having the Debye and skewed-arc characteristics. These equations result from application of the method of Fourier transforms (12, 13) to the equations for the frequency-dependent loci. The time variation of charge on the sample for a step voltage has the same form as the variation of current through the sample for a ramp voltage.

In Table I C_0 is the capacitance of the empty cell, δ_0 the delta function or unit impulse at $t = 0$, $\Gamma_{t/\tau_0}(\beta)$ and $\Gamma(\beta)$ the incomplete and complete gamma-function, respectively. The ratio of the two gamma-functions has been tabulated by Pearson (14), whose parameters are related to the present ones by $u = t/(\tau_0\sqrt{\beta})$ and $p = \beta-1$.

The ramp pulse is the more convenient since it does not give rise to the initial current surge which accompanies application of the step voltage and since it is somewhat simpler to evaluate the required parameters from the experimental transient behavior. However, it is easier to generate a constant voltage than a linearly rising one and the former may be used to advantage in the investigation of comparatively slow relaxation (as has been done, for example, with *n*-propanol at low temperatures (15)). An approximate method has been given by Hamon (16) for converting the results of time-dependent direct-current measurements to the equivalent frequency-dependent dielectric loss form.

In general transient methods do not seem capable of the same accuracy as bridge methods. They are, however, useful for extending the range of temperatures over which measurements of relaxation can be made by some 10 or 20°.

IV. EXPERIMENTAL EVIDENCE FOR THE SKEWED-ARC LOCUS

Hydroxyl Compounds

Practically all monohydroxyl alcohols that have been so far investigated are satisfactorily represented by the Debye semicircle in the complex plane (6), except for secondary dispersion regions (to be discussed below) at comparatively high frequencies which usually make a minor contribution to the value of the static dielectric constant. This semicircular behavior may be regarded as a limiting case of either the circular-arc locus of Cole and Cole (with $\alpha = 0$) or of the skewed-arc locus (with $\beta = 1$). At least one monohydroxyl alcohol, tetrahydrofurfuryl alcohol, exhibits an asymmetric dispersion locus of the skewed type. This is illustrated by Fig. 6 for which the data were obtained by L. Kuhi in this laboratory.

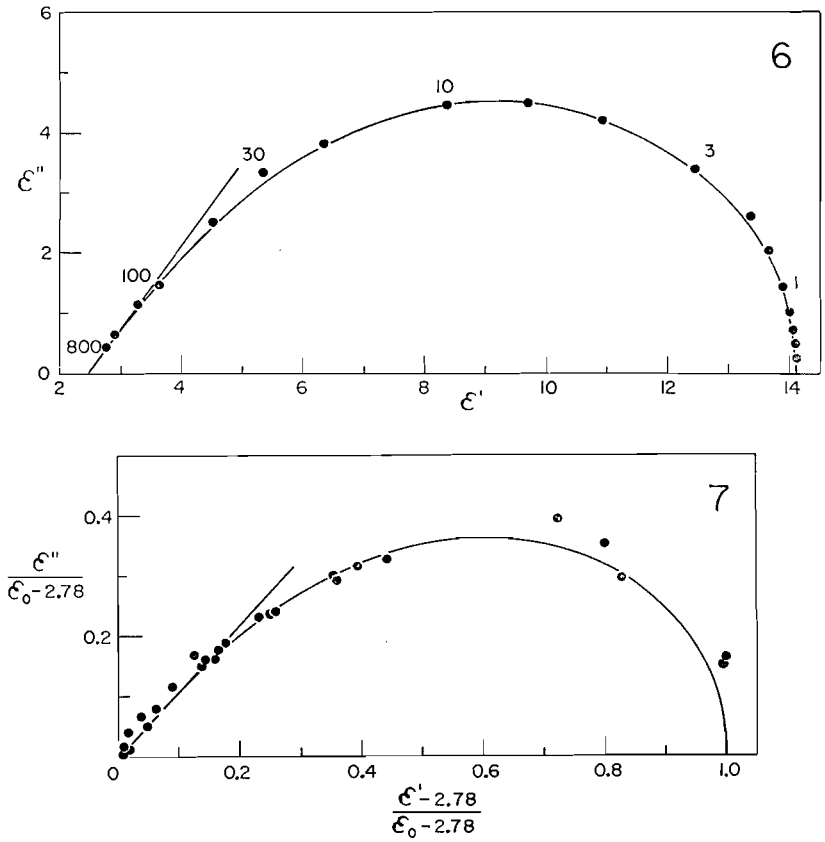

FIG. 6. Tetrahydrofurfuryl alcohol at −105.9° C. Skewed-arc locus is drawn for $\beta = 0.592$. Numbers beside points are frequencies in kc/sec.

FIG. 7. Aggregate plot for 2-methyl-2,4-pentanediol at temperatures between −45 and −79° C and frequencies of 1, 10, 30, and 100 kc/sec. Locus is drawn with $\beta = 0.525$.

The skewed-arc locus was originally used to describe the dispersion–absorption behavior of the polyhydroxyl liquids glycerol (7), 1,2-propanediol (7), and 1,3-propanediol (8). Data for the first two of these liquids are included in Fig. 11. The predicted form of transient current for systems giving skewed-arc loci (formula (4) of Table I) has been shown (12) to fit the transient behavior of glycerol at temperatures at which τ_0 is of the order of milliseconds. Koizumi and Hanai (17) expressed the results of a study of supercooled tetraethylene glycol by the skewed arc.

The dispersion of five isomeric pentanediols is accurately represented by equation [2] (18). 2-Methyl-2,4-pentanediol was examined by White and Morgan (19) whose data for four frequencies and a number of temperatures are shown in the aggregate plot of Fig. 7. The skewed-arc locus drawn represents the results in a satisfactory manner when it is considered that the variation of β with temperature is ignored. Data are not reported at sufficiently small temperature intervals to make analysis by the maximum loss method possible.

Halogen Compounds

Denney (20) has used the skewed-arc locus to describe the dielectric behavior of isobutyl bromide, isoamyl bromide, and isobutyl chloride at low temperatures. Winslow,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Good, and Berghausen (21) found it fitted the behavior of pentachlorobiphenyl (a mixture of isomers bearing the trade name Arochlor 1254) and hexachlorobiphenyl (Arochlor 1260), at temperatures below room temperature. Examination of the Massachusetts Institute of Technology data at 25° C (22), though reported only at frequencies which differ, for the most part, by a factor of 10, shows that in all probability the same behavior extends to higher temperatures. The M.I.T. tables indicate that the other polychlorodiphenyls probably exhibit skewed-arc-locus behavior. This is true also for Arochlor 4465 (a mixture of chlorinated bi- and ter-phenyls) and Arochlor 5460 (nonochloroterphenyls) for which β appears to be of the order of 0.2 and lower frequency measurements show the presence of d-c. conductance.

The skewed-arc behavior of 1,2-dibromopentane is illustrated in Fig. 8(*a*), which gives the results of bridge measurements at $-112°$ where τ_0 is of the order of a millisecond, and in Fig. 8(*b*), which presents transient results at $-127°$ where τ_0 is of the order of 10 seconds.

The method based on the temperature of maximum loss (see III) may be applied to the data of Turkevich and Smyth (23) for 2-methyl-1,2-dichloropropane, shown for low

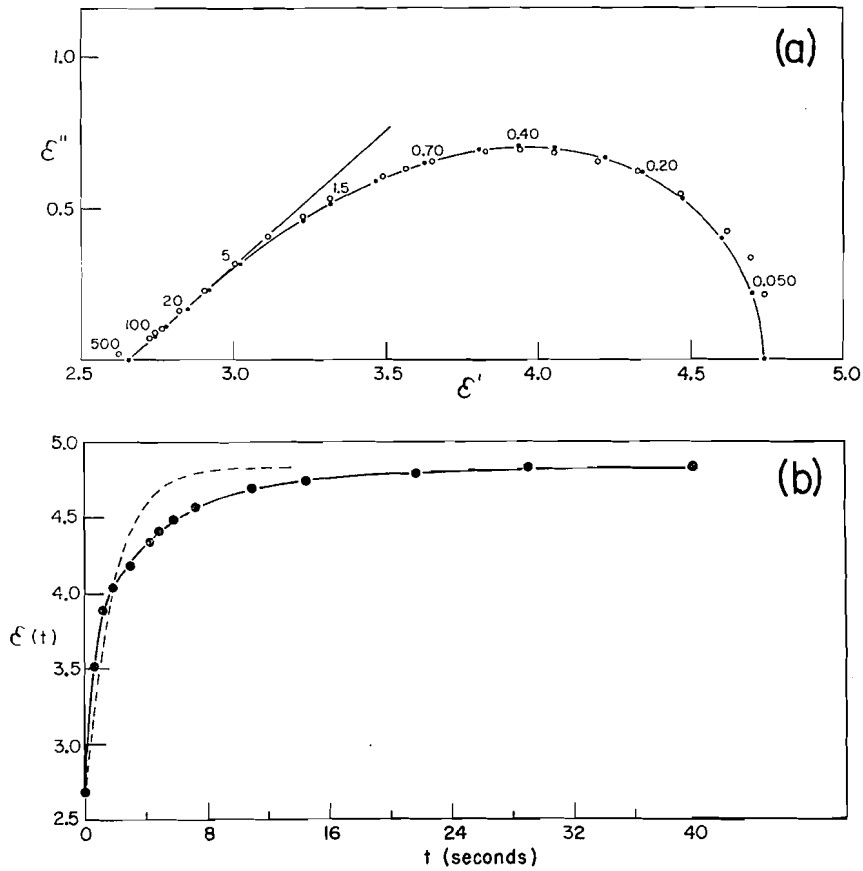

FIG. 8(*a*). ○ Data for 1,2-dibromopentane at $-112.0°$ C, ● calculated points for $\beta = 0.463$, $\tau_0 = 7.58 \times 10^{-4}$ sec.

temperatures in Fig. 9. The 50-kc points show a loss maximum of about 5.45 at −137.9° C. At this temperature and frequency $\epsilon' = 12.65$ and, taking $\epsilon_1 = 2.30$ (a reasonable value since ϵ' approaches 2.36 at −188° C), one finds $(\epsilon' - \epsilon_1)/\epsilon'' = 1.901$. The relaxation time τ_0 (at −137.9° C) is then $1.90/(2\pi \times 50{,}000)$ or 6.1×10^{-6} seconds and $\beta = 0.446$ (equation [9]). For $\Delta = 2 \times 10^{-4}$, T_1 is −141.5° C and T_2 is −134.1° C, which correspond to $\epsilon''/(\epsilon' - \epsilon_1)$ values of about 0.756 and 0.177, respectively. Inspection of Fig. 5, for $\beta = 0.45$ shows a value of $B\Delta$ at T_1 of about 1.37 and at T_2 of about 1.51. This is satisfactory agreement, which may be improved by allowing β to assume values slightly smaller than 0.45. B is then 7.2×10^3 and the "energy of activation" (BR) some 14 kcal/mole. Application of the same technique to the 5-kc points leads to a similar value of β. The loss maximum at 500 c, however, of the order of $(\epsilon_0 - \epsilon_1)/2$, is anomalously high. A similar anomaly for isobutyl chloride at the same frequency (23) is not confirmed by the results of Denney (20).

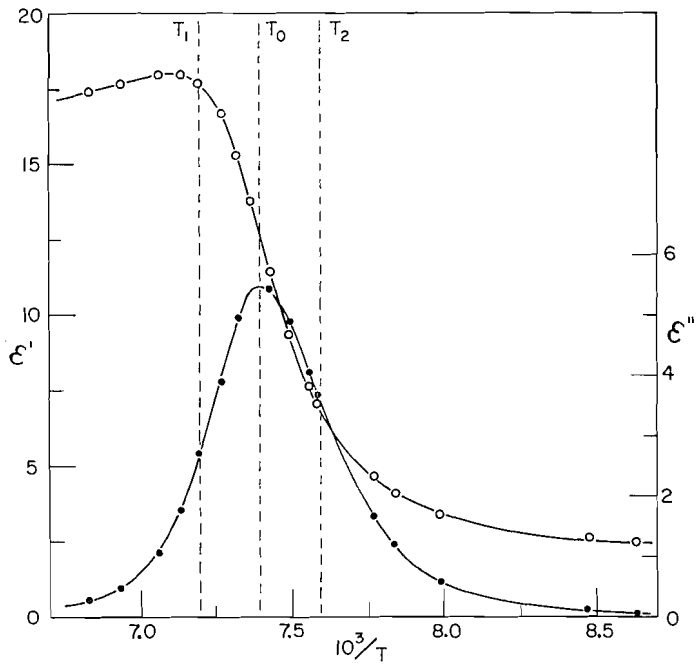

FIG. 9. Low-temperature dielectric behavior of 2-methyl-1,2-dichloropropane at 50 kc/sec.

Miscellaneous Compounds

Grant, Davidson, and Gray (24) found *n*-propyl nitrite at low temperatures to fit the skewed locus (see Fig. 11) as did Winslow, Good, and Berghausen (21) in the case of tolyl xylyl sulphone.

Schallamach's data at 9 Mc for the aldehyde citral (25), analyzed by the method of maximum loss, give results consistent with the skewed-arc locus, with β of the order of 0.75 and an activation energy of some 11 kcal/mole. The same author's results for the corresponding alcohol, geraniol, on the other hand, are adequately described by a single relaxation time ($\beta = 1$).

Polymers

Polar polymers in general exhibit very broad loss spectra (see, for example, the M.I.T.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tables (22)) which, although they may resemble the skewed-arc behavior in some respects, do not accurately conform to it. Dielectric relaxation in polymers proceeds by orientation of chain segments (26) and therefore differs from that in simple liquids.

The case of the poly(vinyl acetates) has been investigated by the author in some detail. Seven Gelvas (Shawinigan Chemicals Limited) ranging in Gelva number from 1.5 to 134 and in number-average molecular weight from 5,000 to ca. 200,000 were studied. The locus shown in Fig. 10, in which the ordinates are in arbitrary capacitance units, is

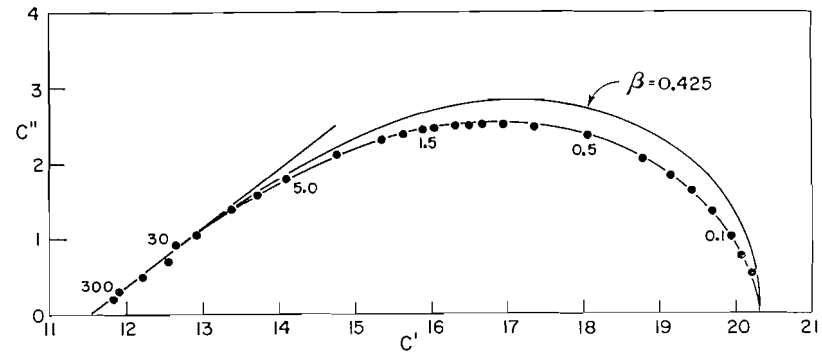

FIG. 10. Poly(vinyl acetate) (Gelva 134) at 68° C.

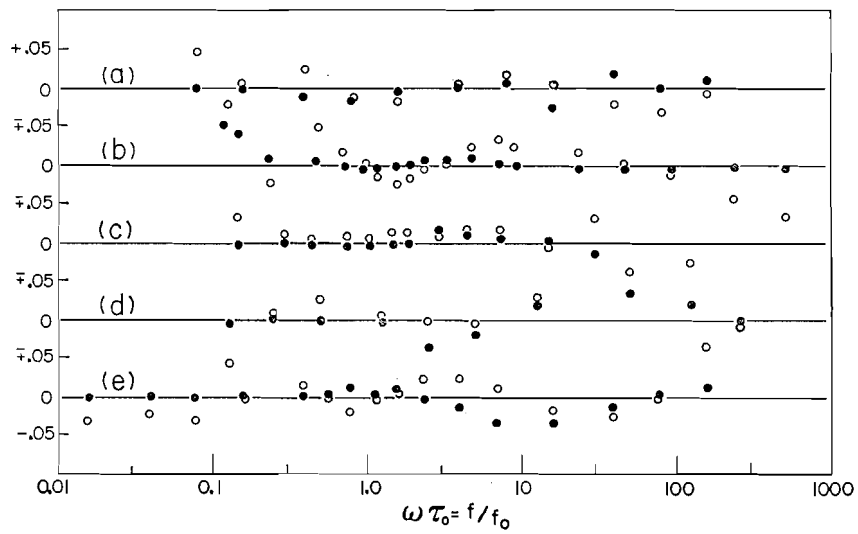

FIG. 11. $(\epsilon_{obs}' - \epsilon_{calc}')/\epsilon_{obs}'$ (●) and $(\epsilon_{obs}'' - \epsilon_{calc}'')/\epsilon_{obs}''$ (○) vs. frequency, for the liquids and parameters listed in Table II.

typical. The loss in the vicinity of the maximum and at lower frequencies is less than would be predicted by equation [2] for a β determined by the high frequency behavior, generally between 0.40 and 0.45. There appears to be no consistent dependence of this high frequency β on molecular weight. There is evidence that the presence of traces of benzene may broaden the loss spectrum.

Figure 11 illustrates the extent of the agreement for five liquids between the experimental values of ϵ' and ϵ'' and those computed from equation [2] with the parameters

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

shown in Table II. There appears to be no systematic disagreement. Periodic variations seem to be due to temperature fluctuations of the sample.

V. THE EFFECT OF TEMPERATURE ON THE DISPERSION

There is therefore good experimental evidence for the rather general occurrence in liquids of a relaxation behavior that can be characterized by the skewed-arc locus. Most of this evidence has been obtained at low temperatures where the relaxation processes are sufficiently slow to be studied by accurate techniques. Whether these observations are valid only at low temperatures or may be extended to higher temperatures as well remains to be determined. Unfortunately many of the experimental results presented in the literature are not sufficiently complete to enable the shape of the dispersion–absorption locus to be adequately defined.

An interesting example of what might be a change in the shape of the dispersion locus with temperature is provided by the case of tetraethylene glycol. In the supercooled state, at temperatures between -44 and $-71°$ C, this glycol shows (17) a dielectric relaxation behavior very near that represented by the skewed arc with a β value of the order of 0.4. Koizumi (27) extended the measurements to higher temperatures and to microwave frequencies and found that the new results could be best represented by the symmetrical-arc locus. The parameter α of the Cole–Cole representation for tetraethylene glycol assumed values ranging from 0.23 at 5° C to 0.14 at 50° C (see Fig. 12(*a*)). An attempt is made to represent Koizumi's microwave data for tetraethylene glycol by the skewed locus in Fig. 12(*b*) by assuming values of β of about 0.60 at 5° and about 0.70 at 50°. It can be seen that this representation is not quite as successful as the circular-arc one, although there is not sufficient data near the top and on the low-frequency side of the locus to establish the preference of either representation with any certainty.

Glarum (28) has recently extended the low temperature measurements of Denney (20) on isoamyl bromide to the temperature range between $-75°$ and 25° and to microwave frequencies. He has concluded that for this liquid the skewed-arc representation probably remains valid at these higher temperatures.

VI. THE RESOLUTION OF RELAXATION PROCESSES

The separation of the effects of different relaxation processes is of obvious importance if the individual mechanisms of relaxation are to be studied. It is necessary to distinguish between (*a*) the case in which each relaxation process is independent of the others and the principle of superposition may be applied to the polarization or the complex dielectric constant and (*b*) the case in which two or more relaxation mechanisms occur either as successive stages or alternate routes in the relaxation process and superposition may not be used to separate the individual components of relaxation. Examples of case (*a*) include orientation of a polar group within the molecule by a different mechanism from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

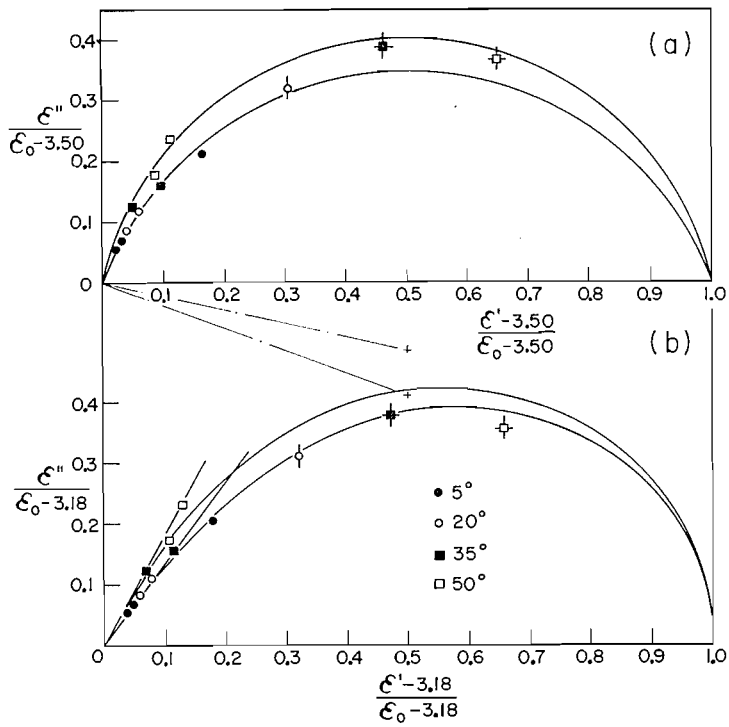

FIG. 12. Comparison of symmetric-arc (*a*) and skewed-arc (*b*) representations of microwave data for tetraethylene glycol.

orientation of the molecule as a whole, and orientation of different molecules in different *fixed* environments by different mechanisms. For each of these examples, assuming only two modes of relaxation, the total polarization decays as

$$P(t) = P_1 e^{-t/\tau_1} + (P_0 - P_1) e^{-t/\tau_2},$$

in which P_0 is the initial polarization, P_1 the polarization contributed by the first process, and τ_1 and τ_2 are the relaxation times of the two processes, each assumed to decay exponentially. An example of case (*b*) is provided by the orientation of molecules whose environments are subject to change during the period of relaxation and whose relaxation rates change with the environment. If there are only two types of environment, the simplest form of the polarization is

$$P(t) = P_0 e^{-t/\tau_1} e^{-t/\tau_2},$$

which is indistinguishable from a simple exponential decay function. Brot has proposed a model to account for the failure of superposition when the resolved dispersion regions apparently overlap (29).

(a) Independent Polarization Processes

Discontinuous Relaxation

Even in this case, the nature of relaxation spectra is such that resolution of different processes is difficult unless the corresponding relaxation times are widely different. This is illustrated in Fig. 13 for the most favorable case possible, that of two independent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

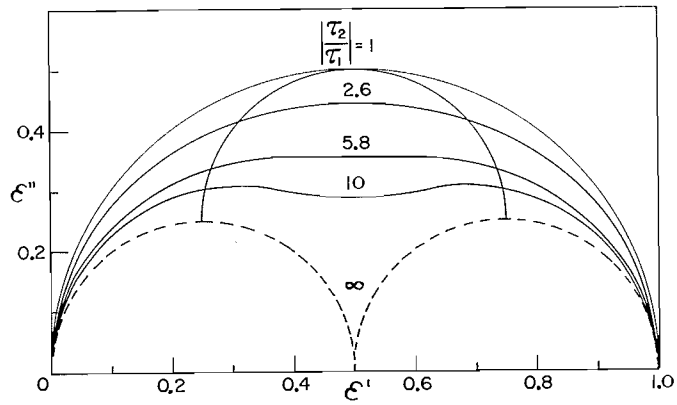

FIG. 13. Dependence of locus of $\epsilon'-i\epsilon'' = 0.5(1+i\omega\tau_1)^{-1}+0.5(1+i\omega\tau_2)^{-1}$ on τ_2/τ_1. Upper semicircle is locus of points at which $\omega = 1/\tau_1$ and $1/\tau_2$.

polarization processes each characterized by a single relaxation time and by the same amplitude of dispersion. Separate loss maxima occur only for relaxation times which differ by more than a factor of 5.8 (strictly, $3+2\sqrt{2}$). If the individual dispersion regions are considerably broader than this and are considerably different in amplitude, separate loss peaks may appear only when the appropriate relaxation times or critical frequencies differ by a factor of 100 or more. It is not surprising that the results may sometimes be analyzed in more than one way.

Examples of solutions for which the relaxation spectra are readily resolvable have been given (30, 31, 32), but most of the liquids that have been extensively studied exhibit broad dispersion–absorption behavior in which separate loss peaks do not occur.

The monohydroxyl alcohols, in addition to the principal (semicircular) dispersion region, show at considerably higher frequencies one or more additional dispersion regions of relatively small amplitude. Although in general not showing separate ϵ'' peaks, the high-frequency data for some alcohols have been reduced to a Cole–Cole arc by subtracting the contributions of the Debye relaxation region. A second dispersion region has been defined in this way for the alcohols from ethanol through the butanols (except for *t*-butanol) (33, 34, 35), for *n*-hexanol (36), cyclohexanol (37), *n*-heptanol (36), and four isomeric octanols (36, 38, 39, 40) and for *n*-propanol-*d* (15) and *n*-octanol-*d* (36). Most of these results also show signs of further dispersion at still higher frequencies which, by a further subtraction of the effects of the second dispersion, has been shown to be representable, within rather large experimental uncertainties, by an additional arc in the cases of *n*-propanol, *n*-propanol-*d*, and the octanols.

The question naturally arises as to whether behavior such as has been described by the asymmetric locus of equation [2] can be represented by the superposition of several discrete relaxation processes. Poley (41) first suggested that the main relaxation properties of glycerol could be attributed to the combined effects of a low-frequency semicircle and a high-frequency symmetric arc. Cole (42) has indicated that a detailed examination of the experimental data for glycerol does not support this suggestion. A number of glycols (1,2-ethanediol, 1,2-propanediol, 1,3-butanediol, and 1,5-pentanediol), which exhibit asymmetric loci have recently been analyzed (43, 44) in terms of one or more high-frequency arcs and a low-frequency semicircle or arc. The relaxation behavior of 1,2-propanediol, for example, over the range of frequencies between 0.1 and 25,000 Mc/sec,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

has been expressed by the superposition of a symmetric arc and a semicircle. The reported (43) parameters at −40° C have been used to construct the locus shown in Fig. 14(*a*).

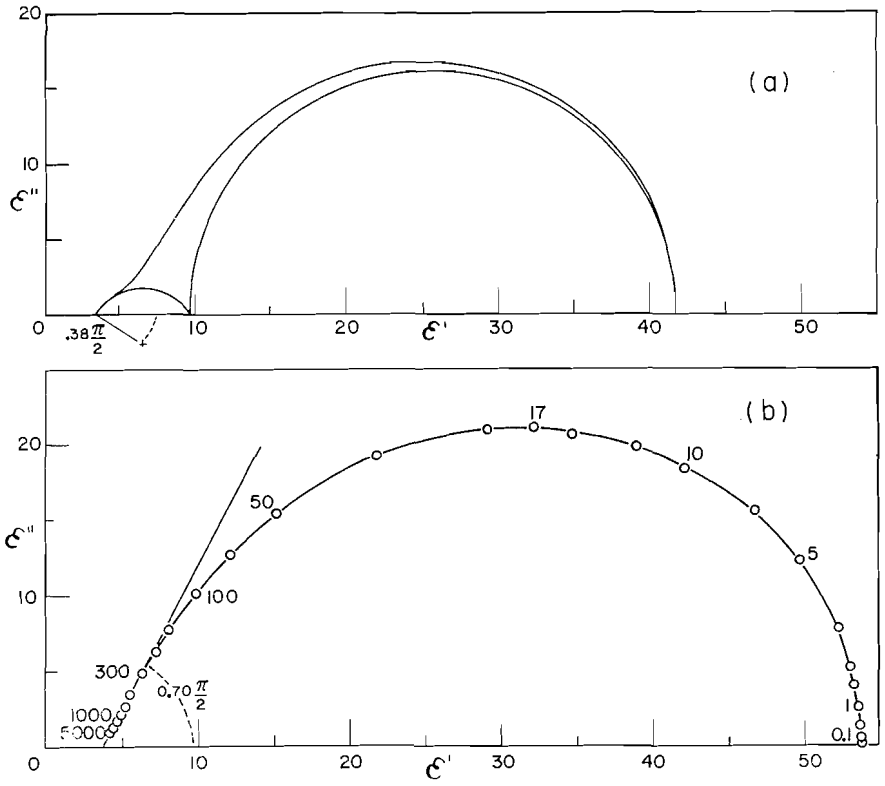

FIG. 14. Comparison for 1,2-propanediol of (*a*) the representation of the behavior at −40° suggested in reference 43 with (*b*) experimental data at −64.2° (●) and skewed-arc locus with $\beta = 0.70$.

From comparison with the locus shown in Fig. 14(*b*), from measurements at −64°C, it must be concluded that either the experimental behavior changes markedly with temperature or that the type of resolution proposed is not justified by the data for this liquid.

In some cases the proposed resolution has led to an overlapping of the resolved regions (29, 38, 44, 45). For example, the low-frequency limiting value of the dielectric constant for the second dispersion region may be appreciably greater than the limiting high-frequency value for the first (low-frequency) dispersion region. Brot (29, 38) has proposed on this basis that the superposition principle, in the form that assumes direct additivity of contributions to the complex dielectric constant from the individual relaxation processes, is violated. Although limitations of space have usually prevented publication of the full experimental data, it appears possible that in at least some cases the data may be adequately described by equation [2] or some other asymmetric representation. It is evident from inspection of Fig. 14(*a*) that a better approximation to the behavior of Fig. 14(*b*) may be realized by allowing the low-frequency side of the arc to overlap the high-frequency side of the semicircle, but it is doubtful whether this will lead to as good a fit of the data as equation [2].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In most liquids to which the skewed-arc behavior has been attributed there is a slight "tailing-off" of the high-frequency end of the experimental locus which is not described by equation [2] (Fig. 15). Although this behavior may correspond to a separate, very broad relaxation process, it is at least qualitatively predicted by the Glarum model to be considered below.

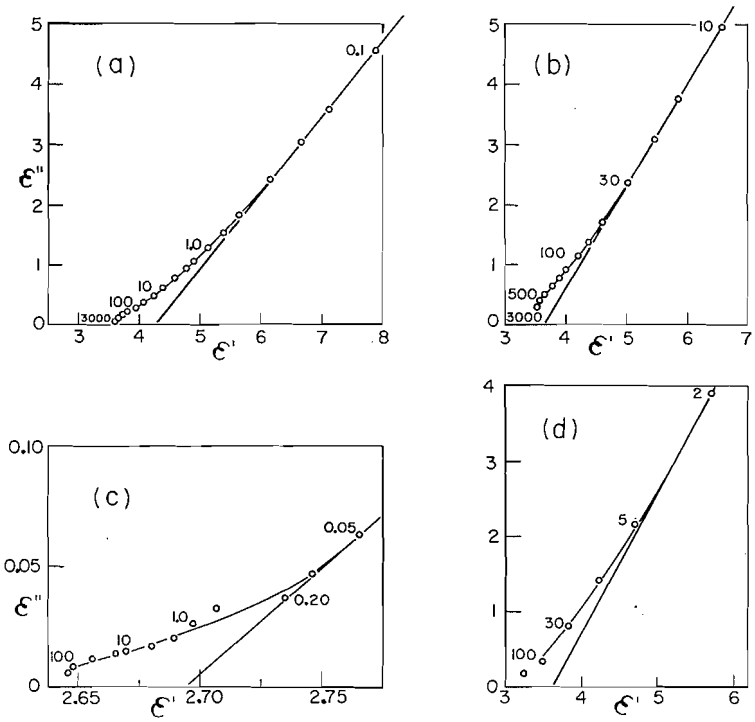

FIG. 15. Departures of dispersion behavior from skewed-arc type (straight lines) at relatively high frequencies for (*a*) glycerol at −70.0°, (*b*) 1,2-propanediol at −77.9°, (*c*) 1,2-dibromopentane at −127.1°, and (*d*) *n*-propyl nitrite at −179°.

Continuous Relaxation

The previous section has mentioned examples of the resolution of dispersion effects into different dispersion regions, some of which are much broader than predicted by the Debye equation. The principle of superposition may be applied to such a dispersion region, assumed to arise from a continuum of simple exponential decay functions, in the form

$$\epsilon(i\omega) = \epsilon_1 + (\epsilon_0 - \epsilon_1) \int_{-\infty}^{\infty} \frac{G(\tau) d \ln \tau}{1 + i\omega\tau}, \qquad [11]$$

which defines, along with $\int_{-\infty}^{\infty} G(\tau) d \ln \tau = 1$, a distribution function $G(\tau)$ such that $G(\tau)\, d \ln \tau$ represents the fractional contribution to $\epsilon_0 - \epsilon_1$ arising from that part of the relaxation process having relaxation times whose logarithms lie between $\ln \tau$ and $\ln \tau + d \ln \tau$.

For the $\epsilon(i\omega)$ of equation [2], $G(\tau)$ becomes (7)

$$G(\tau) = \frac{\sin \beta\pi}{\pi} \left(\frac{\tau}{\tau_0 - \tau} \right)^{\beta}, \qquad \tau \leqslant \tau_0 \qquad [12]$$

$$= 0, \tau > \tau_0,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

a function with a singularity at $\tau = \tau_0$. This form of $G(\tau)$ has been criticized (41) as being physically unrealistic. Such a criticism may be applied with equal relevance to the classical Debye behavior, for which $G(\tau) = \delta[\ln(\tau/\tau_0)]$, the delta function. This is an improper function, with discontinuities on both sides of $\tau = \tau_0$. It is nevertheless of use in quantum mechanics where, as in the present case, it occurs as an integrand (46).

It may be argued that the presence of either a unique relaxation time or of a distribution of relaxation times which ends abruptly at its most probable value is inconsistent with the variations in molecular environment that occur in liquids. They do, however, lead formally to expressions for $\epsilon(i\omega)$ which are capable for many liquids of describing the experimental results within the accuracy of the measurements. It may be that additional accuracy will lead to modifications of these distribution functions. The results of Grant, Buchanan, and Cook (6) suggest that a finite distribution of relaxation times is present in water, although the departure from Debye dispersion is barely detectable. It would be possible to modify equation [12] by replacing the abrupt cutoff at $\tau = \tau_0$ by a rapid but monotonic decline to zero for $\tau > \tau_0$ without producing much change in the resulting form of $\epsilon(i\omega)$.

