The reductions of substituted nitrobenzenes for the preparation of azoxy compounds were performed in 500-ml three-necked flasks fitted with a mercury-sealed stirrer, a condenser, and a thermometer. Magnesium turnings were added in small portions over a 30-minute period. The mixture was refluxed about 15

TABLE I

minutes to complete the reaction and the excess magnesium methylate was destroyed with dilute HCl. The precipitated compound was filtered and subjected to steam distillation, leaving a solid, which was crystallized from a suitable solvent.

The reductions for the structural determination of azo and azoxy compounds (1.0 g) were done in 50-ml round-bottomed flasks fitted with a microcondenser, using excess tin (1.0 g) and 50 ml of a solution containing equal volumes of concentrated HCl and alcohol. When alcohol was used as a solvent, the reaction mixture was always refluxed for another half hour after the disappearance of the initial color of the solution. When acetic acid was the solvent the reaction mixture was kept at about 90° C. After the reduction was over, the reaction mixture was filtered, made alkaline with an excess of 20% alkaline solution, and extracted with ether. In the case of hydroxyazo compounds, the aminophenols which remained in the alkaline solution were either obtained as the benzoyl derivatives by the addition of an excess of benzoyl chloride, or extracted with ether after the careful neutralization of the alkaline solution with dilute HCl.

The reduction products are recorded in Table II together with their analyses. The elemental analyses were performed by Micro-Tech Laboratories, Skokie, Illinois, U.S.A.

2,2'-Dimethyl-5,5'-dichloro-azo- and -azoxy-benzenes

2-Methyl-5-chloronitrobenzene (80 g, 0.47 mole) was dissolved in absolute methanol (700 ml) and, while the mixture was constantly stirred, magnesium turnings (32 g) were added in small portions. The mixture was thereafter refluxed for 5.5 hours. Methanol (200 ml) was added during the heating period to keep the reaction mixture in a semifluid state. When reaction was complete, excess magnesium methylate was destroyed by the addition of concentrated hydrochloric acid. The reaction products were precipitated by dilution with water, and unreacted 2-methyl-5-chloronitrobenzene was removed by steam distillation. The azo and azoxy compounds were separated by fractional crystallization from ethanol, the azo compound being less soluble. Both compounds were further purified by crystallization from ethanol. The azoxy compound melted at 124° C as compared with 123° C found in the literature (5); yield, 25 g (36%). The corresponding azo compound melted at 182–183° C; yield, 25 g (30%). Calc. for $C_{14}H_{12}N_2Cl_2$: Cl, 25.7%. Found: Cl, 25.6%.

2'-Nitro-4,4',5,5'-tetrachloroazoxybenzene, 3,3',4,4'-Tetrachloro-5'-nitroazoxybenzene, and 3,3',4,4'-Tetrachloro-5'-aminohydrazobenzene

3,3',4,4'-Tetrachloroazoxybenzene (1.0 g, 0.003 mole) was dissolved in glacial acetic acid (20 ml), and fuming nitric acid (30 ml) was added. The mixture was then heated at 70° C for 10 minutes. By subsequent dilution with water, a precipitate formed which crystallized from hot glacial acetic acid (50 ml) to give 0.15 g of yellow crystals, m.p. 168–169° C. Calc. for $C_{14}H_5N_3O_3Cl_4$: Cl, 37.3%. Found: Cl, 37.0%. The analysis corresponded to the 5'-nitro compound. When reduced by tin and HCl in glacial acetic acid, white crystals were obtained from ethanol, m.p. 191° C. Yield, 0.25 g (30%). Calc. for $C_{12}H_9N_3Cl_4$: Cl, 42.1%. Found: Cl, 42.4%. This analysis corresponded to the aminohydrazobenzene derivative, which was unusually stable in alkaline solution. When the mother liquor from the above crystallization was diluted with water, a precipitate was formed which, when dissolved in acetone or methanol–benzene, gave a non-crystalline yellow compound, m.p. 128.5° C. Yield, 0.5 g (45%). Calc. for $C_{12}H_5N_3O_3Cl_4$: Cl, 37.3%. Found: Cl, 36.9%. Reduction with tin and HCl gave 3,4-dichloro-1,6-diaminobenzene, m.p. 160° C (lit. 160° C) (7), confirming the position of the 2'-nitro group.

THE PRODUCTS OF THE PREVOST REACTION ON D-GLUCAL TRIACETATE

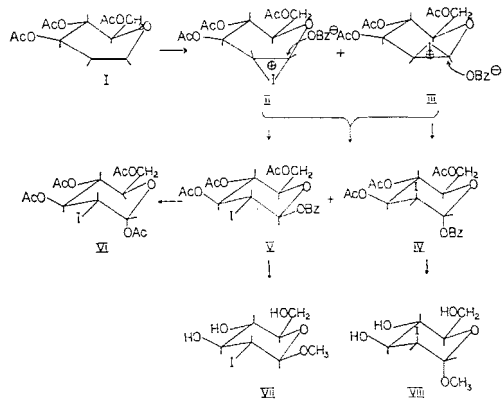
R. U. LEMIEUX[1] AND S. LEVINE[2]
Department of Chemistry, University of Ottawa, Ottawa, Ontario

Received May 7, 1962

ABSTRACT

The compound reported by Stanek and Schwarz (Collection Czechoslov. Chem. Communs. **20**, 42 (1955)) to be 1-*O*-benzoyl-2-iodo-2-deoxy-α-D-glucopyranose triacetate is actually an approximately equimolar mixture of 1-*O*-benzoyl-2-iodo-2-deoxy-β-D-glucopyranose triacetate and the stereoisomer with the α-D-manno configuration. Methanolysis of these compounds yielded methyl 2-iodo-2-deoxy-β-D-glucopyranoside and methyl 2-iodo-2-deoxy-α-D-mannopyranoside, respectively. Hydrogenolysis of the latter iodoglycosides using a palladium catalyst gave near-quantitative yields of the corresponding methyl 2-deoxy-D-glucopyranosides. Several other properties of the iodides are reported.

In 1955, Stanek and Schwarz (1) reacted D-glucal triacetate (I) with iodine and silver benzoate in dry benzene to form a substance termed 1-*O*-benzoyl-2-iodo-2-deoxy-α-D-glucopyranose triacetate, m.p. 129–130°, $[\alpha]_D^{31}$ +21.7° in chloroform. On repeating the experiment, we obtained a nicely crystalline product, $[\alpha]_D$ +25.9° in chloroform, in 96% yield. However, although the product possessed the expected iodine content, the melting point (microstage) was 123–148°.



From a mechanistic point of view, it would be anticipated that, in the first stage of the reaction, both the 1,2-iodonium ions II and III would form. These would subsequently undergo nucleophilic attack by benzoate ion to form 1,2-*trans* adducts of the D-glucal triacetate (I). The positive charge of the iodonium ions should be localized mainly at the anomeric center in view of the ability of the ring oxygen to participate in the delocalization. Certainly, for this reason, nucleophilic attack by benzoate ion should occur largely at the 1-position. It may be noted in this regard that 1,2-anhydro-α-D-glucopyranose triacetate undergoes attack exclusively at the 1-position (2). Therefore, the Prevost reaction (3) would be expected to form, from D-glucal triacetate (I), a

[2]*Present address: Department of Chemistry, University of Saskatchewan, Regina Campus, Regina, Saskatchewan.*

mixture of the two 1-*O*-benzoyl-2-iodo-2-deoxyhexose triacetates IV and V. The relative amounts of these two products presumably would depend either on the relative stabilities of the transition states leading to the two iodonium ions, if these are formed essentially irreversibly in the slow stage of the reaction, or the relative stabilities of the transition states for the nucleophilic attack on the iodonium ions, if the formation of the ions is relatively rapid and reversible. There appears to be no definitive information as to which of these two stages is rate controlling.

The large melting point range that we observed for the product suggested that the substance was a mixture of the isomers IV and V. This condition was clearly substantiated by the nuclear magnetic resonance spectrum of the product, which is reported in Fig. 1. The spectra of the pure compounds are also reproduced in Fig. 1 since this application

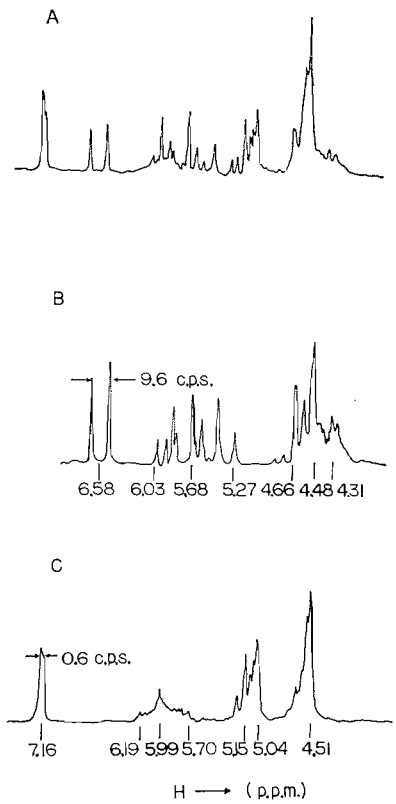

FIG. 1. The proton magnetic resonance spectra measured at 60 Mc/s in chloroform, with tetramethylsilane as an internal standard, of the products which are formed on reacting D-glucal triacetate with iodine and silver benzoate in benzene. Spectrum A is of the crude reaction product and shows that the material is an approximately equimolar mixture of the compounds whose spectra are reproduced in B and C. Spectrum B is of 1-*O*-benzoyl-2-iodo-2-deoxy-β-D-glucopyranose triacetate (V) and spectrum C is of the α-D-manno stereoisomer (IV).

clearly illustrates the power of this relatively new physical tool in the solution of problems related to purity in the field of carbohydrate chemistry. It was at once evident from the appearance of two doublets, at 7.16 and 6.58 p.p.m., in the general region characteristic of anomeric hydrogens for 1-*O*-acyl aldoses (4) that the substance was an approximately 1:1 mixture of two isomeric compounds. The doublet at 6.58 p.p.m. has a spacing of 9.6 c.p.s. and must therefore arise from the isomer (V) with the β-gluco configuration,

wherein the 1-hydrogen is in axial orientation and 1- and 2-hydrogens define a dihedral angle of about 180°. The doublet at lower field has a spacing of only about 0.6 c.p.s. and must arise from a compound with 1- and 2-hydrogens in gauche orientation. From the above-mentioned mechanistic considerations, the signal would be expected to arise from the compound (IV) which has the α-manno configuration. Definitive evidence for this assignment of structure is given below.

A scheme for the separation of IV and V by fractional crystallization was evolved. Compound IV melted at 159.5–160° with $[\alpha]_D$ +45.3° in chloroform whereas compound V melted at 150–151.5° with $[\alpha]_D$ +2.2° in chloroform.

Evidence that compounds IV and V were not anomeric was provided by the following acetolysis and methanolysis experiments. Treatment of V with 1:1 acetic acid – acetic anhydride containing sulphuric acid to constant rotation led to the formation of a substance, m.p. 109.5–111.5°, $[\alpha]_D$ +125° in chloroform, which, in view of its rotation and the fact that the signal for the anomeric hydrogen has a half-band width of only 3 c.p.s., must be 2-iodo-2-deoxy-α-D-glucopyranose tetraacetate (VI). On the other hand, a similar acetolysis of compound IV gave a viscous oil in 91% yield with $[\alpha]_D$ +41.5°. The nuclear magnetic resonance spectrum of this oily substance showed it to be a mixture of presumably anomeric compounds devoid of the benzoate group. The signals for the anomeric hydrogens were at 6.74 and 6.30 p.p.m., whereas the position of the signal for the anomeric hydrogen in compound VI was at 6.85 p.p.m. Therefore, it is highly improbable that compounds IV and V are anomeric since, if they were, they would be expected to yield common products on acetolysis. Treatment of compound V with methanolic hydrogen chloride produced methyl 2-iodo-2-deoxy-β-D-glucopyranoside (VII), m.p. 189–189.5° and $[\alpha]_D$ +6.9° in methanol. The identity of this substance was firmly established by ammonolysis followed by acetylation to methyl 3-amino-3-deoxy-β-D-altropyranoside tetraacetate (5–7). On the other hand, methanolic hydrogen chloride converted compound IV to a methyl 2-iodo-2-deoxyglycoside, VIII, m.p. 146–147° and $[\alpha]_D$ +49.2° in methanol, in 72% yield. Ammonolysis of this compound led to deep-seated degradation without the formation of an aminoglycoside. Further evidence for the configurations of compounds IV and VIII is available from a consideration of the optical rotations shown in Table I. It is seen that there is very good agreement between the molar rotations of compounds IV and VIII and those observed for the corresponding derivatives of α-D-mannose. Although the molar rotations for the configurationally related derivatives of D-glucose do not agree nearly as well, the general agreement is sufficiently good for the present purpose of assigning configurations to the various 2-iodo-2-deoxysugar derivatives. That compounds VII and VIII are in fact 2-iodo-2-deoxyglycosides was firmly established by their hydrogenolysis in near-quantitative yield to the methyl 2-deoxy-β- and -α-D-glucopyranosides, respectively.

Stanek and Schwarz (1) prepared 2-deoxy-D-glucose in low yield by reduction of the substance now known to be a mixture of IV and V using a zinc–copper couple in methanol. We observed this reaction to lead to the formation of water-soluble substances, starting either from IV or V and using the zinc–copper couple described by Shank and Schechter (8). These contained zinc and liberated D-glucal when hydrolyzed with base. Attempts to hydrogenolyze V using a palladium-on-charcoal catalyst in the presence of diethylamine in methanol led to the consumption of 2 moles of hydrogen per mole of V. The product of the reaction was not characterized.

Both the 2-iodo-2-deoxyglycosides VII and VIII rapidly consumed sodium hydroxide. The gluco compound (VII) consumed the base about three times more rapidly than the

manno epimer (VIII), presumably because of the trans configuration of the 2,3-iodohydrin group in VII. However, 1.9 equiv of base were consumed per mole of VII and 2.9 equiv per mole of VIII. These results undoubtedly are related to elimination of the iodine to form initially 2-deoxy-3-ketoglycosides, which under the influence of the base are degraded to acidic products. These reactions are under investigation.

Small amounts of methyl 2-iodo-2-deoxy-β-D-glucopyranoside (VII) were isolated from the methanolysis of pure 1-*O*-benzoyl-2-iodo-2-deoxy-α-D-mannopyranose triacetate (IV). The formation of this compound requires dissociation of the benzoyloxy group, with participation of the iodine atom, to lead initially to a 1,2-iodonium ion. This ion must then decompose to some extent to D-glucal and positive iodine (likely either as methyl hypoiodite or iodine chloride), which recombine to form a 2,3-*trans*-iodonium ion (such as II) which can lead to the formation of VII. It is of interest to note from the point of view of neighboring iodine participation (9) that the methanolysis of V afforded only a 20% yield of VII. Since VII proved highly resistant to change under the conditions of methanolysis, it could not be the main product of the reaction.

EXPERIMENTAL

Mixture of 1-O-Benzoyl-2-iodo-2-deoxy-triacetate Derivatives of β-D-Glucopyranose and α-D-Mannopyranose

D-Glucal triacetate (10), 37.5 g (0.133 mole), was added to 30 g (0.131 mole) of silver benzoate suspended in 400 ml of dry benzene. Iodine, 36 g (0.141 mole), was added to the stirred solution and the purple color which formed after the addition of each portion disappeared almost immediately. After all the iodine had been added the mixture had a faint brown coloration. The mixture was stirred for 30 minutes at room temperature, the silver iodide was collected by filtration, and the filter cake washed with benzene. The combined filtrates were washed with sodium thiosulphate and sodium bicarbonate and finally with water. The benzene was removed *in vacuo* to leave 65.4 g (96%) of a crystalline residue; m.p. 123–148°, $[\alpha]_D$ +25.9° (*c*, 2.0 in chloroform). A study of the solubility properties of the components of the mixture led to the following scheme for their separation by fractional crystallization.

1-O-Benzoyl-2-iodo-2-deoxy-β-D-glucopyranoside Triacetate (V)

The above-mentioned crystalline mixture, 50 g, was dissolved in 75 ml of acetone, and 150 ml of cyclohexane was added. There was obtained 6.13 g of crystals, $[\alpha]_D$ +7.1° (*c*, 2.1 in chloroform), and mother liquor A. After two recrystallizations from methanol there remained 4.70 g of white crystals, $[\alpha]_D$ +2.2 (*c*, 1.9 in chloroform), with a transition beginning at 145°. When the melting point was determined at a sufficiently slow rate to allow completion of the transition, the melting point was 150–151.5°. Further

recrystallization from either methanol or ethanol did not change the melting point or rotation. The n.m.r. spectrum (Fig. 1B) showed the presence of only one type of anomeric hydrogen.

In the presence of onefold excess of sodium hydroxide in 50% aqueous dioxane at 0°, compound V consumed within 60 minutes 5 equiv of base per mole with the liberation of 1 mole-equiv of iodide ion.

Anal. Calc. for $C_{19}H_{21}O_9I$: C, 43.86; H, 4.07; I, 24.40. Found: C, 43.61; H, 4.34; I, 24.71.

1-O-Benzoyl-2-iodo-2-deoxy-α-D-mannopyranose Triacetate (IV)

The crystalline residue obtained after evaporation of solvent from mother liquor A was dissolved in 350 ml of benzene, and 700 ml of 30–60° petroleum ether was added. Crystals, 9.84 g, were deposited, $[\alpha]_D$ +43.1° (*c*, 1.8 in chloroform), in mother liquor B. One recrystallization from methanol gave 7.43 g of large white crystals, $[\alpha]_D$ +45.3° (*c*, 2 in chloroform), m.p. 157–160° with a transition at about 150°. After the transition was complete, the melting point was 159.5–160°. The melting point and rotation were not changed by further recrystallization either from methanol or ethanol. The n.m.r. spectrum of the product (Fig. 1) showed the presence of only one type of anomeric hydrogen.

In the presence of a onefold excess of sodium hydroxide in 50% aqueous dioxane at 0° compound IV consumed within 40 minutes 6 equiv of base per mole with the liberation of 1 mole equiv of iodide ion. It is apparent that the elimination of the iodine atom led to the formation of acidic products.

Anal. Calc. for $C_{19}H_{21}O_9I$: C, 43.86; H, 4.07; I, 24.40. Found: C, 44.13; H, 3.96; I, 24.00.

Evaporation of mother liquor B left a crystalline residue with a composition approximately that of the original reaction product. The fractional crystallization was continued until 9.28 g of mixture remained. It was not possible to obtain a further yield from this residue. The total yields of 1-*O*-benzoyl-2-iodo-2-deoxy-β-D-glucopyranose triacetate and 1-*O*-benzoyl-2-iodo-2-deoxy-α-D-mannopyranose triacetate were 14.3 and 20.9 g, respectively.

Methyl-2-iodo-2-deoxy-β-D-glucopyranoside (VII)

A solution of 10 g (0.0192 mole) of 1-*O*-benzoyl-2-iodo-2-deoxy-β-D-glucopyranose triacetate in 400 ml of 2% methanolic hydrogen chloride was allowed to stand at room temperature until it had attained constant rotation (6 hours). The solution was then neutralized with silver carbonate and, after filtration, hydrogen sulphide was used to remove silver ion. After removal of the methanol, an aqueous solution of the residue was decolorized using charcoal and then evaporated to 5.61 g of viscous oil. Crystallization from ethyl acetate gave 1.19 g (20%) of a crystalline solid, m.p. 189–189.5°, $[\alpha]_D$ +6.9° (*c*, 2.1 in methanol).

Anal. Calc. for $C_7H_{13}O_6I$: C, 27.65; H, 4.31; I, 41.74. Found: C, 27.74; H, 4.53; I, 41.22.

All attempts to isolate crystalline methyl 2-iodo-2-deoxy-α-D-glucopyranoside from the mother liquors were unsuccessful.

Acetylation of VII in the usual manner using acetic anhydride and pyridine provided a near-quantitative yield of methyl 2-iodo-2-deoxy-β-D-glucopyranoside triacetate (IX), m.p. 85–86°, $[\alpha]_D$ +6.2° (*c*, 1.3 in chloroform).

Anal. Calc. for $C_{13}H_{19}O_8I$: C, 36.29; H, 4.45; I, 29.50. Found: C, 36.18; H, 4.69; I, 29.18.

In the presence of a 50% excess of aqueous sodium hydroxide at room temperature, compound VII consumed within 20 hours 1.88 milliequiv of base per mole with the liberation of 1 mole equiv of iodide ion.

Methyl 2-Iodo-2-deoxy-α-D-mannopyranoside (VIII)

Treatment of 1-*O*-benzoyl-2-iodo-2-deoxy-α-D-mannopyranose triacetate (IV) under the same conditions mentioned above for the gluco isomer led to the isolation of a compound, m.p. 145–146°, $[\alpha]_D$ +49.2° (*c*, 1 in methanol).

Calc. for $C_7H_{13}O_5I$: C, 43.86; H, 4.07; I, 24.40%. Found: C, 44.13; H, 3.96; I, 24.00%.

Acetylation of VIII in the usual manner using acetic anhydride and pyridine gave a product (X), $[\alpha]_D$ +44.9° in chloroform, which failed to crystallize. The nuclear magnetic spectrum left no doubt that the compound was essentially pure.

In the presence of a 50% excess of aqueous sodium hydroxide, compound VIII consumed within 40 hours at room temperature 3 equiv per mole with the liberation of 1 mole equiv of iodide ion.

2-Iodo-2-deoxy-α-D-glucopyranose Tetraacetate (VI)

A solution of 0.269 g (0.5 mmole) 1-*O*-benzoyl-2-iodo-2-deoxy-β-D-glucopyranose triacetate in 2 ml of 1:1 acetic anhydride – acetic acid was added to 0.256 g of 95.5% sulphuric acid in 2 ml of the acetic anhydride – acetic acid. After mixing, the volume was adjusted to 5 ml with the 1:1 acetic acid – acetic anhydride mixture to yield a solution 0.5 *M* in sulphuric acid and 0.1 *M* in the glucose derivative. The observed optical rotation in a 2-dm tube of the solution reached a constant value of 13.5° after 15 minutes at room temperature. After standing for 25 minutes, the product was isolated in the usual manner. An oil, 0.20 g (87%), was obtained which crystallized after trituration with 30–60° petroleum ether. Recrystallization from benzene – petroleum ether gave 0.12 g of material; m.p. 109.5–111.5° $[\alpha]_D$ +125° (*c*, 1.7 in chloroform).

Anal. Calc. for $C_{14}H_{19}O_9I$: C, 36.69; H, 4.18; I, 27.70. Found: C, 36.50; H, 3.99; I, 27.82.

Acetolysis of 1-O-Benzoyl-2-iodo-2-deoxy-α-D-mannopyranose Triacetate

The acetolysis was carried out in exactly the same manner as for 1-*O*-benzoyl-2-iodo-2-deoxy-β-D-glucopyranose triacetate. The specific rotation of the solution reached a minimum observed value of 1.47° (using a 2-dm tube) after standing the solution 9 minutes at room temperature and remained at this value for about 42 minutes. The observed rotation of the solution then rose to a constant value of 4.5°. The product, 0.21 g (91%) of a viscous oil, $[\alpha]_D$ +41.5° (*c*, 1.7 in chloroform), was isolated in the usual manner. The nuclear magnetic resonance spectrum showed two signals of about equal intensity in the region characteristic of anomeric hydrogens for this type of compound. One signal was in the form of a singlet at 6.74 p.p.m. and the other a doublet at 6.30 p.p.m. with a spacing of 8.5 c.p.s. The intensities of these signals were considerably lower than expected and it seems likely, therefore, that the reaction was not restricted to replacement of the benzoyloxy group by acetoxy group.

Methyl 3-Acetamido-3-deoxy-β-D-altropyranoside Triacetate

Methyl 2-iodo-2-deoxy-β-D-glucopyranoside, 0.20 g (0.66 mmole), was dissolved in 2.5 ml of dry methanol saturated with ammonia and the solution, in a sealed tube, was heated for 6 hours at 120°. The methanol and ammonia were removed and the residue was dissolved in water. After treatment with silver carbonate and then with hydrogen sulphide, the aqueous solution was decolorized with charcoal. Evaporation of the water *in vacuo* left 0.11 g of a deliquescent white powder, which was acetylated using 1 ml of pyridine and 0.7 ml of acetic anhydride for 22 hours. The product, 0.19 g of a light yellow oil, was isolated in the usual manner and dissolved in a small amount of absolute ethanol. After standing at 4° for 19 hours there was deposited 0.16 g (65%) of a crystalline material, m.p. 189.5–190°, $[\alpha]_D$ −123° (*c*, 1.1 in chloroform), −149° (*c*, 1.2 in methanol). The reported (5–7) physical constants for methyl 3-acetamido-3-deoxy-β-D-altropyranoside triacetate are: m.p. 188°, $[\alpha]_D$ −119° (chloroform).

Anal. Calc. for $C_{15}H_{23}O_9N$: C, 49.86; H, 6.42. Found: C, 50.04; H, 6.51.

Methyl 2-Deoxy-β-D-glucopyranoside

A solution of 0.303 g (1 mmole) of methyl 2-iodo-2-deoxy-β-D-glucopyranoside (VII) and 0.148 (2.04 mmoles) of diethylamine in 10 ml of water was hydrogenated at room temperature and pressure using 0.035 g of palladium on charcoal as catalyst. The theoretical amount of hydrogen was taken up in 16 minutes. After 30 minutes, the catalyst was removed by filtration and the filtrate was treated with silver carbonate to remove iodide ion and then with hydrogen sulphide to remove silver ion. After evaporation of the water and diethylamine *in vacuo* an aqueous solution of the residue was decolorized with charcoal. Evaporation of the water left 0.15 g (84%) of crystalline material which, after recrystallization from ethyl acetate, melted at 121.5–122°, $[\alpha]_D$ −46.9° (*c*, 1.0 water). The physical constants reported (11) for methyl 2-deoxy-β-D-glucopyranoside are: m.p. 122–123°, $[\alpha]_D$ −48.4° (water).

Methyl 2-Deoxy-β-D-glucopyranoside Triacetate

A solution of 0.10 g of methyl 2-deoxy-β-D-glucopyranoside in 0.7 ml of pyridine and 0.5 ml of acetic anhydride was allowed to stand for 18 hours at 4°. The product, 0.17 g of crystalline material, was isolated in the usual manner. After recrystallization from ether – 30–60° petroleum ether, the material melted at 97–99°, $[\alpha]_D$ −34.8° (*c*, 0.9 in chloroform). Methyl 2-deoxy-β-D-glucopyranoside triacetate is reported (5) to melt at 96–97°, $[\alpha]_D$ −30.2° (tetrachloroethane).

Methyl 2-Deoxy-α-D-glucopyranoside

Hydrogenation of 0.303 g (1 mmole) of methyl 2-iodo-2-deoxy-α-D-mannopyranoside (VIII) and purification of the product in the same manner as described above for the β-anomer gave 0.16 g (89%) of material which was recrystallized from ethyl acetate. The substance melted at 93.5–94.5°, $[\alpha]_D$ +143° (*c*, 0.9 in methanol). Methyl 2-deoxy-α-D-glucopyranoside is reported (11) to melt at 92–93°, $[\alpha]_D$ +145° (*c*, 0.8 in methanol). The tri-*O*-acetyl derivative failed to crystallize.

Reductions with Zinc–Copper Couple

1-*O*-Benzoyl-2-iodo-2-deoxy-β-D-glucose triacetate (0.15 g) was dissolved in 6.5 ml of absolute methanol, and 0.7 g of zinc–copper couple (8) was added. The mixture was stirred for 8 hours at room temperature. After filtration, the filtrate was evaporated to dryness *in vacuo* and the residue was taken up in chloroform. Evaporation of the clarified chloroform solution left 0.15 g of a white, semicrystalline, waxy solid which gave a strong positive test for zinc. The material, which was partially soluble in water and gave an immediate precipitate with silver nitrate, was suspended in water and titrated with aqueous sodium hydroxide. One equivalent of base per molecular weight of starting material was rapidly consumed. A further equivalent of base was consumed slightly less rapidly. A non-combustible precipitate was formed, which likely was zinc oxide. Filtration and evaporation *in vacuo* left a residue which was acetylated with pyridine and acetic anhydride. A 74% yield of a substance characterized as D-glucal triacetate (mixed melting point and infrared spectra) was obtained.

A similar reduction of 1-*O*-benzoyl-2-iodo-2-deoxy-α-D-mannopyranose triacetate gave a 79% yield of D-glucal triacetate.

ACKNOWLEDGMENTS

The authors wish to thank the Bristol Laboratories Incorporated and the National Research Council of Canada for the financial support of this research through grants to R. U. L. The nuclear magnetic resonance spectra were determined by Mrs. A. Westland and the microanalyses were conducted by Miss E. Busk of these laboratories.

ELECTROCHEMISTRY OF THE NICKEL OXIDE ELECTRODE

PART IV. ELECTROCHEMICAL KINETIC STUDIES OF REVERSIBLE POTENTIALS AS A FUNCTION OF DEGREE OF OXIDATION

B. E. CONWAY AND E. GILEADI

Department of Chemistry, University of Ottawa, Ottawa, Ontario

Received May 22, 1962

ABSTRACT

Electrochemical kinetic studies have been carried out at the nickel oxide electrode showing that the reversible potential for the Ni^{II}–Ni^{III} system is independent of the state of oxidation of the bulk oxide in the electrode over a wide range of degrees of oxidation. The properties of the electrode are shown to be determined by the state of a surface phase, which is completely charged when the bulk oxide material in the electrode has been charged to 10% of its total charge capacity. Experiments on sparingly charged electrodes have proved that charging of the bulk oxide does not commence significantly until the electrode is charged to about 1.5%. Consecutive electrochemical reactions possibly involved in the charging process are discussed.

INTRODUCTION

The real reversible potential of the nickel oxide (Ni^{II}–Ni^{III}) electrode has been the subject of controversy for some years and previously reported values are misleading since they have not been based on well-defined equilibrium conditions or a well-defined state of the system. Determination of the reversible potential is complicated by the self-discharge processes which occur at the electrode in the oxidized form and also by the fact that the electrode may exist in a range of chemical states corresponding to the extent of conversion of Ni^{2+} to Ni^{3+} (and possibly Ni^{4+} under certain conditions) in the hydrated oxide.

In an earlier paper (1), the true reversible potential of partially charged nickel oxide electrodes at a single controlled state of oxidation "$NiO_{1.25}$" was examined as a function of potassium hydroxide and water activities in aqueous alkali solutions, and distinguished from the mixed potential assumed in previous work (2, also 12, 13) to be the reversible potential. A polarization decay method was employed (1, 3, 4) in which the reversible potential was approached both from the anodic and the cathodic directions.

In the present phase of our work, the same method has now been applied to the study of the potential of partially charged nickel oxide electrodes as a function of the degree of charge, at constant electrolyte composition. This method was found to be applicable only over a limited range of degree of oxidation of the electrode ("$NiO_{1.10}$"–"$NiO_{1.30}$") owing to problems of extrapolation to the reversible potential to be discussed below. Stationary potentials, taken at very long times on open circuit, were therefore also measured as a function of the degree of charge over a much wider range of degree of oxidation ("$NiO_{1.025}$"–"$NiO_{1.50}$").

The role of the surface and bulk phases in determining the measured potential was deduced. It will be shown that three well-defined regions in the charging process can be distinguished experimentally. In the first, the surface phase alone is being charged; in the intermediate region, the Faradaic current is used to charge both phases, until the surface phase is fully charged, after which oxidation of the bulk is the main Faradaic process. (Most of the charging process occurs at a potential anodic to the reversible oxygen electrode, so that oxygen evolution must occur to a certain extent as a parallel process in all three regions described above. It does not, however, become appreciable until most of the bulk material has been charged.)

EXPERIMENTAL

(1) Electrodes

Nickel hydroxide electrodes were prepared in sintered-nickel plaques by methods described in detail previously (1, 3, 5). Each electrode was charged and discharged three times before use, at a 5-hour charging rate, in order to stabilize its electrochemical behavior (3, 4).

(2) Solutions

All solutions and reagents were prepared as described previously (1, 3), and most experiments were carried out in 1 *N* aqueous KOH at 25° C. Some comparative runs were carried out in 7.2 *N* KOH.

(3) Reversible Potentials

The reversible potential of the Ni^{II}–Ni^{III} system was obtained by extrapolating anodic and cathodic e.m.f. decay lines, plotted logarithmically in time, to the potential of their intersection, as described in a previous paper (1).

The "discharged" electrodes still contained a small amount of the higher oxide of nickel, which at the apparent end of discharging is evidently inaccessible, probably due to insulation by the less conducting $Ni(OH)_2$ (6). The electrodes were reduced completely by prolonged cathodic polarization until a total of 3 F/equivalent had been passed. The electrodes were then transferred to another cell containing freshly prepared electrolyte and reference electrodes, and left on open circuit overnight with purified oxygen bubbling through the cell.

The following sequence of operations was then performed at a current corresponding to a 2-hour charging rate, i.e. at 143 ma g^{-1} of active material calculated as $Ni(OH)_2$ (cf. ref. 1).

(*a*) The electrode was charged for 24 minutes to an extent of oxidation of 20% ($NiO_{1.10}$) based on the oxidation change $Ni^{II} \rightarrow Ni^{III}$ in the oxide. The current was then interrupted and open-circuit decay of potential followed for about an hour.

(*b*) Charging was then continued for 24 minutes, followed immediately by discharge for the same length of time. The current was then interrupted and buildup (i.e. recovery of potential on open circuit to more anodic values) was followed for an hour, the degree of charge again being 20%, as in (*a*).

Anodic and cathodic open-circuit decay and recovery of potential were followed in a similar manner at the 40%, 60%, and 80% charged electrodes, corresponding to formal degrees of oxidation of $NiO_{1.20}$, $NiO_{1.30}$, $NiO_{1.40}$ respectively. Charging and discharging curves for one of these experiments are shown in Fig. 1. Similar charging and discharging cycles were carried out to obtain data for electrodes in 25%, 50%, and 75% degrees of oxidation (see Table I).

TABLE I

Degree of charge (%)	KOH concn. (*N*)	Anodic decay slope		Cathodic buildup slope b_3 (mv)	E_{rev}† (mv)	Number of experiments

*See comment in text with regard to these degrees of oxidation.
†The reversible potentials are given vs. that of a Hg/HgO reference electrode in the same solution.

(4) Stationary Potentials

In this series of experiments, the electrodes were charged to a given degree of oxidation, and decay of e.m.f. on open circuit was followed by means of a high-impedance recorder for about a week, at which time the e.m.f. varied at a rate of 1 mv/day or less.

(5) Sparingly Charged Electrodes

A series of experiments was conducted on electrodes charged to a very small extent (0.33% to 5% of total charge capacity).

RESULTS

Plots of decay of e.m.f. after anodic and cathodic polarization vs. log $(t+\theta)$ are shown in Fig. 2. The significance of this type of plot, of e.m.f. decay slopes, and of the parameter θ have been discussed previously (1, 3, 4, 7, 8).

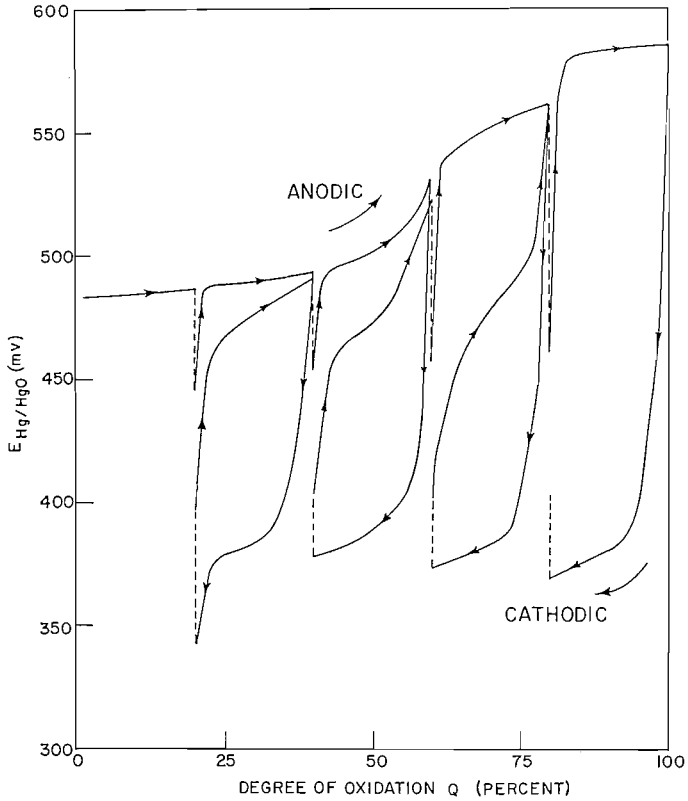

FIG. 1. Anodic and cathodic polarization curves for the nickel oxide electrode in 1 *N* KOH, 2-hour charging rate. Vertical broken lines correspond to open-circuit e.m.f. decay or recovery. Solid lines correspond to changes of potential associated with changes of degree of charge between successive open-circuit measurements.

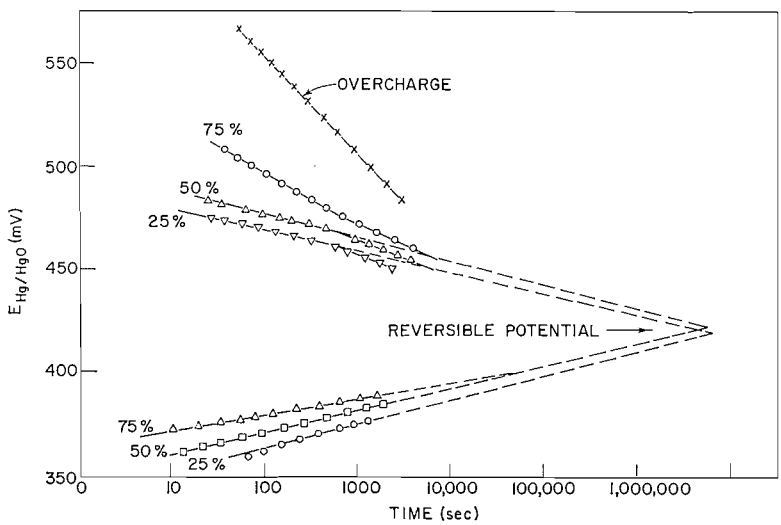

FIG. 2. Decay and recovery of e.m.f. of the nickel oxide electrode in log [time] at various degrees of charge after anodic and cathodic polarization, respectively (data for 1 *N* KOH); compare ref. 1.

All e.m.f. decay lines from anodic polarization are seen to have two distinct regions. For electrodes charged to 50% ("$NiO_{1.25}$") or less, an initial low slope (about −10 mv) is followed by a higher slope (about −20 mv). When the electrode is charged to 75%, a high initial slope (about −32 mv) is followed by the same slope (−20 mv) mentioned above, in the lower-potential region. Electromotive force recovery lines from cathodic polarization have a slope of about +11 mv, independent of degree of charge. Results for a typical individual experiment are given in Fig. 2 and some slight increase of recovery slope is apparent as the charge is reduced; however, this trend does not appear to be very significant statistically (e.g. see Table I).

In Table I, the reversible potentials for the Ni^{II}–Ni^{III} system, obtained by extrapolating cathodic and (initial) anodic e.m.f. decay lines (1), are given for different degrees of charge (between 20% and 50% formal degree of oxidation) of the electrode at 25° C, together with other kinetic parameters. An important result obtained here is that the reversible potential is seen to be *independent* of formal degree of charge over the above range of charge. Similar conclusions were arrived at from two comparative runs in 7.2 *N* KOH.

For reasons to be discussed, it is not possible to obtain the true reversible potentials by extrapolation of cathodic and anodic e.m.f. decay lines above degrees of oxidation of about 50%. In order, however, to study further the potentials of the nickel oxide electrode, the "stationary" or quasi-equilibrium potentials were examined at higher states of oxidation.

In Table II, the "stationary" potentials measured after 4×10^5 and 6×10^5 seconds on

TABLE II

Stationary potentials of the nickel oxide electrode in 1 *N* KOH, 25° C

Degree of charge (%)	Potential reached after 4×10^5 sec (mv, Hg/HgO)	Potential reached after 6×10^5 sec (mv, Hg/HgO)
"Overcharge"	426.5	422.6
50	426.5	424.0
20	420.4	417.2
10	422.6	419.9
7	406.0	404.8
5	401.5	399.3

open circuit are given for various degrees of charge of the electrode between 5% and 100% (overcharged electrode). These results were obtained by reducing the electrode completely, polarizing it anodically to the appropriate degree of charge, and then leaving it on open circuit for 6×10^5 seconds or longer. It is seen that the "stationary potential" measured after a long period of standing on open circuit is still independent of the degree of charge above 10% extent of oxidation ("$NiO_{1.05}$"), and in this respect exhibits a behavior similar to that of the true reversible potentials.

Results of experiments on sparingly charged electrodes (0.33% to 5% degree of oxidation) are shown in Fig. 3, where the e.m.f.–time relation is plotted for decay on open circuit after anodic charging for various degrees of charge. It is seen that the decay process changes qualitatively once quite low degrees of charge are reached. These results can, for the purpose of interpretation, be best represented graphically as plots of the degree of charge, Q, held by the electrode vs. the time required for the electrode potential to decay to a given value (Fig. 4) or in terms of the charge held vs. the potential reached after a given time (Fig. 5). These plots are equivalent to taking cuts at a given value

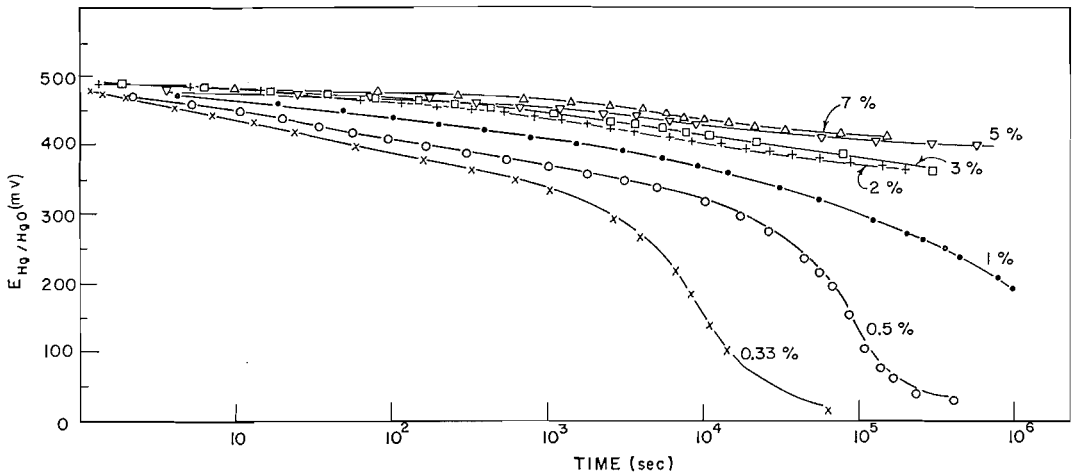

FIG. 3. Plots of e.m.f. decay at sparingly charged electrodes, for various degrees of charge.

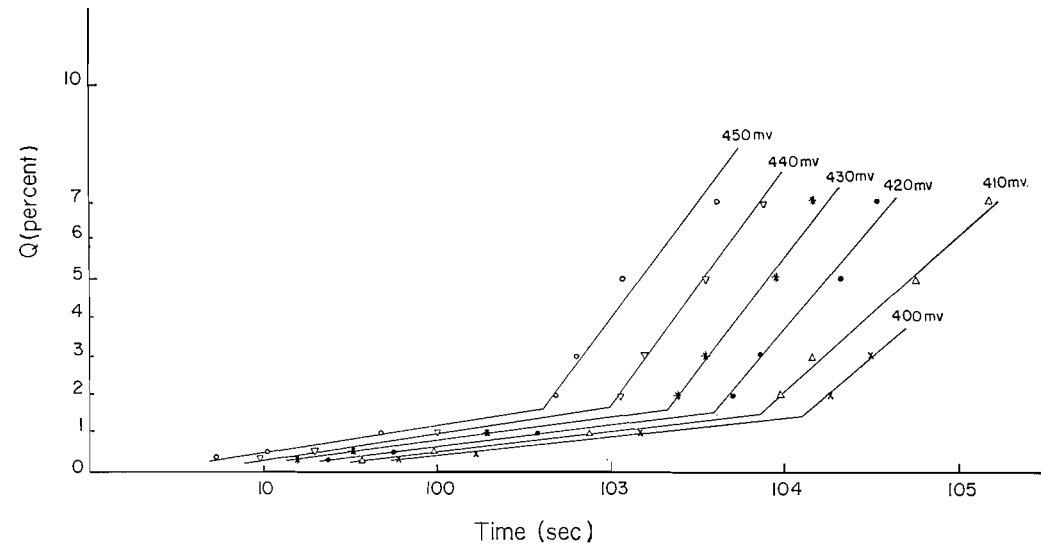

FIG. 4. The length of time necessary for the electrode to reach a certain potential on open circuit vs. the degree of charge of the electrode. (Lines show inflection at common degree of charge $Q = 1.6 \pm 0.1\%$.)

of the abscissa or ordinate in Fig. 3.

It is seen from both these derived plots that two linear regions are observed for each of the two families of lines, which intersect at a degree of charge of ca. $1.5 \pm 0.1\%$. This observation leads to the important conclusion that electrodes charged to 1.5% or less are in a fundamentally different state than electrodes charged to a greater extent of oxidation. This point is further demonstrated by examining the decay slopes listed in Table III below. It was shown previously (1) that the initial low slope (ca. -10 mv) is characteristic of the oxidation of the bulk nickel oxide. In the present work, this slope was only observed for electrodes charged to 2% or more. Below the latter extent of charge, no oxidation of the bulk material appears to occur, and the potential on open circuit drops much more rapidly.

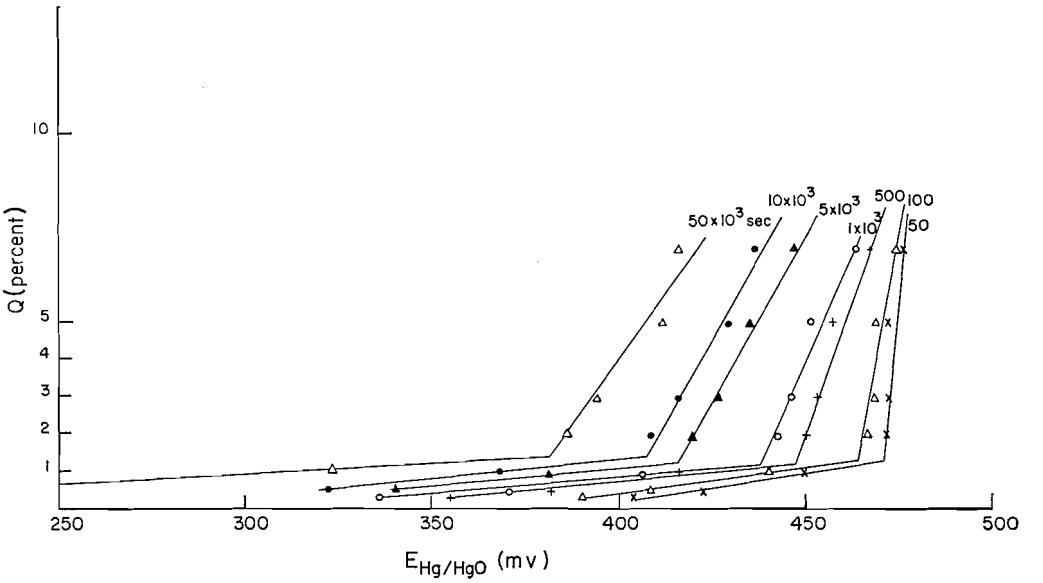

FIG. 5. The potential reached after a given length of time on open circuit vs. the degree of charge. (Lines show inflection at common degree of charge $Q = 1.35 \pm 0.1\%$.)

TABLE III

E.m.f. and e.m.f.–decay behavior at sparingly charged electrodes

Degree of charge (%)	Decay slopes (as in Table I)		E.m.f. V (mv) at time of last measurement	Time of last measurement (10^5 sec) after interruption of polarization	$\Delta V/\Delta t$ for the last day (mv/day)

⅓	−48	>300	18	0.7	1

DISCUSSION

The reversible potential for the Ni^{II}–Ni^{III} system in the electrochemically formed nickel oxide has been shown to be independent of the degree of charge of the electrode. Between 20% and 50% degree of charge, it was measured by extrapolating anodic and cathodic e.m.f. decay lines, plotted logarithmically in time, as described earlier (1). Values of the reversible potential could only be obtained over a limited range of degrees of oxidation (20–50% of total charge) since at a higher degree of charge the initial low anodic slope, characteristic of the oxidation of the bulk material (1), was not observed (see Fig. 2), and at a very low degree of charge, cathodic e.m.f. recovery lines were irregular and difficult to reproduce.

It is of interest to discuss why the reversible potential cannot be obtained by extrapolation of anodic and cathodic polarization decay lines above a degree of charge of about 50%. In Fig. 2 it is evident that the e.m.f. decay line, e.g. for 75% degree of charge, shows two linear regions in "concave" relationship to one another as also found for the

"overcharged" electrode (3), whereas (1) at lower degrees of charge, a "convex" relation is observed between two linear regions. We have previously shown (1, 3) how such relations arise, respectively, from two processes in an overall mechanism which are consecutive, so that one or the other becomes rate determining, depending on the potential range; or the two processes are parallel and the faster determines the kinetics. Above 50% degree of charge (for example, with the 75% charged electrode), it is clear that the former type of process is operative, as it is in oxygen evolution at overcharged nickel oxide electrodes (3); moreover, the Tafel slopes are similar to those obtained for the oxygen evolution process at the overcharged electrode. We cannot hence identify the initial process as involving the Ni^{II}–Ni^{III} oxidation reaction as we have done for the 50% charged electrode (1) and so cannot obtain the true reversible potential by the extrapolation procedure under these conditions. We can have, in effect, two pathways for the anodic reaction which could be written, for example, as

$$M + OH^- \rightarrow MOH + e \qquad (I)$$

$$MOH + OH^- \rightarrow MO + H_2O + e \qquad (II)$$

(A) oxide oxidation in bulk of material

(B) O_2 evolution by further steps (cf. refs. 1, 3, 15)

e.g.

$$MO + MOH \rightarrow MHO_2 \qquad (III)$$

$$MHO_2 + MOH \rightarrow O_2 + H_2O + M \qquad (IV)$$

or

$$MO + OH^- \rightarrow MHO_2 + e \qquad (V)$$

$$MHO_2 + MOH \rightarrow O_2 + H_2O + M \qquad (IV)$$

or

$$2MO \rightarrow O_2. \qquad (VI)$$

At the higher degrees of charge ($> \simeq 50\%$), the pathway is evidently one involving *consecutive* rate-determining steps and is therefore probably associated with the scheme (I), (II) with pathway (B) to oxygen evolution with, for example, (II) or (VI) (cf. ref. 16) rate determining.

At low degrees of charge, 50% or less, the course of the e.m.f. decay corresponds to alternative reactions, one or the other of which becomes predominant as the potential changes, as we have discussed previously (1). The pathway is thus probably (I), (II), and (A) at short times after decay (higher anodic potentials) and (I), (II), and (B) to oxygen evolution at longer times when the pathway which is faster at lower anodic potentials dominates the kinetics of the decay process.

The above discussion is intended only as a qualitative, plausible explanation of the effects associated with the e.m.f. decay behavior, as a function of charge and we have discussed in detail elsewhere (1, 3, 16) the evidence for assignment of some of the mechanisms involved in the oxygen evolution process in the scheme shown above.

In order to supplement the above data on true reversible potentials, steady or quasi-equilibrium potentials were measured over a wider range of degrees of oxidation (5–100%). The significance of these potentials as kinetically determined mixed potentials

has been discussed previously (1). They cannot be related directly to the reversible potential of the system at different degrees of charge, since the exchange current for the nickel II $\rightarrow$ III oxidation process may strictly depend on the degree of charge. Nevertheless, the constancy of these potentials over a large range of formal degree of oxidation of the electrode ("$NiO_{1.05}$" to "$NiO_{1.50}$"), combined with the fact that the true reversible potential has been shown above to be independent of degree of charge in the range where it is directly accessible, makes it most probable that the reversible potential is, in fact, constant over the whole range of degrees of oxidation where the steady potential is found to be constant. This is contrary to conclusions reported by Lukovtsev and Temerin (9) (using electrodes with a graphite matrix), who claimed that the apparent reversible potential of this system follows a Nernst-type equation with a slope of 0.050 v. The observed variation of actual potential during charging and discharging, on which the latter conclusion was based, may be due to a concentration polarization in the solid phase (6, 9), or a change in effective current density due to a change in available surface area, and not due to a variation of the true reversible potential of the system, as claimed by Lukovtsev and Temerin.

Our present findings are not in conflict with the equation

$$E = a + b_2' \log \left(\frac{q_{ox} - q_{red}}{q_{red}} \right),$$

discussed by Lukovtsev and Temerin and examined and evaluated by Conway and Bourgault (4), since that equation refers to the variation of electrode potential with degree of oxidation of the *surface* phase in the overcharge region, and in fact the potential of the electrode was shown (1) to involve a term corresponding to uptake of adsorbed KOH.

For electrodes charged to less than 10%, the open-circuit steady potential was found to depend on the degree of charge to a large extent. Electrodes charged to 1% or less behaved quite differently from those charged to a greater extent. The results suggest that up to a degree of charge $Q = 1.5 \pm 0.1\%$ (i.e., the average value of Q at the points of intersection of the lines in Figs. 4 and 5) only a surface phase is being charged. Above that, and up to a degree of oxidation of about 10%, both surface and bulk phases are being charged. When the electrode has been charged to 10% of its total charge capacity, it appears that the surface phase is completely charged, and any further charging can then only affect the bulk material.

The variation of the observed true reversible, and stationary or quasi-equilibrium potentials as a function of charge in 1 *M* KOH is shown in Fig. 6. The electrochemical behavior of the electrode is evidently determined by the *surface* phase, since the reversible (or steady) potential is independent of the degree of charge so long as the surface phase is apparently completely charged, i.e., above 10% formal degree of oxidation. The theoretical Nernst plot for a one-electron transfer process (in terms of formal degrees of charge) which would be observed for ideal solid-solution behavior, with the bulk material potential determining, is shown in Fig. 6 for comparison.

The independence of reversible (or steady) potential demonstrated, above a degree of oxidation of 10%, could formally arise for either of the following reasons: (*a*) If the electrode were a two-phase mixture of lower and higher oxide, the potential would be independent of apparent degree of oxidation so long as both oxides were present. (*b*) If the potential were determined by a surface phase of constant composition, superimposed on a bulk phase of varying degree of oxidation but not potential determining, the observed potential would be independent of composition of the bulk.

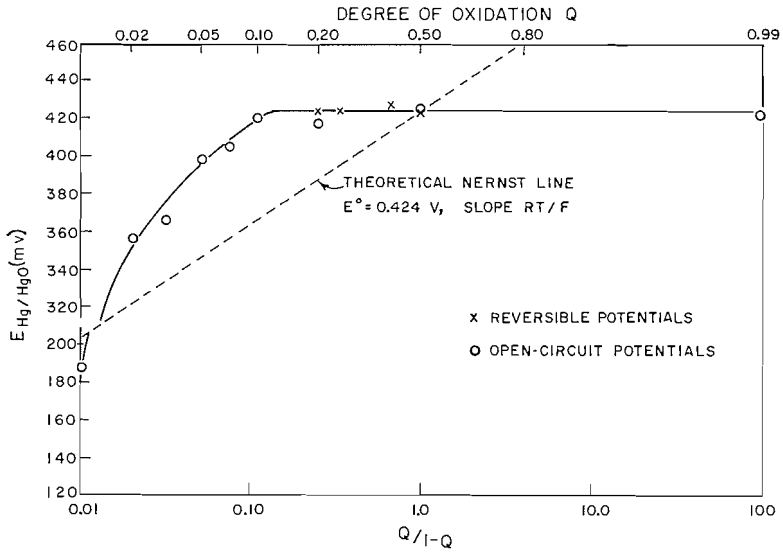

FIG. 6. True reversible potentials and quasi-equilibrium "stationary" potentials of the nickel oxide as a function of degree of oxidation. One-electron theoretical Nernst slope is shown for comparison.

The latter situation, (*b*), is consistent with our previous kinetic conclusions (1) on the mechanism of charging of the bulk material via a surface phase, and our observation of a large adsorption pseudocapacitance associated with the (overcharged) nickel oxide electrode. The former possibility, (*a*), is rendered unlikely by the X-ray diffraction pattern of nickel oxide at various degrees of charge (10, 11) where it was shown that there was a continuous variation of the pattern consistent with a complete range of solid solutions of Ni II and III oxide states. The observed variation of potential between 2% and 10% degree of oxidation confirms the view that a two-phase mixture cannot be present and potential determining, since such a mixture should give a constant potential except at a state of complete oxidation or complete reduction. We must hence conclude that the surface phase is potential determining, and that above a degree of oxidation of 10% of the whole material in the oxide electrode, a more or less constant potential is reached.

We may conclude by summarizing the reasons why previous assignments of reversible potentials (2, 12, 13) are of limited validity:

(*a*) In most cases, kinetically determined mixed potentials were involved which differ from the true reversible values by 0–30 mv depending on concentration of KOH.

(*b*) The species (14), e.g. "NiO_2", to which the potentials were assumed to refer have not been identified or characterized and their existence is doubtful (such species may correspond only to the surface phase at the overcharged electrode).

(*c*) The phase to which the potentials refer is evidently not the bulk phase oxide but the electrochemically active surface phase.

(*d*) Potentials attained during charging or discharging of the electrode differ substantially and neither can be identified with a thermodynamically significant reversible potential.

A PROPOSED STRUCTURE FOR ANNEALED ANODIC OXIDE FILMS OF TANTALUM*

L. D. CALVERT AND P. H. G. DRAPER†
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received June 1, 1962

ABSTRACT

Anodic oxide films (~1500 Å thick) formed on tantalum in saturated H_3BO_3, saturated Na_2SO_4, 86% H_3PO_4, 1% H_2SO_4, and 100% H_2SO_4 have been examined by a simple but sensitive glancing angle X-ray technique. They are amorphous as formed but can be crystallized on annealing at various temperatures between 500 and 1000° C. The times and temperatures required for crystallization depend on the electrolyte used. The crystallization process is competitive with the dissolution of oxygen in the substrate metal. The observed powder diffraction patterns show considerable variation from sample to sample. Similar variations have been reported in the literature for different samples of Ta_2O_5. A structural model is proposed for β-Ta_2O_5 based on the isostructural relationship with U_2O_5, whose structure is related to that of α-UO_3. This proposed structure consists of linear chains of Ta—O—Ta—O— parallel to the *c* axis with varying disorder in the *ab* plane. This disorder accounts for the observed variations in the patterns. The proposed structure is a defect one and the ordering of these defects may account for some of the reports of irreversible transformations observed on heating Ta_2O_5.

INTRODUCTION

The present paper describes the results of an X-ray investigation of the structure of annealed anodic oxide films formed on tantalum sheet. A recent study of the kinetics of the growth of anodic films on tantalum and niobium by Draper (1) has shown that gross changes in electrolyte composition, for example from 0.1 *N* to 100% H_2SO_4, greatly affect the rate of growth and the voltage at which breakdown finally takes place. Radiotracer experiments showed that electrolyte ions were taken up into the films during growth and that these are associated with the anomalous electrical properties. Similar occlusion of foreign material had been observed previously with porous films formed, for example, on aluminum (2), but not with tantalum or niobium. Draper also obtained reflection and transmission electron diffraction patterns from films formed on tantalum single crystal planes of low index, and confirmed the findings of Vermilyea (3) that anodic films are amorphous. On heating, the films were found to crystallize to orthorhombic β-Ta_2O_5 or β-Nb_2O_5. For films stripped from tantalum crystallization occurred after 15 minutes at 715° C whereas films left on the metal crystallized after 15 minutes at 550° C. The transmission electron diffraction was carried out on thin films (~350 Å) stripped from the metal and on thinned foils (1). The reflection electron diffraction technique is open to the objection that only the surface is examined. Draper (1) and Vermilyea (4) have stated that the nature of the film at the metal/oxide interface is not necessarily the same as that at the surface during the anodization process. Furthermore, data taken from stripped films may not be representative for films on the metal. To overcome these difficulties an X-ray method was chosen for the present study and both stripped and attached films were examined. The simple glancing angle technique used yields good photographs from films as thin as 1000–1500 Å (5, 6) and reaches the metal below the oxide film.

The only other recent X-ray work on anodic films on tantalum is that of Vermilyea (3), who formed 5000 Å thick anodic films in 0.1% Na_2SO_4 and then stripped them from the

*N.R.C. No. 6931.

metal mechanically. Before heat treatment only amorphous X-ray halos were observed. Although no crystallization occurred after heating for 4 hours *in vacuo* at 500° C the three strongest lines of β-Ta_2O_5 appeared after 1 hour at 800° C. Subsequently Vermilyea (7) examined stacks of stripped films with a total thickness of about 2 μ. Increasing sharpness of the X-ray diffraction pattern was correlated with a decrease in the rate of solution in 48% hydrofluoric acid. Burgers *et al.* (8) in 1932, using qualitative X-ray techniques, reported that a thick oxide film on tantalum was crystalline Ta_2O_5.

It is convenient at this point to summarize some of the existing data in the literature concerning Ta_2O_5 and Nb_2O_5. Most workers agree that there are two forms, the β form stable below about 1300° C and the α form stable above that temperature. Others report several forms within this temperature range. There is general disagreement on the exact transition temperatures. King *et al.* (9) and Durbin *et al.* (10) while working at the Battelle Memorial Institute made a careful investigation using pure materials. They found two forms of Ta_2O_5, the β form below about 1300° C and the α form stable above about 1400° C. They proposed an orthorhombic unit cell with $a = 6.18$, $b = 3.66$, and $c = 3.88$ Å for the β form. They also pointed out that this was probably only a subcell because a few lines in the powder pattern could not be indexed on this basis. Lagergren and Magnéli (11) also found two forms, with the high-temperature form having an appreciable oxygen pressure. Schönberg (12) found only one form. Holser (13) reported diffraction patterns which could not be indexed on the simple orthorhombic cell proposed by King (9). Holser suggested that these extra lines may indicate a very large unit cell similar to that of $UO_{2.6}$. Zaslavskii (14), Simanov (15), and Harvey (16) have all reported forms of β-Ta_2O_5 requiring a multiple b axis for satisfactory indexing.

Brauer (17) found three forms of Nb_2O_5. Kramers and Smith (18) found that the presence of small amounts of various impurities in Ta_2O_5, both metallic and non-metallic, had a profound effect on the structures observed. Shafer and Roy (19) found three metastable and two stable forms of Nb_2O_5. Their results agree only in part with those of Brauer. Holtzberg *et al.* (20) also found two or possibly three metastable forms of Nb_2O_5. Frevel and Rinn (21) observed different patterns from different samples of Nb_2O_5 and Ta_2O_5 containing varying amounts of impurity. These three groups of observers report varying line widths in their X-ray patterns. Mohler and Hirst (22) have also reported a form of Ta_2O_5 with a modified electron diffraction pattern, but did not report the actual pattern. Lapitskii *et al.* (23) reported two forms of β-Ta_2O_5, one stable from 400° C to 600° C and the other stable above 600° C; both forms were orthorhombic. Wasilewski (24) examined the solubility of oxygen in tantalum and found a maximum solubility of 0.88 wt% at 1050° C. He also found two forms of Ta_2O_5.

EXPERIMENTAL

The tantalum used was in the form of rolled sheet (0.025 cm thick) obtained from A.E.R.E. Harwell, England, with a nominal analysis of 99.99% Ta, the remainder Nb except for 80 to 100 p.p.m. of N_2, O_2, and C. Sheet niobium was obtained from the same source with an analysis of Fe 420, Si 340, C 80, H_2 3, O_2 110, N_2 110 p.p.m. and the remainder Nb. The specimens were cut in the form of plates 2×0.5 cm with a thin, heavily oxidized tag at one corner to serve as a current lead. Each was first degreased, then chemically polished in a fresh solution of 40% HF, 70% HNO_3, 98% H_2SO_4 in the ratio 2:2:5 (3). X-ray examination of the surfaces prepared in this way showed a coarse-grained b.c.c. metal pattern ($a_0 = 3.3030$ Å) with the expected rolling texture. Initially, specimens were formed to a voltage just below breakdown in order to obtain the maximum amount of material. However, the X-ray technique used proved to be so sensitive that the greatest thickness was not needed and the more desirable procedure was adopted of forming all specimens to about 100 v at 1 ma/cm². For a dilute aqueous solution 1 volt ≈ 15 Å of anodic oxide on tantalum and hence these films were roughly 1500 Å thick. This thickness was also estimated from the interference color. The electrolytes used were 1% and 100% H_2SO_4, 86% H_3PO_4, and saturated solutions of Na_2SO_4 and H_3BO_3.

The films were examined in an 11.46 cm diameter powder camera using vanadium foil filtered Cr radiation, 0.25 mm aperture collimators, and an oscillation angle of 10° on either side of the mean glancing angle of 25°. Exposures for the films examined *in situ* ranged from 80 to 120 ma hr whilst stripped films required 650 ma hr. A modified single-crystal Unicam 3 cm diameter cylindrical camera was also used in checking for possible orientation of the oxide film. After examination in the "as-formed" state, specimens were annealed at 550, 700, and 1000° C, a few in open silica tubes and the rest in well degassed silica tubes sealed off at about 10^{-5} mm of air. The temperatures were selected to cover the range thought to be of potential significance. Attempts to extend the annealing range above 1000° C always resulted in the loss of the oxide film. No attempt was made to examine the known influence of electric fields on crystallization (25, 7).

RESULTS

Some 40 specimens were examined in all. The films as formed yielded X-ray patterns showing only the metal substrate plus considerable background scatter. Annealing first reduced this scatter and then produced a crystalline diffraction pattern. The time and temperature required to produce crystallization varied markedly with the forming electrolyte. For example a film formed in saturated boric acid required 15 minutes at 550° C whereas one anodized in 86% H_3PO_4 had not crystallized after heating for 100 hours at 550° C. These observations yield upper limits for the crystallization temperatures of films formed in the various electrolytes as follows: 550° C (25 hours) for 1% H_2SO_4, 700° C (4 minutes) for 100% H_2SO_4, 700° C (8 minutes) for 86% H_3PO_4, 750° C (15 minutes) for saturated Na_2SO_4, and 550° C (15 minutes) for saturated H_3BO_3. Table I gives representative observed patterns and also includes the Battelle Memorial Institute pattern (9) of Ta_2O_5 obtained from the Fansteel Metallurgical Corporation and fired at 1200° C. The observed d values are omitted for brevity, since they are equal to those in the standard pattern within the accuracy of the glancing angle technique used. Intensities were measured by visual comparison with a logarithmic interval scale; a dash signifies that the line in question was not observed; the breadth of the lines is indicated by letters s = sharp, b = broad, vb = very broad. The metal substrate pattern is omitted although present in all cases except the thick film formed by heating in air. The annealed oxide pattern never showed any preferred orientation. The air-formed film is very similar to the material examined by King *et al.* (9) but with the significant absence of the extra lines which they could not index on the basis of their unit cell. The patterns vary considerably, both in intensity and width of the observed lines. Despite this apparent variability it is possible to index all the patterns on the simple unit cell put forward by King *et al.* (9) in the setting $a = 6.18$, $b = 3.66$, $c = 3.88$ Å, provided one assumes varying degrees of disorder for the a or b axes or both. Thus the orders of $00l$ are sharp and the reflections hkl, $hk0$, $h00$, and $0k0$ are broadened to varying degrees, sometimes not being observed at all. The three lines (002) $d = 1.95$, (020) $d = 1.83$, and (310) $d = 1.80$ Å were observed to be particularly sensitive to the degree of ordering present. The pattern for the air-formed film is also similar to that reported by Frevel and Rinn (21).

It was also found that crystallization is a process competitive with the dissolution of oxygen in the substrate. The value of 3.3030 Å for the lattice parameter of the polished surface agrees well with the values of 3.3026 Å (24, 26) and 3.3029 Å (27) for oxygen-free metal. For certain intermediate times and temperatures of annealing much higher values for the metal lattice parameter were observed, e.g. after heating for 8 minutes at 700° C a specimen covered by a film formed in 86% H_3PO_4 gave a metal pattern with $a = 3.3140$ Å, equivalent to 0.75 wt% O_2. These values were associated with marked line broadening for the metal pattern, indicating the existence of a range of oxygen concentration near the surface. Prolonged heating *in vacuo* resulted, in many cases, in complete dissolution of all the available oxygen into the metal, as shown by the disappearance of the oxide

†Stripped film.

diffraction pattern and the sharpening of the metal lines as the surface concentration fell to a constant value somewhat greater than that of the pure metal. However, at other times the oxide pattern remained, apparently because a diffusion barrier was set up between the oxide and metal before appreciable diffusion could take place. When annealed at 1000° C the oxide films coalesced into small particles and broke away completely from the metal. The loss of oxygen to the environment during annealing, while not ruled out, is apparently not a major process.

To examine the possible effect of the metal, some films formed in boric and 1% sulphuric acids were stripped from the substrate by cathodic polarization in 1% H_2SO_4, floated off onto water, and transferred to platinum grids for annealing in air and *in vacuo*. It was not found possible to strip films formed in 100% H_2SO_4. In all but one case these yielded Ta_2O_5 patterns similar to those listed in Table I, with the triplet (002),(020),(310) being present. This exception was a film formed in saturated boric acid and annealed *in vacuo*

for 10 hours at 700° C after stripping. This specimen yielded an hexagonal pattern with $a = 5.150$ and $c = 13.76$ Å which matches closely that reported for $LiNbO_3$ (28). The conditions for its formation, possibly a small loss of oxygen, were not investigated further. In another experiment a film formed by heating a sheet of tantalum in air for 10 minutes gave an hexagonal pattern with $a = 3.18$ and $c = 4.79$ Å. As this cell is closely related to that reported by Schönberg (29) for a Ta–N–O phase it is possible that a nitrogen-containing compound had been formed in this case.

Some preliminary experiments with anodically formed Nb_2O_5 films on niobium sheet indicated a disordered structure after annealing. The results were not extensive enough to establish the disordering scheme, which was not the same as that found for Ta_2O_5. The times and temperatures for crystallization are not the same as those required for similar Ta_2O_5 films.

DISCUSSION

A structure for orthorhombic Ta_2O_5 which accounts for the above results can be derived by noting that Ta_2O_5, Nb_2O_5, Pa_2O_5, and U_2O_5 (Table II) are isomorphous and

isostructural (30, 31, 13). Further, α-UO_3, U_3O_8, and U_2O_5 are special compositions existing within a range of continuous variation (32, 33). The structure derived for α-UO_3 by Zachariasen (31) is shown in Fig. 1. It consists of a somewhat distorted primitive cubic lattice of oxygen ions with uranium ions placed in the center of one out of every three

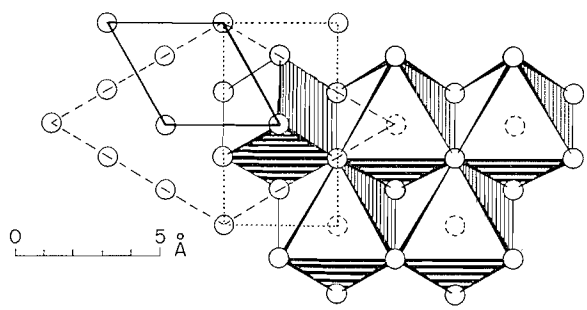

FIG. 1. Zachariasen's (31) structure for α-UO_3. The heavy lines show a single unit cell. Siegel's (34) cell for H.T. U_3O_8 is outlined in dashed lines. The cell proposed by Grønvold (35) for U_3O_8 is outlined in dotted lines. The octahedra of oxygens around the U sites are shown on the right of the diagram. The primitive cube of oxygens is also indicated in the center.

such cubes, giving the composition $U_3O_3-2U = UO_3$. The structure is referred to an hexagonal cell with $a = 3.971$, $c = 4.168$ Å where c is parallel to the body diagonal of the primitive cubic lattice of the oxygen ions. Using the space group $P\bar{3}m1$ (D_{3d}^3) there is one U in 1(a) at 000, one O_I in 1(b) at 0,0,1/2, and two O_{II} in 2(d) at 1/3,2/3,0.17 and 2/3,1/3,0.83. Grønvold (34) has proposed a structure for U_3O_8 that is essentially the same as that for α-UO_3 but the oxygen atoms are not located. The cell used (Fig. 1) is closely related to the orthohexagonal setting of α-UO_3. The densities observed for U_3O_8 (Table II) and U_2O_5 are compatible only with subtractive UO_3 structures. Siegel (33) has deduced a slight variation of the α-UO_3 structure for a high-temperature form of U_3O_8 which can be referred to hexagonal axes related to both the UO_3 axes and the low-temperature U_3O_8 axes (Fig. 1). He notes that the lattice is oxygen deficient to a variable extent depending on the heat treatment. More recently Andresen (36) has determined the U_3O_8 structure by neutron diffraction and found the same closely linked U—O—U—O chains. The U_2O_5 structure is closely related to the UO_3 and U_3O_8 structure (32, 36) and presumably contains the same metal lattice with the vacancies necessary to give the 2:5 formula. This structure will presumably have the same closely linked chains of U—O—U—O atoms (U—$O_I \approx 2.08$ Å) parallel to c with more loosely linked octahedra of six O_{II} atoms around each U (U—$O_{II} \approx 2.39$ Å). Since the O_I atoms are so closely bound to the U it seems reasonable to suppose that the O_{II} atoms will be the ones removed to provide the necessary vacancies in the U_2O_5 structure, as was shown to be the case for U_3O_8 (36). Assuming the same structure for β-Ta_2O_5, as suggested by Elson (30), the observations of disordered Ta_2O_5 diffraction patterns given above can be tentatively described in terms of a simple structural model.

In this model, the structure of Ta_2O_5 consists of linear chains of closely bonded Ta—O—Ta—O ions parallel to c with varying degrees of disorder in the ab plane perpendicular to c, i.e. a chain structure with the chains parallel but rotated randomly with respect to each other. This disorder arises from the possibility of choosing any one of six equivalent O_{II} atoms in each octahedron for the vacancies required by the 2:5 formula. This structure is a notably open one and has both cation and anion vacancies. The c axis, which has been assumed to be parallel to the chains of —Ta—O—Ta—O atoms, has a value close to that calculated on the basis of Zachariasen's equation for interionic distances (35); $D = R_c+R_a+\Delta N-K$. Here D is the interionic distance, R_c and R_a the cation and anion radii, ΔN a correction for coordination number, and K a constant equal to zero for an ionic compound. Taking 0.81 Å for Ta^{5+} and 1.46 Å for O^{2-} with $\Delta N = -0.31$ Å for 2-fold coordination, then $D = 0.81+1.46-0.31 = 1.96$ Å whilst c observed = 3.88 Å (9) $\approx (1.96\times2)$ Å.

From this structure three main types of diffraction pattern may be expected. Firstly, one with defects statistically disordered so that the mean unit cell is the orthorhombic pseudocell with $a = 6.18$, $b = 3.66$, and $c = 3.88$ Å. Secondly, another with the c axis well ordered but the defects so disordered in the plane perpendicular to c that the a or b axes or both are no longer well defined. Finally, in the exceptional cases where the ordering of the defects has been propagated over considerable distances single crystals result with axes which are multiple lengths of the basic mean orthorhombic cell (see Table II). Implicit in this model of the β-Ta_2O_5 structure is the possibility that the observed diffraction pattern for any Ta_2O_5 sample will be a function of its thermal history and that the presence of cationic or anionic impurities may markedly alter both the kinetics and the kind of ordering at any given temperature.

Examples of the diffraction pattern corresponding to a well-ordered structure with the

defects statistically distributed are those observed for the air-formed film or the stripped borate film (Table I). Both contain no lines which cannot be indexed on the orthorhombic Battelle Memorial Institute cell (9). It is interesting to note that the pattern of Frevel and Rinn (21), which is very similar to these two patterns, also contains the same sharp and broad lines.

The other type of diffraction pattern in which the *a* and *b* axes are defined in varying degrees can be represented by the remaining patterns in Table I. The many variations possible within this scheme encompass most of the published patterns for β-Ta_2O_5 and some of those for the isomorphous β-Nb_2O_5. Peterson *et al.* (37), in particular, give a table (their Table I, p. 1041) which shows all the features to be expected from a series of samples having varying degrees of order. Many of the reports of irreversible changes occurring on heating Ta_2O_5 and Nb_2O_5 can be interpreted as successive stages of ordering processes (17, 19, 20), since the difference observed between the various forms consists in the detection of additional lines upon continued annealing and the patterns contain both sharp and broad lines.

Finally in those cases where single crystals or very well crystallized powders have been studied (11, 13–16, 23) a very large unit cell related to the basic orthorhombic unit cell has been found or it has been necessary to use such a cell to index the observed powder pattern. The monoclinic cell reported for the stable β form has a β angle close to 120° and is geometrically related to the hexagonal subcell of the orthorhombic β-Ta_2O_5 cell. Plainly quite extensive variations of the basic orthorhombic cell are probable, as may be seen from the values given in Table II, and these are likely to be sensitively dependent on the presence of foreign material, e.g. water (14, 23) or traces of alkali (9, 10, 21) or common metallic contaminants (18).

It seems probable that the annealing of films in contact with a tantalum surface was responsible for the relative uniformity and simplicity of the X-ray-diffraction results in the present study. The purity of the tantalum and the thinness of the films may also have been determining factors.

CONCLUSIONS

(1) Anodically formed films of Ta_2O_5 are amorphous when formed at voltages below breakdown in the electrolytes used.

(2) Upon heating they crystallize to a disordered form of β-Ta_2O_5 with the *c* axis ordered while the *a* and *b* axes are disordered in varying degrees.

(3) A structural model composed of linear chains of Ta—O—Ta—O parallel to the *c* axis but randomly rotated around the *c* direction is consistent with the observed data.

ORGANOPHOSPHORUS COMPOUNDS

X. PHOSPHORISOCYANATIDIC DIFLUORIDE AND CHLORIDE FLUORIDE. PREPARATION OF ALKYL CARBAMATOPHOSPHORODIFLUORIDATES AND UREIDOPHOSPHORODIFLUORIDATES[1,2]

STEPHEN J. KUHN AND GEORGE A. OLAH

Received April 18, 1962

ABSTRACT

Phosphorisocyanatidic difluoride and phosphorisocyanatidic chloride fluoride were prepared. Addition reactions with alcohols (phenol) and amines were investigated, leading to carbamatophosphorodifluoridates and ureidophosphorodifluoridates.

Phosphorus oxyhalides are used as starting materials for the preparation of many organophosphorus compounds. The reactive halogens can be easily replaced by alkoxy, amido, mercapto groups, etc. The replacement of one of the halogens with an isocyanate group in the phosphoryl halides increases the versatility of these compounds and enables the preparation of many new groups of organophosphorus compounds.

Phosphorisocyanatidic dichloride was prepared by Kirsanov (2) by the interaction of ethylcarbamate and phosphorus pentachloride:

$$CH_3—CH_2—O—\overset{\overset{O}{\|}}{C}—NH_2 + PCl_5 \rightarrow Cl—\overset{\overset{O}{\|}}{\underset{\underset{Cl}{|}}{P}}—NCO + C_2H_5Cl + 2HCl.$$

Phosphorisocyanatidic dichloride partially decomposes when distilled at atmospheric pressure or when stored at room temperature over long periods of time. It was hoped that by preparing the corresponding difluoridate or chlorofluoridate more stable compounds would be obtained. These could be useful new polyfunctional reagents for the preparation of derivatives of fluorophosphoric acid (3).

Phosphorisocyanatidic dichloride readily reacts with antimony trifluoride, in the absence of catalyst, to give a 90% yield of the corresponding difluoride, without interacting with the isocyanate group:

$$6Cl—\overset{\overset{O}{\|}}{\underset{\underset{Cl}{|}}{P}}—NCO + 4SbF_3 \rightarrow 6F—\overset{\overset{O}{\|}}{\underset{\underset{F}{|}}{P}}—NCO + 4SbCl_3.$$

The reaction is fast and exothermic; therefore the antimony trifluoride is added in small portions to the phosphorisocyanatidic dichloride. The lower-boiling difluoride distills out from the reaction vessel as it forms. Phosphorisocyanatidic difluoride is a colorless liquid which fumes if exposed to moist air. It boils at atmospheric pressure at 68–68.5°.

It is readily soluble in solvents like methylene chloride, chloroform, carbon tetrachloride, benzene.

[2]*For Part IX, see reference 1.*

The infrared spectrum shows maxima at 2247, 1458, 1351, 952, 905, 752 cm^{-1}, indicating the presence of the isocyanate group and P—F bonds. (See Fig. 1.)

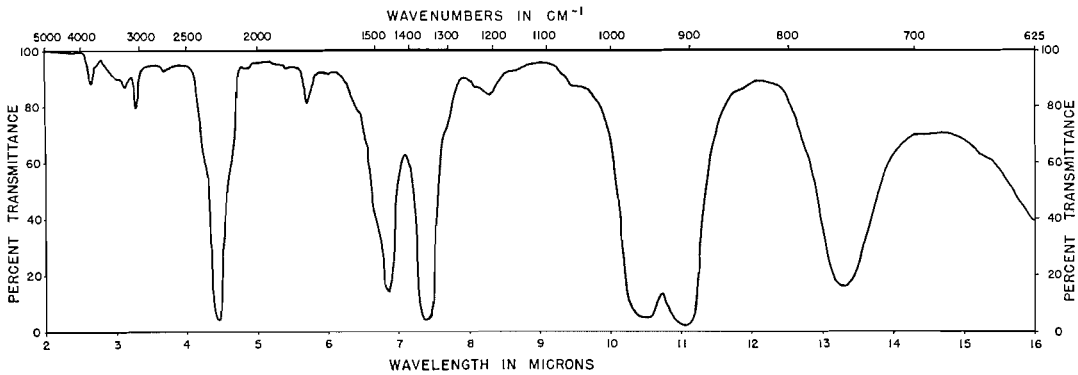

FIG. 1. Infrared spectrum of phosphorisocyanatidic difluoride.

Phosphorisocyanatidic difluoride can be distilled at atmospheric pressure and kept at room temperature for a long time without decomposition. It hydrolyzes, however, very rapidly with water. Therefore all operations must be carried out under dry conditions. In the halogen exchange reaction, in addition to the main product, about 10% phosphorisocyanatidic chloride fluoride, OCNPOFCl, b.p. 101–103°, is formed.

Phosphorisocyanatidic difluoride reacts easily with alcohols (phenol), yielding alkyl carbamatophosphorodifluoridates:

$$F{-}P(=O)(F){-}NCO + ROH \rightarrow F{-}P(=O)(F){-}NH{-}C(=O){-}OR.$$

The carbamate derivatives are stable solid compounds and can be distilled under reduced pressure without decomposition. Table I lists the new carbamates that have been prepared. With an excess of alcohol the fluorides can be replaced by alkoxy groups only with difficulty. The use of sodium alcoholates is more advantageous.

TABLE I

Carbamatophosphorodifluoridates, $RO{-}C(=O){-}NH{-}POF_2$

EXPERIMENTAL

Preparation of Phosphorisocyanatidic Dichloride (2)

One mole of PCl_5 and 1 mole of ethylcarbamate were placed in a 1-liter round-bottomed flask equipped with a reflux condenser and drying tube, and kept at 10° by means of external cooling. In a few minutes HCl formation begins. The temperature of the bath was kept 10° for 45 minutes, then it was carefully raised at a rate of 1°/6 minutes up to 50°, then by 1°/2 minutes up to 80° (5.5 hours total reaction time). The by-product HCl and ethyl chloride escaped through the reflux condenser. Fractionation of the residual liquid product gave 140 g of pure $POCl_2NCO$ (87.5%), b.p. 64–60° at 50 mm. CCl_2NO_2P: found: P 19.5, Cl 44.3, N 8.6; Calc.: P 19.4, Cl 44.37, N 8.75%.

Preparation of Phosphorisocyanatidic Difluoride

Phosphorisocyanatidic dichloride (160 g, 1 mole) was placed into a two-necked flask equipped with powder feeder and condenser. SbF_3 (150 g) was added in 6–10 portions to the chloride. The reaction is exothermic and the product distills out as it forms. After the addition of the SbF_3 the flask was heated to remove all the remaining product. Liquid product (130 g) was obtained, which after fractionation through a 300-mm Widmer column gave two fractions: POF_2NCO: b.p. 68–68.5°; 115 g (90% yield); n_D^{25} 1.3381; d_{25} 1.5899 (CF_2NO_2P (127): calc.: N 11.0, P 24.4, F 29.9; found: N 10.80, P 23.9, F 29.7%) and POFClPNCO: b.p. 101–103°; 10 g; n_D^{25} 1.4024 (calc. N 9.76, P 21.0, Cl 24.7; found: N 9.78, P 21.4, Cl 24.6%).

Reaction of Phosphorisocyanatidic Difluoride with Alcohols

POF_2NCO (0.25 mole) was dissolved in 50 ml of CH_2Cl_2 and into the stirred solution 0.25 mole of alcohol in 20 ml of CH_2Cl_2 was added dropwise at 0°. The reaction is completed in a few minutes. Methylene chloride was pumped off and the residual liquid product fractionated under reduced pressure.

The reaction with phenol was carried out in essentially the same manner, but due to decomposition the product could not be distilled and was purified by recrystallization from chloroform or benzene.

Reaction of Phosphorisocyanatidic Difluoride with Amines

POF_2NCO (0.25 mole) was dissolved in 50 ml of CH_2Cl_2 and into the stirred solution 0.25 mole of amine in 20 ml of CH_2Cl_2 was added dropwise, while the temperature of the mixture was kept around 0°. The reaction is completed in a few minutes. The methylene chlorided was removed by distillation and finally

by pumping the product in vacuum. Attempted distillation of the products, even under pressure, resulted in decomposition. The products, which are essentially pure after removal of the solvent, and any possible volatile starting materials were recrystallized from chloroform or CCl_4.

OBSERVATIONS ON THE KARPLUS CURVE IN RELATION TO THE CONFORMATION OF THE 1,3-DIOXOLANE RING[1]

R. U. LEMIEUX,[2] J. D. STEVENS,[3] AND R. R. FRASER
Department of Chemistry, University of Ottawa, Ottawa, Ontario

Received March 19, 1962

ABSTRACT

The experimental evidence indicates that the Karplus curve, which relates the coupling constant between hydrogens on vicinal carbons and the dihedral angle defined by the hydrogens, is subject to displacement. An upward displacement of 2.2 c.p.s. is required to account for the coupling constants found for the neighboring hydrogens in both 1,3-dioxolane and its 2,2-dimethyl derivative. On this basis, the compounds exist in conformations wherein the cis neighboring hydrogens define dihedral angles of 35° and 41°, respectively.

The formation of cyclic ketals and acetals from glycol groups has found widespread application in isolation, structural, and synthetic studies. The formation of the *O*-isopropylidene derivatives of vicinal hydroxyl groups has been particularly useful. The ease for the preparation of these compounds has received considerable attention from the point of view of conformational analysis (1–6). For this purpose, it has generally been assumed that the 1,3-dioxolane ring is planar (4). Although this assumption has proved useful, it is clearly desirable to obtain more precise information on the conformation of the 1,3-dioxolane ring. Three types of conformations are possible, the planar conformation and the conformations wherein one or two of the atoms are out of the plane of the other atoms in the ring (7).

An examination of a precise conformational model (8) for the 1,3-dioxolane ring clearly indicates that the ring can be puckered substantially without the introduction of valence-angle strain. One of the carbon atoms of the ethylene group can readily move out of the plane of the other four atoms to the extent that the cis neighboring hydrogens define dihedral angles of about 35°. In view of the potential barrier to rotation which is present in ethane (9), the resulting increased staggering of the cis hydrogens must provide a conformation which is, energetically, substantially more favorable than is the planar conformation. In fact, the nuclear magnetic resonance spectrum of 1,3-dioxolane (10) is only readily understood if the compound possesses a puckered conformation. It was found (10) that the average coupling, J, of a hydrogen with one of the neighboring hydrogens plus the average coupling, J', of the same hydrogen with the other neighboring hydrogen was 13.3 c.p.s. The difference $J-J'$ was 1.3 c.p.s. (see Fig. 1). We have confirmed these experimental results. The so-called Karplus curve (11–14) relates coupling constant to the dihedral angle defined by neighboring hydrogens. Should the 1,3-dioxolane ring be planar, then, on the basis of the Karplus values, $J_{0°} = 8.2$ and $J_{120°} = 2.2$ c.p.s., one would expect $J-J'$ to equal 6.0 c.p.s. rather than the observed 1.3 c.p.s. Although, as will be seen below, the Karplus curve is subject to displacement, its general shape has received substantial experimental verification (11–13). Certainly, although values for $J_{0°}-J_{120°}$ somewhat greater than 6 c.p.s. may be anticipated, none of the substantial

$$J = \frac{J_a + J_b}{2} = J_{35°}$$

$$J' = \frac{J'_a + J'_b}{2} = \frac{J_{155°} + J_{85°}}{2}$$

FIG. 1. The two energetically equivalent conformations for 1,3-dioxolane in which one of the C-methylene groups is puckered out of the plane of the other four atoms in the ring. The dihedral angles defined by the neighboring hydrogens are expected to be approximately those indicated. The experimentally determined coupling constants J and J' result from the averaging of the coupling constants in each of the conformations according to the relationships which are shown.

amount of information which has accumulated is in any way suggestive that the trough-shaped Karplus curve can be so very shallow as to provide a value for this difference in coupling constant as small as 1.3 c.p.s. Therefore, it can be concluded that the neighboring cis hydrogens in 1,3-dioxolane are not eclipsed.*

Although all the experimental evidence has substantiated the general shape of the Karplus curve, it is clearly apparent that the curve is subject to displacement depending on the chemical nature of the compound. This fact is demonstrated by the coupling constants reported in Table I for the hydrogens of a freely rotating methyl group and

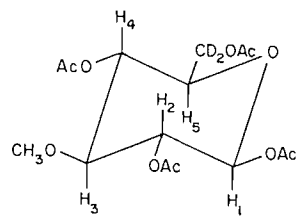
the hydrogens on the neighboring carbon. The only important conformations for these compounds (CH_3CH_2X) are undoubtedly those wherein the hydrogens on the neighboring carbons are in the staggered arrangement. Therefore, on the basis of the Karplus curve, the average coupling of the neighboring hydrogens should be $(J_{180°}+2J_{60°})/3 = 4.2$ c.p.s. However, it is seen that the experimental values are in the range 4.7 to 7.9 c.p.s. For

Since this manuscript was first submitted, a publication appeared (R. J. Abraham, K. A. McLauchlan, L. D. Hall, and L. Hough. Chem. & Ind. (London), 213 (1962)) wherein it was concluded, on the basis of the nuclear magnetic resonance spectra of isopropylidene derivatives of sugars, that the currently held view that 2,2-dimethyldioxolane rings are planar is in need of modification.

compounds of structure $(CH_3)_2CHX$, the values range from 6.0 to 6.4 c.p.s. Karplus (11) has commented on this discrepancy, which renders it clearly apparent that the coupling constant between neighboring hydrogens is not only dependent on the dihedral angle which they define but also on the substituents other than the hydrogens on the vicinal carbons. The data in Table I indicate that a displacement of the Karplus curve can result from a change in the electronegativity of the substituent X in the compounds CH_3CH_2X. Experimental work on polyoxygenated six-membered ring compounds (15) and on substituted camphanes (12) are in good numerical agreement with the theoretical curve, which has also enabled consistent and reasonable conclusions to be drawn about ring conformations of other sugar derivatives (16, 17). However, Williamson and Johnson (18) have adjusted the Karplus curve to provide coupling constants of 16 and 10 c.p.s. for neighboring hydrogens which define dihedral angles of 180° and 0°, respectively, on the basis of the coupling constants found for neighboring hydrogens in the A-ring of 2- and 4-acetoxycholestane-3-ones. It was contended that perhaps the coupling constants for neighboring hydrogens in carbohydrate pyranose rings are smaller because the compounds do not possess conformational rigidity. Considerable evidence in fact exists that for many pyranose structures there must exist a very high degree of conformational purity. It has been ascertained, for example, that the coupling constants in 3-*O*-methyl-6,6-di-*C*-deutero-β-D-glucopyranose tetraacetate (I) are $J_{H_1,H_2} = 8.2$ c.p.s., $J_{H_2,H_3} = J_{H_3,H_4}$



(I)

$= 9.3 \pm 0.1$ c.p.s., and $J_{H_4,H_5} = 9.7$ c.p.s. (19). The success encountered by Lemieux and Chü (20) in accounting for the anomeric equilibria of sugar acetates on the basis of conformational analysis with the pyranose ring in the chair conformation clearly requires conformational purity for many of the hexose pentaacetates. Clearly the indications are that the Karplus curve is subject to considerable displacement depending on the chemical nature of the compound being examined, and the use of the curve for the determination of fine points of conformation will require a knowledge of the position of the curve in the set of coordinates (coupling constant versus dihedral angle) for the type of structure under consideration. Thus, for example, in the above-mentioned glucose derivative, $J_{180°}$ appears to vary from 8.2 to 9.7 c.p.s. depending on the substituents on the various carbon atoms to which the hydrogens are bonded and in the manner expected from the data in Table I.

We have therefore interpreted the results of analysis of 1,3-dioxolane in the following manner. First of all we can calculate the values for $J-J'$ from the Karplus curve for varying amounts of puckering of the ring into a C_s conformation. A consideration of the C_2 conformation was omitted since examination of models showed that the differences in dihedral angles for the two conformations are relatively small. Let θ be the angle between the two hydrogens cis to each other on the two-carbon portion of the ring. Then for $\theta = 0°$, $J-J' = 6.0$; $\theta = 15°$, $J-J' = 5.1$; $\theta = 30°$, $J-J' = 2.65$; $\theta = 35°$, $J-J'$

$= 1.4$; $\theta = 40°$, $J-J' = 0.25$ c.p.s. Thus, it is seen that the value of $J-J'$ is in agreement with the experimental value when $\theta = 35°$, the angle which, on the basis of conformational models, appears near optimum for 1,3-dioxolane. However, the Karplus curve requires for $\theta = 35°$, $J+J'$ to be 11.1 c.p.s. In order to obtain agreement with the observed value of 13.3 c.p.s., it is necessary to displace the curve upwards by 2.2 c.p.s. Such a displacement of course leaves $J-J'$ unchanged.

We have now observed the carbon-13 side-band signal for the ethylenic group of 2,2-dimethyl-1,3-dioxolane. The signal is a triplet of spacing 12.6 c.p.s. Analysis of this signal as the A_2 part of an A_2X_2 spectrum yields $J = J' = 6.3$ c.p.s. (22). The Karplus curve allows $J = J'$ when $\theta = 41°$ and if the same upward displacement of 2.2 c.p.s. is assumed, then the curve yields values for $J_{41°} = 6.3$ c.p.s. and $J' = (J_{161°}+J_{79°})/2 = 6.3$ c.p.s., which are in agreement with the experimental values. It should be noted that only a rather limited variation in either θ ($\pm 2°$) or the upward displacement (± 0.2 c.p.s.) will still provide agreement within experimental error between the observed coupling constants and those predicted from the Karplus curve. On this basis the 1,3-dioxolane ring is puckered to a greater extent by the introduction of the two methyl groups at the 2-position. This conclusion would be in accordance with expectations based on the Thorpe–Ingold *gem*-dimethyl effect (23). That is, the introduction of the methyl groups should tend to decrease the O—C_2—O valence angle and thus requires a greater puckering of the ring.

It is interesting to compare the results of Anet (21) with ours. He found that in *trans*-4-*t*-butylcyclohexanol the coupling constants of the 1-hydrogen with the cis and trans 2-hydrogens were 4.31 and 11.07 c.p.s. respectively. Assuming that the cyclohexane ring exists in the ideal chair form in this compound then these values correspond to an upward displacement of the Karplus curve by 2.5 and 1.9 c.p.s. for $J_{60°}$ and $J_{180°}$, respectively.

The above conclusions regarding the conformations of 1,3-dioxolane rings are of direct importance to conformational analysis. Evidently, the formation of the *O*-isopropylidene derivative of an α-glycol does not require the two C—O bonds to achieve coplanarity. Angyal and MacDonald (2) have pointed out that a decrease of the 60° dihedral angle defined by the oxygen atoms in 1,2-*trans*-cyclohexanediol must introduce severely repulsive non-bonded interactions between opposing axial hydrogens. A distortion of about 19° would be required for the formation of *O*-isopropylidene-1,2-*trans*-cyclohexanediol without strain in the 1,3-dioxolane ring. It is therefore not surprising that the compound can be prepared only under strongly forcing conditions (24). A similar distortion for the cis isomer can be expected (1, 2) to introduce little strain in the cyclohexane ring. In fact, Kuhn has estimated, from the extent of hydrogen bonding, that the two oxygen atoms in 1,2-*cis*-cyclohexanediol define a dihedral angle of about 50°. The compound is well known to be readily transformed into the *O*-isopropylidene derivative. The oxygen atoms in 1,2-*cis*-cyclopentanediol can be expected to define a dihedral angle of about 46° (7), and the *O*-isopropylidene derivative forms readily (6). The dihedral angle defined by the oxygen atoms of the trans isomer is too large to allow formation of the *O*-isopropylidene derivative (6).

The above comments do not contradict the previous conclusions reached in conformational analyses involving the 1,3-dioxolane ring. However, the analyses were based on the erroneous assumption that the 1,3-dioxolane ring is planar. Clearly, the rings should be considered in their preferred puckered conformations unless evidence exists that the neighboring hydroxyl groups of the glycol are held rigidly in the eclipsed condition. Dihedral angles in the range 0–41° can be expected to be favorable for the for-

mation of the isopropylidene derivative, since there should not exist an appreciable barrier to rotation about the O—C_2—O bonds. The somewhat greater puckering of the ring in 2,2-dimethyl-1,3-dioxolane over that of the ring in 1,3-dioxolane can be expected to render it generally easier to prepare the former ring from neighboring hydroxyl groups in structures that resist conformations wherein the hydroxyl groups define angles as small as 40°. Certainly, the experience in carbohydrate chemistry (4) is in good general agreement with this expectation.

EXPERIMENTAL

The spectra were measured using a Varian V-4302 high-resolution spectrometer operating at a frequency of 60 Mc/s.

The 1,3-dioxolane and 2,2-dimethyl-1,3-dioxolane were prepared according to the directions provided by Dauben *et al.* (25) and were purified by fractional distillation using a Todd distillation apparatus. The carbon-13 triplet side bands occurred 74 c.p.s. to either side of the signal for the ethylenic hydrogens.

SYNTHÈSES D'ACIDES AMINOBUTYRIQUES

II. ACIDES ALKYLAMINO-2 HYDROXY-4 BUTYRIQUES

RÉAL LALIBERTÉ ET LOUIS BERLINGUET

Département de Biochimie, Faculté de Médecine, Université Laval, Québec, Qué.

Reçu le 27 septembre 1961

ABSTRACT

Starting from 2-bromo-4-butyrolactone which was treated with primary amines, five new 2-alkylamino-4-hydroxy-N-alkylbutyramides were obtained in good yields. Acid hydrolysis gave the corresponding lactones, which, when treated with $Ba(OH)_2$, gave the 2-alkylamino-4-hydroxybutyric acids. The new derivatives of homoserine thus prepared are: 2-methylamino-4-hydroxybutyric acid, 2-ethylamino-4-hydroxybutyric acid, 2-propylamino-4-hydroxybutyric acid, 2-butylamino-4-hydroxybutyric acid, and 2-cyclohexylamino-4-hydroxybutyric acid.

Some of these amides were easily lactonized in HCl–acetone medium. Two 2-alkylamino-4-chloro-N-alkylbutyramides were also prepared.

INTRODUCTION

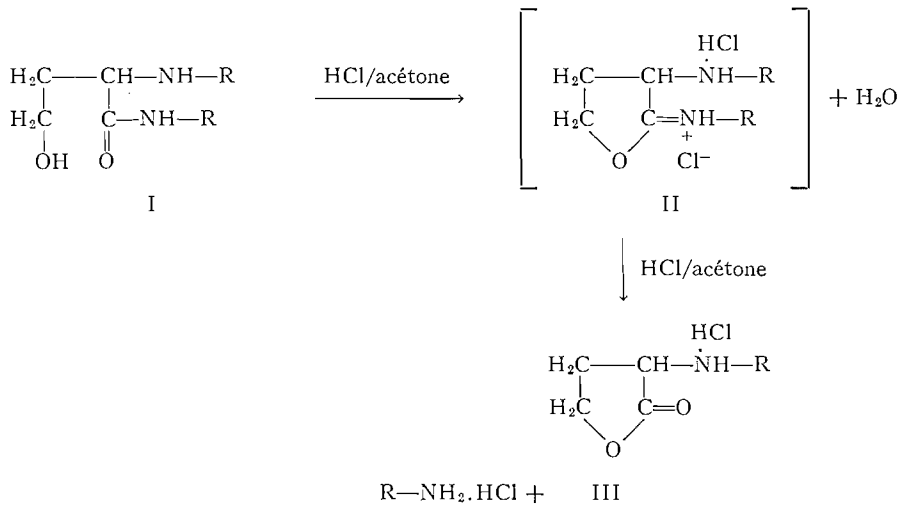
Dans le cadre d'un travail portant sur la synthèse d'acides aminobutyriques N-alkylés (1), nous avons préparé cinq nouveaux dérivés de l'homosérine substitués sur l'azote.

Nous avons utilisé comme produit de départ la bromo-2 butyrolactone-4 (2). Knobler et Frankel (3) ont déjà montré que la bromo-2 butyrolactone-4 réagit avec l'ammoniaque pour donner l'amino-2 hydroxy-4 butyramide, qui après hydrolyse libère l'acide amino-2 hydroxy-4 butyrique (homosérine). En traitant de la même façon la bromo-2 butyrolactone-4 avec des amines primaires, nous avons isolé les amides suivants avec les rendements indiqués: méthylamino-2 hydroxy-4 N-méthylbutyramide (50%); éthylamino-2 hydroxy-4 N-éthylbutyramide (56%), propylamino-2 hydroxy-4 N-propylbutyramide (82%), butylamino-2 hydroxy-4 N-butylbutyramide (55%) et cyclohexylamino-2 hydroxy-4 N-cyclohexylbutyramide (82%).

Cette réaction se fait en deux étapes. Dans l'une, il y a substitution au brome de l'amine et dans l'autre, il y a ouverture du cycle par l'amine en excès pour donner le butyramide N-alkylé. Signalons que Sheradsky, Knobler et Frankel (4) viennent d'obtenir de la même façon le benzylamino-2 hydroxy-4 N-benzylbutyramide.

Ces amides hydroxylés en position 4 se cyclisent en milieu acide pour donner les butyrolactones correspondantes. Cette cyclisation s'effectue dans l'eau par l'acide sulfurique comme nous l'avons fait pour préparer les homosérines. On peut aussi l'effectuer dans un solvant organique saturé de HCl anhydre, ce qui permet l'isolement facile de la lactone. Il semble aussi que la transformation notée par Frankel, Knobler et Sheradsky (5) du benzamido-2 hydroxy-4 butyramide en benzamido-2 chloro-4 butyrate d'éthyle par le HCl anhydre dans l'éthanol se fasse par l'intermédiaire de la benzamido-2 butyrolactone-4.

Nous avons isolé facilement une lactone de ce type en saturant de HCl sec une suspension de cyclohexylamino-2 hydroxy-4 N-cyclohexylbutyramide (I, où $R = C_6H_{11}$) dans l'acétone ou le dioxanne. Dans les deux cas, on obtient après une semaine un rendement quantitatif en chlorhydrate de cyclohexylamino-2 butyrolactone-4 (III, où $R = C_6H_{11}$). Pour expliquer cette lactonisation de l'amide, on peut supposer la formation par l'action de HCl d'un chlorure d'imino-éther (II, où $R = C_6H_{11}$) instable en présence d'un acide fort (6, 7). En se réarrangeant, celui-ci donne la lactone qu'on peut isoler.



On peut répéter cette cyclisation dans des conditions semblables avec l'hydroxy-4 propylamino-2 N-propylbutyramide (I, où R = C_4H_9). Dans ce cas, on obtient le chlorhydrate de la propylamino-2 butyrolactone-4 avec un rendement de 82%.

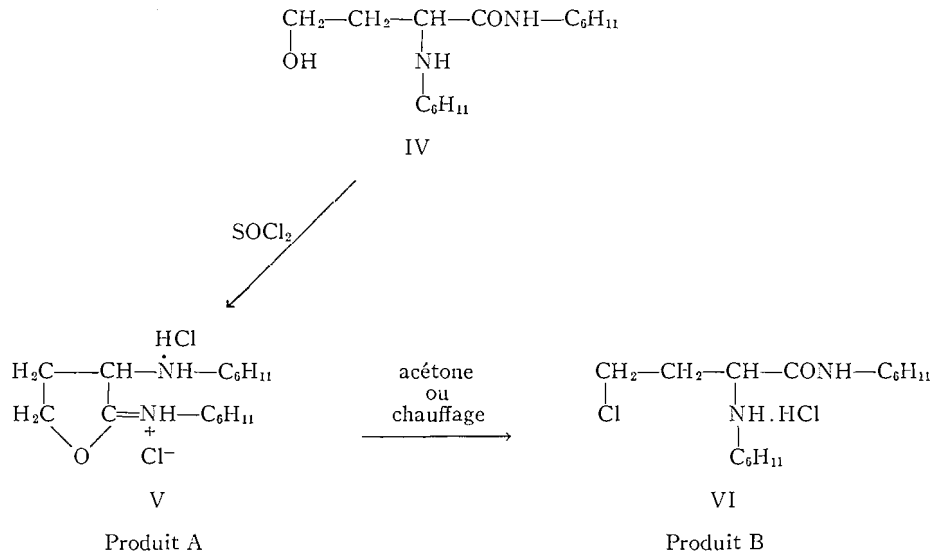
Nous avons constaté que cette lactonisation des alkylamino-2 hydroxy-4 N-alkylbutyramides en alkylamino-2 butyrolactones sous l'action d'un acide fort, se fait plus rapidement dans l'eau que dans un solvant organique. Nous avons donc traité, sans les isoler, les amides résultant de l'action d'amines primaires sur la bromo-2 butyrolactone-4 par un excès d'acide sulfurique dilué à la température de la pièce pendant 24 heures. Nous avons ensuite éliminé l'acide sulfurique par un équivalent d'hydroxyde de baryum, ce qui a provoqué l'ouverture des lactones. Nous avons alors obtenu, avec les rendements indiqués, les acides butyriques suivants: acide méthylamino-2 hydroxy-4 butyrique (80%), acide éthylamino-2 hydroxy-4 butyrique (77%), acide propylamino-2 hydroxy-4 butyrique (70%), acide butylamino-2 hydroxy-4 butyrique (71%) et acide cyclohexylamino-2 hydroxy-4 butyrique (88%).

En traitant le cyclohexylamino-2 hydroxy-4 N-cyclohexylbutyramide et le propylamino-2 hydroxy-4 N-propylbutyramide par du chlorure de thionyle, on obtient les chlorhydrates du cyclohexylamino-2 chloro-4 N-cyclohexylbutyramide (rendement: 80%) et du butylamino-2 chloro-4 N-butylbutyramide (rendement: 50%).

En préparant le chlorhydrate du cyclohexylamino-2 chloro-4 N-cyclohexylbutyramide (IV), nous nous sommes demandé si la structure ouverte attribuée au produit était la bonne ou s'il ne s'agissait pas d'un produit cyclique (V) de type imino-éther comme en décrit Stirling (8). Ceci d'autant plus que l'action à chaud du chlorure de thionyle sur le cyclohexylamino-2 hydroxy-4 N-cyclohexylbutyramide (IV) dans le chloroforme donne un produit solide qui fond vers 130° (produit A). Mais en continuant à chauffer, ce produit redevient rapidement solide pour fondre à nouveau à 219° (produit B). De plus cette substance provenant du chloroforme (produit A) se dissout en quelques secondes dans l'acétone d'où elle cristallise quantitativement après quelques minutes pour donner le produit B.

Mais le produit obtenu de l'acétone (produit B) ne possède qu'un chlore inorganique et présente une bande à 1680 cm^{-1}, caractéristique d'un amide. Ceci n'est compatible qu'avec la structure ouverte (produit B, VI). Tant qu'à l'intermédiaire instable (produit

A), nous n'avons pu déterminer sa structure, mais on peut cependant supposer qu'il s'agit d'un chlorure de cyclohexylamino-2 N-cyclohexyltétrahydroiminofuranne (V).



PARTIE EXPÉRIMENTALE

Alkylamino-2 hydroxy-4 N-alkylbutyramides

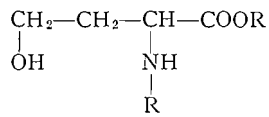
La synthèse des butyramides substitués se fait par addition de la bromo-2 butyrolactone-4 à l'amine choisie, suivant la technique décrite pour la méthylamino-2 hydroxy-4 N-méthylbutyramide.

Dans le cas de la butylamine et de la cyclohexylamine, il y a avantage à maintenir la température du mélange à 75–100° après l'addition, ce qui diminue le temps de réaction à 24 heures et à 2 heures respectivement.

On trouvera au tableau I les constantes physiques des produits obtenus.

TABLEAU I

Alkylamino-2 hydroxy-4 N-alkylbutyramides



R	% rendement	P.f.*	Formule	% N Calculé	% N Trouvé	Solvants de recristallisation
CH_3—	50	95	$C_6H_{14}N_2O_2$	19.15	19.03	BuOH/éther/éther de pétrole

*Les points de fusion ne sont pas corrigés.

Méthylamino-2 hydroxy-4 N-méthylbutyramide

A 200 ml (2.0 moles) de méthylamine en solution aqueuse à 30% placés dans une fiole conique refroidie, on ajoute en agitant 82.5 g (0.50 mole) de bromo-2 butyrolactone-4. La réaction est exothermique. Une fois l'addition terminée, on retire la fiole conique du bain de glace, puis on la laisse au repos pendant plusieurs jours à température de la pièce. On ajoute ensuite 50 ml de soude 10 *N* (0.50 mole), puis on évapore à sec l'excès d'amine. On recristallise l'amide obtenu d'un solvant organique dans lequel le bromure de sodium

demeure insoluble et qu'on filtre (voir tableau I). Le méthylamino-2 hydroxy-4 N-méthylbutyramide cristallise du butanol par addition lente d'un mélange d'éther et d'éther de pétrole. On obtient 36.5 g d'un solide blanc.

Chlorhydrate de cyclohexylamino-2 chloro-4 N-cyclohexylbutyramide

On dissout 10 g (0.035 mole) de cyclohexylamino-2 hydroxy-4 N-cyclohexylbutyramide dans 100 ml de chloroforme, puis on fait passer dans ce milieu du gaz chlorhydrique sec pendant 2 à 3 minutes. On ajoute ensuite 30 g (0.25 mole) de chlorure de thionyle et on chauffe à reflux pendant une heure. On refroidit puis on filtre (produit A). Le solide obtenu est versé en une fois dans 35 ml d'acétone où il se dissout rapidement, semble se réarranger et cristallise rapidement à température de la pièce. On refroidit la suspension dans l'acétone, on filtre et on lave le solide obtenu avec 30 ml d'acétone où il est maintenant insoluble (produit B). On obtient ainsi 10 g d'un solide blanc. Rendement: 84%. P.f. 219°. Anal. Calc. pour $C_{16}H_{29}ClN_2O.HCl$: N, 8.30; Cl, 21.0%. Trouvé: N, 8.28; Cl, 21.2%.

Le produit B ne contient qu'un chlore inorganique. Nous l'avons vérifié en faisant un dosage rapide par gravimétrie (AgCl) sans au préalable digérer la substance en milieu alcalin. Il donne à l'infra-rouge la bande de l'amide à 1680 cm^{-1} (KBr).

Le produit A obtenu du chloroforme est très soluble dans l'acétone. De plus, il fond vers 130° pour redevenir solide vers 150° et refondre à 219° comme le produit B. Mais il est très instable et se transforme très rapidement en produit B dès que nous le dissolvons dans un solvant quelconque. Il donne le même spectre que le produit ci-haut (KBr). Nous supposons cependant qu'il s'agit d'un chlorure d'imino-éther (V) très instable dans ce cas particulier.

Chlorhydrate de butylamino-2 chloro-4 N-butylbutyramide

On dissout 7.8 g (0.035 mole) de butylamino-2 hydroxy-4 N-butylbutyramide dans 100 ml de chloroforme en faisant barboter un peu d'acide chlorhydrique sec. On y ajoute 30 g (0.25 mole) de chlorure de thionyle, puis on fait refluer la solution pendant une heure. On évapore à sec et on dissout le résidu dans du méthanol que l'on traite avec du noir animal. Le produit cristallise en ajoutant de l'éther. On obtient ainsi 5 g de chlorhydrate de butylamino-2 chloro-4 N-butylbutyramide. Rendement: 50%. P.f. 193°. On peut le recristalliser de l'isopropanol. Anal. Calc. pour $C_{12}H_{25}ClN_2O.HCl$: N, 9.81; Cl, 24.86%. Trouvé: N, 9.76; Cl, 25.0%. Nous n'avons observé aucun réarrangement lors de la préparation de ce produit. Un dosage de chlore inorganique ne révèle qu'un halogène.

Chlorhydrate de cyclohexylamino-2 butyrolactone-4

On suspend dans 40 ml d'acétone ou de dioxanne 2 g (0.0071 mole) de cyclohexylamino-2 hydroxy-4 N-cyclohexylbutyramide. On fait passer dans cette suspension un courant d'acide chlorhydrique sec jusqu'à ce que la solution soit saturée à 40°. La lactone cristallise lentement à température de la pièce. Après 7 jours, on obtient avec un rendement quantitatif (1.5 g) le chlorhydrate de cyclohexylamino-2 butyrolactone-4, qu'on lave avec un peu d'acétone. P.f. 259°. Anal. Calc. pour $C_{10}H_{17}NO_2.HCl$: N, 6.37%. Trouvé: N, 6.42%.

Chlorhydrate de propylamino-2 butyrolactone-4

On dissout 3 g (0.014 mole) de propylamino-2 hydroxy-4 N-propylbutyramide dans de l'acétone saturé de HCl sec à 40°. On laisse au repos à température de la pièce pendant une semaine. On porte ensuite la fiole conique au froid où le produit cristallise après quelques jours. On filtre, puis on recristallise le chlorhydrate de propylamino-2 butyrolactone-4 du butanol ou du dioxanne. On obtient ainsi 2.1 g de solide. Rendement: 83%. P.f. 166°. Anal. Calc. pour $C_7H_{13}NO_2.HCl$: N, 7.79%. Trouvé: N, 7.97%.

Acides alkylamino-2 hydroxy-4 butyriques

Les acides substitués peuvent être obtenus par hydrolyse acide des amides. Toutefois on peut y passer directement à partir de la bromo-2 butyrolactone sans isoler les amides, suivant la synthèse décrite pour l'acide méthylamino-2 hydroxy-4 butyrique.

On trouvera au tableau II les constantes physiques des produits obtenus.

Les rendements indiqués sont calculés à partir de la bromo-2 butyrolactone-4.

Acide méthylamino-2 hydroxy-4 butyrique

On ajoute 10 g (0.060 mole) de bromo-2 butyrolactone-4 à 75 ml (0.75 mole) d'une solution à 30% de méthylamine dans l'eau contenue dans une fiole conique plongée dans un bain de glace. Lors de l'addition, on agite pour que les deux liquides se mélangent rapidement. On laisse au repos pendant plusieurs jours à la température de la pièce. On évapore ensuite l'amine en excès. On ajoute 100 ml d'acide sulfurique 6 *N* (0.30 mole). On chauffe la solution sur bain-marie pendant 30 minutes puis on la laisse au repos jusqu'au lendemain. Dans ces conditions, l'amide hydroxylé en position 4 se transforme en lactone. On verse celle-ci dans une solution chaude de 94 g (0.30 mole) de $Ba(OH)_2.8H_2O$. Après avoir laissé le mélange sur un bain-marie bouillant 30 minutes, on filtre le sulfate de baryum. Au filtrat on ajoute un peu de carbonate d'ammonium pour éliminer le léger excès de baryte, puis on filtre. On évapore ensuite le filtrat jusqu'à environ 25 ml. On y ajoute 400 ml d'acétone et on met la solution au froid. L'acide méthylamino-2 hydroxy-4 butyrique cristallise alors lentement à froid pour donner 6.5 g de solide.

TABLEAU II

THE MASS SPECTRA OF THREE DEUTERATED BROMOBUTANES[1]

W. H. McFADDEN[2] AND M. LOUNSBURY
Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario

Received June 4, 1962

ABSTRACT

The mass spectra of 1,1-dideutero-1-bromobutane, 1,1,1,3,3-pentadeutero-2-bromobutane, and 1,1,1,2,3,3-hexadeutero-2-bromobutane have been obtained using 70-volt ionizing electrons. The cracking patterns of the deuterated molecules are compared with those of the undeuterated bromobutanes. It is shown that no hydrogen–deuterium exchange occurs in certain ions formed from the parent ion by simple bond break but that extensive exchange of hydrogen and deuterium occurs in ions formed by further decomposition of unsaturated daughter ions.

Formation of HBr^+ or loss of HBr to form $C_4H_8^+$ from 2-bromobutane is shown to favor sterically the hydrogen on carbon 4 and not to involve that on carbon 2. However, in the case of 1-bromobutane, formation of these ions does not appear to involve any particular hydrogen preferentially, because if one assumes that all hydrogens in the molecule are involved, then the hydrogen on carbon 1 appears to be involved to an almost statistical extent.

In two cases the isotopic substitution so modifies the rate of a metastable reaction that the metastable peak disappears from the spectra of the deuterated species.

INTRODUCTION

Some understanding of the reaction processes induced in alkyl halides by electron impact has been obtained in previous works (1–6). Methyl and ethyl halides have been studied at various electron energies (1, 2, 3). The energetics of several primary reactions were determined and important mechanistic differences were shown to exist between C_2H_5Cl and C_2H_5Br or C_2H_5I. McLafferty has studied series of organic halides and shown correlations between their spectra and that of similar hydrocarbons (4). Related studies have been performed by Momigny (5) and D'Or (6), and in the latter study considerable information was obtained on the fragmentation of bromopentanes from a study of the metastable ions observed. However, no fragmentation studies have been reported on deuterated alkyl halides of more than three carbons. Since this latter technique has often yielded important and sometimes unexpected information with other molecular systems, it seemed desirable to obtain the mass spectra of three deuterated bromobutanes which were available from a previous study (7).

EXPERIMENTAL

The three deuterated bromobutanes used in the present study are 1,1-dideutero-1-bromobutane, 1,1,1,3,3-pentadeutero-2-bromobutane, and 1,1,1,2,3,3-hexadeutero-2-bromobutane (hereafter referred to as *n*-bromobutane-D_2, *sec*-bromobutane-D_5, and *sec*-bromobutane-D_6 respectively). Their synthesis has been described previously (7). Before mass analysis, *n*-bromobutane-D_2 and *sec*-bromobutane-D_5 were purified by gas–liquid chromatography but because only an extremely small quantity of *sec*-bromobutane-D_6 was available it was used without further processing. The handling technique for *sec*-bromobutane-D_6 may have introduced an unknown amount of CO_2 and H_2O, and traces of other chemical impurities may be present due to the known slow decomposition of alkyl bromides.

All three compounds were concluded to be better than 97% isotopically pure from the mass spectra of the deuterated alcohols from which they were prepared (8). However, a good low-voltage analysis has not been obtained so doubt of isotopic purity may exist. This point is elaborated in detail where it is pertinent to the conclusions regarding the mechanics of fragmentation.

[1]*Issued as A.E.C.L. No. 1586.*
[2]*Present address: Western Utilization Research and Development Division, Agricultural Research Service, U.S. Department of Agriculture, Albany, Calif.*

The mass spectrometer (6-inch radius, 90° magnetic sector) and mass analysis techniques have been previously described (9, 8). The reported spectra were obtained with 70-volt electrons. The temperature of the ionization chamber was not measured.

EXPERIMENTAL DATA

The mass spectra of the undeuterated bromobutanes and deuterated bromobutanes are given in Table I. Ion abundances are reported in terms of the percentage of the

total ionization but the contribution due to metastable ions is not included. The usual methods of correcting for background contributions and memory effects have been applied. The corrections were insignificant for most of the important ions except for the CO_2 and H_2O contribution in the spectrum of *sec*-bromobutane-D_6. The H_2O could not be properly estimated and the values at m/e 18 and 17 for *sec*-bromobutane-D_6 are not reliable. The CO_2 contributions at $m/e = 44$ and 28 were obtained by assuming that the ionization observed at $m/e = 22$ was due to CO_2^{++}. The natural C^{13} abundance is reported as observed.

A number of broad non-integral peaks were observed corresponding to the so-called metastable ions. These metastable ions are particularly useful in determining reaction mechanisms because the mass at which they are observed is related to both the mass of the decomposing ion, m_o, and the actual mass of the daughter fragment, m_d. For the type of mass spectrometer used in this work, the relationship is $m^* = m_d^2/m_o$, where m^* is the observed mass of the metastable ion. The existence of a metastable peak definitely establishes the possibility of the corresponding reaction but it may not be used as a measure of its probability. Conversely, the absence of a metastable peak does not preclude the possibility of a particular reaction.

Table II presents the metastable peaks observed for *n*-bromobutane-D_0 and *sec*-bromobutane-D_0 and the corresponding kinetic processes. The metastable data for the

deuterated samples are given in Table III but the possible kinetic processes are not included. In many cases the metastable pattern is excessively smeared out as a result of contributions from various deuterated fragments, and the assignment of mass to the metastable peak is admittedly somewhat arbitrary. In addition the calculated masses for different reactions often have the same value, depending upon the particular deuterium content. An example of this is given by the data for *n*-bromobutane-D_2, from which one might expect the formation of $C_3H_5^+$ from $C_3H_7^+$ and $C_3HD_2^+$ from $C_3H_3D_2^+$. Both processes would give a metastable peak at mass 39.1 with a probable intensity of about 0.03% so that an unequivocal determination of the kinetic process is not possible. Nevertheless, many of the metastable processes occurring with the deuterated molecules can be correlated with those of the undeuterated compounds. Some of these reveal or confirm important features of the fragmentation pattern and are discussed in later sections.

DISCUSSION

(A) General

In the following discussion it is shown that ions from simple bond break occur without significant hydrogen–deuterium exchange, but, on the other hand, ion fragments that

do not contain bromine (C_1, C_2, and C_3 fragments) show extensive exchange. From these experimental facts it is concluded that in the parent ion the rate of H–D exchange is less than the rate of simple bond break (7), and, therefore, the formation of most of the hydrocarbon fragments must occur from the $C_4H_9^+$ ion. The observed metastable ions confirm this conclusion.

The slower rate of exchange observed in saturated parent ions as compared with the exchange rates observed in olefinic parents (10, 11) or radical daughter ions must be a consequence of the necessary intermediate structures of the saturated system, which would involve either pentavalent carbon or divalent hydrogen. The former would require extra energy in order to attain the probable bipyramidal dsp^3 hybridization, while the formation of an intermediate with a divalent hydrogen might impose a steric restriction on the system. On the other hand the exchange in an olefinic or unsaturated system can take place with very little change in the structure of the excited ion.

(B) Ions CH_2Br^+ and $C_2H_4Br^+$

(i) n-Bromobutane

From *n*-bromobutane an ion which contributes 2.4% to the total ionization, that is, the sum of the ionization due to $(C_2H_4Br^{79})^+$ and $(C_2H_4Br^{81})^+$ at $m/e = 107$ and 109, is formed by loss of $\cdot C_2H_5$. From *n*-bromobutane-D_2 this ion appears at 2 mass units higher, with the same percentage of ionization. The statistical probability of such an event is only 0.16 (assuming all hydrogens and deuteriums are equivalent) and the statistical probability for formation of $C_2H_3DBr^+$ from the ensemble $C_4D_2H_7Br^+$ is 0.56.

If a simple model is assumed in which a hydrogen from either carbon 3 or 4 is mixed with the deuterium on carbon 1 and then H or D statistically returned to carbon 3 or 4 (11), it is readily ascertained that with only one exchange of this type the probability of obtaining C_2H_3DBr is 0.66 (assuming no H–D isotope effect). This overly simplified model shows that a molecular system of this type requires very few exchanges in order

to bring about a considerable change in the H–D distribution. From such considerations one may conclude that the reaction $CH_2BrCH_2—CH_2CH_3^+ \rightarrow CH_2BrCH_2^+ + \cdot C_2H_5$ occurs at a rate much greater than the rate of H–D exchange. This conclusion assumes that exchanges occur at approximately the same rate between all carbon positions and that exchanges between carbons 1 and 2 do not occur exclusively (7).

The ion CH_2Br^+ formed by loss of $\cdot C_3H_7$ contributes 0.9% to the total ionization. Approximately 15% of these events appear to involve an exchange of hydrogen and deuterium. This is not likely to be due to the additional possibility of 1–2 exchanges and indicates a slightly slower rate for the reaction $CH_3CH_2CH_2—CH_2Br^+ \rightarrow CH_2Br^+ + \cdot C_3H_7$. It is again emphasized that the amount of exchange observed is considerably less than is expected for one hypothetical exchange of the type discussed.

(ii) sec-Bromobutane

From *sec*-bromobutane the ionization due to loss of $\cdot C_2H_5$ to form $C_2H_5Br^+$ contributes 0.95% to the total. As with loss of $\cdot C_2H_5$ from *n*-bromobutane, the deuterated molecules show no exchange so that one again concludes that the simple bond break occurs faster than the H–D exchange.

The ion CH_2Br^+ contributes only 0.3% to the total ionization and, as would be expected for an ion which requires rearrangement of the parent structure prior to dissociation, the deuterium and hydrogen show considerable exchange. Unfortunately, the amount of ionization is too small to permit speculation on possible mechanisms.

(C) Ions Br^+, HBr^+, and H_2Br^+

These ions contribute about 5% to the total ionization for both *n*-bromobutane and *sec*-bromobutane. From the data for *n*-bromobutane-D_2, it appears that the ion DBr^+ is formed in about 12% of this group of events (after making allowance for H_2Br^+). Statistically one would expect 22% but since the H–D isotope effect would decrease the possible transfer of deuterium to the bromine, the data suggest the possibility that HBr^+ may be formed from *n*-bromobutane by a random selection of hydrogen. This implies that the probable activated complex, $(C_4H_6D_2)—BrH^+$, is sufficiently stable to permit considerable exchange of H and D prior to its dissociation.

The data for the formation of HBr^+ from *sec*-bromobutane is more specific. The ion HBr^+ is formed in 65% of the events in the breakdown of both *sec*-bromobutane-D_5 and *sec*-bromobutane-D_6. The remarkable similarity of the spectra of these two molecules in the Br^+–HBr^+ region ($m/e = 79$ to $m/e = 83$) indicates that the hydrogen on carbon 2 is not involved in the formation of the HBr^+. The 65% of the rearrangement involving hydrogen for both of the deuterated molecules indicates that the hydrogen on carbon 4 is strongly favored, in accordance with accepted views that such rearrangements are often sterically dependent (8, 12). With the present data one cannot distinguish between contributions from carbon 1 and 3.

The ionization due to H_2Br^+ is relatively insignificant (about 0.1%) and nothing can be postulated regarding its formation. However, it must be considered in order to determine the contribution due to DBr^+ at $m/e = 81$ and 83.

(D) C_4 Ions Not Containing Bromine

(i) n-Bromobutane

The most abundant ion in the mass spectrum of *n*-bromobutane is $C_4H_9^+$ and it is formed by the reaction $C_4H_9Br^+ \rightarrow C_4H_9^+ + \cdot Br$. This is indicated by the metastable ions at masses 23.6 and 23.8. The possibility of the reaction $C_4H_9Br + e \rightarrow C_4H_9^+ + Br^- + e$ is however not excluded and such reactions have been shown to occur at

low electron energies (2, 3). The equivalent metastable peaks appear to be present in the spectrum of the deuterated molecule at masses 24.9 and 25.2, but because of the normal peak at 25 and a small metastable peak at 25.18 the unique pattern is partially obscured.

The butylene ion from *n*-bromobutane-D_2 is formed without any significant loss of D from position one. This indicates the expected reaction $C_4H_9Br^+ \rightarrow C_4H_8^+ + HBr$, but no corresponding metastable ions are observed. Because of the small amount of DBr^+ formed (11% of total hydrobromic ion) one might expect a corresponding amount of DBr to be lost in forming the butylene ion but doubts regarding the isotopic purity[3] of this compound make differences of this magnitude undiscernible.

(ii) sec-Bromobutane

The $C_4H_9^+$ ion is again the most abundant ion in the spectra, but contrary to the observations on *n*-bromobutane the metastable ions at masses 23.6 and 23.8 are not observed. This indicates an increase in the rate of the primary reaction $C_4H_9Br^+ \rightarrow C_4H_9^+ + \cdot Br$ so that decompositions do not occur in the metastable region of the mass spectrometer (13). A less likely possibility is that the pair formation reaction, $C_4H_9Br + e \rightarrow C_4H_9^+ + Br^- + e$, becomes predominant.

Metastable ions in the mass spectrum of *sec*-bromobutane-D_0 prove the occurrence of the expected reaction $C_4H_9Br^+ \rightarrow C_4H_8^+ + HBr$. However, before discussing the mechanics of this fragmentation it is necessary to appraise the data on the isotopic purity of the two deuterated samples.

Unfortunately, n.m.r. analysis was not available at the time the samples were mass analyzed (1958) and later n.m.r. analysis (1961) indicated chemical impurities due to the known instability of the alkyl bromides. These impurities were most likely absent during the mass analysis because of the prior purifying techniques but their presence during the n.m.r. analysis precluded any conclusion regarding isotopic purity and location of the deuterium.

The mass spectral data for the corresponding butanols (8) do furnish upper limits. An upper limit of 2.9% isotopic impurity on carbon 1 is obtained for *sec*-bromobutane-D_5 from the ratio of *m/e* 47 to *m/e* 48 from *sec*-butanol-D_5, (1.06% for *m/e* 47 and 36.5% for *m/e* 48). An upper limit of 4.4% isotopic impurity on carbons 1 and 2 is obtained for *sec*-bromobutane-D_6 from the ratio of *m/e* 48 to *m/e* 49 from *sec*-butanol-D_6 (1.68/37.6). If it is assumed from this that the deuteriums of carbons 1 and 3 would contain about 1% isotopic impurity *per deuterium* and carbon 2 about 1.4%, then, as an upper limit, one would have 5% $C_4H_5D_4Br$ in *sec*-$C_4H_4D_5Br$ and 6.4% $C_4H_4D_5Br$ in *sec*-$C_4H_3D_6Br$. These values could definitely be reduced by consideration of the fact that some of the ionization of the alcohols which was assumed due to the isotopic impurity would actually be due to the same species minus hydrogen. In previous work reduction by a factor of about 2 was considered a more reasonable estimate of the isotopic impurity. However, in order to be conservative in the present estimation of hydrogen versus deuterium in formation of the lost HBr group, the above figures were used for correcting the data.

Table IV presents corrected data for this small section of the mass spectra. For the rest of the spectra, in which considerable exchange of the hydrogen and deuterium occurs, such corrections have only modest influences on the nature of the spectra. The

[3]*The ionization at masses 58 and 57 in the mass spectrum of n-butanol-*D_2 *places an extreme upper limit of 11.8% on the isotopic impurity (8). However, the ionization at mass 57 must correspond primarily to loss of* H_3O *(rather than* H_2O *from* C_4H_8DOH*) in order to match the corresponding ionization from n-butanol-*D_0*. Taking this into account it was concluded that about 3.5% is a reasonable upper limit to the isotopic impurity.*

TABLE IV

Corrected partial mass spectra of deuterated *sec*-bromobutanes

D_0		D_5		D_6	
m/e	% ionization	*m/e*	% ionization	*m/e*	% ionization
54	0.24	59	0.9	60	0.8
55	1.83	60	1.5	61	1.3
56	2.33	61	2.0	62	1.7
57	31.3	62	30.6	63	29.8

corrections have been applied here only to the data for the ions due to loss of ·Br or HBr, because only negligible changes would be made in the other values. Because upper limit values of the possible corrections were used, the data at *m/e* 61 and 62 for *sec*-bromobutane-D_5 and *sec*-bromobutane-D_6 respectively may be taken as the minimum amount of ionization due to loss of HBr. The corrections impose uncertainties which make the difference between these values of no significance (D_6 is believed to be the more overcorrected) and because of observed differences in the total ionization of the C_4 group (as obtained from Table I, $\sum C_4$ ions is 38.9, 38.5, 37.4 for D_0, D_5, D_6) it is not certain how much ionization should be attributed to the combined loss of HBr and DBr. Nevertheless, a definite conclusion can be made that more than 86% (2.0/2.33) of the events forming the lost HBr involve either the hydrogen (deuterium) on carbons 2 or 4 and more than 73% (1.7/2.33) of the events involve only the hydrogen on carbon 4.

Because the two bromine isotopes Br^{79} and Br^{81} occur in about a 50–50 abundance the metastable ions corresponding to loss of HBr occur on an overlapping doublet with a characteristic shape. This shape was defined in these experiments from the spectrum of *sec*-bromobutane-D_0. It was observed in the spectrum of *sec*-bromobutane-D_5 with peaks at 26.0 and 26.4 corresponding to loss of HBr, but the metastable peaks corresponding to loss of DBr at *m/e* 25.5 and 25.2 were not observed. This would confirm the conclusions deduced from the corrected data of Table IV, namely, that loss of HBr to form $C_4H_8^+$ primarily involves the hydrogen on carbon 4 and may be considered as sterically dependent.

The spectrum of *sec*-bromobutane-D_6 showed no metastable ion doublet that could be attributed to the same molecular processes involving either loss of HBr or DBr. The absence of these very characteristic peaks must be due to an increase in the rate constant for the loss of HBr due to the additional isotopic substitution. It is interesting that this small isotopic change could so affect the rate of decomposition, but such an observation is in accordance with accepted views (13).

(E) C_3 Ions Not Containing Bromine

The metastable ions observed from the undeuterated bromobutanes indicate that many of the smaller ion fragments which do not contain bromine are secondary daughter fragments with $C_4H_9^+$ or $C_4H_8^+$ as their precursors. This results in an interesting comparison, namely, that many of the metastable peaks are also present in the mass spectra of the saturated and unsaturated hydrocarbons (14). A similar observation has been noted in the mass spectra of bromopentanes (6).

As a consequence of originating from unsaturated precursors, the hydrogens and deuteriums of most of the smaller daughter ions are significantly exchanged and in certain instances may be considered equilibrated. One notable exception is the propyl ion from *n*-bromobutane.

(i) n-Bromobutane

Because the total ionization of the C_3 group is the same for deuterated and undeuterated *n*-bromobutane (23.72% and 23.94%), one may confidently assume that the percentage of ionization for each type of ion is approximately the same. In order to establish the distribution of deuterium in the important ions ($C_3H_7^+$, $C_3H_5^+$, and $C_3H_3^+$) the less abundant ions at masses 42, 40, and 38 are assigned a statistical distribution of H and D. After a first-approximation calculation, minor corrections are made for the carbon 13 isotopes with the assumption of the same distribution of H and D as was found for the carbon 12 analogues. The $C_3H_8^+$ ion was assumed to have the same distribution as the propyl ion. Thus, one can approximate the amount of propyl ion containing zero, one, or two deuteriums. With this information the calculation of deuterium among the $C_3H_5^+$ ions can be determined and finally that for the $C_3H_3^+$ ions. The results are presented in Table V along with the values calculated on a statistical basis.

TABLE V

Distribution of H and D in the ions $C_3H_7^+$, $C_3H_5^+$, and $C_3H_3^+$ from $CD_2BrCH_2CH_2CH_3$

	% ionization					
	$C_3H_7^+$		$C_3H_5^+$		$C_3H_3^+$	
No. of deuteriums	Calc. data	Calc. stat.	Calc. data	Calc. stat.	Calc. data	Calc. stat.
0	1.17	0.04	3.7	4.4	1.5	1.5
1	—	0.53	6.6	8.7	1.6	1.8
2	0.20	0.82	5.5	2.5	0.6	0.3

The data of Table V show that most of the propyl ion is formed without involvement of the deuterium on carbon 1. A small amount (14% of total $C_3H_7^+$) appears to involve both of these deuteriums but apparently the ion $C_3H_6D^+$ is not formed to any appreciable extent. The assignment of the 0.39% of ionization observed at $m/e = 44$ to $C_3H_4D_2^+$, $C_3{}^{13}H_3D_2^+$, and $C_3H_8^+$ could not be in error enough to alter this conclusion. Thus, it appears that most of the propyl ion is formed by simple bond break without H–D exchange from the parent ion. A small amount appears to be formed by a path which involves the hydrogen on carbon 1 but which does not permit significant exchange. The statistically calculated values indicate the improbability of such data if many exchanges were occurring.

The data for the ions $C_3H_5^+$ and $C_3H_3^+$ show, on the other hand, a considerable exchange of hydrogen and deuterium. This is consistent with the observed metastable ion data indicating an unsaturated hydrocarbon ion as the precursor; for such ions, the rate of H–D exchange would be much greater than that obtained in saturated species. Comparison with the statistically calculated values indicates a close approximation to equilibrium with a slight preference for retention of the deuterium, but until a more refined understanding of the isotope effect and the intramolecular exchange reactions is obtained, these small differences cannot be interpreted.

In the spectrum of *n*-bromobutane-D_0 a metastable peak is observed at mass 29.5 corresponding to the reaction $C_4H_9^+ \rightarrow C_3H_5^+ + CH_4$. The equivalent metastable peaks are observed at masses 28.6, 29.9, and 31.3 (Table III) corresponding to the processes

$$\begin{aligned} C_4H_7D_2^+ &\rightarrow C_3H_5^+ + CH_2D_2 \\ &\rightarrow C_3H_4D^+ + CH_3D \\ &\rightarrow C_3H_3D_2^+ + CH_4. \end{aligned}$$

Metastable peak data indicate that $C_3H_3^+$ can be formed by the reactions $C_4H_7^+ \rightarrow C_3H_3^+ + CH_4$ and $C_3H_5^+ \rightarrow C_3H_3^+ + H_2$. The first of these paths gave only 0.004% of the ionization as a metastable ion so that, as is expected, none of the six possible paths leading to equivalent ions are observed in the spectrum of *n*-bromobutane-D_2. The second reaction gave a stronger metastable peak from the undeuterated molecule (0.03%). The six possible equivalent reaction paths for the deuterated molecule are:

$C_3H_5^+ \rightarrow$	$C_3H_3^+ + H_2$	$m^* = 37.1$
$C_3H_4D^+ \rightarrow$	$C_3H_3^+ + HD$	36.2
$\rightarrow$	$C_3H_2D^+ + H_2$	38.1
$C_3H_3D_2^+ \rightarrow$	$C_3H_3^+ + D_2$	35.4
$\rightarrow$	$C_3H_2D^+ + DH$	37.2
$\rightarrow$	$C_3HD_2^+ + H_2$	39.1

and all except $C_3H_3D_2^+ \rightarrow C_3H_3^+ + D_2$ are observed. That this reaction should be absent is a logical result of the low statistical probability for that process, and the small signal observed for the process $C_3H_4D^+ \rightarrow C_3H_3^+ + HD$ may also be attributed to that cause.

(ii) sec-Bromobutane

Determination of the distribution of deuterium among the more predominant C_3 ions from *sec*-bromobutane-D_5 and *sec*-bromobutane-D_6 was made in the same way as for *n*-bromobutane-D_2. Because the propyl ion contributes less to the total and because it makes an uncertain contribution to the mass 48 ionization it was arbitrarily assigned a statistical distribution. The results for the $C_3H_5^+$ and $C_3H_3^+$ ions are given in Table VI.

TABLE VI
Distribution of H and D in the ions $C_3H_5^+$ and $C_3H_3^+$ from $CD_3CHBrCD_2CH_3$ and $CD_3CDBrCD_2CH_3$

	% ionization							
	$CD_3CHBrCD_2CH_3$				$CD_3CDBrCD_2CH_3$			
	$C_3H_5^+$		$C_3H_3^+$		$C_3H_5^+$		$C_3H_3^+$	
No. of deuteriums	Calc. data	Calc. stat.	Calc. data	Calc. stat.	Calc. data	Calc. stat.	Calc. data	Calc. stat.
0	—	—	0.04	0.2	—	—	0.0	0.05
1	1.3	0.7	1.3	1.6	—	—	0.8	1.0
2	5.2	5.4	2.1	2.2	2.8	2.0	1.8	2.5
3	6.2	8.0	1.2	0.6	6.2	8.0	2.4	1.1
4	3.8	2.7			4.9	6.1		
5	0.4	0.1			3.0	0.8		

The data of Table VI again show considerable rearrangement of hydrogen and deuterium. In both cases, however, there is a tendency to retain deuterium, indicating that the lost CH_4 molecule may predominantly involve carbon 4.

The metastable ion at mass 29.5 from the undeuterated compound indicates the process $C_4H_9^+ \rightarrow C_3H_5^+ + CH_4$. From *sec*-bromobutane-D_5 this ion could be expected to occur at masses 28.4, 29.8, 31.2, 32.7, and 34.1, corresponding to formation of $C_3DH_4^+$, $C_3D_2H_3^+$, $C_3D_3H_2^+$, $C_3D_4H^+$, and $C_3D_5^+$. All are observed except that at 28.4 and the intensities are in reasonable agreement with the expected values, considering the difficulty in accurately measuring metastable peak heights.

Metastable ions due to the processes equivalent to $C_3H_5^+ \rightarrow C_3H_3^+ + H_2$ could occur by 11 processes from *sec*-bromobutane-D_5 and 9 from *sec*-bromobutane-D_6. All but two are observed and these two are low probability processes.

(F) C_2 and C_1 Ions Not Containing Bromine

The ethyl and ethylene ions from *n*-bromobutane and *sec*-bromobutane are shown by the metastable peaks to originate to a considerable extent from $C_4H_9^+$ or $C_4H_7^+$ and to be in turn the precursors of the vinyl and acetylene ions (Table II). From such origins one would expect that the hydrogen and deuterium of the deuterated molecules would be considerably exchanged prior to formation of these ions. In Table VII the observed

TABLE VII

	$CD_2BrCH_2CH_2CH_3$		$CD_3CHBrCD_2CH_3$		$CD_3CDBrCD_2CH_3$	
m/e	Obs.	Stat.	Obs.	Stat.	Obs.	Stat.
26	1.1	1.2	0.3	0.2	0.2	0.1
27	4.6	4.3	1.2	1.2	0.8	0.8
28	4.4	5.6	2.4	2.9	2.5	2.1
29	7.0	5.1	3.8	3.7	2.2	3.7
30	6.9	7.4	3.4	2.0	4.2	2.4
31	3.3	3.5	5.6	5.4	3.7	2.9
32			5.9	7.0	6.2	7.1
33			2.7	2.5	4.6	5.3
34			0.3	0.2	1.3	0.9

ion ratio for the C_2 ions of the deuterated species is compared with that calculated assuming all ion types have complete equilibration of the original hydrogen and deuterium. It is seen that the experimental data are close to the statistical calculations and the small deviations may be considered due to isotope effects.

The three metastable processes leading to these ions in the undeuterated molecules (namely, $C_4H_9^+ \rightarrow C_2H_4^+ + \cdot C_2H_5$, $C_4H_9^+ \rightarrow C_2H_5^+ + C_2H_4$, and $C_4H_7^+ \rightarrow C_2H_5^+ + C_2H_2$, Table II) have 13, 19, and 16 equivalent processes from the molecules *n*-bromobutane-D_2, *sec*-bromobutane-D_5, and *sec*-bromobutane-D_6, respectively. This causes considerable overlap and since the position of metastable peaks cannot always be precisely determined, the 12 metastable ions reported in Table III between mass 14.25 and 18.09 cannot all be assigned to an unequivocal reaction. They are all accountable, however. Noteworthy is the fact that the metastable ions corresponding to the different possible isotopic reactions equivalent to $C_4H_9^+ \rightarrow C_2H_5^+ + C_2H_4$ are all absent in the spectra of the two deuterated *sec*-bromobutanes. This most likely indicates a change in the rate of that reaction due to the isotopic substitution.

The C_1 ions (primarily CH_3^+) do not constitute an important part of the total ionization. Considerable H–D exchange occurs, leading to values close to the statistical ones. This suggests that these small ions are formed from a number of the prior daughter fragments, consistent with recent conclusions based on data from large substituted hydrocarbons (15).

ACKNOWLEDGMENTS

We wish to thank Professor A. L. Wahrhaftig for making the deuterated samples available and Dr. R. E. Lundin and Mr. R. B. Block for attempting the belated isotopic analysis by n.m.r.

GAS–LIQUID CHROMATOGRAPHIC ANALYSIS OF LIGNIN OXIDATION PRODUCTS

J. M. Pepper, M. Manolopoulo, and R. Burton
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received July 3, 1962

ABSTRACT

The gas–liquid chromatographic separation of vanillin, syringaldehyde, and *p*-hydroxybenzaldehyde has been effected using a 15% Apiezon N on Fluoropak column at 220° C. Using standard solutions of the reference compounds and measuring peak areas, the percentage composition of mixtures of milligram amounts of these aldehydes may be determined quantitatively to within 5%.

The method has been applied to the quantitative analysis of the phenolic aldehydes resulting from the alkaline nitrobenzene oxidation of aspen and spruce wood and wheat straw meals as well as the lignins isolated from these same plant materials. The results are reproducible and generally in good agreement with those reported earlier for similar lignified substances as determined using the spectrophotometer method of Stone and Blundell.

In a recent communication Pepper and Siddiqueullah (1) reviewed the chemical nature and the methods of separation and estimation of those lignin derivatives obtained by the oxidation and/or alkaline hydrolysis of woody plants and isolated lignins. Of these, the procedure developed in 1951 by Stone and Blundell (2) has been used most extensively for both the identification and quantitative estimation of the phenolic aldehydes vanillin, syringaldehyde, and *p*-hydroxybenzaldehyde. This method involves the paper chromatographic separation of the oxidation products, their extraction from strips cut from these papers, and their subsequent quantitative estimation spectrophotometrically. In our laboratory good reproducible results were obtained only after extensive experience with the procedure, especially with respect to the sampling of the whole oxidation reaction mixture. A modification has been suggested (3) to minimize these difficulties.

It has now been found that these lignin oxidation products may be separated readily and subsequently determined quantitatively using gas–liquid chromatography. The components of a mixture of vanillin, syringaldehyde, and *p*-hydroxybenzaldehyde were readily separated using a 1/4 in.×6 ft 15% Apiezon N on Fluoropak column at 220° C. Retention times of 8.2, 19.3, and 5.8 minutes respectively were observed using 30 p.s.i. helium carrier gas at a flow rate of 0.7 cc/sec. To determine if such an analysis could be used quantitatively, standard curves were prepared relating peak areas to weight of injected sample. The areas were determined by the triangulation method. A 1% solution of each pure aldehyde was prepared in absolute ethanol. For each compound five accurately measured sample volumes ranging from 10 to 60 μl were chromatographed using the column and conditions described above. The results so obtained and subsequently used to plot the standard calibration curves are given in Table I.

Subsequently a synthetic mixture of known composition of the three aldehydes was prepared in ethanol and analyzed using these calibration curves. Symmetrical, well-separated peaks were obtained, which permitted the ready calculation of areas and hence concentration. Agreement with the original composition was within 3%.

It was then necessary to show that a similar quantitative recovery of these aldehydes could be accomplished from the products of an alkaline nitrobenzene oxidation of lignin. To this end a study was made of the products of oxidation of each of a sample of aspen and spruce wood and wheat straw as well as a representative lignin fraction obtained

TABLE I

Relationship of peak area to sample weight for phenolic aldehydes

Sample (μl)	Aldehyde (mg)	Peak areas (cm²)		
		Vanillin	Syringaldehyde	*p*-Hydroxybenzaldehyde
10	0.10	8		7.8
15	0.15			12.0
20	0.20	16.7	15.4	15.8
25	0.25			19.5
30	0.30	24.2	22.8	23.2
35	0.35	28.2		
40	0.40	31.9	30.6	
50	0.50		39.3	
60	0.60		46.3	

from each of them. These six samples were independently oxidized at 180±2° C for 2 hours in small, rocking, stainless steel autoclaves. For each, the alkaline reaction product was extracted with ether to remove excess nitrobenzene and its reduction products, then acidified and re-extracted with ether to remove the lignin oxidation products. This ether extract was water-washed, dried, and concentrated to standard volume. Accurately measured aliquots were injected into the 6-ft Apiezon N on Fluoropak column under conditions as similar as possible to those used to prepare the standard calibration curves.

Well-separated, symmetrical peaks were obtained for each of the major components of each of the six oxidation products, as shown in Fig. 1. For those cases in which only trace

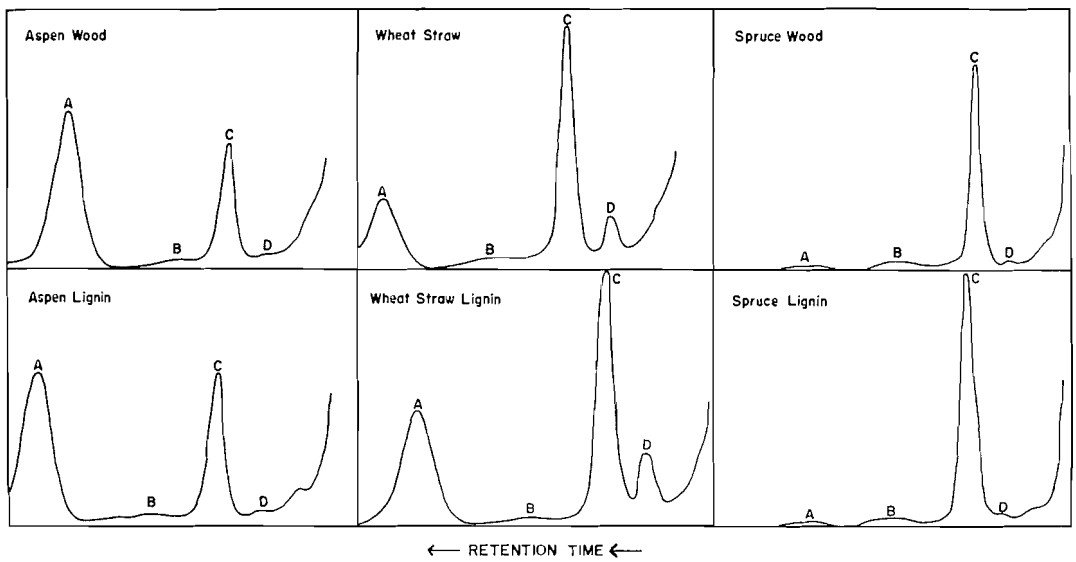

FIG. 1. Chromatographic separation of oxidation products of wood, straw, and isolated lignins. A, syringaldehyde; B, acetoguaiacone; C, vanillin; D, *p*-hydroxybenzaldehyde.

amounts of aldehydes or acetoguaiacone were indicated in these curves, larger, sharper peaks were obtained for these components by injection of a larger sample. From the peak areas both the relative abundance and the yield of each component were determined by reference to the standard calibration curves. From these yields the percentage yields based on either the Klason lignin content of the plant meals or on the isolated lignin

were calculated. These data, together with the yields obtained previously by the method of Stone and Blundell on similar or in some cases identical samples, are given in Table II.

For a simple, rapid analysis of both the chemical nature and the relative abundance of the simple products of lignin oxidation, this gas–liquid chromatographic method is superior to the paper chromatographic methods that have been used previously. For the more precise quantitative analysis of the oxidation products this method compares very favorably with that described by Stone and Blundell (2). It should be emphasized that it may be necessary to check the standardization curves more frequently due to the greater possibility of variation in the experimental conditions and especially in the characteristics of the particular column should it have been in use for any extended length of time. As may be seen from Table II, the percentage yields of the phenolic aldehydes as determined by the two methods are generally in good agreement. No doubt, part of the variation may be attributed to the problems of sampling and of small actual differences within the plant species themselves. Using the gas chromatographic method there is no need for correction for chromatographic losses, as Stone and Blundell suggest must be applied in the calculations using their method.

It is now quite evident that the lignin fraction of representative samples of deciduous and coniferous woods and of cereal straws gives rise to all three types of nuclei as seen in the compounds vanillin, syringaldehyde, and *p*-hydroxybenzaldehyde. However, the relative abundance of each such type still serves adequately as a form of taxonomic classification of such lignified tissues (7).

EXPERIMENTAL

The various samples of pre-extracted wood meals and wheat straw, as well as the lignins isolated from them, had been prepared by other workers, and their method of preparation described earlier (6).

The apparatus used for the oxidations consisted of small cylindrical (6 in.×1 in. O.D., 20-ml capacity) stainless steel reaction vessels with screw caps. Six such vessels could be inserted and held in an aluminum block which was heated electrically. A rocking device permitted a swing through approximately 120° at 50 cycles/min. One such vessel was designed to accommodate a thermometer and was filled with Stanolax oil as the heat exchange medium.

The chromatographic column was made from 6 ft×1/4 in. I.D. copper tubing and packed with Apiezon N grease on Fluoropak 80 (Wilkens Instrument and Research, Inc.) in the ratio of 3 to 17. A Beckman GC-2 chromatograph, with a thermal conductivity detector unit, was used, after some modification, to place the injection system as close as possible to one end of the column.

Oxidation and Analytical Procedure

For each oxidation 2 *N* sodium hydroxide (10 ml) was added to the reaction vessel. Subsequently the pre-extracted wood or straw meals or the isolated lignins were added. The dry weights of the lignified materials that were used to obtain the results given in Table II were 401, 579, 824 mg for the aspen, spruce, and straw meals respectively and 198, 210, and 210 mg for the corresponding isolated lignins. For each oxidation redistilled nitrobenzene (0.6 ml) was added. The vessels were sealed and the contents heated at 180±2° for 2 hours with rocking. After being cooled, the dark-colored reaction mixture was transferred, with careful rinsing with water and ether, to a continuous liquid–liquid extraction apparatus. Excess nitrobenzene and its reduction products were removed by the continuous ether extractions (24–30 hours).

The aqueous layer, after acidification to pH 3 by the slow addition of concentrated hydrochloric acid, was further continuously extracted with ether (24–30 hours) to remove the lignin oxidation products. The ether extract, after being washed with water, was dried over anhydrous magnesium sulphate and concentrated to a volume of 2–3 ml. Complete transfer of this extract to a 5-ml volumetric flask required two or three washings with dry ether, each of which was concentrated to 0.5–1 ml. Finally, by the addition of dry ether, the extract was diluted to exactly 5 ml. At least two samples of equal volume of about 60–100 μl were pipetted quickly from the 5-ml extract and injected immediately into the previously equilibrated column.

ACKNOWLEDGMENT

Grateful acknowledgment is made to the National Research Council of Canada for financial assistance.

MECHANISM OF ALKALINE HYDROLYSIS OF HINDERED AROMATIC ESTERS, THE $B_{AL}2$ MECHANISM

L. R. C. BARCLAY, N. D. HALL, AND G. A. COOKE
Department of Chemistry, Mount Allison University, Sackville, New Brunswick

Received June 27, 1962

ABSTRACT

Kinetic and isotopic exchange data employing H_2O^{18} are presented to establish the bimolecular alkaline hydrolysis with alkyl–oxygen fission ($B_{AL}2$) for the highly hindered ester methyl 2,4,6-tri-*t*-butylbenzoate. Methyl 2-methyl-4,6-di-*t*-butylbenzoate also cleaved predominately by alkyl–oxygen fission. Other hindered esters, methyl 2,4,6-trimethylbenzoate and methyl 2,5-di-*t*-butylbenzoate, hydrolyzed by the usual acyl–oxygen fission.

INTRODUCTION

Attempts have been made to observe the relatively unknown bimolecular alkaline hydrolysis of carboxylic esters with alkyl–oxygen fission ($B_{AL}2$). Mechanistic studies on the saponification of di-ortho-substituted benzoic esters are of special interest. Bulky ortho substituents in the methylbenzoates might be expected to hinder nucleophilic attack at the carbonyl carbon and possibly permit observation of the unusual mechanisms of nucleophilic attack at the alkyl (methyl) carbon atom. In this connection Goering, Rubin, and Newman (1) provided kinetic evidence on the alkaline hydrolysis of 4-substituted-2,6-dimethyl benzoates (i.e. methyl mesitoate) which they suggested was indicative of the $B_{AL}2$ mechanism. The log PZ terms for hydrolysis of mono-ortho-substituted benzoic esters are about 10 times smaller than the value of approximately 8 observed for the meta and para isomers. Therefore the log PZ terms for hydrolysis of di-ortho-substituted benzoic esters were expected to be still smaller (1). However, these terms were at least as large as those observed for the unsubstituted ester and meta and para isomers. This anomalous result prompted Newman and co-workers to suggest a change in mechanisms from the usual acyl–oxygen fission to the unusual alkyl–oxygen fission. Bender and Dewey (2) later provided unequivocal tracer evidence with H_2O^{18} to show that the kinetic results (1) led to an incorrect conclusion. This tracer evidence established that this ester cleaved via acyl–oxygen fission. Bunton and co-workers (3) found that methyl 2,4,6-triphenylbenzoate underwent the usual bimolecular acyl–oxygen fission ($B_{AC}2$) in aqueous dioxane. In aqueous methanol this ester hydrolyzed to some extent by the $B_{AC}2$ mechanism and to some extent by the $B_{AL}2$ mechanism, but in the latter case the reaction apparently proceeded by attack of methoxide rather than hydroxide ion on the alkyl carbon.

Evidence was provided in a preliminary publication (4) for the $B_{AL}2$ mechanisms for hydrolysis of methyl 2,4,6-tri-*t*-butylbenzoate. We now wish to report the details of this research and also to report on the extension of this mechanism to methyl 2-methyl-4,6-di-*t*-butylbenzoate.

Syntheses of Hindered Acids and Esters

(A) Methyl Mesitoate

Mesitoic acid (m.p. 154°), prepared as described in *Organic Syntheses* (5), was esterified with diazomethane in ethyl ether. The pure ester (n_D^{20} 1.5090) was obtained by chromatography in petroleum ether on alumina.

(B) Methyl 2,5-Di-t-butylbenzoate

2,5-Di-*t*-butylbenzoic acid was prepared as previously described (6) and converted into its methyl ester with diazomethane. The ester was purified by chromatography and distilled at 148–150° at 7 mm; n_D^{20} 1.5068.

(C) 2,4,6-Tri-t-butylbenzoic Acid and Methyl Ester

2,4,6-Tri-*t*-butylbenzoic acid was prepared from 2,4,6-tri-*t*-butylbromobenzene by a procedure similar to that previously described (6). The ester, methyl 2,4,6-tri-*t*-butylbenzoate, was prepared from the acid by the diazomethane method. The ester was purified by chromatography on alumina, m.p. 98–99°.

(D) Methyl 2-Methyl-4,6-di-t-butylbenzoic Acid and Related Compounds

(1) 3,5-Di-t-butyltoluene.—3,5-Di-*t*-butyltoluene was prepared by a procedure similar to that reported by Wepster and co-workers (7).

(2) 2-Methyl-4,6-di-t-butylbromobenzene.—3,5-Di-*t*-butyltoluene (20 g, 0.098 mole) was dissolved in 130 cc of glacial acetic acid. Aqueous nitric acid (80 cc of concentrated nitric acid in 80 cc of distilled water) was added to this mixture. Bromine (15 g, 0.094 mole) was added to the solution followed by a solution of 20 g of silver nitrate in 50 cc of water. The aqueous silver nitrate was added dropwise to the stirred reaction mixture over a period of 2 hours and the reaction was allowed to stand overnight. An oily organic layer was separated and traces of bromine were removed by washing with aqueous sodium bisulphite. The product was dried with anhydrous sodium sulphate and purified by distillation to yield 23 g of bromocompound (83%), b.p. 87–89° at 0.2 mm; n_D^{20} 1.5318.

(3) 2-Methyl-4,6-di-t-butylbenzoic acid and methyl ester.— 2-Methyl-4,6-di-*t*-butylbromobenzene (3.70 g, 0.013 mole) in 20 ml of anhydrous ethyl ether was added to 0.026 mole of *n*-butyl lithium in 65 ml of ethyl ether in an atmosphere of dry nitrogen. There was spontaneous refluxing for 15 minutes, which was continued for an additional 30 minutes by heating. Carbon dioxide was passed through the reaction mixture, with stirring, for 5 hours. The solvent was distilled to dryness and the residue treated with water. Acidification of this aqueous layer yielded 2.30 g, 72% of the crude acid, m.p. 147–152°. Crystallization from petroleum ether produced colorless crystals, m.p. 152–153°. The same acid was also prepared by chromic acid oxidation of 2-methyl-4,6-di-*t*-butylbenzyl alcohol, which was synthesized by the method of Beets and co-workers (8). They reported a melting point of 152.3–152.9°. The acid was esterified by the diazomethane method. On crystallization from methanol–water, the methyl ester melted at 46–48°. It was further purified by chromatography on alumina and gave a melting point of 47–48° (lit. (8) m.p. 53.5–54.0°).

(4) Oxidation of 2-methyl-4,6-di-t-butylbenzoic acid.—2-Methyl-4,6-di-*t*-butylbenzoic acid (1.0 g, 0.004 mole) was dissolved in aqueous sodium carbonate. Potassium permanganate (1.30 g) was added in portions and the reaction mixture was heated under reflux until the permanganate color had nearly disappeared (5 hours). Sulphur dioxide was passed into the reaction to destroy the precipitated manganese dioxide and the precipitated organic acid was filtered and dried (1.05 g, 95%). This crude acid was dissolved in aqueous sodium carbonate and reprecipitated, and the melting point found to be 175–183°. The infrared spectrum of this acid (KBr pellet) showed a doublet in the carbonyl region at 1690 and 1710 cm^{-1}. An attempt was made to purify this acid by sublimation *in vacuo*. The sublimed crystals had a melting point of 93–95° and double carbonyl absorption in the infrared (KBr pellet) at 1760 and 1820 cm^{-1}, typical of a cyclic anhydride. Calc. for $C_{16}H_{20}O_3$: C, 73.82; H, 7.74. Found: C, 73.40, 73.44; H, 7.97, 7.86.

Kinetics of Alkaline Hydrolysis of Methyl 2,4,6-Tri-t-butylbenzoate

The methanol which was used as the solvent was purified by the method of Morton and Mark (9). It was then distilled on a podbielniak column and the fraction which gave a negative test for carbonyl compounds used. The dioxane used was purified by the method of Fieser (10) and distilled from lithium aluminum hydride on a podbielniak column in an atmosphere of nitrogen. This solvent gave very large blanks with aqueous alkali in the kinetic apparatus even when the purification was repeated. Its use therefore had to be abandoned in the kinetic runs.

The kinetic runs were made in stainless steel tubes ($8\times\frac{1}{2}$ in.) which were fitted at each end with heavy stainless steel hexagonal caps. The caps contained an expansion chamber into which were fitted pure silver disks. The tubes were sealed by turning the caps on tightly so that the ends of the tubes were seated into the silver disks. The extent of hydrolysis was followed by removing aliquots and titrating the alkali remaining with standard hydrochloric acid from a microburette using phenolphthalein indicator.

The rate constants were determined from the integrated form of the second-order rate equation, $k = 1/t(a-b) \ln [b/a(a-x)/(b-x)]$, where a is the initial concentration of sodium hydroxide, b is the initial concentration of ester, x is the amount reacted at time t, and k is the second-order rate constant in liters/mole sec. The results of the measurements at six temperatures are summarized in Table I.

Isotopic Oxygen Tracer Studies

In the isotopic tracer studies, water enriched in H_2O^{18} was employed.*

The alkaline hydrolysis mixtures containing ester were made up to contain certain percentages of H_2O^{18} by dilution. The amount of oxygen exchange was determined from the isotopic abundance of oxygen in the acid

**Samples enriched to about 1.5% H_2O^{18} were supplied by Dr. R. E. Robertson of the N.R.C. Laboratory. Other samples were obtained from Dajac Laboratories, Philadelphia.*

*These values of k were determined by the method of least squares.

produced in the saponification by decarboxylation of the silver salts of the acids. The procedure was similar to that reported by Bunton and co-workers (3). The silver salts of the acids were prepared by dissolving the acids in ethanol, titrating with standard alcoholic potassium hydroxide, and then adding exactly an equivalent amount of silver nitrate. The silver salt of 2,4,6-tri-*t*-butylbenzoic acid precipitated best from an aqueous medium. These salts were dried by heating *in vacuo* over phosphorus pentoxide. Preliminary decarboxylations were carried out on the silver salts at 290° to establish the best technique to be used and to obtain carbon dioxide for mass spectroscopic analyses of "blanks". The reliability of the isotopic exchange technique was checked with methyl 2,4,6-trimethylbenzoate, known to cleave by acyl–oxygen fission (2). The mass spectroscopic analyses were determined in independent laboratories. The results obtained are summarized in Table II. Isotopic tracer experiments in aqueous dioxane were carried out in a pure silver apparatus manufactured by Johnson, Matthey and Mallory to a design described by Bunton (3).

TABLE II

Isotopic tracer analyses of the mechanism of fission of hindered esters

RESULTS AND DISCUSSION

Structure and Properties of Hindered Aromatic Acids

2,4,6-Tri-*t*-butylbenzoic acid is a weaker acid than benzoic acid and this behavior was attributed to steric hindrance to solvation of the carboxylate ion (4). A similar explanation

can be offered to account for the unusual solubility of this acid. It extracts from aqueous alkali into ethyl ether as its sodium salt. This property was not exhibited by the other acids in this investigation.

The structure of 2-methyl-4,6-di-*t*-butylbenzoic acid was readily confirmed by oxidation to a dicarboxylic acid which spontaneously formed an anhydride.

Kinetics of Alkaline Hydrolysis of Methyl 2,4,6-Tri-t-butylbenzoate

A plot of the second-order rate constant against $1/T$ for the alkaline hydrolysis of methyl 2,4,6-tri-*t*-butylbenzoate is illustrated in Fig. 1.

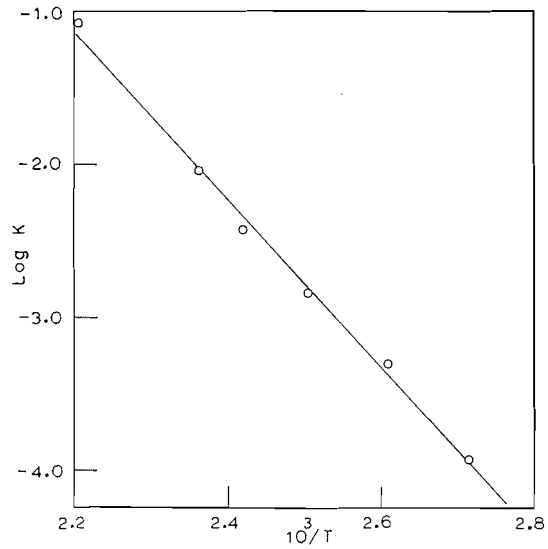

FIG. 1. Plot of log k against the reciprocal of the absolute temperature for the basic hydrolysis of methyl 2,4,6-tri-*t*-butylbenzoate.

The best straight line was estimated by the method of least squares. From this line the energy of activation was found to be 25.07 kcal/mole and the $\log_{10} PZ$ factor 10.93. This factor is much higher (by about at least 100 times) than that observed for alkaline hydrolysis of most benzoic esters which hydrolyze by the $B_{AC}2$ mechanism. The significance of this higher log PZ factor is not entirely obvious. It may be a result of a change in mechanism from the usual $B_{AC}2$, which would be highly hindered in this ester, to attack at the alkyl (methyl) carbon ($B_{AL}2$). The latter mechanism would be free of steric effects in this methyl ester and a resulting higher entropy of activation would be expected. This is reflected in the larger log PZ term. It is interesting that the steric effect in hydrolysis of methyl 2,4,6-trimethylbenzoate was not reflected in a lower log PZ term (1), especially since the cleavage has been found to be acyl–oxygen (2). It is conceivable that this ester undergoes hydrolysis mainly by acyl–oxygen fission but also partly by alkyl–oxygen fission. This could account for the somewhat high log PZ term and such a mixed mechanism might not be detected by the isotopic tracer evidence.

Tracer Evidence of the Position of Bond Fission of Hindered Esters. Evidence for a $B_{AL}2$ Mechanism

The isotopic tracer analysis on methyl 2,4,6-trimethylbenzoate (Table II) confirms the finding of Bender and Dewey that the cleavage is acyl–oxygen. The hindered ester

methyl 2,5-di-*t*-butylbenzoate also cleaved by this mechanism, since the carbon dioxide from the acid was similarly enriched in $CO^{16}O^{18}$ when the hydrolysis was carried out in the presence of H_2O^{18}. With the highly hindered ester methyl 2,4,6-tri-*t*-butylbenzoate, no exchange of O^{18} into the acid could be detected. This was the case not only in aqueous methanol but also in aqueous dioxane, where the reaction is not complicated by the possibility of methanolysis occurring along with hydrolysis (3). A small amount of enrichment in $CO^{16}O^{18}$ was found in the tracer hydrolysis of methyl 2-methyl-4,6-di-*t*-butylbenzoate. This can be interpreted as meaning that this ester cleaves mainly by alkyl–oxygen fission but some acyl–oxygen fission takes place. The $CO^{16}O^{18}$ isotopic tracer studies reported in Table II were determined on a mass spectrometer accurate to only one or at most two decimals. This was sufficient to give a positive or negative answer. In the crucial case of methyl 2,4,6-tri-*t*-butylbenzoate, the tracer analysis using 0.9% H_2O^{18} in aqueous dioxane was repeated for a mass spectroscopic analysis of higher precision. Compared to a standard sample of carbon dioxide, which showed an intensity of 0.04135 (arbitrary scale) for natural abundance of $CO^{16}O^{18}$, the carbon dioxide from the acid formed after 75% hydrolysis gave readings of 0.04137 and 0.04139,* that is, there has been no significant amount of enrichment of the carbon dioxide in $CO^{16}O^{18}$. The hydrolysis takes place practically completely by alkyl–oxygen fission. In view of the kinetic form of the hydrolysis this result establishes unequivocally the unusual $B_{AL}2$ mechanism.

An additional interesting observation on methyl 2,4,6-tri-*t*-butylbenzoate involved the reaction of this ester with the Grignard reagent methyl magnesium iodide. No reaction took place in boiling ethyl ether; however, in boiling butyl ether the ester was converted into an inorganic salt of the acid and ethane gas was evolved as detected by vapor phase chromatography. In other words, the Grignard reagent attacked the alkyl carbon instead of the usual carbonyl carbon.

ACKNOWLEDGMENTS

The mathematical calculations involving least-squares methods were made by Dr. D. Russell of the Mathematics Department. The stainless steel tubes for the kinetic runs were manufactured by Enamel and Heating Products Ltd., Sackville, N.B. We are indebted to the National Research Council for financial support of the research.

CONCURRENT ION–MOLECULE REACTIONS LEADING TO THE SAME PRODUCT ION

A. G. HARRISON AND J. M. S. TAIT
Department of Chemistry, University of Toronto, Toronto, Ontario
Received June 15, 1962

ABSTRACT

Seven of the major secondary ions in the high-pressure mass spectrum of cyclopropane have been studied. A method has been developed for studying concurrent ion–molecule reactions and it has been shown that four of the secondary ions are the products of more than one reaction. Cross sections for the separate reactions are reported. The appearance potentials of the major primary ions in the mass spectrum of cyclopropane have been measured.

INTRODUCTION

Theard and Hamill (1) have pointed out in a recent communication that many of the cross sections reported in the literature for ion–molecule reactions must be considered as suspect. This arises because the method of identification of the reactant ion by measurement of the secondary ion appearance potential only provides information on the reaction of lowest appearance potential. Frequently, other reactions involving ions of higher appearance potential are thermochemically possible, but are not detected due to the limited sensitivity of such determinations. The occurrence of undetected reactions will, of course, lead to erroneous values for reaction cross sections.

Recently, Hutchison and Pobo (2) have outlined a method for studying concurrent ion–molecule reactions leading to the same product ion in binary systems. They have shown that in nitrogen–deuterium systems the N_2D^+ ion is formed by the reaction

$$D_2^+ + N_2 \rightarrow N_2D^+ + D$$

in addition to the reaction detected previously (3, 4):

$$N_2^+ + D_2 \rightarrow N_2D^+ + D.$$

The present paper reports an extension of the method developed by these authors to the study of the major secondary ions in the high-pressure mass spectrum of cyclopropane.

Consider the two ion–molecule reactions

$$P_1^+ + M \rightarrow S^+ + N_1$$
$$P_2^+ + M \rightarrow S^+ + N_2$$

involving the reaction of two different primary ions with substrate molecules to produce the same product ion S^+. The secondary ion current I_s, arising from the two reactions, can be expressed as the sum of two independent contributions in the usual fashion (5):

$$I_s = f_1Q_1d[M]I_{P_1} + f_2Q_2d[M]I_{P_2}, \qquad [1]$$

where f_x is the collision efficiency, Q_x is the phenomenological cross section, d is the distance from the electron beam to the exit slit, [M] is the concentration of neutral molecules, and the I_x terms refer to measured ion currents. We have made the usual assumption that the collection efficiencies for all the ions are the same.

Equation [1] may be rearranged to give the following two equations:

$$\frac{I_s}{I_{P_1}} = f_1 Q_1 d[M] + f_2 Q_2 d[M]\frac{I_{P_2}}{I_{P_1}} \quad [2]$$

$$\frac{I_s}{I_{P_2}} = f_1 Q_1 d[M]\frac{I_{P_1}}{I_{P_2}} + f_2 Q_2 d[M]. \quad [3]$$

Equations [2] and [3] predict that for a secondary ion arising from two concurrent reactions a plot of I_s/I_{P_1} against I_{P_2}/I_{P_1} should lead to a straight line with slope proportional to f_2Q_2 and intercept proportional to f_1Q_1, while the similar plot of I_s/I_{P_2} against I_{P_1}/I_{P_2} should be a straight line with slope and intercept proportional to f_1Q_1 and f_2Q_2, respectively. With a knowledge of d and [M] the individual cross sections can be determined.

The ion current ratios in the above expressions are most easily varied by varying the electron energy at constant source pressure. The success of the method depends on two assumptions: first, that the relative collection efficiencies for the various ionic species do not vary with electron energy and, second, that the reaction cross sections are independent of electron energy. The evidence concerning these assumptions is very limited; however, the success of the method in the present investigation suggests that they are not a serious limitation.

EXPERIMENTAL

The experiments were performed using an Associated Electrical Industries MS-2 mass spectrometer. Rhenium filaments were used throughout the work and considerably more stable source characteristics were observed than have previously been obtained with this instrument using tungsten filaments (6). The ionizing current was 20 μa.

The electrical controls were altered to permit independent control of the repeller voltage from a potentiometer and battery. This voltage was read by a precision voltmeter. The distance from the repeller plate to the exit slit was calculated from the dimensions of the ion source, while the distance from the electron beam to the exit slit was estimated to be 0.12 cm from the variation of the appearance potential of argon with repeller voltage. This value is in agreement with estimates from source dimensions.

The sample inlet system supplied with the MS-2 was replaced by a system permitting measurement of the sample pressure with a Consolidated Electrodynamics micromanometer. For the sample pressures of 2–8 mm required for the ion–molecule reactions a series of expansions from known volumes was required to give pressures in the micromanometer range. For the latter part of the work an Atlas–Werke diaphragm-type micromanometer was added to the system. This manometer gives a direct pressure reading over the range 0.02 to 20 mm with an accuracy of ca. 1%. The molecular concentration in the ion source was related to the pressure in the inlet system by measuring the saturation ion current to the negatively biased repeller. Ion current – pressure measurements were carried out for argon, xenon, oxygen, ethylene, and cyclopropane at 70 v electron energy. Ionization cross sections in agreement with previous results (7, 8) were obtained. It was found that the source concentration was a linear function of the inlet pressure with the relation

$$[M]\ (\text{molecules/cc}) = 2.43\times10^{9}\times\text{pressure}\ (\mu).$$

In studying the ion–molecule reactions, the reactant ion of lowest appearance potential was determined by measurement of the appearance potential of the secondary ion using added krypton or xenon as standard. The reaction identification by this method was in essential agreement with the recent results of Pottie, Lorquet, and Hamill (9). The ratio of secondary ion current to primary ion current was then measured as a function of electron energy at constant source pressure. A decrease in this ratio with decrease in electron energy was taken to indicate the occurrence of a second reaction of higher appearance potential, while an increase in the ratio indicated a second ion of lower appearance potential was involved. The latter behavior was rarely encountered. It was necessary, of course, to select a range of electron energies such that the relative primary ion currents were changing markedly.

The choice of a second reactant ion was thus based on its appearance potential and the thermochemistry of the reaction involved. We have made the usual assumption that endothermic reactions will not occur. The electron energy was adjusted to give conditions, if possible, where only the two reactant ions of interest were of appreciable concentration in the ion source. The ion currents for the two primary ions and the secondary ion were then measured as a function of electron energy and the results treated in the manner indicated by equations [2] and [3]. The details will be discussed in the following section for each of the secondary ions studied.

The above procedure necessitated working at low electron energies and preliminary work at low repeller voltages did not lead to straight-line plots. This difficulty disappeared at high repeller voltages; consequently, no results were obtained at field strengths below 10 v/cm. For studies involving the $C_3H_6^+$ ion, where the lowest electron energies were used, field strengths of greater than 14 v/cm were necessary. This effect is not completely understood; however, it is probable that at low repeller voltages and low electron energies space charge effects in the electron beam are sufficient to change the ionic residence time and thus the apparent reaction cross sections. Similar space charge effects have been observed in the measurement of secondary ion appearance potentials at low repeller voltages (5, 10).

The cyclopropane was of 99.5% purity as supplied and was further purified by bulb-to-bulb distillation. Gas-chromatographic analysis showed no detectable impurities. The primary ion appearance potentials were determined by methods previously discussed (11).

RESULTS AND DISCUSSION

Primary Ion Appearance Potentials

During this work, we have measured the appearance potentials of the major primary ions in the mass spectrum of cyclopropane. The appearance potentials and the ionic heats of formation calculated therefrom are recorded in Table I. The limits of error

TABLE I

Primary ion appearance potentials

$C_2H_2^+$	CH_4	13.28±0.2	14.6	13.62		344	317

represent the average deviation of three or more determinations. In general, the appearance potentials are somewhat lower than those obtained by previous workers (9, 12, 13); however, the calculated ionic heats of formation are in reasonable agreement with the "best values" quoted by Field and Franklin (14).

The major discrepancy in Table I is for the C_3H^+ ion, where the present result and that of Pottie *et al.* (9) differ from the result of Field (12) by over 4 v. From the appearance potential Field calculated $\Delta H_f(C_3H^+) = 306$ kcal/mole and this was supported by later measurements (15) of $A(C_3H^+)$ in 1-butyne and 1,3-butadiene which led to $\Delta H_f(C_3H^+) =$ 282 to 328 kcal/mole. As shown in Table I, the present result is in agreement with this heat of formation if $H_2 + 3H$ are assumed as the neutral fragments. However, we believe the higher value of ca. 415 kcal/mole is to be preferred. As will be shown below, the ion–molecule reaction

$$C_3H^+ + C_3H_6 \rightarrow C_4H_2^+ + C_2H_5$$

has been found to occur. Using $\Delta H_f(C_4H_2^+) = 332$ kcal/mole, the lowest value reported for this ion (16), $\Delta H_f(C_2H_5) = 25$ kcal/mole (17), and $\Delta H_f(C_3H_6) = 12.7$ kcal/mole (18) this reaction is 32 kcal/mole endothermic if $\Delta H_f(C_3H^+) = 311$ kcal/mole. Since the reaction does occur, a considerably higher heat of formation must be in order. To obtain further evidence, the appearance potentials of C_3H^+ in propene and in propyne were determined. The results are summarized in Table II and again the data can be interpreted to give $\Delta H_f(C_3H^+)$ equal to approximately 300 or 400 kcal/mole. We are inclined to

accept the higher value on the basis of the ion–molecule reaction, although we cannot explain the discrepancy with the results of Field (12, 15).

Ion–Molecule Reactions

As has been reported (9), the secondary ions in the high-pressure mass spectrum of cyclopropane consist of a series of ions from $C_4H_2^+$ to $C_4H_8^+$ inclusive with the further ions $C_5H_5^+$, $C_5H_6^+$, $C_5H_7^+$, $C_6H_5^+$, $C_6H_7^+$, and $C_6H_9^+$. The ions in the C_5–C_6 region are of low intensity and could not be treated in the manner described in this paper. The present results are therefore limited to a discussion of the ions in the C_4 region. In calculating the heats of reactions given in the following, the lowest reported heats of formation for the ions in the C_4 region were used to avoid rejection of possible reactions on the basis of a false endothermicity. The heats of formation of the reactant ions were taken from Table I and for neutral species, from standard sources.

m/e = 56 ($C_4H_8^+$)

The only exothermic reactions resulting in this ion are the following:

$$C_3H_6^+ + C_3H_6 \rightarrow C_4H_8^+ + C_2H_4 \qquad \Delta H = -43^* \qquad [4]$$

$$C_3H_4^+ + C_3H_6 \rightarrow C_4H_8^+ + C_2H_2 \qquad \Delta H = -29 \qquad [5]$$

The appearance potential of $C_4H_8^+$ coincided with $A(C_3H_6^+)$, indicating the occurrence of reaction [4]. Figure 1 shows the ion current for $C_4H_8^+$ as a function of I_{42} and I_{40} plotted in the manner of equations [2] and [3]. The zero slope of Fig. 1*a* and the zero intercept of Fig. 1*b* indicate that reaction [5] is not occurring. The results were obtained at a field strength of 14.2 v/cm and a source concentration of 9.80×10^{12} molecules/cc. From the intercept and slope of Fig. 1, *a* and *b* (7.10×10^{-3} and 7.14×10^{-4}, respectively), $fQ = 6.1\times10^{-16}$ cm²/molecule for reaction [4]. This value is in reasonable agreement with the result 10.1×10^{-16} (9) at 12 v/cm and 70 v electron energy.

m/e = 55 ($C_4H_7^+$)

On a thermochemical basis the following reactions can result in the formation of $C_4H_7^+$ by ion–molecule reactions, which involve reasonable neutral fragments. (We have eliminated from consideration, throughout the following, those reactions which would involve fragments such as C_2H, CH_2, and CH, even though these may be exothermic in some cases.)

$$C_3H_6^+ + C_3H_6 \rightarrow C_4H_7^+ + C_2H_5 \qquad \Delta H = -36 \qquad [6]$$

$$C_3H_5^+ + C_3H_6 \rightarrow C_4H_7^+ + C_2H_4 \qquad \Delta H = -27 \qquad [7]$$

$$C_3H_4^+ + C_3H_6 \rightarrow C_4H_7^+ + C_2H_3 \qquad \Delta H = -23 \qquad [8]$$

$$C_3H_3^+ + C_3H_6 \rightarrow C_4H_7^+ + C_2H_2 \qquad \Delta H = -32 \qquad [9]$$

**Throughout this section the heats of reaction given are in the units kcal/mole.*

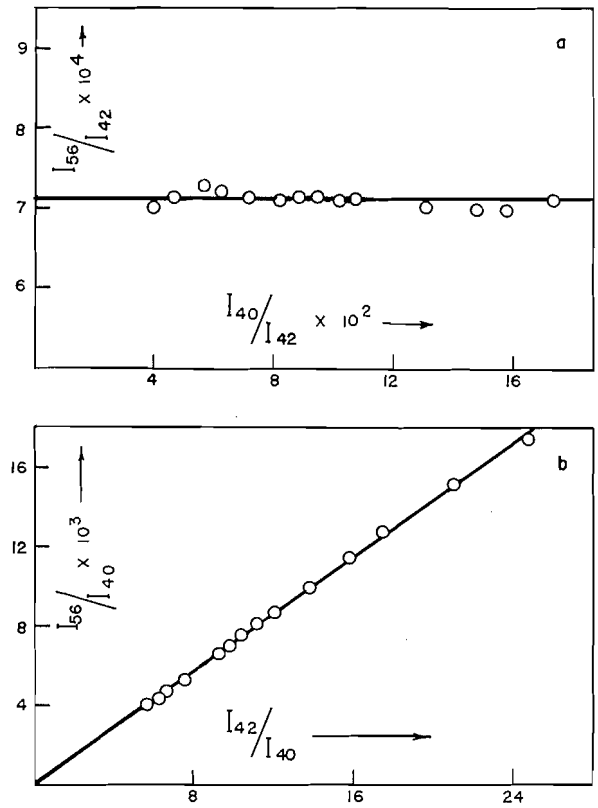

FIG. 1. Dependence of I_{56} ($C_4H_8^+$) on I_{42} ($C_3H_6^+$) and I_{40} ($C_3H_4^+$).

$A(C_4H_7^+)$ was intermediate between the appearance potential of $C_3H_6^+$ and $C_3H_5^+$ (or $C_3H_4^+$), suggesting that both reactions [6] and [7] might be occurring. Figure 2 shows the variation of I_{55} with I_{42} and I_{41} under conditions such that the source concentration of $C_3H_3^+$ was negligible. From the non-zero slopes and intercepts of both plots it is clear that two reactions are involved in the formation of $C_4H_7^+$. Since the ionization efficiency curves for $C_3H_5^+$ and $C_3H_4^+$ are essentially identical, it is impossible to separate the contribution from reactions [7] and [8]. In calculating cross sections, we have assumed that reaction [8] does not occur. Cross sections:

Reaction [6]: intercept (Fig. 2*a*) $= 3.00\times10^{-4}$; slope (Fig. 2*b*) $= 3.06\times10^{-4}$ $\Big\}$ $fQ = 2.5\times10^{-16}$ cm²/molecule

Reaction [7]: intercept (Fig. 2*b*) $= 1.02\times10^{-3}$; slope (Fig. 2*a*) $= 1.04\times10^{-3}$ $\Big\}$ $fQ = 9.0\times10^{-16}$ cm²/molecule

m/e = 54 ($C_4H_6^+$)

The exothermic reactions resulting in the ion $C_4H_6^+$ are the following:

$$C_3H_6^+ + C_3H_6 \rightarrow C_4H_6^+ + C_2H_6 \qquad \Delta H = -47 \qquad [10]$$
$$C_3H_4^+ + C_3H_6 \rightarrow C_4H_6^+ + C_2H_4 \qquad \Delta H = -42 \qquad [11]$$
$$C_3H_2^+ + C_3H_6 \rightarrow C_4H_6^+ + C_2H_2 \qquad \Delta H = -52 \qquad [12]$$
$$C_2H_3^+ + C_3H_6 \rightarrow C_4H_6^+ + CH_3 \qquad \Delta H = -30 \qquad [13]$$

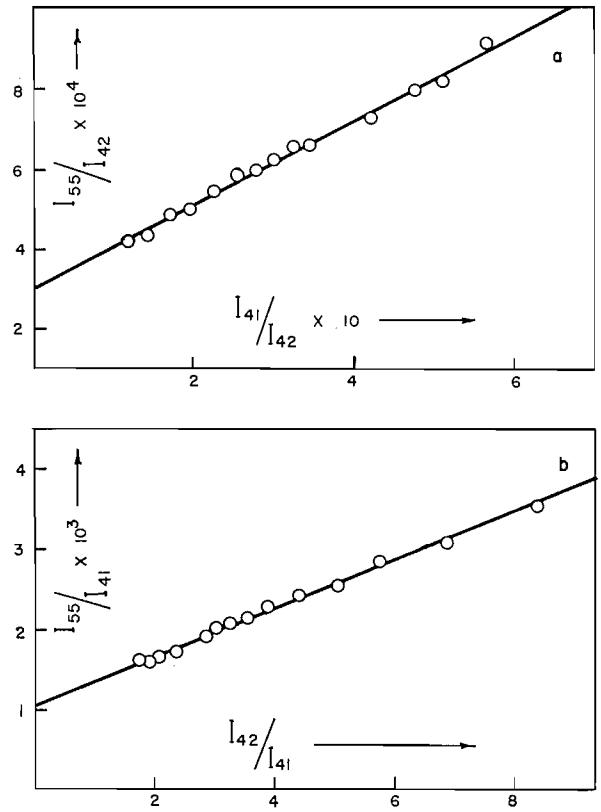

FIG. 2. Dependence of I_{55} ($C_4H_7^+$) on I_{42} ($C_3H_6^+$) and I_{41} ($C_3H_5^+$).

The appearance potential of $C_4H_6^+$ was in agreement with $A(C_3H_4^+)$, thus eliminating any significant contribution from reaction [10]. Figure 3 shows the variation of I_{54} with I_{40} and I_{27}. These results were obtained at 10 v/cm with a source concentration [M] = 11.45×10^{12} molecules/cc, under conditions where the ion $C_3H_2^+$ was of negligible concentration. The results clearly show that reaction [11] is occurring, but that reaction [13] is not. The intercept of Fig. 3*a* (1.10×10^{-3}) is in good agreement with the slope of Fig. 3*b* (1.12×10^{-3}) and leads to $fQ = 8.1\times10^{-16}$ cm^2/molecule for reaction [11]. It is possible that reaction [12] is occurring at higher electron energies. This could not be determined since it was not possible to obtain conditions such that I_{54}, I_{38}, and I_{40} could be measured simultaneously over a significant range.

m/e = 53 ($C_4H_5^+$)

The following reactions are energetically possible:

$$C_3H_5^+ + C_3H_6 \rightarrow C_4H_5^+ + C_2H_6 \qquad \Delta H = -8 \qquad [14]$$
$$C_3H_4^+ + C_3H_6 \rightarrow C_4H_5^+ + C_2H_5 \qquad \Delta H = -12 \qquad [15]$$
$$C_3H_3^+ + C_3H_6 \rightarrow C_4H_5^+ + C_2H_4 \qquad \Delta H = -23 \qquad [16]$$
$$C_3H_2^+ + C_3H_6 \rightarrow C_4H_5^+ + C_2H_3 \qquad \Delta H = -24 \qquad [17]$$
$$C_3H^+ + C_3H_6 \rightarrow C_4H_5^+ + C_2H_2 \qquad \Delta H = -119 \qquad [18]$$
$$C_2H_3^+ + C_3H_6 \rightarrow C_4H_5^+ + CH_4 \qquad \Delta H = -63 \qquad [19]$$
$$C_2H_2^+ + C_3H_6 \rightarrow C_4H_5^+ + CH_3 \qquad \Delta H = -63 \qquad [20]$$

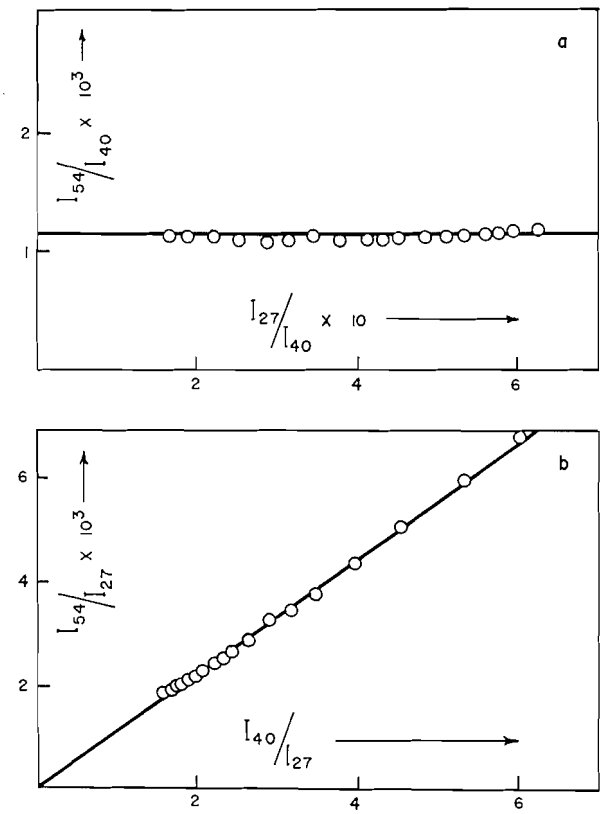

FIG. 3. Dependence of I_{54} ($C_4H_6^+$) on I_{40} ($C_3H_4^+$) and I_{27} ($C_2H_3^+$).

Within experimental error $A(C_4H_5^+)$ coincided with $A(C_3H_3^+)$, thus eliminating significant contributions from reactions [14], [15], [19], and [20]. However, the ratio I_{53}/I_{39} was found to decrease with decreasing electron energy near the appearance potential threshold, suggesting a second reaction of higher appearance potential. The only possible reactions are [17] and [18]; however, the source concentrations of $C_3H_2^+$ and C_3H^+ were negligible. A plot of I_{53} against I_{39} gave a result which was not found in other cases. Figure 4 shows the plot and, for comparison, a plot of I_{54} against I_{40} and a plot of I_{53} against I_{38}. The plot of I_{53} is a straight line, but does not pass through the origin as is found in other cases where a single reaction is occurring (I_{54}). On the other hand, no upward curvature is observed as in the plot of I_{51}, where a second reaction of higher appearance potential is involved (see below). The reasons for this are not clear. One possibility is that the reaction involves an excited $C_3H_3^+$ ion. From the slope of the line shown we estimate $fQ = 18.2 \times 10^{-16}$ cm^2/molecule at 10 v/cm; if an excited ion is involved this result may be in error, since the concentration of excited ions is not necessarily given by the measured ion current.

m/e = 52 ($C_4H_4^+$)

The following reactions are energetically possible:

$$C_3H_4^+ + C_3H_6 \rightarrow C_4H_4^+ + C_2H_6 \qquad \Delta H = -18 \qquad [21]$$
$$C_3H_2^+ + C_3H_6 \rightarrow C_4H_4^+ + C_2H_4 \qquad \Delta H = -38 \qquad [22]$$
$$C_3H^+ + C_3H_6 \rightarrow C_4H_4^+ + C_2H_3 \qquad \Delta H = -69 \qquad [23]$$
$$C_2H_2^+ + C_3H_6 \rightarrow C_4H_4^+ + CH_4 \qquad \Delta H = -74 \qquad [24]$$

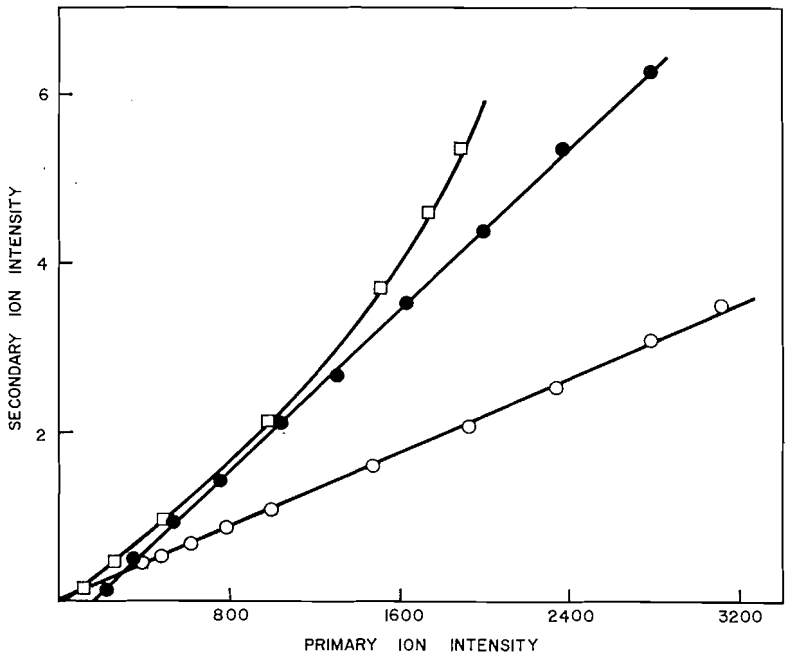

FIG. 4. Dependence of secondary ion intensity on primary ion intensity. □ $I_{51}/2$ as a function of I_{38}, ● I_{53} as a function of I_{39}, ○ I_{54} as a function of I_{40}.

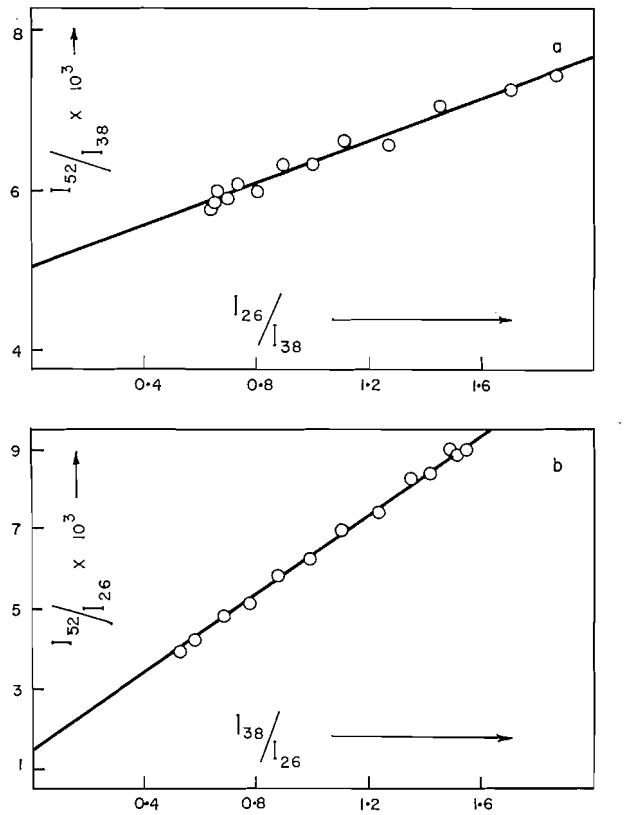

FIG. 5. Dependence of I_{52} ($C_4H_4^+$) on I_{38} ($C_3H_2^+$) and I_{26} ($C_2H_2^+$).

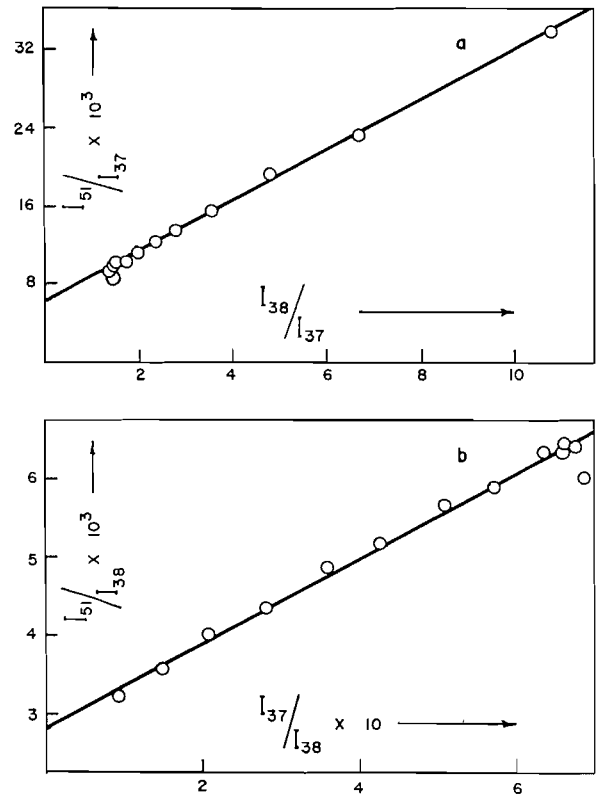

FIG. 6. Dependence of I_{51} ($C_4H_3^+$) on I_{38} ($C_3H_2^+$) and I_{37} (C_3H^+).

The appearance potential of $C_4H_4^+$ suggested the occurrence of reaction [22]; however, the ratio I_{52}/I_{38} increased with decreasing electron energy, suggesting the occurrence of a second reaction. Figure 5 shows the results obtained considering reactions [22] and [24]. The satisfactory straight lines obtained and the non-zero intercepts and slopes show that both reactions are occurring. Cross sections ([M] = 11.87×10^{12} molecules/cc, E = 10 v/cm):

Reaction [22]:	intercept (Fig. 5*a*) = 5.04×10^{-3} slope (Fig. 5*b*) = 4.93×10^{-3}	$fQ = 35.3\times10^{-16}$ cm²/molecule
Reaction [24]:	intercept (Fig. 5*b*) = 1.40×10^{-3} slope (Fig. 5*a*) = 1.30×10^{-3}	$fQ = 9.6\times10^{-16}$ cm²/molecule

m/e = 51 ($C_4H_3^+$)

The following reactions are thermochemically permitted:

$$C_3H_3^+ + C_3H_6 \rightarrow C_4H_3^+ + C_2H_6 \qquad \Delta H = -7 \qquad [25]$$

$$C_3H_2^+ + C_3H_6 \rightarrow C_4H_3^+ + C_2H_5 \qquad \Delta H = -16 \qquad [26]$$

$$C_3H^+ + C_3H_6 \rightarrow C_4H_3^+ + C_2H_4 \qquad \Delta H = -113 \qquad [27]$$

$$C_2H_3^+ + C_3H_6 \rightarrow C_4H_3^+ + CH_4 + H_2 \qquad \Delta H = -15 \qquad [28]$$

$$C_2H_2^+ + C_3H_6 \rightarrow C_4H_3^+ + \begin{Bmatrix} CH_3 + H_2 \\ CH_4 + H \end{Bmatrix} \qquad \Delta H = \begin{matrix} -15 \\ \text{or } -13 \end{matrix} \qquad [29]$$

The appearance potential of $C_4H_3^+$ and the shape of the ionization efficiency curve suggested reaction [26]; however, the variation of I_{51}/I_{38} with electron energy suggested reaction [27] was also occurring. Figure 6 shows the results obtained considering these two reactions. The straight lines obtained lead to the following cross sections at 10 v/cm and [M] = 10.82×10^{12} molecules/cc:

Reaction [26]:	slope (Fig. 6*a*) = 2.60×10^{-3} intercept (Fig. 6*b*) = 2.80×10^{-3}	$fQ = 21.0\times10^{-16}$ cm²/molecule
Reaction [27]:	slope (Fig. 6*b*) = 5.4×10^{-3} intercept (Fig. 6*a*) = 5.7×10^{-3}	$fQ = 43.1\times10^{-16}$ cm²/molecule

m/e = 50 ($C_4H_2^+$)

The exothermic reactions resulting in $C_4H_2^+$ are:

$$C_3H_2^+ + C_3H_6 \rightarrow C_4H_2^+ + C_2H_6 \qquad \Delta H = -32 \qquad [30]$$
$$C_3H^+ + C_3H_6 \rightarrow C_4H_2^+ + C_2H_5 \qquad \Delta H = -71 \qquad [31]$$
$$C_2H_2^+ + C_3H_6 \rightarrow C_4H_2^+ + CH_4 + H_2 \qquad \Delta H = -36 \qquad [32]$$

The appearance potential of $C_4H_2^+$ and the shape of the ionization efficiency curve indicated the occurrence of one or both of reactions [30] and [31]. Figure 7 shows the

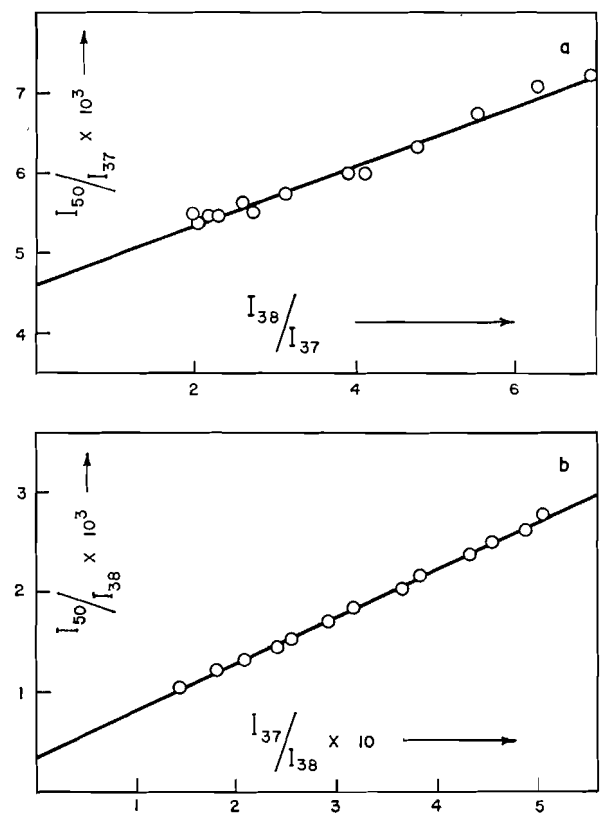

FIG. 7. Dependence of I_{50} ($C_4H_2^+$) on I_{38} ($C_3H_2^+$) and I_{37} (C_3H^+).

results obtained on the assumption that these two reactions are occurring. The straight lines obtained lead to the following cross sections at 10 v/cm and [M] = 15.35×10^{12} molecules/cc:

Reaction [30]:	slope (Fig. 7*a*) = 3.6×10^{-4} intercept (Fig. 7*b*) = 3.4×10^{-4}	$fQ = 2.0\times10^{-16}$ cm²/molecule
Reaction [31]:	slope (Fig. 7*b*) = 4.60×10^{-3} intercept (Fig. 7*a*) = 4.70×10^{-3}	$fQ = 25.4\times10^{-16}$ cm²/molecule

CONCLUSIONS

The present work has shown that four of the seven secondary ions studied in cyclopropane are formed by more than one ion–molecule reaction. A method of separating the contribution of the separate reactions has been developed. The ion–molecule reactions reported for other simple hydrocarbons may also be somewhat suspect due to the occurrence of concurrent ion–molecule reactions. These systems are presently being studied.

INFRARED SPECTRA OF CARBON MONOXIDE AND CARBON DIOXIDE ADSORBED ON CHROMIA–ALUMINA AND ON ALUMINA[1]

L. H. LITTLE[2] AND C. H. AMBERG
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received May 24, 1962

ABSTRACT

Infrared spectra of CO and CO_2 adsorbed on chromia–alumina and on alumina surfaces have been determined. A band near 2200 cm^{-1} formed by CO on both surfaces at room temperature was due to a weak, non-activated sorption, but also contained a contribution from a more strongly sorbed, activated species on the chromia–alumina. The assignment of this band was discussed in some detail. Bands in the region 1200–1800 cm^{-1} were considered in terms of surface CO_2^- species, although in certain instances the appearance of bands at 1750 and 1430 cm^{-1} may have indicated carbonate ion formation.

Following an infrared study of carbon monoxide and carbon dioxide adsorbed on zinc oxide (1) investigations have now been extended to chromia–alumina and alumina catalysts. Previous studies of CO and CO_2 adsorption using the infrared method with both metals and metal oxides include the well-known work of Eischens and Pliskin (2, 3), correlations of vibration frequencies and number of valence electrons of CO surface species by Gardner and Petrucci (4, 5), and work on titania surfaces by Yates (6).

EXPERIMENTAL

The chromia–alumina catalyst was prepared by mixing chromium hydroxide and aluminum hydroxide gels which had been precipitated separately from solutions of the metal nitrates by ammonia. The mixed gel was then dried at 110° C for 24 hours and calcined at 500° C in oxygen, resulting in a composition of 41% by weight of Cr_2O_3. The powder was compressed at 40 tons/in^2 into a thin plate suitable for the infrared studies. The plate, which measured 1.3 cm × 2.8 cm × 0.1 mm, weighed about 100 mg and had a surface area of 108 m^2/g. It was mounted in a cell of 10-cm path length, similar to that described earlier (7). Cells of 5-mm path length were also used occasionally. Evacuation at 300–400° C and 10^{-4}–10^{-5} mm was carried out for 1–2 hours before gases were adsorbed. Spectra were then recorded on a Perkin–Elmer 21 spectrophotometer fitted with a sodium chloride prism. The percentage transmission through the sample was 10–15% at 1800 cm^{-1}. The alumina catalyst was prepared in a manner analogous to that described for the mixed gels.

RESULTS

Figure 1*a* shows the spectrum of the chromia–alumina sample, with a weak band appearing at 1370 cm^{-1} after heating for 1 hour in oxygen at 320° C and outgassing at 10^{-5} mm for 1 hour. Scattering by the sample of infrared radiation at higher frequencies precluded any study above 2500 cm^{-1}.

When the sample was allowed to stand in the cell at room temperature for 24 hours a weak band appeared at 1580 cm^{-1} (Fig. 1*b*). Then after further evacuation at 350° C a broad intense band appeared at 1530 cm^{-1} with shoulders at 1420 cm^{-1} and at about 1350 cm^{-1} (Fig. 1*c*). It was only after first heating the sample in oxygen at 300–350° C and then evacuating that the absorption in the 1300–1600 cm^{-1} region was decreased to the level shown in Fig. 1*a*. This oxygen treatment led to an intensification of the 1370 cm^{-1} band.

[1]*Issued as N.R.C. No. 6932.*
[2]*N.R.C. Postdoctorate Fellow 1958–1960. Present address: Department of Chemistry, University of Western Australia, Nedlands, Western Australia.*

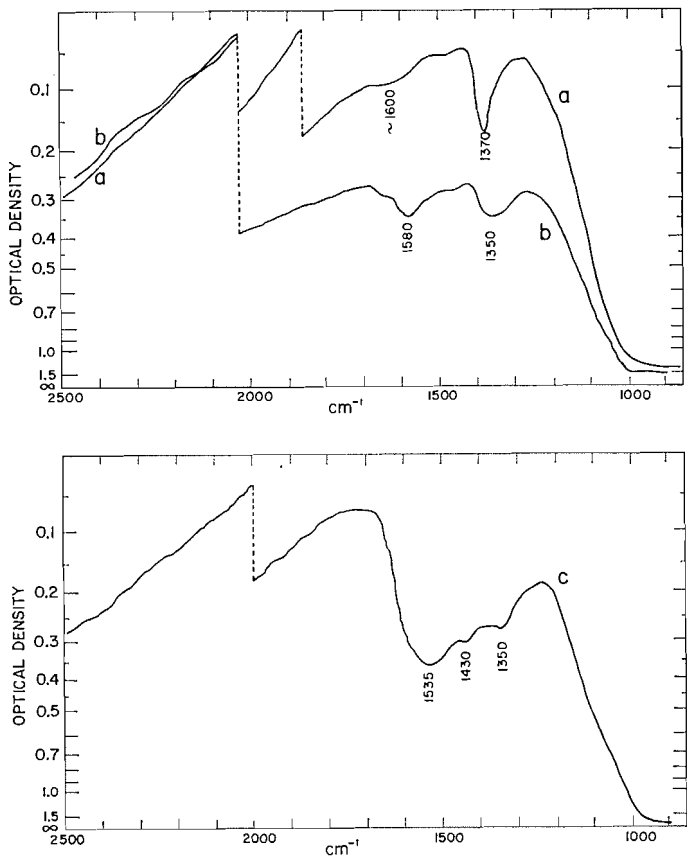

FIG. 1. (*a*) Chromia–alumina heated in 25 cm O_2 at 320° for 1 hour, outgassed to 10^{-5} mm at 320° for 1.5 hours.
(*b*) After 24 hours, standing *in vacuo* at 20°, following (*a*).
(*c*) Further outgassing at 320° for 3 hours, following (*b*).

After the sample had been standing in a cell for 1–2 days, the broad band reappeared at 1580 cm^{-1}. Depending on whether or not the sample had been heated with oxygen before evacuation, the spectrum resembled either that in Fig. 1*a* or Fig. 1*c*. This behavior was characteristic of the chromia–alumina sample.

A strong broad band which grew in intensity appeared at 1627 cm^{-1} upon exposure to the atmosphere of a sample which had been heated in oxygen and outgassed and which, as before, showed only the 1370 cm^{-1} band in its background spectrum. The 1627 cm^{-1} band was readily removed by evacuation at 300° C, without oxygen treatment, and was apparently due to adsorbed water.

When carbon monoxide at 3 cm pressure was admitted to the sample a sharp band immediately appeared at 2200 cm^{-1}. In addition to this, broad absorption occurred between 1500 and 1600 cm^{-1}. On standing for 8 hours the intensity of the 2200 cm^{-1} band remained unaltered while the 1500–1600 cm^{-1} absorption increased and a weak band appeared at 1230 cm^{-1} (Fig. 2*b*).

For the freshly prepared chromia–alumina sample the intensity of the 1370 cm^{-1} band was increased by adsorption of carbon monoxide. After several adsorption and desorption

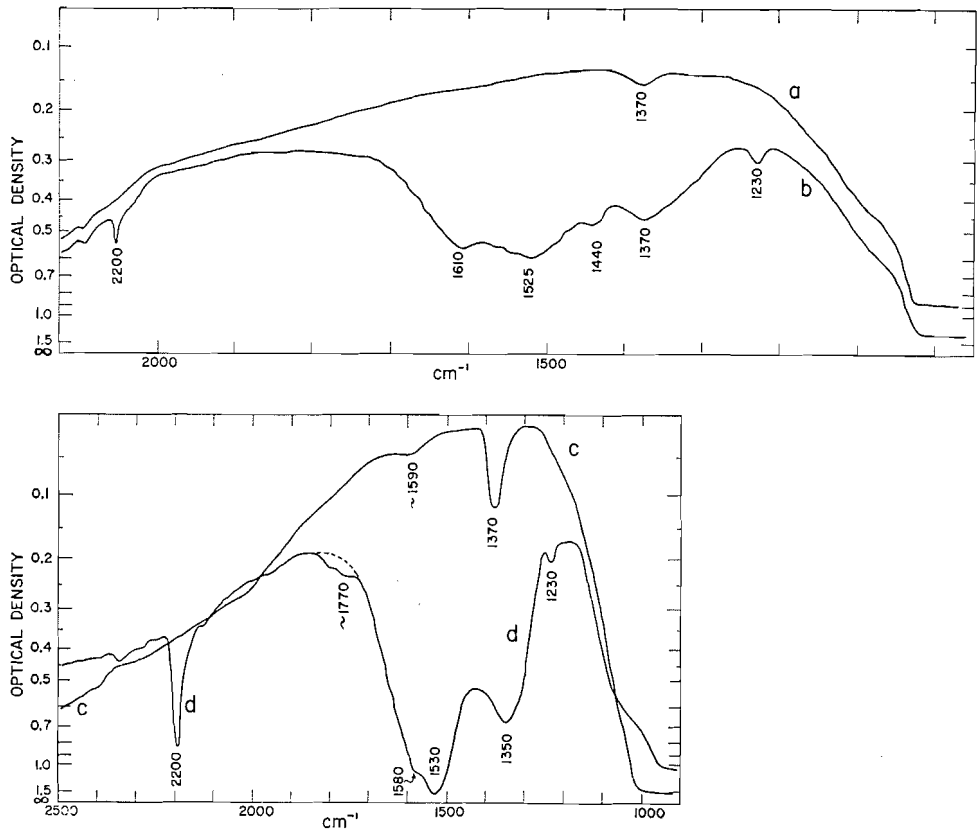

FIG. 2. (*a*) Chromia–alumina heated in 70 cm O_2 at 350° for 0.5 hour, outgassed at 350° for 1 hour.
(*b*) Two hours after admitting 3.8 cm CO at 20°, following (*a*).
(*c*) Sample heated in 30 cm O_2 at 320° for 3 hours, outgassed to 10^{-4} mm at 320° for 1 hour.
(*d*) Heated in 3.5 cm CO at 300° for 20 minutes, following (*c*).

experiments the band intensity eventually increased to the constant value shown in Fig. 3*c*. The intensity was then unaffected by further adsorption of carbon monoxide.

Evacuation at 20° C for 10 minutes entirely removed the species responsible for the 2200 cm^{-1} band, but the other bands were unaltered. The addition of dry oxygen did not change the spectrum. The absorption in the 1500 cm^{-1} region comprised bands at 1490–1500 and 1590–1610 cm^{-1}. The relative intensities of these bands varied slightly in different experiments on the same sample.

After heating the sample in oxygen at 320° C for 3 hours and outgassing at 320° C for 1 hour, the spectrum was the same as that before the addition of carbon monoxide. Further addition of CO to the sample in this condition at 20° C led to an identical sequence of spectra. However, when the chromia–alumina specimen was heated at 300° C for 20 minutes in the presence of 3.5 cm of carbon monoxide, a very great increase in the intensity of the 2200, 1500–1600, and 1230 cm^{-1} bands occurred (Fig. 2*d*). On further standing at 20° C the 2200 cm^{-1} band was unchanged while those at lower frequencies increased. Evacuation at 20° C for 10–15 minutes did not affect the low-frequency bands but greatly decreased the intensity of the 2200 cm^{-1} band, although it was not entirely removed by this treatment. Previously this band had been entirely removed by pumping at 20° C

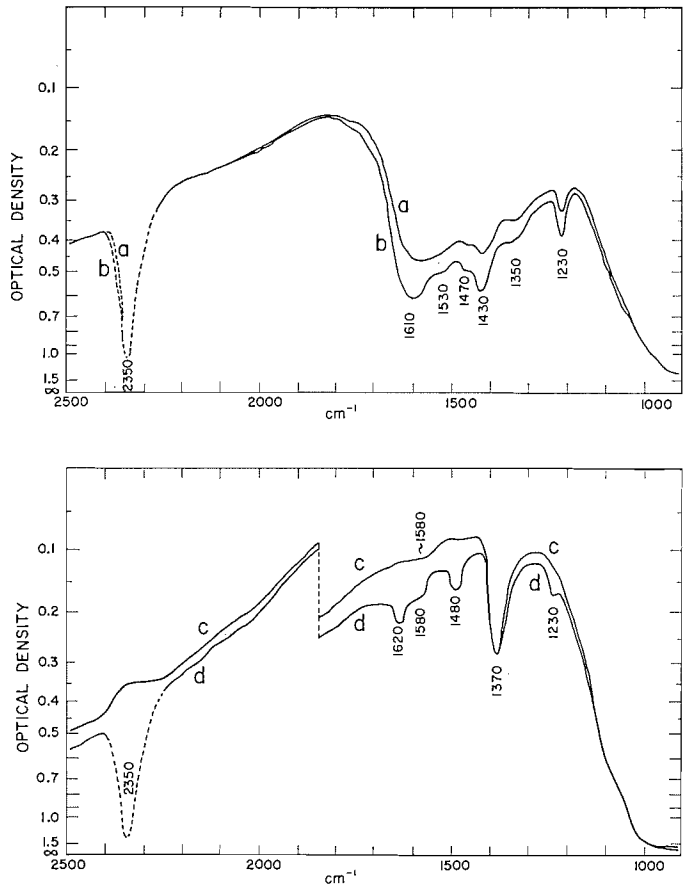

FIG. 3. (*a*) One-half hour after admitting 4.5 cm CO_2 at 20°, following Fig. 1*c*.
(*b*) After standing further 10 hours, following (*a*).
(*c*) After heating in 20 cm O_2 at 320° for 3.5 hours, then outgassing at 320° to 10^{-5} mm for 2 hours, following (*b*).
(*d*) One-half hour after admitting 5.0 cm CO_2 at 20°, following (*c*).

after adsorption had been carried out at the same temperature. The 2200 cm^{-1} band remained after the addition of 10 cm of oxygen at 20° C.

Carbon dioxide (4.5 cm) was admitted to the chromia–alumina sample and within 30 minutes produced absorption bands at 2350, 1620, 1580, 1480, and 1230 cm^{-1} (Fig. 3*d*). When carbon dioxide was adsorbed on a chromia–alumina sample which had been outgassed at 300° C but had not been heated with oxygen before this, a strong band appeared at 1430 cm^{-1} in addition to those above (Fig. 3*b*). This may have arisen from an intensification of an existing band at 1430 cm^{-1} in the background spectrum (Fig. 1*c*) of the sample prepared under these conditions or from the formation of a new surface species. In another experiment, when no band existed at 1430 cm^{-1} in the background spectrum, a weak band appeared at this frequency after CO_2 adsorption.

Bands appeared at 2200 cm^{-1} and weakly at 1750 and 1570 cm^{-1} when carbon monoxide was admitted to a pure alumina sample at 20° C. The latter bands were superimposed on broad bands in the alumina background at 1550 and 1470 cm^{-1}. There was a great intensity

decrease of the 2200 cm^{-1} band when the carbon monoxide was heated with the alumina, unlike the results observed for the chromia–alumina samples. New bands emerged at 1620, 1590, 1380, and 1230 cm^{-1} after the heating. The appearance of the 2200 cm^{-1} band on pure alumina is contrary to the experience of Yates (6), who was not able to observe it.

Carbon dioxide gave bands at 2350, 1750, 1635, 1500, and 1235 cm^{-1} on alumina. The band at 1750 cm^{-1} for carbon dioxide was stronger, judged on the basis of pressure and time of standing, than the band at that frequency for carbon monoxide.

DISCUSSION

Absorption Bands of Adsorbed CO in the Region 2100–2400 cm^{-1}

The adsorption of carbon monoxide on chromia–alumina to give the sharp band at 2200 cm^{-1} was extremely rapid at 20° C and the activation energy for the process must be very small. This band was unaltered in frequency and intensity on standing for 30 hours. The species was readily removed from the surface by evacuation at 20° C for 10–20 minutes; adsorption is thus very weak. Mass spectrometric analysis showed the gas removed from the surface to be entirely carbon monoxide, a result similar to that found for zinc oxide (1).

The proximity of this band to that of gaseous CO, as well as the available chemical evidence, would indicate a weak chemisorption process or adsorption by dipolar forces in which the essential carbon monoxide structure has been retained. Dipole attraction was suggested earlier in the analogous case for zinc oxide (1). However, the rather large displacement of 57 cm^{-1} to higher frequency remains to be rationalized. The shift is in a direction opposite to that normally produced by polar environments: in general it is found that the stretching frequencies of polar groups are displaced to lower values when material is transferred from vapor to liquid (8). This red shift usually increases with increasing polarity of the solvent.

In an endeavor to determine the influence of solvent environment on the carbon monoxide fundamental vibration frequency, the spectra of saturated solutions of the gas in carbon tetrachloride and in chloroform were recorded. The solubility of CO in these solvents is so low that only very weak bands were obtained, resulting in poor accuracy in the frequency values. Nevertheless the values obtained, 2137 ± 5 and 2144 ± 5 cm^{-1} respectively, showed quite clearly that large displacements to high frequency were not caused by solvent effects under homogeneous conditions. It should, however, be remembered that shifts in either direction may be produced by solute–solvent interaction. Buckingham (9) has analyzed the situation for diatomic molecules in an axially directed force field and has cited instances where a blue shift was observed for systems under high pressure. It is conceivable that similar conditions may hold for surface–adsorbate interactions.

Eischens and Pliskin (2) were the first to observe a high-frequency band for adsorbed CO (on nickel oxide, 2193 cm^{-1}), and ascribed it to the asymmetric C—O stretching vibration of a group such as M—O=C=O. The reasons for rejecting this explanation in favor of dipole attraction (1) were reinforced by the present findings in that again no band assignable to the corresponding symmetrical vibration could be detected. If this vibration had produced a band of extremely low intensity then one would have expected the M—O bond to be weak and the O=C=O group to behave essentially as carbon dioxide; in the latter compound this second band is forbidden in the infrared spectrum for symmetry reasons. However, the gas recovered was again CO rather than CO_2, which makes the covalent structure appear unlikely.

An alternative explanation for the spectra of CO adsorbed on metals and their salts in terms of a partially or completely ionized positive surface species has been advanced by Gardner and Petrucci (4). Terenin and Roev (10, 11) had earlier proposed both positive and negative ions as the surface species responsible for both increased and decreased frequencies in the adsorption of NO on transition metals and their salts. The electrons of highest energy in CO in the ground state occupy an antibonding orbital (12), so that ionization of one electron would strengthen the carbon–oxygen bonding, with an increase in the force constant and contraction of the internuclear distance. From the spectroscopic parameters for CO and CO^+ given by Herzberg (13), the vibrational frequencies are 2143 and 2184 cm^{-1}, the internuclear distances 1.128 and 1.115 Å respectively. While this would adequately account for bands at frequencies between the gaseous CO and CO^+ species (1, 4), shifts to frequencies higher than the latter need further explanation.

Apart from the generally possible blue shifts due to solute–solvent interaction mentioned earlier, two specific effects might contribute to a shift of this kind. A decrease in the anharmonicity of the vibration of the CO^+ ion in the adsorbed state could ideally cause shifts of up to 30 cm^{-1} ($\omega_e x_e$ = 15.2 cm^{-1} (13)). Bayliss and Rees some years ago proposed a theory to describe the interaction of a solvent cage with the solute which made use of the concepts of decreased anharmonicity (14). However, it was recently found by Ewing and Pimentel (15) that $\omega_e x_e$ decreases by only 2 cm^{-1} in the gas–solid transition of neutral CO, which makes this explanation unlikely, at least if one wishes to retain the solvent–solute analogy.

As another possibility it is suggested that a contribution from the second antibonding electron to the adsorbent–adsorbate bond could serve to shorten the C—O distance in the CO^+ ion and thus raise the frequency.* A difficulty that remains with all these explanations, and one that has also been noted by Terenin (11) for NO^+ adsorption, is the magnitude of the effect compared with the observed weakness of the adsorptive bond.

Further objections to postulating CO^+ as the surface species responsible for the high-frequency band may be raised, because this would necessitate the donation of an electron to the adsorbent. In the earlier work on zinc oxide (1) no intensity change in the broad electronic infrared absorption band was detectable, nor did Kubokawa (16) find an effect of preadsorbed oxygen on room temperature CO adsorption, oxygen being known in this case to act as an electron trap. Similarly Vilesov and Terenin (17) could not observe an appreciable change in the photoelectric work function for this system. The only way of invalidating this objection would be to assume that the electronic changes in the adsorbent lie below the limit of detectability. An indication that this might be so was given by Heiland *et al.* (18) for a reverse reaction—the trapping of conduction electrons by oxygen adsorption—in that the ratio of electrons trapped to oxygen atoms adsorbed was of the order of $1:10^5$. Unfortunately no infrared electronic absorption has as yet been assigned in chromia–alumina so that we are unable to use it as a criterion in the present case.

A considerable portion of the carbon monoxide responsible for the 2200 cm^{-1} band on chromia–alumina had a measurable activation energy of adsorption, since the intensity of this band increased 5-fold when the sample was heated for 20 minutes to 300° C in contact with 3.5 cm of carbon monoxide. This carbon monoxide was probably adsorbed on the chromia of the sample, since the 2200 cm^{-1} band did not increase when an alumina sample was heated in contact with the gas.

The formation of the 2198 cm^{-1} band for CO adsorbed on zinc oxide (1) also occurred through an activated process, since this frequency was approached only slowly on standing

**Dr. Gardner has calculated a CO^{++} vibration frequency of 2205 cm^{-1}; he has kindly put the data of ref. 5 at our disposal.*

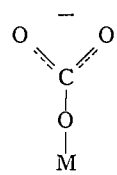
at 25° C, whereas the 2174 cm^{-1} band appeared rapidly. Moreover the 2198 cm^{-1} band was produced occasionally when carbon monoxide adsorption was studied at 155° C on zinc oxide. The activated process by which the 2200 cm^{-1} band was formed may be surface diffusion of the CO molecule to other adsorption sites. It is unlikely to be diffusion into the metal oxide lattice: the band was readily eliminated by evacuation at 25° C and this would not be consistent with removal of carbon monoxide from the bulk.

Absorption Bands of Adsorbed CO and CO_2 in the Region 1200–1800 cm^{-1}

In both the present work and in the work on zinc oxide (1), carbon dioxide gave a band in the region 1610–1630 cm^{-1}, at higher frequency than did carbon monoxide on the corresponding oxide (1580–1610 cm^{-1}). Of the carbon–oxygen species considered by Gatehouse, Livingstone, and Nyholm (19) only the acid carbonates absorbed above 1600 cm^{-1}. This vibration was the asymmetric stretching mode of the $-C\begin{matrix}=O\\ \diagdown\\ \diagup\\ -O\end{matrix}$ group. The symmetric mode appeared at about 1300–1400 cm^{-1}. It is possible that the band above 1600 cm^{-1} for carbon dioxide and the band at 1580–1600 cm^{-1} for carbon monoxide may be due to a bicarbonate species formed by reaction with surface hydroxyl groups. The hydroxyl stretching region cannot be studied for the chromia–alumina samples because of scattering, but no change was observed for zinc oxide catalyst in this region (1).

The low-frequency band of the bicarbonate species may then be one of the bands at 1430 or 1370 cm^{-1}. However, a band persists at 1370 cm^{-1} even after evacuation at 300° C during which all other bands were removed. In view of this it is possible that the adsorption merely intensified the band already existing at 1370 cm^{-1} in the spectrum of the surface.

Eischens and Pliskin (2) have considered the spectrum of bicarbonate with absorption bands at 1630 and 1390 cm^{-1}, due respectively to the asymmetric and symmetric stretching modes of $-C\begin{matrix}=O\\ \diagdown\\ \diagup\\ -O\end{matrix}-$, and then assigned bands at these frequencies in the spectrum of carbon dioxide on nickel oxide to the following structure:



(i)

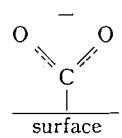
It would appear that the asymmetric $-C\begin{matrix}=O\\ \diagdown\\ \diagup\\ -O\end{matrix}-$ stretching mode of complex metal carbonates such as this would absorb at a rather lower frequency. Thus Gatehouse *et al.* (19) show the asymmetric stretching modes of

$$(\text{Co-en-}CO_3)Cl^* \text{ and } Na_2\left[Cu\begin{matrix}O-CO_2\\ \diagdown\\ \diagup\\ O-CO_2\end{matrix}\right]\cdot 3H_2O$$

to be 1577 and 1529 cm^{-1} respectively while the corresponding symmetric modes absorb at 1280 and 1326 cm^{-1}.

**en = ethylenediamine.*

Taylor and Amberg (1) considered the assignment of bands at 1560 and 1330 cm^{-1} to the asymmetric and symmetric modes of a surface carboxylate group, without specifying the surface atom to which it is bonded. The results of Gatehouse *et al.* (19) would at any rate make a distinction between structures (i) and (ii) uncertain.



(ii)

In the work on chromia–alumina both carbon monoxide and carbon dioxide gave a band at 1230 cm^{-1} whereas for zinc oxide (1) only the latter gas gave a band at this frequency. The intensity of this band for carbon dioxide on chromia–alumina was greater than that for carbon monoxide for similar gas pressures and times of standing. Its assignment is uncertain but it may be the symmetric stretching mode of a structure such as (i) or (ii) displaced to a frequency below normal (19) or to the stretching of a carbon–oxygen single bond raised from the normal range (19) (1000–1100 cm^{-1}).

A weak band, which may be due to the structure  , similar to organic carbonates, appeared at 1750 cm^{-1} when carbon dioxide was heated over chromia–alumina and when carbon dioxide was adsorbed on thick alumina samples. The 1230 cm^{-1} band cannot be the carbon–oxygen single bond stretching mode of this structure since it occurs on samples when no 1750 cm^{-1} band appears.

The band which appears at 1430 cm^{-1} when carbon dioxide and in some cases carbon monoxide was adsorbed on the chromia–alumina may be due to the formation of carbonate ion, since this is the frequency of the asymmetric carbon–oxygen stretching mode of this species.

Absorption Bands of Chromia–Alumina and Alumina

The 1370 cm^{-1} band which appears in the spectrum of chromia–alumina seems independent of other bands in the spectrum. Thus it cannot be due to a complex carbonate species on the surface, since some other accompanying band would be expected, while this band is the only one remaining when the sample is heated with oxygen and outgassed. Carbonaceous impurities might have been introduced into the gel catalyst during its preparation by inclusion of atmospheric carbon dioxide.

The 1370 cm^{-1} band may be due to the carbonate ion vibration displaced to lower frequency from its normal value of 1430 cm^{-1}. It would be expected that carbon dioxide would form this band more readily than carbon monoxide since less oxygen is required, although when adsorption was carried out at 20° C carbon monoxide in certain cases appeared to give intensification of this band, whereas carbon dioxide did not. If the species responsible for the band is a carbonate ion the process may be an activated one. The band was intensified by heating carbon monoxide with both alumina and chromia–alumina samples.

Consideration must be given to the view that the band at 1370 cm^{-1} is due to nitrate impurity incorporated during the sample preparation. It seems unlikely, however, that this explanation is correct, since the intensity of the band fluctuated during the course

of the experiments on one sample and the final band intensity was larger than that for the freshly prepared sample.

The frequencies and intensities of bands in the 1300–1550 cm^{-1} region of the chromia–alumina spectrum have been shown to vary considerably during heating and evacuation, both with and without oxygen, and when no carbon monoxide or carbon dioxide was present. At least some of the bands in this region may be connected with the defect structure of the oxide rather than with the stretching vibrations of definite surface species. A chromia–alumina sample having initially only one band, at 1370 cm^{-1}, in its spectrum, after standing in an evacuated cell for 24 hours had a weak band at 1580 cm^{-1} in addition to the original band, which was decreased somewhat in intensity. Evacuation at 300° C gave a complex spectrum with broad intense bands at 1535, 1430, and 1350 cm^{-1}. When the sample was heated with oxygen and then evacuated only the 1370 cm^{-1} band remained. These changes seem incompatible with the presence of definite surface species. Nevertheless, in spite of some doubt expressed at the time of publication, a similar set of bands on zinc oxide (1) has now been quite definitely shown to arise from carbonaceous impurities (20). A number of differences remain however, in particular with respect to the band at 1370 cm^{-1}, which does not occur on zinc oxide, so that we do not feel justified in drawing the same conclusions by analogy. The 1580 cm^{-1} band cannot be due to the deformation mode of adsorbed water, since on exposing the sample completely to the atmosphere a very intense band appeared at 1627 cm^{-1}. There is no reason why evacuation at 320° C should not completely remove the 1580 cm^{-1} band if it were due to adsorbed water, especially since the band at 1627 cm^{-1} disappeared completely after this treatment.

Finally the possibility that certain bands produced during adsorption of gases such as carbon monoxide, carbon dioxide, or oxygen may be due to the introduction of valency or other defects by the adsorption process cannot be completely disregarded. This is most unlikely in the cases discussed in the previous sections, where the appearance or disappearance of well-characterized bands can be directly correlated with the adsorption or desorption of CO or CO_2. For example, our evidence leaves little doubt that the band at 2200 cm^{-1} arose from an adsorbed CO species; moreover the observed frequency was close enough to the fundamental vibrational frequency of the gaseous molecule to reinforce this view. Defects are equally unlikely to have been the source of spectra which are similar for chromia–alumina and zinc oxide, since these solids differ widely in structure. Thus only where assignments have so far been uncertain, as in some of the cases cited in this section, could defects be considered an alternative to impurities or adsorbates in trying to explain the observed bands.

ACKNOWLEDGMENTS

The authors express their gratitude to Dr. Y. Amenomiya for supplying the catalyst samples and to Dr. H. J. Bernstein for a helpful discussion. Experiments were completed in the Department of Mining and Metallurgy, University of Alberta, Edmonton, and L. H. Little is grateful for spectroscopic facilities provided there.

CARBON-13 KINETIC ISOTOPE EFFECTS IN BIMOLECULAR REACTIONS

J. B. STOTHERS[1] AND A. N. BOURNS
Department of Chemistry, McMaster University, Hamilton, Ontario

Received July 9, 1962

ABSTRACT

Carbon-13 kinetic isotope effects have been measured for the bimolecular reaction of 1-phenyl-1-bromoethane (I) and benzyl bromide (II) with alkoxide ion in alcohol solution. Compound I gave an effect, k^{12}/k^{13}, of 1.0032 ± 0.0005 for reaction with ethoxide ion in ethanol, while II gave $k^{12}/k^{13} = 1.0531 \pm 0.0004$ for reaction with methoxide ion in methanol. These surprisingly different effects are tentatively interpreted in terms of a model for the transition state having varying degrees of ionic character.

INTRODUCTION

Although nucleophilic substitution at a saturated carbon atom is one of the most commonly encountered organic reactions and as such has long been the subject of detailed study, many points concerning the nature of the reaction remain obscure. One of the newer tools available for the study of reaction mechanisms, that of kinetic isotope effects, would appear to provide an additional means of extending our understanding of this reaction, since isotopic fractionation in rate processes is extremely sensitive to bonding changes in the rate-determining stage. A priori, one might have expected that the isotope effect associated with the carbon atom at the seat of displacement could serve to distinguish between the two extremes of S_N1 and S_N2 behavior, since, intuitively, a larger effect might be predicted for a process involving simple bond rupture than for one in which bond rupture and formation are synchronous. This approach has been investigated by Bender and co-workers (1–3), who, contrary to this prediction, observed a much larger effect in the S_N2 reaction of various nucleophiles with methyl iodode-C^{14} ($k^{12}/k^{14} = 1.09$ to 1.14) than in the S_N1 hydrolysis of 2-chloro-2-methylpropane-2-C^{14} ($k^{12}/k^{14} = 1.03$). Melander (4) has recently shown that whereas the Bigeleisen method (5) for the theoretical evaluation of isotope effects leads to the conclusion that a change in mechanism should have very little influence on the magnitude of the effect, a treatment (4) based on an actual calculation of the moments of inertia leads to results which are consistent with Bender's experimental findings. It should be emphasized, however, that there is a danger in making a direct comparison of effects in S_N1 and S_N2 processes involving different substrates and one should not discount the possibility that other factors, such as the nature of the leaving group and the reaction medium, may have an important influence on the observed effect (2).

In a previous communication (6) from this laboratory a very small carbon-13 isotope effect, $k^{12}/k^{13} = 1.0065$, was reported for the S_N1 alcoholysis of 1-bromo-1-phenylethane and was interpreted in terms of a model for the transition state in which the bonding to the isotopic carbon is strengthened by conjugation of the electron-deficient center with the ring. Since this compound is known to undergo mainly bimolecular reaction when treated with an ethanolic solution of ethoxide ion in concentrations of 1.5 M or higher (7, 8), it appeared to be particularly well suited for an investigation of the relative magnitude of isotope effects in S_N1 and S_N2 reactions of the same substrate. Other practical considerations governing the choice of this halide for such a study and the reason for using a compound of natural isotopic abundance have been previously discussed (6).

[1]*Present address: Department of Chemistry, University of Western Ontario, London, Ontario.*

The isotope effect study of the S_N2 reaction of 1-bromo-1-phenylethane with ethoxide ion is described in the present paper and the results compared with those obtained previously (6) for the alcoholysis reaction. On the basis of these results, it appeared desirable to measure the isotope effect in a bimolecular reaction in which the bond-breaking and bond-formation processes are more nearly balanced than in the 1-phenylethyl system. Accordingly, a study has been made of the isotope effect in the reaction of benzyl bromide with methoxide ion in methanol. This work also is now reported.

EXPERIMENTAL

In general, the experimental procedures employed for these studies were similar to those described previously (6). Some minor modifications were introduced for the present system and these are indicated below.

Kinetic Studies

The reaction rates were determined by following the rate of formation of bromide ion in a series of sealed tubes containing aliquots of the reaction mixture. A modified Volhard method was used for this analysis (9) and the quenching mixture contained sufficient nitric acid to neutralize the unreacted base present. The rate constant, k_2, for a particular run was obtained by a least-squares analysis of a plot of time vs. $\log a(b-x)/b(a-x)$.

Isotope Effect Experiments

For each determination of the carbon-13 isotope effect a sample of alkyl bromide was allowed to react with alkoxide ion to a small known extent of reaction (ca. 5%), the reaction was stopped, and the ether product separated from unreacted starting material by fractional distillation. Samples of the product and original bromide were degraded by oxidation and decarboxylation to yield carbon dioxide derived exclusively from the carbon at which displacement occurred. The 1-phenylethyl derivatives were degraded by a two-step oxidation procedure, which has been previously described (6). In the first stage the compounds were treated with potassium permanganate in aqueous pyridine solution to give a mixture of benzoic and benzoylformic acids. This acid mixture, after isolation, was then further oxidized with hydrogen peroxide, whereby the benzoylformic acid was quantitatively converted to benzoic acid. With the benzyl derivatives, only the permanganate oxidation step is required. It was found that better yields (ca. 85%) are obtained for benzyl bromide if it is converted to the methyl ether before oxidation. The remaining steps in the isotope effect determinations were carried out as before.

RESULTS

The results of the kinetic studies are presented in Table I for the reactions of 1-bromo-1-phenylethane with ethoxide ion in ethanol and benzyl bromide with methoxide ion in

TABLE I

methanol. The isotope effect values found for each of these reactions are shown in Tables II and III, respectively. Each determination refers to an individual partial reaction of alkyl bromide followed by degradation of the ether product and a sample of the original halide to carbon dioxide. The rate constant ratios, k^{12}/k^{13}, were calculated from the isotopic ratios and the extent of reaction (10).

DISCUSSION

The carbon-13 isotope effect of 0.3% found for the reaction of 1-bromo-1-phenylethane with ethoxide ion is slightly, but significantly, smaller than the 0.6% previously reported for the alcoholysis of this substrate. This result is the reverse of that reported by Bender (1, 2), who found a considerably higher effect for the S_N2 reaction of methyl iodide than for the hydrolysis of *t*-butyl chloride. As was pointed out in the Introduction, however, when quite different substrates are being compared, factors other than reaction molecularity may be important in determining the relative magnitude of the observed effects.

Since not only the difference in the isotope effects found for the S_N1 and S_N2 reactions of 1-bromo-1-phenylethane, but also the magnitude of the effects themselves, is small, it is rather fruitless to attempt any detailed theoretical interpretation. It is of interest to

note, however, that the temperature-independent factor of the Bigeleisen equation (5), evaluated by the method of Bigeleisen and Wolfsberg (11) using the mass-fragment model (12), has a value very slightly higher for the reaction with ethoxide ion than for the ethanolysis. Consequently, it would appear to be the temperature-dependent (free energy) factor which is mainly responsible for the lower effect in the S_N2 process.

In contrast to the very small isotope effect found for the reaction of alkoxide ion with 1-bromo-1-phenylethane, the reaction of benzyl bromide gives an effect of 5.3%, which is comparable to that reported by Bender (1) for the reaction of hydroxide ion with methyl iodide. Yet both the 1-bromo-1-phenylethane and the benzyl bromide reactions have been found to give good second-order kinetics under the conditions of the present study and they have always been considered to be typical bimolecular or S_N2 processes. This large difference in isotope effect cannot be attributed to the temperature-independent component, which is small and not significantly different in the two reactions. It, therefore, must have its origin in the free energy factor, which implies that there are important differences in the transition states of the two bimolecular reactions, differences which are not disclosed by conventional methods of investigating reaction mechanisms such as stereochemical or ordinary kinetic studies.

Now it is well known on the basis of kinetic studies that the 1-phenylethyl group tends to promote reaction by the unimolecular mechanism (13). For example, reaction with methanolic sodium methoxide has an important first-order component even at very high methoxide ion concentrations, and good second-order kinetics are found in the reaction with sodium ethoxide in ethanol only at an alkoxide ion concentration in excess of 1.5 *M*. It seems reasonable to conclude, then, that the transition state for the bimolecular reaction of this substrate has considerable carbonium ion character. On the other hand, there is strong evidence that in the benzyl system bond formation and bond rupture have occurred to about the same extent at the transition-state configuration (14–17). The present results indicate that this difference in the nature of the transition state is manifested in the observed kinetic isotope effects for the carbon undergoing substitution.

In the 1-phenylethyl system, the carbon atom at the seat of displacement is electron deficient in the transition state and there is conjugative interaction between its fairly well developed vacant p orbital and the π orbitals of the benzene ring. The result will be a contribution to the isotope effect by a free energy factor which is not greatly different from that associated with a unimolecular process. In the benzyl system, however, the charge on the carbon atom undergoing substitution would not be expected to change greatly in going from the initial to the transition state and there will be little conjugative interaction with the adjacent benzene ring. It is suggested that it is this difference in the extent of internal conjugation, and hence of carbon–carbon bond strengthening, in the transition state which is largely responsible for the marked difference in the isotope effect in the two reactions.

Although this interpretation is purely speculative and highly tentative, there is no doubt that kinetic isotope effect measurements provide a very sensitive means of obtaining information about the nature of the transition state. Clearly, more experimental work is required to adequately evaluate the significance of the results so far reported and studies to this end are now underway.

REACTIONS OF METHYL RADICALS WITH NITRIC OXIDE

D. E. HOARE
Chemistry Department, Queen's College, University of St. Andrews, Dundee, Scotland

Received April 24, 1962

ABSTRACT

Methyl radicals have been produced by the photolysis of acetone at 200° C and their reaction with nitric oxide has been studied. The reaction $CH_3 + NO + M \rightarrow CH_3NO + M$ is shown to be third order with a rate constant of 8.8×10^{-31} $cm^6 molecule^{-2} sec^{-1}$, with acetone as M. It is further shown that the nitrosomethane formed reacts with either methyl radicals or nitric oxide. The probability of reactions such as $CH_3CO + NO \rightarrow CH_3CO.NO$ taking place is shown.

INTRODUCTION

The reaction of methyl radicals with nitric oxide has been studied by a number of investigators (3, 5, 6, 9, 10, 11, 17). Usually the reaction has been followed by estimating either the rate of disappearance of nitric oxide or the rate of removal of methyl radicals. The present investigation followed the reaction by both methods and it was therefore possible to discover the presence of other complicating reactions of both methyl radicals and nitric oxide.

EXPERIMENTAL

The apparatus was the same as that used in previous experiments (1). A beam of light, effectively limited to the wavelengths 3130 and 3020 Å, filled a silica reaction cell of 2.8-cm diameter and 20-cm length. The absorbed light intensities were 1.0×10^{13} quanta $cm^{-3} sec^{-1}$ and 1.0×10^{12} quanta $cm^{-3} sec^{-1}$ with 200 mm and 10 mm, respectively, of acetone present. Small amounts of nitric oxide were added to keep its pressure constant during the reaction. A magnetically operated stirrer kept the gases mixed during the reaction, but it was found necessary to allow time for each successive addition to mix, by cutting off the light with a screen immediately before each addition. Quantum yields were calculated by comparison with the yield of carbon monoxide from the photolysis of pure acetone, which is assumed to have a quantum yield of unity at 200° C.

The acetone and oxygen were prepared as described previously (1). Spectroscopically pure nitric oxide was prepared by Dr. P. Warsop from sodium nitrate, potassium iodide, and sulphuric acid. It was redistilled in the apparatus to give a blue liquid (with no traces of green color).

Carbon monoxide and methane were estimated in the usual manner (2) by the use of Le Roy – Ward stills and a mixture of copper and copper oxide heated to 200° C. Nitric oxide was estimated by condensation with ethane at −215° C followed by combustion at 350° C over copper and copper oxide. Small amounts of ethane which were present were thus converted to carbon dioxide and measured.

RESULTS

The photolysis of acetone at 200° C is said to occur by the following mechanism:

$$CH_3COCH_3 + h\nu \rightarrow CH_3CO + CH_3 \quad [1]$$

$$CH_3CO + M \rightarrow CH_3 + CO + M. \quad [2]$$

The methyl radicals may then react with acetone according to reaction [3]:

$$CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_3COCH_2, \quad [3]$$

or react with nitric oxide according to reaction [4]:

$$CH_3 + NO + M \rightarrow CH_3NO + M. \quad [4]$$

Only in the presence of low concentrations of nitric oxide will the reaction

$$2CH_3 \rightarrow C_2H_6 \quad [5]$$

be of importance.

Table I shows the quantum yields of methane and carbon monoxide in typical experiments and relates them to the nitric oxide which has been consumed. The yields of

carbon monoxide were reduced by the addition of nitric oxide (Table I, experiments 2 and 3), and the most plausible explanation is that acetyl radicals may react with nitric oxide, e.g.,

$$CH_3CO + NO \rightarrow CH_3CO.NO, \quad [6]$$

rather than decompose according to reaction [2]. The increase in the yield of carbon monoxide when inert carbon dioxide was added (thus favoring reaction [2]) supports such a hypothesis (Table I, experiments 5 and 7). Below 200 mm pressure, acetone appears more effective than carbon dioxide as third body in reaction [2] (experiments 3, 4, and 6).

The amounts of ethane obtained were, as expected, very small. One would expect, therefore, that reactions [3] and [4] would account for the majority of the methyl radicals produced. Hence $\phi_{CH_4}+\phi_{NO}+2\phi_{C_2H_6}$ should be equal to 2. Table I shows clearly that this is not so and that methyl radicals must have another reaction, probably with the nitrosomethane which has been formed. Since the quantity of nitrosomethane formed would not have varied much from one experiment to another (the total absorbed intensity was kept approximately constant) this hypothesis was best tested by further experiments in which the nitric oxide was deliberately allowed to become very low (and not constant during an experiment). Under such extreme conditions the number of methyl radicals which did not form methane or ethane was very much greater than the number of nitric oxide molecules which were consumed. Even allowing for a possible reaction of methyl radicals with acetonyl (CH_3COCH_2) radicals an average of between 2 and 3 methyl radicals were consumed per nitric oxide molecule. This is illustrated in Table II(*a*).

At the other extreme of conditions, pressures of nitric oxide were used sufficiently high to cause reaction [4] to predominate so that no methane or ethane was experimentally detectable. Under such conditions the rate of consumption of nitric oxide exceeded the rate of formation of methyl radicals and the yield of carbon monoxide was much decreased by the favoring of a reaction such as reaction [6]. Under these conditions a gas which was not condensed at −215° C (presumably nitrogen) was formed in small yields. It was unchanged in volume by passage over heated copper and copper oxide at 350° C. The results are shown in Table II(*b*).

DISCUSSION

The possibility of the reaction between nitric oxide and methyl radicals being third order has been realized for some years. Experimental attempts to prove the kinetic dependence of the reaction upon a third body have often failed because experimentalists failed to realize the specificity of third bodies in their efficiency in performing the role of M. Thus Miller and Steacie (3) added up to 10 cm of nitrogen to 4.5 mm Hg of mercury dimethyl without causing any great increase in the rate of reaction [4]. Nitrogen would be expected to be ineffective compared with mercury dimethyl as M in such an energy transfer reaction. Preliminary results showed that nitric oxide reacted five times as rapidly with methyl radicals as does oxygen when acetone is the third body (4). Christie (5) found reaction [4] to be 100 times as fast as the corresponding reaction of methyl radicals with oxygen when methyl iodide was the third body. However, she neglected to allow for reactions between nitrosomethane and methyl radicals which could modify her conclusions.

The rate constant for reaction [4] in the present work may be derived by comparing it with reaction [3]. Using the experimental values presented in Table I (where the nitric oxide pressure was too low for it to react further with nitrosomethane) and correcting for reaction [6], one finds

$$k_4/k_3 = \frac{\phi_{NO}+\phi_{CO}-1}{\phi_{CH_4}} \times \frac{[\text{acetone}]}{[NO][M]}.$$

The plot of $\{(\phi_{NO}+\phi_{CO}-1)/\phi_{CH_4}\} \times \{[\text{acetone}]/[NO]\}$ $(=R)$ against [M] clearly shows the kinetic dependence of reaction [4] upon [M]. This is illustrated in Fig. 1. The small effect of adding carbon dioxide emphasizes the relative inefficiency of this gas in reaction [4]. Christie (5) found it to be similarly much less efficient than methyl iodide in this same reaction.

The evidence is strong that reaction [4] is third order and indeed it is difficult to account for a steric factor of 10^{-4}, which is obtained if a second-order mechanism is postulated (6). One would expect it to be third order by comparison with the corresponding reaction of methyl radicals with oxygen (7, 8). However, Christie (5) finds evidence of a transition from third to second order at total pressures approaching 100 mm Hg. No evidence of this was found in the present experiments and the discrepancy may be due to her neglect of other possible reactions of methyl radicals.

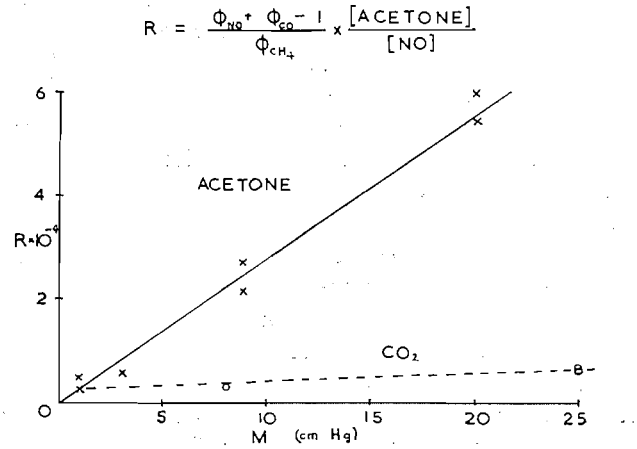

FIG. 1. Dependence of the reaction between CH_3 and NO upon a third body (M = acetone or CO_2).

The values obtained for the absolute rate constant of reaction [4] depend upon the accuracy with which the rate constant of the competing reaction is known. Reaction [3] has been much studied and is usually compared with reaction [5]. If a value of 3.2×10^{-12} $cm^{3/2}molecule^{-1/2}sec^{-1/2}$ is taken for $k_3/k_5^{1/2}$ at 200° C (2), the present work leads to a value for $k_4/k_5^{1/2}$ of 4.3×10^{-26} $cm^{9/2}molecule^{-3/2}sec^{-1/2}$ at 200° C. If reaction [5] is assumed to have a rate constant of 4.2×10^{-10} $cm^3molecule^{-1}sec^{-1}$ at 200° C then $k_4 = 8.8\times10^{-31}$ $cm^6molecule^{-2}sec^{-1}$ at 200° C.

Values calculated from the results of other workers are given in Table III in the same units.

Table III illustrates differing values for the rate constant of reaction [4], many of which depend upon mechanisms or uncertain values of rate constants. Some correlation may be made between the more recent determinations if a negative activation energy (ca. 4 kcal/g-mole) is assumed. This would correspond to a positive activation energy for the decomposition of the activated CH_3NO complex first formed by the combination of methyl radicals and nitric oxide. There is some evidence that at higher pressures of a suitable third body, reaction [4] becomes effectively second order (5, 17).

The nitrosomethane which is formed by reaction [4] has been investigated by Gowenlock and Trotman (12). They have shown that it may dimerize or rearrange to give formaldoxime. The latter reaction involves a high activation energy (ca. 40 kcal/mole) whereas the former is probably a wall reaction. In the present work it has been shown that up to 3 methyl radicals are removed by 1 molecule of nitric oxide without the formation of methane or ethane. The obvious solution is the formation of the molecule $N(CH_3)_2.OCH_3$ (trimethyl hydroxylamine) by addition of methyl radicals across the double bond of nitrosomethane. Such reactions are known to occur with more complex free radicals in solution (14). Similarly Batt and Gowenlock (13) have suggested that the reaction between nitric oxide and nitrosomethane, which they have detected (in agreement with the present work and that of Christie (5)), occurs by addition of 2 molecules of nitric oxide across the double bond of nitrosomethane. The compound formed decomposes with the evolution of some nitrogen, as has been observed in the present work.

It has been suggested earlier that nitric oxide reacts with acetyl radicals, thus reducing the yield of carbon monoxide formed by reaction [2]. Such a phenomena has been previously reported by Anderson and Rollefson (15). The ready reaction of nitric oxide with free radicals favors the plausibility of such a reaction. Reaction [6] appears to occur by a second-order mechanism and is appreciable at lower pressures of nitric oxide than the corresponding reaction of acetyl radicals with oxygen (16). This is to be expected by analogy of the reaction of methyl radicals with nitric oxide and with oxygen (4). It is interesting to note that the similar reaction of nitric oxide with *t*-butyl radicals also occurs readily (9).

Caldwell and Hoare (18) have shown that in the photolysis of acetone at 150 to 200° C oxygen has no effect on the rate of decomposition of acetone, i.e. reaction of oxygen with the triplet state of acetone is not important. This is probably due to the virtual absence of triplet state acetone at those temperatures and therefore one can assume that nitric oxide similarly has no effect on the rate of decomposition of acetone.

EXTRACTIVES FROM POPULUS TREMULOÏDES HEARTWOOD

THE STRUCTURE AND SYNTHESIS OF TREMULONE[1]

R. A. ABRAMOVITCH AND R. G. MICETICH
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

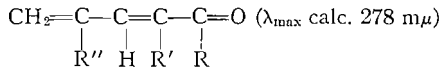
Received May 28, 1962

ABSTRACT

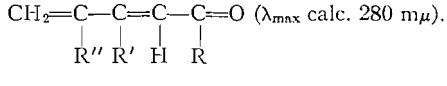
Tremulone, a dienone isolated from *Populus tremuloïdes* heartwood, has been shown to be stigmasta-3,5-diene-7-one. This has been confirmed by a partial synthesis from β-sitosterol. The possibility that tremulone might be an artifact arising from the isolation procedure is discussed.

During a systematic analysis of the nature of the extractives from the heartwood of *Populus tremulöides* (aspen poplar or quaking aspen) (1) a ketone, m.p. 111°, $[\alpha]_D^{22}$ −273°, was isolated in very small yield (0.001% based on dry wood), and was named *tremulone*. Though this was a very minor component, its spectral properties were interesting enough that it was decided to determine its structure. The minor constituents of plant extractives have not, as a rule, been subjected to systematic investigation and it was thought possible that the determination of their structures in this case might, among other things, throw added light onto the biogenetic pathways available in such a plant.

Tremulone is a pleasant smelling compound (even when pure). Microanalytical values were not reproducible on samples obtained after repeated recrystallizations and chromatographic separations on alumina. An analytically pure specimen (melting point unchanged, $[\alpha]_D^{22}$ −288°) was finally obtained by 100-tube countercurrent distribution. Analytical values were consistent with either $C_{29}H_{46}O$ or $C_{30}H_{48}O$; the molecular weight determination (Rast) agreed better with the C_{30} formulation. The infrared spectrum indicated the presence of an α,β-unsaturated ketone grouping (1660 and 1600 cm^{-1}) and what at first was interpreted to be a $\rangle C{=}CH_2$ terminal methylene grouping (883 and 1630 cm^{-1}—the latter somewhat low for this assignment). Periodate–permanganate oxidation of a sample of tremulone before countercurrent purification gave a small amount of formaldehyde (detected by chromotropic acid). The presence of the keto group was confirmed by the ready formation of a 2,4-dinitrophenylhydrazone and an oxime. The ultraviolet absorption spectrum (λ_{max} 278 mμ; ε 20,000) indicated a conjugated dienone and the spectrum of the 2,4-dinitrophenylhydrazone (λ_{max} 375 mμ) was consistent with this formulation (2). Taking into account the suggested presence of a terminal methylene group and applying Woodward's rules (3) two chromophores are possible:



(λ_{max} calc. 278 mμ)



(λ_{max} calc. 280 mμ).

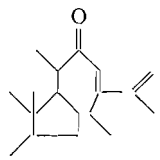
Catalytic hydrogenation of tremulone over palladium–charcoal led to the uptake of 2 molar equivalents of hydrogen and gave tetrahydrotremulone ($\nu_{C=O}$ 1705 cm^{-1}). The

[1]*Presented at the 45th Annual Conference of the Chemical Institute of Canada in Edmonton on May 29th, 1962.*

ketone group is, therefore, either in a side chain or in a six- or higher-membered ring, and the compound is tetracyclic. Again, analytical figures for the saturated ketone and its 2,4-dinitrophenylhydrazone did not lead to an unequivocal molecular formula, being consistent with either $C_{29}H_{50}O$ or $C_{30}H_{52}O$ for tetrahydrotremulone. Sodium borohydride reduction of tremulone did not yield a crystalline alcohol, but the mixture (of probably epimeric alcohols) had an ultraviolet absorption spectrum (λ_{max} 230, 237 mμ, λ_{infl} 245 mμ) indicating the presence of a conjugated diene (4). On the other hand, no band at 883 cm^{-1} was present in the infrared.

Tetrahydrotremulone was subjected to the Huang-Minlon modification of the Wolff–Kishner reduction and gave a hydrocarbon, $C_{29}H_{52}$ or $C_{30}H_{54}$, m.p. 85°, $[\alpha]_D^{22}$ +25.2°. These constants are in good agreement with those of stigmastane (5, p. 1442S), an authentic specimen of which was therefore prepared from β-sitosterol via β-stigmastanyl acetate and stigmastan-3-one. Both synthetic and natural samples exhibited the same infrared and n.m.r. spectra, their melting points were undepressed on admixture, and their retention times on vapor phase chromatography on two columns of different polarities were identical. On the other hand, the X-ray diffraction patterns of the two hydrocarbons were appreciably different. This, however, may be due to polymorphism; it has been shown (6) that in sterols that exhibit polymorphism the X-ray diffraction pattern depends on the crystal form. That the stigmastane ring system was indeed present was confirmed by a very accurate determination of the molecular weights of tremulone, tetrahydrotremulone, and the hydrocarbon by mass spectrometry (determination kindly performed by Mr. A. Burlingame of M.I.T.). The mass numbers found were 410, 414, and 400, respectively, supporting the molecular formulae $C_{29}H_{46}O$ and $C_{29}H_{50}O$ for the unsaturated ketone and its tetrahydro derivative.

The question of the location of the carbonyl group was considered next. If the presence of a terminal methylene group in tremulone is accepted then the keto group must be present in the side chain as in (A). This is biogenetically unlikely. Also, a study of the n.m.r. spectrum of tremulone indicated the absence of a terminal methylene group. Thus,



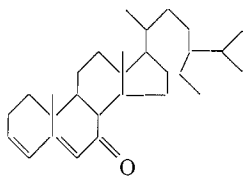
(A)

two signals at 3.9 τ and 4.46 τ in the intensity ratio of 2:1 were observed. These are characteristic of olefinic protons (7). On the other hand, the two-proton absorption was a singlet whereas a multiplet would have been expected for a terminal methylene group (8). The periodate–permanganate oxidation of tremulone was, therefore, reinvestigated but using this time a sample which had been purified by countercurrent distribution. No formaldehyde was detected. This explains the absence of a band at 883 cm^{-1} in the infrared spectrum of the sodium borohydride reduction product of tremulone. Tetrahydrotremulone underwent the Baeyer–Villiger oxidation to give a lactone, $C_{29}H_{50}O_2$, which could be hydrolyzed, but recyclized to the same lactone immediately on treatment with cold dilute mineral acid. The keto group is, therefore, present in a six-membered ring. To determine its position, use was made of the molecular rotations difference method (9). Here difficulties were initially encountered in that, using the values given in Klyne's article (9), the molecular rotation of tetrahydrotremulone was only consistent with its

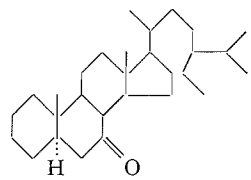
being a 5-β-7-ketone, implying, therefore, an inversion of configuration at C_5 during the Wolff–Kishner reduction. A search of the literature and calculations made on known 7-ketosteroids reveal that the correct value of M_D for a 5-α-7-one is $-233°$ (10) and not $+223°$ (9). Using this value and $M_D = +102°$ for stigmastane gives $M_D = -131°$ for stigmastan-7-one, in good agreement with the value of $M_D = -126°$ found for tetrahydrotremulone.

The band at 883 cm^{-1} in the infrared spectrum of tremulone itself could be due to a C—H out-of-plane deformation in a system —CH$\overset{cis}{=}$CH—C=CH—C=O (which would also account for the observed ultraviolet and n.m.r. spectrum). Indeed, cholesta-3,5-diene-7-one exhibited a band at 883 cm^{-1} in the infrared and its spectrum was almost superimposable onto that of tremulone. Its n.m.r. spectrum also had two bands at 3.9 τ and 4.5 τ whose relative intensities were 2:1. The band at 3.9 τ is clearly due to the cyclic —CH=CH— protons (11) whereas that at 4.5 τ is due to the —C=CH—C=O proton. There is, therefore, no doubt that tremulone is actually stigmasta-3,5-diene-7-one (I). This compound had already been reported by Marker and Rohrmann (12), who prepared it from β-sitosterol via sitosteryl chloride and 7-ketositosteryl chloride. The only constant given for this compound was its melting point (106–107°). An authentic sample of stigmasta-3,5-diene-7-one has now been synthesized from β-sitosteryl acetate. Chromic acid oxidation gave 7-ketositosteryl acetate, which, on heating with p-toluenesulphonic acid in toluene, gave the required dienone in an overall yield of 10%. It was identical in all respects with tremulone. On selective catalytic reduction it gave stigmastan-7-one (II), identical with tetrahydrotremulone.

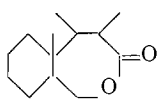
At an earlier stage of the investigation, tetrahydrotremulone was reduced with sodium borohydride in boiling ethanol. A single, crystalline alcohol was obtained in good yield and is formulated as stigmastan-7α-ol on the basis of its molecular rotation (+52.8°). Dauben, Blanz, Jiu, and Micheli (13) have studied the methanolic sodium borohydride reduction of cholestan-7-one and obtained a mixture containing the α- and β-epimeric alcohols in the ratio of 73:27. The predominant formation of the axial isomer was attributed to the steric bulk of the solvated borohydride ion, which would hinder its approach from the α-side. In the present case, no β-isomer was isolated; this is undoubtedly due to the even greater bulk of the solvated borohydride ion in ethanol. Catalytic hydrogenation of (II) over platinum oxide gave a mixture of alcohols as a wax; the epimers could not be separated by fractional crystallization or by column chromatography.



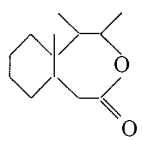
(I)



(II)



(III)



(IV)

Two structures (III or IV) are possible for the seven-membered-ring lactone obtained from the Baeyer–Villiger oxidation of (II). It was expected that (IV) was the more likely structure in view of the known greater ease of migration of tertiary than secondary carbon atoms in this reaction (14). Thus, 7-ketocholestan-3β-ol is oxidized to the lactone arising from migration of C_8 (15). The n.m.r. spectrum supported the assignment of structure (IV) to the lactone, a broad, not clearly resolved, single proton peak being observed at 5.93 τ corresponding to the —CO—O—CH— proton.

Finally, the question arises as to whether tremulone is actually present as such in the heartwood, or, in view of the small quantities in which it is found, whether it is an artifact arising during the isolation process. It is not possible to answer this at the moment. In the case of cholesta-3,5-diene-7-one, which has been isolated from the non-saponifiable fraction of swine spleen, sclerotic aortas, and wool fat, 7-ketocholesterol is considered to be the precursor, the dienone being an artifact (5, p. 2465S). It is known that passing oxygen through aqueous colloidal suspensions of sterols containing the 5-ene-3-ol system gives rise to the 3,7-diol and the 3-ol-7-one (16). Such an oxidation could have taken place in this case during the saponification step, for instance. On the other hand, Mitsui (17) isolated from sugar cane wax a compound in 0.1 to 0.2% yield which he called β-saccharostenone, and to which he assigned the molecular formula $C_{29}H_{48}O$. The melting points of β-saccharostenone (106°), its oxime (163–165°), and its 2,4-dinitrophenylhydrazone (211°) are very close to those found here for tremulone and its derivatives and it is felt that the two steroids are probably the same, though a direct comparison was not possible. It would seem somewhat less likely that up to 0.2% yield of an artifact should be formed under Mitsui's isolation conditions so that it is probable that β-saccharostenone occurs as such in sugar cane wax. It undoubtedly arises in the plant from β-sitosterol, which Mitsui was also able to isolate from the same source.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured on potassium bromide disks of the compounds using a Perkin–Elmer model 21 instrument using sodium chloride optics. Only the main peaks are reported. Ultraviolet absorption spectra were measured on a Cary Model 14 recording spectrophotometer. The *Populus tremuloïdes* heartwood used in this study came from trees grown in the Prince Albert, Saskatchewan, area and was kindly supplied by Nisbet Plywood Co. Ltd., Prince Albert.

Isolation and Purification of Tremulone

The crude ketone mixture (5 g) obtained by column chromatography of the non-saponifiable fraction of the extractives from *Populus tremuloïdes* heartwood (1) was rechromatographed on a column of alumina (Type H; 200 g). Elution with light petroleum (b.p. 40–60°) gave a hydrocarbon (0.765 g). Elution with light petroleum (b.p. 63–65°) – ether (9:1) gave tremulone (1.483 g). Light petroleum (b.p. 63–65°) – ether (4:1) brought down a brown-red oil (1.280 g) whose infrared spectrum indicated it to be probably an unsaturated ketone. It was not investigated further.

Tremulone was recrystallized from acetone and then from methanol to give pleasant smelling, slightly yellow crystals, m.p. 111°, $[\alpha]_D^{22}$ −273° (chloroform). Repeated recrystallizations did not raise the melting point or alter the rotation. It was finally purified by countercurrent distribution in a 100-tube automatic machine (20 ml each phase), the solvents used being 85% methanol and light petroleum (b.p. 63–65°). After 100 transfers the contents of tubes 81–88 were combined and evaporated, and the ketone recrystallized from aqueous acetone to give pure tremulone, m.p. 111°, $[\alpha]_D^{22}$ −288° (chloroform), λ_{max} 278 mμ, ϵ 20,000 (in ethanol). (Found: C, 84.81, 84.83, 84.64; H, 11.30, 11.34, 11.91; mol. wt., 428 (Rast), 410 (mass spec.). Calc. for $C_{29}H_{46}O$: C, 84.81; H, 11.29; mol. wt., 411.) Infrared spectrum: 1660, 1630, 1603, 1390, 1375, 883 cm^{-1}. The *2,4-dinitrophenylhydrazone* separated from ethanol, and was purified by chromatography on a very short column of alumina (Woelm, neutral; Brockman activity III) and recrystallization from chloroform–ethanol. It had m.p. 211°, λ_{max} 395 mμ (in chloroform). (Found: C, 70.96, 71.45; H, 8.37, 8.31; N, 9.14. Calc. for $C_{35}H_{50}O_4N_4$: C, 71.15; H, 8.53; N, 9.48.) The *oxime* was recrystallized twice from aqueous ethanol and had m.p. 169° (decomp.).

Sodium Borohydride Reduction of Tremulone

Tremulone (147 mg), sodium borohydride (211 mg), and 95% ethanol (20 ml) containing a drop of 2 *N* sodium hydroxide were boiled under reflux for 5 hours. An excess of acetone was then added and the mixture was distilled on a steam bath. It was then extracted with chloroform and the extract washed with dilute mineral acid, dried, and evaporated to give a wax (140 mg). This did not crystallize even after chromatography on alumina. Its ultraviolet spectrum (in ethanol) had λ_{max} 230, 237 mμ, λ_{infl} 245 mμ.

Selective Catalytic Reduction of Tremulone—Stigmastan-7-one (Tetrahydrotremulone)

Tremulone (300 mg) in 95% ethanol (200 ml) was hydrogenated at atmospheric pressure and room temperature over 10% palladium-on-charcoal catalyst (50 mg) for 24 hours, when 2 molar equivalents of hydrogen were taken up. Filtration and evaporation gave *stigmastan-7-one*, which was recrystallized from aqueous ethanol and obtained as white needles (220 mg), m.p. 98–99°, $[\alpha]_D^{22}$ −30.3° (chloroform). (Found: C, 83.65, 83.53, 84.07; H, 11.90, 12.35, 11.96; mol. wt., 414 (mass spec.). Calc. for $C_{29}H_{50}O$: C, 83.99; H, 12.15; mol. wt., 414.7.) Infrared spectrum: 1705, 1385, 1375 cm^{-1}. The *2,4-dinitrophenylhydrazone*, purified as above, gave yellow needles, m.p. 188–189°. (Found: C, 70.63; H, 8.98. Calc. for $C_{35}H_{54}O_4N_4$: C, 70.67; H, 9.15.)

Wolff–Kishner Reduction of Tetrahydrotremulone—Stigmastane

Tetrahydrotremulone (126 mg), triethylene glycol (10 ml), hydrazine hydrate (3 ml, 99–100%), and potassium hydroxide (2 pellets) were boiled under reflux for 4 hours, and then distilled until the temperature of the vapors reached 195°. The solution was boiled under reflux for another 6 hours, diluted with water, and extracted with ether. The dried ($MgSO_4$) ether extract was evaporated and the residual oil was chromatographed on a column of Woelm neutral alumina (10 g) (Brockman activity III) and eluted with light petroleum (b.p. 63–65°). The product was sublimed under vacuum and then recrystallized from chloroform–ethanol to give stigmastane (80 mg), m.p. 85°, $[\alpha]_D^{22}$ +25.2° (chloroform), identical (m.p., mixed m.p., infrared and n.m.r. spectra) with the stigmastane prepared from β-sitosterol as described below. (Found: C, 86.54; H, 12.88. Calc. for $C_{29}H_{52}$: C, 86.92; H, 13.08.)

Stigmastane from β-Sitosterol

3-β-Stigmastanyl acetate (500 mg) (18) was hydrolyzed with 3% methanolic potassium hydroxide to give 3-β-stigmastanol, m.p. 136–137°,[$\alpha]_D^{22}$ +24° (chloroform). This was oxidized to stigmastan-3-one (m.p. 155°, $[\alpha]_D^{22}$ +38° (chloroform)) (Ives and O'Neill (18) give m.p. 156–157°, $[\alpha]_D$ +37°) with chromic acid in acetic acid, and the ketone reduced by the Wolff–Kishner method (Huang-Minlon modification) as described above for stigmastan-7-one. The stigmastane so obtained had m.p. 84–85°, $[\alpha]_D^{22}$ +25° (chloroform), in good agreement with the literature values (5, p. 1442S).

The synthetic and "natural" hydrocarbon were each subjected to vapor phase chromatography on two columns of differing polarities: (*a*) a 2½-ft SE-30 on glass beads (0.5% w/w) column operated at 220° and a helium inlet pressure of 30 p.s.i.; (*b*) a 12-ft ethylene glycol succinate polyester on glass beads (0.5% w/w) column operated at 220° and a helium inlet pressure of 25 p.s.i. Anthracene was used as an internal standard. The synthetic and the "natural" hydrocarbon were chromatographically indistinguishable on either column.

Baeyer–Villiger Oxidation of Tetrahydrotremulone

Tetrahydrotremulone (100 mg) in glacial acetic acid (1 ml) was treated with 10% peracetic acid in acetic acid (3 ml) and *p*-toluenesulphonic acid (15 mg), and the mixture kept in the dark at room temperature for 3 days. Water was added and the solid which precipitated was filtered and recrystallized from methanol to give the *lactone* (90 mg), m.p. 140°. (Found: C, 80.60; H, 11.75. Calc. for $C_{29}H_{50}O_2$: C, 80.87; H, 11.70.)

The lactone (50 mg) was boiled under reflux with an excess of 20% aqueous potassium hydroxide for 2 days, during which time an oil separated. On shaking the mixture with ether three layers formed. The ether layer contained very little starting material. The two bottom layers were extracted with chloroform (in which the oil dissolved), the chloroform was dried ($MgSO_4$) and evaporated, leaving behind a yellow solid whose infrared spectrum indicated the presence of an OH group and a —COO^- (characteristic broad band at ca. 1600 cm^{-1}). When this solid was treated with dilute acid the lactone was recovered.

Sodium Borohydride Reduction of Tetrahydrotremulone—Stigmastan-7α-ol

Tetrahydrotremulone (50 mg) in absolute ethanol (10 ml) containing a drop of 2 *N* sodium hydroxide was boiled under reflux and sodium borohydride (25 mg) in ethanol (5 ml) was added over a period of ½ hour. The mixture was boiled for a further 2 hours and then allowed to stand at room temperature overnight. Hydrochloric acid (5%; 2 ml) was added, the mixture was warmed for 5 minutes, and water (25 ml) was added. The ethanol was removed in a stream of air and the residual solution extracted with chloroform. The chloroform extract was washed with aqueous sodium carbonate and filtered through a short column of alumina. The product was recrystallized from acetone to give *stigmastan-7α-ol* (30 mg) as white flakes, m.p. 112°, $[\alpha]_D^{22}$ +12.7° (chloroform) (transparent in the ultraviolet). (Found: C, 83.48; H, 12.85. Calc. for $C_{29}H_{52}O$: C, 83.58; H, 12.58.)

7-Keto-β-sitosteryl Acetate

β-Sitosteryl acetate (500 mg), in glacial acetic acid (10 ml) containing sodium acetate (400 mg), was warmed to 60°, and chromic anhydride (400 mg) added over a period of ½ hour. The solution was warmed for another 4½ hours, diluted with water (10 ml), and the precipitated solid washed with water. The combined filtrates were treated with ethanol and extracted with chloroform. The chloroform extract was washed with aqueous sodium carbonate solution and then with water, dried ($MgSO_4$), and evaporated. The residue was combined with the solid that had precipitated before and was chromatographed on alumina (25 g). Elution with light petroleum (b.p. 40–60°) – ether (9:1) gave unchanged β-sitosteryl acetate (170 mg). Elution with light petroleum (b.p. 40–60°) – ether (1:1) gave 7-keto-β-sitosteryl acetate (183 mg), which was used as such in the next stage. Elution with ether–methanol (1:1) gave β-sitosterol (120 mg).

Stigmasta-3,5-diene-7-one

A mixture of 7-keto-β-sitosteryl acetate (183 mg), *p*-toluenesulphonic acid (150 mg), and toluene (5 ml) was boiled under reflux for 2 hours (solution turned dark brown). The mixture was dissolved in ether and the solution washed with aqueous sodium carbonate solution, then with water, and evaporated to dryness at 80°. The oil thus obtained was chromatographed on alumina to give stigmasta-3,5-diene-7-one (45 mg), m.p. 109°, identical in every respect with tremulone.

ACKNOWLEDGMENTS

This work was carried out during the tenure (by R. G. M.) of a National Research Council Studentship (1961–1962), and was supported financially by a generous grant from the Saskatchewan Research Council. The authors also wish to express their gratitude to Mr. A. L. Burlingame (M.I.T.) for the mass spectroscopic determinations, to Dr. O. E. Edwards (N.R.C.) for some of the n.m.r. spectra, and to Mr. W. Larson for the X-ray diffraction photographs, as well as to Dr. R. Altschul for a sample of 7-ketocholesterol.

OXIMES

II. THE INFRARED SPECTRA OF SOME COMPLEX OXIMES[1]

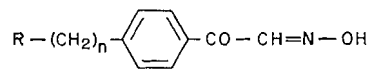
J. J. NORMAN
Defence Research Chemical Laboratories, Ottawa, Canada

Received May 14, 1962

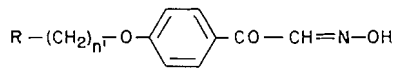
ABSTRACT

The infrared spectra of several ω'-substituted *p*-alkyl- and *p*-alkoxy-2-oximinoacetophenones were investigated. When the ω'-substituent was the dimethylamino group, the spectra were incompatible with a simple α-ketooxime structure. The spectra of these dimethylamino compounds showed a diffuse absorption with broad peaks at 2500 and 1850 cm^{-1}. The hydroxyl band at 3150 cm^{-1} and the dimethylamino doublet at 2820 and 2770 cm^{-1} had nearly disappeared while the carbonyl and N—O frequencies had undergone large shifts. The spectra are best interpreted in terms of a zwitterion carrying a novel anion. The structure of this anion is considered.

A series of oximes with the general structures I and II was prepared. During the syntheses, infrared spectra were obtained routinely to identify the various products



I



II

n = 1, 3, 4

c: R = $I^-.(CH_3)_3\overset{+}{N}$—

obtained and, in some instances, it was found that spectra were incompatible with the structures shown above.

EXPERIMENTAL

The syntheses of the various compounds used in this study have been described elsewhere (1).

All spectra were obtained with 1–1.5% suspensions of the oxime in potassium bromide, pressed into disks. The spectra were obtained with a Baird Model AB-1 double-beam recording infrared spectrophotometer, which was calibrated daily to an accuracy of ± 5 cm^{-1} at 3060 cm^{-1} and ± 15 cm^{-1} at 700 cm^{-1}. No attempt was made to obtain quantitative intensity data, and band positions, quoted to the nearest 5 cm^{-1}, are listed in Table I.

DISCUSSION

Simple oxime spectra exhibit an OH band at 3115-3300 cm^{-1}, a C=N band at about 1640 cm^{-1}, and an N—O band at 950–990 cm^{-1} (2–4). Similarly, various acetophenones

[1]*Issued as D.R.C.L. Report No. 378.*
Presented in part before the 5th Western Regional Conference of the CIC, Regina, 1960.

TABLE I

Group frequencies of some substituted 2-oximinoacetophenones and related compounds

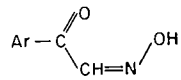
NOTE: w = weak intensity, m = medium intensity, s = strong intensity, vs = very strong intensity, i = inflection.

show a C=O band in the region 1660–1685 cm^{-1} (5). These absorptions are exhibited by 2-oximinoacetophenone, whose spectrum has maxima at 3290 cm^{-1} (OH), 1670 cm^{-1}, (C=O), and 985 cm^{-1} (N—O). Absorption by C=N apparently is masked by that of C=O, although it was noted that an inflection is present on the low-frequency side of the carbonyl band. This shows the positions where one would expect absorption for compounds containing the structure III. On this basis, then, one would expect the spectra



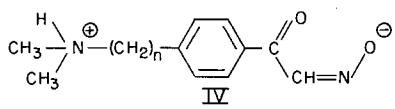
III

of the compounds of the two series I and II to show absorption bands in the above positions, perhaps with minor shifts of position, plus the bands characteristic of the para substituent.

The spectra of the *p*-(ω'-chloroalkoxy)-2-oximinoacetophenones (II*a*: $n' = 3, 4, 5$) exhibited O—H absorption at 3125–3350 cm^{-1}, N—O absorption at 975–985 cm^{-1}, and C=O absorption at 1660 cm^{-1}, while that of C=N appeared to be buried under the C=O peak. These spectral features then indicate that the structure III is present in these molecules.

When the substituent R was the dimethylamino group (I*a*, II*b*), the spectra were vastly different. Dimethylamino compounds normally exhibit a doublet at 2825 and 2775 cm^{-1} arising from the asymmetric and symmetric C—H stretching vibrations of the N—$(CH_3)_2$ group (6), analogous to those of the C—CH_3 and O—CH_3 groups (7, 8). In the present work, this doublet was observed at slightly varying frequencies, 2900–2820 cm^{-1} for the higher and 2810–2760 cm^{-1} for the lower band, with the parent compounds for the series I*a*, the *p*-(ω'-dimethylaminoalkyl)-acetophenones. For the oximes themselves (I*a*: $n = 1, 3, 4$; II*b*: $n' = 2, 3, 4, 5$), this doublet was missing and the O—H peak was greatly reduced in intensity. A diffuse absorption area in the region 3100–1700 cm^{-1}, with broad peaks at approximately 2500 and 1850 cm^{-1}, had appeared. Such a phenomenon had been noted in the spectra of amino acids and is attributed to zwitterion formation (9, 10). Bellamy (11, Ch. 13) ascribes these peaks to N^+—H groupings. Similar broad peaks have been noted (17, 18) in the spectra of isonicotinic, quinaldic, and cinchoninic acids and have been ascribed to *very strong* hydrogen bonding between carbonyl hydrogen and the ring hetero nitrogen atom.

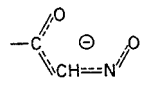
Because the dimethylamino group is much more basic than the oximate ion, it is felt that the proton has been transferred to nitrogen and intact dimethylamino and oximino groups are not present in the molecule but are involved in the formation of a zwitterion such as IV. A very strongly hydrogen bonded structure is, however, also compatible with the spectral data but is thought to be much less likely than the zwitterion.



IV

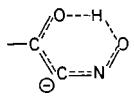
A closer inspection of the spectra indicated the zwitterion to be more complex than this. The N—O band, normally at 950–990 cm^{-1}, has shifted to 1030–1050 cm^{-1}, an effect opposite to that expected for loss of the proton from the N—OH portion of the molecule.

At the same time, the carbonyl group frequency has shifted from the normal position of 1670 cm^{-1} in aromatic α-ketooximes to 1630 cm^{-1}. These are incompatible with a simple enolizing of the anion, where one would expect the disappearance of the C=O band and the appearance of an N=O band at 1570–1590 cm^{-1} (12). The observed effects, however, do agree with a resonance hybrid where carbonyl loses and N—O acquires double-bond character, as in V, although the C=O shift of about 40 cm^{-1} is quite large. It has been



V

reported recently (without experimental details) that with α-oximino esters a very stable pseudoaromatic ring system is formed involving the ester carbonyl and the oximino group (16), which results in a lowering of the carbonyl frequency. It is possible to draw a tautomeric structure, VI, of the anion of IV in which a similar ring system is implicit.



VI

This would be highly unstable as it requires carbon to become the site of negative charge. Formation of the ring system, however, would greatly assist stabilization and might, in large measure, overcome the inherent instability of such an anion. While such a structure could explain the lowering of the carbonyl frequency of these oximinoacetophenones, it is much less probable than the resonance hybrid V.

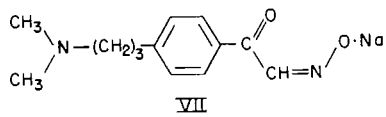
That the aromatic ring is not involved in these end group interactions is shown by the spectra of the aliphatic compounds 5-dimethylamino-3-oximino-2-oxopentane and 6-dimethylamino-3-oximino-2-oxohexane. The spectra of these compounds exhibited at 2500 and 1890 cm^{-1} the zwitterion doublet previously described. The hydroxyl and dimethylamino group absorptions were missing, and the carbonyl group frequency was at 1655 cm^{-1}, an abnormally low value for an aliphatic ketone (11, pp. 134–136). The N—O band was at 1050 cm^{-1}, a higher frequency than expected for an aliphatic oxime (3).

To show that the spectra observed for compounds of the series I*a* and II*b* arise from zwitterion formation, the basicity of the amine function was destroyed by quaternization. The amino group now carries a formal positive charge, resembling closely the dimethylammonium group postulated for the zwitterion. The inductive effects of the positively charged nitrogen, therefore, are unchanged but proton abstraction from the oximino group no longer can occur and no zwitterion can form. The spectra of these methiodide salts show a hydroxyl peak at 3150 cm^{-1}, carbonyl absorption at 1670 cm^{-1}, and the N—O bond is at 985 cm^{-1}, all conforming to the structure III for the ketooxime portion of the molecule. The absorptions at 2500 and 1850 cm^{-1} have disappeared. These peaks then must be characteristic of the zwitterion rather than of charged nitrogen since this latter is still present.

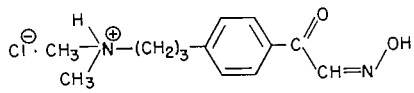
As a further test, *p*-(3′-dimethylaminopropyl)-2-oximinoacetophenone was converted to the sodium salt and to the hydrochloride salt. The spectra of these salts were quite different from that of the parent compound. The spectrum of the sodium salt exhibited

no hydroxyl absorption, the dimethylamino doublet was present at 2835 and 2780 cm^{-1}, while the carbonyl band was present at 1630 cm^{-1}, just resolved from the strong peak at 1610 cm^{-1} arising from aromatic ring vibrations. This low-frequency position of the carbonyl peak would indicate an increase in the amount of single-bond character of this bond. The N—O band, at 1030 cm^{-1} in the zwitterion, was greatly reduced in intensity. Two peaks of medium intensity, however, were observed at 1155 and 885 cm^{-1} and could arise from N—O^- bond vibrations but, because of lack of spectral data on other compounds containing such a bond, no assignments will be made. The spectrum of the hydrochloride salt featured a strong hydroxyl peak at 3115 cm^{-1}, a carbonyl peak at 1650 cm^{-1}, and N—O absorption at 1010 cm^{-1}. The dimethylamino doublet was obscured by the hydroxyl peak but a single intense peak was noted at 2685 cm^{-1}, and is ascribed to the N^+—H structure.

These spectra then indicate the structures VII and VIII for the sodium and hydrochloride salts.

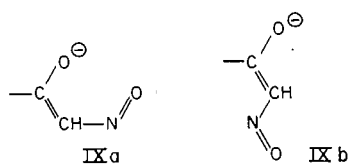


VII



VIII

In connection with the work on the sodium salt, an interesting phenomenon was noted. After recording the spectrum of the salt, the KBr disk was heated, inadvertently, to 50° C. On re-examination, this disk yielded a spectrum which would indicate that the material had undergone an isomerization. The dimethylamino doublet was unaffected, but the carbonyl peak was greatly reduced in intensity and a new band had appeared at 1550 cm^{-1}. This spectral behavior is in accord with loss of a carbonyl group and formation of an N=O bond in the molecule and would suggest that the canonical form of V, IX*a*,

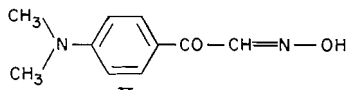


IXa IXb

makes a large contribution to the structure of the anion. This would be further stabilized by shifts in position of the skeletal atoms so that the nitroso oxygen is remote from the enol oxygen, as in IX*b*. This isomerization did not reverse on cooling. A repeat of this work in which the material was heated to 50° C before presssing into a pellet yielded a spectrum identical with that obtained when the KBr disk was heated. That this was an isomerization and did not arise from replacement of sodium ion by potassium ion from the pelleting material was shown by the fact that the potassium salt of the oxime underwent a similar isomerization when heated. On acidification, both carbonyl and nitroso forms of the sodium salt regenerated the original oxime.

It should be mentioned that the peaks at 1155 and 885 cm^{-1} in the spectrum of the keto form of the sodium salt became much less intense in that of the enol form. This would support their assignment to the N—O^- structure.

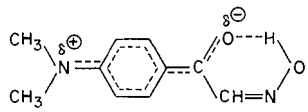
To test the conditions under which zwitterion formation occurs, an oxime was synthesized in which the basicity of the amine function was lowered but not destroyed. The pK_a of dimethylaminoalkanes is 10.0 (13) but that of dimethylaniline is 5.1 (14). This latter value is much lower than the pK_a of the oxime function in 2-oximinoacetophenones, 8.25 (15), and it would be expected that X would not undergo zwitterion formation. Its



X

spectrum, then, in contrast to the spectra of the *p*-(ω'-dimethylaminoalkyl)-2-oximinoacetophenones, would not be expected to exhibit the zwitterion peaks and, indeed, such peaks were not observed experimentally. This spectrum, however, is different from that of other 2-oximinoacetophenones which are not in the zwitterion form, for the carbonyl and hydroxyl band intensities are very weak. In addition, the carbonyl band is at the abnormally low position of 1610 cm^{-1}. The dimethylamino doublet at 2905 and 2860 cm^{-1} (very poorly resolved) and the N—O band at 985 cm^{-1} are in their normal positions. These features are indicative of an interaction between the hydroxyl and carbonyl groups and of no particular change in the N—O portion of the molecule.

It can be seen that in compound X, the dimethylamino group is conjugated through the benzene ring with the carbonyl group. The mesomeric interaction of these two groups will lead to a partial negative charge on the keto oxygen, as in XI, which will greatly



XI

facilitate hydrogen bonding of the OH and C=O groups, hence leading to the much reduced intensities observed for these two absorptions. The very large shift in position of the carbonyl band from its normal position of 1680–1670 cm^{-1} in oximinoacetophenones to 1610 cm^{-1} shows the combined effects of mesomerism with the dimethylamino group and the increased hydrogen bonding with the hydroxyl group. The weak hydroxyl peak is consistent with an intramolecular rather than an intermolecular hydrogen bond, since the latter increases the OH band intensity (11, p. 99).

The fact that the broad bands at 2500 and 1850 cm^{-1} are not observed with this compound cannot be taken as unequivocal proof that these bands in the spectra of other *p*-(ω'-dimethylamino-alkyl and -alkoxy)-2-oximinoacetophenones arise because of zwitterion formation and are not the result of a very tight hydrogen bond. One might not expect evidence for hydrogen bonding to nitrogen in the spectrum of X, since the oximino hydrogen is already involved in a very strong intramolecular hydrogen bond to carbonyl oxygen.

Upon quaternization of X, there can be no mesomeric interaction between the carbonyl and amino nitrogen functions because the free electron pair of the latter has been lost

The enhanced hydrogen bonding between the hydroxyl and carbonyl groups observed for X now should be suppressed and the spectrum of the resulting *p*-trimethylammonium-2-oximinoacetophenone iodide should show normal hydroxyl and carbonyl absorption. In actual fact, the major absorption bands, hydroxyl at 3160 cm^{-1}, carbonyl at 1690 cm^{-1}, and N—O at 975 cm^{-1}, all lie within the ranges normal for simple 2-oximinoacetophenones. The unusual feature of this spectrum is the presence of a small peak on the low-frequency side of the carbonyl peak. This band at 1640 cm^{-1} probably arises from the C=N linkage. Because of the strong inductive effect of the trimethylammonium portion of the molecule, the polarization of the carbonyl group has shifted the carbonyl frequency high enough for the C=N band to be resolved, rather than appearing as a shoulder.

SUMMARY

The incorporation of a highly basic dimethylamino group into an α-ketooxime molecule results in the formation of a zwitterion incorporating a novel anion. Quaternization results in loss of ability to form the zwitterion and the placement of a formal positive charge upon the amino nitrogen. The spectra of these quaternized compounds are quite different from those of the dimethylamino compounds, which also are considered to carry such a charge on the amino nitrogen. The basicity of the amino group was decreased so that no zwitterion formed, but in such a way that a charge was induced upon the carbonyl oxygen by a mesomeric effect. This resulted in formation of a hydrogen-bonded structure of the ketooxime which showed several of the spectral features associated with the zwitterion previously produced. Changes resulting in a suppression of the polarization of the carbonyl group resulted in the loss of these spectral features and the spectra resembled those of simple oximes. Sodium salts of these oximes were shown to undergo an interesting isomerization.

NOTES

THE PREPARATION AND INFRARED AND N.M.R. SPECTRA OF MONODEUTERATED PYRIDINE AND 3-PICOLINE

R. A. Abramovitch, D. J. Kroeger, and B. Staskun

In connection with other studies it was of interest to get an estimate of the relative ground-state π-electron densities at the 2- and 6-positions of 3-picoline and its complex with a simple metallic salt. Smith and Schneider (1) recently estimated the charge distribution in pyridinium ion, assuming a simple proportionality between the proton resonance displacement and the electron charge deficiency on the carbon atom to which the proton is bonded. 3-Picoline-2*d*, 3-picoline-6*d*, and their zinc chloride complexes have been prepared and their n.m.r. and infrared spectra compared.

Bak, Hansen, and Rastrup-Andersen (2) obtained pyridine-2*d* by the action of zinc dust and sulphuric acid-d_2 on 2-bromopyridine. It was prepared more conveniently here from 2-pyridyllithium and deuterium oxide. Preliminary experiments indicated that there was no loss of deuterium when the pyridine-2*d* was extracted with mineral acid instead of being isolated as the mercuric chloride complex. This is in agreement with the recent finding by Katritzky and Ridgewell (3) that pyridine is very resistant to proton exchange. In the same way, 3-picoline-2*d*, 3-picoline-6*d*, and the corresponding tritiated compounds were obtained (the latter by using tritiated water).

The n.m.r. spectra were run in acetonitrile solutions of the compounds, due to the limited solubility of the zinc chloride complexes in carbon tetrachloride and to interference by chloroform when it was used. The results are summarized in Table I. The accuracy is ± 2 cycles/sec.

TABLE I

N.M.R. spectra (at 60 Mc/s) of deuterated picolines and their zinc chloride complexes (solutions in acetonitrile; band positions in cycles/sec from tetramethylsilane as internal standard; no solvent corrections applied)

	H_2, H_6	H_4	H_5	CH_3
3-Picoline	504	450	430	136.6
(3-Picoline)$_2$–$ZnCl_2$	515	475	452.5	143.5
3-Picoline-2*d*	502 (H_6)	450	429.5	135.5
(3-Picoline-2*d*)$_2$–$ZnCl_2$	509.5	475.5	451.2	143.5
3-Picoline-6*d*	504.5 (H_2)	451.5	431.5	136.0
(3-Picoline-6*d*)$_2$–$ZnCl_2$	508	472	449	140.5

In the case of 3-picoline (unlike that of myosmine (4)) and its zinc chloride complex the signals for the 2- and 6-protons overlap and no resolution is possible at 60 Mc/s. The shift between these two protons is seen to be +2.5 cycles/sec from the spectra of 3-picoline-6*d* and 3-picoline-2*d* respectively. From these values, the differences in π-electron densities are estimated to be very small. Complexing, as expected, gives rise to appreciable changes in chemical shift, particularly at the β- and γ-protons. The corresponding shift to lower field of the α-proton is appreciably smaller. This is probably due

to the change in the paramagnetic contribution of the nitrogen atom on complexing. Some "back-bonding" from the zinc chloride might also account for the smaller shift, though in this case one would have expected it to affect the γ- more than the α-protons (5). No clear indication of the relative ground-state π-electron densities at C_2 and C_6 may be obtained from these measurements.

The infrared spectrum of pyridine (6), its zinc chloride complex (7), and pyridine-2*d* (2) have been reported and analyzed. The spectra of (pyridine-2*d*)$_2$–$ZnCl_2$, 3-picoline, (3-picoline)$_2$–$ZnCl_2$, 3-picoline-2*d*, (3-picoline-2*d*)$_2$, 3-picoline-6*d*, and (3-picoline-6*d*)$_2$–$ZnCl_2$ were determined and exhibited no unexpected features. The main bands only are listed in Table II for the zinc chloride complexes.

TABLE II

Infrared spectra of zinc chloride complexes of some pyridine derivatives (as Nujol mulls)

(Pyridine)$_2$ –$ZnCl_2$	(Pyridine-2*d*)$_2$ –$ZnCl_2$	(3-Picoline)$_2$ –$ZnCl_2$	(3-Picoline-2*d*)$_2$ –$ZnCl_2$	(3-Picoline-6*d*)$_2$ –$ZnCl_2$
1609	1602	1612	1600	1604
			1590 (sh)	1575
1488		1480		
1452	1440		1410	1420 (sh)
	1304			1302
1218		1199	1206	1231
1067	1065	1130	1135	1137
1044	1042	1100		
1015	1010	1060		1060
				925 (w)
	901		915	910
	810 (sh)		815 (w)	850
	802		796	819
757	754	784	777 (w)	
			718 (w)	717 (w)
686		693		

An interesting difference was observed between the C—D stretching vibration frequencies of 3-picoline-2*d* and 3-picoline-6*d* (liquid films). Thus, whereas 3-picoline-2*d* exhibited a band at 2244 ± 2 cm^{-1}, the corresponding band for 3-picoline-6*d* was at 2259 ± 2 cm^{-1}. This difference reflects a slightly greater force constant for the C_6—D bond and probably indicates that C_2 is slightly less electronegative than C_6, in accord with simple predictions based on the generally accepted positive inductive effect of the methyl substituent.

EXPERIMENTAL

Deuterium analyses are by J. Nemeth, Urbana, Illinois.

Pyridine-2d

2-Bromopyridine (82 g, redistilled) in ether (10 ml) was added over a period of 10 minutes to a stirred solution of butyllithium (from 8.5 g lithium and 68 g butyl bromide in 250 ml of dry ether) at ca. −60° and stirring was continued for another 5 minutes. To the dark orange solution was added deuterium oxide (20 g, 99.7%) dropwise during 5 minutes and the temperature maintained at about −55° while the mixture was stirred. The stirred suspension was then allowed to reach room temperature. Water (100 ml) was added and then potassium hydroxide pellets to make the solution strongly alkaline, and the product was extracted repeatedly with ether. At this point the ether solution could be treated with a solution of mercuric chloride (200 g) in water (1 l.) to precipitate the mixture of complexes of pyridine-2*d* and 2-bromopyridine (containing some unreacted butyl bromide) according to the procedure of Bak *et al.* (2). Alternatively, and more conveniently, the reaction product which had been treated with water was added to a cooled solution of dilute hydrochloric acid (700 ml), extracted with ether to remove unchanged butyl bromide, the acid layer made strongly alkaline with potassium hydroxide and extracted repeatedly with ether. The dried (KOH)

ether extract was evaporated and the residue distilled to give crude pyridine-2*d*, b.p. 100–130°, followed by 2-bromopyridine (25 g), b.p. 192–194°. The crude pyridine-2*d* fraction was dried and distilled from potassium hydroxide pellets to give pure pyridine-2*d* (9.5 g), b.p. 113–114°. (Found: atom%×D, 18.80. Calc. for C_5H_4DN: 20.) No diminution in deuterium content occurred when the compound was boiled with dilute hydrochloric acid, or kept in hydrochloric acid solution at room temperature for 3 months.

3-Picoline-2d

Prepared similarly from 2-bromo-3-methylpyridine (4.4 g), it was obtained as a colorless liquid (1.1 g), b.p. 141–142°. (Found: atom%×D, 11.67. Calc. for C_6H_6DN: 14.2.)

3-Picoline-6d

It was obtained in 61% yield from 2-bromo-5-methylpyridine. (Found: atom%×D, 11.65. Calc. for C_6H_6DN: 14.2.)

Zinc Chloride Complexes

These were prepared by adding an aqueous solution of the pyridine to zinc chloride in water. A precipitate formed which was recrystallized from 95% ethanol repeatedly and then dried in a vacuum oven. The $(3\text{-picoline})_2$ – zinc chloride complexes had m.p. 143–144°.

ACKNOWLEDGMENTS

The authors are very grateful to Dr. W. G. Schneider for the first determinations of the n.m.r. spectra and for some very helpful comments. Thanks are due Dr. B. Gunn for the use of a Beckmann IR-4 spectrophotometer, and the National Research Council for financial assistance.

SYNTHESIS OF 19-NORTESTOLACTONE

Jehan F. Bagli

Modification of steroidal molecules resulting in dissociation of androgenic and myotropic activity is a problem of interest to steroid chemists. Testolactone is the only known steroid reported (1) to have anabolic activity without any androgenic side effect. It is well established (2) that, everything else being equal, the myotropic/androgenic ratio is increased in compounds devoid of C_{19}-methyl group. It was therefore of interest to synthesize 19-nortestolactone.

19-Nortestolactone[1] was first prepared from a product of the biological transformation of androst-4-ene-3,17-dione (3).

Estrolactone 3-acetate (I) was directly converted to its methyl ether (II) as described (4). A lithium aluminum hydride reduction of II yielded diol III.

[1]*Since completion of this work, an alternative route for the synthesis of 19-nortestolactone has appeared (M. Akhtar and D. H. R. Barton. J. Am. Chem. Soc. 84, 1496 (1962)).*

SYNTHESIS OF 19-NORTESTOLACTONE

Jehan F. Bagli

Modification of steroidal molecules resulting in dissociation of androgenic and myotropic activity is a problem of interest to steroid chemists. Testolactone is the only known steroid reported (1) to have anabolic activity without any androgenic side effect. It is well established (2) that, everything else being equal, the myotropic/androgenic ratio is increased in compounds devoid of C_{19}-methyl group. It was therefore of interest to synthesize 19-nortestolactone.

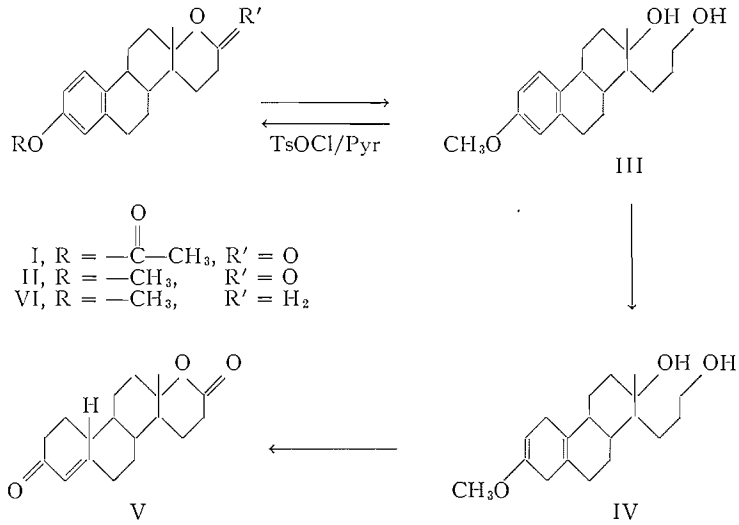
19-Nortestolactone[1] was first prepared from a product of the biological transformation of androst-4-ene-3,17-dione (3).

Estrolactone 3-acetate (I) was directly converted to its methyl ether (II) as described (4). A lithium aluminum hydride reduction of II yielded diol III.

[1]*Since completion of this work, an alternative route for the synthesis of 19-nortestolactone has appeared (M. Akhtar and D. H. R. Barton. J. Am. Chem. Soc. 84, 1496 (1962)).*

Reduction with lithium and liquid ammonia gave 1-(*n*-hydroxypropyl)-2-methyl-2-hydroxy-7-methoxy-1,2,3,4,4*a*,5,8,9,10,10*a*-decahydrophenanthrene (IV) in an overall yield of 42% from estrolactone acetate. Diol IV on treatment with dilute hydrochloric acid, followed by chromic acid oxidation, yielded 19-nortestolactone (V).

Dehydration of diol III with *p*-toluenesulphonyl chloride and pyridine gave the oxide VI (5).



EXPERIMENTAL[2]

1-(n-Hydroxypropyl)-2-methyl-2-hydroxy-7-methoxy-1,2,3,4,4a,9,10,10a-octahydrophenanthrene

Estrolactone methyl ether (12 g) in dry tetrahydrofuran (220 ml) was added over 25 minutes, to a suspension of lithium aluminum hydride (11.8 g) in dry tetrahydrofuran (500 ml). The mixture was stirred for 30 minutes and worked up by adding hydrochloric acid (18%, 320 ml). The organic layer separated, and the aqueous layer was extracted with tetrahydrofuran. The organic liquor was washed with saturated sodium chloride, dried, and the solvent was removed to yield an oily semisolid (12.25 g). Elution from a column of florisil (440 g) with chloroform gave a solid (6.5 g, 54%), m.p. 128–129°. Recrystallization from chloroform–hexane gave an analytical sample, m.p. 130–132°, α_D +108°. Calc. for $C_{19}H_{28}O_3$ (304.41): C, 74.96; H, 9.27. Found: C, 75.04; H, 9.34.

1-(n-Hydroxypropyl)-2-methyl-2-hydroxy-7-methoxy-1,2,3,4,4a,5,8,9,10,10a-decahydrophenanthrene (IV)

Diol III (4.14 g) was dissolved in dry tetrahydrofuran (75 ml), and liquid ammonia (300 ml) was added to it. Lithium wire (4.2 g) was added in small pieces and the mixture was stirred for 25 minutes. Dry ethanol (50 ml) was added dropwise over 20 minutes. Ammonia was then removed and water carefully added. The organic layer was separated and the aqueous layer was extracted with ether. The organic extract was washed with water, dried, and the solvent removed to yield a solid (4 g). A crystallization from aqueous methanol gave colorless plates (3.21 g, 80%), m.p. 147–149°. An analytical sample melted at 148–149°. ν_{max} 1695, 1667 (unconjugated dihydroanisol system) cm^{-1} (6). Calc. for $C_{19}H_{30}O_3$ (306.41): C, 74.47; H, 9.87. Found: C, 74.37; H, 9.47.

19-Nortestolactone (V)

Diol IV (2.5 g) was dissolved in methanol (130 ml) and dilute hydrochloric acid (75 ml), and refluxed under nitrogen for 15 minutes. The mixture was neutralized with sodium carbonate, and the solvent removed under vacuum. The residue was taken up in chloroform, the solution was washed, dried, and the solvent was removed, leaving a colorless oil (2.7 g). λ_{max} 239 mμ (ϵ_{max} 19,350).

[2]*All melting points are uncorrected. Infrared spectra are recorded in chloroform using a Perkin–Elmer Model 21 spectrophotometer, and ultraviolet spectra in 95% ethanol. Rotations were determined in chloroform solution at a concentration of about 1% at room temperature. We wish to thank Dr. G. Papineau-Couture and his associates for microanalyses, rotations, and spectral data.*

Oxidation

The above oil was dissolved in acetone (150 ml, distilled over potassium permanganate), the solution was cooled to 0°, 8 *N* chromic acid (8 ml) was added, and the mixture was stirred for 10 minutes. Excess acid was destroyed with methanol, and the solvent was removed. The residue was taken up in chloroform, and worked up as usual to yield a colorless oil (2.4 g). Two crystallizations from acetone–hexane afforded crystals (0.82 g), m.p. 187–188°. An analytical sample furnished by further crystallizations had m.p. 198–199°, α_D −13°. ν_{max} 1720 (lactone carbonyl), 1667 (3-ketone), 1625 (Δ^4 double bond) cm^{-1}. λ_{max} 238 mμ (ϵ_{max} 19,700). Calc. for $C_{18}H_{24}O_3$ (288.37): C, 74.97; H, 8.39. Found: C, 74.67; H, 8.14.

*3-Methoxy-17a-oxa-*D*-homoestra-1,3,5(10)-triene (VI)*

Diol III (2 g) and *p*-toluenesulphonyl chloride (1.6 g) were dissolved in dry pyridine (26 ml), kept overnight at room temperature, and heated on a steam bath for 1 hour. A few milliliters of water was added and pyridine was removed. The residue was worked up in the usual manner. A crystallization from aqueous methanol afforded colorless plates (0.7 g), m.p. 150–151°. An analytical sample melted at 150–151°, α_D +91°. Calc. for $C_{19}H_{26}O_2$ (286.37): C, 79.68; H, 9.15. Found: C, 79.95; H, 8.86.

THIOCARBONATES AS BLOCKING GROUPS FOR THE SYNTHESIS OF PARTIAL ESTERS OF CARBOHYDRATES

J. J. WILLARD[1]

Cellulose Research Institute, State University of New York College of Forestry, Syracuse, N.Y., U.S.A.

Received May 8, 1962

ABSTRACT

It has been found that the thiocarbonate, or (alkylthio)carbonyl derivative, serves as a versatile blocking group for the synthesis of partial ester derivatives of carbohydrates. The (alkylthio)carbonyl group is readily substituted in pyridine solution, is stable to mild acid conditions, but is decomposed by mild oxidation. Crystalline methyl 4,6-di-*O*-benzoyl-α-D-glucopyranoside has been synthesized and its structure proved by an independent synthesis of its 2,3-di-*O*-phenylcarbamate derivative. Methyl 4,6-di-*O*-benzoyl-β-D-glucopyranoside was also synthesized and its structure proved by acetylation to the known 2,3-di-*O*-acetyl derivative.

INTRODUCTION

During a study of the kinetics of acetylation of methyl glucosides in our laboratories, certain unknown di- and tri-acetate derivatives of the methyl glucosides became of interest. Many of the possible mono-, di-, and tri-acetates of the methyl glucosides are not known, as is true also for the benzoate derivatives (1), and the general methods for their synthesis have been limited. Apart from the few acetates and benzoates which can be synthesized by the specific substitution reactions or those which depend on the controlled migration of an ester group from one hydroxyl to another, the only derivatives known are those which have utilized acid-sensitive blocking groups such as 4,6-benzylidene (giving 2,3-diesters) or the triphenylmethyl ether (giving 2,3,4-triesters) for their preparation.

The (alkylthio)carbonyl[2] group, R—S—C(=O)—, has been utilized as a protective radical for amino groups in peptide synthesis (2). The (benzylthio)carbonyl derivative of methyl-α-D-glucopyranoside was encountered (3) as an intermediate during the two-step removal of the xanthate group from methyl 2,3,4-tri-*O*-benzoyl-6-*O*-(benzylthio)thiocarbonyl-α-D-glucopyranoside, and was shown to be readily decomposed by mild oxidation, the parent alcohol being liberated. Because it was proved that the benzoyl groups did not migrate during the reaction, the (benzylthio)carbonyl group was suggested as a promising blocking group for the synthesis of partial esters of carbohydrates. This paper describes the synthesis and proofs of structure of methyl 4,6-di-*O*-benzoyl-α-D-glucopyranoside and its β-anomer, demonstrating this principle.

[1]*Present address: Chemistry Department, University of Birmingham, Edgbaston, Birmingham 15, England.*

[2]*The nomenclature for thiocarbonates recommended by L. Hough, J. E. Priddle, and R. S. Theobald, Advances in Carbohydrate Chem., **15**, 91 (1960), is used in this communication.*

Methyl 4,6-di-*O*-benzoyl-β-D-glucopyranoside (VI) was synthesized in 21% overall yield, as seen from Fig. 1. Methyl 4,6-*O*-benzylidene-β-D-glucopyranoside (I) was treated

in pyridine solution with a small excess of (benzylthio)carbonyl chloride (II), giving a crystalline 2,3-di-*O*-(benzylthio)carbonyl derivative (III). Removal of the benzylidene group by mild acid hydrolysis afforded methyl 2,3-di-*O*-(benzylthio)carbonyl-β-D-glucopyranoside (IV), which failed to crystallize. However, benzoylation gave a crystalline 4,6-di-*O*-benzoyl derivative (V) and acetylation, the crystalline diacetate (VIII). Oxidation of V with hydrogen peroxide in acetic acid – chloroform solution gave methyl 4,6-di-*O*-benzoyl-β-D-glucopyranoside (VI), the structure of which was proved by acetylation of VI to known (4) methyl 2,3-di-*O*-acetyl-4,6-di-*O*-benzoyl-β-D-glucopyranoside (VII).

Crystalline methyl 4,6-di-*O*-benzoyl-α-D-glucopyranoside (IX), Fig. 2, was synthe-

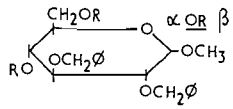
sized in 36% yield in the same manner from methyl 4,6-*O*-benzylidene-α-D-glucopyranoside. It gave a crystalline 2,3-di-*O*-phenylcarbamate derivative (X). Its structure was proved by benzoylation of known (5) methyl 2,3-di-*O*-phenylcarbamyl-α-D-glucopyranoside (XI), giving a product identical with that prepared from the dibenzoate derivative (IX).