Figure 16 illustrates the integral distribution function

$$F(\tau) = \int_0^{\tau} G(\tau) d \ln \tau$$

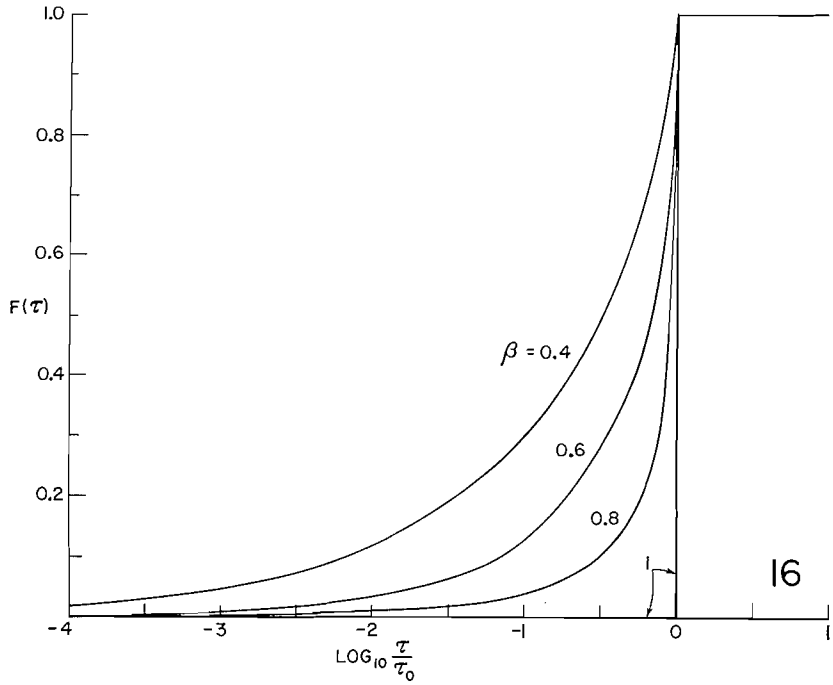
for $G(\tau)$ defined by equation [12]. $F(\tau)$ is a special case of the incomplete β-function (7):

$$[13] \qquad F(\tau) = \frac{\sin \beta\pi}{\pi} \int_0^{\tau/\tau_0} (\tau/\tau_0)^{\beta-1}(1-\tau/\tau_0)^{-\beta} d(\tau/\tau_0), \qquad \tau \leqslant \tau_0,$$
$$= 1, \qquad \tau > \tau_0,$$

which may be evaluated by graphical integration. Pearson (47) has tabulated the incomplete β-function for parameters related to those of equation [13] by $p = \beta$, $q = 1-\beta$, and $x = \tau/\tau_0$, but the large intervals between successive entries make these tables of little use for the range of parameters of interest here.

In Fig. 17 the integrated distribution function for $\beta = 0.70$ is compared with the sum of the integrated functions for the Cole–Cole arc and Debye semicircle suggested (see above) for 1,2-propanediol.

The picture of relaxation which results from the assumption of the physical reality of the distribution function of equation [12] is one of molecular rotation which takes place at rates which differ widely and continuously with the molecular environment by mechanisms each of which makes an additive contribution to the dielectric constant and shows a simple exponential dependence on time. The maximum relaxation time in the distribution may then be the orientation time of molecules in surroundings of greatest order. It is not easy to reconcile this picture with the evidence that liquid relaxation is a co-operative process (see next paragraph) nor with the observation that relaxation in many different liquids may be represented by the same simple analytic expression.



(b) Relaxation Processes not Resolvable by Superposition

It is likely that the behavior characterized by the skewed-arc locus arises from the presence of co-operative processes in which individual molecules in general do not rotate independently of one another.

The evidence for co-operative effects involving many molecules in the relaxation process may be summarized as follows:

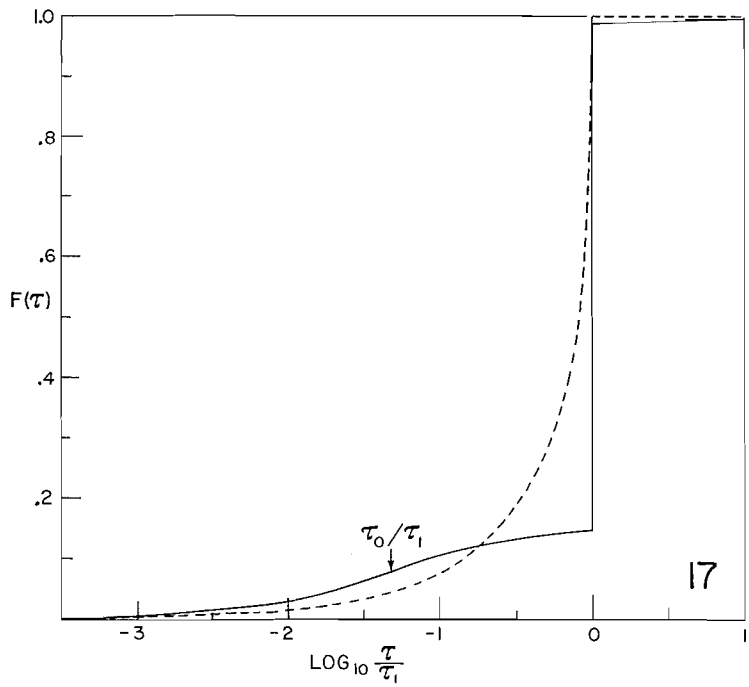

FIG. 16. The integral distribution function of relaxation times for various values of β.
FIG. 17. Comparison of integral distribution function arising from superposition of a semicircle (relaxation time τ_0) and a circular arc ($\alpha = 0.38$, $\tau_1 = 20.9\tau_0$) (solid curve) with that for a skewed arc ($\beta = 0.70$, broken curve).

(*a*) The temperature dependence of the relaxation times of many liquids leads to very large positive entropies of activation (48).

(*b*) Solutions of similar liquids in one another (e.g., alcohols (49) or halides (31)) lead to only one principal dispersion process, with little or no change in the shape of the dispersion. This suggests that the relaxing unit is large enough to contain the different molecules in the same proportion as in bulk solution.

(*c*) A similar inference may be drawn from the effect of electrolytes in changing the relaxation times of water and alcohols (50) without appreciably changing the width of the dispersion region.

(*d*) The similarity between the temperature dependence of such properties as dielectric relaxation time, macroscopic shear viscosity, and d-c. conductance in many liquids at low temperatures (see, for example, references 7 and 9) suggests that a common rate-determining process is involved. Such a process which involves only single molecules is difficult to envisage.

An interesting model which, under some conditions, leads approximately to a skewed-arc locus, has been recently proposed by Glarum (28). The polarization equation is

$$P(t) = P_0 e^{-t/\tau_0}[1-x(t)]$$

where τ_0 is the relaxation time of molecular orientation when there are no defects in the vicinity and $x(t)$ is the mole fraction of molecules which have relaxed completely as a result of the diffusion of defects. For the one-dimensional diffusion of randomly distributed defects in which only the defect initially nearest the molecule is permitted to reach it, the theory (28) leads to

$$\frac{\epsilon(i\omega)-\epsilon_1}{\epsilon_0-\epsilon_1} = \frac{1}{1+i\omega\tau_0} + \frac{i\omega\tau_0}{(1+i\omega\tau_0)[1+\sqrt{a_0(1+i\omega\tau_0)}]}$$

with $a_0 = l_0^2/D\tau_0$, where l_0 is the average distance over which the nearest defect must diffuse to reach the molecule when the diffusion coefficient is D. Since l_0^2/D represents an average diffusion time, a_0 may be considered to be the ratio of a relaxation time arising from the diffusion of defects to a relaxation time in the absence of defects. The locus changes gradually with increasing a_0 from a skewed-arc locus with $\beta = 0.5$ for $a_0 = 1$ to a simple Debye semicircle for $a_0 \gg 1$. The behavior at some intermediate values of a_0 is illustrated in Fig. 18. It is apparent that there is significant departure from a skewed arc only at high frequencies.

As plotted in Fig. 18 the Glarum locus approaches the origin at an angle of 45° with the real axis at high frequencies, a feature which gives the appearance of a small additional dispersion region for values of a_0 greater than unity. Since experimental results frequently show effects of roughly this type (compare Fig. 15), the value of ϵ_1 for "best fit" of the Glarum locus to experimental data is somewhat lower than that which is used for the skewed-arc representation (by an amount $\Delta\epsilon_1$). A more realistic comparison of the two representations than is shown in Fig. 18 is possible if the Glarum locus is expanded by a factor $1+\Delta\epsilon_1/(\epsilon_0-\epsilon_1)$ and the high-frequency intercept shifted a distance of $-\Delta\epsilon_1/(\epsilon_0-\epsilon_1)$ from the origin. The Glarum locus for $a_0 = 8$ has been modified in this way for $\Delta\epsilon_1 = 0.0175(\epsilon_0-\epsilon_1)$, and the results compared with the skewed-arc representation for $\beta = 0.756$ in Table III. For values of $\omega\tau_0$ up to about 30 the differences are well within the likely error of any comparable experimental data.

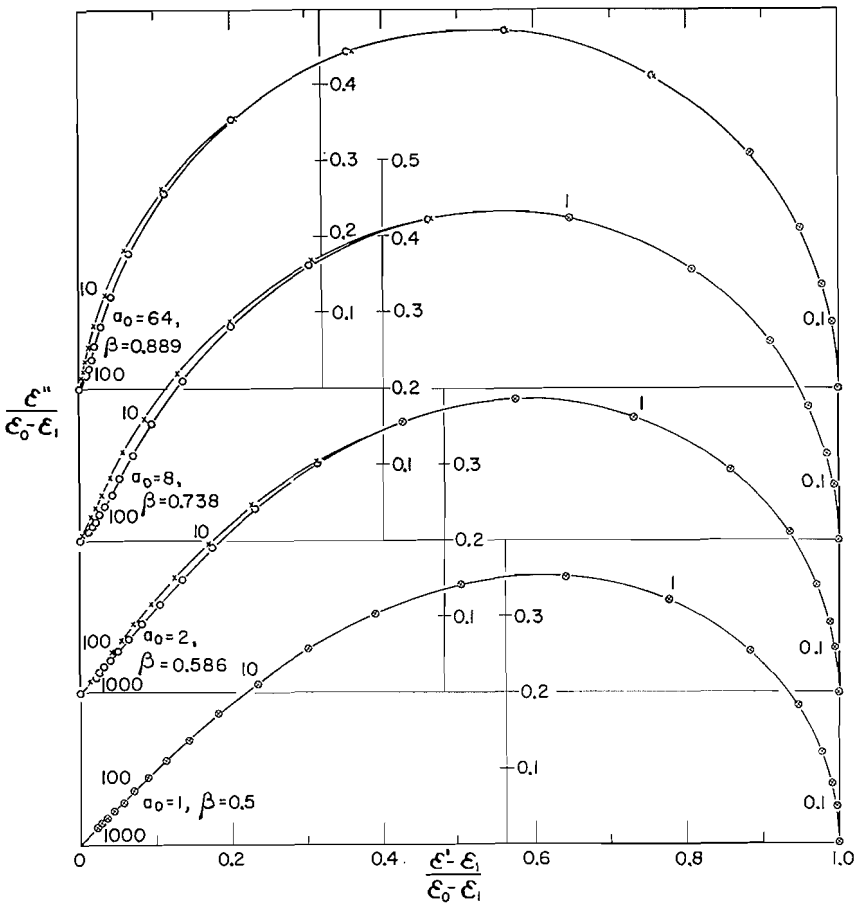

FIG. 18. Comparison of Glarum plots (O) for various values of a_0 with skewed-arc plots (×) for values of $\beta = \sqrt{a_0}/(1+\sqrt{a_0})$. Successive frequencies increase by a factor of 1.585.

As may be inferred from Fig. 18, $\Delta\epsilon_1$ becomes very small as a_0 either gets very large or approaches 1. The Glarum model therefore cannot account for the high-frequency dispersion effects appearing in the spectra of the alcohols (VI(a)) nor for some of the effects illustrated in Fig. 15. It is apparent, however, that a more critical experimental examination of the frequency range above $\omega\tau_0 = 100$ is required.

The Glarum theory shows, for the first time, that relaxation (which may be relatively slow) by an alternative mechanism to simple molecular orientation in a fixed environment may lead to a broadening of the Debye locus in the sense of increased dispersion and absorption on the high-frequency side, that is, in the sense required for skewed-arc behavior. The theory also predicts the Cole–Cole arc behavior in the case in which a_0 is very small (that is, relaxation proceeds by a defect diffusion mechanism only) and has possible application to relaxation in solids, for which symmetric-arc behavior is common.

It is formally possible for the Glarum model to take into account such co-operative effects as are mentioned above. Thus, τ_0 may be identified with the (macroscopic) relaxation time for co-operative molecular orientation in highly ordered regions of the liquid, a concept which requires further elaboration by a statistical approach.

VII. OTHER RELAXATION PHENOMENA

Distributions of relaxation times have long been used in the interpretation of relatively slow viscoelastic or mechanical relaxation processes. More recently (51, p. 454) the need for distributions of relaxation times has been demonstrated by the results of measurements of the dispersion of sound velocity and the absorption of ultrasonic energy in liquids. Although the measurements are not of sufficient accuracy to preclude other possible distributions, and the distribution function is not defined in quite the same way, it is interesting to find that the application of the distribution function of equation [12] to the complex compressional modulus leads to an adequate description of the main aspects of ultrasonic relaxation in a number of polyhydroxyl compounds (51, p. 479).

The classical theory of the nuclear magnetic resonance correlation time has been modified (52) to provide better agreement with experiment by the introduction of a distribution of correlation times. For two of the liquids showing the skewed-arc-locus type of dielectric behavior (glycerol (53) and isobutyl bromide (54)), the "most probable" correlation times are in surprisingly good agreement with dielectric relaxation times derived from the maxima of the dielectric loss curves. A rectangular distribution function is assumed for the correlation times although other distribution functions are equally possible.

It is likely that such a comparison of dielectric, ultrasonic, and n.m.r. relaxation behavior as has been initiated by Powles (53, 54), will facilitate attempts to devise an adequate mechanism of structural relaxation in liquids.

NOTES

CHEMISTRY OF THE TRIFLUOROMETHYL GROUP
PART II. NICKEL (II) COMPLEXES OF TRIFLUOROMETHYL PHOSPHINES*

M. A. A. Beg and H. C. Clark

The ability of tri-alkyl and -aryl phosphines to form co-ordination compounds with transition metal salts is well established. However, this ability is considerably modified when the phosphine contains the highly electronegative trifluoromethyl group. This has been shown in the reactions of methyl-trifluoromethyl-phosphines with boron trifluoride and platinum (II) chloride (1), where the results have been interpreted in terms of the effect of the electron-withdrawing power of the trifluoromethyl group on the donor properties of the phosphines, and of the large steric requirements of the trifluoromethyl group.

These two factors of the perturbing power or ligand field strength of the phosphines, and their steric requirements are just those that have been considered important in producing tetrahedral nickel (II) complexes (2). The first example of an apparently tetrahedral complex was $(PEt_3)_2Ni(NO_3)_2$ (3), although the lack of a full structure determination left room for alternative configurations. For the triphenylphosphine complexes $(PPh_3)_2NiX_2$ where $X = NO_3^-$, Cl^-, Br^-, I^-, detailed studies (4) leave no doubt that they possess tetrahedral structures. Other examples of tetrahedral nickel (II) complexes are now known (5). It therefore seemed of interest to examine the nickel (II) complexes of $(CH_3)_3P$, $(CH_3)_2PCF_3$, $CH_3P(CF_3)_2$, and $P(CF_3)_3$ wherever stable compounds could be isolated. Only the first two of these phosphines gave stable complexes and there were no indications of reaction between nickel (II) salts and either methyl-bistrifluoromethylphosphine or tristrifluoromethylphosphine. The complexes of dimethyl-trifluoromethylphosphine were considerably less stable than those of trimethylphosphine. The properties of the newly prepared compounds are shown in the table.

Compound	Magnetic moment (B.M.)	Color	Absorption maxima
$(Me_3P)_2Ni(NO_3)_2$	3.17	Dark red	4850(m), 3950(s), 3325(s)
$(Me_3P)_2NiCl_2$	Diamagnetic	Crimson	5320(s), 3880(m), 3650(m), 2650(s)
$(Me_3P)_2NiBr_2$	"	Crimson	5400(m), 3800(m), 2700(s), 2425(w)
$(Me_3P)_2NiI_2$	"	Dark brown	5175(m), 3875(w), 2850(vs), 2600(s)
$(Me_3P)_2Ni(SCN)_2$	"	Orange-yellow	4600(sh), 3550(vs), 2975(s), 2600(s)
$(Me_2PCF_3)_2Ni(NO_3)_2$	2.93	Dark red	5550(w), 4850(s), 4150(s), 3270(s)
$(Me_2PCF_3)_2NiCl_2$	Diamagnetic	Pink	4800(w), 4050(m), 3450(s), 2550(s)
$(Me_2PCF_3)_2NiBr_2$	"	Black	4875(s), 3950(s), 2625(s), 2400(s)
$(Me_2PCF_3)_2NiI_2$	"	Dark brown	3750(m), 3550(m), 3140(m), 2280(s)
$(Me_2PCF_3)_2Ni(SCN)_2$	"	Yellow	4600(m), 3675(vs), 2550(s)

The trimethylphospine complexes have not been reported previously and it is not surprising that the nitrate is paramagnetic and like its triethylphosphine analogue may be considered to be tetrahedral. The halogen and thiocyanate complexes are diamagnetic in accordance with the greater ligand strengths of these anions. The complexes of dimethyltrifluoromethyl phosphine are very similar to the trimethylphosphine compounds, only the nitrate is paramagnetic and possibly tetrahedral.

**From part of a thesis submitted by M.A.A.B. in partial fulfillment of the requirements for the Ph.D. degree.*

The intensity of the colors of the solid compounds and of the observed absorption bands suggest that charge-transfer transitions are involved.

The fact that a nickel (II) complex of tristrifluoromethyl phosphine could not be obtained is consistent with its inability to give a platinum (II) compound (1). The smaller size of the nickel atom compared with platinum may explain why the latter but not the former can give a complex with methylbistrifluoromethyl phosphine.

EXPERIMENTAL

The methyl-trifluoromethyl-phosphines were prepared as described previously (1). All nickel salts were prepared in the anhydrous state, except the nitrate which was used as the hexahydrate. The trimethylphosphine complexes were prepared by direct reaction of the phosphines with the nickel salts in 2:1 ratio in sealed evacuated tubes, and were purified by refluxing with butanol for about 30 minutes when crystals of the complexes separated. In the case of nickel nitrate, the product could not be crystallized satisfactorily and solutions of the complex were used where necessary. For the dimethyltrifluoromethyl-phosphine complexes, crystallization was not possible owing to their instability. The preparations in these cases were therefore performed in the presence of excess phosphine which acted as a solvent and gave reasonably pure products. The analyses of the compounds are given in the table.

	% Ni		% X	
Compound	Found	Calc. for $NiX_2(PR_3)_2$	Found	Calc. for $NiX_2(PR_3)_2$
$(PMe_3)_2Ni(NO_3)_2$	17.33	17.37	—	—
$(PMe_3)_2NiCl_2$	20.05	20.56	25.14	25.27
$(PMe_3)_2NiBr_2$	16.01	15.68	42.70	43.24
$(PMe_3)_2NiI_2$	11.85	12.50	54.30	54.72
$(PMe_3)_2Ni(SCN)_2$	17.27	17.79	34.45	34.60
$(Me_2PCF_3)_2Ni(NO_3)_2$	13.22	13.12	—	—
$(Me_2PCF_3)_2NiCl_2$	14.72	14.91	18.15	18.25
$(Me_2PCF_3)_2NiBr_2$	11.84	12.14	34.10	33.47
$(Me_2PCF_3)_2NiI_2$	9.76	10.14	43.80	44.40
$(Me_2PCF_3)_2Ni(SCN)_2$	13.42	13.36	26.25	26.73

All the complexes except the iodides and thiocyanates decomposed in the presence of moisture. Although stable in dry solvents, wet polar solvents caused decomposition. Magnetic measurements were made on a Gouy magnetic balance, using powdered samples except for the nitrates for which solutions were used. Spectra were determined in carbon tetrachloride or methanol solutions using a Cary model 14 spectrophotometer.

PRESSURE EFFECT AND MECHANISM IN ACID CATALYSIS
VI. HYDROLYSIS OF α-D-GLUCOSE-1-PHOSPHATE[1]

A. R. OSBORN[2] AND E. WHALLEY

INTRODUCTION

α-D-Glucose-1-phosphate hydrolyzes by acid catalysis (1) with carbon–oxygen fission (2, 3). It is usually assumed that there is a pre-equilibrium proton transfer to the ester, and that the slow step is either a unimolecular decomposition of the protonated form or a bimolecular attack of water. The conclusion (3) on the basis of the Zucker-Hammett hypothesis that the slow step is unimolecular is invalid because the Zucker-Hammett hypothesis is invalid (4–6). We have measured the effect of pressure on the rate of hydrolysis in order to determine the mechanism. The effect of temperature was also measured.

EXPERIMENTAL METHODS AND RESULTS

Dipotassium α-D-glucopyranose-1-phosphate was obtained from General Biochemicals, Inc. It was about 96% pure according to both optical rotation (7) and hydrolyzable organic phosphate determined by Fiske's method (8). The hydrolyses were carried out at 25° C in at least 2-*M* perchloric acid to suppress the ionization of α-D-glucose-1-phosphate, which has a pK_a of 1.10 (9). The initial concentration of the ester was about 0.1 *M* and so potassium perchlorate was precipitated if the potassium salt was used. Potassium ions were therefore removed by passing a solution of the salt through an ion-exchange column of Dowex 50W-X-8 in the acid form.

The hydrolysis was followed by the change of optical rotation. The rate constants are accurate to about 5%. The high-pressure technique has been described elsewhere (10, 11).

The first-order rate constants are summarized in Table I. At normal pressure the

TABLE I

Acid-catalyzed hydrolysis of α-D-glucose-1-phosphate

p/bar	Temp.	$c°_{HClO_4}$/mole l.$^{-1}$*	$10^6\ k_1$/sec^{-1}
1	25.00°C	2.00	126
1	25.00°	3.00	328
1	30.00°	2.00	290
1	35.00°	2.00	580
500	25.00°	2.00	126
1000	25.00°	2.00	118
1500	25.00°	2.00	105

*$c°_{HClO_4}$ is the concentration of perchloric acid at room pressure and temperature.

ratio of the rates in 3-*M* and 2-*M* perchloric acid is much greater than 1.5, and is near the ratio of the acidity function h_0 of the two solutions, so confirming Barnard *et al.*'s observation (3) that the rate is approximately proportional to h_0. The second-order

[1]*Issued as N.R.C. No. 6164.*

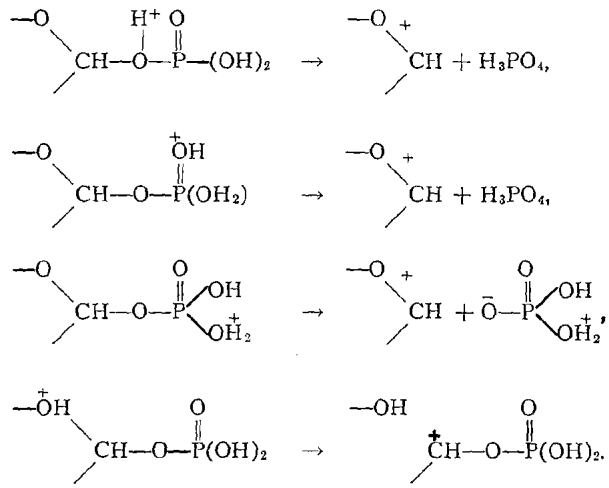
constants in 2-*M* perchloric acid at normal pressure and 25, 30, and 35° C followed the Arrhenius law and yielded

$$E_A = 27.8 \text{ kcal mole}^{-1},$$

$$\log_{10} A/\text{sec}^{-1} = 16.5, \qquad \Delta S^{\ddagger} = 14.8 \text{ cal deg}^{-1} \text{ mole}^{-1}.$$

From the effect of pressure up to 1500 bar at 25.00° C we find graphically



$$\partial \ln k_1/\partial p = 3.2 \pm \sim 1.2 \text{ cm}^3 \text{ mole}^{-1},$$

and assuming the compressibility χ of 2-*M* perchloric acid to be the same as that of water, remembering that $RT\,\partial \ln k_1/\partial p = -\Delta V^{\ddagger} + \chi RT$,

$$\Delta V^{\ddagger} = 4.3 \pm \sim 1.6 \text{ cm}^3 \text{ mole}^{-1}.$$

DISCUSSION

There are many protonated α-D-glucose-1-phosphates and it is not known which of them undergo hydrolysis. The following reactions and their bimolecular counterparts, in which a molecule of water attacks the carbon atom of the pyranose ring, seem to be the most likely. For clarity only the oxygen and one carbon atom of the pyranose ring are shown, and each reaction is presumed to be followed by the usual rapid steps.

The first and last of these were mentioned by Barnard *et al.* (3).

The first, second, and last mechanisms do not result in major changes of polarity and so the volumes of activation should depend mainly on the volume changes of the reactants. According to arguments and experiments in earlier papers in this series they should therefore have small positive volumes of activation if unimolecular, and negative volumes, about -10 cm^3 mole^{-1}, if bimolecular. The measured volume of activation of $4.3 \pm \sim 1.6$ cm^3 mole^{-1} eliminates the bimolecular reactions. In the third mechanism there is a great increase in polarity and so the volume of activation of either the unimolecular or the bimolecular mechanism would be negative because of electrostriction of solvent. Both these can therefore be eliminated. Thus the unimolecular first, second, or last mechanisms are consistent with the measured pressure effect.

The entropy of activation is 14.8 cal deg^{-1} mole^{-1}. Although all or nearly all entropies

of activation of unimolecular acid-catalyzed reactions are positive, it is not easy to understand why they should be (12), and so while the entropy is certainly consistent with the proposed mechanisms, it does not confirm them strongly.

OXIDATION OF CHOLEST-4-EN-3-ONE WITH PERIODATE–PERMANGANATE

J. T. Edward, D. Holder, W. H. Lunn,[1] and I. Puskas[1]

For stereochemical studies (1) we required large quantities of the keto acid, 5-oxo-3,5-seco-A-norcholestan-3-oic acid, first prepared by Windaus (2) by oxidizing cholest-4-en-3-one with alkaline permanganate. Later workers (3, 4) had obtained better yields (60–85%) by oxidizing 2–3 g of the unsaturated ketone with ozone, but we found yields low and capricious when oxidation with this reagent was carried out on a larger scale. However, 50 g of the ketone could be oxidized to the acid in 79–81% yield with the permanganate–periodate reagent of Lemieux and von Rudloff (5, 6), while with 5 g of the ketone the yield rose to 88%.

EXPERIMENTAL

Potassium carbonate (28 g) in water (800 ml) was added with vigorous stirring to a solution of cholest-4-en-3-one (50 g) in *t*-butanol–water azeotrope (3 l.), followed by 500 ml of a solution prepared from sodium metaperiodate (200 g) and water (2.5 l.), and then 50 ml of 0.8% aqueous potassium permanganate. The remainder of the periodate was added at the rate of 110 ml/minute for 10 minutes, and then at 30 ml/minute for the next 30 minutes. Permanganate solution was added when necessary to maintain the permanganate color, 50 ml being usually required after the first 5 minutes and a further 75 ml at intervals over the next 30 minutes.

After 2 hours, the excess permanganate was destroyed with sodium bisulphite. The resultant iodine-colored solution was concentrated at reduced pressure to a volume of about 4 l., cooled to 4° C, acidified with ice-cold 50% sulphuric acid, and extracted with ether (2.5 l., 1.5 l., and 1.5 l.). The ethereal extract was washed with sodium bisulphite solution until free from iodine, with water until neutral, and dried (magnesium

sulphate). It was then concentrated to 700 ml, diluted with hexane, and further concentrated to 250 ml. After standing for 8 hours at room temperature and 8 hours at 4° C, the solution yielded white needles (36.6–38.3 g) of the keto acid, m.p. 153–154° C (lit. m.p. 154–155.5° C (4)). The mother liquors, on being concentrated to about 60 ml and chilled, gave after several days a second crop of impure acid, from which pure acid (4.2–4.9 g), m.p. 153–154° C, was obtained by recrystallization from ether–hexane.

Symposium on Nuclear Chemistry and Radiochemistry

The papers that follow were presented at a symposium held at Atomic Energy of Canada Limited, Chalk River, Ontario, on September 6, 7, and 8, 1960, under the joint auspices of the Inorganic Chemistry Subject Division of the Chemical Institute of Canada, and Atomic Energy of Canada Limited. The meeting was organized by Dr. R. H. Betts of A.E.C.L. Some of the papers presented are not published here because of prior commitments.

The symposium committee wishes to express its appreciation to the sponsoring organizations for their generous support and co-operation, and to the Editor-in-Chief and staff of the Canadian Journal of Chemistry for their valuable assistance.

THE RANGE OF Na^{24} IONS OF KILOELECTRON VOLT ENERGIES IN ALUMINUM[1]

J. A. Davies and G. A. Sims

ABSTRACT

Detailed studies are reported for the depth of penetration in aluminum of monoenergetic Na^{24} ions over the energy region 0.7–60 kev. Below 20 kev the median range (R_M) increases linearly with energy as predicted by the Bohr–Nielsen equation. As was observed in a previous study with Cs^{137} ions in aluminum, the experimental distribution curves are not Gaussian in shape, but consist of a markedly asymmetric peak followed by a pronounced exponential "tail". The results of a Monte Carlo calculation show that the observed distribution curves correspond quite closely to those predicted by an isotropic elastic-scattering model.

Above 20 kev, a slight deviation from the linear range–energy relationship is observed; also, the distribution curves become narrower and more symmetrical, suggesting that electronic interactions are starting to play a significant role in the stopping process. Some preliminary results for the range of accelerated ions of Rb^{86} and K^{42} in aluminum are also included for comparison. Median ranges for each of the alkali metal ions are compared with those predicted by the Bohr–Nielsen treatment.

INTRODUCTION

A program of research on the penetration depth and range straggling of heavy ions in solids at bombardment energies up to 100 kev has been under way in this laboratory for the past three years. Previous papers (1, 2) have described the development of a sufficiently sensitive technique for measuring the extremely small depths of penetration involved, and its application to the study of Cs^{137} ions in aluminum. The present paper extends these measurements in aluminum to other alkali metal ions, particularly Na^{24}, in an attempt to further our understanding of the mechanism of the elastic-scattering process and its dependence on the energy, mass, and atomic number of the bombarding ion. One important advantage of this technique is that it provides detailed information not only on the range but also on the extent of range straggling.

Until recently, there had been almost no reliable experimental results reported for heavy particles below 100 kev. The situation has now improved considerably, particularly as a result of papers being presented at this conference (see footnote 1). Powers (3) has used proton scattering to study accurately the range of several rare-gas ions in carbon, beryllium, boron, and aluminum targets; Schmitt and co-workers (4, 5), by a recoil-atom technique, have determined the average range of the radioactive atoms produced by (γ,n) processes in various solids. However, neither of these methods was sufficiently sensitive to give detailed information on the shape of the range–distribution curve.

EXPERIMENTAL PROCEDURE

Our experimental approach consists simply in bombarding an optically flat aluminum target with a monoenergetic beam of radioactive ions, and then measuring the depth of penetration of the incident beam by dissolving successive uniform layers of aluminum from the target surface and measuring the amount of radioactivity in each layer. The ion bombardments were carried out using an electrostatic accelerator specially designed for the purpose (2). The development of a sufficiently sensitive technique for dissolving extremely thin layers of known thickness from the surface of an aluminum foil has already been described in detail (1). The technique consists essentially of two steps: electrochemical oxidation at constant voltage in aqueous ammonium citrate, followed by chemical removal of the anodic oxide film in a phosphoric acid chromium trioxide solution. Due to the highly protective nature of the anodic oxide film, this process permits highly reproducible surface layers of metal as thin as 37 Å to be removed, the thickness of the layer increasing linearly with the anodic voltage. Furthermore, the process may be repeated as often as desired, so that it is possible to obtain the complete range–distribution curve from a single bombardment.

RESULTS

The results for a typical run, illustrating the determination of the Na^{24} distribution in a bombarded target, are shown in Table I. The thickness W per layer (column 3)

*An extra 0.5 $\mu g/cm^2$ is added to the first layer in each run to take account of the oxygen that was present during the bombardment as an oxide layer on the target surface.

was calculated from the anodic voltage V by using the previously established relationship (1) $W = 0.30\ (V+1.8)$.

As was observed in the earlier study with Cs^{137} (2), the distribution of Na^{24} ions in the target is markedly asymmetric. This may be seen more clearly in Fig. 1, in which the Na^{24} content in each layer is plotted against the total depth beneath the original surface. The distribution curves show a characteristic highly penetrating "tail"; as a result, the most probable range R_P is somewhat less than the median value R_M. It will

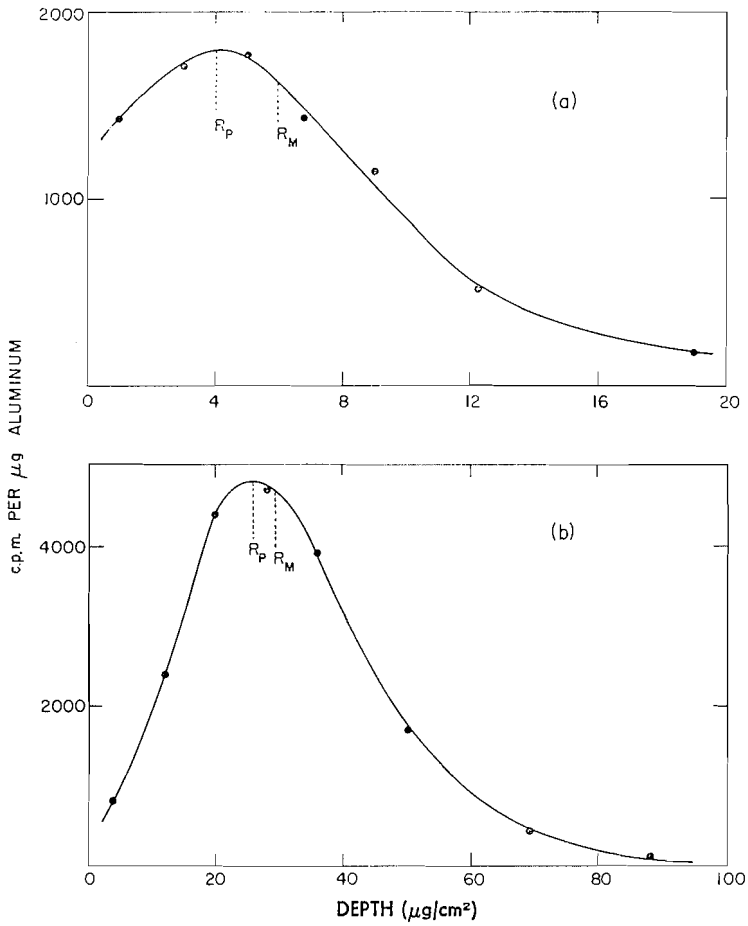

FIG. 1. Depth of penetration of Na^{24} ions in aluminum: (*a*) 10-kev Na^{24} ions, (*b*) 60-kev Na^{24} ions.

be noted, however, that with Na^{24} the asymmetry becomes less pronounced at high energy (Fig. 1*b*), and the peak becomes much sharper. The possible significance of this will be discussed in the next section; it suggests strongly that some process other than elastic scattering is starting to contribute to the rate of energy loss.