DISCUSSION

During the first attempts to synthesize methyl 4,6-di-*O*-benzoyl-α- and -β-D-glucopyranosides use was made of the known (6, 7) 2,3-di-*O*-benzyl ether derivatives (XII). Methyl 2,3-di-*O*-benzyl-α- and -β-D-glucopyranosides were benzoylated to the new crystalline 4,6-di-*O*-benzoyl derivatives (XIII) seen in Fig. 3. Repeated attempts to



XII R = —H

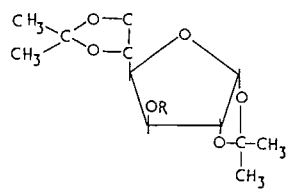
XIII R = —C(=O)Ø

XIV R = —CH3

FIG. 3.

remove the benzyl ether groups by catalytic hydrogenolysis were not successful. This was surprising in view of the experience in this laboratory that methyl 4,6-di-*O*-methyl-β-D-glucopyranoside is readily obtained by catalytic reduction (Pd) of its 2,3-di-*O*-benzyl ether derivative (XIV), a reaction described by Freudenberg and Plankenhorn (8). No reports have been found, in the literature, in which benzyl ether groups were removed by catalytic reduction from a carbohydrate also carrying ester groups. Since no other method is available for removal of benzyl ethers without loss of ester groups, the benzyl ether does not appear to be a useful blocking group in the synthesis of partial esters of the methyl glucosides.

The use of (alkylthio)carbonyl derivatives can be combined with that of any acid-sensitive blocking groups, e.g., condensed aldehydes and ketones, or triphenylmethyl ethers. The action of (benzylthio)carbonyl chloride on 1,2-5,6-di-*O*-isopropylidene-D-glucofuranose (XV), Fig. 4, gave a crystalline (benzylthio)carbonyl derivative, 1,2-5,6-



XV R = —H

XVI R = —C(=O)SCH2Ø

FIG. 4.

di-*O*-isopropylidene-3-*O*-(benzylthio)carbonyl-D-glucofuranose (XVI).

The properties of the thiocarbonate group which contribute to its value as a blocking agent are the following: (1) (benzylthio)carbonyl chloride, prepared by the action of 1 mole of phosgene on benzyl mercaptan in aqueous alkali (3, 9), can be purified by distillation and is stable during storage; (2) thiocarbonates are introduced conveniently

and in high yield in pyridine solution; (3) (benzylthio)carbonyl derivatives are generally crystalline; (4) they are stable under mild acid conditions; and (5) they can be removed by oxidative cleavage or by alkaline hydrolysis.

Although (alkylthio)carbonyl derivatives other than the benzyl analogue are prepared with equal ease, use has been confined chiefly to the (benzylthio)carbonyl ester in this laboratory.

It has been found that treatment of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside with 1 mole of (benzylthio)carbonyl chloride gave a good yield of a crystalline monosubstituted (benzylthio)carbonyl derivative. This derivative increases even further the utility of the thiocarbonate as a precursor to partially esterified methyl glucosides. Investigations of this product will be reported in a later communication.

EXPERIMENTAL[3]

Methyl 2,3-Di-O-benzyl-4,6-di-O-benzoyl-α- and -β-D-glucopyranoside (XIII)

Methyl 4,6-*O*-benzylidene-β-D-glucopyranoside (I) was prepared according to the procedure of Freudenberg (10). It had m.p. 197–199°. This derivative was benzylated directly by the Zemplen procedure (11), the 2,3-di-*O*-benzyl derivative having m.p. 115–117°. The benzylidene group was removed by mild acid hydrolysis according to Bell and Lorber (12), furnishing methyl 2,3-di-*O*-benzyl-β-D-glucopyranoside (XII), m.p. 122–123°.

To 2.0 g XII in 10 ml anhydrous pyridine was added 2.5 ml benzoyl chloride, with cooling in ice bath. After standing overnight at room temperature, the product was isolated by pouring the solution into ice water, extracting the water with chloroform, and extracting the chloroform layer successively with excess 1 *N* hydrochloric acid, sodium bicarbonate solution, and finally with water. The chloroform layer was dried 0.5 hour over magnesium sulphate, filtered, and the chloroform evaporated *in vacuo*. As crystallized from ethanol, the product had m.p. 115–118°. After recrystallization it had m.p. 120–121° and $[\alpha]_D^{23}$ −7.5° (c = 1, $CHCl_3$). Anal. Calc. for $C_{35}H_{34}O_8$: C, 72.2; H, 5.84. Found: C, 70.8; H, 6.04.

The α-anomer was synthesized in the same manner and had m.p. 95–97° and $[\alpha]_D^{22}$ +20.5° (c = 1, $CHCl_3$). The product crystallized as long needles from methanol. Anal. Calc. for $C_{35}H_{34}O_8$: C, 72.4; H, 5.84. Found: C, 72.4; H, 6.04.

Repeated attempts to remove the benzyl ether groups from XIII by catalytic reduction using palladium, palladium on carbon, and platinum catalysts in various solvents resulted only in the recovery of starting materials.

1,2-5,6-Diisopropylidene-3-O-(benzylthio)carbonyl-D-glucofuranose (XVI)

To 2.0 g XV, m.p. 108–109°, in 5 ml anhydrous pyridine 1.2 ml II was added slowly with cooling in an ice bath. After standing several hours at room temperature, the product was worked up as usual. It crystallized from ligroin (unreacted diacetone glucose crystallizing out first from that solvent) after long standing in the refrigerator. The product had m.p. 66–67° and $[\alpha]_D^{22}$ −23.8° (c = 3, $CHCl_3$). Anal. Calc. for $C_{20}H_{26}O_7S$: C, 58.5; H, 6.34; S, 7.81. Found: C, 57.5; H, 6.46; S, 7.39.

(Benzylthio)carbonyl Chloride (II)

Compound II was prepared as described previously (3, 9), and had the following additional properties: $n_D^{22.5}$ 1.5748 and specific gravity 1.235.

Methyl 2,3-Di-O-(benzylthio)carbonyl-4,6-O-benzylidene-α-D-glucopyranoside (XVII)

To 6.0 g methyl 4,6-*O*-benzylidene-α-D-glucopyranoside in anhydrous pyridine was added 7.1 cc of II during 0.5 hour, with cooling in ice bath. It is essential that the pyridine be dry since II reacts preferentially with water in the presence of pyridine. The reaction can also be carried out entirely at room temperature with equivalent yields. The use of a larger excess of II resulted in increased yields.

The mixture was then allowed to come to room temperature during an additional 0.5 hour, after which it was poured into ice water. The product was extracted successively with dilute hydrochloric acid, twice with 0.5 *N* sodium hydroxide, and with water. The chloroform layer was dried over magnesium sulphate. Evaporation of the chloroform gave a sirup which crystallized as long needles from absolute ethanol, giving 10.0 g product with m.p. 130–133°. Two recrystallizations from ethanol gave 8.2 g (66%) having m.p. 133–134°. The product showed $[\alpha]_D^{22}$ +31.7° (c = 2, $CHCl_3$). Its melting point was not changed after recrystallization from methanol. Anal. Calc. for $C_{30}H_{30}O_8S_2$: C, 61.8; H, 5.16; S, 11.0. Found: C, 60.1; H, 5.44; S, 10.7.

[3]*All melting points are uncorrected. Solvents were removed in vacuo at 50°.*

Methyl 2,3-Di-O-(benzylthio)carbonyl-α-D-glucopyranoside (XVIII)

To 0.5 g of XVII in 20.0 cc of pure, dry acetone was added 6.0 cc of 0.20 *N* hydrochloric acid. The solution was refluxed and the optical rotation observed at 0.5-hour intervals. Although the material was not entirely soluble at room temperature initially, after 0.5 hour of refluxing it showed $[\alpha]_D$ +51°. A plot of the data log $(\alpha_{final}-\alpha)$ against time fits a final $[\alpha]_D$ of 87°. The solution was neutralized with barium carbonate after 3.5 hours' refluxing, the $[\alpha]_D$ being then +85.6°. The solution was filtered, evaporated to dryness, the sirup was taken up in anhydrous ether and filtered to remove additional insoluble salts. The product could not be obtained in crystalline form. It showed $[\alpha]_D^{22}$ +85.7° (c = 2, $CHCl_3$).

Methyl 2,3-Di-O-(benzylthio)carbonyl-4,6-di-O-benzoyl-α-D-glucopyranoside (XIX)

To 3.0 g of XVIII in 10 cc anhydrous pyridine was added 2.8 cc benzoyl chloride, with cooling in ice bath. The solution stood for 20 hours at room temperature. The reaction mixture was poured into ice water and isolated in the usual way. Evaporation of the chloroform solvent gave a sirup which failed to crystallize. It showed $[\alpha]_D^{22}$ +34.5° (c = 2, $CHCl_3$).

Methyl 4,6-Di-O-benzoyl-α-D-glucopyranoside (IX)

The product XIX from the previous experiment was dissolved in 15 cc glacial acetic acid. One gram of potassium acetate and 5.7 cc of 30% hydrogen peroxide solution were added. The reaction mixture stood at room temperature for 4 days, after which it was poured into water containing sufficient sodium bicarbonate to neutralize the acetic acid. The product was extracted into chloroform and the chloroform layer dried over magnesium sulphate. Evaporation of the chloroform gave a sirup which readily crystallized as fine needles from ether on the addition of petroleum ether. It showed m.p. 131–132°. Recrystallization from ethyl acetate – petroleum ether gave 1.35 g (55%) showing m.p. 133–133.5° and $[\alpha]_D^{22}$ +145.7° (c = 2, $CHCl_3$). Anal. Calc. for $C_{21}H_{22}O_8$: C, 62.8; H, 5.47. Found: C, 62.8; H, 5.44.

Methyl 2,3-Di-O-phenylcarbamyl-4,6-di-O-benzoyl-α-D-glucopyranoside (X)

To ½ g of IX dissolved in 10 cc anhydrous pyridine was added 1 cc of phenylisocyanate, and the mixture was warmed for 1 hour on the steam bath. After cooling, the reaction mixture was poured into ice water and isolated by the usual procedure. The product crystallized as needles from ethanol–water and had m.p. 154–155°. Recrystallization from ether – petroleum ether gave 0.71 g (90%) with m.p. 154–156°. The product showed $[\alpha]_D^{22}$ +56.5° (c = 2, $CHCl_3$). Anal. Calc. for $C_{35}H_{32}O_{10}N_2$: C, 65.7; H, 5.00; N, 4.38. Found: C, 66.6; H, 5.38; N, 4.10.

X from Methyl 2,3-Di-O-phenylcarbamyl-α-D-glucopyranoside

Methyl 2,3-di-*O*-phenylcarbamyl-4,6-*O*-benzylidene-α-D-glucopyranoside was prepared as described by Hearon, Hiatt, and Fordyce and had m.p. 216–217°. Reported (5) 216–217°. The benzylidene group was removed from 0.35 g by refluxing 5 hours in 20 cc acetone containing 6.0 cc 0.20 *N* hydrochloric acid. The product was recovered by the usual procedure, furnishing a sirup which was benzoylated directly, giving 0.13 g, crystallizing first from ethanol–water then from ether – petroleum ether. The product had m.p. 155–156° and $[\alpha]_D^{22}$ +56.7°. A mixed melting point with X from the previous experiment was not depressed.

Methyl 2,3-Di-O-(benzylthio)carbonyl-4,6-O-benzylidene-β-D-glucopyranoside (III)

This compound was prepared in 71% yield in the same manner as its alpha anomer, XVII, from methyl 4,6-*O*-benzylidene-β-D-glucopyranoside. The product was crystallized from a large quantity of ethanol and had m.p. 159–160° and $[\alpha]_D^{22}$ −54.75° (c = 2, $CHCl_3$). It was recrystallized from acetone – ether – petroleum ether and showed the same melting point. Anal. Calc. for $C_{30}H_{30}O_8S_2$: C, 61.8; H, 5.16; S, 11.0. Found: C, 61.8; H, 5.22; S, 10.87.

Methyl 2,3-Di-O-(benzylthio)carbonyl-β-D-glucopyranoside (IV)

One-half gram of III was treated with hydrochloric acid in acetone exactly as described for the alpha anomer while the reaction was observed polarimetrically. Five hours of reflux was required before the optical rotation was constant, its $[\alpha]_D$ then being +1.53°. The product, isolated as before, was obtained as a sirup with $[\alpha]_D^{22}$ +1.55° (c = 2, $CHCl_3$).

Methyl 2,3-Di-O-(benzylthio)carbonyl-4,6-di-O-benzoyl-β-D-glucopyranoside (V)

The product IV obtained from 4.0 g of III was benzoylated as described before for the alpha anomer. Evaporation of the chloroform gave a solid residue, which was triturated with a small amount of 95% ethanol and crystallized from 150 cc absolute ethanol, yielding 3.3 g (69%) of V, m.p. 115–116°. After recrystallization from methanol the product had m.p. 119–120° and $[\alpha]_D^{22}$ −10.7° (c = 2, $CHCl_3$). Anal. Calc. for $C_{37}H_{34}O_{10}S_2$: C, 63.3; H, 4.84; S, 9.13. Found: C, 63.1; H, 4.88; S, 9.23.

Methyl 4,6-Di-O-benzoyl-β-D-glucopyranoside (VI)

To 1.8 g of V dissolved in 20 cc glacial acetic acid containing 5 cc chloroform was added 4.2 cc 30% hydrogen peroxide and 0.6 g potassium acetate. After standing for 4 days at room temperature, the product was isolated as with the alpha anomer IX. The addition of water to an ethanol solution of the product gave 0.3 g of an unidentified product having m.p. 85° after recrystallization from ether – petroleum ether.

After the addition of more water to the filtrate and long standing, more crystalline material (needles) was obtained, giving 0.49 g (48%) with m.p. 135–137°. Recrystallization of the latter from ether – petroleum ether raised the melting point to 137–138°. The product had $[\alpha]_D^{22}$ +20.7° (c = 2, $CHCl_3$). Anal. Calc. for $C_{21}H_{22}O_8$: C, 62.8; H, 5.47. Found: C, 63.3; H, 5.50.

Methyl 2,3-Di-O-acetyl-4,6-di-O-benzoyl-β-D-glucopyranoside (VII)

To 0.30 g of VI in 5 cc anhydrous pyridine was added 1 cc of acetic anhydride. The solution was warmed 2 hours on the steam bath and cooled. On pouring the solution into ice water, a white solid was obtained which was recovered by filtration and washed with water. After crystallization twice from anhydrous ether there was obtained as prisms 0.26 g (72%) of VII, m.p. 165.5–166° and $[\alpha]_D^{22}$ −12.2° (c = 2, $CHCl_3$). Reported (4) for VII: m.p. 164–165° and $[\alpha]_D^{20}$ −5.8° (c = 2, $CHCl_3$).

Methyl 2,3-Di-O-(benzylthio)carbonyl-4,6-di-O-acetyl-β-D-glucopyranoside (VIII)

The benzylidene group was removed from 0.80 g of III as described before. The product was dissolved in 5 cc anhydrous pyridine and 2 cc acetic anhydride. After standing 24 hours at room temperature and warming 1 hour on the steam bath, the product was isolated in the usual manner. It crystallized as needles on standing in the presence of petroleum ether and was recrystallized twice from ether – petroleum ether, giving 0.60 g (75%) having m.p. 96–97° and $[\alpha]_D^{22}$ −3.0 (c = 2, $CHCl_3$). Anal. Calc. for $C_{27}H_{30}O_{10}S_2$: C, 56.0; H, 5.18; S, 11.1. Found: C, 55.6; H, 4.94; S, 11.3.

ACKNOWLEDGMENT

This investigation was carried out during the tenure of a Postdoctoral Fellowship supported by the National Science Foundation.

3,4-DIHYDRO-β-CARBOLINES

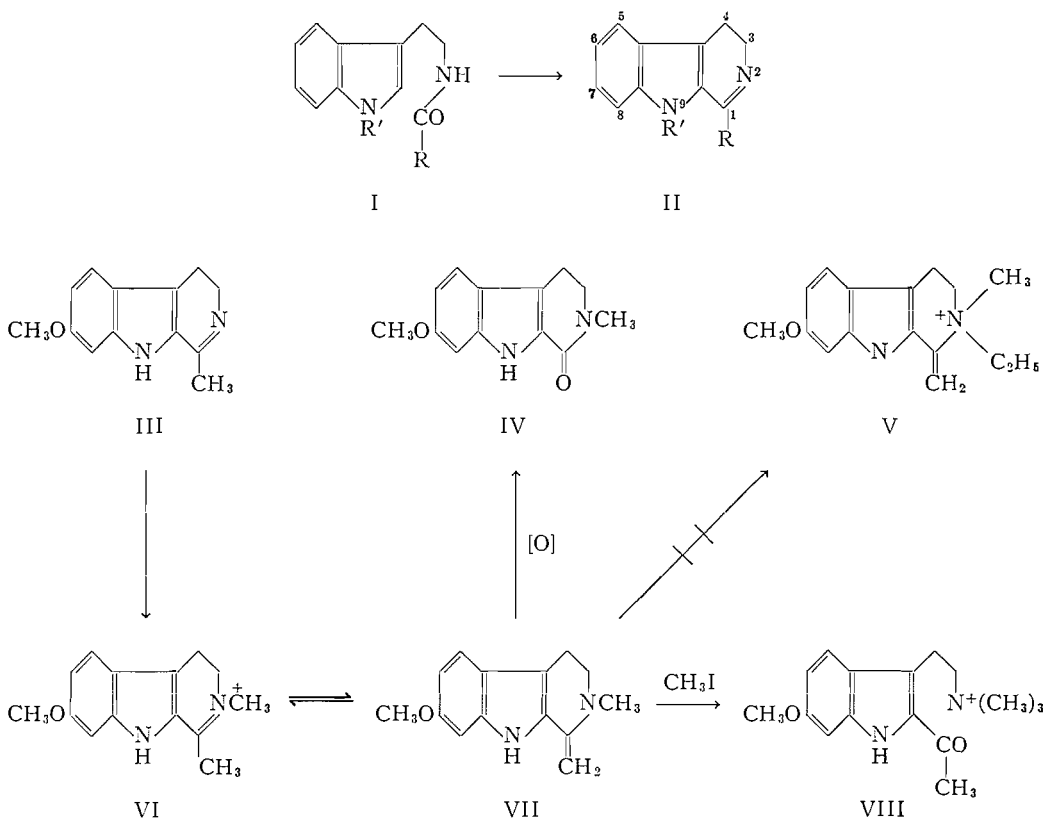
I. THE ALKYLATION OF 1-SUBSTITUTED N_β-ALKYL-3,4-DIHYDRO-β-CARBOLINE ANHYDRO BASES

R. N. Gupta and Ian D. Spenser
Department of Chemistry, McMaster University, Hamilton, Ontario
Received June 13, 1962

ABSTRACT

Methylation of the anhydro base derived from 1-methyl-3,4-dihydro-β-carboline methiodide is accompanied by ring opening and yields 3-[2-acetylindolyl]-β-ethyltrimethylammonium iodide, and not a 2,2-dialkyl-1-methylene-1,2,3,4-tetrahydro-β-carbolinium salt, as reported.

Present knowledge of the reactions of the 3,4-dihydro-β-carboline (II) ring system is due almost entirely to the classical work of the schools of Fischer (1–5) and of Perkin and Robinson (6–11) on the structure of the alkaloid harmaline (III). The most recent relevant reference quoted in a current review (12) dates back more than 30 years.



Harmaline (III) and a large number of other 1-substituted 3,4-dihydro-β-carbolines have been synthesized, almost invariably by Bischler–Napieralski ring closure of N-acyltryptamines (I) (13, 14). Three other methods of synthesis, based on cyclization of

2-acyltryptamines (10), and on controlled oxidation (7, 15) or dehydration (15) of suitably substituted 1,2,3,4-tetrahydro-β-carbolines, have so far found only limited application.

Alkylation studies in the 3,4-dihydro-β-carboline series have been carried out with harmaline (III) (1, 3, 5, 7, 9, 16). Quaternization of the base yielded the quaternary methiodide (VI), which on treatment with alkali gave an anhydro base, formulated as (VII) (9) because of its facile oxidation to the 1-oxoderivative (IV).

The structure of the anhydro base (VII) corresponds to that postulated for analogous 3,4-dihydroisoquinolines (cf. ref. 17) but differs markedly from that of the anhydro bases derived from 2-alkyl-β-carbolinium salts (18, and earlier references cited therein).

Reports on the course of further alkylation of 2-methylharmaline anhydro base (VII) are conflicting. On the one hand it was found by Fischer (5) that alkylation of harmaline (III) with methyl iodide in alcoholic solution yielded, in addition to the methiodide (VI), small amounts of another alkylation product of unknown structure, referred to as 'dimethylharmaline iodide', which on treatment with aqueous potassium hydroxide gave trimethylamine. On the other hand Konowalowa and Orechoff (16) claimed to have obtained alkali-stable salts of structure V by further alkylation of 2-alkylharmaline anhydro bases (e.g., VII).

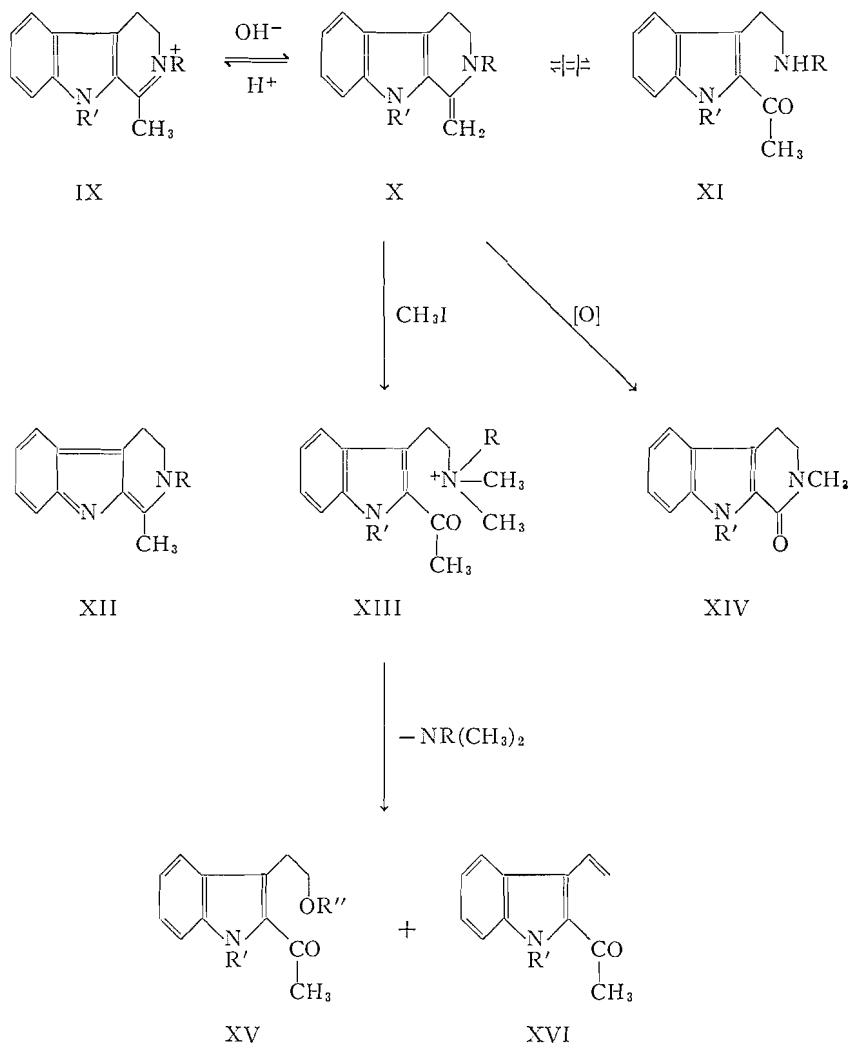
We have reinvestigated the alkylation of 3,4-dihydro-β-carboline derivatives. Compounds used in this study were 1-methyl- (15), 1-ethyl- (14), and 1,9-dimethyl-3,4-dihydro-β-carboline. The latter was prepared by our new method (15) from 1-hydroxymethyl-9-methyl-1,2,3,4-tetrahydro-β-carboline. The 3,4-dihydro-β-carbolines were purified by high-vacuum distillation, when, contrary to a recent report (19), no decomposition was observed.

The ultraviolet spectra of 1-methyl-, 1-ethyl- and 1,9-dimethyl-3,4-dihydro-β-carboline (II) showed the expected bathochromic shift (20) accompanying the transformation $C{=}N \rightarrow C{=}\overset{+}{N}H$. In alcoholic solution, or in the presence of base, the compounds absorbed at 315 mμ. In acid solution a strong band at 350 mμ, due to the dihydro-β-carbolinium ion, was observed (cf. ref. 15, Fig. 1). In the infrared region the compounds showed bands of medium intensity at 1600–1620 cm^{-1} due to C=N stretching vibrations (21). Absorption due to NH was absent in the Nujol spectra. Similarly only weak NH absorption had been observed in the spectrum of harmaline (22).

Treatment of the bases with alkyl iodide in benzene solution gave the corresponding alkiodides (IX) in good yield. The infrared absorption curves of these 2-alkyl-3,4-dihydro-β-carbolinium salts showed strong bands due to $C{=}\overset{+}{N}$ at 1615–1650 cm^{-1} (20, 21). Their ultraviolet curves in water and in acid were identical, and similar to those of the parent bases in acid solution except for the expected bathochromic shift of 5–10 mμ due to N-alkylation (cf. ref. 18).

In alkaline solution, curves similar to those of the parent bases and that of 2-formylindole were obtained (cf. ref. 18, Fig. 4). Formation of anhydro bases of the accepted enamine (X) or of a ketoamine (XI) structure could account for this type of spectrum. Since the 9-methyl derivative also gave this absorption, an anhydro base structure (XII), of the type obtained in the β-carboline series, formation of which requires deprotonation at the indole nitrogen, is excluded.

The anhydro bases (X) were obtained as oily or amorphous yellow solids when an aqueous solution of the corresponding quaternary salt (IX) was treated with sodium hydroxide solution. The anhydro base derived from the methiodide of 1-methyl-3,4-dihydro-β-carboline was purified by distillation and obtained as a light yellow solid



which darkened on keeping. Analysis showed the absence of oxygen and tends to eliminate a ketoamine structure (XI). The anhydro base from 1,9-dimethyl-3,4-dihydro-β-carboline methiodide oxidized on distillation. The small amount of distillate showed an ultraviolet spectrum with a band at 310 mμ, unaffected by change of pH, and an infrared spectrum identical with that of authentic 2,9-dimethyl-1-oxo-1,2,3,4-tetrahydro-β-carboline (XIV, R′ = CH_3) (23). An analogous compound, 2-methyl-1-oxo-1,2,3,4-tetrahydro-β-carboline (XIV, R′ = H), was obtained (23) by oxidation of the anhydro base derived from 1-methyl-3,4-dihydro-β-carboline methiodide.

The infrared spectra of the anhydro bases showed bands at 1625–1655 cm^{-1} which were not of high enough intensity to be attributable to carbonyl absorption; these bands are presumably due to C=C stretching vibrations. Infrared evidence thus also eliminates a ketoamine structure (XI). In accord with the known behavior of anhydro bases, all of which revert in ionizing solvents to the quaternary ion from which they are derived (cf. ref. 18 and earlier references cited therein), the ultraviolet absorption of the compounds

was that of the 3,4-dihydro-β-carbolinium ion, not only in acid solution, but also in ethanol. In non-ionizing solvents, such as ether and chloroform, and in alcoholic sodium hydroxide solution, absorption curves of the free anhydro bases, identical with those given by the parent salt in alkaline solution, were obtained.

Further alkylation of the anhydro bases is not as facile a reaction as reported by Konowalowa and Orechoff (16), who claimed to have obtained an almost theoretical yield of 2,2-dialkylated salts of structure V, when a 2-alkylharmaline anhydro base (VII) was refluxed with alkyl halide in alcoholic solution. We have found that alkylation does not take place readily under these conditions. The crystalline products which were obtained proved to be pure 3,4-dihydro-β-carbolinium alkiodides (IX) to which the anhydro bases had reverted. The hydriodic acid required for this reversal was presumably generated by solvolysis of the alkylating agent.

Alkylation of the enamine carbon atom, found in anhydro bases derived from fully aromatic systems in which N-alkylation would result in loss of ring resonance (e.g., ref. 24), and also known to compete with N-alkylation in some aliphatic enamine systems (e.g., ref. 25), was not observed. The ultraviolet spectra of the mother liquors from these alkylation experiments did show additional absorption at 310 mμ in acid solution. The compounds giving rise to this absorption were obtained as the major reaction products when alkylation was carried out under basic conditions.

Methylation of the anhydro bases in aqueous alcoholic potassium carbonate suspension gave a new quaternary salt in each case. These new compounds showed intense carbonyl absorption at 1645 cm^{-1}, and their ultraviolet spectra were unaffected by change of pH and were similar to that of 2-formylindole. Thus the anhydro base X (R = CH_3, R′ = H) gave a compound $C_{15}H_{21}IN_2O$ (XIII, R = CH_3, R′ = H) and the anhydro base X (R = n-C_3H_7, R′ = H) a compound $C_{17}H_{25}IN_2O$ (XIII, R = n-C_3H_7, R′ = H). On Hofmann degradation these yielded, respectively, trimethylamine and dimethyl-n-propylamine, characterized as picrates. Alkylation had thus taken place at N_β, and the methylation products must be formulated as 3-[2-acetylindolyl]-β-ethyltrialkylammonium iodides (XIII).

The neutral fragments from the Hofmann degradation of the two compounds were identical. They consisted of a mixture of the displacement product, 2-acetyl-3-[β-alkoxyethyl]-indole (XV, R′ = H), whose constitution, with respect to the ether group R″, depended on the alcohol used as a solvent in the experiment, and of the elimination product, 2-acetyl-3-vinylindole (XVI, R′ = H), which proved difficult to isolate. The ethers showed ultraviolet absorption curves, unaffected by change of pH, similar to that of 2-formylindole, and in the infrared had strong carbonyl absorption at 1660 cm^{-1} and ether absorption at 1000–1200 cm^{-1}. Methylation of the anhydro base derived from 1,9-dimethyl-3,4-dihydro-β-carboline methiodide (X, R = R′ = CH_3) yielded 3-[2-acetyl-1-methylindolyl]-β-ethyltrimethylammonium iodide, $C_{16}H_{23}IN_2O$ (XIII, R = R′ = CH_3), which on Hofmann degradation gave trimethylamine and 2-acetyl-1-methyl-3-vinylindole (XVI, R′ = CH_3). The infrared spectrum of this compound showed bands due to carbonyl (1650 cm^{-1}) and due to vinyl (912, 992 cm^{-1}) absorption, and in the ultraviolet region an intensification of absorption at 325 mμ was observed, consistent with the constitution of the compound.

No evidence for structures corresponding to V, of the type postulated by Konowalowa and Orechoff (16), was obtained. This structure was put forward on the basis of the supposed identity of two quaternary iodides obtained respectively by methylation of 2-ethylharmaline anhydro base and ethylation of 2-methylharmaline anhydro base. The

reported criteria of identity, mixed melting points and incomplete analysis (iodine only), were obviously inadequate. The fact that these products were obtained under conditions which have now been shown to lead to reconversion of the anhydro bases to their parent salts indicates that the compounds obtained by Konowalowa and Orechoff were in fact harmaline methiodide (VI) and ethiodide, and not dialkylated salts.

Fischer's 'dimethylharmaline iodide' (5), on the other hand, was presumably the quaternary salt (VIII), 3-[2-acetyl-6-methoxyindolyl]-β-ethyltrimethylammonium iodide.

EXPERIMENTAL

1-Alkyl-3,4-dihydro-β-carbolines

1-Methyl-3,4-dihydro-β-carboline (Harmalan)

Harmalan was obtained by dehydration of 1-hydroxymethyl-1,2,3,4-tetrahydro-β-carboline (15).

1-Ethyl-3,4-dihydro-β-carboline

This base was prepared by dehydration of N_β-propionyltryptamine, as described by Späth and Lederer (14).

1,9-Dimethyl-3,4-dihydro-β-carboline

The starting material for this preparation was ind-N-methyltryptamine, which was prepared by the gramine route from N-methylindole (26). The latter was obtained by lithium aluminum hydride reduction of N-methylindoxyl (27).

1-Hydroxymethyl-9-methyl-1,2,3,4-tetrahydro-β-carboline.—A solution of ind-N-methyltryptamine (3.4 g) and glycolaldehyde (1.27 g) in 200 ml water containing 20 ml 2 *N* hydrochloric acid was refluxed for 2 hours. The solution was decolorized, extracted with ether to remove non-basic impurities, and made alkaline with sodium hydroxide. A dark brown solid was obtained, which was dissolved in ethanol, decolorized, and crystallized from aqueous ethanol. It sublimed at 2.10^{-3} mm and 140–160° to give *1-hydroxymethyl-9-methyl-1,2,3,4-tetrahydro-β-carboline* (3 g, 70%) as a colorless crystalline solid melting at 144°. (Found: C, 72.4; H, 7.7; N, 13.1. $C_{13}H_{16}N_2O$ requires: C, 72.2; H, 7.5; N, 13.0%.)

1,9-Dimethyl-3,4-dihydro-β-carboline.—The above tetrahydro-β-carboline (2.5 g) was wetted with water, 85% phosphoric acid (30 ml) was added, and the mixture was kept on the steam bath until the absorption band at 280 mμ, characteristic of the indole chromophore of the starting material, had disappeared (4 hours). The dark brown solution was diluted with water, decolorized, and made alkaline with 20% sodium hydroxide, and the product was extracted into ether. The extract was dried, ether was removed, and the solid residue was dissolved in methanol. The solution was decolorized and evaporated and the residue was sublimed at 2.10^{-3} mm and 90° to yield 1,9-dimethyl-3,4-dihydro-β-carboline (1.2 g, 58%), melting at 80–84°, as a colorless solid. (Found: C, 78.8; H, 7.4; N, 14.2. Calc. for $C_{13}H_{14}N_2$: C, 78.8; H, 7.1; N, 14.1%.) (Reported melting point (14): 91–92°.) Infrared absorption (Nujol) (cm^{-1}): 1610 (m) (C=N). Ultraviolet absorption (λ_{max}, mμ (log ε)): in 0.1 *N* HCl: 352 (4.2), 250 (4.0); in 0.1 *N* NaOH: 318 (4.0).

1-Alkyl-3,4-dihydro-β-carboline Alkiodides and Anhydro Bases Derived from These Salts

1-Methyl-3,4-dihydro-β-carboline Methiodide (Harmalan Methiodide)

Harmalan (0.5 g) was suspended in nitrobenzene (5 ml), and benzene (100 ml) was added when a clear solution was obtained. Methyl iodide (2 ml) was added and the mixture was kept at 37° for 48 hours. A yellow precipitate was obtained which was crystallized from methanol after treatment with charcoal, yielding light yellow needles of the *methiodide* (0.8 g, 80%) melting at 288–290°. (Found: C, 47.8; H, 4.7; N, 8.7. $C_{13}H_{15}IN_2$ requires: C, 47.8; H, 4.6; N, 8.6%.) Infrared absorption (Nujol) (cm^{-1}): 3130 (m) (NH); 1618 (s) ($C{=}\overset{+}{N}$). Ultraviolet absorption (λ_{max}, mμ (log ε)): in 0.1 *N* HCl: 355 (4.3), 250 (4.1); in 0.1 *N* NaOH: 315 (4.2).

Anhydro base derived from 1-methyl-3,4-dihydro-β-carboline methiodide (i.e., 2-methyl-1-methylene-1,2,3,4-tetrahydro-β-carboline).—An aqueous solution of harmalan methiodide (0.5 g) was treated with 20% sodium hydroxide, when a yellow turbidity appeared. The solution was extracted with ether, the ether extract was dried and concentrated, and the residue distilled at 2.10^{-3} mm and 110–120° to give the *anhydro base*, melting at 115° after sintering at 105°, as a colorless solid which turned yellow on standing. (Found: C, 78.6; H, 7.2; N, 14.0. $C_{13}H_{14}N_2$ requires: C, 78.8; H, 7.1; N, 14.1%.) Infrared absorption (Nujol) (cm^{-1}): 3410 (m) (NH); 1625 (m) (C=C).

1-Methyl-3,4-dihydro-β-carboline n-Propiodide

Harmalan (0.5 g) was dissolved in a mixture of nitrobenzene (10 ml) and benzene (100 ml). 1-Iodopropane (3 ml) was added and the solution kept at 37° for 72 hours. An orange precipitate was obtained which crystallized from methanol after treatment with charcoal to yield *1-methyl-3,4-dihydro-β-carboline n-propiodide* (0.73 g, 70%) melting at 269–270°. (Found: C, 50.7; H, 5.5; N, 7.9. $C_{15}H_{19}IN_2$ requires: C, 50.8; H, 5.4;

N, 7.9%.) Infrared absorption (Nujol) (cm^{-1}): 3130 (m) (NH); 1615 (s) ($C{=}\overset{+}{N}$). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)): in 0.1 *N* HCl: 360 (4.4), 250 (4.1); in 0.1 *N* NaOH: 320 (4.2).

Anhydro base derived from 1-methyl-3,4-dihydro-β-carboline n-propiodide (i.e., 1-methylene-2-n-propyl-1,2,3,4-tetrahydro-β-carboline).—Treatment of an aqueous solution of harmalan propiodide with 20% sodium hydroxide gave a brown solid, melting at 104–106°, which darkened on drying in air. Sublimation under reduced pressure gave a glassy solid, which was not analyzed. Infrared absorption (Nujol) (cm^{-1}): 3410 (m) (NH); 1630 (m) (C=C).

1-Ethyl-3,4-dihydro-β-carboline Methiodide

1-Ethyl-3,4-dihydro-β-carboline (0.5 g), dissolved in a mixture of benzene (100 ml) and nitrobenzene (10 ml), was incubated at 40° with methyl iodide (2 ml). After 48 hours the yellow crystalline product was separated, washed with benzene and with ether, and recrystallized from ethanol, to yield the *methiodide* (0.64 g, 73%) as yellow needles, melting at 221–222°. (Found: C, 49.1; H, 5.2. $C_{14}H_{17}IN_2$ requires: C, 49.4; H, 5.0%.) Infrared absorption (Nujol) (cm^{-1}) 3100 (m) (NH); 1615 (s) ($C{=}\overset{+}{N}$). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)): in 0.1 *N* HCl: 355 (4.2); in 0.1 *N* NaOH: 315 (4.2).

1,9-Dimethyl-3,4-dihydro-β-carboline Methiodide

1,9-Dimethyl-3,4-dihydro-β-carboline (0.5 g) was treated with methyl iodide (2 ml) in 100 ml benzene and allowed to stand for 24 hours at 39°. A yellow solid was obtained, which was crystallized from water after treatment with charcoal, yielding the *methiodide* (0.8 g, 80%) in yellow needles melting at 216–218°. (Found: C, 49.6; H, 5.4; N, 7.9. $C_{14}H_{17}IN_2$ requires: C, 49.4; H, 5.0; N, 8.2%.) Infrared absorption (Nujol) (cm^{-1}): 1661 (m) ($C{=}\overset{+}{N}$). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)): in 0.1 *N* HCl: 355 (4.2), 250 (4.0); in 0.1 *N* NaOH: 310 (4.0).

Anhydro base derived from 1,9-dimethyl-3,4-dihydro-β-carboline methiodide (i.e., 2,9-dimethyl-1-methylene-1,2,3,4-tetrahydro-β-carboline).—The above methiodide (0.4 g) was dissolved in hot water and treated with 20% sodium hydroxide, when the anhydro base separated as a colorless solid which discolored rapidly on standing.

A sample of the product was distilled at 2.10^{-3} mm. The major portion decomposed but a small amount of distillate was obtained which showed ultraviolet and infrared absorption spectra identical with those of an authentic sample of 1-oxo-2,9-dimethyl-1,2,3,4-tetrahydro-β-carboline (23).

Exhaustive Methylation of 3,4-Dihydro-β-carboline Anhydro Bases

Further Methylation of 2-Methyl-1-methylene-1,2,3,4-tetrahydro-β-carboline

Attempted methylation in methanol solution.—Harmalan methiodide (0.20 g) was dissolved in hot water, 20% sodium hydroxide added, the solution was cooled and extracted with ether, and the dried ether extract concentrated. The residue was dissolved in methanol (10 ml), methyl iodide (2 ml) was added, and the mixture was refluxed 6 hours. Concentration of the reaction mixture and recrystallization of the residue from methanol gave harmalan methiodide (0.11 g, 55%), melting at 286°. (Found: C, 48.0; H, 4.7; N, 8.8. Calc. for $C_{13}H_{15}IN_2$: C, 47.8; H, 4.6; N, 8.6%.)

3-[2-Acetylindolyl]-β-ethyltrimethylammonium iodide.—Harmalan methiodide (1.0 g) was dissolved in hot water, 20% sodium hydroxide added, the solution cooled and extracted with ether. The ether extract was dried, solvent evaporated, and the residue dissolved in 50 ml moist methanol. Potassium carbonate (0.4 g) and methyl iodide (5 ml) were added. The mixture was kept for 24 hours at 40°. The solvent was evaporated and the residue washed with cold water and crystallized from 50% aqueous methanol after treatment with charcoal. Pale yellow plates (0.88 g, 70%) of the *quaternary salt*, melting at 278°, were obtained. (Found: C, 48.0; H, 5.4; N, 7.4. $C_{15}H_{21}IN_2O$ requires: C, 48.4; H, 5.7; N, 7.5%.) Infrared absorption (Nujol) (cm^{-1}): 3280 (m) (NH); 1660 (vs) (C=O). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)): in 0.1 *N* HCl and 0.1 *N* NaOH: 315 (4.1), 242 (4.1).

Hofmann degradation of 3-[2-acetylindolyl]-β-ethyltrimethylammonium iodide with methanolic potassium hydroxide.—The above quaternary salt (0.70 g) was treated with 2% methanolic potassium hydroxide (40 ml). The solution was kept at 50°, a current of nitrogen was passed for 4 hours, and the issuing gas passed through an alcoholic solution of picric acid. Concentration of the picric acid solution gave a picrate (0.45 g) melting at 216° (decomp.) after recrystallization from methanol, which was identified as trimethylamine picrate by comparison with an authentic sample and by analysis. (Found: C, 37.7; H, 4.1; N, 19.2. Calc. for $C_9H_{12}N_4O_7$: C, 37.5; H, 4.2; N, 19.4%.)

The reaction mixture was evaporated, water was added to the residue, the solution was extracted with ether, and the ether extract dried and evaporated. The residue was dissolved in benzene and applied to an alumina column. The column was eluted with benzene and the colorless eluate collected and evaporated, when *2-acetyl-3-[β-methoxyethyl]-indole* (0.10 g) was obtained as a colorless residue melting at 140°. (Found: OCH_3, 14.1; C, 71.7; H, 7.3; N, 6.2. $C_{13}H_{15}NO_2$ requires: OCH_3, 14.3; C, 71.9; H, 7.0; N, 6.5%.) Infrared absorption (Nujol) (cm^{-1}): 3250 (m) (NH); 1660 (vs) (C=O); 1028 (m), 1065 (m), 1090 (s) (OCH_3). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)): in 0.1 *N* HCl and in 0.1 *N* NaOH: 315 (4.1).

Hofmann degradation of 3-[2-acetylindolyl]-β-ethyltrimethylammonium iodide with ethanolic potassium hydroxide.—The quaternary salt was degraded as before with ethanolic potassium hydroxide. The basic

fragment was isolated as trimethylamine picrate and the neutral fragment was *2-acetyl-3-[β-ethoxyethyl]-indole*, isolated as a colorless solid, melting at 118°. (Found: OC_2H_5, 18.4; C, 72.4; H, 7.9; N, 6.1. $C_{14}H_{17}NO_2$ requires: OC_2H_5, 19.5; C, 72.7; H, 7.4; N, 6.1%.) Infrared absorption (Nujol) (cm^{-1}): 3230 (m) (NH); 1664 (vs) (C=O); 1032 (m), 1065 (m), 1090 (vs) (OC_2H_5). Ultraviolet absorption (λ_{max}, mμ (log ϵ)): in 0.1 *N* HCl and in 0.1 *N* NaOH: 315 (4.1).

Further Methylation of 1-Methylene-2-n-propyl-1,2,3,4-tetrahydro-β-carboline

3-[2-Acetylindolyl]-β-ethyldimethyl-n-propylammonium iodide.—Harmalan propiodide (1.0 g) was dissolved in hot water, treated with sodium hydroxide, the anhydro base extracted into ether and quaternized with methyl iodide as described earlier. The *quaternary salt* was isolated as pale yellow plates (0.87 g, 70%) melting at 197°. (Found: C, 51.1; H, 6.5; N, 6.6; I, 31.9. $C_{17}H_{25}IN_2O$ requires: C, 51.0; H, 6.3; N, 7.0; I, 31.8%.) Infrared absorption (Nujol) (cm^{-1}): 3390 (m, broad) (NH); 1640 (vs) (C=O). Ultraviolet absorption (λ_{max}, mμ (log ϵ)): in 0.1 *N* HCl and in 0.1 *N* NaOH: 315 (4.1).

Hofmann degradation of 3-[2-acetylindolyl]-β-ethyldimethyl-n-propylammonium iodide.—Treatment of the above quaternary salt with methanolic and ethanolic potassium hydroxide in the usual manner, and purification of the degradation products as before gave 2-acetyl-3-[β-methoxyethyl]-indole and 2-acetyl-3-[β-ethoxyethyl]-indole respectively, identical with those obtained by degradation of the corresponding trimethylammonium salt. The corresponding compounds had identical melting points and gave overlapping infrared spectra.

Isolation of dimethyl-n-propylamine picrate.—As before, the volatile degradation products were swept into an alcoholic solution of picric acid by means of a stream of nitrogen. After concentration of the solution dimethyl-*n*-propylamine picrate was obtained as lemon yellow plates melting at 108–109°, after recrystallization from ethyl acetate. (Found: C, 42.0; H, 5.3; N, 17.3. Calc. for $C_{11}H_{16}N_4O_7$: C, 41.8; H, 5.1; N, 17.7%.) There was no depression in the melting point on admixture of an authentic sample of dimethyl-*n*-propylamine picrate.

Further Methylation of 2,9-Dimethyl-1-methylene-1,2,3,4-tetrahydro-β-carboline

3-[2-Acetyl-1-methylindolyl]-β-ethyltrimethylammonium iodide.—Anhydro base, obtained from 0.5 g 1,9-dimethyl-3,4-dihydro-β-carboline methiodide, was dissolved in 25 ml methanol. Methyl iodide (2 ml) and potassium carbonate (0.4 g) were added and the reaction mixture was kept at 40° for 24 hours. The monohydrate of the *quaternary salt* (0.35 g, 62%), melting at 215–216°, crystallized from aqueous methanol. (Found: C, 48.0; H, 6.4; N, 7.2; I, 32.1. $C_{16}H_{23}IN_2O,H_2O$ requires: C, 47.5; H, 6.2; N, 6.9; I, 31.4%.) Infrared absorption (Nujol) (cm^{-1}): 1640 (vs) (C=O). Ultraviolet absorption (λ_{max}, mμ (log ϵ)): in 0.1 *N* HCl and in 0.1 *N* NaOH: 315 (4.1).

Hofmann degradation of the quaternary salt.—The above quaternary salt (0.2 g) was treated with 5% methanolic potassium hydroxide (20 ml) in the usual manner. The basic fragment was isolated and identified as trimethylamine picrate.

The reaction mixture was evaporated, water was added to the residue, the solution was extracted with ether, and the extract dried and evaporated. The residue was dissolved in methanol, the solution decolorized with charcoal and again evaporated. The residue was sublimed at 3.10^{-3} mm and 70°, when pale yellow crystals (0.02 g) of *2-acetyl-1-methyl-3-vinylindole* melting at 54° were obtained. (Found: C, 78.7; H, 6.9; N, 6.8. $C_{13}H_{13}NO$ requires: C, 78.4; H, 6.6; N, 7.0%.) Infrared absorption (Nujol) (cm^{-1}): 1650 (vs) (C=O); 1605 (s) (C=C); 912 (m), 992 (m) (vinyl).

3,4-DIHYDRO-β-CARBOLINES

II. THE EXHAUSTIVE METHYLATION OF 3,4-DIHYDRO-β-CARBOLINE

R. N. GUPTA AND IAN D. SPENSER
Department of Chemistry, McMaster University, Hamilton, Ontario

Received June 13, 1962

ABSTRACT

The methiodide of 3,4-dihydro-β-carboline yields a dimeric anhydro base which, on heating, disproportionates to a β-carboline and a tetrahydro-β-carboline derivative, and on methylation is converted to 3-[2-formylindolyl]-β-ethyltrimethylammonium iodide.

Although a large number of 1-substituted 3,4-dihydro-β-carbolines have been synthesized (1, 2), the parent base itself (II, R=H) has not been well characterized. 3,4-Dihydro-β-carboline was first obtained (3) by degradation of evodiamine. It was isolated as a tarry mass, which yielded a picrate, and was identified by oxidation to β-carboline (4). Attempted synthesis by conventional Bischler–Napieralski ring closure of N_β-formyltryptamine (I, R = H) gave an uncharacterized product in 2% yield (2). The base was later obtained by this method in 36% yield as an amorphous powder of indeterminate melting point, yielding a picrate and a perchlorate (5).

Crude 3,4-dihydro-β-carboline (II, R = H) has now been obtained in 50% yield from N_β-formyltryptamine (I, R = H), using polyphosphoric acid as the dehydrating agent. The compound resisted purification because of its sensitivity towards aqueous acid and its tendency to polymerization. Analysis of the free base was unsatisfactory. The methiodide, however, showed the expected composition. 9-Methyl-3,4-dihydro-β-carboline (II, R = CH_3), obtained from N_β-formyl-1-methyltryptamine (I, R = CH_3), behaved similarly. The ultraviolet absorption curves of both compounds (Fig. 1) were similar to those of 1-alkyl-3,4-dihydro-β-carbolines (6), and the infrared spectra were also consistent with the assigned structure.

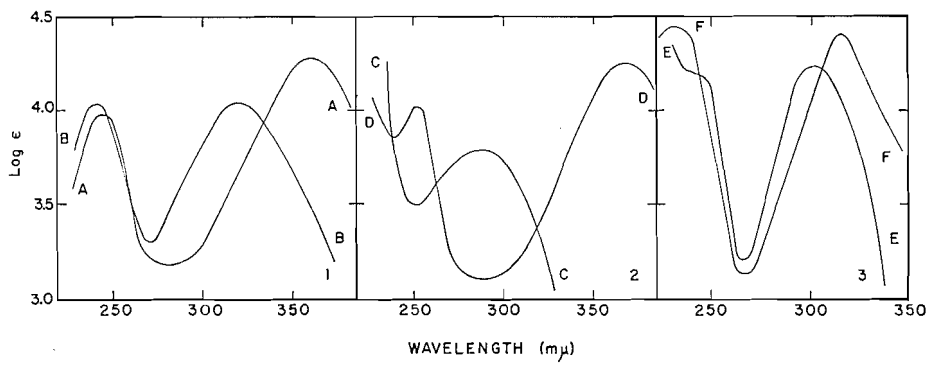

FIG. 1. 3,4-Dihydro-β-carboline (norharmalan). Curve A, in 0.1 *N* HCl in aqueous ethanol; curve B, in 0.1 *N* NaOH in aqueous ethanol.
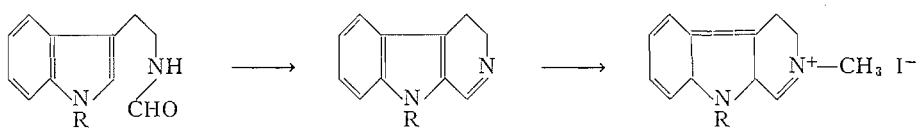
FIG. 2. 3,4-Dihydro-β-carboline methiodide. Curve C, in 0.1 *N* NaOH in aqueous ethanol; curve D, in 0.1 *N* HCl in aqueous ethanol.
FIG. 3. Curve E: 2-methyl-1-oxo-1,2,3,4-tetrahydro-β-carboline in 0.1 *N* HCl in aqueous ethanol. Curve F: 2-formylindole in ethanol (20).

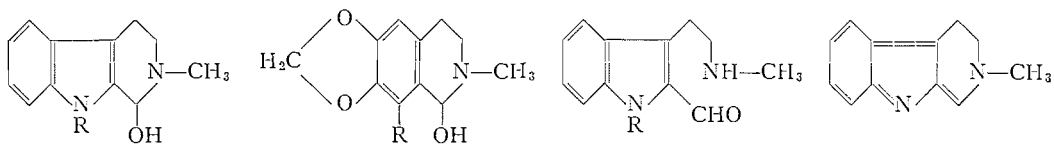
The difficulties encountered in the purification of the bases are in line with experience with analogous compounds of the dihydroisoquinoline series (7). A trimer, corresponding in structure to N,N′,N″-triphenylethylaminomalonamide (8), a substance obtained as a by-product in the cyclodehydration of N-formylphenylethylamine, was not detected in the intractable by-products of the present preparations.



I II III

Treatment of the compounds with methyl iodide gave the corresponding methiodides (III) in good yield. The infrared curves of these 2-methyl-3,4-dihydro-β-carbolinium salts showed strong $C{=}\overset{+}{N}$ absorption at 1640 cm^{-1} (cf. ref. 9). Their ultraviolet absorption in alcohol and in 0.1 *M* acid was identical (Fig. 2, curve D), and similar to that of the parent bases in acid solution (Fig. 1, curve A). In alkaline solution absorption characteristic of indole was obtained (Fig. 2, curve C). This spectral change is consistent with the formation of pseudobases of structure IV, i.e., of 1-hydroxy-2-methyl-1,2,3,4-tetrahydro-β-carbolines, analogous in constitution to the pseudobases of the 3,4-dihydroisoquinoline series, such as hydrastinine (V, R = H) and cotarnine (V, R = OCH_3). This type of spectrum eliminates an aldehyde–amine formulation (VI), which would be expected to show absorption similar to that of 2-formylindole (Fig. 3, curve F). An anhydro base structure (VII) of the β-carboline type, formation of which would require deprotonation at the indole nitrogen, is also excluded, since the 9-methyl derivative also gave an indole spectrum in alkaline solution.

The compounds containing the indole chromophore were isolated when the parent salts were treated with aqueous alkali.



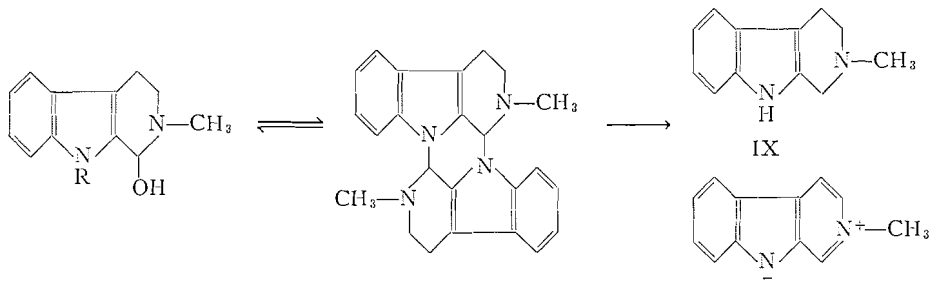
IV V VI VII

The 'pseudobase' derived from 3,4-dihydro-β-carboline methiodide was a colorless solid, melting at 185°. In non-aqueous solvents and in alkaline solution the compound gave an ultraviolet spectrum similar to that of indole. In aqueous acid the 3,4-dihydro-β-carbolinium spectrum of the parent salt was observed. Such behavior is characteristic of pseudobases and anhydro bases in general. The infrared spectrum of the compound did not show carbonyl absorption, confirming the absence of the aldehyde–amine structure VI, nor bands attributable to OH and NH. This lack of OH and NH absorption is not conclusive evidence against the carbinolamine structure IV (R = H). The absence of NH absorption in Nujol spectra of other 3,4-dihydro-β-carbolines has been noted (6), and a lack of OH absorption has been observed in other pseudobasic carbinolamines, such as hydrastinine (10) and cotarnine (11), while only very weak OH bands were observed in the infrared spectrum of vomalidine (12). Elementary analysis, although low in carbon,

indicated that carbon, hydrogen, and nitrogen fully accounted for the composition of the compound, which cannot therefore be represented either as the pseudobase (IV, R = H), or as an 'ether base' (cf. ref. 13).

Molecular weight determination showed the compound to be dimeric. The weight of evidence favors formulation of the product as a dimeric anhydro base (VIII). A similar dimeric structure has been proposed for a derivative obtained by dehydration of 1-hydroxy-1,2,3,4-tetrahydrocarbazole (14).

A chemical property of the compound, which is accounted for by this dimeric structure, is an unusual pyrolytic disproportionation reaction. On high-vacuum distillation the compound decomposes into 2-methyl-1,2,3,4-tetrahydro-β-carboline (IX) and 2-methyl-β-carboline anhydro base (X), whose identities were confirmed by comparison with authentic



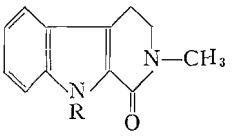
IV, R = H VIII X

samples (see refs. 15 and 16 respectively). 1-Phenyl-3,4-dihydroisoquinoline is known to undergo a similar pyrolytic disproportionation (17). Recently (18) such a disproportionation has been ascribed also to 1-methyl-3,4-dihydro-β-carboline to account for the chromatographic detection of 1-methyl-β-carboline, 1-methyl-3,4-dihydro-β-carboline, and 1-methyl-1,2,3,4-tetrahydro-β-carboline amongst the distillation products of 1-methyl-3,4-dihydro-β-carboline-3-carboxylic acid. 1-Methyl-3,4-dihydro-β-carboline has now been found (6) to distill without decomposition, however, and another explanation for the appearance of these decomposition products of the carbolinecarboxylic acid is therefore required.

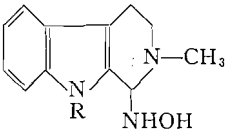
9-Methyl-3,4-dihydro-β-carboline methiodide (III, R = CH_3), on treatment with alkali, gave the corresponding pseudobase (IV, R = CH_3) as a low-melting solid which decomposed on attempted distillation. The small amount of distillate consisted of an oxidation product, 2,9-dimethyl-1-oxo-1,2,3,4-tetrahydro-β-carboline (XI, R = CH_3), identical in infrared and ultraviolet absorption with an authentic specimen obtained by oxidation of 2,9-dimethyl-3,4-dihydro-β-carboline pseudobase (IV, R = CH_3) with alkaline ferricyanide. The same compound was also obtained as a minor product when the pseudobase was refluxed in alkaline solution, conditions which left the major portion of the starting material unchanged. Neither the dimeric anhydro base (VIII) nor the pseudobase (IV, R = CH_3) underwent base-catalyzed disproportionation to the 1,2,3,4-tetrahydro and the 1-oxo-1,2,3,4-tetrahydro derivatives,[1] analogous to the well-known conversion of hydrastinine to hydrohydrastinine and oxohydrastinine (19). This may be related to the fact that 2-formylindole does not appear to undergo the Cannizzaro reaction (20).

[1]*An authentic specimen of 2-methyl-1-oxo-1,2,3,4-tetrahydro-β-carboline (XI, R = H) was prepared by oxidation of harmalan methiodide.*

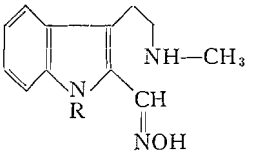
The dimeric anhydro base (VIII) and the pseudobase (IV, R = CH_3) reacted with hydroxylamine to yield products whose infrared spectra did not show oxime absorption and must therefore be formulated as 1-hydroxylamino-1,2,3,4-tetrahydro-β-carboline derivatives (XII), rather than as derivatives of the oxime of indole-2-aldehyde (XIII).



XI



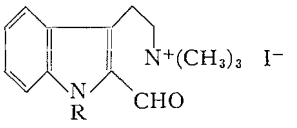
XII



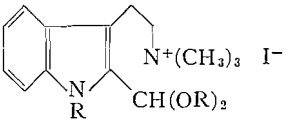
XIII

This accords with recent work (10, 11) on the structure of the hydroxylamine adducts of hydrastinine and cotarnine. The ultraviolet spectra of the hydroxylamine adducts, however, were similar to that of 2-formylindole rather than indole. This would appear to favor their existence in solution as XIII.

Methylation of the dimeric anhydro base and of the pseudobase in aqueous methanolic potassium carbonate suspension gave quaternary salts $C_{12}H_{19}IN_2O$ and $C_{15}H_{21}IN_2O$, respectively, which showed intense carbonyl absorption in the infrared, and whose ultraviolet absorption curves were similar to that of 2-formylindole. On Hofmann degradation both compounds yielded trimethylamine. From the neutral fraction of the Hofmann degradation, 2-formyl-3-vinylindole and 2-formyl-3-[β-methoxyethyl]-indole were isolated in the former case, 2-formyl-1-methyl-3-vinylindole in the latter. The methylation products are therefore 3-[2-formylindolyl]-β-ethyltrimethylammonium iodide (XIV, R = H) and its 1-methyl derivative (XIV, R = CH_3).



XIV



XV

When methylation was carried out under anhydrous conditions, acetals (XV) of the quaternary salts were obtained. These also yielded trimethylamine on Hofmann degradation.

The infrared absorption curves of these acetals showed ether bands in the region 1000–1200 cm^{-1} and lacked carbonyl absorption. Their ultraviolet absorption spectra in alkaline solution showed an indole chromophore. On acidification the absorption changed irreversibly to that of 2-formylindole. The acetals had been hydrolyzed to formyl derivatives on treatment with acid.

On exhaustive alkylation 3,4-dihydro-β-carboline and its 9-methyl derivative yield products which are analogous to those obtained similarly from 3,4-dihydroisoquinoline (21).

EXPERIMENTAL

3,4-Dihydro-β-carboline (Norharmalan)

$N_β$-Formyltryptamine (5) (1.5 g) and polyphosphoric acid (10 g) were heated at 100–110° for 40 minutes with constant stirring. The dark melt was poured into cold water, the solution was diluted to about 1 liter and decolorized. The clear filtrate was extracted with ether to remove non-basic impurities and was made

alkaline with 10% sodium hydroxide. The turbid solution was extracted with ether and the ether extract dried and evaporated, yielding crude 3,4-dihydro-β-carboline. Attempted purification by crystallization or chromatography gave an intractable brown polymeric material.

Sublimation at 2.10^{-3} mm and 130–140° gave 3,4-dihydro-β-carboline as a glassy solid (0.74 g, 52%) melting at 120–130° after sintering at 90°, pK_a 7.8. The product did not give a satisfactory analysis. Infrared absorption (Nujol) (cm^{-1}): 3380 (m) (NH); 1615 (m) (C=N). Ultraviolet absorption (λ_{max}, mμ (log ε)): in 0.1 *N* HCl: 355 (4.2), 245 (4.0); in 0.1 *N* NaOH: 318 (4.0), 242 (4.1).

A sample was converted to the picrate, melting at 233–234°. (Found: C, 51.1; H, 3.2. Calc. for $C_{17}H_{13}N_5O_7$: C, 51.1; H, 3.3%.) Reported melting point 241–242° (decomp.) (3), 233° (5).

9-Methyl-3,4-dihydro-β-carboline

Ind-N-methyl-N$_β$-formyltryptamine

Reduction of N-methylindoxyl with lithium aluminum hydride gave N-methylindole (22), which was converted to Ind-N-methyltryptamine by the gramine route (23).

Ind-N-methyltryptamine (3 g) was heated in a sealed tube with freshly distilled ethyl formate (25 ml) at 100° for 2 hours. The solution was diluted with ether, washed with dilute hydrochloric acid and with water, and dried. Ethyl formate and ether were evaporated and the residue was distilled at 5.10^{-3} mm and 165–170° to give *Ind-N-methyl-N$_β$-formyltryptamine* as a colorless viscous oil (2.8 g, 80%). (Found: N, 13.8. $C_{12}H_{14}N_2O$ requires: N, 13.9%.) Infrared absorption (Nujol) (cm^{-1}): 1640 (vs) (C=O).

9-Methyl-3,4-dihydro-β-carboline

Ind-N-methyl-N$_β$-formyltryptamine (1.5 g) was stirred for 1 hour with polyphosphoric acid (10 g) at 110–120°. The reaction mixture was worked up as in the preparation of 3,4-dihydro-β-carboline. The crude product was sublimed at 5.10^{-3} mm and 120°, when the product (0.75 g, 55%), melting at 120–130°, was obtained as a colorless solid. It did not give a satisfactory analysis. Infrared absorption (Nujol) (cm^{-1}): 1600 (m), 1620 (w) (C=N). Ultraviolet absorption (λ_{max}, mμ (log ε)): in 0.1 *N* HCl: 360 (4.1), 248 (4.1); in 0.1 *N* NaOH: 322 (4.0), 252 (3.9).

A sample was converted to the picrate, melting at 248–249° (decomp.). (Found: N, 16.6. $C_{18}H_{15}N_5O_7$ requires: N, 16.9%.)

3,4-Dihydro-β-carboline Methiodide

3,4-Dihydro-β-carboline (1 g) was dissolved in 50 ml dry benzene, the solution was filtered, and the residue rejected. The filtrate was diluted to 250 ml with dry benzene, methyl iodide (3 ml) was added and the mixture was allowed to stand at room temperature for 48 hours, when yellow needles, contaminated with a brown impurity, had deposited. The solid was dissolved in methanol, the solution treated with charcoal and concentrated, and the residue crystallized from aqueous methanol, when the *methiodide* (1.4 g, 70%) was obtained as long needles of the monohydrate, melting at 223° after sintering at 215°. (Found: H_2O, 4.9. $C_{12}H_{13}IN_2,H_2O$ requires: H_2O, 5.4%. After drying to constant weight, found: C, 46.2; H, 4.4; N. 8.9. $C_{12}H_{13}IN_2$ requires: C, 46.1; H, 4.2; N, 9.0%.) Infrared absorption (Nujol) (cm^{-1}): 3160 (m) (NH); 1640 (s) ($C=N^+$). Ultraviolet absorption (λ_{max}, mμ (log ε)): in 0.1 *N* HCl: 360 (4.3), 248 (4.0); in 0.1 *N* NaOH: 282 (3.7).

Dimeric Anhydro Base from 3,4-Dihydro-β-carboline Methiodide

3,4-Dihydro-β-carboline methiodide (0.25 g) was dissolved in 20 ml water, and 10% sodium hydroxide was added with constant stirring. The light yellow precipitate was washed with water, rubbed with methanol (5 ml), filtered, and again washed with a little methanol to yield a colorless amorphous powder (0.12 g, 85%), melting at 184–185°. The same product was obtained when more dilute sodium hydroxide or ammonia was used to liberate the anhydro base. Crystallization from dry chloroform did not raise the melting point. (Found: molecular weight,[2] 346±35; C,[3] 77.4; H, 6.8; N, 15.4. $(C_{12}H_{12}N_2)_2$ requires: molecular weight, 368; C, 78.2; H, 6.6; N, 15.2%.) Addition to a small quantity of the anhydro base of concentrated sulphuric acid containing a trace of ferric chloride gave an ultramarine color which on standing changed to crimson.

Treatment of the Dimeric Anhydro Base with Alkali

The anhydro base (0.02 g) was suspended in 30% potassium hydroxide in aqueous methanol (5 ml) and the solution refluxed on the steam bath for 4 hours. Alcohol was evaporated and the residue acidified with hydrochloric acid. The solution was extracted with ether, the ether extract dried and concentrated. The ether extract did not contain material absorbing in the ultraviolet region of the spectrum.

When the aqueous solution was made alkaline with excess 10% sodium hydroxide unchanged starting material was recovered.

Distillation of the Dimeric Anhydro Base

The anhydro base (0.1 g) was distilled at 1.10^{-2} mm and 140–150°. A mixture of a colorless and a yellow substance sublimed and a black residue remained. When the sublimate was redistilled at 1.10^{-2} mm below 100° the colorless substance sublimed and the yellow substance remained as residue.

[2]*Schwarzkopf Microanalytical Laboratory, Woodside, N.Y., U.S.A.*

[3]*Consistently low analytical values for carbon (eight determinations) were presumably due to contamination of the dimeric product by small amounts of pseudobase (IV, R = H).*

The colorless substance was 2-methyl-1,2,3,4-tetrahydro-β-carboline, melting at 216–217°, identical in melting point and infrared and ultraviolet spectra with an authentic sample (15).

The yellow substance, melting at 212–214°, proved to be identical by similar criteria with an authentic sample of 2-methyl-β-carboline anhydro base (16).

1-Hydroxylamino-2-methyl-1,2,3,4-tetrahydro-β-carboline

A solution of the dimeric anhydro base (0.1 g) and hydroxylamine hydrochloride (0.05 g) in methanol (25 ml) was refluxed for 15 minutes. The solvent was distilled off and the residue was dissolved in water. Addition of ammonia gave a precipitate, which was dissolved in ether. The ether solution was dried, the solvent evaporated, and the residue crystallized from methanol, yielding colorless crystals of *1-hydroxylamino-2-methyl-1,2,3,4-tetrahydro-β-carboline* (0.08 g, 75%) melting at 182°. (Found: C, 66.6; H, 7.5; N, 18.9. $C_{12}H_{15}N_3O$ requires: C, 66.3; H, 7.0; N, 19.3%.) Ultraviolet absorption (λ_{max}, mμ (log ε)): in 0.1 *N* HCl: 310 (4.3), 250 (4.2); in 0.1 *N* NaOH: 315 (4.3).

9-Methyl-3,4-dihydro-β-carboline Methiodide

9-Methyl-3,4-dihydro-β-carboline (0.5 g) was dissolved in 75 ml benzene, methyl iodide (2 ml) was added, and the solution was kept at 37° for 24 hours. A yellow solid separated which was recrystallized from water to give the *methiodide* as pale yellow needles (0.7 g, 70%) melting at 228°. (Found: C, 48.1; H, 4.9; N, 8.6; I, 38.9. $C_{13}H_{15}IN_2$ requires: C, 47.9; H, 4.6; N, 8.6; I, 39.0%.) Infrared absorption (Nujol) (cm^{-1}): 1648 (s) ($C{=}\overset{+}{N}$). Ultraviolet absorption (λ_{max}, mμ (log ε)): in 0.1 *N* HCl: 364 (4.4), 252 (4.1); in 0.1 *N* NaOH: 286 (3.8).

Attempted Characterization of 2,9-Dimethyl-1-hydroxy-1,2,3,4-tetrahydro-β-carboline

The above methiodide (0.5 g) was dissolved in a small amount of water. Addition of 20% sodium hydroxide gave an oil which, on cooling, solidified to an amorphous, light green solid melting at 55°. Ultraviolet absorption (λ_{max}, mμ): in 0.1 *N* HCl: 364, 252; in 0.1 *N* NaOH: 286; in ether: 287. The product was not analyzed.

High-vacuum distillation did not lead to a purer product and was accompanied by oxidation. At 3.10^{-3} mm and 110° a dark yellow oil was obtained. This was dissolved in ether, the solution was extracted with *N* hydrochloric acid, the acid extract made alkaline and extracted with ether, and the ether extract dried (Na_2SO_4) and evaporated. The amorphous residue showed an infrared spectrum identical with that of the crude pseudobase. The original ether solution, containing the non-basic fraction, was dried and evaporated. A small amount of colorless residue, melting at 68–70°, was obtained whose infrared absorption was identical with that of 2,9-dimethyl-1-oxo-1,2,3,4-tetrahydro-β-carboline.

Pseudobase obtained from 0.5 g methiodide was refluxed 2 hours with 35% potassium hydroxide solution (10 ml). The solution was extracted with ether, the ether extract was washed with *N* hydrochloric acid and with water, dried (Na_2SO_4), and evaporated. Sublimation of the residue at 3.10^{-3} mm and 90° gave 2,9-dimethyl-1-oxo-1,2,3,4-tetrahydro-β-carboline as a colorless solid melting at 68–70° identical in melting point and infrared and ultraviolet absorption with an authentic specimen (*vide infra*).

2,9-Dimethyl-1-hydroxylamino-1,2,3,4-tetrahydro-β-carboline

Pseudobase from 0.5 g methiodide was dissolved in methanol (30 ml), and hydroxylamine hydrochloride (0.13 g) and potassium carbonate (0.20 g) was added. The mixture was kept at 40° for 2 hours, the solvent was evaporated, the residue was washed with cold water (2×3 ml) and was crystallized from methanol after treatment with charcoal. The *product* (0.23 g, 65%) was obtained as a colorless solid melting at 156°. (Found: C, 67.2; H, 7.5; N, 18.1. $C_{13}H_{17}N_3O$ requires: C, 67.5; H, 7.4; N, 18.2%.) Ultraviolet absorption (λ_{max}, mμ (log ε)): in 0.1 *N* HCl: 310 (4.3), 243 (4.3); in 0.1 *N* NaOH: 315 (4.3).

2-Methyl-1-oxo-1,2,3,4-tetrahydro-β-carboline

1-Methyl-3,4-dihydro-β-carboline methiodide (6) (0.33 g) was dissolved in hot water. Acetone (50 ml) and *N* sodium hydroxide (2 ml) was added, the solution was cooled to −5°, and finely ground potassium permanganate (0.50 g) was added in small portions. The solution was acidified with *N* hydrochloric acid (2.5 ml), excess permanganate destroyed by addition of hydrogen peroxide, the mixture filtered, and the filtrate concentrated. Recrystallization of the residue from a large volume of boiling water gave fine needles of *2-methyl-1-oxo-1,2,3,4-tetrahydro-β-carboline* (0.09 g, 45%) melting at 237–238°. (Found: C, 72.1; H, 6.2. $C_{12}H_{12}N_2O$ requires: C, 72.0; H, 6.1%.) Infrared absorption (Nujol) (cm^{-1}): 3190 (m) (NH); 1620 (vs) (C=O). Ultraviolet absorption (λ_{max}, mμ (log ε)): in 0.1 *N* HCl and NaOH: 303 (4.2), 240 (4.2, shoulder) (Fig. 3, curve E).

2,9-Dimethyl-1-oxo-1,2,3,4-tetrahydro-β-carboline

Pseudobase from 0.32 g 9-methyl-3,4-dihydro-β-carboline methiodide was suspended in 10 ml 5% potassium hydroxide solution. Potassium ferricyanide (0.4 g), dissolved in 20 ml water, was added and the mixture heated on the steam bath for 4 hours. The solution was extracted with ether, the extract washed with *N* hydrochloric acid and with water, dried (Na_2SO_4), and the solvent evaporated. The residue sublimed at 3.10^{-3} and 80°, giving colorless crystals (0.07 g, 32%) of 2,9-dimethyl-1-oxo-1,2,3,4-tetrahydro-β-carboline melting at 69–71°. (Found: C, 72.8; H, 7.0; N, 13.1. Calc. for $C_{13}H_{14}N_2O$: C, 72.9; H, 6.6; N, 13.1%.)

Reported melting point: 65–66° (24). Infrared absorption (Nujol) (cm^{-1}): 1640 (vs) (C=O). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)): in 0.1 *N* HCl and 0.1 *N* NaOH: 305 (4.1).

Exhaustive Methylation of the Dimeric Anhydro Base

3-[2-Formylindolyl]-β-ethyltrimethylammonium Iodide

Dimeric anhydro base (0.4 g) was suspended in methanol (20 ml). Potassium carbonate (0.2 g) and methyl iodide (5 ml) were added and the mixture was kept at 40° for 24 hours. The solvent was evaporated, the residue was washed with cold water (3 ml) and crystallized from 50% aqueous methanol after treatment with charcoal, when colorless needles (0.42 g, 70%) of the *quaternary iodide*, melting at 270°, were obtained. (Found: C, 46.9; H, 5.3; N, 7.6; I, 35.8. $C_{14}H_{19}IN_2O$ requires: C, 46.9; H, 5.3; N, 7.8; I, 35.5%.) Infrared absorption (Nujol) (cm^{-1}): 3280 (m, broad) (NH); 1655 (vs) (C=O). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)): in 0.1 *N* HCl and in 0.1 *N* NaOH: 315 (4.1), 237 (4.1).

Hofmann Degradation of 3-[2-Formylindolyl]-β-ethyltrimethylammonium Iodide

A stream of nitrogen gas was passed for 2 hours through a solution of the above quaternary salt (0.35 g) in 5% methanolic potassium hydroxide (20 ml) at 50°. The issuing gas was passed through an alcoholic solution of picric acid. Concentration of the picric acid solution gave a picrate (0.28 g) which melted at 216° (decomp.) after recrystallization from methanol, and was identified as trimethylamine picrate by comparison with an authentic sample. (Found: C, 37.7; H, 4.3; N, 19.2. Calc. for $C_9H_{12}N_4O_7$: C, 37.5; H, 4.2; N, 19.4%.)

The reaction mixture was evaporated *in vacuo*, water (10 ml) was added to the residue, and the mixture was extracted with ether. The ether extract was washed with water, dried, and evaporated. The residue was dissolved in methanol, the solution decolorized with charcoal and evaporated. The residue was distilled at 3.10^{-3} mm and 70°, when two fractions were obtained.

The first fraction (0.035 g), a colorless solid melting at 110°, was *2-formyl-3-[β-methoxyethyl]-indole.* (Found: C, 70.9; H, 6.6. $C_{12}H_{13}NO_2$ requires: C, 70.9; H, 6.5%.) Infrared absorption (Nujol) (cm^{-1}): 3210 (m) (NH); 1650 (vs) (C=O); 1012 (m), 1070 (m), 1094 (s) (OCH_3). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)): in 0.1 *N* HCl and in 0.1 *N* NaOH: 317 (4.2), 238 (4.1).

The second fraction, a pale yellow solid (0.045 g) melting at 126° after sintering at 115°, was *2-formyl-3-vinylindole.* (Found: C, 77.0; H, 5.4; N, 8.0. $C_{11}H_9NO$ requires: C, 77.2; H, 5.3; N, 8.2%.) Infrared absorption (Nujol) (cm^{-1}): 3280 (m) (NH); 1640 (vs) (C=O); 1615 (s) (C=C); 918 (m), 972 (m) (vinyl). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)): in 0.1 *N* HCl and in 0.1 *N* NaOH: 322 (4.2), 252 (4.1).

Dimethylacetal of 3-[2-Formylindolyl]-β-ethyltrimethylammonium Iodide

Dimeric anhydro base (0.4 g) was suspended in 20 ml methanol. Anhydrous potassium carbonate (2.0 g) and methyl iodide (5 ml) were added and the reaction mixture was kept at 40° for 24 hours. The solvent was evaporated, the residue was washed with cold water (3 ml) and crystallized from aqueous methanol after treatment with charcoal to give colorless needles (0.58 g, 66%) of the *dimethylacetal* melting at 180°. (Found: C, 47.4; H, 6.2; N, 7.0. $C_{16}H_{25}IN_2O_2$ requires: C, 47.5; H, 6.2; N, 6.9%.) Infrared absorption (Nujol) (cm^{-1}): 3330 (m) (NH); 1030 (m), 1090 (s) (—OCH_3). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)): in 0.1 *N* HCl: 318 (3.9); in 0.1 *N* NaOH: 282 (3.7).

Hofmann Degradation of the Dimethylacetal

The acetal (0.20 g) was dissolved in 5% methanolic potassium hydroxide (20 ml). The solution was kept at 60° and swept out with a current of nitrogen for 4 hours and the issuing gas passed through an alcoholic solution of picric acid, from which trimethylamine picrate was isolated as described earlier. The reaction mixture was evaporated *in vacuo*, water was added to the residue, and the solution was extracted with ether. The ether extract was washed with water, dried, and evaporated. The residue was dissolved in methanol, treated with charcoal, and again evaporated.

The residue was distilled at 3.10^{-3} mm and 70°, when a small amount of a colorless solid, melting at 115°, was obtained, which may have been the dimethylacetal of 2-formyl-3-vinylindole. The quantity obtained was insufficient for analysis. Infrared absorption (Nujol) (cm^{-1}): 3215 (m) (NH); 1635 (s) (C=C); 970 (m), 910 (m) (vinyl); 1090 (m), 1045 (m) (OCH_3). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)): in 0.1 *N* HCl: 319 (4.1); in 0.1 *N* NaOH: 317 (3.9).

Diethylacetal of 3-[2-Formylindolyl]-β-Ethyltrimethylammonium Iodide

Dimeric 2-methyl-3,4-dihydro-β-carboline anhydro base was methylated in the presence of anhydrous potassium carbonate in ethanol suspension.

The *diethylacetal* was obtained in the form of colorless needles melting at 230°. (Found: C, 50.3; H, 6.8; N, 6.4. $C_{18}H_{29}IN_2O_2$ requires: C, 50.0; H, 6.7; N, 6.5%.) Infrared absorption (Nujol) (cm^{-1}): 3380 (m) (NH); 1030 (m), (1090) (s) (OC_2H_5). Ultraviolet absorption (λ_{max}, $m\mu$ (log ϵ)): in 0.1 *N* HCl: 318 (3.9); in 0.1 *N* NaOH: 282 (3.7).

Exhaustive Methylation of 2,9-Dimethyl-1-hydroxy-1,2,3,4-tetrahydro-β-carboline

3-[2-Formyl-1-methylindolyl]-β-ethyltrimethylammonium Iodide

Pseudobase from 0.5 g 9-methyl-3,4-dihydro-β-carboline methiodide was dissolved in methanol (20 ml). Potassium carbonate (0.2 g) and methyl iodide (5 ml) were added and the mixture kept at 40° for 24 hours.

The solvent was evaporated, the residue was washed with water and crystallized from 50% aqueous methanol after treatment with charcoal. Pale, shining plates (0.38 g, 60%) of the monohydrate of the *quaternary salt*, melting at 244°, were obtained. (Found: C, 46.3; H, 6.1; N, 6.8; I, 32.4. $C_{15}H_{21}IN_2O,H_2O$ requires: C, 46.2; H, 5.9; N, 7.2; I, 32.6%.) Infrared absorption (Nujol) (cm^{-1}): 1652 (vs) (C=O). Ultraviolet absorption (λ_{max}, mμ (log ϵ)): in 0.1 *N* HCl and 0.1 *N* NaOH: 318 (4.2), 240 (4.2).

Hofmann Degradation of 3-[2-Formyl-1-methylindolyl]-β-ethyltrimethylammonium Iodide

The above quaternary salt (0.25 g) was treated with 5% methanolic potassium hydroxide (15 ml) under nitrogen as described earlier and products isolated as before. The basic product was isolated as the picrate (0.17 g) melting at 216° (decomp.) and identified as trimethylamine picrate by comparison with an authentic sample.

The neutral product, *2-formyl-1-methyl-3-vinylindole*, was obtained as pale yellow crystals (0.020 g) melting at 82°. (Found: C, 77.9; H, 6.3; N, 7.6. $C_{12}H_{11}NO$ requires: 77.8; H, 6.0; N, 7.6%.) Infrared absorption (Nujol) (cm^{-1}): 1650 (vs) (C=O), 1605 (s) (C=C); 928 (m), 992 (m) (vinyl). Ultraviolet absorption (λ_{max}, mμ (log ϵ)): in 0.1 *N* HCl and in 0.1 *N* NaOH: 322 (4.2), 253 (4.2).

Oxime of 3-[2-Formyl-1-methylindolyl]-β-ethyltrimethylammonium Iodide

3-[2-Formyl-1-methylindolyl]-β-ethyltrimethylammonium iodide (0.20 g) was dissolved in 50% aqueous alcohol. Hydroxylamine hydrochloride (0.05 g) and potassium carbonate (0.05 g) were added. The reaction mixture was kept at 60° for ½ hour. Concentration yielded the *oxime* (0.15 g, 75%), melting at 256°, after recrystallization from aqueous alcohol. (Found: C, 46.6; H, 6.0; N, 11.1. $C_{15}H_{22}IN_3O$ requires: C, 46.3; H, 5.7; N, 10.9%.) Ultraviolet absorption (λ_{max}, mμ (log ϵ)): in 0.1 *N* HCl: 310 (4.1); in 0.1 *N* NaOH: 315 (4.1), 254 (4.1).

Dimethylacetal of 3-[2-Formyl-1-methylindolyl]-β-ethyltrimethylammonium Iodide

When the pseudobase was methylated in methanol solution in the presence of a large excess of anhydrous potassium carbonate, the *dimethylacetal* was obtained as colorless needles melting at 233°. (Found: C, 48.7; H, 6.6. $C_{17}H_{27}IN_2O_2$ requires: C, 48.8; H, 6.5%.) Infrared absorption (Nujol) (cm^{-1}): 1040 (m), 1095 (s) (OCH_3). Ultraviolet absorption (λ_{max}, mμ (log ϵ)): in 0.1 *N* HCl: 318 (4.3); in 0.1 *N* NaOH: 282 (4.0) (broad).

THE ULTRAVIOLET ABSORPTION SPECTRUM OF NITROUS ACID IN THE VAPOR STATE

G. W. KING AND D. MOULE[1]
Department of Chemistry, McMaster University, Hamilton, Ontario
Received July 3, 1962

ABSTRACT

The diffuse absorption bands of $HON^{14}O$, $HON^{15}O$, $DON^{14}O$, and $DON^{15}O$ in the near ultraviolet have been examined. Transitions from both rotational isomers of nitrous acid contribute to the vibrational structure, with the excited state $\sigma(N{=}O)$ stretching vibrations active in the most intense progressions. The cis–trans energy separation increases from 500 cal/mole in the ground state to 1200 cal/mole in the upper state. This is attributed to weakening of the internal hydrogen bond in the cis state upon an electronic promotion of primarily $n_O \rightarrow \pi^*$ type. The accompanying change in geometry is responsible for the appearance of the cis ground-state $\delta(ONO)$ bending mode in the spectrum.

INTRODUCTION

Gaseous mixtures of NO, NO_2, and water vapor exhibit a system of diffuse absorption bands in the 4000–3000 Å spectral region (1). The isotopic wavelength shift upon deuteration eliminates NO_2, N_2O_3, and N_2O_4, all of which absorb in the same region, as possible carrier species (2, 3). The intensity of absorption varies in proportion to the calculated equilibrium concentration of nitrous acid in gas mixtures of different composition and temperature and the spectrum is attributed to this molecule. Alkyl nitrites in general show, in the same spectral region, a similar diffuse absorption spectrum (4) which is typical of the —O—N=O group. Analysis of the nitrous acid spectrum is complicated by the diffuse nature of the bands, by the discrete background absorption of the NO_2 present in the gas mixture, and by perturbations between vibrational levels of the excited DONO molecule.

In addition to examining the spectra of HONO and DONO containing the naturally occurring N^{14} isotope under improved experimental conditions, we have also investigated the spectra of the additional isotopically substituted species $HON^{15}O$ and $DON^{15}O$. In this paper, the arguments of previous investigators are reconsidered in the light of our data, and a plausible interpretation of the spectrum of nitrous acid vapor is given. In a subsequent paper, the spectrum of nitrous acid in various solvents will be discussed on the basis of this interpretation.

EXPERIMENTAL

In order to minimize contamination of the nitrous acid spectrum by the intense discrete absorption bands of NO_2, the partial pressure of this oxide in the gas mixture was kept small. A typical mixture showing minimum background absorption was obtained by equilibrating NO, NO_2, and H_2O at initial partial pressures of 740, 2, and 15 mm respectively in a 50 cm path length absorption cell. The NO and NO_2 (Matheson Co. Inc.) were taken from cylinders without further purification. DONO was formed by substituting D_2O with deuterium content >99.7% for the H_2O in the mixture.

Five hundred cubic centimeters of $N^{15}O$ at S.T.P., with N^{15} content >98%, was supplied by the Isomet Corporation. Half of this was mixed at 260 mm pressure with O_2 at 1 mm and H_2O at 15 mm directly in the absorption cell to form $HON^{15}O$. The other half was used to form $DON^{15}O$ by a similar procedure.

Spectra of all four isotopic species were taken on a Bausch and Lomb 1.5-m grating spectrograph (Model 11), used in the first and second orders with resolving powers of 35,000 and 70,000 respectively. Wavelength measurements of the intensity maxima of the bands were made off microdensitometer traces, by interpolation between iron arc reference spectra that were also recorded on the spectrograms. The vacuum

peak, and (3) refers to weak bands overlapped by other bands. The bracketed wave numbers represent HONO and DONO bands which could not be clearly distinguished from the residual NO_2 absorption on the spectrograms, and which were measured off the spectrophotometer records described below.

In order to study the variation of absorption intensity of HONO and DONO with temperature, a Perkin–Elmer Spectracord Model 4000 was modified to accommodate an electrically heated absorption cell with a 1-m optical path length in the sample beam. The cell was sealed after filling with gas mixture and spectra were recorded over the temperature range 25–130° C. A 10-cm gas cell was inserted in the reference beam and heated to the same temperature as that of the sample cell. Before each spectrum was recorded, the reference cell was filled with sufficient NO_2 to balance out the interfering background, together with dry NO to bring the total pressure to 1 atm. This procedure also partly balanced out a weak continuous background absorption, probably due to N_2O_3 and N_2O_4, that was also present. Very clean nitrous acid spectra could be obtained in this manner; the residual continuous background absorption did not affect the temperature dependence studies, which involved comparison of the intensities of adjacent strong bands in the nitrous acid spectrum.

RESULTS

The ultraviolet absorption spectrum of HONO at 25° C is shown in Fig. 1. This is taken from a spectrophotometer record with compensated background. Comparison of microdensitometer traces of spectrograms of HONO and HON^{15}O shows that the two spectra have identical overall patterns apart from isotopic wavelength shifts. Three progressions of bands appear in both spectra. Each of these is labelled alphabetically in accordance with the nomenclature of previous workers (3) and identified below as the A, A', or A'' progression respectively.

The spectrum of DONO at 25° C is presented in Fig. 2. The prominent bands again can be grouped into three strong progressions, labelled A, A', and A'', and are displaced

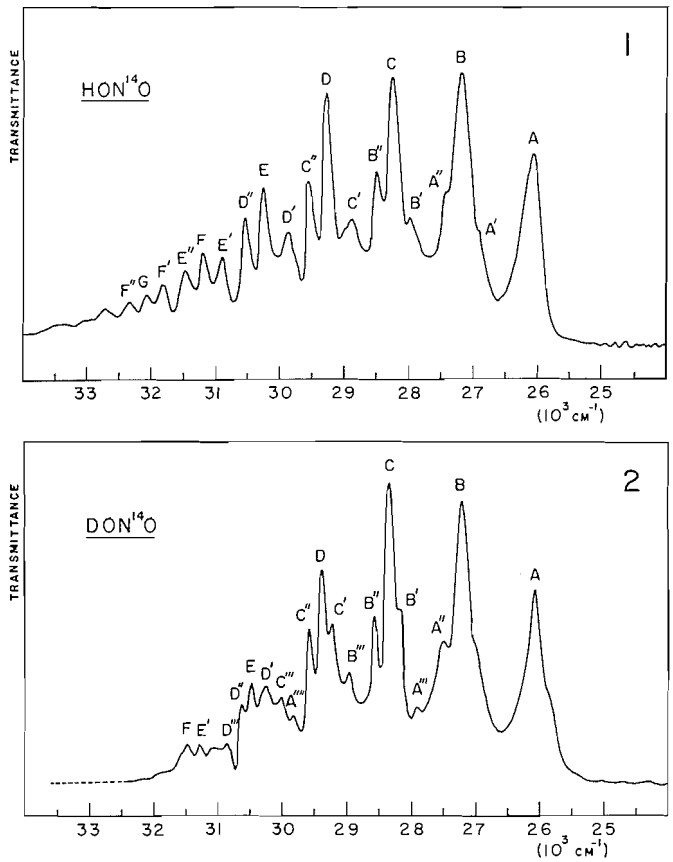

FIG. 1. The absorption spectrum of HONO at 25° C.
FIG. 2. The absorption spectrum of DONO at 25° C.

to slightly higher frequencies by comparison with their counterparts in the HONO spectrum. In addition, four weak bands labelled A''', B''', C''', and A'''' are also present in the DONO spectrum. The spectrum of DON^{15}O shows the same number of bands, with the same relative positions and intensities, as does the DONO spectrum.

The bands in all of the spectra show a peculiar diffuseness, having a symmetric form that is devoid of local undulations. No traces of fine structure were apparent even when the bands were photographed on a 20-ft grating spectrograph with a resolving power of 150,000; in these experiments, the lowest total pressure of the absorbing gas mixture that gave a detectable concentration of nitrous acid was 40 mm, so it is possible, but highly unlikely, that the diffuseness was due to residual pressure broadening. The band profiles did not alter as the pressure was decreased, an observation which indicates that intermolecular association is absent.

The A band in each spectrum is slightly broader, but apart from this, all the other strong bands are uniformly diffuse with a half width of $\sim$60 cm^{-1}. This diffuseness is different from the usual type that is observed in the spectra of light polyatomic molecules,

which is caused by vibrational predissociation in the excited electronic state and which increases markedly towards higher wave numbers.

At elevated temperatures, the increase of NO_2 and N_2O_4 and the decrease of nitrous acid concentration in the equilibrium gas mixture make band intensities difficult to measure accurately, owing to the greater background contamination appearing in the spectrum. Nevertheless, the intensities of the A', A'', and A''' progressions detectably increase relative to the A progression in each spectrum as the temperature is raised. This is illustrated by the portions of the HONO and DONO spectra shown in Fig. 3.

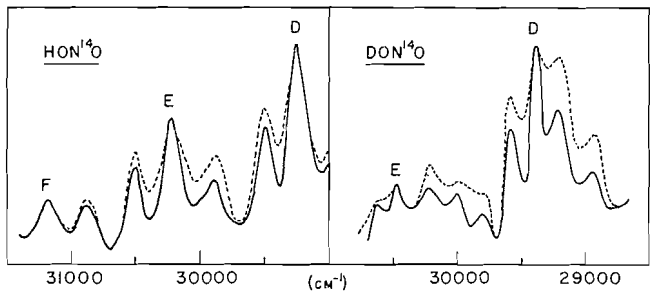

FIG. 3. Portions of the HONO and DONO spectra at 25° C (solid curves) and 135° C (broken curves).

ANALYSIS

Analysis of the infrared spectrum (5, 6) shows that nitrous acid consists of a mixture of two planar isomeric forms in the ground electronic state. These have the dimensions (5) shown in Fig. 4. The cis form is 506±250 cal/mole higher in energy than the trans form, with $p_{trans}/p_{cis} \sim 2.5$ at 25° C. The fundamental frequencies are listed in Table II.

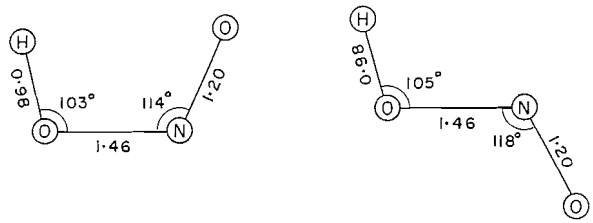

FIG. 4. Estimated dimensions (Å) of *cis*- and *trans*-nitrous acid in the ground state.

*Revised—see text.

Rotational isomerism is common in the ground states of alkyl nitrites (7–9) and the calculated barrier height of ~10 kcal/mole in nitrous acid (10) agrees with the value of ~9 kcal/mole for primary nitrites (9).

A singlet–singlet $n \rightarrow \pi^*$ type of electronic transition is undoubtedly responsible for the near-ultraviolet spectra of nitrites and nitrous acid. The low absorption intensity ($f = 0.002$ and $\epsilon_{max} = 110$ for nitrous acid in aqueous solution) is characteristic of such transitions and cannot be ascribed to an electronically forbidden $\pi \rightarrow \pi^*$ transition, since both the alkyl nitrites and nitrous acid are classified under the C_s point group for which all transitions are symmetry allowed.

The *A* progression is the most prominent feature in the spectrum of each isotopic species. The intensity distribution and wave number separations between successive bands in the progression are similar in the four spectra, and indicate an active excited-state vibration of ~1130 cm^{-1}. A similar interval is also prominent in the spectra of alkyl nitrites (7); hence the vibration must be localized primarily in the —O—N=O group: this interpretation is confirmed for nitrous acid by the observed small decrease in frequency upon N^{15} substitution and the absence of a large frequency decrease upon deuteration, both of which are apparent from the frequency differences listed in Table III. An electronic $n \rightarrow \pi^*$ excitation, in which a non-bonding electron is promoted into a

TABLE III

Band separations (cm^{-1}) in the *A* progression

G–F	(900)			

relatively antibonding molecular orbital, is expected to cause a general decrease in the vibrational frequencies of groups affected by the promotion. This is true for such transitions in carbonyl compounds, where, for example, the C=O stretching frequency drops to ~1300 cm^{-1} from 1700 cm^{-1} in the ground state. At this stage in the analysis, therefore, we assign the intervals in the *A* progression to an excited-state N=O stretching vibration of nitrous acid. A similar frequency assignment has been made for nitroso and nitro compounds in their excited states (11).

Previous interpretations of the other bands in the spectrum (2, 4) were made before the cis–trans isomerism of the ground state was recognized, and it was assumed that only one absorbing species was present. An analysis would still be possible on this basis if the oscillator strength of the electronic transition differed greatly between the two isomers. The suggestion (2) that the intervals *A''–A*, *B''–B*, . . . represent an excited-state vibration of ~1350 cm^{-1} can be discounted, since the negligible change of frequency on deuteration shows that the motion would be localized in the ONO group; and it is unlikely that ν_4'' and ν_5'' would show a large frequency increase upon electronic excitation of the molecule. Another suggestion has been (4) that the intervals B–A'', C–B'', . . . represent a low-frequency torsional oscillation in the upper state, but these intervals are not constant in each of the spectra of the isotopic species. Neither of the suggested frequencies is active in the spectra of alkyl nitrites (7). Furthermore, these assignments would require

both the A and A'' progressions to show the same variation of intensity with temperature, whereas only the A'' progression is temperature dependent.

The most satisfactory explanation is that the A and A'' progressions are caused by excitation of the N=O stretching mode ν_2' in the excited trans and cis isomers respectively, with the temperature-dependent A'' progression bands originating in the isomer of higher ground-state energy. Both isomers must retain their approximate geometrical form upon electronic excitation, otherwise the Franck–Condon principle predicts the appearance of long and prominent progressions in those vibrations which would bring the nuclei into coincident positions in the combining electronic states, whereas maximum intensity occurs in the second or third members of all the observed progressions.

The A band is assigned to the 0–0 (trans) transition; but if the A'' band is assigned to the corresponding 0–0 (cis) transition, the separation between the cis and trans electronically excited states would be 4.5 kcal, an unexplicably large value. However, the broadness of the A band and also the slight displacement from its calculated position in the A progression leads to the suspicion that a second component is present here. If this is the 0–0 (cis) band and the A'' band is actually the second member of the progression, then the measured bands in the A'' progressions of HONO and $HON^{15}O$ can be fitted to an equation of type

$$[1] \qquad G(\nu_i) = G(0\text{–}0)+\omega_i^0\nu_i+x_{ii}^0\nu_i^2$$

to give

$$\text{HONO (cis)} \quad G(\nu_2') = 26{,}320+1126.9\nu_2'-19.75(\nu_2')^2$$

$$\text{HON}^{15}\text{O (cis)} \quad G(\nu_2') = 26{,}328+1113.0\nu_2'-19.25(\nu_2')^2.$$

In similar manner, the bands in the A progression, with $\nu_2' = 0$ for the A band itself, give

$$\text{HONO (trans)} \; G(\nu_2') = 26{,}034+1139.3\nu_2'-22.3(\nu_2')^2$$

$$\text{HON}^{15}\text{O (trans)} \; G(\nu_2') = 26{,}043+1127.2\nu_2'-22.3(\nu_2')^2.$$

This scheme of band numbering yields satisfactory isotope shifts of +8 and +9 cm^{-1} in the cis and trans isomers respectively for $G(0\text{–}0)$ upon N^{15} substitution. The substitution decreases the zero-point energy more in the ground than in the excited state, which is a reasonable expectation if the $n \rightarrow \pi^*$ excitation decreases the molecular binding. On the other hand, if the A'' band is assigned to the 0–0 (cis) transition, the isotope shift in the cis state only would be to lower frequencies, and this would imply large anomalous values for the cross-terms of type x_{ij}^0 that are necessarily ignored in equation [1].

The intensity distribution in the A and A'' progressions cannot be accurately determined because of the background of overlapping bands. However, a calculation after the method of Craig (12), with the simplifying assumption that the ν_2' motion is localized in the N=O bond, gives the extension of this in the excited state as 0.08 Å. This indicates $r_{NO}' \sim 1.28$ Å in both the cis and trans upper states. An extension of similar magnitude occurs in the $n \rightarrow \pi^*$ ($^1A_2 \leftarrow {}^1A_1$) transition in formaldehyde, for which $r''(CO) = 1.22$ Å and $r'(CO) = 1.32$ Å, although the bonding in this molecule is modified by the non-planar geometry of the excited state (13).

Porter (2) has attributed the enhanced separation between successive bands in the A progression of DONO to a perturbation between N=O stretching and D—O—N bending vibrations in the excited molecule. He assigned a frequency of "just under 1000 cm^{-1}"

to the latter motion. Our analysis confirms and extends this idea; Table III shows that anomalous frequency intervals also occur in the A progression bands of DON^{15}O but not of HON^{15}O. The E and F bands in the DONO and DON^{15}O spectra are strongly reduced in intensity and this is also attributable to the perturbation. The intervals between the A'', B'', and C'' bands for DONO and DON^{15}O also decrease irregularly by comparison with their undeuterated counterparts, and a similar kind of perturbation in the excited cis molecule may well be responsible. We conclude that ν_2' and ν_3' have similar values for both deuterated isomers, and that there is only a small drop in frequency of the ν_3'' vibration upon electronic excitation.

Although the bands in the A' and A''' progressions are weak and cannot be measured with precision, consideration of the frequency differences between bands in the spectra of all four isotopic species reveals that only one interpretation appears to be possible within the limits of experimental error. According to this, the A' progressions in the HONO and HON^{15}O spectra and the A''' progressions in the DONO and DON^{15}O spectra are produced by transitions from a cis ground-state level in which one quantum of a vibration of frequency $\sim$ 620 cm^{-1} is excited to upper-state levels in which successive quanta of ν_2' (cis) are excited. This assignment is consistent with the observed increase of intensity of the progressions with temperature.

In order to assign the 620 cm^{-1} interval to a lower-state vibrational mode, it is necessary to re-examine previous analyses of the infrared spectrum. D'Or and Tarte (6) have assigned values of 525 and 517 cm^{-1} to ν_5'' in *cis*-HONO and -DONO respectively, but these values are unexpectedly much smaller than the corresponding frequencies of 598 and 591 cm^{-1} in the trans species. In the alkyl nitrites, ν_5'' (cis) and ν_5'' (trans) are both at $\sim$600 cm^{-1} (7); indeed, this frequency is actually larger for *cis*-methyl nitrite than for *trans*-methyl nitrite, owing to internal non-bonded hydrogen–oxygen interactions in the former configuration. D'Or and Tarte's assignments for ν_5'' (cis) stem from two extremely weak bands in the KBr spectral region that were not observed by Jones, Badger, and Moore (5); the latter assume ν_5'' (cis) is buried under the strong ν_5'' (trans) band at 598 cm^{-1} in the HONO spectrum. This interpretation is preferable, since it enables us to assign the 620 cm^{-1} interval to ν_5'' (cis). Further support comes from the work of Balderschweiler and Pimentel (14), who produced enhanced concentrations of *cis*-nitrous acid in nitrogen matrices by irradiation, and yet reported no absorption bands in the 500–550 cm^{-1} region.

Finally, we note that the intervals B'–A'', C'–B'', . . . have the constant values of 660 and 645 cm^{-1} in the DONO and DON^{15}O spectra respectively, and tentatively assign these frequencies to ν_4' (cis) in the deuterated molecules.

DISCUSSION

According to the simple molecular orbital picture, the electronic transition may be either $n_O \rightarrow \pi^*$, $^1U \leftarrow {}^1A$ or $n_N \rightarrow \pi^*$, $^1W \leftarrow {}^1A$, in terms of Platt's notation (15). In either case, the overall symmetry change is $^1A'' \leftarrow {}^1A'$ with the transition moment perpendicular to the molecule plane. The lowest-energy transitions in nitroso and nitro compounds are often assigned as $n_N \rightarrow \pi^*$ on the grounds that nitrogen lone-pair electrons have a smaller ionization potential and are therefore more readily excited (16). This view may well be oversimplified, since more sophisticated molecular orbital calculations by McEwen (17) show that the promoted electron comes from an LCAO/MO in which the n_O orbital has the largest coefficient. In a review article by Sidman (18), differences in intensity are used as a criterion to distinguish between $^1W \leftarrow {}^1A$ ($f \sim 10^{-2}$, $\epsilon_{max} \sim 10^3$) and $^1U \leftarrow {}^1A$ ($f \sim 10^{-4}$, $\epsilon_{max} \sim 10^3$) transitions. Because of the low intensity, Sidman assigns the near-ultraviolet absorption of nitrites, and also of the nitrite ion which is

isoelectronic with nitrous acid, to an $n_O \rightarrow \pi^*$ transition, since $^1U \leftarrow {}^1A$ is forbidden by the local symmetry of the nitro group. The low intensity of the nitrous acid absorption ($f \sim 10^{-3}$, $\epsilon_{max} \sim 10^2$) indicates that the transition is *mainly* of $n_O \rightarrow \pi^*$ type, in the sense that n_O–n_N mixing occurs in LCAO/MO formation, but one-center ($2s$, $2p$) components localized on the hybridized nitrogen atom only make a small contribution to the transition moment.

In the ground state of *cis*-nitrous acid the separation between the terminal atoms is 2.17 Å, considerably less than 2.6 Å for the sum of the van der Waals radii of hydrogen and oxygen. Since the cis isomer is only 500 cal/mole less stable than the trans, hydrogen bonding to oppose the steric repulsion has been postulated in the ground state of the former species (5, 6, 10). The decrease of ν_1'', the increase of ν_3'' and ν_5'', and the decrease of $\angle$ NOH and $\angle$ ONO in the cis isomer relative to the trans isomer all indicate such bonding, which, from the molecular geometry, must be primarily an interaction between the hydrogen atom and the lone-pair n_O terminal oxygen electrons. The separation of the (0–0) band origins shows that the energy separation between the cis and trans isomers increases to 1300 cal/mole in the excited state, the intramolecular hydrogen bond being weakened by the electronic promotion. The ONO bond angle is expected to open slightly when the hydrogen bond is weakened, and since this motion of the nuclei is linked to the redistribution of charge that occurs in the electronic transition, we might predict that the ν_5 vibration would be active in the spectrum of *cis*-nitrous acid, as is actually the case. On the other hand, Goodman and Kasha's rule (19) that angular bending vibrations about the nitrogen atom are prominent in the spectrum of $n_N \rightarrow \pi^*$ transitions should apply to both *cis*- and *trans*-nitrous acid, whereas the angular deformation mode was not observed in the spectrum of the latter. It might be argued that transitions from the $1\nu_5''$ (trans) ground-state level are not observed because the bands are buried beneath other stronger bands. But if this were the case, the transition to the vibrationless excited state should appear $\sim$600 cm^{-1} to the red of the A band, and there is no trace of discrete absorption in this region. Owing to the displacement of the cis and trans band origins, the corresponding transition for the cis molecule is at the long wavelength edge of the A band; and this edge does indeed appear to broaden as the temperature is increased.

In a crude approximation, two mechanisms can contribute to the weakening of the hydrogen bond: (i) electrostatic interactions of the type normally associated with hydrogen bonding (20) are decreased by $n_O \rightarrow \pi^*$ excitation; (ii) orbital redistribution of electrons after excitation may produce changes in molecular geometry that increase the (O – – – H) separation and so indirectly weaken the bond. This could occur, for example, in an $n_N \rightarrow \pi^*$ transition where rehybridization occurs at the N atom. However, (i) is expected to predominate here, with a small contribution from (ii) due to the increased (N=O) distance in the excited state. The well-known "blue shifts" for $n \rightarrow \pi$ absorption bands that occur when ketonic compounds are dissolved in hydroxylic solvents have been ascribed to breaking of intramolecular hydrogen bonds upon electronic excitation (21). These shifts indicate bond energies of 0.5–4 kcal/mole, but this may only be the amount by which the bond is weakened (22); in any case, the magnitude of such blue shifts is of the same order as the increase in the cis–trans energy separation in nitrous acid upon excitation.

EXOCELLULAR BACTERIAL POLYSACCHARIDE FROM XANTHOMONAS CAMPESTRIS NRRL B-1459

PART I. CONSTITUTION[1]

J. H. Sloneker and Allene Jeanes

Northern Regional Research Laboratory, Northern Utilization Research and Development Division, Agricultural Research Service, U.S. Department of Agriculture, Peoria, Ill., U.S.A.

Received May 22, 1962

ABSTRACT

Polysaccharide B-1459 is the first bacterial polysaccharide reported to contain pyruvic acid as a constituent. The polysaccharide, isolated as the potassium salt, was shown to be composed of D-glucose, D-mannose, and D-glucuronic acid, acetic acid, and pyruvic acid in the ratio 2.8:3.0:2.0:1.7:0.51–0.63. One-third of the total mannose was released readily as free mannose by graded acid hydrolysis with only a slow loss of the high solution viscosity. The remainder of the mannose was isolated as the acid-stable aldobiouronic acid 2-*O*-(β-D-glucopyranosyluronic acid)-D-mannose. Partial acid hydrolysis and preparative paper chromatography afforded two higher oligosaccharides: an aldotriouronic acid composed of glucuronic acid β-linked 1,2 to mannose with glucose as the reducing end group, and what appears to be an aldotetraouronic acid composed of glucuronic acid, mannose, and glucose.

INTRODUCTION

Exocellular polysaccharides have been produced by several species of the bacterium *Xanthomonas* (1), but only that from a strain of *X. phaseoli* has been characterized (2). This highly viscous material is composed of D-glucose, D-mannose, and D-glucuronic acid in the ratio 1:1:1. At this laboratory a similar polysaccharide has been isolated from *X. campestris* NRRL B-1459 (3) and has been produced on a practical scale (4). Polysaccharide B-1459 has possibilities for utility based on its highly viscous, homogenous dispersions, its acid stability, and its unusual behavior with salts (3). Atypical of a polyelectrolyte, at low polysaccharide concentrations the viscosity is relatively insensitive to salts, and at higher polysaccharide concentrations salts increase the viscosity markedly. Furthermore, salts stabilize the viscosity to heat (3). In this investigation we have sought to correlate the unusual physical properties of this polysaccharide with its chemical constitution and structure. Succeeding papers will be concerned with the detailed structural aspects of this problem.

EXPERIMENTAL

Chromatography

The chromatographic solvents employed were as follows: for the free sugars (A) ethyl acetate – acetic acid – water (3:1:3) (5) and (B) *n*-butyl alcohol – pyridine – water (6:4:3) (6); for the hydroxamic acids (C) *n*-amyl alcohol – formic acid – water (4:1:5) and (D) *n*-butyl alcohol – acetic acid – water (4:1:5) (7); and for the polyalcohols (E) 2-butanone – acetic acid – water saturated with boric acid (9:1:1) (8) (all v/v). Spray reagents used for the detection of sugars and their derivatives were (A) *O*-aminobiphenyl (9) and (B) periodate–permanganate (10). Whatman paper No. 1[2] was used for quantitative and qualitative chromatography and No. 3MM was used to separate and isolate larger quantities of pure sugars.

Materials

Polysaccharide B-1459 is isolated as the potassium salt from cell-free media by a series of alcohol precipitations in the presence of 1% potassium chloride. The final precipitate is either dissolved in water and freeze-dried or dehydrated with alcohol and vacuum-dried. Products thus obtained contain only traces of

[1]*Presented before the Division of Carbohydrate Chemistry at the 137th Meeting of the American Chemical Society, Cleveland, Ohio, April 1961.*

[2]*Mention of trade names should not be construed as a recommendation or endorsement by the Department of Agriculture over those not mentioned.*

nitrogen, chloride, and phosphorus (3). Two different preparations were used in the composition studies and are designated T-42, a laboratory preparation (3), and MP-3, an experimental pilot-plant preparation (4).

Deacetylated MP-3 and T-42 were obtained by hydrolyzing a 1% solution of polysaccharide in 0.025 *N* potassium hydroxide and 1% potassium chloride (w/v) for 2 hours at 24–25° C under an atmosphere of nitrogen. The alkali was neutralized with 0.125 *N* hydrochloric acid and the polysaccharide was dialyzed until free of salt. The pH of the solution was adjusted to 6.5, and the polysaccharide was recovered by lyophilization.

Graded Acid Hydrolysis of Polysaccharide B-1459

To 36 mg of T-42 dissolved in 2 ml of water was added 2 ml of 8 *N* sulphuric acid, and the solution was heated at 100° C. At various time intervals 0.5-ml samples were removed, neutralized with saturated barium hydroxide, and centrifuged. The neutralized centrifugates were reduced in volume and qualitatively chromatographed in solvents A and B. In 20 minutes D-mannose appeared in the hydrolyzate in rather large amounts. After 45 minutes D-glucose appeared along with an aldobiouronic acid and several higher oligosaccharides. The hexuronic acid, D-glucuronic acid, appeared only weakly after 60 minutes.

Quantitative Determination of the Sugars in Polysaccharide B-1459

A sample of polysaccharide (100–120 mg) was dissolved in 30 ml of 2 *N* hydrochloric acid and heated for 2.5 hours at 100° C. After cooling in an ice bath, the hydrolyzate was neutralized with silver carbonate and filtered through Celite to remove silver chloride. Excess silver ions were precipitated with hydrogen sulphide, and the solution was reduced in volume and filtered through Celite into a 5-ml volumetric flask. The hydrolyzate, containing considerable quantities of aldobiouronic acid, D-glucose, and D-mannose along with smaller quantities of two higher oligosaccharides (approximately 5% total weight), was chromatographed in solvent (A) for 36 hours. The respective sugar fractions were eluted from the paper and determined quantitatively by the phenol – sulphuric acid method (11).

The D-glucuronic acid content was determined by the carbazole method on the intact polysaccharide (12). Reference materials for the determinations were as follows: U.S. National Bureau of Standards D-glucose; commercial mannose recrystallized from methanol; glucuronic acid dihydrate of established purity; and a chromatographically pure sample of the barium salt of the aldobiouronic acid 2-*O*-(β-D-glucopyranosyluronic acid)-D-mannose isolated from polysaccharide B-1459. For the small quantities of the two higher oligosaccharides, very pure polysaccharide was used as the standard. Between 90 and 95% of the polysaccharide sugars was recovered.

Table I summarizes the sugar analyses run on both native and deacetylated samples of polysaccharide

TABLE I

Composition of polysaccharide B-1459

Polysaccharide sample	Equivalents of: D-Glucose	D-Mannose	D-Glucuronic acid	Acetic acid	Pyruvic acid
Native					
T-42	2.8	3.0	2.0 (22.0%)*	1.73	0.627
MP-3			(22.0%)	1.74	0.509
Deacetylated					
T-42	2.6	2.8	2.0 (24.8%)	0.0	0.634
MP-3			(24.8%)	0.0	

*Determined on the intact polysaccharide by the carbazole method and expressed as $C_6H_8O_6$.

B-1459. Deacetylation produced no change (within experimental error) in the sugar composition, and the D-glucuronic acid content of all the samples is in good agreement.

Identification and Determination of the Acyl Group

Native polysaccharide B-1459 (3 g) was hydrolyzed for 1 hour in 300 ml of 4 *N* sulphuric acid at 100° C and extracted with 6 volumes of ethyl ether. The ether was reduced in volume under vacuum, titrated to pH 7 with 0.01 *N* potassium hydroxide, and then taken to dryness. Hydroxamic acid derivatives were prepared from a portion of the dry residue according to Block *et al.* (13) and chromatographed in solvents (C) and (D). Three spots appeared on the chromatogram when developed with acidic ferric chloride and were identified as to origin as follows: The major spot was from acetic acid; the second spot of medium intensity appeared to be from pyruvic acid; and the third, very weak spot was from formic acid, which probably originates as a breakdown product during hydrolysis.

The acyl content of polysaccharide B-1459 was determined by two methods. First, the polysaccharide (0.1% solution) was deacetylated in an oxygen-free system with 0.01 *N* potassium hydroxide in the presence

of potassium chloride (1% w/v) at room temperature. Aliquots were removed periodically and titrated with 0.01 *N* sulphuric acid with the aid of a pH meter. The acetyl content was 4.7% and the hydrolysis was complete in 5 hours (Table I). The second method was a colorimetric procedure based on the color complex formation of an acyl hydroxamic acid and ferric ions (14). The acetyl content was 4.6%.

Isolation and Determination of Pyruvic Acid

Pyruvic acid, which was identified tentatively as its hydroxamic acid during a routine identification of the acetyl groups in polysaccharide B-1459, was identified positively as its 2,4-dinitrophenylhydrazone derivative. A 2,4-dinitrophenylhydrazine reagent (15) was added to a water solution of a portion of the dry residue from the neutralized ether extract of acid-hydrolyzed polysaccharide used for the identification of the acyl groups. Small yellow crystals formed immediately. After three crystallizations from ethanol–water, 21.0 mg of a bright yellow crystalline material was obtained which had a melting point of 216° C. The melting point did not change when the sample was mixed with authentic pyruvic acid 2,4-dinitrophenylhydrazone. Calc. for $C_9H_8N_4O_6$: C, 40.3%; H, 3.01%; N, 20.9%. Found: C, 40.5%; H, 3.14%; N, 21.2%.

Quantitative analysis of the pyruvic acid as its 2,4-dinitrophenylhydrazone (16) revealed that the pyruvate content varied slightly between different polysaccharide preparations (Table I).

Neutral Equivalent Determination for Polysaccharide B-1459

A 0.1% solution of polysaccharide B-1459 as its potassium salt was passed slowly with the aid of pressure over a column containing a 30-fold excess of Dowex 50-X4, 20–50 mesh resin (H^+ form). The column was washed with at least six holdup volumes of water. The sample and washings were combined and concentrated in a rotary evaporator at 40° C. The sample was titrated with 0.01 *N* sodium hydroxide using a pH meter. The neutral equivalent values found by alkali titration of deionized native and deacetylated samples of polysaccharide and those obtained by calculation from the glucuronate and pyruvate contents are summarized in Table II.

TABLE II

Equivalent weight of polysaccharide B-1459

Polysaccharide sample	Equivalent weight	
	Theoretical*	By alkali titration
Native		
T-42	594	764
MP-3	594	675±21
Deacetylated		
MP-3	526	635±7

*Calculated from the glucuronic and pyruvic acid contents.

Isolation of the Acidic Oligosaccharides

Polysaccharide B-1459 (5.0 g) was hydrolyzed in 500 ml of 4 *N* sulphuric acid for 3 hours at 100° C. The solution was neutralized with barium carbonate, centrifuged, reduced in volume to 10 ml, and filtered to remove residual barium carbonate. A 300-ml aliquot of absolute ethanol was added, and the precipitate which formed was allowed to settle out at 4° C. The precipitate collected by centrifugation was redissolved in 10 ml of water, reprecipitated, and was finally washed with absolute ethanol. The yield as the barium salt after drying was 1.96 g.

The acidic oligosaccharides were separated by paper chromatography (200 mg per sheet) in solvent (A) for 6 days. The papers were dried overnight, and the fractions, four in all, were detected on guide strips with spray (A). The fractions were recovered by macerating the paper in distilled water, removing the pulp on a sintered-glass funnel, reducing the volume of the filtrate, and neutralizing to pH 7.0 with a saturated barium hydroxide solution. The fractions were then precipitated with ethanol, collected by centrifugation, and dried in vacuum over phosphorus pentoxide. The yield of each fraction was:

Fraction	Yield, mg
1	130
2	904
3	69
4	19

Identification of Fraction 1 as D-*Glucuronic Acid*

Fraction 1 was identified chromatographically in solvent (A) as D-glucuronic acid.

*Identification of Fraction 2 as 2-O-(β-*D-*Glucopyranosyluronic acid)-*D-*mannose*

Fraction 2 (4 mg) was hydrolyzed in 0.5 ml of 4 *N* sulphuric acid for 3 hours at 100° C. The hydrolyzate was neutralized with barium hydroxide, the precipitate was removed by centrifugation, and the supernatant solution was reduced in volume and chromatographed in solvent (A). The hydrolyzate contained D-glucuronic acid, D-mannose, and starting material.

Fraction 2 had an $[\alpha]_D^{25}$ value of −30.6 (*c*, 0.240, water). The specific rotation reported for the barium salt of 2-*O*-(β-D-glucopyranosyluronic acid)-D-mannose is $[\alpha]_D^{25}$ −30.0 (*c*, 0.96, water) (17). An authentic sample of 2-*O*-(β-D-glucopyranosyluronic acid)-D-mannose and fraction 2 both gave the same chromatographic results; neither reacted with triphenyltetrazolium chloride, a behavior characteristic of a 1,2-linked reducing disaccharide (18 and references cited therein). With spray reagent (A) both compounds gave an unexpected orange-brown spot in contrast to the characteristic greenish-brown color of hexoses (9) shown by 4-*O*-(glucopyranosyluronic acid)-D-galactose as well as by neutral disaccharides (maltose, isomaltose, and gentiobiose).

Both fraction 2 and the barium salt of 2-*O*-(β-D-glucopyranosyluronic acid)-D-mannose were oxidized with lead tetraacetate as described by Charlson and Perlin (19). In 9 hours fraction 2 reduced 13.6 moles of lead tetraacetate and produced 5.6 moles of carbon dioxide. In comparison, the known aldobiouronic acid reduced 13.4 moles of lead tetraacetate and produced 5.9 moles of carbon dioxide. Fraction 2, therefore, is 2-*O*-(β-D-glucopyranosyluronic acid)-D-mannose.

Identification of Fraction 3 as an Aldotriouronic Acid

Fraction 3 (4 mg) was hydrolyzed and chromatographed as described for fraction 2. The hydrolyzate showed D-glucose (strong), 2-*O*-(β-D-glucopyranosyluronic acid)-D-mannose (strong), D-mannose, and D-glucuronic acid (both weak). A second sample of fraction 3 (4 mg) was dissolved in 0.2 ml of water. Ten milligrams of sodium borohydride was added and was allowed to react at room temperature overnight. The solution was neutralized with solid carbon dioxide and was decationized by passing it through a Dowex 50 H^+ column. The eluate was taken to dryness, and the boric acid was removed with dilute methanolic hydrogen chloride. The residue was hydrolyzed in 4 *N* sulphuric acid for 2 hours and was neutralized as described. Chromatography of the hydrolyzed, reduced sample in solvent (E) revealed that the glucose was completely converted to sorbitol. The presence of sorbitol indicates that fraction 3 is a trisaccharide composed of D-glucuronic acid, D-mannose, and D-glucose, with D-glucose the reducing end group.

Identification of Fraction 4 as an Aldotetraouronic Acid

Fraction 4 (5 mg) was hydrolyzed in 4 *N* sulphuric acid for 1 hour at 100° C. The hydrolyzate was neutralized and chromatographed as described. The substances found and their relative concentrations were: D-glucose, high; 2-*O*-(β-D-glucopyranosyluronic acid)-D-mannose, medium; and the aldotriouronic acid, weak. This chromatographic evidence indicates that fraction 4 is an aldotetraouronic acid in which two glucose residues are adjacent.

RESULTS AND DISCUSSION

The polysaccharides produced in the laboratory (T-42) or on a pilot-plant scale (MP-3) appear to be the same in composition and structure except for a small variation in the pyruvic acid content (Table I). The polysaccharide from *X. phaseoli* contains the same sugar constituents but in a different ratio (1:1:1) (2). Acetic and pyruvic acids were not reported for this polysaccharide. The optical rotations, however, of the polysaccharides from both genera of *Xanthomonas* are zero, indicating some degree of structural similarity. The acetic acid (4.7% as acetyl) in polysaccharide B-1459 appears to be present as an ester because it can be removed readily with dilute alkali at room temperature. Removal of the acetyl groups produces a polysaccharide with improved physical properties, e.g., its viscosity in the presence of salts is significantly greater and it produces stronger and more flexible films than the native polysaccharide (20).

Pyruvic acid, a unique polysaccharide constituent, comprises 3.0 to 3.5% of the total weight of polysaccharide B-1459. Previously, only commercial preparations of a red seaweed agar have been reported to contain 1.0% pyruvic acid as a 4,6-*O*-(1-carboxyethylidene) unit attached to D-galactose (21). In the seaweed polysaccharide pyruvic acid is suspected of imparting gel properties to the polymer. In polysaccharide B-1459 there is evidence that the pyruvic acid is attached by the same linkage to a glucose unit (22). The effect that pyruvate has on the physical properties of the polysaccharide is

unknown. The small differences in the pyruvate content of the two preparations of polysaccharide B-1459 are possibly due to slight variations in fermentation conditions.

Neutral equivalent data determined on native and deacetylated polysaccharide B-1459 indicate that lactonization is occurring when the polysaccharide is decationized with ion exchange resin. Measurement of neutral equivalents of both native and deacetylated polysaccharide should, theoretically, reveal the extent of carboxyl esterification since the conditions of deacetylation are sufficient to saponify esters of either glucuronic acid or pyruvic acid if they exist. Any difference in the neutral equivalent between the two samples, beyond that caused by the weight loss of acetyl groups, would be a measure of the carboxyl ester content. However, when such measurements were made on decationized material, both native and deacetylated polysaccharide samples gave results that were inconsistent and also high as compared with theoretical values based on the sum of pyruvic and glucuronic acid contents (Table II). Like polysaccharide B-1459, the exocellular polysaccharide from *X. phaseoli* exhibited an inconsistency of neutral equivalent values (391 to 599) when determined by a similar method (2). These discrepancies probably result from formation of the 3,6-lactone of glucuronic acid in the polymer by the action of the acidic ion exchange resin. Extensive lactone formation has been reported previously in certain other polysaccharides containing 1,4-linked glucuronic or mannuronic acid when isolated from an acidic medium (23). On the other hand, free galacturonic acid lactonizes to a minor extent, if at all (24, 25). In a polysaccharide it should lactonize only negligibly and titration of a polymer containing galacturonic acid should give an accurate measure of carboxyl content. As expected, pectic substances yield identical results when the hexuronic acid content is measured either by alkali titration or by the carbazole assay (26).

In graded acid hydrolysis studies approximately one-third of the mannose is released rapidly into the hydrolysis medium and is presumed to be a single side-chain unit. The quantity of labile mannose liberated is equivalent to one mannose side chain for every eight sugar residues. Stability of the polysaccharide backbone, however, is indicated by the persistence of viscosity even after 1 hour's hydrolysis in 4 *N* sulphuric acid at 100° C. This acid stability coupled with an optical rotation of zero indicates that the majority of the glycosidic linkages are in the β-configuration.

The sugar sequence of the polysaccharide backbone is revealed in part through the oligosaccharides isolated by partial acid hydrolysis. The majority of the mannose that is stable to mild acid hydrolysis was recovered as an acid-stable aldobiouronic acid, 2-*O*-(β-D-glucopyranosyluronic acid)-D-mannose.

Isolated in lesser yield was an aldotriouronic acid composed of the above aldobiouronic acid and glucose, which occupies the reducing end position. A third acidic oligosaccharide isolated in quite small yield was also made up of the aldobiouronic acid and glucose. However, its rate of migration on paper chromatograms as compared with that of the aldotriouronic acid is somewhat slower and therefore it is believed to be an aldotetraouronic acid which contains two adjacent glucose residues. No other oligosaccharides were observed.

Polysaccharide B-1459 appears to be a relatively high molecular weight linear polymer which forms highly viscous gel-like solutions that produce strong, flexible films (3, 20, 27). From the chemical composition studies, the polysaccharide may be depicted as a linear polymer with an acid-stable β-linked backbone containing D-glucose, D-mannose, and D-glucuronic acid with 1 mannose side chain unit for every 8 sugar residues and possibly a 4,6-*O*-(1-carboxyethylidene)-D-glucose side-chain residue for every 16 sugar residues (22).

Additional structural details based on periodate oxidation procedures will be described in a subsequent paper.

ACKNOWLEDGMENTS

We wish to thank Dr. G. O. Aspinall and Dr. A. M. Stephens for their gifts of 2-*O*-(β-D-glucopyranosyluronic acid)-D-mannose and 4-*O*-(α-D-glucopyranosyluronic acid)-D-galactose. Our appreciation is also extended to Mr. S. P. Rogovin for supplying us with polysaccharide preparation MP-3 and to Mrs. Danute Orentas for portions of the analytical data presented.

STABILIZATION OF POLYMERIC CARBOHYDRATE NITRATES FROM STUDIES ON STARCH, AMYLOSE, AMYLOPECTIN, AND GLYCOGEN

AHMED MUSTAFA, ABDEL FATTAH DAWOUD, AND SALAH EL-SHOURBANI

Department of Chemistry, Faculty of Science, Cairo University, Cairo, U.A.R.

ABSTRACT

Whole starch, amylose, amylopectin, and glycogen (polymeric carbohydrates of the α-D-glycosidic linkage type) were nitrated by nitric acid in the presence of phosphoric anhydride and stability properties of the nitrated products were studied. Crude amylose nitrate is more stable than amylopectin nitrate and the latter is less stable than the whole-starch nitrate as judged by the Bergmann–Junk test. The stability of glycogen nitrate is closely similar to that of amylopectin nitrate.

Appreciable stabilization of the crude nitrates was brought about by boiling with slightly alkaline water for long periods (60–70 hours). All stabilized samples were found to possess closely similar stability properties. The Bergmann–Junk values of all examined nitrates ranged from 2.2 to 1.7 mg of nitrogen per gram sample; the latter value seems to represent the maximum stabilization which could be attained for the polymeric carbohydrate nitrates of the α-D-glycosidic linkage type. In the case of cellulose nitrate (β-D-glycosidic linkage type) Bergmann–Junk values of 1 to 1.25 mg of nitrogen were obtained.

Extensive work has been carried out on starch nitrate (from 1833 onwards) by different investigators (6, 7, 14), but most of this work has centered on the preparation and stabilization of whole-starch nitrate. Some trials, however, were made by Berl and Kunze (4), Centola (11), and Snelling (20) to separate the nitrated starch into two different fractions, namely, the amylose and amylopectin nitrates, and to study their properties; but the difficulty was that the authors did not have either a true amylose (unbranched fraction) or a true amylopectin (branched fraction), since, at that time, these two principal components of starch had not been thoroughly established (7).

In recent years improved techniques have been developed for fractionation of starch into its separate components (2, 17, 18). The availability of two starch fractions, namely, amylose and amylopectin, simplified the study of two considerably different polymeric carbohydrate nitrates (2, 8, 9, 24). Thus, recently the Will and Lenze method for the preparation of whole-starch nitrate (23) was revived once again by Ashford, Evans, and Hibbert (2) for nitrating the amylose and the amylopectin fractions of the starch granule. The nitrated products were fractionated by dissolution in ethanol. The authors have indicated that the unfractionated amylose nitrate possesses greater stability than the unfractionated amylopectin nitrate. A high stability was also found with both the alcohol-soluble and alcohol-insoluble amylose nitrate fractions, those of the corresponding amylopectin nitrate being less stable.

The method of Will and Lenze appeared to be experimentally tedious and gave products that required considerable effort to stabilize (24). On the other hand, it has been previously claimed that nitration of whole starch with nitric acid alone (12) or with nitric acid in the presence of phosphoric acid and/or phosphoric anhydride (3, 4, 7) gives nitrates of higher stabilities and higher viscosities (through less degradation). The investigation, herein described, was initiated in the belief that a study of the properties of the nitrates of starch, amylose (unbranched fraction), and amylopectin (branched fraction), prepared

by nitric acid in the presence of phosphoric anhydride, would provide valuable data on stability properties of those polymeric carbohydrate nitrates; an elusive problem in the chemistry of polymeric carbohydrate nitrates is that of stability. Moreover, the availability of glycogen, a polymeric carbohydrate possessing the branched-type structure of α-D-glycosidic linkages like that of amylopectin (branches of glycogen are shorter than those of amylopectin (13)), gives a new material for study of the nitration and stabilization of another polymeric carbohydrate nitrate of the α-D-glycosidic linkage type. No work has been done previously on the stabilization of glycogen nitrate.

DISCUSSION

Many tests have been devised to measure the stability of the nitrated polysaccharides (5, pp. 41–61; 15). The Abel heat test and the Bergmann–Junk test are the two most widely used tests for measuring the stability of starch nitrates.

There are some objections, however, to the application of the Abel test; the most essential ones are: (*a*) the test is extremely sensitive, the standard tint being produced by 0.000135 mg of nitrogen peroxide; (*b*) the test time is greatly affected by the moisture content of the sample (15); and (*c*) short test time is obtained for carefully stabilized explosives when the water used in the stabilization treatment has a high content of certain salts and impurities (5, pp. 41–61); on the contrary, the presence of minute amounts of certain adulterants, e.g., mercuric chloride, methanol, ethanol, etc., prolongs the test time (15).

In contrast to the Abel test, the Bergmann–Junk test is quantitative and gives a better idea of the actual stability or storage ability of explosives (5, pp. 41–61). This test was taken as the main measure of stability during the course of the present experiments. The ignition temperatures of the nitrates were recorded throughout all the work.

The crude nitrated products of whole starch, amylose, amylopectin, and glycogen were found to possess different stability properties as judged by the Bergmann–Junk test. Amylose nitrate is more stable than the amylopectin nitrate and the latter is less stable than the whole-starch nitrate. The stability of glycogen nitrate is closely similar to that of amylopectin nitrate. In the ignition temperature test, the examined nitrates had different ignition temperatures, as shown in Table I. The ignition temperature of glycogen nitrate is about 2.5° C lower than that for the amylopectin and for the whole-starch nitrates. Amylose nitrate has a higher ignition temperature (178° C).

Stabilization of the crude nitrates was brought about by boiling either with distilled water or with slightly alkaline water (0.025% sodium carbonate solution), for long periods, as followed in the industrial stabilization treatment of cellulose nitrates (16). The following results were obtained.

(1) Stability properties of the crude nitrates were improved by boiling with distilled water for 72 hours (cf. Table I). Although the Bergmann–Junk stability values of the so treated nitrates were still far away from the specifications of stable explosives (1.25 mg nitrogen for cellulose nitrate (5, pp. 41–61)), yet the most important observation was that the difference in stability properties of the examined esters was practically negligible. The ignition temperatures of the nitrates were also improved but still there is a slight difference, as shown in Table I; brown fumes appeared at about 169° C.

(2) Appreciable stabilization of the crude nitrates was brought about by boiling with slightly alkaline water. Thus, boiling with slightly alkaline water for 24 hours effected more stabilization than boiling with distilled water for 72 hours. A slight decrease in nitrogen content was observed in the first case. The stability of the esters was greatly

TABLE I

Nitrate sample	Nitrogen content, %	Ignition temp. test		Bergmann–Junk test, mg nitrogen	Abel heat test at 80° C (ref. 5, pp. 41–61), min

Glycogen	11.85	170	175.5	1.65	—

improved by alkaline boiling for a period of 60 hours. It is to be noted that the so treated nitrates of starch, amylose, amylopectin, and glycogen possessed closely similar stability Bergmann–Junk values.

(3) Further improvement in stability of the discussed esters was obtained by boiling in slightly alkaline water for 72 hours, whereby an appreciable decrease in nitrogen content was also traced. This represents the most favorable conditions for attaining the best stabilization results, since boiling for 84 hours caused marked loss in nitrogen content and no appreciable improvement of the Bergmann–Junk stability values (cf. Table I).

Examinations of the explosive properties of the stabilized samples of glycogen, amylopectin, and whole-starch nitrates boiled for 60 hours (with carbonate solution) had shown that their nitrogen contents still provided them with good explosive properties; the Trauzl lead block test showed a net expansion of 325, 330, 340 ml respectively, as compared with a net expansion of 280 ml for standard T.N.T. The ignition temperature of glycogen nitrate was still lower (ca. 3° C) than that for the amylopectin and for the whole-starch nitrates. The amylose nitrate had a higher ignition temperature than all the examined nitrates.

In a nitrating medium composed of nitric acid and phosphoric anhydride the instability of the nitrated starch and its fractions is mainly attributed to the presence, in very small amounts, of either free mineral acid or certain nitrated oxidation products formed during the nitration reaction (10, 16). The fact that stabilization of the esters by boiling with slightly alkaline water is more effective than boiling with distilled water is not surprising, since (*a*) the dilute alkaline boiling is reported to effect decomposition of the unstable nitrated oxidation products (16) and (*b*) alkaline hydrolysis is more rapid and effects rapid fall in nitrogen content.

It remains, now, to interpret the solubility results of the above-discussed nitrates in absolute ethanol. The crude nitrated products were found to possess widely different solubilities. Amylopectin and glycogen nitrates are much more soluble, in absolute ethanol, than the amylose nitrate (59, 56, and 21% respectively). The whole-starch nitrate is less soluble than the amylose ester (16.5 and 21% respectively). The widely different solubilities of either amylopectin nitrate or glycogen nitrate, and of the amylose ester, may be related to the structural difference between amylose, amylopectin, and glycogen. It is evident that the amylose ester, which is composed of linear molecules capable of close packing, would be more insoluble than the somewhat loosely packed molecules of amylopectin ester (22). The glycogen nitrate is expected to behave like the amylopectin nitrate due to similarity in their branched-type structure (13). In the case of whole-starch nitrate the solvent is unable to break associative bonds necesssary for solution, while when the amylopectin is separated from the amylose, associative bonding is greatly lessened and solution of the former component can take place more readily; the amylose is responsible for association in whole-starch nitrate (cf. ref. 2).

On the basis of the above results, it could be concluded that stabilization of polymeric carbohydrate nitrates of amylose, amylopectin, whole starch, and glycogen, by boiling with slightly alkaline water, gives products of closely similar stability properties as judged by the Bergmann–Junk test. The stabilized samples had Bergmann–Junk values ranging from 2.2 mg of nitrogen (60 hours' boiling) to ca. 1.7 mg of nitrogen (72 hours' boiling) per gram sample, and these values are probably the maximum stability values attained for those polymeric carbohydrate nitrates of the α-D-glycosidic linkage type. When samples of commercial cellulose nitrates (β-D-glycosidic linkage type) were examined, during the course of the present experiments, Bergmann–Junk values ranging from 1 to 1.25 mg of nitrogen per gram sample were obtained. The present stability results throw light on stability of starch nitrate, and further investigations on the subject will follow.

EXPERIMENTAL

Amylopectin and glycogen (provided by the British Drug Houses) as well as potato starch (provided by Carlo Erba, Italy) were used during the course of the present experiments. Amylose was obtained from the potato starch by means of the selective adsorption method employing cotton cellulose as the adsorbent (2, 19, 21).

Preparation of the Nitrates

Nitration of starch, amylose, amylopectin, and glycogen was carried out under the following conditions: nitric acid/P_2O_5 (by weight), 19:1; starch/nitrating medium, 1:50; time of nitration, 3 hours; temperature of nitration, 10° C.

Nitration

Five hundred cubic centimeters of concentrated nitric acid (*d*, 1.52), in a 1-liter three-necked flask, fitted with a stirring motor, was placed in an ice bath at a temperature of about 10° C. Forty grams of phosphorus pentoxide (P_2O_5) were added to the nitric acid, in portions, so that the temperature of the nitrating mixture did not exceed 10° C. Well-dried starch, amylose, amylopectin, and glycogen (16 g) were added to the nitrating mixture over a period of 1 hour, during which time the mixture was stirred vigorously

and the temperature maintained at 10° C. Nitration was completed by continuing the stirring for a period of 2 hours at the same temperature.

The nitrated products were isolated by pouring the nitration mixture onto vigorously stirred, finely chopped ice, followed by filtration and then washing, on the filter, with large quantities of water. The crude ester was placed in a beaker with 250 ml of dilute sodium carbonate solution (0.025%) and boiled for ½ hour, cooled, filtered, and then washed with large quantities of cold water.

The nitrated products were dried cautiously at 45–55° C and weighed. Yields amounted to ca. 27.5 g, 172%.

Stabilization Treatment

Stabilization of the crude nitrates was carried out by boiling either with distilled water or with slightly alkaline water (0.025% sodium carbonate solution) for long periods, as followed in the industrial stabilization treatment of commercial cellulose nitrates (16). The nitrates were boiled under reflux for the periods illustrated in Table I; liquor ratio 15:1. After the boiling treatment the treated esters were washed thoroughly with water, followed by washing with 0.1% solution of ammonium hydroxide, and then finally with water.

Determination of Nitrogen Content

Nitrogen contents were obtained by the nitrometer method. The Lunge–Sederholm nitrometer (5, pp. 160–161) was used.

Solubility of the Nitrates in Absolute Ethanol

One-half gram of dry sample of nitrate was weighed out in a 250-ml glass cylinder. One hundred cubic centimeters of absolute ethanol (provided by E. Merck) was added and the stoppered cylinder was then shaken on a shaker for 2 hours. After centrifugation, 50 cc of ethanol was withdrawn by means of a pipette and evaporated in a tared glass dish on a water bath. It was then dried, cooled in a desiccator, and weighed to constant weight. The percentage of soluble matter was calculated.

Determination of Stabilities

The Bergmann–Junk Test

In the official Bergmann–Junk test, 2 g of the explosive of the cellulose nitrate type is heated at 132° C (±0.5° C) for a period of 2 hours, at the end of which the quantity of nitric oxide evolved per gram of sample is quantitatively determined as a measure of the stability of the explosive under examination. Results are usually given in milligram of nitrogen per gram of sample. The amount of nitric oxide present can be estimated by the Schultze–Tiemann method (15) or by titrimetric procedures (5, pp. 41–61).

The Bofor's titrimetric procedure, using 0.05 *N* sodium hydroxide solution and phenolphthalein as indicator (1 ml of 0.05 *N* sodium hydroxide is equivalent to 1 ml of nitric oxide (5, pp. 41–61), was employed. Results were checked by the Schultze–Tiemann method whereby reliable results were obtained. Triplicate samples were used.

During the course of the present investigation, the Bergmann-Junk test was modified in one respect only, namely, in the weight of the sample used. One-half-gram samples were used in the primary stabilization experiments and compared with 0.5-g samples of standard starch nitrate. When the best favorable conditions of stabilization were attained (e.g., by boiling with slightly alkaline water for 60 hours) the official Bergmann–Junk test with the 2-g sample was employed.

Determination of the Ignition Temperature

The ignition temperatures were obtained using Bofor's ignition temperature apparatus (5, pp. 41–61). The experiments were carried out by inserting four ignition test tubes, each containing 0.1 g of dry sample of the nitrate, into the corresponding holes of the ignition apparatus, as soon as its temperature attained 100° C. Heating was controlled to allow a rise of 5° C per minute.

IDENTIFICATION OF CONJUGATED TRIENE FATTY ACIDS IN CERTAIN SEED OILS[1, 2]

C. Y. Hopkins and Mary J. Chisholm
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received July 17, 1962

ABSTRACT

Seed oils were hydrolyzed under mild conditions and the major conjugated fatty acid of each oil was isolated and identified. In two families, species which were closely related botanically contained different but isomeric acids. Thus, in the Bignoniaceae, *Jacaranda chelonia* had *cis,trans,cis*-8,10,12-octadecatrienoic acid as a major acid while *Catalpa speciosa* had *trans,trans,cis*-9,11,13-octadecatrienoic acid. In the Cucurbitaceae, *Momordica charantia* had the ordinary *cis,trans,trans*-9,11,13-octadecatrienoic (α-eleostearic) acid while *M. balsamina* had *cis,trans,cis*-9,11,13-octadecatrienoic (punicic) acid. *M. balsamina* is a new and convenient source of punicic acid. α-Eleostearic acid was identified as a major acid in examples of Valerianaceae and Rosaceae. Further proof was obtained that the fatty acid of *Calendula officinalis* (Compositae) is *trans,trans,cis*-8,10,12-octadecatrienoic acid.

Until the year 1956 only two simple conjugated triene fatty acids were known to occur in seed oils, viz. α-eleostearic and punicic acids. Three additional acids of this type have been discovered since then (1, 2, 3, 4). All five of these simple conjugated acids have an 18-carbon straight chain; in two of them the unsaturated grouping occupies the 8,10,12 position but in the other three it is in the 9,11,13 position. The present work reveals the occurrence of four of these acids in plant species in which they were not known previously (Table I). Positive identification of each acid was made by orthodox chemical procedures.

TABLE I

Occurrence of conjugated octadecatrienoic acids

$CH_3(CH_2)_xCH{=}CH{-}CH{=}CH{-}CH{=}CH(CH_2)_yCOOH$

Species	Formula	Unsaturated grouping		Reference
		Position	Configuration	
Jacaranda chelonia (Bignoniaceae)	I	8,10,12	cis,trans,cis	*
Catalpa speciosa (Bignoniaceae)	II	9,11,13	trans,trans,cis	*
Momordica charantia (Cucurbitaceae)	III	9,11,13	cis,trans,trans (α-eleostearic)	5
Momordica balsamina (Cucurbitaceae)	IV	9,11,13	cis,trans,cis (punicic)	*
Calendula officinalis (Compositae)	V	8,10,12	trans,trans,cis	1, 2
Centranthus ruber (Valerianaceae)	III	9,11,13	cis,trans,trans	*
Cotia chestnut (Rosaceae, see text)	III	9,11,13	cis,trans,trans	*
Prunus mahaleb (Rosaceae)	III	9,11,13	cis,trans,trans	6

*Present work

Seed of *Jacaranda chelonia* Griseb. (Bignoniaceae) yielded an oil containing a substantial amount of conjugated triene acid, as shown by its ultraviolet spectrum. The acid was isolated and identified as *cis,trans,cis*-8,10,12-octadecatrienoic acid (I) by melting point, mixed melting point, and ultraviolet spectrum. The only previously known occurrence of this acid is in the oil of *Jacaranda mimosifolia* D. Don (4).

[1]*Presented in part at the VIth Congress of the International Society for Fat Research, London, April 9–13, 1962.*
[2]*Issued as N.R.C. No. 7006.*

The seed oil of *Catalpa speciosa* Warder, also a member of the Bignoniaceae family, yielded a different triene acid. It melted at 31–32° and gave an adduct with maleic anhydride which melted at 72–73°. Its ultraviolet spectrum indicated a triene grouping of two trans and one cis bond (cf. ref. 7). The acid was identified as *trans,trans,cis*-9,11,13-octadecatrienoic acid (II) by mixed melting point with an authentic sample. This was confirmed by mixed melting point of the maleic anhydride adducts. The acid is known to occur in the oil of *Catalpa ovata* Don (3) but has not been observed elsewhere. Occurrence of this trans,trans,cis acid nullifies an earlier suggestion that the 9:10 double bond in natural triene acids is always cis (8).

The existence of acid I in two species of *Jacaranda* and of acid II in two species of *Catalpa* provides rather striking confirmation of the botanical classification of these plants. It is notable that one genus produces the 8,10,12-triene while the other produces the 9,11,13-triene, also that the two acids differ in their geometric configuration. Although it cannot be taken for granted that a given species of plant will always produce the same isomer of a conjugated fatty acid, we are not aware of any evidence to the contrary.

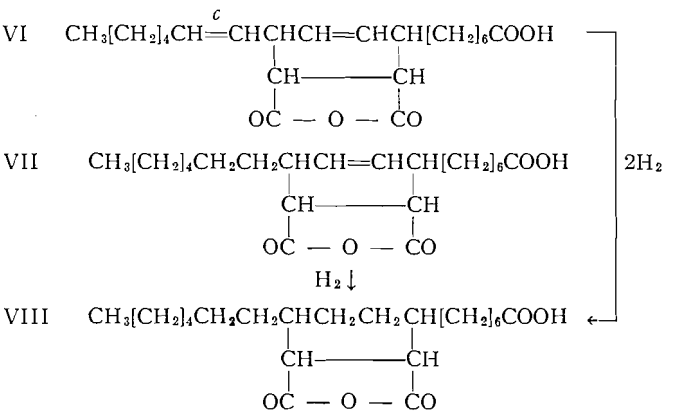
The oil of *Momordica charantia* L. (Cucurbitaceae) has been studied in the past and the presence of α-eleostearic acid has been reported. Claims that the oil contained trichosanic (punicic) acid have apparently not been substantiated. Verma and Aggarwal (5) isolated the acid and identified it as α-eleostearic by melting point, ultraviolet absorption, and conversion to the all-trans form. However, they did not report any mixed melting points. Our sample of *Momordica charantia* seed yielded α-eleostearic acid (III) as the major acid and its identity was proved conclusively, thus confirming the work of Verma and Aggarwal.

Another species of the same genus, *M. balsamina* L., contained a different acid. Earle and co-workers (9) reported that the oil of this species contained 50% of a conjugated triene acid and listed it as trichosanic acid, although evidence of its identification was not given. Our sample of the oil was estimated to contain 58% of a conjugated triene acid which was identified unambiguously as punicic acid (synonymous with trichosanic), i.e. *cis,trans,cis*-9,11,13-octadecatrienoic acid (IV). Thus it appears that two species of the same genus produce different major fatty acids, indicating a marked specificity of fatty acid biosynthesis. The two acids from these species differ only in geometric configuration (cis,trans,trans and cis,trans,cis).

Punicic acid has been available hitherto only from *Punica granatum* (Punicaceae) and from *Trichosanthes* sp. (Cucurbitaceae). *Momordica balsamina* constitutes a useful new source of the acid since the seed is available commercially and the oil has a high content of punicic acid.

The oil of *Calendula officinalis* L. (Compositae) was shown by McLean and Clark to contain an 8,10,12-octadecatrienoic acid (1). Later, the configuration of this acid was found to be trans,trans,cis (V) by infrared studies and by degradation of its maleic anhydride adduct (2). The trans,trans,cis configuration was confirmed in the present work by hydrogenating the adduct (VI) and comparing the product with the compound (VIII) obtained by hydrogenating the adduct (VII) of *trans,trans*-8,10-octadecadienoic acid; both melted at 105.5–106.5° and a mixed melting point determination showed that they were identical. Hence, the two trans double bonds of the triene acid must be at positions 8 and 10.

Seed oil of *Centranthus ruber* DC. (Valerianaceae) was found to contain a conjugated triene acid which was isolated and identified as α-eleostearic acid. This appears to be the first identification of a conjugated triene acid in this family although Earle and co-



workers (9) reported infrared evidence for a triene acid in *Valeriana officinalis* that was listed as eleostearic acid. *Valerianella olitoria*, of the same family, was shown by Steger and van Loon to contain no conjugated acid (10) and we have confirmed this.

Two species of Rosaceae were examined. The kernel oil of the cotia chestnut was reported earlier to contain a conjugated acid on the basis of its diene value and drying properties (11). Our sample of this nut, obtained from the vicinity of Tefe, Amazonas, Brazil, yielded an oil containing about 23% of α-eleostearic acid, identified by means of its maleic anhydride adduct. There was no evidence of an hydroxy acid. The cotia chestnut is considered to be a species of *Parinarium* or *Licania* (family Rosaceae) but there is still some doubt concerning its classification.

The oil of *Prunus mahaleb* L. was re-examined. It was studied by Alpar and Esin (6), who isolated the triene acid and prepared derivatives which showed fairly conclusively that it was α-eleostearic acid. In the present work its identity has been confirmed by means of spectral analysis and mixed melting points of the acid and derivatives.

These results, taken in conjunction with previous data, indicate that α-eleostearic is the most commonly occurring conjugated triene acid; it is found in species of Rosaceae, Euphorbiaceae, Cucurbitaceae, and Valerianaceae. Punicic acid occurs in three species of Cucurbitaceae and one of Punicaceae. Other positional or geometric isomers of octadecatrienoic acid are found in four species of Bignoniaceae and one of Compositae.

EXPERIMENTAL

Cotia chestnuts were supplied through the kindness of Dr. K. S. Markley. Other seeds were obtained from commercial sources. Melting points were determined in capillary tubes and are corrected. Ultraviolet spectra were determined in cyclohexane solution, except where noted, with a Beckman DU spectrophotometer. Infrared spectra were determined in carbon disulphide in a Perkin–Elmer model 21 spectrophotometer with sodium chloride prism.

Jacaranda chelonia

Seed of *J. chelonia* Griseb. (10 g) was ground and extracted at room temperature by stirring with 30–60° petroleum ether. It yielded 19% of oil. The solvent was removed at 25–30° under nitrogen. The oil (1.9 g) had ultraviolet absorption λ_{max} 265, 275, 287 mμ and absorptivity $E^{1\%}_{1\ cm}$ 540 at 275 mμ, equivalent to about 31% of conjugated triene fatty acid. The oil was hydrolyzed, the unsaponifiable matter removed, and the acids recovered by methods described previously (3). The mixed acids were crystallized from acetone and then from pentane in the usual way (3), yielding 0.38 g of pure conjugated acid, m.p. 43.5–44°, λ_{max} 265, 275, 287 mμ. The melting point was unchanged in admixture with an authentic sample of *cis,trans,cis*-8,10,12-octadecatrienoic acid prepared from the oil of *J. mimosifolia* (4).

Catalpa speciosa

Seed of *C. speciosa* Warder, treated as described above, yielded 22% of oil having λ_{max} 262, 272, 283 mμ and absorptivity $E^{1\%}_{1\ cm}$ 604 at 272 mμ, equivalent to about 34% of conjugated triene fatty acid. The mixed

acids were crystallized at low temperature, giving a triene acid, m.p. 31–32°, λ_{max} 262, 272, 283 mμ. It reacted readily with maleic anhydride, giving an adduct, m.p. 72.5–73.5°. The melting point was unchanged in admixture with the corresponding adduct of *trans,trans,cis*-9,11,13-octadecatrienoic acid, prepared from the oil of *C. ovata* (3).

Momordica charantia

Seed of *M. charantia* L. was extracted and the fatty acids of the oil were crystallized in the usual way (3). A triene acid was obtained. It melted at 46–47°, alone and mixed with authentic α-eleostearic acid prepared from tung oil. Its maleic anhydride adduct melted at 63–64°, alone and mixed with the maleic anhydride adduct of α-eleostearic acid.

Momordica balsamina

Seed of *M. balsamina* L. yielded an oil having λ_{max} 266, 275, 286 mμ and absorptivity at 275 mμ equivalent to about 58% of conjugated triene fatty acid. Crystallization of the fatty acids yielded a triene acid, m.p. 44–45°, unchanged in admixture with punicic acid prepared from *Punica granatum*. The pure *Momordica* acid had λ_{max} 265, 275, 287 mμ; absorptivity $E^{1\%}_{1\,cm}$ 1694 at 275 mμ; infrared absorption, ν_{max} 933 (s), 983 (s) cm^{-1}. The absorption maxima were identical with those of punicic acid. The *Momordica* acid did not form an adduct with maleic anhydride under the normal conditions for this reaction. It formed a *p*-phenylphenacyl ester, m.p. 61.5–63.5°, alone and mixed with an authentic sample of the *p*-phenylphenacyl ester of punicic acid (4).

Calendula officinalis

trans,trans-8,10-Octadecadienoic acid was prepared from oleic acid by the method of Gupta and Kummerow (12). The diene acid (0.24 g), m.p. 55–56°, was refluxed with benzene (20 ml) containing maleic anhydride (0.21 g) for 6 hours. The product was crystallized from ether:petroleum ether (3:4) at 0°, giving 0.18 g of the pure adduct, 3-6′-carboxyhexyl-6-heptylcyclohexene-4,5-dicarboxylic anhydride (VII), m.p. 109–110°. Von Mikusch gives m.p. 110° (13). Calcd. for $C_{22}H_{34}O_5$: C, 69.8; H, 9.05. Found: C, 70.1; H, 9.06.

The adduct (VII) was hydrogenated in methanol with Adams catalyst and the product was crystallized from methanol at −30°, giving 3-6′-carboxyhexyl-6-heptylcyclohexane-1,2-dicarboxylic anhydride (VIII), m.p. 105.5–106.5°. Calcd. for $C_{22}H_{36}O_5$: C, 69.4; H, 9.5. Found: C, 69.5; H, 9.7.

The triene acid of *Calendula officinalis* L., 8,10,12-octadecatrienoic acid, and its adduct with maleic anhydride were prepared as described previously (2). The adduct, m.p. 73–74°, considered to be 3-6′-carboxyhexyl-6-*cis*-1′-heptenylcyclohexene-4,5-dicarboxylic anhydride (VI), was hydrogenated in methanol with Adams catalyst; it absorbed 2 moles of hydrogen. The product was crystallized from methanol at 0°. It melted at 105.5–106.5° and the melting point was not depressed in admixture with compound VIII, prepared from *trans,trans*-8,10-octadecadienoic acid. Hence the identity of VI is confirmed.

Centranthus ruber

Seed of *C. ruber* DC. yielded an oil having λ_{max} 262, 271, 282 mμ and absorptivity at 271 mμ equivalent to about 43% of conjugated triene fatty acid. The mixed fatty acids were crystallized, giving a triene acid that was somewhat difficult to purify. It melted at 42–43°. On treatment with iodine in pentane it gave β-eleostearic acid, m.p. and mixed m.p. 70–71°. The unisomerized acid reacted readily with maleic anhydride to give an adduct, m.p. 63.5–64.5° alone and mixed with the adduct of α-eleostearic acid (14).

Oil of *Valerianella olitoria* Poll. had negligible ultraviolet absorption in the conjugated triene region.

Cotia chestnut

Kernels of the cotia chestnut were extracted, yielding 61% of oil. The oil had λ_{max} 261, 270, 282 mμ in isooctane; absorptivity equivalent to about 24% of conjugated triene fatty acid; ν_{max} 957 (w), 986 (s) cm^{-1}. The triene acid was concentrated by crystallization but retained some saturated fatty acid. The concentrate was allowed to react with maleic anhydride, giving an adduct, m.p. 63–64° alone and mixed with the adduct of α-eleostearic acid.

Prunus mahaleb

Whole seeds of *P. mahaleb* L. yielded 15% of oil. The oil had λ_{max} 261, 270, 282 mμ in isooctane and absorptivity equivalent to about 29% of conjugated triene fatty acid. The mixed methyl esters of the fatty acids had infrared maxima at 960 (w) and 988 (vs) cm^{-1}. A concentrate of the triene acid was prepared and a portion was converted to its maleic anhydride adduct. The adduct melted at 63–64°, alone and mixed with the adduct of α-eleostearic acid. Another portion was isomerized by iodine in pentane solution to the all-trans form, m.p. and mixed m.p. with β-eleostearic acid, 70–71°.

ACKNOWLEDGMENTS

The authors are indebted to Mr. R. Lauzon for determination of infrared spectra and to Mr. H. Seguin for the microanalyses.

GAS–LIQUID PARTITION CHROMATOGRAPHY OF SESQUITERPENE COMPOUNDS

ISHWAR C. NIGAM[1] AND LEO LEVI
Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Canada

Received July 5, 1962

ABSTRACT

Sesquiterpene compounds were effectively separated by gas chromatography and identified by infrared spectrophotometry. Examples given include the recovery and characterization of β-caryophyllene and β-humulene from oil of balsam copaiba, of α- and β-vetivone from oil of vetiver, and of α- and β-santalol from oil of sandalwood.

INTRODUCTION

Gas–liquid partition chromatography has become a technique of choice for the investigation of volatile substances, particularly essential oils and related products. An increasing number of researches are being published dealing with its application to the characterization and estimation of major as well as minor constituents in natural and synthetic products used by the essential oils, flavor, cosmetic, and perfume industry. Recently, preparative columns have enabled investigators to collect effluent fractions in quantities sufficient for further physicochemical analysis by infrared and ultraviolet spectroscopy as well as the formation of characteristic derivatives.

Most efforts have, however, been directed toward the examination of monoterpene compounds (1, 2, 3, 4). Corresponding studies of sesquiterpenes are lacking, although some notable contributions have been made (5, 6, 7, 8, 9, 10, 11). Paucity of systematized data may, in part, be due to the low vapor pressure of these compounds—a property that restricts the choice of stationary phases permitting reasonable retention times—combined with a rather delicate nature, rendering them prone to degradation when kept at elevated temperature on potentially catalytic surfaces for some length of time.

Experiments carried out in the authors' laboratory showed that these compounds can be resolved effectively by gas chromatography within less than 30 minutes under relatively mild conditions. It is the purpose of this paper to report the separation of typical sesquiterpenoid mixtures occurring in balsam copaiba, vetiver, and sandalwood oil.

EXPERIMENTAL RESULTS AND DISCUSSION

Apparatus.—Gas chromatograph. Burrell Kromo-Tog K-2 equipped with thermal conductivity detector cell and separate heating baths for column and detector, respectively.

Column.—Glass tubing, 0.6 cm inside diameter, 215 cm long.

Packing.—Reoplex 400 (20 parts) deposited from ethanolic solution on 60- to 80-mesh, acid-washed Chromosorb W (80 parts). Length of packed column, 200 cm.

Carrier Gas.—Helium, inlet pressure 1.1 atm; outlet pressure 1.0 atm.

Recorder.—0 to 1 mv full scale deflection; 1 second.

Chart Speed.—0.5 inch per minute.

Analytical procedures were previously described (12, 13).

Infrared spectra of the eluates collected were charted by a Perkin–Elmer Model 221 spectrophotometer operated with fivefold ordinate scale expansion and their identity confirmed through reference to literature data (14).

Caryophyllene Fraction of Oil of Balsam Copaiba

Oil of balsam copaiba is known to contain a number of sesquiterpene hydrocarbons. α- and β-Caryophyllene were isolated in 1892 (15) and *l*-cadinene was detected in 1910 (16). α-Caryophyllene, later identified as

[1]*National Research Council of Canada Postdoctoral Fellow, 1961–62.*

humulene, is now itself considered to be composed of two isomers, α- and β-humulene. Separation of β-caryophyllene–humulene mixtures has been accomplished by careful distillation and repurification of the isolates via extensive column chromatography (17, 18).

Figure 1 shows the chromatogram of a fraction, b.p. 116–125° C/10 mm, obtained by vacuum distillation of a genuine Brasilian oil and the infrared spectra of the eluates, β-caryophyllene and β-humulene, collected

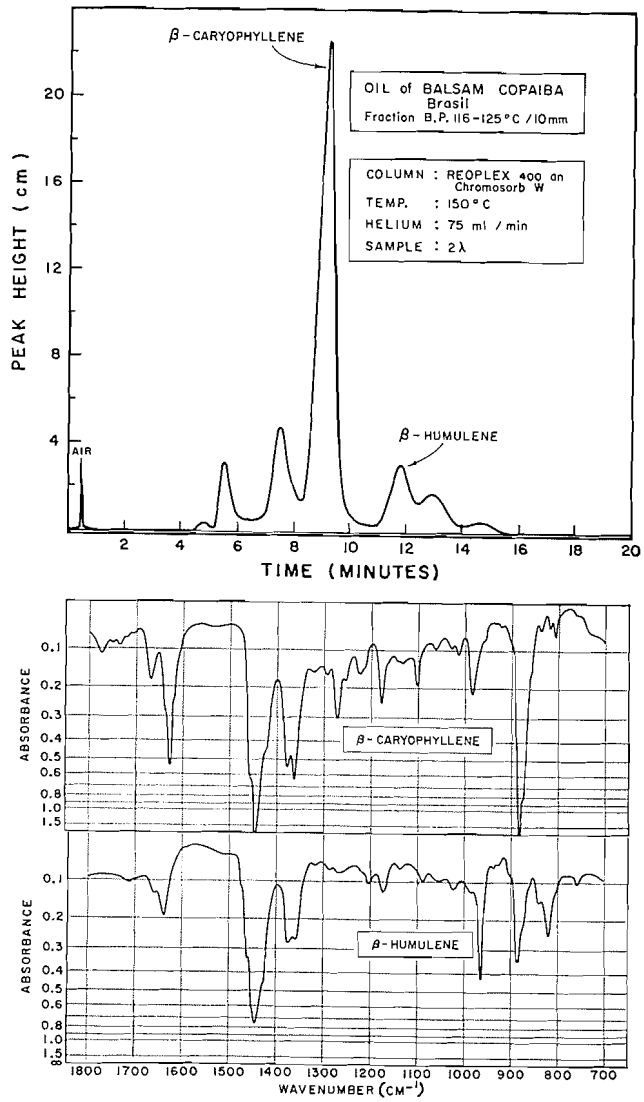

FIG. 1. Gas chromatographic separation and infrared spectra of sesquiterpenes. β-Caryophyllene: isolate from 10-λ sample injection examined with fivefold ordinate scale expansion; β-humulene: isolate from 3×8-λ sample injection examined with fivefold ordinate scale expansion.

for analysis. The identity of three other sesquiterpene compounds present and likewise well resolved is being established.

A column of SAIB (19) operated at 170° C was found to separate the hydrocarbons with equal efficiency.

Vetivone-enriched Fraction of Vetiver Oil

α- and β-Vetivone, two stereoisomeric sesquiterpene ketones differing only in the spatial configuration about their asymmetric $\rangle CH—CH_3$ group, are the major ketones present in oil of vetiver and considered

responsible for its characteristic odor. Their isolation has been achieved by treatment of the oil with Girard T reagent, conversion of the complexes formed to semicarbazones, and decomposition of the derivatives with phthalic anhydride following repeated fractional recrystallizations, or by careful distillation of the oil, reaction of the ketone fraction with semicarbazide, and analogous treatment of the isolated semicarbazones. Each method involves tedious and time-consuming operations and yields are poor (20, 21, 22, 23).

Figure 2 shows the chromatogram of a vetivone-enriched fraction obtained by column chromatography of a sample of Réunion Island vetiver oil and the infrared spectra of the well-separated isomers collected for examination. Characterization of other sesquiterpene ketones present and effectively resolved is underway.

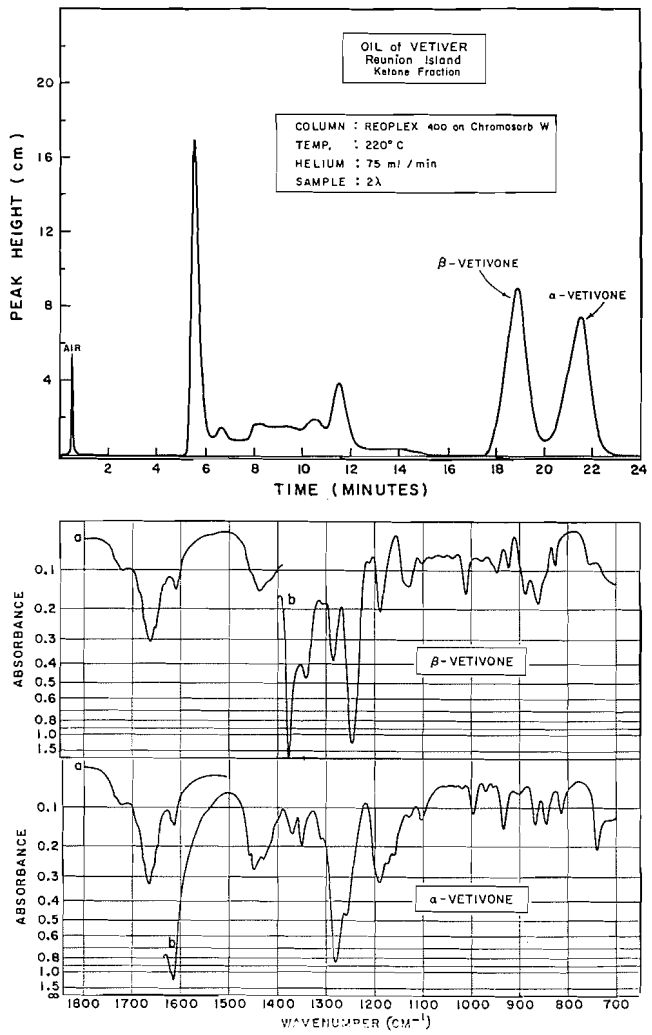

FIG. 2. Gas chromotographic separation and infrared spectra of sesquiterpene ketones. α- and β-Vetivone isolates from 8-λ sample injection examined (*a*) without and (*b*) with fivefold ordinate scale expansion.

East Indian Sandalwood Oil

East Indian sandalwood oil contains more than 90% of santalol, a high-boiling sesquiterpene alcohol occurring as an α- and β-isomer, respectively. Official methods of analysis based on acetylation and saponification reactions lack selectivity (24, 25, 26). An infrared procedure utilizing measurements of specific extinction coefficients observed throughout the 3.2–3.3 and 9.8–10.0 μ regions, respectively, has also been reported. Considered to be characteristic of cyclopropane ring compounds present, it provides an index of total cyclopropyl content including, in addition to α-santalol, such constituents as α-santalene, teresantalic acid, teresantalol, and nortricycloekasantalane, but leaving β-santalol unaccounted for (27).

Figure 3 shows the chromatogram of this oil and the infrared spectra of both isomers collected from a single 8-λ sample injection. Requiring only microamounts of products for analysis the method described should prove of general value to workers in the field.

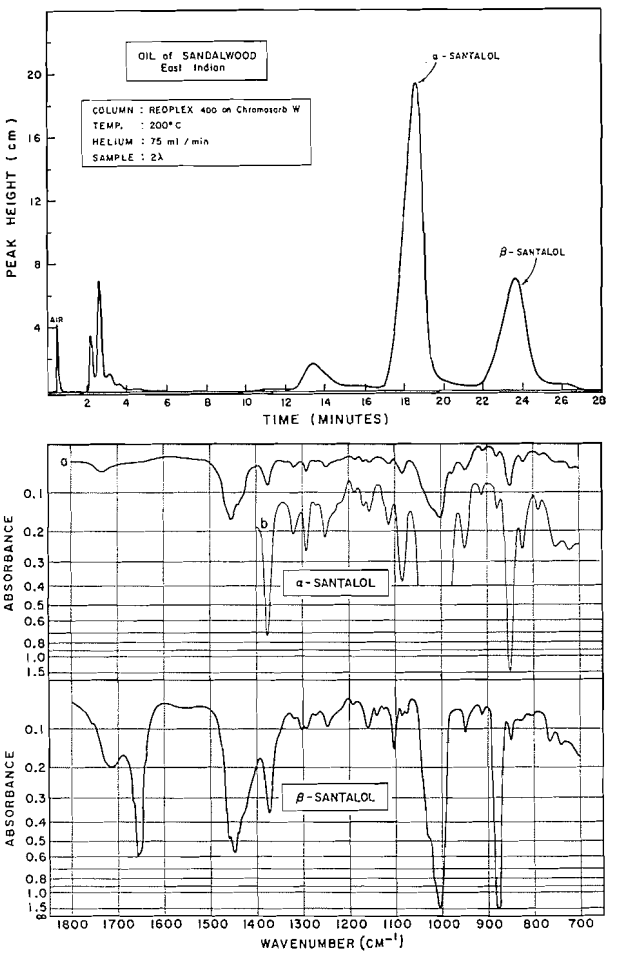

FIG. 3. Gas chromatographic separation and infrared spectra of sesquiterpene alcohols. α-Santalol: isolate from 8-λ sample injection examined (*a*) without and (*b*) with fivefold ordinate scale expansion; β-santalol: isolate from 8-λ sample injection examined with fivefold ordinate scale expansion.

Application of the technique to the examination and recognition of sandalwood oils of different geographical origins and further illustrations of sesquiterpene analyses by gas–liquid partition chromatography will be reported in forthcoming publications.

ACKNOWLEDGMENTS

The authors are indebted to Dr. E. Guenther, Fritzsche Brothers, Inc., New York, U.S.A., for the balsam copaiba oil fraction used in this study; to Dr. J. Gondran, Société Comores Bambao, Paris, France, for an authentic sample of Réunion Island vetiver oil; to Dr. Y. R. Naves, Givaudan and Co., Geneva, Switzerland, for a genuine specimen of β-vetivone; and to Dr. S. C. Bhattacharyya, National Chemical Laboratory, Poona, India, for an authentic sample of Mysore sandalwood oil.

LYCOPODIUM ALKALOIDS

IV. THE CONSTITUTION AND STEREOCHEMISTRY OF LYCOCLAVINE, AN ALKALOID OF LYCOPODIUM CLAVATUM VAR. MEGASTACHYON[1]

W. A. Ayer and D. A. Law
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received May 22, 1962

ABSTRACT

The alkaloids of *Lycopodium clavatum* var. *megastachyon* have been examined and two hitherto unreported alkaloids, lycoclavine and acetyllycoclavine, were isolated and their structures determined. The nuclear magnetic resonance spectra of these and related compounds are discussed in terms of the conformation of ring B in these alkaloids.

The alkaloids of *Lycopodium clavatum* Linn. have been examined extensively (1–4) and a total of 16 different alkaloids isolated. We have now investigated the alkaloidal content of *L. clavatum* var. *megastachyon* Fern. and Bissel (5), and two closely related, but hitherto unreported, alkaloids have been isolated and their structures established. In addition, four other alkaloids of known constitution were isolated, along with a small amount of a base of undetermined constitution.

The total crude alkaloid of *L. clavatum* var. *megastachyon*, obtained by methanol extraction, amounted to approximately 0.12% of the dry weight of the plant. Separation of the alkaloids, achieved mainly by chromatographic techniques (see Experimental), yielded the following compounds: (i) lycopodine (30% of the total basic material); (ii) clavolonine (11%);[2] (iii) a compound, $C_{18}H_{29}O_3N$, m.p. 212–213° (7.5%), which appears to be new and which we have named lycoclavine; (iv) a compound, $C_{20}H_{31}O_4N$, m.p. 144–145° (11%), which proved to be the O-acetyl derivative of lycoclavine; (v) a substance, $C_{32}H_{52}O_3N_2$, m.p. 213–214° (1.5%), which was shown to be a 1:1 molecular complex of dihydrolycopodine ($C_{16}H_{27}ON$) and flabelliformine ($C_{16}H_{25}O_2N$).[3] In addition to the above-mentioned alkaloids, a small amount of an apparently new alkaloid, m.p. 261–263°, analyzing best for $C_{16}H_{25-27}O_2N$, was also isolated but has not yet been further characterized.

The structures of lycopodine (6), dihydrolycopodine (6), flabelliformine (7),[4] and clavolonine (8) are known. Furthermore, a comparison of the infrared spectrum of clavolonine with that of alkaloid L.34, first isolated by Manske in 1953 from *Lycopodium densum* Labill. (9), revealed their identity.[5] The composition of the molecular complex mentioned in (v) above was established in the following manner. Attempts to separate the complex by fractional crystallization and by chromatography were unsuccessful. However, treatment of the complex with chromium trioxide in pyridine oxidized the dihydrolycopodine to lycopodine and left the flabelliformine unchanged. The two components were then easily separable by chromatography. Finally, combination of equimolar quantities of dihydrolycopodine and flabelliformine gave a high yield of the C_{32} complex, identical in

[5]*We wish to thank Dr. Manske for a sample of alkaloid L.34.*

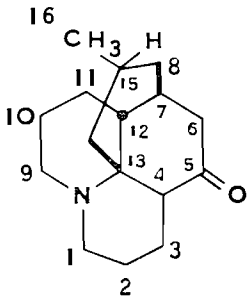
all respects with that obtained from the plant. It is interesting to note that flabelliformine also forms stable 1:1 molecular complexes with both lycopodine and lycodoline, although these latter are readily separable by chromatography (10).

Turning now to the determination of the structure of lycoclavine, $C_{18}H_{29}O_3N$, the presence of a hydroxyl group and an acetoxyl group was established by the following observations. The infrared spectrum (in dilute CCl_4) showed a concentration-independent peak at 3600 cm^{-1}, with a shoulder at 3620 cm^{-1}, indicative (11) of an intramolecularly hydrogen-bonded hydroxyl group. Peaks at 1736 cm^{-1} and 1240 cm^{-1} in the infrared, and at 7.93 τ (3 H) in the n.m.r. suggested the presence of an O-acetyl group and this was confirmed by hydrolysis to acetic acid and a diol, $C_{16}H_{27}O_2N$, henceforth called desacetyllycoclavine. The secondary nature of these functional groups was indicated by the n.m.r. spectra of lycoclavine, which showed one-proton peaks at 5.11 τ (doublet, splitting 6.9 c.p.s., $\rangle$*C*HOAc) and 6.40 τ (singlet, $\rangle$*C*HOH). Acetyllycoclavine, prepared by acetylation of lycoclavine with acetic anhydride – pyridine, showed similar peaks at 4.92 τ (doublet, splitting 6.8 c.p.s.) and 5.32 τ (singlet), the latter peak being attributed to the proton on the carbon bearing the hydroxyl group in the unacetylated compound. The n.m.r. spectra also revealed the presence of a secondary C-methyl group (doublets at 9.09 τ and 9.08 τ, splitting ca. 6 c.p.s., in lycoclavine and acetyllycoclavine, respectively). Lack of NH absorption in the infrared spectra of lycoclavine and its acetyl derivative indicated the tertiary nature of the amino nitrogen. Since lycoclavine could not be reduced catalytically and showed no olefinic protons in the n.m.r., it appeared to be tetracyclic.

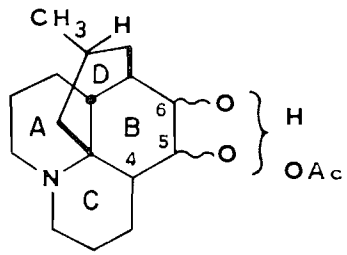
Oxidation of lycoclavine with chromic acid in acetic acid, followed by chromatography over alumina, yielded a basic compound, $C_{18}H_{27}O_2N$, m.p. 174–175°, which showed peaks in the infrared at 1751 cm^{-1} (O-acetyl) and 1724 cm^{-1} (cyclohexanone), and in the ultraviolet at 282 mμ (log ϵ, 2.56). Hydrolysis of this ketone, which we shall refer to as "lycoclavinone", with dilute sodium hydroxide yielded an amphoteric compound, $C_{16}H_{23}O_2N$, which had the properties of a diosphenol. In particular, the ultraviolet spectrum showed a maximum at 282 mμ (log ϵ, 3.99) in neutral solution, shifted to 327 mμ in dilute base, and to 248 mμ on acetylation. These values are indicative of the presence of the grouping  (12). The formation of the enolic α-diketone indicated that lycoclavinone was an α-acetoxy ketone, the α-diketone arising from aerial oxidation of the initially formed α-ketol. The susceptibility of α-ketols to aerial oxidation in alkaline solution is well authenticated (13) and it was found that the rate of formation of the diketone (as determined by the rate of increase of the ϵ value at 327 mμ) was substantially reduced when the reaction was carried out in a nitrogen atmosphere and accelerated when oxygen was bubbled through the hydrolysis solution. Hydrolysis of lycoclavinone with aqueous acid yielded the α-ketol, which underwent aerial oxidation to the diosphenol in alkaline solution. These results demonstrate the presence of the grouping —CHOH—CHOAc—, flanked on at least one side by a methine group, in lycoclavine.

The presence of the above-mentioned grouping, a $\rangle$$CHCH_3$ group, and a tertiary nitrogen, together with the fact that lycoclavine occurs along with lycopodine (I) and several other alkaloids having a lycopodine skeleton, and that all *Lycopodium* alkaloids

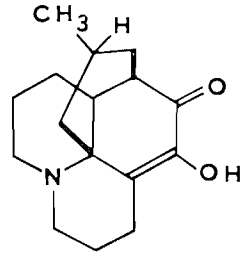
of known constitution bear an oxygen or its biogenetic equivalent (i.e. unsaturation or nitrogen) at C-5, suggested structure II (without stereochemical implications) as a possibility for lycoclavine, and hence III for the enolic α-diketone. Indeed, oxidation of lycopodine with 1 mole[6] of SeO_2 in refluxing dioxane gave, in addition to unchanged lycopodine, the enolic diketone III (25% yield), identical in all respects with that prepared from lycoclavine. Compound III has also been prepared by hydrolysis of bromolycopodine in the presence of air (14).



I



II



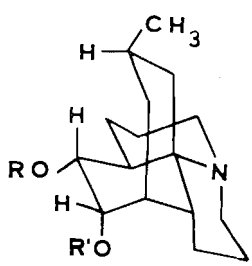
III

Since both the relative (15) and absolute (16) stereochemistry of lycopodine are known these results show that lycoclavine is represented by II, the only remaining points to be determined being the relative positions of the hydroxyl and acetoxyl groups and the stereochemistry at C-4, C-5, and C-6.[7] In order to simplify the discussion, the hydrogen at C-4 will now be placed trans to the C-7, C-13 bridge as in structures IV–VII. That this is indeed the correct orientation at C-4 will be demonstrated later.

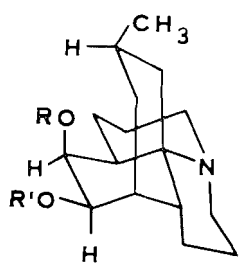
On the basis of the n.m.r. data presented earlier, structure IV (R = Ac, R′ = H) was first favored for lycoclavine, since in this structure the axial proton on C-5 is flanked by an axial proton on C-4 which could lead to the observed splitting (ca. 7 c.p.s.), whereas the equatorial proton on C-6 is flanked by gauche protons on C-5 and C-7 and might be expected to be weakly coupled, resulting in the broadened singlet (half-height width about 3.5 c.p.s.) actually observed (17). Several facts, however, were not in agreement with this formulation. Thus, although lycoclavine showed weak intramolecular hydrogen bonding in the infrared, the corresponding diol, desacetyllycoclavine, obtained by alkaline hydrolysis or, better, by $LiAlH_4$ reduction of lycoclavine, showed a single OH stretching vibration at 3620 cm^{-1}. The diol was also resistant to oxidation with periodic acid. Both these facts speak against the cis relationship of the two groups. Furthermore, hydrolysis of acetyllycoclavine with refluxing 10% aqueous HCl for $1\frac{1}{2}$ hours gave lycoclavine in better than 90% yield. If IV (R = Ac, R′ = Ac) were indeed the correct formulation for the diacetate, the retention of the relatively unhindered equatorial acetoxyl at C-5 while the hindered axial acetoxyl group at C-6 was hydrolyzed would not be expected.

Structure V would also be expected to lead to a diol which would show intramolecular hydrogen bonding and react with periodic acid. Since it was felt that the oxygenated ring might be considerably distorted from the chair form (see below) structures VI and VII remained for consideration.

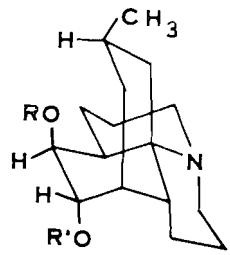
[6]*Use of excess* SeO_2 *led to the formation of compound(s) absorbing at 306, 340, and 380 mμ in the ultraviolet.*
[7]*The numbering system used (see structure I) is that suggested by K. Wiesner (16(b)).*



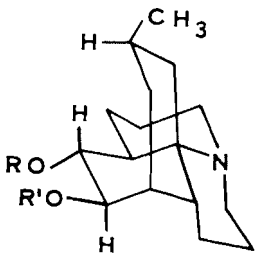
IV



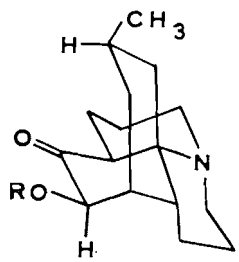
V



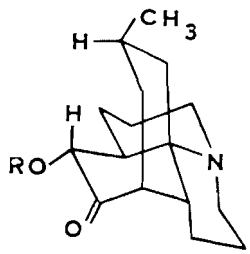
VI



VII



VIII

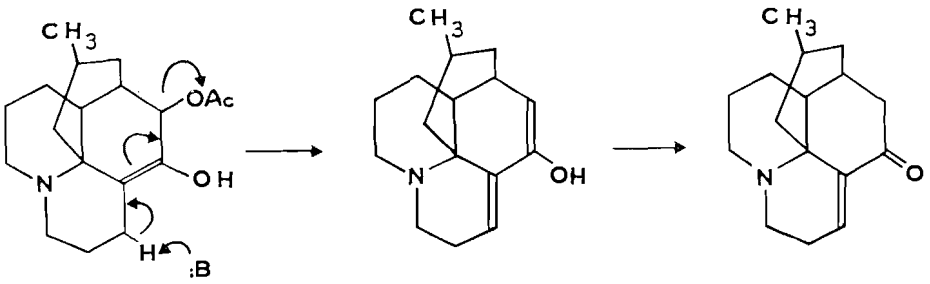


IX

The position of the acetoxyl group was determined in the following manner. Lycoclavinone, mentioned above, could be assigned structure VIII (R = Ac) on the following basis. The optical rotatory dispersion curve showed a positive Cotton effect with extrema at 308 mμ and 271 mμ and an amplitude of 23,000°. Lycopodine (VIII, RO replaced by H) under the same conditions also shows a positive Cotton effect with extrema at 306 mμ and 271 mμ, amplitude 17,000°. The octant rule (18) predicts a positive Cotton effect if the keto group is at C-5 (as in VIII) and a negative Cotton effect if it is at C-6 (as in IX). The equatorial nature of the acetoxyl group is indicated both by the position of the extrema in the optical rotatory dispersion spectrum (19) and by the position (282 mμ, lycopodine 285 mμ) of the ketonic maximum in the ultraviolet (20). The fact that the α-ketol obtained by acid hydrolysis of the acetoxy ketone was reconverted by acetic anhydride – pyridine to the same acetoxy ketone is also consistent with structure VIII, since under these equilibrating conditions ketol VIII (R = H), in which the serious non-bonded interaction between C-15 and C-5 is minimized, should be favored over ketol IX (R = H). The fact that the hydroxyl group in the ketol is intramolecularly hydrogen bonded (concentration-independent band at 3500 cm^{-1} in the infrared) is consistent with the assigned equatorial position.

Pyrolysis of VIII (R = Ac) at 240° for 8 minutes led to a good yield of the α,β-unsaturated ketone X, which had previously been prepared from bromolycopodine (14). Presumably this facile elimination of acetic acid proceeds via the enol form of the ketone, as formulated below, with the reacting material acting as its own base.

It was now important to determine whether lycoclavinone (VIII, R = Ac), which is



X

presumably the thermodynamically more stable of the four possible C-5, C-6 acetoxyketones, was actually the first product of the oxidation of lycoclavine. It was found that if the acetic acid oxidation solution was first diluted with $CHCl_3$ and then ice-cold ammonium hydroxide added, evaporation of the $CHCl_3$ extract and crystallization from *n*-hexane gave, instead of lycoclavinone, the α-acetoxyketone XI, m.p. 115–118°. If the oxidation solution was first made basic by addition of ammonium hydroxide, then extracted with $CHCl_3$ and filtered *rapidly* through alumina, the ketone IX (R = Ac), m.p. 143°, was obtained. Both IX (R = Ac) and XI were isomerized to VIII (R = Ac) when adsorbed on basic alumina for any extended length of time. Similar isomerizations of steroidal α-acetoxyketones have been reported (21). Acid hydrolysis of IX (R = Ac) gave the α-ketol VIII (R = H). The structural assignments are based mainly on optical rotatory dispersion and ultraviolet measurements. Both IX and XI showed *negative* Cotton effect curves, as predicted by the octant rule (see above). The extrema for IX (R = Ac) were at 312 mμ and 280 mμ (amplitude −2300°), for XI at 334 mμ and 297 mμ (amplitude −11,300°), indicative (19) of equatorial and axial α-acetoxy groups, respectively. The ultraviolet maxima were at 286 mμ for IX and 308 mμ for XI. The fact that XI shows a more negative Cotton effect than does IX no doubt reflects the distortion of the ketone-containing ring from an ideal chair (see below). Similar observations have been made with α-acetoxy 11- and 12-ketosteroids (22).

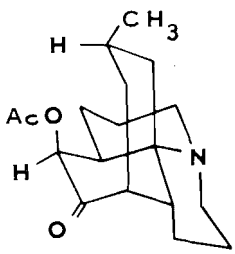
The formation of lycoclavinone I thus proceeds via the sequence

$$\text{lycoclavine} \xrightarrow{CrO_3\text{–HOAc}} \text{XI} \xrightarrow[Al_2O_3]{NH_4OH \text{ or}} \text{IX} \xrightarrow{Al_2O_3} \text{VIII}$$

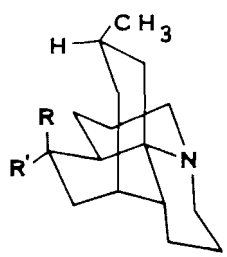
and hence the acetoxyl group in lycoclavine is located on C-5 cis to the C-7, C-13 bridge, in agreement with structure VI (R = Ac, R′ = H) but not with structure VII.

Further evidence for the diaxial orientation of the substituents at C-5 and C-6 and for the configuration at C-4 was obtained by a study of the reduction products obtained from the various isomeric α-ketols and α-acetoxylketones now available to us. It has been shown (8) that lithium aluminum hydride reduction of lycopodine (I) leads to the axial alcohol dihydrolycopodine (XII, R = OH, R′ = H), whereas dissolving metal reduction gives the equatorial alcohol α-dihydrolycopodine (XII, R = H, R′ = OH). We have independently arrived at this same conclusion,[8] and, furthermore, have shown that

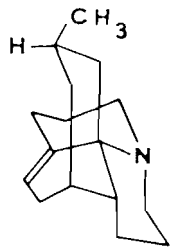
[8]*Since the previous workers (8) have not reported physical constants or experimental details for the preparation of α-dihydrolycopodine, this is included in the experimental section.*



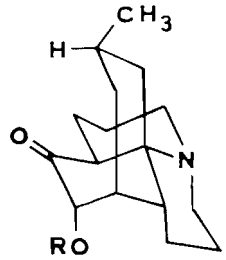
XI



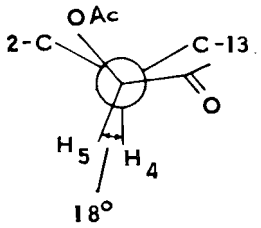
XII



XIII



XIV



XV

the methiodide of the xanthate (XII, R = H, R′ = OCS_2CH_3), derived from α-dihydrolycopodine, yields anhydrodihydrolycopodine (XIII) on pyrolysis, confirming the cis arrangement of the hydroxyl and the C-4 hydrogen.

Reduction of alkaloid L.20 (XIV, R = H), in which the configuration at C-4 is known (14), with lithium aluminum hydride in ether yielded the diol VI (R = R′ = H) identical in all respects with desacetyllycoclavine. The structure VI (R = R′ = H) was assigned on the assumption that the approach of the reducing agent would be on the side opposite to the C-7, C-13 bridge, as is the case with lycopodine. This assumption is supported by the results obtained on reduction of ketones VIII and IX. Reduction of the ketol VIII (R = H) with $LiAlH_4$ gave a new diol, m.p. 230–231°, assigned structure V (R = R′ = H) on the basis of its mode of formation. Lithium–ammonia–methanol reduction of ketol VIII yielded a third diol, m.p. 209–210°, assigned the diequatorial structure VII (R = R′ = H), again on the basis of its mode of formation. Attempts to prepare the fourth diol (IV, R = R′ = H) by dissolving metal reduction of alkaloid L.20 were unsuccessful, leading only to reductive removal of the C-6 hydroxyl (14). However, reduction of IX (R = Ac) with $LiAlH_4$ led to a diol, m.p. 234–235°, differing from the other three, and therefore assigned structure IV (R = R′ = H). All four diols showed different infrared spectra, single spots on paper chromatography, and depression of mixed melting points, where appropriate. It is interesting to note that hydride reduction of IX (R = Ac) involves approach of the reducing species from the same side as the C-7, C-13 bridge. Presumably in this case approach to the opposite side is hindered by the C-12 methylene group. Since each of the latter three diols must have at least one equatorial

hydroxyl group, the hydride reduction product of alkaloid L.20, and hence desacetyllycoclavine, is the diaxial diol VI (R = R′ = H), and lycoclavine itself is VI (R = Ac, R′ = H).

As noted above, lycoclavine shows intramolecular hydrogen bonding but the corresponding diol does not. To account for this, it must be assumed that the oxygenated ring is severely distorted toward the half-chair, i.e., the dihedral angle between the two groups must approach 120°. It is known, for instance, that *trans*-1,2-pentanediol does not show intramolecular hydrogen bonding, but that the corresponding monoacetyl derivative does (23). Measurements on Drieding models indicate an internuclear distance of ca. 1 Å between the C-5 oxygen and the C-15 hydrogen in lycoclavine. The sum of the van der Waals radii is 2.6 Å, so that a distortion of ring B (and presumably also ring D) is to be expected.

A more quantitative estimate of this distortion can be obtained by a consideration of the n.m.r. spectra (Table I) of some of the compounds mentioned earlier. It is well

TABLE I

§Approximate center of multiplet.

known (17) that the coupling constant between vicinal hydrogens is related to their dihedral angle. In the particular case of α-acetoxycyclohexanones in fused-ring systems, the following relationships have been found (24) to apply:

$$J_{HH'} \begin{cases} 10\cos^2\phi & 0° \leqslant \phi \leqslant 90° \\ 16\cos^2\phi & 90° \leqslant \phi \leqslant 180°. \end{cases}$$

In compound XI the coupling constant between the protons on C-4 and C-5 (J_{45}) is 9 c.p.s. Using the Johnson expression given above this indicates a dihedral angle of about 18°, indicating a considerable distortion from the normal 60° angle. This is illustrated in the Newman projection XV. Compound IX (R = Ac) shows a similar distortion (J_{45} = 11.5 c.p.s., ϕ = 142° instead of 180°). In the C-5 ketone VIII (R = Ac), where the C-5, C-15 interaction is minimized because of the trigonal nature of C-5, the calculated angle is 42° ($J_{67} \simeq 5.5$ c.p.s.). The acetyl derivative of XIV gave a broadened singlet (width at half height about 3.5 c.p.s.), indicative of an angle of about 60°. Thus it appears that in the C-6 ketone series the non-bonded interaction between C-5 and C-15 is relieved, at least in part, by a distortion of ring B from an ideal chair towards the half-chair. This

strain could also be relieved if ring D assumed the boat conformation, but as has been pointed out previously (15), this introduces a serious bowsprit–flagpole interaction between C-12 and C-16. The n.m.r. results obtained with the C-5 ketones indicate a similar, but smaller, distortion of ring B in this series. Such a flattening of the B ring would increase the angle between C-4 and C-6 and account for the unusually low (1700 cm^{-1}) (6) carbonyl stretching frequency of lycopodine (27).

The n.m.r. spectra of lycoclavine and its acetyl derivative (Table I) are in good agreement with the proposed structure if we make the reasonable assumption that ring B is distorted to at least the same extent as in the C-6 ketones. Applying the Karplus–Conroy correlation (17) (the Johnson expression applies only to six-membered rings containing a trigonal carbon atom adjacent to the bonds under consideration (24)) a H_4—C—C—H_5 dihedral angle of 20° would lead to a coupling constant J_{45} of 7 c.p.s. (observed, 6.8 and 6.9 c.p.s.). J_{56} and J_{67} would be expected to be small (both angles approach 90–100° in the distorted chair), explaining the fact that C—H_5 is not further split and C—H_6 is a somewhat broadened singlet.

Inspection of Table I suggests a possible relationship between the chemical shift of the C-16 methyl group and the presence or absence of a carbonyl group at C-5. Thus those compounds with a C-5 keto group show the C-methyl resonance at 9.14–9.17 τ, while, with one exception, those without a carbonyl group in ring B show this peak at 9.08–9.09 τ. The exception is compound XII (R = R′ = H), not previously mentioned but readily available by Wolff–Kishner reduction of lycopodine, which has the C-methyl doublet centered at 9.13. The differences noted are possibly due to the long-range shielding effect of the carbonyl group (25). Inspection of models reveals that in the C-6 ketones the C-methyl group no longer lies in the shielding region of the carbonyl and may in fact be deshielded by it. In agreement with this view, the two C-6 ketones absorb at 8.96 τ and 9.03 τ.

In view of the fact that acetyllycoclavine is hydrolyzed by hot dilute mineral acid to lycoclavine, the possibility arose that the lycoclavine isolated was actually formed during the isolation process. Although this possibility cannot be completely excluded, it seems unlikely, since lycoclavine can also be isolated in good yield by percolation of the ground plant with cold dilute acetic acid and immediate extraction of the alkaloids into chloroform.

EXPERIMENTAL

Ultraviolet spectra were measured in 95% ethanol and, unless otherwise specified, infrared spectra in carbon tetrachloride. For hydrogen-bonding studies, spectra were determined on 0.1, 0.05, and 0.025 *M* solutions in CCl_4 using a Perkin–Elmer Model 221 spectrophotometer. Nuclear magnetic resonance spectra were measured on ca. 10% w/v solutions in chloroform using a Varian Associates Model A-60 spectrometer. Internal tetramethylsilane was used as a standard. Some of the optical rotatory dispersion curves were obtained by Dr. M. M. Marsh, Eli Lilly, Indianapolis, to whom we extend our best thanks; the others were determined by Mr. R. N. Swindlehurst of these laboratories using a Rudolph Automatic Recording Spectropolarimeter. Melting points were determined on a hot stage and are uncorrected. Alumina, unless otherwise specified, means basic alumina of activity III. Skellysolve B refers to Skelly Oil Company light petroleum, b.p. 62–70°. Microanalyses are by Pascher Mikroanalytisches Laboratorium, Bonn, West Germany, and C. Daesslé, Montreal, Quebec.

Isolation of the Alkaloids

Dried, powdered *L. Clavatum* var. *megastachyon* (15.5 kg) was Soxhlet-extracted for 24 hours with methanol. Most of the methanol was removed by distillation and the residue treated with ice-cold 1% hydrochloric acid (5 l.). The acid solution was filtered (celite) from insoluble material. The insoluble material was then vigorously stirred with cold 1% HCl (5 l.) for several hours, and the mixture again filtered. The combined acid solutions were basified (NH_4OH, ice) and extracted five times with chloroform. The chloroform was removed by distillation and the oily residue dissolved in ice-cold 1% HCl (5 l.) and washed three

times with ether to remove neutral material. The aqueous solution was then basified (ice-cold NH_4OH) and extracted four times with chloroform. Evaporation of the chloroform left 18.2 g of basic material as a dark brown gum.

Purification of the Alkaloids

The crude alkaloid was placed on a column of alumina (1 lb) in ether and eluted in four fractions: A, 9.01 g, 3 l. ether; B, 1.88 g, 6 l. ether; C, 8.50 g, 6 l. $CHCl_3$; D, 3.32 g, 1 l. MeOH.

Fraction B was crystallized from acetone to give the dihydrolycopodine–flabelliformine complex, m.p. 213–214° (0.3 g). Calc. for $C_{32}H_{52}O_3N_2$: C, 75.00; H, 10.16; O, 9.37; N, 5.47%. Found: C, 74.78; H, 10.16; O, 9.82; N, 5.44%. Infrared spectrum: ν_{max} (nujol) 3300–2600 (broad OH superimposed on C—H), 1710 cm^{-1} (C=O).

Fraction C crystallized from acetone to given clavolonine, m.p. 233–234° (1.53 g), identical with an authentic sample furnished by Dr. R. H. Burnell.

Fraction D was chromatographed over alumina and yielded further clavolonine (0.50 g) when eluted with $CHCl_3$. Elution with $CHCl_3$–MeOH (99:1) and crystallization from methanol–ether yielded 70 mg colorless needles, m.p. 261–263°. Found: C, 72.36, 72.49; H, 9.36, 9.58; N, 5.60%. The infrared spectrum (nujol) showed strong —OH absorption (3400 cm^{-1}) but no carbonyl absorption. This compound has not been further investigated.

Fraction A and the residues from fractions B and C were combined and carefully chromatographed over alumina (1 lb). Elution with benzene (5 l.) yielded lycopodine (5.36 g), identical with an authentic sample. Elution with ether (5 l.) and crystallization from Skellysolve B gave *acetyllycoclavine*, m.p. 144–145° (2.03 g). Calc. for $C_{20}H_{31}O_4N$: C, 68.74; H, 8.94; O, 18.31; N, 4.01%. Found: C, 68.74, 68.54; H, 8.69, 9.15; O, 19.03; N, 3.55%. Infrared spectrum: ν_{max} 1745, 1225 cm^{-1} ($OCOCH_3$).

Elution with chloroform and crystallization of the eluates from acetone yielded *lycoclavine* (1.32 g). The analytical sample, m.p. 212–213°, $[\alpha]_D$ −9° (95% ethanol), was prepared by several recrystallizations from acetone. Calc. for $C_{18}H_{29}O_3N$: C, 70.32; H, 9.51; N, 4.54; O, 15.57%. Found: C, 70.11, 70.19; H, 9.43, 9.48; N, 4.57; O, 15.71%. pK_a (50% MeOH) 9.6. Infrared spectrum: ν_{max} 3620 (sh), 3600, 1736, 1240 cm^{-1}. The methiodide melted at 314°, the perchlorate at 283–286°, and the hydrochloride at 281–285°.

Further small quantities of crystalline material could be obtained by chromatography of the mother liquors from the above operations.

Proof of Composition of Molecular Complex M.p. 213–214°

Dihydrolycopodine (10.6 mg) and flabelliformine (11.2 mg) were combined in hot acetone. The solution deposited colorless crystals (15.2 mg), m.p. 204–206°. The infrared spectrum (nujol) was identical with that of the material isolated from the plant, and the mixed melting point (206–210°) showed no depression.

Oxidation of the complex with CrO_3–pyridine and alumina chromatography of the resulting product yielded lycopodine (eluted with benzene) and flabelliformine (eluted with ether).

Desacetyllycoclavine (VI, R = R′ = H)

(a) By Alkaline Hydrolysis of Lycoclavine

Lycoclavine (0.109 g) was refluxed for 1 hour with 2% NaOH in 80% methanol. Removal of most of the methanol, dilution with water, and extraction with chloroform gave, after removal of solvents, a colorless foam (0.09 g). Crystallization from a small volume of acetone yielded elongated prisms (40 mg), m.p. 207–208°. The compound was difficult to crystallize in good yield and was sublimed for analysis. Calc. for $C_{16}H_{27}O_2N$: C, 72.41; H, 10.25; N, 5.28%. Found: C, 72.28, 72.48; H, 10.30, 10.34; N, 5.45%. The infrared spectrum showed a concentration-independent band at 3620 cm^{-1} and no carbonyl absorption.

The perchlorate, prepared by neutralization of an acetone solution of the base with 70% perchloric acid and crystallization from either acetone–ether or methanol–ether, exists in two crystalline forms, one melting at 230–238° and the other at 276–278°. The two forms have different infrared spectra (nujol mulls) but are readily interconverted by seeding.

(b) By $LiAlH_4$ Reduction of Acetyllycoclavine

Acetyllycoclavine (VI, R = R′ = Ac) (0.20 g) in ether (50 ml) was refluxed for 2½ hours with lithium aluminum hydride (0.25 g), then worked up using the method of Mićović and Mihailović (26). Sublimation of the crude product gave the diol (0.148 g), m.p. 203–206°, identical with that obtained above. Similar reduction of lycoclavine also gave the diol in good yield.

(c) By Acid Hydrolysis of Acetyllycoclavine

Acetyllycoclavine (60 mg) was refluxed for 16 hours in 20% aqueous HCl (30 ml), then the solution neutralized with sodium bicarbonate and continuously extracted with ether. Evaporation of the dried ether extract gave a colorless solid which on sublimation affords desacetyllycoclavine (32 mg), m.p. 201–206°.

(d) By $LiAlH_4$ Reduction of Alkaloid L.20

Alkaloid L.20 (XIV, R = H) (38 mg) was added to a slurry of $LiAlH_4$ (0.102 g) in ether (50 ml), and the mixture refluxed for 12 hours, then worked up as in part (*b*). Sublimation of the colorless semisolid remaining after removal of the solvents gave a colorless solid (32 mg), m.p. 191–196°, whose infrared

spectrum was virtually identical with that of authentic desacetyllycoclavine. The perchlorate, prepared from the sublimed material, was identical in all respects (melting point, mixed melting point, infrared spectrum) with the perchlorate of desacetyllycoclavine.

Acetylation of Lycoclavine

Lycoclavine (87 mg) was kept for 18 hours in acetic anhydride (4 ml) – pyridine (2 ml). The solution was then diluted with chloroform and shaken with ice-cold dilute ammonium hydroxide. The chloroform layer was separated, washed with water, dried, and evaporated. The off-white solid obtained was chromatographed on alumina (5 g). Elution with ether yielded a colorless solid (86 mg). Crystallization from Skellysolve B gave *actyllycoclavine*, m.p. 144–145°, identical in all respects with the naturally occurring compound described above.

Similar treatment of desacetyllycoclavine also gave acetyllycoclavine in high yield.

Lycoclavine from Acetyllycoclavine

Acetyllycoclavine (0.87 g) was refluxed for 1½ hours with 10% aqueous HCl, then the solution was neutralized with sodium bicarbonate and continuously extracted with ether. Evaporation of the ether and crystallization of the residue from acetone gave lycoclavine (0.71 g), m.p. 211–213°, identical with the natural material.

"Lycoclavinone" (VIII, R = Ac)

Lycoclavine (68 mg) was dissolved in 98% acetic acid (20 ml) containing chromium trioxide (70 mg) and the resulting solution kept at room temperature for 18 hours, then made basic with cold dilute ammonium hydroxide and extracted six times with chloroform. Evaporation of the chloroform gave a colorless semisolid (69 mg), which was chromatographed over alumina (5 g). Elution with ether gave "lycoclavinone" (40 mg). Elution with chloroform yielded unreacted lycoclavine (15 mg). Lycoclavinone, after recrystallization from Skellysolve B, melted at 174–175°. Calc. for $C_{18}H_{27}O_3N$: C, 70.79; H, 8.92; O, 15.72%. Found: C, 70.39, 70.64; H, 9.11, 9.06; O, 15.73%. Infrared spectrum: ν_{max} 1751, 1245 ($OCOCH_3$), 1724 cm^{-1} (C=O). Ultraviolet spectrum: λ_{max} 282 mμ (log ϵ 2.56). Rotatory dispersion in methanol (*c* 0.023): $[\phi]_{400}$ +290°, $[\phi]_{308}$ +8,300°, $[\phi]_{271}$ −15,400°, $[\phi]_{260}$ −7,500°.

Ketol VIII (R = H)

Lycoclavinone (VIII, R = Ac) (45 mg) was dissolved in 10% aqueous HCl and the solution refluxed for 2 hours, then cooled, basified with sodium bicarbonate, and extracted four times with chloroform. Evaporation of the chloroform and sublimation of the residue gave a colorless solid (23 mg), m.p. 127–132°. Four recrystallizations from Skellysolve-B gave analytically pure material, m.p. 135–136°. Occasionally, a second crystalline form, m.p. 122–123°, was obtained. The two forms had different infrared spectra in nujol mull, but identical solution spectra. Calc. for $C_{16}H_{25}O_2N$: C, 72.96; H, 9.57; N, 5.32%. Found: C, 72.88, 73.00; H, 9.62, 9.76; N, 5.26%. Infrared spectrum: ν_{max} 3510 (bonded OH), 1710 cm^{-1} (C=O). Ultraviolet spectrum: λ_{max} 280 mμ (log ϵ 1.95). Rotatory dispersion in methanol (*c* 0.11): $[\phi]_{400}$ 0∓20°, $[\phi]_{304}$ +6,400°, $[\phi]_{253}$ −19,100°, $[\phi]_{250}$ −19,000°.

Acetylation of the ketol VIII with pyridine – acetic anhydride at room temperature gave lycoclavinone in high yield.

Diosphenol III

(a) From Lycoclavinone

Lycoclavinone (VIII, R = Ac) (53 mg) was stirred at room temperature for 12 hours with 2% NaOH in 20% methanol (30 ml). The solution was then adjusted to pH 7.5 with dilute acetic acid and extracted with four 30-ml portions of chloroform. Evaporation of the chloroform gave a colorless solid which did not crystallize readily and was purified by sublimation. The analytical sample melted at 185–186°, $[\alpha]_D$ −45° (0.5 in ethanol). Calc. for $C_{16}H_{23}O_2N$: C, 73.53; H, 8.87; O, 12.24; N, 5.36%. Found: C, 73.41; H, 8.95; O, 12.12; N, 5.33%. Infrared spectrum: ν_{max} 3440 (bonded OH), 1672 (C=O), 1648 cm^{-1} (C=C). Ultraviolet spectrum: λ_{max} 282 mμ (log ϵ 3.99) shifted to 327 mμ in ethanolic NaOH.

When the reaction was carried out in an atmosphere of nitrogen the peak at 327 mμ developed at about one seventh the rate in air. When oxygen was bubbled through the reaction solution the rate of formation of diketone was about 1½ times that in air.

Acetylation of the diosphenol III with acetic anhydride – pyridine gave an oily product which showed a maximum at 248 mμ in the ultraviolet.

(b) From Lycopodine

A solution of lycopodine (I) (0.83 g) in dioxane (70 ml) was refluxed for 18 hours with selenium dioxide (0.37 g). The dark brown solution was then filtered from selenium and the dioxane removed at the pump. The resulting red-brown resin was dissolved in water, the pH adjusted to 7.5 with bicarbonate, and the solution extracted six times with chloroform. The reddish-brown oil (0.63 g) obtained by removal of the chloroform was chromatographed over alumina (12 g). Elution with ether gave a pale yellow solid (0.30 g) which proved to be mainly lycopodine. Elution with chloroform–methanol (49:1) yielded a dark brown

semisolid (0.22 g) which on sublimation furnished fairly pure diosphenol III, m.p. 183–185°, identical (infrared spectrum, ultraviolet spectrum, mixed melting point, rotation) with that prepared from lycoclavinone.

Pyrolysis of Lycoclavinone

Lycoclavinone (28 mg) was heated at 240° in a nitrogen atmosphere for 8 minutes, then cooled to 120° and distilled (0.1 mm). The distillate, a pale yellow oil, was chromatographed over alumina. Elution with ether gave a colorless oil (13 mg) which showed a maximum in the ultraviolet at 244 mμ (log ε, 3.9) and bands in the infrared at 1680 and 1610 cm^{-1}. Treatment of an acetone solution of the oil with methyl iodide yielded a solid methiodide which melted, after recrystallization from methanol–ether, at 273–274°. The methiodide was identical with an authentic sample (14) of the methiodide of X.

Acetoxyketone XI

A solution of lycoclavine (0.47 g) and chromium trioxide (0.47 g) in 98% acetic acid (20 ml) was kept at room temperature for 18 hours, then diluted with chloroform (50 ml), and the resulting solution washed with enough dilute ice-cold ammonium hydroxide to neutralize the acetic acid. The chloroform layer was separated, washed with water, and evaporated to leave a colorless oil (0.41 g). Crystallization from Skellysolve B gave compound XI (234 mg), m.p. 115–118°. Calc. for $C_{18}H_{27}O_3N$: C, 70.79; H, 8.92; N, 4.59%. Found: C, 71.03, 70.91; H, 8.88, 8.94; N, 4.63%. Infrared spectrum (nujol): ν_{max} 1747, 1260 ($OCOCH_3$), 1712 cm^{-1} (C=O). Ultraviolet spectrum: λ_{max} 308 mμ (log ε 1.85). Rotatory dispersion in methanol (*c* 0.11): $[\phi]_{589}$ −200°, $[\phi]_{500}$ −500°, $[\phi]_{333}$ −5060°, $[\phi]_{298}$ +6100°, $[\phi]_{280}$ +1100°.

Isomerization of XI to VIII (R = Ac)

The acetoxyketone XI (50 mg) was adsorbed on alumina (5 g) in ether and eluted (ether) after 2 hours. Crystallization of the product from Skellysolve-B gave lycoclavinone (32 mg), m.p. 172–174°, identical with an authentic sample. The infrared spectrum of the mother liquors from the crystallization indicated a mixture of acetoxyketones VIII and IX.

Acetoxyketone IX (R = Ac)

A solution of lycoclavine (0.39 g) and chromium trioxide (0.39 g) in 98% acetic acid (40 ml) was kept at room temperature for 20 hours, then made basic with cold dilute ammonium hydroxide and extracted four times with chloroform. Evaporation of the chloroform left a tan-colored oil (0.4 g), which was dissolved in ether and filtered rapidly through alumina (5 g) to give a colorless oil (0.30 g) which crystallized (0.22 g) from Skellysolve-B. The analytical sample, prepared by two recrystallizations from Skellysolve-B followed by sublimation, melted at 143°. Calc. for $C_{18}H_{27}O_3N$: C, 70.79; H, 8.93; N, 4.59%. Found: C, 70.96; H, 8.77; N, 4.36%. Infrared spectrum (nujol): 1752, 1238 (OAc), 1720 cm^{-1} (C=O). Ultraviolet spectrum: λ_{max} 286 mμ (log ε 1.79). Rotatory dispersion in methanol (*c* 0.1): $[\phi]_{589}$ −80°, $[\phi]_{400}$ −315°, $[\phi]_{312}$ −2135°, $[\phi]_{280}$ +190°, $[\phi]_{265}$ −1000°.

Isomerization to VIII (R = Ac) was carried out on an alumina column as described above for ketone XI. Hydrolysis of IX (R = Ac) with 10% HCl (as described above for VIII (R = Ac)) gave ketol VIII in 85% yield.

α-Dihydrolycopodine (XII, R = H, R′ = OH)

Lithium metal (0.9 g) was added in small portions over a period of 30 minutes to a solution of lycopodine (0.76 g) in methanol (40 ml) – liquid ammonia (200 ml). After most of the ammonia had evaporated, water (200 ml) was added and the mixture extracted four times with chloroform. Evaporation of the chloroform left a colorless glass (0.77 g) which crystallized from ether in colorless needles (0.63 g). The analytically pure material, obtained by recrystallization from ether, melted at 133–134°. Calc. for $C_{16}H_{27}ON$: C, 77.06; H, 10.91; N, 5.62%. Found: C, 76.93; H, 11.00; N, 4.69%. Infrared spectrum: ν_{max} 3620 cm^{-1}.

The perchlorate, after recrystallization from acetone–ether, melted at 245–246°. Calc. for $C_{16}H_{27}ON \cdot HClO_4$: C, 54.94; H, 8.01; N, 4.01%. Found: C, 55.31; H, 8.24; N, 4.44%.

Acetylation with pyridine – acetic anhydride at room temperature gave acetyl-α-dihydrolycopodine as a colorless oil (no OH in infrared) in almost quantitative yield. The perchlorate, after recrystallization from acetone–ether, melted at 276–278° (decomp.). Calc. for $C_{18}H_{29}O_2N \cdot HClO_4$: C, 55.24; H, 7.67; N, 3.58%. Found: C, 55.17; H, 7.68; N, 4.15%. Infrared spectrum (nujol): 3120 (+NH), 1730, and 1250 cm^{-1} (OAc). The free base, liberated from the perchlorate, solidified, and after distillation melted at 74–76°.

Anhydrodihydrolycopodine (XIII) from α-Dihydrolycopodine

Treatment of α-dihydrolycopodine with phosphorus oxychloride in pyridine gave the chloro compound XII (R or R′ = Cl), characterized as the perchlorate, m.p. 230–231°, in good yield. However, heating the xanthate (XII, R = H, R′ = OCS_2CH_3) methiodide (0.12 g) at 265° for 20 minutes followed by distillation (0.1 mm, 140°) gave anhydrodihydrolycopodine (XIII) (0.04 g), identified as the perchlorate, m.p. 238–239°. The xanthate was prepared by refluxing an ethereal solution of α-dihydrolycopodine (0.48 g) with sodium (0.06 g) for 60 hours, then adding carbon disulphide (1 ml) and refluxing for a further 24 hours. Addition of methyl iodide and further heating caused a white precipitate to separate. The precipitate

was filtered and recrystallized from ethanol to give the xanthate methiodide (0.54 g), m.p. 280–282° (decomp.). Calc. for $C_{18}H_{29}OS_2N \cdot CH_3I$: C, 47.39; H, 6.70; S, 13.32; N, 2.91; I, 26.36%. Found: C, 47.49, 47.69; H, 6.85, 6.66; S, 13.22; N, 3.07; I, 26.41%.

Diol V (R = R′ = H)

The ketol VIII (R = H) (86 mg) was refluxed for 3 hours with a slurry of $LiAlH_4$ (0.15 g) in ether (50 ml). Working up in the usual manner gave a colorless solid (84 mg), m.p. 217–222°. The analytical sample, m.p. 230–231°, was prepared by recrystallization from acetone followed by sublimation. Calc. for $C_{16}H_{27}O_2N$: C, 72.41; H, 10.25; N, 5.28%. Found: C, 71.78; H, 10.29; N, 5.44%. The infrared spectrum (nujol) showed a sharp band at 3500 cm^{-1} and broad —OH absorption at 2600–3300 cm^{-1}.

Diol VII (R = R′ = H)

A solution of the ketol VIII (R = H) (85 mg) in methanol (10 ml) was added to liquid ammonia (150 ml). The solution was stirred vigorously and lithium (0.2 g) added in small pieces over 10 minutes, then the ammonia was evaporated and water (100 ml) added. Continuous ether extraction yielded a yellow oil which, on distillation (0.1 mm, 150°), afforded a colorless oil that solidified on scratching. Four recrystallizations from acetone gave small, colorless needles of diol VII, m.p. 209–210°. Calc. for $C_{16}H_{27}O_2N$: C, 72.41; H, 10.25; N, 5.28%. Found (sublimed sample): C, 72.38, 72.21; 10.52, 10.55; N, 4.94%. Analysis of unsublimed material suggested that it was a monohydrate (found: C, 67.84; H, 9.31%). The infrared spectrum (nujol) showed OH stretching vibrations at 3580 (sharp) and 3080 (broad) cm^{-1}. The perchlorate melted at 243–245°. The mixed melting point with diol VI (m.p. 207–208°) was 176–184°.

Diol IV (R = R′ = H)

Acetoxyketone IX (27 mg) was refluxed with $LiAlH_4$ (0.1 g) in ether (30 ml) for 6 hours, then worked up in the usual manner to give a colorless solid (22 mg), m.p. 219–226°. Recrystallization from acetone raised the melting point to 234–235°. The compound, even after sublimation, analyzed as a hemihydrate. Calc. for $C_{16}H_{27}O_2N \cdot \frac{1}{2}H_2O$: C, 70.03; H, 10.28; N, 5.10%. Found: C, 70.38, 70.04; H, 10.49, 10.32; N, 5.79%. The mixed melting point with diol V (m.p. 230–231°) was 223–230°.

Wolff–Kishner Reduction of Lycopodine

Sodium (0.10 g) in diethylene glycol (40 ml) was heated to 180° and anhydrous hydrazine added until the solution refluxed freely at 180°. The solution was then cooled and lycopodine (0.63 g) added and refluxed for 17 hours. The temperature was then raised to 210° by distilling off excess hydrazine and refluxing was continued at this temperature for 24 hours. The cooled solution was diluted with water, acidified with hydrochloric acid, and continuously extracted with ether for 24 hours to remove diethylene glycol. Basification of the aqueous layer and further extraction with ether yield a colorless semisolid (0.5 g) which could not be recrystallized, but which was purified as the perchlorate, m.p. 224–225° (from ethanol–ether). Calc. for $C_{16}H_{27}N \cdot HClO_4$: C, 57.56; H, 8.45; N, 4.20%. Found: C, 57.38, 57.32; H, 8.73, 8.40; N, 4.71%. The free base, regenerated from the perchlorate, showed no absorption in the 3000–3600 cm^{-1} or 1500–1800 cm^{-1} regions in the infrared. The methiodide melted at 288–289° after recrystallization from ethanol–ether.

ACKNOWLEDGMENTS

We wish to thank Mr. M. A. Stillwell, Mouth of Keswick, New Brunswick, for the collection and identification of the plant material, Mr. R. N. Swindlehurst and Miss Gail Stayura for most of the infrared, nuclear magnetic resonance, and optical rotatory dispersion measurements, and the National Research Council of Canada for financial support.

THE CONSTITUTION OF A SYNTHETIC XYLAN

II. CONTROLLED PERIODATE DEGRADATION

G. G. S. DUTTON AND A. M. UNRAU[1]
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received June 29, 1962

ABSTRACT

The controlled periodate degradation of the synthetic xylan resulted in the formation of ethylene glycol, glycerol, xylose, and at least eight non-reducing oligosaccharides. The composition, approximate D.P., periodate oxidation, and possible structure of these oligosaccharides are reported and discussed.

In a previous communication (1), some preliminary structural investigations of the xylan (2) used in this study were reported. These studies indicated that the xylan possessed a complex structure and evidence was obtained for the possible existence of some open-chain xylose residues. This communication is concerned with the application of the Smith periodate degradation (3) to the synthetic xylan. This structural analysis has been applied with considerable success and interesting consequences to a number of naturally occurring polysaccharides (3–6) and by the authors (7) to a synthetic glucan (8). Although it may be difficult to separate or resolve the various types of fragments that are formed when this degradation is applied to some polymers, it can be most useful in determining the fine structure of certain polysaccharides.

The controlled periodate degradation of the synthetic xylan gave ethylene glycol (from the non-reducing xylopyranose end units), glycerol (from internal xylose and non-reducing xylofuranose end units), xylose (from readily hydrolyzable xylofuranoside structural units), and at least eight different non-reducing oligosaccharides with R_{xylose} values ranging from 2.32 to 0.17, see Table I.

Component 2 was identified as 1′-*O*-glyceryl-D-xylofuranoside by the following reactions. Hydrolysis gave xylose and glycerol in a 1:1 ratio. Periodate oxidation gave 1 mole of formaldehyde and borohydride reduction of the trialdehyde followed by hydrolysis gave ethylene glycol and glycerol in a 1:1 ratio. Component 6 was treated similarly and gave xylose and glycerol in a 1:1 ratio but only ethylene glycol was obtained from the periodated and reduced material. Thus component 6 must be 1′-*O*-glyceryl-D-xylopyranoside. The isolation of these two components thus indicates the existence in the xylan of xylofuranosyl $1 \rightarrow 5$ xylose units and xylopyranosyl $1 \rightarrow 5$ xylose units.

The other oligosaccharides apparently possessed progressively more complex structures. Components 4 and 7 were primarily composed of 1′-*O*-glyceryl xylobioside units. In each molecule, apparently one xylose unit was substituted at either C_2 or C_3 to render it immune to periodate attack. Since the formaldehyde involved in the periodate oxidation suggested an approximate D.P. of 3, the ethylene glycol arose from the glyceryl residues linked through C_1 whereas glycerol then must have originated primarily from xylofuranose end units. Component 8 was apparently composed mainly of 1′-*O*-glyceryl xylotrioside residues, although, in this case, a proportionately lesser amount of formaldehyde was produced and indicated a D.P. of 4.7 or approximately 5. This observation suggested

[1]*Present address: Department of Plant Science, University of Manitoba, Winnipeg, Manitoba.*

that some of the molecules were terminated by 2′-*O*-glyceryl structures. Ethylene glycol primarily originated from 1′-*O*-glyceryl structures while glycerol probably arose mostly from xylofuranose end units. The 1:1.2:1.85 ethylene glycol:glycerol:xylose ratio suggested that a few internal 1,4-linked xylopyranose and 1,5-xylofuranose units would, however, also furnish glycerol; consequently the observed ratio of the three components cannot by itself be used to suggest branching or other glycerol-producing structures in the periodate degradation.

Although the structure of components 9 and 10 was generally comparable to that of component 8, even less-specific details could be deduced. In both cases formaldehyde undoubtedly arose from 1′-*O*-glyceryl structures and a comparable amount of ethylene glycol would be expected. Some ethylene glycol could also have arisen from xylopyranose end units. A comparison of the xylose:glycerol ratios of the undegraded oligosaccharides (approximately 4:1 and 6:1 for components 9 and 10, respectively) with the D.P. estimated from the formaldehyde produced upon periodate oxidation (6.2 and 9.9 for components 9 and 10, respectively) indicates that some molecules are terminated by 2′-*O*-glyceryl structures and hence some of the glycerol in the subsequent hydrolysis would originate from such a structural feature. Some of the glycerol probably arose from xylofuranose end units although internal $1 \rightarrow 4$ linked xylopyranose units would also furnish glycerol. Although it was suspected that some branched molecules were probably present, further investigations would be necessary to establish this possibility. In this connection methylation of the oligosaccharide fragments and the investigation of their hydrolytic products by vapor phase chromatography would be most useful.

The results presented here confirm the existence of xylofuranose units in the xylan and further demonstrate the utility of the Smith degradation.

EXPERIMENTAL

Chromatographic separations were carried out using the descending technique. Whatman No. 1 filter paper was used throughout unless otherwise stated. Solvent systems employed were (A) ethyl acetate:acetic acid:water (8:2:2), (B) ethyl acetate:pyridine:water (9:2:2), and (C) butanone:water azeotrope. Ammoniacal silver nitrate and *p*-anisidine trichloroacetate spray reagents were used for detection of compounds on paper chromatograms.

Evaporations were carried out under reduced pressure at bath temperatures of 40 to 45° C. Optical rotations are equilibrium values at 21±2° C. Melting points are uncorrected.

Periodate Oxidation of Xylan

Some details of the periodate oxidations of the synthetic xylan were reported in a previous communication (6). Xylan (2.50 g) dissolved in cold water (160 ml) was treated with periodic acid (40 ml 0.5 *M*) and the oxidation followed by the usual arsenite titration technique. After 18 hours' standing at 5° C, 0.905 mole of periodate had been consumed per xylose unit and 0.910 mole of periodate was consumed per monomer unit after 28 hours. The solution was neutralized ($BaCO_3$), a solution (40 ml) of sodium borohydride added (2.0 g), and the reduction allowed to proceed at room temperature for 24 hours. After neutralization with acetic acid, the solution was evaporated to dryness and borate removed by addition of methanol containing 2% hydrogen chloride followed by evaporation under vacuum at 25–28° C. The residue was dissolved in 0.1 *N* hydrochloric acid (90 ml) and left at room temperature for 4 hours. The solution was neutralized ($PbCO_3$), evaporated to a thick syrup, and chromatographed. The mixture was resolved using sheets of Whatman No. 1 paper and solvent A. The mobilities and quantities of the components are recorded in Table I.

Characterization of Components

Component 1.—37.5 mg, originating from xylopyranose end units, was treated with a 15% molar excess of *p*-nitrobenzoyl chloride in pyridine (3 ml) and the mixture heated at 70° for 45 minutes. After addition of saturated sodium bicarbonate solution, the insoluble di-*p*-nitrobenzoate of ethylene glycol was recrystallized from acetone–ethanol, m.p. and mixed m.p. 138–140° C.

Component 2.—98 mg, $[\alpha]_D^{22}$ 10.2° (*c*, 1.0 in water) was hydrolyzed in part (39 mg) in *N* sulphuric acid (steam bath, 14 hours). The solution was neutralized ($BaCO_3$), evaporated, and chromatographed. Glycerol and xylose were identified. The ratio of the two compounds was determined chromatographically using the

TABLE I

Smith degradation of synthetic xylan

Component No.	R_{xylose} Solvent A	R_{xylose} Solvent B	Yield (mg)
1 (ethylene glycol)	3.48	3.18	37.5
2	2.38	2.32	98.0
3 (glycerol)	2.43	1.92	93.3
4	1.46	1.29	120.1
5 (xylose)	1.00	1.00	113.0
6	0.86	0.79	75.8
7	0.74	0.68	88.2
8	0.64	0.51	105.7
9	0.36	0.30	143.8
10	0.21	0.17	291.7

periodate – chromatropic acid technique (9) for the polyols and the phenol – sulphuric acid method (10) for the sugar. In a typical analysis of the mixture, 128.3 mg or 1.395 μmoles glycerol and 232 mg or 1.545 μmoles xylose was found on a paper chromatogram. The ratio of xylose:glycerol was about 1:1. To an aliquot (49 mg) of the substance in water (5 ml) was added (2 ml) periodic acid solution (0.5 *M*) and the mixture left in the dark at 5° C. After 48 and 72 hours, formaldehyde was determined (9) and at these intervals 6.48 and 6.58 mg formaldehyde had been evolved. Using an average molecular weight of xylose and glycerol, and assuming that 1 mole of formaldehyde was formed from the glyceryl xyloside, the D.P. was calculated to be approximately 2. After 72 hours, the above mixture was neutralized ($BaCO_3$) and to the solution was added sodium borohydride (50 mg). The reduction was allowed to proceed at room temperature for approximately 20 hours after which time the solution was acidified, boiled for 3 hours, deionized, and evaporated to give a small quantity of syrupy material. Chromatographic examination using solvents A, B, and C revealed the presence of glycerol and ethylene glycol. In a typical analysis, 1.01 μmoles glycerol and 1.13 μmoles ethylene glycol were found on a chromatogram or the ratio of the two alcohols was about 1:1.

Component 3.—93.3 mg, was optically inactive and had a chromatographic mobility in solvents A, B, and C identical with that of glycerol. Treatment of the oily material with *p*-nitrobenzoyl chloride as described for ethylene glycol gave glycerol tri-*p*-nitrobenzoate, m.p. and mixed m.p. 189–191° C.

Component 4.—120 mg, $[\alpha]_D^{22}$ 26° (*c*, 1.2 in water), was analyzed as described for component 2. Hydrolysis of a portion (48 mg) gave two components identified by paper chromatography as xylose and glycerol. The ratio of xylose:glycerol was found to be about 2:1. Periodate oxidation of a sample (60 mg) gave 4.65 and 4.71 mg formaldehyde after 48 and 72 hours, which corresponded to an approximate D.P. of 3. Reduction ($NaBH_4$) and hydrolysis gave rise to ethylene glycol, glycerol, and xylose in a ratio of 1:1.3:1.2.

Component 5.—113 mg, $[\alpha]_D^{22}$ 17.5° (*c*, 1.1 in water), had a mobility identical with that of xylose in solvents A, B, and C. The substance reacted with *p*-anisidine trichloroacetate, hence was reducing. Upon standing, the sugar crystallized, m.p. and mixed m.p. 143–145°.

Component 6.—75.8 mg, $[\alpha]_D^{22}$ 29° (*c*, 0.8 in water), gave, upon hydrolysis of a sample (30 mg), xylose and glycerol in an approximate ratio of 1:1. Periodate degradation of a portion (40 mg) gave, after 48 and 72 hours, 4.45 and 4.58 mg formaldehyde. The estimated approximate D.P. was 2. Reduction ($NaBH_4$) and hydrolysis gave ethylene glycol and a trace of glycerol and xylose.

Component 7.—88 mg, $[\alpha]_D^{22}$ 32° (*c*, 0.9 in water), gave, upon hydrolysis of a portion (35 mg), xylose and glycerol in an approximate ratio of 2:1. Periodate oxidation of a sample (44 mg) gave, after 48 and 72 hours, 2.91 and 3.16 mg formaldehyde, which corresponded to a D.P. of 3.4. Reduction ($NaBH_4$) and hydrolysis gave ethylene glycol, glycerol, and xylose in approximately equimolar proportions.

Component 8.—106 mg, $[\alpha]_D^{22}$ 30° (*c*, 1.1 in water) gave, upon hydrolysis of a portion (42 mg), xylose and glycerol in a ratio of 3.3:1 or approximately 3:1. Periodate oxidation of a sample (53 mg) gave, after 48 and 72 hours, 2.07 and 2.16 mg formaldehyde, which corresponded to a D.P. of 4.7 or about 5. Reduction and hydrolysis gave ethylene glycol, glycerol, and xylose in a ratio of 1:1.2:1.85.

Component 9.—144 mg, $[\alpha]_D^{22}$ 33.5° (*c*, 1.4 in water), gave, upon hydrolysis of a sample (58 mg), xylose and glycerol in ratio of 4.5:1. Periodate oxidation (72 mg) gave, after 48 and 72 hours, 2.10 and 2.12 mg formaldehyde, which corresponded to a D.P. of 6.3. Reduction and hydrolysis gave ethylene glycol, glycerol, and xylose in a ratio of 1:3.2:2.2.

Component 10.—292 mg, $[\alpha]_D^{22}$ 24° (*c*, 1.45 in water), yielded, upon hydrolysis of a sample (58 mg), xylose and glycerol in a 6:1 ratio. Periodate oxidation (73 mg) gave, after 48 and 72 hours, 2.69 and 2.68 mg formaldehyde, which corresponded to a D.P. of 9.9. Reduction and hydrolysis gave ethylene glycol, glycerol, and xylose in a ratio of 1:2.8:5.1.

Identification of Components in Hydrolyzates

The hydrolyzates of the above oligosaccharides were combined and resolved by paper chromatography using solvent C. The xylose and glycerol areas were eluted and the solutions evaporated to a syrup. D-*Xylose*, the syrup, had $[\alpha]_D^{22}$ 17.7° (*c*, 1.3 in water) and crystallized upon standing, m.p. and mixed m.p. 144–145° C. *Glycerol* gave, upon treatment with *p*-nitrobenzoyl chloride in pyridine in the usual manner, the corresponding tri-*p*-nitrobenzoate, m.p. and mixed m.p. 188–191° C.

Identification of Periodate Degradation Products of the Oligosaccharides

The hydrolyzates from the different polyalcohols were combined and the components resolved by paper chromatography as described in the previous section. *Ethylene glycol*, treatment of the oily residue with *p*-nitrobenzoyl chloride in pyridine gave the di-*p*-nitrobenzoate, m.p. and mixed m.p. 139–142° C. *Glycerol*, similarly, converted to the tri-*p*-nitrobenzoate, m.p. and mixed m.p. 188–191° C. D-*Xylose*, the syrup, had $[\alpha]_D^{22}$ 17.3° (*c*, 1.2 in water) and upon standing crystallized. Recrystallization from acetronitrile gave D-xylose, m.p. 142–146° C.

ACKNOWLEDGMENTS

This investigation was supported by a research grant (RG 7652) from the Division of General Medical Sciences, Public Health Service (U.S.A.), to whom we express our thanks. We are also indebted to Miss J. Hunter for skillful technical assistance.

THE CONSTITUTION OF A SYNTHETIC XYLAN

III. METHYLATION STUDIES[1]

G. G. S. DUTTON AND A. M. UNRAU[2]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received June 29, 1962

ABSTRACT

Hydrolysis of the fully methylated xylan gave a complex mixture of sugars indicating the highly branched nature of the polysaccharide. At least 27% of the internal xylose units were furanose and 38% of the terminal units were also furanose.

An earlier paper (1) has described the general properties of a synthetic xylan made by polymerizing D-xylose at 120° in the presence of phosphorous acid (2). The present paper is an attempt to investigate the structure of this synthetic xylan by the methylation technique. Previous workers (3, 4) have commented on the difficulty of completely methylating synthetic glucans and we have experienced similar trouble in the present study. Only after repeated treatments using the methods of Haworth (5), Kuhn (6), and Purdie (7) was a methylated xylan obtained which showed no hydroxyl absorption in the infrared and had a methoxyl content of 39.1%. The fully methylated polysaccharide showed unusual solubility properties in being soluble in petroleum ether (30–60°) containing as little as 5% chloroform. In this respect it resembled a methylated synthetic glucan (8).

Hydrolysis of the methylated xylan under conditions reported (9) to minimize demethylation gave tri-, di-, and mono-*O*-methyl-D-xyloses together with D-xylose in the ratio of 31:33:19:5 as determined by the phenol – sulphuric acid method (10). Many of the methyl ethers were positively identified as crystalline derivatives but because of the complexity of the hydrolysis products some were only identified by their chromatographic and electrophoretic mobilities. Separations were carried out on a cellulose–hydrocellulose column (11) using butanone–water azeotrope (12).

From the optical rotation of the tri-*O*-methyl-D-xylose fraction, it was calculated that 2,3,5-tri-*O*-methyl-D-xylose comprised 38% of the mixture, the remainder being the 2,3,4-tri-*O*-methyl isomer. The ease of methyl furanoside formation of the former was employed so that the water-insoluble 2,3,4-tri-*O*-methyl-D-xylose-1-*p*-nitrobenzoate could be obtained. The water-soluble trimethyl furanoside was subsequently hydrolyzed, reduced ($NaBH_4$) to the corresponding xylitol, and characterized as the crystalline di-*p*-nitrobenzoate. The above experimental result definitely showed that some of the terminal non-reducing xylose units were present in the polymer in the furanose form.

The different di-*O*-methyl xylose ethers were eventually separated by column chromatography and paper electrophoresis. By column chromatography, three fractions were obtained. The fastest-migrating fraction (R_f 0.63) was shown by electrophoresis to be composed of 3,5- and 2,5-di-*O*-methyl-D-xyloses. The next fraction (R_f 0.55) was shown by electrophoresis to be composed of 2,3- and 3,4-di-*O*-methyl-D-xyloses. The slowest-moving dimethyl xylose (R_f 0.45) was obtained crystalline and was 2,4-di-*O*-methyl-D-xylose. The ratio of 2,5- plus 3,5:2,3- plus 3,4-:2,4-di-*O*-methyl-D-xylose was approximately

[1]*Presented at the 45th Chemical Institute of Chemistry Conference, May 1962, Edmonton, Alberta.*
[2]*Present address: Department of Plant Science, University of Manitoba, Winnipeg, Manitoba.*

1.7:3.6:1. Approximately 27% of the internal xylose residues were thus shown to exist in the polymer in the furanose form. This value does not include the 2,3-di-*O*-methyl-D-xylose residues, which may also have existed in the furanose form in the original methylated xylan. Although 2,5- and 3,5-di-*O*-methyl-D-xylose have very different electrophoretic mobilities (borate buffer), the recovery of the sugars from the borate-impregnated paper was extremely poor. Similarly, a very low recovery was experienced when 2,3- and 3,4-di-*O*-methyl-D-xyloses were separated.

The various di-*O*-methyl sugars were identified as follows: 3,5-di-*O*-methyl-D-xylose as the *p*-bromophenylosazone; 2,5-di-*O*-methyl-D-xylose was oxidized to the acid and the derived amide shown to give a negative Weerman test (18) and the corresponding xylitol failed to give formaldehyde on periodate oxidation; 3,4-di-*O*-methyl-D-xylose on oxidation gave a positive Weerman test, the xylitol gave 1 mole of formaldehyde on periodate oxidation and the sugar gave the *p*-bromophenylosazone; 2,3-di-*O*-methyl-D-xylose on oxidation gave a negative Weerman test, the xylitol gave 1 mole of formaldehyde on periodate oxidation but the *N*-phenylglycosylamine was only obtained as a sirup.

The mono-*O*-methyl ethers of xylose were identified by electrophoresis. The apparent absence of 5-*O*-methyl-D-xylose indicated that the highly branched xylose residues existed in the pyranose form or, alternatively, those existing in the furanose form were also substituted at C_5.

The significant yield (5.2%) of D-xylose considering the hydrolysis conditions used (9) indicated that some xylose units were fully substituted.

These results confirm the earlier findings (1) based on periodate oxidation that this synthetic xylan contains an appreciable proportion of D-xylofuranose units. It is interesting to compare these findings with those of Bishop (13), who examined a xylan of low D.P. obtained by polymerizing D-xylose at room temperature in the presence of concentrated hydrochloric acid. In this case (13) there was no evidence for any D-xylofuranose units.

In our previous paper (1) we commented on the rapid liberation of formaldehyde when the xylan was oxidized with periodate and suggested the possible existence of D-*aldehydo*-xylose residues with the formaldehyde coming from a C_{4-5} glycol system. This would require that amongst the hydrolysis products of the methylated polysaccharide there should be at least 4,5-di-*O*-methyl-D-xylose. This was not detected but may have been missed in the rather complex di-*O*-methyl ether fraction.

EXPERIMENTAL

Paper chromatographic separations were carried out using the descending technique and butanone:water azeotrope as the developing solvent. Whatman No. 1 filter paper was employed and sugars were detected with the *p*-anisidine trichloroacetate spray reagent (14).

Evaporations were carried out under reduced pressure at a bath temperature of 40–45° C. Optical rotations recorded are equilibrium values at 21±2° C. Melting points quoted are uncorrected.

Methylation of the Xylan

Polyxylose (4.5 g) was methylated once by the Haworth procedure. The product, which was insoluble in water, was subsequently methylated by dissolving it in dimethylformamide and adding excess silver oxide and methyl iodide (3) and raising the temperature to the reflux temperature of methyl iodide. The mixture was continuously stirred by means of a magnetic stirrer. The product, a yellow, brittle glass, showed a small but definite OH absorption band in the infrared spectrum; consequently it was dissolved in methyl iodide, silver oxide was added, and the mixture boiled in a flask fitted with an efficient condenser on a steam bath for at least 96 hours before re-isolation. This treatment was repeated four times until finally no OH band was found in the infrared spectrum. The yellow, resinous product contained 39.1% methoxyl and was soluble in petroleum ether (30–60°) containing 4% chloroform. The final yield of methylated product was 4.24 g and had $[\alpha]_D^{22}$ 45.2° (*c*, 8.1 in $CHCl_3$).

Hydrolysis of Methylated Xylan

The bulk (4.05 g) of the methylated xylan was dissolved in 72% sulphuric acid (9); the sirupy and rather dark mixture was diluted with cold water until the acid was 2 *N*. The solution was boiled for 12 hours after which time the acid was neutralized ($BaCO_3$), decolorized with charcoal, and filtered. Evaporation of the filtrate gave a sirup which, upon chromatography, was apparently composed of xylose, and mono-, di-, and tri-methyl xyloses. The ratio of the four classes of sugars was determined paper chromatographically using the phenol – sulphuric acid method (10) and the standard curve for xylose. The result of the analysis is recorded below.

Components	μg on paper	Molar ratio
Xylose	5.0	5
Mono-*O*-methyl	18.8	19
Di-*O*-methyl	31.6	32
Tri-*O*-methyl	31.3	31

Resolution of Mixture by Cellulose Chromatography (11)

The mixture of sugars (4.05 g) was placed on a cellulose–hydrocellulose column in about four equal portions and the column irrigated with butanone:water azeotrope. The effluent was collected in tubes at 6-minute intervals for the tri- and di-methyl xyloses and at 30-minute intervals for the monomethyl xyloses and xylose. By chromatographic examination of the tubes containing the dimethyl xyloses, three quite distinct components were obtained after the column separation. The yield of the different components, their R_f values, and their probable identity are summarized in Table I.

TABLE I

Hydrolysis products of methylated xylan

Component	Description	Weight (g)	R_f
1	Trimethyl (2,3,4 and 2,3,5)	1.265	0.80
2	Tri- and di-methyl mixture	0.050	
3	Dimethyl (2,5 and 3,5)	0.344	0.63
4	Dimethyl mixture	0.070	
5	Dimethyl (2,3 and 3,4)	0.736	0.55
6	Dimethyl mixture	0.065	
7	Dimethyl (crystalline) (2,4)	0.205	0.45
8	Unknown	0.035	0.32
9	Monomethyl	0.615	0.22
10	Xylose	0.200	0.06
		3.585	

Identification of Components

Component 1 had $[\alpha]_D^{22}$ 22.2° in water. Reported rotation for 2,3,5-tri-*O*-methyl-D-xylose is 29.5° and that for 2,3,4-tri-*O*-methyl-D-xylose is 18.0° (15). The component is therefore a mixture containing 37.5% of 2,3,5-tri-*O*-methyl-D-xylose or approximately 470 mg. The two isomers were identified in the following manner. The sirup was dissolved in dry methanol containing 1% hydrogen chloride and the solution left at room temperature until no further change in the rotation could be observed. The solution was neutralized (Ag_2CO_3) and evaporated to a sirup. The product was dissolved in pyridine (6 ml) an excess quantity of *p*-nitrobenzoyl chloride was added (5% molar excess assuming all material was 2,3,4-tri-*O*-methyl-D-xylose) and the mixture was heated at 60° C for about 45 minutes, then left overnight at room temperature. Saturated sodium bicarbonate was added and the insoluble *p*-nitrobenzoate removed. The 2,3,4-tri-*O*-methyl-D-xylose-1-*p*-nitrobenzoate was recrystallized from a mixture of acetone and ether, m.p. 133–135° C, $[\alpha]_D^{22}$ −75.2° (*c*, 1.5 in $CHCl_3$), lit. m.p. 136°, $[\alpha]_D$ −76° in $CHCl_3$ (16). The filtrate, which presumably contained the methyl 2,3,5-tri-*O*-methyl-D-xyloside, was evaporated to remove pyridine and an aqueous solution of the residue extracted with chloroform. The product (375 mg) was boiled in 0.5 *N* sulphuric acid (15 ml) for 3 hours after which time the solution was neutralized ($BaCO_3$) and evaporated to a sirup, $[\alpha]_D^{22}$ 28.9° (*c*, 2.5 in water). The sugar in water (20 ml) was reduced with sodium borohydride (350 mg) at room temperature for 48 hours. The solution was neutralized (HCl) and evaporated and an aqueous solution of the residue extracted with chloroform. Evaporation of the solvent gave a sirupy product (335 mg) which did not react with Tollens reagent. The alcohol was treated with *p*-nitrobenzoyl chloride in the usual way to give 2,3,5-tri-*O*-methyl-1,4-di-*p*-nitrobenzoyl-D-xylitol, which, after recrystallization from acetone, had m.p. and mixed m.p. 147–150° C, $[\alpha]_D^{22}$ 7.1° (*c*, 1.8 in pyridine). An authentic sample was prepared from methyl αβ-D-xylofuranoside. Calculated for $C_{22}H_{24}N_2O_{10}$: N, 5.9; OCH_3, 19.5%. Found: N, 5.6; OCH_3, 19.2%.

Component 3 showed $[\alpha]_D^{22}$ 33° (*c*, 2.5 in water). Electrophoresis using 0.05 *M* borate buffer, Whatman No. 1 paper, 1000 volts, 35 milliamperes for 45 minutes revealed the presence of two components with M_g (migration relative to D-glucose) values 0.0 and 0.88. A trace of material had M_g 0.16. The substance with M_g 0.88 corresponded to 3,5-di-*O*-methyl-D-xylose whereas 2,5-di-*O*-methyl-D-xylose would not be expected to migrate and was presumed to be the substance with M_g 0.00. The ratio of the two sugars was determined by the phenol – sulphuric acid method and found to be about 1:1. The mixture was resolved using Whatman 3 MM paper and the above specified conditions. The recovery of the sugars was extremely low. *3,5-Di-O-methyl-D-xylose*, 12 mg, $[\alpha]_D^{22}$ 23.5° (*c*, 0.55 in water), 10.3° (*c*, 0.55 in $CHCl_3$), was dissolved in 80% aqueous ethanol (5 ml) and a 5% molar excess of *p*-bromophenylhydrazine in ethanol (20 ml) added. The mixture was heated on a steam bath for 45 minutes and, upon cooling, the *p*-bromophenylosazone of 3,5-di-*O*-methyl-D-xylose separated. The product was collected on a filter paper, dried with ether and petroleum ether, and had m.p. 103–105° C, lit. m.p. 107–108° (17). *2,5-Di-O-methyl-D-xylose*, 18.8 mg, $[\alpha]_D^{22}$ 43° (*c*, 0.38 in water), 15.5° (*c*, 0.94 in ethanol). A small portion (3 mg approx.) was oxidized with bromine and the Weerman test (18) applied. The test was negative, indicating that C_2 was blocked by methoxyl. The remainder was reduced with sodium borohydride in the usual manner and the 2,5-di-*O*-methyl-D-xylitol obtained as a sirup. Oxidation of a small portion (about 2.5 mg) gave no formaldehyde. The alcohol was treated with *p*-nitrobenzoyl chloride in the usual manner to give the insoluble *p*-nitrobenzoate, which was not obtained crystalline.

Compound 5, 836 mg, showed $[\alpha]_D^{22}$ 21° (*c*, 4.2 in water). Electrophoretic examination of the sirup as described for component 3 showed that two compounds were present, one with an M_g value of 0.26 and corresponding to that of 3,4-di-*O*-methyl xylose, the other with an M_g of 0.0 was 2,3-di-*O*-methyl xylose. The electrophoretic behavior in conjunction with the R_f of 0.55 for the mixture indicated that the two sugars were 3,4- and 2,3-di-*O*-methyl-D-xylose. The components were separated by electrophoresis using Whatman 3 MM paper and the conditions described previously except that the time was increased to 105 minutes. The recovery of material was extremely poor, approximately 15%. *3,4-Di-O-methyl-D-xylose*, 82 mg, showed $[\alpha]_D^{22}$ 19.8° (*c*, 1.64 in water), 39° (*c*, 1.64 in $CHCl_3$). About 5 mg was oxidized and the Weerman test (18) applied to the derived amide. The test gave positive results, hence the C_2-hydroxyl was not substituted. Similarly, 5 mg of the sugar was reduced ($NaBH_4$) to the corresponding xylitol and after removal of borate, the alcohol was oxidized with periodate and the amount of formaldehyde liberated was determined (19). Approximately 0.835 mg formaldehyde or almost 1 molar proportion of the aldehyde was formed. The remainder (about 70 mg) was dissolved in 75% aqueous ethanol (15 ml), a 5% molar excess of *p*-bromophenylhydrazine in ethanol (30 ml) added, and the solution refluxed. Upon cooling, the osazone separated and was collected by centrifugation. After drying in a vacuum desiccator, the compound had m.p. 130–134° C. *2,3-Di-O-methyl-D-xylose*, 28 mg, showed $[\alpha]_D^{22}$ 22° (*c*, 1.4 in water). The sirupy material did not crystallize. A small portion (3 mg) was oxidized with bromine and after conversion to the amide a negative Weerman test (18) was obtained, showing that the C_2-hydroxyl was substituted. Another small portion (3 mg) was reduced ($NaBH_4$) and the alcohol subsequently oxidized with periodate as described previously. Approximately 0.490 mg formaldehyde or 1 molar proportion of the aldehyde was liberated. The remaining material (about 20 mg) was dissolved in absolute ethanol (5 ml), freshly distilled aniline (2 drops) was added, and the mixture refluxed for 1 hour. Evaporation of the solvent under vacuum gave a sirupy product, $[\alpha]_D^{22}$ 170° in ethyl acetate having the characteristically high rotation of 2,3-di-*O*-methyl-*N*-phenylxylosylamine but which failed to crystallize. *2,4-Di-O-methyl-D-xylose*, 205 mg, showed $[\alpha]_D^{22}$ 21° (*c*, 1.5 in water), −24.5° (*c*, 1.5 in $CHCl_3$). The sirup crystallized upon standing. When it was washed with cold ether and petroleum ether and dried on a porous plate, the compound had melting point 109–112° C, lit. (20, 21) m.p. 111°, 114–116° C. Mixed m.p. 110–112° C. The crystalline compound mutarotated in water, $[\alpha]_D^{22}$ −28° → +22°. The physical constants obtained show that the sugar was 2,4-di-*O*-methyl-D-xylose.

Component 8, 35 mg, had an M_g value of 0.05 upon electrophoresis. The sirup was boiled in *N* sulphuric acid (10 ml) for 6 hours. The solution was neutralized ($BaCO_3$) and evaporated, and the residue chromatographed. Compounds were observed corresponding to tri-, di-, and mono-*O*-methylxyloses and xylose.

Component 9, 615 mg, was found to be composed of three different mono-*O*-methyl xyloses, with M_g values of 0.82 (3-*O*-methyl-D-xylose), 0.25 (2-*O*-methyl-D-xylose), and 0.16 (4-*O*-methyl-D-xylose). No 5-*O*-methyl-D-xylose was apparently present. The ratio of 3-, 2-, and 4-*O*-methyl-D-xylose, determined by the phenol – sulphuric acid method was about 3:4:1.

Component 10, D-xylose, 200 mg, showed $[\alpha]_D^{22}$ 17.8° in water. The sirup crystallized upon standing. Recrystallization from hot ethanol gave D-xylose, m.p. and mixed m.p. 143–145° C.

ACKNOWLEDGMENTS

This investigation was supported by a P.H.S. research grant (RG 7652) from the Division of General Medical Sciences, Public Health Service (U.S.A.), to whom we express our thanks. We are also indebted to Miss J. Hunter for skillful technical assistance, to Dr. Elizabeth Percival for a sample of 2,4-di-*O*-methyl-D-xylose, and to Mrs. A. Aldridge for analyses.

ABSTRACT

An investigation has been carried out on the infrared spectra of 3-mercapto-4-methyl-5-ethyl-1,2,4-triazole and 2-mercaptothiazoline, both in solution and in the crystalline form. The spectra of the deuterated compounds and the silver salts have also been examined. The results allow some assignment of bands to be made. The spectra of these compounds adsorbed on silver iodide were then examined. It would appear that in the concentration range examined physical adsorption occurs.

INTRODUCTION

Although many studies have been made of the adsorption of various types of organic molecules on silver halide particles, little direct evidence is available as to the actual state of the molecule on the surface. In many cases the material adsorbed was an organic ion and the adsorption was electrostatic in nature (1); in such cases little change in structure of the ion would be expected. However, there are a number of organic compounds which are of great importance in flotation processes and in the photographic industry which contain the —N(H)—C(=S)— grouping; these are often added to suspensions at a pH where they exist mainly as unionized molecules. Compounds such as 3-mercapto-4-methyl-5-ethyl-1,2,4-triazole flocculate silver halides at neutral pH and are also found to influence the crystal shapes of silver iodide when crystallization is carried out in their presence (2). The latter behavior appeared to be due to the preferential adsorption of this material onto certain crystal faces of silver iodide. The exact mode of adsorption was not easy to determine but it appeared highly probable that perturbation of the —N(H)—C(=S)— group would occur in the adsorbed state and that this would be detectable by infrared spectroscopy.

The infrared spectroscopic technique has proved invaluable in the elucidation of the structures of adsorbed molecules in many systems but there is considerable limitation to its application, owing to the loss of radiation, by absorption and scattering, in the solid substrate upon which the molecules are adsorbed. The difficulties inherent in the technique have been discussed by Eischens and Pliskin (3) for adsorption at the gas–solid interface.

[1]*Issued as N.R.C. No. 6965.*
[2]*Present address: Department of Chemistry, University of Western Australia, Nedlands, W. Australia.*

Two further problems may arise when adsorption is studied at the liquid–solid interface. Firstly, the molecules studied in these systems are invariably larger than those studied at the gas–solid interface and consequently at high concentrations of adsorbate, multilayer adsorption may occur. In such cases it may not be possible to distinguish the first layer, which interacts with the substrate, from subsequent overlaying deposits. Secondly, adsorption of solvent may compete with that of the adsorbate under investigation and wide spectral regions may be excluded from study if the solvent absorption is intense. In the present system investigation was confined to regions considerably below completion of a monolayer of adsorbate and no problems were encountered due to retention of water by the solid.

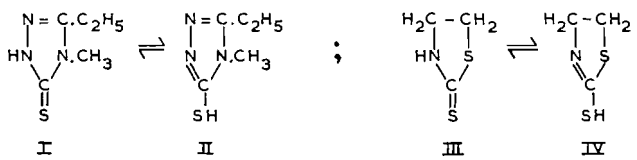
Silver halides, moreover, form suitable adsorbents since they do not have absorption bands of their own in the regions to be studied. By using finely divided sols a relatively large surface area can be obtained and thus sufficient adsorbed material can be included in the sample to yield a spectrum of moderate intensity. Further, with such finely divided materials, radiation losses by scattering are not large, especially at frequencies below ca. 2000 cm^{-1}.

EXPERIMENTAL

Materials

All inorganic chemicals used were of A.R. grade.

3-Mercapto-4-methyl-5-ethyl-1,2,4-triazole (I, II) was kindly supplied by Messrs. Ilford Ltd.,* and 2-mercaptothiazoline (III, IV) by Messrs. I.C.I. Ltd.* These compounds are referred to as MCT and MCTH respectively.



Preparation and Flocculation of Sols

Two methods may be employed to study the flocculation of sols by a specific reagent. Either the reagent may be added to a preformed sol (4) or alternatively the sol may be formed in the presence of the reagent (5). In the latter case the effect of the reagent on the nucleation and the crystal growth process may also be investigated. Both methods have been utilized in the present studies. All silver iodide sols and suspensions were employed at pI = 4 to ensure a negative charge on the particles (4).

Preparation of Silver Iodide Sols in the Presence of MCT

Silver nitrate (0.16 ml, 0.0155 *N*) was added with stirring to 5 ml of a solution composed of 0.5 ml 0.0207 *N* potassium iodide, 0.9 ml 0.1393 *M* MCT, and 3.6 ml distilled water. Flocculation of the sol occurred rapidly under these conditions and the whitish fluffy floccules settled out in a few hours. The suspension was then centrifuged, the supernatant decanted, and the floccules washed several times with distilled water followed by centrifugation; it appeared unlikely that a strongly adsorbed film would be removed by this washing procedure. After removal of as much supernatant as possible the remaining water was pumped off. The dried material was then ground up in a small volume of nujol and examined in this state in the spectrometer. Nujol and hexachlorobutadiene were used as mulling agents to provide complete coverage of the spectrum between 4000 and 650 cm^{-1}. Spectra were recorded on a Perkin–Elmer 21 spectrophotometer fitted with a calcium fluoride or a sodium chloride prism.

These conditions were employed since it has been shown that it is at this concentration of MCT that flocculation occurs; this point also corresponds with the zero point of charge as measured by microelectrophoresis (6). From experiments with other systems it has been found that this point usually corresponds to ca. 30% of a monolayer (4). The silver iodide particles formed under these conditions do not have the usual hexagonal or tetrahedral shapes but form long rods, suggesting the strong adsorption of the MCT onto certain crystal faces (2). Microelectron diffraction patterns indicated that the crystals were silver iodide; spots due to silver mercaptotriazole were not detected, suggesting that coprecipitation had not occurred.

**We wish to express our thanks to these organizations for gifts of material.*

Experiments with Preformed Silver Iodide Sols

Concentrated silver iodide sols with an average particle diameter of 500 Å were prepared in the manner described by Harmsen, van Schooten, and Overbeek (7). MCT solution (1.5 ml, 0.1038 *M*) was added to 1.5 ml of the concentrated sol (ca. 40% w/v). Instantaneous flocculation of the sol occurred and the particles were then spun down and treated as previously described. In this manner a sample of large specific surface was obtained.

Alternatively, powdered silver iodide having a specific surface of 0.7 m^2/g was employed (2). To 0.5 g of this powder 1.25 ml of 0.1038 *M* MCT solution was added. The suspension was agitated for 4 hours and then treated as described above.

Preparation of Deuterated MCT

To assist in the assignment of vibrational bands a study was also made of the spectrum of deuterated MCT.

MCT (70 mg) was sealed in a glass ampoule with 4 ml of heavy water. The ampoule was heated to 70° C until all the MCT had dissolved and was then allowed to stand for 24 hours at room temperature. The solvent was then pumped off and the sample stored *in vacuo*. This treatment gave about 50% deuteration, so a further sample was treated with successive amounts of D_2O. Complete deuteration was still not achieved, suggesting that very stringent precautions are necessary to prevent exchange with atmospheric water vapor. Preparation of samples for infrared purposes was carried out in a dry box.

Preparation of Silver MCT

The silver salt of MCT was prepared for spectral comparison with MCT adsorbed on silver iodide. The preparation was carried out by adding excess silver nitrate solution to an MCT solution, centrifuging off the precipitate, washing with water, and then drying.

Experiments with MCTH

Experiments and preparations parallel to those described above for MCT were carried out with MCTH. The infrared spectrum of MCTH, while similar in some respects to that of MCT, was generally much simpler and was of assistance in assigning bands in the MCT spectrum.

RESULTS AND DISCUSSION

Infrared Spectra of MCT and MCTH

Absorption in the Region 3500–2000 cm^{-1}

Cyclic secondary thioamides such as MCT have been studied previously (8, 9) but since certain difficulties are associated with their spectra some discussion is warranted before the spectra of films adsorbed on silver iodide are considered. It has been shown that such compounds exist in the thiolactam form (I, III) rather than in the mercapto form (II, IV). Figure 1 shows the spectrum of MCT in the solid state and in solution in chloroform. SH— absorption is apparently absent whilst bands due to the —N—H stretching vibration, at ca. 3100 cm^{-1} (solid) and 3410 cm^{-1} (solution), are intense. There are some very weak bands at 2550 and 2480 cm^{-1} in the spectrum of solid MCT, at 2450 cm^{-1} in the spectrum of the chloroform solution, and at 2450 cm^{-1} in the spectrum of MCTH in carbon tetrachloride solution. This is the region where S—H groups might be expected to absorb (10). However, any S—H group in the solid material would be hydrogen bonded and would probably absorb at frequencies below that found for the solutions in carbon tetrachloride and chloroform. It is possible that these weak bands are overtones of bands at lower frequencies. The N—H groups are all hydrogen bonded in the crystalline material, possibly as dimers.

The spectrum of MCT was examined in solution in carbon tetrachloride, carbon disulphide, and in chloroform. The molecules again exist largely, if not entirely, in the N—H form rather than in the S—H form. However, in solution there is a large proportion of N—H groups not involved in hydrogen bonding and hence a mixture exists of free molecules with dimers or higher combinations. Similarly MCTH exists in the thiolactam form rather than in the mercapto form.

Absorption in the Region 2000–650 cm^{-1}

One of the most prominent features of the spectra of MCT and MCTH is the intense band at 1500–1520 cm^{-1}. Since these compounds are secondary thioamides it is expected

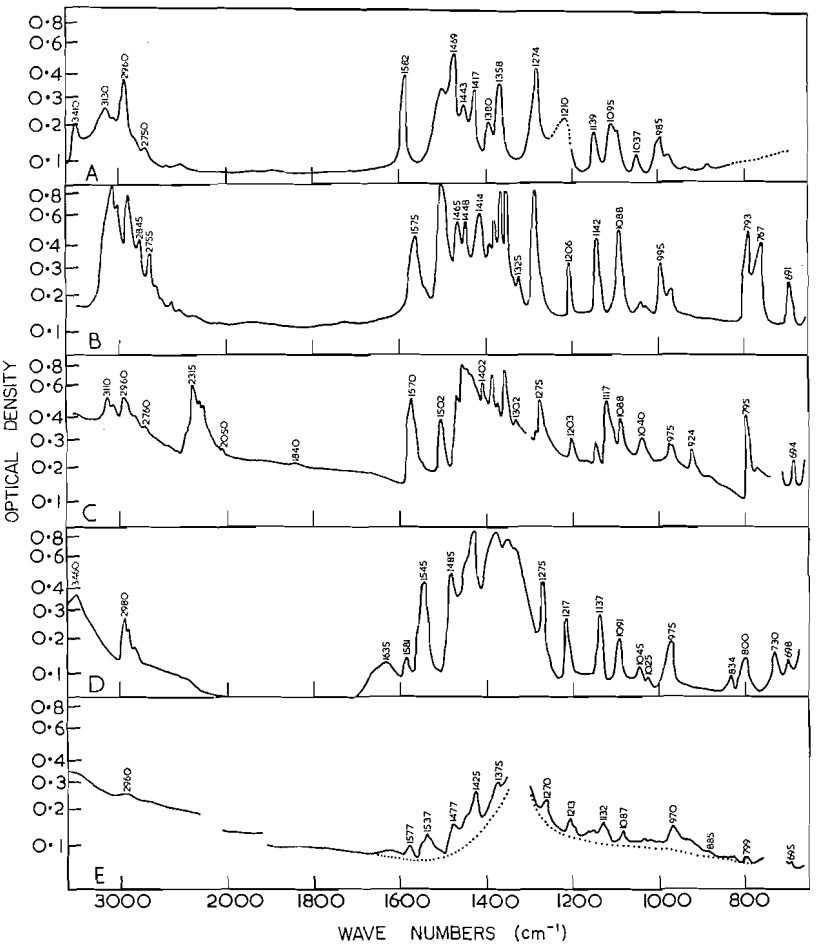


FIG. 1. Infrared spectra of (A) MCT solution in chloroform, (B) MCT mull, (C) MCT (partly deuterated) mull, (D and E) silver MCT mull.

that a band will appear in this region of the spectrum similar to that classified as the amide II band (10). Considerable controversy has surrounded the assignment of this band and it has been variously attributed to the N—H in-plane deformation vibration and to the C—N stretching vibration of the amide group. The frequency is higher than that normally associated with the C—N single bond, but this fact is attributed to the partial double-bond character of the band in the thioamide structure.

Previous deuteration studies (10) have favored the assignment of the 1500–1550 cm^{-1} band to the in-plane N—H deformation mode, since, on substitution of deuterium for hydrogen, the band disappears and a new band appears at about 1120 cm^{-1}. The frequency displacement is that expected for substitution of H by D (12). In the present study deuteration of MCT and MCTH was accompanied by a decrease in intensity of the 1500–1520 cm^{-1} band and the appearance of a new band at 1110–1120 cm^{-1} (Figs. 1 and 2). With more complete deuteration of the MCT than that shown in Fig. 1C, the band at 1502 cm^{-1} almost entirely disappeared.

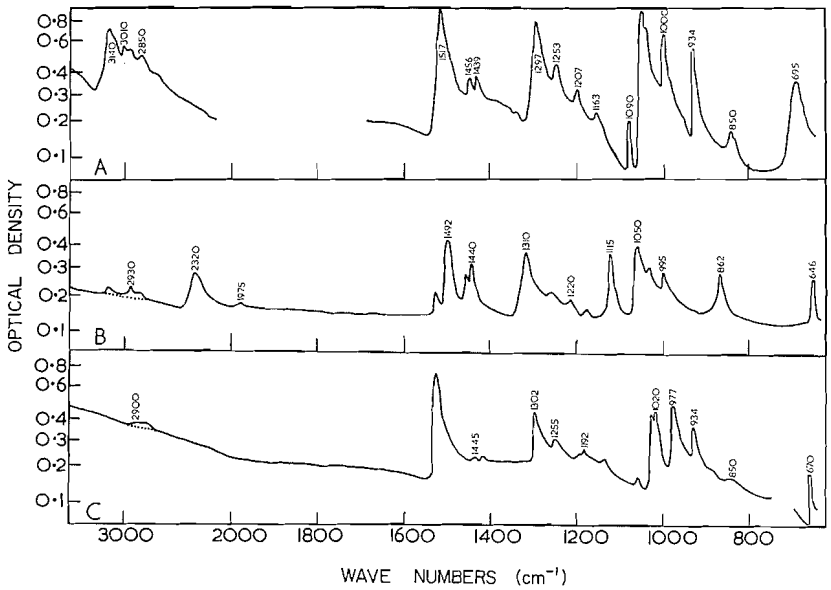

FIG. 2. Infrared spectra of (A) MCTH mull, (B) deuterated MCTH mull, (C) silver MCTH mull.

When MCT was dissolved in chloroform the 1502 cm^{-1} band was displaced to 1480 cm^{-1}. In carbon tetrachloride the frequency of the 1520 cm^{-1} band of MCTH was displaced to 1490 cm^{-1}. The direction of displacement is that expected if the band was due to a deformation mode, since hydrogen bonding in the crystal would stiffen the N—H group against deformation and increase the frequency of the vibration.

However, the spectra of silver MCT and silver MCTH do not support the latter conclusion. When the silver salts are formed the N—H stretching band disappears completely, as indicated by the spectra (Figs. 1 and 2), thus proving the complete replacement of hydrogen by silver. The frequency of the 1520 cm^{-1} band of MCTH, whose assignment is in question, was merely displaced upwards by 10 cm^{-1} and the intensity was unaffected on formation of the silver salt. The situation was not so well defined in the case of the silver salt of MCT, but the 1500 cm^{-1} band still remained, being either displaced upwards in frequency to 1540 cm^{-1} or downward to 1485 cm^{-1}, as discussed below. The displacement of this band from 1500 cm^{-1} in solid MCT to 1485 cm^{-1} in chloroform solution was mentioned earlier. The 1500–1520 cm^{-1} band cannot, therefore, be due to the N—H deformation mode and must largely be due to the C=N stretching of the thiolactam group.

The band which appeared at 3440 cm^{-1} in the spectrum of the silver salt of MCT (Fig. 1D) is not due to a N—H stretching vibration. The frequency and half width of this band show that it belongs to a hydrogen-bonded O—H stretching vibration. This must be due to adsorbed water on the silver salt and the assignment is confirmed by the presence of the O—H deformation band of water at 1630 cm^{-1}.

Chatt, Duncanson, and Vinanzi (11) found an intense band at 1480–1530 cm^{-1} in the spectrum of N,N-dialkyldithiocarbamates. No N—H group occurred in these compounds and this band was assigned to the stretching vibration of the C—N group, which has partial double-bond character. They found that the frequency of the 1500 cm^{-1} band of methyl N,N-dimethyldithiocarbamate and of several metal N,N-dialkyldithiocarbamates

was decreased when the solid material was dissolved in solvents. These results are in agreement with those mentioned above for MCT and again suggest that the 1500 cm^{-1} band cannot be assigned to the N—H deformation vibration.

It would appear that, in the spectra of deuterated MCT and MCTH, the band which appears at 1115 cm^{-1} is due to the N—D in-plane deformation vibration. Although the 1500 cm^{-1} band decreased on deuteration, a new intense band appeared at 1450 cm^{-1}, superimposed on existing bands of MCT. This suggests that the band did not disappear completely, but was displaced to a lower frequency. For MCTH the 1520 cm^{-1} is the strongest band in this region and it can readily be seen that the corresponding band in deuterated MCTH occurs at 1492 cm^{-1}. This band must be due to C—N stretching. The sensitivity of the C=N band to the replacement of hydrogen by deuterium must mean that the N—H in-plane deformation mode contributes to the C=N stretching mode. Hadži (12) has concluded that the two vibrations are strongly coupled in secondary thioamides. In the absence of a separate band, which may be assigned to the N—H in-plane deformation mode in the spectra of MCT and MCTH, it must be concluded that the deformation mode is strongly coupled with the C=N stretching mode, which absorbs at 1500–1520 cm^{-1} in the solid.

The intense band at 1570 cm^{-1} in the spectrum of MCT was due to the 3,4 C=N stretching vibration. The 3,4 bond is saturated in MCTH and consequently the band does not appear in the spectrum of this compound.

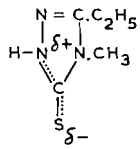
Two possible explanations may be advanced for the changes which occur in the region 1450–1600 cm^{-1} when silver MCT is formed. Firstly, the 1502 cm^{-1} band due to the C=N stretching mode is displaced downward in frequency to 1430–1480 cm^{-1} and the 3,4 C=N stretching mode is displaced from 1575 cm^{-1} to 1545 cm^{-1}. The small remaining band at 1575 cm^{-1} in the silver MCT spectrum must then belong to some unreacted MCT. Secondly, with the formation of the silver salt the frequency of the 1502 cm^{-1} band of solid MCT is raised to 1545 cm^{-1} and the 1575 cm^{-1} band suffers a very great intensity decrease. In favor of the second explanation is the observation that the C=N stretching frequency of MCTH is raised 10 cm^{-1} on forming the silver salt of this compound. There seems no reason to expect the intensity of the 3,4 C=N stretching vibration of MCT to be affected so greatly by silver salt formation, although it is possible that the C=N group is rendered less polar by the replacement of the thioamide hydrogen atom with silver, and as a result the intensity of the C=N stretching vibration is decreased.

In other instances, the C=N band frequency has shown variations over a range similar to that considered for MCT and silver MCT, i.e. 1502–1545 cm^{-1}. Thus the frequency of the C=N band of metal N,N-dialkyldithiocarbamates was found to range from 1480 to 1530 cm^{-1} as the metal was varied (11). However, the systems are not completely similar since in the latter compounds the metal is attached to the sulphur atom, whereas in silver MCTH, and probably in silver MCT, the silver atom replaces hydrogen from the nitrogen. This is shown by the appearance of the C=S stretching band with normal frequency and intensity in the silver MCTH spectrum (Fig. 2).

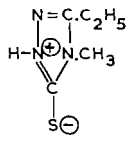
A band appearing at 1050 cm^{-1} in the MCTH spectrum has been assigned by Mecke *et al.* (13) to the C=S stretching mode of the thioamide group. The band is one of the most intense in the spectrum of MCTH (Fig. 2). With the formation of the silver salt the frequency of this band was displaced downward by about 20 cm^{-1}.

Although several moderately intense bands occur in this region in the spectrum of MCT, no band appears which may be assigned with certainty to the C=S stretching vibration of this compound. The two compounds MCT and MCTH differ in that the

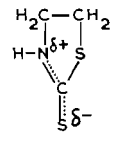
former has a double bond in the 3,4 position. Should the interpretation of the 1500–1520 cm^{-1} band assignment be correct, in so far as the C—N bond in the 1,2 position has double-bond character, then conjugation may occur between the two double bonds in MCT and be responsible for the difference between its spectrum and that of MCTH. It is of interest to consider that in the case of MCT conjugation effects may cause the structure to lie somewhere between V and VI.



V

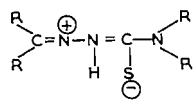


VI



VII

According to the magnitude of the contribution of VI to the structure, the carbon–sulphur stretching vibration may not absorb as a normal C=S mode. MCTH, without the opportunity for conjugation, may exist more as a structure of type V, i.e. the carbon–sulphur bond preserves essentially double-bond character as in VII. Gingras *et al.* (14) consider from chemical evidence that, for thiosemicarbazones, the polar form



contributes to the overall structure because of stabilization by conjugation.

If the zwitterion form VI contributes more to the structure of MCT than to that of MCTH, it would be expected that this effect should be reflected in different frequencies for the N—H stretching modes for these compounds. However, this is not supported by the spectral evidence. The frequencies of the N—H stretching modes are identical in solution and the value for solid MCT is only slightly below that for solid MCTH.

Refn (15) considers that the N—H stretching mode of $=\overset{+}{N}H-$ in pyrazol-5-ones absorbs at about 1800–2400 cm^{-1} due to strong hydrogen bonding of the zwitterion form. This is well below the frequencies found in the present work but stronger bonding should be expected in the system $\overset{+}{N}—H\cdots\overset{-}{O}-$ than in $\overset{+}{N}—H\cdots\overset{-}{S}—$.

The study of solvent effects on the C=S stretching vibration led Bellamy and Rogasch (16) to develop a technique for the assignment of this vibration. However, they found that mercaptobenzothiazole, which exists in the C=S form, did not show the expected solvent-induced frequency displacements. This was attributed to the molecules existing as dimers in solution. None of the bands at 1350, 1275, 1140, 1090, 985, or 965 cm^{-1} in the spectrum of MCT follow the solvent frequency pattern expected for normal C=S stretching bands in carbon tetrachloride, carbon disulphide, and chloroform, although a considerable proportion of the molecules exists as single species in these solutions (see discussion above). A band in the 1200 cm^{-1} region was obscured by strong solvent absorption in chloroform and in carbon tetrachloride. However, this band occurred at 1206 cm^{-1} in the spectrum of solid MCT and at 1201 cm^{-1} in carbon disulphide solution, a result which is not expected for a C=S stretching mode. MCTH was too insoluble for a complete investigation.

Assignment of the 770 cm^{-1} band in the spectrum of MCT to the out-of-plane N—H deformation mode was confirmed by deuteration studies. The spectra were measured with a cesium bromide prism. The only change in the spectrum between 800 and 300 cm^{-1}, on deuteration, was the replacement of the 770 cm^{-1} band by one at 550 cm^{-1}. This band is normally referred to as the amide V band (10).

The band at 1275 cm^{-1} in the MCTH spectrum and at 1297 cm^{-1} in that of MCTH must be the one normally classified as the amide III band (10). When the amide II band is attributed to the N—H in-plane deformation this band is associated with the C—N stretching vibration (10). However, its origin is uncertain when the amide II band is largely due to C=N stretching. The band is little affected by the various environments shown in Figs. 1–5.

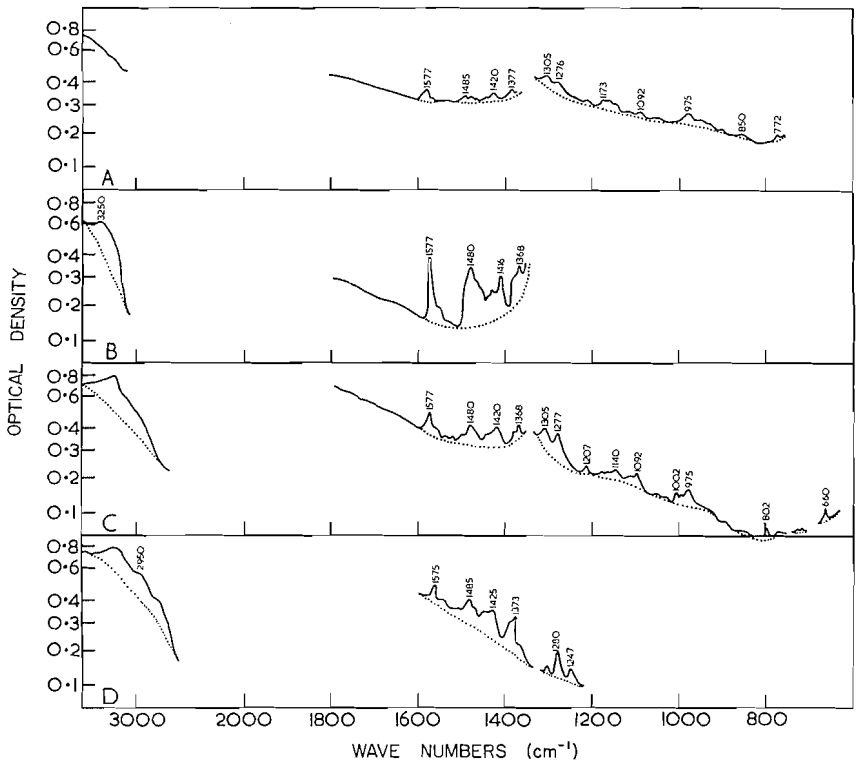


FIG. 3. Infrared spectra of (A, B, C) MCT adsorbed on preformed silver iodide sol, (D) MCT adsorbed on silver iodide powder.

Adsorption Studies

Adsorption of MCT on Silver Iodide

The spectra (Figs. 3 and 4) show that MCT adsorbed on silver iodide has a similar structure to that of the material in bulk or in solution. This appears to be independent of whether the MCT was used to coagulate a preformed sol or whether the sol was formed in its presence. Titration studies have shown that MCT behaves as a weak acid with a pK of ca. 8.5 (17). This means that at the pH of the coagulation, ca. 5.0, the MCT would be present in aqueous solution mainly in the non-ionized form. On this basis the spectra would be consistent with adsorption of the MCT molecule in the neutral form.

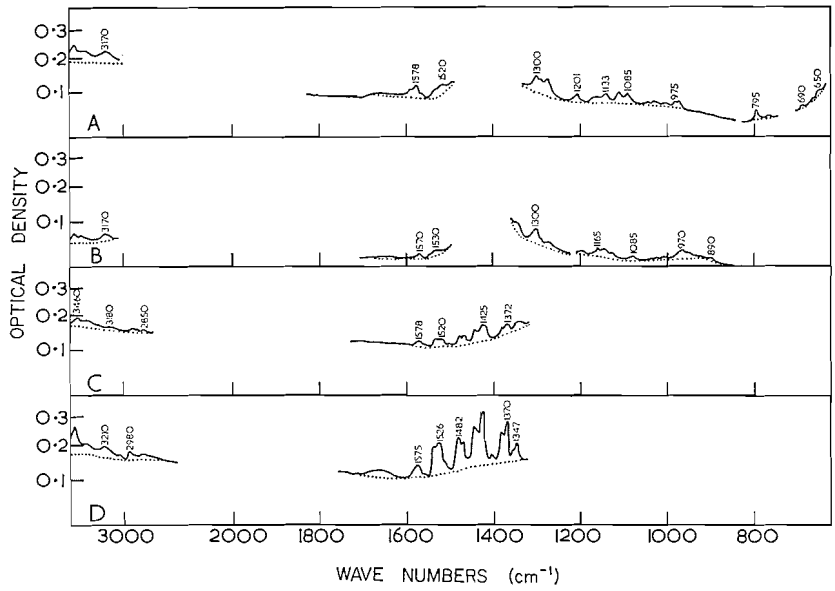

FIG. 4. Infrared spectra obtained from silver iodide formed in the presence of MCT.

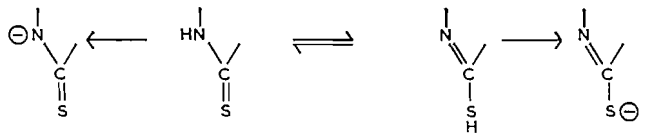
MCT may ionize by two possible mechanisms to give either a negative nitrogen or a negative sulphur, or more probably a mesomeric anion:



The close resemblance between the titration curves of benztriazole and MCT would infer that it is the NH group which is the group involved in ionization. This is supported by the spectra of the silver salt, since the N—H stretching frequency (3100–3140 cm^{-1}) disappears and the C=S band remains unchanged, at least in the case of MCTH, where a definite C=S assignment has been made. Results of ultraviolet spectra also suggested that the thione form HN—C=S is the stable one (18–20).

It is attractive to consider that adsorption of MCT on the surface of silver iodide occurs via an ion-exchange mechanism, viz. replacement by the MCT anion of the I^- on the surface, but this does not seem to be supported by the pK value or the spectra. For instance, from Fig. 4 it can be seen that in the case of silver iodide formed in the presence of MCT the N—H stretching vibration is retained. The particle size in this case was very small. Hence the scatter was small and good spectra were obtained in the 3000 cm^{-1} region.

In the case of preformed silver iodide sols coagulated by MCT, precise study of the region 3000–4000 cm^{-1} was not possible owing to scatter by the larger particles. However, the spectra appear to indicate that in this case the NH group is also retained. In this case many features of the spectra in the region 1480–1600 cm^{-1} have little resemblance to those of silver MCT, and it seems unlikely that the adsorbed species is an adsorbed silver MCT molecule.

Figure 1 shows that in solid MCT all N—H groups are involved in hydrogen bonding.

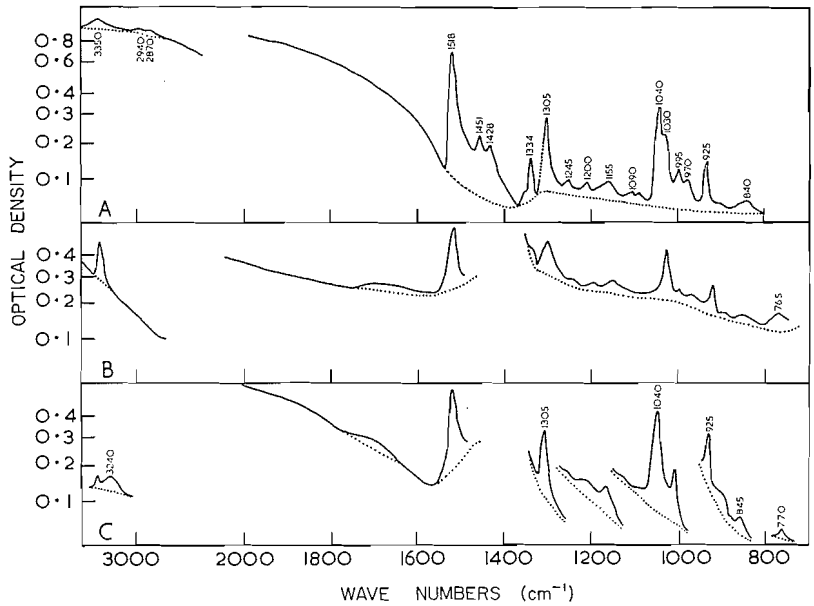


FIG. 5. Infrared spectra of (A) MCTH adsorbed on silver iodide powder, (B) silver iodide formed in the presence of MCTH, (C) MCTH adsorbed on preformed silver iodide sol.

However, in the case of silver iodide formed in the presence of MCT the greater proportion of the molecules appears to be adsorbed with free NH groups. Thus the strong sharp band at 3460 cm^{-1} (Fig. 4) is due to the stretching of free N—H groups on the surface. This would infer, therefore, that adsorption of the molecules responsible for this band cannot occur via the N—H group, for example, by hydrogen bonding of the N—H to the potential-determining iodide ion. In Fig. 4 the presence of adsorbed water is shown by the H—O—H deformation band at ca. 1650 cm^{-1}. The broad O—H stretching band accompanying this must lie beneath the sharp N—H band at 3460 cm^{-1}. The bands at 3390, 3200, and 3070 cm^{-1} are due to the stretching modes of N—H groups in varying degrees of hydrogen bonding, or to combination bands whose intensities have been increased by Fermi resonance with the N—H vibration. From the relative intensities of the free and hydrogen-bonded N—H groups there is clearly a high proportion of free N—H groups since the intrinsic intensity of the bonded N—H stretching band is far greater than that of the free. Although in very dilute solutions of MCT, in polar and non-polar solvents, there is a considerable amount of NH which is free from hydrogen bonding (Fig. 1A), the proportion of free groupings is even greater for material in the adsorbed state (Fig. 4).

One other possibility is that the MCT molecule is adsorbed to the silver iodide surface by means of the polarizable C=S bond. Unfortunately, it is not clear whether a definite band can be associated with the C=S bond in MCT. Bands between 800 and 1280 cm^{-1} do not seem to be greatly different for MCT, silver MCT, or MCT adsorbed on silver iodide particles. Since the C=S stretching mode would be expected to occur in the region 800–1300 cm^{-1} (16), the suggestion is that no great change has occurred in this mode.

In the spectral region 1300–1600 cm^{-1}, several bands which appear single in the MCT and silver MCT spectra (Fig. 1) are doubled in the spectrum of MCT adsorbed on silver iodide (Figs. 3 and 4). This splitting may be due to the heterogeneous nature of the surface of the silver iodide perturbing the molecular vibrations to varying degrees.

The spectra of the preformed sols coagulated with MCT are masked by scattering in the region 3000–4000 cm^{-1} but it does appear that NH groups are present and that most of these are hydrogen bonded; a broad band appears between 3200 and 3300 cm^{-1} (Fig. 3). If this assignment is correct, hydrogen bonding in these samples is not as strong as in crystalline MCT, where the frequency is displaced to 3050–3090 cm^{-1}. In Fig. 3D the band at 3200–3280 cm^{-1} due to weakly hydrogen-bonded molecules is more readily observed because of the lower scatter for this particular sample. The band at 3500 cm^{-1} may well be due to adsorbed water on the sample rather than to adsorbed molecules with free N—H groups.

Other differences also occur in the region 1450–1600 cm^{-1} of the spectra of the sol coagulated with MCT and that formed in the presence of MCT. In the former case the 3,4 C=N stretching band appears at the normal position (1575 cm^{-1}) found for MCT crystals, for MCT in solution in organic solvents, and for deuterated MCT (Fig. 1). However, the C=N stretching band of the thiolactam group was displaced from 1500 cm^{-1} to ca. 1480 cm^{-1} when MCT was used to coagulate a silver iodide sol. This is rather similar to the shift caused by deuteration or by solution in chloroform.

In the case of silver iodide formed in the presence of MCT the spectrum is considerably different in the region 1450–1600 cm^{-1} to that of MCT in the solid state or in solution. The double band at 1526 and 1536 cm^{-1} (Fig. 4) probably is that which occurs at 1545 cm^{-1} in the spectrum of silver MCT; two possibilities were considered for the interpretation of this band. If the band at 1545 cm^{-1} in the spectrum of silver MCT is due to the 3,4 C=N stretching mode (the weak band at 1580 cm^{-1} was ascribed to a small amount of unchanged MCT) then two forms of adsorbed MCT would occur when silver iodide is formed in the presence of MCT, one form with the 3,4 C=N stretching mode at 1575 cm^{-1}, as in the case of MCT adsorbed on preformed silver iodide particles, and the other form having the 3,4 C=N stretching band at 1526–1536 cm^{-1}, as in the case of silver MCT. The bands at 1471–1482 cm^{-1} and, perhaps, at 1428–1447 cm^{-1}, which appear abnormally strong, are then the C=N stretching bands of the two forms.

The alternative explanation assigned the 1580 cm^{-1} band of the silver MCT spectrum to the 3,4 C=N stretching mode, whose intensity was weakened by replacement of hydrogen by silver. The 1545 cm^{-1} band was then due to the C=N stretching mode. On this basis only one form of MCT need be considered when silver iodide is formed in the presence of the organic compound.

A weak but distinct band appears at 1530–1540 cm^{-1} in the spectrum of the preformed sol coagulated with MCT (Fig. 3). Thus in this system there is a small amount of surface material similar to that adsorbed on silver iodide formed in the presence of MCT.

It would appear that in the concentration range investigated MCT is physically adsorbed onto the surface of silver iodide. No evidence has been found that adsorption proceeds via formation of silver MCT on the surface, or that adsorption is preceded by formation of silver MCT in the liquid phase. Solubility conditions would in any case be unfavorable for the latter situation to occur. It would appear from the spectra, however, that the adsorption process is connected with the 3,4 C=N and the C=N group in the MCT molecule, since bands corresponding to the stretching motions of these groups are most strongly affected by adsorption; this would be consistent with physical adsorption via the C=S with consequent polarization of the bond. The high proportion of free NH groups (non-hydrogen-bonded) may be an indication that this grouping is directed away from the surface.

The lack of evidence for a chemisorption process involving either the breaking of the —NH or C═S bond is surprising in view of the fact that MCT will reverse the charge of silver iodide at a concentration of ca. 10^{-3} *M*, and above 10^{-1} *M* the silver iodide appears to dissolve to give a silver MCT complex. The nature of these complexes, however, does not appear to have been completely investigated. Certainly, from infrared spectra there appears little evidence for the formation of a chemisorbed complex on the surface of silver iodide and it seems unlikely that if a chemisorbed layer had been formed it would be removed easily by washing.

Adsorption of MCTH on Silver Iodide

The spectrum of MCTH adsorbed on silver iodide is very similar to that of the material in the bulk phase (cf. Figs. 2 and 5).

The frequency of the N—H stretching vibration of the thiolactam group in the adsorbed material (3350 cm^{-1}) is below that of MCTH in dilute solution in organic solvents (3450 cm^{-1}), showing that weak hydrogen bonding occurs in the former state. However, as in the case of adsorbed MCT considered above, the adsorbed MCTH is not as strongly hydrogen bonded as in the crystalline material, where the N—H stretching frequency is between 3050 and 3150 cm^{-1}.

The spectrum in the N—H stretching region of MCT adsorbed on a preformed silver iodide sol was different to that of silver iodide formed in the presence of MCT. In the case of MCTH, bands occurred at 3350 cm^{-1}, for both methods of sample preparation, suggesting that hydrogen bonding occurred with —NH but to a lesser extent than in the crystal of MCTH. Figures 5B and 5C indicate that there is more hydrogen bonding in the case of adsorption on a preformed sol than in the case of silver iodide formed in the presence of MCTH.

Only very slight changes were observed in other regions of the spectrum of adsorbed MCTH compared to that of the bulk material. The C═N stretching vibration (1520 cm^{-1}) is practically unaffected by adsorption. The C═S stretching frequency in the adsorbed state (1040 cm^{-1}) is slightly below that of MCTH in the solid (1050 cm^{-1}) but the effect is small and less than that accompanying the silver salt formation. It is clear that there has been little perturbation of the molecule by adsorption onto silver iodide.

THE NUCLEAR MAGNETIC RESONANCE SPECTRA OF PARA-SUBSTITUTED PHENOLS[1]

W. G. Paterson and N. R. Tipman
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 25, 1962

ABSTRACT

The nuclear magnetic resonance spectra of a number of para-substituted phenols have been examined. The —OH chemical shifts, extrapolated to infinite dilution in benzene and in carbon tetrachloride, were found to be almost independent of the nature of the ring substituent. Approximately linear relationships were observed between the internal chemical shift of the ring protons and other physical properties.

INTRODUCTION

Nuclear magnetic resonance spectroscopy has been used extensively in the study of intermolecular hydrogen bonding in phenols (1–12). However, in nearly all instances, measurements were not extended to regions of very low concentration. The results quoted in the present paper indicate that caution should be taken in the extrapolation of chemical shift data to infinite dilution. The electric field theory of Buckingham (13) has been applied to para-substituted phenols and the predictions of the theory with regard to internal ring proton shifts have been qualitatively verified.

EXPERIMENTAL

The nuclear magnetic resonance spectra were obtained at approximately 40° C on a Varian A-60 analytical n.m.r. spectrometer operating at 60 Mc/sec. The line positions were measured by the usual audio-frequency side-band technique (14) using a Hewlett–Packard Model 200AB audio-oscillator and a Hewlett–Packard Model 521C frequency counter.

All the phenols were of reagent grade quality or better and were dried over a suitable desiccant before use. Small amounts of spectroscopic grade cyclohexane (mole fraction 0.01 or less) were used as internal reference and were taken into account in the calculation of mole fraction. Carbon tetrachloride, benzene, and acetone were dried by shaking repeatedly with anhydrous $MgSO_4$, followed by distillation in a protected atmosphere. A middle cut was collected. The moisture content of the solvents was negligible, as indicated by their infrared spectra recorded at high gain. Due to the high noise level in the n.m.r. spectra of very dilute solutions, and also to the uncertainties involved in the extrapolation of data to infinite dilution, a considerable error is quoted for the chemical shift measurements listed in Table I.

[1]*Abstracted in part from the B.Sc. Research Report of N. R. Tipman, University of Alberta, 1962.*

RESULTS AND DISCUSSION

The variation of —OH chemical shift with concentration for solutions of several para-substituted phenols in carbon tetrachloride and in benzene is shown in Figs. 1 and 2.

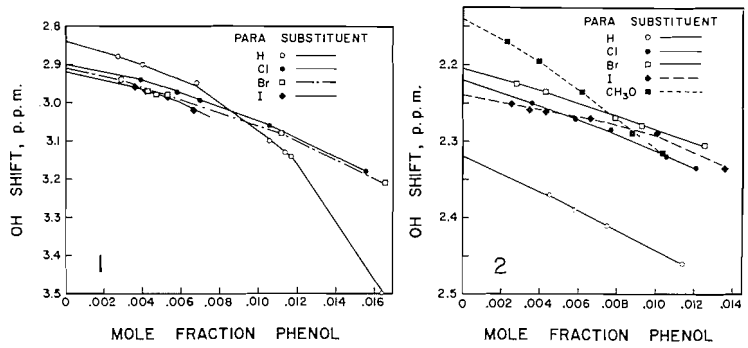

FIG. 1. Variation of —OH shift (in p.p.m. to low field from C_6H_{12} as internal reference) of para-substituted phenols with concentration in CCl_4.

FIG 2. Variation of —OH shift (in p.p.m. to low field from C_6H_{12} as internal reference) of para-substituted phenols with concentration in C_6H_6.

The —OH chemical shift at infinite dilution in a particular solvent appears to be almost independent of the nature of the ring substituent. The data are summarized in Table I.

The value of 2.84 p.p.m. for phenol in CCl_4 is in satisfactory agreement with the value of 2.8 p.p.m. reported by Huggins *et al.* (2), but their value of 3.3 p.p.m. for *p*-chlorophenol is in disagreement with the value of 2.90 p.p.m. in Table I. Their measurements on *p*-chlorophenol were not extended below 0.025 mole fraction, so their extrapolation is perhaps somewhat uncertain. Huggins *et al.* also reported the slopes at infinite dilution of the chemical shift vs. concentration curve. For phenol and *p*-chlorophenol, the limiting slopes differed by a factor of 2, which yielded 13 ± 7 and 9 ± 4, respectively, as the values of the dimerization equilibrium constant. In the present work (Fig. 1), it was found that the slopes were nearly the same. On the basis of infrared measurements, Maguire and West (15) reported recently that the dimerization equilibrium constants for phenol and *p*-chlorophenol were 7.22 and 6.24, respectively. These more accurate measurements substantiate the data reported in Table I and Figs. 1 and 2.

Due to the similarity of the extrapolated —OH shift values in a given solvent, a comparison of these data with Hammett or Taft substituent constants (16, 17) is unjustified. The shifts of the —OH signal to high field and low field observed in benzene and in acetone respectively, relative to that in carbon tetrachloride, are in the directions predicted by the well-known anisotropies of the benzene ring and the carbonyl group (18).

The n.m.r. spectra of the ring protons of para-substituted phenols in dilute acetone solution (approximately 3% by weight) consist, to a good approximation, of two superimposed AB spectra (19, 20). The intramolecular ring shifts and coupling constants of some para-substituted phenols are summarized in Table II. The ring shifts were compared with other data. No correlation was found with group electronegativity (21), suggesting that the ring shifts are due both to inductive and to resonance effects (20). The variation of ring shift with the Hammett substituent constant σ_p (16) is shown in Fig. 3. Although the points are widely scattered, a definite trend is apparent. No significant improvement in the plot was obtained with the modified constants proposed by Taft (17, 22).

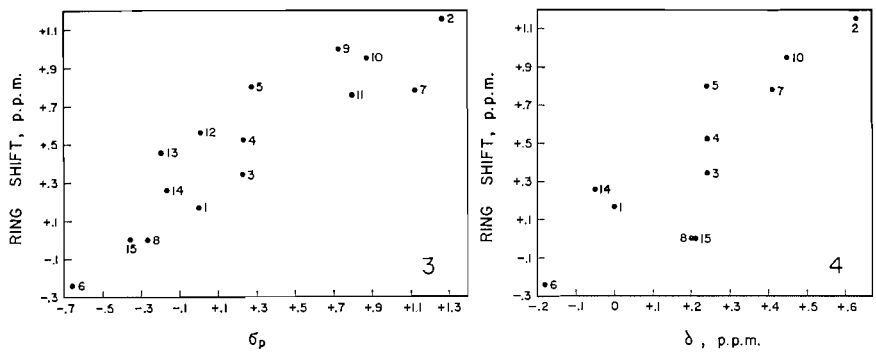

FIG. 3. Variation of internal ortho ring proton shift with Hammett substituent constant σ_p (16, 26). The numbering of points corresponds with that of Table II. The ring shift of p-$NH_2C_6H_4OH$ fits the correlation regardless of its sign.

FIG. 4. Comparison of observed ortho ring proton shift with the calculated contribution δ to this shift from the polarity of the para-substituent. The numbering of the points corresponds with that of Table II.

A theory proposed recently by Buckingham (13) indicates that the electric field E at a particular proton due to polar groups in other parts of the molecule can give rise to chemical shifts in the n.m.r. spectrum proportional to the first power of the electric field strength. The change $\Delta\sigma$ in the proton screening constant under these conditions is given by

$$[1] \qquad \Delta\sigma = -2\times10^{-12}E_z - 10^{-18}E^2,$$

where E_z is the component of E in the bond direction. Formulae were given by Buckingham for the calculation of E_z and E^2 at various positions in the ring and also for the differential ring shifts caused by the reaction field of the solvent. For phenol itself, a calculation such as that described above predicts a differential ring shift of 0.05 p.p.m., while the observed shift is 0.16 p.p.m. (Table II). In the case of p-nitrophenol, the calculated shift of 0.18 p.p.m. compares very poorly with the observed shift of 1.15 p.p.m.

Similarly, Buckingham (13) calculated that the ring shift between protons ortho and meta to the nitro group in nitrobenzene should be 0.29 p.p.m. in a mixture of equal volumes of cyclohexane and nitrobenzene, while the observed shift was actually 0.67 p.p.m. (23). Anomalies of this kind have been ascribed to a specific association between solute and solvent (13). However, if in the series p-XC_6H_4OH, the solute–solvent interaction and the reaction field from the polarized solvent remain approximately constant, then there should be a linear correlation between the observed ring shift and the calculated contribution to this shift from the polarity of X. The results plotted in Fig. 4 suggest that this is qualitatively true. Dipole moment data were taken from references 24 and 25.

ACKNOWLEDGMENTS

This work was supported in part by the National Research Council of Canada, whose financial assistance is greatly appreciated. The authors wish to express their thanks to Mr. R. Swindlehurst and Miss G. B. Stayura, who measured many of the spectra, and to Dr. R. J. Crawford for helpful discussion.

N-MUSTARD DERIVATIVES OF ESTROGENS

THOMAS NOGRADY,[1] KITTY M. VAGI, AND VINCENT W. ADAMKIEWICZ
Department of Physiology, University of Montreal, Montreal, Que.

Received March 14, 1962

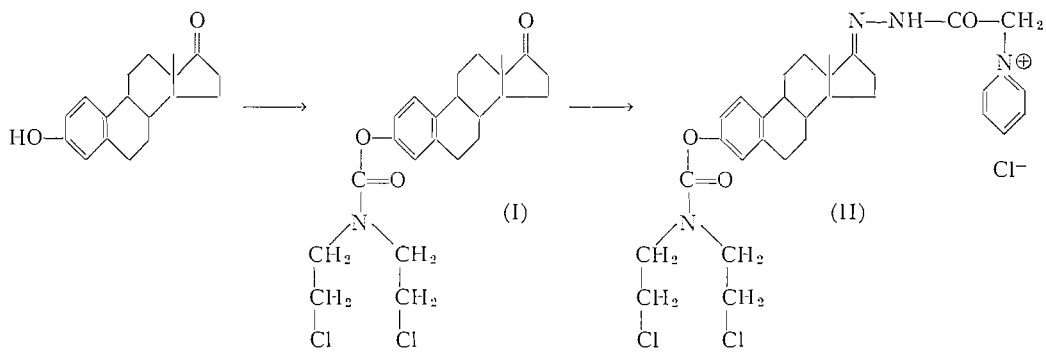
ABSTRACT

N-Mustard urethanes of estrone and stilbestrol, as well as an N-mustard-phosphoramidate of stilbestrol, were synthesized. Only the estrone derivative proved to be slightly active against an adenocarcinoma.

Efforts to influence the transport characteristics of nitrogen mustards resulted in the synthesis of a large number of compounds (1), several among them bearing steroid carriers (2–6). Most of the steroids used were, however, physiologically inactive in themselves, e.g. cholestene, ergostatriene, and stigmastadiene. 3β-[Bis-(β-chloroethyl)-aminoethyl]-Δ^5-cholestene (4) was reported to be inactive; 3-cholesteryl-N-[4′-N-bis-(β-chloroethyl)-aminophenyl]-carbamate (5) and 3-cholesteryl-[4′-N-bis-(β-chloroethyl)-aminophenyl]-sulphonate (6) were found to be nontoxic, but possessed a slight activity only. Steroid hormones were used as carriers by Burstein and Ringold (7) as well as by Rao and Price (8).

We prepared a few N-mustard derivatives of estrone and diethylstilbestrol, hoping to be able to influence estrogen-dependent tumors more selectively.

3-Esteryl-bis-(β-chloroethyl)-carbamate (I) was obtained from estrone and chloroformyl-bis-(β-chloroethyl) amine:

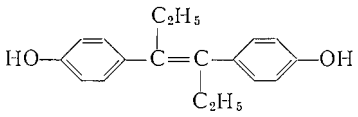


Due to its water insolubility, it was difficult to administer compound I to experimental animals. Therefore a water-soluble but amorphous hydrazone (II) with Girard's P reagent was also prepared.

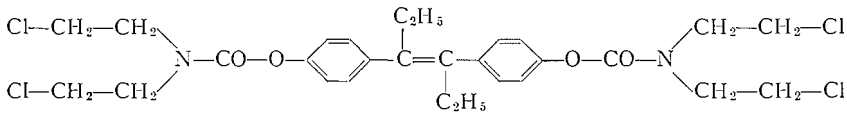
The same urethane-type mustard (IV) (cf. ref. 9) was also synthesized from diethylstilbestrol, in the usual way.

Stilbestrol-phosphate is reported (10) to have a beneficial effect on prostate tumors, because the high phosphatase activity of prostatic tissue liberates stilbestrol selectively from the ester. It seemed, therefore, interesting to see a N-mustard-phosphate bound to stilbestrol. It was expected that a double selectivity should result: first, the selective

[1]*Present address: Department of Chemistry, Loyola College, Montreal 28, Que.*



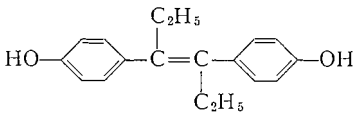
(III)



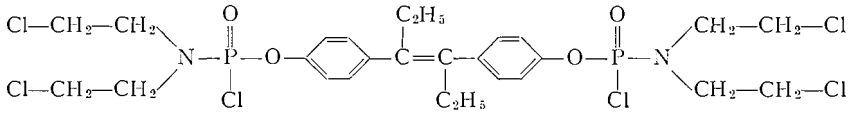
(IV)

accumulation of the compound in prostatic or mammary tissue, due to the carrier, and secondly, the preferential splitting of the phosphate bond at the sites of high phosphatase activity. Moreover, the "hidden" N-mustard group should be nontoxic at sites of low phosphatase activity, thus decreasing the general toxicity.

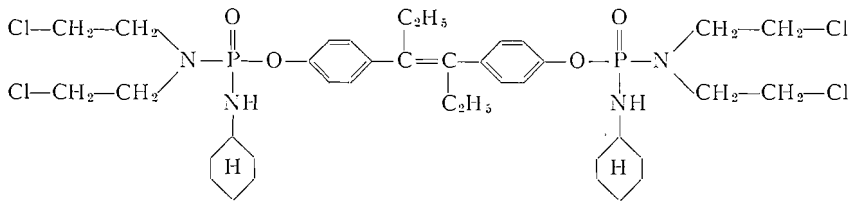
To test this hypothesis, the diethylstilbesteryl-phosphoramidic chloride (V) was prepared, according to the method of Friedman and Seligman (11). From this, we wished to prepare either the free phosphoric acid or an amide. After lengthy experimentation, it



(III)



(V)



(VI)

was found that only the cyclohexyl amide (VI) could be obtained as a crystalline solid. The free acid and amides with aniline, piperidine, or morpholine were oily.

Pharmacological Results

Screened on mammary adenocarcinoma BN/10232, the estrone urethane (I) showed a 30% inhibition at a dosage level of 5 mg per day per mouse for 14 days, with a 15% mortality. Interestingly, the analogous stilbestrol derivative (IV) proved inactive at the

same dosage level, with a 5% mortality. Tested under similar circumstances, the stilbestrol-phosphoramidate (VI) was inactive too.

EXPERIMENTAL*

3-Esteryl-bis-(β-chloroethyl)-carbamate (I)

Ten grams of estrone (USP grade) and 7.8 g chloroformyl-bis-(β-chloroethyl)amine in 37 ml pyridine solution stood for 4 days at room temperature. When the solution was poured into ice water a solid crystallized out. The precipitate was filtered off, washed with water and methanol, and recrystallized from 250 ml isopropanol, yielding 10.02 g (52.4%) of colorless crystals, m.p. 143–145°. $[\alpha]_D^{20}+109.5°$ (*c* 2, chloroform). Anal. Calc. for $C_{23}H_{29}Cl_2NO_3$: C, 63.01; H, 6.67; N, 3.20. Found: C, 63.2; H, 6.9; N, 3.3.

Hydrazone with Girard's P Reagent (II)

Compound I (0.44 g) and Girard's P reagent (0.19 g) were refluxed in a mixture of 10 ml ethanol and 1 ml acetic acid, for 1 hour. On evaporation, the solution left a colorless water-soluble syrup which solidified to an amorphous precipitate when it was triturated with diisopropyl ether. In a few months it turned brown. Anal. Calc. for $C_{30}H_{37}Cl_3N_4O_3$: Cl, 17.5. Found: Cl, 17.1.

Diethylstilbesteryl bis-[di-(β-chloroethyl)]-carbamate (IV)

The solution of 3.14 g diethylstilbestrol (III) and 4.28 g (3.12 ml) of chloroformyl-bis-(β-chloroethyl)-amine in 10 ml dry pyridine stood at room temperature for 4 days. The solution was decanted from the precipitated pyridine hydrochloride, evaporated under reduced pressure, and the semisolid mass freed from the last traces of pyridine by azeotropic distillation with toluene. Recrystallized from methanol, it yielded 2.94 g (48.8%) colorless crystals, m.p. 139–140°. Anal. Calc. for $C_{28}H_{34}Cl_4N_2O_4$: C, 55.65; H, 5.67; N, 4.67. Found: C, 55.5; H, 5.9; N, 4.7.

Diethylstilbesteryl bis-[di-(β-chloroethyl)-phosphoramidic chloride] (V)

Diethylstilbestrol (1.57 g), bis-(β-chloroethyl)-phosphoramidic dichloride (2.60 g), and triethylamine (1.4 ml) were refluxed and stirred in 25 ml dry benzene for 1½ hours. After the reaction mixture was chilled, the separated triethylamine hydrochloride was filtered off (95.6% of the theoretical amount), and the benzene solution evaporated. The resulting colorless syrup (3.07 g, 86.1%) was used for further experiments. Anal. Calc. for $C_{26}H_{34}Cl_6N_2O_4P_2$: N, 3.93. Found: N, 3.78.

Diethylstilbesteryl bis-[N-di-(β-chloroethyl)-N'-cyclohexyl-phosphorodiamidate] (VI)

The phosphoramidic chloride (V) prepared from 7.6 g diethylstilbestrol was refluxed and stirred with 11.0 ml cyclohexylamine in 150 ml dry toluene for 4 hours, until neutral. The separated cyclohexylamine hydrochloride was filtered off from the hot reaction mixture. On cooling, the solution deposited 9.85 g of colorless crystals, which was recrystallized from 135 ml isopropanol, yielding 7.87 g (38.6%) of compound VI, melting at 206–208°. Anal. Calc. for $C_{38}H_{58}Cl_4N_4O_4P_2$: C, 54.16; H, 6.94; Cl, 16.38; N, 6.65. Found: C, 54.3; H, 7.0; Cl, 16.2; N, 6.7.

ACKNOWLEDGMENTS

This investigation was supported by the National Cancer Institute of Canada, the U.S. Department of Health, Education and Welfare, National Institutes of Health (Grant No. 2260), and the National Research Council of Canada (Grant No. MA 640).

We wish to thank Dr. R. Gaudry, research director of Ayerst, McKenna & Harrison Ltd. (Montreal) for his generous gifts of estrone and stilbestrol. The carcinostatic screening was done by Dr. R. Herne of Ayerst, McKenna & Harrison Ltd., and details will be published elsewhere. We thank Dr. Herne for permission to publish his findings.

KINETIC STUDY OF THE ISOMERIZATION OF *n*-BUTENES ON CHROMIA–ALUMINA*

Y. AMENOMIYA AND R. J. CVETANOVIĆ
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received July 17, 1962

ABSTRACT

Mutual interconversions of the three *n*-butenes on a chromia–alumina catalyst have been studied in a temperature range between 210 and 260° C and in a pressure range from about 10 to about 100 mm. Dependence of initial rates on the initial pressures of the reactants was determined experimentally. The initial rates of isomerization could be, in each case, expressed empirically by a rate equation conforming to the Langmuir–Hinshelwood formula. It was possible to explain the experimental results by assuming the existence of three different adsorbed species for the three *n*-butene isomers and their surface interconversions as the rate-determining step.

INTRODUCTION

Catalytic isomerization of butenes has been extensively investigated in attempts to contribute to the understanding of the mechanism of the catalytic isomerization of olefins. It is well known that the presence of hydrogen is necessary for the olefin isomerization on some metallic catalysts (1–6), while the reaction occurs in the absence of hydrogen on metal oxide, alkali, and acid catalysts (6–20). Several kinetic studies have been carried out on metallic catalysts and the mechanism of olefin isomerization has been discussed in conjunction with the mechanism of hydrogenation (2–5). On the other hand, relatively few kinetic studies of olefin isomerizations on oxide catalysts are available (12, 13, 18, 21).

Carbonium ions and carbanions have been postulated by many investigators as intermediates in the catalytic reactions of olefins and have been also recently invoked to explain the stereoselectivity in the catalytic isomerization of butenes (6, 15). It is felt, however, that further kinetic studies of these reactions, on catalytic materials of various types, are necessary, and the present work has, therefore, been carried out with the object of obtaining kinetic information on butene isomerization on a chromia–alumina catalyst. This catalyst is used commercially as a dehydro-isomerization catalyst.

EXPERIMENTAL

Catalyst

Chromia–alumina catalyst was prepared by mixing and grinding aluminum hydroxide and chromium hydroxide, both of which were spearately precipitated by adding ammonium hydroxide to the solutions of the respective nitrates. The composition of the catalyst was about 20% Cr_2O_3 and 80% Al_2O_3 by weight, as calculated from the loss on ignition of the two hydroxides. The catalyst was heated at 500° C for 1 hour, and crushed into pieces of convenient size. The same catalyst sample, weighing 0.0038 g, was used in all kinetic measurements. The surface area of the catalyst, determined by the B.E.T. method with nitrogen, was 100.5 m^2/g.

Research grade butenes of Phillips Petroleum Co. were used as reactants. They were twice condensed in liquid nitrogen traps followed by evacuation, and were kept in a 3-l. reservoir. The impurities in 1-butene and *cis*-butene were negligibly small, but *trans*-butene contained a small amount of *cis*-butene, which was subtracted from the amount of *cis*-butene produced.

Apparatus

The apparatus used consisted of a plunger-type glass circulating pump and a spiral-type reactor, as shown in Fig. 1. The reactants in the reaction system were circulated to prevent the reaction from becoming

**Issued as N.R.C. No. 7015.*

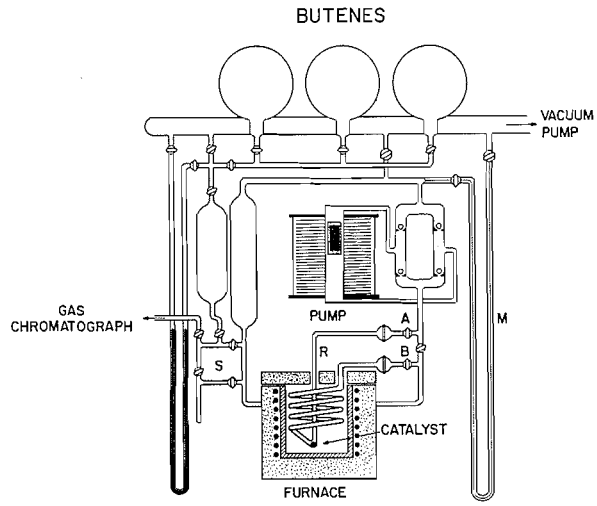

FIG. 1. Apparatus.

controlled by the diffusion of the reactant. Prior to the kinetic measurements lack of diffusion control was verified; it was observed that reaction rates were proportional to the amount of the catalyst up to 0.03 g at the pumping speed used subsequently in the kinetic measurements with 0.0038 g of the catalyst.

The reactor was provided with a spiral preheater made of quartz tubing about 160 cm in length, which assured only a very small drop in the catalyst temperature when the reactants were circulated through the reactor. This was checked by placing a thermocouple in place of the catalyst under conditions similar to those used in kinetic measurements. The reactor was placed in a stainless steel block furnace, the temperature of which was regulated to $\pm 0.5°$ C. The total volume of the reaction system was about 560 cc, of which about 90 cc was kept at the reaction temperature. A temperature range between 210 and 260° C was employed and the pressure of butenes was varied from 10 to 100 mm. The circulation pump was found to be sufficiently effective to homogenize the gases in the reaction system within 30 seconds.