Typical distribution curves for the residual target activity (column 5, Table I) at various energies are shown in Fig. 2. In each case, the activity eventually falls off exponentially with depth.

Values of R_P, R_M, and the half-thickness ($X_{1/2}$) of the exponential region are shown as a function of energy in Table II, together with previous results for Cs^{137} (2). It will be noted that, over the energy region studied, the range increases approximately linearly with energy. However, a careful analysis of the data shows that at higher energies, a slight deviation from linearity occurs, and R_P and R_M gradually approach one another (see Table III). Some preliminary data for K^{42} and Rb^{86} have been included for comparison.

NOTE: The estimated experimental error is ±6% except where otherwise noted.

DISCUSSION OF RESULTS

The most striking feature about these results—the marked asymmetry in the distribution curves—can be explained quite readily. Nielsen (6) has pointed out that scattering in a screened Coulomb field should be approximately isotropic in the center-of-mass

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

system. This means that, even with Cs^{137} in aluminum, the average energy loss per collision is almost 30%; hence, only the first few collisions contribute significantly to the total range.

Under such conditions, it has been shown (2), by a somewhat oversimplified mathematical approach, that the predicted distribution curve would in fact consist of an asymmetric peak, followed eventually by an exponential region of half-thickness identical with that for the first collision. The problem was treated analytically in a manner analogous to that used by Bateman (7) for resolving growth and decay curves of successive radioactive transformations, only with distance replacing time as the independent variable. This analytical treatment provides a qualitative explanation for the experimentally observed distribution curves, but is not suitable for quantitative comparison: it makes no allowance for variations in energy transfer from one collision to another (all collisions were assumed to transfer exactly the average energy), nor for the difference between the total path length and the depth of penetration. The latter difference may quite easily be taken into account by replacing the mean free path λ by its projection λ in the forward direction,

i.e.

$$\lambda_0 = \lambda_0,$$

$$\lambda_1 = \lambda_1 \cos \bar{\psi},$$

and

$$\lambda_n = \lambda_n \cos^n \bar{\psi},$$

where the subscript refers to the number of collisions which the incident ion has undergone and $\bar{\psi}$ is the scattering angle in laboratory co-ordinates for an "average collision". When this relationship is inserted into the Bateman equation (see appendix to reference 2), the following series of exponential terms is obtained:

$$\sum_{n=1}^{n=\infty} \frac{1}{a_n} \left\{ \exp -[(1-\bar{T}) \cos \bar{\psi}]^n \cdot \frac{r}{\lambda_0} \right\}.$$

This series is rapidly convergent and leads to the distribution curves shown as (*a*) in Fig. 3. It has been assumed that the mean free path λ decreases linearly with the ion energy, and that the average energy transfer per collision ($\bar{T}$) is equal to $0.5T_{max}$. The dotted line represents the distribution of incident particles which have not yet had a single collision.

A much more satisfactory method of calculating the shape of the distribution curve has recently been developed (8), viz. a Monte Carlo type of calculation, which permits both the angular scattering and the fractional energy transfer to be varied at random from one collision to another. The resulting distribution curves (*b*) are shown in Fig. 3. In order to test the validity of Nielsen's prediction (6), the scattering process was assumed to be isotropic in center-of-mass co-ordinates. The close agreement between curves (*a*) and (*b*), particularly at the higher mass ratio, suggests that one may use the much simpler "average collision" method to predict the approximate shape of range–distribution curves. Experimental results for two runs (10-kev Na^{24}, and 30-kev Cs^{137}) have been included for comparison; the abscissa scales were normalized by letting $\lambda_0 = 3.9$ $\mu g/cm^2$ and 5.7 $\mu g/cm^2$ for the Na^{24} and Cs^{137} runs, respectively. It will be noted that the isotropic scattering model predicts both the height and the shape of the experimental peaks extremely well, even in the extreme case of Na^{24} in aluminum, where the masses of the incident ion and the target atom are approximately equal. In such a case, T_{max} is

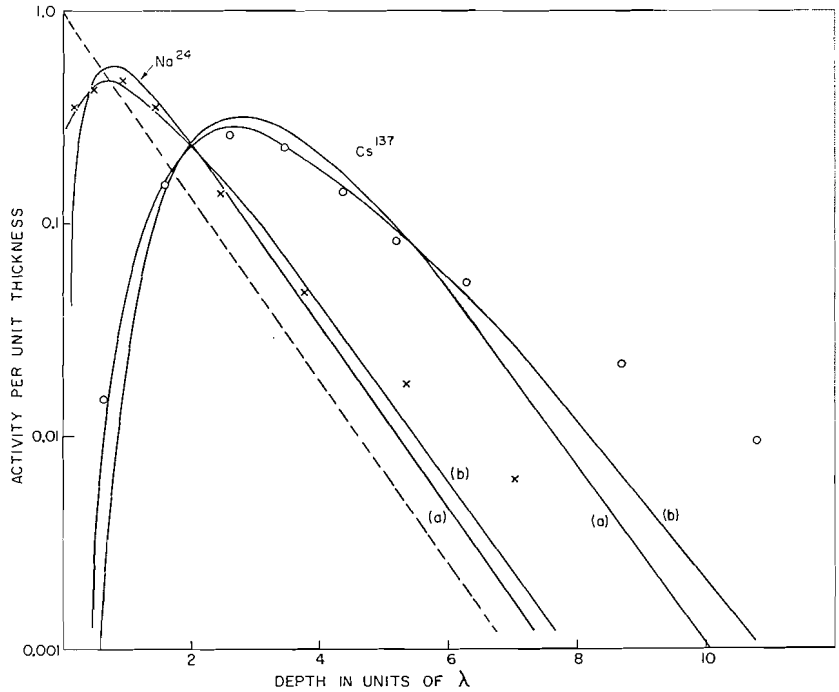

FIG. 3. Calculated distribution curves for Na^{24} and for Cs^{137} in aluminum using: (*a*) "average" collision method, (*b*) Monte Carlo method. Experimental results: ×, 10.5-kev Na^{24}; O, 30-kev Cs^{137}.

equal to 0.997, and hence the incident ion may lose almost all its energy in a single collision.

For both Na^{24} and Cs^{137} ions, a significant deviation between the predicted and observed distribution curves occurs at large depths of penetration. At about twice the median range, the experimental curve exhibits a point of inflection (see Fig. 2) which is not predicted by either the Monte Carlo or the "average collision" calculations. The half thickness ($X_{1/2}$) of the subsequent exponential "tail" is almost exactly a factor of two larger than the predicted value. A satisfactory explanation for this deviation has not yet been found. However, it involves less than 5% of the incident particles and hence should not appreciably affect the determination of R_P and R_M.

One very sensitive test of the agreement between the observed distribution and that predicted by the isotropic scattering model is to determine, for different mass ratios, how rapidly the curve falls off on either side of the maximum. The usual criterion for making such a comparison is the straggling parameter; however, with a markedly asymmetric peak, the normal definition of a straggling parameter has little theoretical significance.

Instead, let us consider the relative height (N/N_{max}) of the distribution curve at two selected abscissa values: at $x = \frac{1}{4}R_P$ and at $x = 2R_P$. In Fig. 4, the two solid lines represent the variation of N/N_{max} with the mass ratio, as determined by the Monte Carlo calculations. Typical experimental values for each of the alkali metal ions have been plotted, together with an estimate of the experimental error. With the exception of the higher-energy Na^{24} runs, the isotropic scattering model fits the observed straggling.

Furthermore, the discrepancy with Na^{24} at higher energies may quite reasonably be

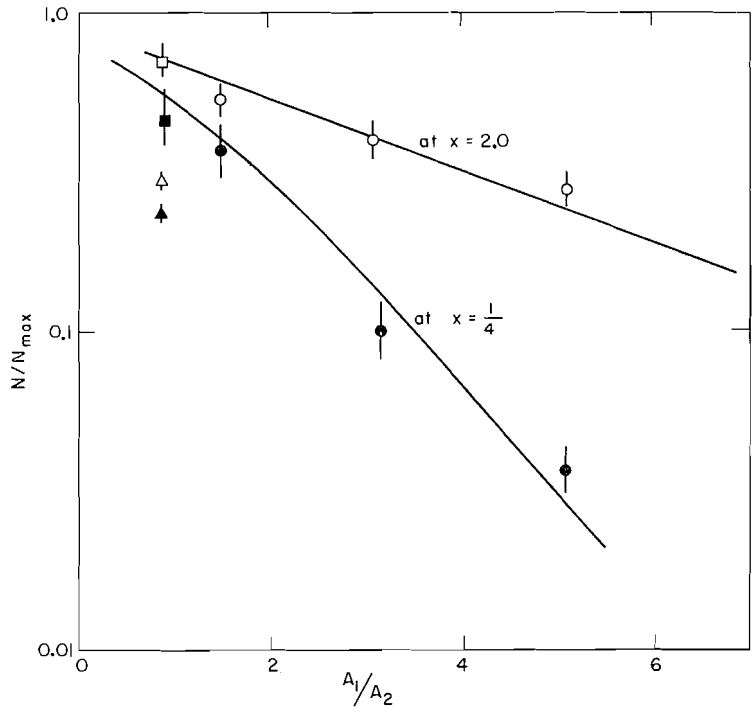

FIG. 4. Relative activity (N/N_{max}) vs. mass ratio. Solid lines are calculated from Monte Carlo distribution curves. Experimental points: ■□, 10.5 kev; ●○, 30 kev; ▲△, 60 kev; solid points at $x = \frac{1}{4}R_P$; open points at $x = 2R_P$.

attributed to a gradual increase in the significance of electronic interactions as a slowing-down process at higher velocities. It has been shown (9, 10) that heavy recoil atoms from α-decay undergo significant electronic interactions along their path, dissipating perhaps 20% of their energy in this manner. Yet these atoms have an initial velocity less than that of a 60-kev Na^{24} atom. Electronic stopping involves extremely small energy transfers per "collision", and so would tend to produce a narrower, more symmetrical peak. Such a trend was in fact observed (Fig. 1), and would account, at least qualitatively, for the low relative activity of 60-kev Na^{24} in Fig. 4.

Another convenient parameter for describing the degree of asymmetry is the ratio (R_P/R_M) of the most probable range to the median range (Table III). For electronic

scattering (where the fractional energy transfer is extremely small), the ratio should be almost exactly unity, whereas for elastic scattering (where large fractional energy transfers occur), the ratio would be much less. Once again, with the exception of the higher-energy Na^{24} runs, the agreement with the isotropic scattering model is quite reasonable. In the case of Na^{24}, the measured ratio at 30 kev is approximately halfway between the theoretical values for elastic nuclear collision and for electronic interactions. It would seem therefore that at this energy the two processes are of roughly equal importance. Since velocity rather than energy is the significant criterion for determining the relative importance of the two processes, it is not surprising that no such discrepancy was observed in the earlier work with Cs^{137}.

So far, we have discussed only the shape of the range–distribution curve; the actual magnitude of the range is much more difficult to predict. The most commonly used theoretical approach is based on Bohr's (11) treatment of collisions in a screened Coulomb field, from which Nielsen (6) has derived the familiar range–energy relationship,

$$[1] \qquad \frac{R}{E} = 0.60\,\frac{A_1+A_2}{A_1}\cdot\frac{A_2}{Z_2}\cdot\frac{(Z_1^{2/3}+Z_2^{2/3})^{1/2}}{Z_1},$$

where R is the range in micrograms per square centimeter, E is the energy of the incident ion in kiloelectron volts, A_1, A_2 are the masses, and Z_1, Z_2 are the atomic numbers of the incident and target atoms respectively.

One necessary criterion for screened-field scattering is that the collision diameter, or minimum distance of approach in a head-on collision, must be somewhat larger than the screening parameter. Otherwise, unscreened or Rutherford-type scattering can occur. Using Bohr's value for the screening parameter, viz. $0.528\times10^{-8}/(Z_1^{2/3}+Z_2^{2/3})^{1/2}$, it can be shown that this criterion is fulfilled at the energies used in the present work, except for some of the Na^{24} runs where the critical energy is only 25 kev. For Cs^{137}, on the other hand, the critical energy is over 500 kev. Since, as noted above, the runs with Na^{24} at higher energies also involve a significant contribution from electronic stopping, their interpretation is obviously much more complicated and will not be discussed further at this time.

Unfortunately, in testing the validity of Bohr's screened-field model, it is not possible to use the above range–energy relationship for a direct comparison with our experimental data; this is because the equation may be applied only when $A_1 \gg A_2$. This restriction arises because equation [1] was obtained by integrating an expression for the stopping power ($\Delta E/\Delta R$). Such an integration assumes that the energy decrease per collision is small enough that the stepwise slowing-down process may be replaced by a smooth curve. Secondly, the expression predicts the total path length travelled rather than the actual depth of penetration. Neither of these assumptions holds true when using an aluminum target. Even with Cs^{137} ions, where $A_1 = 5.1A_2$, the energy transfer per collision can be as large as 55%; with Na^{24}, up to 99.7% of the energy may be lost in a single collision and the average angular deflection in laboratory co-ordinates is approximately 45°.

However, by a somewhat modified theoretical treatment combined with the results of the Monte Carlo calculations (Fig. 3), it is possible to develop a completely general expression for the depth of penetration, one which is applicable for any value of A_1/A_2. Nielsen's expression for the stopping power may be written as follows:

$$[2] \qquad -\frac{\Delta E}{\Delta R} = 1.68\,\frac{A_1}{(A_1+A_2)A_2}\cdot\frac{Z_1Z_2}{(Z_1^{2/3}+Z_2^{2/3})^{1/2}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where $(\Delta E/\Delta R)$ is expressed in kev cm^2 μg^{-1}. Instead of integrating, we may write an alternative expression for the stopping power in terms of the average fractional energy transfer $\bar{T}$ per collision and the mean free path λ of the particle,

$$[3] \qquad -\frac{\Delta E}{\Delta R} = \frac{\bar{T}E}{\lambda}.$$

λ must be expressed in the same units as R, viz. micrograms per square centimeter. If the scattering process is approximately isotropic, then $\bar{T}$ may be expressed as $2A_1A_2/(A_1+A_2)^2$ and hence

$$[4] \qquad -\frac{\Delta E}{\Delta R} = \frac{2A_1A_2}{(A_1+A_2)^2}\cdot\frac{E}{\lambda}.$$

Combining equations [2] and [4], we obtain the following expression for the mean free path of the incident ion:

$$[5] \qquad \lambda = 1.19\frac{A_2^{\,2}}{A_1+A_2}\cdot\frac{(Z_1^{\,2/3}+Z_2^{\,2/3})^{1/2}}{Z_1Z_2}\cdot E.$$

It should be recognized that λ is only an "effective" mean free path: it applies to the approximately isotropic scattering process, but does not include the increased frequency of very small angular deflections which, according to Nielsen, have a negligible influence on the over-all rate of energy loss.

To calculate R_P, R_M, or the mean range $\bar{R}$ from equation [5], one simply multiplies λ by a numerical factor (k_P, k_M, or $\bar{k}$) for each mass ratio. These factors are computed from Monte Carlo distribution curves such as those in Fig. 3. Appropriate values for various mass ratios are given in Table IV.

In Table V, these factors are used to compare the predicted and experimental ranges

TABLE IV

k-Factors for various mass ratios

have recently criticized Nielsen's replacement of the Bohr screened-field potential by an $(1/r^2)$ potential. They also point out that the predicted range is extremely sensitive to the choice of screening parameter "a", since "a" occurs in the exponential term determining the interaction potential.

However, while it is interesting to speculate on possible causes for the discrepancy between experiment and theory, it is felt that further discussion should be postponed until more data become available.

ACKNOWLEDGMENTS

It is a pleasure to acknowledge our gratitude to Dr. R. H. Betts for his advice and encouragement throughout this work. We are also particularly indebted to Dr. J. M. Kennedy and B. Miles for suggesting and programing the Monte Carlo calculations used in interpreting the experimental results.

ISOTOPE EFFECT IN HEAVY ION RANGE STUDIES[1]

J. A. DAVIES, J. D. MCINTYRE,[2] AND G. A. SIMS

ABSTRACT

From measurements of the isotope ratio (Na^{22}/Na^{24}) at various depths of penetration, it has been possible to determine at 24 kev the small difference in the median ranges of the sodium isotopes. Na^{22} has the slightly larger median range, as is predicted by the Nielsen equation. Monte Carlo calculations show that an isotropic elastic-scattering model provides a reasonable explanation for the magnitude of the range difference and for the observed variation in the isotope ratio as a function of depth.

INTRODUCTION

The preceding paper on the range of alkali metal ions of kiloelectron volt energies in aluminum (1) showed that although the mean depth of penetration increases linearly with ion energy as predicted by Bohr (2), the variation with mass and atomic number of the incident ion was considerably smaller than would be expected on theoretical grounds.

In order to determine the relative contribution of each term to the observed depths of penetration, it was decided to investigate the possible existence and magnitude of an isotope effect, i.e. to study the effect of a variation in mass without varying the atomic number.

The sodium isotopes, Na^{22} and Na^{24}, were selected for this experiment for three reasons: (*a*) the fractional mass difference is large; (*b*) the mass ratio between the incident ion and the target atoms (Al^{27}) is close to unity, a situation where one might expect to observe the maximum effect; (*c*) both isotopes are radioactive and can be readily detected and measured.

According to the Nielsen equation (3), the ratio of the mean ranges for two isotopes of the same ion is given by

$$\frac{R_1}{R_2} = \frac{A_2}{A_1} \cdot \frac{A_1 + A_T}{A_2 + A_T}$$

where A_T is the mass of the target atoms. For the case of sodium ion in aluminum, R_{22}/R_{24} would be 1.048. However, the Nielsen equation is applicable only as a limiting case, i.e. when A_1 (and A_2) $\gg A_T$. If the more general treatment outlined in the preceding paper (1) is used, then the predicted ratio is even smaller.

Since the reproducibility between duplicate runs in our previous range studies was no better than $\pm 5\%$, it was obviously not feasible to study such a small isotope effect by measuring R_{22} and R_{24} independently in separate runs. However, by bombarding the target simultaneously with a mixture of Na^{22} and Na^{24} ions, and then measuring the Na^{22}/Na^{24} activity ratio at various depths beneath the surface, it is possible to obtain R_{22}/R_{24} directly from a single run. In this way, most of the sources of error are eliminated, except those involved in the actual counting process.

EXPERIMENTAL PROCEDURE

The method used for bombarding aluminum targets with monoenergetic radioactive ions, and for subsequently removing thin, uniform layers of aluminum of accurately known thickness has been described in detail elsewhere (4, 5).

The ion source for each run was prepared by evaporating a small volume of aqueous Na_2SO_4 containing appropriate amounts of the radiochemical isotopes Na^{22} and Na^{24}. For maximum statistical accuracy during the subsequent counting operations, the initial relative activity was chosen to be approximately 20% Na^{22} and 80% Na^{24}. Immediately after the bombardment, a series of thin layers were removed successively from the target; the thickness of each layer was chosen so that approximately equal amounts of radioactivity were present in each one. The anodizing and film-stripping solutions from each layer were combined and γ-counted in a 5-ml volumetric flask using a 3×3 in. NaI well-type scintillation counter.

The total activity ($Na^{22}+Na^{24}$) in each flask was measured immediately after the bombardment. The samples were then set aside for 2 weeks to allow the Na^{24} to decay completely, and carefully recounted to obtain the Na^{22} activity. The original Na^{24} activity was determined by difference.

On each occasion the sample was counted at least three times, for a total period sufficient to reduce the standard deviation to less than 0.5%. The Na^{24} counts were corrected for decay to a standard time, using a value of 15.0 hours for the half-life. The maximum decay time involved in such corrections never exceeded 6 hours; furthermore, the samples were counted in random sequence in order to reduce the contribution from any subjective counting errors.

Sets of 5-ml counting flasks were carefully selected from a much larger number on the basis of uniformity of weight, bulb diameter, and position of graduation mark. To test their reproducibility, several flasks from each set were used to measure the isotopic composition of the Na_2SO_4 stock solution. The ratios of Na^{22}/Na^{24} activity obtained with different flasks from any one set agreed within the statistical counting error. A different set was used for each complete run.

RESULTS

Results for a typical run, illustrating the variation of isotope ratio with depth of penetration, are shown in Table I. The estimated standard deviation for the normalized isotope ratios is $\pm.005$. Three runs have been carried out, all using 24-kev sodium ions in aluminum. In each case, an abnormally high Na^{22} content was observed in the first

TABLE I

layer; the subsequent variation with depth agrees at least qualitatively with the prediction that Na^{22} has a slightly longer mean range.

By plotting the distribution curves on an expanded scale and interpolating, it is possible to obtain the ratio of the median ranges quite accurately. The results of this interpolation are shown in Table II. The absolute value of each median range has a

TABLE II

Median range (R) of 24-kev sodium ions in aluminum

Run No.	R_{22}	R_{24}	R_{22}/R_{24}
1	13.6_8	13.4_4	1.018
2	13.0_2	12.7_3	1.023
3	13.0_6	12.8_8	1.014
			1.018±.004

probable error of at least ±5%, but, as noted above, most of this error cancels out in determining the isotope ratio R_{22}/R_{24}.

DISCUSSION OF RESULTS

In order to obtain a theoretical estimate for the magnitude of the isotope effect, let us apply the generalized treatment of the elastic-scattering process outlined in the preceding paper (1), viz.

$$R_M = k_M\lambda,$$

where λ is the mean free path of the incident ion and k_M, a numerical factor, is a function only of the mass ratio of the incident ion to the target atom. Appropriate values of k_M for each of the sodium isotopes in aluminum have been evaluated by using a Monte Carlo calculation based on an isotropic scattering model (details of this calculation will be described in a later paper). The resulting values are 1.204 for Na^{22} and 1.230 for Na^{24}.

Hence, the isotope effect may be expressed as

$$\frac{R_{22}}{R_{24}} = \frac{1.204\lambda_{22}}{1.230\lambda_{24}} = 0.979\left(\frac{\lambda_{22}}{\lambda_{24}}\right).$$

But, from equation 5 in the preceding paper

$$\lambda \propto \frac{A_T^2}{A_{ion}+A_T}.$$

Therefore,

$$\frac{\lambda_{22}}{\lambda_{24}} = \frac{24+27}{22+27} = 1.041$$

and

$$R_{22}/R_{24} = 0.979\times1.041 = 1.019.$$

It will be noted that this predicted ratio agrees with the measured values of 1.018, 1.023, and 1.014 within the estimated experimental error of ±0.5%.

In the preceding paper, the Na^{24} range studies indicated that, above 10 kev, elastic scattering is not the only significant process contributing to the slowing down of the incident ion, but that electronic interactions become increasingly important at higher energies. Unfortunately, the existence of significant electronic interactions at such low energies was not fully realized when these isotope effect measurements were undertaken; as a result, the energy selected for the present study is somewhat higher than would now seem desirable. However, it is probably safe to conclude that, even at 24 kev, elastic scattering is still the more significant mechanism.

A qualitative explanation for the observed variation in isotope ratio as a function of depth (Table I) can quite readily be found: Na^{22} has the larger velocity, and hence the longer mean free path; this produces a normalized Na^{22}/Na^{24} ratio slightly less than unity at depths less than the median range, and slightly greater than unity at depths greater than the median range. The only abnormal result is the very large Na^{22} content in the surface layer. This may be attributed to the fact that Na^{22}, being the lighter ion, suffers larger angular deflections per collision. It can be shown that, if the scattering process is approximately isotropic in center-of-mass co-ordinates, then in the laboratory co-ordinate system approximately 20% of the Na^{22} ions are deflected through 90° or more in a single collision, whereas the corresponding figure for Na^{24} is only 15%. This considerable difference in the frequency of large-angle deflections is sufficient to produce the enhanced Na^{22} content observed in the first layer. The sodium content in the first layer is caused almost entirely by those ions that undergo large angular deflections in their *first* collision, and that have this collision near the surface. In such a collision, more than 95% of the energy is lost, and hence these ions do not travel much further.

A modification of the Monte Carlo method for calculating the shape of distribution curves (1) may be used to put the above explanation on a more quantitative basis. The statistical accuracy obtainable in Monte Carlo calculations is determined by the number of individual particle tracks followed; and it would require a prohibitive amount of computer time to reduce the statistical error to $\pm 0.5\%$ for the Na^{22} and Na^{24} abundances in each of the seven layers in Table I. However, the random numbers used to characterize each collision in the calculation are not truly random in that they are generated by some arithmetical device: in other words, they are only "pseudo-random", and it is possible to regenerate exactly the same sequence if desired.

Therefore, in order to compute the isotope ratio theoretically, a reasonable number of particles ($\sim 10^4$) were followed through a random sequence of collisions (six collisions per particle) with the mass ratio set at 0.81, i.e. the Na^{22} ion case; then, with the mass ratio set at 0.89 (the Na^{24} case), the same number of particles were followed through exactly the same "random" sequence. Since we are interested only in the *ratio* of the Na^{22} activity to the Na^{24} activity at various depths, most of the statistical fluctuations cancel out.

These Monte Carlo calculations give the isotopic distribution (Na^{22}/Na^{24}) at various multiples of the mean free path (λ) of the incident ion. In order to compare the calculated and experimentally measured ratios at various depths, it is necessary to introduce the ratio of the mean free paths ($\lambda_{22}/\lambda_{24}$). The value of 1.041 obtained above in computing the ratio of median ranges was used for this purpose. The resulting values for the predicted variation of isotope ratio with depth are compared with experiment in Table III. Considering the errors involved both in the calculation and in the experimental measurement, the agreement between the observed and calculated ratios is quite satisfactory, and provides further support for the approximate validity of the isotropic

TABLE III

Variation in isotope ratio with depth of penetration

Depth ($\mu g/cm^2$)	Na^{22}/Na^{24} activity ratio

THE KINETIC ENERGY OF Cs^{136} PRIMARY FRAGMENTS FROM FISSION OF U^{235} [1]

F. Brown and B. H. Oliver

ABSTRACT

The ranges of Cs^{136}, Cs^{137}, and Ba^{140} fission fragments in aluminum have been measured using an anodizing technique to strip layers from the aluminum together with radiochemical methods to determine the fission products. The mean ranges are, in milligrams per square centimeter: Cs^{136}, 2.64; Cs^{137}, 2.91; and Ba^{140}, 2.82. The range distributions were of near-Gaussian form with the following percentage full widths at half height; Cs^{136}, 17.7; Cs^{137}, 17.0; and Ba^{140}, 17.5. The range–energy relationship of Bohr, R = const. $A^{1/2}E^{1/2}Z^{-2/3}$, was tested using the range data of Katcoff (7) and of Niday (2) together with the kinetic energy data of Milton and Fraser (15) and found to be accurate, within experimental error, over any limited range of fragment masses. Using this formula it then appears that the total kinetic energy in the fission mode leading to Cs^{136} is ~21 Mev less than normal.

INTRODUCTION

The general features of the distribution of nuclear charge in low-energy fission are well known. The situation is usually described in terms of the distribution in primary charge of fragments having a fixed mass. It is then found that the charge distribution is, at least approximately, independent of the particular mass chosen and can be represented by a Gaussian-like distribution around a most probable charge Z_p. The value of Z_p for any mass can be found using the empirical rule due to Glendenin (1) known as the "equal chain length hypothesis". An alternative, but equivalent, description is obtained by considering the distribution in mass of fragments having a fixed primary charge.

This latter distribution emphasizes the fact that the observed charge distribution can be modified by neutron emission from the fragments (a phenomenon which is well known in high-energy fission). The number of neutrons emitted in fission is not constant, and one can therefore ask whether those primary fragments found relatively close to stability (i.e. having less than the most probable mass for a fixed primary charge) have emitted more than the average number of neutrons. One associates a more than average neutron emission with fragments which possess more than average internal excitation and, if the total energy release for the formation of these fragments is normal, one then expects them to have less than normal kinetic energy.

Ideally one would like to have measurements of the total energy release, the kinetic energy, the γ-ray energy, and the neutron emission for fragments formed close to stability (and likewise for those formed exceptionally far from stability) but such fragments are rare and the present techniques for such measurements, by time of flight and so on, are not applicable. This suggests the use of radiochemical methods, which are highly specific. In particular it is possible, in principle, to measure the range of any fission fragment and given the range–energy relationship to obtain its kinetic energy. The paper presents the results of experiments to measure the kinetic energy of the fragment Cs^{136} which, being a shielded nuclide, is a primary fragment.

A collimated beam of fission fragments was directed into an aluminum catcher foil.

Issued as A.E.C.L. No. 1151.

Successive layers of the foil were dissolved by an anodizing technique and analyzed for Cs^{136}, Cs^{137}, and Ba^{140}. The relationship between range and energy was derived from theory and confirmed by the Cs^{137} and Ba^{140} data together with other data from the literature.

The results of these experiments show that, as anticipated, the range of Cs^{136} fragments is abnormally low. During the preparation of this work for publication a new set of range measurements, for U^{235} fragments in uranium, has become available (Niday (2)). These measurements also show that Cs^{136} and Rb^{86} (another shielded nuclide) have abnormally low ranges. The significance of these observations on shielded nuclides is discussed at the end of this paper.

EXPERIMENTAL

Apparatus

An electropolished aluminum plate approximately 1.5×4.0 cm was covered with a layer of U^{235} as oxide deposited using the lacquer technique and of thickness ~100 μg U^{235}/cm^2. This plate was covered with an aluminum collimating plate 3/16 in. thick drilled with 1/16 in. diameter holes. Against this was placed the catcher foil, a plate of electropolished, high-purity aluminum. The assembly was placed in an irradiation container, filled with hydrogen at atmospheric pressure, and hermetically sealed. The hydrogen was introduced to provide some cooling to the container walls. An irradiation of 1 week was made in a vacant fuel rod position of the NRX reactor at a neutron flux of $\sim 5 \times 10^{13}$ neutrons/cm^2 sec.

Sampling

After removal from the reactor and disassembly by remote handling the catcher foil was "stripped" using the anodizing technique developed by Davies (3). In this technique the specimen is anodized by applying a known voltage in a citrate buffer solution which causes an oxide layer to form whose thickness is proportional to the voltage and essentially independent of time after the first 5 minutes. The specimen is then removed, washed, and placed in a hot (95° C) stripping solution of chromic oxide and phosphoric acid which rapidly dissolves the oxide (2 minutes) but does not attack the metal. The process is then repeated as required. In the present case the anodizing voltage was 100 volts, which results in the stripping of ~25 μg/cm^2 of aluminum in each cycle. Since this is an unnecessarily small layer two oxide layers were dissolved in each sample of stripping solution so that each sample contained ~50 μg/cm^2 of the specimen. The actual amount stripped was determined by weighing the specimen after every seven samples and was found to be 54.3 μg/cm^2 per sample (in agreement with the data obtained by Davies). This figure could be in error by about 3% due to a possible error in measuring the area of the foil; the electropolishing process caused the edges of the foil to be somewhat rounded. This error would affect only the absolute values of the ranges measured.

The consistency in sampling was indicated by comparing the weights removed in each group of seven samples. The standard deviation from the mean was 1.4%. The weight loss for seven samples was ~5.0 mg, the error in the weighings ~0.05 mg, so that within the accuracy of measurement there were no significant variations between the groups of seven samples.

Purification

Each sample of stripping solution contained measured quantities of cesium and barium carriers. The barium was precipitated as carbonate, purified by the hydrochloric acid – ether method of Glendenin (4), collected on weighed filter papers, weighed as $BaCl_2 . 2H_2O$,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and finally mounted for γ-ray counting. The cesium was purified by the sodium tetraphenyl boron method of Handley and Burros (5). It was found necessary to apply this procedure twice in order to obtain sufficient radiochemical purity. Thus the precipitate of cesium tetraphenyl boron obtained from the first purification cycle was destroyed by fuming nitric acid and the whole cycle was repeated. The final precipitate was collected, weighed, and mounted for γ-ray counting as in the barium case.

Counting

The samples were counted by a 3×3 in. sodium iodide crystal mounted as recommended by Heath (6). For the cesium counting this was connected to a 100-channel kicksorter equipped with typewriter readout. The stability of both counting rate and energy scale was checked using Cs^{137} and Co^{60} standards and no corrections were found to be necessary. The spectra, corrected for background, showed the 661-kev peak from Cs^{137} and peaks from Cs^{136} at 822 kev, 1.04 Mev, and higher energies. The Cs^{136} counting rate was taken as the total rate in the 822-kev and 1.04-Mev peaks corrected for the high-energy tail from the 661-kev Cs^{137} peak. This correction was actually negligible except in the few samples which contained a very high Cs^{137}/Cs^{136} ratio when it amounted to $\sim$3%. The Cs^{137} counting rate was taken as the rate in the 661-kev peak corrected for the Compton contribution from the higher-energy Cs^{136} γ-rays. This contribution was estimated by comparing spectra of pure Cs^{137} with those from various Cs^{136}–Cs^{137} mixtures. The correction varied from $\sim$1% to $\sim$25% depending on the Cs^{136}/Cs^{137} ratio. In the samples of greatest interest it was $\sim$5%. These data were then corrected for the chemical yield and for decay of the Cs^{136} to obtain the results shown in Fig. 1.

For the Ba^{140} counting the crystal was connected to a discriminator and the total γ-ray count above 700 kev was recorded. All samples had been allowed to decay sufficiently before counting so that the La^{140} had reached secular equilibrium. The rates were corrected for background and chemical yield and are shown in Fig. 1. No corrections for decay were required since all the samples were counted within a short space of time and only relative rates were required.

RESULTS

The experimental data are shown in Fig. 1 where the activity for each nuclide, in arbitrary units, is plotted against the sample number. In each case the distribution shows the expected Gaussian-type distribution plus a tail of approximately constant level on the low-range side. This tail could arise from U^{235} lost from the source during irradiation and deposited on the surface of the catcher foil. The experiment was repeated with the uranium covered by $\sim$700 $\mu g/cm^2$ of aluminum in order to prevent transfer of uranium. The intensity of the tail was reduced to about one half. The remaining tail is presumably caused by scattering but it would seem desirable to perform experiments specifically designed to study this effect before attempting to draw any firm conclusions. Corrections for these tails were made by assuming they consisted of a square distribution smeared by a Gaussian of the same width as the main peak. The data so corrected are shown on Fig. 2. Typical errors are shown by the vertical bars. In the case of Ba^{140} and Cs^{137} they arise mainly from the chemical yield determinations, but in the Cs^{136} case the uncertainty in background correction is also involved and thus the errors are relatively larger for the low-activity points.

In order to test the shape of the distributions the data were integrated and plotted on probability paper; it was found that the mean range was, in all cases, slightly less

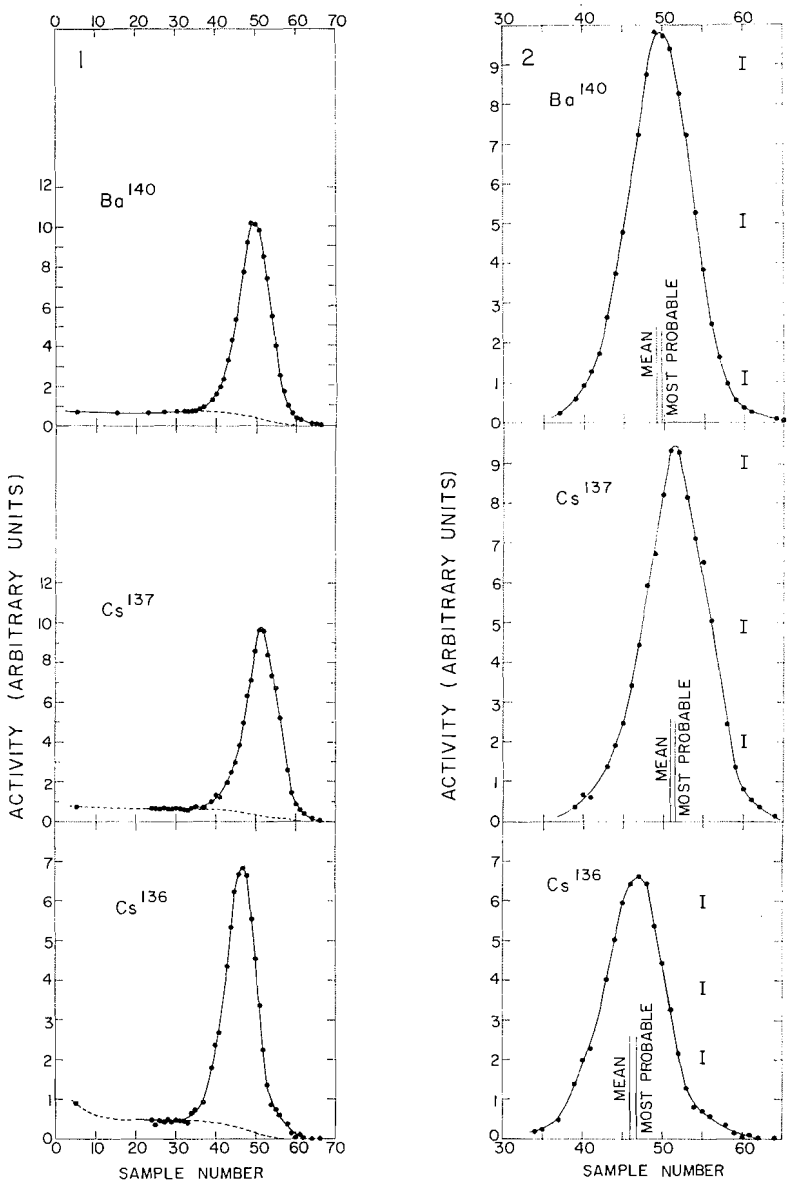

FIG. 1. Range distributions, uncorrected.
FIG. 2. Range distributions, corrected.

than the most probable, the difference being between 1 and 2%. This agrees qualitatively with the results of Katcoff *et al.* (7), who found, for Pu^{239} fission fragments in air, that the distributions were slightly steeper on the high-range side. As in the case of the Katcoff experiment it is not clear whether this small effect is fundamental or is caused by the experimental setup.

To convert sample number to range in aluminum it is necessary to multiply by 54.3 $\mu g/cm^2$ and to add a small correction for the weight of hydrogen in the collimator holes and for the source thickness. This correction amounts to the equivalent of ~2.3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

samples and although it is not accurately established it has no significant effect on the final analysis. After making this correction one obtains the results shown in Table I for the mean ranges and full widths at half maximum of the distributions.

TABLE I

Ranges and range dispersions in aluminum

Nuclide	Range (mg/cm²)	Width (%)
Ba^{140}	2.82	17.5
Cs^{137}	2.91	17.0
Cs^{136}	2.64	17.7

The precision of the mean range values is ~0.4%; their absolute accuracy is about 4%. This is set by the error in correcting for source thickness and hydrogen absorption (~2%) and the error in the value for the weight removed per sample (~3%). The precision of the widths is ~3% and thus the variation in widths between the three nuclides is not significant.

The present experiments were designed primarily to detect differences in ranges rather than to set absolute values. The absolute range of the Ba^{140} fragments can be compared directly with the value obtained by Finkle *et al.* (8) for Ba^{140} from U^{235} stopping in aluminum, viz. 2.75 mg/cm². A recent measurement by Alexander and Gallagher (9) gives a value of 2.98 mg/cm².

The widths obtained by Good and Wollan (10) for I^{137} fragments from U^{235} stopping in various gases are: H_2, 4.3%; D_2, 8.0%; He, 6.3%; air, 15.7%; A, 18.2%. The width obtained by Katcoff *et al.* for the Ba^{140} fragments from Pu^{239} stopping in air was 12.6%. The widths obtained with the present technique appear therefore to be reasonable.

It should be noted that the range dispersion in all but the lightest stopping media is due almost entirely to straggling; the contributions from the variations in kinetic energy and nuclear charge are small in comparison. In the present experiment the contributions from source thickness (~1%) and finite collimator angle (~2.5%) are also very small.

DISCUSSION

The following discussion is presented in three parts: (*a*) range–energy relationships for fission fragments, (*b*) calculation of the kinetic energy released in forming Cs^{136}, and (*c*) the significance of the kinetic energy deficit which is found in the formation of Cs^{136}.

(a) Range–Energy Relationships for Fission Fragments

It is clear from the present experiment and from the results of Niday (2) that the Cs^{136} fragments have abnormally low ranges. Before discussing the significance of this fact it is necessary to know what this amounts to in terms of the kinetic energy of the fragment and it is in this question that the greatest difficulty arises. The only range data for particles of fission product masses and initial energies are those obtained on fission products themselves. Whilst, in principle, these range data can be combined with fragment energy data obtained by time-of-flight techniques in order to establish some relationship between fragment mass A, nuclear charge Z, and initial energy E, in practice it is difficult to draw any unambiguous conclusions. The difficulty is that, for normal fission fragments, A, Z, and E are correlated, viz. Z is approximately proportional

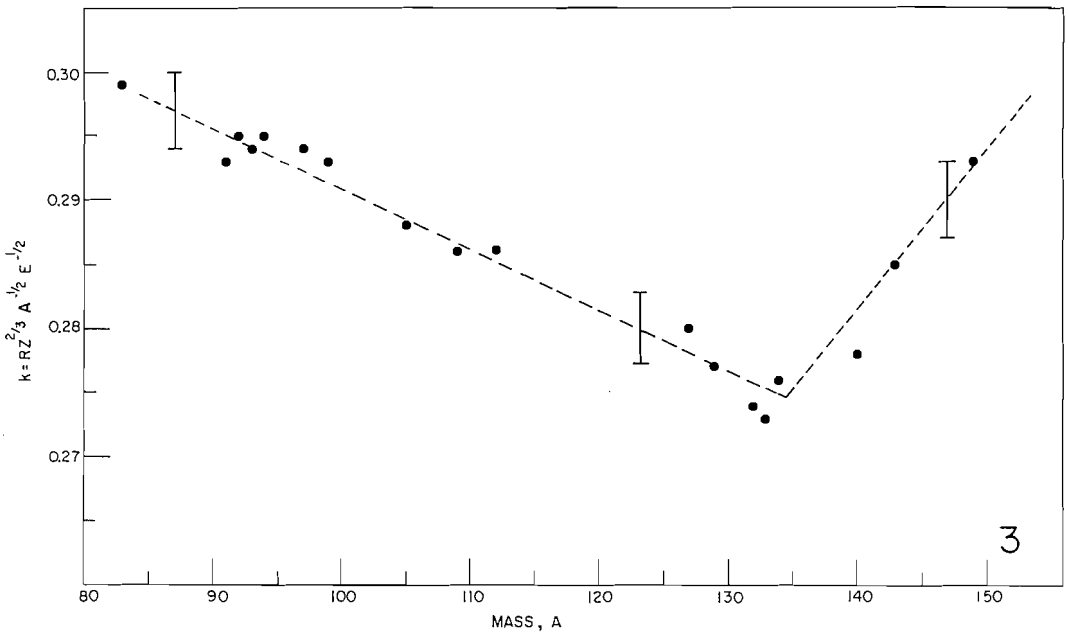
to A and E is very approximately inversely proportional to A. Another set of potentially useful data are those concerning the rate of energy loss dE/dx or rate of velocity loss dV/dx obtained by Lassen (11), Leachman and Schmitt (12), and Fulmer (13). Apart from the fact these studies involve only the "median light" and "median heavy" fragments there is also a fundamental difficulty in using them to establish a range–energy relationship, viz. the range–energy relationship changes as the fission fragments slow down. This is due to the change in effective charge as the fragment slows down, which means that the mechanism of energy loss changes from being predominantly ionization at high velocities to predominantly screened field scattering at low velocities. For the present purpose we are interested in the effect on the range when the initial energy is changed by only a rather small amount from the normal. We should also pay special attention to the effect of nuclear charge because the nuclear charge of a Cs^{136} fragment is abnormally high in relationship to its mass.

An approximate formula for the range, R, can be obtained from Bohr's theoretical discussions (14),

$$[1] \qquad R = k\frac{A^{1/2}E^{1/2}}{Z^{2/3}}$$

where k is a constant depending on the stopping material. This can be approximated to $R = E^{1/2}A^{-1/6}$ (see reference 7) by assuming Z proportional to A; however, for the present, it is preferable to retain the Z dependence. The validity of the expression can be checked to some extent by using the range data of Katcoff *et al.* (7) for fragments from Pu^{239} stopping in air and the range data of Niday (2) for U^{235} fission fragments stopping in uranium together with the fragment kinetic energy data obtained by time-of-flight techniques. We have used here the energy data obtained by Milton and Fraser (15), corrected for neutron emission as follows. Let E_p be the total prompt kinetic energy measured at prompt mass ratio A_H/A_L. The prompt kinetic energies of the separate fragments are given as usual by $E_p/(1+A_L/A_H)$ and $E_p/(1+A_H/A_L)$ but the kinetic energies of interest in range studies are those after neutron emission, which are given by



$$\left[\frac{E_p}{(1+A_L/A_H)}\right]\frac{A_L-\nu_L}{A_L} \quad \text{and} \quad \left[\frac{E_p}{(1+A_H/A_L)}\right]\frac{A_H-\nu_H}{A_H}$$

where ν_L and ν_H are the numbers of neutrons emitted by the light and heavy fragments respectively. The corresponding masses, as observed in range studies are of course $A_L-\nu_L$ and $A_H-\nu_L$. In the case of U^{235} the value of ν_L and ν_H was obtained from the data of Apalin *et al.* (16); in the Pu^{239} case the following relationships, due to Milton (17), were employed:

$$\nu_L = \frac{2.89}{2} + (A_L-100)\,0.045 \quad \text{and} \quad \nu_H = \frac{2.89}{2} + (A_H-140)\,0.067.$$

The appropriate values of Z are the most probable charges Z_p and were obtained from the empirical Z_p function of Wahl (18). We have then calculated the values of the constant k for each fragment measured and we have plotted the results in Fig. 3 (Katcoff's data (7) for fragments stopping in air) and Fig. 4 (Niday's data (2) for fragments stopping in uranium). Both figures show small but significant trends in the "constant" k, but for fragments whose masses differ by only a few units the formula is as good as the data used to check it. (The lines in Figs. 3 and 4, which have been drawn only for illustration,

have slopes of 0.12 and 0.06% per mass unit respectively. The vertical bars show deviations of $\pm 1.0\%$ in k.)

Niday (2) in the interpretation of his data for fission fragment ranges in uranium has

discussed Bohr's treatment of ranges and used the theoretical expressions as a basis for a semiempirical range formula as follows:

[2] $$R = \frac{A(V_1 - V_c)}{2.411(K + 4.762K^{5/3})}$$

where V_1 is the initial fragment velocity, V_c the velocity at which the collision diameter becomes greater than the screening parameter (see reference 2 for definition of these quantities), and $K = 1.077Z^{1/3}$. This formula was fitted to the range data and the velocity data of Stein (19). With the numerical constants given it applies to ranges in uranium. It may be noted that this expression, equation [2], approximates to the simpler expression, equation [1]. Thus V_c is small compared with V_1, the term K is small compared with the term $4.762K^{5/3}$, and since $V_1 = (2E/A)^{1/2}$ we then have

$$R = \text{const.} \frac{A^{1/2}E^{1/2}}{Z^{5/9}}.$$

Alexander and Gallagher (9) have considered the range–energy relationship for "median heavy" and "median light" fragments. Leachman and Schmitt's data (12) give the velocity (V) of these "average" fragments after passing through aluminum foils of known thickness, whilst Fulmer's data (13) give their energies (E), measured by a cesium iodide crystal, after passing through known thicknesses of various materials including aluminum. Alexander and Gallagher found that for these "average" fragments whose mass and charge, although not precisely defined, are constant, the range–energy data are fitted by either of two relationships,

[3] $$R = kV - \Delta$$

or

[4] $$R = KE^{2/3},$$

where k, K, and Δ are constants. Both these expressions fit the available data reasonably well over a rather *wide range* of energies. However, if we consider data for fragments slowed down only *slightly* we find that the range is more nearly proportional to $E^{1/2}$. This is of course implied by equation [3] since for fragments having their normal initial velocities or thereabouts the term Δ is small compared to kV; compare also equation [2]. This point is demonstrated by the data in Table III. To obtain this we have proceeded as follows. Let R_1 be the range of the unslowed fragment in aluminum and let E_1 be its initial energy. After passing through a given thickness of aluminum, t, its energy is E_2 (as given by Leachman and Schmitt (12) or by Fulmer (13)) and its range R_2 is just $R_1 - t$. We used our value for the Ba^{140} range as representative of the median heavy fragment to which Table III applies. The table lists (R_1/R_2), $(E_1/E_2)^{1/2}$, and $(E_1/E_2)^{2/3}$ and although the $E^{2/3}$ dependence gives the best over-all fit the $E^{1/2}$ dependence is better when E_2 is close to E_1. This test is of course of poor sensitivity when E_2 is close to E_1 and we present the table to illustrate the trend.

When equations [3] and [4] are applied to the ranges of fragments of different masses it is found that the "constants" Δ and K vary with mass. This is to be expected since the equations have no allowance for the effect of A and Z, but provided the variation is smooth and can be established, as was done by Alexander and Gallagher, it is possible to interpolate for K or Δ. It is interesting to note that equation [1] becomes equation [4] if we make the approximation that Z is proportional to A and A is inversely proportional to E.

(b) The Kinetic Energy Released in the Formation of Cs^{136}

We have used equation [1] to obtain the kinetic energy of the Cs^{136} fragments because (*a*) it contains terms for the Z and A dependence and (*b*) the constant of proportionality k is established by our own data on Cs^{137} and Ba^{140}. The Z dependence is important because the change from $Z = 52.6$ (Z_p for mass 136) to $Z = 55.0$ (Z for Cs^{136}) accounts for a change in range of some 2.8% (for a $1/Z^{2/3}$ dependence) out of an observed range anomaly of some 10%.

Z_p values were taken from Wahl (18). Kinetic energies were obtained from the data of Milton and Fraser (15) corrected for neutron emission as before. From the measured Cs^{137} and Ba^{140} ranges the constant k in equation [1] was obtained: the values were 0.418 and 0.419, respectively, in excellent agreement. The kinetic energy of the Cs^{136} fragment was then calculated using $k = 0.418$ and found to be 61.0 Mev. Assuming that two neutrons were emitted in the formation of this fragment, the kinetic energy of the prompt fragment (Cs^{138}) was 61.9 Mev and by conservation of momentum the total kinetic energy (for the two fragments) was 149.0 Mev. The total kinetic energy for a normal fission into prompt masses 138 and 98 is, according to Milton and Fraser, 169.8 Mev; by normal we mean having the normal charge distribution appropriate to the masses involved. The fission to produce Cs^{136}, whose Z is 55 compared with a Z_p of 52.6 for mass 136, has therefore about 21 Mev less kinetic energy than the normal fission to mass 136.

This conclusion relies on the range formula and although we have data (12, 13) to show that the energy dependence of the range is not likely to be in *serious* error we do not have any direct evidence for the relationship between range and charge or between range and mass. It is, however, encouraging to note that Niday (2), using his own range data and equation [2], calculated the kinetic energy of the Cs^{136} fragment to be 61.6 Mev, compared with our value of 61.0 Mev. It is also interesting to find that using energies from Milton and Fraser, range data from the present work and Alexander's range–energy relationship (equation [4], above) we find the kinetic energy of the Cs^{136} to be 60.5 Mev. If Niday's range data are used with this equation the result is again 60.5 Mev.

It is clear, therefore, that if we trust our present ideas on fission fragment ranges and energies we must conclude that the production of Cs^{136} involves some 21 Mev less total kinetic energy than is normal for this mass ratio. Niday's results show that the situation is similar in the production of Rb^{86}, another shielded nuclide; the deficit in total kinetic energy is again ~20 Mev. The following sections of this paper are an attempt to discuss the significance of these facts.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(c) The Kinetic Energy Deficit in the Formation of Cs^{136}

We expect the fissions which produce Cs^{136} as a primary fragment to produce less kinetic energy than normal for two reasons. (*a*) Because Cs^{136} is neutron deficient (for a fission fragment) it will be associated with events which involve greater than average neutron emission, which means greater than average internal excitation of the fragments and hence less kinetic energy for any given total energy release. (*b*) Because the charge division required to produce Cs^{136} is a long way from the most probable charge division there will be less total energy release.

We shall next attempt to make quantitative estimates of these two effects beginning with the question of neutron emission in the formation of Cs^{136}. Ideally we wish to know the distribution of neutron emission probabilities for heavy fragments in the mass range 136 to about 140. The distribution of neutron emission probabilities averaged over *all pairs* of fragments is known; Terrell (20) has shown that this distribution can be represented by a Gaussian with standard deviation $\sigma_{H+L} = 1.08$. We also know from the work of Apalin *et al.* (16) that the average numbers of neutrons from the heavy and light fragments are approximately the same at the mass ratio corresponding to Cs^{136}. To obtain the distribution for the heavy fragment alone we shall make two alternative assumptions. (*a*) Assume that the distributions for the light and heavy fragments are not correlated to each other. In this case the standard deviation for the heavy fragment is $\sigma_H = \sigma_{H+L}/\sqrt{2} = 1.08/\sqrt{2}$. (*b*) Assume that the distributions for heavy and light fragments are correlated in a positive sense, i.e. if the heavy fragment emits more than the average number of neutrons the light fragment also does; this implies that the two fragments share the available excitation energy in a constant proportion. In this case $\sigma_H = \sigma_{H+L}/2 = 1.08/2$. Using these distributions we can now calculate the probabilities, P_ν, that a fragment of mass 136 is formed from fragments of prompt mass 136, 137, 138, etc. by emission of 0, 1, 2, etc. neutrons.

In order to say how many of these mass 136 fragments so formed will actually be Cs^{136} we must know the probability P_{55} that each of the prompt mass precursors will have a nuclear charge 55. We thus need the charge distribution before neutron emission. The charge distribution after neutron emission is known; Nethaway and Wahl (21) have shown that it can be presented by a Gaussian with standard deviation σ_{obs} where $2\sigma_{obs}^2 = 1.0$. We can correct the charge distribution for neutron emission as follows. The fluctuations in the mass of the heavy fragment due to neutron emission have a standard deviation σ_H (defined above) and since for the heavy fragments $\Delta Z/\Delta A = 0.49$ this corresponds to a fluctuation in charge of $\sigma_Z = \sigma_H \times 0.49$. The corrected charge distribution will thus have a standard deviation σ_{cor} given by $\sigma_{cor}^2 = \sigma_{obs}^2 - \sigma_Z^2$ where $2\sigma_{obs}^2 = 1.0$, $\sigma_Z = \sigma_H \times 0.49$, and σ_H is either $1.08/\sqrt{2}$ or $1.08/2$ according to the alternative assumptions discussed above. It is interesting to see that the effect of neutron emission in broadening the observed charge distribution is not negligible.

From the corrected charge distribution we now obtain the probabilities P_{55} that each prompt mass, 136, 137, 138, etc., will have $Z = 55$. We have previously calculated the probabilities P_ν that each of these precursors will yield a fragment of mass 136 by emission of ν neutrons. The product $P_\nu P_{55}$ is the probability that Cs^{136} will be formed by emission of ν neutrons. The number of neutrons emitted in forming Cs^{136} is thus $\Sigma \nu P_\nu P_{55}$, the number of Cs^{136} fragments formed is $\Sigma P_\nu P_{55}$, and the average number of neutrons $\bar{\nu}_{Cs^{136}}$ emitted in forming Cs^{136} is given by

$$\bar{\nu}_{Cs^{136}} = \frac{\Sigma \nu P_\nu P_{55}}{\Sigma P_\nu P_{55}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

These calculations show that for assumption (*a*) (uncorrelated neutron emissions from light and heavy fragments) $\bar{\nu}_{Cs^{136}}$ is 2.52. The normal neutron emission from the heavy fragment at this mass ratio is 1.21 neutrons (16) and thus the *extra* neutron emission in forming Cs^{136} is $\Delta\nu_{Cs^{136}} = 2.52-1.21 = 1.31$ neutrons. If we assume that the emission of each neutron involves the expenditure of 6.7 Mev (Terrell (22)) this requires an extra 8.8 Mev of excitation and leaves, correspondingly, 8.8 Mev less kinetic energy. For assumption (*b*) (correlated neutron emission from light and heavy fragments) the value of $\bar{\nu}_{Cs^{136}}$ is 2.01 and thus $\Delta\nu_{Cs^{136}}$ is $2.01-1.21 = 0.80$. Since we have assumed correlated neutron emissions the light fragment will also emit an equal number of extra neutrons so that the extra neutron emission involved is $2\times0.80 = 1.60$ neutrons. This involves 10.7 Mev extra excitation and thus 10.7 Mev less kinetic energy.

Having estimated the deficit in kinetic energy due to extra neutron emission we must add to it the deficit in total energy release caused by unfavorable charge division in order to obtain the total deficit in kinetic energy. The deficit in total energy release can be obtained using the mass tables of Cameron (23) provided we know the prompt masses involved. We have assumed $\bar{\nu}_{Cs^{136}} = 2.0$, i.e. a prompt mass ratio of 138:98. The most probable charge division for this mass ratio is almost exactly 53:39 and gives a total energy release of 183.9 Mev. The production of cesium by a charge division of 55:37 releases 176.2 Mev, i.e. 7.7 Mev less.

Thus our estimates for the deficit in kinetic energy involved in forming Cs^{136} are, for assumption (*a*), $8.8+7.7 = 16.5$ Mev and, for assumption (*b*), $10.7+7.7 = 18.4$ Mev. The measured deficit is 21 Mev.

Both estimates are low, but the agreement is reasonable considering the assumptions involved. We derived the number of neutrons emitted in forming Cs^{136} from the average distribution of neutron emission probabilities measured for all fissions. This could be a mistake, due, for example, to the existence of the 82-neutron shell in the precursor Cs^{137}. We have also assumed that the emission of each neutron requires an energy of 6.7 Mev; again this figure is an average for all fissions and could be quite inappropriate for the particular fragments we are discussing. Finally, in estimating the deficit in total energy release by means of Cameron's mass formula we have taken a unique prompt mass ratio, 138:98 and compared two unique charge divisions 53:39 and 55:37. We should have considered suitably weighted averages over several mass ratios and charge divisions but the uncertainty regarding neutron emissions makes it impossible to do this rigorously. We could also account for the difference between our estimates and measurement if we assumed that the internal excitation of the fragments is greater when the charge division is unfavorable.

In summary, considering the uncertainties in the estimates and the reliance we have placed on the range formula, we can say that the results of this experiment are in general agreement with expectations based on our present knowledge of the fission process.

ACKNOWLEDGMENTS

The authors wish to thank Dr. J. A. Davies of A.E.C.L., for advice concerning the anodizing technique and for helpful discussions on the ranges of heavy ions. They are also very grateful to Mr. G. C. Hanna, of A.E.C.L., who has contributed much to the interpretation and discussion of the experimental results.

THE THERMAL NEUTRON FISSION YIELDS OF U^{233} [1]

D. R. Bidinosti, D. E. Irish, and R. H. Tomlinson

ABSTRACT

Using the mass spectrometer and isotope dilution technique, 27 cumulative fission yields from the thermal neutron fission of U^{233} along with 13 other fission product chains relative to each other have been determined. After normalization of the latter, values are obtained for all but seven fission decay chains whose yields are in excess of 0.5%.

INTRODUCTION

Numerous studies have been made of the thermal neutron fission yields of U^{233}. Katcoff (1) has summarized the work preceding 1958, but since this time further mass spectrometric studies by Ivanov *et al.* (2) and radiochemical studies by Santry and Yaffe (3) and Bartholomew *et al.* (4) have been published.

In the present work, fission yields have been determined for isotopes of the elements rubidium, strontium, zirconium, molybdenum, ruthenium, cesium, cerium, neodymium, and samarium. These yields, together with the relative yields of the isotopes of krypton and xenon previously published from this laboratory (5), make the most complete study of the fission yields of U^{233} that have been made up to this time.

EXPERIMENTAL

Samples of U^{233} diluted with U^{238} were irradiated as U_3O_8 in quartz capsules along with cobalt flux monitors in the NRX Chalk River reactor. The U^{238} was added as a diluant to minimize flux depression in the samples. Since the U^{238} was a separated isotope obtained from the Oak Ridge National Laboratories, the U^{235} present in the samples was found to be less than 1% of the U^{233}.

The cobalt flux monitors, weighing approximately 1.14 mg, were made of 0.13 mm diameter cobalt wire which was sealed in aluminum tubing. After irradiation the activity of the cobalt monitors was measured with a well-type ionization chamber (Harwell type T.P.A. Mk II) relative to standards provided by R. C. Hawkins of Chalk River. The evaluation of the neutron flux by this method has been previously described (6). Sample 3 was not monitored in this manner, an approximate flux value being obtained from the extent of depletion of Cs^{135} which results from neutron absorption during the irradiation. Sample 4 was irradiated in a thermal column at a flux less than 10^{11} neutron/cm^2 sec. This sample was used to obtain the relative yield of the mass 135 and 137 chains, since at this flux Xe^{135} removal is small. The irradiation data for the various samples is shown in Table I.

The number of fissions (F) in samples 1 and 2 were computed from the relation

$$F = N^{233}\frac{\hat{\sigma}_f}{\hat{\sigma}_a}(1-e^{-\hat{\sigma}_a\phi t})$$

where N^{233} is the number of U^{233} atoms in each sample, $\hat{\sigma}_f$ and $\hat{\sigma}_a$ are the effective fission and absorption cross sections of uranium as defined by Westcott (7), and ϕt the integrated flux. The effective cross sections for samples 1 and 2 have been obtained from the tables of Westcoff (7) assuming the thermal neutron cross section values of $\sigma_f = 534$ barns and $\sigma_a = 589$ barns (8), and Westcott's r values of 0.026 and 0.018 which were appropriate to the irradiation positions in the reactor. Values of 6.91×10^{17} and 1.036×10^{17} have been estimated for the number of fissions in samples 1 and 2.

Irradiation data for U^{233} samples

Sample	U^{238}/U^{233}	Weight of U_3O_8 sample (grams)	Time in reactor (days)	ϕt, neutrons/cm^2 $\times 10^{-19}$
1	13.30±0.05	0.04085	55.9	2.16
2	18.54±0.10	0.03641	30.4	4.77
3	18.54±0.10	0.02938	30.4	2
4	13.30±0.05	0.07335	309	0.23

The analysis of the fission products in the samples were carried out by means of the mass spectrometer and isotope dilution techniques as has been previously described (9). Essentially complete recovery of the fission products was obtained by dissolution of the end of the quartz ampoule, which contained the sample, with hydrogen fluoride. After most of the contents had fallen from the ampoule, the remainder was obtained by rinsing the quartz until all radioactivity had been recovered.

Relative yields of masses 85 and 87 have been obtained from rubidium fission products; 88, 89, and 90 from strontium; 91, 92, 93, 94, 95, and 96 from zirconium; 95, 97, 98, and 100 from molybdenum; and 101, 102, 104, and 106 from ruthenium. The relative yields of the six zirconium isotopes were normalized to the four molybdenum isotopes by means of the common measurement at mass 95. Two samples of zirconium fission products were analyzed at less than the Zr^{95} half-life from the time of their formation. The yield of the mass 95 chain relative to other zirconium chains was therefore obtained after decay corrections were applied to the observed mass spectrometric ratios. The molybdenum 95 was observed from the samples after the Zr^{95} had decayed. The ruthenium yields have been normalized to the molybdenum and zirconium yields by the radiochemical normalization given by Katcoff (1). The rubidium yields were normalized to the previously published yields (5) of the krypton isotopes through the mass 85 fission chain, which is common to both elements. The absolute yields of these isotopes were obtained from the previously published (5) ratio of Kr^{86} to Cs^{133} = 0.567 and the absolute yield of Cs^{133} = 5.77%, which is obtained below. The absolute yields of the three strontium isotopes were obtained by isotope dilutions.

The present work together with the previously reported mass spectrometric work from this laboratory therefore gives absolute yields of mass chains 83–90 constituting 32.04% of the light mass fission products. Yields of chains below mass 83 have been obtained by extrapolation and when added to the measured yields give a total of 32.94% yield for fragments of mass 90 or less. The yields of masses 91–117 must therefore total 67.06%. The yields of the zirconium, molybdenum, and ruthenium isotopes which had been normalized to each other along with interpolated yields at 99, 103, 105 and extrapolated yields between 107 and 117 have been forced to total 67.06%. Although there are many assumed yields in this grouping their total is only 6.94% of which the assumed yield of 4.84% for mass 99 is the major contribution. The fission yields of the light mass fragments obtained in this manner together with some of the recent literature values are given in Table II. Graphical representation of the present data is given in Fig. 1.

For the heavy mass fragments yields the following procedures were followed. The relative yields of the cesium isotopes 133 and 137 to those of the xenon isotopes 131, 132, and 134 have been previously measured in this laboratory (5). The fission products used in this previous study were formed at high fluxes and the observed Cs^{135} was highly depleted and the observed Xe^{136} equally enhanced by Xe^{135} burning. It was therefore only possible in this work to obtain the sum of the 135 and 136 yields. From sample 4

it was possible to obtain the relative yields of the 133, 135, and 137 chains since the correction for Xe^{135} burning was only 1.4%. With the relative yield of the 135 chain it was possible to correct the previously published Xe^{136} yields. The relative yields of Cs^{133} and Cs^{137} found in the fission products of the present samples were essentially the same as those previously published.

Relative yields of the 140, 142, and 144 chains were obtained from cerium isotopes and these were normalized to the relative neodymium yields of isotopes 143, 144, 145, 146, 148, and 150 by means of the isobaric 144 nuclides. The values for the relative yields of the samarium isotopes 149, 151, 152, and 154 have been taken from previously published work from this laboratory (10) since the high neutron cross sections of Sm^{149} and Sm^{151} together with the large integrated fluxes severely altered the measured yields. The sum of Sm^{149} and Sm^{150} relative to the sum of Sm^{151} and Sm^{152} did correspond to the same ratio obtained in the earlier work.

Isotope dilution of the samarium made possible the determination of the number of atoms of Sm^{149} and Sm^{150}, which, together, are the cumulative number of atoms of the mass 149 fission chain. This made possible the normalization of the relative samarium yields to those of neodymium and cesium since both of the latter elements were also isotope diluted. The yields of isotopes of xenon, cesium, cerium, neodymium, and samarium were therefore all normalized to each other.

The atom yields of mass chains 138, 139, 141, 147, and 153 were obtained by interpolation and the yields between 117 and 131 as well as those above 154 were obtained by extrapolation. The atom yields obtained in this manner for the samples 1, 2, and 3 have normalized to total 100%. The average yields obtained from these three determinations are shown in Table III along with some of the recent literature values. The maximum difference between the three values obtained for any yield in the mass region 131–150 was less than 2.0% of the average value for that yield. The yields given in Table I are shown graphically in Fig. 2.

DISCUSSION

It is difficult to assess the absolute accuracy of the yields of the light mass fragments shown in Table II. Only those values between masses 82 and 90 may be considered as absolute, the remainder being relative yields whose normalization has been chosen so that all yields total 100%. It is believed that the values should be within 4% error at each mass.

In general, the yields obtained in the present work are in very good agreement with those listed by Katcoff (1). With the exception of the ruthenium normalization, which involves about 8 fission yield per cent, the yields in this work are independently normalized from those given by Katcoff. The absolute zirconium, molybdenum, and ruthenium yields given by Katcoff are mass spectrometric relative yields by Steinberg *et al.* (11) normalized to the Steinberg radiochemical values for Sr^{89}, Zr^{95}, and Ru^{103}. With these yields and the relative krypton yields of Fleming *et al.* (5), Katcoff has drawn a smooth curve so that the total of the yields is 100%. It is to be noted that Katcoff's zirconium yields are in general higher than those reported in this work, whereas his molybdenum yields are slightly lower. The zirconium–molybdenum normalization given in the present work, through mass spectrometric relative yields determined for mass 95, should be more reliable. The absolute strontium yields, as determined by isotope dilution,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

along with the relative rubidium yields, normalized to the krypton yields, give a more complete picture of the left side of the light mass curve than was given by Katcoff.