Procedure

Before use the catalyst was heated up to 700° C and treated with 680 mm of circulating air at the same temperature for 2 hours, then evacuated for 1 hour at 700° C at a pressure below 10^{-4} mm and cooled to the reaction temperature *in vacuo*. The same treatment was repeated before each run in order to maintain the catalyst activity constant. Occasional experiments were carried out under the same conditions to check the constancy of catalyst activity (expts. 175, 176, 196, and 259). They showed that the activity of the catalyst remained constant in the course of 127 runs performed.

The reaction was started by opening the taps A and B (Fig. 1) after the circulating pump had been turned on. Gaseous samples were withdrawn into the small samplers S by expansion at intervals of several minutes (usually every 2–3 minutes), and were analyzed by gas chromatography. The change in total pressure resulting from the withdrawal of a sample was within 1%, and this effect on the rate of reaction in a run was neglected. Unless samples were taken, no pressure change was observed on the manometer M during the reaction (at least up to 30 minutes), and no hydrocarbons lower than C_4 were observed chromatographically. Therefore neither polymerization nor cracking appeared to take place to any appreciable extent.

Analysis

The products of the reactions of 1-butene and *cis*-butene were analyzed gas chromatographically on a 11-m column of dimethyl sulpholane on activated alumina, and those of *trans*-butene were analyzed on a 10-m column of propylene carbonate on firebrick. Correction factors for peak-area responses were obtained from standard samples.

RESULTS AND DISCUSSIONS

A trace of 1,3-butadiene was observed at reaction temperatures higher than 250° C, but the amount was so small (less than 0.1%) that the formation of this compound was neglected. No detectable amounts of *n*-butane, isobutane, or isobutene were observed, indicating that no hydrogenation or skeletal isomerization had occurred.

The results obtained are summarized in Tables I, II, and III. The pressure changes of each of the three butene isomers in the course of a run, obtained from gas chromato-

extrapolating to zero conversion. These extrapolations are only approximate; as an example, the ratios of *trans*- to *cis*-butene-2 formed in the isomerization of 1-butene are

shown in Fig. 3, which contains all the experimental points taken independently of the pressure of butene-1 used. The good linearity in the figure of the plots of the product

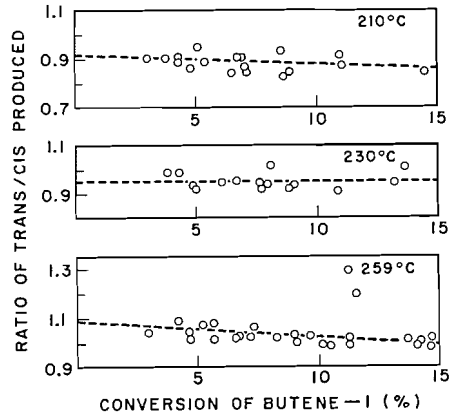

FIG. 3. Ratio of *trans*-butene-2/*cis*-butene-2 produced from butene-1 as a function of conversion.

ratio against conversion suggests that the reactions forming the two products are parallel rather than being consecutive.

In Fig. 4 the initial rates are plotted against the initial pressure of the reactant. From the shape of these curves the reaction orders of the reactant-consuming and the product-forming reactions seem to be between 1 and 0.

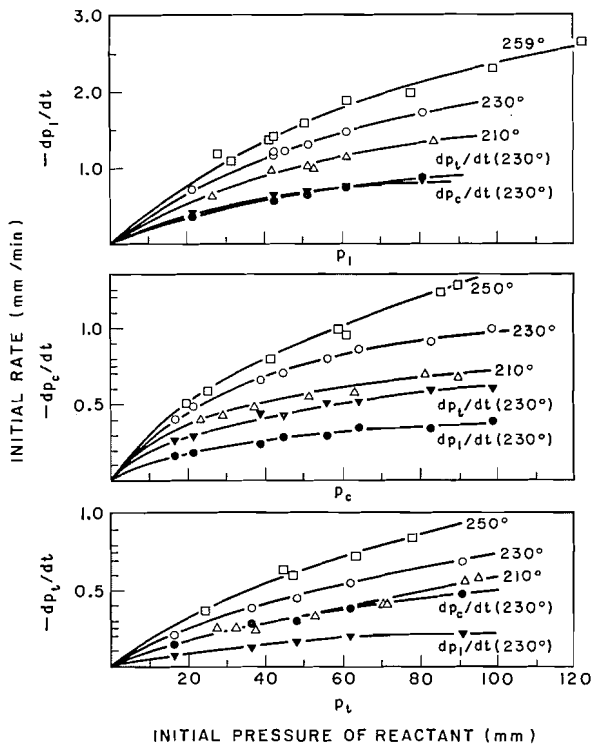

FIG. 4. Dependence of the initial rates on the initial pressure of the reactants. (Catalyst weight 0.0038 g. The rates of product formation at 230° C only are plotted.)

The mechanism shown in Fig. 5 is based on the assumption that there are three different adsorbed species for the three *n*-butene isomers. If it is assumed that the interconversions

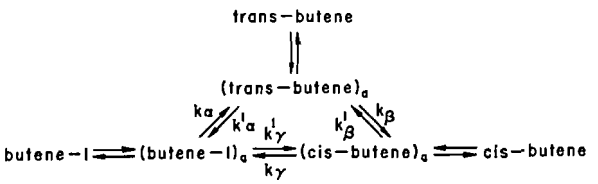

FIG. 5. The proposed mechanism of isomerization. (Subscript "a" denotes an adsorbed state.)

of the three *n*-butenes on the chromia–alumina catalyst proceed by this mechanism and that the rate-determining steps of these reactions are the respective surface reactions of the adsorbed molecules, the rates of the isomerization reactions are given by the equations

$$[1] \qquad -dp_1/dt = (dp_t/dt)+(dp_c/dt) = k_\alpha K_1 p_1/(1+K_1 p_1)+k_\gamma' K_1 p_1/(1+K_1 p_1) \quad \text{(from 1-butene)},$$

$$[2] \qquad -dp_c/dt = (dp_1/dt)+(dp_t/dt) = k_\gamma K_c p_c(1+K_c p_c)+k_\beta' K_c p_c/(1+K_c p_c) \quad \text{(from } cis\text{-butene)},$$

$$[3] \qquad -dp_t/dt = (dp_c/dt)+(dp_1/dt) = k_\beta K_t p_t/(1+K_t p_t)+k_\alpha' K_t p_t/(1+K_t p_t) \quad \text{(from } trans\text{-butene)},$$

where p stands for the partial pressures, K for the equilibrium constants of adsorption (simplified in the following to "adsorption constants") of the respective butenes, and k and k' for the rate constants of the respective surface reactions, as illustrated in Fig. 5. It is also assumed that the adsorption of the products is negligible because of their very small partial pressures in the initial stages of the reaction. In accord with the above equations, plots of the reciprocal initial rates against the reciprocal reactant pressure should be linear, and their intercepts and slopes should provide the various rate and adsorption constants. Such plots have been obtained in Fig. 6 by replotting the curves of Fig. 4. It is evident that the observed initial rates agree well with the above equations.

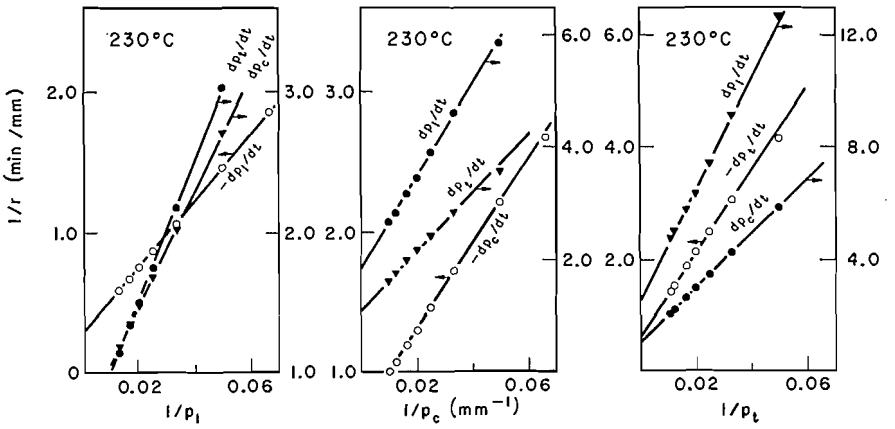

FIG. 6. Plots of the reciprocal initial rates vs. reciprocal pressures.

In the figures the rates of product formation are plotted as well as the rates of reactant consumption (the overall reaction). From the latter the adsorption constants can be obtained separately and should be identical with the values obtained from the rates of product formation.

The values obtained are shown in Table IV. It is seen in Table IV(i) that there is a fair agreement between the adsorption constants for butene-1 (K_1). The Arrhenius plot

(iii) Isomerization of *trans*-butene

Temp. (°C)	K_t obtained from the plot of: dp_1/dt	dp_c/dt	$-dp_t/dt$	K_t, mean	k_α'	k_β
250	0.0098	0.0082	0.0096	0.0092	0.571	1.562
230	0.0124	0.0098	0.0083	0.0102	0.408	1.020
210	0.0020	0.0025	0.0042		1.15	2.13

*The units are: k, mm/min; K, 1/mm; heat of adsorption and activation energy, kcal/mole.
†These values were obtained from the plots in Figs. 7 and 8.

of the mean value of K_1 is shown in Fig. 7, from which the heat of adsorption of butene-1 was found to be 3.6 kcal/mole. The Arrhenius plots of the rate constants k_α and k_γ' of the two surface reactions are given in Fig. 8. The activation energies are, respectively, 7.9 and 5.0 kcal/mole, as listed in the table.

The values of K_c calculated from the dp_1/dt plot are 0.0188, 0.0288, and 0.0296 at 210, 230, and 250° C, respectively, i.e., they show an increase rather than a decrease with temperature. However, the equilibrium composition of butene-1 in *n*-butenes is only about 10% at these temperatures and it might therefore be necessary in this case to consider the reverse reaction (butene-1 → *cis*-butene) as well. The values K_c and k_β' calculated from the dp_t/dt plot are shown in Table IV(ii), and their Arrhenius plots in Figs. 7 and 8, from which the heat of adsorption and the activation energy were found to be 10.4 and 12.6 kcal/mole respectively.

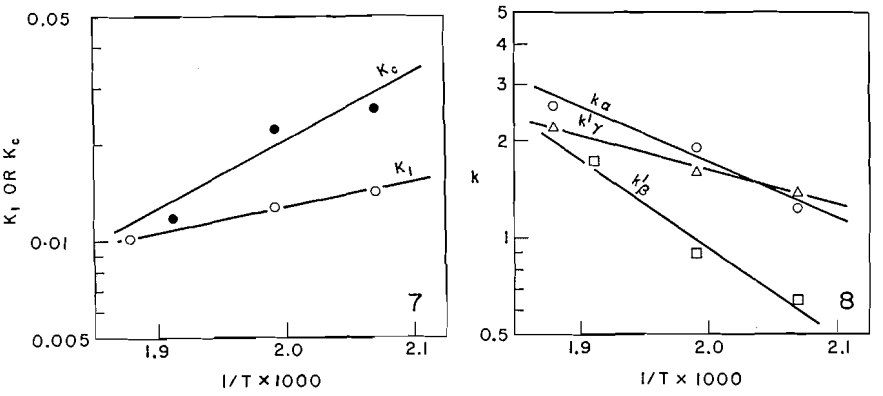

FIG. 7. Arrhenius plots of adsorption constants.
FIG. 8. Arrhenius plots of the rate constants.

It is seen in Table IV(iii) that the three K_t values obtained agree reasonably well with each other at 250 and 230° C, but at 210° C K_t, k_α', and k_β show abnormal values. The following discussion will be first confined to the values of constants at 250 and 230° C, ignoring for the moment the abnormality at 210° C.

When butene-1, *trans*-butene-2, and *cis*-butene-2 are equilibrated in the presence of the catalyst, the forward rates of surface reactions must be equal to their respective reverse reactions, that is,

$$k_\alpha K_1 p_1/(1+K_1p_1+K_tp_t+K_cp_c) = k_\alpha' K_t p_t/(1+K_1p_1+K_tp_t+K_cp_c),$$
$$k_\beta K_t p_t/(1+K_1p_1+K_tp_t+K_cp_c) = k_\beta' K_c p_c/(1+K_1p_1+K_tp_t+K_cp_c),$$
$$k_\gamma K_c p_c/(1+K_1p_1+K_tp_t+K_cp_c) = k_\gamma' K_1 p_1/(1+K_1p_1+K_tp_t+K_cp_c),$$

and therefore

[4] $$k_\alpha K_1 = k_\alpha' K_t (p_t/p_1)_e = k_\alpha' K_t/K_\alpha,$$

[5] $$k_\beta K_t = k_\beta' K_c (p_c/p_t)_e = k_\beta' K_c/K_\beta,$$

[6] $$k_\gamma K_c = k_\gamma' K_1 (p_1/p_c)_e = k_\gamma' K_1/K_\gamma,$$

where $(p_t/p_1)_e$, etc. are the equilibrium ratios of each pair of two isomers and are denoted by K_α, etc. These values are listed in Table V. In the above equations, values of $k_\alpha K_1$

and $k_\beta K_t$ can be calculated from Tables IV(i) and IV(iii), respectively, and can be compared with $k_\alpha' K_t/K_\alpha$ and $k_\beta' K_c/K_\beta$, which are calculated from the data in Tables IV(iii), IV(ii), and V. The results obtained are shown in Table VI. In agreement with

equations [4] and [5], excellent agreement is seen between $k_\alpha K_1$ and $k_\alpha' K_t/K_\alpha$ and between $k_\beta K_t$ and $k_\beta' K_c/K_\beta$, all of which were obtained from independent reactions. This fact, as well as the linearity of plots in Fig. 6, indicates that the mechanism and the rate-determining steps assumed are consistent with the present results.

The abnormal values of K_t, k_α', and k_β at 210° cannot be explained in the same manner. They may have been caused partly by increased analytical uncertainties, since *trans*-butene is the predominant isomer under these conditions. It is also possible that at the lower temperature a change in the type of the rate-determining step might begin to occur.

Other mechanisms and rate-determining steps also considered but found to be inconsistent with the experimental results were: (1) only one adsorbed species common to the three isomers; (2) two different adsorbed species, one of which corresponds to butene-1, the other common to the two 2-butenes; (3) desorption of the products as the alternative rate-determining step in the mechanism of Fig. 5.

The formal kinetic treatment discussed here does not provide information on the nature of the three adsorbed species and these could be adsorbed organic ions as is frequently postulated. Equally well they could be physically adsorbed butene molecules, in which case the rate-determining step (k_α, k_β, k_γ, . . . , in Fig. 5) is their interaction with the active catalytic sites. Brouwer (21) has recently shown that the 1/*trans* ratio formed from *cis*-butene on γ-alumina varies greatly as the catalyst is poisoned with water or other substances. He has suggested that the catalytic surface has to meet different requirements for the double-bond shift and cis–trans isomerization. The double-bond shift is assumed to occur by the concerted "*hydrogen switch*" mechanism of Turkevich and Smith (11), while cis–trans isomerization proceeds by carbonium ion mechanism. Foster and Cvetanović (6, 20) had similarly considered dual function of the catalyst surface in the isomerization of *n*-butenes, with cis–trans isomerization involving predominantly the carbonium ion or the "associative" radical mechanism, and double-bond migration predominantly the carbanion, the "dissociative" radical, or the hydrogen switch mechanism, depending on the type of catalyst. All these processes could involve a slow interaction of a physically adsorbed olefin molecule with the active sites of the catalyst. Stereoselectivity in the catalytic isomerization of *n*-butenes is also found in the present work, as shown, for example, by initial formation from butene-1 of the thermodynamically less stable *cis*-butene in greater amounts than *trans*-butene-2. This is evident

from the data in Tables I, II, and III. In the present instance the stereoselectivity is associated with the magnitudes of the rate constants of the surface reactions. These are likely to depend on the acid properties of the surface of the catalyst, although no generalizations appear possible on the basis of the present results without additional experimental information.

ON THE EVALUATION OF CERTAIN TWO- AND THREE-CENTER MOLECULAR INTEGRALS OCCURRING IN ELECTROSTATIC CALCULATIONS

R. F. W. BADER
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received June 29, 1962

ABSTRACT

A general method is developed for the evaluation of the three-center integrals which occur in the application of the Hellmann–Feynman theorem to the study of molecular binding. The method employs Gegenbauer polynomials for the series expansion of the radial dependence of the electric field. It is also shown that the same expansion greatly simplifies the evaluation of the two-center electrostatic penetration integrals. General formulae are presented for these latter integrals for all nonvanishing combinations of *s*, *p*, and *d* atomic orbitals for all principal quantum numbers.

I. INTRODUCTION

The Hellmann–Feynman theorem enables one to calculate the forces acting on a nucleus in a molecule if the electron density function is known. The integrals which occur in such calculations fall into three general classes when the electron density is expressed in terms of atomic orbitals. All three classes of integrals are of the general form

$$I = \int \mathscr{D}_{\alpha x}\phi_i\phi_j d\tau,$$

where $\mathscr{D}_{\alpha x}$ is the x-component of the electric field produced by a unit charge at nucleus α and ϕ_i and ϕ_j are atomic orbitals. It is the positioning of the two atomic orbitals with respect to atom α which distinguishes the three classes of integrals.

(*a*) When ϕ_i and ϕ_j are both situated on the same atom but not on atom α, the integral (I) represents the force exerted on nucleus α by the charge density on some other atom β. These are labelled penetration integrals. The penetration integrals may be evaluated by the method usually employed for two-center molecular integrals, i.e. expressing them in terms of spheroidal coordinates. However, in these cases a second coordinate transformation is necessary, to an orthogonal set obtained by a rotation of the λ and μ axes of the spheroidal set. The method is long and cumbersome and takes no advantage of the inherent symmetry of the integrals. We report here a new method which allows for their evaluation in terms of a few simple integrations about one center only. This method greatly reduces both the labor involved and the possibility of committing errors.

(*b*) When ϕ_i and ϕ_j are situated on different atoms neither of which is atom α, the result is a three-center integral. Hurley (1) has pointed out that this type of three-center one-electron integral is the most complicated type that can arise in the application of the Hellmann–Feynman theorem to polyatomic molecules. We describe in this paper a general method for the evaluation of such three-center integrals.

(*c*) When ϕ_i is situated on atom α and ϕ_j on some other atom, the integral (I) represents the force exerted on nucleus α by the charge density arising from the overlap of $\phi_{i(\alpha)}\phi_{j(\beta)}$. These integrals may be evaluated by expressing them in terms of spheroidal coordinates. The methods described in this paper offer no advantages in the evaluation of this third

type of integral. Coulson (2) and Bader and Jones (3) have given analytical expression for many of these integrals.

The basis of the present method is in the use of the Gegenbauer polynomials for the expansion of the radial dependence of the electric field about another atomic center. In both the two- and three-center integrals, $\mathscr{D}_{\alpha x}$ and $\mathscr{D}_{\alpha y}$ are expanded about center β (see Fig. 1):

$$[1] \qquad \mathscr{D}_{\alpha x} = \frac{\cos\theta_\alpha}{r_\alpha^2} = \frac{1}{r_\alpha^3}(\rho - r\cos\theta) = (\rho - r\cos\theta)\sum_{k=0}^{\infty}\frac{1}{\rho^3}\left(\frac{r}{\rho}\right)^k C_k^{3/2}(\cos\theta)$$

$$[2] \qquad \mathscr{D}_{\alpha y} = \frac{\sin\theta_\alpha\cos\phi}{r_\alpha^2} = \frac{1}{r_\alpha^3}(r\sin\theta\cos\phi) = (r\sin\theta\cos\phi)\sum_{k=0}^{\infty}\frac{1}{\rho^3}\left(\frac{r}{\rho}\right)^k C_k^{3/2}(\cos\theta).$$

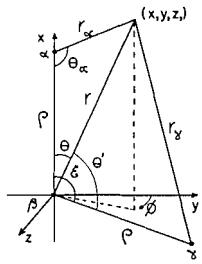

FIG. 1. The coordinate system for the two- and three-center integrals. The bond distance is designated by ρ and the bond angle by ξ.

(Both [1] and [2] are written for $\rho > r$; ρ and r are interchanged in the expressions when $r > \rho$.) The $C_k^{\nu}(\cos\theta)$ are Gegenbauer polynomials of the first kind. These particular polynomials permit the expansion of any inverse power of the distance. The Neumann expansion of r^{-1} in terms of Legendre polynomials is a special case of the more general expansion of $r^{-2\nu}$ in terms of the Gegenbauer polynomials, as the $C_k^{\nu}(\cos\theta)$ reduce to the $P_k(\cos\theta)$ when $\nu = 1/2$. The properties of the C_k^{ν} are well described by Whittaker and Watson (4), Magnus and Oberhettinger (5), and Prigogine (6). The $C_k^{\nu}(\cos\theta)$ may be related to the associated Legendre polynomials $P_k^m(\cos\theta)$ for any value of ν (5). Specifically, the relationship for $\nu = 3/2$ is

$$C_k^{3/2}(\cos\theta) = \frac{1}{\sin\theta}P_{k+1}^1(\cos\theta).$$

II. EVALUATION OF THE PENETRATION INTEGRALS

We shall consider first those integrals expressing the force directed along the bond axis:

$$P_{\parallel} = \int \mathscr{D}_{\alpha x}\phi_{i(\beta)}\phi_{j(\beta)}d\tau.$$

The ϕ_i are Slater atomic orbitals and may be expressed as

$$\phi_j(n,l,m) = N_n \exp(-ar)r^{n-1}\Theta_l^m(\cos\theta)\Phi_m(\phi),$$

where

$$\Theta_l^m(\cos\theta) = [\{(2l+1)/2\}\{(l-m)!/(l+m)!\}]^{1/2}P_l^m(\cos\theta)$$

are the normalized associated Legendre polynomials, and

$$\Phi_0(\phi) = (2\pi)^{-1/2};\ \Phi_m(\phi) = (\pi)^{-1/2}\begin{Bmatrix}\sin m\phi\\ \cos m\phi\end{Bmatrix}$$

$$N_n = (2a)^{n+1/2}/[(2n)!]^{1/2}.$$

When equation [1] is substituted for $\mathscr{D}_{ax}$ in $P_\parallel$ ($P_\parallel{}^0 = P_\parallel/N_nN_{n'}$) the result is

$$[3]\qquad P_\parallel{}^0 = \sum_{k=0}^{\infty}[\{\rho^{-(k+2)}A_{(u+k)}(\kappa,\rho)+\rho^{(k+1)}B_{(u-k-3)}(\kappa,\rho)\}\int\Theta_l{}^m\Theta_{l'}{}^{m'}P_{k+1}^1\,d\theta$$
$$-\{\rho^{-(k+3)}A_{(u+k+1)}(\kappa,\rho)+\rho^kB_{(u-k-2)}(\kappa,\rho)\}\int\Theta_l{}^m\Theta_{l'}{}^{m'}\cos\theta\,P_{k+1}^1\,d\theta]\int\Phi_m\Phi_{m'}d\phi,$$

where $u = n+n'$ (when $n = n'$, $u = 2n$); $\kappa = a+b$, the sum of the orbital exponents of ϕ_i and ϕ_j; and the $A_z(\kappa,\rho)$ and $B_z(\kappa,\rho)$ are the incomplete gamma functions defined by

$$A_z(\kappa,\rho) = \int_0^\rho e^{-\kappa r}r^z dr;\quad B_z(\kappa,\rho) = \int_\rho^\infty e^{-\kappa r}r^z dr.$$

Equation [3] terminates after the first few terms in any particular case due to the orthogonality and recurrence relationships of the Legendre polynomials. In Table I we have listed the resulting general formulae for all of the nonvanishing penetration integrals involving s, p, and d atomic orbitals of any principal quantum number.

$nd\delta$	$n'd\delta$	$[\rho^{-2}A_{(u)}-(6/7)\rho^{-4}A_{(u+2)}+(5/21)\rho^{-6}A_{(u+4)}+(4/7)\rho B_{(u-3)}-(4/21)\rho^3B_{(u-5)}]$
$ns\sigma$	$n'p\sigma$	$(1/\sqrt{3})[2\rho^{-3}A_{(u+1)}-B_{(u-2)}]$
$ns\sigma$	$n'd\sigma$	$(1/\sqrt{5})[3\rho^{-1}A_{(u+2)}-2\rho B_{(u-3)}]$
$np\sigma$	$n'd\sigma$	$(1/\sqrt{15})[4\rho^{-3}A_{(u+1)}+(36/7)\rho^{-5}A_{(u+3)}-2B_{(u-2)}-(27/7)\rho^2B_{(u-4)}]$
$np\pi$	$n'd\pi$	$(1/\sqrt{5})[2\rho^{-3}A_{(u+1)}-(12/7)\rho^{-5}A_{(u+3)}-B_{(u-2)}+(9/7)\rho^2B_{(u-4)}]$

*Formulae for some particular cases ($n = n' = 1, 2$; $l = l' = 0, 1$ and $n = n' = 2$; $l = 0$, $l' = 1$) have been given previously (3).

The manner in which equation [3] reduces in a particular case will be illustrated for $n \neq n'$, $l = l' = 1$, and $m = m' = 0$. Consider first the two integrations over θ in equation [3]. When $l = l' = 1$ the first integral is zero unless k is an even integer and the second is zero unless k is odd. Thus equation [3] may be written

$$P_\parallel{}^0 = \frac{3}{2}\sum_{k=0,2,\ldots}^{\infty}[\{\rho^{-(k+2)}A_{(u+k)}+\rho^{(k+1)}B_{(u-k-3)}\}\int\cos^2\theta\,P_{k+1}^1\,d\theta$$
$$-\{\rho^{-(k+4)}\,A_{(u+k+2)}+\rho^{(k+1)}B_{(u-k-3)}\}\int\cos^3\theta\,P_{k+2}^1\,d\theta].$$

From the definition of $P_l{}^m(\cos\theta)$ in terms of $P_l(\cos\theta)$ and the recurrence relationship

$$zP_{k+1}'(z) = P_k{}'(z)+(k+1)P_{k+1}(z),$$

where the prime denotes (d/dz), one can show that

$$[4] \qquad \int \cos^2\theta\, P^1_{k+1}\, d\theta = \int \cos^3\theta\, P^1_{k+2}\, d\theta - (k+2)\int \sin\theta \cos^2\theta\, P_{k+2} d\theta.$$

The last integral in equation [4] is different from zero only for $k = 0$, when it has the value of 8/15. This result terminates the expansion after $k = 2$, and for $k = 2$ only $A_{(u+2)}$ remains. All succeeding terms are cancelled out, the B's within the same k term and the A's by the term which follows. The result is the expression listed in Table I for $np\sigma$, $n'p\sigma$.

We shall consider next the penetration integrals determining the force perpendicular to the bond axis:

$$P_\perp = \int \mathscr{D}_{\alpha\gamma}\phi_{i(\beta)}\phi_{j(\beta)}d\tau.$$

These integrals arise in the calculation of the forces operative in polyatomic molecules and play an important role in determining the equilibrium bond angles in such molecules. Substitution of equation [2] for $\mathscr{D}_{\alpha\gamma}$ into $P_\perp$ gives (again dividing out the normalizing factors)

$$P_\perp{}^0 = \sum_{k=0}^{\infty} \{\rho^{-(k+3)}A_{(u+k+1)} + \rho^k B_{(u-k-2)}\} \cdot \int \Theta_l{}^m \Theta_{l'}{}^{m'} P^1_{k+1} \sin\theta\, d\theta \int \cos\phi\, \Phi_m \Phi_{m'} d\phi.$$

The general formulae for all the nonvanishing $P_\perp$ integrals for s, p, and d orbital combinations are listed in Table II.

TABLE II

III. EVALUATION OF THE THREE-CENTER INTEGRALS

The integrals are of the form (see Fig. 1)

$$I = \int \mathscr{D}_{\alpha z}\phi_{i(\beta)}\phi_{j(\gamma)}d\tau.$$

The technique employed in their evaluation is to expand both $\mathscr{D}_{\alpha z}$ (or $\mathscr{D}_{\alpha\gamma}$) and $\phi_{j(\gamma)}$ about center β. This is analogous to the method developed by Coulson (7, 8) for three-center integrals of the somewhat simpler form

$$\int \frac{1}{r_\alpha}\phi_{i(\beta)}\phi_{j(\gamma)}d\tau.$$

In the molecular integrals arising from the Hellmann–Feynman theorem, one must contend with the term $r_\alpha{}^{-3}$ from $\mathscr{D}_{\alpha z}$ as opposed to the $r_\alpha{}^{-1}$ considered previously. $\mathscr{D}_{\alpha z}$ is again expanded in terms of the Gegenbauer polynomials as given by equation [2] (or [3]

for $\mathscr{D}_{\alpha\gamma}$). The orbital $\phi_{j(\gamma)}$ is also expanded about center β using the method developed by Coulson (7, 8):

$$r_\gamma^{m-1}\exp(-cr_\gamma) = \sum_{n=0}^{\infty}\frac{2n+1}{(r\rho)^{1/2}}P_n(\cos\theta')\zeta_{m,n}(c,r;\rho).$$

The $\zeta_{m,n}$ are functions of c, r, and ρ and are fully described by Coulson and Barnett (8). The result of making these two substitutions is to transform the integral into a product of two integrals, one over the radial dependence and the other over the angular factors, which involves products of Gegenbauer and Legendre polynomials. Both integrations are over but one center and are therefore, easily effected.

An example of such a three-center integral arises in the calculation of the forces which determine the bond angle in H_2O and in NH_3. One is interested in determining the force operative on one of the hydrogen nuclei (center α) due to the charge density arising from the overlap of a $2p\pi$ orbital on the oxygen atom (center β) and the $1s$ orbital on another hydrogen atom. The integral is

$$I = \int\frac{\sin\theta_\alpha\cos^2\phi}{r_\alpha^2}r\sin\theta\exp(-br-cr_\gamma)d\tau.$$

On making the above-mentioned substitutions for $\mathscr{D}_{\alpha\gamma}$ and e^{-cr_γ} one obtains, upon some reduction,

$$I = \sum_{k=0}^{\infty}\sum_{n=0}^{\infty}R_{kn}(r)\cdot Q_{knm}(\theta,\phi),$$

where

$$R_{kn}(r) = \alpha^{-2}\tau^{-1/2}\left(\tau^{-(k+2)}\int_0^\tau t^{9/2+k}[\gamma_{n-1}(1,t;\tau)-\gamma_{n+1}(1,t;\tau)]e^{-\kappa t}dt + \tau^{(k+1)}\int_\tau^\infty t^{3/2-k}[\gamma_{n-1}(1,t;\tau)-\gamma_{n+1}(1,t;\tau)]e^{-\kappa t}dt\right)$$

(the $\gamma_n(1,t;\tau)$ are products of Bessel functions of imaginary argument, $t = cr$, $\kappa = b/c$, and $\tau = c\rho$), and where

$$Q_{knm} = \int_0^\pi\int_0^{2\pi}\sin^2\theta\, C_k^{3/2}(\cos\theta)P_n(\cos\theta')\cos^2\phi\sin\theta\, d\theta\, d\phi.$$

The $P_n(\cos\theta')$ may be expressed in terms of $P_n^m(\cos\theta)$ and $P_n^m(\cos\xi)$ by means of the well-known addition theorem for Legendre polynomials. Because of the Q_{knm} integral a large number of terms in the double sum vanish, the only terms remaining besides $n = k = 0$ and 1 being those where $k = n$ or $n-2$. Thus after the integrations over θ and ϕ, each $R_{kn}(r)$ is multiplied by some numerical constant and a trigonometric function of ξ. The advantage of this method is that a variation of the bond angle ξ entails no further work beyond looking up new sine and cosine values for this angle. When ξ goes to zero in the present example ($\theta = \theta'$) the integral is transformed into a two-center one of type (*c*) described in the introduction. This case of $\xi = 0$ can be put into an independent analytical

form and thus provides a valuable check of the method reported here. When $\xi = 0$, recurrence and orthogonality relationships give

$$Q_{knm} = Q_{kn} = (\pm 1)\frac{\pi}{(2n+1)}\frac{2(k+2)(k+1)}{2k+3}.$$

$$(+ \text{ when } k = n, - \text{ when } k = n-2)$$

The analytical expression for the case $\xi = 0$ gives a value of 0.02907 for the integral. After 12 terms in the expansion the present method yields an answer of 0.02909. (The slight difference in the final figure is due to round off error.) It should be pointed out that the case of $\xi = 0$ is in no ways a special one as the same expansions are employed as when $\xi \neq 0$. From these two results it is evident that the present method is capable of giving reliable answers for the three-center integrals which arise in applications of the Hellmann–Feynman theorem.

The author wishes to acknowledge helpful discussions of the three-center problem with Miss G. A. Jones, Professor V. Linis, and Dr. J. L. Howland. He also thanks Miss V. Zahradnitzky for checking the numerical work.

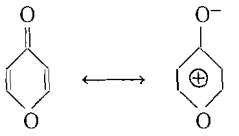
ABSTRACT

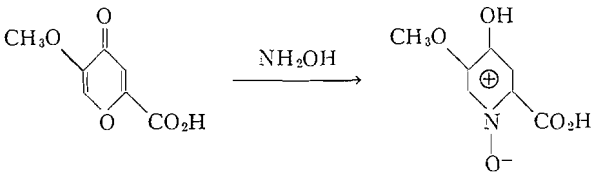
Treatment of 2,6-dimethyl-4-pyrone with hydroxylamine gives 4-hydroxyamino-2,6-lutidine 1-oxide. Under the influence of light or in weakly basic media this is converted in the presence of air to 4,4′-azoxydi-2,6-lutidine 1,1′-dioxide. In a strongly basic medium it is converted to 4,4′-azodi-2,6-lutidine 1,1′-dioxide. Similar results are obtained in the case of 2,6-diethyl-4-pyrone.

On treatment with hydroxylamine, 4-pyrones usually fail to give oximes (1). In some cases, no reaction occurs; this lack of reactivity can be attributed to the quasi-aromatic nature of the 4-pyrone ring system (I) (1, 2). In other cases, reaction proceeds via opening



I

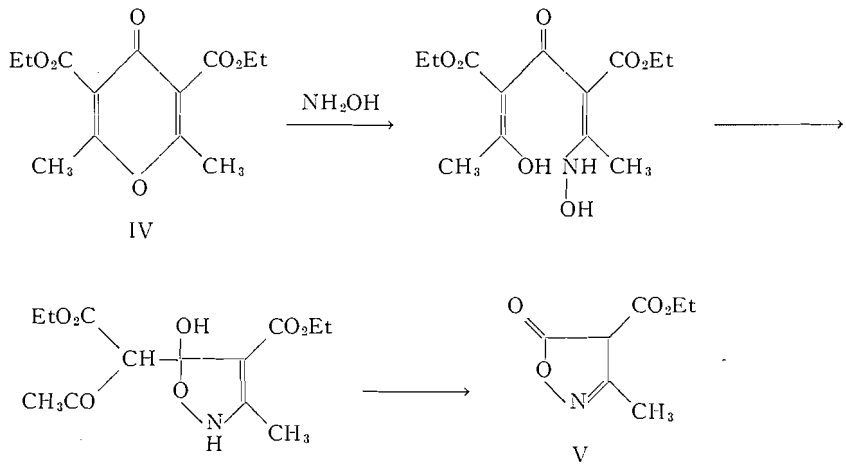
of the pyrone ring; for example, the methyl ether of comenic acid (II) forms the 4-hydroxypyridine-1-oxide derivative III (or its tautomer) (3). The reaction of 2,6-dimethyl-3,5-



II III

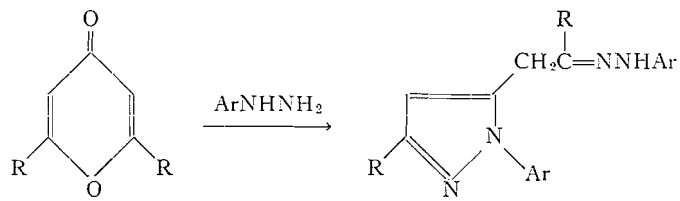
dicarboethoxy-4-pyrone (IV) with hydroxylamine also must involve initial ring opening, but the intermediate in this case recloses to give an isoxazole derivative (V) (4). The following route seems probable:

[1]*To whom inquiries may be addressed at the University of Toronto, Toronto, Ontario.*
[2]*N.I.H. Fellow, 1957–58.*



IV V

Related complexities often attend the reactions of 4-pyrones with other amines; thus, Ainsworth and Jones (5) have observed that 2,6-dialkyl-4-pyrones (VI) give pyrazole derivatives (VII) with phenylhydrazine and its derivatives.



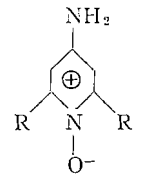
VI VII

In connection with studies on the oximes of the photodimers of 4-pyrones (6) we have had occasion to examine the reactions of hydroxylamine with 2,6-dimethyl- and 2,6-diethyl-4-pyrone and have found that here too simple derivative formation does not occur.

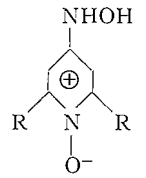
Treatment of 2,6-dimethyl-4-pyrone with an excess of hydroxylamine hydrochloride and pyridine in boiling ethanol gives two crystalline products. When pure these are colorless, but in the presence of traces of bases or of light they rapidly assume a yellow or pink color. Their elemental composition corresponds to the empirical formulae $C_7H_{10}N_2O_2$ and $C_7H_{10}N_2O_2.HCl$. The latter compound was demonstrated to be the hydrochloride of the former by the interconversion of the two products under mild conditions.

The ultraviolet spectrum (λ_{max}^{EtOH} 280 mμ (log ϵ 4.31), 215 mμ (shoulder, log ϵ 4.27)) of the free base, $C_7H_{10}N_2O_2$, closely resembles that of 4-amino-2,6-lutidine 1-oxide (VIII*a*)[3] (λ_{max}^{EtOH} 275 mμ (log ϵ 4.23), 210 mμ (apparent, log ϵ 4.21)). Its infrared spectrum (Nujol) shows strong bands at 3.10, 6.10, and 8.37 μ. This product is therefore assigned structure IX*a*, whose formation involves, in undetermined order, ring opening, reclosure, and oxime formation by the pyrone. This formulation is preferred to the tautomeric structure X on the basis of the presence of a very strong band at 8.37 μ in the infrared spectrum of the compound, which may be assigned to the N^+—O^- group (9), and of analogy to the case of 4-aminopyridine-1-oxide (VIII*b*) (10).

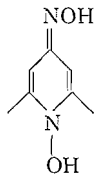
[3]*Prepared by hydrogenation of 4-nitro-2,6-lutidine 1-oxide (7); this compound has been prepared independently in similar fashion by other workers (8).*



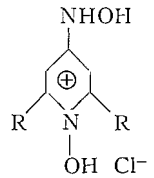
VIII*a*, R = CH_3
VIII*b*, R = H



IX*a*, R = CH_3
IX*b*, R = C_2H_5



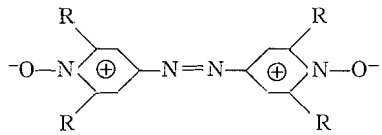
X



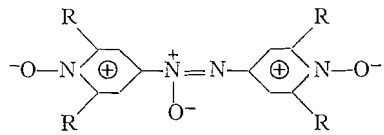
XI*a*, R = CH_3
XI*b*, R = C_2H_5

The ultraviolet spectrum of the hydrochloride, $C_7H_{10}N_2O_2.HCl$, is very similar to that of the parent base, and its infrared spectrum (λ_{max}^{Nujol} 3.20, 3.65 (sh), 3.80 (sh), 6.10 μ) shows only medium intensity absorption in the 7.5- to 8.5-μ region. This product is therefore considered to have structure XI*a*, rather than that derived by protonation of the nitrogen atom of the hydroxyamino group in IX*a*. The observed position of protonation is in accord with expectation based on theoretical considerations and on analogy with the case of VIII*b* (10, 11).

When either IX*a* or XI*a* is treated with aqueous 10% sodium hydroxide, a deep red coloration immediately occurs and an orange-red crystalline product, $C_{14}H_{16}N_4O_2$, is formed. The source and color of this compound suggested that it is the azo compound XII*a*. This view is supported by the close correspondence of its ultraviolet spectrum



XII*a*, R = CH_3
XII*b*, R = H
XII*c*, R = C_2H_5



XIII*a*, R = CH_3
XIII*b*, R = H
XIII*c*, R = C_2H_5

to that of 4,4′-azodipyridine 1,1′-dioxide (XII*b*) (Table I). An independent synthesis of XII*a* was therefore carried out by the reduction of 4-nitro-2,6-lutidine 1-oxide with sodium nitrite and base (12):[4] the product was shown to be identical with that obtained from IX*a* or XI*a*.

TABLE I

Ultraviolet spectra

	λ_{max}^{EtOH} (mμ)	log ϵ
4,4′-Azodipyridine 1,1′-dioxide (XII*b*)*	405	4.5
	255	4.05

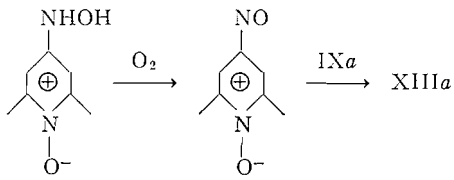
*H. J. den Hertog, C. H. Henkens, and J. H. van Roon. Rec. Trav. Chim. **71**, 1145 (1952).

[4]*After this phase of our investigation had been completed, a report (8) became available to us which describes the preparation of XII*a *and XIII*a *from 4-nitro-2,6-lutidine 1-oxide by methods similar to those described here.*

Exposure of aqueous solutions of IX*a* or XI*a* to light leads to the formation of a yellow crystalline product, $C_{14}H_{16}N_4O_3$. The same product is obtained much more rapidly when these compounds are treated with dilute aqueous ammonia or with aqueous sodium bicarbonate. Its ultraviolet spectrum (Table I) and infrared spectrum are similar to those of XII*a*. It was established to be the azoxy compound XIII*a* by its independent synthesis by the reduction of 4-nitro-2,6-lutidine 1-oxide with zinc (12).[4]

The formation of the azoxy compound XIII*a* from the hydroxylamine derivative IX*a* is analogous to the formation of azoxybenzene from *N*-phenylhydroxylamine. One route for the latter reaction has been found to involve oxidation of the hydroxylamine with atmospheric oxygen (13). This has been shown also to be the case for the present reaction, since it was found that XI*a* is not converted to the azoxy compound by the action of light nor by aqueous sodium bicarbonate when air is rigidly excluded from the reaction system. The formation of the azoxy compound can then be suggested to occur by the following route, analogous to that proposed for the formation of azoxybenzene (13(*a*), 14):



IX*a* XIV

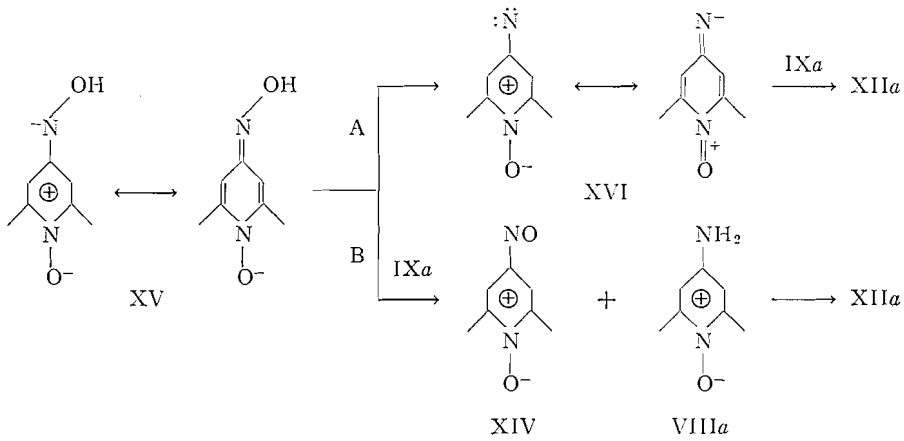
The photochemically induced oxidation of the hydroxyamino compound IX*a* to the nitroso compound XIV may be analogous to other autoxidation reactions, which are accelerated by light (15). The formation of XIII*a* in the presence of either aqueous ammonia or sodium bicarbonate (pH 7–9) proceeds in the absence of light. The pH of the reaction solution plays a critical role in the dark reaction, for at pH 5–6 no azoxy compound is formed, while at pH 12–13 (aqueous sodium hydroxide) only the azo compound XII*a* is formed; however, the data available at present do not permit the designation of the function of the basic reagents in the formation of the azoxy compound.[5]

The formation of the azo compound at pH 12–13 was found to proceed in the absence of both air and light.[6] It is possible that this reaction involves proton abstraction from IX*a* by hydroxide ion to form XV. Formation of the azo compound XII*a* could then occur either by α-elimination to give XVI followed by reaction of this with unchanged hydroxyamino compound IX*a* (route A) or by hydride transfer to IX*a* to give the disproportionation products XIV and VIII*a* followed by condensation of these (route B). The fact that no azoxy compound is formed under the strongly basic conditions militates against, but does not exclude, the intermediacy of the nitroso compound XIV in this case; route A is therefore preferred.

The reaction of 2,6-diethyl-4-pyrone with hydroxylamine hydrochloride and pyridine follows a similar course to that of the 2,6-dimethyl compound, giving the hydroxyamino compound IX*b*. Treatment of this product with aqueous 10% sodium hydroxide yields the azo compound XII*c*. In the case of IX*b*, unlike that of IX*a*, treatment with concentrated aqueous ammonia in the presence of air yields a mixture of azoxy compound

[5]*Bases have also been found to accelerate the oxidation of N-phenylhydroxylamine by air (13). The influence of pH on the autoxidation of amines is known to be complex (16).*

[6]*In the absence of air, N-phenylhydroxylamine gives azoxybenzene and aniline when treated with aqueous sodium hydroxide, while on treatment with ethanolic hydroxide it gives azobenzene as the sole product (13(b)).*



(XIII*c*) and azo compound (XII*c*) in comparable quantities. However, the azoxy compound is the sole product when an aqueous solution of IX*b* is irradiated. The structures XII*c* and XIII*c* are assigned to these products on the basis of their origin and elemental analyses and the correspondence of their infrared and ultraviolet spectra (Table I) to those of the azo and azoxy compounds obtained in the 2,6-dimethyl series.[7]

EXPERIMENTAL[8]

Reaction of 2,6-Dimethyl-4-pyrone with Hydroxylamine. Formation of IXa and XIa[9]

A mixture of 2,6-dimethyl-4-pyrone (20.0 g, 0.16 mole), hydroxylamine hydrochloride (20.0 g, 0.28 mole), dry pyridine (120 ml), and ethanol (120 ml) was boiled under reflux for 6 hours. The ethanol was then removed at room temperature under reduced pressure and the remaining solution was treated with water (50 ml) and cooled at 0° for 72 hours. The yellow solid (14.0 g) which separated was crystallized from a mixture of aqueous ethanol and chloroform to give IX*a* as pale yellow plates (2.7 g, 11%). This was recrystallized five times from methanol/acetone, giving colorless plates. The product did not melt sharply: when heated above 100° it turned yellow and a slow transition to a red-colored product occurred between 100° and 200°, followed by melting at ca. 200°.

Anal. Calc. for $C_7H_{10}N_2O_2$: C, 54.53; H, 6.54; N, 18.17. Found: C, 54.54; H, 6.66; N, 18.40.

λ_{max}^{Nujol} 2.85 (w), 3.10 (sh), 6.10 (vs), 8.37 (vs) μ; λ_{max}^{EtOH} 215 mμ (sh, log ϵ 4.27), 280 mμ (log ϵ 4.31).

Ethanol and chloroform were removed at room temperature under reduced pressure from the mother liquor from the first crystallization of IX*a*. The remaining yellow aqueous solution was treated with acetone and cooled at 0° for several days to give XI*a* as pale yellow plates (2.2 g, 9%). This was recrystallized seven times from aqueous acetone, giving colorless plates whose behavior on heating was similar to that of IX*a*.

Anal. Calc. for $C_7H_{11}ClN_2O_2$: C, 44.09; H, 5.82; Cl, 18.63; N, 14.70. Found: C, 44.04; H, 6.15; Cl, 18.35; N, 14.65.

λ_{max}^{Nujol} 3.20 (vs), 3.65 (sh), 3.80 (sh), 6.10 (vs), 8.30 (m), 8.45 (m); λ_{max}^{EtOH} 218 mμ (log ϵ 4.13), 280 mμ (log ϵ 4.27).

Reaction of XIa with Pyridine. Formation of IXa

A mixture of XI*a* (0.15 g) and dry pyridine (2 ml) was stirred until solution was complete (4–5 minutes). Most of the pyridine was removed under reduced pressure and the residue was dissolved in water (10 ml). The solution was treated with chloroform (70 ml) and the mixture was cooled at 0° for several hours, when a solid (0.072 g) separated. This was shown to be identical with IX*a* by infrared spectral comparison.

Reaction of IXa with Hydrochloric Acid. Formation of XIa

A solution of IX*a* (0.10 g) in dilute hydrochloric acid (1:10; 10 ml) was treated with acetone (70 ml). The solution was cooled at 0° for several days, when a solid (0.044 g) separated, which was shown to be identical with XI*a* by infrared spectral comparison.[10]

[7]*After this manuscript had been completed, Dr. A. R. Katritzky, Cambridge University, kindly drew our attention to the fact that related results have recently been reported for the case of 4-pyrone (17).*

[8]*Melting points are uncorrected.*

[9]*These products were found to be very sensitive to light and bases (vide infra); their preparation and purification were carried out in acid-washed glassware in the dark or in subdued light.*

[10]*For storage, it was found advantageous to convert IXa to the hydrochloride.*

4-Amino-2,6-lutidine 1-Oxide (VIIIa)

A solution of 4-nitro-2,6-lutidine 1-oxide (7) (0.51 g) in ethanol (75 ml) was hydrogenated over 5% palladium–charcoal (0.053 g). After 1 hour 3 molar equiv. of hydrogen had been absorbed. The solution was then filtered and the ethanol was removed under reduced pressure. The residue was recrystallized from ethanol/benzene to give VIII*a* as white needles, m.p. 265° decomp. (lit. (8) m.p. 264–266°); λ_{max}^{Nujol} 2.80, 3.00, 5.90 (sh), 6.05, 8.35, 8.45 μ; λ_{max}^{EtOH} 275 mμ (log ϵ 4.23), 210 mμ (apparent, log ϵ 4.21).

Reaction of XIa with Aqueous Bases[11]

(i) pH 12–13. Formation of XIIa

A solution of XI*a* (0.30 g) in water (20 ml) was brought to pH 12–13 with aqueous 10% sodium hydroxide. The resulting dark red solution immediately deposited a fluffy, orange-red solid (0.20 g, 90%). Crystallization from aqueous ethanol afforded XII*a* as orange-red needles, m.p. 257–259° decomp.

Anal. Calc. for $C_{14}H_{16}N_4O_2$: C, 61.75; H, 5.92; N, 20.58. Found: C, 61.50; H, 5.91; N, 20.31.

$\lambda_{max}^{CHCl_3}$ 3.0 (w), 4.1 (w), 6.18, 6.40, 6.86, 7.28, 8.82 μ.

When this experiment was performed with the rigid exclusion of oxygen, XII*a* was again obtained in 80% yield. The same product was also obtained when the reaction was carried out in the dark.

The azoxy compound XIII*a* was recovered unchanged after treatment with aqueous 10% sodium hydroxide.

(ii) pH 7–9. Formation of XIIIa

A solution of XI*a* (0.055 g) in water (10 ml) was brought to pH 7–8 with aqueous 10% sodium bicarbonate. During 30 minutes a yellow solid (0.037 g, 85%) was deposited. Crystallization from aqueous ethanol gave XIII*a* as yellow needles, m.p. 248–250° decomp.

Anal. Calc. for $C_{14}H_{16}N_4O_3$: C, 58.32; H, 5.59; N, 19.44. Found: C, 58.22; H, 5.56; N, 19.31.

$\lambda_{max}^{CHCl_3}$ 3.0 (w), 4.1 (w), 6.19, 6.45, 6.71, 7.26, 8.75, 9.12 μ.

The azo compound XII*a* was recovered unchanged after subjection to the conditions of this experiment.

When XI*a* was treated with aqueous 10% sodium bicarbonate with the exclusion of oxygen, no reaction occurred.

Treatment of an aqueous solution of XI*a* with dilute aqueous ammonia at pH 8–9 in the presence of air also gave XIII*a* (70%); the reaction proceeded in both the presence and absence of light. Concentration of the aqueous mother liquor in this case gave further XIII*a* and a trace of the azo compound XII*a*, identified by infrared spectral comparison and mixture melting point.

Effect of Light on XIa.[11] *Formation of XIIIa*

When an aqueous solution of XI*a* (pH 5–6) was exposed to daylight it turned yellow and slowly deposited yellow needles of XIII*a*, identified by infrared spectral comparison and melting point. When oxygen was rigidly excluded from the solution, no reaction occurred.

4,4′-Azodi-2,6-lutidine 1,1′-Dioxide (XIIa)

An authentic sample of this compound was prepared by the reduction of 4-nitro-2,6-lutidine 1-oxide (7) with aqueous sodium nitrite and sodium hydroxide according to the method used by Ochiai (12) for the preparation of 4,4′-azodipyridine 1,1′-dioxide from 4-nitropyridine 1-oxide. The product crystallized from ethanol as orange-red needles, m.p. 257–259° decomp. (lit. (8) m.p. 248° decomp.).[12] This was shown by infrared spectral comparison and a mixture melting point determination to be identical with the product, m.p. 257–259° decomp., obtained from XI*a*.

4,4′-Azoxydi-2,6-lutidine 1,1′-Dioxide (XIIIa)

An authentic sample of this compound was prepared by the reduction of 4-nitro-2,6-lutidine 1-oxide (7) in aqueous solution with zinc according to the method used by Ochiai (12) for the preparation of 4,4′-azoxydipyridine 1,1′-dioxide from 4-nitropyridine 1-oxide. The product crystallized from ethanol as yellow needles, m.p. 248–250° decomp. (lit. (8) m.p. 233° decomp.).[12] This was shown by infrared spectral comparison and a mixture melting point determination to be identical with the product, m.p. 248–250° decomp., obtained from XI*a*.

Reaction of 2,6-Diethyl-4-pyrone with Hydroxylamine. Formation of IXb

A solution of 2,6-diethyl-4-pyrone (5 g, 0.033 mole) and hydroxylamine hydrochloride (5 g, 0.072 mole) in ethanol (30 ml) and pyridine (30 ml) was boiled under reflux for 6 hours. The reaction mixture was freed from solvent under reduced pressure. The brown oily residue was dissolved in water (20 ml) and cooled at 0° for 72 hours, when a viscous oil separated. The aqueous solution was decanted and cooled at 0° for a further 48 hours, giving a yellow solid deposit (1.2 g, 20%). Several crystallizations from ethanol/acetone gave IX*b* as colorless flakes. This product did not melt sharply; when heated at 135° it turned yellow and melted with decomposition at ca. 170°.

[11]*Similar results were obtained with the parent compound, IXa.*

[12]*The melting points of the azo and azoxy compounds are very sensitive to the rate of heating; we have also obtained melting points similar to those reported earlier (8).*

Anal. Calc. for $C_9H_{14}N_2O_2$: C, 59.32; H, 7.74; N, 15.38. Found: C, 59.06; H, 7.79; N, 15.41.
λ_{max}^{Nujol} 3.2 (sh), 3.75 (sh), 6.12 (s), 8.45 (m), 8.56 (m) μ.

Reaction of IXb with Aqueous Bases

(i) pH 12–13. Formation of XIIc

A solution of IX*b* (0.10 g) in water (4 ml) was brought to pH 12–13 with aqueous 10% sodium hydroxide. The azo compound XII*c* (0.060 g, 65%) precipitated rapidly and after crystallization from aqueous ethanol was obtained as red needles, m.p. 176–177°.

Anal. Calc. for $C_{18}H_{24}N_4O_2$: C, 65.83; H, 7.37; N, 17.07. Found: C, 65.54; H, 7.46; N, 16.97.
$\lambda_{max}^{CHCl_3}$ 2.95 (w), 4.1 (w), 6.20, 6.41, 6.83, 8.82 μ.

(ii) pH 7–9. Formation of XIIc and XIIIc

When aqueous solutions of IX*b* were brought to pH 7–9 with either aqueous 10% sodium bicarbonate or dilute aqueous ammonia, an orange-colored product was deposited which was shown to be a mixture of the azo compound XII*c* and the azoxy compound XIII*c* by infrared spectral comparison.

Irradiation of IXb. Formation of XIIIc

A solution of IX*b* (0.10 g) in water (10 ml) was irradiated with a fluorescent lamp for 60 hours. A red crystalline solid (0.055 g) separated. The aqueous mother liquor was extracted with ethyl acetate and the extract was dried and freed of solvent under reduced pressure, giving an orange solid (0.021 g). The combined solid material (80%) was crystallized three times from aqueous ethanol and once from petroleum ether (b.p. 60–70°) to give XIII*c* as orange needles, m.p. 127–128°.

Anal. Calc. for $C_{18}H_{24}N_4O_3$: C, 62.77; H, 7.02; N, 16.27. Found: C, 62.61; H, 7.09; N, 16.11.
$\lambda_{max}^{CHCl_3}$ 2.95 (w), 4.1 (w), 6.18, 6.46, 6.75, 8.76, 9.05 μ.

STEROIDS AND RELATED PRODUCTS

XIX.[1] THE SYNTHESIS OF 3,9,12,20-TETRAOXYGENATED 9,12-*seco* STEROIDS. PART III.[2] 11-AZA STEROIDS. PART I[3]

CH. R. ENGEL AND S. RAKHIT[4]
Department of Chemistry, Laval University, Quebec, Que.
Received July 9, 1962

ABSTRACT

The smooth conversion of 3β-acetoxy-5α-pregnane-12,20-dione (IV), readily available from hecogenin (I), to $\Delta^{9(11)}$-3β,20β-diacetoxy-5α-pregnan-12-one (VIII) is reported. Ozonolysis of this product in ethyl acetate gave, in almost 90% yield, 3β-hydroxy-20β-acetoxy-9-oxo-9,12-*seco*-11-nor-5α-pregnan-12-oic acid (XI), further characterized by its ester derivatives XI*a* and XI*b*. The conversion of the *seco* acid XI to $\Delta^{8(9)}$-3β-hydroxy-20β-acetoxy-9-amino-9,12-*seco*-11-nor-5α-pregnen-12-oic acid lactam (12 → 9) (XII) and thence to $\Delta^{8(9)}$-N-acetyl-3β,20β-diacetoxy-11-aza-5α-pregnene (XIV*a*), the first 11-aza steroids to be known, is described. On the other hand, $\Delta^{9(11)}$-3β,20β-diacetoxy-5α-pregnen-12-one (VIII) is readily transformed to the 9α,11α-glycol VII with osmium tetroxide and thence, with periodic acid, to 3β,9α-dihydroxy-20β-acetoxy-11-oxo-11,12-*seco*-5α-pregnan-12-oic acid (X), characterized as the methyl ester X*a* and diacetoxy methyl ester X*b*, and easily converted to the acetoxy hydroxy keto dicarboxylic *seco* acid XIII. In the course of this work it is shown that, whereas ketalization of the saturated 12,20-diketone IV with ethylene glycol and boron trifluoride etherate gives a good yield of the 12-monoketal (in accordance with the reports of the literature), treatment of the analogous 16-unsaturated 12,20-diketone with the same reagents under the same conditions leads not to ketal formation but to addition of ethylene glycol in position 16.

In Part II of this study (2) we showed that the opening of ring C of the steroid molecule, by ozonolysis of a 9,11-unsaturated 12-ketone, proceeded with significantly better yields in the case of a trans fusion of rings A and B than in the case of a cis fusion of these rings (cf. also ref. 3). We were thus able to prepare 3β,20α-dihydroxy-9-oxo-9,12-*seco*-11-nor-5α-pregnan-12-oic acid, the 20-epimer of the saponification product of XI, in 17% yield, from the corresponding $\Delta^{9(11)}$-12-ketone.

We intended to use 3,20-dioxygenated 9-oxo-9,12-*seco*-12-pregnanoic acids as starting materials for the synthesis of 11-aza steroids. The investigation of such compounds appears attractive not only in view of the chemical and biological interest of natural steroid alkaloids but also in consideration of the possible biological importance of certain aza derivatives of steroid hormones. Among the great number of aza derivatives of steroid hormones, the synthesis of which can be contemplated, we regard of greatest interest those in which the nitrogen function occupies a position of established biological importance. Such compounds should not only be investigated for their hormone-like activities but also for their hormone-antagonistic properties. To date no true 11-aza steroids, with an unexpanded C-ring, have been described, in spite of the biological significance of the 11-position, primarily with respect to gluco-corticoid activity. This, however, is not surprising since such 11-aza steroids cannot be obtained by a simple Beckmann rearrangement of readily available steroids and because of the difficulty of the synthesis of ring C-*seco* derivatives suitable for further transformations to 11-aza derivatives.[5]

Under the circumstances, a reinvestigation and improvement of the synthesis of 3,20-dioxygenated 9-oxo-9,12-*seco*-12-pregnanoic acids seemed called for. At first, the yields of the actual opening of ring C, by ozonolysis of a 9,11-unsaturated 12-ketone, were, even in the A/B-trans series, still not very satisfactory. Furthermore, our previous synthesis made use of a somewhat tedious partial acetylation, in positions 3β and 20α, of 5α-pregnane-3β,12β,20α-triol (2). As we endeavor to show in this paper, we have now surmounted both these difficulties and we were also able to introduce, with concomitant recyclization, a nitrogen function in lieu of the 11-carbon atom.

As in our previous experiments, 3β-acetoxy-5α-pregnane-12,20-dione (IV), readily available from hecogenin (I) through the Δ^{16}-12,20-diketone II, served as starting material. Instead of reducing this product to a 3,12,20-triol, protecting the alcohol functions in positions 3 and 20 by partial esterification, and reoxidizing the unprotected 12-hydroxy group to a 12-ketone (2), we protected the 12-ketone by preferential ketalization with ethylene glycol and the boron trifluoride ether complex (6, 7), reduced the 12-monoketal V with lithium aluminum hydride or with sodium borohydride to the 3β,20β-dihydroxy ketal VI (7), removed the 12-ketal protection by an exchange reaction with acetone in the presence of *p*-toluenesulphonic acid (cf. ref. 8), and acetylated the thus-obtained 3β,20β-dihydroxy 12-ketone IX (cf. ref. 7) to the diacetate IX*a* (7). Be effecting the ketalization reaction in a homogeneous medium we were able to raise the yield of this step from the 57%, obtained by following the procedure of Petrow's group (7), to 74%. The British authors did not establish the configuration of the 20-hydroxy function of compounds VI, IX, and IX*a*, formed by metal hydride reduction of the ketone V; with the help of molecular rotational differences, we can, however, assign without hesitation the β-configuration to this hydroxyl function. Indeed, acetylation of the 20-hydroxy group results in an increment of molecular rotation of 145° (cf. ref. 7), which is in excellent agreement with a β-configuration, but which contrasts with the results obtained upon acetylation of a 20α-hydroxy group (9). Thus, the reduction of a 20-ketone with metal hydrides, in the presence of a 12-ethylenedioxy substituent, takes the same stereochemical course as in the presence of a 12α-acetoxy function (3) but differs stereochemically from the reduction of a 20-ketone in the presence of a 12α-hydroxy or a 12-keto function (2, 10). We consider these findings of interest and we shall discuss them in connection with their implications on the conformation of the methyl ketone side chain in the following paper of this series (11).

We also investigated the possibility of partial ketalization of the 16-unsaturated 12,20-diketone II. Since α,β-unsaturated ketones are ketalized less readily than the corresponding saturated ketones, one could consider the possibility of increasing the selectivity of ketalization in position 12 by using the unsaturated diketone II as the substrate. However, since the Δ^{16}-20-keto moiety of the diketone II assumes predominantly a *s*-trans conformation (cf. ref. 12),[6] the 12-keto function is markedly hindered; it is therefore not surprising that under the previously described reaction conditions, the 12-ketone is not attacked. It is furthermore understandable that no ketalization in position 20 occurs. We found that, under the circumstances, ethylene glycol is added to the Δ^{16}-double bond (compare III); the spectra of the reaction product and of its acetate, III*a*, show the absence of the Δ^{16}-20-keto chromophore and agree in every respect with the

[6]*As a matter of fact, the α,β-unsaturated diketone II does not exist wholly in the s-trans conformation, as indicated by the ratio of the integrated band intensities of the 20-*C=O *and 16,17-*C=C *stretching vibrations in the infrared (5.18; for values of fixed s-cisoid and fixed s-transoid systems, see ref. 13) and by the extinction coefficient of the ultraviolet absorption band of the Δ^{16}-20-keto moiety (8150; for mean values of s-cisoid and s-transoid systems, compare refs. 13 and 14).*

proposed structure. The analytical data of the adduct III*a*, including an acetyl determination, are in excellent agreement with the assigned constitution; the tetranitromethane test indicates the absence of a double bond; furthermore, even prolonged and vigorous treatment of the acetylated reaction product (compare III*a*) with acetone and *p*-toluenesulphonic acid does not restore the chromophore of the α,β-unsaturated ketone, which also demonstrates that the absence of this chromophore in the adducts III and III*a* is not due to ketalization of the 20-ketone. By analogy with the findings of Mattox (15) and Gould *et al.* (16), who described the acid-catalyzed addition of monohydric alcohols to Δ^{16}-20-ketones, we can assume that the 16-hydroxyalkyl moiety of compound III occupies the α-configuration.[7]

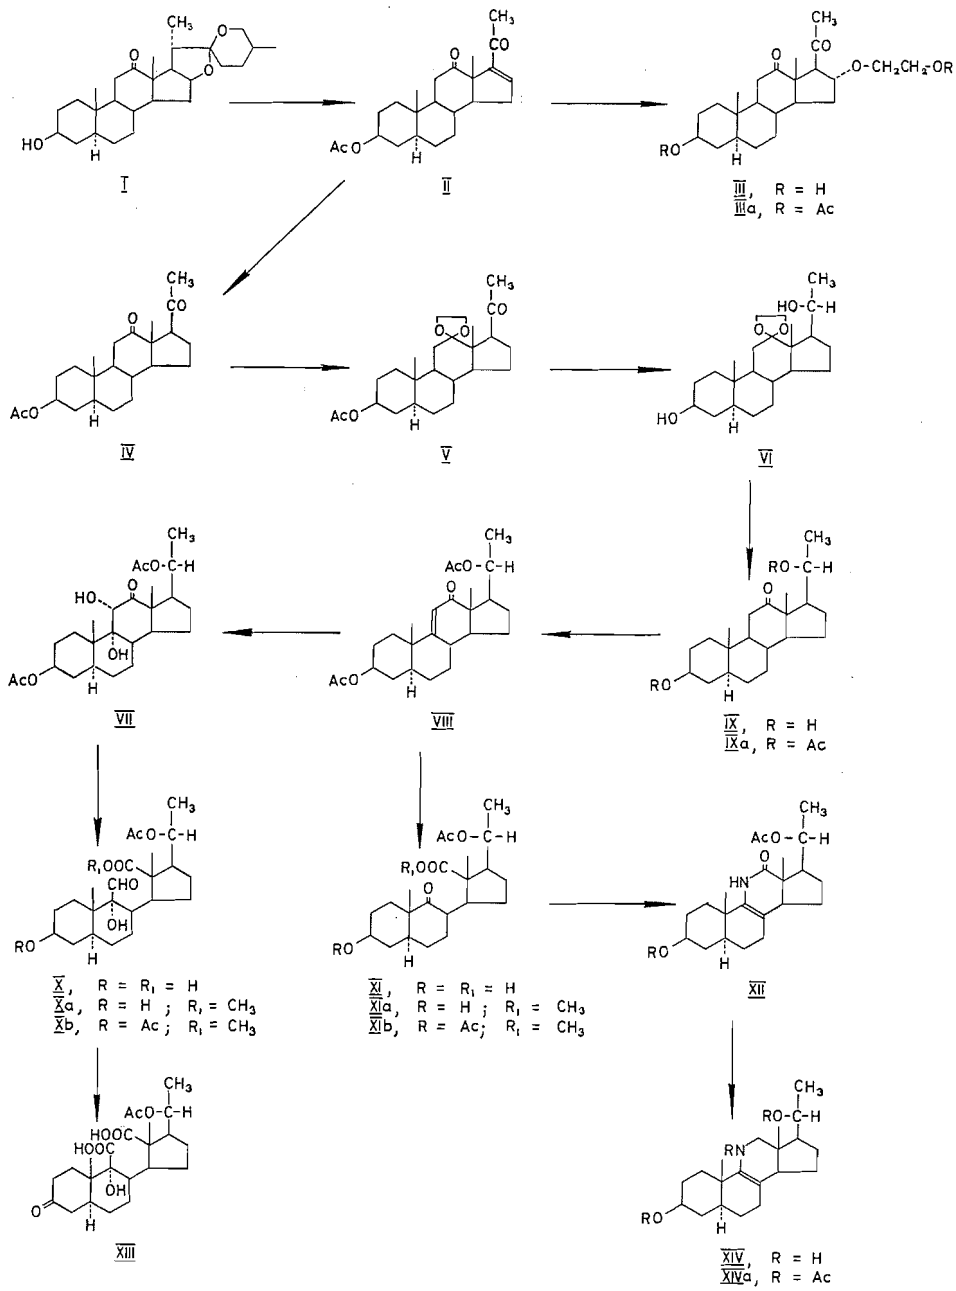
We now reverted to the main pathway of our synthesis and introduced, as previously (2, 3), the $\Delta^{9(11)}$-double bond into the diacetoxy ketone IX*a*, with selenium dioxide (19), achieving a yield of 85%. Ozonolysis of the resulting unsaturated diacetoxy ketone, VIII, under conditions analogous to those employed in the previous experiments of the series (2, 3), in ethyl acetate – acetic acid, gave a 67.5% yield of crystalline 3β-hydroxy-20β-acetoxy-9-oxo-9,12-*seco*-11-nor-5α-pregnan-12-oic acid (XI), further characterized by its methyl ester derivative, XI*a*, and its diacetoxy methyl ester, XI*b*. We were able to raise the yield of the ozonolysis reaction further, to almost 90%, by performing the reaction in ethyl acetate without the addition of acetic acid. We have thus solved the problem of synthesizing in high yield, by a simple route, a 3,20-dioxygenated 9,12-*seco*-9-keto-12-pregnanoic acid suitable for transformations to 11-aza steroids.

As a matter of interest, we wished to study the possibility of applying the osmium tetroxide – periodate fission of double bonds, discovered by Pappo *et al.* (20), to the transformation of $\Delta^{9(11)}$-12-keto steroids to ring C-*seco* derivatives. However, this procedure gave unsatisfactory results and no well-defined reaction product could be isolated from the obtained mixture apart from appreciable amounts of starting material. We therefore prepared and isolated the diacetoxy keto glycol VII, employing the usual osmium tetroxide oxidation in pyridine, under the conditions described by Baran (21). We assign the 9α,11α-configuration to the glycol VII, since attack from the α-side is much less hindered than attack from the β-side; Hirschmann *et al.* (22) have attributed the same configuration to a glycol obtained by osmium tetroxide oxidation of a 9,11-double bond. Treatment of glycol VII with periodic acid in dioxane–water gave an amorphous aldehydo acid to which we assign the structure of 3β,9α-dihydroxy-20β-acetoxy-11-oxo-11,12-*seco*-5α-pregnan-12-oic acid (X). The product gave with diazomethane a crystalline methyl ester, X*a*, which afforded upon treatment with acetic anhydride in pyridine, at room temperature, the 3β,20β-diacetoxy methyl ester X*b*; oxidation of the amorphous dihydroxy acetoxy aldehydo acid X with chromic acid, in acetone and sulphuric acid, gave the crystalline 20β-acetoxy-9α-hydroxy-3-oxo-11,12-*seco*-5α-pregnane-11,12-dioic acid (XIII). When the oxidation of glycol VII was carried out in methanol–water, an appreciable part of the reaction product consisted of methyl ester X*a*.

Although the *seco* aldehydo acid X and the *seco* dicarboxylic acid XIII present considerable interest as intermediates for the synthesis of 11-aza steroids, we decided to study first, as originally planned, the transformation of 9-oxo-9,12-*seco*-12-pregnanoic acids of type XI to 11-aza pregnane derivatives. Since we had found (23) that even in the A/B-trans series the 9-keto function of 9-keto-9,12-*seco*-12-acids of type XI was extremely resistant to oxime formation,[8] we attempted to transform the *seco* keto acid

[7] *Adams et al. (17) reported that in the presence of a 12-ketone the base-catalyzed addition of methanol to Δ^{16}-20-ketones (cf. ref. 18) is markedly facilitated.*

[8] *Wieland and Posternak (24) reported already in 1931 that an analogous 3,20-non-oxygenated seco keto acid of the A/B-cis series did not yield an oxime.*



XI to the unsaturated lactam XII, by treatment with alcoholic ammonia in a sealed tube (cf. ref. 5). The lactam XII was indeed formed in very good yield (77.5%) and could be reduced by prolonged treatment with lithium aluminum hydride in boiling tetrahydrofuran to $\Delta^{8(9)}$-3β,20β-dihydroxy-11-aza-5α-pregnene (XIV), characterized as the N-acetyl-3β,20β-diacetate XIV*a*. The spectral and analytical data of the compounds XII and XIV*a*, *which represent the first known 11-aza steroids with an unexpanded C-ring*, fully

corroborate the assigned structures. In subsequent papers of this series we shall describe other reactions of the 9-keto-9,12-*seco*-12-acid XI, the reduction of the unsaturated 11-aza steroids XII and XIV*a*, and the preparation of further 11-aza derivatives.

EXPERIMENTAL[9, 10, 11]

3β-Acetoxy-16α-(2-acetoxyethoxy)-5α-pregnane-12,20-dione (IIIa)

A suspension of 530 mg of Δ^{16}-3β-acetoxy-5α-pregnene-12,20-dione (II) (13, 25; cf. also refs. 2 and 26), m.p. 178–180°, in 4 cc of freshly distilled ethylene glycol and 0.7 cc of boron trifluoride etherate, was shaken at room temperature for 72 hours. Subsequently, the dark brown solution was stirred into a cold sodium bicarbonate solution and the precipitate was extracted with ether. The organic layer was washed with water and was dried over sodium sulphate. Removal of the solvent afforded the crude amorphous product of the addition of ethylene glycol to the Δ^{16}-double bond (compare III) which showed no ultraviolet absorption typical of an α,β-unsaturated ketone, and the infrared spectrum of which revealed the hydrolysis of the 3-acetate; ν_{max}^{KBr} 3430 cm^{-1} (broad dihydroxy band), 1706 cm^{-1} (broad 12,20-diketo band), 1066 and 1045 cm^{-1} (complex hydroxy and ether bands). The crude product was acetylated with 2 cc of acetic anhydride in 4 cc of pyridine, at room temperature, for 16 hours. The usual working up yielded 435 mg of a yellow amorphous product which, upon crystallization from ether, gave 200 mg of the diacetylated addition product (III*a*), m.p. 121–122°. The mother liquors were dissolved in petroleum ether – benzene (4:1) and absorbed on 10 g of aluminum oxide, activity III. Elutions with petroleum ether – benzene mixtures (1:1 and 1:4) yielded another 155 mg of crystalline diacetate III*a*, m.p. 120–121° (total yield 60%). A sample was recrystallized three times from ether–hexane for analysis. Colorless needles; m.p. 124.5–125.5°; $[\alpha]_D^{25}$ 42° (*c*, 1.000 in $CHCl_3$); ν_{max}^{KBr} 1745 cm^{-1} (diacetate), 1705 cm^{-1} (12,20-diketone), 1245 cm^{-1} (broad diacetate band), 1040 cm^{-1} (16-ether band); tetranitromethane test negative; no ultraviolet absorption band between 225 and 260 mμ. Anal. Calc. for $C_{26}H_{38}O_7$: C, 67.51; H, 8.28; saponifiable CH_3CO, 18.6. Found: C, 67.53; H, 8.38; saponifiable CH_3CO (after 90 minutes alcoholic 1 *N* KOH), 17.24.

Hydrolysis

A portion of 110 mg of the 16-ether derivative III*a* was dissolved in 12.5 cc of absolute acetone and treated for 18 hours, at room temperature, with 40 mg of *p*-toluenesulphonic acid. Subsequently, the mixture was refluxed for 2 hours with exclusion of moisture and was worked up in the usual fashion. The resulting product (97 mg) showed no ultraviolet absorption typical of an α,β-unsaturated ketone and consisted of crude starting material, III*a*, from which the pure product was isolated by chromatography on aluminum oxide.

3β-Acetoxy-12-ethylenedioxy-5α-pregnan-20-one (V) (cf. Ref. 7)

(a) Ketalization without Solvent

According to the procedure of Kirk *et al.* (7), a suspension of 530 mg of 3β-acetoxy-5α-pregnane-12,20-dione (IV) (12, cf. also ref. 2), m.p. 180–182°, in 3.4 cc of freshly distilled ethylene glycol and 0.7 cc of boron trifluoride etherate was shaken at room temperature for 72 hours. The mixture was poured into ice water and the solid precipitate was extracted with dichloromethane. The organic solution was washed with sodium bicarbonate solution and with water and was dried over sodium sulphate. Removal of the solvent yielded 540 mg of a yellow amorphous product, the infrared spectrum of which indicated that partial hydrolysis in position 3 had occurred. The material was acetylated in the usual fashion with 2 cc of acetic anhydride in 5 cc of pyridine at room temperature. Thus, 550 mg of a yellow amorphous product was obtained. Crystallization from ether gave 50 mg of 3β-acetoxy-12-ethylenedioxy-5α-pregnan-20-one (V), m.p. 157–158°. The mother liquors were chromatographed on 45 g of aluminum oxide, activity III. Elutions with petroleum ether – benzene (1:1) yielded 330 mg of crude monoketal V, m.p. 145–149°, which, upon crystallization from ether, gave 290 mg of pure monoketal, m.p. 158–159° (total yield 57%). A sample was recrystallized twice from ether–hexane for analysis. Small prisms; m.p. 158–160°; $[\alpha]_D^{25}$ 99.8° (*c*, 0.850 in $CHCl_3$); ν_{max}^{KBr} 1735 and 1245 cm^{-1} (acetate), 1701 cm^{-1} (20-ketone), 1060 cm^{-1} (12-ketal). Anal. Calc. for $C_{25}H_{38}O_5$: C, 71.74; H, 9.18. Found: C, 71.89; H, 9.01.

(b) Ketalization in Dichloromethane Solution

A solution of 530 mg of 3β-acetoxy-5α-pregnane-12,20-dione (IV), m.p. 180–182°, in 2 cc of absolute dichloromethane was stored at room temperature, for 72 hours, with 3.4 cc of freshly distilled ethylene glycol and 0.7 cc of boron trifluoride etherate. Large quantities of water and dichloromethane were added and the mixture was worked up as described under (*a*). The resulting product was reacetylated as described above and gave 590 mg of a yellow amorphous product which yielded, upon crystallization from ether, 420 mg of 3β-acetoxy-12-ethylenedioxy-5α-pregnan-20-one (V), m.p. 155–157°. The mother liquors were chromato-

[9]*The melting points were taken in evacuated capillaries and the temperatures were corrected.*

[10]*We are indebted to Dr. C. Daesslé, Montreal, Que., Canada, and to Mr. A. Bernhardt, Mülheim, Germany, for the microanalyses, and we extend to them our sincere appreciation.*

[11]*If not otherwise stated, non-alkaline aluminum oxide Woelm and Davison's silica gel No. 923 were used for chromatography.*

graphed on 6 g of aluminum oxide, activity III. Elutions with petroleum ether – benzene (1:1) yielded another 30 mg of monoketal V (total yield 74%). The twice-recrystallized product melted at 158–160°, $[\alpha]_D^{24}$ 100.2° (*c*, 0.850 in $CHCl_3$). The melting point was not depressed upon admixture of a sample of the ketal prepared as described under (*a*) and the infrared spectra of both products were identical.

3β,20β-Dihydroxy-12-ethylenedioxy-5α-pregnane (VI) (7)

(a) Reduction with Sodium Borohydride

According to the procedure of Kirk *et al.* (7), 250 mg of 3β-acetoxy-12-ethylenedioxy-5α-pregnan-20-one (V), m.p. 155–157°, was reduced with sodium borohydride, in methanol, in the presence of sodium hydroxide (compound V dissolved in 30 cc of methanol, 150 mg of sodium hydroxide, and 60 mg of sodium borohydride in 6 cc of 50% methanol). The usual working up afforded 205 mg (98% yield) of crystalline dihydroxy ketal VI, m.p. 195–196°; no carbonyl absorption in the infrared. A sample was recrystallized twice from methanol–ether for analysis. Small prisms; m.p. 198–200°; $[\alpha]_D^{24}$ 39.6° (*c*, 1.000 in $CHCl_3$); ν_{max}^{KBr} 3485 and 3410 cm^{-1} (3,20-dihydroxy groups), 1058 cm^{-1} (12-ketal). Anal. Calc. for $C_{23}H_{38}O_4$: C, 72.97; H, 10.12. Found: C, 72.88; H, 10.11.

(b) Reduction with Lithium Aluminum Hydride

A solution of 3.7 g of 3β-acetoxy-12-ethylenedioxy-5α-pregnan-20-one (V), m.p. 155–157°, in 250 cc of absolute tetrahydrofuran, was added over a period of 25 minutes and with vigorous stirring to a slurry of 1.9 g of lithium aluminum hydride in 300 cc of absolute tetrahydrofuran. While the stirring was continued, the mixture was refluxed for 1 hour and was subsequently stored at room temperature for another 16 hours. The excess reagent was decomposed by addition of moist ethyl acetate and, subsequently, of ice water. A cold solution of ammonium chloride was added and the organic layer was washed with cold water until neutral. The solution was dried over sodium sulphate and the solvent was removed. There was obtained 3.26 g (98%) of crystalline 3β,20β-dihydroxy-12-ethylenedioxy-5α-pregnane (VI), m.p. 196–198°. The melting point was not depressed upon admixture of the sample prepared as described under (*a*) and the infrared spectra of both products were identical.

3β,20β-Dihydroxy-5α-pregnan-12-one (IX) (7)

A solution of 3.6 g of 3β,20β-dihydroxy-12-ethylenedioxy-5α-pregnane (VI), m.p. 196–198°, in 155 cc of absolute acetone was refluxed, for 40 minutes, with 450 mg of *p*-toluenesulphonic acid. The volume of the solution was reduced *in vacuo* to approximately 50 cc and the product was poured into an iced sodium bicarbonate solution. The precipitate was extracted with dichloromethane and the organic layer was washed with water and was dried over sodium sulphate. Removal of the solvent afforded 3.24 g of a yellow amorphous material which gave, upon crystallization from acetone, 2.24 g of crystalline 3β,20β-dihydroxy-5α-pregnan-12-one (IX), m.p. 232–233°. The mother liquors were chromatographed on 30 g of aluminum oxide, activity III. Elutions with benzene–ether (4:1) afforded 500 mg of the dihydroxy ketone IX, m.p. 231–233° (total yield 86.5%). A sample was recrystallized twice from dichloromethane–acetone for analysis. Plates; m.p. 232.5–234°; $[\alpha]_D^{24}$ 88.5° (*c*, 0.867 in $CHCl_3$); ν_{max}^{KBr} 3450 and 3400 cm^{-1} (3,20-dihydroxy groups), 1692 cm^{-1} (hydrogen-bonded 12-ketone). Anal. Calc. for $C_{21}H_{34}O_3$: C, 75.41; H, 10.24. Found: C, 75.30; H, 10.06.

Diacetate IXa (cf. Ref. 7)

A solution of 18.9 g of 3β,20β-dihydroxy-5α-pregnan-12-one (IX), m.p. 231–233°, in 60 cc of pyridine and 40 cc of acetic anhydride was heated, for 16 hours, to 100°. After cooling, 100 cc of methanol was slowly added while the flask was shaken in an ice bath. The product was poured into 1.5 liters of cold water and the precipitate was extracted with ether. The ethereal solution was washed with cold 2 *N* hydrochloric acid, with water, cold sodium bicarbonate solution, and again with water and was dried over sodium sulphate. Upon removal of the solvent, 21.9 g of a yellowish amorphous product was obtained. Crystallization from ether–hexane afforded 16 g of 3β,20β-diacetoxy-5α-pregnan-12-one (IX*a*), m.p. 135–136°. The mother liquors (5.35 g) were absorbed on 150 g of aluminum oxide, activity III. Elutions with petroleum ether – benzene mixtures (1:1 and 1:4) and with pure benzene yielded another 4.5 g of diacetate IX*a*, m.p. 134–136° (total yield 90%). A sample was recrystallized twice from ether–hexane for analysis. Needles; m.p. 135–136°; $[\alpha]_D^{24}$ 98.5° (*c*, 1.000 in $CHCl_3$); ν_{max}^{KBr} 1740 cm^{-1} (3,20-diacetate band), 1715 cm^{-1} (12-ketone), 1255 cm^{-1} (3,20-diacetate band). Anal. Calc. for $C_{25}H_{38}O_5$: C, 71.75; H, 9.15. Found: C, 71.85; H, 9.04.

$\Delta^{9(11)}$-3β,20β-Diacetoxy-5α-pregnen-12-one (VIII)

To a solution of 16 g of 3β,20β-diacetoxy-5α-pregnan-12-one (IX*a*), m.p. 135–136°, in 140 cc of a 0.0006 *N* hydrogen chloride solution in acetic acid, 12 g of selenium dioxide was added. The mixture was refluxed for 20 hours, cooled, and diluted with 1.5 liters of ether. The product was filtered over sodium sulphate and celite and the filtrate was washed with water, iced dilute hydrochloric acid, cold sodium carbonate solution, and again with water, and was dried over sodium sulphate. Upon removal of the solvent, 15.7 g of a yellow amorphous product was obtained, which was absorbed on 450 g of aluminum oxide, activity III. Elutions with petroleum ether – benzene yielded 13.85 g (86.9%) of crystalline $\Delta^{9(11)}$-3β,20β-diacetoxy-5α-pregnen-12-one (VIII), m.p. 128–132°. Recrystallization from ether afforded 13.71 g (86%) of the pure unsaturated

diacetoxy ketone VIII, m.p. 132–133°. A sample was recrystallized twice from ether for analysis. Needles; m.p. 133–134°; $[\alpha]_D^{25}$ 69° (*c*, 1.000 in $CHCl_3$); λ_{max}^{EtOH} 238 mμ (log ε 4.19); ν_{max}^{KBr} 1735 cm^{-1} (3,20-diacetate band), 1682 and 1602 cm^{-1} ($\Delta^{9(11)}$-12-keto doublet), 1250 and 1240 cm^{-1} (3,20-diacetate). Anal. Calc. for $C_{25}H_{36}O_5$: C, 72.08; H, 8.71. Found: C, 72.07; H, 8.80.

3β-Hydroxy-20β-acetoxy-9-oxo-9,12-seco-11-nor-5α-pregnan-12-oic Acid (XI)

(a) By Ozonolysis In Ethyl Acetate – Acetic Acid

At −10°, a stream of oxygen containing 5.1% of ozone was passed at a rate of 180 cc per minute, for a period of 3 hours, through a solution of 800 mg of $\Delta^{9(11)}$-3β,20β-diacetoxy-5α-pregnen-12-one (VIII), m.p. 132–133°, in 25 cc of ethyl acetate and 25 cc of acetic acid. To the product there were added 0.7 cc of a 30% hydrogen peroxide solution and 1 cc of water, and the mixture was shaken repeatedly and was stored at room temperature for 16 hours. Water and ether were added and the organic product was extracted with ether. The ethereal solution was washed with water, then six times with cold 2 *N* sodium hydroxide solution, and again with water. The solution was dried over sodium sulphate and the solvent was removed. Thus 200 mg of neutral material was obtained. The sodium hydroxide washings were combined with the first water washings following the sodium hydroxide extraction and the solution was acidified with cold 2 *N* sulphuric acid to the Congo-blue reaction. The organic product was extracted with ether, the ethereal solution was washed repeatedly with water and was dried over sodium sulphate. Removal of the solvent afforded 510 mg (67.5%) of crystalline 3β-hydroxy-20β-acetoxy-9-oxo-9,12-*seco*-11-nor-5α-pregnan-12-oic acid (XI), m.p. 210–212°. A sample was recrystallized three times from dichloromethane–ether for analysis. Plates; m.p. 211–212°; $[\alpha]_D^{25}$ −30.6° (*c*, 1.000 in $CHCl_3$); λ_{max}^{EtOH} 290 mμ (log ε 1.48); ν_{max}^{KBr} 3400 cm^{-1} (broad, associated OH bands), 1725 cm^{-1} (acetate), 1708 (shoulder) and 1700 cm^{-1} (9-keto-12-acid bands), 1245 cm^{-1} (acetate). Anal. Calc. for $C_{22}H_{34}O_6$: C, 66.98; H, 8.69. Found: C, 66.69; H, 8.53.

(b) By Ozonolysis in Pure Ethyl Acetate

Two batches of 3 g each of $\Delta^{9(11)}$-3β,20β-diacetoxy-5α-pregnen-12-one (VIII), m.p. 132–133°, were dissolved in 60 cc of ethyl acetate each. Both batches were ozonized separately as described under (*a*), at −10°, with an oxygen stream containing 5% of ozone and flowing at a rate of 170 cc per minute, for 3 hours. Each batch was treated with 2 cc of a 30% hydrogen peroxide solution and with 4 cc of water and was left at room temperature for 16 hours. The reaction products were worked up as described under (*a*). The combined neutral fractions of both batches amounted to 55 mg and the combined acid fractions to 5.75 g .Recrystallization of the acidic material from dichloromethane gave 5 g (87.5% yield) of the *seco* acid XI, m.p. 212–214°. The identity of this product with the material prepared as described under (*a*) was established by a mixed melting point and by comparison of the infrared spectra.

Methyl Ester XIa

At 0°, 10 cc of a 2% ethereal diazomethane solution was added slowly to a solution of 310 mg of *seco* acid XI, m.p. 212–214°, in 14 cc of absolute ether and 6 cc of absolute methanol, and the resulting mixture was allowed to warm to room temperature. After 14 hours, the excess reagent was destroyed with a few drops of acetic acid and the solution was taken to dryness *in vacuo*. Thus, 320 mg of crystalline methyl ester XI*a*, m.p. 137–139°, was obtained (quantitative yield). A portion was recrystallized three times from ether–hexane for analysis. Needles; m.p. 139–141°; $[\alpha]_D^{25}$ −40.5° (*c*, 1.000 in $CHCl_3$); ν_{max}^{KBr} 3520 cm^{-1} (3-hydroxy band), 1730 cm^{-1} (broad, multiple acetate and methyl ester band), 1712 cm^{-1} (9-ketone), 1250 cm^{-1} (broad, multiple ester bands). Anal. Calc. for $C_{23}H_{36}O_6$: C, 67.49; H, 8.87. Found: C, 67.51; H, 8.94.

Diacetoxy Methyl Ester XIb

A portion of 290 mg of methyl ester XI*a* was acetylated in the usual fashion with 2 cc of acetic anhydride in 5 cc of pyridine, at room temperature, for 16 hours. Thus there was obtained 300 mg (94% yield) of crystalline diacetoxy methyl ester XI*b*, m.p. 101–102°. A sample was recrystallized three times from ether–hexane for analysis. Needles; m.p. 105–106°; $[\alpha]_D^{25}$ −45.1° (*c*, 0.950 in $CHCl_3$); ν_{max}^{KBr} 1730 cm^{-1} (broad acetate and methyl ester bands), 1715 cm^{-1} (shoulder, 9-ketone), 1252 and 1260 cm^{-1} (broad ester and acetate bands). Anal. Calc. for $C_{25}H_{38}O_7$: C, 66.64; H, 8.50. Found: C, 66.52; H, 8.32.

3β,20β-Diacetoxy-9α,11α-dihydroxy-5α-pregnan-12-one (VII)

To a solution of 5 g of $\Delta^{9(11)}$-3β,20β-diacetoxy-5α-pregnen-12-one (VIII), m.p. 132–133°, in 85 cc of pyridine, a solution of 5 g of osmic acid in 9 cc of pyridine was added. The mixture was stored in the dark, at room temperature, for 6 days, and subsequently a solution of 10 g of sodium sulphite in 150 cc of water was added (cf. ref. 21); the resulting ratio of pyridine – water – sodium sulphite amounted to 35:30:2. The mixture was stored for 1 hour, by which time the color turned from dark brown to orange. The product was extracted with chloroform, the chloroform solution was washed with cold dilute hydrochloric acid, water, cold sodium bicarbonate solution, and again with water and was dried over sodium sulphate. Removal of the solvent afforded 5.35 g of an amorphous material, which was crystallized from acetone–ether to give 4.35 g of 3β,20β-diacetoxy-9α,11α-dihydroxy-5α-pregnan-12-one (VII), m.p. 185–186°. The mother liquors (1 g) were absorbed on 30 g of aluminum oxide, activity III. Elutions with petroleum ether – benzene (1:1 and 1:4), pure benzene, and benzene–ether (4:1) afforded 960 mg of crystalline VII, m.p. 179–183°; one recrystallization from acetone–ether gave 800 mg of pure glycol VII, m.p. 185–186° (total yield 95.5%). A

sample was recrystallized twice from ether–acetone for analysis. Rods; m.p. 186–187°; $[\alpha]_D^{25}$ 60° (*c*, 1.000 in $CHCl_3$); ν_{max}^{KBr} 3520 and 3475 cm^{-1} (9,11-diol), 1720 cm^{-1} (broad diacetate band), 1715 cm^{-1} (shoulder, 12-ketone), 1260 and 1250 cm^{-1} (3,20-diacetate). Anal. Calc. for $C_{25}H_{38}O_7$: C, 66.84; H, 8.50. Found: C, 67.15; H, 8.62.

20β-Acetoxy-3β,9α-dihydroxy-11-oxo-11,12-seco-5α-pregnan-12-oic Acid (X)

(a) By Periodic Acid Oxidation of Glycol VII in Methanol–Water

To a solution of 2 g of 3β,20β-diacetoxy-9α,11α-dihydroxy-5α-pregnan-12-one (VII), m.p. 185–186°, in 150 cc of methanol, a solution of 5 g of periodic acid dihydrate in 20 cc of water was added, with stirring. The mixture was stirred at room temperature and in the dark for 20 hours and was neutralized with a sodium carbonate solution. After concentration *in vacuo* the product was acidified with 2 *N* hydrochloric acid to the Congo-blue reaction and the resulting mixture was extracted with ether. The ethereal solution was extracted six times with a 2 *N* sodium hydroxide solution and was then washed until neutral and dried over sodium sulphate. Removal of the solvent afforded 1.015 g of an amorphous neutral product showing no ultraviolet absorption maximum typical of an α,β-unsaturated ketone and representing crude *dihydroxy acetoxy aldehydo methyl ester Xa (vide infra)*. The first water washings of the neutral ethereal solution were combined with the sodium hydroxide extracts and acidified with cold 2 *N* hydrochloric acid to the Congo-blue reaction. The product was extracted with ether and the ethereal solution was washed repeatedly with water and was dried over sodium sulphate. Removal of the solvent afforded 855 mg (43%) of crude *acid X* which resisted all attempts of crystallization.

(b) By Periodic Acid Oxidation in Dioxane–Water

A solution of 200 mg of periodic acid dihydrate in 5 cc of water was added, with stirring, to a solution of 300 mg of 3β,20β-diacetoxy-9α,11α-dihydroxy-5α-pregnan-12-one (VII), m.p. 185–186°, in 50 cc of dioxane. The mixture was stored at room temperature, in the dark, for 18 hours and was worked up as described under (*a*). Thus 5 mg of an amorphous neutral product and 280 mg (99% yield) of amorphous aldehydo acid X were obtained; positive Tollens reaction; ν_{max}^{KBr} 3520 and 3430 cm^{-1} (very broad, multiple, highly associated hydroxyl bands), 1735 cm^{-1} (20-acetate), 1721 and 1716 cm^{-1} (broad double band of 11-aldehyde and 12-acid), 1245 cm^{-1} (acetate); a comparison of the infrared spectra of the samples prepared as described under (*a*) and (*b*) revealed the identity of the products.

Methyl Ester Xa

To a solution of 225 mg of the above-described dihydroxy acetoxy aldehydo acid X in 35 cc of absolute ether and 15 cc of absolute methanol, 15 cc of a 1.5% ethereal diazomethane solution was added, at 0°. The temperature of the reaction mixture was allowed to rise to 25° and the product was stored for another 14 hours at this temperature. The excess reagent was destroyed with acetic acid and the solvent was removed *in vacuo*. Thus, 240 mg of a semicrystalline residue was obtained. Crystallization from ether gave 85 mg of pure methyl ester X*a*, m.p. 149–150°. A sample was recrystallized once from ether–acetone for analysis. Needles; m.p. 151–152°; $[\alpha]_D^{25}$ −12° (*c*, 1.000 in $CHCl_3$); λ_{max}^{EtOH} 295 mμ (log ε 1.6); ν_{max}^{KBr} 3560 cm^{-1} (hydroxyl groups), 1740–1735 cm^{-1} (acetate and methyl ester), 1718 cm^{-1} (shoulder, 11-aldehyde), 1255 and 1245 cm^{-1} (ester groups). Anal. Calc. for $C_{24}H_{38}O_7 . CH_3COCH_3$: C, 65.29; H, 8.91. Found: C, 65.19; H, 8.89.

Diacetoxy Methyl Ester Xb

(*a*) A portion of 160 mg of the mother liquors of the crystallization of methyl ester X*a* was acetylated in the usual fashion with 1 cc of acetic anhydride in 2 cc of pyridine, at room temperature. The resulting 185 mg of amorphous product was crystallized from ether and afforded 160 mg of the diacetoxy methyl ester X*b*, m.p. 185–187°. A further recrystallization from ether yielded 140 mg of pure product melting at 191–192°. The product showed a positive Tollens reaction. A sample was recrystallized from ether–hexane for analysis. Needles; m.p. 190–192°; $[\alpha]_D^{25}$ −15° (*c*, 1.000 in $CHCl_3$); ν_{max}^{KBr} 3520 cm^{-1} (hydroxy group), 2750 cm^{-1} (C—H stretching of aldehyde), 1730–1720 cm^{-1} (broad, multiple 11-aldehyde, acetate, and methyl ester bands), 1245 cm^{-1} (broad, multiple ester bands). Anal. Calc. for $C_{26}H_{40}O_8$: C, 64.98; H, 8.39. Found: C, 64.58; H, 8.31.

(*b*) The neutral product (1.01 g) obtained during the periodic acid oxidation of glycol VII in methanol–water (*vide supra*), was dissolved in 5 cc of absolute pyridine and acetylated with 2 cc of acetic anhydride, at room temperature, for 16 hours. The usual working up afforded 1.1 g of amorphous product which, upon crystallization from ether, gave 300 mg of authentic crystalline diacetoxy methyl ester X*b*, m.p. 185–187°, identified by the comparison of the infrared spectra and by a mixed melting point with the product prepared as described under (*a*). Recrystallization raised the melting point to 190–192°. The mother liquors of the first crystallization failed to give a well-defined product upon chromatography on aluminum oxide.

20β-Acetoxy-9α-hydroxy-3-oxo-11,12-seco-5α-pregnane-11,12-dioic Acid (XIII)

To a solution of 280 mg of the crude, amorphous dihydroxy acetoxy aldehydo acid X (obtained by periodic acid oxidation of glycol VII in dioxane–water) in 15 cc of absolute acetone, 1 cc of an 8 *N* chromic acid solution in sulphuric acid (cf. ref. 27) was added and the mixture was stored at room temperature for 10 minutes. The excess chromic acid was decomposed by addition of methanol and the product was poured

into ice water. The precipitate was extracted with dichloromethane, the organic solution was washed with water and was dried over sodium sulphate. Removal of the solvent afforded 270 mg of a semicrystalline material which gave, upon crystallization from dichloromethane–ether, 150 mg of the crystalline hydroxy acetoxy keto dicarboxylic acid XIII, m.p. 193–194°. A sample was recrystallized once from dichloromethane–ether for analysis. Needles; m.p. 194–195°; $[\alpha]_D^{25}$ −18° (*c*, 1.000 in $CHCl_3$). Anal. Calc. for $C_{23}H_{34}O_7$: C, 65.38; H, 8.11. Found: C, 65.49; H, 8.24.

$\Delta^{8(9)}$-3β-Hydroxy-20β-acetoxy-9-amino-9,12-seco-11-nor-5α-pregnen-12-oic Acid Lactam (12 → 9) (XII)

Through a solution of 1.65 g of 3β-hydroxy-20β-acetoxy-9-oxo-9,12-*seco*-11-nor-5α-pregnan-12-oic acid (XI), m.p. 212–214°, in 35 cc of ethanol, ammonia gas was passed for a period of 1 hour, at 0°. Subsequently, the solution was heated in a sealed tube at 145°, for 15 hours. The product was taken to dryness *in vacuo* and the dark brown amorphous residue (1.6 g) was taken up in a mixture (4:1) of benzene – ethyl acetate and was absorbed on 160 g of silica gel, deactivated by addition of 10% water. Elutions with benzene – ethyl acetate mixtures (70:30 and 50:50) afforded 1.2 g (77.5%) of the crystalline unsaturated lactam XII, m.p. 161–163°. A sample was recrystallized three times from acetone–hexane for analysis. Small plates; m.p. 165–167°; $[\alpha]_D^{25}$ 205° (*c*, 0.800 in $CHCl_3$); λ_{max}^{EtOH} 254 mμ (log ε 3.95); ν_{max}^{KBr} 3350 cm^{-1} (hydroxy group), 3250 cm^{-1} (N—H stretching), 1665 and 1653 cm^{-1} (lactam), 1630 cm^{-1} (double bond), 1240 cm^{-1} (acetate). Anal. Calc. for $C_{22}H_{33}NO_4$: C, 70.36; H, 8.86; N, 3.74. Found: C, 70.64; H, 8.70; N, 3.89.

$\Delta^{8(9)}$-3β,20β-Diacetoxy-11-aza-N-acetyl-5α-pregnene (XIVa)

A solution of 500 mg of the unsaturated lactam XII, m.p. 161–163°, in 100 cc of absolute tetrahydrofuran was added with stirring and with the exclusion of moisture to a slurry of 1 g of lithium aluminum hydride in 200 cc of absolute tetrahydrofuran. The mixture was refluxed with stirring for 18 hours and was subsequently cooled; the excess reagent was decomposed by careful addition of ice. The inorganic salts were filtered off and washed several times with tetrahydrofuran. The organic filtrate and the washings were combined and dried over sodium sulphate. Removal of the solvent afforded 400 mg of a yellow amorphous material which resisted crystallization and which represented crude *$\Delta^{8(9)}$-11-aza pregnene-3β,20β-diol (XIV)*. The product was dissolved in 4 cc of pyridine and treated with 4 cc of acetic anhydride at 100°, for 16 hours. The excess acetic anhydride was decomposed by addition of methanol and the solvents were removed under reduced pressure. The dark brown residue was taken up in ethyl acetate, the solution was washed with cold water, cold sodium bicarbonate solution, and again with water and was dried over sodium sulphate. Removal of the solvent gave 450 mg of a dark brown oil. The product was dissolved in a petroleum ether – benzene (1:1) mixture and was absorbed on 12 g of aluminum oxide, activity III. Elutions with petroleum ether – benzene (1:4) and pure benzene gave 135 mg of *$\Delta^{8(9)}$-3β,20β-diacetoxy-N-acetyl-11-aza-5α-pregnene (XIVa)*, m.p. 225–228°. A sample was recrystallized three times from ether–dichloromethane for analysis. Small prisms; m.p. 235–237°; $[\alpha]_D^{25}$ 64.2° (*c*, 0.700 in $CHCl_3$); ν_{max}^{KBr} 1745 cm^{-1} (acetate bands), 1645 cm^{-1} (amide), 1245–1240 cm^{-1} (broad acetate bands). Anal. Calc. for $C_{26}H_{39}NO_5$: C, 70.08; H, 8.82; N, 3.14. Found: C, 69.90; H, 8.91; N, 3.38.

ACKNOWLEDGMENTS

We extend sincerest thanks to Mrs. J. Capitaine and Mr. D. Capitaine for their devoted and expert assistance, and we express our gratitude to the National Research Council of Canada, the Schering Corporation, Bloomfield, N.J., and the Schering Corporation Ltd., Montreal, for financial support of this project.

THE CONFORMATIONS OF THE 20-KETO SIDE CHAIN OF C_{21}-STEROIDS[1]

S. RAKHIT[2] AND CH. R. ENGEL[3]

A number of important steroid hormones, such as progesterone, the mineralo-corticoids, and the gluco-corticoids, possess a two-carbon keto side chain. Whereas progesterone has a simple 21-methyl-20-keto side chain, the corticoids all bear a hydroxyl substituent at position 21. The biological activity of such steroids is markedly influenced by substituents on the carbon atoms adjacent to the 20-carbonyl group, for instance, by the presence of an additional hydroxy function in position 17, the point of origin of the side chain. It is well known that C_{21}-steroids exhibit marked hormonal activity only if the side chain occupies the β-configuration. The study of models, particularly of the Stuart type, shows clearly that the methyl keto side chain, or the derived ketol side chain, cannot rotate completely freely around the C_{17}—C_{20} single bond and that there exist four preferred conformations, which we designate as A_1, A_2, B_1, and B_2 (compare Fig. 1).[4] These conformations can readily be subjected to small rotational transformations but are separated from each other by energy barriers (the conversions $A_1 \rightleftarrows B_1$ and $A_2 \rightleftarrows B_2$ are achieved with greater ease than the conversions $A_1 \rightleftarrows A_2$ and $B_1 \rightleftarrows B_2$.

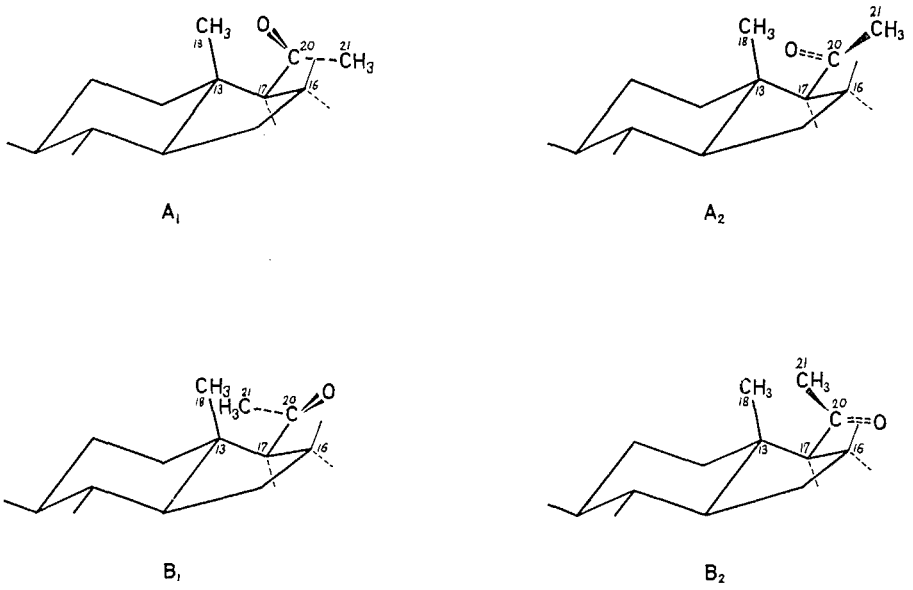

FIG. 1. Preferred conformations of the 20-keto side chain of C_{21}-steroids.

[1]*This communication represents paper XX in our series on Steroids and Related Products (for Paper XIX, see ref. 1). The main aspects of the problems discussed in this note were related in a communication presented before the XXIXth Congress of the French Canadian Association for the Advancement of Science, Ottawa, October 1961.*

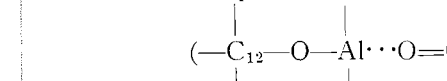
[3]*Correspondence should be addressed to this author.*

[4]*The drawings of ring D are only approximations; in this paper we do not intend to take issue with the problem of the actual conformation of ring D of individual steroids (cf. ref. 2).*

The question in which of these main conformations individual C_{21}-20-keto steroids predominantly exist merits attention, both as a matter of stereochemical interest and because of the biochemical and biological implications of the problem. The 20-keto function of C_{21}-hormones seems indeed to play an important role in their biological action and it is therefore logical to assume that the geometry of this group should be of biological significance. The contact or interaction of this function with a receptor should be influenced by its position in space, its distances from other centers, and its "availability" or "inavailability" for biochemical actions.

As we have already briefly indicated in a previous publication (3), the stereochemical course of metal hydride reductions, particularly of lithium aluminum hydride reduction, of 20-keto steroids can shed some light on the conformation of the side chain. Just and Nagarajan (4) reported recently that the reduction of 3α,12α-dihydroxypregnan-20-one with lithium aluminum hydride gives a high yield of the 20α-hydroxy derivative (58.5% in tetrahydrofuran, 65.8% in diethyl ether), in contradistinction to the reduction of the corresponding 3α,12α-diacetate, which gives predominantly the 20β-alcohol (5), in contradistinction also to the stereochemical course of metal hydride reductions of the majority of 20-keto steroids (cf. ref. 6, pp. 568 and 622 and the pertinent references therein). As an explanation, Just and Nagarajan put forward the hypothesis that in the course of the reduction of the 12α-hydroxy-20-ketone there is formed an intermediate aluminum complex which links the oxygen functions in positions 12 and 20 in a bridge-like fashion



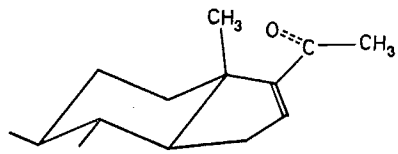
($-C_{12}-O-Al\cdots O=C_{20}-$). In order to make such a link possible, the 20-keto side chain must assume a conformation which should induce, according to Cram's rule (7), the predominant formation of a 20α-alcohol upon lithium aluminum hydride reduction. This assumption was further corroborated by our own experiments. We were able to show that lithium aluminum hydride reduction of a 12,20-diketone leads, practically exclusively, to a 12β,20α-diol (3), whereas the reduction of a 12-ethylenedioxy-20-ketone affords in high yield the 20β-alcohol (1). This fits well Just and Nagarajan's theory, since a 12,20-diketone should lend itself readily to the formation of an intermediate complex of the aluminum species with the oxygen atoms in positions 12 and 20 and should hence be expected to yield predominantly a 20α-alcohol; on the other hand, the formation of such a complex is not likely with a 12-ethylenedioxy group and, consequently, the methyl ketone side chain should, in this instance, not be forced into a conformation inducive to the formation of a 20α-alcohol.[5] Furthermore, if the aluminum hydride reagent were to form two distinct complexes with the oxygen functions in positions 12 and 20, the steric repulsion between these two complexes would result in a side-chain conformation inducive to reduction to a 20β-alcohol. As a matter of fact, the high stereospecificity of the reduction of a 12-ethylenedioxy-20-ketone with lithium aluminum hydride could be accounted for by the steric repulsion between the 12-ketal group and the complex formed between the aluminum hydride and the 20-ketone.

Just and Nagarajan had already pointed out that their theory provided an explanation for the finding that 17α-hydroxy-20-ketones are reduced by lithium aluminum hydride predominantly to 20α-alcohols (8, 9, cf. also ref. 10). As we endeavor to show in this

[5]*The great stereospecificity of the reduction of the 12,20-diketone as compared to that of the reduction of an 12α-hydroxy-20-ketone is understandable if one considers that the geometry of the* C=O *bond of a 12-ketone and, especially, of a 12β-hydroxy derivative (predominantly formed by metal hydride reduction of a 12-ketone) lends itself better to the formation of a bridge complex with the 20-oxygen atom than the geometry of the* C—O *bond of a 12α-hydroxy derivative.*

paper, the axis of the carbonyl group of 17α-hydroxy-21-methyl-20-keto steroids is almost coplanar with the C—O link of the 17α-hydroxy function. If an aluminum hydride link between the 17α-hydroxy group and the 20-carbonyl function is to be formed in the course of lithium aluminum hydride reduction, the side chain must undergo a rotation around the C_{17}—C_{20} bond in order to accommodate the aluminum species between the two oxygen functions. In this instance the formation of two distinct complexes of aluminum hydride with the oxygen functions in positions 17 and 20 would have the same result: the repulsion between these two complexes would drive the side chain into another conformation. The rotation of the side chain should occur towards conformation A_2, since the passage to conformation B_1 would require the clearing of a higher energy barrier. Hydride attack on a complex of the aluminum species with the 20-carbonyl function in conformation A_2, should afford predominantly the 20α-alcohol, which corresponds indeed to the experimental facts.

The stereochemical course of lithium aluminum hydride reduction of Δ16-*20-keto steroids* can also be explained readily by the consideration of the conformation of the side chain. Mueller *et al.* (11) showed that this conformation is of the *s*-trans type (cf. also ref. 1).[6]



The conformation of the methyl ketone side chain of Δ16-20-keto steroids thus resembles conformation A_2 of the saturated products and should result in the predominant formation of 20α-alcohols upon reduction with aluminum hydrides, which is indeed the case (cf. ref. 12).[7]

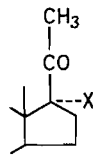
As a corollary of these considerations it can be concluded that if the molecule does not contain groups which, by the formation of intermediate complexes or by other compelling steric factors, force the side chain out of its "normal" conformation, the hydride attack will occur on a complex having a conformation similar to that of the original 20-keto side chain. Thus, the stereochemical analysis of the lithium aluminum hydride reduction products of such 20-ketones should allow one to draw direct conclusions on the predominant conformation of the original side chain. In the absence of "interfering" oxygen functions (such as 12-hydroxy and 12-keto groups, a 17α-hydroxy function, or a 16,17-unsaturation) lithium aluminum hydride reduction yields predominantly 20β-alcohols; according to Cram's rule this is only possible if the intermediate complex of the carbonyl

[6]*In the absence of a 12-keto or 12-acetoxy function and consequently in the absence of repulsion between such groups and the 20-keto function, the ratio of s-trans conformation to s-cis conformation is even higher. Thus, the ratio of the integrated band intensities of the 20-C=O and 16,17-C=C stretching vibrations is 6.63 in the case of Δ16-3α-acetoxypregnene-11,20-dione, as compared to 5.18 in the case of Δ16-3β-acetoxy-5α-pregnene-12,20-dione; the extinction coefficient of the ultraviolet absorption maximum of the unsaturated ketone of Δ16-3α-acetoxypregnene-11,20-dione is 9050, that of Δ16-pregnene-3,20-dione 9800, as compared to 8510 for Δ16-3β-acetoxy-5α-pregnene-12,20-dione (our own unpublished results, cf. also footnote 6 of ref. 1).*

[7]*Shapiro et al. (12) suggested that the predominant formation of 20α-alcohols upon lithium aluminum hydride reduction of 16-unsaturated 20-ketones is due to a lesser hinderance of the 20-carbonyl function of such products as compared to that of the saturated compounds. In fact, in the s-trans conformation the unsaturated ketones are considerably hindered, which seems to be borne out by chemical evidence (cf. ref. 1); however, it is possible that the (small) portion of the ketone which occupies the s-cis conformation reacts rapidly with lithium aluminum hydride, that the equilibrium between the s-cis and s-trans forms is constantly restored, and that consequently the whole reaction takes place as if the side chain would occupy the s-cis conformation. Our own explanation would make such an assumption superfluous, since it rationalizes the predominant formation of the 20α-epimer without postulating a shift to the s-cis conformation.*

group with the aluminum hydride species exists predominantly in either conformation B_1 or B_2. As just pointed out, we can assume that in these instances the conformation of the original 20-keto side chain will be similar. In other words, the fact that, in the absence of groups which interfere with the geometry of intermediate complexes, lithium aluminum hydride reduction of 20-keto steroids yields predominantly 20β-alcohols allows us to conclude that the conformation of the original 20-keto side chain of such compounds must be, predominantly, either of type B_1 or B_2. A choice between these two conformations can, however, not be made on the basis of the stereochemical analysis of the reduction products, since both conformations should be inducive to the formation of 20β-alcohols.[8, 9]

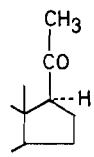
Physical data are in agreement with our conclusions. Thus Djerassi *et al.* (14) have shown, by the application of the "axial halo keto rule" (15), that *17α-bromo-* and *17α-chloro-20-keto steroids* (cf. partial formula I) exist in a conformation of type B, in contra-



I, X = Br, Cl

distinction to 18-nor-20-keto steroids, the general conformation of which appears to be of type A (16, 17, cf. also ref. 18).[10] Djerassi *et al.* do not discuss specifically the two conformations B_1 and B_2; however, in this instance an assignment can be made readily on the grounds of spectral evidence. Indeed, if 17α-halo-20-ketones were to exist in conformation B_2, the C_{17}—X and C_{20}—O bonds would be almost coplanar and, as in the case of cyclic equatorial α-halo ketones, the resulting dipole interaction should be noticeable in the infrared (cf. refs. 20 and 21). However, the carbonyl frequency of the 20-keto group is hardly changed by the introduction of a 17α-halo substituent (cf. for instance ref. 20). We can thus conclude that the *actual conformation of 17α-halo-20-keto pregnanes is of type B_1.*

In a recent publication, Allinger and DaRooge (22) established, with the help of dipole moment measurements, that even in the absence of a 17α-halogen substituent the 21-methyl-20-keto side chain of the progesterone type (compare partial formula II) occupies the general conformation B. These authors briefly considered the choice between the two



II

[8]*An inspection of models demonstrates that conformation B_2 should be particularly favorable for the reduction to a 20β-alcohol, the intermediate complex being particularly little hindered; but this does in no way mean that conformation B_2 represents the actual conformation of the majority of 20-keto steroids.*

[9]*In connection with their work on 18-oxygenated 20-keto pregnane derivatives, Heusler and Wettstein arrived independently at somewhat similar conclusions, which they published in an article (13) which appeared after our presentation before the Congress of the Canadian Association for the Advancement of Science. In their discussion, the Swiss authors do not consider conformation B_2.*

[10]*In this connection it seems of interest to point out that 18-nor- and 18,19-bis-nor-progesterones show only low progestational activity (18, 19).*

possible conformations B_1 and B_2, but dismissed, almost perfunctorily, the possibility of conformation B_2. Quite correctly, they point out that in this conformation the geometry of the C_{18}- and C_{21}-methyl groups resembles that of 1,3-diaxial methyl groups on a cyclohexane ring, an arrangement with a high energy content (cf. ref. 23). While we tend to agree that conformation B_1 is probably energetically more favored than conformation B_2, the difference between the energy contents of the two conformations seems less drastic than it would appear from Allinger's and DaRooge's article. Indeed, while the geometry of the C_{18}- and C_{21}-methyl groups of conformation B_2 is *similar* to that of a diaxial 1,3-dimethyl cyclohexane, it is by no means identical. As can be seen quite readily by inspection of models, particularly of the Stuart type, the interaction between the C_{18}- and C_{21}-methyl groups of conformation B_2 is definitely less severe than that of diaxial 1,3-dimethyl cyclohexane substituents (compare Fig. 2). Furthermore, in the alternative

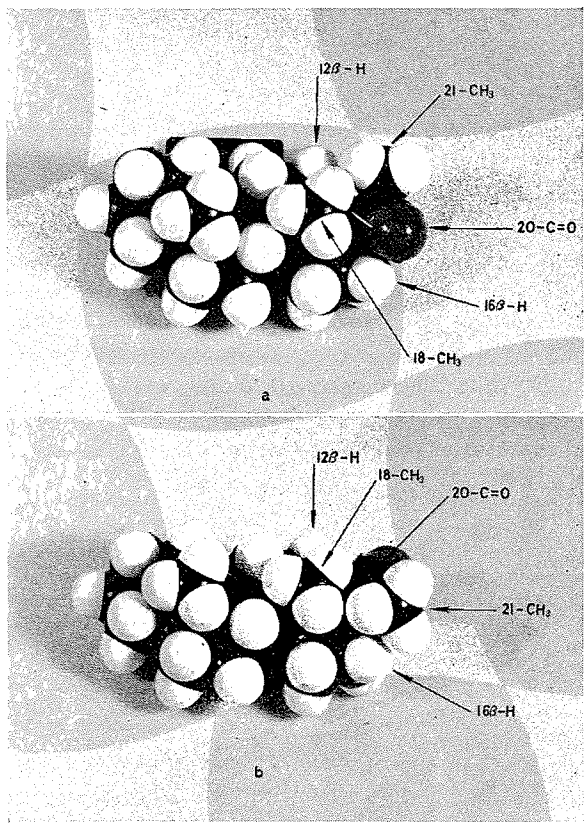


FIG. 2. Stuart models of 20-keto C_{21}-steroids: (*a*) conformation B_1; (*b*) conformation B_2.

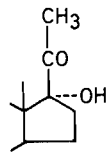
conformation, B_1, there also exists an interaction between the hydrogen atoms of the two methyl groups (although it is smaller than in the case of conformation B_2) and an interaction between the 21-methyl group and the 12β-hydrogen atom; and there exists a marked interaction between the oxygen atom of the carbonyl group and the 16β-hydrogen atom (cf. Fig. 2). We can readily see that the last-mentioned interaction should not be neglected if we consider that a somewhat similar (although more severe) interaction between the 20-oxygen function and the C_{18}-methyl group must be responsible for the

fact that 21-methyl-20-ketones of the natural series (with an angular C_{18}-methyl substituent) do not generally exist in conformation A_1. (In the case of conformation A_2, another factor of thermodynamic instability has to be considered: an interaction between the 21-methyl group and the 16β-hydrogen atom.) As long as we are not in possession of further experimental evidence, our dismissal of conformation B_2 for 21-methyl-20-ketones should, therefore, be formulated with some caution.[11]

On the other hand, it seems logical to admit that *17α-hydroxy-21-methyl-20-ketones* (of the type of 17α-hydroxyprogesterone, cf. partial formula III) *exist to a considerable extent in conformation B_2*. This is indeed the only conformation which allows for the marked

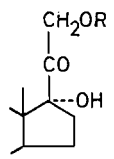


III

hydrogen bonding which can be observed between the 17α-hydroxy group and the 20-carbonyl function (27). Since lithium aluminum hydride reduction of 17α-hydroxy-21-methyl-20-ketones affords predominantly 20α-alcohols and since conformation B_2 is inducive to the formation of 20β-alcohols, we must conclude that during the reduction shift a to conformation A_2 occurs. We have already discussed this point above.

The case of *12β-hydroxy-21-methyl-20-keto steroids* is somewhat similar: the marked hydrogen bonding between the 12-hydroxy function and the 20-keto group (cf. refs. 28, 29) allows only for one predominant conformation: *conformation A_2*.

It is interesting that while the preferred conformation of 17α-hydroxy-21-methyl-20-keto steroids seems to be conformation B_2, compounds with a *dihydroxyacetone side chain*, i.e. with an additional hydroxy substituent in position 21 (cf. partial formula IV), as



IV, R = H
IVa, R = Ac

well as 21-acetate derivatives of such products, exist predominantly in a different conformation, namely B_1. If products of this structure were to occur in conformation B_2, their infrared spectra should reveal, as in the case of the 21-unsubstituted 17α-hydroxy-20-ketones, pronounced hydrogen bonding between the 20-carbonyl function and the 17α-hydroxy group. This is not the case (27). On the other hand, lithium aluminum hydride

[11]*If biological data could be used as evidence in the determination of the exact conformation of the side chain of 17-unsubstituted 21-methyl-20-ketones, they would speak in favor of conformation B_1. Bulky 17α-substituents, which should definitely not favor conformation B_2, increase in general progestational activity (cf. ref. 24); thus 17α-bromoprogesterone is a highly active luteoid (25), whereas 17α-hydroxyprogesterone, which occurs to a considerable extent in conformation B_2 (vide infra), is almost inactive (26). It would not be unreasonable to assume that progesterone, the actual hormone of the corpus luteum, should also exist in conformation B_1, in which particularly active compounds occur, and not in conformation B_2, in which the almost inactive 17α-hydroxyprogesterone predominantly exists. Needless to emphasize, this argument has only limited value since the activating and deactivating actions of various substituents are generally due to a multitude of distinct factors.*

reduction of compounds of type IV*a* yields predominantly 20β-alcohols (30–33), which indicates that the general conformation of the side chain is of type B. Since the conformation cannot be of type B_2, we must assume that, in contradistinction to the 21-desoxy compounds, products of the type of cortisol and cortisone exist mainly in *conformation* B_1.[12]

By analogy, we can assume that the conformation of 17-unsubstituted 21-hydroxy-20-keto steroids, such as desoxycorticosterone, is of the general type B, probably of type B_1.[12, 13]

We may summarize the preferred conformations of various types of 20-keto C_{21}-steroids in Table I.[14, 15]

TABLE I

Substituents					Preferred conformation
12	13	16	17α	21	
H_2	CH_3	H_2	Br or Cl	H_3	B_1
H_2	CH_3	H_2	H	H_3	B (B_1?)
H_2	CH_3	H_2	OH	H_3	B_2
12α-H, 12β-OH	CH_3	H_2	H	H_3	A_2
H_2	CH_3	H_2	OH	OH, H_2	B_1
H_2	CH_3	H_2	H	OH, H_2	B (B_1?)
H_2	CH_3	$\Delta^{16,17}$	$\Delta^{16,17}$	H_3	A_2
H_2	H	H_2	H	H_3	A

In conclusion, it might be of interest to point out that the predominant side-chain conformation of products which exhibit marked hormonal activity always seems to be of the general type B, probably of the particular type B_1.[16] Whereas a coincidental relationship cannot be ruled out, we believe that the geometry of a group biologically as significant as the 20-keto side chain of C_{21}-steroids should be a factor of some consequence with respect to biological activity. One might be tempted to consider that conformations of the general type B, and in particular of type B_1, are favorable for hormonal action.

ACKNOWLEDGMENT

We express sincere thanks to the National Research Council of Canada for the generous support of our studies.

[12]*In a recent oral communication (cf. ref. 34), presented after the preparation of this manuscript, Birmingham, Ward, and Traikov advanced that the study of the near-infrared spectra of 17α,21-dihydroxy-20-ketones and of 21-acetoxy-17α-hydroxy-20-ketones suggests some hydrogen bonding between the 17α-hydroxy group and the 20-carbonyl function. This would mean that such compounds exist to some extent in conformation* B_2.

[13]*Such an assumption is relatively safe. Indeed, if not even a 17α-hydroxy substituent can induce, by hydrogen bonding, the ketol side chain to assume conformation* B_2, *ketols without this 17α-substituent should have even less reason to exist in this conformation. One could stretch this argument even further in favor of a more definite establishment of conformation* B_1 *for 20-ketones unsubstituted in both the 17 and 21 positions; however, the situation is not completely analogous because a 21-hydroxy or a 21-acetoxy substituent exercises, as we have seen, a marked influence on the conformation of the side chain.*

[14]*We have not discussed the conformation of 16α,17α-epoxy-20-keto steroids. Their reduction with lithium aluminum hydride leads to a mixture of 20-alcohols in which the β-epimer predominates, but to a lesser extent than in the absence of the epoxy group (31). This is not surprising since a 17α-hydroxy derivative is formed during the reduction. Furthermore, the geometry of the side chain is not the same as in the case of ring-D-saturated steroids. The available evidence points to conformation B for 16,17-epoxy-20-steroids; for obvious steric reasons conformation* B_1 *seems more probable. Likewise, one has to be cautious when interpreting the predominant reduction to a 20α-alcohol of 17α-acetoxy-20-keto steroids (9); one has to consider that during the reduction an aluminum hydride complex with a 17α-oxygen function is formed; we have seen that in the presence of such a substituent the main reduction product is a 20α-alcohol.*

[15]*In this article we are not discussing the side-chain conformations of 18-oxygenated steroids. For certain aspects we refer to the already cited article by Heusler and Wettstein (13) and to their preceding article (35).*

[16]*We refer only to products belonging to the groups discussed in Table I.*

THE PURIFICATION OF SOLVENTS FOR ULTRAVIOLET ABSORPTION SPECTROSCOPY

SERGE N. VINOGRADOV

The purification of hydrocarbons for use as solvents in ultraviolet absorption spectroscopy is usually achieved through repeated and prolonged shaking with concentrated sulphuric acid or sulphuric acid – nitric acid mixture, washing with water, and finally distillation or passage through a column of suitable adsorbent such as alumina or silica gel (1–4). In the course of the purification of a large number of hydrocarbons ranging from pentane to tetradecane and cyclopentane to cyclooctane, for use in 5 to 10 cm thicknesses in the 2500–2600 Å region, the following procedure was found to be not only thorough but also quick and convenient. About 200–300 ml of the hydrocarbon was shaken in a 500-ml separatory funnel with about 100 ml of a 1:1 by volume mixture of

THE PURIFICATION OF SOLVENTS FOR ULTRAVIOLET ABSORPTION SPECTROSCOPY

SERGE N. VINOGRADOV

The purification of hydrocarbons for use as solvents in ultraviolet absorption spectroscopy is usually achieved through repeated and prolonged shaking with concentrated sulphuric acid or sulphuric acid – nitric acid mixture, washing with water, and finally distillation or passage through a column of suitable adsorbent such as alumina or silica gel (1–4). In the course of the purification of a large number of hydrocarbons ranging from pentane to tetradecane and cyclopentane to cyclooctane, for use in 5 to 10 cm thicknesses in the 2500–2600 Å region, the following procedure was found to be not only thorough but also quick and convenient. About 200–300 ml of the hydrocarbon was shaken in a 500-ml separatory funnel with about 100 ml of a 1:1 by volume mixture of

concentrated nitric and sulphuric acids, twice, for 30 seconds each time, then shaken two or three times for 15 seconds with 100 ml concentrated sulphuric acid, washed three times with distilled water, dried over anhydrous calcium sulphate, and passed through ca. 60 cm of silica gel (Davison grade 12, mesh size 60–200) packed in an ordinary 50-ml burette. This amount of silica gel was sufficient for the purification of 200–300 ml of hydrocarbon; it usually was possible to observe visually the progress of the adsorbed, slightly yellowish impurities down the column. In the case of the low-boiling hydrocarbons it was found best to chill the mixture before shaking because of the large amount of heat evolved. It was observed that in most cases shaking with concentrated sulphuric acid (unless very lengthy) and (or) passage through a silica gel column did not result in sufficient improvement in the transmission of the hydrocarbons in the 2500 Å region. Prolonged shaking (>1 minute) with the acid mixture was found to be superfluous for our purposes. It may be necessary perhaps in cases where the best possible transmission is desired at wavelengths down to 2100 Å.

Figure 1 shows some typical results obtained with the method described above. The compounds used were reagent grade or had a stipulated purity of better than 99 mole%.

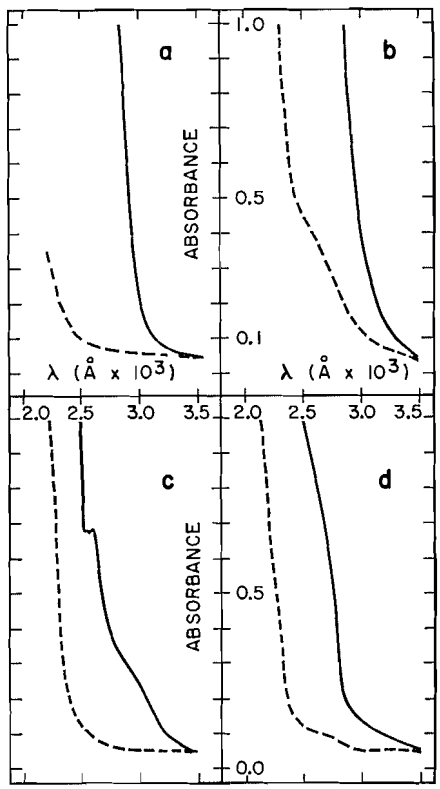

FIG. 1. The spectra of some ultraviolet solvents: (*a*) *n*-hexane, 5 cm; (*b*) *n*-tetradecane, 2 cm; (*c*) cyclohexane, 5 cm; (*d*) FC-75, 5 cm. —— original solvent; – – – purified solvent.

The hydrocarbons thus purified were at least as good as or better than the available and much more expensive Eastman Kodak or Matheson, Coleman and Bell spectrograde solvents. FC-75 is a mixture of isomers of the perfluorinated cyclic ether $C_8F_{16}O$ available commercially from Minnesota Mining and Manufacturing Company.

In conclusion, it should be noted that the limiting factor with respect to the time required by the procedure is the rate of passage of the solvent through the silica gel column.

THE FRANCK–CONDON PRINCIPLE AND THE IONIZATION OF MOLECULES

JACQUES E. COLLIN

Ionization potentials obtained by electron impact or photon impact are generally discussed with reference to the Franck–Condon principle for both ground and ionic states concerned. By doing so it is admitted that the interaction time of the ionizing particle and the molecule, and the time necessary for the electron to leave the interested bond region of the molecule, were short, compared to the time of a complete vibration, considering only here diatomics.

In a recent paper, Stevenson (1) indicated that the particularly well-known case of hydrogen seemed to be in conflict with the Franck–Condon principle; this conclusion was based on a careful consideration of potential curves and observed ionization potentials. It was shown that, although the Franck–Condon principle would predict the highest probability for the transition to the vibrationally excited $v = 2$ state of the ion, the experimental data gave the 0–0 transition. This was later explained, thanks to the beautiful work of Marmet and Kerwin, who showed that it was mainly a matter of sensitivity of the detecting device (2).

The H—H bond being strong and the atoms light, the fundamental frequency is very high: 4276 cm^{-1}. This is thus a case where non-applicability of the Franck–Condon principle might be encountered, but Marmet and Kerwin's work lead to the theoretically expected relative cross sections for the 0–0, 0–1, 0–2 transitions.

In the case of heavier molecules, particularly the halogens having low fundamental frequencies, differences between electron or photon impact ionization potentials and those obtained by ultraviolet spectroscopy should be increasing, at least if there is an important modification of internuclear distance in the ion. This is indeed found experimentally.

Very few experimental data on vibrational quantum levels of ionic states of simple molecules are known. They have been summarized in Table I, where vibrational frequencies, ionization potentials, equilibrium distances, most probable ionization-calculated transitions, and most probable experimental values are given. Vibrational overlap integrals estimations, admitting the harmonic approximation, have been used for the calculated transition probabilities (3–6). It is interesting to compare the most probable theoretical transitions with those deduced from the experimental ionization potentials determined by mass spectrometry or photoionization:

In conclusion, it should be noted that the limiting factor with respect to the time required by the procedure is the rate of passage of the solvent through the silica gel column.

THE FRANCK–CONDON PRINCIPLE AND THE IONIZATION OF MOLECULES

JACQUES E. COLLIN

Ionization potentials obtained by electron impact or photon impact are generally discussed with reference to the Franck–Condon principle for both ground and ionic states concerned. By doing so it is admitted that the interaction time of the ionizing particle and the molecule, and the time necessary for the electron to leave the interested bond region of the molecule, were short, compared to the time of a complete vibration, considering only here diatomics.

In a recent paper, Stevenson (1) indicated that the particularly well-known case of hydrogen seemed to be in conflict with the Franck–Condon principle; this conclusion was based on a careful consideration of potential curves and observed ionization potentials. It was shown that, although the Franck–Condon principle would predict the highest probability for the transition to the vibrationally excited $v = 2$ state of the ion, the experimental data gave the 0–0 transition. This was later explained, thanks to the beautiful work of Marmet and Kerwin, who showed that it was mainly a matter of sensitivity of the detecting device (2).

The H—H bond being strong and the atoms light, the fundamental frequency is very high: 4276 cm^{-1}. This is thus a case where non-applicability of the Franck–Condon principle might be encountered, but Marmet and Kerwin's work lead to the theoretically expected relative cross sections for the 0–0, 0–1, 0–2 transitions.

In the case of heavier molecules, particularly the halogens having low fundamental frequencies, differences between electron or photon impact ionization potentials and those obtained by ultraviolet spectroscopy should be increasing, at least if there is an important modification of internuclear distance in the ion. This is indeed found experimentally.

Very few experimental data on vibrational quantum levels of ionic states of simple molecules are known. They have been summarized in Table I, where vibrational frequencies, ionization potentials, equilibrium distances, most probable ionization-calculated transitions, and most probable experimental values are given. Vibrational overlap integrals estimations, admitting the harmonic approximation, have been used for the calculated transition probabilities (3–6). It is interesting to compare the most probable theoretical transitions with those deduced from the experimental ionization potentials determined by mass spectrometry or photoionization:

	Vibrational transition probability		
	Theoretical	Lowest experimental	Most probable experimental
H_2	0–2	0–0	0–2
N_2	0–0	0–0	—
O_2	0–1	0–0	—
CO	0–0	0–0	—
NO	0–1	0–0	0–1
Cl_2	0–2	0–4	—

At first glance, the experimental and theoretical results coincide only in two cases: N_2 and CO. In one other case, Cl_2, one gets experimentally too high a value, and in three cases, O_2, H_2, NO, too low a value. The H_2 low value appears to correspond to the 0–0 transition, which has a non-negligible probability (4/10 of the most probable 0–2 transition), as Kerwin and Marmet have shown. A similar situation exists for NO and was examined by Cloutier and Schiff (4). For Cl_2, the discrepancy is serious and unexpected indeed. The 0–2 transition is theoretically the most probable, but the 0–0 transition is quite probable too (3/4 that for 0–2) and the same situation as in hydrogen is found. On the contrary the experimental evidence corresponds to a higher transition. The vibrational quantum is quite small ($0.081v$) however, and one or two vibrational jumps might have been missed, due to experimental errors, although the reproducibility of the measurements is good and the same results have been found by different authors. Thus simple application of the Franck–Condon principle appears difficult. It should be noted that the ionic state Cl_2^+ has an equilibrium distance considerably shorter than that for the molecular ground state, the difference being of the order of 5%.

For fluorine, the lack of experimental data on vibrational frequencies for ionic states does not allow a safe discussion. Assuming a variation similar to that for chlorine, however, it seems that the most probable transition is the 0–1 one.

The case of Br_2, as well as of I_2, is similar, but it becomes difficult to discuss the ionization potential differences, the vibrational quanta being of the order of magnitude of the thermal energy of the molecules. The experimental data, however, seem always to indicate a transition to a higher vibrationally excited state of the ion; apparently, as in Cl_2^+, the nuclear distance is shorter in the ion.

For the corresponding hydracids, the 0–0 transition appears to be the most probable, although, at least for HCl, the nuclear distance has undergone a variation of 3.5%. The spectroscopic ionization potential, however, is not very well known and the interpretation must be considered as tentative. For the variation of the distances in the ion, the following may be observed. In all cases where the 0–0 transition is observed and the ionic nuclear distance is known the variation in nuclear separation from the molecule to the ion is not greater than 3%. When there is a transition mainly to an excited vibrational state of the ion and when the nuclear distances are known, the variation of the latter has been found to be 30, 9, 8, and 4.5% respectively for H_2, O_2, NO, and Cl_2, the case of hydrogen being an extreme one. These facts may be used to estimate the nuclear distances in the molecular ions when no spectroscopic data are available, which is the case for F_2, Br_2, I_2, HF, HBr, and HI. It may be anticipated that in F_2^+, Br_2^+ (perhaps also I_2^+) the nuclear distance in the ion is considerably shorter than that in the molecule itself. On the contrary, in the acids HF, HBr, and HI, it may be expected that the nuclear distances are much the same in the molecule and in the molecular ion.

On the basis of experimental data, we also calculated the dissociation energies of the molecular ion, $D(A—B^+)$, and we obtained the values given in Table II.

TABLE II

Dissociation energies (kcal/mole)

	D(A—B)	$D(A—B)^{+}_{B^{+}}$	Transition
HF	135	158	0–0
HCl	102	108	0–0
HBr	87	93	0–0
HI	71	74–78	0–0
F_2	37	77	0–4 ?
Cl_2	57	97	0–2 or 0–4 ?
Br_2	45.4	83	0–4 ?
I_2	35.5	80	0–1

It is obvious that $D(A—B)^{+}_{B^{+}}$, leading to B^{+}, is much higher than D(A—B) in the halogens themselves, whereas for the hydracids, one gets very much the same value for both molecular and ionic states. This is precisely the case when the 0–0 transition is positively observed, as was expected since there must not be important changes in nuclear distances. On the contrary, for the halogens the considerable increase of the dissociation energy in the ion should result in a considerable shortening of the bond distance. It is then expected that the transition to vibrationally excited states will have a greater probability.

If one thus takes these considerations into account, it seems that the Franck–Condon principle is fairly well respected and discrepancies between accurately determined ionization potentials obtained by electron impact or photoionization and spectroscopic ionization potentials might be taken as a means of evaluating the modification of internuclear distances in the ions when no better means are available.

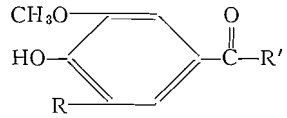
THE SYNTHESIS OF LIGNIN MODEL SUBSTANCES: 5-HYDROXYVANILLIN AND 5-HYDROXYACETOGUAIACONE

S. K. Banerjee, M. Manolopoulo, and J. M. Pepper

In connection with studies on the oxidation of lignin it became necessary to prepare various lignin model substances, one of which was 5-hydroxyvanillin (II).



(I) R = R′ = H (IV) R = H, R′ = CH_3

(II) R = OH, R′ = H (V) R = OH, R′ = CH_3

(III) R = I, R′ = H (VI) R = I, R′ = CH_3

An examination of the reported syntheses (1, 2, 3, 4) indicated that no simple method was available other than those requiring heated autoclaves. A study was made, therefore, of the most promising procedure, which involved the copper-catalyzed hydrolysis of 5-halovanillin. It was early shown that 5-iodovanillin (III) underwent reaction much more readily than either the 5-bromo- or 5-chloro-derivatives. A satisfactory synthesis of II could indeed be obtained under reflux conditions, thus avoiding the need for reactions under pressure as had been recommended by previous workers. Of importance was the recognition that both the effectiveness of the catalyst as well as the nature of the products obtained were markedly dependent on the particular copper that was used. The authors maintained that only if a reproducible catalyst could be described would a synthetic procedure be of real value. This desire was achieved by the discovery that the addition of cupric ions provided the necessary catalytic activity for this alkaline hydrolysis reaction.

A study of the ratio of reactants, and the time and temperature of the reaction, resulted in a procedure whereby complete conversion of 5-iodovanillin (III) was achieved. The major product was 5-hydroxyvanillin (II) but in all cases a minor amount of the reductive dehalogenation product, vanillin (I), was also formed. The separation and identification of these products was made using both paper and gas–liquid chromatography. Separation and purification of the required II was readily achieved by recrystallization from benzene. The yield of purified product was 65–70% based on III.

This ready conversion of vanillin to 5-hydroxyvanillin prompted the attempt to similarly convert another lignin oxidation product, acetoguaiacone (IV) (also known as acetovanillone), to the previously unreported 5-hydroxyacetoguaiacone (V). No difficulty was experienced in this synthesis. The only modification involved an increase in the time of reflux from 4.5 to 6.5 hours in order to convert all the 5-iodoacetoguaiacone (VI). As expected, the only other product to accompany the major product (V), but in much less amount, was the reductive dehalogenation compound, acetoguaiacone (IV). The structure of V was confirmed by analyses, absorption spectra, and conversion, by methylation, to the previously known 3,4,5-trimethoxyphenyl methyl ketone. The yield of recrystallized product was 45–50%.

A more complete discussion of the significance of the role of the copper catalyst and of the mechanism of formation of the products in such copper-catalyzed alkaline dehalogenation reactions is being prepared.

EXPERIMENTAL

Melting points are uncorrected. The infrared spectrum was measured using a Perkin–Elmer Model 21 instrument with sodium chloride optics.

Paper Chromatography

5-Hydroxyvanillin, vanillin, and 5-iodovanillin were separated by descending chromatography using Whatman No. 1 paper and the solvent system of *n*-butanol saturated with 2% ammonia. A saturated solution of 2,4-dinitrophenylhydrazine in 1 *N* hydrochloric acid was the spray reagent. For these compounds the R_f values were 0.38, 0.50, and 0.48 respectively.

Gas–Liquid Chromatography

A Beckman GC-2 chromatograph, with a thermal conductivity detector unit, was used after some modification to place the injection system as close as possible to one end of the column, and to make it more comparable electronically to the GC-2A. The column was made from 3 ft×1/4 in. I.D. copper tubing and packed with Apiezon N grease on Fluoropak 80 (Wilkens Instrument and Research Inc.) in the ratio of 3 to 17. The chromatographic separations were effected at 220° using 30 p.s.i. helium carrier gas at a flow rate of 0.9 cc/second. Under these conditions the retention times for vanillin, 5-hydroxyvanillin, and 5-iodovanillin were 2.25, 4.7, and 12.0 minutes respectively, and for acetoguaiacone, 5-hydroxyacetoguaiacone, and 5-iodoacetoguaiacone they were 3.0, 6.7, and 19.5 minutes respectively.

5-Hydroxyvanillin

5-Iodovanillin (2.8 g), hydrated cupric sulphate (1.6 g), and 4 *N* sodium hydroxide (76 ml) were refluxed (105°) for 4.5 hours with continuous stirring under nitrogen. After cooling to 60–70°, the mixture was filtered under suction and the residue washed with hot water (3×10 ml). The alkaline solution was cooled to 10° and acidified to pH 3–4, by the dropwise addition of concentrated hydrochloric acid. During this addition the mixture was stirred continuously and the temperature maintained below 25°.

The resulting mixture, which contained a small amount of precipitate, was extracted continuously with ether for 16 hours. After being dried over anhydrous magnesium sulphate, the ether was removed (60–65°) to leave a dark gray product, 1.5 g. All but 0.10 g was dissolved in hot benzene, from which, after concentration to 75 ml, 5-hydroxyvanillin crystallized (1.15 g, 68%), m.p. 128–129°. Recrystallization from benzene, with charcoaling, gave a chromatographically pure product, m.p. 133–134°; reported 132–134° (2). With the exception of traces of 5-hydroxyvanillin the mother liquors contained only vanillin as indicated by gas–liquid chromatography.

5-Hydroxyacetoguaiacone

5-Iodoacetoguaiacone (2.9 g) (5), hydrated copper sulphate (1.6 g), and 4 *N* sodium hydroxide (76 ml) were refluxed (105°) for 6.5 hours with continuous stirring under nitrogen. As a result of a procedure similar to that used for the isolation of II, an ether extract (1.3 g) was obtained. Of this, 0.3 g was sparingly soluble in boiling benzene but the remainder crystallized on cooling of the benzene solution to yield crude 5-hydroxyacetoguaiacone (0.8 g, 44%), m.p. 162–166°. A sample recrystallized from *n*-hexane–ethanol (5:1) melted at 166–167°. Calc. for $C_9H_{10}O_4$: C, 59.33; H, 5.53%. Found: C, 58.99; H, 5.64%. Infrared spectrum (KBr disk) (main peaks only): 3500–3300 (s), 1657 (m), 1600 (s), 1528 (m), 1470 (m), 1357 (s), 1320 (s), 1200 (s), 870 cm^{-1} (m). Methylation with alkaline dimethylsulphate gave 3,4,5-trimethoxyphenyl methyl ketone, m.p. 77–78°; mixed m.p. with an authentic sample, 77–78°. The infrared spectrum was identical with that of the authentic sample.

THE *p*-BROMOPHENYLOSAZONES OF 3- AND 5-*O*-METHYL-D-XYLOSE AND AN APPLICATION OF THIN-LAYER CHROMATOGRAPHY

D. A. Applegarth, G. G. S. Dutton, and Y. Tanaka

In connection with our study of the monomethyl ethers produced in the partial methylation of D-xylose diethyl dithioacetal (1) it was necessary to prepare crystalline derivatives of the 3- and 5-*O*-methyl ethers. The only derivative reported (2) for the latter compound is the *p*-bromophenylosazone and the preparation of this osazone from both ethers has been described by Levene and Raymond (3). These authors reported that 3-*O*-methyl-D-xylose *p*-bromophenylosazone melted at 153–155° C with darkening and softening at 142–143° and that 5-*O*-methyl-D-xylose *p*-bromophenylosazone melted at 170–171° C and had $[\alpha]_D$ $-50° \rightarrow -30°$ (24 hours). We are in agreement with the figures quoted but find that the data for the two isomers have inadvertently been transposed in the original article.

5-Hydroxyvanillin

5-Iodovanillin (2.8 g), hydrated cupric sulphate (1.6 g), and 4 *N* sodium hydroxide (76 ml) were refluxed (105°) for 4.5 hours with continuous stirring under nitrogen. After cooling to 60–70°, the mixture was filtered under suction and the residue washed with hot water (3×10 ml). The alkaline solution was cooled to 10° and acidified to pH 3–4, by the dropwise addition of concentrated hydrochloric acid. During this addition the mixture was stirred continuously and the temperature maintained below 25°.

The resulting mixture, which contained a small amount of precipitate, was extracted continuously with ether for 16 hours. After being dried over anhydrous magnesium sulphate, the ether was removed (60–65°) to leave a dark gray product, 1.5 g. All but 0.10 g was dissolved in hot benzene, from which, after concentration to 75 ml, 5-hydroxyvanillin crystallized (1.15 g, 68%), m.p. 128–129°. Recrystallization from benzene, with charcoaling, gave a chromatographically pure product, m.p. 133–134°; reported 132–134° (2). With the exception of traces of 5-hydroxyvanillin the mother liquors contained only vanillin as indicated by gas–liquid chromatography.

5-Hydroxyacetoguaiacone

5-Iodoacetoguaiacone (2.9 g) (5), hydrated copper sulphate (1.6 g), and 4 *N* sodium hydroxide (76 ml) were refluxed (105°) for 6.5 hours with continuous stirring under nitrogen. As a result of a procedure similar to that used for the isolation of II, an ether extract (1.3 g) was obtained. Of this, 0.3 g was sparingly soluble in boiling benzene but the remainder crystallized on cooling of the benzene solution to yield crude 5-hydroxyacetoguaiacone (0.8 g, 44%), m.p. 162–166°. A sample recrystallized from *n*-hexane–ethanol (5:1) melted at 166–167°. Calc. for $C_9H_{10}O_4$: C, 59.33; H, 5.53%. Found: C, 58.99; H, 5.64%. Infrared spectrum (KBr disk) (main peaks only): 3500–3300 (s), 1657 (m), 1600 (s), 1528 (m), 1470 (m), 1357 (s), 1320 (s), 1200 (s), 870 cm^{-1} (m). Methylation with alkaline dimethylsulphate gave 3,4,5-trimethoxyphenyl methyl ketone, m.p. 77–78°; mixed m.p. with an authentic sample, 77–78°. The infrared spectrum was identical with that of the authentic sample.

THE *p*-BROMOPHENYLOSAZONES OF 3- AND 5-*O*-METHYL-D-XYLOSE AND AN APPLICATION OF THIN-LAYER CHROMATOGRAPHY

D. A. Applegarth, G. G. S. Dutton, and Y. Tanaka

In connection with our study of the monomethyl ethers produced in the partial methylation of D-xylose diethyl dithioacetal (1) it was necessary to prepare crystalline derivatives of the 3- and 5-*O*-methyl ethers. The only derivative reported (2) for the latter compound is the *p*-bromophenylosazone and the preparation of this osazone from both ethers has been described by Levene and Raymond (3). These authors reported that 3-*O*-methyl-D-xylose *p*-bromophenylosazone melted at 153–155° C with darkening and softening at 142–143° and that 5-*O*-methyl-D-xylose *p*-bromophenylosazone melted at 170–171° C and had $[\alpha]_D$ $-50° \rightarrow -30°$ (24 hours). We are in agreement with the figures quoted but find that the data for the two isomers have inadvertently been transposed in the original article.

The formation of *p*-bromophenylosazones was found to be rapid; the relatively long heating periods used earlier (3) are disadvantageous, promoting tar formation. Thin-layer chromatography was found to be ideally suited to determining the optimum reaction conditions. A variety of sugars was tested, and it is concluded that a 5–10 minute reaction period of the free base and the sugar in acetic acid is optimal for preparation of these derivatives. It is likely that phenylhydrazine and other substituted phenylhydrazines behave similarly.

EXPERIMENTAL

3-O-Methyl-D-xylose

This was prepared from 3-*O*-methyl-1,2-*O*-isopropylidene-D-glucose by a reported procedure (4). The compound had m.p. and mixed m.p. 101° and $[\alpha]_D^{22}$ 16° with an R_f in butanone–water azeotrope of 0.23. *p*-Bromophenylhydrazine (85 mg) and 3-*O*-methyl-D-xylose (25 mg) were dissolved in glacial acetic acid (0.75 ml) and the solution diluted with water (0.5 ml). When the solution was heated on the steam bath for 5 minutes, then cooled to room temperature, a mass of orange-yellow crystals separated. After it was washed with aqueous acetic acid, the osazone was recrystallized from ethyl acetate – petroleum ether (30–60°). 3-*O*-Methyl-D-xylose *p*-bromophenylosazone had m.p. 174–175° and $[\alpha]_D^{23}$ −55° → −27° (*c*, 0.5 in pyridine–ethanol, 2:3) (24 hours). Anal. calc. for $C_{18}H_{20}N_4O_3Br_2$: C, 43.2; H, 4.0; N, 11.2%. Found: C, 43.44; H, 3.97; N, 11.0%.

5-O-Methyl-D-xylose

This was prepared from 3,5-anhydro-1,2-*O*-isopropylidene-D-xylose by reaction with sodium methoxide as previously described (3). 1,2-*O*-Isopropylidene-5-*O*-methyl-D-xylose (m.p. 85°) was hydrolyzed with sulphuric acid (1 *N*) on the steam bath for 1 hour and the solution deionized with Duolite A4 resin. Chromatographic examination of the resulting sirup showed four components having R_f values 0.32 (VS), 0.19 (W), 0.09 (W), and 0.04 (W). Separation on a cellulose–hydrocellulose column gave 5-*O*-methyl-D-xylose as a chromatographically pure sirup with R_f 0.32 in butanone–water. 5-*O*-Methyl-D-xylose (293 mg), *p*-bromophenylhydrazine hydrocloride (1.2 g), and anhydrous sodium acetate (0.5 g) were dissolved in water and the solution heated for 3 hours on the steam bath. On cooling, the *p*-bromophenylosazone was obtained in poor yield and was recrystallized from ethanol–water, m.p. 152–154° C with softening at about 140° C. When the osazone was purified on a column of florisil and recrystallized from benzene – petroleum ether (30–60°) the m.p. was 153–155° C.

General Procedure

p-Bromophenylosazones were prepared from the following representative sugars: D-glucose, D-galactose, D-mannose, D-xylose, L-arabinose, maltose, 3-*O*-methyl-D-glucose (5), 6-*O*-methyl-D-galactose (6), 3,4-di-*O*-methyl-L-xylose (7) as follows. The sugar (25 mg) and *p*-bromophenylhydrazine (85 mg) were dissolved in glacial acetic acid (0.75 ml) and the solution diluted with water (0.5 ml). The reaction mixture was heated on the steam bath and samples were spotted on a thin plate of silica gel with calcium sulphate binder (Camag. apparatus) at zero time, 5, 10 . . . minutes and the plates developed once in benzene–methanol (9:1 v/v) (about 40 minutes). Unchanged reagent, after aerial oxidation, showed as a brown spot having an R_f of about 0.75 and the *p*-bromophenylosazones as bright yellow spots. Approximate R_f values for the osazones were pentoses 0.10, hexoses 0.04, monomethylpentoses 0.24, monomethylhexoses 0.18, dimethylpentoses 0.29.

The derivative from maltose had R_f 0.00 and further heating gave a faster yellow component streaking to an R_f of 0.10, presumably due to hydrolysis.

Glucose and mannose formed a pale yellow precipitate in the cold and this was replaced by a bright yellow precipitate which separated from the hot solution. For other sugars it was necessary to cool the solution before the product separated. In all cases crystalline solids were obtained and although these were not further examined they were judged to be the *p*-bromophenylosazones from their color and chromatographic behavior.

ACKNOWLEDGMENTS

We gratefully acknowledge the financial support of The Research Corporation and the Pioneering Research Program of The Institute of Paper Chemistry. One of us (Y. T.) thanks the National Research Council for the award of a studentship and we are indebted to Mrs. A. Aldridge for the analyses.

SOME EXAMPLES OF THE USE OF OXYGEN AS A DIAGNOSTIC TEST FOR THE TRIPLET STATE IN CHEMICAL REACTIONS[1,2]

D. W. SETSER,[3] D. W. PLACZEK,[3] R. J. CVETANOVIĆ,[4] AND B. S. RABINOVITCH[4,5]

It is known that oxygen in the gas phase may remove triplet-state species and may do this by both chemical and physical quenching (1, 2). Indeed, it is commonly believed that oxygen interacts efficiently with the triplet-state molecules, as is definitely known in some cases (1–4), and has been used in photochemical systems as a diagnostic test (see, for example, ref. 5) for the presence of triplet-state species.

This note describes some experiments on the application of oxygen as a scavenger of triplet-state species. These are the excited molecules of some olefins and of cyclopropane produced by mercury photosensitization. Vibrationally excited lowest electronically excited triplet states of these molecules are presumably formed in these reactions. The results show that information of considerable value is gained by scavenging with oxygen, but a cautionary remark must also be made, namely, that even relatively very large amounts of oxygen should not be expected to scavenge triplet biradical intermediates in a manner comparable to the well-known efficiency of small amounts of oxygen for removing alkyl radicals and for inhibiting formation of their conventional products.