The data as plotted in Fig. 1 indicates fine structure in the mass 90 region. Since the break from a smooth curve occurs at the mass where the zirconium yields are normalized to the strontium yields, this fine structure may not be real. It is worth noting, however, that the yield of the complementary fragment (approximately mass 142) is also high. A similar fine structure at masses 90 and 144 are observed in U^{235} fission (12) which may lend some weight to the reality of that found in this work. Bartholomew *et al.* (4) have given the ratio of Sr^{89} to Zr^{91} as 1.05:1.00. This is considerably greater than the ratio of 0.95:1.00 found in this work. Had the Bartholomew value been used to normalize the strontium and zirconium yields, the yield of mass 90 would be 15% greater than that of mass 91 and the total of the fission yields would be only 94%.

The yields of the heavy mass fragments given in Table III are considered accurate to within 3%. There are various reasons for considering this to be the case. Firstly, there was excellent correspondence between the yields obtained from the three independent measurements, no yield being as much as 2.0% different from the mean. Secondly, the methods used to normalize the yields of the isotopes of the various elements to each other were direct. Isobaric yield determinations were used to normalize the isotopes of xenon to those of cesium as well as the cerium to the neodymium. Isotope dilution was used to normalize the cesium, neodymium, and samarium element yields. Thirdly, in the cases of samples 1 and 2, whose flux had been monitored, it was possible to estimate the number of fissions and compare these values to the total number of atoms found in all heavy mass fission chains. In samples 1 and 2 the number of fissions estimated were lower than the sum of the atoms found by 4% and 2% respectively. With the possible errors in monitoring the flux and the uncertainty of the fission cross section for the neutron spectra of the irradiation positions, these differences are considered slight. The importance of estimating the number of fissions from the flux and cross section is that this serves as a check against gross errors in normalizing by isotope dilution procedures. Had the differences been greater than were found, considerably less faith would have been given to the yields in Table III.

The yields of the heavy mass fragments found in this work are smaller for the 131–139 mass region and larger for the chains of mass greater than 140 than estimated by Katcoff (1). Since the Katcoff values are largely relative mass spectrometric yields from this laboratory that have been normalized by arbitrary means, there is no inconsistency with the present data. On the other hand the values reported more recently by Yaffe (3) are much lower at every mass with significant yield as are those of Bartholomew *et al.* (4) and Ivanov (2).

There are several criteria for concluding that the present values are approximately correct. Firstly the values measured, together with a relatively small percentage of interpolated values, total 100%. It is difficult to see how this condition can be met by any of the other recent measurements. A critical test of any fission yield curve is the estimation of the total number of neutrons liberated per fission. For U^{233} this may be obtained from the relation

$$\nu = 234 - \frac{\sum \text{mass} \times \text{yield}}{\text{yield}}$$

where ν is the average number of neutrons, including delayed neutrons, liberated per fission. This relation should be valid provided that insignificant amounts of light particles

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and ternary fission products are formed. Since ν obtained from this relation is the difference between two comparable numbers it is very sensitive to small errors in the values of the yields used. With the yields given in Tables II and III a value of 2.32 is obtained which may be considered in fair agreement with the accepted value of 2.51 given by Hughes and Harvey (8).

Careful normalization of the xenon and cesium yields, and cesium ratios obtained from a thermal column irradiation, ensure the reality of the fine structure appearing at mass 134 (Fig. 2). Although it is much smaller in magnitude, it is similar to that found in the thermal neutron fission of U^{235} and other nuclides. The apparently high yield at mass 136 can in part be smoothed out by correction for delayed neutron emission.

Keepin *et al.* (13) attribute a 0.197% chain transfer to delayed neutron emission by I^{137}. Together with delayed neutron emission in the mass 138 and 139 chains (13) most of the mass 136 fine structure would be removed.

DISTRIBUTION OF NUCLEAR CHARGE IN THE PROTON-INDUCED FISSION OF Th^{232}

PART II[1]

A. KJELBERG,[2] H. TANIGUCHI,[3] AND L. YAFFE

ABSTRACT

The fractional chain yields of Ga^{72}, Br^{82}, Ag^{112}, and La^{140}, formed in the proton-induced fission of Th^{232}, have been measured at proton energies ranging between 12.8 and 82.4 Mev. The yields are compared with data previously obtained by others from uranium and thorium fission, and with predictions made by Coryell.

During the course of this investigation, the half-life of Zn^{72} was checked and found to be 46.5 ± 0.1 hours, rather than 49 hours as previously reported.

INTRODUCTION

A great deal of data has been amassed dealing with the distribution of nuclear mass in fission. Nevertheless, studies in this aspect are still going on since many of the data published are in disagreement, especially those obtained by mass spectrometry as compared with those obtained radiochemically. While the above state of affairs is semisatisfactory, that of the charge distribution in fission is as yet highly unsatisfactory. A small amount of data has been accumulated for thermal fission and very much less for higher-energy fission.

One attempts to obtain a value for the most probable charge, Z_p, by reference to various postulates regarding the mechanism in which the fission act takes place. These postulates are summarized below:

(1) Unchanged Charge Distribution (UCD)

This suggests that, by analogy to the simplest form of the liquid drop model, the charge divides in the same manner as it was present in the fissioning nucleus, i.e. the neutron-to-proton ratio is the same in the fragments as in the parent nucleus.

(2) Minimum Potential Energy (MPE)

This proposes that the fission act is preceded by a nucleonic rearrangement such that the fission will take place in a manner to minimize the sum of the binding energies, the decay energies, and the electrostatic energy of mutual repulsion (calculated from two spheres in contact).

The thermal fission data collected did not support either hypothesis, although some evidence purported to show that the former held true for higher-energy fission.

(3) The Postulate of Equal Charge Distribution (ECD)

This suggestion was empirically derived by Glendenin, Coryell, and Edwards (1). In effect, mathematically, it tells us that

$$Z_{p_L} - Z_{A_L} = Z_{p_H} - Z_{A_H}$$

where L and H refer to the heavy and light fragments, Z_p again is the most probable charge, and Z_A is the non-integral value of the most stable charge for nuclides of mass A.

[3]*Present address: Department of National Health and Welfare, Ottawa, Ontario.*

(4) The Postulate of Non-Uniform Charge Distribution (NUCD)

This theory, proposed originally by Present (2), proposes a division of charge calculated on the basis of two spherical nuclei in contact. The charge distribution in such a system is expected to be non-uniform radially due to the tendency of the charge to collect at the surface of a body and will result in the smaller fraction of an asymmetric division having a greater charge-to-mass ratio than the larger.

The latter two postulates give predictions which, at thermal energies, are reasonably concordant with the data. Inherent in the third postulate is the assumption that the same symmetrical charge distribution curve can be used to describe all fission-product chains. Indeed it has been used for all heavy fissioning nuclei.

A great deal of discussion has taken place regarding the proper value of Z_A to be used. Glendenin *et al.* (1) used a continuous Z_A function while Pappas (3) and others have suggested a Z_A function that was discontinuous at shell edges. This controversy is still raging.

Wahl (4) suggested the use of an empirical Z_p curve obtained directly from independent and cumulative yield values and the universal charge distribution curve. This showed a good degree of success for thermal fission as most data were found to lie on the empirical Z_p curve.

Unfortunately very little of the above-mentioned reasoning applies in the case of higher-energy fission. No satisfactory postulate for determining Z_p has as yet appeared. No universal charge distribution curve is known. Neutron emission soon begins to compete favorably with fission so that a variety of fissioning nuclei have to be taken into account.

The problem is made more difficult because of the paucity of high-energy independent yield data available. The paper by Pate, Foster, and Yaffe (5) summarizes those up to the beginning of 1958. Other papers of interest are those of Alexander and Coryell (6) and Stevenson *et al.* (7), which give some later references. It rapidly becomes apparent that one cannot use a single-charge distribution curve to fit all the data. Thus it is of some interest then to accumulate independent yield data to determine the best method of finding Z_p.

The paper by Pate, Foster, and Yaffe gave values for independent yields of isotopes of iodine and tellurium in the mass range 130 to 135. A study of this mass range permitted conclusions to be drawn regarding the variation with energy of the charge distribution, neglecting possible effects of mass number.

The previous work has been extended to give information about the range of mass numbers 72 to 140. Similar results at higher energies are now available for the proton-induced fission of uranium. These enable one to study the variation of charge distribution with atomic number of target and mass number of the products.

For the study of charge distribution the relatively few shielded nuclides are best suited. There are, however, also some semishielded nuclides, with a precursor of a long half-life compared with that of the daughter, and these can, under specific conditions, give valuable information. A study of the shielded nuclide Br^{82}, and the semishielded nuclides Ga^{72}, Ag^{112}, and La^{140}, in the energy interval of 15 to 85 Mev, is reported here.

EXPERIMENTAL TECHNIQUES

(a) Target and Irradiation

The target and irradiation details were essentially as reported by Pate *et al.* (5). Three thorium metal foils of about 200 mg/cm^2 superficial density were carefully aligned and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

bombarded in the internal proton beam of the McGill 82-in. synchrocyclotron. The outer foils, serving as guard foils correcting for recoil losses, were discarded and the central foil was used for chemical processing. As the calculations of fractional yields were independent of absolute yield determinations, no monitoring of the proton beam was necessary.

The energy of the bombarding protons was obtained from a known radius–energy relation (8). Corrections for energy loss for the protons in the target itself were calculated using data from Aron *et al.* (9). Bombardments were of $\frac{1}{2}$- to 1-hour duration.

(b) Chemical Processing and Measurement

In the case of the semishielded isotopes, two separations of the nuclide in question were performed from the same master solution. The first sample contained the activity formed independently and that produced by decay during bombardment and in the short time interval before the separation from the precursor in the chain. The second sample contained activity formed by decay of the precursor only and gave information on the chain yield. Complete separation of the nuclide from its precursor and accurate timing of the separations were essential.

(i) Ga^{72}

This nuclide occurs in the following fission product chain:

$$Zn^{72} \xrightarrow[46.5\ \text{hours}]{\beta^-} Ga^{72} \xrightarrow[14.1\ \text{hours}]{\beta^-} Ge^{72}\ (\text{stable}).$$

The thorium target foil was dissolved in concentrated hydrochloric acid (with SiF_6^{--} catalyst present) shortly after bombardment. The separation occurred essentially as described by Siegel and Glendenin (10), except for the elimination of $Ga_4[Fe(CN)_6]_3$ precipitation, which had been found to be unsatisfactory (11). Briefly, gallium and zinc carriers were added and gallium was separated from zinc and most fission products by twice extracting with ethyl ether from 6 *N* hydrochloric acid. The time of the second ether extraction was used as the time of separation of Ga^{72} from Zn^{72}. Gallium was further purified by a number of scavenging precipitations and repeated extractions. Care was taken in all operations to avoid any loss of Zn^{72}. Gallium carrier was added to the master solution containing the zinc, and after about 1 day a second separation was performed using the same procedure. The two samples obtained, Ga-I and Ga-II, were made to equal volume in counting vials and the activity determined using a well-type gamma scintillation counter. Since all measurements were relative, absolute disintegration rates did not have to be determined.

By tracer experiments it was found that the loss of zinc by coextraction with gallium, and the retention of gallium with zinc, were 1% or less under the experimental conditions used. Chemical yields were determined by EDTA titrations (12).

(ii) Br^{82}

This nuclide (35.9 hours) is shielded. Br^{83}, which occurs in the chain,

$$Se^{83} \xrightarrow[\beta]{\substack{67\ \text{seconds} \\ 25\ \text{minutes}}} Br^{83} \xrightarrow[2.4\ \text{hours}]{\beta^-} Kr^{83m} \xrightarrow[1.9\ \text{hours}]{\gamma} Kr^{83}\ (\text{stable}),$$

was used as an internal monitor for Br^{82} (see section "Treatment of Data"). After dissolution of the target (ice-cooled), bromine was separated about 4 hours after bombardment. This allowed complete decay of Se^{83} to Br^{83}. The chemical method used was,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with minor modifications, that of Glendenin *et al.* (13), and is based on cyclic extractions of bromine into and out of carbon tetrachloride by successive oxidation and reduction steps.

Two points were specifically checked, namely possible loss of bromine during dissolution of the target, and completeness of exchange between carrier and active bromine. In one experiment, during dissolution, air was slowly bubbled through the ice-cooled solution and any bromine possibly escaping was trapped in sulphurous acid. No evidence of bromine activity was found in the trap, as determined by measurement of the activity of the chemically separated bromine. Also in one case the initial separation was carried out in duplicate using bromine and bromate carriers, respectively, to check the exchange. The bromate portion was reduced with hydrogen sulphide and the separation was continued in a manner identical with that used with the bromide carrier. No detectable difference attributable to the different carriers was found in the resultant samples. This is similar to results obtained for iodine when the irradiated material is a metallic matrix. Therefore the direct use of bromide carrier was chosen for subsequent separations.

The final solution was slightly acidic with the activity in the form of bromide. To prevent losses due to volatilization, the solution was neutralized with a measured amount of lithium hydroxide. The chemical yields were determined by titration according to Volhard's method.

The activity was measured with a 4π β-counter (14–18). To prevent loss of bromine during preparation of the samples (heating under an infrared lamp), about 100% excess silver nitrate was added. This is the same technique used by Pate *et al.* (5). It was found that the Kr^{83m} formed by decay of Br^{83} contributed significantly to the count rate of the sample through the conversion electrons from its 0.033-Mev gamma transition.

This krypton activity could not be removed by reheating the sample. Fresh samples therefore were periodically prepared to construct the decay curve of Br^{83}. This introduced a slight uncertainty in the time for the last separation from krypton, as the drying of the sample required about 30 minutes. It was later found that the addition of silver nitrate to the bromide solution was unnecessary, provided a slight excess of lithium hydroxide was present. The lithium bromide sources were much thinner and more uniform and permitted the krypton to diffuse out of the sample completely. No loss of bromine activity was detected using this technique. The thinner sources were also better suited for accurate self-absorption corrections. Incidentally, a similar technique was found to work well for iodine samples in so far as lithium iodide continually released xenon formed by decay of iodine activity, in contrast to what was found for silver iodide (5). No measurable loss of iodine activity was found.

(iii) Ag^{112}

This nuclide occurs in the following fission product chain:

$$Pd^{112} \xrightarrow[21 \text{ hours}]{\beta^-} Ag^{112} \xrightarrow[3.2 \text{ hours}]{\beta^-} Cd^{112} \text{ (stable).}$$

The target foil was dissolved in concentrated nitric acid containing silver carrier to prevent adsorption losses of active silver (19). The separation essentially followed the procedure of Glendenin (20) and was based on silver chloride precipitations alternated by scavenging precipitations. The time of separation of Ag^{112} from Pd^{112} was taken as the time of centrifugation of the silver chloride first precipitated, about 2 minutes after precipitation. This should therefore take care of exchange between silver chloride and active silver after precipitation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The second sample was separated by adding silver carrier to the hot master solution. After 2 minutes of vigorous stirring, the silver chloride was centrifuged and further purified. The time for separation of Ag^{112} from Pd^{112} was again taken as the time at the start of centrifugation.

Tracer experiments showed that less than 2% of Pd^{112} was lost from the collected master solution by the silver chloride precipitations. Another point of concern was whether complete exchange was obtained between Ag^{112} and silver carrier added for the second silver sample, Ag-II. As this carrier was added to a solution containing some hydrochloric acid (less than 1 *N*), one inevitably had precipitation of silver chloride before complete mixing took place. Sunderman and Meinke (21) have found that the exchange between freshly precipitated inactive silver chloride and active silver tracer is very rapid at high temperatures. Their data indicate that, under the conditions used, well above 95% exchange was obtained. The reproducibility of the experiments was quite good, confirming a rapid exchange. The chemical yields were determined by titration according to Volhard's method. In a few ammoniacal samples, EDTA titrations (22) were used.

The two samples Ag-I and Ag-II were made up of equal volume and the activity determined by gamma-ray measurement. Ag^{112} and Ag^{113} have half-lives which are fairly close, 3.2 and 5.3 hours respectively. Since Ag^{113} was reputed to have no gamma ray with energy greater than 0.3 Mev, an attempt was made to measure only the high-energy gamma rays of Ag^{112}. It was soon found that a considerable portion of the Ag^{113} decay took place via high-energy gamma transitions (23). Subsequent measurements were performed using a 3 in.×3 in. NaI (Tl) crystal coupled to a 100-channel pulse-height analyzer. Gamma rays of 1.3 Mev and higher gave a pure 3.2-hour decay curve for Ag^{112}.

(iv) La^{140}

This nuclide occurs in the following fission product chain:

$$Xe^{140} \xrightarrow[16\text{ seconds}]{\beta^-} Cs^{140} \xrightarrow[66\text{ seconds}]{\beta^-} Ba^{140} \xrightarrow[12.8\text{ days}]{\beta^-} La^{140} \xrightarrow[40.2\text{ hours}]{\beta^-} Ce^{140}\text{ (stable).}$$

The target foil was dissolved in nitric acid in the presence of lanthanum and barium carriers. Barium chloride was then separated from the ice-cooled solution by addition of hydrochloric acid – ether mixture. Twice again barium carrier was added to complete the removal of Ba^{140}. The combined barium chloride precipitates were dissolved and a small precipitate formed by the addition of ammonia (caused by traces of thorium and lanthanum). This precipitate was further purified to remove barium and combined with the master solution for later separation of La-I. To the combined solutions containing barium was added lanthanum carrier, and this was stored for subsequent separation of La-II. According to Sunderman and Meinke (21) the above procedure should separate barium from lanthanum without loss.

The La-I was further purified by removal of thorium by precipitation as iodate. The solution was allowed to stand for 2 days so that short-lived activities could die away, cerium carrier was added, oxidized with bromate, and removed by precipitation as iodate. Ruthenium sulphide was next precipitated, and the final purification performed by passing a solution in 9 *N* hydrochloric acid through a Dowex-1 anion exchange column. The time of the first precipitation with ammonia in the barium solution was taken as the time of separation of La^{140} from Ba^{140} in La-I.

The samples were made to equal volume. It was found, despite the fact that no attempt had been made to effect a separation of lanthanum from the rest of the rare

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

earth elements, that a measurement of the 1.6-Mev gamma peak gave a decay curve with a 40.2-hour half-life (less than 1% long-lived contamination).

RESULTS AND DISCUSSION

(a) Decay Curves

The gallium samples Ga-I showed a very high proportion of the 4.87-hour Ga^{73}. When this was allowed to decay, the 14.1-hour Ga^{72} could be quite easily measured, although at the very lowest bombardment energies the activity of Ga^{72} was very low. A few samples showed long-lived contaminating activities, for which corrections were made. The Ga-II samples generally showed a pure 14.1-hour decay curve.

The half-life of Zn^{72} was checked and was found to be 46.5 ± 0.1 hours rather than 49.0 ± 1 hours as reported (24).

The bromine samples showed only the 35.9-hour Br^{82} and 2.4-hour Br^{83} activities, with 1.9-hour Kr^{83m} contributing in some samples, as discussed previously.

In the silver samples which were measured on the gamma spectrometer, only the 3.2-hour Ag^{112} was observed, with a trace of a long-lived tail in the Ag-I samples, presumably the 270-day Ag^{110m}.

The lanthanum samples showed a decay of 40.2 hours, the half-life of La^{140}, with the La-I samples containing less than 1% of longer-lived activities.

(b) Treatment of the Data

Using the same symbols as Pate *et al.* (5), the general case under consideration is

$$\begin{array}{l} \xrightarrow{\sigma_a} A \xrightarrow{\lambda_a} B \xrightarrow{\lambda_b} C, \\ \qquad\quad \xrightarrow{\sigma_b} B \xrightarrow{\lambda_b} C, \\ \qquad\qquad\quad \xrightarrow{\sigma_c} C. \end{array}$$

The fractional chain yield of B is then given by

$$[1] \qquad f = \frac{\sigma_b}{\sigma_a+\sigma_b+\sigma_c}$$

where it is assumed that σ_a represents the total yield of A formed independently and by decay of the short-lived precursors in the chain. These are assumed to have disintegration constants very much larger than A and will not be present at the time of chemical separation.

The rate of formation of any nuclide n is given by

$$[2] \qquad r_n = Nf\sigma_n$$

where N and f are the number of target nuclei and bombarding particle flux, respectively, and σ_n is the appropriate cross section.

The bombardment time is T, the time between the end of bombardment and the first separation of the nuclide B from its precursor A is t_1, the time between the first and second separation t_2. Generally, the disintegration rate $D_b(T,t_1)$ of B at time t_1 is

$$[3] \qquad D_b(T,t_1) = Nf\left[\sigma_a\left[\frac{\lambda_b}{\lambda_b-\lambda_a}(1-e^{-\lambda_a T})e^{-\lambda_a t_1} - \frac{\lambda_a}{\lambda_b-\lambda_a}(1-e^{-\lambda_b T})e^{-\lambda_b t_1}\right] + \sigma_b[(1-e^{-\lambda_b T})e^{-\lambda_b t_1}]\right].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

For a shielded nuclide, where A is stable, this reduces to

$$[4] \qquad D_b(T,t_1) = Nf\sigma_b(1-e^{-\lambda_b T})e^{-\lambda_b t_1}.$$

If $\lambda_a > \lambda_b$, and $t_1 \gg \ln 2/\lambda_a$, equation [3] can be transformed into

$$[5] \qquad D_b(T,t_1) = Nf(\sigma_a+\sigma_b)(1-e^{-\lambda_b T})e^{-\lambda_b t_1}\times P$$

where

$$[6] \qquad P = \frac{\lambda_a}{\lambda_a-\lambda_b}\left(1-\frac{\lambda_b}{\lambda_a}\frac{\sigma_b}{\sigma_a+\sigma_a}\right).$$

The factor P is always larger than unity and less than $\lambda_a/(\lambda_a-\lambda_b)$.

If $\lambda_a < \lambda_b$ and $t_1 < (\ln 2/\lambda_a)$, equation [3] applies and gives the amount of B formed independently and by decay from A.

A second separation of B from A at the time t_2 after the first separation will give B formed by decay from A only and will be given by

$$[7] \qquad D_b(t_2) = Nf\sigma_a(1-e^{-\lambda_a T})e^{-\lambda_a t_1}\frac{\lambda_b}{\lambda_b-\lambda_a}(e^{-\lambda_a t_2}-e^{-\lambda_b t_2}).$$

In the experiments with Ga^{72}, Ag^{112}, and La^{140}, the appropriate equations are [3] and [7]. Here, N, f, σ_a, and σ_b are unknown, the rest are experimentally determinable terms. If therefore for these determinable terms one inserts 'constants' k_i as follows, equations [3] and [7] become

$$[8] \qquad k_1 = Nf(\sigma_a k_2+\sigma_b k_3),$$

$$[9] \qquad k_4 = Nf\sigma_a k_5.$$

If equation [8] is divided by equation [9] and terms are rearranged, then

$$[10] \qquad \frac{\sigma_b}{\sigma_a} = \frac{1}{k_3}\left(\frac{k_1 k_5}{k_4}-k_2\right) = k_6.$$

Substitution in equation [10] to solve for k_6 gives

$$[11] \qquad k_6 = \frac{1}{\lambda_b-\lambda_a}\left\{\lambda_b\frac{1-e^{-\lambda_a T}}{1-e^{-\lambda_b T}}e^{(\lambda_b-\lambda_a)t_1}\left[\frac{D_b(T,t_1)}{D_b(t_2)}(e^{-\lambda_a t_2}-e^{-\lambda_b t_2})-1\right]+\lambda_a\right\}.$$

The fractional chain yield as defined in equation [1] becomes

$$[12] \qquad f = \frac{\sigma_b}{\sigma_a+\sigma_b+\sigma_c} \simeq \frac{\sigma_b}{\sigma_a+\sigma_b} = \frac{k_6}{1+k_6}$$

provided $\sigma_c \ll \sigma_a+\sigma_b$, which generally is the case in these experiments. For the worst possible case, La^{140} at the highest energy, this would give a yield about 4% too high.

It is seen that only the ratio between the disintegration rates for two samples is required, thus facilitating the simple sample preparation and counting method used.

In the case of the shielded nuclide Br^{82}, the Br^{83} was used as an internal monitor for the beam. In equations [4] and [5] the factors N and f are the same for Br^{82} and Br^{83}, but the cross sections refer to different chains. Provided a relation between the yields for the chains 82 and 83 were known, such as

$$[13] \qquad (\sigma_a+\sigma_b)_{82} = R(E)(\sigma_a+\sigma_b)_{83}$$

where $R(E)$ is an energy-dependent function, equations [4] and [5] can be used directly.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

With the previous notation, if $x = Br^{82}$, $y = Br^{83}$, and $z = Se^{83}$, then

$$[14] \qquad \frac{D_x(T, t_1)}{D_y(T,t^1)} = \frac{\sigma_x(1-e^{-\lambda_x T})e^{-\lambda_x t}}{P(\sigma_z+\sigma_y)(1-e^{-\lambda_y T})e^{-\lambda_y t^1}}$$

or

$$[15] \qquad f = \frac{\sigma_x}{R(E)(\sigma_z+\sigma_y)} = \frac{PD_x(T, t_1)(1-e^{-\lambda_y T})e^{-\lambda_y t^1}}{R(E)D_y(T, t^1)(1-e^{-\lambda_x T})e^{-\lambda_x t}}$$

where t and t^1 are times after bombardment when the activities of Br^{82} and Br^{83} were measured. According to equation [6], for this specific chain

$$[16] \qquad P = \frac{\lambda_{Se^{83}}}{\lambda_{Se^{83}}-\lambda_{Br^{83}}}\left[1-\frac{\lambda_{Br^{83}}\sigma_{Br^{83}}}{\lambda_{Se^{83}}(\sigma_{Se^{83}}+\sigma_{Br^{83}})}\right].$$

An estimate of the function $R(E)$ as defined in equation [13] can be made using the rather limited chain yield data available for thorium and uranium proton-induced fission at higher energies. For thorium, data are available only for the energy interval 8 to 21 Mev (25), except for one value at 450 Mev (26). Therefore data for uranium have been used to establish a trend, and a somewhat idealized curve for the function $R(E)$ for uranium has been established. The same curve shape has been assumed valid for thorium, with a shift in ordinate as shown in Fig. 1. The equation for $R(E)$ for

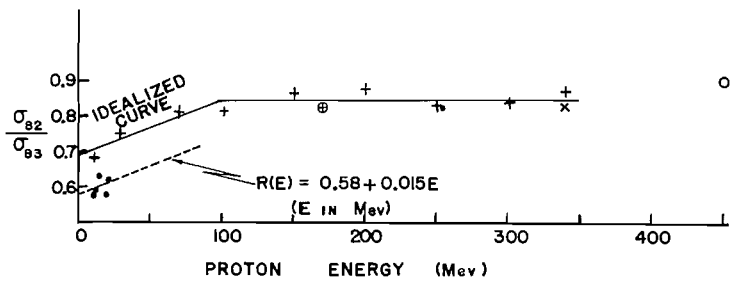

FIG. 1. Variation of the ratio of yields of Br^{82} to Br^{83} with proton-bombarding energy: ● Th fission (25), ○ Th fission (26), + U fission (7), × U fission (30), ⊕ U fission (27).

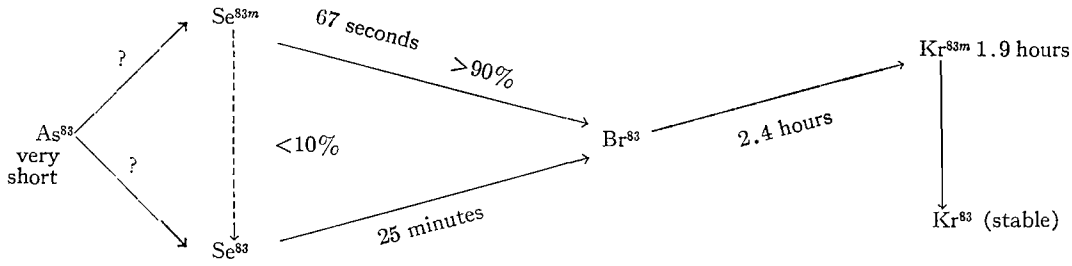
thorium deduced on this basis is

$$[15] \qquad R(E) = 0.58+0.015E$$

where E is in Mev. The energy interval of interest was 15 to 85 Mev, and here $R(E)$ varies between 0.60 and 0.71, and the absolute uncertainty in these values is probably not more than about 10%.

The factor P in equation [14] has also been estimated. Inserting values for the disintegration constants one gets



$$[16] \qquad P = 1.21\left(1-0.174\frac{\sigma_{Br^{83}}}{\sigma_{Se^{83}}+\sigma_{Br^{83}}}\right).$$

The ratio of the independent cross section of Br^{83} to that of the chain up to and including that nuclide can be estimated from Fig. 8 in reference 5 to be about 0 to 0.19 for the energy interval of concern. (Allowance has been made for the finding in the present

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

work that the abscissa scale should be shifted about 1.0 unit to the left for the mass number 83, i.e. to indicate a longer chain.) P therefore varies from 1.17 to 1.21 for the energy interval 15 to 85 Mev.

A more difficult factor to evaluate is the effect of the short-lived isomer Se^{83m}. The decay scheme for the 83-chain is

The factor P as already calculated is a maximum value, as it is assumed that all of Br^{83} is produced via Se^{83}. Any Se^{83m} in the chain produced by decay or by independent formation will make P approach 1.00.

No general conclusion as to the variation of the yields of isomers with energy can presently be drawn from the limited amount of experimental data available (26). In addition, the chain contribution from As^{83} is unknown. Therefore, a mean value for P of 1.10 for the whole energy interval was used, a factor which at most can have an error of 10%.

The fractional yields for Ga^{72}, Br^{82}, Ag^{112}, and La^{140} are given in Table I. Figure 2 gives these results together with similar data taken from reference 5. Also given are the values of $Z_A - Z$, the distance of the nuclide from the most stable charge for the mass number A (27, 28). For comparison, Fig. 3 gives similar data for uranium fission (7, 29).

TABLE I

Fractional chain yields, in per cent

Energy in Mev	12.8	17.2	18.6	25.8	36.1	39.5	40.7	55.5	82.4
Ga^{72}					2.1		3.3	6.8	13.2
Br^{82}	0.43		0.67			3.5		6.2	10.9
									12.5
Ag^{112}		1.8		3.5			5.8	7.7	15.4
								8.9	15.8
La^{140}				4.3				22	22

The errors associated with the fractional yield data are due mainly to (*a*) uncertainty in the exact proton energy at which the bombardments were made due to the radial distribution of the proton beam and (*b*) energy losses in the target itself as calculated (9). Nevertheless the beam energy was probably known to 2–5 Mev. The disintegration rates were measured relatively so that errors associated with these are small (~1%). The graphical decay curve analyses, associated extrapolation data and chemical analyses, present no difficulties and these errors are certainly less than 5%. It is believed that an uncertainty of ±10–15% on an over-all basis would cover the above and include systematic errors.

It is very difficult at this point, with the scarcity of data available in this energy range, to discuss the results theoretically. One cannot draw reasonable charge distribution curves to obtain a Z_p value at each energy as Pate, Foster, and Yaffe (5) did since the range of $Z_A - Z$ values covered here is so small.

Coryell (31) has devised an elegant method for deriving Z_p values for any nuclide formed in fission at the energies with which we are concerned. Essentially he assumes that the excited nucleus, after bombardment, will de-excite by neutron emission and,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

after neutron boil-off, fission then occurs. He then used the Z_p values obtained from U^{235} thermal fission and derives the appropriate Z_p value for another mode of fission by the following equation:

$$Z_{p_{corr}} = Z_p - \tfrac{1}{2}(Z_c - 92) + 0.21(A_c - 236) - 0.19 \times 0.12(E^* - 6.5)$$

where $Z_{p_{corr}}$ and Z_p are the most probable charges for that mass for the mode of fission being investigated and for U^{235} fission respectively.

Z_c and A_c are charge and mass of the compound nucleus, and E^* is the excitation energy calculated by means of an appropriate mass formula.

No complete application of this equation has been made to our data, but qualitatively the fit on this basis between the Pate, Foster, and Yaffe (5) data and those presented in this paper is good. Further data are now being accumulated to enable an appropriate check of this equation at these medium energies.

SEARCH FOR CORRELATIONS OF MOST PROBABLE NUCLEAR CHARGE Z_P OF PRIMARY FISSION FRAGMENTS WITH COMPOSITION AND EXCITATION ENERGY[1]

CHARLES D. CORYELL, MORTON KAPLAN,[2] AND RICHARD D. FINK[3]

ABSTRACT

The repartition of nuclear charge in fission has a narrower dispersion than almost any other property connected with the fission process. To a crude approximation, the distribution of nuclear charge between light and heavy partners L and H leads to the most probable charges $(Z_P)_L$ and $(Z_P)_H$ displaced from the respective charges Z_A of β-stability by the same amount for the two fragments (Glendenin rule of equal charge displacement ECD, 1946). The existence of shell offsets in the Z_A vs. A function for different neutron- and proton-shell regions must be considered. All available data for thermal fission $U^{235}(n_{th},F)$ are examined critically. The data show sudden offset-like drifts (fine structure) that may well be associated with shell properties of the products before the "neck" has dissolved. It is shown that these data eliminate naive equal charge displacement ECD, also an older competitive prescription of constant charge ratio CCR for the products, and an empirical Russian prescription (Apalin *et al.*, 1960). The data are also examined in the light of the postulate that fission gives minimum nuclear plus coulombic potential energy (Present 1947, Fong 1955, Swiatecki-Blann 1960), and it is shown that the present mass formulas give too much uncertainty three to four β-decays from stability to give a useful test, but that shell effects in masses must be retained. Data from charged-particle fission with energy deposit up to 40–50 Mev are in reasonable accord with the low-energy data on correcting for composition and neutron boil-off. It is concluded from experiment that Z_P is a single-valued function of A, known to about ± 0.15 unit for low-energy fission and ± 0.25 unit for medium-energy fission, and that the fine structure very probably present is an indication of intrinsic nuclear chemistry.

The early thinking on the wartime Manhattan Project about nuclear charge distribution in low-energy fission, before any yield data were available, was based on the concept (1, 2) of constant charge ratio CCR. Professor Wheeler had suggested (4) a search for positron emitters to see how wide the charge dispersion might be: the results of crude searches in the products of U^{235} (n_{th},F) were, of course, negative (5). Way and Wigner (7) postulated that the charge would distribute to give a minimum nuclear potential energy, and Present (8) postulated a minimum for the sum of nuclear potential energy plus coulombic energy (equal to final kinetic energy). Present took considerable pains to handle the coulombic term for polarizable spheres with non-uniform proton density.