Isomerization of Cyclopropane

The $Hg(^3P_1)$ photosensitized geometric isomerization of cyclopropane-d_2 is believed to proceed via the formation of the triplet state (6). Added amounts of oxygen up to 14% (expt. *a*, *b*, *c*, Table I) have obviously not quenched reaction, particularly when cognizance is taken of the high relative quenching cross section of O_2 (7) (cyclopropane:O_2 = 1.1:13.2). The present result can be due simply to rapid internal conversion of the excited (isomerized) cyclopropane to the ground singlet state, or to similar collision-induced transitions in which the cyclopropane reactant, which is present in larger amount, acts preponderantly as the deactivating inert gas.

Isomerization of trans-Ethylene-d_2

The $Hg(^3P_1)$ photosensitized decomposition of ethylene-d_2 to acetylene (8) and its geometric and structural isomerization (9) is believed to proceed via the biradical triplet state and with collisional inert gas inhibition of the decomposition (8, 9).[6]

†Defined as the percentage loss of cyclopropane or of ethylene plus acetylene, as appropriate.
‡A decline of percentage polymerization with rise of total pressure is characteristic of the reaction even in the absence of oxygen (see ref. 6).
§Believed to be unreliable value.

The following scheme (9) is largely (10) adequate:

$$\text{trans} \xrightarrow{\text{Hg}(^3P_1)} T^* \longrightarrow \text{cis} + \text{trans}$$
$$T^* \xrightarrow{k_i} E^* \xrightarrow{k_M} \text{asym} + \text{cis} + \text{trans}$$
$$E^* \xrightarrow{k_s} A^* \xrightarrow{k_M} \text{acetylene} (+ H_2, \text{HD, or } D_2)$$

where T* is believed to be the T state of ethylene, E* is another triplet species such as ethylidine, and A* is a triplet acetylene product molecule.

The isomerization reactions are particularly useful: although added O_2 inhibits acetylene formation by quenching triplet intermediates by both physical or chemical (reaction) mechanisms, the cis and asymmetric isomerization products can be inhibited below normal yields only by chemical quenching and not by physical deactivation of the intermediate triplet states by the "inert" gas. In short, the rate laws for the formation of decomposition and isomerization products differ in their dependence on *total* quenching (11). However, if a triplet acetylene product is also chemically quenched by O_2 *after* formation, then all the products might behave similarly with respect to effects due to O_2.

In practice, low percentages of oxygen appear to have only negligible effect on decomposition and isomerization in this system (runs *d* and *e*, Table I). The experiments were

conducted in the manner previously described (6) with the following important modification. The light from the 2537 Å resonance lamp transmitted *through* the reaction cell (used in a constant-geometry arrangement) was monitored by a photomultiplier cell. The light intensity was constant and remained so during each run for all comparable series of pure ethylene and ethylene–O_2 experiments. This signifies that there was *no* mercury depletion by reaction with oxygen species such that *less* light was absorbed in the cell for O_2 runs. There was therefore a constant light energy input to the system for all runs of a series.

Polymerization (runs *f*, *g*, and *h*, Table I) is enhanced considerably (compare ref. 5) in the presence of high percentages of O_2 at high pressures. At least part of the polymerization may occur due to the presence of O_2^* or due to O-atom formation rather than, or in addition to, attack of O_2 on the triplet species. It is of interest to note, however, that very extensive isomerization is still found even at high percentages of oxygen (runs *i* and *j*, *k* and *l*), in amounts which, if not subjected to (or not accessible to) quantitative scrutiny, might (erroneously) lend themselves to the qualitative interpretation that O_2 has little effect and that reaction is somewhat reduced, mainly insofar as part of the excited mercury is quenched by O_2.

Runs *m* and *n*, and also *e*, *f*, and *g*, illustrate that the isomerization which is still found in the presence of O_2 does not apparently arise via an excited oxygen molecule or oxygen atom (12) catalysis process. Thus, all of the above results presumably signify an efficiency of less than unity for oxygen inhibition of triplet-intermediate processes in the sense that these are not extinguished by large proportions of O_2 in the way that alkyl radical products are by smaller amounts of O_2.

The most unequivocal data for quantitative interpretation of the role of O_2 were those obtained at lower pressures and summarized in Table II. The relative amounts of the decomposition and isomerization products are given in Table III, taking in each case

cis-$C_2H_2D_2$ as unity. Apart from the large experimental error, it is evident that the relative product fractions of asym, cis, and of acetylene are grossly unaltered by the

presence of O_2, relative to runs at the same total pressure of pure ethylene. This means either that chemical deactivation of T* and E* by O_2 cannot be occurring significantly, since the *cis-* plus *asym*-ethylene product percentages should then decline relatively, or that if cis and asymmetric production is inhibited by O_2 then the acetylene product A* is similarly destroyed. That the latter explanation is required is evident from Table II. The percentage difference of the normalized yields of products in the presence of oxygen from those obtained under comparable conditions with pure ethylene should be compared with the calculated maximum possible difference in the last column. The latter has been obtained by correcting for the quenching of the excited mercury atoms by O_2 (with use of the ratio 13:24[7] as a mean of several possible values for the relative quenching cross sections of O_2:C_2H_4) and assuming unit chemical quenching efficiency for O_2.

The comparison shows that O_2 has considerable efficiency per collision for inhibition of the formation of the products, i.e., for reaction with T*, E*, and A*. The data show large and apparently random error and fluctuations but the preceding conclusion seems justified.

The efficiency of ethylene for deactivation of the excited state has heretofore referred only to vibrational de-excitation (8, 9). The considerable chemical quenching efficiency of O_2 demands that ethylene be efficient for electronic de-excitation as well. Of course, all statements of efficiency are relative, only ethylene and O_2 being compared.

Isomerization of Butenes

A related finding is an isolated experiment wherein the $Hg(^3P_1)$ photosensitized isomerization of *cis*-butene-2 at 25° and 2 atm total pressure was not completely inhibited with 20% oxygen, although all characteristic radical products were eliminated.

In the $Hg(^3P_1)$ photosensitized isomerization of butene-1 (13), another triplet process, the addition of 6% of O_2 to the system reduced significantly, but did not completely inhibit, the isomerization to methylcyclopropane.

Conclusion

In the above reactions, there is good evidence for chemical removal of triplet-state molecules by O_2. A fact worth stressing, however, is that the mere presence of O_2, in amounts enormously greater than trace, does not necessarily completely inhibit reaction in these examples where triplet mechanisms are believed to occur. The inefficiency of oxygen in this respect may in large part be due to very fast competing unimolecular or collision-induced reactions of the excited species, and in part, depending upon circumstances, due to some inefficiency of chemical reaction of oxygen with triplet species. Since methyl radicals and nitric oxide, for example, are fairly inefficient (14) for recombination, this latter finding need not be considered exceptional in nature.

High Pressures and Product Yield

In the course of this work at high pressures, the authors reverted to very small reactors which were tubes of diameter 1 and 4 mm. In experiments with *trans*-ethylene-d_2, under conditions of constant vessel size and irradiation, it was found that although the yield of cis products was roughly constant from 0.2–1 atm (11), it declined markedly at pressures above 2 atm. The results in these vessels are interpreted to mean inefficient absorption of the resonance radiation at the higher pressure, due to line shift and pressure broadening (15). A similar result was also found with *cis*-butene-2 (1 atm) and added nitrogen,

[7]*This number is obtained by comparison with the original data on oxygen of Zemansky (7). Some confusion on the oxygen base, which exists in the literature, will be discussed by one of us (R. J. C., Progr. in Chem. Kinet., to be published).*

although in careful experiments with similar *cis*-butene-2 – N_2 mixtures, in a vessel of diameter 5 cm, no such decline occurred at nitrogen pressures up to 4 atm—as is reasonable in view of the longer light path.

We call attention to this difficulty as a reminder to others who may work at high pressure.

THE CHEMISTRY OF ALUMINUM–NITROGEN COMPOUNDS
III. THE STRUCTURE AND PYROLYSIS OF $Me_3Al{:}Me_2NN{=}NNMe_2$

NEIL R. FETTER, FREDERICK E. BRINCKMAN, JR.,* AND DONALD W. MOORE†

INTRODUCTION

In a survey of reactions between tetramethyltetrazene (TMT) and aluminum alkyls published recently (1) we reported a complex, for which elemental analysis implied the formula $Al(NMe_2)_3$. However, the physical properties of this material did not agree with those published by other authors (2, 3, 4).

Further study of the reaction between tetramethyltetrazene and trimethylaluminum has shown that $Al(NMe_2)_3$ is not formed, but rather the simple 1:1 adduct, $Me_3Al{:}Me_2NN{=}NNMe_2$, and the other products obtained, i.e. $Me_2Al{-}NMe_2$ and a red polymer do not arise from a second reaction route as proposed (1), but only from the decomposition of this adduct. Not only have $Me_2Al{-}NMe_2$ and red polymer been obtained from decomposition under mild conditions, but nitrogen, tetramethyltetrazene, and small quantities of methyl azide and methane were also obtained.

THE CHEMISTRY OF ALUMINUM–NITROGEN COMPOUNDS
III. THE STRUCTURE AND PYROLYSIS OF $Me_3Al{:}Me_2NN{=}NNMe_2$

NEIL R. FETTER, FREDERICK E. BRINCKMAN, JR.,* AND DONALD W. MOORE†

INTRODUCTION

In a survey of reactions between tetramethyltetrazene (TMT) and aluminum alkyls published recently (1) we reported a complex, for which elemental analysis implied the formula $Al(NMe_2)_3$. However, the physical properties of this material did not agree with those published by other authors (2, 3, 4).

Further study of the reaction between tetramethyltetrazene and trimethylaluminum has shown that $Al(NMe_2)_3$ is not formed, but rather the simple 1:1 adduct, $Me_3Al{:}Me_2NN{=}NNMe_2$, and the other products obtained, i.e. $Me_2Al{-}NMe_2$ and a red polymer do not arise from a second reaction route as proposed (1), but only from the decomposition of this adduct. Not only have $Me_2Al{-}NMe_2$ and red polymer been obtained from decomposition under mild conditions, but nitrogen, tetramethyltetrazene, and small quantities of methyl azide and methane were also obtained.

**Present address: Research and Development Department, U.S. Naval Propellant Plant, Indian Head, Maryland.*
†*Chemistry Division, U.S. Naval Ordnance Test Station, China Lake, California.*

The $Me_3Al{:}Me_2NN{=}NNMe_2$ adduct reacts quantitatively with trimethylamine to form $Me_3Al{:}NMe_3$ and the free tetramethyltetrazene; reaction with D_2O gives rise to the expected amount of CH_3D required for the $Al(CH_3)_2CH_3$ moiety. The proton resonance spectrum of the adduct shows that it is symmetrically bonded to the aluminum atom in a unique "cyclic" structure.

EXPERIMENTAL

Apparatus and Reagents

The apparatus and starting materials employed have been described previously (1, 5). The elemental analyses were performed by the Schwarzkopf Microanalytical Laboratory, Woodside, New York.

N.M.R. Spectra

The proton resonance spectra were obtained with a Varian Associates Model V-4302 Spectrometer at 60 Mc. The samples containing 10% by weight of benzene for internal reference purposes were vacuum sealed into 5-mm Pyrex tubes and maintained at −15° C before spectra were taken at room temperature.

Reaction of Tetramethyltetrazene with Trimethylaluminum at 25° C

By means of vacuum transfer, 2.78 g (24.0 mmoles) of tetramethyltetrazene was added to a 50-ml flask containing 1.71 g (23.8 mmoles) of Me_3Al dissolved in 25 ml of *n*-heptane. After transfer, the mixture was allowed to warm from −196° C to room temperature and it then stood at approximately 25° C for 36 hours. Apparently a period of 20 hours is required for completion of this reaction, for if the solvent is removed shortly after the mixture reaches room temperature, a violent explosion will follow. During this period the mixture acquired a faint yellow color. The solvent and any excess TMT were removed *in vacuo* and the remaining liquid vacuum transferred under high vacuum at room temperature. A −15° C cold finger was placed in the vacuum system to trap any $Me_2Al{-}NMe_2$ that formed and the collection flask was maintained at −78° C. Along with the liquid complex, 0.05 g of $Me_2Al{-}NMe_2$ and 0.48 g of red residue were obtained.

By raising the temperature of the collection flask to −30° C and pumping through a −196° C trap a trace of methyl azide, heptane, and TMT was also obtained. The methyl azide was characterized by comparison of the recovered gas with infrared spectrum of an authentic sample as published by Pierson, Fletcher, and Gantz (6).

Although the distilled complex was slightly yellow, a yield of approximately 80 mole% was obtained. By distilling it again under the conditions described above, a clear colorless liquid was obtained. This material turns slowly yellow at room temperature, but may be stored for at least 2 months at −10° C without discoloration. Because of its instability, elemental analysis of the complex is difficult; however, an analysis of a freshly distilled sample gave results which are in fair agreement with the empirical formula $Me_3Al{:}Me_2NN{=}NNMe_2$. Anal. Calc. for $C_7H_{21}N_4Al$: C, 44.65; H, 11.24; N, 29.76; Al, 14.32. Found: C, 41.32; H, 11.95; N, 27.13; Al, 13.93.

Reaction of $Me_3Al{:}Me_2NN{=}NNMe_2$ with Trimethylamine

In order to elucidate the analysis given above, 4.92 mmoles of trimethylamine was condensed on 0.407 g (2.16 mmoles) of $Me_3Al{:}Me_2NN{=}NNMe_2$ at −196° C. The mixture was allowed to warm to room temperature (25° C) and stand overnight. The reaction was quantitative* with the consumption of 2.5 mmoles of trimethylamine and the formation of white crystals. The crystals were vacuum sublimed at 50° C and the sublimate proved from its melting point (100–103° C) and infrared spectrum to be $Me_3Al{:}NMe_3$. Although some was lost during purification, approximately 0.2 g of TMT was recovered.

The reaction is then:

$$Me_3Al{:}Me_2NN{=}NNMe_2 + NMe_3 \xrightarrow{25^\circ\,C} Me_3Al{:}NMe_3 + Me_2NN{=}NNMe_2.$$

Reaction of $Me_3Al{:}Me_2NN{=}NNMe_2$ with Deuterium Oxide

Treatment of 0.514 g (3.23 mmoles) of $Me_3Al{:}Me_2NN{=}NNMe_2$ with an excess of D_2O resulted in evolution of a gas (213 cc STP) which proved to be CH_3D by infrared and mass spectrometric examination. These results indicate three aluminum–carbon bonds exist in the structural moiety $Al(CH_3)_2CH_3$ (Al/C: Calc. 1:3, found 1:2.94) and supports the 1:1 adduct structure.

**The slightly high value for the NMe_3 consumed (calc. 21 mmole) may be accounted for by the presence of TMT.*

Proton Resonance Studies of Me_3Al:$Me_2NN{=}NNMe_2$

The n.m.r. spectrum (Fig. 1) shows two sharp peaks in the ratio of approximately 4:3 and with chemica l shifts (in tau values) of 7.25 and 10.82 p.p.m. The larger, low-field peak represents all N-protons and the other all Al-protons. Weak lines representing decomposition products appear even in the freshly prepared material and increase with time at room temperature.

It should be noted that both N-methyl and Al-methyl chemical shifts are close to those of the uncomplexed compounds. The shift of TMT is 7.21 p.p.m. and Groenewage *et al.* (7) have reported a shift of 10.69 p.p.m. for the non-bridging methyls in trimethylaluminum dimer and 9.59 p.p.m. for the bridge methyls. The small difference between these values and those observed for the complex suggests only weak dative bonds between Me_3Al and TMT.

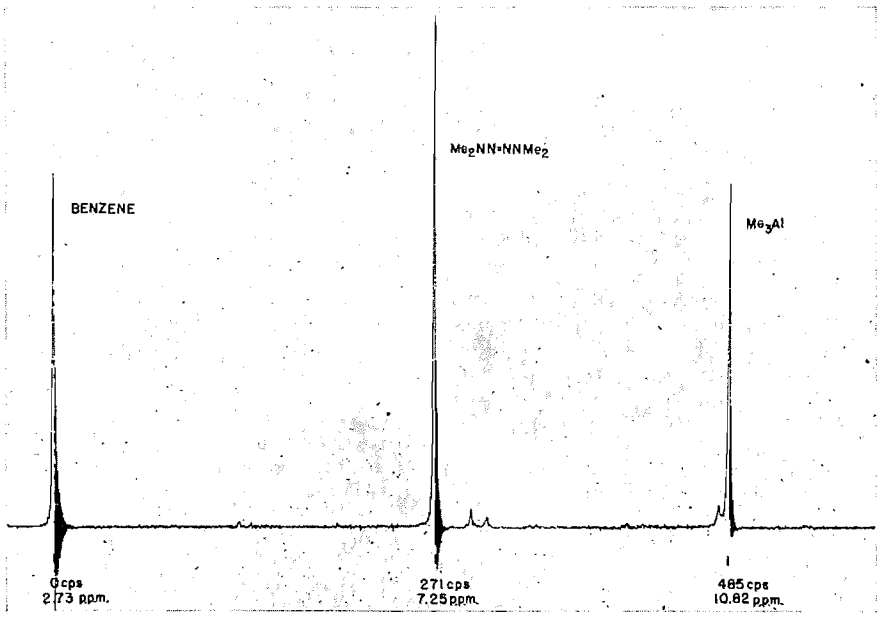

FIG. 1. N.M.R. spectrum of Me_3Al:$Me_2NN{=}NNMe_2$.

Pyrolysis of Me_3Al:$Me_2NN{=}NNMe_2$

To determine whether the compounds obtained in the reaction at 80° C resulted from the decomposition of Me_3Al:$Me_2NN{=}NNMe_2$ and not from an interaction of the starting materials and to obtain an exact mass balance of decomposition products, 0.416 g (2.21 mmoles) of the complex was heated under vacuum at 90° C for 18 hours. At the end of this period, gas evolution had ceased and the decomposition was assumed to be finished. In Table I are listed the quantities of materials obtained. The 0.050-g discrepancy between the starting weight of complex and the total recovered may be accounted for by the presence of a trace of stopcock grease in the flask containing the red residue.

TABLE I

Pyrolysis products of Me_3Al:$Me_2NN{=}NNMe_2$

Compound	g	Yield (wt. %)	mmoles
N_2	0.0835	20.0	2.88
CH_4	0.0045	1.1	0.28
CH_3N_2	0.0057	1.4	0.10
$Me_2NN{=}NNMe_2$	0.0620	14.8	0.54
$Me_2Al{-}NMe_2$	0.1195	28.8	1.09
Red polymer	0.1907	45.7	—
Total	0.4659		

DISCUSSION

It may be seen from the data presented above that the reaction scheme originally proposed for this reaction (1) does not proceed via multiple routes; instead, all of the

products obtained originate from the decomposition of an intermediate, $Me_3Al{:}Me_2NN{=}NNMe_2$. This complex is stable enough at room temperature that it may be purified by vacuum transfer but it must be maintained near $-10°$ C for prolonged storage. At room temperature the complex decomposes slowly over a period of weeks and at 90° C is 80% decomposed within an hour. In our first report of this reaction (1) a distillation temperature of 40° C was employed which was high enough to cause decomposition such that approximately equal amounts of $Me_3Al{:}Me_2NN{=}NNMe_2$, $Me_2Al{-}NMe_2$, and red polymer were recovered.

The two earlier elemental analyses (1) of the complex which agreed closely with the empirical formula for $Al(NMe_2)_3$ appear to have been fortuitous, i.e., the two samples had decomposed about the same degree before analysis. Even the freshly prepared sample, whose analysis is given above, has low nitrogen and carbon values, indicating some decomposition had occurred in the few days required to ship the sample to the analyst.

Subsequent analyses of the red polymer indicate that composition varies considerably and nothing can be said about its constitution at this point except that it contains hydrolyzable methyl groups, aluminum, and nitrogen. A sample of polymer was hydrolyzed with D_2O to see if $-AlCH_2Al-$ bonding was present; however, only CH_3D was obtained, indicating only terminal $Al{-}CH_3$ groups. Also, because the composition of the polymer is not known, it is difficult to fully elucidate the mechanism of pyrolysis.

However, the presence of methyl azide and $Me_2Al{-}NMe_2$, along with the proton resonance spectrum shown above, gives a clue to the structure of the complex. The n.m.r. spectrum of freshly prepared $Me_3Al{:}Me_2NN{=}NNMe_2$ is surprisingly simple with one peak at 7.25 p.p.m. upfield (benzene is taken as 2.73 p.p.m.) representing the protons on nitrogen methyl groups and another peak at 10.82 p.p.m. upfield representing the protons on aluminum methyl groups. The N-proton and Al-proton peaks are in the expected four to three ratio and their singularity indicates that N-protons are in an equivalent magnetic environment as are all Al-protons. It should also be noted that the molecular weight values (cryoscopic) of 193 and 199 obtained earlier (1) agree closely with that calculated for *monomeric* $Me_3Al{:}Me_2NN{=}NNMe_2$ (calc. 188.2).

Among the possible structures, Fig. 2 satisfies the n.m.r. data, and further, if asymmetric cleavage occurs, appears a reasonable precursor to the pyrolysis products $Me_2Al{-}NMe_2$ and methyl azide. Further work is in progress.

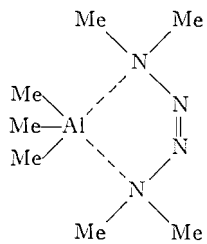

FIG. 2. Structural configuration of $Me_3Al{:}Me_2NN{=}NNMe_2$.

EXOCELLULAR BACTERIAL POLYSACCHARIDE FROM XANTHOMONAS CAMPESTRIS NRRL B-1459

PART II. LINKAGE OF THE PYRUVIC ACID

J. H. SLONEKER AND DANUTE G. ORENTAS

Recently it was reported that the polysaccharide produced by the bacterium *Xanthomonas campestris* NRRL B-1459 contains 3.0–3.5% pyruvic acid (1). Previously, the only other polysaccharide reported to contain pyruvic acid as a constituent was a commercial red seaweed agar, which is composed of D-galactose, 3,6-anhydro-L-galactose, and 1% pyruvic acid attached to D-galactose as a 4,6-*O*-(1-carboxyethylidene) group (2). Polysaccharide B-1459 contains, in addition to pyruvic acid, D-glucose, D-mannose, D-glucuronic acid, and acetyl in the ratio 2.8:3.0:2.0:1.7 (3). Experimental evidence presented here indicates that the pyruvic acid in polysaccharide B-1459 is attached to certain of the glucose residues also by a 4,6-*O*-(1-carboxyethylidene) linkage.

EXPERIMENTAL

In order to isolate a compound that contained pyruvate, the polysaccharide was degraded by the technique of periodate oxidation and sodium borohydride reduction, followed by mild acid hydrolysis (4). This procedure hydrolyzes the acetal bond of periodate-oxidized glycosides without apparent cleavage of the pyruvate bond.

A 1.5-g sample of polysaccharide B-1459, which had consumed 1.2 moles of sodium metaperiodate per sugar unit and had been reduced with sodium borohydride, was hydrolyzed in 1 *N* hydrochloric acid for 24 hours at room temperature. The neutralized hydrolyzate was fractionated on a Dowex 1-X4, 300-mesh acetate column (2×40 cm) by exponential gradient elution starting with 1500 ml of water in the mixing chamber and introducing 3 *N* acetic acid. A fraction was obtained between 2.90 and 3.25 liters of effluent that contained 50% of the pyruvic acid applied. The fraction was lyophilized to dryness and the residue was neutralized with saturated barium hydroxide. The barium salt, precipitated as a soft gel from 70% ethanol upon addition of acetone, formed a white amorphous powder when dried. Calc. for $(C_7H_{11}O_6)_2Ba$: C, 33.7%; H, 4.27%; Ba, 26.4%. Found: C, 33.1%; H, 4.77%; Ba, 26.2%. The compound was not oxidized by periodate even under strong oxidation conditions. However, upon acid hydrolysis (1 *N* hydrochloric acid for 3 hours at 100° C) it was degraded to pyruvic acid and erythritol as shown by paper chromatography. Quantitative analysis (1, 5) of these products revealed that they are in a 1:1 ratio.

RESULTS AND DISCUSSION

The combined evidence indicates that the compound isolated from polysaccharide B-1459 is the barium salt of 1,3-*O*-(1-carboxyethylidene)-erythritol (II). The infrared and nuclear magnetic resonance spectra support this structure. In potassium bromide the infrared spectrum displays strong carboxyl ion absorption bands at 6.2 and 7.1 μ. Also, two strong bands are present at 8.5 and 9.4 μ. These bands are reported to be

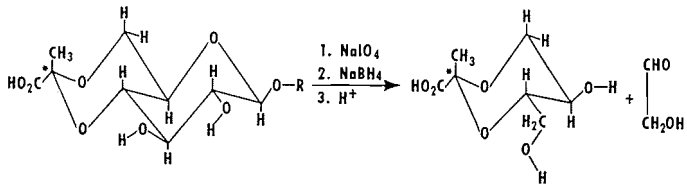
A fraction was obtained between 2.90 and 3.25 liters of effluent that contained 50% of the pyruvic acid applied. The fraction was lyophilized to dryness and the residue was neutralized with saturated barium hydroxide. The barium salt, precipitated as a soft gel from 70% ethanol upon addition of acetone, formed a white amorphous powder when dried. Calc. for $(C_7H_{11}O_6)_2Ba$: C, 33.7%; H, 4.27%; Ba, 26.4%. Found: C, 33.1%; H, 4.77%; Ba, 26.2%. The compound was not oxidized by periodate even under strong oxidation conditions. However, upon acid hydrolysis (1 *N* hydrochloric acid for 3 hours at 100° C) it was degraded to pyruvic acid and erythritol as shown by paper chromatography. Quantitative analysis (1, 5) of these products revealed that they are in a 1:1 ratio.

RESULTS AND DISCUSSION

The combined evidence indicates that the compound isolated from polysaccharide B-1459 is the barium salt of 1,3-*O*-(1-carboxyethylidene)-erythritol (II). The infrared and nuclear magnetic resonance spectra support this structure. In potassium bromide the infrared spectrum displays strong carboxyl ion absorption bands at 6.2 and 7.1 μ. Also, two strong bands are present at 8.5 and 9.4 μ. These bands are reported to be



(I) (II)

R = Polysaccharide main chain
* = Configuration unknown

characteristic of a cyclic structure containing a —C—O—C—O—C— group (6). The n.m.r. spectrum shows several hydrogen resonances: CH_3 at 86, —CH—O and —CH_2—O at 218 and 226, and —OH at 332 c.p.s. ($(CH_3)_3Si(CH_2)_3SO_3H$ reference).

The erythritol that formed on hydrolysis of periodate-oxidized borohydride-reduced polysaccharide B-1459 can be derived only from the glucose moiety (7). Therefore, since the isolated pyruvate is bound to erythritol, it must be bound to glucose originally in the intact polymer. The pyruvate ketal of erythritol (II) can then arise under the conditions described from a glucose residue bearing pyruvic acid as a 4,6-*O*-(1-carboxyethylidene) group (I) provided that glucose exists as a side-chain unit.

SYNTHESIS AND PROPERTIES OF HOMOTAURINE

N. P. Sen

In the course of recent investigations in this laboratory, it became necessary to prepare homotaurine. The methods used were similar to those employed by Marvel *et al.* (1) (method I), and by Cortese (2) (method II) for the synthesis of taurine. The first method involved the preparation of 3-bromo-1-propanesulphonic acid followed by its ammonolysis to homotaurine, while in the second method, 3-bromopropylamine hydrobromide was first prepared, and it was then converted to homotaurine according to reaction 1:

$$HOCH_2CH_2CH_2NH_2 + HBr \rightarrow BrCH_2CH_2CH_2NH_3Br,$$

Reaction 1

$$BrCH_2CH_2CH_2NH_3Br + Na_2SO_3 \rightarrow HO_3SCH_2CH_2CH_2NH_2 + 2NaBr.$$

SYNTHESIS AND PROPERTIES OF HOMOTAURINE

N. P. Sen

In the course of recent investigations in this laboratory, it became necessary to prepare homotaurine. The methods used were similar to those employed by Marvel *et al.* (1) (method I), and by Cortese (2) (method II) for the synthesis of taurine. The first method involved the preparation of 3-bromo-1-propanesulphonic acid followed by its ammonolysis to homotaurine, while in the second method, 3-bromopropylamine hydrobromide was first prepared, and it was then converted to homotaurine according to reaction 1:

$$HOCH_2CH_2CH_2NH_2 + HBr \rightarrow BrCH_2CH_2CH_2NH_3Br,$$

Reaction 1

$$BrCH_2CH_2CH_2NH_3Br + Na_2SO_3 \rightarrow HO_3SCH_2CH_2CH_2NH_2 + 2NaBr.$$

Both methods were found to work satisfactorily. However, since method I was not studied in detail, only method II will be described.

EXPERIMENTAL

3-Bromopropylamine hydrobromide.—Twenty-five grams (0.33 mole) of ice-cold 3-amino-1-propanol was added, through a dropping funnel, with vigorous stirring, to 175 ml (1.3 mole) of ice-cold hydrobromic acid in a 500-ml round-bottom flask. The flask was attached to a fractionating column and heated so that the solution refluxed with only a small portion of the liquid distilling off. This was continued for 16–18 hours, by which time about 125–130 ml of distillate had been collected and white fumes were starting to be given off. The distillation was discontinued at this point and the liquid was allowed to cool to about 70°. The hot mixture was poured into a beaker and 80 ml of acetone was added with stirring. The mixture was kept at 4° C overnight and the crystals of 3-bromopropylamine hydrobromide were collected on a filter and washed with acetone until colorless. The combined filtrate was concentrated under a vacuum and cooled, after it was seeded with a few crystals of the product. Thus, a second crop of the product was obtained. A third crop of less pure product could also be obtained. The total yield was 43.7 g (0.199 mole), 60.3% of the theoretical.

Homotaurine.—About 32.9 g (0.15 mole) of 3-bromopropylamine hydrobromide and 26 g (0.2 mole) of anhydrous sodium sulphite were dissolved in 95 ml of water. The mixture was concentrated on a hot plate (low heat) to a nearly dry cake; 24 hours were required for this operation. The residual cake was well triturated with 60 ml of concentrated HCl and the mixture filtered off on an asbestos mat. The solid on the mat was washed with ten 6-ml portions of concentrated HCl. The combined filtrate was concentrated to about 25 ml over a free flame. Then 95 ml of 95% ethanol was added to the hot solution with vigorous stirring and the mixture was allowed to cool. The precipitated crude product was filtered off. The crude product was dissolved in four times its weight of hot water, the water boiled with 1 g of Norite, the mixture filtered while hot, and the filtrate mixed with five volumes of 95% ethanol. When the filtrate was cooled, fine crystals of homotaurine were obtained. The product was filtered and dried in a vacuum desiccator. The total yield was 13.76 g (66%). The product gave only one ninhydrin spot on chromatographing in several solvents and had different R_f values than the chemicals from which it was synthesized. It decomposed at about 282–283° C. The product was found to be hygroscopic. Anal. Calc. for $C_3H_9O_3NS$: C, 25.86; H, 6.53; N, 10.00; S, 23.03. Found: C, 26.14; H, 6.61; N, 9.75; S, 23.24.

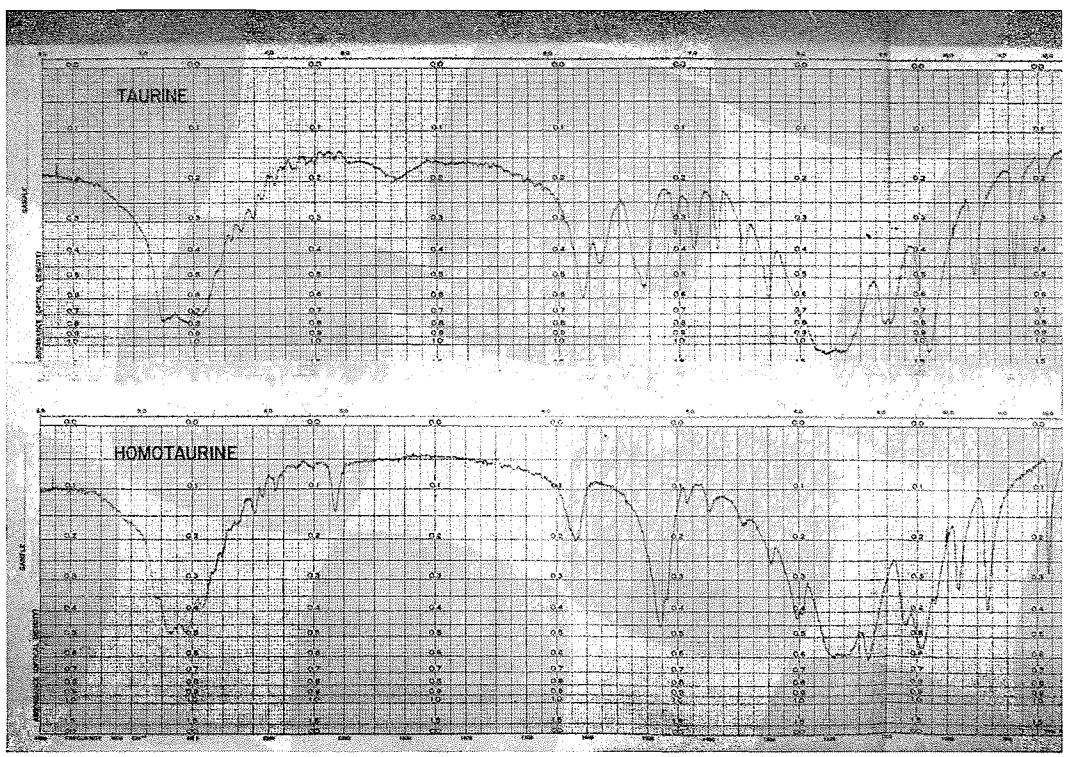

FIG. 1. Infrared spectra of taurine and homotaurine. KBr pellet.

Infrared spectra of taurine and homotaurine.—Figure 1 shows the infrared spectra of taurine and homotaurine. The series of low-intensity bands lying in the region from 3000–2400 cm^{-1} indicate the presence of an amino group. Two peaks near 1200–1160 cm^{-1} and 1050–1025 cm^{-1}, respectively, represent the presence of a sulphonic acid group.

Paper chromatography and paper electrophoresis of taurine and homotaurine.—Taurine and homotaurine, as indicated in Table I, have nearly identical R_f values in the solvent systems studied. Homotaurine can easily be distinguished from taurine, however, by paper electrophoresis, although the behavior of these two compounds is peculiar in a way. When 0.05 *N* NH_4OH (pH 10.95) solution was used as the electrolyte, taurine moved faster than homotaurine towards the anode. But when other basic solutions such as phosphate buffer and sodium hydroxide solution of the same pH, 10.95, were used these two compounds failed to separate from each other. On the other hand, use of a solution containing 0.001 equivalent of NaOH and 0.05 equivalent of NH_4OH per liter (final pH, 11.2) gave a clear separation of the two compounds. The results are noted in Table I. No. 3 Whatman paper was used as the supporting medium.

THERMAL DECOMPOSITION OF SODIUM AZIDE CRYSTALS

E. A. Secco*

A study of the kinetics of thermal decomposition of sodium azide single crystals recently carried out in this laboratory has revealed some novel results on the progress of decomposition through the crystal.

Single crystals, transparent and colorless, of sodium azide in the form of platelets were obtained by crystallization from aqueous solution. Technical grade sodium azide was dissolved in distilled water and filtered. The solution was saturated by slow evaporation at 45–50° C and allowed to cool slowly (3–4 hours) to room temperature. The crystals

**On leave of absence from St. Francis Xavier University, Antigonish, Nova Scotia, and holder of a NATO Overseas Fellowship.*

were recovered by filtration, dried, and stored in a desiccator with P_2O_5. These crystals had the *c*-axis parallel to the plane of the plate.

A single crystal of sodium azide was selected from the batch of crystals, weighed, and placed in a quartz bucket. The bucket, with the crystal, was suspended in a conventional vacuum system and degassed at room temperature. Under a final holding vacuum of 2×10^{-6} mm Hg the bucket was lowered into the furnace at the required temperature.

The progress of the reaction was followed with a Pirani gauge connected to a Fielden Servograph previously calibrated with a McLeod gauge. After a fraction of the crystal had decomposed, the crystal was withdrawn and examined with a microscope and photographed.

Figure 1 shows a photograph by reflected light of a crystal partially decomposed at 275° C in vacuum. It is evident that decomposition begins on preferred crystallographic faces and moves towards the center of the crystal. The relative rates of reaction on the various edges can be judged by the amount of white residue. The white residue is porous in structure and chemically identical with the original salt. The other significant features to be noted are the sharp purple line of demarcation at the undecomposed azide and white residue interface and the absence of reaction on the surface except for a few imperfect surface growths.

The experimental results for the rate of decomposition of NaN_3 crystals fall approximately into three temperature regions: (*a*) low temperature, below 300° C, where the rate follows, after a rapid initial stage (ca. 5%), a linear relation, leaving a white residue in the shape of the original crystal; curve I of Fig. 2; (*b*) medium temperature, 300–345° C,

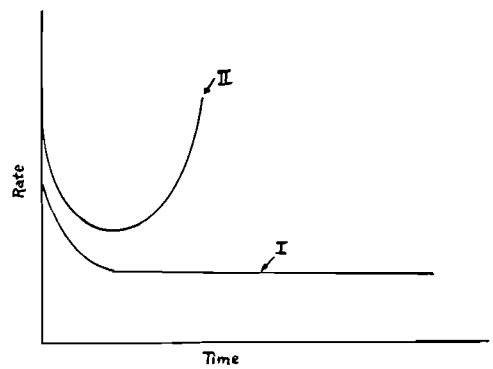

FIG. 2. Rate versus time curves at different temperatures.

where the rate is of the common sigmoid type, leaving a white residue; and finally (*c*) high temperature, above 350° C, where the decomposition follows two different linear rates, the latter being 100 times faster than the first, with no detectable residue; curve II of Fig. 2.

A more detailed account of this work will be reported later and these results will be discussed in the light of the early data on NaN_3 thermal decomposition (1) and the parallel case of ammonium perchlorate (2).

The author is indebted to the National Research Council of Canada for the award of a NATO Overseas Fellowship, to Dr. F. P. Bowden for providing laboratory facilities, and to Dr. A. Yoffe for helpful discussions.

THERMAL DECOMPOSITION OF MOLECULAR COMPLEXES

I. UREA–*n*-PARAFFIN INCLUSION COMPOUNDS[1]

H. G. MCADIE

Department of Chemistry, Ontario Research Foundation, Toronto, Ontario

Received July 16, 1962

ABSTRACT

The molecular complexes of urea and even-numbered *n*-paraffins up to C_{28} undergo thermal decomposition below the melting point of urea at temperatures which increase with the *n*-paraffin chain length. The decomposition is endothermal and is accompanied by changes in crystal structure, appearance, and by loss of the *n*-paraffin. Based on the enthalpy change a mechanism for the decomposition process is proposed.

The variety of molecular complexes now known provides the means for examining many molecules of different size and shape in an environment more or less isolated from others of their own kind. Within the canals which penetrate the structure of urea inclusion compounds, long-chain guest molecules are longitudinally isolated from one another by the canal walls but are permitted end-group interactions between successive chains, affording a means for comparing these interactions in different homologous series through their contribution to the thermal stability of the complex.

The decomposition of urea inclusion compounds at temperatures below the melting point of urea was first observed by Knight *et al.* (1) as a darkening of the normally translucent complex crystal when heated at a slow rate on a hot-stage microscope. The temperature at which darkening first occurred could be reproduced usually to $\pm 1.5°$ C provided optically suitable crystals were examined. For members of several homologous series the decomposition temperatures of the corresponding urea complexes were found to increase linearly with chain length up to about 18 carbon atoms. The thermal decomposition of the urea–*n*-paraffin series of complexes was not studied in this work, although a partial examination was made by Yata (2), who claimed values similar to those for the methyl esters reported by Knight. The decomposition of the even-numbered urea–*n*-paraffin complexes has been studied using differential thermal analysis (3–6), in which the samples were generally contaminated with free *n*-paraffin, and a discontinuity in the decomposition temperature – chain length curve was indicated in the vicinity of C_{18} to C_{20}. The present paper deals with the thermal decomposition of urea complexes of even-numbered *n*-paraffins in greater detail than previously, including an examination of the decomposition mechanism. Subsequent papers will describe the decomposition of other series of complexes in which there is increasing end-group interaction between successive guest molecules.

[1]*These results were presented in part at the 138th and 141st Meetings of the American Chemical Society.*

EXPERIMENTAL METHODS

Preparation of Complexes

The *n*-paraffins from C_{10} to C_{18} inclusive were fractionally distilled before use; C_{20}, C_{22}, and C_{28} were Eastman white label grade (or equivalent) used without further purification; C_{24} and C_{26} were research samples supplied by American Petroleum Institute Project 42. Other materials were reagent grade.

To prepare the complexes 5 g urea was dissolved in 20 g methanol, and 1 g *n*-paraffin added at room temperature. The mixture was warmed to 65° C and isopropanol added until the solution was homogeneous. On slow cooling crystallization of the complex was largely complete at temperatures above the melting point of the respective pure *n*-paraffin. The complex was filtered under suction and air-dried.

Visual Microscopy

The decomposition temperatures of the complexes were observed using polarized light and a calibrated Kofler micro hot-stage. The technique was similar to that of Knight *et al.* (1), a thin glass slide being substituted for the copper slide. A heating rate of 0.5° C min^{-1} was used to within 5° C of the decomposition temperature and reduced to 0.2° C min^{-1} thereafter. Results were generally reproducible to better than ±1° C over the multiple determinations made during a single heating period, provided careful selection of crystals was made initially. Slower heating rates did not improve this reproducibility. The average temperature at which opacity was first clearly distinguished was taken as the visual decomposition temperature, although the subjective evaluation of this point varied somewhat between operators.

X-Ray Diffraction

The presence of the hexagonal urea complex lattice was confirmed for all complexes by Debye–Scherrer powder patterns obtained using Cu $K\alpha$ radiation with a nickel filter.

Using a specially designed glancing-angle X-ray diffraction camera, containing a small copper block which could be held at a controlled temperature, it was possible to confirm the destruction of the hexagonal lattice at the decomposition temperature. A 0.5-mm lead-free glass capillary, open at one end, containing the complex was mounted on the copper block and a diffraction pattern obtained. It was then heated to a few degrees above the decomposition temperature and a second pattern obtained. The block was returned to room temperature before obtaining a final pattern.

Differential Thermal Analysis (DTA)

Part of this work was carried out on an instrument described earlier (7). Subsequently, a second instrument was constructed employing a horizontal furnace wound with 15-gauge Kanthal A wire, manually programmed by twin Variacs in series, and a palladium block having separate cavities for sample and reference material. The temperature of a thermal event was that of the block at that instant, measured on a calibrated potentiometric recorder. The differential temperature was sensed by a pair of Pt–Pt/13% Rh thermocouples amplified by a stabilized microvolt amplifier and displayed on a second recorder. Under normal operating conditions a sensitivity equivalent to 0.8 μv cm^{-1} of chart was used, although higher sensitivities were obtainable.

Samples were ground to pass a 325-mesh screen and diluted to 20% by weight in ignited α-alumina, which was also used as reference material.

Thermogravimetric Analysis (TGA)

A manually operated thermobalance was constructed from a standard analytical balance and a furnace of the same type as used in the DTA studies. The vertical core of this furnace was flushed with a preheated dry nitrogen stream at 50 cc min^{-1} and the appropriate buoyancy–temperature corrections made. A manually programmed heating rate of 1° C min^{-1} was used.

The sample holder was of the open-pan variety described by Garn and Kessler (8) with provision for measuring the pan temperature rather than that of the furnace. Approximately 0.3 g of −100 mesh complex was spread evenly over the pan to a depth of 2–3 mm. Weighings were made at 1° C intervals in sample block temperature.

RESULTS

Visual Decomposition Temperature

Average decomposition temperatures determined by the method of Knight *et al.* (1) are given in Table I together with the standard deviation in each case. Two sets of complexes were prepared, one of which was recrystallized from a methanol–isopropanol mixture containing a small amount of urea. The observed decomposition temperatures agreed within the standard deviation of a single sample so that recrystallization appears to have little effect on sample purity.

Although complexes decomposing above 120° C were increasingly difficult to observe

PLATE I

26	126.2±0.7	123	123.3±0.2	130.0±0.1
28	—	—	125.3	131.2

by this technique due to sublimation of the urea, a discontinuity was apparent in the C_{18} region, which is beyond the region of linear behavior of complexes previously studied by this method.

X-Ray Diffraction Studies

While X-ray diffraction techniques do not permit the distinction of individual complexes, the method does differentiate clearly between the hexagonal lattice of the complex and the normal tetragonal lattice of urea as shown in Fig. 1. No evidence of the tetragonal lattice could be detected in patterns of the complexes prior to decomposition.

After accounting for lines due to copper in the patterns obtained using the glancing-angle camera, the patterns obtained before heating were characteristic of the hexagonal lattice and those obtained after heating were characteristic of the tetragonal lattice. Thus the complex was confirmed to be destroyed at the observed transition temperature.

However, if the sample capillary was sealed prior to heating, the pattern above the decomposition temperature was again that of tetragonal urea, while on cooling the pattern slowly reverted to that of the hexagonal lattice, indicating re-formation of the complex under conditions where the *n*-paraffin could not escape. It was also noticed that there was an improved definition in the tetragonal urea pattern resulting after decomposition, suggesting that this material is in a finer state of subdivision than the complex from which it was formed and supporting earlier reports (1, 9) of increased surface area following complex decomposition.

Differential Thermal Analysis

The differential thermograms of a series of unrecrystallized complexes are shown in Fig. 2. The urea fusion endotherm provides a convenient internal calibration of each system with respect to temperature and to the enthalpy equivalence of peak area. A further indication of sample purity, beyond the absence of tetragonal urea lines in the diffraction patterns of the complexes, was the absence of any low-temperature phase transition and fusion endotherms such as were found with complexes contaminated with free *n*-paraffin (3–6).

The C_{10} complex, being somewhat unstable at room temperature, was partially decomposed during preparation of the DTA sample. At the longer chain lengths the complex decomposition endotherm became increasingly superimposed on the urea fusion endotherm and further resolution was unsuccessful.

The regular progression of the temperature of the complex decomposition endotherm

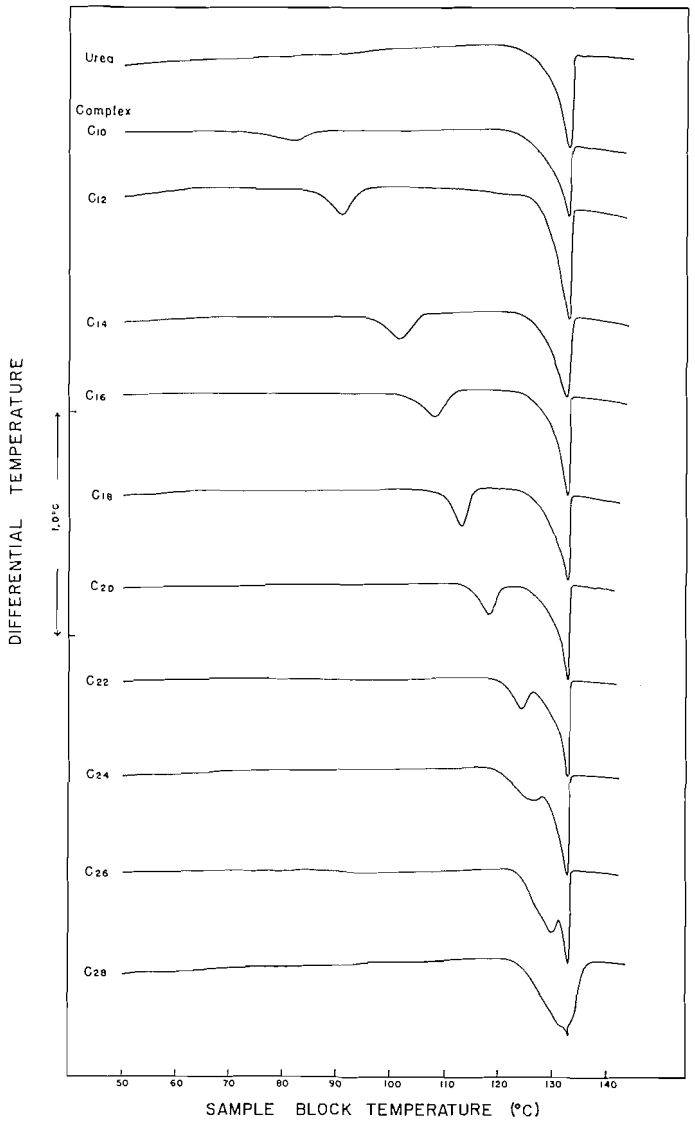

FIG. 2. Differential thermograms of urea and a series of urea–*n*-paraffin complexes.

with increasing chain length is given in Table I, again indicating the standard deviation over a series of samples of a given complex. The "incipient temperatures" were taken at the intersection of a projection of the thermogram base line with a projection of the low-temperature side of the endotherm (10). The discontinuity in the region of C_{18} is not as evident by this technique but, rather, a continuous curve is found asymptotically approaching the melting point of urea. In all cases temperatures were corrected to a value of 132.7° C for the peak of the urea fusion endotherm.

By comparison of the areas under the complex decomposition and urea fusion endotherms (Fig. 2), together with data on the ratio of urea to *n*-paraffin in the complex (11), and the heat of fusion of urea (12), an estimation of the heat of decomposition was made as follows:

$$\Delta H_d = m \cdot \frac{a_C}{a_U} \cdot \Delta H_f,$$

where

ΔH_d = heat of complex decomposition (kcal mole^{-1} *n*-paraffin),
m = molar ratio urea:*n*-paraffin,
a_C = area of complex decomposition peak,
a_U = area of urea fusion peak,
ΔH_f = heat of fusion (kcal mole^{-1} urea).

The results are given in Table II, and Fig. 3 shows a comparison with heats of reaction for three possible decomposition processes estimated from equilibrium data in the

20	23.5	26.6	68.7	4.52
22	29.6	29.6	75.4	4.55

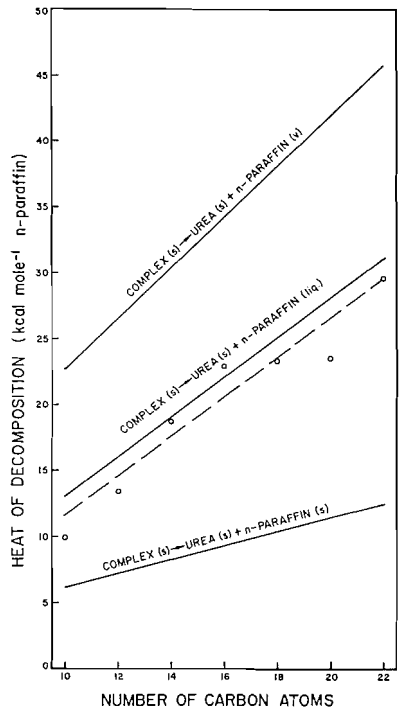

FIG. 3. Heat of decomposition of urea–*n*-paraffin complexes as a function of chain length. Solid lines represent data calculated from the literature; the broken line represents least-squares fit to experimental data (O).

literature (13–15). This comparison was possible only up to the C_{22} complex due to the extensive overlapping of the complex decomposition and urea fusion endotherms beyond this chain length. A least-squares fit of the experimental points indicates that the decomposition process is energetically equivalent to:

$$\text{complex (s)} = \text{urea (s)} + n\text{-paraffin (liq.)}.$$

An estimate of the entropy change accompanying decomposition, based on the observed enthalpy change at the transition temperature, is also shown in Table II.

Thermogravimetric Analysis

The loss in weight due to eventual vaporization of the *n*-paraffin after destruction of the complex made possible the study of this decomposition by TGA. Weight-loss curves are shown in Fig. 4, plotted as percentage of complex decomposition using an inverted ordinate so that decomposition in excess of 100% corresponds to degradation of the

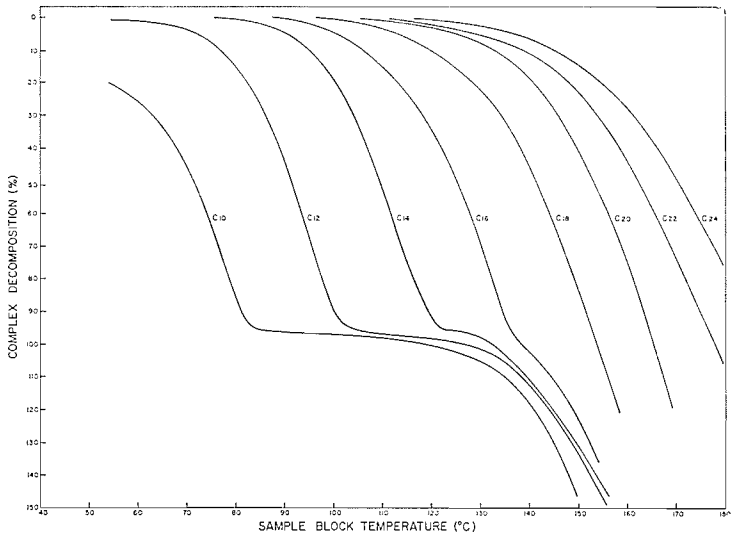

FIG. 4. Thermogravimetric analysis curves for a series of urea–*n*-paraffin complexes.

urea. At about 125° C urea begins to exhibit a measurable weight loss; consequently decomposition of the complexes above C_{16} could not be resolved into the two consecutive processes at a heating rate of 1° C min^{-1}. Decomposition temperatures, estimated at the point of incipient weight loss, appear in Table I. Due to urea degradation, decomposition temperatures determined by TGA reach essentially a constant value in the complexes of longer chain lengths.

DISCUSSION

It is evident that only "procedural decomposition temperatures" (16) have been determined in this work. Much of the variation in decomposition temperatures measured by different techniques is due to two factors: (i) sample environment and (ii) the point at which the decomposition process is observed.

Comparison of enthalpy changes involved (Fig. 3) indicates the decomposition process to be:

$$\text{complex (s)} = \text{urea (s)} + n\text{-paraffin (liq.)},$$

for which the equilibrium constant is $K = p/p_0$, where p is the decomposition pressure of the complex and p_0 the saturation vapor pressure of the pure n-paraffin. Although in none of the techniques used does a thermodynamic equilibrium exist, any factor which tends to alter p will also influence the decomposition temperature. In the cases of visual microscopy and TGA the sample is spread out as individual crystals or in a thin layer, respectively, so that the diffusion of liberated n-paraffin is relatively unimpeded. In DTA a narrow cylinder of compressed sample offers considerable impedence to diffusion of the large n-paraffin molecules and hence the decomposition temperatures are higher. Further, each technique observes a different stage of the decomposition process:

(i) TGA: the temperature at which continuous weight loss begins; sample is 1–2% decomposed;

(ii) visual: the temperature at which opacity is first clearly evident in the crystal, which is subjective, and the extent of decomposition will vary;

(iii) DTA: incipient temperatures probably correspond to about 5% decomposition; peak temperatures to 50–80% decomposition depending upon the reaction rate.

The combination of these factors tends to place the respective procedural decomposition temperatures in the observed relationship to one another.

The similarity in shape between the urea complex decomposition temperature curve and the melting point curve for the pure, even-numbered n-paraffins (Fig. 5), together with the observed enthalpy change during the decomposition process, support the suggested decomposition mechanism. Energetically (9, 11), the state of the n-paraffin chains

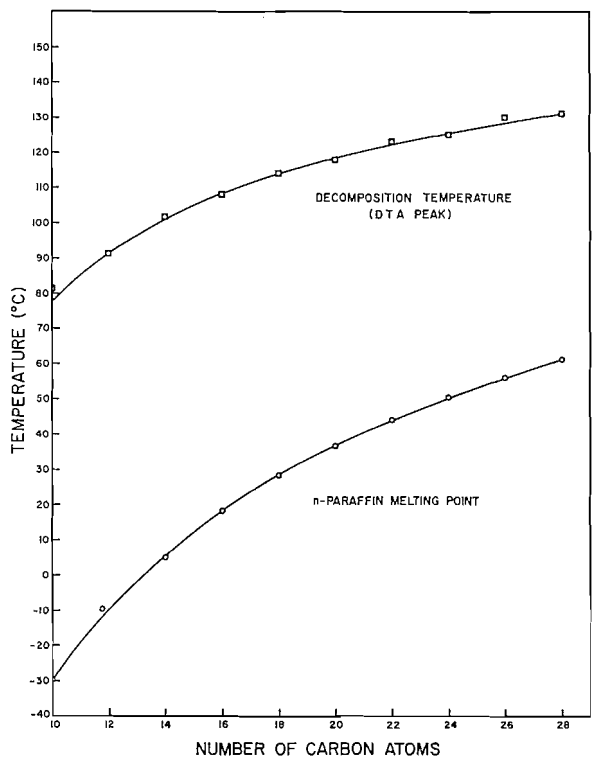

FIG. 5. Comparison of the decomposition temperature of urea–n-paraffin complexes and the melting points of pure n-paraffins as a function of chain length.

within the complex is similar to that in the pure solid. The bonds holding an *n*-paraffin molecule in the pure crystal lattice are associated with $(n-2)$ CH_2 groups, while the terminal CH_3 groups are repelled by the lattice (17). When the crystal melts, these $(n-2)$ intermolecular attractions must be broken by the potential of the terminal groups and the vibrational–rotational energy of the molecule as a whole. In the urea complex, the chain–chain interactions along the length of a chain are replaced by weak van der Waals interactions between the chain and the urea canal wall. These chains are in restricted motion within the canal (18) and it may be that once they acquire sufficient energy to permit substantially free rotation about the canal axis then the chain may escape. Unless its place is immediately filled by another chain, the hexagonal lattice cannot remain stable and rearranges to the tetragonal form.

The decomposition always occurs at a temperature above the melting point of the corresponding *n*-paraffin, which, therefore, emerges in a state energetically equivalent to that of the liquid and slowly vaporizes. This slow secondary vaporization is supported by the fact that the time required for loss of *n*-paraffin from a freely exposed decomposing sample is considerably greater than the time required for the completion of the enthalpy change even in the more confined DTA sample. The estimated entropy change accompanying decomposition *per mole of n-paraffin* increases rapidly with chain length, while the entropy change *per mole of urea* increases only slowly with chain length (Table II), indicating that it is largely associated with the transformation of the urea lattice resulting from removal of the *n*-paraffin chain.

These considerations of the decomposition mechanism apply for complexes which decompose at temperatures below the melting point of urea. Given a sufficiently long chain, the complex is stable up to the melting point of urea, at which temperature the urea cage simply melts, liberating the enclosed *n*-paraffin chain. As yet there is no definite evidence that urea in the hexagonal form will melt at a temperature measurably different from the melting point of urea in the tetragonal form.

ACKNOWLEDGMENTS

The writer wishes to acknowledge the kindness of Professor J. A. Dixon and the American Petroleum Institute Project 42 for supplying samples of *n*-C_{24} and *n*-C_{26}, and the technical assistance of T. J. Shannon and J. S. Haskill.

This work was carried out under a research grant to the Ontario Research Foundation from the Province of Ontario received through the Department of Economics and Development.

ABSTRACT

The extracellular polysaccharide isolated from cultures of *Xanthomonas oryzae* is composed of D-glucose (5 molecular proportions), D-glucuronic acid (2 molecular proportions), and D-mannose (5 molecular proportions). Acid hydrolysis of this polysaccharide, which contains 0.3% combined pyruvic acid, yields 2-*O*-β-D-glucopyranosyluronic acid D-mannose, which has been characterized as its crystalline fully methylated β-glycoside. Hydrolysis of the methylated polysaccharide gives 2,3,4,6-tetra-*O*-methyl-D-mannose (3 molecular proportions), 2,3,4-tri-*O*-methyl-D-glucuronic acid (1 molecular proportion), 2,3,6-tri-*O*-methyl-D-glucose (4 molecular proportions), 3,4,6-tri-*O*-methyl-D-mannose (2 molecular proportions), 2,6-di-*O*-methyl-D-glucose (3 molecular proportions), 2,3-di-*O*-methyl-D-glucose (1 molecular proportion). The polyalcohol derived from the polysaccharide by periodate oxidation followed by sodium borohydride reduction gives upon acid hydrolysis glycerol (2 molecular proportions), erythritol (1 molecular proportion), and D-glucose (1 molecular proportion). The general structural significance of these findings is discussed.

Xanthomonas oryzae (1) has long been known as a plant pathogenic microorganism responsible for the leaf blight disease of the rice plant (*Oryzae sativa*) in Japan and characterized by the fact that when growing on the natural host plant it is highly resistant to inhibitors. When this gram-negative organism was grown in a synthetic medium containing glucose or sucrose, under aerobic conditions, the medium became viscous due to the production of an extracellular polysaccharide which was composed of glucose, mannose, and glucuronic acid. After purification by copper hydroxide complex formation this acidic polysaccharide showed $[\alpha]_D$ −11° (in *N* NaOH) and had an equivalent weight of 988. Acid hydrolysis of the polysaccharide, which proceeded relatively slowly, was found to give rise to D-glucose (2.5 molecular proportions), D-mannose (2.7 molecular proportions), and D-glucuronic acid (1.0 molecular proportion), each of which was identified as the crystalline derivative.

Controlled acid hydrolysis furnished an aldobiouronic acid, 2-*O*-β-D-glucopyranosyluronic acid-D-mannose, recognized by its transformation into the characteristic crystalline methyl 2-*O*-[methyl (2,3,4-tri-*O*-methyl-β-D-glucosyl)uronate]-3,4,6-tri-*O*-methyl-D-mannoside (2).

Methylation of the *X. oryzae* polysaccharide first with methyl sulphate and sodium hydroxide and then with methyl iodide and silver oxide afforded a methylated derivative ($[\alpha]_D$ +44.5° ($CHCl_3$)). Hydrolysis of this methylated polysaccharide followed by column

*Paper No. 4875, Scientific Journal Series, Minnesota Agricultural Experiment Station, St. Paul 1, Minnesota.

chromatography (3) gave 2,3,4,6-tetra- (3 molecular proportions), 3,4,6-tri- (2 molecular proportions), and 3,4-di-*O*-methyl-D-mannose (2 molecular proportions); 2,3,6-tri- (4 molecular proportions) and 2,6-di-*O*-methyl-D-glucose (3 molecular proportions); and 2,3,4-tri- (1 molecular proportion) and 2,3-di-*O*-methyl-D-glucuronic acid (2 molecular proportions). Each of the above cleavage fragments was identified as a crystalline compound. In addition there was also produced approximately 1 molecular proportion of a mixture of 2- and 3-*O*-methyl-D-glucose, recognized only by paper electrophoresis.

The precise structure of the *X. oryzae* polysaccharide cannot be deduced from the data available so far but the general structural features of the polymer are apparent from the experimental findings. Inspection of the molar proportions of the cleavage fragments of the methylated polysaccharide (see Table I) shows that the molar ratio

TABLE I

Hydrolysis products of the methylated *Xanthomonas oryzae* polysaccharide

Component No.	Identity	Mol. props.	Structural feature indicated
1	2,3,4,6-Tetra-*O*-methyl-D-mannose	3	[D-Manp] 1 →
2	3,4,6-Tri-*O*-methyl-D-mannose	2	→ 2 [D-Manp] 1 →
3	2,3,6-Tri-*O*-methyl-D-glucose	4	→ 4 [D-Gp] 1 →
4	3,4-Di-*O*-methyl-D-mannose	2	→ 2, → 6 [D-Manp] 1 →
5	2,6-Di-*O*-methyl-D-glucose	3	→ 3, → 4 [D-Gp] 1 →
6	2,3,4-Tri-*O*-methyl-D-glucuronic acid	1	[D-GpA] 1 →
7	2,3-Di-*O*-methyl-D-glucuronic acid	2	→ 4 [D-GpA] 1 →

glucose:mannose:glucuronic acid is 2.3:2.3:1, a result in fairly good agreement with the corresponding ratio 2.5:2.7:1 calculated from the proportions of the glucose, mannose, and glucuronic acid formed by hydrolysis of the unmethylated polysaccharide. This deduction is in accord with the equivalent weight of 988 found for the polysaccharide, which corresponds to a repeating unit composed of one glucuronic acid residue and five hexose residues (calc. equiv. wt., 986). It seems reasonable to conclude from the above results that the molar ratio of glucuronic acid:glucose:mannose is approximately 1:2.5:2.5.

From the identity and proportions of the cleavage fragments of the methylated polysaccharide it is evident that the polymer possesses a highly branched structure. The exact proportions of the cleavage fragments of the methylated polysaccharide cannot be arrived at because the recovery (86% approx.) was not quantitative and also because of the formation of the mono-*O*-methyl glucose component, which for the present is regarded as an artifact probably derived from the 2,3,6-tri-*O*-methyl derivative and hence of no structural significance, since this would necessitate the formation of a much greater proportion of non-reducing terminal units than was actually encountered. Thus, for an average of about 17 to 18 sugar residues which make up the repeating unit of the polysaccharide there are 4 terminal non-reducing residues consisting of 3 units of mannose and 1 of glucuronic acid. There are also five residues, three of glucose and two of mannose, at which branching occurs in the polysaccharide. The remaining nine non-terminal

residues consist of two 1 → 2-linked mannose residues, five 1 → 4-linked glucose residues (this includes the mono-*O*-methyl fraction assumed to be derived from the 2,3,6-tri-*O*-methyl-D-glucose by demethylation), and two 1 → 4-linked glucuronic acid residues.

The identity of the components recorded in Table I coupled with the stability of the polysaccharide to acid hydrolysis show that all the building units in the polysaccharide are of the pyranose type. Moreover the negative specific optical rotation (−11°) of the polysaccharide indicates that many of the glycosidic bonds joining the sugar residues, all of which belong to the D-series, are of the β-type.

Support for these general structural features was furnished by periodate oxidation studies. Inspection of Table I will show that out of the repeating unit of 17 sugar residues consisting of (*a*) 3 terminal units of mannose and 1 of glucuronic acid, (*b*) 2 non-terminal units of mannose, 4 of glucose, and 2 of glucuronic acid, and (*c*) 2 branching units of mannose and 3 of glucose, only the 3 branching units of glucose, which give rise upon methylation and hydrolysis to 2,6-di-*O*-methyl-D-glucose (component 5), will be stable to periodate oxidation, whereas the remaining 14 will be cleaved.

Further consideration of the results in Table I will show that analysis of the polyalcohol, derived from the polysaccharide by periodate oxidation followed by reduction with sodium borohydride (4), should provide results in agreement with the following: (*a*) the erythritol must arise only from the 1 → 4-linked D-glucose units, (*b*) glycerol should be produced from the terminal, non-terminal, and also from the branching D-mannose residues, that is, from all the mannose building units, and (*c*) glucose surviving periodate cleavage should arise from the branching glucose residues joined through positions C_1, C_3, and C_4. Clearly, therefore, if the equimolar ratio of mannose to glucose as calculated from the compositional analysis is correct, then in the hydrolyzate of the *Xanthomonas* polyalcohol the sum of the molar proportions of erythritol and the molar proportions of periodate-stable glucose should be equal to the molar proportions of glycerol. This is borne out reasonably well by the experimental facts (see p. 2212).

The isolation, by graded acid hydrolysis of the polysaccharide, of an aldobiouronic acid composed of D-glucuronic acid joined to D-mannose by a 1 → 2-β linkage strongly suggests, if the repetitive structural feature of other polyuronides is generally applicable, that in the polysaccharide probably all of the units of glucuronic acid are joined to mannose residues in the same manner. Furthermore, the tentative identification of an aldotriouronic acid composed of 2-*O*-(β-D-glucopyranosyluronic acid)-D-mannose joined to a glucose residue indicates that some, although probably not all, of the aldobiouronic acid residues are joined to glucose in the following manner: D-GpA-(1 → 2)-D-Manp-(1 → 3 or 4)-D-Gp.

It is not yet possible to say whether the aldobiouronic acid residues constitute side chains directly attached to a glucomannan main chain or whether non-terminal 1 → 4-linked glucose units are interposed between the main chain and these aldobiouronic acid side chains but since three out of four terminal non-reducing units consist of mannose units it seems reasonably certain that two out of the three aldobiouronic acid side chains are terminated by mannose units, thus giving rise to the sequence D-Manp-(1 → 4)-D-GpA-(1 → 2)-D-Manp-(1 → 3 or 4)-D-Gp-1 →.

Structural deductions beyond this are not warranted until such time as oligosaccharides with and without glucuronic acid residues have been isolated. When these are forthcoming perhaps light will be thrown upon the unexpected property of this highly branched heteropolymer being insoluble in water, a property usually associated with either strictly linear character or repetitive and relatively simple side chains attached to linear chains.

The *X. oryzae* polysaccharide is similar to the extracellular polysaccharide derived from *Xanthomonas phaseoli* (5) and that from *Xanthomonas campestris* (6) inasmuch as they all contain D-glucose, D-mannose, and D-glucuronic acid. Another point of interest is that the polysaccharide from *X. oryzae* resembled that from *X. campestris* since both contained combined pyruvic acid, the former 0.3% and the latter 2.8 to 3.5% (7). Although the structural significance of the pyruvic acid in these polysaccharides is not yet understood, it appears to be present as a ketal group, as in the case of the red seaweed polysaccharides (8), since the pyruvic acid residues are removed by acid but not by alkali.

EXPERIMENTAL

All evaporations were carried out under reduced pressure at 40–50° C. Paper chromatography was performed by the descending method on filter paper (Whatman No. 1) using the following solvent systems: (A) 1-butanol:ethanol:water (4:1:5) (9), (B) ethyl acetate:pyridine:water (2.5:1:3.5) (10), (C) 1-butanol: acetic acid:water (2:1:1) (11), (D) butanone:water azeotrope (12).

Paper electrophoresis (13) was carried out on filter paper (Whatman No. 1) using 0.1 *M* borate buffer, 600 volts, for 3.5 hours. Chromatograms were sprayed with silver nitrate, *p*-anisidine trichloroacetic acid (11), or *p*-anisidine hydrochloride in 1-butanol saturated with water.

Production and Separation of Polysaccharide

The strain of *X. oryzae* was kindly provided by Dr. S. Matsunaka, National Institute of Agriculture, Tokyo, Japan. Preliminary experiments on cultural conditions showed that the following medium was suitable for polysaccharide production by the shaking flask culture technique: 3–5% glucose, 0.2% yeast extract (Difco), 0.1% L-glutamic acid, 0.2% $(NH_4)_2SO_4$, 0.07% Na_2HPO_4, 0.05% KH_2PO_4, 0.03% $MgSO_4$, and 0.1% NaCl (pH adjusted to 7.0 with NaOH). Each 400 ml of the medium was sterilized in a 2-l. Erlenmeyer flask for 30 minutes at 15 p.s.i., and inoculated with 20 ml of the preculture grown for 24 hours in the same medium at 25° C. The culture was mechanically shaken at 25° C for several days. Polysaccharide production proceeded smoothly, the cultural broth became viscous, and after 5 days no reducing sugars remained (tested with Fehling solution). At the end of this time, the broth (1.2 l.) was heated at 80° C to effect sterilization and clarified by centrifugation. The crude polysaccharide was precipitated by pouring the supernatant liquid into 3 volumes of ethanol. The polysaccharide was dissolved in water (200 ml), and the solution was centrifuged and treated with ethanol (3 vols.). The polysaccharide was then purified by copper hydroxide complex formation as follows: A solution of the polysaccharide in water (200 ml) was treated with Fehling solution (300 ml). The precipitated complex was collected (centrifuge) and washed repeatedly with 80% ethanol containing 4% hydrogen chloride until no more blue color remained in the precipitate.

The white precipitate thus obtained was washed successively with ethanol, diethyl ether, petroleum ether and dried *in vacuo* (yield 1.5 g or 5% based on the glucose present in the original culture medium).

The purified polysaccharide was a light fibrous material which showed $[\alpha]_D^{25}$ −11° in *N* sodium hydroxide (*c* 1.0). Whereas the crude polysaccharide precipitated directly with ethanol was soluble in water, the polysaccharide purified through its copper hydroxide complex and freed from salt was insoluble in water. Glass paper electrophoresis (14) showed that the polysaccharide was homogeneous.

When the polysaccharide was dissolved in sodium hydroxide (0.02 *N*) and dialyzed against water, the polysaccharide (salt form) was precipitated during the dialysis. These facts suggested that either the physical properties were changed during the purification process or the solubility of polysaccharide was greatly influenced by ions, especially OH^- ions.

Determination of the Equivalent Weight of the Polysaccharide

The purified and salt-free polysaccharide (67.2 mg) obtained by prolonged dialysis first against dilute sulphuric acid and then against water was dissolved in 0.01 *N* NaOH (20 ml) and the excess alkali was back-titrated with 0.01 *N* H_2SO_4. The result showed that the equivalent weight of the acidic polysaccharide was 988, which corresponded to 18.5% of glucuronic acid, or one unit of glucuronic acid for every five hexose units.

Hydrolysis of the Polysaccharide and Identification of the Components

The polysaccharide (120 mg) was hydrolyzed with *N* sulphuric acid in a sealed tube for 18 hours at 100° C. The solution was neutralized ($BaCO_3$), filtered, passed through Amberlite IR-120 (H^+ form) resin (1.5×10 cm), and evaporated to a sirup. Paper chromatography of this sirup using solvents A and B showed that the hydrolyzate contained glucose and mannose, a finding confirmed by paper electrophoresis. Chromatography (solvent C, time 35 hours) revealed the presence of glucuronolactone (R_{Rh} (mobility relative to that of L-rhamnose) 0.90), glucuronic acid (R_{Rh} 0.45), and an aldobiouronic acid (R_{Rh} 0.27) in addition to glucose and mannose.

Hydrolyzates of both the crude polysaccharide (precipitated from the cultural broth with ethanol) and the material purified through its copper hydroxide complex showed the same component sugars on paper chromatograms.

For identification of the component sugars, the hydrolyzate from the purified polysaccharide was passed through a column (1.5×10 cm) of Duolite A-4 (OH^- form) resin and the column was washed with water. The combined eluate and washing was evaporated to give a mixture of neutral sugars (86 mg). The anion column was then eluted with 0.2 *N* sodium hydroxide and the eluate was passed through Amberlite IR-120 (H^+ form). Evaporation of the acidic eluate gave a sirup which was found by paper chromatography (solvent C) to consist of glucuronic acid (10.2 mg) and aldobiouronic acid (8.1 mg).

Separation and Identification of the Neutral Components

A portion of the neutral fraction (25 mg) was subjected to paper electrophoresis. Each component was separated and freed from borate by treatment with 1% methanolic hydrogen chloride (13) followed by ion exchange resin. Evaporation of the solution in each case gave two sirupy components, D-glucose and D-mannose.

The glucose component (9.7 mg), which showed $[\alpha]_D^{25}$ +51° in water (*c*, 2.0), was treated with *p*-nitroaniline (15) in boiling methanolic hydrogen chloride (0.07%) for 15 minutes. This provided the *p*-nitroaniline derivative of D-glucose, which was recrystallized from methanol, m.p. and mixed m.p. 191–192° C (15).

The sirupy mannose component (11.9 mg), which showed $[\alpha]_D^{25}$ +14.4° in water (*c*, 3.0), was converted to D-mannose phenylhydrazone, in the usual way, m.p. and mixed m.p. 199–200° C (after recrystallization from ethanol) (16).

Identification of the Acidic Components

The D-glucuronic acid fraction (10.2 mg) was lactonized by heating for 1 hour at 80° C, and treated for 15 minutes with *p*-nitroaniline (10 mg) in boiling methanol (0.2 ml) containing hydrogen chloride (0.07%). Evaporation of the solvent afforded the crystalline *p*-nitroaniline derivative of D-glucuronolactone, which was recrystallized from methanol, m.p. and mixed m.p. 130° C (17).

Quantitative Determination of Component Sugars

For the quantitative determination of component sugars, the polysaccharide (45 mg) was completely hydrolyzed by heating (sealed tube) with 2 *N* sulphuric acid for 12 hours at 100° C. The D-glucose and D-mannose fractions were separated by paper electrophoresis, after previous passage of the hydrolyzate through an ion exchange resin as described above. Both sugars were determined colorimetrically by the phenol – sulphuric acid method (18), at 490 mμ, after previous removal of borate by treatment with methanolic hydrogen chloride (13). It was found that the molar ratio of D-mannose to D-glucose was 1.1:1.0. The D-glucuronic acid content was estimated by the carbazole method (19). Prior to the determination, partial hydrolysis of the polysaccharide (9.4 mg) was effected by treatment with 1.5 *N* sulphuric acid (1.5 ml) for 1 hour at 100° C in order to render the polysaccharide soluble. The hydrolyzate was diluted with water and an aliquot was used for the uronic acid determination. The polysaccharide contained 16.05% D-glucuronic acid, a result in fairly good agreement with that (18.5%) obtained by the titration method above. The lower figure obtained by the carbazole method may be due to decomposition caused by the pretreatment with acid. The molar ratio of the three components, D-glucose:D-mannose:D-glucuronic acid, was 2.5:2.7:1.0.

Isolation and Identification of 2-O-(β-D-Glucuronosyluronic acid)-D-mannose

The polysaccharide (800 mg) was refluxed with *N* sulphuric acid (40 ml) for 8 hours. The hydrolyzate was neutralized ($BaCO_3$), after which the neutral (580 mg) and acidic components (92 mg) were separated using ion exchange resins as described above.

Paper chromatographic separation of the acidic components so obtained using solvent C gave D-glucuronic acid (trace), an aldobiouronic acid (40 mg), an aldotriouronic acid (10.5 mg), and a trace of an unknown acidic oligosaccharide.

Identification of the Aldobiouronic Acid

The mobility of the aldobiouronic acid fraction on paper chromatography (R_{Rh} 0.275, solvent C) and on paper electrophoresis (M_g 0.82) coupled with its specific optical rotation, $[\alpha]_D^{25}$ −28.0° in water, showed that the aldobiouronic acid was probably 2-*O*-(β-D-glucuronic acid)-D-mannose, which has been isolated previously from the polysaccharide of *Brasenia schreberi* (20) and from *Virgilia oroboides* gum (2). Hydrolysis of the aldobiouronic acid with a cation exchange resin (IR-120, H^+ form) at 100° C, for 30 hours, followed by paper chromatography (solvents A and C) revealed the presence of D-glucuronolactone, D-glucuronic acid, D-mannose, and unchanged aldobiouronic acid.

Methylation of the Aldobiouronic Acid

The above aldobiouronic acid (40 mg) was dissolved in water (1 ml) and methylated with dimethyl sulphate (9 ml) and 30% (w/v) aqueous sodium hydroxide (25 ml) for 3 hours at 5° C and for 5 hours

at room temperature, thorough mixing being effected with a stream of nitrogen. The reaction mixture was heated for 20 minutes at 65° C, cooled (ice bath), and neutralized with 5 *N* sulphuric acid. Addition of ethanol (final concn. 60%) to precipitate sodium sulphate followed by filtration and evaporation of the solution gave a residue consisting of the partially methylated aldobiouronic acid and inorganic salts. The residue so obtained was subjected to a second methylation as before for 4 hours at room temperature and for 2.5 hours at 50–55° C. After acidifying the reaction mixture with 5 *N* H_2SO_4 the methylated product was extracted with chloroform (4×50 ml) (yield 35.3 mg). After a third methylation in the same way, the methylation of the aldobiouronic acid (25 mg) was completed with silver oxide (0.5 g) and methyl iodide (3 ml) under reflux for 10 hours. After evaporation of solvent, the residue was extracted with chloroform and the chloroform solution evaporated to a sirup. The sirup was dissolved in diethyl ether and the solution filtered to remove a trace of insoluble impurity. Slow evaporation of the solvent gave crystals of the fully methylated aldobiouronic acid (23 mg) which showed $[\alpha]_D^{25}$ −19° in methanol (*c*, 0.8) and had m.p. and mixed m.p. with an authentic specimen of methyl 2-*O*-[methyl (2,3,4-tri-*O*-methyl-β-D-glucosyl)uronate]-3,4,6-tri-*O*-methyl-D-mannoside 142–143° C (after recrystallization from a mixture of diethyl ether and petroleum ether (1:1)) (2).

Preparation of Amide

A portion of the above crystals was dissolved in methanol (2 ml) and the solution saturated with ammonia at 0° C. The reaction mixture was kept at room temperature overnight, and the solvent evaporated under reduced pressure. After the residue was dissolved in ethanol (0.5 ml) and diethyl ether and petroleum ether were added, there separated crystalline methyl 2-*O*-(2,3,4-tri-*O*-methyl-β-D-glucosyluronamide)-3,4,6-tri-*O*-methyl-D-mannoside (yield almost quantitative), which after recrystallization from a mixture of ethanol and diethyl ether had m.p. and mixed m.p. 186–187° C and $[\alpha]_D^{25}$ −64.4° in water (*c*, 0.9).

Examination of the Aldotriouronic Acid

This component (10.5 mg), judged to be an aldotriouronic acid from its mobility on chromatograms, *R* (aldobiouronic acid) 0.42, solvent C, showed $[\alpha]_D^{25}$ −4° in water (*c*, 2.5). Hydrolysis of this aldotriouronic acid with cation resin (IR-120, H^+ form) in water for 48 hours at 100° C gave D-mannose, D-glucose, aldobiouronic acid, and the original component, as revealed by chromatography.

It appears, therefore, that this fraction is an aldotriouronic acid, in which D-glucose is attached to 2-*O*-(β-D-glucopyranosyluronic acid)-D-mannose. The structure of this aldotriouronic acid remains to be determined.

The Presence of Pyruvic Acid in the Polysaccharide

In order to determine whether pyruvic acid was present in the polysaccharide as in the case of polysaccharides from some red seaweeds (8) and in *X. campestris* (7), the *X. oryzae* polysaccharide (500 mg) was hydrolyzed (7) with *N* sulphuric acid (20 ml) for 5 hours. After cooling, the solution was extracted with diethyl ether (5×100 ml). Evaporation of the diethyl ether gave a small residue which when examined by paper chromatography (solvent A) was found to contain a small proportion of pyruvic acid, detectable with a slightly alkaline bromphenol blue spray. The above residue was therefore dissolved in water (2 ml) and 0.5% 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid (2 ml) was added. The reaction mixture, which showed a little turbidity after 30 minutes, was extracted with ethyl acetate (5 ml). The ethyl acetate layer was then extracted with 10% aqueous sodium carbonate solution (3×5 ml). Determination of the absorption spectrum of the solution showed a characteristic selective absorption band at 375 mμ (21) identical with that for the 2,4-dinitrophenylhydrazone of pyruvic acid. Since this absorption band is relatively non-specific for either pyruvic acid (370 mμ) or α-ketoglutaric acid (380 mμ), according to Koepsell (21), a portion of the above 2,4-dinitrophenylhydrazone in alkaline solution was re-extracted with ethyl acetate and the extract examined by paper chromatography using solvent A. This revealed a yellow component (R_f 0.37) (22) corresponding to that of the 2,4-dinitrophenylhydrazone of pyruvic acid; an unidentified faint yellow component (R_f 0.55), possibly a stereoisomer (23), was also detected. Because of the minute amount of 2,4-dinitrophenylhydrazone of pyruvic acid available, recrystallization was impossible.

The colorimetric determination of what is believed to be pyruvic acid in the polysaccharide was performed by measuring the yellow color of the 2,4-dinitrophenylhydrazone in alkaline solution at 375 mμ. This showed that the polysaccharide contained 0.31% of pyruvic acid. Because of the small amount it is not yet known whether pyruvic acid is present as a significant structural feature of the polysaccharide or whether it is a metabolic "birthmark".

Methylation of the Xanthomonas oryzae Polysaccharide

Since acetylation of the polysaccharide was difficult because of its insolubility in either pyridine or formamide the polysaccharide was methylated directly by the usual Haworth method.

The polysaccharide (2 g) was dissolved in 30% sodium hydroxide (80 ml) and the thick solution was stirred mechanically during the dropwise addition of dimethyl sulphate (25 ml) for 4 hours at 40° C; a second addition of dimethyl sulphate (40 ml) and 30% sodium hydroxide was made during a further 3 hours at 55° C, after which the mixture was heated for 30 minutes at 90–100° C. After cooling, the reaction mixture was neutralized with 5 *N* sulphuric acid, whereupon the partially methylated polysaccharide

separated as a curd on the surface of the liquid. After removal of as much of the methylated product as possible, the reaction mixture was dialyzed against water for 3 days and then evaporated to dryness. The partially methylated product and the residue from the dialyzate were combined and retreated with dimethyl sulphate (45 ml) and sodium hydroxide (120 ml) at 55° C as before. After decomposition of the excess of the dimethyl sulphate by heating, the reaction mixture was cooled, neutralized with dilute sulphuric acid, and treated with ethanol (final concn. 50% v/v). The precipitated salts were filtered and washed with 50% aqueous ethanol. Evaporation of the filtrate gave a residue which was dissolved in 80% aqueous 1,4-dioxane (30 ml) and methylated with dimethyl sulphate (45 ml) and 30% sodium hydroxide (110 ml). A slight excess of dilute sulphuric acid was added to the reaction mixture and the solution was extracted with chloroform (3×300 ml). The combined chloroform extracts were dried ($MgSO_4$), evaporated, and the residue again treated with dimethyl sulphate and 30% sodium hydroxide as before. The methylated product obtained in this manner was subjected to two treatments with Purdie reagents in the usual way using methyl iodide (30 ml) and silver oxide (3 g). The resulting fully methylated polysaccharide was dissolved in chloroform (10 ml) and precipitated by adding excess petroleum ether (60 ml). Yield 1.4 g, $[\alpha]_D^{25}$ +44.5° in chloroform (*c*, 1.8); found: OCH_3, 41.1%.

Hydrolysis of the Methylated Polysaccharide

A solution of the methylated polysaccharide (543 mg) in 3.7% methanolic hydrogen chloride (25 ml) was refluxed for 15 hours. The solution was neutralized (Ag_2CO_3), filtered, and evaporated. The mixture of methylated methyl glycosides was then hydrolyzed by heating with *N* sulphuric acid (20 ml) for 24 hours at 100° C; the solution was neutralized ($BaCO_3$), filtered, and evaporated to a dry residue (335 mg). Paper chromatography using solvents A and D revealed five components which corresponded to tetra-*O*-methylhexose (glucose or mannose), tri-*O*-methylhexose (glucose or mannose), 3,4-di-*O*-methylmannose, 2,6-di-*O*-methylglucose, and a mono-*O*-methylhexose, and one component (pink color with *p*-anisidine) remaining at the starting line which appeared to be a uronic acid derivative. The hydrolyzate was dissolved in water (20 ml) and passed first through an IR-120 (H^+ form) column (1×10 cm), then through a Duolite A-4 (OH^- form) column (1×10 cm). The eluate was evaporated to give the neutral methylated sugars as a sirup (yield, 261 mg). The acidic sugars were eluted from the anion column with dilute sodium hydroxide (see below).

Separation and Identification of Methyl Sugar Components

Neutral Components

The above mixture of the neutral sugars (260 mg) was dissolved in solvent D (1 ml) and put on the cellulose–hydrocellulose column (3) (3.5×38 cm) and fractionated with solvent D using an automatic fraction collector adjusted to collect 11 ml/20 min. Examination of the fractions of the eluate by paper chromatography gave the results in Table II.

TABLE II

Cleavage fragments of the methylated *Xanthomonas oryzae* polysaccharide

Fraction	Tube No.	Yield (mg)	Components
1	7–22	50.6	2,3,4,6-Tetra-*O*-methyl-D-mannose
2	27–32	13.2	3,4,6-Tri-*O*-methyl-D-mannose
3*	33–37	22.8	3,4,6-Tri-*O*-methyl-D-mannose (18.5 mg) 2,3,6-Tri-*O*-methyl-D-glucose (4.3 mg)
4	38–50	53.5	2,3,6-Tri-*O*-methyl-D-glucose
5	80–113	28.8	3,4-Di-*O*-methyl-D-mannose
6	145–200	40.3	2,6-Di-*O*-methyl-D-glucose
7†		13.7	2- and 3-*O*-Methyl-D-glucose
	Total	222.9	

*Quantitative separation on paper electrophoresis indicated that this fraction consisted of 18.5 mg of 3,4,6-tri-*O*-methyl-D-mannose and 4.3 mg of 2,3,6-tri-*O*-methyl-D-glucose.
†Eluted with 500 ml of solvent D:methanol (4:1).

Identification of 2,3,4,6-tetra-O-methyl-D-mannose.—Fraction 1 (50.6 mg), which was chromatographically identical with 2,3,4,6-tetra-*O*-methyl-D-glucose or -mannose (R_f 0.78, solvent D), showed $[\alpha]_D^{25}$ +12° in water (*c*, 1.5). A portion (23.4 mg) was heated with aniline (100 mg) in absolute ethanol (1 ml) for 6 hours under reflux. The solvent and excess aniline were evaporated *in vacuo*, giving a crystalline product (30 mg). Recrystallization from ethanol – diethyl ether gave *N*-phenyl 2,3,4,6-tetra-*O*-methyl-D-mannosylamine, m.p. and mixed m.p. 145–146° C, $[\alpha]_D^{25}$ −8° equilibrium value in methanol (*c*, 1.0) (24, 25).

Identification of 3,4,6-tri-O-methyl-D-mannose.—Fraction 2 (13.2 mg) showed a slightly higher R_f (0.58 in solvent D) on a paper chromatogram than fraction 4 (R_f 0.56) and a slightly different color with the *p*-anisidine spray reagent. Paper electrophoresis showed that fraction 2 consisted largely of 3,4,6-tri-*O*-

methyl-D-mannose (M_g 0.24) together with a trace of 2,3,6-tri-*O*-methyl-D-glucose (M_g 0.0). Upon nucleation with 3,4,6-tri-*O*-methyl-D-mannose fraction 2 crystallized immediately and after recrystallization from diethyl ether had m.p. and mixed m.p. 103–104° C, $[\alpha]_D^{25}$ +10° equilibrium value in water (*c*, 2.0) (25).

Identification of 2,3,6-tri-O-methyl-D-glucose.—Fraction 4 (53.5 mg), which corresponded to 2,3,6-tri-*O*-methyl-D-glucose, showed $[\alpha]_D^{25}$ +65° in water (*c*, 1.0), and R_f 0.56 (in solvent D). Paper electrophoresis showed that this fraction consisted mostly of 2,3,6-tri-*O*-methyl-D-glucose (M_g 0.0) with a trace of 3,4,6-tri-*O*-methyl-D-mannose (M_g 0.24). Upon standing at room temperature, fraction 4 crystallized slowly and after recrystallization from diethyl ether the 2,3,6-tri-*O*-methyl-D-glucose had m.p. and mixed m.p. 120–121° C (26).

A portion of the above material (20 mg), treated with *p*-nitrobenzoyl chloride (200 mg) in dry pyridine (2 ml) in the usual way, gave the characteristic di-*p*-nitrobenzoate, m.p. and mixed m.p. 190–191° C, $[\alpha]_D^{25}$ −34° in chloroform (*c*, 1.0) (27).

Identification of 3,4-di-O-methyl-D-mannose.—Fraction 5 (28.8 mg), which crystallized spontaneously, had R_f 0.32 (solvent D) and M_g 0.34 and corresponded to 3,4-di-*O*-methyl-D-mannose. After recrystallization from ethanol–ether, the 3,4-di-*O*-methyl-D-mannose had m.p. and mixed m.p. 80–81° C, $[\alpha]_D^{25}$ +5.4°, equilibrium value in water (*c*, 3.7) (28).

Identification of 2,6-di-O-methyl-D-glucose.—Fraction 6 (40.3 mg), which failed to crystallize, showed $[\alpha]_D^{25}$ +66° in water (*c*, 1.7) and R_f 0.18 (solvent D), corresponding to di-*O*-methyl-D-glucose. By paper electrophoresis, the migration (M_g 0.24) and color reaction with *p*-anisidine were identical with those of 2,6-di-*O*-methyl-D-glucose but differed from those shown by the 2,3-, 2,4-, and the 4,6-di-*O*-methyl derivatives. A portion of this sirup (6 mg) was dissolved in dry pyridine (2.5 ml), and *p*-phenylazobenzoyl chloride (150 mg) was added, and the mixture was kept for 48 hours at 40° C. The excess reagent was decomposed by addition of water and the mixture was evaporated to dryness. The residue was triturated with chloroform (10 ml) and filtered. The filtrate was passed through a zinc carbonate column (1×15 cm) under pressure. The column was washed with chloroform and the eluate was evaporated to a sirup. Trituration of this sirup with ethyl acetate afforded a crystalline azobenzoate derivative (22 mg), which was recrystallized from a mixture of ethyl acetate and petroleum ether, m.p. 210–211° C, undepressed upon mixture with authentic 1,3,4-tri-*O*-*p*-phenylazobenzoyl-2,6-di-*O*-methyl-D-glucose, and $[\alpha]_D^{25}$ −333° in chloroform (*c*, 0.5) (29).

Examination of the mono-O-methyl-D-glucose fraction.—After fraction 6 had emerged from the column, fraction 7 (13.7 mg) was eluted with solvent D containing 20% methanol (500 ml). Paper chromatography showed that this fraction was composed of a single component, R_f 0.07 (solvent D), which corresponded to mono-*O*-methyl-D-glucose, whereas paper electrophoresis revealed at least two components, one corresponding to 2-*O*-methyl-D-glucose (M_g 0.24) and the other to 3-*O*-methyl-D-glucose (M_g 0.60). There were not sufficient amounts of either of these materials for complete identification.

Acidic Components

After separation of the neutral sugar components, the acidic components adsorbed on Duolite A-4 column were eluted with 0.2 *N* sodium hydroxide (200 ml) and the eluate passed through an IR-120 (H^+ form) column (1×10 cm). The acidic eluate was evaporated to a sirup (yield 52 mg). On a paper chromatogram using solvent C, two pink spots (with *p*-anisidine spray reagent) were revealed, corresponding respectively to 2,3,4-tri-*O*-methyl-D-glucuronic acid (R_f 0.65) and 2,3-di-*O*-methyl-D-glucuronic acid (R_f 0.48). A slow-moving spot (R_f 0.30–0.33), probably a methylated aldobiouronic acid, was also detected. A portion (25 mg) of the above sirup was separated by paper chromatography (solvent C), giving 2,3,4-tri-*O*-methyl-D-glucuronic acid (6.0 mg) and 2,3-di-*O*-methyl-D-glucuronic acid (9.0 mg).

Identification of 2,3,4-tri-O-methyl-D-glucuronic acid.—The tri-*O*-methyluronic acid fraction was heated with methanolic hydrogen chloride (2.5%) for 12 hours under reflux, neutralized (Ag_2CO_3), and freed from solvent. Treatment of the sirupy residue with methanolic ammonia afforded crystalline methyl 2,3,4-tri-*O*-methyl-α-D-glucosiduronamide, m.p. and mixed m.p. 183° C (30).

Identification of 2,3-di-O-methyl-D-glucuronic acid.—The di-*O*-methyl-D-glucuronic acid fraction was treated with methanolic hydrogen chloride as described above and the product (4 mg) so formed was dissolved in ethanol (0.2 ml) containing freshly distilled phenylhydrazine (2 mg). The solution was heated for 20 minutes at about 80° C, after which the solvent was allowed to evaporate. The residue was heated for 8 hours at 110° C, after which the reaction mixture was extracted by refluxing with diethyl ether. Upon evaporation of the solvent a crystalline phenylhydrazide was formed. Recrystallization from acetone–petroleum ether gave the phenylhydrazide of methyl 2,3-di-*O*-methyl-D-glucosiduronic acid, m.p. and mixed m.p. 219–220° C (31).

Quantitative separation by paper chromatography and weighing of the two components showed that the molar ratio of 2,3,4-tri-*O*-methyl-D-glucuronic acid to 2,3-di-*O*-methyl-D-glucuronic acid was 1:1.7.

Periodate Oxidation and Reduction of the Polysaccharide

The polysaccharide (169 mg) was oxidized with 0.1 *M* sodium metaperiodate (100 ml) at room temperature (25° C) in the dark. At suitable intervals aliquots were removed and the periodate consumption was determined by the usual arsenite method (32); the formic acid production was determined by titration with 0.01 *N* sodium hydroxide (33) (a correction was applied for the presence of carboxyl groups by a blank

titration of the acidic polysaccharide itself; see p. 2207). The results showed that oxidation was complete after 10 days; the molar periodate consumption was 1.15 per hexose unit and the liberation of formic acid was 0.51 mole per hexose unit.

In another experiment, the polysaccharide (200 mg) was suspended in 0.1 *N* periodic acid (100 ml) and the oxidation was carried out at 10° C. After complete oxidation (25 days, periodate consumption 1.25 molecular proportions per hexose unit), the oxidized polysaccharide was separated (centrifuge), washed with water, then suspended in water (50 ml) and reduced with sodium borohydride (200 mg) as previously described (34), during which reaction the product dissolved. The excess of the sodium borohydride was decomposed by acidification with acetic acid and the polysaccharide polyalcohol was subjected to hydrolysis by refluxing for 12 hours with sulphuric acid (adjusted to concn. 0.15 *N*). After cooling, the hydrolyzate was neutralized with barium carbonate, filtered, and the filtrate was evaporated to dryness. Borate in the residue was removed by repeated evaporation with 1% methanolic hydrogen chloride at room temperature and subsequent deionization by passage first through cation exchange (IR-120, H^+ form) and then through the anion exchange (Duolite A-4, OH^- form) resin. The neutral solution was evaporated to a sirup (yield 139 mg) which was shown by paper chromatographic analysis (solvents A and B) to contain glucose, glycerol, and erythritol but little or no mannose.

Separation and Identification of the Products from the Polysaccharide Polyalcohol

A portion (50 mg) of the above hydrolyzate of the polyalcohol was fractionated by paper chromatography using solvent B. The zone of the paper containing each component was extracted with water (20 ml) and evaporated.

(i) Glucose

The glucose fraction (10 mg) was treated with acidified methanolic *p*-nitroaniline (20 mg) as described previously, and the crystalline *p*-nitroanilide of D-glucose was obtained, m.p. and mixed m.p. 190–192° C (15).

(ii) Glycerol

The glycerol fraction (5 mg) was dissolved in dry pyridine (1.5 ml), and *p*-nitrobenzoyl chloride (50 mg) was added. The solution was heated for 2 hours at 80–90° C, then poured into cold sodium bicarbonate solution (15 ml). After extraction with chloroform, the chloroform layer was washed with water and dried ($MgSO_4$). Upon evaporation of the chloroform extract, the crystalline tri-*p*-nitrobenzoate of glycerol was obtained, m.p. and mixed m.p. 191–192° C (after recrystallization from chloroform–ethanol at 0° C).

(iii) Erythritol

The erythritol fraction (8.5 mg) was dissolved in dry pyridine (1.5 ml), and *p*-nitrobenzoyl chloride (50 mg) was added. The mixture was kept for 24 hours at room temperature, poured into cold water (15 ml) saturated with sodium bicarbonate and the product was extracted with chloroform. The chloroform extract was washed with water, dried, and evaporated, when the crystalline tetra-*p*-nitrobenzoate of erythritol was obtained, m.p. and mixed m.p. 258–260° C (after recrystallization from acetone–ethanol).

Quantitative Determination of Glucose, Glycerol, and Erythritol

After separation of the hydrolyzate of the polyalcohol by paper chromatography in the manner described above, each component was extracted from the appropriate area of the paper with water (10 ml) and an aliquot of the solution was used for colorimetric determination. D-Glucose was determined by the phenol – sulphuric acid method (18) at 490 mμ, while glycerol and erythritol were determined by the chromotropic acid method at 570 mμ (35). The results showed that the molar ratio of glucose:glycerol:erythritol was 1.1:2.2:1.0, a result in agreement with the methylation findings.

ABSTRACT

Six new dipeptides containing either 1-aminocyclopentanecarboxylic acid or 1-aminocyclohexanecarboxylic acid placed at either the N- or the C-terminal of L-phenylalanine or L-leucine have been synthesized. Two molecules of 1-aminocyclopentanecarboxylic acid were also linked with a peptide bond. These seven dipeptides were cyclized into the corresponding substituted 2,5-piperazinediones.

INTRODUCTION

The synthetic amino acid 1-aminocyclopentanecarboxylic acid has been shown to be an interesting amino acid. It is active against certain types of tumors (1–3). The biochemical studies done so far have not yet elucidated its mechanism of action (4), nor explained its toxicity. It is known that the alkylation of the cyclopentane ring destroys the antitumor activity of the compound. However, the incorporation of this synthetic amino acid into a short peptide chain preserves the antitumor effect (2), while lowering the toxicity.

In order to enhance the antitumor index, Connors and Ross (5) and Tailleur and Berlinguet (6) have recently reported the synthesis of a few short-chain peptides having glycine and DL-phenylalanine attached to 1-aminocyclopentanecarboxylic acid or to 1-aminocyclohexanecarboxylic acid. Shankman *et al.* (7) have just reported the synthesis of other peptides containing 1-aminocyclopentanecarboxylic acid.

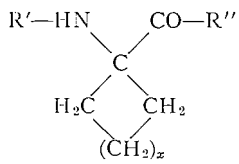
Since these peptides were intended for biological assays, it was important to incorporate the L-form of the natural amino acids. We have synthesized six new dipeptides containing either 1-aminocyclopentanecarboxylic acid or 1-aminocyclohexanecarboxylic acid attached to L-leucine or L-phenylalanine. We have also prepared the dipeptide containing two molecules of 1-aminocyclopentanecarboxylic acid. The list of these peptides is given in Table I. For these syntheses the classical method of Sheehan and Hess (8) was used in which the N-carbobenzoxy derivative of one amino acid was condensed with the benzyl ester of the other amino acid in the presence of N,N′-dicyclohexylcarbodiimide. The protected dipeptides were then hydrogenolized in the presence of 10% palladium on carbon, and the free dipeptides isolated by two different procedures according to their solubilities.

During these manipulations, the free peptides had a strong tendency to cyclize into the corresponding diketopiperazines, especially when heated in anhydrous conditions. Therefore, one has to be careful when purifying the free peptide because in some cases the solubilities of the peptide and of the cyclized diketopiperazine are quite similar, the analytical values being also very close. We found that the separation by chromatography and the analysis by titration are the most reliable methods to detect traces of contamination by diketopiperazines.

In order to prevent this cyclization three methods can be used: (1) water can be added

[1]*For part I, see reference 6.*

TABLE I



R′	R″	x	Name	
L-Leucyl-	-H	2	1-(L-Leucylamino)cyclopentanecarboxylic acid	(XI)
L-Leucyl-	-H	3	1-(L-Leucylamino)cyclohexanecarboxylic acid	(XII)
L-Phenylalanyl-	-H	2	1-(L-Phenylalanylamino)cyclopentanecarboxylic acid	(XIII)
L-Phenylalanyl-	-H	3	1-(L-Phenylalanylamino)cyclohexanecarboxylic acid	(XIV)
H-	-L-Phenylalanine	2	1-Aminocyclopentanecarbonyl-L-phenylalanine	(VIII)
H-	-L-Phenylalanine	3	1-Aminocyclohexanecarbonyl-L-phenylalanine	(IX)
H-	-1-Aminocyclopentane carboxylic acid	2	1-Aminocyclopentanecarbonyl-1-aminocyclopentanecarboxylic acid	(X)

to the ethanolic solution of the protected dipeptide before hydrogenolysis, (2) the hydrogenolysis can be done in acid medium where the liberated peptide would be ionized, thus preventing cyclization, and (3) if these conditions are not realized, care must be taken to avoid too much heating of the solutions especially if the content of water is low.

The spatial configuration of 1-aminocyclopentanecarboxylic acid and 1-aminocyclohexanecarboxylic acid seems to be responsible for the tendency to cyclize of the peptides containing these two amino acids attached to L-phenylalanine or L-leucine either by the C- or N-terminals. In fact, when those dipeptides are heated, they give a sublimate between 175° and 200° which melts between 175° and 195° depending on the peptide. The corresponding diketopiperazines obtained by different syntheses also give a sublimate between 175° and 200°. When these peptides are heated separately at 200° for a few minutes and then studied chromatographically they give two spots, one corresponding to the unchanged dipeptide and the other spot corresponding to the diketopiperazine. The dipeptide containing two molecules of 1-aminocyclopentanecarboxylic acid also cyclizes very easily by heating.

Preliminary testing of these peptides on tumors are now in progress and will be reported elsewhere.

EXPERIMENTAL

All melting points are uncorrected. The optical rotations were measured on a Rudolph polarimeter with a photoelectric cell alignment. The carbobenzoxy derivatives of L-leucine (9), L-phenylalanine (10), 1-aminocyclopentanecarboxylic acid (6), 1-aminocyclohexanecarboxylic acid (6), and the benzyl esters of L-phenylalanine (11), 1-aminocyclopentanecarboxylic acid (6), and 1-aminocyclohexanecarboxylic acid (6) were prepared according to published procedures.

N-Carbobenzoxydipeptide Benzyl Esters

The protected dipeptides were prepared as follows: to 0.01 mole of the N-carbobenzoxyamino acid dissolved in methylene chloride were added 0.011 mole of the appropriate amino acid benzyl ester and 0.011 mole of N,N′-dicyclohexylcarbodiimide. After 4 hours at room temperature, the N,N′-dicyclohexylurea formed was removed by filtration and the filtrate evaporated *in vacuo* on a water bath, after the addition of 2 ml of glacial acetic, which decomposes the excess of carbodiimide.

The oily residue was dissolved in 25 ml of ethyl acetate, and the solution filtered after 20 minutes to remove

the excess of N,N′-dicyclohexylurea formed after the addition of acetic acid. The filtrate was successively washed with 1 *N* hydrochloric acid, 1 *M* sodium carbonate, and water, and dried over anhydrous sodium sulphate. The solution was evaporated to dryness, and the N-carbobenzoxydipeptide benzyl ester was crystallized with the appropriate solvent system. The optical rotations were taken at 25° at a concentration of 2% in ethanol.

(I) Benzyl N-carbobenzoxy-1-(L-leucylamino)cyclopentanecarboxylate.—Yield: 3.7 g (78%), m.p. 116°, from ether–*n*-hexane, $[\alpha]_D$ −28°. Anal. Calc. for $C_{27}H_{34}N_2O_5$: N, 6.00%. Found: N, 6.08%.

(II) Benzyl N-carbobenzoxy-1-(L-leucylamino)cyclohexanecarboxylate.—Yield: 3.9 g (81%), m.p. 124–126°, from ether–*n*-hexane, $[\alpha]_D$ −31°. Anal. Calc. for $C_{28}H_{36}N_2O_5$: N, 5.85%. Found: 5.91%.

(III) Benzyl N-carbobenzoxy-1-(L-phenylalanylamino)cyclopentanecarboxylate.—Crude yield of the product which was isolated as an oil: 4.1 g (82%).

(IV) Benzyl N-carbobenzoxy-1-(L-phenylalanylamino)cyclohexanecarboxylate.—Crude yield of the product which was isolated as an oil: 4.0 g (78%).

(V) N-Carbobenzoxy-1-aminocyclopentanecarbonyl-L-phenylalanine benzyl ester.—Yield: 4.0 g (80%), m.p. 117°, from ethanol – petroleum ether, $[\alpha]_D$ −13°. Anal. Calc. for $C_{30}H_{32}N_2O_5$: N, 5.59%. Found: N, 5.58%.

(VI) N-Carbobenzoxy-1-aminocyclohexanecarbonyl-L-phenylalanine benzyl ester.—Yield: 4.2 g (82%), m.p. 98°, from ethanol – petroleum ether, $[\alpha]_D$ −9°. Anal. Calc. for $C_{31}H_{34}N_2O_5$: N, 5.44%. Found: 5.56%.

(VII) Benzyl N-carbobenzoxy-1-aminocyclopentanecarbonyl-1-aminocyclopentanecarboxylate.—Yield: 3.7 g (80%), m.p. 138°, from ethanol – petroleum ether. Anal. Calc. for $C_{27}H_{32}N_2O_5$: N, 6.03%. Found: N, 5.92%.

Free Dipeptides

The neutral equivalent values of the peptides were determined by titration with perchloric acid in glacial acetic acid, using crystal violet as indicator, according to Toennies and Callan (12). It was assumed that the molecular weight and the neutral equivalent are identical. The R_f values are for ascending chromatography in collidine–lutidine–water (1:1:2), the dipeptides and substituted diketopiperazines being detected by the Cl_2–KI–starch method of Rydon and Smith (13). The optical rotations were taken at 25° at a concentration of 1% in the given solvent.

(a) Peptides Soluble in Water

The appropriate N-carbobenzoxydipeptide benzyl ester (0.01 mole) was dissolved in 30 ml of hot ethanol containing 1 ml of glacial acetic acid. Then a suspension of 0.3 g of palladium (10%) on carbon in 6 ml of water was added. This hot solution was hydrogenolized at low pressure during 6 hours in a Parr apparatus, after which time the solution was heated if necessary to entirely dissolve the peptide, and the catalyst was removed by filtration. The clear filtrate was evaporated to a few milliliters, and then was added a mixture of water and ether to dissolve respectively the free dipeptide and the unreacted protected dipeptide. If at this stage there remains an insoluble product it is the substituted diketopiperazine. Being insoluble in both these solvents it is easily removed by filtration and can be identified by melting point and chromatography. The ethereal extract was decanted and discarded, and the aqueous fraction concentrated to allow the peptide to crystallize in the cold after the addition of acetone.

(VIII) 1-Aminocyclopentanecarbonyl-L-phenylalalanine.—Yield: 2.0 g (72%), m.p. 278–280° (subl. 180°), from water–acetone, $[\alpha]_D$ −2.0° (in water), R_f 0.64. Anal. Calc. for $C_{15}H_{20}N_2O_3$: N, 10.13%; mol. wt., 276. Found: N, 10.20%; mol. wt., 277.

(XIX) 1-Aminocyclohexanecarbonyl-L-phenylalanine.—Yield: 2.0 g (69%), m.p. 278–280° (subl. 180°), from water–acetone, $[\alpha]_D$ −1.3° (in water), R_f 0.67. Anal. Calc. for $C_{16}H_{22}N_2O_3$; N, 9.63%; mol. wt., 290. Found: N, 9.60%; mol. wt., 296.

(X) 1-Aminocyclopentanecarbonyl-1-aminocyclopentanecarboxylic acid.—Yield: 1.6 g (66%). The compound sublimates at 185° and does not decompose below 300°. It was recrystallized from water–acetone and had a R_f value of 0.54. Anal. Calc. for $C_{12}H_{20}N_2O_3$: N, 11.65%; mol. wt., 240. Found: N, 11.60%; mol. wt., 243.

(b) Peptides Insoluble in Water

The N-carbobenzoxydipeptide benzyl ester (0.01 mole) was dissolved in 20 ml of hot ethanol, and then 3.0 ml of 3.5 *N* hydrochloric acid and 0.3 g of palladium (10%) on carbon were added. This solution was hydrogenolized as described in the preceding part. After the water–ether treatment, there was no insoluble compound. The ethereal fraction was discarded and the water fraction neutralized with 3.5 *N* sodium hydroxide. The precipitated peptide was then filtered and washed with a little cold water, and recrystallized with the appropriate solvent system.

(XI) 1-(L-Leucylamino)cyclopentanecarboxylic acid.—Yield: 1.9 g (78%), m.p. 291–292° (subl.), from methanol–water, $[\alpha]_D$ +10.0° (in methanol), R_f 0.50. Anal. Calc. for $C_{12}H_{22}N_2O_3$: N, 11.54%; mol. wt., 242. Found: N, 11.45%; mol. wt., 241.

(XII) 1-(L-Leucylamino)cyclohexanecarboxylic acid.—Yield: 2.1 g (82%), m.p. 295–297° (subl.), from methanol–water, $[\alpha]_D$ +22.5° (in methanol), R_f 0.60. Anal. Calc. for $C_{13}H_{24}N_2O_3$: N, 10.92%; mol. wt., 256. Found: N, 10.87%; mol. wt., 260.

(XIII) 1-(L-Phenylalanylamino)cyclopentanecarboxylic acid.—Yield: 2.0 g (72%), m.p. 284–285° (subl. 180°), from aqueous ethanol 60%, $[\alpha]_D$ +57° (in glacial acetic acid), R_f 0.61. Anal. Calc. for $C_{15}H_{20}N_2O_3$: N, 10.13%; mol. wt., 276. Found: N, 9.98%; mol. wt., 279.

(XIV) 1-(L-Phenylalanylamino)cyclohexanecarboxylic acid.—Yield: 2.2 g (75%), m.p. 278° (subl. 180°),

from aqueous ethanol 60%, $[\alpha]_D$ +46° (in glacial acetic acid), R_f 0.63. Anal. Calc. for $C_{16}H_{22}N_2O_3$: N, 9.63%; mol. wt., 290. Found: N, 9.59%; mol. wt., 294.

Cyclization of Dipeptides into Substituted Diketopiperazines

The dipeptides (0.002 mole) were heated during 3 hours at 145° in 4 g of β-naphthol according to Lichtenstein (14).

The yellowish solutions so obtained were cooled and then thoroughly washed with four portions of 15 ml of ether to remove the β-naphthol. The insoluble 2,5-piperazinediones were crystallized with the appropriate solvent. The optical rotations were taken at 25° at a concentration of 0.2% in glacial acetic acid.

(XV) 1,4-Diazaspiro[4.5]decane-2,5-dione-3-benzyl.—(*a*) From 1-aminocyclopentanecarbonyl-L-phenylalanine: Yield: 0.41 g (79%), m.p. 287–289° (subl. 180°), from *n*-butanol, $[\alpha]_D$ +58°, R_f 0.90. Anal. Calc. for $C_{15}H_{18}N_2O_2$: N, 10.83%. Found: N, 10.78%. (*b*) From 1-(L-phenylalanylamino)cyclopentanecarboxylic acid: Yield: 0.42 g (80%), m.p. 289° (subl. 180°), from *n*-butanol, $[\alpha]_D$ +60°, R_f 0.91. Anal. Calc. for $C_{15}H_{18}N_2O_2$: N, 10.83%. Found: N, 10.87%.

(XVI) 1,4-Diazaspiro[5.5]undecane-2,5-dione-3-benzyl.—(*a*) From 1-aminocyclohexanecarbonyl-L-phenylalanine: Yield: 0.43 g (80%), m.p. 289–291° (subl. 180°), from *n*-butanol, $[\alpha]_D$ +59°, R_f 0.91. Anal. Calc. for $C_{16}H_{20}N_2O_2$: N, 10.28%. Found: N, 10.40%. (*b*) From 1-(L-phenylalanylamino)cyclohexanecarboxylic acid: Yield: 0.43 g (80%), m.p. 290–291° (subl. 180°), from *n*-butanol, $[\alpha]_D$ +56°, R_f 0.92. Anal. Calc. for $C_{16}H_{20}N_2O_2$: N, 10.28%. Found: N, 10.38%.

(XVII) 6,13-Diazaspiro[4.2.4.2]tetradecane-7,14-dione.—Yield: 0.36 g (82%), from 1-aminocyclopentanecarbonyl-1-aminocyclopentanecarboxylic acid. The compound, recrystallized from 75% acetic acid, began to sublime at 185°, and decomposed above 300°, R_f 0.92. Anal. Calc. for $C_{12}H_{18}N_2O_2$: N, 12.62%. Found: N, 12.70%.

(XVIII) 1,4-Diazaspiro[4.5]decane-2,5-dione-3-isobutyl.—Yield: 0.35 g (77%), from 1-(L-leucylamino)-cyclopentanecarboxylic acid, m.p. 289–293° (subl.), from *n*-butanol, $[\alpha]_D$ −10°, R_f 0.92. Anal. Calc. for $C_{12}H_{20}N_2O_2$: N, 12.51%. Found: N, 12.56%.

(XIX) 1,4-Diazaspiro[5.5]undecane-2,5-dione-3-isobutyl.—Yield: 0.38 g (80%), from 1-(L-leucylamino)-cyclohexanecarboxylic acid, $[\alpha]_D$ −20°, R_f 0.92. Anal. Calc. for $C_{13}H_{22}N_2O_2$: N, 11.76%. Found: N, 11.85%.

ACKNOWLEDGMENTS

RÉSUMÉ

On décrit la synthèse de six nouveaux dipeptides non-naturels. Ils contiennent d'une part un acide aminé de synthèse, soit l'acide amino-1 cyclopentane carboxylique, soit l'acide amino-1 cyclohexane carboxylique et, d'autre part, un acide aminé naturel, soit la L-phénylalanine, soit la L-leucine. On rapporte aussi la synthèse d'un dipeptide contenant deux molécules d'acide amino-1 cyclopentane carboxylique. Ces sept peptides furent cyclisés en pipérazinedione-2,5 substituées.

COORDINATION COMPLEXES OF METAL ALKOXIDES

PART II. METAL ALKOXIDE – ETHYLENEDIAMINE COMPLEXES[1]

M. S. BAINS[2] AND D. C. BRADLEY

Department of Chemistry, The University of Western Ontario, London, Ontario

Received July 26, 1962

ABSTRACT

Some complexes of titanium isopropoxide, titanium ethoxide, aluminum isopropoxide, tantalum isopropoxide, and zirconium isopropoxide with ethylenediamine (en) are described. Two complexes of titanium isopropoxide with ethylenediamine, i.e. $Ti(OPr^i)_4$,en and $Ti_2(OPr^i)_8$,en, were established by cryoscopic, X-ray powder photograph, and phase rule studies. The structure and stability of these complexes is discussed. Also isolated were $Ti_2(OEt)_8$,en; $Zr_2(OPr^i)_8$,en; $Ta_2(OPr^i)_{10}$,en, and $Al_2(OPr^i)_6$,en. Cryoscopic studies on the aluminum complex suggested that an octameric complex, $Al_8(OPr^i)_{24}$,$(en)_4$, is present in equilibrium with the dimer. The structural implications of the existence of these complexes are discussed.

Phase studies on the binary systems containing titanium tetraisopropoxide and pyridine, diethylamine, or *tert*-butyl acetate gave no clear indication of complex formation.

INTRODUCTION

In the previous publication in this series (1) it was mentioned that metal alkoxides form polymers or alkoxide salts in preference to addition compounds. Nevertheless, it is believed that the catalytic activity of metal alkoxides in numerous organic reactions (2) involves the ready formation of weak complexes between metal alkoxides and organic ligands. Our work with hydrazine (1) revealed that moderately stable complexes were formed by this ligand with metal alkoxides. Recently Cook (3) demonstrated by means of a tensiometric technique that two weak complexes, $Ti(OPr^i)_4$,$EtNH_2$ and $Ti(OPr^i)_4$, $2EtNH_2$, were formed in *n*-decane. The same author disclosed (3) that Gulledge had obtained crystalline $Ti(OPr^i)_4$,$EtNH_2$ from concentrated solution in cyclohexane. It thus seemed reasonable to suppose that ethylenediamine with its facility for chelation might form more stable complexes with metal alkoxides. In this paper we report the formation of several complexes involving ethylenediamine and metal alkoxides with particular reference to complexes involving titanium isopropoxide. The latter were studied using a variety of techniques. Phase studies on the systems involving $Ti(OPr^i)_4$ and pyridine, diethylamine, or isobutyl acetate are also described.

EXPERIMENTAL

Materials

Alkoxides

The metal alkoxides were prepared by the methods already described in the literature, i.e., aluminum isopropoxide (4, 5), titanium isopropoxide (6), titanium ethoxide (7), zirconium isopropoxide isopropylate (8), and tantalum isopropoxide (9) were purified by distillation under reduced pressure.

The purity of the above compounds was checked by the analytical methods given in the cited literature.

Solvents

Benzene and cyclohexane were of "Analytical Reagent" grade. These were dried azeotropically and stored over molecular sieve drying agent. Anhydrous diethyl ether, "Analytical Grade", was used directly from the cans in which it was supplied.

[1]*For Part I, see ref. 1.*

[2]*National Research Council Postdoctorate Fellow, 1959–1961. Present address: Department of Chemistry, The Panjab University, Chandigarh 3, India.*

Bases and Other Reagents

Pyridine was kept over potassium hydroxide pellets overnight and then distilled over fresh potassium hydroxide twice and collected at a constant temperature. Anhydrous diethylamine from an ampoule was kept over sodium metal and then distilled. *tert*-Butyl acetate was fractionally distilled three times. Ethylenediamine was purified from a 98% sample. It was kept over sodium hydroxide overnight and then the upper layer (base) was separated and distilled over sodium metal. The pure sample was analyzed by titration (found: 99.6, 99.8% purity).

Analytical Methods

Zirconium, titanium, tantalum, and aluminum were determined by the methods used in the references describing the preparation of the alkoxides. The alkoxide content was determined by the method developed by Bradley *et al.* (10) in the case of pure alkoxides.

Ethylenediamine was determined by acid titration in the case of titanium and tantalum alkoxide complexes. A weighed sample of the complex was dissolved in benzene (25 ml), and water was added to make the volume up to 200 ml. The titration was then performed using modified methyl orange as indicator. In the case of zirconium and aluminum alkoxide complexes, the sample was dissolved in the minimum amount of benzene, then a few milliliters of water was added, followed by 50 ml of cold, concentrated sodium hydroxide solution. This solution was then evaporated under reduced pressure and the volatile contents including water were collected in a clean cold-trap. The contents of the cold-trap were allowed to warm and then were titrated for the estimation of the ethylenediamine. To be sure of the reliability of this method blank experiments were performed using pure ethylenediamine (found: 99.8, 100.1% recovery).

Phase Studies

The liquidus for mixtures of $Ti(OPr^i)_4$ and ligand was obtained by determining melt points of a series of mixtures over the entire range of mole fractions. A slow rate of heating was ensured by surrounding the inner vessel by an air jacket. The temperature at which liquefaction appeared complete was measured to $\pm 0.1°$ C.

The results are shown graphically in Figs. 1 and 2.

X-Ray Powder Photographs

The compounds $Ti_2(OPr^i)_8$,en and $Ti(OPr^i)_4$,en were sealed into lithium glass capillaries of 0.5-mm diameter in the dry box. In the case of the latter compound great care was taken to avoid warming it during handling. The material was chilled before being filled into the capillary and was kept cool during the filling process; the powder photographs were taken immediately. The former compound was quite stable and could be handled easily under anhydrous conditions. A half-radian camera was used with Cu K_α radiation and a nickel filter. The calculated spacings for the more intense lines are given in Tables I and II.

Cryoscopy

A Beckmann apparatus was modified for use with compounds requiring rigorously anhydrous conditions and magnetic stirring was employed. The apparatus was cleaned and then dried in an oven at 150° C. Dry nitrogen was passed through the apparatus as it cooled. About 50 ml of solvent was weighed into the apparatus and the freezing point was determined in the usual manner. Weighed quantities of solute were introduced through a side arm whilst a countercurrent of nitrogen was maintained to exclude air. The following cryoscopic constants were used: benzene, 5.2; cyclohexane, 20.2.

The results are shown graphically in Fig. 3, where the number-average molecular weight of $Ti_2(OPr^i)_8$,en is plotted against molarity. The calculated data are given in Tables III and IV. The molecular weight of $Ti(OPr^i)_4$ was also determined over a range of concentrations and the results are given in Table V.

Preparation of Ethylenediamine Complexes with Metal Alkoxides

1. Aluminum Isopropoxide – Ethylenediamine Complex

To a solution of aluminum isopropoxide (10.0 g) in benzene, ethylenediamine (3.5 g) was added, but no precipitate appeared. The solution was evaporated at 0.1 mm pressure (10–11 hours at 30–35° C) and gave a fine powdery product whose analysis corresponded with the composition $Al_2(OPr^i)_6$,en (where en = ethylenediamine). Found: Al, 11.80, 11.85; en, 12.95, 12.90. $Al_2(OPr^i)_6$,en requires: Al, 11.55; en, 12.80%.

2. Tantalum Isopropoxide – Ethylenediamine Complex

To a freshly sublimed sample of tantalum isopropoxide (2 g) in benzene, an excess of ethylenediamine was added. After the mixture was allowed to stand for some time, benzene and volatile materials were removed under vacuum (0.1 mm). The residue was a sticky fluid mass which on warming melted to a clear liquid. When heated under reduced pressure the liquid gave a solid condensate which had an analysis corresponding to $Ta_2(OPr^i)_{10}$,en. Found: Ta, 35.67, 35.83; en, 5.93, 6.02. $Ta_2(OPr^i)_{10}$,en requires: Ta, 35.75; en, 5.93%.

The non-volatile residue was brown. Found: Ta, 38.86, 38.95; en, 6.18. [$Ta(OPr^i)_4$,$Ta(OPr^i)_5$,en] requires: Ta, 38.0; en, 6.29%.

3. Titanium Isopropoxide – Ethylenediamine Complex (2:1 Compound)

Titanium isopropoxide and ethylenediamine were mixed in equimolecular proportions and an exothermic reaction occurred. After drying *in vacuo* (0.1 mm) a white crystalline powder remained and its analysis

corresponded to $Ti_2(OPr^i)_8$,en. Found: Ti, 15.10, 15.32; en, 9.85, 9.80. $Ti_2(OPr^i)_8$,en requires: Ti, 15.29; en, 9.6%.

Other experiments were performed using an excess of ethylenediamine but the final solid product after drying *in vacuo* was always the complex $Ti_2(OPr^i)_8$,en. This compound sublimed at 60–64° C at 0.05 mm pressure. At temperatures above about 70° C the complex appeared to dissociate.

At a lower pressure (10^{-3} mm) the complex may readily be sublimed at around 40° C provided that the sublimate is cooled to about 12° C. The analysis of the sublimate agreed with the formula $Ti_2(OPr^i)_8$,en. Under normal pressure the complex melts at 75–76° C.

4. Titanium Isopropoxide – Ethylenediamine Complex (1:1 Compound)

Ethylenediamine (1.3 g) was added to a solution of titanium isopropoxide (2.83 g) in diethyl ether (50 ml) and after about 5 minutes the solution was cooled to induce crystallization. After the ethereal mother liquor was decanted off the white crystals were washed four times by decantation with ether (10 ml). The solvent was then removed under 40 mm pressure and the product thus obtained was the 1:1 complex $Ti(OPr^i)_4$,en. Found: Ti, 13.82, 13.83; en, 17.65, 17.80. $Ti(OPr^i)_4$,en requires: Ti, 13.95; en, 17.50%.

In another similar experiment the product had the following analysis: Found: Ti, 13.76, 14.09; en, 17.53, 17.70%.

5. Titanium Ethoxide – Ethylenediamine Complex

The addition of an excess of ethylenediamine (1 g) to a solution of redistilled titanium ethoxide (4 g) in benzene (25 ml) caused an exothermic reaction. The solution was allowed to stand for ½ hour and then the solvent was evaporated off *in vacuo* (0.1 mm). After drying *in vacuo* at room temperature a white crystalline solid remained which was shown by analysis to be $Ti_2(OEt)_8$,en. Found: Ti, 18.86, 18.85; en, 11.45, 11.50. $Ti_2(OEt)_8$,en requires: Ti, 18.60; en, 11.63%.

In a separate experiment where titanium ethoxide (10 g) was again treated with an excess of ethylenediamine (2 g) in ether a precipitate appeared. After about 10 minutes the solid product was filtered using a sintered-glass apparatus and washed three times with ether (20 ml). The ether was then removed by aspirating dry nitrogen through the product for 20 minutes. Found: Ti, 18.50, 18.40; en, 11.45%.

The product was then maintained at 0.1 mm pressure but no change in composition occurred. Found: Ti, 18.40, 18.45; en, 11.55, 11.40%.

6. Zirconium Isopropoxide – Ethylenediamine Complex

To a clear solution of zirconium isopropoxide (15 g) in ether (60 ml), ethylenediamine (2 g) was added, and a mild exothermic reaction occurred. After the system was warmed to 30–33° C for ½ hour, it was allowed to cool, when a large bulky precipitate appeared. When the system was cooled to 0° C it was filtered through an apparatus specially designed to exclude moisture. The solid product was washed with ether (15 ml, each) three times and then dried by aspirating with nitrogen. The white crystalline material amounted to about 75% yield and its analysis corresponded to the formula $Zr_2(OPr^i)_8$,en. Found: Zr, 25.75, 25.60; en, 8.35, 8.54. $Zr_2(OPr^i)_8$,en requires: Zr, 25.6; en, 8.41%.

DISCUSSION

Phase Studies

Among all the ligands used as the second component in the binary systems with titanium isopropoxide, only ethylenediamine clearly formed addition compounds. They are moderately stable compounds, which have been isolated by independent methods. The shape of the liquidus in this case is very interesting (Fig. 1) for the following reasons: (i) There is a sudden rise in the liquidus on both sides of the temperature–composition curve. The system has the melt point above or around 60° C when composition reaches 5–8 mole% of either component. (ii) Between these compositions the curve flattens out. (iii) The maximum temperature is just discernible at 33–34 mole% of ethylenediamine, corresponding to the composition $Ti_2(OPr^i)_8$,en. There are indications of a break at approximately 45 mole% ethylenediamine, corresponding with the formation of the 1:1 complex $Ti(OPr^i)_4$,en.

The flattening of the curve is presumably due to considerable dissociation of the respective complexes at these temperatures. The following type of general equilibria may be visualized:

$$Ti_2(OPr^i)_8,en \rightleftharpoons Ti(OPr^i)_4,en + Ti(OPr^i)_4 \quad [1]$$

$$3Ti(OPr^i)_4,en \rightleftharpoons Ti(OPr^i)_4,(en)_2 + Ti_2(OPr^i)_8,en. \quad [2]$$

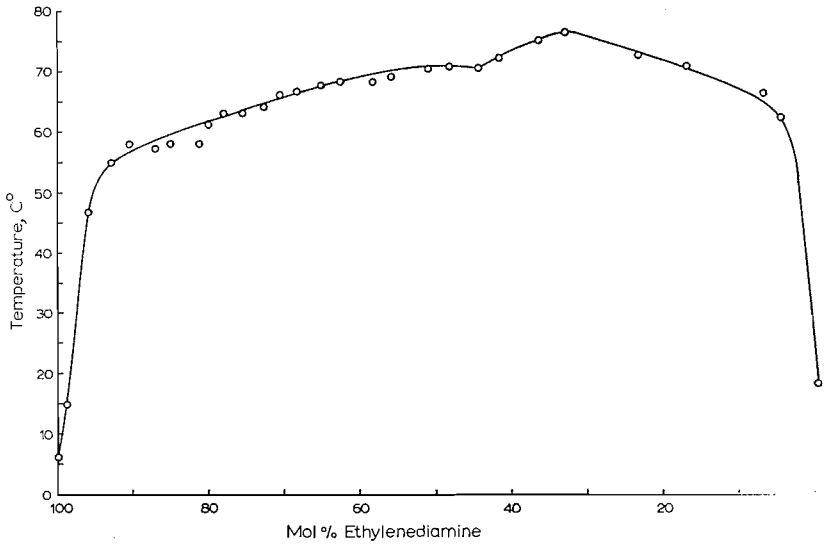

FIG. 1. Liquidus for the $Ti(OPr^i)_4$–$C_2H_4(NH_2)_2$ system.

In the case of the pyridine – titanium isopropoxide binary system (Fig. 2) there are indications of a break at approximately 50 mole% of pyridine, and the existence of a weak 1:1 complex could be inferred. The curves (Fig. 2) for the diethylamine – titanium isopropoxide and *tert*-butyl acetate – titanium isopropoxide systems do not give any clear indications of the formation of complexes, although there is a suspicion of a break corresponding to $Ti(OPr^i)_4,2Et_2NH$.

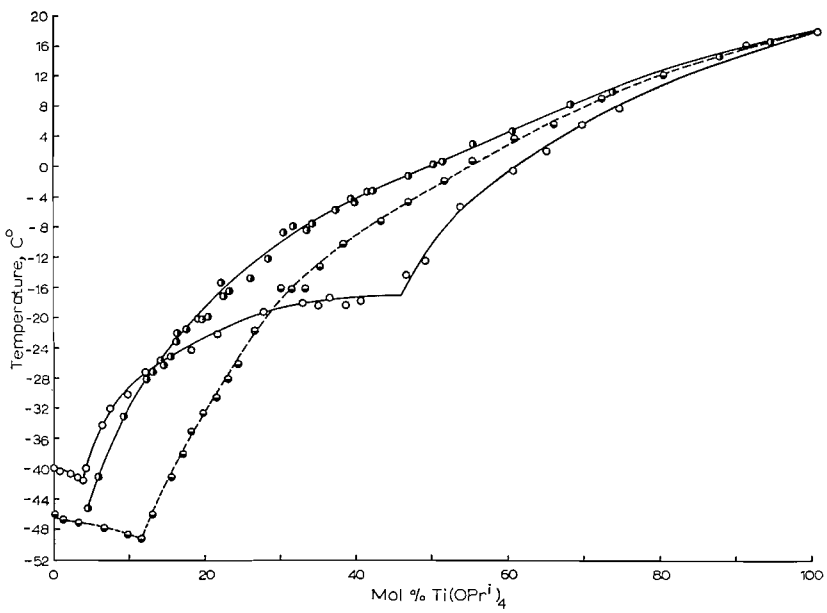

FIG. 2. $Ti(OPr^i)_4$ – *tert*-butyl acetate system, ◑–◑; $Ti(OPr^i)_4$–diethylamine system, ◒ - - ◒; $Ti(OPr^i)_4$–pyridine system, O–O.

X-Ray Studies

The X-ray powder diffraction patterns of $Ti_2(OPr^i)_8$,en (Table I) and $Ti(OPr^i)_4$,en (Table II) showed only two spacings in common (8.66 and 7.09 Å). The pattern was clearer and the lines in the pattern were generally more intense for $Ti_2(OPr^i)_8$,en than for $Ti(OPr^i)_4$,en. Comparison of the data in Tables I and II leaves no doubt that the two compounds are structurally distinct in the solid state.

Cryoscopic Results

Cryoscopic measurements were made on solutions of $Ti_2(OPr^i)_8$,en (A) in benzene and in cyclohexane and the results are illustrated in Fig. 3, in which molecular weight is

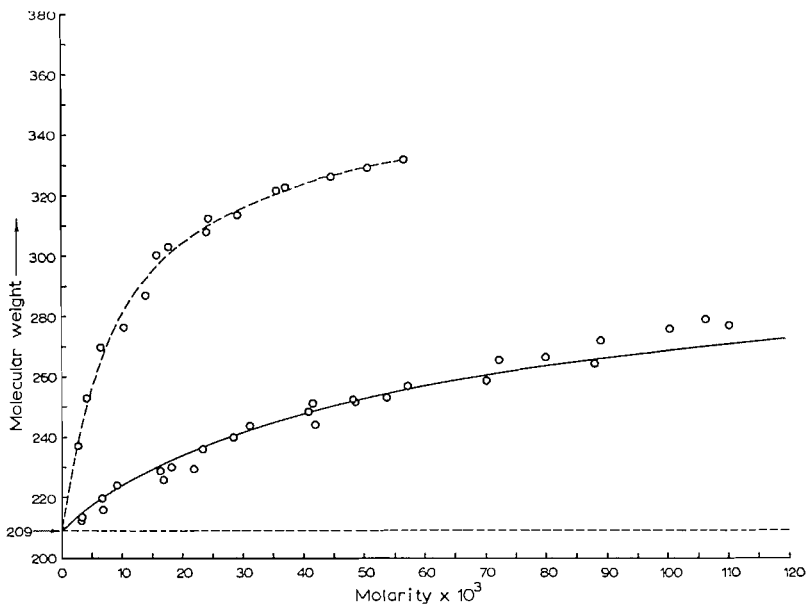

FIG. 3. Cryoscopic measurements on $Ti_2(OPr^i)_8$,en: in benzene, O—O; in cyclohexane, O - - O.

plotted as a function of molarity. In the case of cyclohexane solutions A began precipitating at about 66 mmoles/liter and the corresponding molecular weight was 340. But in contrast to this, at a concentration of 110 mmoles/liter of A in benzene the molecular weight is only 276. From the figure it is also clear that as the concentration approaches zero the molecular weight tends to the same value in both solutions.

The undissociated complex A should have a molecular weight of 628 whilst complete dissociation into three particles as shown in equation [3] requires an average molecular weight of 209.3 (horizontal dotted line in Fig. 3). Over the entire concentration range

$$Ti_2(OPr^i)_8,en \rightarrow 2Ti(OPr^i)_4 + en \qquad [3]$$

studied in benzene the molecular weight is lower than the 314 required for dissociation into the two molecular species indicated in equation [1]. However, in cyclohexane solution the molecular weight exceeds 314 at the higher concentrations.

The cryoscopic data are given in Tables III and IV for benzene and cyclohexane solutions respectively. To rationalize this data three equilibrium schemes were considered.

In the first case it is assumed that the complex A dissociates completely into $Ti(OPr^i)_4,en$ (B) and $Ti(OPr^i)_4$ (C). An equilibrium is then established between complex B and its components C and ethylenediamine (D) (equation [4]) with $K_B = [C][D]/[B]$. This

$$Ti_2(OPr^i)_8,en \xrightarrow[\text{dissociation}]{\text{complete}} Ti(OPr^i)_4,en + Ti(OPr^i)_4$$
$$\Big\Downarrow K_B$$
$$Ti(OPr^i)_4 + en \qquad [4]$$

56.88	331.8	1.89	199	5.5	1.1

assumption leads to the conclusion that in benzene the molecular weight will always be less than 314. The data for benzene solution gave reasonable agreement for an equilibrium constant $K_B = 7\times10^{-2}$ mole/liter over the 40-fold range in concentration. Individual values of K_B calculated for each concentration are given in Table III. The solid line passing through the data for benzene solution in Fig. 3 is one calculated for $K_B = 7\times10^{-2}$ mole/liter. In view of the experimental difficulties involved the agreement seems to establish the equilibrium of equation [4].

A second scheme involving the equilibria shown in equation [5] applies to the solution of complex A in cyclohexane. By a trial and error technique the data in Table IV were

$$\begin{array}{ccc} Ti_2(OPr^i)_8,en & \overset{K_A}{\rightleftharpoons} & Ti(OPr^i)_4,en + Ti(OPr^i)_4 \\ & & \Big\uparrow\Big\downarrow K_B \\ & & Ti(OPr^i)_4 + en \end{array} \qquad [5]$$

fitted to values for the constants $K_A = [C][B]/[A]$ and K_B shown in the table. The overall constant $K = K_A \cdot K_B$ presented in the last column was calculated from the individual constants. Bearing in mind the experimental difficulties the agreement is satisfactory and there are no significant trends in the values of the equilibrium constants.

It is clear that whereas in benzene the complex B is the stable species and dissociation of complex A into complex B and alkoxide is complete, in cyclohexane both the species A and B are present in comparable concentrations. The slightly higher dielectric constant of benzene compared with cyclohexane should not contribute significantly as far as the dielectric nature of the solvent is concerned. However, it is possible that benzene by virtue of its π-electrons may act as a weak donor solvent towards titanium isopropoxide and thus tend to dissociate the complexes. In cyclohexane there are no π-electrons and hence less tendency to solvate the components of the complexes. Molecular weights were also determined on titanium isopropoxide in benzene and in cyclohexane (Table V). In benzene the alkoxide was monomeric over a threefold change in concentration. In cyclohexane the molecular weight increased slightly over a 10-fold increase in concentration but the data did not meet the requirements of any simple monomer–polymer equilibrium.

TABLE V

Molecular weights of $Ti(OPr^i)_4$ in benzene and in cyclohexane

The tetrameric nature of aluminum isopropoxide was confirmed by molecular weight determinations in benzene (found: M.W., 810). Molecular weight determinations on $Al_2(OPr^i)_6$,en in benzene (Table VI) showed that the complex was binuclear at low

TABLE VI

Cryoscopic measurements on $Al_2(OPr^i)_6$,en in benzene

$10^2 \times$molarity of $Al_2(OPr^i)_6$,en	Mol. wt.	Average no. of aluminum atoms per osmotic particle	$10^6 \times K$ ($kg^3/mole^3$)

concentrations but the number-average degree of polymerization, n, increased with increase in concentration. A number of feasible equilibria were considered in an attempt to explain the concentration dependence of the number-average degree of polymerization. The best agreement was found for a system involving polymerization of $Al_2(OPr^i)_6$,en to an octameric species $Al_8(OPr^i)_{24}(en)_4$, viz. equation [6]. An average dissociation

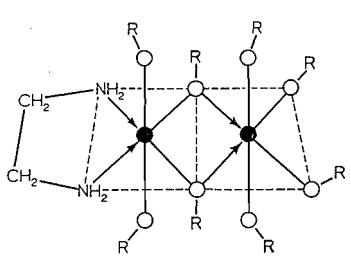
$$4Al_2(OPr^i)_6,en \rightleftharpoons Al_8(OPr^i)_{24},(en)_4 \qquad [6]$$

constant $K \sim 1.5 \times 10^6$ $kg^3/mole^3$ was obtained from the calculated values shown in Table VI. The constancy of K is probably as good as can be expected in view of the limitations of the technique.

Structural Aspects of Metal Alkoxide – Ethylenediamine Complexes

The following new complexes have been identified and studied in more or less detail: $Ti_2(OEt)_8$,en; $Ti(OPr^i)_4$,en; $Ti_2(OPr^i)_8$,en; $Zr_2(OPr^i)_8$,en; $Ta_2(OPr^i)_{10}$,en; and $Al_2(OPr^i)_6$,en. The formulae of some of these compounds raise some interesting structural problems.

Since titanium tetraethoxide tends to trimerize due to alkoxide bridging it is not surprising that a complex $Ti_2(OEt)_8$,en is formed and the structures shown in Figs. 4 and 5 seem reasonable based on octahedral titanium. In particular Fig. 4 with the ethylenediamine behaving as a chelating ligand seems likely, although models do not rule out the structure in Fig. 5. The formation of ethylenediamine – titanium isopropoxide complexes was surprising because titanium tetraisopropoxide is monomeric, presumably because steric factors oppose polymerization through isopropoxide bridges (2). However, the phase studies and cryoscopic measurements show that $Ti_2(OPr^i)_8$,en and $Ti(OPr^i)_4$,en



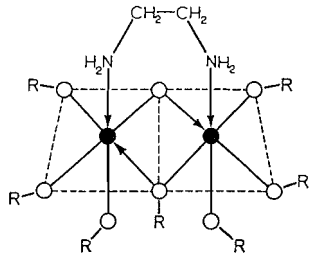


FIG. 4. Structure for $M_2(OR)_8$,en. ● = M (Ti or Zr); ○ = oxygen in OR; R = ethyl or isopropyl.
FIG. 5. Structure for $M_2(OR)_8$,en. ● = M (Ti or Zr); ○ = oxygen in OR; R = ethyl or isopropyl.

are rather weak complexes and it is also true that steric hindrance to coordination of ethylenediamine may be less than the steric hindrance to polymerization of the isopropoxide. There is the additional factor that ethylenediamine is a strong donor molecule. We presume that $Ti(OPr^i)_4$,en is the mononuclear chelate complex shown in Fig. 6 and

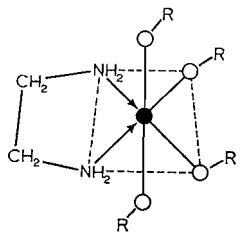

FIG. 6. Structure for $Ti(OPr^i)_4$,en. ● = Ti; ○ = oxygen in OR; R = isopropyl.

that $Ti_2(OPr^i)_8$,en has one of the structures shown in Figs. 4 and 5. Alternative structures may be formulated involving 5-coordinated titanium but we do not feel there is any justification for considering them seriously at present. Since the dimeric solvate $Zr_2(OPr^i)_8$,$(Pr^iOH)_2$ has been formulated as involving octahedral zirconium (2), it is logical to infer that $Zr_2(OPr^i)_8$,en has one of the structures shown in Figs. 4 and 5. With regard to the tantalum complex $Ta_2(OPr^i)_{10}$,en two possibilities are worthy of consideration. If the tantalum is octahedrally 6-coordinated then the ethylenediamine can only act as a chelate in a complex salt such as $[Ta(OPr^i)_4,en]^+[Ta(OPr^i)_6]^-$. The nature of the complex (e.g. volatile, soluble in benzene) suggested that it is not a salt. Thus, if the tantalum is 6-coordinated the ethylenediamine must form a flexible bridge between the two tantalum atoms as shown in Fig. 7. However, it is possible that the tantalum is 8-coordinated as shown in Fig. 8, with ethylenediamine acting as a chelating ligand. A cubic structure is shown for simplicity but there is no reason to exclude a square antiprismatic configuration for the 8-coordinated tantalums. A similar problem arises in assigning a structure to the aluminum complex $Al_2(OPr^i)_6$,en. If the aluminums are tetrahedrally 4-coordinated, as seems most likely, then the ethylenediamine must form a flexible bridge as shown in Fig. 9. It is not possible to construct a structure for $Al_2(OPr^i)_6$,en in which both aluminums are octahedral. However, if one aluminum is tetrahedrally coordinated and the other octahedrally coordinated the structure shown in Fig. 10 is a possibility, with the ethylenediamine acting as a chelating ligand. At

higher concentrations in benzene the complex $Al_2(OPr^i)_6$,en appears (from cryoscopic measurements) to polymerize to the octamer $Al_8(OPr^i)_{24}$,$(en)_4$. It is possible to construct an octamer containing octahedrally coordinated aluminum and with the ethylenediamine acting as a chelating ligand. An isomer of the octameric complex is shown in Fig. 11.

THE CARBOHYDRATE–PROTEIN LINKAGE IN GLYCOPROTEINS

PART II. THE SYNTHESIS OF N-L-SERYL-D-GLUCOSAMINE AND N-L-THREONYL-D-GLUCOSAMINE

J. K. N. Jones, J. P. Millington, and M. B. Perry

Department of Organic Chemistry, Queen's University, Kingston, Ontario

Received June 6, 1962

ABSTRACT

N-L-Seryl-D-glucosamine has been prepared by the condensation of *N*-carbobenzoxy-L-serine with D-glucosamine in the presence of dicyclohexyl carbodiimide followed by hydrogenolysis of the resulting *N*-(*N*-carbobenzoxy-L-seryl)-D-glucosamine to remove the *N*-carbobenzoxy protecting group.

N-L-Threonyl-D-glucosamine has been prepared by (*a*) the condensation of 1,3,4,6-tetra-*O*-acetyl-α- (and β-) D-glucosamine and *N*-carbobenzoxy-*O*-tetrahydropyranyl-L-threonine in the presence of diisopropyl carbodiimide followed by the removal of the protecting groups from the resulting *N*-(*N*-carbobenzoxy-*O*-tetrahydropyranyl-L-threonyl)-1,3,4,6-tetra-*O*-acetyl-α- (and β-) D-glucosamine, and (*b*) by the condensation of *N*-carbobenzoxy-L-threonine with D-glucosamine in the presence of dicyclohexyl carbodiimide followed by removal of the *N*-carbobenzoxy group from the resulting *N*-(*N*-carbobenzoxy-L-threonyl)-D-glucosamine by hydrogenolysis.

INTRODUCTION

As part of a program in this laboratory aimed at the determination of the nature of the carbohydrate–peptide bonds occurring in natural glycoproteins (1) the synthesis of model amino acid – glycose compounds linked by *N*-glycoside, *O*-glycoside, ester, and amide bonds is being undertaken. A study of the stability of these model compounds and of the conditions required for their successful paper chromatographic and electrophoretic separation will aid in the selection of experimental conditions required for the isolation of such derivatives from glycoproteins. The derivatives may subsequently be of use as reference compounds for the identification of the hydrolytic degradation products of glycoproteins and mucoproteins.

This paper records the synthesis of two *N*-amino acyl derivatives of D-glucosamine. The original methods used in the synthesis of this type of compound involved the reaction of *N*-carbobenzoxy amino acyl chlorides with fully *O*-acetylated 2-amino-2-deoxyaldohexoses (2) or the condensation of suitably protected 2-amino-2-deoxyhexoses with a *N*-carbobenzoxy amino acid derivative by the carbodiimide method (1, 3, 4). In either case the protecting groups must be subsequently removed in order to obtain the unsubstituted *N*-amino acyl aminohexose compounds.

A simple and convenient method for the preparation of amino acyl derivatives of glycoses has recently been reported by Kochetkov and his co-workers (5, 6) which involves the condensation of an unprotected glycose with a *N*-carbobenzoxy amino acid in the presence of carbodiimide. It was found that *N*-carbobenzoxy amino acids condensed readily with 2-amino-2-deoxyhexoses in the presence of dicyclohexyl carbodiimide in aqueous pyridine solution at room temperature to form *N*-(*N*-carbobenzoxy amino acyl)-hexosamines, the exclusive formation of the *N*-substituted derivatives under these conditions being attributed to the specific action of carbodiimide and the instability of *O*-acyl derivatives in aqueous pyridine solution. This procedure has now been applied to the synthesis of *N*-seryl-D-glucosamine and *N*-threonyl-D-glucosamine.

EXPERIMENTAL

All melting points were determined using the Fisher–Johns block and are uncorrected. Solutions were concentrated by rotary evaporation under reduced pressure below 40° C.

Paper chromatography was performed by the descending method on Whatman No. 1 paper, using butan-1-ol/ethanol/water (3:1:1 v/v). The following spray reagents were used to detect the compounds on the developed chromatograms: (A) 2% solution of *p*-anisidine hydrochloride in butan-1-ol (7), (B) 1% solution of silver nitrate in acetone, followed by 2% ethanolic sodium hydroxide solution (8), and (C) 2% ninhydrin in butan-1-ol (9). The rate of movement of the compounds on the chromatograms is given relative to that of D-glucosamine hydrochloride ($R_{GN.HCl}$) or *N*-acetyl-D-glucosamine (R_{GNAc}).

The infrared spectra of the compounds were measured as 0.8% dispersions in potassium bromide disks, or as 6% solutions in chloroform or methylene chloride, using the Perkin–Elmer Model 21 spectrophotometer.

1. N-L-Seryl-D-glucosamine

(a) N-(N-Carbobenzoxy-L-seryl)-D-glucosamine

The procedure of Kochetkov and his co-workers was followed (5, 6). D-Glucosamine hydrochloride (2.15 g, 0.01 mole) was dissolved in water (5 ml) and to the cooled, mechanically stirred solution was added 2 *N* sodium hydroxide solution (5 ml) followed by *N*-carbobenzoxy-L-serine (2.39 g, 0.01 mole) dissolved in dry redistilled pyridine, and dicyclohexyl carbodiimide (3.09 g, 0.015 mole) dissolved in pyridine (20 ml). The solution was allowed to warm to room temperature and stirring was continued for 24 hours. The precipitated dicyclohexyl urea (ca. 0.01 mole) was removed by filtration and the unreacted dicyclohexyl carbodiimide was removed by extraction with ether (2×50 ml).

The aqueous solution was concentrated to a small volume and the product which crystallized out was collected by filtration and was then recrystallized from methanol solution. The *N*-(*N*-carbobenzoxy-L-seryl)-D-glucosamine (38% yield) had m.p. 217° C (decomp.) and $[\alpha]_D^{23}$ +73.5° (*c*, 4.0 chloroform).

The compound had R_{GNAc} 2.09 on paper chromatograms and was free from D-glucosamine and L-serine. The infrared spectrum exhibited absorption bands at 3460 cm^{-1} (s, hydroxyl) and 1682 and 1495 cm^{-1} (amide). Anal. Found: C, 50.7; H, 6.5; N, 6.8%. $C_{17}H_{24}O_9N_2$ requires: C, 50.99; H, 6.04; N, 7.0%.

(b) N-(L-Seryl hydrochloride)-D-glucosamine

The *N*-carbobenzoxy group was removed from the *N*-(*N*-carbobenzoxy-L-seryl)-D-glucosamine by hydrogenolysis in dilute hydrochloric acid solution using palladized charcoal as a catalyst according to the procedure of Jones *et al.* (1). The *N*-(L-seryl hydrochloride)-D-glucosamine, obtained as fine crystals from methanol/ether mixture (85% yield), had $R_{GN.HCl}$ 0.55 on paper chromatograms and its infrared spectrum exhibited absorption bands at 3460 cm^{-1} (wide, hydroxyl), 1682 cm^{-1} (amide), and 1495 cm^{-1} (ionic nitrogen). Attempts to prepare the free amine failed since the initial product blackened before it could be isolated.

2. N-L-Threonyl-D-glucosamine

Method A

(a) N-Carbobenzoxy-L-threonine

N-Carbobenzoxy-L-threonine was prepared in 90% yield by the method of Moore *et al.* (3). The product after recrystallization from ethyl acetate had m.p. 102° C and $[\alpha]_D^{21}$ −4.3° (*c*, 4.25 acetic acid). Anal. Found: C, 57.0; H, 5.9; N, 5.6%. $C_{12}H_{15}O_5N$ requires: C, 56.91; H, 5.97; N, 5.53%.

(b) Methyl N-Carbobenzoxy-L-threonate

N-Carbobenzoxy-L-threonine (8.0 g) was dissolved in 2.5% methanolic hydrogen chloride solution (100 ml), and after 12 hours at room temperature the solution was neutralized by passage through a column of Duolite A4 (OH^-) ion-exchange resin. The solution was concentrated to a syrup which gave crystalline methyl *N*-carbobenzoxy-L-threonate (89% yield) having m.p. 90° C and $[\alpha]_D^{20}$ −16.1° (*c*, 4.25 methanol). Anal. Found: C, 57.9; H, 6.5; N, 5.3%. $C_{13}H_{17}O_5N$ requires: C, 58.42; H, 6.41; N, 5.24%.

(c) Methyl N-Carbobenzoxy-O-tetrahydropyranyl-L-threonate

The procedure of Iselin and Schwyzer (10) was followed. Hydrogen chloride (2 *N*) in anhydrous ethyl acetate (0.5 ml) was added to a solution of methyl *N*-carbobenzoxy-L-threonate (7.5 g) in purified 2,3-dihydro-4-pyran (4 g). The reaction mixture was kept at room temperature for 24 hours after which it was diluted with ether and then washed with dilute sodium bicarbonate solution followed by water. The ether solution was dried (anhyd. sodium sulphate), filtered, and then concentrated to a yellow oil (80% yield).

(d) Hydrolysis of Methyl N-Carbobenzoxy-O-tetrahydropyranyl-L-threonate

Methyl *N*-carbobenzoxy-*O*-tetrahydropyranyl-L-threonate (8.0 g) was dissolved in methanol (25 ml) and was then saponified by the addition of *N* methanolic sodium hydroxide solution (50 ml) according to the method of Iselin and Schwyzer (10) to yield *N*-carbobenzoxy-*O*-tetrahydropyranyl-L-threonine (4.21 g, 55% yield) as a yellow syrup which failed to crystallize. The syrup had equivalent weight 345 (theory 337) and its infrared spectrum showed absorption bands at 987 and 1125 cm^{-1} (tetrahydropyranyl group).

A second compound crystallized from the reaction product which had m.p. 183° C and equivalent weight 238. Anal. Found: C, 60.8; H, 5.7; N, 6.0%. $C_{12}H_{13}O_4N$ requires: C, 61.27; H, 5.57; N, 5.96%.

(e) 1,3,4,6-Tetra-O-acetyl-α- (and β-) D-glucosamine

These derivatives were prepared by the method described by Jones *et al.* (1). α-Anomer: 65% yield, m.p. 118° C, $[\alpha]_D^{20}$ +145° (*c*, 2 chloroform); β-anomer: 65% yield, m.p. 143° C, $[\alpha]_D^{20}$ +27° (*c*, 2 chloroform).

(f) N-(N-Carbobenzoxy-O-tetrahydropyranyl-L-threonyl)-1,3,4,6-tetra-O-acetyl-α- (and β-) D-glucosamine

N-Carbobenzoxy-*O*-tetrahydropyranyl-L-threonine (0.460 g), 1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine (0.510 g), and diisopropyl carbodiimide (0.178 g) were dissolved in methylene chloride (6 ml) and the mixture was shaken mechanically at room temperature for 24 hours. The precipitated diisopropyl urea by-product was removed by filtration and the filtrate was washed with dilute hydrochloric acid, dilute sodium bicarbonate solution, and finally with water. The dried (anhyd. magnesium sulphate) methylene chloride solution on concentration gave a white solid (5% yield) which had m.p. 185° C and $[\alpha]_D^{20}$ +74.4° (*c*, 0.5 methanol).

The above procedure was repeated using 1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine to give the β-anomer as a syrup (50% yield) which failed to crystallize. It had $[\alpha]_D^{20}$ +12.3° (*c*, 4.0 methanol).

The infrared absorption spectra of both the above products exhibited absorption bands at 1745 cm^{-1} (carbonyl, *O*-acetyl), 1670 cm^{-1} (amide I), 1555 cm^{-1} (amide II), 1130 and 987 cm^{-1} (tetrahydropyranyl group), and 695 cm^{-1} (phenyl group).