The identification of shielded nuclides[4] 36-hour Br^{82}, 19-day Rb^{86}, and 13-day Cs^{136} among the fission products gave the first experimental leverage on charge distribution. The first detailed treatment of the problem (5) established the classical rule, or prescription (3, 6) of equal charge displacement ECD; namely that the nuclear charge distribution between light and heavy partners L and H leads to most probable charges Z_P displaced from stability Z_A by about the same amount for the two fragments,

$$[1] \qquad (Z_A - Z_P)_L = (Z_A - Z_P)_H.$$

[4]*A shielded nuclide is one unlikely to be formed by negatron decay since the isobar of $Z-1$ is stable, with little prospect of having a β-unstable isomer.*

There is often ambiguity about whether the prescription is meant for usage before or after prompt neutron emission. Equation [1] may be sharpened to give the most probable charge Z_P of a fission product of final mass number A_1 after the emission of ν_1 neutrons,

$$[2] \qquad Z_P(A_1) = Z_{(A_1+\nu_1)} - \tfrac{1}{2}[Z_{(A_1+\nu_1)} + Z_{(A_C-A_1-\nu_1)} - Z_C],$$

where Z_C and A_C denote the charge and mass of the compound nucleus formed by the target plus bombarding particle, and Z_A is the most stable charge associated with mass number A.

This first treatment was based on the fractional chain yields of the three species mentioned above and 9.2-hour Xe^{135}, a quasi-shielded nuclide[5] in U^{235} (n_{th},F), together with the roughly 10-fold higher fractional chain yield of Cs^{136} in Pu^{239}(n_{th},F). It was postulated that the charge dispersion curve, f_1 vs. $Z-Z_P{}^j$ would be an A-independent curve, symmetric about zero abscissa, if a reasonable j-th prescription $Z_P{}^j$ were found. The area under the curve must be unity. The very low yields found for Br^{82} and Rb^{86} showed that f_1 falls very rapidly with $|Z-Z_P|$ when this is more than 2.0. The analytical method usually employed was to invoke a rule for some $Z_P{}^j$, and test the experimental f_1 values against $Z-Z_P{}^j$ for coherence, continuity, and reasonable shape. The charge-dispersion curve for correlation of $\log f_1$ with $Z-Z_P$ seems to be approximately Gaussian when $\log f_1 > -2.0$, and linear when $\log f_1$ is < -2.0.

The CCR rule for products after the emission of ν_T total prompt neutrons (both fragments) is

$$[3] \qquad Z_P = \frac{Z_C A_1}{A_C - \nu_T}.$$

Low-energy fission data do not agree with this rule (5, 18, 19, 20), but evidence has been cited for high-energy data, beginning with the Goeckermann and Perlman study (9) of bismuth fission with 190-Mev deuterons, Bi^{209}(d_{190},F). A number of papers (10–16), mostly at Berkeley, examine this rule in the intermediate energy region (~50 Mev), and give it partial support. Pate (17) has, however, established a strong case against CCR and for ECD even up to very high-energy deposition before fission.

The postulate of minimal nuclear potential energy (7) seemed to have been eliminated by the first test (5), but question should be raised as to the validity of the mass equation[6] used in the calculations of Z_P. These were based on Bohr and Wheeler data (21). The related postulate of Present (8) was later tested by Glendenin (22); this was found to be in fair accord with the apparent empirical observation (5) of ECD except for very light or very heavy fragments, where data still are few.[7]

The ECD rule (eq. [1]) received substantial support in 1955 in two major reviews (19, 22). Pappas and Coryell (18) had raised the question of how discontinuities in Z_A

[5] *A quasi-shielded nuclide is one formed by the negatron decay of a moderately long-lived precursor of charge Z–1, whose half-life is long enough that daughter growth during irradiation and separation does not prevent estimation of the activity independently formed in fission. It may be shown that the ratio of the activity $A_2{}^d$ formed in decay to that $A_2{}^i$ formed independently is $\lambda_1 t/f_2$, where λ_1 is the disintegration constant of the precursor, t is the time to chemical separation after a very short burst of fission, and f_2 is the fractional chain yield of the quasi-shielded nuclide (Z,A).*

[6] *All available data indicate that nuclear potential energy is essentially parabolic with Z at constant A, with pairing terms p.t. for oddness or evenness of Z and N, namely,*

$$M(Z,A) = M(Z_A,A) + (B_A/2)(Z_A - Z)^2 + \text{p.t.}$$

Numerous evaluations of B_A and p.t. are available; see especially Coryell (23, 24), Fix (25), Green (26), Levy (27), and Cameron (28).

[7] *The senior author has weighted the ECD (equal charge displacement) postulate more heavily than that of minimum potential energy MPE, although both were given similar weight in an earlier review (22).*

caused by the crossing of neutron- and proton-shell edges[8] should effect Z_P. If ECD (eq. [1]) holds strictly, then Z_P is set solely by properties of the primary products. One would expect by eq. [1] frequent discontinuities in Z_P as A increases, whenever the composition of the fragment crosses a neutron- or proton-shell number, the discontinuities being half of those given in footnote 8. Correspondingly, discontinuities should occur when the complementary fragment crosses any shell number. Dispersion in neutron emission should change the discontinuities from breaks to sudden steep drifts in the Z_P vs. composition curve. Note, however, that the point in Z_P vs. composition diagrams where steep drifts occur for shell crossings in the complementary fragment are dependent on Z_C and A_C of the fissioning nucleus.

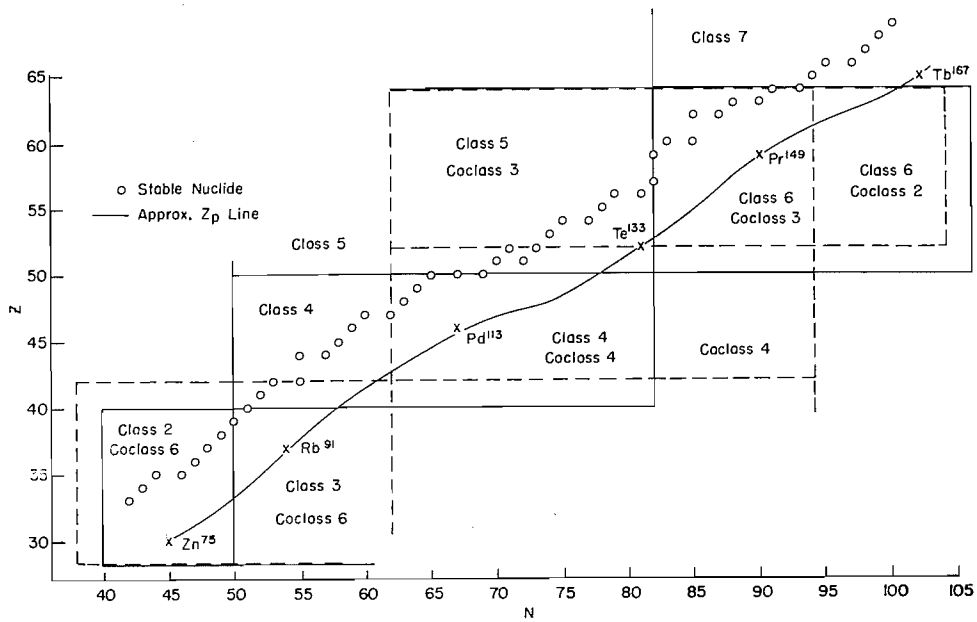

FIG. 1. Designation for $U^{235}(n,F)$ of shell classes for fragment and complement.

Figure 1 is a graphical breakdown of the shell classes of the pairs of fragments in the products of fission of U^{236} (as from thermal neutron fission of U^{235} at excitation energy $E^* = 6.5$ Mev) before neutron emission. The various rectangles designate classes: solid lines for the nucleus in question, broken lines for the complement (coclasses). The shell crossings designated are from the successive lines in Levy's master tables (27),[9] but the chart covers principally regions of interest in fission chemistry. Going to larger Z_C raises the ordinates of the Z-coclass lines; similarly going to larger $N_C = A_C - Z_C$ raises the abscissas of the N-coclass lines.

For reference, the stable odd-A nuclides ($Z_{stable} = Z_A \pm 0.5$) are shown, together with a rough idea of Z_P given as the sinuous curve. This Z_P line is taken from Glendenin (5) to avoid shell-edge prejudice.

[8]*It is well established (18, 23) that Z_A is essentially linear with A in a given nucleon-shell region, with slope ~0.4, but that Z_A undergoes upward discontinuity on crossing a neutron-shell edge, and downward discontinuity on crossing a proton-shell edge, the discontinuities ΔZ for $N = 50$, $N = 82$, and $Z = 50$ being (23) +0.9, +1.4, and −1.3 charge units, respectively.*

[9]*Levy's shell class distinctions (27) can be represented in the array: cl.1 ($N = 40$) cl.2 ($N = 50$) cl.3 ($Z = 40$) cl.4 ($Z = 50$) cl.5 ($N = 82$) cl.6 ($Z = 64$) cl.7 ($Z = 82$, $N = 126$) cl.8 ($N = 140$) cl 9. The numbers in parentheses are the shell crossings dividing the classes.*

Pappas (18) tried to determine how shell-crossings affect Z_P with few data to guide him (see Coryell (29) for criticism of paucity of data). He made the *ad hoc* decision, now not considered necessary, that the shell class and coclass that are to be used are those at the end of the decay chains. Steinberg and Glendenin (20) assumed that ECD was valid with a drift over three to four units of A in going from one shell-class set to the next.

It was established fairly well (18, 19, 20) that the data from thermal neutron fission of U^{235}, U^{233}, and Pu^{239} were compatible on a plot of $\log f_1$ vs. $Z-Z_P$ when Z_P is computed by eq. [1], assuming ECD. Similar analyses of the fission of U^{238} and Th^{232} with 14-Mev deuterons (30) and of U^{235} with 14-Mev deuterons and 24-Mev alpha particles (31) showed that fission with excitation energy near 20 Mev gave compatible results on the assumption of reasonable values for neutron emission ν_1.

In 1958 Wahl (32) made a very significant contribution. He used data for 28 fission products in the reaction U^{235} (n_{th},F) to show that one can reverse the conventional procedure of using consistency in the dispersion of f_1 with $Z-Z_P$ to check $Z_P{}^1$ values. He proposed using the Glendenin (5) charge-dispersion curve to obtain $Z-Z_P$ values from experimental f_1 values. This method established empirical Z_P values. He found a continuous but somewhat winding curve in a plot of Z_P vs. A and that the $(Z_P)_L$ values and the $(Z_P)_H$ values intercompare well using average neutron emission $\bar{\nu} = 2.5$. Until Wahl's paper, no firm values existed for cumulative fractional chain yields f_c for very early members of chains, obtained for example by gas sweeping of krypton and xenon (2), or by rapid quantitative precipitation of short-lived halogens, with yields determined by radiochemical assay of long-lived descendants. Yield values for such species, which will be called "swept-out" nuclides, would give the first measurements[10] on the left side of the curve for $\log f_1$ vs. $Z-Z_P$. Wahl (32) obtained results for krypton isotopes up to 3-second Kr^{92} and xenon isotopes up to 1-second Xe^{143} and ~1-second Xe^{141}. This study provided the first examples of even-Z species except for Xe^{135}, and the first even-Z – even-N species. It failed to show evidence for the odd–even sawtooth in observed fission yields that Herrington (33) predicted by simple evaporation theory from an assumed primordial yield-mass curve smooth in A. Further data have been obtained by Wahl and co-workers on other krypton and xenon isotopes (34), strontium, barium, and cerium isotopes (35, 36), and other species of odd Z, including (37) the three niobium isotopes[11] of mass number 96, 97, and 98.

This new body of data (32, 34–37) has led to a reanalysis of the charge dispersion curve (38). Figure 2 shows the Glendenin curve (5), labelled GCE, together with three Gaussian curves

$$y_1 = \frac{1}{\sqrt{\pi C}} e^{-(Z-Z_P)^2/C} \qquad [4]$$

with the parameter C for variance as 0.8, 1.0, and 1.43. It is seen that the Glendenin curve is very close to the Gaussian of $C = 1.43$ for $|Z-Z_P| < 1.8$. At high values of $|Z-Z_P|$ it is found that the curve is exponential,

$$\frac{d \log_{10} f_1}{d(Z-Z_P)} \cong \pm 3.2 \qquad \text{for } (|Z-Z_P| > 2.2), \qquad [5]$$

as far as experimental calibrations exist.[12] Wahl reports (38) that most data for chains

[10] *The change from observed f_c to computed f_i is obvious (32).*

[11] *Considerations of isomerism indicate that in niobium only the yields of high-spin isomers of even A are being measured.*

[12] *The curve is calibrated at present out to about $Z-Z_P = 3.2$, and extrapolations to ~4 are made.*

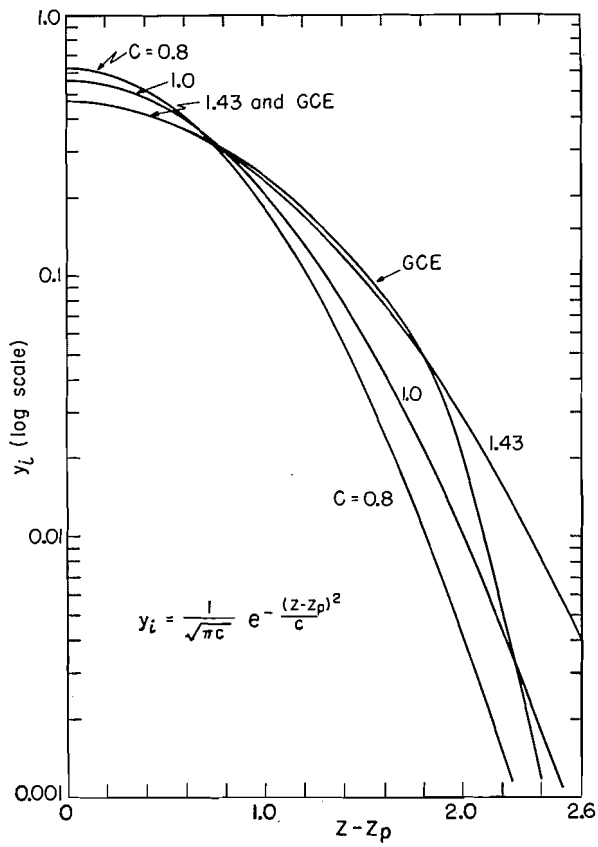

FIG. 2. Charge dispersion.

with several f_1 points at different Z values follow Gaussians with $0.8 < C < 1.0$. He now uses this type of curve (38) to measure Z_P by the 1958 method (32); the present paper is based on this method (32) but we still use the Glendenin curve (5, 32), one which gives a somewhat larger scatter in Z_P values.

It will be of interest to search for correlation of Z_P with Z_A, particularly with reference to fine structure (breaks or sudden drifts) in the former data, which are treated as a continuous curve in Z_P vs. A co-ordinates for a given type of fission. The type of fission chosen is $U^{235}(n_{th},F)$, the one best studied and most accessible. It may be noted that in the fission-product region, the average slope dZ_A/dA in a given shell region is 0.37_5 (23, 24, 25). It is clear that dZ_P/dA must be about the same. It is therefore useful to present all Z_A and Z_P data as $Z_A - 0.4A$ and $Z_P - 0.4A$ when plotting against A as abscissa as this function removes most of the drift present. This procedure will be used throughout this paper.

It is useful to check various prescriptions against the fairly comprehensive body of data for f_1 values for shielded, quasi-shielded, and swept-out nuclides formed in the reaction $U^{235}(n_{th},F)$. A summary of these data is presented in Table I; half-lives are from Katcoff (39) and most of the yield data are given in the Croall review (40), except that values obtained by difference (35, 36) are not included.

In Fig. 3 is a test by which eq. [3] for CCR fails for $U^{235}(n_{th},F)$. The ordinate is

*Cumulative yield (37).

$Z-0.4A$, the upper set of tilted lines corresponding to different shell regions of Z_A, with N- and Z-shell numbers indicated. The lower line is the prediction of eq. [3], the crosses marking computed points for products after neutron emission.[13] The double circle at $Z_P = 46.0$, $A = 116.75$ represents the requirement in exactly symmetric fission that $Z_P = Z_C/2$.

We prefer to treat the experimental data in three categories:

(i) Early members of chains (here only krypton and xenon isotopes) where $Z-Z_P$ is negative: these come from fissions where the fragment of interest has had very low neutron boil-off.

(ii) Low-yield species ($f_i < 0.1$ or $Z-Z_P > 1.5$): these come from fissions of rather high neutron boil-off.

(iii) High-yield species ($f_i > 0.1$), where the Glendenin curve is less precise in setting $Z-Z_P$.

There is no evidence, however, in Fig. 3 that the data from any of these three classes diverge from the others.

[13]*The average value of 1.25 is taken for ν_1 throughout this paper for $U^{235}(n_{th},F)$, ignoring for the present the Whetstone–Vladimirskii effect (42, 43, 44), namely that ν_A is a double sawtooth function of A. Incorporation of this effect would make little difference.*

The remarkable part of Fig. 3 is that it reveals that the large body of data on $Z_P-0.4A$ from Table I represents a coherent body, in that checks agree well except at $A \cong 141$. There is a sharp drift up in Z_P (or $Z_P-0.4A$) between $A = 90$ and 93, and a sudden drop between Kr^{95} and Nb^{96}, Kr^{97}, and Nb^{97}, the latter two species not being affected by isomerism (see footnote 11). Another sharp fall is apparent between the Kennett and Thode data (45) for I^{128} and I^{130} (reflected also in $U^{233}(n_{th},F)$ and $Pu^{239}(n_{th},F)$). The blurred rise near $A = 141$ has been mentioned, and problems with $A = 141$ are discussed elsewhere (35).

The present authors consider that the data, as presented here, show that

(i) *Z_P is a single-valued function of A.*

(ii) *Z_P is known to about ± 0.15 unit.*[14]

(iii) *Z_P shows fine structure* (an indication of nuclear chemistry).

In Fig. 4 there is provided a test for a recent Russian prescription, given casually by Apalin *et al.* (44). This prescription is based on eq. [3] for CCR after neutron boil-off with a correction term vanishing for symmetric fission; it is

$$[6] \qquad (Z_P)_L = \frac{A_L}{A_H} Z_{P_H} + 5.90 - 0.05A_L.$$

This can be expressed in explicit form as

$$[7a] \qquad (Z_P)_L = 5.90 + 0.319A_L + 0.000214A_L^2,$$

$$[7b] \qquad (Z_P)_H = 0.419A_H - 0.000214A_H^2.$$

It is seen that the curve in the lower part of Fig. 4 for $Z_P-0.4A$ (Russian Z_P), based on crosses for computed points, fits the experimental data better than does CCR (Fig. 3). The prescription carries no provision for the fine structure which we admire. The average deviation would be lower if the coefficient of A_L in the last term of eq. [6] were taken near 0.033.

Figure 5 presents a test of an unpublished empirical (essentially graphical) prescription of Wahl (38). This prescription is based on a composite of data (32, 38, 40) for thermal neutron fission (U^{235}, U^{233}, Pu^{239}) and a few points (38) for spontaneous fission (Cm^{244}, Cf^{252}). The fit to the data is excellent; it is even better if the improved Wahl Z_P values (see footnote 14) are taken. It would seem, however, that the Wahl prescription is characteristic of the fission process, not of the composition of the products, as is indicated in Fig. 6, where there is given a schematic representation of the prescription as applied to $U^{235}(n_{th},F)$, $U^{235}(\alpha_{40},F)$, and Cf^{252}(spont. F), characterized by their compound nuclei and excitation energy E^*.

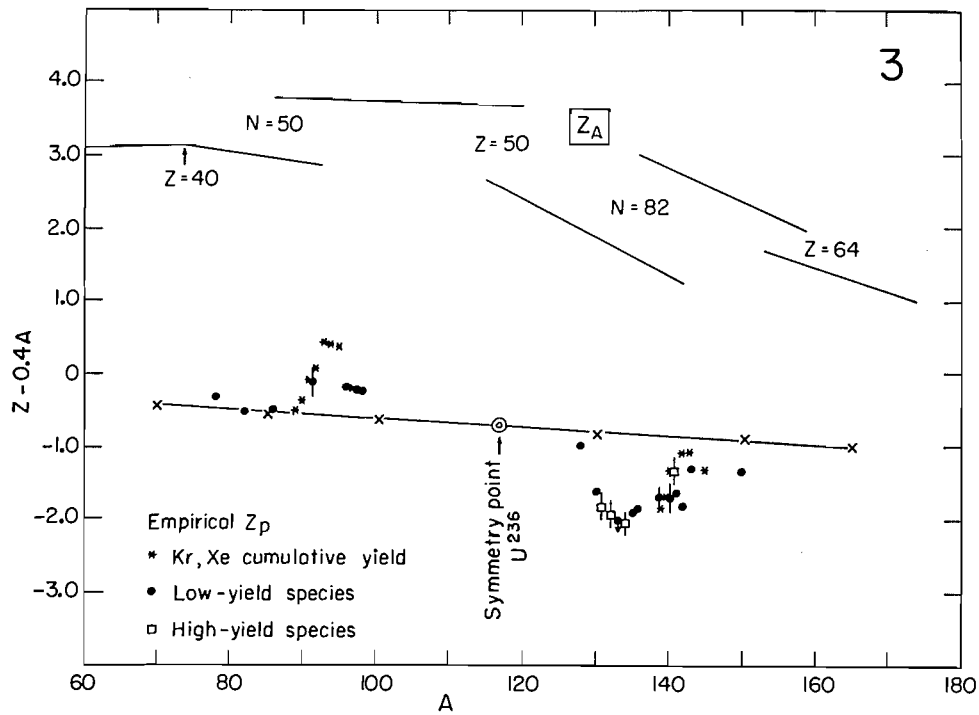

Figure 7 represents a treatment of the same data in the framework of the classical ECD approach of eqs. [1] and [2], with full recognition of shell effects (18, 19, 23, 24). Near-vertical broken lines represent the divisions between different shell regions for the Z and A values of the nucleus in question and its complement, denoted as "comp." The plot refers to $U^{235}(n_{th},F)$ with (see footnote 13) $\nu_T = 2.5$, so the sum of the charges is 92 and the sum of the A values is 233.5. Going to compound nuclides of higher Z_C or $N_C - \nu_T$ for the fission source leads to a rightward motion of the proton complementary lines or a rightward motion of the neutron complementary lines.

The Pappas prescription (18, 19) that the shell structure at the end of decay chain

[14]*Professor Wahl reports (38) that the new empirical Z_P curve is within 0.1 charge unit of the sums of the uncertainties (in the calculated Z_P values) due to experimental error and to the charge distribution curve ($C=0.8$ to 1.0) for greater than 80% of the points (Wahl 1960 method of determining Z_P).*

sets the Z_A from which Z_P is calculated by ECD from eq. [1] or [2] would require that neutron-shell breaks in the data occur to the right of the offsets shown in the Z_P lines, not inconsistent with the observations. It also requires neutron breaks for shell in the complement to occur to the left. Opposite effects are required for proton shell-breaks in species and complement. Difficulties are seen at $A = 96$, ~129, and 150. If on the other hand it be considered, as del Marmol and Coryell suggest (31), that occurrence of neutron or proton shells is "sensed" by the two nascent nuclei before contact is lost, underestimation of neutrons and protons should occur by the number of each coming from the neck. Thus breaks should be expected to occur to the right of the offsets shown in the Z_P lines for both neutron and proton shells and to the left for the complements. This new prescription is not inconsistent with the breaks at 91, 95, and 141, but has trouble with I^{128} and probably Pm^{150}. The identification of "breaks" is considered more important than the verification of eq. [1] or [2] (ECD) for predicting absolute values of Z_P.

Regarding the broken Z_P lines in the lower part of Fig. 7 (related to the breaks in the Z_A lines in the upper part), it should be noted that the breaks for the different shell crossings are comparable in magnitude to the sudden drifts in the experimental Z_P values shown as points. The approach of Fig. 7 differs greatly from that of Fig. 5, in that it presumes that all of the fine structure comes from composition of the fission products. Little change in the breaks would come from considering the effects of the sawtooth ν_1 function (see footnote 13, Whetstone–Vladimirskii effect (42, 43, 44)).

It should be pointed out also that the general closeness of the experimental Z_P points to the various segments of Z_P lines predicted by ECD, as shown in Fig. 7, is an empirical justification for the Glendenin ECD rule.[15] The rule is totally *ad hoc*, however, with no theoretical justification, as Halperin (6) also decides.

Until recently there has been no convenient and attractive way to intercompare $Z_P(A)$ among various types of fission differing in Z_C, A_C, and E^* or ν_T. The regularities in Z_A, and the approximate parallel relation between Z_P and Z_A (Fig. 7), show an easy way to handle changes in Z_C and A_C. Recalling (23, 24, 25) that

$$[8] \qquad \frac{dZ_A}{dA} = \frac{dZ_A}{d\nu} \cong 0.38$$

it can be shown that eq. [2] transforms to

$$[9] \qquad Z_P(A) = \tfrac{1}{2}[Z_A + 0.38\nu_1 - Z_{(A_C - A - \nu_T)} - 0.38\nu_2 + Z_C].$$

Using the approximation (see footnote 13)

$$[10] \qquad \nu_1 = \nu_T - \nu_2 \cong \nu_2$$

we find that

$$[11] \qquad Z_P(A) = \tfrac{1}{2}[Z_C + Z_A - Z_{(A_C - A - \nu_T)}].$$

Consider as a reference type of fission that of $U^{235}(n_{th},F)$, for which $A_C = 236$, $Z_C = 92$, and $\nu_T = 2.5$, for which eq. [11] is

$$[12] \qquad Z_P(A)^{ref} = \tfrac{1}{2}[92 + Z_A - Z_{(233.5-A)}].$$

By subtracting eq. [12] from eq. [11], it is seen that the difference $\Delta Z_P(A)$ is

$$[13a] \qquad \Delta Z_P(A) = Z_P(A) - Z_P(A)^{ref} = \tfrac{1}{2}(Z_C - 92) - \tfrac{1}{2}[Z_{(A_C - A - \nu_T)} - Z_{(233.5-A)}].$$

[15] *This means that the drifts are not very far from the breaks in predicted Z_P lines.*

The effect of increasing energy deposit on the type of fission is assumed to be only that of increasing the total neutron boil-off, in the amount

$$[14] \qquad \frac{d\nu_T}{dE} = 0.12\ \text{Mev}^{-1},$$

as shown by Leachman (46, 53) for spontaneous fission and for neutron-induced fission in the energy region 0 to 14 Mev. Thus the last term on the right of eq. [13] can be expressed as

$$[15] \qquad [Z_{(A_C-A-\nu_T)} - Z_{(233.5-A)}] = 0.38(A_C-236) - 0.38(\nu_T-2.5).$$

Thus eq. [13] for the shift $\Delta Z_P(A)$ for a given chain A by changing A_C, Z_C, and ν_T from that for the reference state of $U^{235}(n_{th},F)$ becomes[16]

$$[16] \qquad \Delta Z_P(A) = \tfrac{1}{2}(Z_C-92) - 0.19(A_C-236) + 0.19(\nu_T-2.5).$$

Equation [16] can be used to correct a $Z_P(A)$ value for a given type of fission (determined by the Wahl 1958 method (see footnote 14) (32)) to the reference state $U^{235}(n_{th},F)$:

$$[13b] \qquad Z_P{}^{corr} = Z_P(A) - \Delta Z_P(A).$$

The ΔZ_P values are independent of A and can be computed at once for a given Z_C, A_C, and E^* (or given target and projectile energy).

In Fig. 8 are shown $Z_P{}^{corr}$ values for various shielded and quasi-shielded nuclides from typical studies of medium-energy fission: del Marmol (31), $U^{235}(d_{14},F)$ and $U^{235}(\alpha_{25},F)$; Chu (14), $U^{235}(\alpha_{46},F)$; and Yellin (47), $U^{235}(d_{14},F)$ for 3.2-hour Ag^{112}. In our experience, most other recent data with energy deposit of 20 to 60 Mev fall in the same general region. These data are presented in a framework like that of Fig. 7, and the general course of the $U^{235}(n_{th},F)$ data are presented as a cross-hatched background.

It is concluded from Fig. 8 that $Z_P{}^{corr}$ values for medium-energy fission (with E^* up to about 50 Mev) show a somewhat greater scatter than for low-energy fission (E^* up to 7 Mev), but that they lie near the low-energy fission $Z_P{}^{corr}$ curve. It seems that there is a filling in of the Z_P hollow near $A = 135$. For further specific results on 13-day Cs^{136}, see Appendix I.

It has been proposed by Swiatecki (48, 49) that earlier theories of Way and Wigner (7), Present (8), and Fong (50) hold considerable promise, i.e., that the most probable division of charge in fission is that which leads to a minimum in the sum of nuclear potential energy and coulombic energy. This corresponds to maximizing the excitation energy and, in a rough way, the level density (50). The contribution of the coulombic term is less important than that of the nuclear potential energy.

Blann (49) has shown the comparison between Z_P data for $U^{235}(n_{th},F)$ and predictions of CCR by eq. [3], ECD by eq. [1], and the Swiatecki (48) prescription, a simplification of that of Present (8). The energy to be minimized for each mass split can be visualized roughly as the sum of the two steep concave-up energy parabolas (see footnote 6) for the light and heavy fragments, the first centered on $(Z_A)_L$, the second on $(Z_A)_H$, plus an inverted flat parabola for the coulombic term centered on $Z_C/2$. The net result, except for small pairing terms p.t. and shell offsets (23–29), is essentially a parabola, whose

[16] *Dr. J. P. Butler has pointed out that there is a fairly steady rise in ν_T for various fissioning species with A (46), so that the coefficient of the second term on the right should be raised to about 0.21 with ν_T as the nominal value of $0.12(E^*-6.5)$.*

minimum (called Z_0) is hopefully to be identified as Z_P. Swiatecki and Blann (49) computed Z_P by this prescription for maximum excitation energy. They selected the Grummitt and Milton (51) continuous Z_A values and basic B_A values of Green (26) before shell corrections were evaluated (a so-called liquid-drop formula). This odd prescription for Z_P (on graphical correlation with experiment) fits the low-energy data fairly well and agrees rather well with ECD. Part of its promise lies in the fact that it represents fairly well the Z_P function for the high-energy fission of gold with 112-Mev C^{12} ions, Au^{197} ($C_{112}{}^{12}$,F).

The dropping of shell terms from the mass equation (nuclear potential energy) removes all chance of representing fine structure in the Z_P vs. A correlation in low-energy fission. The apparent filling in Fig. 8 of the hollow at $A = 135$ with medium-energy fission (E^* of 20 to 40 Mev) may reflect the decrease in shell effects with increasing excitation, culminating in the Blann success (49) in the 110-Mev region.

The basic idea, however, of maximum excitation computed with shell terms included would seem to be an attractive one for further study. We have explored this in Fig. 9 using the tabulated Levy (27) mass data. Fine structure is present to some degree, principally in the region of highly asymmetric fission, in the opposite direction from the Present prediction (8). In Fig. 10 is given the same type of calculation using the tabulations of the Cameron mass equation (28). The fine structure is quite different. This shows that randomly chosen mass equations differ greatly in predictions of nuclear mass in regions about three to four β-decays from stability.

The parabolas in Fig. 11 emphasize differences between two popular, readily accessible

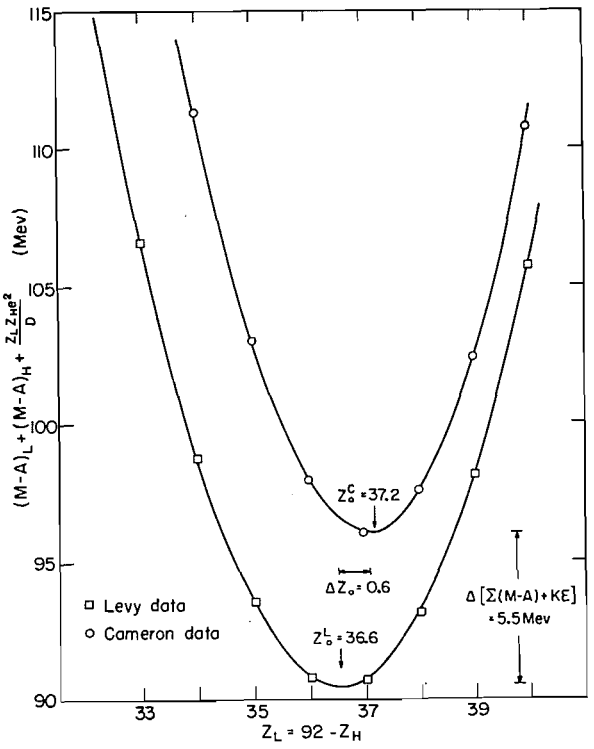

FIG. 11. Swiatecki prescription. Nuclear P.E.+(coulombic P.E. = K.E.) is at minimum for $Z = Z_P$, called Z_0. Prescription largely dependent on mass formula used. Total energy for split $A_L = 93$, $A_H = 143$ (no shell crossing).

mass tabulations for the mass split $A_L = 93$, $A_H = 143$, as from $U^{235}(n_{th},F)$ before prompt neutron emission. This split was chosen to avoid shell effects in the Z_L region near known Z_P. The energy function we wish to minimize is plotted in Fig. 11 against the charge Z_L of the light fragment,

$$[17] \qquad F(P.E.+K.E.) = (M-A)_L+(M-A)_H+\frac{Z_L(92-Z_L)e^2}{D}$$

where value of D is an internuclear distance (53) parameter, larger than $r_0(A_L^{1/3}+A_H^{1/3})$ by about 15% to account for the experimental kinetic energy of 167 Mev (46, 53).

The upper parabolic curve in Fig. 11 is the curve for the Cameron masses (28), with a minimum for eq. [17] at $Z_0 = 37.2$ at about 96 Mev. The lower parabola is that for the Levy masses (27), with a minimum at $Z_0 = 36.6$ at about 90.5 Mev. These two modern mass formulas give results for Z_0 (which we would like to call Z_P) differing by 0.6 charge unit, far beyond the uncertainty of the experimental data. The energy difference between the minima (5.5 Mev) is equally surprising.

It may not be too much to hope that the experimental course of Z_P as a function of A may be used to derive a more reliable mass formula. It will be interesting to see how firm the evidence is for fine structure, and how this relates to mass and nuclear shells, if the principle of maximum excitation (48) is established as a good approximation. These prospects make fission radiochemistry exciting.