(g) N-(N-Carbobenzoxy-L-threonyl)-1,3,4,6-tetra-O-acetyl-β-D-glucosamine

N-(*N*-Carbobenzoxy-*O*-tetrahydropyranyl-L-threonyl)-1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine (0.50 g) was heated in boiling 50% acetic acid solution (10 ml) for 10 minutes and the cooled solution was diluted with water and extracted with chloroform (4×20 ml). The dried (anhyd. magnesium sulphate) chloroform extract was concentrated to dryness to yield a syrup (0.25 g, 58% yield) which had $[\alpha]_D^{18}$ +30° (*c*, 3.0 chloroform) and whose infrared spectrum did not show absorption bands due to the tetrahydropyranyl group at either 1130 or 987 cm^{-1}.

(h) N-(N-Carbobenzoxy-L-threonyl)-D-glucosamine

N-(*N*-Carbobenzoxy-L-threonyl)-1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine (100 mg) dissolved in dry methanol (4 ml) was treated with 0.4 *N* barium methoxide in methanol (2 ml) and the mixture was kept at 5° C for 24 hours. Slightly less than the equivalent amount of 0.01 *N* sulphuric acid was added to the reaction mixture, the precipitated barium sulphate was removed by filtration, and the filtrate was further deionized by passage through a column of mixed IR 120 (H^+) and Duolite A4 (OH^-) ion-exchange resins. On concentration of the methanol solution, *N*-(*N*-carbobenzoxy-L-threonyl)-D-glucosamine was obtained as a white solid (30 mg). It had m.p. 209° (decomp.) and $[\alpha]_D^{14}$ +20.4° (*c*, 2.8 methanol). On paper chromatography and detection with spray reagents A and B the compound was revealed as a single spot having R_{GNAc} 2.90 and was not contaminated with either D-glucosamine or L-threonine.

The infrared spectrum of the compound exhibited absorption bands at 3360 cm^{-1} (broad, hydroxyl group) and 1670 and 1550 cm^{-1} (amide) but no absorption band at 1745 cm^{-1} (carbonyl, *O*-acetyl).

Method B

(a) N-(N-Carbobenzoxy-L-threonyl)-D-glucosamine

The procedure of Kochetkov and his co-workers (5, 6) was used. D-Glucosamine hydrochloride (2.15 g, 0.01 mole) dissolved in water (5 ml) was cooled to 0° C and neutralized by the addition of 2 *N* sodium hydroxide solution (5 ml). The mechanically stirred solution was immediately treated with a solution of *N*-carbobenzoxy-L-threonine (2.53 g, 0.01 mole) in dry pyridine (7 ml) followed by a solution of dicyclohexyl carbodiimide (3.09 g, 0.015 mole) in dry pyridine (20 ml) and the stirring was continued for a further 24 hours. The precipitated dicyclohexyl urea was removed by filtration and the unreacted dicyclohexyl carbodiimide was removed by extraction with ether (2×50 ml). The *N*-(*N*-carbobenzoxy-L-threonyl)-D-glucosamine isolated from the concentrated aqueous solution was obtained as crystals which, after several recrystallizations from methanol (final yield 0.415 g), had m.p. 209° C (decomp.) and $[\alpha]_D^{20}$ +21.0° (*c*, 3.0 methanol). The compound was indistinguishable on paper chromatograms from the product obtained by method A and the infrared spectra of the two products were identical. Anal. Found: C, 51.7; H, 6.2; N, 6.7%. $C_{18}H_{26}O_9N_2$ requires: C, 52.17; H, 6.32; N, 6.76%.

(b) N-L-Threonyl-D-glucosamine

N-(*N*-Carbobenzoxy-L-threonyl)-D-glucosamine (25 mg) was dissolved in chloroform/ethanol mixture, and palladized charcoal (25 mg) was added. The mixture was shaken for 24 hours at room temperature in an atmosphere of hydrogen (1.3 atm). The catalyst was removed by filtration and the filtrate was concentrated to a dark yellow syrup (7 mg). On paper chromatography a single spot, which had $R_{GN.HCl}$ 0.44, was revealed by the ninhydrin spray whereas the silver nitrate spray revealed a series of spots indicating the presence of decomposition products.

(c) N-(L-Threonyl hydrochloride)-D-glucosamine

N-(*N*-Carbobenzoxy-L-threonyl)-D-glucosamine (28 mg) was subjected to hydrogenolysis as described above with the inclusion of *N* hydrochloric acid (0.7 ml) in the reaction mixture. The *N*-(L-threonyl

hydrochloride)-D-glucosamine (9.5 mg) was obtained as a clear syrup which failed to crystallize. The syrup had $[\alpha]_D^{20}$ −13° (*c*, 1.0 methanol) and on paper chromatograms it gave a single ninhydrin and silver nitrate positive spot having $R_{GN.HCl}$ 0.46. The infrared absorption spectrum of the compound showed a broad band at 3360 cm^{-1} due to hydroxyl and amino group absorption, but no bands due to the phenyl group corresponding to the original carbobenzoxy group.

Attempts to prepare the free amine from *N*-(L-threonyl hydrochloride)-D-glucosamine using Duolite A4 ($CO_3^=$) ion-exchange resin or Duolite A4 (OH^-) resin failed owing to the rapid decomposition of the initial product.

DISCUSSION

N-(L-Seryl hydrochloride)-D-glucosamine was prepared according to the general procedure of Kochetkov and his co-workers (5, 6). D-Glucosamine was condensed with *N*-carbobenzoxy-L-serine in aqueous pyridine solution in the presence of dicyclohexyl carbodiimide to give *N*-(*N*-carbobenzoxy-L-seryl)-D-glucosamine, from which the protecting *N*-carbobenzoxy group was removed by hydrogenolysis in the presence of dilute hydrochloric acid to yield *N*-(L-seryl hydrochloride)-D-glucosamine in 32% overall yield. The compound was stable in aqueous solution, but attempts to prepare the free *N*-L-seryl-D-glucosamine by careful neutralization with dilute alkali or by the use of mild basic ion-exchange resins failed owing to the rapid decomposition of the free amine under the conditions used.

The *N*-(L-seryl hydrochloride)-D-glucosamine was chromatographically identical with, and had an infrared spectrum indistinguishable from that of, the same derivative prepared earlier by Jones *et al.* (1) in greatly reduced overall yield by the condensation of *N*-carbobenzoxy-*O*-tetrahydropyranyl-L-serine with 1,3,4,6-tetra-*O*-acetyl-D-glucosamine in the presence of diisopropyl carbodiimide to give *N*-(*N*-carbobenzoxy-*O*-tetrahydropyranyl-L-seryl)-1,3,4,6-tetra-*O*-acetyl-D-glucosamine, from which the protecting groups were subsequently removed to yield the required product.

N-(L-Threonyl hydrochloride)-D-glucosamine was prepared in low overall yield by the condensation of *N*-carbobenzoxy-*O*-tetrahydropyranyl-L-threonine with 1,3,4,6-tetra-*O*-acetyl-D-glucosamine in the presence of diisopropyl carbodiimide to give *N*-(*N*-carbobenzoxy-*O*-tetrahydropyranyl-L-threonyl)-1,3,4,6-tetra-*O*-acetyl-D-glucosamine, from which the protecting groups were removed to yield the amino acyl-glycosamine derivative.

An unexpected crystalline product was obtained from the saponification product of methyl-*N*-carbobenzoxy-*O*-tetrahydropyranyl-L-threonate which had an equivalent weight of 238 and whose analysis agrees with the formula $C_{12}H_{13}O_4N$. The compound is tentatively identified as *N*-carbobenzoxy-2-amino-buten-3-oic acid, possibly formed by the elimination of a molecule of water from *N*-carbobenzoxy-L-threonine.

A greatly improved yield of *N*-(L-threonyl hydrochloride)-D-glucosamine was achieved when the general procedure of Kochetkov *et al.* (5, 6) was used. D-Glucosamine was condensed with *N*-carbobenzoxy-L-threonine in aqueous pyridine solution in the presence of dicyclohexyl carbodiimide to give *N*-(*N*-carbobenzoxy-L-threonyl)-D-glucosamine, which on hydrogenolysis in the presence of dilute hydrochloric acid afforded *N*-(L-threonyl hydrochloride)-D-glucosamine in 5% overall yield. The final products obtained by the two different routes were chromatographically identical and their infrared spectra were indistinguishable from each other.

Attempts to prepare *N*-L-threonyl-D-glucosamine by hydrogenolysis of the *N*-(*N*-carbobenzoxy-L-threonyl)-D-glucosamine in neutral media, or by neutralization of the *N*-(L-threonyl hydrochloride)-D-glucosamine by dilute alkali or by using mild basic ion-exchange resins failed to give a pure product owing to the rapid decomposition of the initial free amine. The hydrochloride salt, however, was stable in aqueous solution.

COORDINATION COMPLEXES OF TITANIUM (IV) HALIDES

III. PREPARATION AND INFRARED SPECTRA OF THE COMPLEXES OF TITANIUM TETRACHLORIDE WITH UREA, THIOUREA, AND SOME OF THEIR DERIVATIVES[1]

ROLAND RIVEST

Department of Chemistry, University of Montreal, Montreal, Que.

Received June 19, 1962

ABSTRACT

The following coordination complexes of titanium (IV) have been prepared: $TiCl_4.2CO(NH_2)_2$, $TiCl_4.CO(NHCH_3)_2$, $TiCl_4.2CO(NHCH_3)_2$, $2TiCl_4.2NH_2CON(C_6H_5)_2$, $2TiCl_4.2CO(NHC_6H_5)_2$, $TiCl_4.2CS(NH_2)_2$, $2TiCl_4.CS(NHC_2H_5)_2$, $2TiCl_4.NH_2CSN(C_6H_5)_2$, and $2TiCl_4.CS(NHC_6H_5)_2$; their infrared spectra have been measured and their molecular weight determined. For urea and its derivatives the coordination to titanium (IV) is always through the oxygen atom. The phenyl derivatives of urea led to dinuclear complexes which were best explained by assuming halogen bridging between the titanium atoms. Thiourea and its derivatives gave complexes in which coordination occurred through one of the nitrogens in the case of thiourea and through both nitrogens in the case of the derivatives. Halogen bridging was again assumed to explain the formation of the dinuclear complexes.

INTRODUCTION

Many coordination complexes in which the donor bases were urea and thiourea have been reported. Quagliano and co-workers (1) have established that among the urea complexes, some coordinated through one of the nitrogen atoms and some through the oxygen atom of the urea molecule. We have prepared (2, 3) several coordination complexes of titanium (IV) halides with ordinary amides and found that in these complexes the donor atom was oxygen. It has been assumed, then, that coordination through nitrogen would hinder one of the two resonance forms of amides. In urea, the presence of two amino groups in the molecule leads to three resonating structures (4) of which only one would be hindered by coordination through one of the nitrogens. It seemed of interest to prepare and study the complexes formed by urea and its derivatives by reaction on titanium tetrachloride.

Quagliano (5) and his co-workers have prepared some thiourea complexes in which the sulphur atom of the ligand was exclusively involved as donor atom in coordination. Some addition compounds possessing a coordination bond between titanium (IV) and sulphur have been prepared, $TiCl_4.2H_2S$ being a good example of this.

The present investigation was undertaken to compare the relative donor abilities of sulphur and nitrogen toward coordination with titanium tetrachloride, by using thiourea and its derivatives as donor bases. Some substituted thioureas were studied to determine whether steric hindrance would lead to 5-coordinated complexes or to halogen-bridged complexes.

EXPERIMENTAL

Materials and Manipulations

Reagent grade titanium tetrachloride was purified by the method of Gilchrist (6) and the medium fraction was used for our experiment. Reagent grade urea (U); 1,3-dimethylurea (DMU); 1,1-diphenylurea (1,1-DPU); 1,3-diphenylurea (1,3-DPU); thiourea (TU); 1,3-diethylthiourea (DETU); 1,1-diphenylthiourea (1,1-DPTU); and 1,3-diphenylthiourea (1,3-DPTU) were dried over phosphorus pentoxide and used as such.

The solvents used for our experiments were anhydrous and their water content was checked by the Karl

[1]*Presented at the 45th Chemical Institute of Canada Annual Conference and Exhibition, Edmonton, May 27–30, 1962.*

Fisher method. The water-sensitive complexes were prepared and handled in a dry box continuously flushed with dry nitrogen. The method of analysis for chlorine, titanium, carbon, and hydrogen was described previously (9). Nitrogen was determined by the Kjeldahl method or the micro-Dumas method as specified in each case.

The infrared spectra were carried out on a Perkin–Elmer spectrophotometer model 21 using a sodium chloride prism. The spectra of the soluble complexes were determined in solutions of suitable solvents, and the spectra of the insoluble ones were taken as nujol mulls or using the KBr disk method.

The molecular weights were determined using two Gallenkamp ebulliometers, one for the solvent and the other one for the solution of the solute under investigation. This setup permitted simultaneous measurements and therefore eliminated possible errors due to change in atmospheric pressure.

The System $TiCl_4.2U$

Titanium tetrachloride was added in excess to a suspension of urea in methylene chloride. This reaction, being between a solid and a liquid, was very slow. After the suspension was stirred for 5 or 6 days, the reaction seemed to be complete and a yellow precipitate had replaced the urea crystals. The excess of titanium tetrachloride was washed out by methylene chloride on a sintered-glass filter and the precipitate was then dried under vacuum at room temperature. This precipitate was found to be insoluble in all the inert solvents. It melted with decomposition at about 215° C. The precipitate was then analyzed and the results are included in Table I.

TABLE I

Complexes	Analytical results found and calculated					
	Ti%	Cl%	N%*	C%	H%	M.W.
$TiCl_4.2U$	15.63	45.47	18.4*d*	7.76	3.36	—

	15.76	—	4.61	25.66	1.99	608

**k*: Kjeldahl method; *d*: micro-Dumas method.

The System $TiCl_4.DMU$

Titanium tetrachloride in excess was added to a suspension of DMU. The reaction was quite slow, but after 2 days of agitation the reaction seemed to be complete and a yellow powder had replaced the white DMU crystals. The excess of titanium tetrachloride was removed by repeated washing with dichloroethane on a sintered-glass filter and the precipitate was dried under vacuum at room temperature. The precipitate is insoluble in non-polar organic solvents. Its melting point was found to be 209° C and it decomposed at 220°. The analytical results are included in Table I. They are in good agreement with the formula $TiCl_4.1DMU$.

If a 10% $TiCl_4$ solution in dichloroethane or cyclohexane was used instead of an excess of pure titanium tetrachloride, a different compound, $TiCl_4.2DMU$, was formed. This compound melted at 228° C and decomposed at 230° C. The analytical results are included in Table I.

When an excess of dimethylurea was used, many other pseudo addition compounds were obtained, but with no definite stoichiometry. Since there was no means of removing the excess of the donor base, it has not been possible to draw definite conclusions on these compounds.

The System $TiCl_4.1,1\text{-}DPU$

An excess of a 50% solution of titanium tetrachloride in methylene chloride was added to a suspension

of 5 g of the donor base in the same solvent. The compound so formed, being soluble, turned the solution a deep red color. After 2 days of agitation a dark orange precipitate was formed, which was filtered, washed, and dried as usual. It was then dissolved in CH_2Cl_2 and recrystallized, yielding orange crystals. The analytical results, indicating an acceptor–donor ratio of 1 to 1, are included in Table I. The melting point of this compound was found to be 89–90° C. The molecular weight determinations, included in Table I, indicated a 2:2 molar ratio.

The System $TiCl_4$.1,3-DPU

The technique used to prepare the complex $2TiCl_4$.2(1,3-DPU) was almost the same as the one used to prepare $2TiCl_4$.2(1,1-DPU). The brown complex thus obtained melted at 162–169° C. Its analytical results and its molecular weight values are included in Table I.

The System $TiCl_4$.1,3-DETU

Excess pure $TiCl_4$ was added to DETU dispersed in methylene chloride and cyclohexane. Dropwise addition of $TiCl_4$ led to a dark red coloration with adhesion of viscous material to the wall of the reacting flask. After 2 days of agitation, a brown powder extremely sensitive to moisture was obtained. The melting point was found to be 62°. The analytical results are included in Table I.

The System $TiCl_4$.TU

The technique used was the same as the one used to prepare $TiCl_4$.2U. The compound obtained was a dark brown powder melting with decomposition at around 130° C. The results of the elementary analyses are included in Table I.

The System $TiCl_4$.1,1-DPTU

An excess of pure titanium tetrachloride was added to a suspension of the donor base in cyclohexane. A dark brown suspension was obtained which was at first very viscous and which then separated into an orange-yellow powder after 2 days of agitation. The compound was filtered off, washed on the filter with cyclohexane, and dried under vacuum at room temperature. On recrystallization from a dichloroethane solution reddish brown crystals were obtained. It melted without decomposition at 126° C.

The System $TiCl_4$.1,3-DPTU

The technique used here was very similar to the one used to prepare $2TiCl_4$.1,1-DPTU. The powder obtained, however, was dark brown, and recrystallization from a dichloroethane solution led to orange-yellow crystals of which the melting point was found to be 109–112°. The analytical results are included in Table I.

INFRARED SPECTRA AND STRUCTURAL DISCUSSION

The infrared spectra of urea, substituted ureas, and their coordination complexes are included in Table II, and illustrated in Figs. 1, 2.

*KBr disks.
†Methylene chloride solutions.
‡Fluorolube mulls.

A comparison of the infrared spectrum of urea with that of its complex indicates that the N—H stretching frequency is unchanged in the complex, but that the absorption bands observed in the carbonyl frequency region are shifted to lower values; this is an indication that the oxygen atom of urea is involved in coordination. The formula is then simply $TiCl_4$.2U, in which the urea molecules probably occupy cis positions.

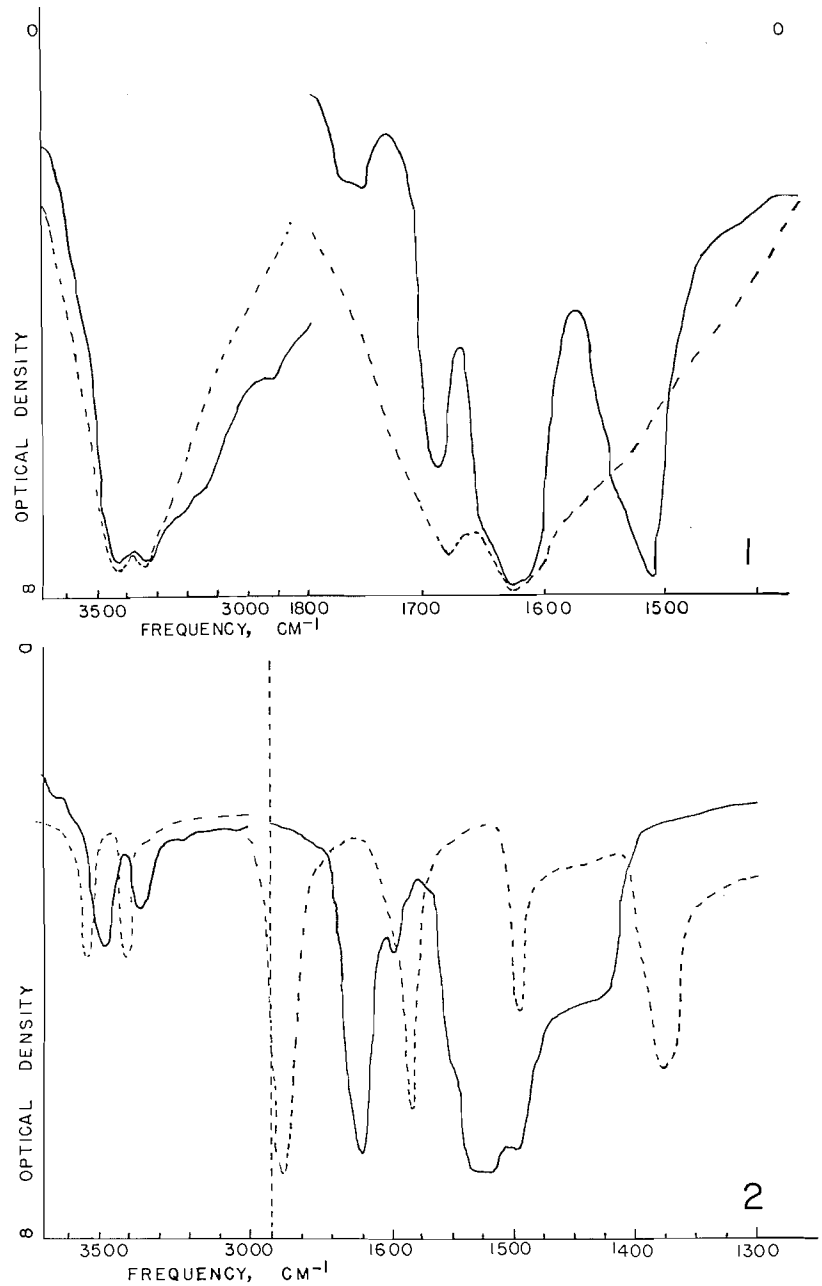

FIG. 1. Infrared spectra as KBr disks; – – – urea, —— $TiCl_4.2U$.
FIG. 2. Infrared spectra in methylene chloride solutions; – – – 1,1-DPU, —— $2TiCl_4.2(1,1\text{-DPU})$.

The changes in the spectra of the substituted urea when complexed to titanium (IV) are much larger. When 1,1-DPU is the donor base, complexing with titanium (IV) causes a bathochromic effect of some 40 cm^{-1} in the N—H stretching frequency region and of some 68 cm^{-1} in the carbonyl frequency region. Since molecular weight determinations of the complexes indicate dimeric values $2TiCl_4.2(1,1\text{-DPU})$, one could believe

that coordination in this compound takes place through oxygen and through one of the nitrogen atoms, probably of the NH_2 group. Then, two molecules of 1,1-DPU would act as bridging groups between the two $TiCl_4$ molecules. In such a case, however, the shift in the N—H stretching frequency should be much larger than 35 cm^{-1}. Quagliano (1) and co-workers have proposed 150 cm^{-1}. It seems, then, very reasonable to believe that the shift is due to intramolecular hydrogen bonding and that the dimeric nature of the complex is explained by assuming coordination through the oxygen, and halogen bridging between the two titanium (IV) atoms. This is illustrated schematically in Fig. 3, where it is shown that the two chlorines fill two coordinating positions each and where the broken lines indicate hydrogen bonding between the nitrogens.

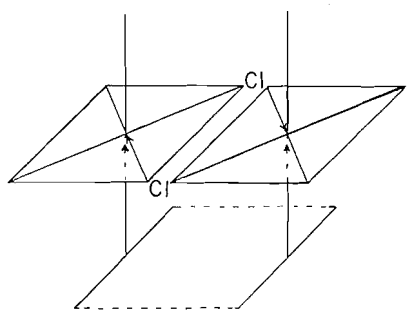

FIG. 3. Schematic representation of the complexes between $TiCl_4$ and 1,1-DPU and 1,3-DPU.

The complex formed with 1,3-DPU as donor base should have the same configuration as its analogue $2TiCl_4.2$(1,1-DPU). There is a difference in the sign of the N—H stretching frequency shift, but this difference is probably due to less favorable conditions for hydrogen bonding in the complex than in the pure 1,3-DPU. It is noticeable that the melting point of 1,3-DPU is considerably higher than that of 1,1-DPU, and this is certainly due to a difference in hydrogen bonding strength.

The infrared spectra of thiourea, substituted thioureas, and their coordination complexes are included in Tables III and IV and illustrated in Figs. 4, 5, and 6.

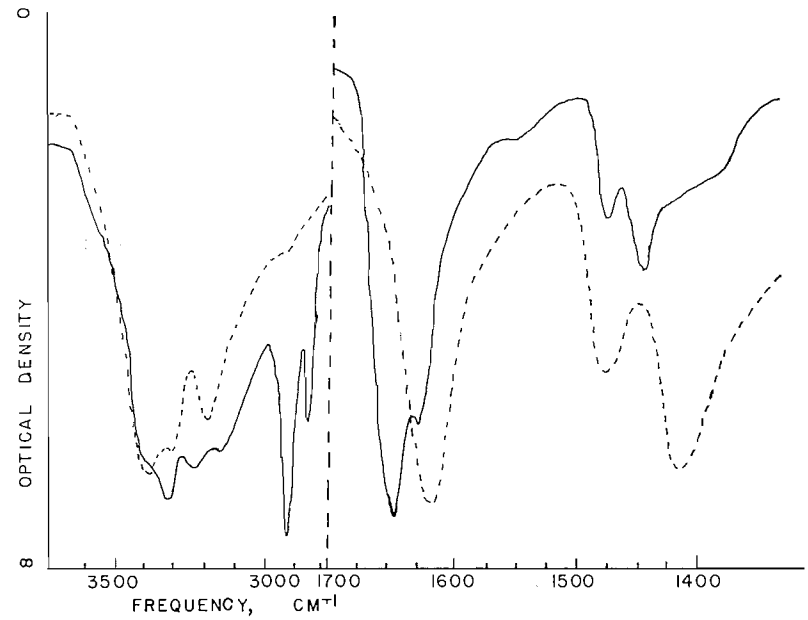

FIG. 4. Infrared spectra as KBr disks; - - - TU, —— $TiCl_4$.2TU.

The spectrum of thiourea when compared to the spectrum of $TiCl_4$.2TU shows a marked difference in the N—H stretching region and in the region attributed to NH_2 deformation and C=S stretching. A large negative shift observed in the N—H region combined with a positive shift in the C=S stretching region strongly suggests coordination through one of the nitrogens of thiourea. This would leave an uncoordinated nitrogen in each thiourea molecule and explain why the bands attributed to pure thiourea in the 3000 cm^{-1} region are still present in the spectrum of the complex. The formula proposed is simply, then, $TiCl_4$.2TU, in which the thioureas probably occupy cis positions on the titanium (IV) octahedron.

The complexes of substituted thioureas are quite interesting as monomeric species, especially because of their general formula $2TiCl_4$.1 donor base, which was confirmed by molecular weight determinations.

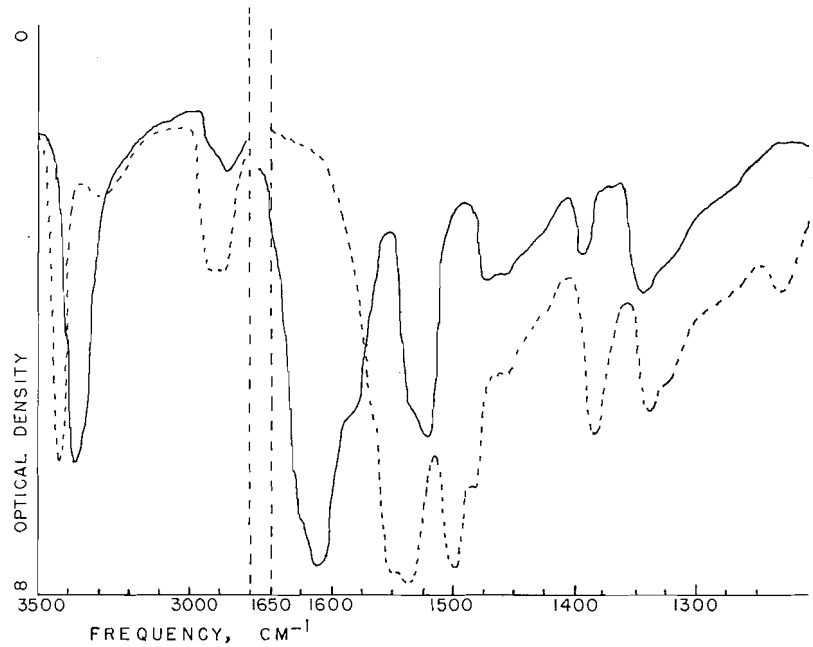

FIG. 5. Infrared spectra in methylene chloride solutions; - - - 1,3-DETU, —— $2TiCl_4$.1,3-DETU.

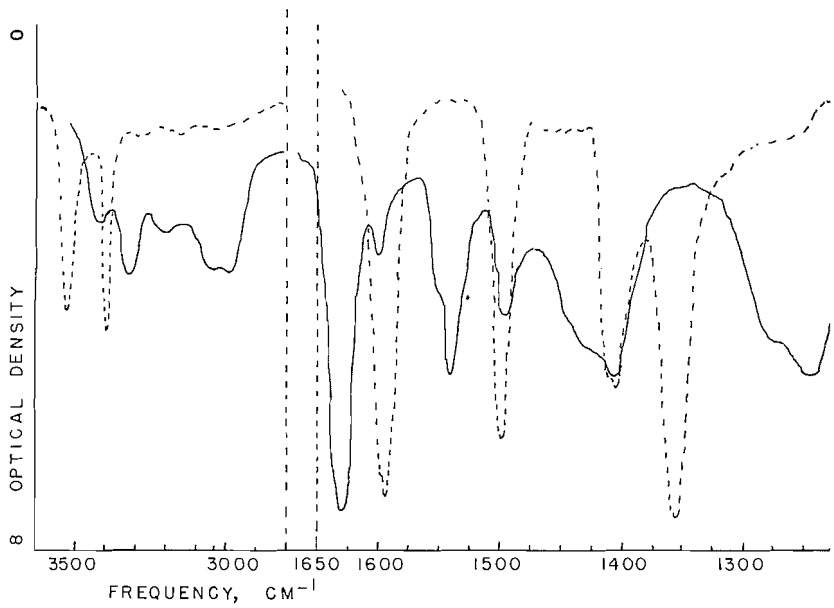

FIG. 6. Infrared spectra in methylene chloride solutions; - - - 1,1-DPTU, —— $2TiCl_4$.1,1-DPTU.

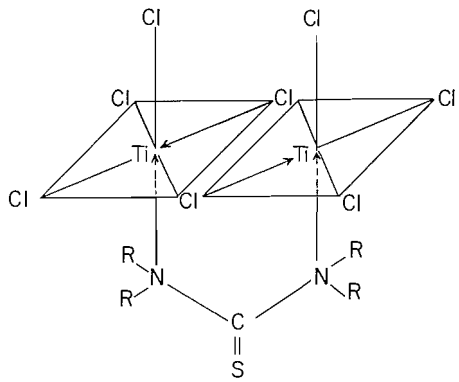
The infrared spectrum of the complex of DETU in methylene chloride solution showed only small differences from the spectrum of the pure donor base under the same condition. There is a negative N—H frequency shift of 30 cm^{-1}, a small positive shift for the NH deformation band and for the C=S stretching band. This is in agreement with the great

instability of this complex compound. Even if the perturbations in the spectrum are rather small, it is still believed that coordination involves the nitrogens of the ligand as donor atoms. If the donor atoms involved were one of the nitrogens and the sulphur atom, one should observe the original band at 3420 cm^{-1} in the spectrum of the complex molecule and the shifted band at lower frequency. This is not so. It seems, then, reasonable to assume that either the two titanium atoms have a coordination number of 5 and are held together by the bidentate DETU, or that they have a coordination number of 6 and the sixth position is occupied by halogen bridging of two chlorines.

For the system $2TiCl_4$.1,1-DPTU, the perturbation of the spectrum is much greater when going from the donor base to the complex. The N—H stretching frequency is shifted by 120 cm^{-1}, the N—H_2 deformation frequency is increased by about 30 cm^{-1}, and the C=S stretching is shifted to higher frequency by 37 cm^{-1} or to lower frequency by over 100 cm^{-1}. This last hypothesis is very unlikely because the shift due to complexing of the sulphur atom should be less than the one due to complexing of the oxygen atom and the carbonyl frequency shift observed in the spectrum of the complex $2TiCl_4$.2 (1,1-DPU) was found to be around 66 cm^{-1}. To find out if the presence of two phenyl groups on the donor atom would hinder the donor–acceptor reaction we have reacted diphenylamine and diphenyl ether with $TiCl_4$ and found that there was reaction in both cases. It seems quite reasonable to suppose that the two nitrogens of the 1,1-DPTU molecule are involved in coordination.

For the complex $2TiCl_4$.1,3-DPTU, the evidence of coordination through the two nitrogens of 1,3-DPTU is about the same, namely, a N—H frequency shift of 120 cm^{-1}, a N—H deformation frequency shift, and a positive shift for C=S stretching frequency. Moreover, since the original absorption band in the spectrum of 1,3-DPTU for the N—H stretching is not present in the spectrum of the complexes, it seems quite reasonable to believe that, in the complex, the two nitrogens are identical. This would not be true if only one nitrogen acted as donor atom. All the complexes prepared with the substituted thioureas can be represented by the following formula, in which R means a hydrogen, an alkyl, or an aryl radical:



ACKNOWLEDGMENTS

The author is glad to thank Mr. Gilles Murphy for the preparation and analysis of some of the complexes and also the National Research Council of Canada for the financial support of this work.

SOMMAIRE

Les complexes suivants du titane (IV) ont été préparés: $TiCl_4.2CO(NH_2)_2$, $TiCl_4.CO(NHCH_3)_2$, $TiCl_4.2CO(NHCH_3)_2$, $2TiCl_4.2NH_2CON(C_6H_5)_2$, $2TiCl_4.2CO(NHC_6H_5)_2$, $TiCl_4.2CS(NH_2)_2$, $2TiCl_4.CS(NHC_2H_5)_2$, $2TiCl_4.NH_2CSN(C_6H_5)_2$, and $2TiCl_4.CS(NHC_6H_5)_2$. On a aussi mesuré leurs spectres infrarouges et déterminé leur poids moléculaire. L'urée et ses dérivés coordonne au titane (IV) par l'atome d'oxygène. Les dérivés phényl de l'urée donnent des complexes binucléaires dûs à la formation de ponts halogénés entre les titanes. La thiourée et ses dérivés ont donné des complexes pour lesquels la coordination implique un atome d'azote dans le cas de la thiourée et les deux atomes d'azote dans les autres cas. La formation de pont halogénés explique aussi dans ce cas la formation de complexes binucléaires.

COORDINATION COMPLEXES OF TITANIUM (IV) HALIDES

IV. PREPARATION AND INFRARED SPECTRA OF THE COMPLEXES OF TITANIUM TETRACHLORIDE WITH CHLORINE-SUBSTITUTED ESTERS OF MONOBASIC ACIDS AS LIGANDS

SUMER CHAND JAIN AND ROLAND RIVEST
Department of Chemistry, University of Montreal, Montreal, Que.

Received June 29, 1962

ABSTRACT

Coordination complexes between titanium tetrachloride and some chlorine-substituted monoesters have been prepared.

Infrared spectra of these complexes and their melting points indicate that the strength of the coordination bonds decreases as the number of chlorines increases in the acid radical. When the substitution is in the alkyl radical, it is possible to prepare complexes of the formula $TiCl_4.2$ ester, since the chlorine substitution decreases the basic properties of the oxygen of the ether group in the ligand.

INTRODUCTION

Many coordination compounds between esters of monobasic acids and titanium tetrachloride have been reported previously (1–4). Physicochemical investigations on properties such as electrical conductance, viscosity, dipole moment, surface tension, density, specific heat, etc. have been carried out by Osipov (5, 6), Suchkov, and others but little work has been done on the effect of halogen substitution, in various esters, on complex formation.

Halogen substitution on the acid radical should lower the double-bond character of the carbonyl bond, thus weakening the bond between titanium (IV) and the carbonyl group. This should be evidenced by a lowering in the infrared carbonyl stretching frequency and also by a lowering in the melting points, since the melting point is the temperature at which almost all the sigma bonds are broken (7).

In order to prove these assumptions, we have prepared and studied the complexes formed between $TiCl_4$ and ethyl acetate, ethyl monochloroacetate, ethyl dichloroacetate, and ethyl trichloroacetate.

In a previous paper (3), it was postulated that the 1:1 addition compounds of monoester to titanium tetrachloride were due to the formation of a four-membered-ring chelate in which the two oxygens of the monoester were involved in coordination. It seemed of interest, then, to prepare some complexes in which the alkyl radical was substituted. β-Chloroethyl acetate was used for that purpose.

EXPERIMENTAL

Materials and Manipulations

Reagent grade titanium tetrachloride was purified by the method of Gilchrist (9), redistilled, and the medium fraction was used for our experiments.

The esters were dried over molecular sieves and used as such. The solvents used were normal hexane and methylene chloride, both of which were made absolutely dry by appropriate methods: normal hexane was kept dry with sodium wire, and methylene chloride, after being dried with phosphorus pentoxide, was distilled and kept in a dry box of very low humidity.

The complexes prepared were very sensitive to moisture and were, to avoid humidity, handled in the manner described in an earlier paper (8). The methods of analyses of titanium and chlorine have been described previously (8).

The infrared spectra measurements were carried out on a Perkin–Elmer infrared spectrophotometer,

Model 21, using a sodium chloride prism. The spectra were taken in solutions of suitable solvents and as nujol mulls.

Preparation of the Complexes

The preparation of these complexes was performed in normal hexane with solutions of the reactants ranging in concentration from 10 to 25%. The complexes prepared were yellow powders. The analytical results indicate that except for β-chloroethyl acetate, all the complexes are of 1:1 stoichiometric composition. Preparation of complexes of other molecular ratios have failed except for the specific case mentioned above. The analytical results of these complexes are included in Table I.

TABLE I

Analytical results

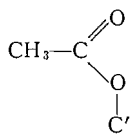
INFRARED SPECTRA AND STRUCTURAL DISCUSSION

Nolin and Jones (10, 11) have studied extensively the spectra of methyl acetate and ethyl acetate, and by selective deuteration they were able to assign most of the infrared absorption frequencies. Lappert (12) has discussed also the infrared spectra of the carboxylic esters as ligands. From these papers it seemed that the infrared spectra of these esters contain three absorption bands that can be easily identified and that are likely to be influenced by coordination. These bands are the carbonyl stretching frequency at 1741 cm^{-1} and two skeletal vibrations, one at 1238 cm^{-1} and the other one at 1046 cm^{-1}, all these bands being from the spectrum of liquid ethyl acetate.

According to this skeleton:



C—O would be represented by the 1238 cm^{-1} frequency, and C′—O by the 1046 cm^{-1} band. In the spectra of the complexes with halogenated esters as donor bases, it has not been possible to assign with reasonable certainty the band attributed to C—O in the 1250 cm^{-1} region because of the large number of bands with similar intensities in this region. However, the carbonyl frequencies ν_1 and C′—O frequencies ν_2 could be assigned easily and are given in Table II.

From this table, it can be seen that the presence of halogens in the acid or in the alkyl radical strongly influences the position of the two bands mentioned. The electronic pull of the chlorines decreases the double-bond character of the carbonyl bond and decreases the electronic density of the other bond. This effect is dependent upon the number of halogens on the acid radical, as is illustrated in Fig. 1. A bathochromic effect of ν_1 varying from 9 to 20 cm^{-1} and of ν_2 varying from 20 to 27 cm^{-1} is observed.

TABLE II

Infrared spectra in nujol mulls

β-Chloroethyl acetate	1748	1650	98	1043	1033	10	1:2

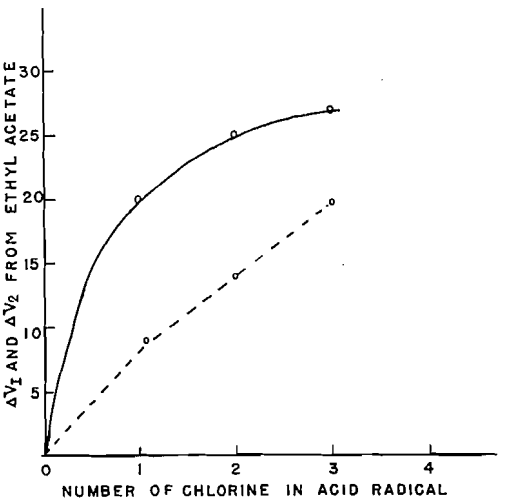

FIG. 1. Variation of the carbonyl stretching frequency and of the C—O frequency with respect to the number of chlorines in the acid radical; – – – $\Delta\nu_1$ variation, —— $\Delta\nu_2$ variation.

Walsh (13) and Cook (14) have proposed a relation between the ionization potential (IP) and the corresponding stretching frequency of a carbonyl group:

$$\nu_{C=O} = 49.351IP + 1249 \text{ cm}^{-1}. \quad [1]$$

This equation indicates that the smaller the carbonyl stretching frequency the smaller will be the ionization potential. Since the ionization potential is an indication of the electron availability, the smaller it is, the better will be the oxygen as a donor atom.

Since coordination to a Lewis acid usually causes a negative shift of the carbonyl frequency, the value of the shift should parallel the decrease in basic strength of the oxygen. Figure 2 is a plot of the bathochromic effect as a function of the number of chlorines on the acid radical. It indicates very clearly that the basicity decreases with an increase in the degree of halogen substitution. This is also indicated by a decrease in melting points, as shown in Table I. The fact that the melting point indicates breakage of the coordination bond can be illustrated by using the infrared spectrum of a complex taken at a temperature which is very close to its melting point. Ethyl trichloroacetate complex melting at 23–24° C was chosen for that purpose. Its infrared spectrum measured at room temperature is illustrated in Fig. 3; a peak in the 1768 cm^{-1} region due to the

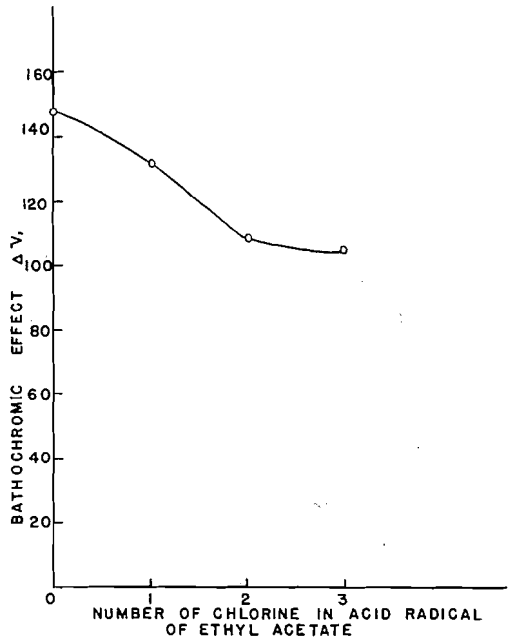

FIG. 2. Variation of the bathochromic effect as a function of the number of chlorines in the acid radical.

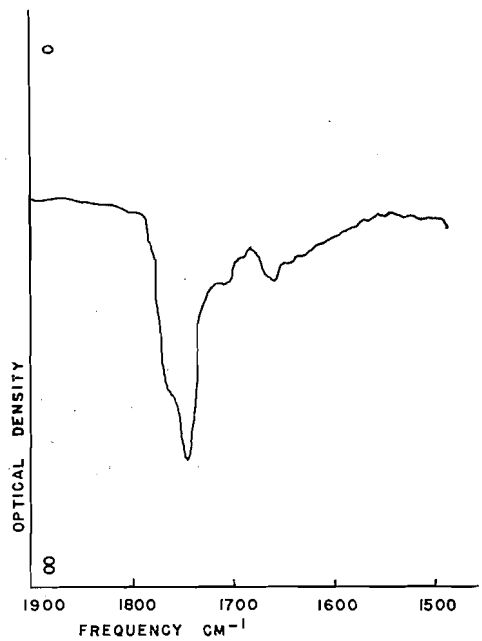

FIG. 3. Infrared spectrum of the trichloroacetate complex in nujol.

free ester is quite prominent in comparison with the one at 1663 cm^{-1} due to coordinated carbonyl group, thus indicating a very strong dissociation. This observation does not fit with the proposed reactions of Lysenko and Osipov (15), in which they presupposed that the dissociation in the liquid state proceeds according to the following scheme:

$$[TiCl_4.E]_2 \rightleftarrows [TiCl_2.2E][TiCl_6] \rightleftarrows [TiCl_2.2E]^{2+} + [TiCl_6]^{2-} \quad [2]$$

$$[TiCl_4.2E]_2 \rightleftarrows [TiCl_2.4E][TiCl_6] \rightleftarrows [TiCl_2.4E]^{2+} + [TiCl_6]^{2-}. \quad [3]$$

If this scheme were true, no uncoordinated carbonyl absorption bands would be observed in the infrared spectra of the species in the liquid state or in solution. Since we could not take the infrared spectra of all the complexes in the liquid state, we have taken them as solutions in methylene chloride. The results appear in Table III and are illustrated in Fig. 4. They indicate very clearly that as the melting point is approached, dissociation increases, this dissociation giving, always, uncoordinated carbonyl group.

TABLE III

Bathochromic effect of the carbonyl stretching frequency in methylene chloride solution

When the position of chlorine is shifted from the acid radical to the alkyl radical of the ester, the infrared spectra and the melting points again indicate some change in the donor properties of the ester. In Table IV, a comparison between complexes formed with

TABLE IV

Comparative data on addition complexes with isomeric esters (in nujol)

Ester in the complex	Shift in carbonyl stretching frequency (cm^{-1})	Shift in C—O stretching frequency (cm^{-1})	Melting point (°C)	Nature of adduct
$CH_2ClCOOEt$	132	34	109–110	1:1
$CH_3COOCH_2CH_2Cl$	98	16	78–80	1:1
$CH_3COOCH_2CH_2Cl$	98	10	74–76	1:2

isomeric esters, it is indicated that ethyl chloroacetate forms only a 1:1 addition compound. This was always observed even in experiments in which a large excess of the ester was used. This is different from the β-chloroethyl acetate, which gives 1:1 and 1:2 complexes. If one assumes that in the 1:1 addition compound there is formation of a four-membered-ring chelate, it is quite reasonable to believe that the replacement of one hydrogen by one chlorine would lead to a weaker coordinated bond of the oxygen of the ether group and facilitate the formation of the 1:2 complex.

ACKNOWLEDGMENT

The authors are indebted to the National Research Council of Canada for support of this work.

SOMMAIRE

Des complexes de coordination entre le tétrachlorure de titane et quelques monoesters chlorés ont été préparés. Les spectres infrarouges de ces complexes et leurs points de fusion indiquent que la force du lien de coordination diminue avec l'augmentation du nombre de chlores contenus dans le radical acide. Si la substitution a lieu sur le radical alkyl, il est possible de préparer des complexes de formule $TiCl_4.2$ ester, parce que la substitution d'un chlore à un hydrogène diminue les propriétés basiques de l'oxygène éthéré du ligand.

STUDIES ON THE MECHANISM OF PERSULPHATE-INITIATED GRAFTING ONTO CELLULOSE

S. M. SANKALIA, D. K. RAY CHAUDHURI,* AND J. J. HERMANS†

Cellulose Research Institute, State University, College of Forestry, Syracuse, N.Y., U.S.A.

Received July 11, 1962

ABSTRACT

When the polymerization of vinyl acetate or acrylonitrile is initiated by persulphate in the presence of cellophane, grafting onto the cellulosic backbone occurs. This is proved by comparing the graft with a physical mixture of cellulose and homopolymer.

Some aspects of the mechanism of this grafting are studied by means of model compounds, in particular pinacol. It is found that the rate of polymerization of acrylonitrile initiated by persulphate is increased by the addition of pinacol, but decreases on addition of more pinacol. This may be explained by assuming that the radicals formed from the pinacol can terminate each other and that this reaction competes with the reaction between these radicals and the monomer. The amount of acetone formed by the persulphate oxidation of pinacol at low pinacol concentrations is about 0.5 mole per mole persulphate and decreases with increasing pinacol concentration. This indicates complexities that do not exist in the ceric ion oxidation of pinacol.

INTRODUCTION

It has been shown by Kolthoff and Miller (1) that the decomposition of persulphate ions produces sulphate ion radicals according to a first-order reaction. In addition, a decomposition takes place that does not produce radicals, but the rate of this second process is very small compared with that of the first when pH > 4.

Methanol accelerates the decomposition of persulphate (2), and it was shown by Kolthoff, Meehan, and Carr (3) that this is due to a reaction between persulphate ions and alcohol radicals (reaction [3]). This is demonstrated by the fact that the rate of

$$S_2O_8^{=} \rightarrow 2SO_4^{-}\cdot\text{; rate constant } k_0 \qquad [1]$$

$$SO_4^{-}\cdot + \text{Alc} \rightarrow HSO_4^{-} + \text{Alc}\cdot\text{; rate constant } k_1 \qquad [2]$$

$$\text{Alc}\cdot + S_2O_8^{=} \rightarrow \text{aldehyde} + HSO_4^{-} + SO_4^{-}\cdot \qquad [3]$$

decomposition of persulphate is reduced to the much lower value observed in the absence of methanol when a monomer is added to the system. In this case, the SO_4^{-} radicals produced by reaction [1] react with the monomer:

$$SO_4^{-}\cdot + M \rightarrow P\cdot\text{; rate constant } k_i. \qquad [4]$$

P· represents the polymer radical. This has been interpreted as meaning that reaction [2], and therefore also reaction [3], are suppressed. It is also possible, however, that only reaction [3] is suppressed and that the alcohol radicals react with monomer. This has an obvious bearing on the question as to whether polymerization initiated by persulphate in the presence of cellulose, starch, or other polyalcohols leads to grafting onto the polyalcohol. Haydel *et al.* (4) reported experiments with cotton in acrylonitrile vapor, but they refer to the process as deposition in and coating of the cotton, without investigating whether grafting occurred. Hayes (5) reported that grafting took place when the (emulsion) polymerization of butadiene was initiated by persulphate in the presence of highly cross-linked butadiene, and attributed this result to chain transfer. In principle, it cannot be excluded that chain transfer from a growing polymer chain to cellulosic

*Ontario Research Foundation, 43 Queen's Park, Toronto, Ontario.
†Present address: Chemstrand Research Center, Inc., Durham, N.C.

molecules (6) also takes place. However, cellulosic radicals may also be formed directly, since reaction [2] between SO_4^- radicals and methanol suggests that a similar reaction occurs between SO_4^- radicals and cellulose. The cellulosic radical formed could then initiate polymerization and form a graft. On the basis of the reactions established by Kolthoff, Meehan, and Carr, it may be expected that the likelihood of this type of grafting is determined by a competition between cellulose and monomer. For grafting to occur, it is necessary that reaction [2] takes place to an appreciable extent even when monomer is present and that the alcoholic radicals formed take part in the initiation of the polymerization. It may be expected, therefore, that the result will depend on the conditions of the experiment.

GRAFTING ONTO CELLOPHANE

Gel cellophane was soaked in an aqueous solution of persulphate and subsequently brought into contact with pure monomer. It is believed that this procedure creates conditions favorable to grafting. Since the monomer is a poor solvent for the persulphate, only small amounts of catalyst will diffuse from the gel into the monomer phase, so that little if any homopolymer is formed outside the cellophane. The concentration of cellulose in the gel being high, the rate of reaction [2] is large, so that the monomer which diffuses into the gel finds a high concentration of cellulosic radicals with which to react.

All experiments were done in a nitrogen atmosphere. After completion of the reaction, the film was thoroughly extracted with a solvent for the homopolymer, then dried in a vacuum oven at 60° C for 48 hours and weighed. The results are given in Table I. It is possible that part of the weight increase is due to homopolymer that could not be removed by solvent extraction. The following experiment shows, however, that an appreciable amount of graft was formed.

TABLE I

Monomer	c	Reaction time (hr)	Reaction temp. (°C)	G	H
Vinyl acetate	0.1	1.5	60	40.5	0.7
Vinyl acetate	0.1	1.5	50	15.4	
Vinyl acetate	0.1	4.8	60	80.7	1.0
Vinyl acetate	0.2	1.5	60	70.0	1.0
Acrylonitrile	0.1	0.4	50	84	2.7

NOTE: c = concentration of persulphate solution (mole/l.) used to soak film; G = % weight increase of film on basis of dry weight of cellophane; H = % homopolymer, on basis of total monomer used.

The product containing 80 g polyvinyl acetate per 100 g dry cellulose was hydrolyzed with 0.25 N alcoholic sodium hydroxide solution at about 50° C for 20 hours. This was done under nitrogen to minimize degradation of the cellulose. After conversion of the polyvinyl acetate chains to polyvinyl alcohol, the product was completely soluble in cupriethylenediamine. On acidifying this solution with 4% HCl, a precipitate resulted, which was washed with rochelle salt solution and then water. The infrared spectrum (KBr pellet) showed absorption in the region 12–13 μ, due to the presence of polyvinyl alcohol in the precipitate. This absorption is absent when the same procedure is followed with a physical mixture of 1 g dry cellophane and 0.8 g polyvinyl acetate. It follows that at least part of the weight increase was due to grafting.

To learn more about the possible mechanism of this grafting, studies were made with low molecular weight model compounds, as described in the next section.

STUDIES WITH LOW MOLECULAR WEIGHT COMPOUNDS

1. Serine Methyl Ester

The oxidation of the hydrochloride of serine methyl ester by persulphate in aqueous solution produces formaldehyde, as indicated by the color reaction with chromotropic acid (7). This suggests that the following radical is formed:

$$HOCH_2—\underset{\displaystyle NH_3Cl}{\underset{|}{CH}}—COOCH_3 \longrightarrow \cdot\underset{\displaystyle NH_3Cl}{\underset{|}{CH}}—COOCH_3.$$

Since this radical contains both an amine and an ester end group, it opens a possibility for checking whether this radical initiates polymerization. To explore this possibility, serine methyl ester was reacted with persulphate in the presence of acrylonitrile. The polymer formed was washed carefully. Infrared absorption revealed that it contained both NH_2 and $COOCH_3$ groups.

2. Pinacol

Pinacol was chosen as a model substance because its oxidation by ceric ions in aqueous solution has been studied in detail by Mino, Kaizerman, and Rasmussen (8), who found that in the absence of a monomer, each mole of ceric ion that is reduced to cerous ion produces 1 mole of acetone. In the presence of a monomer only half this amount of acetone is formed. This is explained by the following mechanism:

$$(CH_3)_2C(OH)—C(OH)C(CH_3)_2 + Ce^{IV} \rightarrow (CH_3)_2CO + \cdot C(OH)(CH_3)_2 + Ce^{III} + H^+.$$

In the absence of a monomer, the radical formed is oxidized to acetone by one more mole of Ce^{IV}, but when sufficient monomer is present, the alcoholic radical is used up to initiate the polymerization, and a second mole of ceric ion is used in the termination step without producing any acetone. For details see reference 8. It was hoped that similar, clear-cut, results would be found when pinacol was oxidized by persulphate.

Pinacol (Eastman Kodak) was purified by distillation at atmospheric pressure (b.p. 169.5–170.5° C). Acrylonitrile (Eastman Kodak) was freshly distilled, likewise at atmospheric pressure (b.p. 76.5–77.5° C), at the beginning of each experimental run when the solutions were prepared. The persulphate was Certified Fisher Reagent, 99.5% pure by iodometric titration (9). The reagents used for the titration were of Analytical Reagent grade.

All the experiments were carried out in a nitrogen stream at 50° C, in the presence of 0.05 *M* phosphate buffer, pH = 7. Loss of water or monomer was prevented by means of a reflux condensor. Samples were withdrawn at various times for analysis. In those cases in which acrylonitrile was present, the polymer formed precipitated. It was washed, dried, and weighed.

Table II shows the rate of persulphate decomposition under various conditions. The possible experimental error in this rate is about 10%. It is seen that the rate is increased by the presence of pinacol when no monomer is present, but this acceleration is very much smaller than that caused by methanol (3). When monomer is added, the rate of persulphate decomposition in the presence of pinacol is reduced again to that observed in the absence of pinacol. It even appears to drop slightly below this value, although it is not certain that this effect is outside the experimental error.

Figure 1 shows the monomer conversion as a function of time under the conditions listed in Table II. The inset in Fig. 1 gives the amount of polymer formed after 4 hours as a function of pinacol content, showing that the rate of polymerization first increases but subsequently decreases with increasing pinacol concentration.

TABLE II

Rate of decomposition (% per hour) of 0.01 *M* persulphate in various mixtures at 50° C, pH = 7

Pinacol (mole/l.)	Acrylonitrile (mole/l.)	Rate (% per hr)
0	0	0.79
0.05	0	1.17
0.10	0	1.30
0	0.3	0.72
0.05	0.3	0.71
0.10	0.3	0.67
~0.3	0.3	0.65

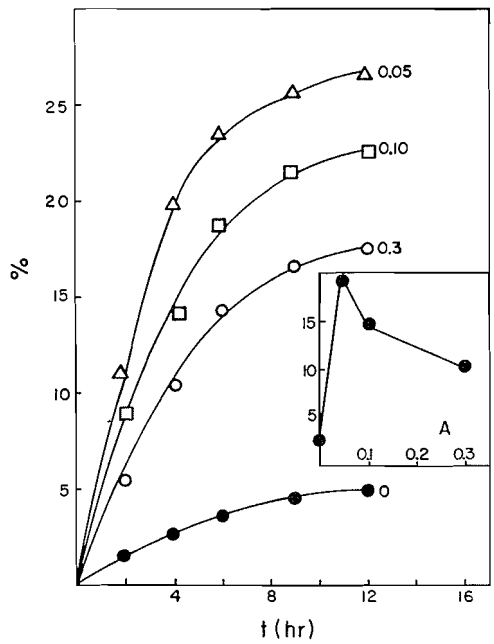

FIG. 1. Percent conversion of monomer as a function of time for pinacol concentrations 0–0.05–0.1 and about 0.3 *M*. Inset: % conversion after 4 hours as a function of pinacol concentration.

Some attempts were made to determine the amount of acetone formed, using the spectrophotometric method of Behre and Benedict (10). In analogy with the oxidation by ceric ions (8), it was hoped that the principal reaction would be

$$SO_4^{-}\cdot + (CH_3)_2C(OH)—C(OH)C(CH_3)_2 \rightarrow HSO_4^{-} + (CH_3)_2\dot{C}OH + (CH_3)_2CO,$$

followed, perhaps, by further oxidation (to acetone) of the radical formed. If this were correct, the amount of acetone produced for every mole of persulphate decomposed would be at least 2 mole. It was found, however, that only about 1/2 mole of acetone was formed for every mole of persulphate reduced when the pinacol concentration was 0.05 *M* and that this figure was decreased to about 1/3 mole acetone when the pinacol concentration was increased to 0.1 *M*. The persulphate concentration in both cases was 0.01 *M*, pH = 7, temp. 50° C. The result shows that some of the sulphate ion radicals are ineffective in the oxidation of pinacol (compare reaction [5] below) or else that products other than acetone are formed.

3. Glucose

The results with pinacol, although qualitatively similar to those found for methanol (3), suggest that, quantitatively, different alcohols may differ considerably in their behavior toward persulphate. A study with D-glucose showed that this alcohol, like the others, increased the rate of decomposition of persulphate. This effect was of the same order of magnitude as that observed with pinacol, but the addition of acrylonitrile this time did not reduce the rate of persulphate decomposition to the value found in the absence of glucose. The measurements were done at pH = 7 and at 50° C in an aqueous solution of persulphate, 0.01 *M*, and acrylonitrile, 0.3 *M*. In the presence of 0.1 *M* D-glucose, the rate of persulphate decomposition was 1.18% per hour. In the presence of 0.3 *M* glucose it was 1.83% per hour. These figures are to be compared with the value of about 0.7 in the absence of glucose (see Table II). The monomer conversion was the same within experimental error: about 30% after about 10 hours in both experiments.

DISCUSSION

In analogy with the mechanism proposed by Kolthoff, the following tentative explanation of the data is suggested.

Sulphate ion radicals are produced by reaction [1]. In the absence of reducing agents, these radicals disappear:

$$2SO_4^-\cdot \rightarrow \text{end products; rate constant } \lambda. \qquad [5]$$

The details of this reaction will not be considered. It may involve reaction with water under formation of OH radicals, which subsequently form H_2O_2. This would mean that one may have to consider reactions of alcohol and monomer with OH radicals instead of (or in addition to) reactions with $SO_4^-\cdot$. The reaction scheme would then become quite complicated, but the general conclusions arrived at would not be affected.

Reaction [3] accounts for the fact that the rate of decomposition of persulphate is increased by the presence of pinacol. This effect is not very large and is suppressed by acrylonitrile. The increase in the rate of polymerization on addition of alcohol indicates that reaction [2] is not suppressed. Alcohol radicals are formed and become progressively more important in the initiation step:

$$\text{Alc}\cdot + \text{M} \rightarrow \text{P}\cdot; \text{ rate constant } k_i'. \qquad [6]$$

However, as the concentration of these alcohol radicals is increased, there will also be an increased rate of termination, and this radical-destroying reaction,

$$2\text{Alc}\cdot \rightarrow \text{end products; rate constant } \mu, \qquad [7]$$

may eventually become so important that the rate of polymerization decreases again. This could explain why the rate of polymerization—although increased by the addition of pinacol—is decreased again on addition of more pinacol. This argument can be given in more quantitative terms, as follows. If we add the termination step

$$\text{P}\cdot + \text{P}\cdot \rightarrow \text{polymer; rate constant } k_t, \qquad [8]$$

the kinetics are supposed to be fully described by the reactions [1]–[8]. Of these reactions, [3] is suppressed by the presence of the monomer and will therefore be omitted. Then, if c is the concentration of persulphate, A that of the alcohol, m that of monomer, and if x, y, and r represent the concentrations of $SO_4^-\cdot$ radicals, alcohol radicals, and polymer radicals respectively,

$$2k_0c - 2\lambda x^2 - k_1Ax - k_tmx = 0 \qquad [9]$$

$$-2\mu y^2+k_1Ax-k_i'my = 0 \quad [10]$$

$$k_imx+k_i'my-2k_tr^2 = 0 \quad [11]$$

$$-dm/dt = m(k_ix+k_i'y+k_pr), \quad [12]$$

where k_p is the propagation rate constant. The equations [9], [10], and [11] give the expressions for dx/dt, dy/dt, and dr/dt respectively. They have been equated to zero on the (usual) assumption that "quasi steady state" conditions prevail. Eliminating r from equations [11] and [12], it is seen that the rate of polymerization for a given value of m is determined by the quantity

$$R = k_ix+k_i'y, \quad [13]$$

namely:

$$-dm/mdt = R+CR^{1/2},$$

where

$$C = k_p(m/2k_t)^{1/2}.$$

It will be shown that R increases on addition of alcohol but may decrease again on the addition of more alcohol. To this end, equations [9] and [10] are differentiated with respect to A at constant c and m. From the equations obtained one can solve for dx/dA and dy/dA, with the result

$$dx/dA = -(k_ix/N)(4\mu y+k_i'm) \quad [14]$$

$$dy/dA = (k_ix/N)(4\lambda x+k_im) \quad [15]$$

$$N = (4\mu y+k_i'm)(4\lambda x+k_im+k_iA).$$

This shows that dx/dA is negative and dy/dA positive for all values of A. Using the definition of R given in equation [13], it follows from equations [14] and [15] that

$$dR/dA = (4k_ix/N)(\lambda k_i'x-\mu k_iy). \quad [16]$$

At low alcohol concentrations, y is small so that dR/dA is positive. However, on increasing A, we know that x decreases and y increases, so that dR/dA will become smaller and may eventually become negative. This is the behavior found in Fig. 1 (inset).

CONCLUSION

The considerations in the preceding section are semiquantitative, because only a limited number of the possible reactions have been considered. A more complete reaction scheme would not, however, change the nature of the conclusions arrived at. The increase and subsequent decrease in the rate of polymerization when the pinacol concentration is increased may thus be considered as a natural consequence of the reactions involved.

These same reactions may have a bearing on the observation that the amount of acetone formed per mole of persulphate reduced decreases when the pinacol concentration is increased, but this statement is only tentative because the mechanism of the oxidation of pinacol by persulphate is not clear.

If our conjectures are correct, the results with glucose mean that in this case the reaction [3] is not suppressed by the presence of the monomer, even though the rate of polymerization is increased by the presence of the glucose. It must be borne in mind

that the oxidation of glucose by persulphate may be a complicated reaction in which several oxidation products and quite a few intermediates are formed. Any detailed speculation would be premature at the present stage.

The results obtained with the low molecular weight compounds indicate that grafting onto polymeric alcohols by the mechanism suggested in the introduction—although not firmly established—may be considered as a very likely process.

HYDROLYSIS PRODUCTS OF PERIODATE-OXIDIZED PHOSPHOMANNAN Y-2448

ALLENE JEANES, J. E. PITTSLEY, P. R. WATSON, AND J. H. SLONEKER

Northern Regional Research Laboratory, Northern Utilization Research and Development Division, Agricultural Research Service, U.S. Department of Agriculture, Peoria, Ill., U.S.A.

Received May 17, 1962

ABSTRACT

Sequences of at least three α-1,3-linked mannose units have been shown to occur in phosphomannan Y-2448 through isolation of 3-O-[3-O-(α-D-mannopyranosyl)-α-D-mannopyranosyl]-D-mannose from partial acid hydrolyzates of both the native and the periodate-oxidized phosphomannan. 3-O-(α-D-Mannopyranosyl)-D-mannose has been obtained also. The mannosidic bond in these oligosaccharides appears to be more stable to acid hydrolysis than that by which the mannose 6-phosphate unit is held in this macromolecular polysaccharide derivative. It has been established that the D-mannose 6-phosphate unit is oxidized by periodate and that orthophosphate is the form which occurs in this phosphomannan.

The phosphomannan produced exocellularly by the yeast *Hansenula holstii* NRRL Y-2448 and isolated as the potassium salt is comprised of D-mannose, phosphate, and potassium in the molar ratio of 5:1:1 (1). The phosphate occurs in diester linkage between the carbon-6 position of one mannose unit (2) and the carbon-1 hemiacetal position of another (1, 2). Periodate oxidation indicates that 33% of the D-mannose units are linked through carbons-1 and -2, and 47% through carbons-1 and -3 (3).

Data from periodate oxidation of this phosphomannan indicate that significant structural information as well as saccharides heretofore unavailable might be obtained through hydrolysis of the periodate-oxidized product (3). The fact that inorganic phosphate could be eliminated by alkali from the periodate-oxidized but not from the native phosphomannan offered a means of establishing the form, either ortho or pyro, in which phosphate occurs in this unusual polysaccharide derivative. The absence of D-mannose 6-phosphate from among the products of acid hydrolysis would confirm other indications that this unit was oxidized by periodate (3). The fact that the mannose units were α-linked and that about 47% of them were inert to oxidation indicated an attractive source from which α-1,3-linked mannose oligosaccharides might be obtained by mild acid hydrolysis. Previously, 3-O-(α-D-mannopyranosyl)-D-mannose has been obtained only by acid reversion of D-mannose (4). Other members of this homologous series have not been reported.

RESULTS AND DISCUSSION

The form of phosphate that occurs in phosphomannan Y-2448 was shown to be ortho. Inorganic orthophosphate was demonstrated in phosphomannan which had been oxidized by periodate and subsequently treated with alkali, by paper chromatography and by a selective method of phosphorus analysis (5, 6). To avoid the possibility of hydrolysis of pyrophosphate, if it had been present, the conditions for all chemical reactions and physical operations were those under which inorganic pyrophosphate controls had been shown to be stable.

Several observations attested that the D-mannose 6-phosphate unit of phosphomannan Y-2448 is oxidized by periodate. Paper chromatography showed that this unit was not

among the products of autohydrolysis or of formic acid hydrolysis of the periodate-oxidized phosphomannan. Low molecular weight organic phosphate (possibly phosphoglyceraldehyde) and inorganic orthophosphate appeared during early stages of hydrolysis. Hydrolysis liberated inorganic orthophosphate from periodate-oxidized phosphomannan more rapidly and much more completely than from native phosphomannan.

Preliminary observations on acid hydrolysis of native phosphomannan (hydrogen form) showed that in 5 *N* formic acid at 100° C, maximum reducing power was reached in about 36 hours at a value 95% of that expected for complete hydrolysis to mannose. Products present at this time were D-mannose, D-mannose 6-phosphate, some inorganic orthophosphate, and traces of neutral oligosaccharides. After only 6 hours' hydrolysis under these conditions, substantial amounts of neutral di-, tri-, and tetra-saccharides were present in the hydrolyzate (Table I). Other work (2) has shown that the initial

action of acid on native phosphomannan Y-2448 liberates oligosaccharide phosphomonoesters and that further hydrolysis produces D-mannose 6-phosphate in high yields.

When hydrolyzed in 5 *N* formic acid, the periodate-oxidized phosphomannan appeared to reach any given stage of partial hydrolysis about twice as fast as the native phosphomannan. When autohydrolyzed, the periodate-oxidized product depolymerized slowly enough that good yields of neutral di- and tri-saccharides were obtained (Table I). Autohydrolysis of the native phosphomannan progressed even more slowly, but permitted accumulation in hydrolyzates of neutral saccharides of D.P. 2, 3, and 4; at early stages of hydrolysis traces of a saccharide of D.P. 5 were also apparent. The neutral oligosaccharides from native and periodate-oxidized phosphomannans displayed identical chromatographic behavior.

These observations indicate that native phosphomannan Y-2448 has some sequences of at least four neutral mannose units and that these, as well as sequences of three units, are freed rather readily from mannose 6-phosphate units, which are believed to have been attached to (or near) them (3). Liberation of these neutral oligosaccharides apparently is not dependent on hydrolysis of the carbon-6 phosphate–ester bond since, under the conditions of hydrolysis (Table I), mannose 6-phosphate was found in the hydrolyzate of the native phosphomannan but essentially no inorganic phosphate was present. Thus, the glycosidic bond by which mannose 6-phosphate units are attached to mannose units seems more labile to hydrolysis than the bond joining the neutral mannose units. This appears to be contrary to the reported stabilization by phosphate of galactosidic bonds in di- and tri-saccharides terminated by galactose 6-phosphate (7).

In periodate-oxidized phosphomannan, the maximum sequence of units inert to periodate is restricted almost exclusively to three (Table I). Apparently, one unit in the sequence of four observed in the native phosphomannan has been oxidized by periodate. This possibility is in keeping with other structural details on phosphomannan Y-2448 (Fig. 1 of reference 3) as is also the indication (Table I) that the di-, tri-, and possibly even the mono-saccharides may originate mainly as blocks from the periodate-oxidized phosphomannan.

The identity of the neutral di- and tri-saccharides has been established as 3-O-(α-D-mannopyranosyl)-D-mannose and 3-O-[3-O-(α-D-mannopyranosyl)-α-D-mannopyranosyl]-D-mannose, respectively. The relatively high specific optical rotations, +57.6° and +79.8°, correlate with α-configurations. The specific optical rotation of the disaccharide is higher than that reported previously (4) and is the same as one (8) of the two values (4, 8) reported for 6-O-(α-D-mannopyranosyl)-D-mannose. However, lead tetraacetate oxidation (10) by a technique based on that of Perlin (11) gave results for the disaccharide in agreement with those previously reported for 3-O-(α-D-mannopyranosyl)-D-mannose (9) obtained by acid reversion of D-mannose (4), that is, about 1.6 moles of carbon dioxide were given off in 6 hours and D-arabinose was identified among the hydrolyzed oxidation products after both 2 and 20 hours. The trisaccharide produced 1.1 moles of carbon dioxide in 6 hours; after 20 hours' oxidation, both D-arabinose and D-mannose were present among the hydrolyzed oxidation products. These results are consistent with those expected for a 1,3-linked structure and eliminate the possibility of other linkages.

EXPERIMENTAL

Preparation of Materials, and Hydrolysis

Periodate-oxidized phosphomannan Y-2448, the product of a 240-hour oxidation at 4° C, was prepared as previously described (3). Excess periodate was removed by ethylene glycol (stoichiometric amount) and the solution was dialyzed against distilled water at 4° C until free of inorganic salts. Visking[1] dialysis tubing (1-7/8 S.S.) was washed repeatedly or boiled in water before use (5).

The dialysis residue was passed through Dowex 50X2, 50–100 mesh (H^+ form) cation exchange resin and then hydrolyzed at 0.3% concentration and 100° C in its own acidity (pH 2.5). At 72 hours' autohydrolysis, when the oligosaccharide concentrations were near their maxima, all phosphate was in the inorganic form. The hydrolyzate was used directly for qualitative paper chromatographic examination for organic phosphates but was deanionized (Dowex 3X4, 20–50 mesh) before quantitative paper chromatographic analysis and isolation of neutral oligosaccharides.

Dialyzates were neutralized and concentrated *in vacuo* at solution temperatures not exceeding 30° C.

Similarly, dialyzates were obtained from periodate-oxidized phosphomannan Y-2448 that had been treated with alkali or glycine buffer, to eliminate phosphate in inorganic form as previously described (3), and neutralized. These solutions were concentrated under conditions that did not hydrolyze inorganic pyrophosphate controls, that is, at solution temperatures not exceeding 30° C and at pH's in the range 6.5–8.5.

Native phosphomannan Y-2448 (1), decationized by Dowex 50X2, 50–100 mesh (H^+ form) exchange resin, hydrolyzed slowly in its own acidity (pH 2.2) at 100° C. Hydrolyzates obtained under these conditions were suitable for examination of products by paper chromatography, but for observations on rate and completeness of hydrolysis, a 0.2% concentration of decationized phosphomannan was treated with 5 *N* formic acid in sealed tubes at 100° C. Individual tubes were opened at chosen times, the hydrolyzate was transferred to a small flask, and formic acid was removed by evaporation, first *in vacuo* and then in the presence of toluene. Measurements of reducing power were made on these solutions (12). For isolation of products, larger amounts of hydrolyzate (from 0.65% phosphomannan concentration) were treated similarly except that for complete removal of formic acid, residues were taken to dryness, redissolved in water or ethanol, and dried again several times. Analysis showed that after 6 hours' hydrolysis essentially all the phosphate was in the organic form, but after 22 hours, 20% was inorganic. Phosphate and phosphate esters then were removed from hydrolyzates by use of Dowex 3X4, 20–50 mesh (amine form).

Paper Chromatography

Solvent systems used for separating the inorganic components of dialyzates were: (*a*) *n*-propyl alcohol –

[1]*Mention of trade names should not be construed as a recommendation or endorsement by the U.S. Department of Agriculture over those not mentioned.*

water – aqua ammonia (sp. gr. 0.90) (6:1:3) (13); and (*b*) the upper phase of *n*-butyl alcohol – pyridine – 1.5 *N* ammonium hydroxide (2:1:2) (14) (all v/v). Solvent systems used for separating carbohydrate components of hydrolyzates were: (*c*) *n*-butyl alcohol – pyridine – water (6:4:3) (15); (*d*) the upper phase of ethyl acetate – acetic acid – water (3:1:3) (16); and (*e*) ethyl acetate – acetic acid – water (3:3:1) (17) (all v/v).

Phosphate was detected by dipping chromatograms in an ammonium molybdate – perchloric acid reagent (18) and using ultraviolet light (2537 Å) to bring out the spots (19). Reducing sugars were detected by *o*-aminobiphenyl phosphate in glacial acetic acid (20).

For quantitative chromatography of hydrolyzates, Whatman No. 1 papers were spotted in triplicate with 1000–3000 μg of sugar per spot and the papers were irrigated for two 20-hour periods (15) with solvent *c*. The spots and corresponding blanks were eluted; the eluates were filtered through sintered glass and analyzed by the phenol – sulphuric acid method (21).

Isolation and Characterization of Oligosaccharides

For separation and isolation of neutral oligosaccharides, hydrolyzates were streaked on Whatman 3 MM paper and irrigated with solvent *c* for 40 hours. The sugars were eluted, the eluates were concentrated *in vacuo*, and the residues were taken up in water and filtered through decolorizing carbon. The sugars were precipitated several successive times from aqueous solution by ethanol and dried *in vacuo*.

On papergrams, the di- and tri-saccharides migrated slightly faster than the α-1,6-linked isomaltose and isomaltotriose (22). The di-, tri-, and tetra-saccharides did not show a positive reaction for phosphate when the papergram was dipped in an ammonium molybdate – perchloric acid reagent and irradiated with ultraviolet light under conditions known to detect difficultly hydrolyzable sugar phosphates (19). The di- and tri-saccharides reacted with triphenyltetrazolium chloride reagent, as would be expected from the presence of a free hydroxyl at carbon-2 in the reducing sugar units (23). Plots of log distance traveled (in solvent *c*) vs. D.P. for D-mannose and for the di-, tri-, and tetra-saccharides gave essentially straight lines. However, this rough indication of an homologous series (15) could be misleading in relation to the tetrasaccharide.

The disaccharide showed $[\alpha]_D^{25}$ +53.6° → +57.6° at 20 hours (*c*. 0.434, water). Anal. Calc. for $C_{12}H_{22}O_{11}$: C, 42.10; H, 6.49. Found: C, 41.42; H, 6.54.

The trisaccharide showed $[\alpha]_D^{25}$ +79.8° at 6 hours (*c*. 0.708, water). Anal. Calc. for $C_{18}H_{32}O_{16}$: C, 42.86; H, 6.39. Found: C, 43.54; H, 6.75.

Lead tetraacetate oxidation of the oligosaccharides was conducted by a technique (10) based on that of Perlin (11). Preparatory to paper chromatography in solvent *c*, oxidation solutions were treated with oxalic acid to remove lead ions and then were hydrolyzed by *N* hydrochloric acid for 2 hours at 100° C.

ACKNOWLEDGMENT

We are pleased to acknowledge that Mrs. Clara E. McGrew carried out the carbon and hydrogen analyses.

PHYSICOCHEMICAL STUDIES OF WATER CHESTNUT STARCH (TRAPA BISPINOSA ROXB)

V. L. N. Murty, D. Choudhury, and P. Bagchi
Department of Macromolecules, Indian Association for the Cultivation of Science, Calcutta, India

Received June 25, 1962

ABSTRACT

The starch present in the kernel of water chestnut (*Trapa bispinosa* Roxb) has been isolated and obtained free from protein. Potentiometric titration showed that the starch contained 15% amylose. The starch was resolved into amylose and amylopectin through complex formation. The components were characterized by chemical and enzymic techniques. The average length of unit chain has been shown to be 22 in the amylopectin and 360 in amylose by both methylation and periodate oxidation studies. Molecular weights of the two components by viscosity and light scattering are also described.

Although the starchy nature of the kernel of water chestnut (*Trapa bispinosa* Roxb) has been reported (1) no detailed study of this material has been made previously. Those starches on which detailed structural investigations have been carried out belong either to the class of tuber starches or to the cereal variety. Water chestnut starch possesses the peculiarity that it originates from the kernel of an aquatic plant.

The starch was isolated in granular form, the use of reagents likely to cause degradation being avoided. The granules resembled those of potato starch in the X-ray powder diagram. Protein contamination was reduced to 0.7% under mild conditions (2). The purified starch showed an amylose content of 15% from the iodine affinity measurements, a value similar to that of other starches (cf. banana, pearl manioc, tapioca, etc. (3)). It was fractionated into its components, amylose and amylopectin, employing two methods. In the first thymol was used as the complexing agent for the initial precipitation (4) and butanol (5–7) for successive recrystallizations. The second method made use of aqueous pyridine as the precipitant for amylose, a 20% solution (7) being employed for the isolation of the amylopectin (the amylose fraction in this was discarded) and a 15% solution (8) for the isolation of amylose. The amylose obtained in the latter case was purified by successive reprecipitations as the butanol complex. The amylose obtained by the first method after five butanol recrystallizations showed a maximum iodine binding power of 19.5% and a blue value of 1.25, which could not be improved by further recrystallizations. In the second method the yield of amylose was poor and the blue value less (1.16). Hence the components obtained by the first method were used in further investigations. The properties of the components obtained are shown in Table I.

TABLE I

	Iodine affinity	Blue value	Purity*
Amylose	19.5	1.25	97.8
Amylopectin	0.10	0.06	97.5

*Determined by alkaline ferricyanide method.

It has been observed that the initial methylation of a polysaccharide is facilitated by converting it to an acetyl derivative and subjecting the latter to the action of dimethyl sulphate and alkali, when simultaneous deacetylation and methylation take place. Both

the components of water chestnut starch were, therefore, acetylated by dispersion in formamide (9) and then treatment with pyridine and acetic anhydride at room temperature (10). This method has been stated to cause minimum degradation (2). The acetylated products were directly methylated by repeated treatments with dimethyl sulphate and solid sodium hydroxide (11) and then by Purdie's method (12). The resulting methylated amylose and amylopectin showed no hydroxyl absorption band in the infrared spectrum.

Methanolysis and hydrolysis of the fully methylated amylopectin yielded a mixture which, on paper chromatographic examination, revealed the presence of 2,3,4,6-tetra-*O*-methyl-D-glucose, 2,3,6-tri-*O*-methyl-D-glucose, and 2,3-di-*O*-methyl-D-glucose together with a small amount of a mixture of probably 2,6- and 3,6-di-*O*-methyl-D-glucose. Trace amounts of monomethyl glucose and glucose were also obtained. The mixture of dimethyl sugars was resolved by paper chromatography into two fractions, the major component consisting of 2,3-di-*O*-methyl-D-glucose. All three sugars were identified through crystalline derivatives. The quantity of tetra-*O*-methyl glucose corresponds to the presence of one non-reducing terminal group per 20–21 glucose residues. The presence of other dimethyl sugars, probably 2,6- and 3,6-di-*O*-methylglucose, is not considered to have any structural significance, since they may have arisen from incomplete methylation of the polysaccharide and by demethylation during hydrolysis. Similar observations have been made in connection with methylation studies on amylopectin from malted barley (13) and rubber seed (2). The yield of formic acid during periodate oxidation on both the amylopectin and the whole starch corresponds to one non-reducing end group per 22 glucose residues in the amylopectin, a value in good agreement with that obtained from the methylation data. Estimation of the glucose obtained on hydrolysis of the periodate-oxidized amylopectin showed that 0.57% of the glucose residues was unattacked by periodate, indicating that at least 88% of the linkages between unit chains was of the $1 \rightarrow 6$ type. Small amounts (0.5–1.5%) of glucose have previously been detected in the hydrolyzate of periodate-oxidized starch from other sources (13(*a*)).

The structure of the amylopectin component of water chestnut starch was further confirmed by degradation studies with β-amylase. Soya bean was chosen as the source of β-amylase as it has been claimed that this enzyme is free from contamination by α-amylase and maltase (14). Purified β-amylase was prepared from soya bean by Peat, Pirt, and Whelan's method (15), which includes deactivation of Z-enzyme by heat treatment of the protein in acid medium. The enzyme preparation showed no maltase, α-amylase, or Z-enzyme activity. Stock β-amylase was also prepared by eliminating the heat treatment. Use of purified β-amylase under standard conditions led to 57% conversion to maltose, in agreement with the values (52–62%) found for amylopectins from other sources (16). The same conversion value was reached even when the digest was acted upon by stock β-amylase. The isolated β-limit dextrin contained 9–10 glucose residues, as determined by oxidation with periodate. The average length of the original external chains of the amylopectin was 15 anhydroglucose units.

The fully methylated amylose on methanolysis and hydrolysis furnished 2,3,4,6-tetra-*O*-methyl-D-glucose, 2,3,6-tri-*O*-methyl-D-glucose, and a mixture of di-*O*-methylglucoses. The presence of dimethyl sugars may be due to incomplete methylation or demethylation during hydrolysis and may not have any structural significance. Such an observation was made in the methylation studies of amyloses from other sources (17). The quantity of tetra-*O*-methylglucose corresponded to the presence of one non-reducing terminal group for every 370 glucose residues. The average chain length of the amylose obtained from periodate oxidation studies was 359, a value in good agreement with that obtained

from methylation data. The absence of glucose in the periodate-oxidized amylose is quite significant. The water chestnut amylose, therefore, consisted of an unbranched chain of ca. 360 glucose residues.

Treatment of the amylose with purified β-amylase led to 73% conversion to maltose, a value within the range (65–85%) observed in the case of amyloses prepared via complex formation (18, 19). That the observed conversion was not due to retrogradation was deduced from the fact that the limit was reached in the course of a few hours and could not be raised by further addition of the enzyme. Complete conversion to maltose was attained when the amylose was treated with stock β-amylase.

The intrinsic viscosities of the amylopectin in aqueous potassium hydroxide and of the acetate derivative in chloroform were 0.97 and 1.9 dl/g, respectively. Light scattering measurements on a solution of amylopectin acetate in chloroform, assuming a random coil model, gave a weight-average molecular weight of 23.6×10^6. It is interesting to note that the plot of HC/τ vs. C exhibited a negative slope. A negative slope at low concentration has been ascribed to association effects which decrease with decreasing concentration (20). Intrinsic viscosity measurements were made on both the water chestnut amylose and its acetylated product and the $\overline{\text{D.P.}}$ compared with the empirical relation of Cowie and Greenwood (21). A value of 430 for the $\overline{\text{D.P.}}$ of amylose was obtained against 370 and 360 from methylation and periodate oxidation studies respectively. Considering that the amylose was unfractionated and the solution viscosity measurements give $\bar{M}_v$ rather than $\bar{M}_n$ (given by end group assay methods such as methylation and periodate oxidation studies) the agreement is considered to be satisfactory.

The weight-average molecular weight of the amylose acetate as determined by light scattering was 6.7×10^6. Paschal and Foster (22) reported a value of 3×10^6 for a corn starch amylose which decreased to 4×10^5 on keeping for 24 hours. They attribute it to be due to disaggregation of an unusual type of aggregate. Water chestnut starch, therefore, appears to be similar in composition to starches from other sources. The detailed molecular architecture, size, and shape of the components are also of the same type.

EXPERIMENTAL

Paper chromatography was carried out by the descending method. Whatman No. 1 and No. 3 MM filter papers were used, the latter for preparative purposes. The solvent was allowed to run against the machine line. The following solvent mixtures were used for separating the sugars: (A) ethyl acetate:pyridine:water (8:2:1); (B) *n*-butanol:acetic acid:water (4:1:5), upper layer; (C) *n*-butanol:pyridine:benzene:water (5:3:1:3), upper layer; (D) ethyl methyl ketone – water azeotrope; (E) *n*-butanol:ethanol:water (4:1:5), upper layer. Aniline oxalate in water and ammonical silver nitrate were used as spray reagents.

Unless otherwise stated all evaporations were carried out *in vacuo* at 30–40° C. All the values of specific rotation given are at equilibrium except where mutarotation values are given.

Isolation and Purification of Starch

Fresh and middle-aged fruits of water chestnut were collected, peeled, and the pericarp removed. The kernel so obtained was minced into alcohol to inhibit enzymic activity and macerated in a "Kenmix 55" blender. The resulting slurry was filtered through a 100-mesh sieve and the filtrate centrifuged to yield a crude starch. The sediment was washed repeatedly with 0.1 *M* sodium chloride solution. The residue left on the sieve was macerated four times with 0.1 *M* sodium chloride in the blender and the resulting slurry filtered through a 100-mesh sieve; the fibrous material left on the sieve was rejected.

The starch products so obtained were combined, suspended in 0.1 *M* aqueous sodium chloride solution, and shaken with toluene (1/10 vol.) overnight to denature the protein. The brown toluene layer containing the protein was removed by centrifugation, this treatment being repeated four times. The sedimented starch formed two layers, the upper brown still containing protein. Further purification was effected by the method of Greenwood and Robertson (2). Salts were removed by washing with water followed by centrifugation, and the pure starch was stored under methanol at 5° C. The purified starch was then refluxed with aqueous methanol (80%) to remove residual fats and this material, after drying, was used for subsequent investigations. $[\alpha]_D^{25}$ +154° (*c*, 0.77 in *N* NaOH). Anal.: N, 0.014%; ash, 0.07%; blue value, 0.236.

Potentiometric Titration for Determination of Iodine Binding Powers

Iodine binding powers of water chestnut starch and its fractions were determined by a modification of the method of Schoch (24). A platinum electrode in conjunction with a saturated calomel half-cell was used. The potentials were measured with a Leeds Northrup potentiometer using a spot-type galvanometer. The total free iodine in the starch solution was plotted against the bound iodine and the iodine binding power was estimated by extrapolation of the linear portion of the titration curve to zero free iodine concentration. Calculation of the percentage of amylose was made from the observed iodine binding power of the starch, and the iodine binding power of the pure water chestnut amylose determined in a separate experiment (19.5%). Results showed water chestnut starch had 15% amylose content.

Estimation of Length of Unit Chain of Amylopectin

Starch (109.5 mg) was dispersed in water (50 ml) and subjected to oxidation by shaking with sodium metaperiodate (0.1 *M*, 50 ml) in the dark at 3° C. The liberated formic acid and the periodate consumption were estimated at regular intervals by the method of Fleury and Lange (25). The formic acid liberated corresponded to a chain length of 26 anhydroglucose residues in the starch. This value corresponded to a chain of 22 anhydroglucose residues in the amylopectin fraction.

Examination of the Amylopectin Fraction

Amylopectin had $[\alpha]_D^{25}$ +146.9° (*c*, 1.0 in *N* NaOH) and a blue value of 0.06. On hydrolysis this fraction yielded only glucose (97.6%). Potentiometric titration for the iodine binding power showed the presence of 0.53% amylose.

Periodate Oxidation of Amylopectin

The method described for the original starch was employed. The liberation of formic acid corresponded to 22 anhydroglucose units per mole of formic acid.

Determination of Glucose Residues Linked through C_1, C_4, and C_6

Amylopectin (0.5552 g) was dissolved in water (80 ml) containing potassium chloride (5 g), and sodium metaperiodate (30 ml, 0.3 *M*) was added. The reaction was allowed to proceed in the dark for 240 hours and the excess oxidant was destroyed with ethylene glycol. The oxidized amylopectin was dissolved in sodium hydroxide (30 ml, 0.2 *N*) and after the addition of sodium borohydride (0.25 g) the solution was left overnight. It was then neutralized with acetic acid, dialyzed, and evaporated to dryness. The resulting residue was hydrolyzed and the glucose estimated by quantitative paper chromatography. The results showed that 0.57% of the glucose residues in the amylopectin was unattacked by periodate.

Acetylation of the Amylopectin

Amylopectin (2 g) was dissolved in water and precipitated by the addition of ethanol. The precipitate was collected by filtration and washed with ethanol and ether. It was dispersed in formamide (9) (30 ml), and pyridine (50 ml) was added, followed by acetic anhydride (40 ml). The reaction was allowed to proceed at room temperature (10) for 2 hours. The partially acetylated amylopectin (acetyl content, 41%) was subjected to further acetylation as described above to give a product with $[\alpha]_D^{25}$ +165° (*c*, 1.0 in chloroform). Anal.: acetyl, 44.8%.

Methylation of the Amylopectin

The acetylated amylopectin (0.8 g) was dissolved in tetrahydrofuran (20 ml) and methylated (11) directly using dimethyl sulphate (15 ml) and solid sodium hydroxide (13 g). The partially methylated derivative was extracted with chloroform and subjected to methylation thrice by Purdie's method (12). $[\alpha]_D^{25}$ +198° (*c*, 0.5 in chloroform). Anal.: methoxyl, 43.5%.

Hydrolysis of the Methylated Amylopectin

The methylated amylopectin (300 mg) was refluxed with methanolic hydrogen chloride (20 ml, 1%) for 5 hours. The solution was evaporated to a syrup under reduced pressure and the resulting mixture of methyl glycosides was hydrolyzed with hydrochloric acid (30 ml, 0.5 *N*). The acid was neutralized with silver carbonate and solids were removed by filtration. The resulting solution, after deionization with Amberlite IR-120 (H) and Amberlite IR-45 (OH), was evaporated to a small quantity of a syrup. Examination by paper chromatography (solvent E) revealed the presence of 2,3,4,6-tetra-*O*-methyl-D-glucose, 2,3,6-tri-*O*-methyl-D-glucose, 2,3-di-*O*-methyl-D-glucose, and 2,6- and/or 3,6-di-methyl-D-glucose. Trace amounts of monomethylglucose and glucose were also detected. The mixture (ca. 250 mg) was resolved on sheets of Whatman No. 3 MM filter papers. The strips corresponding to tetra-, tri-, and di-*O*-methyl sugars were excised, eluted, and evaporated to dry syrups separately. They were present in a ratio of 11.9:214.1:18 respectively.

Characterization of O-Methyl Sugars

The 2,3,4,6-tetra-*O*-methyl-D-glucose fraction, $[\alpha]_D^{30}$ +82° (*c*, 0.2 in water), lit. +83°(13), was characterized as crystalline 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-glucosylamine, m.p. and mixed m.p. 136–137°, lit. 136–138° (13).

The tri-*O*-methylglucose, $[\alpha]_D^{25}$ +67° (13), +70° (30), was characterized as the 1,4-di-*p*-nitrobenzoate derivative, m.p. 190–192° (26). The mixture of di-*O*-methyl sugars was resolved by paper chromatography. The major component was characterized as 2,3-di-*O*-methyl-D-glucose through its phenyl hydrazide, m.p. 160-162° C (13).

Quantitative Estimation of O-Methyl Sugars

A small portion of the methylated sugar mixture was resolved quantitatively and the tetra-, tri-, and di-*O*-methyl sugars were eluted and estimated by the alkaline hypoiodite method (27). The ratio was 1:17.7:1.9 respectively.

β-Amylolysis of the Amylopectin

Purified β-amylase was prepared from soya bean flour by the method of Peat, Pirt, and Whelan (15), in which the Z-enzyme is inactivated by a heat treatment of the protein in acid medium. Stock β-amylase containing Z-enzyme was also prepared by eliminating the heat treatment.

A digest was prepared by dissolving amylopectin (102.3 mg) in *N* sodium hydroxide solution (10 ml) and the pH was brought to 4.6 by acetate buffer. The concentration of enzyme was such that the reaction was complete in a few hours, but the digests were left for 24 hours before the concentration of the amylopectin and liberated maltose were separately estimated by the alkaline ferricyanide method (28). The amount of maltose liberated was 56.9%. No increase in the yield of maltose was noticed when the amylopectin was treated with stock β-amylase.

Isolation of Amylopectin β-Limit Dextrin

For isolation of amylopectin β-limit dextrin, the polysaccharide was incubated at pH 4.6 as described above (13). The formic acid produced on oxidation with periodate corresponded to one non-reducing end group per 9–10 anhydroglucose residues.

Measurement of Intrinsic Viscosity

The specific viscosity (η_{sp}) of the amylopectin in *M* potassium hydroxide solution was determined at several concentrations in an Ostwald viscometer at 35° C and the intrinsic viscosity [η] was determined graphically by extrapolation to zero concentration. Accurate dilutions were made to five concentrations and flow times were measured. The average of three readings was taken for each concentration. The concentrations were determined by hydrolyzing a portion and estimating the glucose by the alkaline ferricyanide method (28). Concentrations were expressed as g/100 ml. From the graph the intrinsic viscosity [η] of amylopectin in *M* potassium hydroxide was found to be 0.97 dl/g (average of two sets of readings). Intrinsic viscosity measurements were also made on the acetylated amylopectin in chloroform as in the above case. Concentrations were estimated by the dry weight method. [η], 1.96 dl/g (mean of two sets of measurements).

Light Scattering Measurements

Acetylated amylopectin was employed for the measurements. Solvent chloroform, twice distilled, was filtered through sintered glass G-5 under dust free conditions to remove any inherent dust particles. Measurements were taken with a Brice–Phoenix photometer (Model OM 1000 A) as described by Brice *et al.* (29). Turbidities (τ) were determined by the working standard method at 546 mμ. The dissymmetry ratio ($I_{45°}/I_{135°}$) was also measured. Turbidity of the solvent was measured first and successive aliquots of the clarified solution (passed through sintered glass G-4) were added to a known volume of the solvent in the scattering cell to form concentration series in the range of $(1\text{–}5)\times10^{-4}$ g/ml. Concentrations were determined by dry weight method. The molecular weight ($\bar{M}_w$) was calculated from the relationship

$$\frac{HC}{\tau} = \frac{1}{M(P_{90°})} + \frac{2B(P_{90°})C}{RT},$$

where

$$H = \frac{32\pi^3 n_0^2}{3N\lambda^4}\left(\frac{dn}{dc}\right)^2.$$

P_{90} is the particle scattering factor. *B* is a constant. The refractive index increment (dn/dc) was measured at 546 mμ with a Brice–Phoenix differential refractometer. From the plot of HC/τ vs. *C* and assuming a random coil model for the amylopectin acetate molecule the corrected molecular weight was to be 23.6×10^6.

Examination of Water Chestnut Amylose

Amylose had $[\alpha]_D^{25}$ +147.7° (*c*, 0.5 in *N* NaOH) and a blue value of 1.25. Potentiometric titration (23, 24) showed that the amylose had a maximum iodine affinity of 19.5%. Hydrolysis of the sample gave only glucose (97.8%).

Periodate Oxidation of Amylose

Amylose (0.1025 g) was subjected to periodate oxidation as described earlier. The formic acid corresponded to a chain length of 360 anhydroglucose residues, assuming the liberation of 3 moles of formic acid per mole of

amylose. Periodate-oxidized amylose after reduction and hydrolysis as described for amylopectin gave no spot corresponding to glucose on paper chromatographic examination.

Methylation of the Amylose

Acetylated amylose (0.8 g) was directly methylated by treatment with dimethyl sulphate and solid sodium hydroxide in tetrahydrofuran (11) and then thrice by Purdie's method (12), as described in the case of amylopectin. $[\alpha]_D^{28}$ +200° (*c*, 0.5 in chloroform). Anal.: —OCH_3, 44.5%.

Hydrolysis of the Methylated Amylose and Identification and Estimation of the Component Sugars

The methylated amylose (500 mg) after methanolysis and hydrolysis yielded a syrup which, on paper chromatographic examination, revealed the presence of a tetra-*O*-methylglucose, a tri-*O*-methylglucose, and several di-*O*-methylglucoses.

The neutral sugar mixture (450 mg) was resolved on Whatman No. 3 MM filter papers into pure components. The 2,3,4,6-tetra-*O*-methyl-D-glucose had $[\alpha]_D^{30}$ +81° (*c*, 0.1 in water) and moved at the same rate as an authentic sample on paper chromatograms.

The tri-*O*-methyl fraction, $[\alpha]_D^{30}$ +67° in water (*c*, 1.0 in water), lit. +70° (30), was identified as 2,3,6-tri-*O*-methyl-D-glucose by conversion to crystalline 2,3,6-tri-*O*-methyl-D-glucose-1,4-di-*p*-nitrobenzoate, m.p. 190–192° (26).

The mixture containing the di-*O*-methyl fraction on chromatographic examination gave spots corresponding to 2,3-, 2,6-, and/or 3,6-di-*O*-methyl-D-glucose. These were not further characterized. A small portion of the mixture was resolved quantitatively by paper chromatography and the tetra- and tri-*O*-methyl sugars were estimated by the alkaline hypoiodite method (27). The tetra- and tri-methyl sugars were present in the ratio of 1:370 respectively.

β-Amylolysis of Amylose

A digest was prepared with amylose (102.4 mg) and hydrolysis carried out at pH 4.6 with purified β-amylase. The liberated maltose was estimated as in the case of amylopectin at 35° C. A conversion limit of 73% for the liberation of maltose was obtained. Digests were also prepared with amylose and allowed to be acted upon by stock β-amylase; a conversion limit of 99.4% was reached.

Intrinsic Viscosity of the Amylose

Limiting viscosity numbers $[\eta]$ for both amylose in *M* potassium hydroxide and its acetate derivative in chloroform were determined at 35° C using the same technique used for the amylopectin. Concentrations were estimated as described in the earlier case. The intrinsic viscosities of the amylopectin and its acetate derivative were 0.59 and 1.38 dl/g, respectively.

Light Scattering Measurements

Measurements were carried out with a Brice–Phoenix Photometer (Model OM 1000 A) following the working standard method in the concentration series in the range $(3\text{–}15)\times10^{-4}$ g/ml. Acetylated amylose was employed and the technique was similar to that used for the acetylated amylopectin. The uncorrected molecular weight was 3.2×10^6. Assuming the random coil model for the amylose molecule the corrected molecular weight is 6.7×10^6.

ABSTRACT

Solvent effects on the keto–enol equilibria of ethyl acetoacetate, acetylacetone, ethyl cyclopentanone-2-carboxylate, and methyl 4-methylcyclopentane-1,2-dione-3,4,5-tricarboxylate have been studied by ultraviolet spectroscopy. The extent of enolization is mainly determined by the stabilization of the keto form by local association with polar or proton-donating solvent molecules, just as in the case of $n \rightarrow \pi^*$ transitions and infrared stretching frequencies. Solvent effects on infrared spectra reveal useful information regarding the characteristic frequencies of the tautomers.

Keto–enol tautomerism has been investigated extensively by ultraviolet (1), infrared (2), and n.m.r. (3) spectroscopy. Keto–enol equilibria are extremely solvent sensitive and the proportion of enol form is found to be much greater in non-polar solvents such as cyclohexane than in polar solvents such as alcohol or water. This is probably due to the stabilization of the keto form by polar solvents through local association. Recently in this laboratory we have investigated the solvent effects on the $n \rightarrow \pi^*$ transitions of several chromophores and have evaluated contributions from different factors (4). These studies clearly indicate that solvent effects on the $n \rightarrow \pi^*$ transitions are mainly controlled by local association between the solute and the solvent molecules and that the magnitude of the solvent blue shifts are determined by the polarity and/or proton-donating ability of the solvents. Studies of the solvent effects on infrared group frequencies have also shown that local association is an important factor in the determination of the solvent shifts (5). It was considered interesting to systematically investigate the keto–enol equilibria of a few systems in several solvents and correlate the observed effects with the solvent effects on the $n \rightarrow \pi^*$ transitions and the stretching vibration frequencies of carbonyl groups. We have now studied the keto–enol equilibria of ethyl acetoacetate, acetylacetone, ethyl cyclopentanone-2-carboxylate, and methyl 4-methylcyclopentane-1,2-dione-3,4,5-tricarboxylate (I) in solvents of varying degree of polarity or/and proton-donating ability.

EXPERIMENTAL

Commercial samples of ethyl acetoacetate and acetylacetone were used after suitable purification. Ethyl cyclopentanone-2-carboxylate was prepared by the procedure described in *Organic Syntheses* (6) and methyl 4-methylcyclopentane-1,2-dione-3,4,5-tricarboxylate was prepared according to the method of Chuang and Ma (7). All the solvents were purified and fractionated before use.

Ultraviolet absorption spectra were recorded with a Hilger Uvispek, model H 700, spectrophotometer. The infrared spectra were recorded with a Perkin–Elmer infrared spectrometer, model 137, with sodium chloride optics.

Percentage of the enol form was calculated from the extinction coefficient in the ultraviolet spectrum using the formula $100(\epsilon_o/\epsilon_a)$, where ϵ_o is the observed molar extinction coefficient and ϵ_a the assumed value for the chromophoric system of the enol form.

[1]*Taken in part from the Ph.D. Thesis of A. S. N. Murthy to be submitted to the Indian Institute of Science under the guidance of C. N. R. Rao.*

[2]*To whom all the correspondence should be addressed.*

RESULTS AND DISCUSSION

The ultraviolet absorption data and the percentage enol in the case of ethyl acetoacetate and acetylacetone are summarized in Table I and Fig. 1. The ϵ_a values for these are 16,000

TABLE I

Percentage of enol in the keto–enol equilibria of a few systems in different solvents

Solvent	Percentage of enol in: Ethyl acetoacetate (λ_{max} ~244mμ)	Acetylacetone (λ_{max} ~272 mμ)	Ethyl cyclopentanone-2-carboxylate (λ_{max} ~254 mμ)	Methyl 4-methylcyclopentane-1,2-dione-3,4,5-tricarboxylate† II (λ_{max} ~270 mμ)	Methyl 4-methylcyclopentane-1,2-dione-3,4,5-tricarboxylate† III (λ_{max} ~325 mμ)
Cyclohexane	43	88	22	34	49

Water	0.5	16	0.4	44	27

*Could not be determined because of solvent cutoff.
†The percentage-of-enol values for this compound are very approximate since the ϵ_a value is only arbitrary.

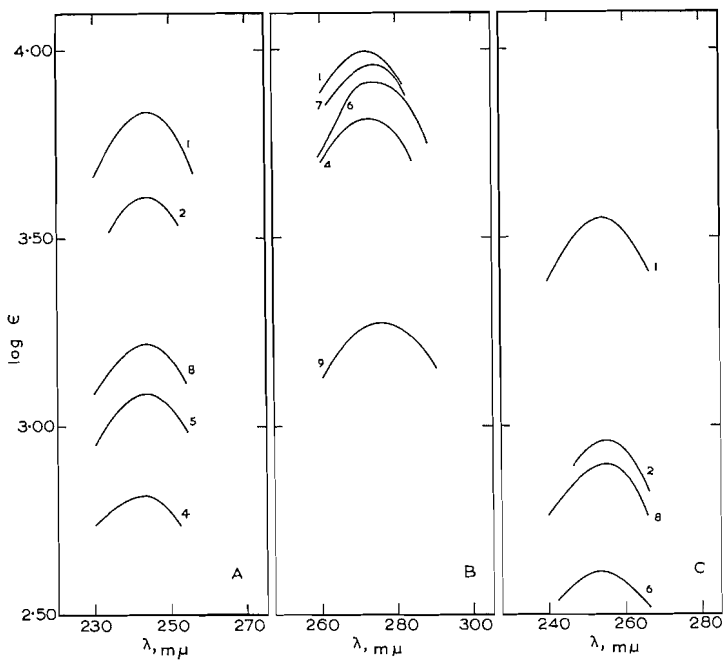

FIG. 1. Ultraviolet spectra of ethyl acetoacetate (A), acetylacetone (B), and ethyl cyclopentanone-2-carboxylate (C) in different solvents: (1) cyclohexane, (2) diethyl ether, (4) acetonitrile, (5) ethanol, (6) methanol, (7) *i*-propanol, (8) *t*-butanol, and (9) water.

and 12,000 respectively. In order to study the keto–enol equilibria in polar solvents of varying dielectric constant (which cannot donate protons), mixtures of acetonitrile and ether were employed. It was made certain that the observed extinction coefficients were not dependent on solute concentration, thereby indicating negligible association of the solute molecules in the enol form (8, 9). It can be seen that the percentage of enol is greatest in non-polar solvents and decreases with increasing polarity and/or proton-donating ability of the solvent. This trend in solvent effects is similar to that observed in the case of $n \rightarrow \pi^*$ transitions of chromophores (4). The $n \rightarrow \pi^*$ frequency of the carbonyl group increases with the polarity of the solvent, due to stabilization by local association. In the case of polar solvents which cannot donate protons, the solvent blue shifts are determined mainly by the dielectric constant of the solvent. In proton-donating solvents, however, the major contribution is due to hydrogen bonding. In the extreme case of water, where the carbonyl $n \rightarrow \pi^*$ frequency is highest, the percentage of enol is also lowest. In Fig. 2, the percentage of enol in ethyl acetoacetate has been plotted against

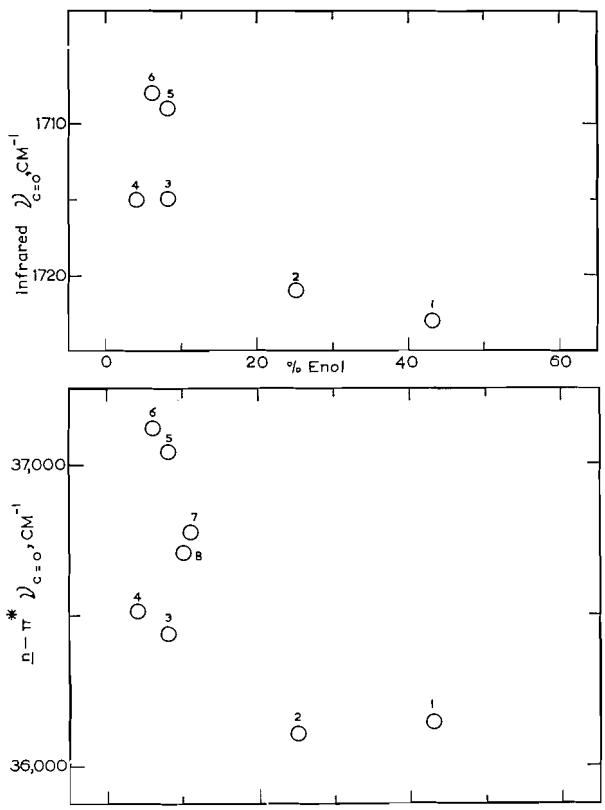

FIG. 2. Plots of percentage of enol of ethyl acetoacetate against the carbonyl infrared stretching frequency and the $n \rightarrow \pi^*$ frequency of acetone in different solvents: (1) cyclohexane, (2) diethyl ether, (3) dioxane, (4) acetonitrile, (5) ethanol, (6) methanol, (7) *i*-propanol, (8) *t*-butanol, and (9) water.

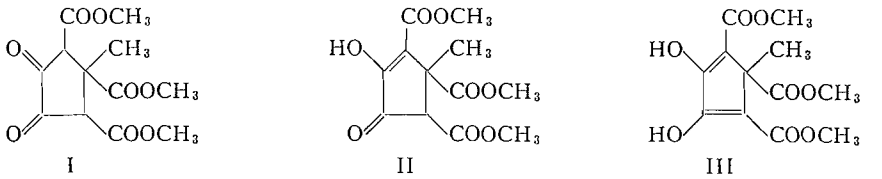
the $n \rightarrow \pi^*$ and the stretching vibration frequencies of the carbonyl group of acetone. It can be seen that the trends in these three quantities are similar, indicating that the stabilization of the carbonyl group by polar solvent molecules is the major controlling factor. In the case of polar solvents which cannot donate protons, the dielectric constant

of the solvent seems to be very important in the determination of the keto–enol equilibria, as indicated by the data obtained from acetonitrile and acetonitrile–ether mixtures.

Methyl 4-methylcyclopentane-1,2-dione-3,4,5-tricarboxylate (I) can give rise to two tautomeric species, II and III. The absorption maxima around 270 and 325 mμ (Fig. 3)



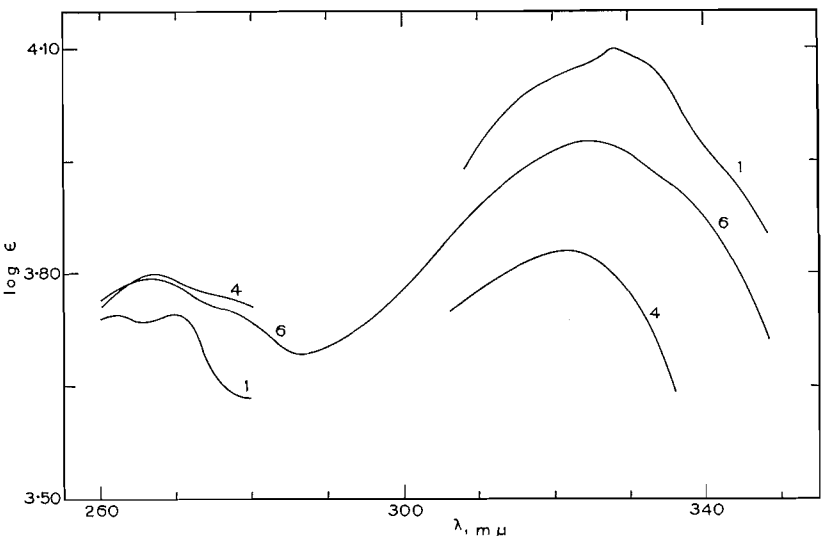


FIG. 3. Ultraviolet spectra of methyl 4-methylcyclopentane-1,2-dione-3,4,5-tricarboxylate in different solvents: (1) cyclohexane, (4) acetonitrile, and (6) methanol.

are assigned to the tautomers II and III respectively. The behavior of the model compound ethyl cyclopentanone-2-carboxylate is analogous to that of ethyl acetoacetate (Table I and Fig. 1). In compound I, the 270 mμ band (tautomer II) is nearly insensitive to the polarity of the solvent, whereas the intensity of the 325 mμ band (tautomer III) decreases with the polarity and/or proton-donating ability of the solvent (Fig. 3). The proportions of the two enol forms have been calculated by taking the ϵ_a values arbitrarily as 16,000 and 25,000, and the results are shown in Table I. It was considered worthwhile to study the solvent effects on the infrared spectra of these systems.

The double-bond regions in the infrared spectra of ethyl cyclopentanone-2-carboxylate and compound I in carbon tetrachloride and acetonitrile solutions are shown in Fig. 4. Ethyl cyclopentanone-2-carboxylate shows bands at 1750 cm^{-1} (ring ketone), 1730 cm^{-1} (β-keto ester), 1670 cm^{-1} (enolized β-keto ester), and 1620 cm^{-1} (C=C stretching) in carbon tetrachloride solution, where there is partial enolization (ca. 22%). In acetonitrile solution, where there is negligible enolization (<1%), bands are found around 1750, 1730, 1670, and 1620 (very weak) cm^{-1}. In carbon tetrachloride solution, I is present almost completely in the enolized form and distinct peaks are found in the double-bond region around 1750 cm^{-1} (ring ketone and saturated ester), 1680 cm^{-1} (enolized β-keto

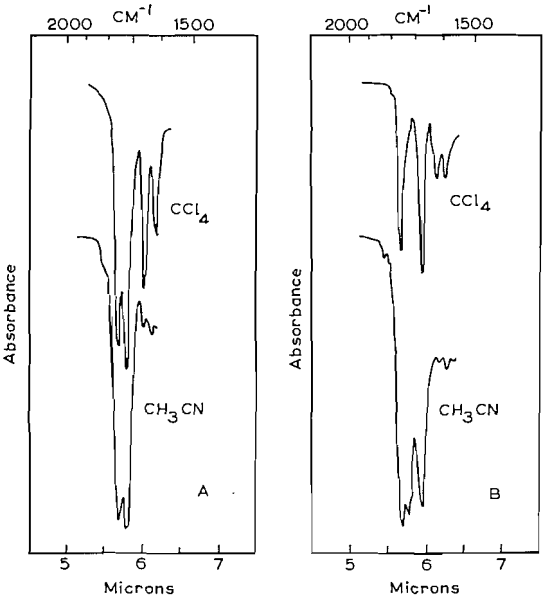

FIG. 4. The double-bond region in the infrared spectra of ethyl cyclopentanone-2-carboxylate (A) and methyl 4-methylcyclopentane-1,2-dione-3,4,5-tricarboxylate (B) in carbon tetrachloride and acetonitrile solutions.

ester), and 1618 and 1580 cm^{-1} (C=C stretching vibrations of II and III). In acetonitrile solution, where there is less enolization, the infrared spectrum shows bands around 1750 cm^{-1} (ring ketone and saturated ester), 1730 cm^{-1} (β-keto ester), 1680 cm^{-1} (weak, enolized β-keto ester), and 1600 cm^{-1} (very weak, C=C stretching). These results show how solvent effects on infrared spectra can also reveal interesting information regarding the two tautomers. Thus the C=O band due to the unenolized β-keto ester is only seen in acetonitrile solution in the case of compound I.

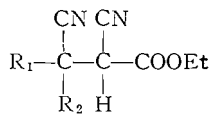
ABSTRACT

1,2-Dicyano esters show an absorption band around 245 mμ in alcoholic solutions which is not found in non-polar and other polar solvents. This anomalous behavior has been found to be due to the unusual solvent dependence of the equilibrium between the keto and enol forms. The intensity of the absorption band in alcoholic solutions decreases with increase in concentration of the 1,2-dicyano ester, indicating association of the enol form. The keto–enol equilibrium is also found to be sensitive to the substituent R of the alcohol ROH.

INTRODUCTION

1,2-Dicyano esters are often prepared as synthetic intermediates by the addition of hydrocyanic acid to unsaturated cyano esters. Kasturi (1) observed that some of the 1,2-dicyano esters exhibited fairly intense absorption bands around 245 mμ even after

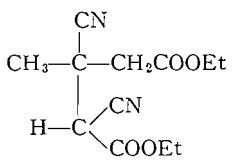


I

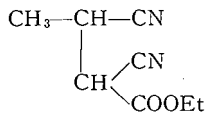
making certain, by infrared spectra, that there was no impurity of the parent olefin remaining. This is rather surprising since there is no absorbing chromophore in these derivatives (2). In this communication, we have reported the ultraviolet absorption spectra of several 1,2-dicyano esters and also certain model compounds, with a view to understanding the mechanism of absorption.

EXPERIMENTAL

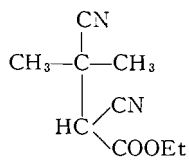
The following 1,2-dicyano esters were studied and they were prepared by the addition of hydrocyanic acid to unsaturated cyano esters (for compound (i) see ref. 3; (ii), 4; (iii), 5; (iv), 6; (v), 6; (vii), 7; (viii), 1):



(i)

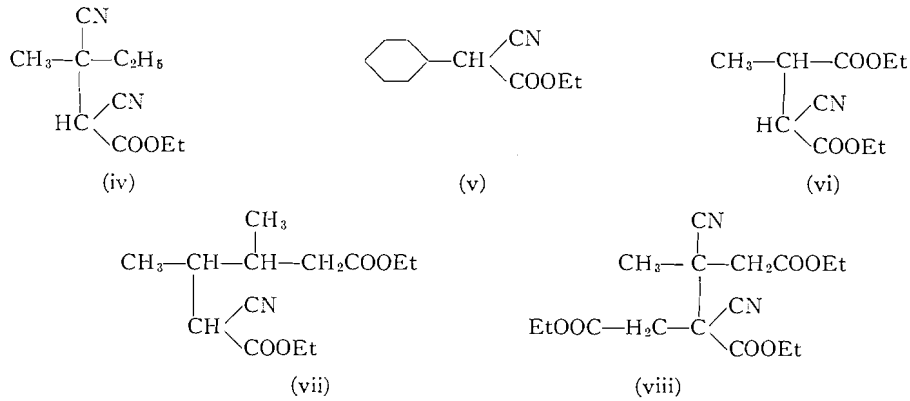


(ii)



(iii)

[1]*Material taken from the Ph.D. Thesis of A. Balasubramanian submitted to the Indian Institute of Science under the guidance of C. N. R. Rao.*
[2]*To whom all the correspondence should be addressed.*



(iv) (v) (vi)

(vii) (viii)

These compounds were purified either by fractional distillation or by recrystallization before use. All the solvents employed were dried and distilled just before use.

The near-ultraviolet absorption spectra were recorded on a Hilger H700 UVispek spectrophotometer with matched quartz cells of 0.5-, 1.0-, 2.0-, and 4.0-cm path lengths. The infrared spectra were recorded on a Perkin-Elmer Infracord, model 137B, fitted with NaCl optics.

RESULTS AND DISCUSSION

The absorption data of several 1,2-dicyano esters in ethanol are summarized in Table I. First, it was considered that keto–enol tautomerism (I $\rightleftharpoons$ II) might be the possible cause

TABLE I

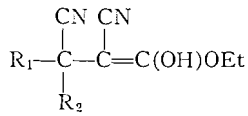
		5.14×10^{-4}	246	260

*Shoulder.

of this absorption. But these derivatives fail to show any distinct absorption band in heptane and acetonitrile (Fig. 1). In simple compounds such as ethyl acetoacetate and



II

acetylacetone the band due to the enol form is much more intense in a non-polar solvent, such as heptane, than in alcohol or acetonitrile, since the keto form is more favored in polar or proton-donating solvents due to the stabilization of the C=O group (2, 8). But, the presence of the active hydrogen on the cyano ester residue is found to be necessary

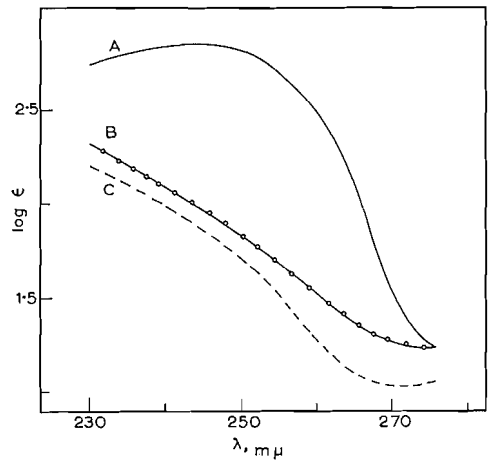


FIG. 1. The near-ultraviolet absorption spectra of a 1,2-dicyano ester (I, $R_1 = CH_3$, $R_2 = CH_2COOC_2H_5$) in heptane (C), acetonitrile (B), and ethanol (A).

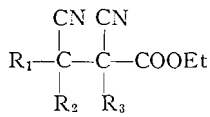
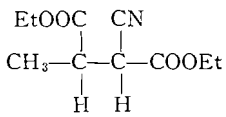
for the absorption in these derivatives. Thus, derivatives III ($R_3 = CH_3$ or CH_2COOEt) do not absorb in the near-ultraviolet region.

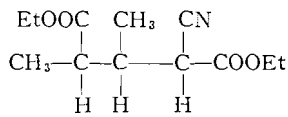


III

In view of these interesting results it was considered worthwhile to investigate the absorption spectra of a number of model compounds. A simple saturated dinitrile such as succinonitrile is transparent in the near-ultraviolet region. It is necessary to have a nitrile group on the carbon adjacent to the cyano ester moiety to observe this absorption (Table I). Thus, compounds IV and V do not absorb in the near-ultraviolet region.



IV



V

The 245 mμ band of 1,2-dicyano esters in ethanol is highly dependent on the concentration of the solute (Fig. 2 and Table I), unlike simple systems where there are keto–enol equilibria (8). The spectra recorded in different ethanol–heptane mixtures show that the extinction is also markedly dependent on the concentration of ethanol (Fig. 3). The extinction of the 245 mμ band is also found to be dependent on the substituent R of the alcohol ROH, the intensity generally decreasing in the order methanol, ethanol, *i*-propanol, and *t*-butanol (Table II). These results seem to point out that there is some solute association and also that the alcohol solvent is an important factor in the mechanism of the absorption.

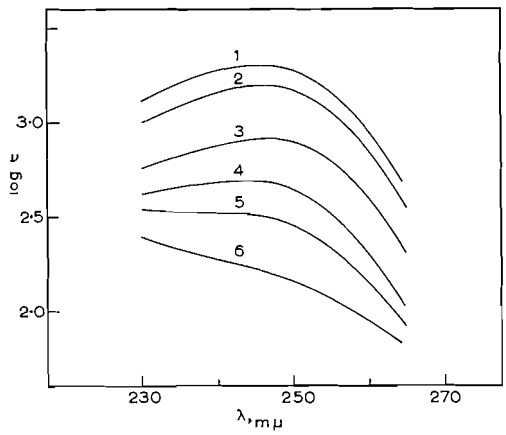


FIG. 2. Concentration dependence of the ultraviolet absorption spectrum of a 1,2-dicyano ester (I, $R_1 = CH_3$, $R_2 = CH_2COOC_2H_5$) in ethanol: (1) 6.5×10^{-5} *M*, (2) 2.5×10^{-4} *M*, (3) 6×10^{-4} *M*, (4) 2.4×10^{-3} *M*, (5) 5×10^{-3} *M*, and (6) 9.75×10^{-3} *M*.

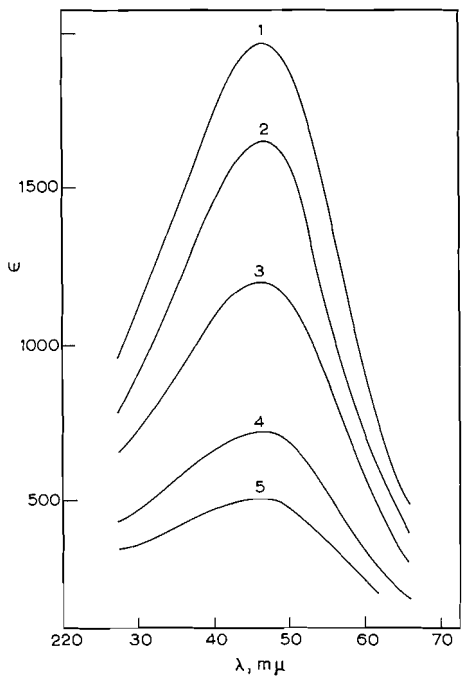

FIG. 3. The near-ultraviolet absorption of a 1,2-dicyano ester (I, $R_1 = CH_3$, $R_2 = CH_2COOC_2H_5$) in heptane–alcohol mixtures: (1) 0%, (2) 10%, (3) 40%, (4) 60%, and (5) 70% by volume of heptane.

Any mechanism offered to explain the absorption of 1,2-dicyano esters should necessarily explain the following observations:

(i) the necessity of the active hydrogen on the cyano ester moiety,
(ii) the necessity of the nitrile group on the adjacent carbon,
(iii) dependence of the extinction on the solute concentration, and
(iv) participation by the alcohol solvent.

TABLE II

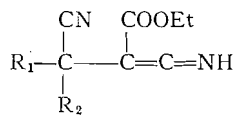
*Shoulder.

It is possible that tautomerism, I $\rightleftharpoons$ VI, may be the cause of the absorption of these derivatives in the near-ultraviolet region.



VI

In order to identify the nature of the species in alcohol media, infrared spectra of a 1,2-dicyano ester (I, $R_1 = CH_3$, $R_2 = CH_2COOEt$) were recorded in solutions of CCl_4 and 1:1 CCl_4–*i*-propanol mixture (Fig. 4). The most striking difference in the spectra in

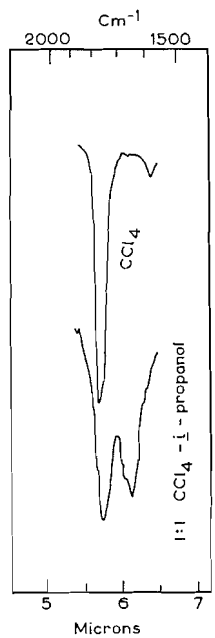


FIG. 4. The double-bond region of the infrared spectrum of a 1,2-dicyano ester (I, $R_1 = CH_3$, $R_2 = CH_3COOC_2H_5$) in CCl_4 and 1:1 CCl_4–*i*-propanol mixtures.

these two solvents is found in the double-bond stretching region. In the CCl_4–*i*-propanol solvent mixture, an intense band is found around 1650 cm^{-1} which can only be due to the C=C stretching vibration. A weak band around 2220 cm^{-1} (conjugated nitrile) is also seen in addition to the 2270 cm^{-1} band due to the saturated nitrile. If VI were the species, there should have been a fairly intense band around 2000 cm^{-1} due to the X=C=X type of group (9). These infrared results suggest that a keto–enol tautomerism (I $\rightleftharpoons$ II) with an unusual solvent dependence is responsible for the 247 mμ absorption of 1,2-dicyano esters in alcohol solvent. Apparently, the nitrile group of the cyano ester moiety is stabilized to a greater extent than the carbonyl group in alcohol solvents, probably due to the greater dipole moment associated with the nitrile group. The concentration dependence of the extinction may be explained in terms of association of the tautomer II, since the monomeric form may be quite unstable. The extent of such association as well as the associated species will vary with concentration and hence the concentration dependence of the extinction. At high concentrations of the solute, the species is only polymeric and the extinction is low.

THE CRYSTALLINE FORM OF 1,3,5,7-TETRANITRO-1,3,5,7-TETRAZACYCLOOCTANE (HMX)

M. BEDARD, H. HUBER, J. L. MYERS, AND GEORGE F WRIGHT
Department of Chemistry, University of Toronto, Toronto, Ontario

Received August 11, 1962

ABSTRACT

The absorption spectra and dielectric constants of three of the four polymorphs of 1,3,5,7-tetranitro-1,3,5,7-tetrazacyclooctane (HMX) have been examined. The difference in absorption frequencies shows that these crystal forms are more distinctive than are most polymorphs. Likewise the distortion polarizations of HMX-I, -II, and -III are markedly different whereas identical distortion polarizations have been found among typical polymorphic systems. The distortion polarizations of HMX-II and -III also are unique because they are appreciably temperature dependent, although this electrical property ought to be temperature independent. Because of these unique behaviors we have postulated that the so-called HMX polymorphs actually are lattice-caged conformational modifications.

During the preparation of 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX, Cyclonite, Hexogen) there is a contaminant formed in every process involving hexamethylenetetramine (1). This by-product, called HMX because of its high melting point (2), is known to be 1,3,5,7-tetranitro-1,3,5,7-tetrazacyclooctane (3). It has been found to exist in four polymorphic forms, HMX-I (β), -II (α), -III (γ), and -IV (δ) (4). The first three are workably stable at room pressure and temperature but HMX-IV transforms so readily that little has been done with it.

The classification as polymorphs has been derived from a consideration of physical properties. Only one graphic structure is required to explain the properties of HMX in solution. Only one melting point (280°) is known but solid-state transitions may be observed. The X-ray diffraction powder patterns of the polymorphs are quite distinctive, although frequently there is evidence of total or partial transformation during analysis of HMX-IV. However, the X-ray powder patterns of HMX-I, -II, and -III are quite as unique as those of the polymorphs of α- and β-resorcinol and of the 5-↑-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↑-3-↓-dicarboxylic acid polymorphs, which are included among others in Table I. Finally, the infrared spectra of the four forms of HMX in pellet dispersion are quite distinctive.

Indeed the infrared differences are so striking that they serve as well as the X-ray diffraction patterns for identification. The differences are apparent in the spectra of Fig. 1, the exact values of which are shown in Table I. In general the spectrum of HMX-I differs largely from those of HMX-II, -III, and -IV both in respect of the several methylene modes and also of the strong NNO_2 absorption in the 1300 cm^{-1} range.

It is of interest to compare the HMX spectra (Table II) with the spectra of the two substances shown in Table III. The two polymorphs of resorcinol, the structures of which are known, (5, 6) have very similar spectra; the notable difference (medium absorption at 1233 cm^{-1} in the beta but not in the alpha polymorph) is an expected one in view of the differences in hydrogen bonding that cause these crystalline modifications. The other pair of spectra shown in Table III depict the total effect of the crystal lattice because amorphous triphenylguanidine (obtained by quenching the molten substance on a cold metal plate (5), no X-ray diffraction pattern observed) is contrasted with the crystalline

TABLE II

Spectra of HMX-I, -II, -III, and -IV in the 3000–650 cm^{-1} range

	Wavelength (cm^{-1})
HMX-I	2999, 1575, 1460, 1432, 1385, 1348, 1280, 1239, 1202, 1148, 1090, 968, 949, 919, 864, 832, 773, 762
HMX-II	3030, 1575, 1545, 1455, 1415, 1394, 1368, 1323, 1270, 1218, 1111, 1090, 1034, 947, 919, 866, 849, 768, 754, 742, 714
HMX-III	3001, 1561, 1437, 1410, 1379, 1365, 1316, 1280, 1210, 1088, 1015, 967, 940, 911, 862, 840, 764, 751, 732, 707
HMX-IV	2993, 1715, 1551, 1440, 1409, 1375, 1308, 1267, 1242, 1212, 1105, 1088, 1011, 909, 864, 841, 763, 749, 733, 708

form. Although differences exist they are less than those among the HMX modifications. Moreover, in the "skeletal region" both substances of Table III show closely similar absorption by contrast with the marked difference in the 800–650 cm^{-1} region shown by HMX-I versus HMX-II, -III, and -IV.

These differences at the longer wavelength shown in Tables II and III are to be expected with the polymorphs and they ought to be even more characteristic in the 650–300 cm^{-1} region. However, this frequency range has not been favorable for examination of unstable species such as polymorphs because relatively high pressures (with consequent error due to strain) are required to pellet potassium chloride, which is used in order to utilize the spectrum at a frequency as low as 300 cm^{-1}. Of course, oils such as Nujol are transparent in this region but mulls are notoriously unreliable when precise comparisons are

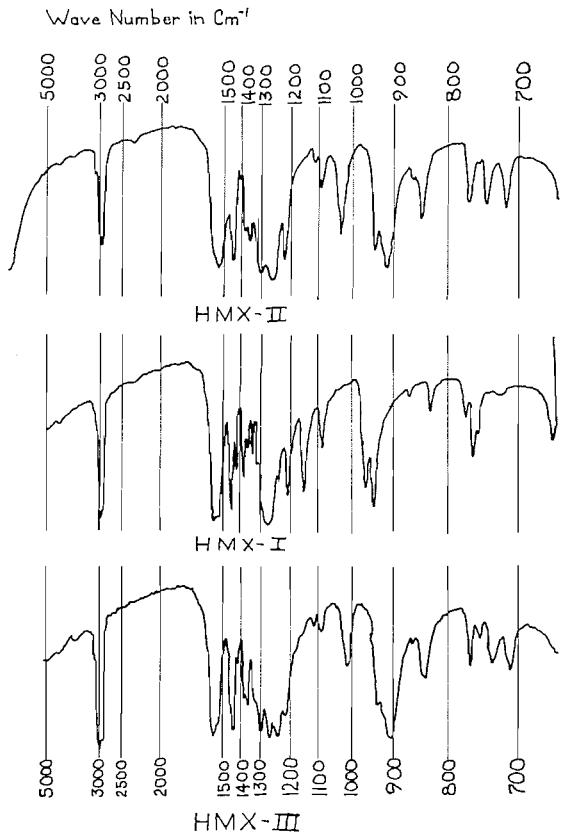

FIG. 1.

required. We have arrived at a compromise between these two media by use of polyethylene wax (molecular weight about 5000). A uniform mixture of the spectral candidate substance with this wax may be obtained and then pelleted easily (6000 p.s.i. for a pellet 2 cm²). Since polyethylene wax is suitably transparent (except for the CH_2 rocking mode at about 720 cm^{-1} at which frequency potassium bromide transmits) throughout the 300–900 cm^{-1} region it is the superior medium for examination of polymorphic substances.

The data of Table IV show absorptions in the 900–300 cm^{-1} region which are characteristically different for crystalline versus amorphous triphenylguanidine, for α- versus β-resorcinol, and for the differently melting polymorphs of 5-↑-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-3-↑-dicarboxylic acid (7). Nevertheless there are similarities which lattice force differences cannot conceal. By contrast the spectra of the HMX polymorphs I, II, and III are seen, in Table V, to be as different from one another as they are different from a number of other cyclic nitramines, which have been included for purposes of comparison. The distinctiveness is sufficient to suggest that phenomena other than simple polymorphism are involved with the HMX modifications.

The differences in extinction coefficient among polymorphs in the 900–300 cm^{-1} region ought to be the result of lattice force restriction on the structural absorption frequencies of the molecule. As such they ought to be sensitive to lattice dimension and, therefore, to variation in temperature. The polyethylene wax pellet is well adapted to temperature changes, so we have tested this variable from +40° to −39° in a special cell equipped

*W.N. = wave number.

with very thin latex rubber windows and have found (after correction for change of density) that absorption frequency is constant within our precision but that measurable differences in E_{max} occur for every absorption listed for HMX in Table VI. These differences appear greatest for the most dense (HMX-I) and least for the least dense (HMX-III) crystal modification, as would be expected if lattice restriction is effective. That is to say there is greater freedom for the molecule in HMX-III than in HMX-I. In consequence the thermal effects on lattice dimension will be more significant in HMX-I than in HMX-II and -III.

Since the dependence of extinction coefficient upon temperature has been interpreted in terms related to this geometry of the molecule it is of interest to consider the results of Table VI in view of those in Table VII. In Table VII are recorded the effects of decreasing temperature on part of the spectrum of *dd,ll*-2,5-dimethyl-2,5-dimethoxy-3,4-diphenylhexane. It may be seen that all of these skeletal absorptions are augmented by decreasing temperature and, therefore, are affected in the same way as the electrical moment (8) in benzene or carbon tetrachloride solution. But the higher dipole moment at the lower temperature is related to the most stable conformation that this tetrasubstituted ethane can assume. One may expect that as the population of this stable configuration becomes more preponderant the excitations characteristic of it will increase, with consequent narrowing of the absorption band to a greater peak.

Although this study of *dd,ll*-2,5-dimethyl-2,5-dimethoxy-3,4-diphenylhexane involves its solutions and as such is not directly applicable to the polymorphic solid states of HMX it does suggest that some relationship might be observed between infrared absorption and electrical polarization.

A method is available whereby the electrical polarization of crystalline solids (the distortion polarization) may be measured (9, 10). The method is not now applicable to solids melting below 50°, so crystalline dimethyldimethoxydiphenylhexane cannot be measured in this manner. However, the polymorphs of HMX are adequately high

melting, and reliable dielectric constants have been determined for HMX-I, -II, and -III. The distortion polarization may then be calculated from $(\epsilon-1)/(\epsilon+2)(M/D)$, where the density has been determined by air displacement (11).* Although polymorphic transformations are immanent under the manipulations required for this measurement it can be shown by X-ray or infrared analysis after the measurement that with care the transformation may be avoided. The results of the measurements are recorded, among others, in Table VIII, both as distortion polarizations (P_D) and as the residua after subtraction

TABLE VIII

Distortion polarizations

Polymorphs	d_4^{20}	ϵ	P_{E+A} (cc)	P_e* (cc)	P_A
α-Resorcinol (stable)	1.275	2.956	34.1	29.5	4.6

*These electronic polarizations were calculated by summation of the constituent bond refractions.

of the electronic polarizations (P_E), which are equivalent to molecular refraction calculated from bond (12) or atom and group (13) refractions. These residua are called the atom polarizations (P_A). They include the electromagnetic polarizabilities at frequencies which atomic structures can follow and exclude polarizabilities due to orientation of the molecule as a whole. The latter are at any rate supposedly excluded in the solid state.

The atomic polarization (P_A) ordinarily may be expected to comprise only a small (2–5%) amount of the distortion polarization (P_{E+A}) because the energy corresponding to atomic and skeletal vibration is much less than that of electronic polarization. However, there are exceptions (not completely understood) where the atomic polarization is abnormally high. Such abnormalities seem to involve the presence of permanent dipoles (14, 15), although many substances with obvious dipoles do not display this abnormality (16). Whatever may be the cause, all of the substances listed in Table VIII show abnormally high atom polarizations. The first three of these substances have been chosen on the basis of high P_A in order that the effect of crystal lattice forces toward atom polarization might be discernible.

For the first three substances reported in the table the lattice forces seem not to be effective toward alteration of atom polarization within the precision of our measurements. The distortion polarizations (Table VIII) of α- and β-resorcinol are almost identical. Likewise the polymorphic forms of 5-↑-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↑-3-↓-dicarboxylic acid (7) differ in P_{E+A} by only 0.4 cc. Indeed the dis-

It is a consequence of the determinations that density determined by air displacement is less precise than the determinations by flotation. Moreover much more substance (0.5 g) is required for the air displacement method. However, problems of solubility and chemical reaction are obviated by air displacement. Consequently the air displacement method is more accurate and, therefore, is used whenever sufficient substance is available.

tortion polarization seems to be practically independent of lattice forces. This independence is exemplified by comparison of the amorphous triphenylguanidine (7) with its crystalline modification. The distortion polarization of the pair differs only by 0.6 cc. This difference is approximately the limit of the analytical precision.

Within this limit the crystal forms of these three typical substances do not affect their atom polarization. In contrast are the distortion polarizations found for HMX-I, -II, and -III. Assuming that their electronic polarizations are identical (58.3 cc) and calculable from bond refractions (12), as seems justified by earlier studies with nitramines (15), the atom polarization of HMX-I ($P_E-(\epsilon-1/\epsilon+2)(M/d)$) is 5.3 cc. On the same basis of calculation (ϵ = dielectric constant, M = molecular weight, and d = density), the atom polarization of HMX-II is 28.7 cc while that of HMX-III is 21.2 cc. No value has been determined for HMX-IV because of its great tendency to transform at room temperature.

The relative order of these atom polarizations (I < III < II) follows neither the order of densities nor the order of the thermal stabilities (I > II > III) and thus does not seem to be related simply to lattice packing or lattice energies. A more fruitful correlation may be sought from a previous study (15) where markedly high atom polarizations were found to exist among crystalline nitramines. These atom polarizations (4–7 cc per nitramino group) are not unexpected if they are due to charge separation because this group is responsible for large dipole moments in substances containing it (15).

A relationship of high atom polarization might have been predicted from the distortion polarizations of the alkali halides. The correlation ought to follow a function including ionic volume and charge separation, i.e. MF < MBr < MCl < MI, where M is an alkali metal ion, although the previous experimental evidence is equivocal. The predicted order was indeed found by Heydweiler (17) but not by Errera (18). To our satisfaction we have resolved this discrepancy by application of our wafer technique (8) to the crystalline sodium and potassium halides. In conformity with Errera we find the polarization to be independent of frequency between the limits of 0.5–5.0 mc but, as may be seen from Table IX we confirm Heydweiler (for the salts that he examined) rather than Errera in

TABLE IX

Distortion polarization of alkali metal halides at 20° C

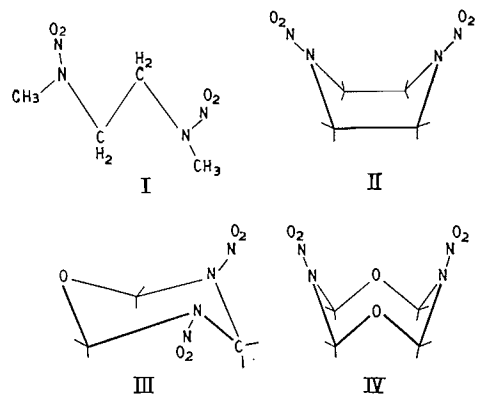
respect of the order (F < Br < Cl < I) of the atom polarization of the sodium and potassium halides. Therefore, the preponderance of evidence supports the idea that

abnormally high atom polarization in (at least) an ionic crystal is related to the extent of charge separation among the atoms.

It is reasonable to presume that permanent charge separation in a covalent molecule likewise may contribute to the atom polarization. Indeed the nitramines (of which HMX is an example) in microcrystalline wafers show in general an amount of distortion polarization which cannot be accounted as electronic and so has been called atomic. This assignment of atom polarization amounts to about 7 cc per nitramino group (=NNO_2). Moreover the atom polarization is roughly additive, as is shown by the two nitramino groups in the linear N-methylnitramino-*bis*-ethane, I, the P_A of which is 14.5 cc.

However, if a relationship among nitramines exists in the solid state between charge separation and atom polarization it is not a simple one. When several nitramino groups are present in relatively fixed portions in a molecule (in contrast to I) the resultant atom polarization tends to be lowered. For example N,N′-dinitropiperazine, II, is found (15) to have an atom polarization ($P_D - P_E$) of 3.7 cc rather than of 14 cc expected (from group summation) such as occurs in the non-cyclic I. A limiting instance is that of 1,3-dinitro-1,3-diaza-5-oxacyclohexane, III, where no atom polarization at all is detectable ($P_D = P_E$).

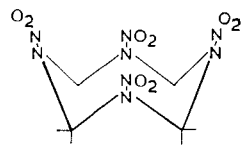


It is reasonable to draw from these observations the conclusion that when polar groups are in structural apposition they tend mutually to cancel the atom polarization of each group. The magnitude of this cancellation is in qualitative agreement with the expectation that the nitramino group is planar (or nearly so) as a consequence of resonance hybridization (19). The sp^2 character of the ring nitrogen disposes these groups equatorially and thus closely in apposition. On the other hand this sp^2 character might be expected to "fold" the molecule of 1,5-dinitro-1,5-diaza-3,7-dioxacyclooctane, IV, so that the atom polarizations of the nitramino group are geometrically additive rather than subtractive. It is tempting to attribute the 16.9 cc (Table VIII, $P_D - P_E$) of atom polarization found for IV entirely to this additive effect, but probably the geometry does not justify all of this magnitude. Flexibility of the molecule (to be discussed later) undoubtedly contributes as well.

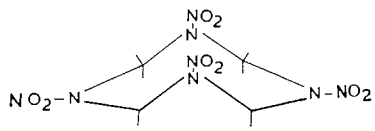
It must be noted that these concepts are contradictory to the theory of Coop and Sutton (20), who attributed the appreciable difference between total and electronic polarization of a group of substances with opposed dipoles to atom polarization because inspection of the formulas indicated that orientation polarization could not occur. This theory became unacceptable to us when our "wafer" measurements showed that some

of these substances either showed no abnormality of atom polarization or else much less P_A (21, 15) than Coop and Sutton specified. Moreover certain of the substances, such as *p*-benzoquinone, tetramethylcyclobutane, and *p*-dinitrobenzene, were shown to have measurable orientation polarizations. In view of these experimental results we must at the present time favor our concept of group apposition rather than that of Coop and Sutton.

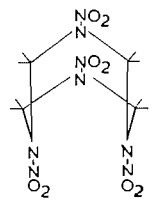
However, neither the theory of Coop and Sutton nor our own concept explains fully the difference in atom polarization shown by HMX-I, -II, and -III by contrast to the solid-state modifications of other substances in Table VIII. Therefore, we suggest for these HMX modifications some possible differences in conformation which would be labile in solution but may persist in the crystals. From at least five probable conformations we shall select three which are free from transannular methylene interaction. The conformation V has all four carbons in one plane and all aza nitrogens in another plane while in conformation VII all carbons are in one plane but two each of the aza nitrogens are in planes above and below the plane of methylene carbon. Intermediate between these extremes is VI, in which the four methylene carbons and two aza nitrogens as slightly puckered out of a plane and the remaining aza nitrogens are above this "plane".



V, HMX-II (P_A, 28.7 cc)



VI, HMX-III (P_A, 21.2 cc)



VII, HMX-I (P_A, 5.3 cc)

Assuming again that the NNO_2 group is chiefly planar the four groups in V ought to be geometrically additive while those in VII are subtractive. In VI two nitramino groups are strongly additive while the other two are weakly so. Therefore, V ought to represent HMX-II, VII corresponds to the low P_A of HMX-I, and the 21.2 cc atom polarization of HMX-III is best described by VI.

It is obvious by inspection that the amount of space occupied by these three conformers will be VI > V > VII. Although the density of lattice packing is not necessarily related to the volume of the molecules contained in the lattice it may be significant that the

structural assignments correspond with the densities (HMX-I > -II > -III) of the polymorphs.

The assignment of conformation V to HMX-II would seem nominally to be at variance with a recent single-crystal X-ray diffraction study (22) which favors conformation VI for this polymorph. The contradiction may be more apparent than real. Each scientific observer sees his evidence through the window of his method. The X-ray diffraction method "sees" mean position of electronic charge, which is assumed to be stagnant and centered by a nucleus. By contrast the reactance in an applied electrical field is accentuated by charge separation and thus "sees" preferentially the most strongly polar states of a system. It follows that different interpretations will be made if the structure of the substance is dynamic rather than static. But both X-ray and dielectric measurements agree that the difference in the HMX solid states is conformational. It remains to ascertain whether there is sufficient freedom in the crystal array to allow for that conformational motion which would cause the results of X-ray diffraction to differ from those of dielectric measurements.

Empty space in a crystal lattice is metastable at temperatures at which thermal agitation does not warrant its existence. The transformations of forms like HMX-II and -III into HMX-I at room temperature exemplify the metastability. However, it may be expected that other molecules might also fill these empty spaces if they were geometrically compatible with the space. The existence of a 1:1 molecular complex of HMX and dimethylformamide (23) therefore is not unexpected. In conformity with the expectation of a stoichiometric crystal complex (not a clathrate) is the analysis and the stability of HMX–dimethylformamide. An examination of the characteristic absorptions in the infrared spectral region shows a closer resemblance to HMX-II or -III than to HMX-I.

In absence of space-filling addenda one may assume that some conformational motion occurs within the lattice restriction which prevents transformation from HMX-III or -II to HMX-I at room temperature. If the interpretation of the HMX polymorphs is correct then these values ought to be temperature dependent.

In order to test this postulation several alterations in our technique for dielectric measurements have been necessary for the temperature range (−40 to +28°) which we have chosen. Instead of gold amalgam as a wafer surface layer we have used indium foil as the conductor. The foil-coated wafer is aligned on the flat Kovar metal cylindrical platform at the top of the non-grounded terminal D in Fig. 2. The sliding grounded terminal P not only completes the capacitance circuit but also transmits any change in thickness of the wafer assembly to the machinist's gauge K at the top. The temperature is measured by two thermistors situated as close to the wafer assembly as is possible. Ingress of moisture is prevented by dry nitrogen, in at N and out around the upper end of P.

The temperature may be lowered to −40° C by passage of dry air through the liquid-nitrogen-cooled coil at A and thence through the middle of three annuli and out at C. The outer, highly evacuated annulus is strip-silvered to reduce radiation and to shield the capacitance of the wafer which is being measured. The inner annulus, at atmospheric pressure, permits gradual and uniform heat exchange. About 1 hour is required to decrease the temperature to −40° after which the temperature is gradually increased to +28° during 5 hours by regulation of the airflow. Although the change in pellet thickness and capacitance is recorded during this interval (to detect abnormalities such as wafer fracture or foil separation) only the capacitance and thickness at −40° and +28° are used for calculation. Subsequently the dielectric constant and the thickness of the wafer are measured in the apparatus (Fig. 3) described previously (10).

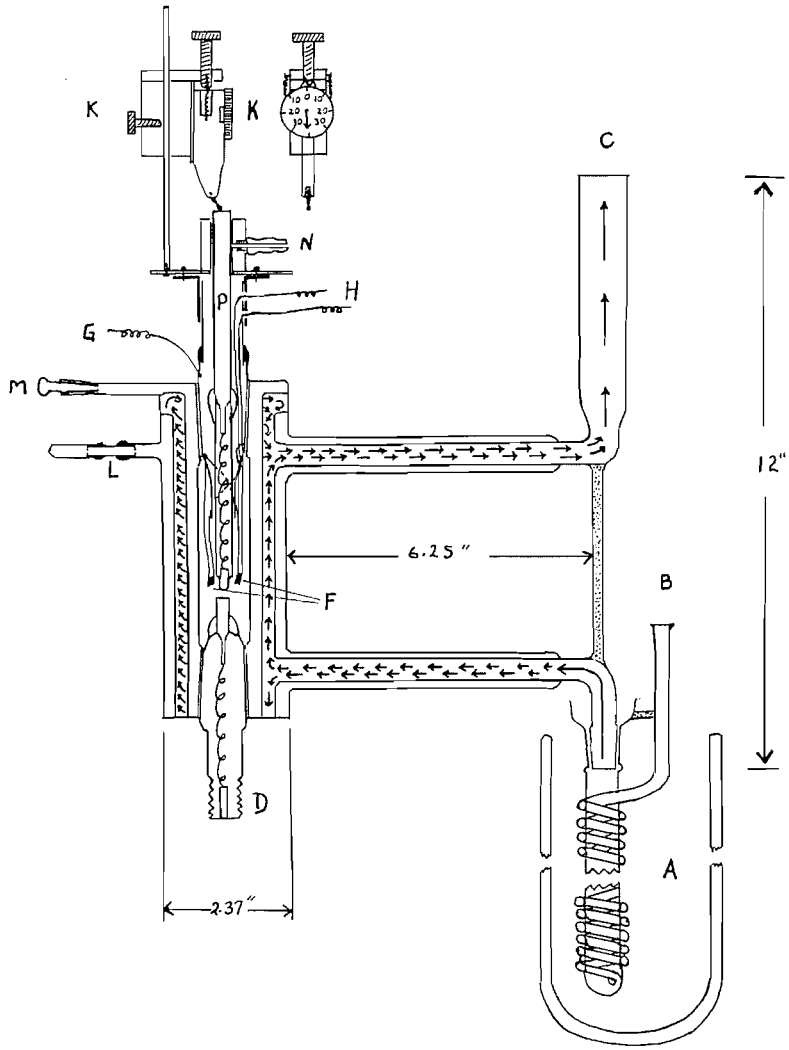


FIG. 2.

Since the measurement does not take into account the "edge effect" the dielectric constants derived at +28 and −40° are in error. For correction of the error a series of wafers of various thickness is examined and the apparent dielectric constants are plotted against thickness in order that the true dielectric constant may be ascertained by extrapolation to infinitesimal thickness (zero edge effect).

Several of these plots are shown in Fig. 4. It may be seen that the deviation is too great for graphic extrapolation and the method of least squares must be utilized. The least satisfactory of all the determinations is that of HMX-I. This latter result should not be considered to be typical because great difficulties were encountered in the preparation and maintenance of the wafers prepared for this polymorph even though 2% of polyethylene wax was incorporated for the purpose of consolidation.

The distortion polarizations calculated from the dielectric constants at +28° and −40° for a series of representative substances are shown in Table X. When the distortion

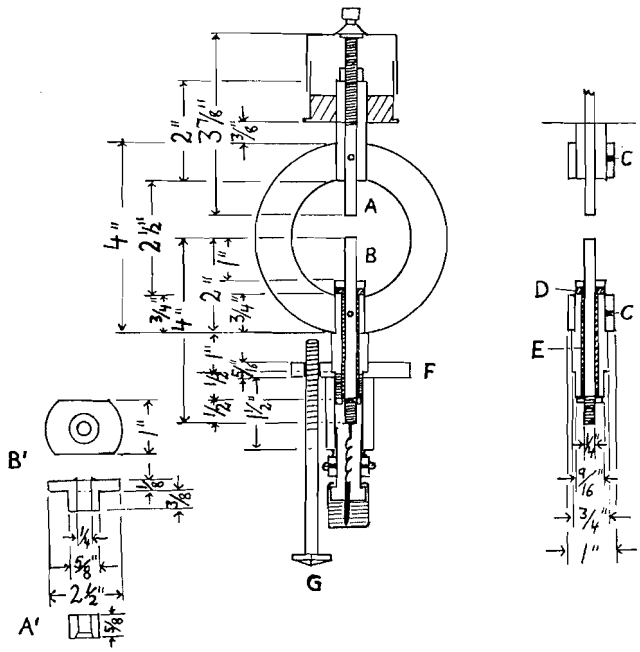

FIG. 3.

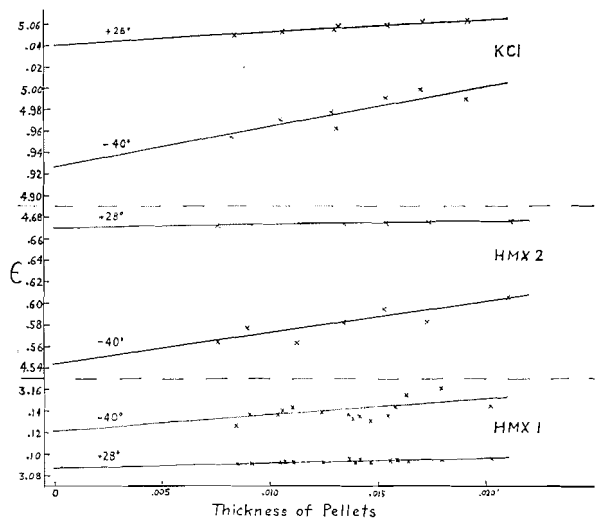

FIG. 4.

polarization is close in value to that of the temperature-invariant electronic polarization (i.e. when atom polarization is normally low) it ought to be the same at +28° and at −40°. Consequently the variations (+0.27 cc, +0.12 cc) over this temperature range for anthraquinone and hexachlorobenzene may be considered to be representative of experimental error. With this assignment of error the high atom polarization of zirconium acetylacetonate (10) must be declared invariant with respect to temperature. Likewise the appreciable atom polarization of sodium and potassium chlorides are temperature

TABLE X

Distortion polarization at $+28°$ (t_1) versus that at $-40°$ (t_2)

Substance	t (°C)	ϵ	d_4^{20}	P_D (cc)	ΔP_D (t_2-t_1)
Anthraquinone	t_1	3.200	1.421	62.0	
	t_2	3.217		62.3	+0.3
Zirconium acetylacetonate	t_1	2.937	1.412	135.3	
	t_2	2.938		135.4	+0.1

	t_2	5.944		16.8	−0.3
Potassium chloride	t_1	5.040	1.984	21.6	
	t_2	4.927		21.3	−0.3
HMX-I	t_1	3.087	1.91	63.6	
P_A = 5.3 cc at 23°	t_2	3.118		64.1	+0.5
HMX-II	t_1	4.671	1.87	87.0	
P_A = 28.7 cc at 23°	t_2	4.544		85.8	−1.2
HMX-III	t_1	3.868	1.82	79.5	
P_A = 21.2 cc at 23°	t_2	3.776		78.2	−1.3

independent within our limit of error. These results are not unexpected in view of the commonly accepted concept of atom polarization.

On the other hand the ΔP_D of the HMX polymorphs is each beyond our limits of experimental error. Because of the difficulties in manipulation of HMX-I (exemplified by the ϵ vs. thickness plot of Fig. 4) we are reluctant to attach any meaning to the positive ΔP_D of 0.5 cc found for this polymorph. On the other hand the wafers of HMX-II and -III were prepared easily and the consequent plots of dielectric constant versus thickness are at least as good as those of the other substances listed in Table X. It seems clear that an appreciable diminution in distortion polarization is characteristic of HMX-II and -III at low temperatures. This behavior is the expected one if conformational motion were indeed occurring in these lattices of lesser density than that of the close-packed, centrosymmetrical HMX-I.

The extent of diminution in P_D with respect to temperature in HMX-II and -III is inversely related to the amount of "abnormality" in P_A. This might be interpretated as evidence of greater flexibility in HMX-III than in HMX-II. However, it seems more reasonable to attribute the higher ΔP_D in HMX-III to the geometry of our conformational assignments. It is a consequence of the symmetrical arrangement of the nitramino groups in conformation V, which we have assigned to HMX-II, that small deviations from this symmetry will be less effective in altering the resultant of the four directed dipoles than in the conformation VI, attributed to HMX-III, because the resultant of the axially aligned dipoles in VI will not be altered as much by small deviations in conformation as will be the resultant of the equatorial dipoles.

In summary the evidence from spectral absorption studies and electrical polarization studies seems to indicate that HMX-I, -II, and -III are lattice-caged conformational isomers which may undergo a restricted type of orientation polarization. On this basis it might be said that their abnormal P_D values do not involve high atom polarization and, indeed, that they are not properly to be classified as polymorphs. However, the etymological classification of natural phenomena is of less importance than the physical definition of these phenomena. Undoubtedly other crystals can be found in which conformational motion is detectable by the techniques of infrared spectroscopy and dielectric constant evaluation. We are searching for them.