ACKNOWLEDGMENTS

We are indeed grateful to Professor Arthur C. Wahl of the Washington University of St. Louis for providing us with the latest information from his group, for advance information on his correlation of Z_P, and for many fruitful discussions. The senior author wishes to express his gratification with the sessions on fission at the very constructive Chalk River Conference on Nuclear Chemistry and Radiochemistry. It was a great help that Atomic Energy of Canada, Ltd., furnished photo-offset preprints of the figures for this paper.

Many other people have given substantial help, especially Drs. John M. Alexander, Glen E. Gordon, Lawrence E. Glendenin, Ellis P. Steinberg, Leo Yaffe, and Nathan Sugarman. We also thank Mrs. Virginia Ekman, Grace Rowe, and Norma Osborne for indispensable aid.

APPENDIX I

Intercomparison of $Z_P(A)$ Values: Z_P^{corr} for 13-day Cs^{136}

Reference to Fig. 8 shows considerable drift in Z_P^{corr}, filling in the hollow around $A = 135$ on moving the type of fission into the medium-energy region. It is interesting to explore this effect, and it is useful to provide the reader with explicit examples of the method of calculating Z_P^{corr} from Z_P values derived either by Wahl's 1958 or 1960 formulas, (32) or (38).

We anticipate the improvement of eq. [16] by the suggestion (see footnote 16) of Butler, and offer the prescription

$$[18] \qquad Z_P^{corr} = Z_P-\tfrac{1}{2}(Z_C-92)+0.21(A_C-236)-0.19\times 0.12(E^*-6.5).$$

We choose $A = 136$, where coherence among the data is poor, but where numerous data on f_I for Cs^{136} are to be found. Typical values are given in Table II.

TABLE II

Data for fractional chain yield and Z_P for Cs^{136} in various fission types

Type	E^*(Mev)	Fractional chain yield	$Z-Z_P$	Z_P^{corr}	$Z_P^{corr}-0.4A$	Reference
$U^{235}(n_{th},F)$	6.5	$1.\times10^{-2}$	2.42	52.58	−1.82	32
$U^{233}(n_{th},F)$	6.76	0.0181	2.02	52.55	−1.85	39
Cm^{242}(sp.F)	0	0.123	1.50	52.80	−1.60	20
$Pu^{239}(n_{th},F)$	6.38	0.0166	2.03	52.81	−1.59	39
Cf^{252}(sp.F)	0	5.69×10^{-3}	2.18	52.92	−1.48	55
$U^{235}(n_{14},F)$	20.5	0.040	1.87	52.97	−1.43	54
$Th^{232}(d_{13.6},F)$	21.93	0.033	1.91	52.99	−1.41	30
$U^{238}(\alpha_{24},F)$	19.00	0.0292	1.93	53.03	−1.37	14
$U^{235}(\alpha_{24},F)$	18.76	0.2847	0.86	53.48	−0.98	14
$U^{235}(\alpha_{24},F)$	18.76	0.084	1.60	52.74	−1.66	31
$U^{238}(d_{14},F)$	22.10	0.037	1.88	53.09	−1.31	30
$U^{235}(\alpha_{45.7},F)$	40.50	0.4435	0.28	53.55	−0.85	14

The first column gives the type of fission; subscripts for the projectiles denote the projectile energy in million electron volts. The second column gives the excitation energy based on the nuclear masses of Everling *et al.* (52). The third column gives values of the fractional chain yield found by workers cited in the last column. The $Z-Z_P$ values of the fourth column were found by using the Glendenin curve given in Fig. 2, or taken from the literature (5, 19, 20, 32), reading the $Z-Z_P$ abscissa corresponding to the observed $\log f_1$ ordinate. (The Wahl 1960 method (38) should be better (see footnote 14).) The fifth column gives Z_P^{corr}, using the revised eq. [18], which differs but slightly from the eq. [16] used for Fig. 8. The sixth column is $Z_P^{corr}-0.4A$, column five diminished by 54.4, giving values like those plotted in Figs. 3–10.

The data in Table II have been presented in order of increasing Z_P or $Z_P-0.4A$. The low-energy fission data are in fair agreement, although the values seem to rise about 0.3 unit with A going up 16 units to Cf^{252} (spont. F). There is a discrepancy of factor 3.4 between f_1 data of Chu (14) and del Marmol (31) for Cs^{136} in $U^{235}(\alpha_{24},F)$ leading to a difference in Z_P of 0.7. It is hard to see a dependence of A in the medium-energy region, but there may be a dependence on E^*.

As is noted in Fig. 8, the Z_P^{corr} values for say Br^{82} scatter far less than the values around $A = 136$.

APPENDIX II

An Alternative E^* Treatment of ΔZ_P

An alternative to eq. [16] was outlined by Kaplan (56), using an empirical calibration for the effect of excitation energy E^* rather than using eq. [14] to estimate ν_T. He used the energy dependence of Z_P established by Pate, Foster, and Yaffe (57) based on f_1 values of tellurium and iodine isotopes for the reaction $Th^{232}(p,F)$. This gave a term $\delta_2 Z_P(E^*)$ to replace the ν_T term in eq. [16]. This new term is thought to be valid up to $E^* \sim 40$ Mev, since the charge dispersion seems to be independent of E^* for this energy region.

When all available data in the energy region $0 < E^* < 40$ are so treated, average deviations of Z_P^{corr} from a median curve are about ±0.2 charge unit, slightly larger than that from the treatment based on eq. [16] as given above.

THE ATTACHMENT OF INERT GASES TO POWDERS FOLLOWING (n,γ) EVENTS[1]

ROGER KELLY

ABSTRACT

It has been found that, when argon, krypton, and xenon are irradiated with neutrons in the presence of various powders, a portion of the inert-gas activity becomes "attached" to the powder. The attached activity was shown to be highly enriched, and to be distinguishable from adsorbed activity. Expressing the attachment in terms of the *attachment efficiency*, $A \equiv$ (inert-gas activity attached to target)/(total inert-gas activity), it was found that A was independent of irradiation time and neutron flux, and for fine powders was also independent of pressure between 0.7 and 700 mm. The use of a very coarse powder or no powder at all led to a decrease in A, on the basis of which it was estimated that the maximum distance from a surface that attached activity can originate is about 200 mean free paths. The following miscellaneous relations were observed to hold: (i) $A \ll 1$, (ii) $A_{Ar} > A_{Kr} > A_{Xe}$, (iii) $A_{oxide} > A_{metal}$ (approximate). The results were in general consistent with a mechanism of attachment based on electrical attraction: inert-gas atoms first acquire a high charge due to vacancy cascades initiated by the conversion of capture gamma rays; they then wander about, and, upon approaching a solid surface, are accelerated electrically into it.

In accordance with I.U.P.A.C. recommendations (1), the symbol "Ar" has been used for argon. In addition, left superscripts are used for mass numbers, thus leaving the right superscript position free for indicating ionic charge (cf. equations [4]).

The chemical effects of beta and gamma emission from radioactive atoms have been studied from several points of view. Most of the work has been done on the breaking of chemical bonds due either to the recoil of the emitting atom or to the state of charge acquired by the emitting atom (2). A limited amount of work on "release"[2] effects has also been described; for example, Yosim and Davies (4) have considered the release of ^{116}In and ^{198}Au from the surfaces of the metal lattices following (n,γ) events, while, in a related study, Baulch and Duncan (5) observed the release of ^{212}Bi from PbO and Pb_3O_4 following the beta decay of adsorbed ^{212}Pb. Complementary to the release work is that in which the "attachment"[2] of the products of beta or gamma emission to a target is studied. Species with which attachment studies have been made include: (i) metal atoms released from a metal film which is being irradiated with neutrons (4, 6), (ii) atomic bromine and iodine formed in neutron-irradiated ethyl bromide and iodide (7), and (iii) atomic tellurium formed in the decay of gaseous $^{127m}Te(C_2H_5)_2$ and $^{129m}Te(C_2H_5)_2$ (8).

The present work was concerned with attachment, in particular attachment following (n,γ) events in the inert gases. It was anticipated that the use of inert gases would yield information not obtainable with more reactive substances, such as were used in references 4, 6, 7, and 8. The reason is the difference in exchangeability. Material which becomes attached to a target in connection with (n,γ) events (e.g. ^{198}Au) will at first contain a smaller proportion of the parent isotopes (e.g. ^{197}Au) than does the unattached material; i.e. it will be *isotopically enriched* in the products of the (n,γ) event. With a reactive substance, the enrichment will tend to persist regardless of whether the attachment is

[2]*The terms "release" and "attachment" are used in preference to "emanation" and "penetration" since they are more general. For example, "emanation" is usually applied strictly to the release of inert gases (3).*

due to penetration into the lattice of the target or simply to surficial adsorption or reaction, for the chemical or physical differences between the attached and unattached material will inhibit exchange. In other words, the details of the attachment will be obscured. With substances which are simultaneously *unreactive*, *monatomic*, and *gaseous*, on the other hand, it is likely that enrichment will persist only under conditions of penetrative attachment. A distinction between penetrative and surficial attachment is then possible, and the mechanism of the attachment can be developed in detail.

The method used was quite simple. Inert gases were irradiated with neutrons in the presence of fine powders, and the distribution of inert-gas activity between the gas phase and the powder was then determined.

EXPERIMENTAL

For each experiment, a capsule was made from thin-walled quartz tubing having an I.D. of about 0.47 cm. The capsule was filled to a depth of between 2.5 and 3 cm with a given powder, drawn down close above the surface of the powder, and attached to a vacuum system with black wax. The inert gas (argon, krypton, or xenon) was now added, and the capsule was sealed off by applying a flame to the drawn portion.

After irradiation in a thermal neutron flux of between 2 and 27×10^{12} neutrons cm^{-2} sec^{-1} for a period of about 12 hours, the capsule was loaded into the "sample holder" as shown in Fig. 1A, and the sample holder was evacuated to about 40 mm. The capsule was cracked open by lifting a nail magnetically and dropping it, the residual air helping to prevent dispersal of the powder. The gases in the sample holder, including that portion of the inert-gas activity still remaining in the gas phase, were led to a trap containing activated charcoal and cooled with liquid nitrogen, henceforth called the "counting trap" (Fig. 1B). The unattached activity was now measured with a single-channel gamma counter. (The presence of activated charcoal was found to be essential for a quantitative collection of inert-gas activities. Thus, without charcoal, xenon activity was lost at the rate of 18% per hour when the counting trap was pumped upon, and the other activities were lost even more rapidly.)

After no further activity could be drawn from the sample holder, the counting trap was freed from activity. With argon and krypton this was accomplished simply by heating the trap with a carbonizing flame, though the charcoal generally had to be changed to eliminate the last traces of xenon activity. A furnace (F in Fig. 1A) was now drawn up over the bottom of the sample holder and the latter was heated, first to about 200° C to confirm that the powder was truly free of *unattached* activity, and then to about 1000° C to remove the *attached* activity. The adequacy of a temperature of 1000° C in removing attached activity was demonstrated by the fact that there was no appreciable release of activity when powder, previously heated to 700° C, was (i) heated to 1000° C (cf. Fig. 2) or (ii) dissolved in a suitable acid or flux.

Several points concerning the counting techniques require comment. With the irradiation and decay times used, the only readily countable isotopes were ^{41}Ar (1.83 hours), ^{85m}Kr (4.4 hours), and ^{125}Xe (18 hours), though ^{133}Xe (5.27 days) was easily distinguished after the shorter-lived ^{125}Xe had decayed for several days. While ^{135}Xe (9.2 hours) was presumably also present, the photopeak could not be resolved from the larger ^{125}Xe photopeak. Activities were expressed in terms of the integrated count, less background, in the region of the photopeak. It was not necessary to consider absolute counting rates, since ratios of activities were used. Resolving-time errors in high activities and background errors in low activities were minimized by the appropriate positioning of the

C = powdered SiO_2 to protect the bottom of A. D = thermocouple wires. E = assembly for admitting the thermocouple wires. The assembly consists of a perforated Teflon plug which can be shrunk around the wires by means of a suitably shaped brass fitting, the latter being soldered to the copper portion of a tubular "Housekeeper" seal. F = furnace. The temperature of the furnace was regulated by feeding the output of a thermocouple (*not* D) located outside A into a Minneapolis-Honeywell "Pulse Pyrovane" controller.

(B) System for trapping and counting (drawn to 2/3 the scale used in (A)). A = lead castle with lid split into two parts such that one part can be slid aside. The inside of the castle, including the lid, is lined with 0.15 cm of cadmium and 0.051 cm of copper. B = counting trap containing activated charcoal. C = Dewar for liquid nitrogen. D = 2-in. NaI(Tl) scintillation crystal. E = photomultiplier. F = preamplifier. G = supporting piece which extends through a vertical slit in the castle wall and bears a 14-cm rack at the end. H = pinion to move rack and thence scintillation crystal. The counting rate could be varied by a factor of 7.7 according to the position of the crystal.

scintillation crystal using the elevating mechanism shown in Fig. 1B (G and H). Errors due to the unreproducible dispersion of activity throughout the charcoal of the counting trap amounted to about $\pm 10\%$ for high crystal positions. Occasional experiments were ruined due to the attached activity being increased by krypton and xenon activities formed by the fission of uranium impurities. (The possible presence of fission activities was indicated whenever the integrated count *above* the photopeak was excessive.)

RESULTS

It soon became apparent in the course of the experiments that when the inert gases argon, krypton, and xenon were irradiated with neutrons in the presence of a powder, a portion of the inert-gas activity became attached to the powder.

Enrichment

The activities attached to the powders were shown to be highly enriched in the products of the (n,γ) reactions. A Xe–TiO_2 mixture was irradiated with neutrons, the xenon activity attached to the TiO_2 was released at 1000° C, and the ^{125}Xe was counted. The activity was then transferred to a quartz capsule containing a small amount of charcoal, allowed to decay for several weeks, and finally reirradiated under conditions similar to those of the original irradiation. It was found that the amount of gaseous activity with gamma energies in the region of the ^{125}Xe photopeak was now only 2 to 3% of the original attached activity. The experiment was done in duplicate.

Release of Attached Activity

Attached activity was shown to be released much less readily than adsorbed activity. Thus, activity which had become attached to a powder did not come off at a measurable rate until the powder was heated, a temperature of between 600 and 700° C being necessary to drive off 95% of the activity (Fig. 2). By contrast, activity which had been frozen down with liquid nitrogen to a glass or charcoal surface, i.e. to either an empty trap or a trap filled with activated charcoal, was 95% released within a few minutes after the coolant was removed (Fig. 3). Note how the rate of release was independent of whether or not the activity was enriched. The 8-minute induction period observed in the release of activity from charcoal presumably represents the time required for the charcoal to warm up.

The characteristic plateaus observed in the release of attached activity (Fig. 2) are evidently not an idiosyncrasy of the system Xe–TiO_2, for similar plateaus were observed in the release of argon from TiO_2 and xenon from silver.

Time and Flux Variation

Before considering further results, it is convenient to define the *attachment efficiency*,

$$[1] \qquad A \equiv \frac{(\text{inert-gas activity attached to target})}{(\text{total inert-gas activity})}.$$

The results given in Tables I and II show that A is independent of irradiation time

TABLE I

Effect on A of variation in irradiation time

System*	Time (hours)	A (equation [1])
Ar–Al	2	.019
Ar–Al	6	.014
Ar–Al	110	.021
Xe–Al	2	.010

Xe–Al	110	.0095

*Inert gas at about 700 mm.

and neutron flux, at least for the times and fluxes used. In addition, A is unaffected by an increase in the proportion of fast neutrons (Table II, fifth line).

Variation in Pressure and Particle Size

The attachment efficiency, A, was found to be independent of pressure using a fine powder, but to vary in an inverse manner with pressure when a very coarse powder or no powder at all was used. Thus, referring to Table III, it is seen that the values of A

TABLE II

Effect on A of variation in neutron flux

System*	Position†	Approximate neutron flux (neutrons cm^{-2} $sec^{-1} \times 10^{-12}$)	A (equation [1])

†Mean value based on data given in Tables I and II.

for systems involving $<10\ \mu$ TiO_2 were essentially the same whether the inert gas was at 700 or 70 mm (or even at a lower pressure in the case of the system Ar–TiO_2). On the other hand, with 590–840 μ aluminum, A increased by a factor of 5 when the pressure was lowered from 700 to 70 mm. The value of A observed at the lower pressure was evidently the limiting value, since it agrees with the value obtained with $<10\ \mu$ aluminum. To further demonstrate the effect of using a coarse powder, inert gases were irradiated in the usual quartz capsules *but without any powder present.* A was now exceedingly low at 700 mm, though it increased rapidly as pressure was decreased. The values of A obtained with powdered SiO_2 or crushed quartz tubing presumably represent the limits

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

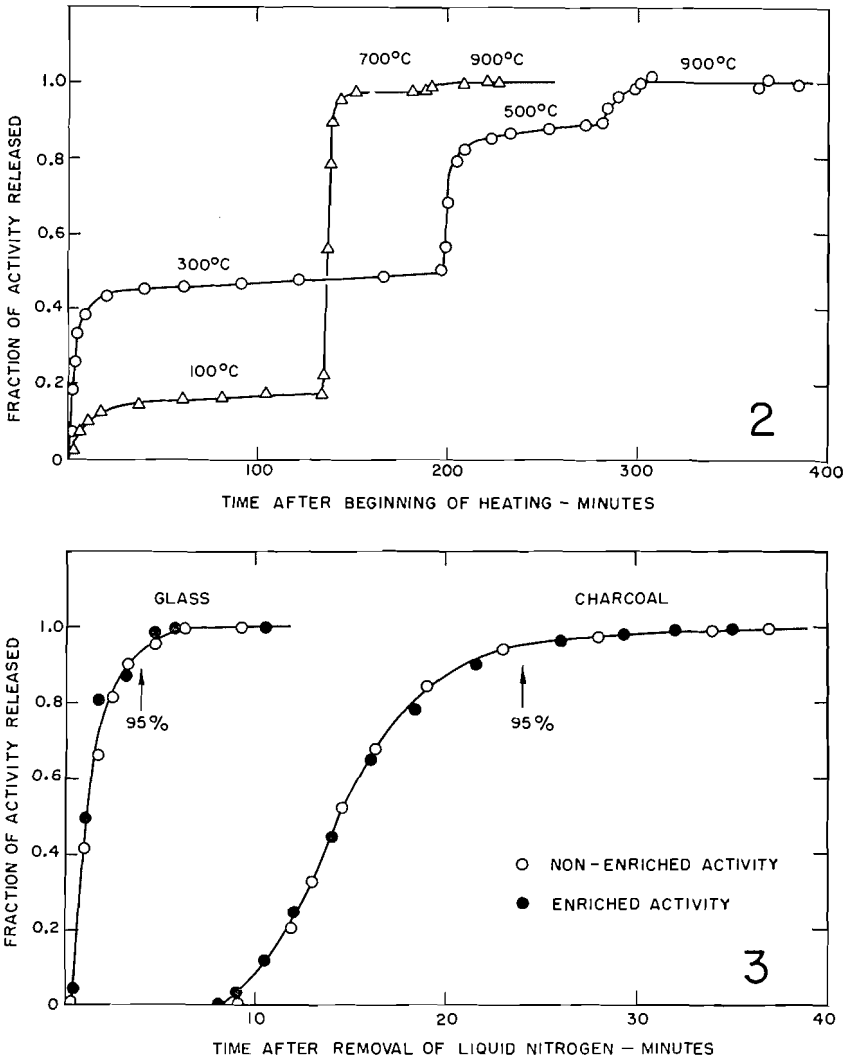

FIG. 2. Release of ^{125}Xe activity which has become attached to TiO_2. Two typical experiments out of a total of 11 are shown. In each experiment the temperature was raised rapidly (i.e. within 2 to 3 minutes) to a given value, was held constant until a well-defined plateau was reached, and was then raised to the next value indicated.

FIG. 3. Release of ^{125}Xe activity from glass and charcoal surfaces. The activity was frozen down to the surfaces at liquid-nitrogen temperature, and at zero time the liquid nitrogen was removed. The enriched activity was obtained by driving attached activity out of silicon.

of the increase. (The possibility that the small activities attached to the quartz capsules were due to ^{135}Xe formed by the fission of uranium impurities was tentatively eliminated in blank experiments, i.e. by irradiating evacuated quartz capsules.)

The "Collection Distance"

The results of the experiments on pressure and particle-size variation will be more suited for subsequent discussion if they are expressed in terms of the "collection distance", i.e. the apparent maximum distance from which attached activity can originate. Consider the empty-quartz-capsule experiments. The capsules were cylinders with an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

I.D. ($2r$) of 0.47 cm and a length (l) of about 2.5 cm. Assuming that one half of the activity in a layer the thickness of the collection distance (d) will reach the capsule in an attachable state, then

$$[2] \qquad A_{\text{observed}} = \left(\frac{A_0}{2}\right)\left(\frac{2\pi rld + 2\pi r^2 d}{\pi r^2 l}\right),$$

where A_0 is the attachment efficiency under conditions when the limiting value is observed, i.e. using a fine powder. Interpreting the experimental data (Table III) in terms of equation [2], one obtains $d = 16\ \mu$ for argon at 700 mm and $d = 15\ \mu$ for xenon at 700 mm. (The figure for xenon represents the mean of all relevant experiments, with A corrected to 700 mm where necessary.) A collection distance is less readily derived from the powder experiments in Table III, since it is difficult to define the pore spacing in a loosely packed powder. However, assuming that the spacing is comparable to the grain size, it follows that $d > 10\ \mu$ (i.e. there was *no* pressure effect with $<10\ \mu$ TiO_2), $d < 590$–$840\ \mu$ (i.e. there *was* a pressure effect with 590–840 μ aluminum).

The mean free path at 700 mm is 0.11 μ in argon, 0.07 μ in xenon. The values obtained for the collection distance are therefore about 200 times larger than the mean free paths.

Trends among the Different Gases and Powders

The values of A for a number of different systems involving argon and xenon are given in Table IV; data for the system Kr–TiO_2 were included in Table III. In assessing these results, it should be noted that the experimental variables had values such that A will be largely unaffected (i) by differences in irradiation time, neutron flux, pressure, and particle size, or (ii) by activity attached to the quartz capsule or formed from uranium impurities in the quartz. Any trends among the different systems should therefore be real.

The most obvious trends are the following:

(i) $A \ll 1$. Thus for systems involving argon, A generally lies between 0.011 and 0.14; when xenon is used, the range is 0.0025 to 0.026.

(ii) $A_{\text{Ar}} > A_{\text{Xe}}$. Judging from the one system in which krypton was used, this relation can likely be extended to $A_{\text{Ar}} > A_{\text{Kr}} > A_{\text{Xe}}$.

(iii) $A_{\text{oxide}} > A_{\text{metal}}$. There is a fair number of exceptions to this trend.

(iv) Considering just the systems involving elemental solids, it appears that A does *not* vary systematically with the atomic weight of the solid.

DISCUSSION

It has been found that, when the inert gases argon, krypton, and xenon are irradiated with neutrons in the presence of various powders, a portion of the inert-gas activity becomes attached to the powder. A number of empirical characteristics of the attachment has already been considered, and it remains only to discuss certain general matters.

Mechanism of Attachment

It was pointed out in the introductory section that material which becomes attached to a target in connection with (n,γ) events will, at the moment of attachment, be isotopically enriched in the products of the (n,γ) event. However, if the attached material is an inert gas, the enrichment will persist only if the attachment is penetrative, as distinct from surficial. The high degree of enrichment observed in the present work therefore points to attachment which (i) is due to (n,γ) events, and (ii) is penetrative. Penetrative attachment is also suggested by the fact that the attached activity was released much less readily than adsorbed activity.

NOTE: Pairs of systems which are exceptions to the trends $A_{Ar} > A_{Xe}$ and $A_{oxide} > A_{metal}$ are indicated with double lines.

*The inert gas was always at about 700 mm. The powders generally had assorted grain sizes ranging up to about 75 μ, though in certain cases the grains were consistently smaller than 10 μ (C-graphite, Al, TiO_2, Co, Se, and Rh). In one case (Al_2O_3), the grains were consistently coarse. See also footnote * of Table III.

†Mean value based on data given in Tables I and II.

At least two mechanisms can be envisaged by which penetrative attachment could come about following (n,γ) events. According to what may be called the "recoil mechanism", the emission of the capture gamma rays might cause the capturing atoms to recoil directly into the target. Gamma-recoil energies are given by

$$[3] \qquad E_{recoil} = 536E_\gamma^2/M,$$

where E_{recoil} is in electron volts, E_γ in million electron volts, and M in atomic mass units. The recoil energies thus vary in the right direction to explain the trend $A_{Ar} > A_{Kr} > A_{Xe}$. Consider, however, the actual values of E_{recoil}. Assuming capture gamma energies of 4 Mev (there is nothing published on the capture spectra of the inert gases), E_{recoil} works out to about 210 ev for argon and 70 ev for xenon. Energies this low would probably

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

be degraded below the level at which penetration is possible within a few collisions.[3] Accordingly, it appears that a recoil mechanism would *by itself* be quite incompatible with the experiments on pressure and particle-size variation, for, as has been shown, these experiments require that attached activity be able to originate from a distance about 200 times larger than the mean free path.

An alternative mechanism of penetration is the "attraction mechanism", which is based on the electrical attraction between charged inert-gas atoms and solid surfaces. Atoms undergoing (n,γ) reactions not only gain recoil energy (equation [3]), but may also become highly charged. The charge is acquired due to the twofold effect of inner electrons being expelled by the conversion of capture gamma rays (7, 10), plus the vacancy-cascade process which occurs whenever there is an inner electron vacancy and in which still further electrons are expelled ("Auger electrons"). Thus, the conversion of a single inner electron has been observed to lead to mean charges of +4.3 for argon (11)[4] and +8 for krypton and xenon (12, 13). The steps leading to the build-up of charge are summarized in equations [4]:

$$[4] \qquad \begin{cases} n + {}^{124}\mathrm{Xe} \rightarrow {}^{125*}\mathrm{Xe} \rightarrow \begin{cases} {}^{125}\mathrm{Xe} + m\gamma \\ {}^{125}\mathrm{Xe}^{+} + (m-1)\gamma + \mathrm{e}^{-} \end{cases} \\ {}^{125}\mathrm{Xe}^{+} \rightarrow {}^{125}\mathrm{Xe}^{(p+1)+} + p\mathrm{e}^{-}, \end{cases}$$

where m is a number between 1 and 6 (14), and p is a number between 0 and about 20 (13). Suppose that the charged atoms escaped neutralization in the gas phase for a sufficient number of collisions that they finally found themselves in the vicinity of a solid surface. Then, *regardless of whether or not recoil energy was still present*, they would be accelerated electrically towards the surface. The acceleration might come about in several ways: (i) electric-image attraction, (ii) attraction between the charged atoms and their separated electrons (the latter would presumably accumulate on surfaces), or (iii) attraction between the charged atoms and electrons formed as a result of the passage of pile gamma rays through the sample. The acceleration would continue until, at a distance of a few angstroms from the surface, the atoms would probably lose their charge due to electron transitions (15). The neutral atoms would then coast the remaining distance to the surface, and, provided sufficient energy had been gained, might penetrate.

The main requirement of the attraction mechanism is seen to be that the charged atoms formed in the (n,γ) events must escape neutralization in the gas phase; in other words, the charge-exchange cross sections must be small. While the cross sections for charge exchange between ions and the corresponding neutral species have, unfortunately, not been studied beyond charges of +3 (16), there is reason to believe that they become exceedingly small with increasing charge.[5] The attraction mechanism is therefore more nearly compatible than the recoil mechanism with the large values observed for the collection distance.

On the other hand, the attraction mechanism has several weaknesses. The extent to which the capture gamma rays are converted may be very low in the nuclides with which the present work is concerned. Also, the trend $A_{\mathrm{Ar}} > A_{\mathrm{Kr}} > A_{\mathrm{Xe}}$ is the reverse to what might be expected: (i) the nuclear-level density increases with mass (17, p.

[3]*The minimum energy at which penetration can occur is perhaps to be identified with the displacement energy,* E_d. *The value of* E_d *is about 25 ev (9).*

[4]*It was shown in the work of reference 11 that the* ^{37}Cl *atoms formed by* electron capture *in* ^{37}Ar *have a mean charge of 3.3. Other things being equal,* conversion *in argon would accordingly lead to a mean charge of 4.3.*

[5]*This view was expressed by Dr. J. B. Hasted (University College, London, England) in a private communication. Further discussion of charge exchange will be postponed for a subsequent paper.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

406), so that heavy atoms should have a greater number of low-energy capture gamma rays than light atoms (conversion coefficients vary inversely with gamma energy (17, p. 222)); (ii) the conversion coefficients at a given gamma energy increase with atomic number (17, p. 223); (iii) the charge produced in vacancy cascades is greater for krypton and xenon than for argon (11, 12, 13). A more detailed discussion of the attraction mechanism will be possible when work currently underway at this laboratory on the capture spectra of the inert gases is completed.

The observation that A is independent of time and flux is compatible with either of the mechanisms that has been considered, for it implies simply that the rate of attachment is independent of time and directly dependent on flux. It is conceivable, however, that for very large values of (time)$\times$(flux) the rate of attachment, and thence A, will decrease to zero due to the surfaces of the powder becoming saturated.

Sample Heating

If a powder became heated to much over 200° C while under irradiation, the penetrated inert gas would be partially released (cf. Fig. 2). That sample heating is not ordinarily important is shown both by the fact that A is independent of neutron flux when TiO_2 is used, and the fact that the selenium and tin did not melt. On the other hand, sample heating might well account for the unusually low values of A in systems involving boron, silver, and Ag_2O. Boron will heat up owing to the prominent (n,α) reaction in ^{10}B, and silver and Ag_2O owing to the high cross sections with which the short-lived beta emitters ^{108}Ag and ^{110}Ag are formed. Similarly, the fact that three of the six exceptions to the trends $A_{Ar} > A_{Xe}$ and $A_{oxide} > A_{metal}$ are associated with boron, silver, and Ag_2O may be due to non-uniformity in the effects of sample heating among different systems. (Rhodium should also heat up, though the value of A for the system Ar–Rh appears to be normal.)

Enrichment and Storage of Activity

It is difficult to see how bond-breaking or release effects could be applied to enriching inert-gas activities. The present work indicates that *attachment*, on the other hand, is quite effective in bringing about enrichment with the inert gases. An attachment technique has the added advantage that the enriched activity is in a form convenient for handling or storing. (Compare the method of introducing ^{85}Kr into clathrate compounds (18).)

The possibility of using attachment for enriching activities with substances other than the inert gases was previously suggested by Magnusson (6), who succeeded in applying an attachment technique to gold.

ACKNOWLEDGMENTS

The writer wishes to acknowledge the contributions to the present work made by Drs. J. A. Davies and W. H. Stevens, who assisted in the interpretation of the results. The method of sealing thermocouple wires shown in Fig. 1A (E) was devised by Mr. V. T. Buckley, and the latter also helped design the castle and elevating mechanism.

HALF-LIVES OF Rb^{94}, Sr^{94}, Y^{94}, Rb^{95}, Sr^{95}, Y^{95} [1]

K. FRITZE, T. J. KENNETT, AND W. V. PRESTWICH[2]

ABSTRACT

The existence of a new rubidium isotope, Rb^{94}, has been established and its half-life measured. The half-life of this fission product was determined using the technique of timed precipitations. The value obtained for Rb^{94} was 2.9 ± 0.3 seconds. With this same technique only an upper limit of 2.5 seconds could be assigned to Rb^{95}. The half-lives of the strontium and yttrium daughters were also determined. The strontium isotopes were studied both by timed precipitations and direct measurements. The half-lives of Sr^{94} and Sr^{95} were found to be 1.36 ± 0.06 minutes and 0.8 ± 0.15 minute, respectively. Direct measurements lead to half-lives of 20.35 ± 0.20 minutes for Y^{94} and 10.9 ± 0.2 minutes for Y^{95}.

Experiments, carried out by Hahn and Strassmann (1, 2) and Dillard *et al.* (3, 4), showed the existence of krypton ancestors of Y^{94} and Zr^{95}. Since essentially all fission products decay by β-emission, these experiments also proved the existence of all the intermediate members of the two decay chains (Rb^{94}, Sr^{94} and Rb^{95}, Sr^{95}, Y^{95}, respectively). More direct measurements of some of these nuclides were done by Hahn and Strassmann (1, 2) and Knight *et al.* (5) for Sr^{94}, by Hoffman *et al.* (6) for Sr^{95}, and by Knight *et al.* for Y^{95} (7). This paper reports the first measurement of the Rb^{94} half-life as well as remeasurements of the half-lives of Sr^{94}, Sr^{95}, Y^{94}, and Y^{95}. In addition an estimate for the upper limit of the Rb^{95} half-life is given.

(A) Rubidium 94

The timed precipitation technique as described previously (8) was used to determine the half-life of Rb^{94}. Briefly, this method proceeds as follows: U^{235} is irradiated in a solution which is divided into two portions after the end of the irradiation and rubidium precipitated as perchlorate in both samples at two different times. The two precipitates are later (after almost complete decay of the 1.36-minute Sr^{94}) analyzed radiochemically for Y^{94}. From the amount of Y^{94} in each precipitate, the time interval between the two precipitations and the chemical yields, the half-life of Rb^{94} can be calculated. The experimental details as far as the chemistry is concerned were essentially the same as in the determination of the half-lives of Rb^{92} and Rb^{93} (8). However, the whole procedure had to be accelerated because of the relatively short 20-minute half-life of Y^{94}. Furthermore, the rubidium carrier was added to the uranium solution before the start of the irradiation in order to save time. Counting was usually started approximately 30 minutes after the end of the irradiation.

A gross β-decay curve of yttrium isolated from quickly precipitated rubidium perchlorate clearly shows the following components: 20.35-minute Y^{94}, 3.53-hour Y^{92}, 10.1-hour Y^{93}, and some long-lived Y^{91}. These decay curves, however, are not particularly suitable to determine the relative quantities of Y^{94} in two different samples since these amounts are rather small in comparison with the Y^{92} and Y^{93} present. This arises from the low independent yield and the short half-life of Rb^{94} compared with both the Rb^{92} and Rb^{93} half-lives. For this reason the Y^{94} was counted in a way which would discriminate against the other yttrium isotopes. In the first run this was done by com-

[1]*Manuscript received November 3, 1960.*

[2]*Holder of an Ontario Research Foundation Scholarship 1960–61.*

paring the intensities of the 920-kev γ-ray associated with the decay of Y^{94} (5) in the two yttrium samples. A 3×3 in. NaI(Tl) crystal and a 256-channel analyzer was employed. The two samples were counted for a total time of 20 minutes. The samples were alternated in such a way as to cancel the half-life effects. The events of sample No. 1 were stored in the first 128 channels and those of sample No. 2 in channels 129–256. Each group of 128 channels covered the energy region from 0.2 to 1.5 Mev. In run No. 2 the counting was done similarly. However, the selected energy range was from 0.5 to 4.0 Mev and the samples were directly attached to the aluminum can of the NaI(Tl) crystal. Consequently a large number of high-energy β-rays were counted in addition to any γ-rays of this energy range. The decay of the yttrium samples was followed for several half-lives. The high-energy end of this type of spectrum contained only a 20-minute component. This was to be expected since Y^{94} emits β-rays of up to 5.0 Mev and γ-rays of up to 3.5 Mev (5) whereas the β- and γ-energies of the other three yttrium isotopes are considerably lower (5, 9). The counting rates of all channels which contained only events due to the decay of Y^{94} were added and used as a measure of the relative content of Y^{94} in the two rubidium perchlorate precipitates. This second method was also used for runs Nos. 3 and 4. The results of the four half-life measurements for Rb^{94} are given in Table I.

TABLE I

Summary of Rb^{94} half-life data

Run	U^{235} (μg)	Flux (neutrons cm^{-2} sec^{-1})	Duration of irradiation (seconds)	$RbClO_4$ precipitation times (seconds)		Rb^{94} half-life (seconds)
				1st ppt.	2nd ppt.	
1	200	3×10^{12}	10	9.0	11.7	2.8_1
2	400	3×10^{12}	10	7.6	11.1	2.6_5
3	400	3×10^{12}	10	8.9	12.9	3.1_5
4	300	3×10^{12}	10	6.1	9.1	2.8_5

The half-life values given in Table I are seen to have good internal consistency. The suggested value is 2.9 ± 0.3 seconds. The sources of error which may not effect this consistency have been discussed previously (8).

In order to check the reliability of the method, the yttrium samples can be analyzed for both Y^{93} and Y^{94} from which one can obtain the ratios of the Rb^{93} and Rb^{94} half-lives. This ratio is, of course, independent of the precipitation times provided that the half-lives and independent yields of the precursors are similar. This ratio $T_{1/2}(Rb^{94})/T_{1/2}(Rb^{93})$ was determined for runs No. 2, 3, and 4, and yielded a value of 0.48 ± 0.05. Using 5.6 seconds (8) for the half-life of Rb^{93} one obtains 2.7 ± 0.3 seconds for Rb^{94}. This value is expected to be somewhat low because of precursor effects.

(B) Strontium 94

Hahn and Strassmann (1) showed the existence of a decay period of approximately 2 minutes among the strontium isotopes produced in fission. They also were able to establish the genetic relationship to the 20-minute Y^{94} (1). Knight *et al.* (5) measured the half-life of Sr^{94} by milking yttrium from a purified fission product strontium sample and obtained 1.3 ± 0.2 minutes. Two methods were used in this work; the timed precipitation technique and direct counting. Strontium can be precipitated quickly and in sufficient purity as the nitrate. The coprecipitation of yttrium was found to be around 0.1%. The procedure employed is completely analogous to the one used for the half-life

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

determination of Rb^{94} with one exception; the strontium nitrate precipitate was separated from the supernatant solution of 80% nitric acid by means of glass filter crucibles having medium porosity and selected for fast filtration speed. A separation in approximately 15 seconds was achieved when a precipitating volume of 10 ml was used. The strontium nitrate was analyzed for its Y^{94} content starting approximately 8 minutes after the end of the irradiation. The amounts of Y^{94} were either obtained by unravelling gross β-decay curves using a least-squares method (runs No. 1 and No. 2) or by comparing the intensities of the 920-kev γ-ray (5) associated with the decay of Y^{94} (run No. 3). The results of these measurements are:

(1) 1.37 minutes,
(2) 1.31 minutes,
(3) 1.45 minutes,
average 1.38 ± 0.07 minutes.

This half-life, although short, makes feasible the observation of the γ-rays associated with the decay of Sr^{94}. To do this the following procedure was used. Immediately after the irradiation of U^{235}, strontium and barium were precipitated as nitrates. The barium was removed as the chromate and the filtrate was counted using a 3×3 in. NaI(Tl) crystal and a 256-channel pulse-height analyzer. The counting began about 1.7 minutes after the end of the irradiation. The spectrum, which was rather complex, extended to about 3.5 Mev. The two major periods associated with the spectrum were about 1 minute ($Sr^{94}+Sr^{95}$) and 7.5 minutes (Sr^{93}). A prominent γ-ray of 1.42 Mev was assigned to Sr^{94} on the basis of apparent half-life. Consequently this transition was used to determine the half-life of Sr^{94} by direct measurement. A series of measurements was carried out in which the spectra were recorded as a function of time, using the four 64-channel subgroups of the analyzer. Three such runs were done and the area of the 1.42-Mev photopeak was determined for each spectrum.

The half-lives determined from these runs are:

(1) 1.34 minutes,
(2) 1.33 minutes,
(3) 1.36 minutes,
average 1.34 ± 0.04 minutes.

The direct measurement agrees very well with the results of the timed precipitation experiment. The combined values give a half-life of 1.35 ± 0.05 minutes, which is entirely consistent with the results of Knight (5).

(C) Yttrium 94

Most authors agree that the half-life of this nuclide is 20 minutes (1, 5, 10) with the exception of Brown and Katcoff, who report 16.5 minutes (11). The decay of Y^{94} was measured by observing the rate of disappearance of the 920-kev line in the γ-spectrum of Y^{94} (5). The counting system for this purpose has been described previously (8). This method has the obvious advantage of discriminating strongly against other yttrium isotopes. The yttrium was isolated from fission product strontium which had been precipitated as a nitrate. Since the half-life of Sr^{95} is about half that of Sr^{94} one can by proper choice of the separation time discriminate against ingrowing Y^{95}. The radiostrontium was allowed to decay for a few minutes and then the yttrium was separated as the hydroxide. In this way the Y^{92} and Y^{93} content of the final sample was kept as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

low as possible. The yttrium was then purified using standard procedures (12). A decay curve is shown in Fig. 1 and the results of two such measurements obtained from a least-squares analysis of the data were:

(1) 20.4 minutes,
(2) 20.3 minutes,
average 20.35±0.2 minutes.

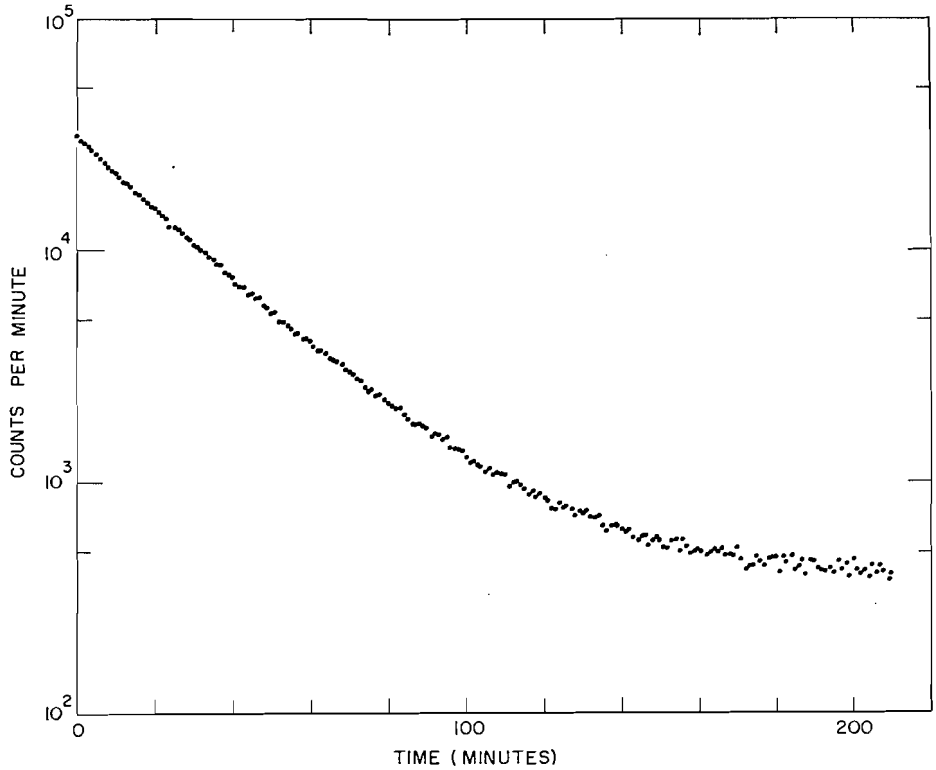

FIG. 1. A decay curve obtained for Y^{91}. The only events recorded were those whose pulse height fell within a 6% window centered about the 920-kev γ-ray line.

This value is in very good agreement with most of the previously reported measurements. An explanation for the lower value of 16.5 minutes is the undetected presence of 10.9-minute Y^{95}.

(D) Rubidium 95

An attempt was made to prove the existence of Rb^{95} directly. Rubidium perchlorate was precipitated 8 seconds after the end of a 10-second irradiation of 400 μg of U^{235} at a flux of 3×10^{12} neutrons/cm^2 sec. The rubidium isotopes and their respective strontium daughters were then allowed to decay for 10 minutes after which the sample was analyzed for radioyttrium. The sample was directly mounted on the face of a 3×3 in. NaI(Tl) crystal. A single-channel analyzer was set to accept γ-rays in the interval 2.0 to 3.7 Mev. The thin aluminum can of the crystal also permits β-counting. The decay of the combined radiations was followed for 220 minutes and the decay curve is shown in Fig. 2. It can be seen from Fig. 2 that there is no indication of a 10.9-minute Y^{95}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

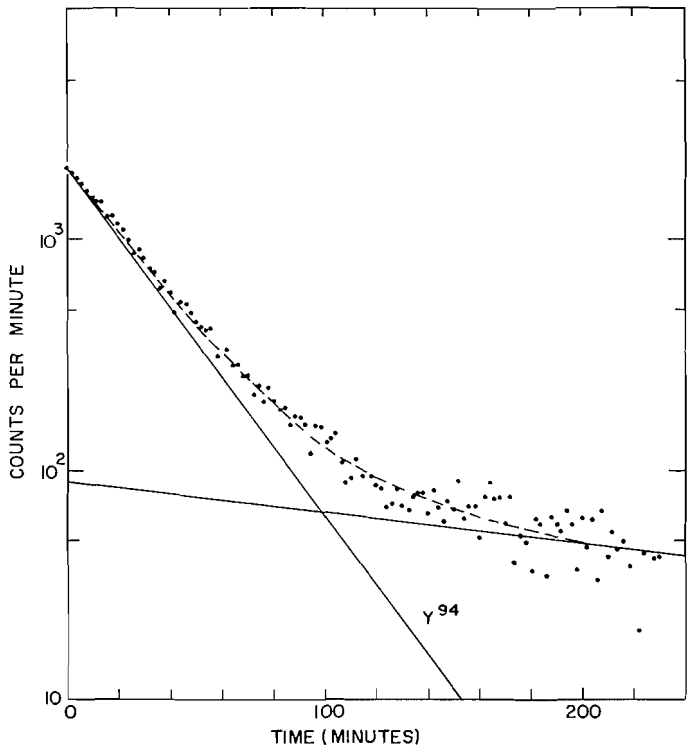

FIG. 2. This decay curve was used to infer that the half-life of Rb^{95} is less than 2.5 seconds. If Rb^{95} had a half-life greater than or equal to 2.5 seconds, the decay curve shown would have had a 10.9-minute Y^{95} component with an initial counting rate of 500 c.p.m. Since the curve is represented quite well by 20-minute Y^{94} and 3.5-hour Y^{92} components, the Y^{95} component must be small.

component, although its decay characteristics do satisfy the imposed counting conditions. From the time schedule of the whole experiment and the independent yields of Rb^{94} and Rb^{95} (13) an upper limit of 2.5 seconds for the Rb^{95} half-life can be estimated. This is based on the assumption that a 25% contribution of Y^{95} to the original counting rate would have been found.

(E) Strontium 95

So far the only half-life measurement of Sr^{95} was done by Hoffman *et al.* (6), who obtained approximately 0.7 minute. It can be assumed that their method was the same as the one used by Knight *et al.* (5) for Sr^{94}.

Two values for the half-life of Sr^{95} were obtained from the relative quantities of Y^{95} in the yttrium samples of runs No. 1 and No. 2 which are mentioned in Section (*B*). The values obtained were:

(1) 0.6_8 minute,
(2) 0.8_8 minute,
average 0.8 ± 0.15 minute.

An attempt was made to measure the half-life directly by observing the high-energy β-rays emitted from rapidly separated strontium. The results were consistent with the value quoted above. However, the technical difficulties encountered restricted the usefulness of the method.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(F) Yttrium 95

Only two values for the half-life of Y^{95} have been reported. Knight, Burgus, and Prestwood (7) quote 10.5 minutes in private communication and Knight *et al.* (5) mention a 9.5 minute Y^{95} activity as a low-intensity component in gross β-decay curves of fission product yttrium.

In order to remeasure the decay period of Y^{95} a sample was prepared in the following way. Immediately after the irradiation of U^{235} and the addition of strontium carrier, strontium nitrate was precipitated, centrifuged, and washed with 80% nitric acid. The strontium nitrate was dissolved in water, reprecipitated as the nitrate, and centrifuged. The supernate was directly used for a tributylphosphate extraction (12) of the yttrium which had grown in during the 3-minute interval between the two strontium nitrate precipitations. In this way the Y^{95} was enriched as much as chemically possible. The yttrium was further purified and finally β-counted as the oxalate long enough to allow a correction to be made for the small contribution due to the long-lived components. The data were then subjected to a least-squares analysis for two components. Half-lives of 10.9 ± 0.2 minutes and 20.4 ± 0.3 minutes were obtained for Y^{95} and Y^{94} respectively. The value of 20.4 ± 0.3 minutes agrees very well with the results given in Section (*C*) for Y^{94}.

HALF-LIFE OF Cs^{137} [1]

H. FARRAR, A. K. DASGUPTA, AND R. H. TOMLINSON

ABSTRACT

The half-life of Cs^{137} was found to be 30.4 ± 0.4 years by determining the amount of Ba^{137} produced in various times from a known number of Cs^{137} atoms. The numbers of barium and cesium atoms were determined from isotope dilution data obtained with a mass spectrometer.

INTRODUCTION

In recent years there have been numerous measurements of the half-life of Cs^{137}. The original estimate by Glendenin and Metcalf (1) was 33 ± 3 years. Wiles and Thode (2) later published a value 33 ± 2 years which was obtained with a mass spectrometer by observing, over a period of years, the decrease in the relative amount of Cs^{137} with respect to Cs^{133} in fission product cesium.

Later experiments used the isotope dilution technique with a mass spectrometer to determine the number of Cs^{137} atoms in a given sample, and 4π absolute β-counting to determine the activity. In this way, values of 26.6 ± 0.4 years (3), 30.0 ± 0.4 years (4), $28.6 \pm {}^{2}_{1}$ years (5), and 32.6 ± 1.6 years (6) were obtained. Owing to the considerable disagreement in these values, a new method was desirable.

Rather than determine the rate of decay of Cs^{137} by counting the radiation released, the present work reports on the determination of the half-life by measuring the rate of formation of the daughter nuclide, Ba^{137}, from a known amount of Cs^{137}. Both measurements use isotope dilution technique with a mass spectrometer, and do not require any absolute counting procedures. It is also important that the present method is independent of the decay scheme and of radioactive contaminants.

EXPERIMENTAL

About 0.5 mg of fission product cesium was used for this experiment, amounting to about 20 mc of activity and generating about 1×10^{-8} grams of Ba^{137} per day.

Preliminary experiments with a 0.4-ml column of Dowex 50 cation exchange resin (100–200 mesh) in the acid form were made to determine conditions for the separation of barium from cesium. Using 0.5 mg of Cs^{133} with tracer Cs^{137}, and also the radioisotope Ba^{139}, it was found that when the column was eluted with 1 *M* HCl, virtually all the cesium was removed within the first 15 ml, the maximum coming off in the 9th ml, whereas the barium remained adsorbed until after the 90th ml. It was found that after the 22nd ml, an increase in concentration to 3 *M* HCl removed the barium tracer within a further 30 ml of eluate.

The fission product cesium was adsorbed on a new column and eluted as previously described. The eluate was set aside to allow the accumulation of Ba^{137}. While this was taking place, a weighed aliquot of isotope-enriched Ba^{134} solution was added. At the end of a measured period, the cesium plus the mixture of Ba^{137} and Ba^{134} were adsorbed on a new column. The cesium was eluted as before with 1 *M* HCl and was retained for a further period. The concentration of the elutriant was increased after the 22nd ml to 3 *M*, and the Ba^{137} plus the Ba^{134} were collected. Complete elution of the barium was

[1]*Manuscript received November 3, 1960.*
Contribution from Hamilton College, McMaster University, Hamilton, Ontario. Presented at the Third Symposium on Nuclear Chemistry and Radiochemistry held at Atomic Energy of Canada Limited, Chalk River, Ontario, September 6–8, 1960.

unnecessary since only the ratio of the Ba^{134} and Ba^{137} isotopes was needed to determine the number of Ba^{137} formed in the period. The barium solution was evaporated first in a pyrex beaker and then on a teflon sheet to one drop, which was placed on the filament of a 90° solid source mass spectrometer, for isotopic analysis.

RESULTS

Small amounts of natural barium were evident in the mass spectrograms. Since the isotopic content of natural barium is principally Ba^{138}, which is very different from the enriched Ba^{134} solution, a measurement of the ratio of Ba^{134} to Ba^{138} in any sample gives a precise knowledge of the amount of Ba^{137} contamination present. This correction varied almost linearly from 20% for the shortest period of growth to 0.8% for the longest.

Measurements of the amount of Ba^{137} formed in eight different periods have been made. The period in each case was the time between similar parts of consecutive cesium elutions. In case the rate of elution were to vary from one separation to the next, these parts were chosen when the 9th ml of eluate, which included most of the cesium, left the column.

Apart from the correction to the Ba^{137} for natural barium contamination, which already has been mentioned, the only correction made was that due to the loss and decay of Cs^{137} during the series of separations. To obtain this correction, the relative activity of the total sample was counted between each separation with a 4π ionization chamber.

The original number of Cs^{137} atoms, found by three independent isotope dilutions with natural cesium, had an average value of 7.592×10^{17} atoms. The maximum deviation from this was 0.4%. To prevent excessive increases of Cs^{133} in the sample, the first two isotope dilutions were performed with a small known fraction of the total. In the third case, the total sample was used.

The concentration of the barium isotopes in the Ba^{134} enriched isotope dilution solution was found by three independent isotope dilutions using natural barium. The average concentration was found to be 5.861×10^{14} atoms of Ba^{134} per gram of solution, the maximum deviation from this being 0.7%.

One cesium and one barium isotope dilution were performed without the use of the electron multiplier in the mass spectrometer. These results showed no difference from those obtained with the electron multiplier. Furthermore, a careful determination of the relative abundances of natural barium isotopes has been made both with and without the electron multiplier. Since both sets of results were identical and also in agreement with the values obtained by Nier (7), it can be concluded that no significant mass discrimination occurred at the electron multiplier.

The results of the data obtained for each separation are shown in Table I.

TABLE I

Accumulation of Ba^{137} for various periods

Period, days	Number of Ba^{137} formed
0.924	$0.459\pm0.008\times10^{14}$
2.975	$1.415\pm0.005\times10^{14}$
5.046	$2.338\pm0.014\times10^{14}$
6.074	$2.968\pm0.021\times10^{14}$
8.215	$3.948\pm0.043\times10^{14}$
10.085	$4.794\pm0.044\times10^{14}$
16.715	$7.91\pm0.10\times10^{14}$
48.960	$23.25\pm0.13\times10^{14}$

Column 2 gives the numbers of Ba^{137} formed from the initial amount of Cs^{137}, which are corrected to allow for loss and decay of the Cs^{137}. This correction accumulated to 5.00% for the final period. Of this, approximately 1% was due to decay and almost all the rest was lost in the separation between the fifth and sixth periods. A linear least-squares plot of the data in Table I is shown in Fig. 1. The slope for points obtained before

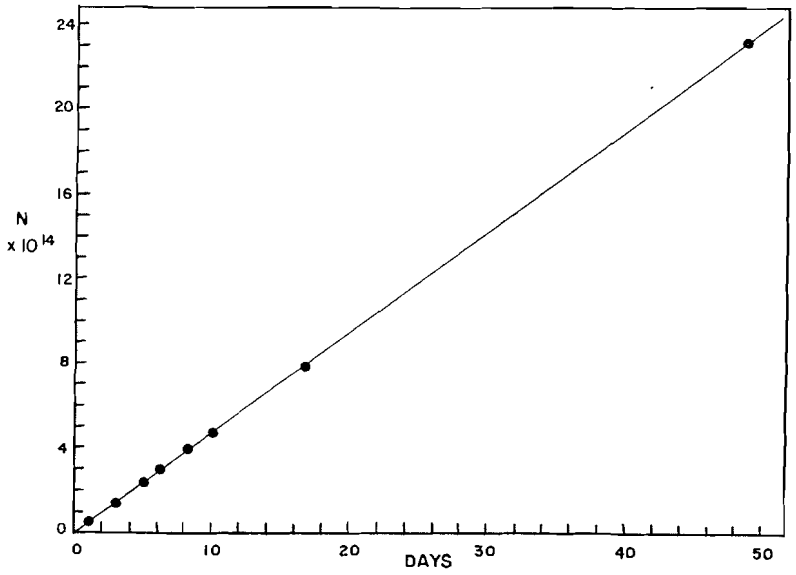

FIG. 1. Rate of growth of Ba^{137}.

the loss of cesium is the same as the slope for points obtained after, the appropriate corrections having been made. The slope thus obtained was found to be 4.746×10^{13} Ba^{137} per day. An error of $\pm 1.2\%$ has been arbitrarily assigned to this slope noting that six of the nine points, including (0,0), lie within these limits. The least-squares plot passes close to the origin, giving, at $t = 0$, 33 minutes of growth of Ba^{137}, which is small compared with the time intervals.

From these data, the half-life was calculated to be 30.4 ± 0.4 years. The error in the half-life has been estimated from the assigned errors in each of the measured quantities.

SEARCH FOR THE (n,t) REACTION AT 14 MEV IN SOME MEDIUM WEIGHT NUCLEI[1]

A. P. BAERG AND G. C. BOWES

ABSTRACT

The (n,t) reaction at 14.6 Mev has been observed to occur in S^{32} with a cross section of 4 ± 1 microbarns. Upper limits for the cross section of this reaction are also given for Ca^{40}, Cr^{50}, Fe^{54}, and Zn^{64} and the results are discussed qualitatively in the light of recently reported (10) (n,He^3) reactions.

INTRODUCTION

Among various types of nuclear reactions which are energetically possible with 14-Mev neutrons, the (n,t) reaction has been studied only in very light nuclei (1, 2, 3, 4). In accordance with the reciprocity theorem such reactions should be important in some cases since reactions of the type (t,n) are known to occur at 2.65 Mev in medium weight nuclei (5, 6).

Intuitively the emission of a complex loosely bound structure such as a triton seems much less probable than that of single-particle emission. In early work on (p,t) reactions, however, Cohen and Handley (7) already concluded that the inherent probability for triton emission, in the breakup of a compound nucleus at least, was little, if any, less than that for protons or neutrons. Reactions of the type (n,t) are in general characterized by large negative Q values and on the statistical theory the cross sections are expected to be generally very small. In lighter elements, however, a strong component of direct interaction is evident in Li^6 and Li^7 (1) as well as in Be^9 (3). More recent work by Cohen and others (8, 9) on the (p,t) reaction at 23 Mev shows strong evidence for a pickup mechanism for this reaction in heavier elements.

Recently Kumabe *et al.* (10) have reported the occurrence of (n,He^3) reactions at 14.8 Mev in Mn^{55}, Co^{59}, As^{75}, and Rh^{103}. The cross sections observed range in value from 1 to 6 millibarns and the authors have suggested several possible direct interaction mechanisms to account for the cross-section magnitudes.

In view of the accumulating evidence of significant contributions from direct interaction in 14-Mev neutron reactions, we have made a cursory search for the (n,t) reaction in medium weight elements. Several isotopes were selected for study by the activation method, from a consideration of reaction Q values and unambiguous identification of the product nucleus with the (n,t) reaction. This has restricted us to stable even–even target nuclei of low neutron number, to avoid interference from (n,p) or (n,d) reactions on other isotopes.

EXPERIMENTAL

The various targets were bombarded with neutrons of average energy 14.6 Mev (11) from the $T(d,n)He^4$ reaction using about 1 ma of 120-kev deuterons incident on a thick tritium-loaded titanium target.* Cross sections were measured by comparison of the positron activity induced in the sample with that induced in a fluorine "flux monitor"

[1]*Manuscript received November 3, 1960.*

**A 150-kilovolt Texas Nuclear Corporation neutron generator was used.*

from the (*n*,2*n*) reaction on F^{19} giving 112-minute F^{18}. The cross section for the latter reaction was taken to be 53 millibarns (cf. 61 millibarns ref. 12), as measured in separate experiments relative to 556 millibarns for the (*n*,2*n*) reaction on Cu^{63} (13). The fluorine monitors were used in the form of sheets of "teflon", $(C_2F_4)_n$, placed on either side of the samples for the irradiation. During the irradiation the neutron flux was maintained constant within 5% as determined by continuous monitoring with a BF_3-filled ionization chamber and a $B^{10}F_3$ "long counter".

The positron activities were detected by scintillation counting of the annihilation radiation and identified by half-life measurements. Chemical separations were not made. The radiations from samples and fluorine monitors were measured under conditions identical, as nearly as possible, with respect to geometry and absorber material. (For the type of detector used see reference 14.) It is estimated that a maximum systematic error of 15% may be applicable to the relative activity measurements.

The samples were prepared from the elements or from suitable compounds such as hydrides, oxides, or organic salts which do not produce interfering activities. In several cases atmospheric nitrogen adsorbed in the sample produced interfering 10-minute N^{13} from the (*n*,2*n*) reaction on N^{14}. This was reduced to tolerable levels by evacuation of the samples and irradiation in an atmosphere of pure methane or helium.

RESULTS AND DISCUSSION

Among the five isotopes studied (S^{32}, Ca^{40}, Cr^{50}, Fe^{54}, and Zn^{64}) the (*n*,*t*) reaction was observed to occur only in S^{32}, producing the 2.5-minute P^{30} positron emitter with, however, a very small cross section. The gamma-ray spectrum of the irradiated sulphur is shown in Fig. 1 in which only the 0.511-Mev photopeak ascribed to P^{30} is present. In

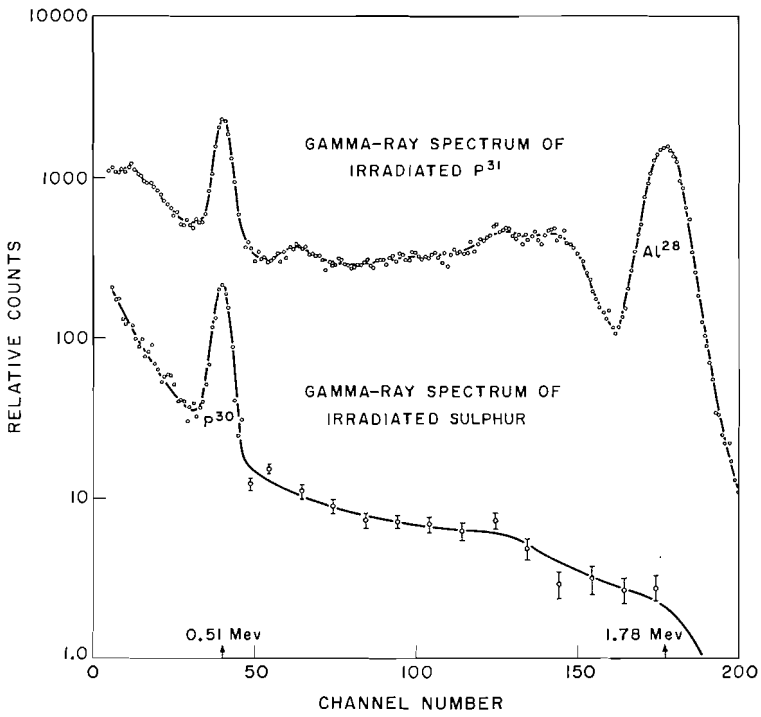

FIG. 1. Gamma-ray spectra of irradiated sulphur and phosphorus.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

order to demonstrate that this activity did not arise from an $(n,2n)$ reaction on possible phosphorous impurity, the gamma-ray spectrum of irradiated P^{31} is given as well in this figure. This shows, in addition to the 0.511-Mev line, a strong peak at 1.78 Mev due to Al^{28} from the (n,α) reaction, which, however, is absent in the irradiated sulphur spectrum.

The decay of the 0.511-Mev photopeak showed a half-life of about 2.5 minutes with a smaller 10-minute component. This longer-lived component is ascribed to N^{13} resulting from an $(n,2n)$ reaction on a small amount of residual nitrogen in the samples. A typical decay curve is shown in Fig. 2.

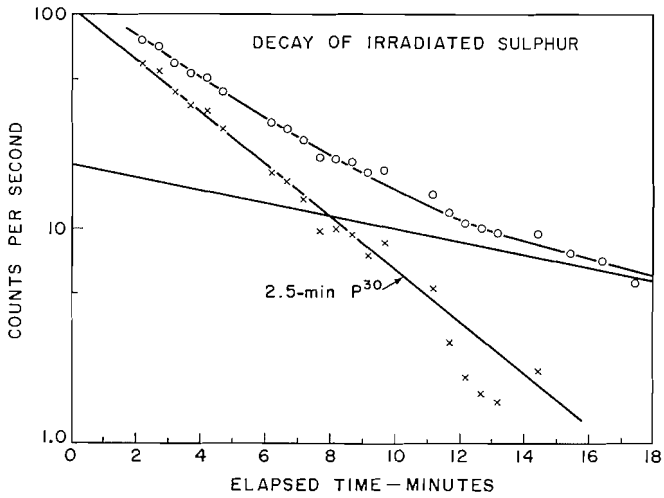

FIG. 2. Decay of 0.511-Mev photopeak in irradiated sulphur.

The experimental data and calculated cross sections for six irradiations of different samples are given in Table I. The cross sections are given relative to 53 millibarns for

TABLE I

Experimental results for (n,t) reaction on S^{32}

Sample	Duration of irradiation, minutes	P^{30} activity, c.p.m./g S^{32}	F^{18} activity, c.p.m./g F^{19}	Cross section, barns$\times 10^6$
Elemental sulphur	2.5	80.1	55.5×10^3	4.0
Elemental sulphur	2.5	73.4	54.3×10^3	3.7
Carbon disulphide	3.0	23.3	21.1×10^3	3.2
Carbon disulphide	3.0	60.1	37.8×10^3	4.6

the $(n,2n)$ reaction on F^{19}.

Activities resulting from the (n,t) reaction on the other nuclides studied were not definitely observed and upper limits only have been assigned for the cross sections. These assignments were made on the basis of a careful analysis of counting data and gamma spectra, taking into account isotopic abundances and positron branching ratios (15). The results for the various reactions sought are given in Table II together with the reaction

Fe^{54} (n,t) Mn^{52}g.s.	−13.16	5.6 days	<75	0.001
Zn^{64} (n,t) Cu^{62}	−9.72	9.7 minutes	<100	2

Q values taken from the nuclear mass and binding energy tabulation given by Cameron (16). The sulphur experiments yield an average cross-section value of 4±1 microbarns with the error based on a standard deviation of 10% and a possible systematic error of 15% in the relative activity measurements.

The last column in Table II gives approximate theoretical cross sections calculated on the compound nucleus formalism (17, 18). Since there are rather large uncertainties (~200 kev) associated with the reaction Q values, approximate solutions only have been given but these are believed reliable to within a factor of 5. These calculated values are thus intended as a guide to the order of magnitude expected on the compound nucleus model. Since cross-section upper limits only were obtained experimentally for most of the reactions, the comparison with calculated values has some significance only in the case of S^{32} where the agreement is very satisfactory.

Perhaps a more instructive comparison is that with the (n,He^3) cross sections recently reported by Kumabe *et al.* (10) in Mn^{55}, Co^{59}, As^{75}, and Rh^{103}. The cross sections lie in the range 1 to 6 millibarns while the reaction Q values are comparable with those for the (n,t) reactions in the present study (e.g. for $Mn^{55}(n,He^3)V^{53}$, $Q = -12.65$ Mev). Thus the (n,He^3) cross sections given by Kumabe *et al.* are at least one or two orders of magnitude greater than the (n,t) cross sections for the nuclides studied here. This result seems surprising in view of the generally higher coulomb barriers for the nuclides studied by Kumabe *et al.* and the lower barrier penetrability to be expected for He^3 particles relative to that for tritons.

On the basis of evidence given by Wilkinson (19) for nucleon clustering in the nuclear surface, Kumabe *et al.* have suggested a direct interaction mechanism for the (n,He^3) reactions in which the incident neutron knocks out a preformed He^3 cluster. In this concept, the results on (n,t) reactions would imply a much lower probability for triton clusters relative to He^3 clusters.

As a further possibility these authors suggest a double-proton pickup mechanism. McManus (20) notes that the two protons would, in the usual case, be picked up from a given shell model state, i.e. from the last shell being filled. In deuteron pickup, however, i.e. in the (n,t) reaction, the neutron and proton picked up would normally occupy states of quite different energy in the target nucleus. On these grounds, since rather little energy is available for the reactions under consideration, the deuteron pickup might be expected to be a much less probable event. In this connection it is interesting to note that in N^{14}, with an odd proton and an odd neutron outside of the stable C^{12} core, a large (n,t) cross section is observed at 7 to 8.2 Mev (4). It is perhaps also noteworthy that the analogous (p,t) reactions are well-known while (p,He^3) reactions, involving deuteron pickup, appear generally to be inhibited (21).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In order to decide on the mechanism involved in the (n,He^3) reactions and to arrive at the explanation for the apparent difference with (n,t) reactions, further information such as angular and energy distributions of outgoing particles is obviously required. Unfortunately this is difficult to obtain with presently available neutron sources and measuring techniques.

ACKNOWLEDGMENTS

The authors wish to thank Dr. H. McManus and Dr. E. Vogt for valuable discussions in connection with this work.