EXPERIMENTAL

Temperature Coefficient of Distortion Polarization

A. Preparation of Wafers

Two techniques are used depending upon the physical characteristics of the candidate substance. According to method I the substance is first pressed at about half the usual compression (7500 lb dead load) in the die shown in the cross section in Fig. 5. Then the upper and lower (long and short) pistons are removed after the

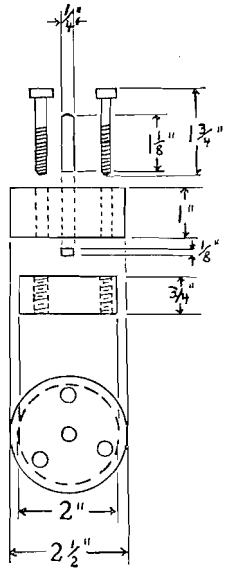

FIG. 5.

lower piston has been extruded slightly and disks of indium foil 0.01 inch thick and of diameter equal to that of the die cylinder are inserted onto both faces of the wafer *in situ*. The pistons are then reinserted and a maximum compression (15,000 lb dead load) is applied to the assembled die before the wafer is removed.

According to method II an indium disk is placed on the top of the small piston in the die and the finely powdered candidate substance is placed on top of it. The upper surface of the powder is now levelled by a circular motion of the upper piston. Then another indium disk is placed on top and the assembly is subjected to maximum compression.

By either of these methods the indium foil is likely to be extruded over the lateral wall of the wafer. This excess must be removed carefully by means of a very sharp knife. It is advisable to allow the wafers to "age" for 1 day during which time blisters may form on the surface. These blisters may be punctured with a needle and then flattened smoothly with a spoon-shaped tool. The reliability of a wafer also may be ascertained by cooling it quickly to $-40°$ in a test tube and then allowing it slowly to warm to room temperature.

B. Apparatus for Temperature-variant Measurement of Dielectric Constant

The cylindrical apparatus shown in Fig. 2 in cross section consists mainly of a lower electrode, an upper electrode, and a glass jacket. The jacket is triple walled. The outer annulus is highly evacuated and also is strip silvered; the silvering is continuous around top and bottom and it extends over the inner surface of the Kovar-glass seal, L, so that external grounding of L provides effective shielding from external influence. The middle annulus accommodates the cooling air which enters at B, is chilled by liquid nitrogen in A, and which leaves the apparatus at C. The inner annulus contains stagnant gas (usually air) at any desired pressure (usually atmospheric) but is variable by means of the tapered joint closure at M. The inside surface of this inner annulus is tooled and ground, and top as bottom, for 24/40 taper.

The lower electrode consists of a uniaxial fitting D surmounted by a 24/40 joint to which is sealed a Kovar rod platform upon which the test wafer is situated. The upper electrode is equipped with two thermistors F that are mutually grounded onto silver which is plated on the 24/40 cone. The insulated thermistor leads, H, are connected to two vacuum tube Wheatstone bridges off which the temperature can be read to $\pm 0.1°$ from a 10-turn potentiometer where a 6E5 magic eye tube indicates balance. The upper electrode is shown in more detail in Fig. 6, which depicts the guide platform as well as the internally grounded prolongation of the 24/40 joint and consists of a Trubore tube to which a rounded Kovar pin is sealed at

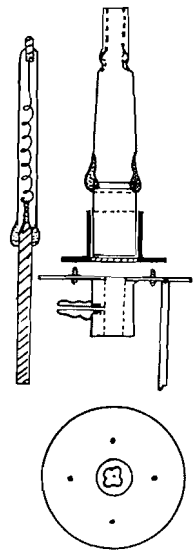

FIG. 6.

the bottom and a 5/16 Kovar rod is sealed at the top. Ground connection through this electrode is established by the interconnecting silver wire and the contact with the point of the machinist's gauge at the top. The dry nitrogen entrance at N blankets the interior of the assembly by emergence around the platform guide.

C. Apparatus for Room-temperature Measurement of the Dielectric Constant

This apparatus has already been described briefly (10). Constructional details are shown in Fig. 3 for a cross-sectional side view and end view. Also shown are polymethacrylate accessories A′, which slides on A as a centering device for the wafer, and B′, which slides on B for the same purpose as well as to catch droplets of gold amalgam when the latter is used as a wafer coating. It has been found necessary to install a rigidly attached ring, F, in which are threaded three equally spaced screws (one shown as G) which serve to keep the uniaxial connector under tension, thus to establish stability of the entire measuring device.

Insulation of the lower electrode is effected by means of the precisely concentric Steatite ring D and the glass tubing E. Around E at the bottom is a fiber insulating washer retained by a nut which completes the rigid assembly.

The lower electrode and upper electrode (which is the spindle of the 2 inch diameter Shardlaw head) are each secured into the soft steel ring which comprises the body of the apparatus by two Allen screws normal to each other. Adjustment to these screws compensates misalignment of the electrodes due to tightening of either screw.

Measurement of dielectric constant is accomplished by perfect alignment of the wafer coated either with indium foil or with the 15% gold amalgam. When the latter is used, about a minute should be allowed for the initially soft amalgam to become semirigid so that it can be brushed to concentricity with electrodes and wafer (the amalgam again becomes soft when it is rubbed in a mortar). After the oscillator circuit has been brought into balance with a fixed frequency (5 Mc) the wafer and coating are removed quickly and the air gap is closed until the oscillator is again in balance. This air gap dimension is then included with measurement of the uncoated wafer at the four quadrants and the center (these thicknesses being averaged) to give the dielectric constant, ϵ, as the ratio of thicknesses of substance and air.

D. Measurements from +28 to −40° with Wafers

With the lower electrode attached at D (Fig. 2) to the oscillator circuits the indium-coated wafer is installed concentrically on the top of D. The cooling jacket and grounded electrode assembly is added snugly and carefully.

The capacitance measurement is made by use of a connector comprised of a two-prong short-circuiting plug which may be repeatedly inserted and removed without capacitance alteration greater than 0.001 pf. A frequency balance is obtained with the test capacitor connected and then disconnected. The difference in capacitance is that of the candidate wafer after the cell capacitance (determined as described below) is subtracted.

An initial capacitance measurement is made at ambient temperature and then dry air, cooled by liquid nitrogen around A, is blown through the jacket and out at C. The change in dimension shown by the indicator dial K indicates, by communication via the grounded electrode E, the change in thickness of the wafer

assembly. After about 1 hour the temperature has been lowered to −40° C (as is indicated independently by the two thermistors F) and adjusted to constancy. The final thickness and the capacitance at −40° are determined. Now the temperature is raised slowly during 5–6 hours and is brought to constancy at intervals of 4° C for determination of capacitance. These intermediate measurements are made to detect any unusual deviation which would indicate that the wafer has developed a fault, but only the lowest and highest temperatures are utilized for the evaluation of temperature coefficient. After completion of measurement at the highest temperature the wafer is transferred to the device shown in Fig. 3, where apparent dielectric constant is determined in the usual manner, the foil being finally removed in order to measure the absolute thickness of the wafer and the indium foil at room temperature.

Although the change in thickness is closely followed in the determination it has been found to be worthwhile also to determine the coefficient of expansion of the candidate substance by temperature cycling of a comparatively thick wafer without indium foil in the apparatus of Fig. 2 while only the change in thickness is measured. Of course, the wafer must be sufficiently thin to ensure that its density is maximal.

The measurements described above would be in error because of dimensional and electrical variations in the apparatus of Fig. 2 had these not previously been determined. The change in capacitance of the apparatus with respect to temperature is made by maintaining the grounded electrode about 0.3 inch above the lower electrode while capacitance of the apparatus without a wafer is determined from +28 to −40°. In like manner the dimensional change of the apparatus in respect of temperature is made with observation of the indicator gauge K while the top and bottom electrodes are in direct contact, one with the other. Correction curves have been constructed for both of these variables and the capacitance of the cell is checked to ensure precision of assembly before every experiment.

E. Calculation of Distortion Polarization

The dielectric constant at −40° cannot be obtained directly because the air capacitance corresponding to capacitance of the wafer is not measured by the apparatus of Fig. 2. However, the air capacitance at +28° may be measured in the apparatus of Fig. 3. Then the distortion polarization P_D may be evaluated:

$$P_{D\rho} = \frac{(C_{S\rho} - C_{A\sigma})(H_\rho/H_\sigma)}{(C_{S\rho} + 2C_{A\sigma})(H_\rho/H_\sigma)M(1-3[H_\sigma - H_\rho])/d_\sigma},$$

where $\rho = -40°$, $\sigma = +28°$, C_S = capacitance of wafer, and C_A is the corresponding capacitance of air (C_S/ϵ) for thickness H of the wafer, density d, and molecular weight M.

X-Ray Diffraction Patterns

The d spacings in angstroms obtained with the HMX polymorphs and the various other compounds mentioned in this report are shown with their relative intensities (I/I_1) in Table 1. In all cases the diffraction patterns were determined using Cu $K\alpha$ radiations with a nickel filter.

Spectral Studies

For the spectral range 2500–700 cm^{-1} a Perkin–Elmer Model 21 instrument was used with potassium bromide pellets prepared in the usual manner. A Beckman IR-4 instrument was used from 900–300 cm^{-1}. Partial spectra were obtained in the latter range by the double-beam technique for a 1.7% solution of HMX in acetone (three strong bands at 597, 615–620, and 760 cm^{-1}) and for 2.25% solutions in dimethylformamide (four strong bands at 598, 615–620, 765, and 840–850 cm^{-1}). Complete spectra in the 900–300 cm^{-1} range were obtained by use of wafers prepared with polyethylene wax* (average molecular weight ca. 5000). This wax as received is comminuted in a Wiley Mill using an 80-mesh screen. The powder is tightly bottled. In order to prepare a wafer the candidate substance is ground to 1- to 10-μ size and then is mixed with the powdered wax to the desired concentration (1–25%) in a 15×150 mm test tube, the inside wall of which has been roughened to opacity by use of 300- to 500-mesh carborundum. The stoppered test tube is then rotated axially for 15 minutes (conveniently on Fisher Scientific Company motor-driven glass blowers' rollers). Enough of the mixture (190–200 mg) to make a wafer 0.4 mm thick is then introduced into the die shown in Fig. 7.

The body and lower plate of this die is fabricated from SPS-245 alloy steel inclusive of the bolts which hold the two taper-pinned halves of the body together. These parts are hardened to 45–50 Rockwell-C. The piston is made from high-carbon steel, case hardened and lapped to a fit in the body of ±0.0002 inch. The top of the plate and the bottom of the piston are finely surfaced to avoid adhesion of the completed wafer, and are wiped with Nujol before each use. The Nujol film must not be visible.

The mixture of sample and wax is evenly distributed in the die and then is pressed (without vacuum) under a dead load of 15,000 lb. Then the bottom plate is removed and the wafer is extruded carefully. It is mounted in a frame consisting of three pieces of filling card cut externally to fit into the IR-4 cell holder and internally so as to hold the wafer in the central card and to retain it with the outer cards, the three finally being stapled together. The "window" must be large enough to contain all of the light beam. These wafer holders may be filed together with reference wafers containing the same weight of wax. There is no mechanical or optical deterioration after 4 years of storage.

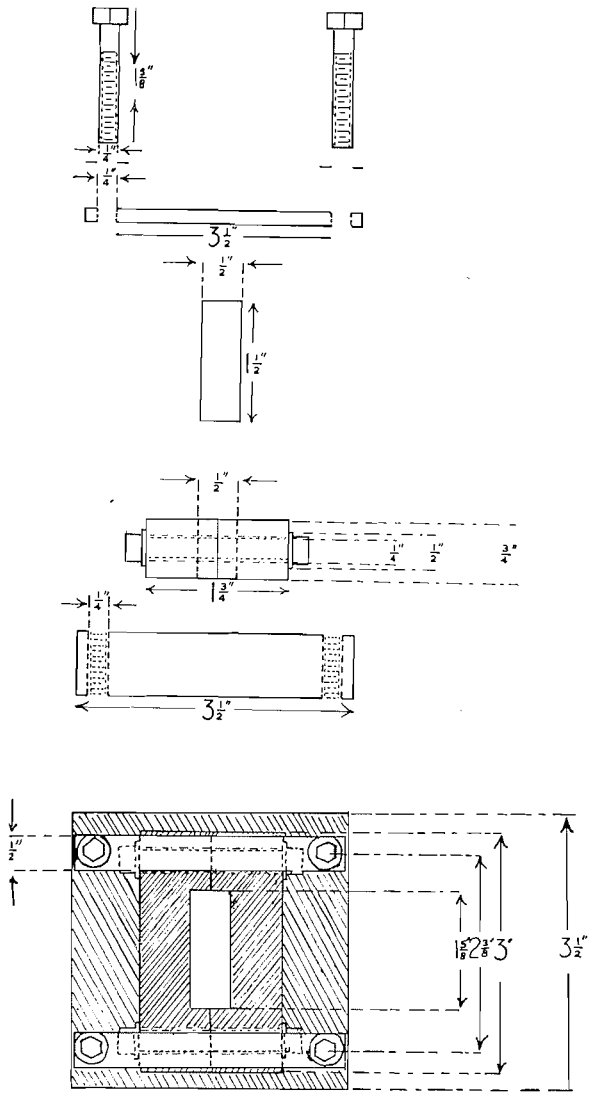

FIG. 7.

Temperature Coefficient of Infrared Absorption

1. Holders for Polyethylene Wax Pellets

The pellet holder for temperature-variable measurement is shown in Fig. 8. The median slotted plate A (into which the polyethylene wax pellet fits) is bounded by the brass plate B and by the bakelite plate C, which is drilled to accept the air inlet D at the bottom and the head thermistor E with its leads at the top. Over one side of detached A is stretched a cured latex rubber sheet of thickness 0.06 mm, supplied by courtesy of the Viceroy Rubber Co., Toronto. The rubber sheet is rendered non-tacky during this manipulation by a light layer of talc but the latter must be washed off by use of water–ethanol while the rubber sheet is held in its stretched condition. Then B is applied to A and secured by the eight screws so that the rubber cell window is firmly emplaced. A rubber window is similarly installed between A and C after small holes are made in it by hot wire so that the air inlet and the thermistor have access to the slot.

The pair of pellet holders used in the sample and reference beam of the Beckman IR-4 spectrometer are calibrated with respect to temperature by insertion in an empty 6-l. vacuum jar the cover of which holds (1) a glass tube of 40-mm O.D. to contain dry ice – acetone, (2) a motor-equipped 4×1 inch rotating rubber blade for air circulation, and (3) a precision thermometer between the two pellet holders which are hung

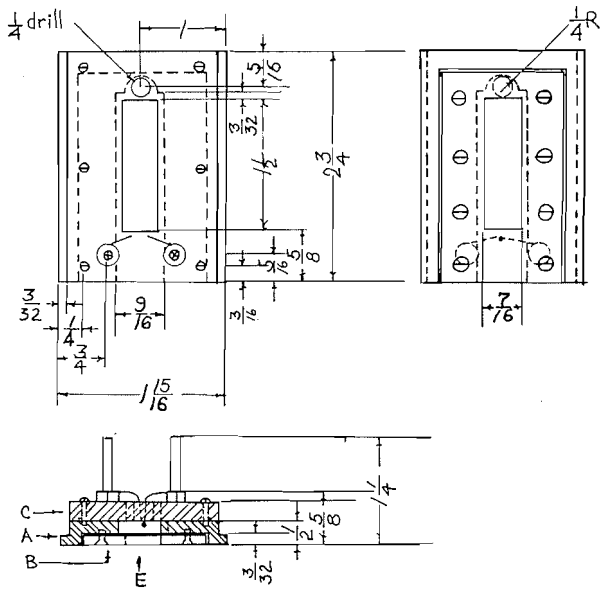

FIG. 8.

in close proximity to it. The thermistor leads from each holder are led each to its vacuum-tube-amplified Wheatstone bridge in which balance is indicated by a 6E5 magic eye tube.

Part of the air used for purging the IR-4 spectrometer (dried by a bed of pellet sodium hydroxide 4 ft long and then by a 30-inch length of Linde 3A molecular sieves) is divided by two valves into lines leading to water removal traps immersed in liquid nitrogen. Thence the two airstreams are led to separate copper coils immersed in a 5-l. spherical vacuum flask containing liquid nitrogen. The outlets of these copper tubes are connected to silvered and evacuated double-walled glass lines which carry the cold air through the cover that has been built over the IR-4 cell compartment and then to the air inlet tubes of the pellet holders in sample and reference path. With this equipment the pellet holders are reduced in temperature from 40° C to −39° C in 30 minutes by about 1 c.f.m. of cold airflow. Temperature regulation or temperature rise is controlled by the two valves.

2. Cooling Jackets for Standard Beckman Cells

The standard Beckman cells for use with solutions may be chilled to −40° *in situ* by use of the bakelite – polyurethane foam device shown in Fig. 9. The bottom and sides of the device form a yoke, A, which slips snugly (because of the foam) around the cell and provides air passage around the cell plates from bottom air inlet to top. After installation on the cell the yoke is retained by the bakelite bar B across the top, which bears a head thermistor like those used in the pellet holders (1, above) and also a vent for exit of cold air. About 1.5 c.f.m. of airflow is required to decrease the cell temperature to −40°.

Electrical Measurements

The distortion polarizations were determined according to an earlier report (10). It was found necessary with HMX to include 2% of Koroseal in order to make satisfactory pellets. Density of the polymorphs have been determined by flotation. After determination of dielectric constant each X-ray diffraction pattern was redetermined. The dipole moment of HMX was determined in dioxane at 20° C in equipment described earlier (9). Since $\Delta\epsilon/\Delta\omega = 9.80$ and $\Delta V/\Delta\omega = 0.445$ the total polarization is 519 cc. Subtraction of the additive group refractions of HMX (58.3 cc) enables an evaluation of electric moment as 4.68 D.

Preparation of Crystalline HMX Modifications

1. HMX-I

Several methods have been used to prepare this form but the preferred one is by cooling a hot saturated solution of HMX in acetone or acetonitrile. This method gives very pure beta crystals providing the solution is cooled in a stoppered flask and kept in agitation by means of a magnetic stirrer. Purity was confirmed by infrared and microscopic examination to ensure that the product was satisfactory for use. Calc. for $C_4H_8N_8O_8$: C, 16.2; H, 2.72. Found: C, 16.6; H, 2.96.

2. HMX-II

About 4 g of HMX was dissolved in 80 cc of 70% nitric acid by warming on a hot plate until slight fuming occurred. The flask was then insulated by wrapping lightly with a towel so that the contents cooled

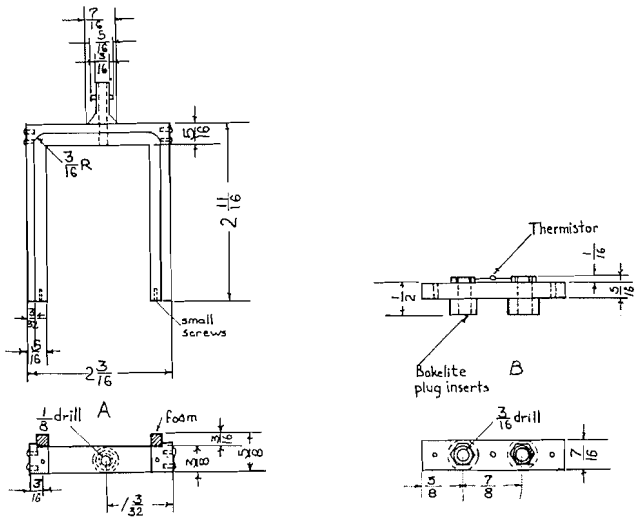

FIG. 9.

to room temperature in about ½ hour. The crystals were then filtered off, washed with water until free from acid, and dried in a vacuum oven at 50° C. The absence of other forms of HMX was confirmed by microscopic and infrared examination. Calc. for $C_4H_8N_8O_8$: C, 16.2; H, 2.72. Found: C, 16.5; H, 2.93.

3. HMX-III

About 1 g of finely ground beta HMX was dissolved by warming in 280 ml of 50% aqueous acetic acid. When dissolved, the flask and contents were cooled rapidly by swirling in an ice-water bath. The temperature dropped to 20° C in about 4 minutes. On filtration well-formed triangular plates were obtained. Microscopic and infrared examination showed the product to be free from other forms.

Some HMX-III was also prepared by steam-distilling off the solvent from a hot saturated solution of HMX in water-saturated cyclohexanone. After the cyclohexanone–water azeotrope had been stripped off at 96° C the precipitated HMX was filtered off and dried in a vacuum oven at 50° C .The product consisted of small, poorly defined crystals but its purity as shown by infrared examination was somewhat better than the product obtained from acetic acid. Calc. for $C_4H_8N_8O_8$: C, 16.2; H, 2.72. Found: C, 16.4; H, 2.92.

4. HMX-IV

Samples for X-ray diffraction studies of HMX-IV were prepared by sublimation of HMX-I at 180° C onto cold microscope slides. The slides were then washed with chloroform and vacuum-dried for 8 hours at 25° C. The reflections arranged in order of decreasing intensity (I/I_1) are: (10) 3.64, 5.43; (9) 6.67; (8) *3.17*, *3.48*, *5.16*; (7) *3.82*; (6) 5.69; (5) 4.21; (4) 2.71; (3) 2.51; (2) 2.35, 2.22; (1) 2.15, 2.63, where those in italics are very similar to lines found for HMX-III. The rest are not found among the reflections of the other polymorphs.

5. HMX–Dimethylformamide Complex

This form is prepared by simple crystallization from dimethylformamide (DMF). In the procedure used here a hot saturated solution was first prepared by adding ground HMX to about 100 ml of boiling DMF. The solution was then diluted with another 10 ml of DMF, poured into a petrie dish, and allowed to cool slowly. After filtration the crystals were dried in a vacuum oven at 50° C.

To prove that the product was a 1:1 HMX–DMF solvate, accurately weighed samples of about 2 g were refluxed in boiling water for 2 days. After cooling and filtration through a sintered-glass crucible the crystals were dried under vacuum to constant weight. The loss in weight in all experiments was 25.55% of the dry residue, giving a mole ratio of 1:1.02. Infrared examination of the residue revealed that it was completely converted to HMX-I.

The proportion of DMF present was also confirmed by dissolving a weighed sample in acetonitrile and then determining the quantity of DMF released by measuring the carbonyl absorption at 5.9 μ. With the aid of a calibration curve for DMF in acetonitrile it was shown that the mole ratio of DMF to HMX was exactly 1:1 even with a sample that had been finely ground.

The stability of this crystalline form is also shown by the following experiment: One gram of the complex was ground to about 20-μ size, let stand 1 year in a large bottle, and then was heated 1 hour at 80° C with 20 ml of water. After cooling, the system was filtered to remove HMX-I. The filtrate was treated with 5 ml of concentrated hydrochloric acid and then was evaporated to dryness, finally in an air stream. The residual

crystals were treated with $M/5$ aqueous triethanolamine picrate. Filtration removed 0.12 g of dimethylamine picrate, m.p. 157–158° C. A mixture melting point* with an authentic specimen was not lowered. Calc. for $C_7H_{15}N_9O_9$: C, 22.8; H, 4.09; N, 34.2. Found: C, 23.0; H, 4.09; N, 34.1.

When the complex was heated under observation through crossed Nicol prisms a transition was observed at 92° C. After a sample was heated under vacuum to 93° C during 1 hour and then cooled during 1 hour it had been transformed to HMX-I.

Stable and Labile Resorcinol

Resorcinol purified by crystallization from water was used as such (stable α form) or was heated to 70° C for 1 hour in a test tube which then was chilled quickly. The difference in melting point reported previously (5) could not be discerned, but the X-ray diffraction patterns (Table I) are distinctive and reproducible before and after pelleting. The densities, determined at 22° C by air displacement (11), are slightly different from those reported by Lautz (α, 1.271; β, 1.292 at 20° C).

Triphenylguanidine

After repeated crystallization from hot 95% ethanol to remove an insoluble impurity the substance melted at 143.8° C. We were unable to isolate the reported (5) polymorph, m.p. 138° C, but when the molten substance was poured onto a cold brass plate the amorphous form was obtained. This glass is stable at 25° C but it is converted to the crystalline form, m.p. 143.8° C, when it is maintained at 70° C for 3 hours.

ACKNOWLEDGMENTS

The authors are grateful to Peter Podleschka, Rudolph Deuringer, and Brigitte Kalnins for aid in the experimental work. The research has been supported by the Defence Research Board.

THE VIBRATIONAL MECHANISM OF THE FUNDAMENTAL NH_2 STRETCHING VIBRATIONS IN ANILINES*

PETER J. KRUEGER
Department of Chemistry, University of Alberta, Calgary, Alberta

Received July 27, 1962

ABSTRACT

The integrated intensities, frequencies, and half-band widths of the fundamental symmetric and asymmetric NH_2 stretching vibrations in 33 ortho-substituted anilines, measured in dilute carbon tetrachloride solution, have been examined in relation to the corresponding absorption band parameters for 31 meta- and para-substituted anilines, taking into consideration the electronic effects of the substituents. From an almost tetrahedral configuration in *p*-phenylenediamine, the calculated *s*-character of the nitrogen atom gradually increases as the substituent groups become more electron withdrawing, with a resultant increase in the apparent HNH angle and the NH force constant. Ortho substitution in general leads to enhanced HNH angle opening, probably because of intramolecular hydrogen bonding. The decrease in half-band width for both vibrational modes in ortho-substituted anilines with respect to corresponding values in meta and para compounds is ascribed to steric hindrance to solvation of the amino group.

The asymmetric intensities in ortho-substituted anilines are generally increased over corresponding values in meta and para compounds, unlike the behavior of the symmetric mode. These results are consistent with a vibrational mechanism taking into account the following factors for each mode: (i) the direction of the transition moment, (ii) the extent of nitrogen lone pair and aromatic π-electron participation, and (iii) the direct field effect of the ortho substituent.

INTRODUCTION

The vibrations localized in characteristic functional groups attached to the aromatic ring have in recent years been studied extensively as a function of electronic changes in the molecule. The frequencies of absorption maxima and the absorption intensities have been correlated with the Hammett σ constants (1, 2) of the substituents for the —OH stretching vibration in phenols (3), the C≡N stretching vibration in benzonitriles (4–6), the C=O stretching vibration in benzaldehydes, ethyl benzoates, and acetophenones (7, 8), the —NH stretching vibration in N-methylanilines (9), the two —NH_2 stretching vibrations in anilines (5, 9–12), and the C—O—C stretching vibration in anisoles (13).

For meta- and para-substituted benzene derivatives the frequency/σ correlations may be expressed by a Hammett-type equation (14),

$$[1] \qquad \nu = \nu_0 + \rho\sigma,$$

where ν is the observed group frequency in the substituted compound, ν_0 is the group frequency of the "parent" compound in the series, and ρ expresses the sensitivity of the frequency to substituent effects. These plots sometimes exhibit slight curvature as the frequency rises or falls with increasing electrophilic character of the substituents. A similar linear relationship has been sought (15) between ν and the electrophilic substituent constants σ^+ (16, 17). Rao and Venkataraghavan (14) have recently shown that a statistical evaluation of 18 sets of frequencies indicates that both σ and σ^+ correlate the frequencies equally well.

The integrated band intensities (A) of vibrations in functional groups in meta- and

Presented in part at the 13th Annual Mid-America Spectroscopy Symposium, Chicago, Illinois, April 30–May 3, 1962.

para-substituted benzenes have been correlated linearly through a logarithmic function so that

$$\log A = \log (A_0) + \rho'\sigma \quad [2]$$

or alternatively

$$\log A = \log (A_0^+) + \rho^+\sigma^+. \quad [3]$$

Statistical evaluation has indicated that the latter correlation is slightly better (14).

On the basis of a simple molecular orbital model Brown (18) has proposed that the quantity $A^{1/2}$ should be linearly related to the appropriate substituent constants σ or σ^+. Statistically this correlation appears to be as good as the correlation with log A (14). Brown suggests further that the success of these correlations indicates that the changes in electron distribution which occur in the molecule during vibrational distortions closely parallel those which occur in the formation of the transition state during chemical reactions.

In a previous publication Krueger and Thompson (5) showed that for a wide range of vibrational types the log A and ν values also correlated well with the inductive (σ_I) and resonance (σ_R) parameters deduced by Taft (19, pp. 594 ff.) on the basis that

$$\text{para-}\sigma_{\text{Hammett}} = \sigma_I + \sigma_R \quad [4]$$

as a first approximation. These relationships could be expressed explicitly as

$$\log A = \log (A_0) + \alpha\sigma_I + \beta\sigma_R \quad [5]$$

and

$$\nu = \nu_0 + \alpha'\sigma_I + \beta'\sigma_R, \quad [6]$$

where the α's and β's could be interpreted as the relative susceptibility of the correlated quantity to the inductive and resonance effects. The significance of this has been discussed.

The Hammett treatment of kinetic data is restricted to meta and para substituents to avoid complications due to the effect of neighboring groups, although Farthing and Nam (20) have made an attempt to extend it to ortho-substituted compounds. Krueger and Thompson (5) previously reported some spectroscopic measurements on ortho-substituted benzonitriles, anilines, phenols, ethyl benzoates, and benzaldehydes, and attempted to relate these values to those for meta- and para-substituted compounds. The substituent constants derived by Taft (19, p. 618) for ortho substituents were used in integrating all the data, since these σ_{ortho} values are on the same scale as the Hammett σ_{meta} and σ_{para} values. The additivity principle proposed by Jaffe (2) was used as a first approximation to get a $\sum\sigma$ value for compounds with several substituents. This was reasonably successful for the sterically favorable benzonitrile series, but a number of unexplained anomalies remained for the phenols and anilines.

The data available for the aniline series have now been re-examined and some conclusions drawn concerning the nature of the amino group and its response to ortho substitution. Further high-resolution infrared measurements have also been made on selected model compounds.

EXPERIMENTAL METHODS

A Perkin–Elmer 12C single-beam spectrometer was employed for the earlier measurements, using a LiF prism to improve the resolution in the 3-μ region. Standard absorption lines of water vapor and ammonia were used as frequency calibrants. The effective slit width was calculated to be about 8 cm^{-1} in this region. Quartz absorption cells up to 5 cm in length were used to keep the maximum aniline concentrations below 0.01 M in carbon tetrachloride. Measurements were made over a wide concentration range at several path lengths, the band areas determined by numerical integration, and the apparent intensities extrapolated to zero peak absorbance to eliminate slit effects (21). Since the true shape of liquid phase absorption bands is still in doubt, no "wing corrections" (22) were applied. Integration limits were set at those points where the recorder noise level became comparable with the residual absorbance. Due to slight overlapping of the two bands, a small amount of graphical separation was necessary.

The high-resolution measurements were made with a Beckman IR-7 spectrophotometer with a NaCl foreprism and a 75 lines/mm grating blazed at 12 μ. The instrument was calibrated as previously described (23) and the accuracy of the frequency measurements is believed to be limited only by the widths of the bands themselves. These measurements were made in the fourth grating order, where the slit width was calculated to be about 1 cm^{-1} in this region. A pair of matched 2-cm quartz cells was used. The use of a programmed slit, double-beam operation, linear absorbance, and linear frequency (cm^{-1}) recording permitted the direct evaluation of band areas by numerical integration. Slit width effects were found to be negligible in most cases (the calculated slit width is less than 5% of almost all the band widths measured), and the A and $\Delta\nu_{1/2}$[a] values reported are the averages of at least two completely independent measurements, except in a few cases where the small amount of material available precluded this.

Most of the compounds were commercial products, purified by recrystallization, sublimation, or fractional distillation under reduced pressure. A few were synthesized following standard procedures in the literature. "Spectrograde" carbon tetrachloride was used, and the solutions were made up volumetrically. In the high-resolution measurements the cell temperature was held at 25° C.

RESULTS

The detailed experimental results and the calculated parameters derived from them are given in Table I. In the graphical analyses points of special interest are numbered, and these refer to the respective compounds as listed in this table. For compounds where both high- and low-resolution intensity measurements were made the mean was used in the calculations.

For the purposes of this discussion the total electronic effect of the aromatic ring substituents on the NH_2 group is considered to be proportional to the additive sum of the substituent constants ($\sum\sigma$) as originally defined by Hammett (1) and Taft (19, p. 618). Wherever possible the more recent σ values from the critical analysis by McDaniel and Brown (24) were used. A few constants were taken from the review by Jaffe (2). For a number of ortho substituents σ values were estimated on the basis that $\sigma_{ortho} \approx \sigma_{para}$, since no kinetic data for them were available in the literature. The validity of this approximation is substantiated by the work of Taft and his associates.

Figure 1 shows plots of $\log_{10} A$ versus $\sum\sigma$ for the asymmetric and for the symmetric vibration. Considering that this presentation adjusts all the data for the varying electronic effects involved, the general conclusion can be drawn that for ortho compounds the symmetric intensities are not significantly different from those for meta and para compounds over most of the range. For the asymmetric vibration the intensities for ortho compounds are about 30–40% higher than the corresponding values for meta and para compounds. Only where the adjacent substituents are alkyl groups (and NH_2) is there no apparent increase in the asymmetric intensities, and a slight decrease in the symmetric intensities. Compounds 63 and 64 are extremely insoluble in CCl_4, and hence these intensities may be too low.

The frequency/$\sum\sigma$ correlations are shown in Fig. 2. Because of the two interacting vibrational modes, and the possibility that the geometry of the amino group may change in the aniline series, these are best discussed in terms of the HNH angle and the average NH stretching force constant.

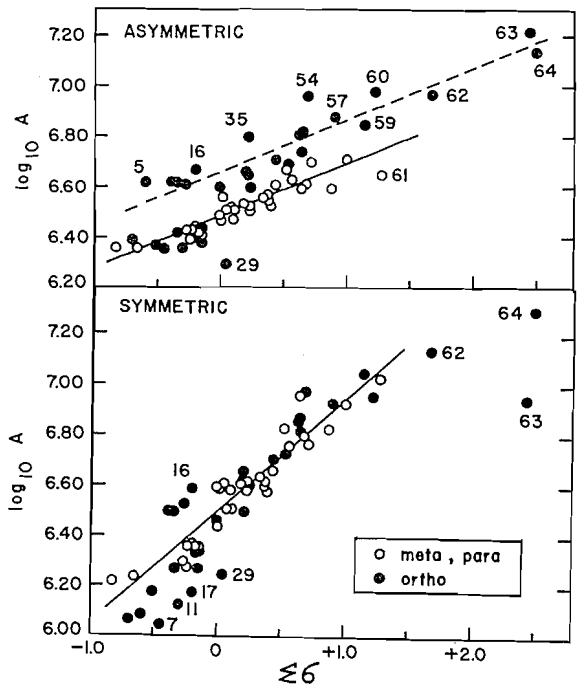

FIG. 1. Correlation of the intensity of the NH_2 stretching vibrations in substituted anilines with the electronic nature of the substituents. The units of A are cm mole^{-1} ($\log_e$).

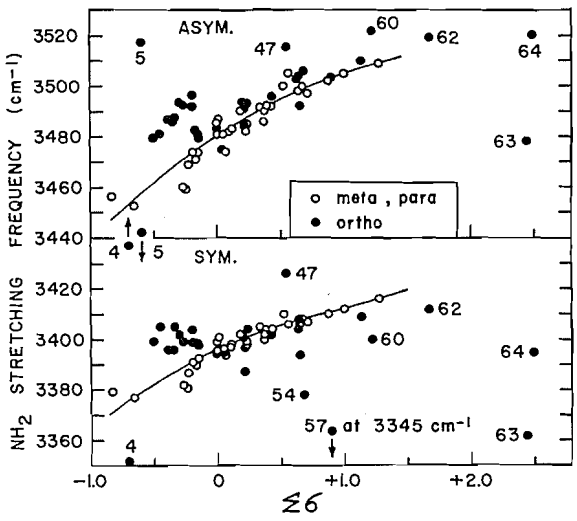

FIG. 2. The dependence of the NH_2 stretching frequencies on the electronic nature of the substituents in substituted anilines.

Our attention was first directed to a re-examination of the available data by a comparison of the apparent half-band widths ($\Delta\nu_{1/2}{}^a$), which are shown in Fig. 3 as a function of $\sum\sigma$. In general, both NH_2 bands are significantly narrower in ortho-substituted anilines than in meta- and para-substituted anilines. Since most of the band widths shown in

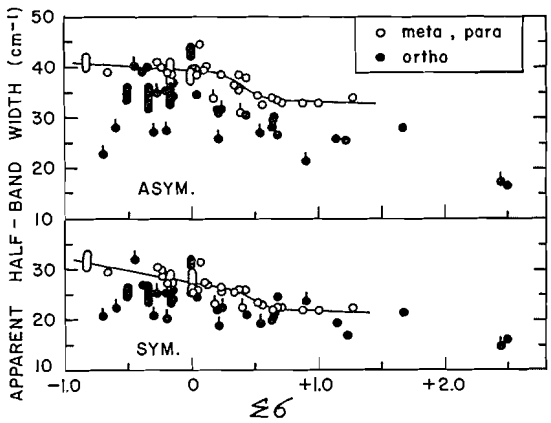

FIG. 3. The relationship of $\Delta\nu_{1/2}^{a}$ to the electronic nature and position of the substituents in substituted anilines. High-resolution measurements indicated by points with vertical tails, and by bottom ends of oval points.

Fig. 3 were obtained with an effective slit width of about 8 cm^{-1}, they will be somewhat wider than the limiting true widths, but relative values should still be correct. The extent of this distortion is also portrayed in Fig. 3, as indicated by the lower end of the elongated points, corresponding to measurements repeated with the better resolution of the grating spectrophotometer.

DISCUSSION

An interpretation of these observations is advanced along the lines of a simplified model for the two vibrational modes illustrated schematically in Fig. 4. The essential difference

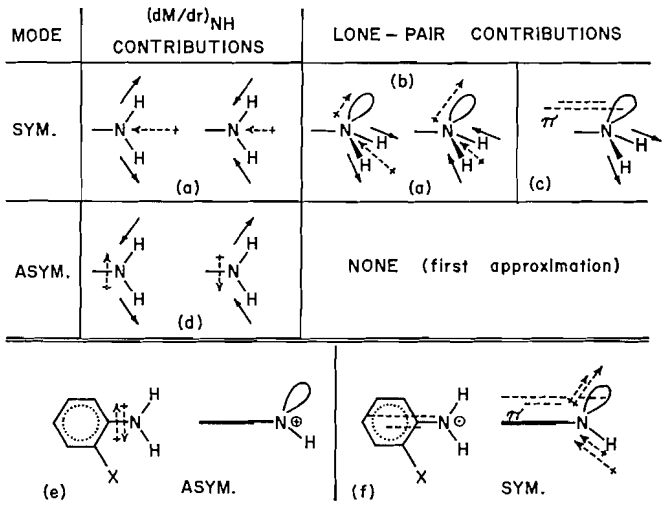

FIG. 4. A simple vibrational mechanism for the NH_2 group. (*a–d*) Contributions to the transition moment. (*e–f*) Orientation of the components of dipole moment change with respect to the aromatic system and ortho substituents. Solid arrows refer to atomic motion; broken arrows to dipole moment.

between these vibrational modes has previously been pointed out by Orville-Thomas, Parsons, and Ogden (27).

To a good approximation the only nuclei involved in the ν_s and ν_{as} vibrations are the nitrogen and hydrogen atoms. Thus changes in NH bond lengths during the vibration can be used to define the normal coordinate Q. The intensity of a fundamental infrared absorption band is proportional to $(\partial M/\partial Q)^2$, i.e. to the square of the variation of molecular dipole moment M with respect to the normal coordinate during the vibration. The dipole moment of the amino group in its equilibrium configuration can be separated into two NH bond moments, and a third component due to the atomic dipole of the lone-pair electrons. Coulson (28) has recently emphasized the importance of lone pair electron contributions to molecular dipole moment changes during vibrations, as well as the unexpected contributions that may be due to hybridization changes as the atoms move.

As the H atoms oscillate in the asymmetric mode the change in dipole moment is perpendicular to the symmetry axis of the NH_2 group, and parallel to the plane of the aromatic ring,* as summarized schematically in Fig. 4(*e*). The decrease in *s*-character of one nitrogen bonding orbital as that NH bond lengthens is exactly compensated by the increase in *s*-character of the other NH bond as it contracts. The *s*-character of the lone-pair orbital should remain unchanged, and $(\partial M/\partial Q)$ should depend on the small polarity changes in the NH bonds. During the second half of the vibrational cycle this small resultant dipole moment reverses sign, leading to contribution (*d*) in Fig. 4.

During the symmetric mode of vibration the s/p ratio of the nitrogen bonding orbitals will vary in phase, and this will give rise to a compensating change in *s*-character of the lone-pair orbital, as shown by contribution (*b*) in Fig. 4. Another component, (*a*), would be due to changes in the NH bond moments. Both (*a*) and (*b*) would lie in a plane along the CN bond and perpendicular to the aromatic ring. A third contribution, (*c*), to the net dipole moment change in the symmetric mode will arise from a variation of conjugation of the lone-pair electrons with the aromatic π-electrons during a vibrational cycle. When both H atoms move away from the N nucleus the *s*-character of the lone-pair orbital increases and it cannot combine as effectively with the π-orbitals (these have odd symmetry, whereas an *s*-orbital has even symmetry with respect to the plane of the ring). When the H atoms approach the N nucleus, the increase in *p*-character of the lone-pair orbital leads to more extensive interaction with the π-electrons. Thus the π-electron component of the permanent dipole of the aromatic part of the molecule contributes to the transition moment for this vibration as it varies in phase with the symmetric motion of the H atoms, to an extent determined by the hybridization of the N atom, i.e. leading to a very small contribution when the N atom is effectively sp^3, and a maximum when it is effectively sp^2. Figure 4(*f*) summarizes the contributions to $(\partial M/\partial Q)_s$.

A comparison of Fig. 4(*e*) and (*f*) shows that a substituent ortho to the NH_2 group might be expected to enhance A_{as} by a direct field effect if it were strongly electrophilic or nucleophilic, since the sign of the dipole that leads to contribution (*d*) reverses at every half cycle, and since the substituent group is almost directly in line with the direction of the transition moment. In the symmetric mode the ortho group is not intimately involved because it is well removed from the transition moment direction, and would likely only influence A_s by the inductive/resonance mechanism operating through the aromatic carbon skeleton and the π-electrons respectively. This factor also contributes to A_{as}, and is accounted for in the comparison on the σ basis. These views are borne out by Fig. 1. For the $\log_{10} A_{as}/\sum\sigma$ correlation the ortho compounds in which intensity

**On the basis of the absorption intensity of the 234-mμ ultraviolet band in substituted anilines, Wepster (29) has concluded that the lone-pair electrons of the amino group are oriented for maximum overlap with the aromatic π-electrons even with bulky tert-butyl groups in the 2,6-positions. Essery and Schofield (30) support this view on the basis of limited infrared measurements on a few ortho-alkyl anilines.*

enhancement is not observed are those where the substituents are 2,4,6-tri-CH_3, 2,4,6-tri-$CH(CH_3)_2$, 2,6-di-CH_3, 2,5-di-$C(CH_3)_3$, 2-$C(CH_3)_3$, 2-CH_3, 2-$CH(CH_3)_2$, and 2-CH_2CH_3. This is in harmony with the relatively low polarizing ability of alkyl groups. Some of the other deviations from the established patterns remain unexplained, but the effect of ortho substitution on the mechanical and electrical anharmonicity of these vibrations is being investigated in an attempt to provide some further information on the interaction mechanisms (31).

The apparent HNH bond angle (θ) and the NH stretching force constant (k) can be calculated from the two absorption frequencies of a primary amine by means of the valency force field equations of Linnett (32):

$$[7] \qquad 4\pi^2\nu_s^2 = k[1/m_H+(1+\cos\theta)/m_N]$$

$$[8] \qquad 4\pi^2\nu_{as}^2 = k[1/m_H+(1-\cos\theta)/m_N],$$

where m_H and m_N refer to the masses of the hydrogen and nitrogen atoms respectively. This treatment assumes that the nitrogen and hydrogen atoms move along the NH bond directions, and that the stretching force constant is much larger than the deformation and interaction force constants. McKean and Schatz (33) have shown that this would be a valid assumption for the ammonia molecule. Mason (34) has successfully applied these equations to a wide range of primary amines, and has found θ to vary from 104° in $LiNH_2$ to about 119° in heteroaromatic compounds such as 2-aminopyrimidine, 4-aminopyrimidine, and 3-amino-1,2,4-triazine. Although aniline itself was included in his study (θ = 111.8°), conclusive evidence for substituent effects on the hybridization state of the NH_2 group in the aromatic amine series has not been reported.

Figure 5 shows that for meta- and para-substituted anilines θ increases linearly with increasing electron-withdrawing power of the substituents, from a value of 109.6° in

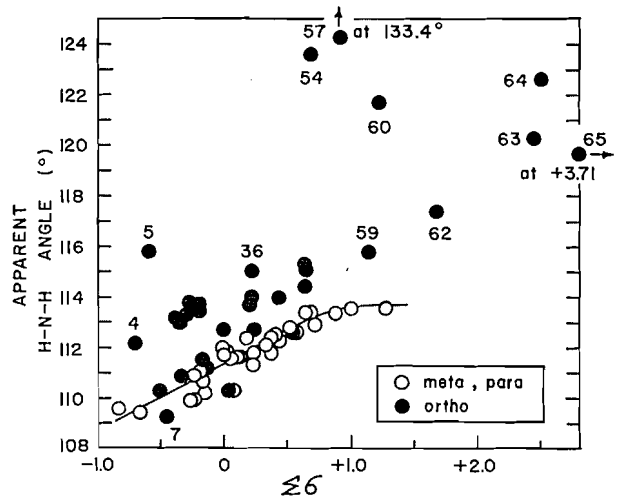

FIG. 5. The HNH bond angle in substituted anilines and its dependence on the electronic nature and position of ring substituents.

N,N-dimethyl-*p*-phenylenediamine and 109.4° in *p*-phenylenediamine (almost exactly sp^3) to a limiting value of 113.6°, which is reached in *p*-aminobenzonitrile and *p*-nitroaniline. This is in agreement with the predicted change in lone-pair conjugation with the

aromatic π-electrons. Ortho-substituted anilines show extensive HNH angle opening, except in those cases where the substituents involved are one or two methyl, ethyl, or isopropyl groups, or the CF_3 group. Undoubtedly there are a number of factors responsible for this increase in θ. For those cases where the angle is close to or exceeds 120°, as in 2,4,6-trinitroaniline (119.7°), 2,6-dinitroaniline (120.3°), 2-nitroaniline (121.7°), 2,4-dinitroaniline (122.6°), ethyl orthoanthranilate (123.6°), and 2-aminoacetophenone (133.4°), intramolecular hydrogen bonding is suggested, and similar interaction of a weak nature may account for the behavior of ortho-CN, -halogen, -OR, and $-NH_2$ groups. Weak bonding of an amino hydrogen atom to the π-electrons of an adjacent phenyl group can also be envisaged.

The increased apparent HNH angles for 2-nitro-, 2,4-dinitro, 2,6-dinitro-, and 2,4,6-trinitro-aniline are of interest in view of some recent controversy in the literature as to whether or not intramolecular hydrogen bonding is present in the first compound. Lutskii and Alexseeva (35), Moritz (36), and Farmer and Thompson (37) have concluded that there is intramolecular hydrogen bonding in 2-nitroaniline; Dyall (26) claims that solvent effect studies show it is absent in 2-nitro- and 2,4-dinitro-aniline, but present in 2,6-dinitro- and 2,4,6-trinitro-aniline. In view of the fact that the largest apparent HNH angle found in this work (133.4°) occurs in 2-aminoacetophenone, where hydrogen bonding is strongly favored because of the formation of a six-membered chelate ring, the enhanced angles in the nitroanilines also suggest a similar interaction mechanism.

The compound 1-naphthylamine (No. 29) appears to behave in an anomalous manner in that both A_s and A_{as} are smaller than expected, as is the calculated HNH angle. This suggests that the conjugation of the lone-pair electrons with the aromatic π-electrons is disturbed by some interference due to the *peri*-H atom. Elliott and Mason (38) have postulated "bending" of the nitrogen bonding orbital due to repulsion, and a slight twisting of the NH_2 group to reduce the conjugation. Narrower band widths for this compound support this view due to steric hindrance to solvation of the NH_2 group, as will be described later. 2-Naphthylamine (No. 28) behaves like a normal meta-substituted aniline.

A weakness in the calculation of θ for ortho-substituted anilines from equations [7] and [8] may arise in the underlying assumption that the two NH bonds be equivalent.* However, the fact that anilines which are symmetrically substituted in the 2,6-positions (compounds 5, 49, 52, 59, 62, 63, and 65) and thus should meet this requirement lead to similarly enhanced θ values provides some proof for the validity of the method. This variation in HNH angle in the aniline series can be further confirmed by applying the same type of calculation to the limiting cases of a primary alkyl amine (sp^3) and a primary acid amide (sp^2). Using the data of Orville-Thomas *et al.* (27) for methylamine in CCl_4 solution, the calculated HNH angle is 103.8°; and for acetamide in dilute $CHCl_3$ solution the measurements of Davies (39) lead to 120.3°.

For ortho-halogenated anilines, the apparent HNH angle is found to increase in the order F < Cl < Br < I. Intramolecular hydrogen bonding of the OH group in phenols to ortho-halogen atoms is well-known. Baker and Kaeding (40) have shown that the order of increasing hydrogen bond strength in the ortho-phenol series is really I < F < Br < Cl, which can be attributed to both the varying size of the halogens and an "orbital–orbital repulsive interaction" which increases in the order Cl < Br < I. These authors have also concluded that Badger's rule (41) does not apply in cases where the interacting groups

**We are indebted to a referee for pointing out that in all cases where $\theta > 120°$ the compound has a single ortho substituent, but for compounds 63 and 65, where two NO_2 groups flank the NH_2 group, the apparent HNH angle is almost exactly 120°, which tends to support this argument.*

are not free to take up their preferred orientation or interacting distance. In the aniline series the HNH . . . F interaction may be extremely weak because the small size of the fluorine prevents the H atom from getting close to its lone-pair orbitals. The increase in size of the halogens appears to more than offset the corresponding decrease in electronegativity.* The concept of intramolecular hydrogen bonding would account for the "normal" HNH angles in anilines with ortho-methyl, -ethyl, and -isopropyl groups. The large angle of 115.8° in 2,4,6-tri-*tert*-butylaniline could arise as the NH_2 group is forced into greater planarity with the aromatic ring by the bulky *tert*-butyl groups which flank it (see Fig. 9(*a*)). Qualitatively this could account for the marked increase in A_{as} relative to A_s in terms of NH bond moment contributions, the lone-pair conjugation being small because of the electron-donating characteristics of the three *tert*-butyl groups. To a lesser extent this could also account for A_{as} increases in 2-*tert*-butyl- and 2,5-di-*tert*-butyl-aniline.

The calculated NH stretching force constant increases smoothly with $\sum\sigma$ for meta- and para-substituted anilines (Fig. 6). The complex deviation of ortho-substituted

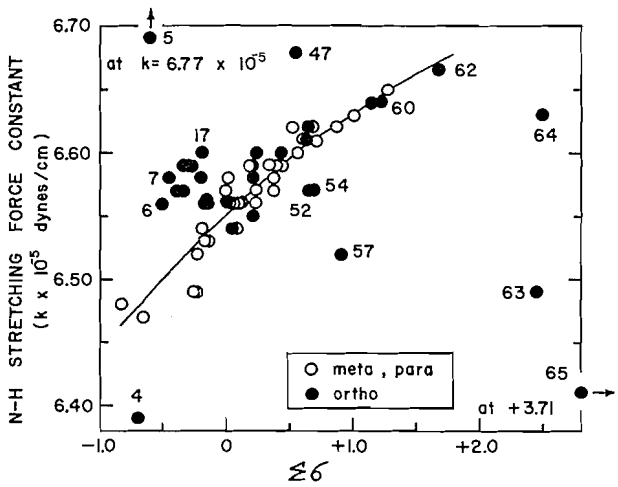

FIG. 6. The dependence of the calculated NH stretching force constant on the electronic nature and position of ring substituents in anilines.

compounds is a direct reflection of the dependence of the force constant on the effective charge on the nitrogen atom, as well as on its hybridization state (32, 42).

Once the bond angle θ is known, the contribution of $2s$ and $2p$ orbitals to the hybrid nitrogen bonding orbitals may be calculated (34). The coefficient b in the hybrid orbital

$$\psi_{\text{hybrid}} = b\psi_{2s} + \sqrt{(1-b^2)}\cdot\psi_{2p} \qquad [9]$$

can be used as a measure of s-character, and may be calculated from

$$b^2 = -\cos\theta/(1-\cos\theta) \qquad [10]$$

provided the two NH bonds are equivalent and the hybrid orbitals of N binding the H atoms are orthogonal. For meta and para anilines, k is a linear function of s-character (Fig. 7). This is in excellent agreement with Mason's calculations (34) based on Slater

Unambiguous data obtained by von R. Schleyer and West (P. von R. Schleyer and R. West. J. Am. Chem. Soc. **81, 3164 (1959)) for the intermolecular hydrogen bonding of methanol and phenol to alkyl halides confirms that the relative electron donor ability of the covalently bonded halogen atom increases in the order* F < Cl < Br < I.

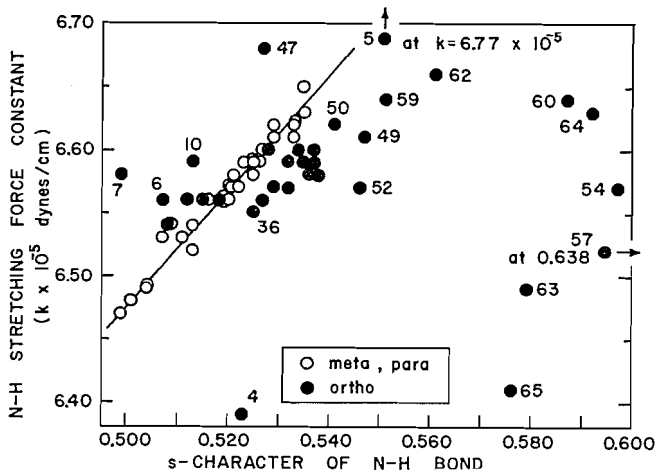

FIG. 7. Relation between the NH stretching force constant and the *s*-character of the hybrid orbitals bonding these atoms in substituted anilines. A *b* value of 0.500 corresponds to sp^3 hybridization of the N atom.

orbitals which show that the overlap integral (measuring the strength of the NH bond, as does the force constant) for a hybrid orbital of nitrogen according to equation [9] and a 1*s* orbital of hydrogen increases linearly with *b*. Figure 7 also shows that changes in the apparent HNH angle alone cannot account for the difference between the NH stretching force constants of ortho anilines and those for meta and para anilines. For a given HNH angle, an increase in the effective charge on the nitrogen atom should decrease its electronegativity and hence lower the NH stretching force constant and vice versa (34). Farmer and Thompson (37) have indicated that hydrogen bond formation with an amino hydrogen atom must induce a negative charge on the nitrogen atom. This would account for those points in Fig. 7 which are below the meta–para line.

The points above this line correspond to ortho-alkyl substituents (and *o*-CF_3). Since the bulkiest ortho-alkyl groups lead to the greatest increase in the NH force constant, a type of "internal specific solvation" of the amino group is suggested, whereby the effective dielectric environment of the amino group has acquired a larger hydrocarbon nature as CCl_4 molecules are crowded out. This should raise the NH force constant. The NH force constant for aniline in *n*-hexane does show a slight increase, whereas for 2,6-dimethylaniline in *n*-hexane it is identical with that calculated from frequencies obtained in CCl_4. Changes of force constant of less than 1% due to this effect would account for almost all of the positive deviations observed.

Crystallographic data available are in agreement with the concept of increasing sp^2 character of the amino nitrogen atom as ring substituents become more electrophilic. The C—N bond lengths (43) in *p*-hydroxyaniline, *p*-iodoaniline, and the *sym*-trinitrobenzene complex of *p*-nitroaniline are 1.47, 1.43, and 1.37 Å respectively, denoting increasing bond order. All three are classed as planar, with C_{2v} symmetry. The maximum displacement from the mean plane in the *p*-nitroaniline complex is given as 0.06 Å. Since the X-ray method is not suitable for the determination of H atom positions, these results are not at variance with the ideas advanced here. Recently Ritschl (44) has assigned the C—N stretching frequency in 10 anilines, and has shown that it increases linearly with the Hammett σ values of the substituents, also implying increasing bond order.

The integrated intensity (A) of a fundamental infrared absorption band depends on the square of the dipole moment change with the normal coordinate of the vibration ($\partial M/\partial Q$):

$$A = (N\pi/3c)(\partial M/\partial Q)^2, \quad [11]$$

where N is the Avogadro number and c is the velocity of light. If only the changes of NH bond moments with bond length (dM/dr) contributed to the transition moment, and if the contributions from both NH bond moments were equal and additive, then (dM/dr) could be calculated in two independent ways from the experimental intensities, using the expressions

$$(\partial M/\partial Q_s) = (2/\mu_s)^{1/2} \cos(\theta/2)\cdot(dM/dr) \quad [12]$$

$$(\partial M/\partial Q_{as}) = (2/\mu_{as})^{1/2} \sin(\theta/2)\cdot(dM/dr), \quad [13]$$

where the μ's are the effective reduced masses governing the amplitudes of vibration. These simplified expressions arise because the resultant NH bond dipole gradients in the symmetric and asymmetric stretching vibrations lie along the internal and external bisectors of the HNH angle respectively. Alternatively, the equations [12] and [13] can be used to estimate θ from the experimental intensities through

$$(A_s/A_{as}) = \tan^2(\theta/2). \quad [14]$$

Mason (34) attempted this for N-heteroaromatic primary amines, and found that these θ values never exceeded 92°, and were not even in the same relative order as the very reasonable θ values calculated from the frequencies. Further, Mason found that the two (dM/dr) values that could be derived independently from [12] and [13] did not agree, the calculation based on A_s always giving a larger value. The author concluded that because of the possibility of large lone-pair contributions to A_s, equation [13] may be a better approximation. It would fail insofar as the asymmetric vibration is anharmonic and has a small dipole moment gradient along the internal bisector of the HNH angle and small in-phase pulsations in s-character of the lone-pair orbital.

The present measurements and calculations lend strong support to this vibrational mechanism (Fig. 8). For p-phenylenediamine and N,N-dimethyl-p-phenylenediamine θ values of 109.4° and 109.6° respectively indicate virtual sp^3 hybridization, since $\theta = 106.8°$ in cyclohexylamine (34) and 106.78° in ammonia (45). With the lone-pair electrons localized on the nitrogen atom and effectively isolated from the π-electrons, the symmetric intensity is due to variation in the NH bond moments and in the atomic dipole. The NH bond moment component in the asymmetric mode exceeds the corresponding component in the symmetric mode for $\theta > 90°$. Table II gives the relative contributions of these bond moments, assuming a fixed vibrational amplitude and a fixed charge distribution in the bond. The numerical values are normalized to the contributions for $\theta = 90°$, where they are equal for both modes. Since $A_{as} > A_s$ for anilines with large negative substituent constants (9) it appears that the atomic dipole contribution is not large enough to outweigh the deficiency in the NH bond dipole component in the symmetric mode. The calculated values of (dM/dr) for these compounds from equations [12] and [13] are 0.8 and 0.6 D/Å respectively. The enhancement of 0.2 D/Å in the value based on A_s reflects the lone-pair contribution.

As the substituent constants become more positive and the HNH angle begins to

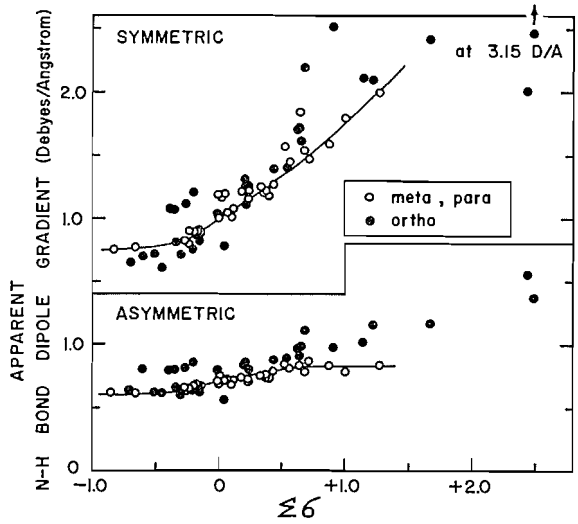

FIG. 8. The substituent dependence of the calculated NH bond moment gradients based on the intensities observed in the two vibrational modes.

TABLE II

Relative contributions of NH bond moments to the resultant dipole moment change in the NH_2 group, for a fixed vibrational amplitude, and fixed charges on the N and H atoms

	θ (°)	Asymmetric mode (dipole moment change along external bisector of ∠HNH)*	Symmetric mode (dipole moment change along internal bisector of ∠HNH)
	90°	1.00	1.00
(sp^3)	109.4°	1.16	0.83
	113.6°	1.20	0.79
(sp^2)	120°	1.25	0.71

*In the asymmetric mode this dipole moment change reverses sign after every half cycle of the vibration.

approach the trigonal angle of 120°, the lone-pair orbital becomes more extensively delocalized over the aromatic ring. Since the lone-pair conjugation will vary during a complete vibrational cycle, as already described, this should lead to a gradually increasing π-electron component as θ increases. This is no doubt a dominant factor in determining the intensities, and explains the pronounced rise in the apparent (dM/dr) values as calculated from A_s by a method neglecting this contribution (Fig. 8). When θ is large, the π-electron component ((*c*) in Fig. 4) more than outweighs the deficiency in the NH bond dipole contribution in the symmetric mode relative to the asymmetric mode (Table II). These results, as summarized in Table III, also explain the crossing of the log A_s/σ and log A_{as}/σ correlation lines near $\sigma = 0$ (parent compound, aniline*) previously reported by us (9).

The calculated (dM/dr) values based on A_{as} are probably reliable as far as order of magnitude is concerned. Figure 8 shows that this value rises slightly as θ increases, which is predicted (Table II). The bond dipole gradients for ortho-substituted anilines are slightly larger than those for corresponding meta and para anilines, as based on both A_s and A_{as}. This is a more sensitive plot than Fig. 1, symmetric stretching, which does not take into account HNH angle changes. Slight enhancement of (dM/dr) on ortho

**Coulson (46) has calculated the π-electron density on the nitrogen atom in aniline to be 1.91, using a molecular orbital method. This is consistent with an* HNH *angle of about 111.7°, as found in this work.*

TABLE III

Resultant dipole moment change in the NH_2 group

$\theta(°)$	b	σ	Contributions in vibrational modes*			Relative intensities	
			Asymmetric		Symmetric	Predicted	Observed A_{as}/A_s
109.4	0.499	-0.83 ($p-NH_2C_6H_4NH_2$)	d_{min}	$>$	resultant of $a_{max}+b$	$A_{as} > A_s$	1.30
111.7	0.520	0 ($C_6H_5NH_2$)	$d_{min}+\delta$	$\approx$	resultant of $(a_{max}-\delta)+c$	$A_{as} \approx A_s$	1.06

*Refer to Fig. 4 for the identity of the components.

substitution would be expected to show up in calculations based on both vibrational modes if intramolecular hydrogen bonding were involved. For 2,6-dinitroaniline, (dM/dr) based on the symmetric mode is unusually low (see also point No. 63 in Fig. 1, symmetric stretching), whereas the largest value is obtained from calculations based on the asymmetric mode. This must arise from abnormal charge fluctuations arising as the amino group is flanked on both sides by negatively charged oxygen atoms of the nitro groups.

Further evidence for this vibrational interpretation is provided by the log A_s and log A_{as} correlations with σ_I and σ_R according to equation [5] (5). For the asymmetric vibration, (α/β) was found to be 1.7, whereas for the symmetric vibration this ratio was 1.1, indicating that A_s is much more sensitive to the resonance effect than A_{as}.

In liquids and solutions collision broadening is considered to be the dominant factor contributing to vibrational band width, since Ramsay (22) has concluded that natural line widths would be $\sim 10^{-6}$ cm^{-1}, and Doppler broadening would lead to widths of only $\sim 10^{-3}$ cm^{-1}. The decrease in $\Delta\nu_{1/2}$ as the substituents become more electron withdrawing can be attributed generally to a rise in force constant, which makes the solvent perturbation of energy levels less significant. However, factors such as a certain amount of torsional libration of the $-NH_2$ group relative to the aromatic ring, without significant loss of π-electron overlap, cannot be excluded.* Such torsional motion would no doubt lead to band widening, and would decrease with increasing C—N bond order. Califano and Moccia (48) have assigned some of the additional vibrations of the $-NH_2$ group in a few substituted anilines, and Stewart (49) reports the $-NH_2$ torsional oscillation (twisting of the C—N bond) in the far infrared at ~ 290 cm^{-1}. Further studies on substituent effects on these vibrational modes are now in progress.

In ortho-substituted anilines the half-band widths are significantly narrower than those for corresponding meta and para compounds (Fig. 3). This narrowing is ascribed to a decrease in the number of effective collisions of solvent molecules with the amino group due to the shielding nature of the adjacent substituent(s). As expected, 2,4,6-tri-*tert*-butyl-, 2,5-di-*tert*-butyl-, and 2-*tert*-butyl-aniline (points 5, 11, and 17) show very extensive narrowing. Scale molecular models show that the NH_2 group must be vibrating in what is effectively a methyl cage in 2,4,6-tri-*tert*-butylaniline (shown schematically in Fig. 9(*a*)). Free rotation of the *tert*-butyl groups is not possible. Wepster and co-workers

*Jones, Forbes, and Mueller (47) have suggested that in ortho-substituted acetophenones the acetyl group may actually be in a state of minimum energy when it is displaced slightly from the plane of the ring.

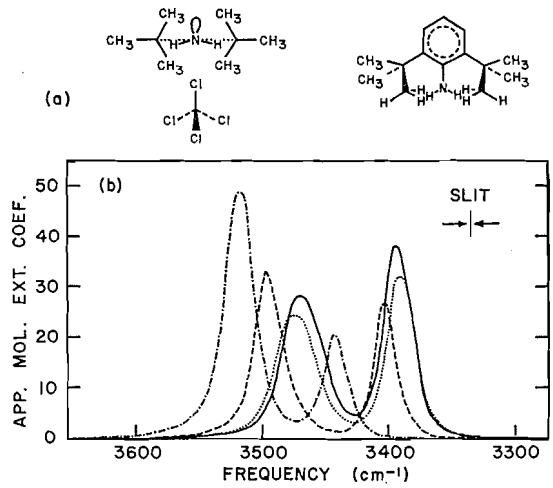

FIG. 9. (*a*) Steric hindrance to solvation in 2,6-di-*tert*-butylaniline. (*b*) Typical high-resolution amine absorption spectra (dilute CCl_4 solution); ——— aniline, . . . 4-*tert*-butylaniline, – – – 2-*tert*-butylaniline, – · – 2,4,6-tri-*tert*-butylaniline.

(50) report that the base strength of 2,6-di-*tert*-butylaniline is lower by a factor of 10^3 than would be expected, and Bartlett *et al.* (51) found that the pK_A of 2,4,6-tri-*tert*-butylaniline was <2 (in comparison with pK_A values of 4.14, 4.00, and 3.39 for aniline, *p*-*tert*-butylaniline, and *o*-*tert*-butylaniline respectively). Both anomalies were ascribed to steric hindrance to solvation. Very narrow bands are also observed in *o*-phenylenediamine. It is interesting to note that steric hindrance of ortho-alkyl groups has also been found to impair the chromatographic adsorption of anilines (52).

The spectacular increases in the integrated absorption intensity often observed for the fundamental hydrogenic stretching vibration on intermolecular hydrogen bond formation are not observed for the intramolecular association of ortho-substituted anilines. It is probable that for highly bent hydrogen bonds, charge transfer effects, which are largely responsible for the increase in band intensity, are of only secondary importance to the electrostatic interaction. For intermolecular association the increase in band width due to hydrogen bonding has not been satisfactorily explained for all systems, but factors such as a variety of absorbing species and a continuous range of configurations have found some support. The narrow band widths for ortho-substituted compounds are in agreement with the concept of intramolecular hydrogen bonding, since the interacting distance involved and the rotational configuration of the amino group are extremely restricted, especially as the lone-pair conjugation with the aromatic π-electrons increases. A further loss of degrees of freedom of the system occurs on hydrogen bond formation (40).

The high-resolution measurements indicate that almost all the NH_2 bands have some asymmetry on the low-frequency side. The significance of this is not known as yet. Cabana and Sandorfy (53) have pointed out a similar effect in the C≡N stretching vibration in benzonitriles, and have suggested an intramolecular Stark effect where highly polarizable groups are involved.

ACKNOWLEDGMENTS

Professor B. M. Wepster (Technische Hogeschool, Delft) and Professor L. R. C. Barclay (Mt. Allison University, Sackville, New Brunswick) generously supplied some

samples of ortho-substituted amines. The technical assistance of Mrs. G. D. Brown with the high-resolution measurements is gratefully acknowledged. The author is indebted to the Royal Dutch Shell Group for a Postgraduate Scholarship, during the tenure of which some of this work was done.

THE REDUCTION OF NITROBENZENE BY HYDROSULPHIDE ION IN AQUEOUS MEDIA[1]

O. J. Cope and R. K. Brown

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 11, 1962

ABSTRACT

The reduction of nitrobenzene by sodium hydrosulphide and sodium hydrodisulphide in aqueous media at 50° has been examined. Goldschmidt's report of first-order dependence upon both nitrobenzene and hydrosulphide is corroborated. The action of hydrosulphide on nitrobenzene produces phenylhydroxylamine, which is reduced by hydrosulphide much more slowly than is nitrobenzene. As reaction progresses, nitrobenzene reduction produces yellow hydrodisulphide, which is responsible for the observed autocatalytic effect. Hydrodisulphide reduces phenylhydroxylamine more rapidly than it does the original nitrobenzene, and hence as reaction time is extended, phenylhydroxylamine disappears more rapidly than does nitrobenzene, yielding only aniline and some unreacted nitrobenzene towards the end of the reaction. Hydrosulphide reduction of phenylhydroxylamine to aniline produces thiosulphate but apparently no hydrodisulphide. Hydro*di*sulphide reduction of the phenylhydroxylamine leads only to conversion of the yellow hydrodisulphide to a colorless species, apparently thiosulphate. On the other hand hydrosulphide or hydrodisulphide reduction of nitrobenzene is accompanied by thiosulphate formation and some increase in hydrodisulphide. A comparison of the rate constants shows that under the conditions of the reaction, hydrodisulphide ion reduces nitrobenzene about seven times more rapidly than does hydrosulphide ion while phenylhydroxylamine is reduced two to three times more rapidly by hydrodisulphide than is nitrobenzene.

INTRODUCTION

The use of sodium hydrosulphide for the selective reduction of nitro groups in the aromatic nucleus is well known. This reagent has been prepared for this purpose by treatment of sodium monosulphide with 1 equivalent of sodium bicarbonate (1), or, in the form of more acidic systems, by bubbling hydrogen sulphide through a solution of the reducible substance containing a catalytic amount of ammonia (2). The addition of excess ammonium salts to a solution of hydrosulphide has also been employed to produce hydrosulphide under conditions designed to maintain a pH of 7.5 to 8.0 (3).

The only reported kinetic study of the hydrosulphide reduction is that of Goldschmidt and Larsen (4), who investigated the reduction in aqueous solution at 25° C of various nitro compounds by sodium hydrosulphide saturated with hydrogen sulphide. The conditions of their reaction resulted in conversion of the nitrobenzene to the corresponding N-phenylhydroxylamine along with complete precipitation of the sulphur formed according to equation (*a*). The rate of reduction was found to be first order in nitrobenzene, first order in hydrosulphide ion, and independent of hydrogen sulphide concentration.

$$C_6H_5NO_2 + 2NaHS + H_2O \rightarrow C_6H_5NHOH + 2S^0 + 2NaOH \qquad (a)$$

In a previous paper (5) we have shown that the $S_x^=$ species reduces nitrobenzene much faster than does the $S^=$, HS^-, or HS_x^- species. In the present work the reduction of nitrobenzene by sodium hydrosulphide has been studied in greater detail. Experimental conditions were devised which allowed at least a semiquantitative estimate to be made of the relative reducing abilities of HS^- and HS_2^-.*

[1]*Taken from the thesis of O. J. Cope submitted to the Graduate School of the University of Alberta in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*

**For reasons indicated in the previous paper (5) the assumption is made that at low sulphur concentration compared with hydrosulphide ion concentration the predominating polysulphide species is* HS_2^-.

Normally reductions by hydrosulphide ion involve an increase in pH due to the formation of hydroxyl ions according to equation (*a*). This in turn gives rise to reaction (*b*) in which elemental sulphur is considered to be lost by conversion to sulphide and thiosulphate ions. Equation (*b*) has been utilized to account for thiosulphate ion formation *during* reductions of nitrobenzene with disulphide (6) and monosulphide ions (5). In

$$6OH^- + 4S^0 \rightarrow S_2O_3^= + 2S^= + 3H_2O \qquad (b)$$

his review of methods of reduction of nitro compounds Schröter (7) suggests that in the case of ammonium hydrosulphide reduction, thiosulphate formation occurs directly as the result of the two reactions (*c*) and (*d*). However, it is likely that the thiosulphate

$$RNO_2 + 6NH_4SH \rightarrow RNH_2 + 3(NH_4)_2S_2 + 2H_2O \qquad (c)$$

$$RNO_2 + (NH_4)_2S_2 + H_2O \rightarrow RNH_2 + (NH_4)_2S_2O_3 \qquad (d)$$

arises indirectly through a reaction such as (*b*) (6). If that is so, then by keeping the hydroxyl ion concentration low relative to the hydrosulphide ion concentration, it should be possible to minimize or eliminate the formation of thiosulphate ion, thus retaining the elemental sulphur either as S^0 or as HS_x^-, as has been done by Bullock and Forbes (6) for sulphide and disulphide reductions of nitro compounds.

It is important to operate under conditions which eliminate atmospheric oxygen to avoid the possibility of conversion of hydrosulphide to thiosulphate. Thiosulphate formation has been shown to occur when air is bubbled through a solution of sodium sulphide.

EXPERIMENTAL

Analytical Methods

The reductions were carried out using essentially the same apparatus and procedure as in the previous work with sodium monosulphide (5). The reflux condenser was dispensed with, however, as in trial experiments it was found that considerable condensation of hydrogen disulphide took place there, followed by decomposition and deposition of sulphur. The reaction mixture was at all times blanketed by nitrogen which had been passed through alkaline pyrogallol. Two hundred and fifty milliliters of an aqueous solution of nitrobenzene was pipetted into the reaction vessel and allowed to reach the thermostatted bath temperature (50.00±0.03° C). Then 50 ml of a 0.900 *M* sodium sulphide – ammonium chloride solution, first brought to 50° in a jacketted vessel, was introduced from an automatic pipette. The solution was thus 0.150 *M* with respect to hydrosulphide and 0.015 *M* or less in nitrobenzene. Time measurements were begun when all this solution had been added.

For spectrophotometric measurements of polysulphide in the visible region at 450 mμ, a portion of the reaction mixture was transferred by means of a warmed pipette to a glass-stoppered sample cell in the thermostatted cell compartment of a Beckman DU spectrophotometer. The glass cell, previously flushed with a stream of nitrogen, was filled *completely* with the solution so that no space was left between the solution surface and the stopper. It was important that the stopper fitted well (a small quantity of Apiezon grease was used) in order to exclude atmospheric oxygen and to prevent loss of H_2S and other volatile components of the reaction solution. The standard double thermospacer equipment was provided with an asbestos-coated wooden lid. It was found that once thermal equilibrium had been attained the temperature of the cell contents could be maintained quite well at 50.00±0.03° C.

The spectrophotometric method previously used for estimating the nitrobenzene concentration (5) was modified so that the 1-ml samples removed from the reaction mixture at timed intervals were diluted to 200 ml with 0.002 *M* aqueous hydrochloric acid. This procedure effectively "froze" the reaction and caused any polysulphide to be precipitated as sulphur, leaving a residual "blank" absorbance due to the inorganic components. This blank was found to be constant for the course of the reaction. However, as the precipitated sulphur appeared in a very finely divided form, it was necessary to allow the diluted sample to stand for 24 hours before the sulphur settled completely and absorption measurements at 267 mμ were made.

Preparation of Solutions

The water used was boiled and cooled in an atmosphere of nitrogen. Subsequently, all solutions were kept under nitrogen.

Na_2S–NH_4Cl Solutions

Two liters of a stock solution of 0.900 *M* sodium sulphide (from $Na_2S.9H_2O$) were prepared and solid ammonium chloride was added to the stirred solution until its pH had been reduced to 10.5 (at 25°). The solution, thus 0.944 *M* in ammonium chloride, was practically colorless and it was calculated that at this pH all the sulphide ion was in the protonated form. This stock solution was used throughout the experiments recorded here and was introduced into the reaction vessel via the automatic pipette under nitrogen pressure.

Polysulphide Solutions

Different amounts of sulphur were weighed into glass-stoppered Erlenmeyer flasks provided with magnetic stirring bars. The requisite volume of 0.150 *M* hydrosulphide solution was added and air expelled with a stream of nitrogen before the flasks were stoppered. In order to effect complete solution of the sulphur at room temperature it was necessary to have the mixtures stirred overnight. For absorbance measurements the solutions were introduced into the thermostatted cell, under the usual precautions of exclusion of air and attainment of thermal equilibrium (50.0° C).

Search for Organic Products of the Reduction of Nitrobenzene or Phenylhydroxylamine by Hydrosulphide or Hydrodisulphide Ion

A. Nitrobenzene Reduction by Hydrosulphide

Utility of vapor phase chromatography.—A Burrell Kromotog K-2 was used for all V.P.C. analyses. A 2.5-m column, containing a celite support coated with 20% of its weight of silicone rubber, at a temperature of 210° C, with a helium flow rate of 70 ml/min, gave good separation of a known mixture of aniline, phenylhydroxylamine, and nitrobenzene.

At elevated temperatures (120°) phenylhydroxylamine is known to decompose into products, two of which are believed to be aniline and azoxybenzene (8). Under our conditions, authentic azoxybenzene showed no retention band on the chart, whereas phenyl hydroxylamine gave two peaks of retention time 135 and 180 seconds. The second band was shown to be due to aniline. The identity of the first band was not established, although it may have been due to unchanged hydroxylamine. The important observation made was that the *ratio* of these two peaks under the conditions of our analysis was found to be constant at a value of second peak/first peak = 1.13±0.03, regardless of the original quantity of phenylhydroxylamine, or solvent used, or the presence of nitrobenzene or other possible reduction products of nitrobenzene. By calibration with authentic aniline and phenylhydroxylamine it was thus possible to analyze mixtures of aniline and phenylhydroxylamine by first measuring the area of the peak of retention time 135 seconds and multiplying it by the factor 1.13 to obtain the area of the peak for the aniline produced by phenylhydroxylamine's decomposition during the analysis. The difference between this calculated area and the actual area was due to additional aniline present with the phenylhydroxylamine *before* the V.P.C. determination. The analysis of several such synthetic mixtures did show clearly the presence of as little as 5% aniline originally present. Although this analysis was not highly accurate it did show qualitatively the presence or absence of phenylhydroxylamine and aniline as reduction products. This analysis was used in conjunction with infrared analyses for OH stretching at 3580 and 3700 cm^{-1} due to phenylhydroxylamine (9).

Analysis of the reaction mixture after 60 minutes' reduction.—The practically colorless mixture, 0.010 *M* in nitrobenzene and 0.150 *M* in hydrosulphide, was allowed to react. A slow development of yellow color (measurable at 450 mμ) due to hydrodisulphide occurred. After 60 minutes of reaction a 100-ml aliquot was extracted with ether, the ether extract dried ($MgSO_4$) and then freed of solvent. The residue was taken up in chloroform. Analysis by V.P.C. indicated the presence of very little aniline, approximately 1–2%, but much phenylhydroxylamine as well as unchanged nitrobenzene. Strong absorption in the infrared characteristic of phenylhydroxylamine corroborated these results.

Analysis of the reaction mixture after 18 hours' reduction.—A 100-ml aliquot of the above yellow reaction mixture, removed after 18 hours of reaction, when treated as above showed by V.P.C. analysis the presence only of aniline along with a small amount of unchanged nitrobenzene. No absorption in the infrared region due to phenylhydroxylamine could be detected.

Other organic reduction products of nitrobenzene.—A carbon tetrachloride solution of the extracted reduction products, taken at intervals during the course of the reaction, was at all times colorless. Measurements at the λ_{max} at which azoxybenzene and azobenzene absorb showed no increase in absorption, thus demonstrating that bimolecular reduction products were absent.

B. Phenylhydroxylamine Reduction by Hydrosulphide

An aqueous solution, 0.01 *M* in phenylhydroxylamine and 0.150 *M* in hydrosulphide, was allowed to react at 50°. No development of yellow color due to hydrodisulphide occurred throughout the course of reduction. A 100-ml aliquot was removed after 50 minutes of reaction time and analyzed. Vapor phase chromatography showed no significant formation of aniline, thus indicating no significant reduction during this time. The same results were obtained from an aliquot removed after 90 minutes of reaction.

After a 24-hour reaction period, however, a considerable amount of aniline had been produced, indicating that a slow reaction did occur between phenylhydroxylamine and sodium hydrosulphide.

C. Phenylhydroxylamine Reduction by Hydrodisulphide

An aqueous solution was prepared 0.01 *M* in phenylhydroxylamine and 0.150 *M* with respect to hydrosulphide ion, containing enough elemental sulphur predissolved in the sodium hydrosulphide solution to convert about 7–8% of the hydrosulphide to hydrodisulphide. The concentration of hydrodisulphide was measured by reference to a Beers' law plot of absorption at 450 mμ, versus concentration of sulphur in aqueous 0.150 *M* sodium hydrosulphide.

A continual decrease in absorption at 450 mμ occurred as reduction progressed. An aliquot removed after 70 minutes of reaction indicated by V.P.C. analysis that about 30% of the phenylhydroxylamine had been converted to aniline. After 1000 minutes of reaction approximately 90% of the hydroxylamine had become aniline.

General Procedure for Thiosulphate Estimation

An excess of a freshly prepared suspension of cadmium carbonate was used to precipitate sulphide and di- (or poly-) sulphide from a 100-ml aliquot of the reaction mixture. It was found necessary to remove the organic material (chiefly aniline) from the aliquot of the reaction mixture by ether extraction prior to the treatment with cadmium carbonate. If this was not done, complete precipitation of sulphide and disulphide could be brought about only by repeated treatments with cadmium carbonate. Moreover, the filtrations involved were hampered by the tendency of the precipitate to clog the porous plate of the filter, thus making the procedure quite time consuming. By prior removal of the aniline it was possible to obtain complete precipitation of the sulphide species by only one application of cadmium carbonate suspension, vigorously stirred with the aliquot for 10 minutes. Following the removal of all precipitate by filtration, it was found that the pH of the resultant solution was above 9, due to the presence of sodium carbonate. This base interfered in the titration with iodine by giving an indefinite end point. However, addition of ammonium chloride reduced the pH to a value less than 8 and permitted satisfactory titration of thiosulphate with 0.0500 *N* iodine to a starch end point.

Hydrodisulphide Estimation

This analysis was accomplished by measurement of the absorption at 450 mμ due to hydrodisulphide. A Beer's law plot of concentration of sulphur as hydrodisulphide (in 0.150 *M* hydrosulphide) versus absorption at 450 mμ gave a molar extinction coefficient of 35, which was then used to calculate the concentration of hydrodisulphide from absorption measurements. Details of the apparatus used are described at the beginning of the discussion of analytical methods.

RESULTS AND DISCUSSION

Products of the Reduction of Nitrobenzene and of Phenylhydroxylamine by Hydrosulphide and Hydrodisulphide

In previous work (5, and references therein) it had been established that the only organic reduction product of nitrobenzene by sodium sulphide or sodium disulphide was aniline. Since Goldschmidt and Larsen (4) had obtained N-phenylhydroxylamine as the principal product of the reduction of nitrobenzene by sodium hydrosulphide in water at 25°, it was necessary to determine the products of our reduction conditions. The analysis of aliquots of the reduction mixtures for organic products by vapor phase chromatography (see Experimental) and also by the use of infrared absorption at 3580 and 3700 cm^{-1} to detect the presence of phenylhydroxylamine is summarized in Table I. In addition, Table I includes the results of analyses for hydrodisulphide and thiosulphate.

The results (Table I) show clearly that hydrosulphide reduced phenylhydroxylamine extremely slowly, requiring 48 hours for near-completion of the reaction. No reduction apparently occurred for the first 90 minutes. On the other hand hydrosulphide with 8% of the hydrosulphide as hydro*di*sulphide reduced phenylhydroxylamine to the amine essentially completely in 1200 minutes. In both cases no hydrodisulphide accumulated. Instead the hydrodisulphide originally present was converted to a colorless species, most likely thiosulphate, since thiosulphate was found to increase during the reduction.

At the beginning of the reaction between *nitrobenzene* and hydrosulphide, only hydroxylamine was produced. Further reduction of the phenylhydroxylamine to aniline proceeded

TABLE I

Products obtained during the reduction of nitrobenzene or N-phenylhydroxylamine by sodium hydrosulphide or sodium hydrodisulphide in aqueous media at 50°

Initial reducible material (molarity)	Reducing agent (molarity)	Time of reduction (min)	Products of reduction				
			HS_2^-	$S_2O_3^=$	Phenylhydroxyl-amine	Aniline	Unchanged nitrobenzene
Nitrobenzene (0.010)	NaHS (0.150)	60 min	Increased by 0.0024 *M*	Increased by 0.0005 *M*	25%	~1%	75%
		3 hr	Increased to max. 0.0066 *M*		45%	20%	35%
		18 hr	Dropped to 0.0035 *M*	Increased by 0.0067 *M*	None	Practically all aniline	Trace
Phenylhydroxylamine (0.010)	NaHS (0.150)	50 min	None	Unchanged	Unchanged	None	—
		90 min	Trace	Unchanged	Unchanged	None	—
		24 hr	None	Increased	Considerably decreased	Much aniline	—
		48 hr	None	Increased	Small amount	Mostly aniline	—
Phenylhydroxylamine (0.010)	NaHS (0.150) containing 8% sulphur as HS_2^-	70 min	Decreased by 0.0026 *M*	Increased	60%	40%	—
		1000 min	Decreased by 0.0072 *M*	Increased by 0.0045 *M*	10%	90%	—

much more slowly than did its formation from nitrobenzene; hence phenylhydroxylamine accumulated during the first portion of the reaction. As the reduction of nitrobenzene progressed, hydro*di*sulphide also accumulated. The hydrodisulphide thus formed reduced phenylhydroxylamine more readily than it reduced nitrobenzene. Thus towards the *end* of the reduction of nitrobenzene by sodium hydrosulphide, the phenylhydroxylamine disappeared, leaving only aniline and some nitrobenzene yet to be reduced. Here again, as reduction progressed, thiosulphate ion increased. In fact, no increase in thiosulphate occurred unless reduction of either nitrobenzene or phenylhydroxylamine took place, in agreement with a similar observation in the case of nitrobenzene reduction by sulphide or disulphide ions (5). Also, in the case of nitrobenzene reduction by hydrosulphide, the amount of hydrodisulphide formed increased to a maximum after 3 hours' reaction, whereupon the total hydrodisulphide concentration decreased till the end of the reduction occurred. At this stage some hydrodisulphide still remained.

Autocatalytic Nature of Hydrosulphide Reduction of Nitrobenzene

In this work it was found that the reduction of nitrobenzene by hydrosulphide ion is also an autocatalytic process, but not to as marked an extent as for the analogous reduction by sulphide ion (5). This was shown by following the decrease of nitrobenzene (Fig. 1) or the increase in sulphur as hydrodisulphide (Fig. 2) during the reduction. In all cases an acceleration of rate is noted for the first portion of the reaction. In following the

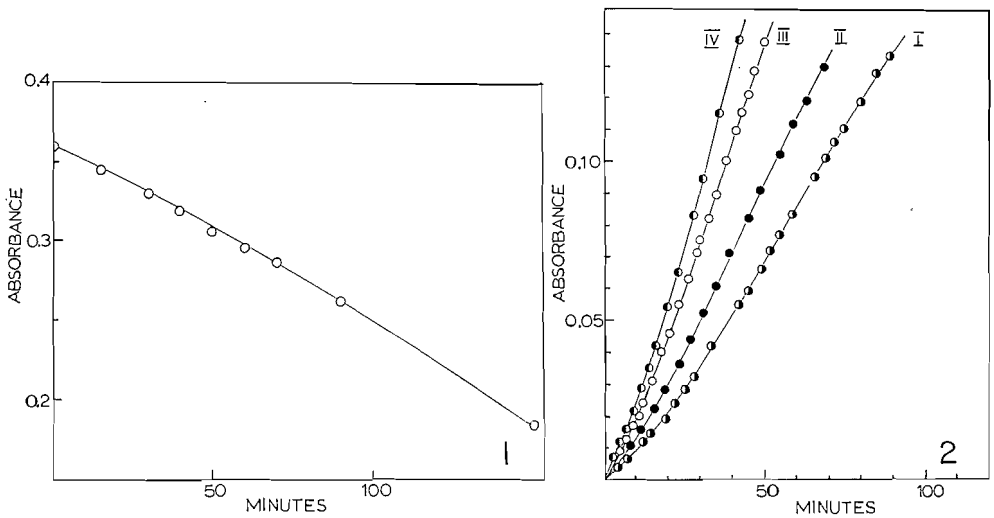

FIG. 1. Change in concentration of nitrobenzene (absorbance at 267 mμ) during reduction with aqueous sodium hydrosulphide at 50° C. Initial concentration of nitrobenzene and sodium hydrosulphide, 0.0098 *M* and 0.150 *M* respectively.

FIG. 2. Absorbance at 450 mμ of hydrodisulphide ion produced during the reduction of nitrobenzene by aqueous sodium hydrosulphide at 50° C. The initial concentration of nitrobenzene for all cases was 0.0094 *M*. Initial concentration of sodium hydrosulphide for runs I, II, III, and IV was 0.150 *M*, 0.200 *M*, 0.250 *M*, and 0.300 *M* respectively.

reduction by measurement of the absorption of nitrobenzene at 267 mμ, allowance for the absorption at 267 mμ due to phenylhydroxylamine was found to be necessary. Ogatas' technique (10) of acidification of the reduction mixture with hydrochloric acid and measurement of absorption of the residual nitrobenzene at 267 mμ was quite satisfactory for sulphide reductions of nitrobenzene (5) since the hydrochloride of aniline, the only reduction product, gave negligible absorption at this wavelength. However,

phenylhydroxylamine hydrochloride has an extinction coefficient at 267 mμ of 1.0×10^3 as compared with one of 7.4×10^3 for nitrobenzene. Since over the first 60 minutes of the hydrosulphide reduction of nitrobenzene, phenylhydroxylamine is essentially the only product, and the amount of hydro*di*sulphide produced is still small, simultaneous loss of phenylhydroxylamine by reduction due to hydrodisulphide would thus be very small. Hence for this first portion of the reduction it is true that 1 molecule of phenylhydroxylamine is produced as 1 molecule of nitrobenzene disappears. Setting the drop in absorbance at 267 mμ due to disappearance of nitrobenzene equal to X and the corresponding increase in absorbance due to phenylhydroxylamine as $(1.0\times10^3)/(7.4\times10^3)\cdot X$, the true decrease in absorption of nitrobenzene becomes $X = 1.15A_{obs}$, where A_{obs} is the observed decrease in absorption at 267 mμ. This factor has been used to obtain the corrected initial slopes in the plot of nitrobenzene absorption versus time in both Figs. 1 and 3.

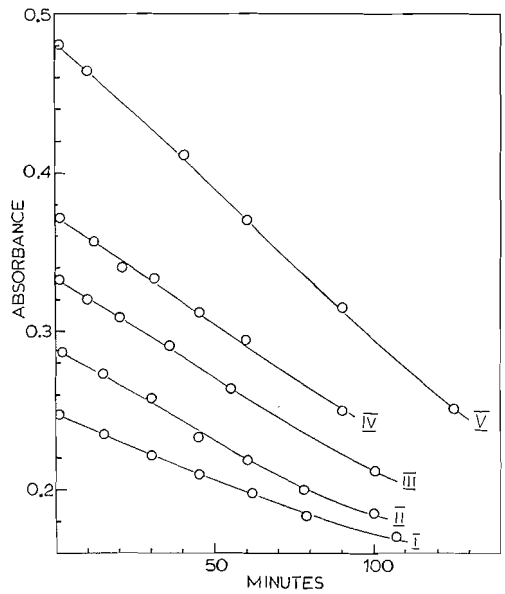

FIG. 3. Effect of change in the initial concentration of nitrobenzene on the rate of its reduction by aqueous 0.150 M hydrosulphide at 50° C. Initial concentration of nitrobenenze for runs I to V are 0.0068 M, 0.0079 M, 0.009 M, 0.0102 M, and 0.0132 M respectively.

Dependence of the Rate of Nitrobenzene Reduction on Nitrobenzene and on Hydrosulphide Ion Concentration

First-order dependence upon both hydrosulphide and nitrobenzene in the sodium hydrosulphide reduction of nitrobenzene in aqueous media was first pointed out by Goldschmidt and Larsen (4). This has been corroborated, over the limited range of concentration employed in this work. Initial slopes, obtained from the plots of nitrobenzene concentration versus time (Fig. 3), divided by the concentration of nitrobenzene gave a constant value (Table II). Similarly, by use of initial slopes of the plots of the appearance of hydrodisulphide ion versus time (Fig. 2), first-order dependence upon hydrosulphide ion concentration was illustrated (Table III). In the latter case, the upward drift of the figures in column 3 (Table III) may be due to the increase in ionic strength as one increases the sodium hydrosulphide concentration. A positive salt effect for the reaction has been found by Goldschmidt and Larsen (4).

TABLE II

Dependence of reduction of nitrobenzene by hydrosulphide ion on nitrobenzene concentration
(Initial hydrosulphide ion concentration, 0.150 M; solvent, H_2O; reaction temperature, 50.0°)

Initial nitrobenzene concentration (absorbance at 267 mμ)	Rate of decrease* in absorbance at 267 mμ, $\times 10^3$ (min^{-1})	Rate of decrease in absorbance ÷ absorbance of nitrobenzene, $\times 10^2$ (min^{-1})
0.482	1.94	4.03
0.373	1.51	4.05

Comparison of Ease of Reduction of Nitrobenzene by Hydrosulphide and Hydrodisulphide

In order to test the relative reducing abilities of hydrosulphide and hydrodisulphide at the pH (10.3) and temperature (50°) of the solutions employed, one run was carried out wherein sufficient sulphur was predissolved in the 0.150 M solution of hydrosulphide to make it 0.0150 M in hydrodisulphide. Figure 4 shows that the deliberate addition of this sulphur as hydrodisulphide definitely accelerated the rate of reduction by a

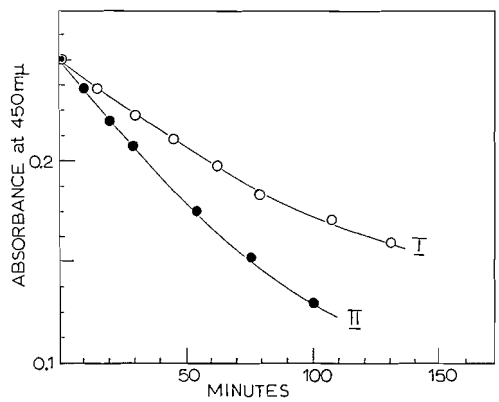

FIG. 4. The effect of addition of sulphur as hydrodisulphide to a solution of sodium hydrosulphide on the rate of reduction of nitrobenzene. Initial concentration of nitrobenzene, 0.0068 M. (I) Reduction by 0.150 M solution of sodium hydrosulphide. (II) Reduction by 0.150 M solution of sodium hydrosulphide containing 0.015 M of sulphur as hydrodisulphide.

factor of 1.8 (after correction for interference of phenylhydroxylamine at 267 mμ). This information is evidence that hydrodisulphide ion does reduce nitrobenzene more readily than does hydrosulphide ion and that hydrodisulphide is the entity responsible for the autocatalytic nature of the reaction. The conclusion made in our previous publication (5) that hydrodisulphide and hydrosulphide in aqueous ethanol possessed *comparable* reducing abilities must now be modified for the reduction in completely aqueous media. It is likely that in aqueous ethanol the hydrodisulphide is also somewhat more effective than is hydrosulphide but the difficulty and consequent error involved in estimating the interference of the hydrodisulphide at 267 mμ under those conditions (5) could readily have masked the relatively small increase in rate due to hydrodisulphide. In the *aqueous* media used in the present work there was no comparable difficulty in measuring the hydrodisulphide absorption (and concentration) and hence its interference at the λ_{max} of 267 mμ for nitrobenzene, since all polysulphide sulphur was completely removed by precipitation before absorption measurements were made.

The initial reduction, quite evident in Fig. 1 and in Fig. 4 (plot I), is due chiefly to HS^-. A small contribution may arise from the unavoidable traces of hydrodisulphide present. From absorption measurements, the highest concentration of this contaminating hydrodisulphide was 0.5% of the hydrosulphide. However, the fact that the rate of reduction was increased by a factor of only 1.8 when as much as 10% of the hydrosulphide was in the form of hydrodisulphide, shows that small traces of the latter as a contaminant could not have contributed much to the rate of reduction shown initially by the solution of sodium hydrosulphide.

Determination of Rate Constants for the Hydrosulphide and Hydrodisulphide Reduction of Nitrobenzene

An attempt has been made to obtain a quantitative comparison of the ability of sodium hydrosulphide and sodium hydrodisulphide to reduce nitrobenzene, as follows.

An approximate value of the rate constant (k_1) for hydrosulphide reduction of nitrobenzene in aqueous media can be obtained from the data in Table II. Using the expression $-dA_n/dt = k_1[HS^-]A_n$, where A_n is the concentration of nitrobenzene in terms of absorbance, and noting that the average value of $(-dA_n/dt)/A_n = 4.02\times10^{-3}$ min^{-1}, k_1 becomes 2.68×10^{-2} liter mole^{-1} min^{-1}. This figure may be slightly high since the contribution to the rate by traces of hydrodisulphide ion has been neglected for the reason stated in the preceding section.

From this value of k_1, and with the information available in Fig. 4, it is now possible to obtain a value for the hydro*di*sulphide reduction rate constant, k_2. Here it is assumed that the solution of elemental sulphur (S_8) in a large excess of sodium hydrosulphide produces only the species HS_2^-, although the solution may actually contain a *mixture* of higher polysulphides as contaminants (5). Accordingly, from Fig. 4, plot II, where $[HS^-] = 0.135\ M$, $[HS_2^-] = 0.015\ M$, $A_n = 0.500$, and the initial slope is $dA_n/dt = 3.5\times10^{-3}$ min^{-1}, appropriate substitution in the expression

$$-dA_n/dt = k_1[HS^-]A_n + k_2[HS_2^-]A_n$$

gives $k_2 = 1.92\times10^{-1}$ liter mole^{-1} min^{-1}.

Comparison of these rate constants shows that the sodium hydrodisulphide reduces nitrobenzene about seven times more rapidly than does sodium hydrosulphide.

Under our conditions, the sulphide ion is practically all in the protonated form as hydrosulphide. However, the extent of hydrolysis of the disulphide ion under these

conditions may be considerably less. The hydrolysis constant of the disulphide ion is not known, although Ogata (10) indicates that it is less than that of the sulphide ion. It is thus possible that in our solutions of sodium hydrosulphide containing as much as 10% of the hydrodisulphide, we are actually dealing with an appreciable concentration of the $S_2^=$ species, which is known to reduce nitrobenzene rapidly (5). This then may be the active species in our solution and it would be incorrect to attribute the rate expressed by $k_2 = 1.92\times10^{-1}$ liter mole^{-1} min^{-1} to the HS_2^- only. However, this can be taken into consideration using the expression

$$-dA_n/dt = A_n(k_1[HS^-]+k'[HS_2^-]+k''[S_2^=]).$$

Knowing that $[S_2^=] = [HS_2^-][OH^-]/K_h$, where K_h is the hydrolysis constant (unknown) of the disulphide ion, the observed rate constant is $k_2 = k'+k''[OH]/K_h$.

The Reduction of Phenylhydroxylamine by Hydrodisulphide Ion

The reduction of phenylhydroxylamine by aqueous sodium hydrosulphide containing hydrodisulphide is due essentially to the hydrodisulphide species. Hydrosulphide itself reduces the hydroxylamine very slowly (Table I). Certainly in the first 90 minutes of reaction, reduction with a mixture of hydrosulphide and hydrodisulphide occurs practically only by hydrodisulphide, with simultaneous decrease in the hydrodisulphide concentration. It has been possible to follow the reduction of phenylhydroxylamine during the first 90–100 minutes by measuring the decrease in absorption of hydrodisulphide at 450 mμ. The results are shown in Fig. 5.

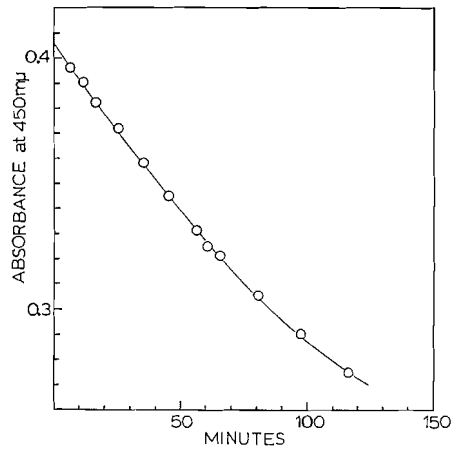

FIG. 5. Disappearance of hydrodisulphide ion during the reduction of a 0.010 M solution of N-phenylhydroxylamine by 0.150 M aqueous sodium hydrosulphide containing sufficient elemental sulphur to convert about 8% of the hydrosulphide to hydrodisulphide.

If it is assumed that the reaction between phenylhydroxylamine and hydrodisulphide is first order in each component, a value can be obtained for the rate constant k_3 for the disappearance of hydrodisulphide by use of the expression $-dA_{HS_2^-}/dt = k_3$[hydroxylamine][HS_2^-]. From a measurement of the initial rate, $dA_{HS_2^-}/dt = 2.00\times10^{-3}$ min^{-1}, obtained from Fig. 5, where $A_{HS_2^-}$ is the absorbance of hydrodisulphide, the concentration of the hydrodisulphide is 0.406 expressed as absorbance, and the concentration of phenylhydroxylamine is 0.010 M, substitution in the above expression gives $k_3 = 5.1\times10^{-1}$ liter mole^{-1} min^{-1}. This indicates that phenylhydroxylamine is reduced by hydrodisulphide about 2.7 times more rapidly than is nitrobenzene. This difference in rate

explains the findings in Table I, and the failure to find phenylhydroxylamine in nitrobenzene reduction by hydrodisulphide towards the end of the reaction.

Stoichiometry of the Overall Reduction of Nitrobenzene to Aniline by Sodium Hydrosulphide

The quantitative analyses of the initial reaction mixture and of the mixture obtained at the end of the reduction gave the results of Table IV. Thus both $S_2O_3^=$ and HS_2^- are produced during the reaction and are found at the end of the reduction in the concentration shown.

TABLE IV
(Compare Table I)

	Nitrobenzene	$S_2O_3^=$	HS_2^-
Initial concentration (M)	0.01	0.0035	0.0005
Final concentration (M)	0.00	0.0102	0.0035
Overall change (M)	−0.01	0.0067	0.0030

Assuming that HS^- reduction of nitrobenzene to aniline yields only HS_2^- one can write the following overall redox equation:

$$RNO_2 + 6HS^- + H_2O \rightarrow RNH_2 + 3HS_2^- + 3OH^-. \qquad (e)$$

On the other hand, the formation of only $S_2O_3^=$ is satisfied by the overall redox equation

$$4RNO_2 + 6HS^- + H_2O \rightarrow 4RNH_2 + 3S_2O_3^=. \qquad (f)$$

Equation (e) shows that the production of 1 mole of HS_2^- required 1/3 mole of nitrobenzene. Since in our reduction 0.0030 M of HS_2^- was produced, according to the preceding statement the amount of nitrobenzene consumed in this direction must have been 0.0010 M. The remainder of the nitrobenzene (0.0090 M) then gave $S_2O_3^=$ only. The stoichiometry of equation (f) shows that 1 mole of nitrobenzene yields 3/4 mole of $S_2O_3^=$. Accordingly, the 0.0090 M of nitrobenzene should yield 0.00675 M of the thiosulphate. The amount actually found (0.0067 M) agrees with this very well.

Stoichiometry of the Hydrodisulphide Reduction of Phenylhydroxylamine

Quantitative analysis of the initial and final reduction mixtures yielded the results of Table V.

TABLE V
(Compare Table I)

	Phenylhydroxylamine	$S_2O_3^=$	HS_2^-
Initial concentration (M)	0.010	0.0035	0.0116
Final concentration (M)	0.00	0.0080	0.0041
Overall change (M)	−0.01	0.0045	−0.0075

Reaction of either HS^- or HS_2^- with phenylhydroxylamine *apparently* failed to produce HS_2^-, but instead consumed any HS_2^- present. However, the amount of $S_2O_3^=$ increased considerably. The following overall redox equation agrees with these results but points out that 1 mole of phenylhydroxylamine yields 0.5 mole of $S_2O_3^=$:

$$2RNHOH + 2HS_2^- + 2OH^- \rightarrow 2RNH_2 + S_2O_3^= + 2HS^- + H_2O. \qquad (g)$$

The formation of 0.0045 mole of $S_2O_3^=$ from the reduction of 0.01 mole of phenylhydroxylamine supports this formulation. The slight decrease from the amount expected theoretically can be attributed to the simultaneous though much slower reduction of the phenylhydroxylamine by the HS^- (equation *h*) which is present in a concentration about 10

$$4RNHOH + 2HS^- \rightarrow 4RNH_2 + S_2O_3^= + H_2O \qquad (h)$$

times that of HS_2^-. Support for the view that HS^- also participates in the reaction is obtained from the quantitative data in Table V. Since only 0.0075 mole of HS_2^- was consumed, 0.0025 mole of HS^- must also have reacted to complete the supply of electrons required for the reduction of 0.01 mole of the phenylhydroxylamine to aniline. This gave 0.0025 mole of S^0, which by equation (*b*) must have led to the production of 1/4(0.0025) or 0.0006 mole of $S_2O_3^=$. The amount of $S_2O_3^=$ produced by these two paths then would be 1/2(0.0075)+0.0006 = 0.0044 *M*. The amount of $S_2O_3^=$ actually found (0.0045 *M*) is in very close agreement with this.

NUCLEAR MAGNETIC RESONANCE STUDIES

PART II. SOLVENT EFFECTS IN THE N.M.R. SPECTRA OF AROMATIC ALDEHYDES[1]

R. E. KLINCK AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ontario

Received August 15, 1962

ABSTRACT

The chemical shifts for the aromatic and formyl protons of a series of substituted benzaldehydes have been obtained in a number of solvents. Relative to the shifts observed in chloroform, pronounced effects are observed in acetone and benzene solutions. In general, the shielding of these nuclei is decreased in acetone and increased in benzene, while in benzene the magnitude of the solvent shift for a given proton depends markedly on the nature of the substituent group. These results can be rationalized in terms of a specific solute–solvent interaction in which the site of association is governed by the electron distribution in the solute molecule. The nature of the solvent interactions in this and related systems is discussed.

INTRODUCTION

In a recent paper (1) on the various factors contributing to the chemical shift of the formyl proton in aromatic aldehydes, some interesting solvent effects were presented and an interpretation based on the occurrence of specific solute–solvent associations was suggested. Further tests of this interpretation include a study of the solvent dependence of the chemical shifts of *all* the solute protons and an examination of the temperature dependence of the formyl shifts in these solvents. The present paper reports the results of these tests, all of which confirm the previous suggestions.

On the basis of the preliminary observations, it was suggested that in benzene solution a specific molecular complex is formed in which a benzene molecule tends to lie over a solute molecule while acting as a donor to the electron-deficient portion of the solute structure. This is to say that, on a time average, a solvent molecule is more closely associated with a particular part of the solute molecule. An example of complex formation in the chloroform–mesitylene system has been presented by Reeves and Schneider (2), who have detected its presence using both N.M.R. and other techniques. More recently, Abraham (3), Hatton and Richards (4, 5), and Hatton and Schneider (6) have discussed similar solute–solvent interactions involving a number of polar solutes in aromatic solvents.

In the case of acetone as solvent, the observed shifts, although qualitatively similar, are not so pronounced and may be rationalized in terms of a hydrogen-bonded complex involving one of the aromatic protons and the carbonyl oxygen of the solvent as suggested originally by Schaefer and Schneider (7).

In order to investigate these solute–solvent interactions in more detail, a series of para-substituted benzaldehydes was examined in acetone, benzene, and chloroform solutions and the chemical shifts of *all* solute protons determined. Throughout this study all chemical shift measurements were determined relative to an internal tetramethylsilane reference to eliminate effects due to the bulk diamagnetic susceptibility of the solvent as well as any non-specific effect of the solvent diamagnetic anisotropy. Because of solubility problems with some of the examples, all results are compared with those obtained in chloroform solution. We have found no evidence that this solvent causes differential shifts

[1]*These results were reported at the 45th Annual Conference of the Chemical Institute of Canada, Edmonton, Alberta, May 27–30, 1962.*

of the solute protons, although weak hydrogen bonding is to be expected between the solvent proton and the formyl oxygen atom. Therefore, differential shifts of the solute protons in benzene or acetone relative to chloroform solution would tend to confirm the existence of specific solute–solvent interactions as well as to provide evidence for their stereochemistry.

In benzene, the close approach of a solvent molecule to a given preferred site of the solute molecule should affect the solute protons in a predictable way, since the benzene molecule is anisotropic and exhibits a ring current effect arising from the induced (by the applied field) diamagnetic circulation of the mobile π-electrons around the ring. This secondary field tends to augment the applied field in the plane of the ring and to diminish it above and below this plane (8). The field experienced by a given proton in close proximity to an aromatic ring, therefore, will depend on the mutual orientation of the two groups, and one can predict with confidence, at least qualitatively, the way in which a given position within a solute molecule will be affected. Thus, if a molecular complex of the proposed geometry is involved in the present system, differential chemical shifts of the solute protons relative to their shifts in chloroform should indicate a preferred orientation of the solvent molecule(s). For example, in the case of a strong electron-withdrawing substituent, one can envisage an association of the donor solvent molecule with the opposite end of the solute molecule (i.e. lying over the carbon bearing the formyl group), while for an efficient electron-releasing group, association should be favored between the substituent group and the solvent. A suggested model for these two extreme cases is presented in Fig. 1. For the former case, one would expect both the formyl proton and the

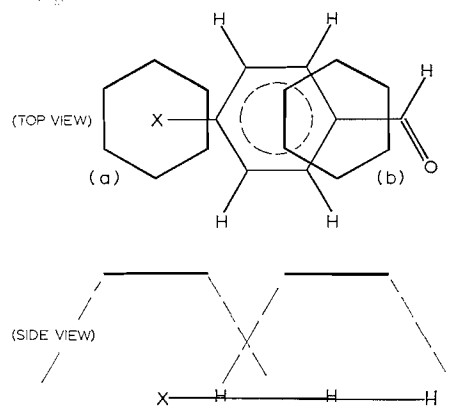

FIG. 1. Diagrammatic representation of the molecular complex formed by benzene with an aromatic aldehyde bearing (*a*) an electron-releasing group and (*b*) an electron-withdrawing group.

aromatic protons ortho thereto to experience a shielding effect while the meta protons would be affected to a lesser extent, whereas in the other extreme situation the shielding effect should be maximal at the substituent protons, if any, and would decrease progressively at the meta, ortho, and formyl positions, respectively. Indeed, it might be possible to realize a deshielding effect at the formyl proton.

For further evidence bearing on the nature of these associations in aromatic solvents, three additional series of experiments were carried out. First, the solvent effects of toluene, mesitylene, 1,3,5-triisopropylbenzene, nitrobenzene, and N,N-dimethylaniline on the formyl shifts of benzaldehyde and its *p*-nitro, *p*-formyl, and *p*-dimethylamino derivatives were determined for comparison with the shifts observed in benzene solutions. Secondly, the temperature dependence of these formyl shifts was measured in benzene and toluene.

Toluene was used in this study to allow observations over a wider temperature range (−35° to 100° C). Thirdly, the generality of these trends in acetone and benzene solutions was tested by an examination of the chemical shifts of the protons in a number of para-substituted toluenes and acetophenones.

EXPERIMENTAL

All of the compounds used in this study are commercially available and purification was effected by recrystallization or distillation before use. Similarly, the solvents employed were carefully purified before the solutions were prepared. Benzene-d_6 and chloroform-d were obtained from Merck, Sharp, and Dohme, with minimum deuterium content of 99.5%. To approximate "infinite dilution" conditions, 5 mole% solutions were used throughout and para-substituted compounds were chosen since these give rise to a nearly symmetrical A_2B_2 spectrum for the aromatic protons which can be analyzed approximately as a simple AB system to determine the chemical shifts of the aromatic protons. Since the benzene solvent peak obscures the aromatic proton pattern in some cases, benzene-d_6 was used to allow spectral analysis.

All spectra were obtained at 60 Mc/sec using a Varian spectrometer (DP-60) and were calibrated by interpolation between audio side bands of the internal tetramethylsilane signal placed on either side of the peak to be measured. The precision is estimated to be ±0.5 cycle/sec. To confirm certain assignments, some spin decoupling experiments were performed using an N.M.R. Specialties S.D. 60 unit operating at 4.3 and 56.4 Mc/sec (N^{14} and F^{19} resonance frequencies, respectively). The temperature studies were carried out using a Varian V-4340 Variable Temperature Probe Accessory.

RESULTS

Some typical data for the aromatic protons in some para-substituted benzaldehydes, acetophenones, and toluenes are listed in Table I, in which the internal chemical shift

of the ring protons is given for benzene, acetone, and chloroform solutions. A related study by Schaefer and Schneider (7) compared the internal shifts of the aromatic protons of some para-substituted toluenes and fluorobenzenes in acetone, benzene, and *n*-hexane solutions. For comparative purposes, a few of their results are given in parentheses in Table I. It is to be noted that the data obtained in chloroform compare favorably with those in *n*-hexane. In general, it can be seen that benzene tends to increase the internal chemical shift while acetone tends to diminish it. The important point to note, however,

is that the two positions are affected differently in these solvents. The differential shifts of the solute protons are presented graphically in Figs. 2, 3, 4, and 5, in which the chemical

shifts in acetone and benzene solution are shown relative to the shifts observed in chloroform. In the following, the ortho and meta positions will be considered relative to the parent grouping (CHO, $COCH_3$, and CH_3) unless otherwise indicated.

The effect of adding benzene to a chloroform solution of a solute exhibiting large shifts in an aromatic solvent was studied in the case of *p*-nitro- and *p*-dimethylamino-benzaldehyde and the chemical shift for the formyl and N-methyl protons is plotted for the various solvent compositions in Fig. 6. DISCUSSION

(a) Acetone Solutions

From Fig. 2 and Table I, the results for various solutes in acetone solution show that one of the aromatic protons is, in general, affected to a greater extent than the other. In this solvent, Schaefer and Schneider (7) have suggested that one of the aromatic positions (that which is meta to the stronger electron-withdrawing group) is preferentially "hydrogen-bonded" to the carbonyl oxygen of a solvent molecule and so is deshielded relative to the other aromatic proton. (Their suggested model is included in Fig. 2.) Furthermore, a neighboring proton should be slightly affected by the close approach of the anisotropic carbonyl double bond and it is interesting that the formyl proton is shifted more in the *p*-NO_2, *p*-CN, and *p*-Cl derivatives, as expected for this model. In only one case is an up-field shift observed (*o*-protons in the *p*-dimethylamino derivatives). In all these examples, it is consistently observed that the proton meta to the stronger electron-withdrawing substituent appears at lower field in acetone solution *relative* to its shift in chloroform.

(b) Benzene Solutions

In benzene solution, the relative shifts of the solute protons appear to vary in a regular fashion in each of the three series of compounds (Figs. 3, 4, and 5). Again, since the relative chemical shifts of the solute protons change with different substituents, stereospecific interactions of some type are strongly indicated. An examination of the trends observed in these various series, therefore, will support or deny previous suggestions as to the nature of these associations.

For each of these series, the trend exhibited by the change in chemical shift for the aromatic protons is similar. For the *p*-dimethylamino derivatives, the meta proton is shielded more strongly, whereas the ortho proton is more strongly affected in the *p*-nitro derivatives. As noted previously (1), the parent grouping experiences an increased shielding as the electronic character of the substituent is changed progressively from a strong electron-releasing type to a strong electron-withdrawing species (i.e., *p*-NMe_2 to *p*-NO_2). In addition, those substituents bearing protons show the expected trend in that the shielding decreases as the electron-releasing power diminishes.

Presumably, in the benzaldehyde series, a strong electron-withdrawing substituent, such as the *p*-nitro group, aids association at the carbon bearing the formyl group since this carbon would be expected to be slightly positive. A benzene molecule(s) lying over this position would tend to shield the ortho and formyl protons strongly and the meta protons less strongly. At the other limit, the case of a strongly electron-donating grouping such as the *p*-NMe_2, the slightly positive substituent would attract a solvent molecule preferentially. Thus the N-methyl protons would be expected to experience a strong shielding effect which would be progressively smaller at the meta, ortho, and formyl protons, respectively. Indeed, the formyl proton appears to be slightly deshielded in the case of *p*-dimethylaminobenzaldehyde. The other substituents appear to give results intermediate between these two extremes. It is interesting to note that Hatton and Richards (6, 7) have recently presented evidence that similar complexes are involved in solutions of amides in aromatic solvents. In these cases the complexes appear to involve a close association between the aromatic ring of the solvent molecule and the slightly positive nitrogen atom in such a way that the electron-rich carbonyl group lies as far from the ring as possible.

An interesting comparison between the *p*-dimethylamino- and *p*-nitro-benzaldehydes can be made by an examination of the shift of the formyl and N-methyl protons as a chloroform solution of each is diluted with benzene in stages up to and including a pure benzene solvent. In all cases the solutes were present in a concentration of 5 mole% (Fig. 6). The changes in shift of the N-methyl protons in the *p*-dimethylamino compound and the formyl proton in the *p*-nitro compound can be seen to be virtually parallel while the shift of the formyl proton in the former is only slightly affected by these changes in solvent composition. Clearly the causes for these parallel shifts can be assumed to be similar.

The close similarity between the results obtained for the three series lends further support to the hypothesis that a complex with the proposed geometry is involved in solutions of aromatic solutes in aromatic solvents. Slight differences are observed in the substituted acetophenones relative to the aldehydes in that the methyl ketone protons are strongly shielded in four of the five cases examined. This could be taken as an indication that more than one solvent molecule tends to associate with a single ketone solute molecule.

In the substituted toluenes, the same general trend is still apparent, although the relative shifts are smaller for the compounds with electron-releasing substituents. These observations are consistent with the formation of a weaker complex in this than in the other series since the charges would be less highly developed.

(c) Other Aromatic Solvents

The shift of the aromatic formyl proton in solutions of a few other aromatic solvents was examined to determine the contribution of substituents in the solvent molecule to these interactions. According to the present model for the complex, the solvent molecule acts as a donor to the electron-deficient region of the solute molecule owing to the high π-electron density of the aromatic ring, and polar substituents would be expected to affect the stability of the complex in a predictable fashion. Electron-releasing substituents should stabilize the complex by rendering the solvent a better donor, whereas electron-withdrawing substituents should weaken the solute–solvent association. In addition to the polar effect, the substituents on the solvent molecule could conceivably introduce a steric factor such that complex formation at a given position on the solute molecule would be sterically hindered.

The formation of these complexes can be represented by the following equilibrium:

$$\text{solute} + \text{solvent} \rightleftharpoons \text{associated complex} \qquad [1]$$

and the substituent effects can be considered on the basis of this equation. Since the observed chemical shift of a given solute proton will be the weighted average of the shifts for that proton in each of the two extreme environments, any change in the equilibrium position will be reflected by the observed shift. Any factor favoring complex formation would be expected, in general, to give rise to an up-field shift and the reverse effect would be observed for any destabilizing factor.

An alternative view of the situation would consider the relative distances between the solute and solvent molecules in the complex. Since the ring current effect of a solvent molecule on a solute proton X Å from the center of the aromatic nucleus decreases as $1/X^3$, the solvent shift will decrease as this distance increases. Presumably, the weaker the complex, the greater is the distance between the interacting species, and therefore the interaction would be less specific with regard to a particular region of the solute molecule (i.e., a less stable complex). Thus a prediction of the effect of substituents in the aromatic solvent molecule would be the same as before.

To test for possible substituent effects the following aromatic solvents were chosen: for polar effects—nitrobenzene and N,N-dimethylaniline; for steric effects—toluene, mesitylene, and 1,3,5-triisopropylbenzene; as substrates, benzaldehyde and its *p*-nitro, *p*-formyl, and *p*-dimethylamino derivatives were selected. The results of these measurements are listed in Table II, in which the shifts in chloroform solution are included for comparison.

Considering first the results for benzaldehyde and its *p*-nitro and *p*-formyl derivatives (columns 2, 3, and 4), it is clear that the shielding of the formyl proton is increased in N,N-dimethylaniline and decreased in nitrobenzene relative to that observed in benzene solution. This is the expected behavior in terms of the present model. In the hydrocarbon solvents, the shielding increases slightly with increasing methylation of the solvent. This trend can be attributed to the polar characteristics of these solvents since their ability to act as donors would be enhanced slightly by substitution of hydrogen by methyl groups. Since the shifts are to higher field, no steric effect is evident. In 1,3,5-triisopropylbenzene, however, the shift is to lower field relative to that observed in mesitylene and an indication of steric interference would thereby be presented but for the fact that the isopropyl group is a poorer electron-releasing grouping than methyl. At any rate, evidence of steric hindrance of complex formation as a major factor appears to be lacking for these solutes in this series of solvents.

In the fourth case, *p*-dimethylaminobenzaldehyde (columns 5 and 6, Table II), the trend of the formyl shifts in the various solvents is not so clear cut. This is not unexpected since, on the basis of the evidence discussed earlier, association of the solvent appears to involve the substituent nitrogen atom and, hence, the solvating molecule(s) is relatively distant from the formyl proton. Furthermore, the contribution of dipolar resonance forms to the electron distribution in this solute will be greater than in the other examples and the possibility of other dipolar associations in nitrobenzene and dimethylaniline solutions cannot be dismissed. The solvent shifts of the N-methyl protons, on the other hand, appear to fit a pattern similar to that exhibited by the formyl protons in the other three examples, particularly in the polar solvents. Although it is not possible to determine this shift precisely in N,N-dimethylaniline, since a solvent peak appears in the same region, the N-methyl protons are significantly shielded. The fact that the shielding is less than

that observed in benzene solution might well be explained by steric hindrance to complex formation caused by the bulky substituent. Furthermore, in hydrocarbon solvents, the shielding of the N-methyl protons decreases with increasing alkyl substitution on the aromatic solvent; this trend is exactly analogous to that found for some N,N-dialkyl amides in aromatic solvents (5). In the present case, it seems reasonable that the alkyl groups of the solvent hinder its close approach to a solute molecule since one of the substituent groups would be forced to lie over the aromatic ring of the solute. In the previous examples, the aromatic rings would overlap instead and steric hindrance of complex formation would be much less. Indeed, in the case of terephthalaldehyde, the rings of solute and solvent would presumably be coaxially oriented in the complex.

(d) Temperature Effects

In the preceding discussion, evidence has been presented to confirm the existence of molecular complexes in solutions of a number of substituted benzenes in aromatic solvents and their formation has been represented by equation [1]. Since the equilibrium position in a given system will be temperature dependent (such that lowering the temperature favors complex formation), the observed chemical shift of a given solute proton should also be temperature dependent. In general, one would expect an increased shift to higher field as the temperature is lowered. To test this point, toluene solutions of benzaldehyde and its *p*-NO_2, *p*-CHO, and *p*-NMe_2 derivatives were examined at various temperatures and the chemical shifts of the formyl and N-methyl protons measured. The results are summarized in Table III.

Clearly, the shifts for the formyl protons in the first three examples are temperature dependent (last line of Table III) while the shift for the formyl proton in *p*-dimethylaminobenzaldehyde is not. It can be seen, however, that the N-methyl shift for the latter example changes with temperature in approximately the same way as other formyl shifts, although over a narrower temperature range. These results provide further proof of the stereospecificity of these solute–solvent interactions, since only those protons close to the solvating molecule(s) are affected by changes in temperature.

It is planned to extend the range of these temperature studies and to determine the chemical shift changes of all the solute protons in an effort to evaluate the parameters which govern the formation of these complexes.

CONCLUSIONS

On the basis of these results the original suggestion that a benzene solvent molecule(s) tends to form weak molecular complexes with substituted aromatic solutes appears to be substantiated. Strong evidence in support of this conclusion is provided by the observation that the solvent shifts of all the solute protons are interpretable, qualitatively at least, in terms of the ring current of a closely associated aromatic molecule occupying a preferred orientation which is governed by the substituents of the solute molecule. Furthermore, the effect of substituents on the aromatic solvent molecule is found to be completely in accord with this interpretation. Polar factors appear to dominate in the formation of these complexes while steric effects seem to be minor except possibly in the case of association between the solvent and the substituent grouping of the solute molecule. The temperature dependence of the solvent shifts also provides additional support for the formation of a stereospecific complex.

In acetone solution, the present results are in agreement with those expected for an association involving a type of "hydrogen bonding" between the aromatic protons and

the carbonyl oxygen atom of the solvent as was first suggested by Schaefer and Schneider (7). An alternative interpretation* of these relatively small effects would attribute the observed shifts to the polar effect of the acetone as discussed by Buckingham, Schaefer, and Schneider (9); but it is difficult to distinguish between these two possibilities when the shifts are small.

ACKNOWLEDGMENTS

This work was supported by grants from the National Research Council of Canada and the Petroleum Research Fund administered by the American Chemical Society. We wish to express our thanks to the donors of these funds. We also thank Farbenfabriken Bayer AG, Leverkusen, West Germany, for the generous sample of 1,3,5-triisopropylbenzene.

THE MERCURY-PHOTOSENSITIZED DECOMPOSITION OF METHANE[1]

R. A. BACK AND D. VAN DER AUWERA[2]

Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received August 15, 1962

ABSTRACT

The mercury-photosensitized decomposition of methane has been studied at temperatures ranging from about 25 to 400° C, and pressures from about 100 to 1000 mm. Very low conversions and light intensities were employed, and it was shown that at temperatures of 120° C and above, the hydrogen produced was a direct measure of the primary yield of hydrogen atoms. The low, temperature-dependent quantum yield found in earlier studies persisted even under these conditions, and it seems necessary to postulate an inefficiency in the primary quenching process, involving essentially the quenching of $^3P_1$ mercury atoms by methane without decomposition of the methane.

Experiments with added ethylene showed that practically all the hydrogen produced in the decomposition of methane was scavengeable by ethylene, indicating that only atomic hydrogen was produced in the primary process. The rate of addition of hydrogen atoms to ethylene was estimated to be about 4×10^5 times faster than the rate of abstraction from methane at 120° C.

INTRODUCTION

There has been much evidence accumulated in recent years to suggest that the mercury-photosensitized decomposition of most of the alkanes proceeds by an initial reaction,

$$Hg^* + RH \rightarrow Hg + R + H,$$

with an efficiency close to unity. If care is taken to avoid (or make corrections for) the loss of hydrogen atoms by addition to olefins present, or by combination with radicals, the quantum yield of hydrogen formed by the reaction

$$H + RH \rightarrow H_2 + R$$

approaches a value close to 1, independent of temperature and pressure (1–3). Methane (4, 5) and neopentane (6) are the only apparent exceptions to this behavior.

An early study of the methane decomposition by Taylor *et al.* (4) showed a quantum yield of hydrogen which was about 0.004 at 98° C, and increased markedly with temperature to a maximum observed value of about 1 at 400° C. These experiments, and more recent ones made by Mains and Newton (5), were made under conditions (high conversion, high light intensity, doubtful purity of methane) such that complications by secondary reactions made it difficult to reach any conclusions about the efficiency of the primary quenching process or about the cause of the low quantum yield of hydrogen. The present work was undertaken to see whether, under suitable conditions, the decomposition could be made to follow the simple mechanism

$$CH_4 + Hg^* \rightarrow CH_3 + H + Hg \quad [1]$$

$$H + CH_4 \rightarrow CH_3 + H_2 \quad [2]$$

$$2CH_3 \rightarrow C_2H_6 \quad [3]$$

so that the hydrogen yield would become a measure of reaction [1]. To achieve this simple mechanism, two requirements must be fulfilled.

[1]*Issued as N.R.C. No. 7043.*

[2]*National Research Council of Canada Postdoctoral Fellow, 1959–61. Present address: Manufacture Belge de Lampes et de Materiel Electronique, Brussels, Belgium.*

(1) The light intensity must be low enough so that loss of hydrogen atoms in the second-order (in atoms and radicals) recombination reactions

$$H + CH_3 + M \rightarrow CH_4 + M \quad [4]$$

$$H + H + M \rightarrow H_2 + M, \quad [5]$$

which compete with reaction [2], and are favored by high intensity and high radical concentrations, may be neglected.

(2) Concentrations of products and impurities must be kept low enough so that only methane quenches $Hg(^3P_1)$ atoms, and so that secondary reactions such as

$$H + C_2H_6 \rightarrow H_2 + C_2H_5 \quad [6]$$

$$CH_3 + H_2 \rightarrow CH_4 + H \quad [7]$$

$$CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5 \quad [8]$$

are negligible compared to [2] and [3].

EXPERIMENTAL

The reaction was studied in a conventional cylindrical quartz vessel, 10 cm long and 5 cm in diameter, of about 200-ml volume, with plane windows at each end. In order to keep the percentage decomposition of methane low, the reaction vessel was made part of a closed flow circuit of about 4-l. volume, which included a thermosiphon as a circulating pump (7). In the flow circuit, the methane passed over a mercury saturator heated to 50° C, and through cold traps before and after the reaction vessel, which controlled the vapor pressure of mercury in the reaction system. The reaction vessel was contained in an air thermostat which operated up to temperatures of 200° C. For higher temperatures, a tubular metal furnace was placed directly around the reaction vessel. The mercury resonance lamp was made in the form of a tight, flat spiral of 1-cm tubing, about 5 cm in diameter, mounted outside the air thermostat 20 cm from and parallel to one end of the reaction vessel. From the spiral, the two arms leading to the electrodes were fitted with jackets through which water maintained at 24.3° C was circulated to control the vapor pressure of mercury in the lamp. The lamp was filled with a few millimeters of neon, and operated at a rather low current of 5 ma, a-c., controlled by a ballast resistor.

Methane (both Matheson C.P. and Phillips Research Grade were used) and other gases were handled in a conventional vacuum apparatus. Methane was purified by careful degassing at −210° C to remove traces of permanent gases, bulb-to-bulb distillation from −196 to −210° C to remove small amounts of C_2-hydrocarbons, and finally by treatment with bromine to remove traces of ethylene. A small quantity (about 1 ml) of bromine, carefully degassed, was condensed onto activated charcoal previously baked out under vacuum. Methane was condensed onto the same charcoal at −196° C, then warmed to give a pressure of about 600 mm over the charcoal and allowed to stand for 1 hour. Methane was finally distilled from the charcoal at a temperature low enough to give complete separation from the absorbed bromine.

The ethylene used was Phillips Research Grade, while ethylene-d_4 was supplied by Merck and Company, with a stated deuterium content of 99%.

The hydrogen produced in the reaction was analyzed by gas chromatography. After an irradiation, the methane and other products were transferred from the reaction vessel into a trap of much smaller volume (300 cc), first by condensation at −210° C, then by pumping for about 2 hours with a mercury diffusion pump and a Toepler pump until the residual pressure in the reaction vessel was less than 10^{-5} mm. The hydrogen, together with about 20 μmoles of methane, was removed from the trap by pumping for 10 minutes with another mercury diffusion pump and Toepler pump. These pumped the gases into a small, U-shaped volume (~10 cc) between two three-way stopcocks, from which the sample could be picked up by a stream of nitrogen and analyzed on a 6-ft column of silica gel at 0° C, which gave a good separation of hydrogen from the methane. Blank experiments showed that this analytical procedure recovered about 99% of samples of hydrogen added to methane in amounts comparable to the reaction products. In most of the experiments the yield of hydrogen was between 0.01 and 0.10 μmoles, corresponding to between 0.1 and 5 p.p.m. methane. An average overall reproducibility of 5% might be estimated for these measurements of hydrogen yield, with a rather better reproducibility for the larger quantities of hydrogen.

Hydrogen was the only product measured in most of the experiments. In a few instances, the ethane produced was measured by gas chromatography and found to be approximately equal to the hydrogen. No hydrocarbon products higher than ethane could be detected. The higher products observed by Mains and Newton (5) arose from secondary reactions of products, and would not be expected at the low conversions used in the present work.

Preliminary experiments were made to determine whether impurities, in particular ethylene, might be affecting the hydrogen yield. Analysis by gas chromatography and mass spectrometry showed small amounts

(~0.1%) of ethane, ethylene, and argon in both Phillips and Matheson methane. Careful distillation at −196 to −210° C reduced the ethane to <0.003%, and the ethylene to <0.01%. This purified methane was irradiated at 120° C, and the hydrgeon yield measured. Upon subsequent treatment of the methane with bromine, the hydrogen yield was approximately doubled, but could not be further increased by repeated treatment with bromine. The addition of a trace of ethylene sharply reduced the hydrogen yield, while subsequent treatment with bromine restored it to its original value. This same yield of hydrogen could be obtained with methane from either source, following the bromine treatment, and was quite reproducible. It was concluded that the ethylene content of methane purified by bromination was low enough so that it did not interfere in the reaction, and all subsequent experiments were made with methane purified in this way.

In all the experiments the concentration of hydrogen produced was low enough that the quenching of mercury by hydrogen was negligible, assuming quenching cross sections of 0.06 and 8.9×10^{-16} cm² for methane and hydrogen respectively (8, 9). One sample of methane was sometimes used for several experiments, the hydrogen being removed after each run but the ethane being retained. The accumulated ethane was always low enough that quenching by ethane ($\sigma = 0.42\times10^{-16}$ cm²) should have been negligible (8). The hydrogen yield was observed to be independent of conversion both in single experiments and in sequences of experiments starting with pure methane and allowing ethane to accumulate. This is further evidence that neither hydrogen nor ethane was quenching $Hg(^3P_1)$ atoms, or was affecting the hydrogen yield in any other way. It also supports the conclusion that residual ethylene impurity had no effect on the system, since any such ethylene should disappear quite rapidly by reaction with hydrogen atoms, so that the hydrogen yield would rise with increasing conversion. A few experiments, carried to much higher than normal conversions, did show an increase in hydrogen yield which may be attributed to quenching by-products.

The intensity of the 2537 Å resonance line absorbed in the system was measured by the mercury-photosensitized decomposition of propane at conversions less than 0.005%, assuming the quantum yield of hydrogen, which was independent of temperature and pressure, to be unity (1).

RESULTS AND DISCUSSION

Figure 1 shows the rate of hydrogen production as a function of methane concentration at four different temperatures, using constant light intensity and mercury vapor pressure.

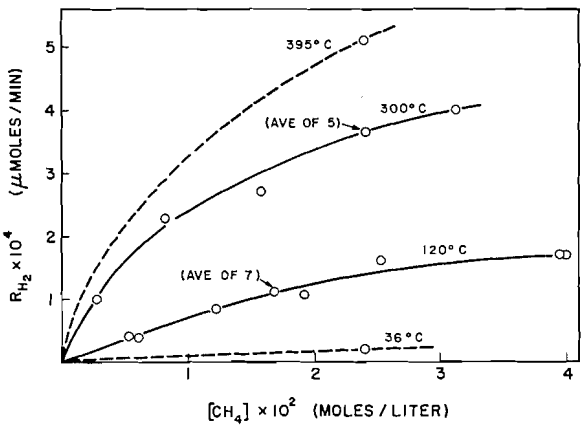

FIG. 1. Hydrogen production vs. methane pressure.

The strong temperature dependence observed by earlier workers was obviously confirmed. The reaction at 36° C was rather slow for practical purposes, while at 395° C some thermal decomposition of methane (probably a surface reaction) was becoming evident, and a small correction had to be made to the hydrogen yield. For these reasons, the reaction was studied in detail only at 120 and 300° C. At the highest methane pressures used (1000 mm), the hydrogen yield was not yet independent of pressure, although it appeared to be levelling out at values which are temperature dependent and which are much less than the hydrogen yield from propane under the same conditions (12×10^{-4} μmole/min).

The temperature dependence of the reaction is shown again in Fig. 2, where $\log_{10}$ of the quantum yield of hydrogen is plotted against the reciprocal of the absolute tem-

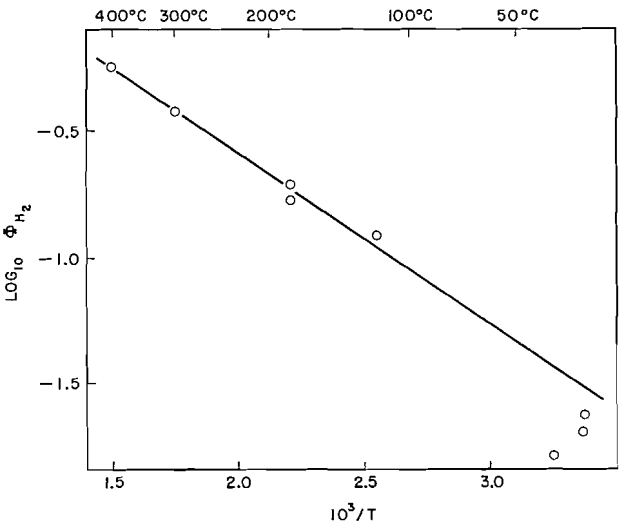

FIG. 2. Arrhenius plot of the quantum yield of hydrogen.

perature, with constant light intensity and constant methane concentration of 2.4×10^{-2} mole/liter. In obtaining these data, small corrections were made for measured differences in the absorption of the mercury resonance radiation in the propane and methane systems.

In Fig. 3, the hydrogen yield at constant methane concentration of 2.4×10^{-2} mole/liter is plotted against the light intensity for temperatures of 24, 120, and 300° C. The slopes of these log–log plots are 0.72, 0.98, and 1.00 respectively, so that the hydrogen yield at temperatures of 120° C and above appears to be close to a linear function of light

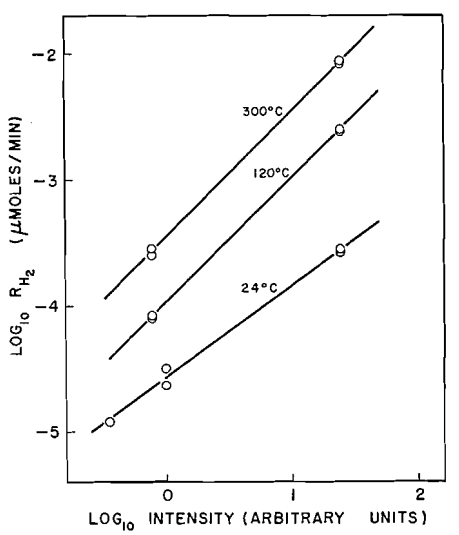

FIG. 3. Log–log plot of hydrogen yield vs. light intensity.

intensity. This linear dependence at the higher temperatures is most simply interpreted as indicating that every hydrogen atom produced in reaction [1] reacted with methane by reaction [2], while the less-than-linear dependence at 24° C suggests that reactions [4] and [5] were of some importance at the lower temperature. Some support is lent to this interpretation by a simple calculation of the relative rates of reactions [2], [4], and [5]. Since hydrogen and ethane were the only products, then $R_{H_2} = R_{C_2H_6}$, and the methyl radical concentration may be calculated, using the literature value (10) for k_3. Then, using Le Roy's values (11) for k_2 ($E_3 = 6.6$ kcal/mole, $P = 10^{-4}$), and assuming $E_4 = 0$ and $P_4 = 1$, the ratio of rates, R_2/R_4, was calculated to be 1.4, 6.6, and 54 at 24, 120, and 300° C respectively, for the *highest* light intensities shown in Fig. 3. These numbers are certainly compatible, within the considerable uncertainties of the calculations, with complete scavenging of hydrogen atoms by reaction [2] at the two higher temperatures, with some loss by reaction [4] at 24° C. If reactions [4] and [5] were not important at the higher temperatures, it also follows that the back reaction, [7], the reverse of [2], can have had no effect in the system. This is confirmed by the independence of hydrogen yield on conversion.

Loss of hydrogen atoms by reaction [5], proceeding in the gas phase, may be shown by similar calculations to be quite negligible. It is less easy to dispose of the possibility of recombination of hydrogen atoms on the surface, although the most reasonable calculation suggests that only a small fraction of atoms would have reached the wall before reacting. The occurrence of reaction [2] together with surface combination of atoms would probably not give a linear dependence of hydrogen yield on light intensity; it could only reduce the quantum yield of hydrogen to 0.5 at the most, and would not explain the dependence on light intensity at 24° C.

Thus it seems reasonably certain that at temperatures of 120° C and above all the hydrogen atoms formed in the primary process reacted with methane to form hydrogen, so that the yield of hydrogen should reflect the extent of the primary decomposition. It appears, therefore, that the low quantum yields of hydrogen observed in the present work are not due to loss of hydrogen through back reactions, but must be attributed to an inefficiency in the primary quenching process.[3]

An obvious cause of such an inefficiency could be the incomplete quenching of the $^3P_1$ mercury atoms by methane, with consequent escape of the resonance radiation from the reaction vessel. There is considerable uncertainty in the value of the quenching cross section of methane. It is undoubtedly very small, and there is some possibility that the quenching observed and attributed to methane was caused largely by traces of strongly quenching impurities such as ethylene, oxygen, and ethane. From Bates' data (8), it may be estimated that quenching should have been complete at a pressure of a few hundred millimeters of methane, which would rule out incomplete quenching as the cause of the low quantum yield. To further test this conclusion, experiments were made in which the partial pressure of mercury vapor was varied from 0.19 μ, the equilibrium pressure at 0° C, which was used in most of the work, to 25 μ. After a small correction was made for the increased primary absorption of light, the yield of hydrogen was found to be almost independent of mercury vapor pressure, decreasing slightly only at the highest pressure used. This decrease, which was more marked at lower temperatures, was probably due to the enhancement of reaction [4] caused by the higher local absorbed light intensity. If the low yield of hydrogen had been due to incomplete quenching, then an increase of

[3]*It should be noted that in previous work, all done with much higher light intensities and higher conversions, this was probably not true, and back reactions were probably important.*

the mercury vapor pressure by a factor of 10 or 100 should have sharply increased the hydrogen yield, as the resonance radiation would have been trapped much more effectively in the reaction vessel, with consequent improved chances of quenching by methane. Thus the evidence indicates that incomplete quenching of $^3P_1$ mercury does not account for the low quantum yields of hydrogen.

In Fig. 4 is shown the effect of added ethylene on the reaction at 120° C, with a methane pressure of 590 mm. The hydrogen yield was reduced to about one half by the addition of

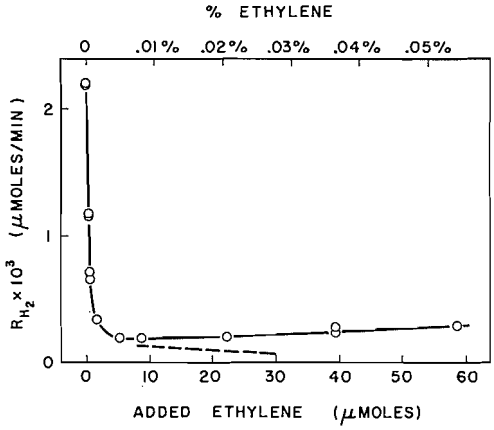

FIG. 4. The effect of added ethylene on the hydrogen yield at 120° C, with 590 mm pressure of methane.

2 p.p.m. ethylene, and fell to a minimum of about one tenth of its original value at about 50 p.p.m. As more ethylene was added, the hydrogen yield rose again slowly, presumably as ethylene itself was decomposed. The final, approximately linear part of the curve in Fig. 4 may be extrapolated to zero ethylene concentration to give a positive intercept which could be interpreted to indicate that some (about 7%) of the hydrogen from the methane decomposition was produced as molecular hydrogen and could not be scavenged by ethylene. However, experiments with C_2D_4 (Table I) showed that this was not so. The

TABLE I

Experiments with C_2D_4

C_2D_4 added (μmoles)	Composition of hydrogen produced		
	% H_2	% HD	% D_2
0.0	100	—	—
1.0	100	—	—
4.8	72	5	23
27.8	18	4	78

broken curve in Fig. 4 shows the yield of hydrogen from the methane decomposition corrected for hydrogen produced by the decomposition of ethylene, which was estimated from the yields of D_2 in Table I. The observed hydrogen yield is thus seen to be the sum of two curves: one, the hydrogen yield from the methane decomposition, which fell slowly to zero as scavenging of hydrogen atoms and quenching of $^3P_1$ mercury by ethylene became complete; the other, the hydrogen yield from the ethylene decomposition, which rose linearly at first, then more slowly, and would become constant when quenching by

ethylene was complete.[4] Thus the experiments with added ethylene may be completely explained in terms of reaction [1], yielding hydrogen atoms, as the only primary process in the methane decomposition.

The experiments with C_2D_4 also show that the initial rapid drop in the hydrogen yield was almost entirely due to the reaction

$$H + C_2H_4 \rightarrow C_2H_5 \qquad [9]$$

in competition with reaction [2], with competitive quenching of $Hg(^3P_1)$ only becoming important at higher concentrations of ethylene. The equation

$$(R_{H_2})_0/R_{H_2} = 1+k_9[C_2H_4]/k_2[CH_4],$$

where $(R_{H_2})_0$ is the hydrogen yield from pure methane, should describe the simple competition between reactions [9] and [2], and in Fig. 5, values of the left-hand side of this

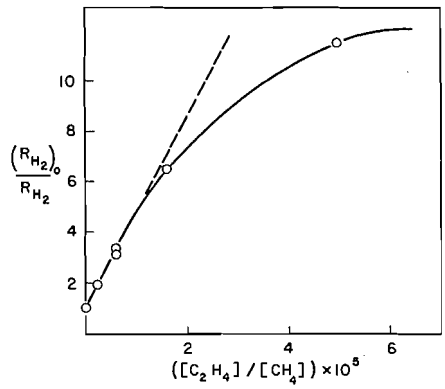

FIG. 5. Linear plot of the data from experiments with added ethylene.

equation are plotted against $[C_2H_4]/[CH_4]$. The experiments at the four lowest ethylene concentrations yielded a good straight line, and from its slope a value of $k_9/k_2 = 3.8\times10^5$ at 120° C may be estimated. At higher ethylene concentrations, of course, the data must fall off from the linear relation as quenching by ethylene becomes an important source of hydrogen. The large magnitude of k_9/k_2, and the consequent effectiveness of a few parts per million of ethylene, apparent in Fig. 4, emphasize the importance of trace impurities in the methane decomposition.

Finally, the conclusions to be drawn from the present study may be summarized. The low, temperature-dependent quantum yields of hydrogen observed in previous work on the mercury-photosensitized decomposition of methane have been found to persist even under conditions of low light intensity and low conversions, when the reaction was shown to follow the simple sequence of reactions [1], [2], and [3] at temperatures of 120° C and above. Both back reactions and incomplete quenching of $^3P_1$ mercury may be fairly certainly ruled out as causes of the low quantum yield, and it appears necessary to postulate an inefficiency in the primary quenching process. In the most general terms, a reaction,

$$CH_4 + Hg^* \rightarrow CH_4 + Hg, \qquad [10]$$

[4]*In one experiment in which 1700 μmoles (1.6%) of ethylene was added, so that quenching by ethylene should have been almost complete, 0.75×10^{-3} μmole/min of hydrogen was produced, corresponding to a quantum yield of about 2×10^{-2}. This is in fair agreement with previous studies of the ethylene decomposition (12), and the observed yields of D_2 from C_2D_4 are compatible with a final constant hydrogen yield of about this value.*

which quenches $^3P_1$ mercury in competition with reaction [1], but does not decompose methane, would seem to be required. The observed temperature dependence would then derive from a difference between the temperature dependences of reactions [1] and [10]. More specifically, one possible mechanism might involve a competition between collisional quenching and decomposition of an excited methane molecule,

$$\mathrm{Hg^* + CH_4 \rightarrow Hg + CH_4^*} \begin{cases} \nearrow \mathrm{CH_3 + H} & [1A] \\ \searrow + \mathrm{CH_4 \rightarrow 2CH_4} & [10A] \end{cases},$$

although the pressure dependence of the hydrogen yield (Fig. 1) does not support (but also does not disprove) this mechanism, which would predict a maximum in the plot of hydrogen yield against pressure.

A perhaps more likely mechanism is one which invokes two quite distinct reactions, for example,

$$\mathrm{Hg^* + CH_4 \rightarrow HgH + CH_3 \rightarrow Hg + H + CH_3} \qquad [1B]$$

and

$$\mathrm{Hg^* + CH_4 \rightarrow Hg + CH_4^* \rightarrow Hg + CH_4,} \qquad [10B]$$

where [10B] is a "physical" quenching process in which CH_4^*, probably vibrationally excited, is always deactivated by collision at the fairly high methane pressures used. Hydrogen abstraction reactions such as [1B], with HgH as an intermediate, have long been suggested in the mercury-photosensitized reactions of the alkanes (13), although there is almost no proof for or against their occurrence. The temperature dependence of the methane decomposition appears to favor this latter mechanism. Reaction [1] is exothermic by about 11 kcal/mole, and if it proceeded through an energy transfer process, as in [1A], an activation energy of about 3 kcal/mole, as observed, would seem most unlikely. Reaction [1B], on the other hand, might well show such an activation energy, although it is difficult to see why methane should be so much less reactive than ethane, as the difference in C—H bond energy is small compared to the exothermicities of both reactions. This raises the question of whether the primary process in the methane decomposition is qualitatively different from those of the higher alkanes, or is similar in mechanism but much slower because of the higher bond energy or some other property of the methane molecule. Molecular symmetry has been suggested as a cause of the low quantum yield of the mercury-photosensitized decomposition of methane and neopentane (6), since the latter has bond energies very similar to those of ethane but shows a much lower yield of hydrogen; however, it is difficult to see exactly what part symmetry could play in the process.

Another possible mechanism for the methane decomposition involves the quenching of mercury to the $^3P_0$ state as a primary process,

$$\mathrm{Hg(^3P_1) + CH_4 \rightarrow Hg(^3P_0) + CH_4,} \qquad [11]$$

followed by the rather slower reaction

$$\mathrm{Hg(^3P_0) + CH_4 \rightarrow Hg(^1S_0) + CH_3 + H.} \qquad [12]$$

The low yield of hydrogen would then be attributed to loss of $Hg(^3P_0)$ by the reactions

$$\mathrm{Hg(^3P_0) + wall \rightarrow Hg(^1S_0) + wall} \qquad [13]$$

$$\mathrm{Hg(^3P_0) \rightarrow} h\nu\ (2656\ \text{Å}) + \mathrm{Hg(^1S_0)} \qquad [14]$$

$$\mathrm{Hg(^3P_0) + CH_4 \rightarrow} h\nu\ (2656\ \text{Å}) + \mathrm{Hg(^1S_0) + CH_4.} \qquad [15]$$

Once the $^3P_1$ mercury has been quenched to the $^3P_0$ state, effective radiation trapping is no longer possible, and the observed independence of the hydrogen yield on mercury vapor pressure is explained. It is interesting that Bates (8) concluded from the quenching behavior of methane that quenching to the $^3P_0$ state was the main process. Reactions [13] and [14] have been recently shown to occur in a study (14) of the interaction of nitrogen with $Hg(^3P_1)$. Reaction [15] is kinetically equivalent to the general reaction, [10], and thus could account for the observed pressure dependence of the hydrogen yield. Kimbell and Le Roy (14) found it necessary to postulate a similar emission of the "forbidden" 2656 Å radiation induced by collision with nitrogen. The observed temperature dependence of the hydrogen yield would require reaction [12], which might or might not proceed through formation of HgH, to have an activation energy of about 3 kcal/mole.

The present results with methane do not distinguish clearly between the several possible causes of the inefficiency of the primary process, and, in this respect, an extension of the measurements to higher pressures, in the range from 1 to 10 atm, would be very useful, but it presents some experimental difficulties and is not planned at the present time. The whole problem of the nature of the primary process in the mercury-photosensitized decomposition of the alkanes is a very elusive one. A careful re-examination of quantum yields and quenching cross sections of a number of alkanes, in particular methane, ethane, and neopentane, over a wide range of pressure and temperature, and under conditions which prevent back reactions and internal scavenging by olefins, would seem to be required for its solution.

A CONTINUOUS FLOW BETA SCINTILLATION DETECTOR FOR AQUEOUS SOLUTIONS[1]

R. TKACHUK

Grain Research Laboratory, Board of Grain Commissioners for Canada, Winnipeg, Manitoba

Received July 12, 1962

ABSTRACT

Counting of beta emitters in aqueous solutions was carried out with a detector whose detecting element is a packed column of a finely divided plastic scintillator. The efficiencies under practical operating conditions for C^{14}, Sr^{90}–Y^{90}, and K^{40} are 36, 74, and 82% at backgrounds of 27 ± 2 c.p.m.

INTRODUCTION

A need arose in this laboratory to determine continuously the activity of C^{14}-labelled amino acids and their derivatives in the effluents from ion exchange columns on a Spinco Model 120 automatic amino acid analyzer. A spiral capillary plastic scintillation flow detector as described by Funt and Hetherington (1) was first tried for this purpose. However, because of the low efficiency of 5.7% for C^{14}, and the small sample volume of 0.28 ml of this detector, useful results could not be obtained for the low specific activity of the compounds to be analyzed. The present report describes a detector which incorporates the useful features of the spiral capillary system and the method reported by Steinberg, who used a suspension of anthracene for C^{14}-assay of aqueous solutions, an efficiency as high as 54% being reached (2, 3).

The detecting element of the present system is a packed column of a finely divided plastic scintillator incorporated in a Lucite container. The detector is used in conjunction with a single multiplier tube and appropriate electronics, but with no refrigeration equipment. The features of this detection system are a direct reproducible measurement of C^{14}-activity in aqueous or alcoholic solutions without further sample preparation, and a good counting efficiency with low background which is not time dependent and not influenced by most impurity quenching effects nor by differences in counter filling compositions. Detectors with large sample volumes may be easily constructed. The detector may be used to monitor continuously the activity of ion exchange column effluents, or to measure the activities of single samples.

EXPERIMENTAL METHODS AND MATERIALS

Preparation of Scintillator

The plastic scintillator was prepared in the following manner. The plastic phosphor NE102 (Nuclear Enterprises, Winnipeg, Manitoba, Canada), in the form of lathe turnings, was initially reduced in size by treatment for 5–10 minutes in a Waring blendor operating at high speed. The more finely divided material was sieved out and further reduced in size by grinding with a mortar and pestle. A little water was judiciously added during the latter and subsequent procedures to eliminate the profound static electrical properties of the finely ground plastic. The 100- to 200-mesh fraction of nearly dry material was saved. The fines in the latter fraction were removed by settling in a graduated flask of water containing a little detergent. The main bulk of the resin was isolated by collecting on a sintered-glass funnel, washing with water, and air drying.

Construction of Detector

The detector was constructed from a $2\frac{1}{4} \times 2\frac{1}{4}$-inch block of Lucite by drilling three closely and evenly

[1]*Submitted as Paper No. 213, of the Grain Research Laboratory.*
Presented in part at the 45th Conference of the Chemical Institute of Canada, Edmonton, Alberta, May 27–30, 1962.

spaced holes in it, 0.48 cm in diameter and 3.7 cm deep. The holes were suitably interconnected with 0.5 mm diameter channels. The inlet and outlet connections were constructed by cementing into place a 20 gauge stainless steel hypodermic needle with an epoxyresin (Hysol (Canada) Ltd., Toronto, Ont., Canada). After small wads of Pyrex glass wool were placed in the bottom of the three holes, the detector was filled with increments of the previously prepared finely ground plastic scintillator. Each increment was settled in by tapping the Lucite block, and then firmly tamped in with an aluminum rod whose diameter was only slightly smaller than the hole being filled. When the columns were nearly full, disks of a Pyrex glass filter paper were firmly tamped in, and the columns of plastic scintillator sealed in with a piece of Lucite. The assembly was then trimmed into a semihemispherical shape, in accordance with good reflectance geometry for scattering out of the plane side as much as possible of the light originating in the plastic scintillator. (It is important to have the holes completely filled with a well-packed mass of plastic scintillator and glass filter paper; a loosely filled detector tends to clog and also to give unreproducible behavior.) The whole surface of the detector was then rubbed with a fine-textured sandpaper, in order to increase light reflection, and the semihemispherical surface was painted with a reflector TiO_2 paint (Nuclear Enterprises), until an opaque coat was obtained. The detector is illustrated in Fig. 1.

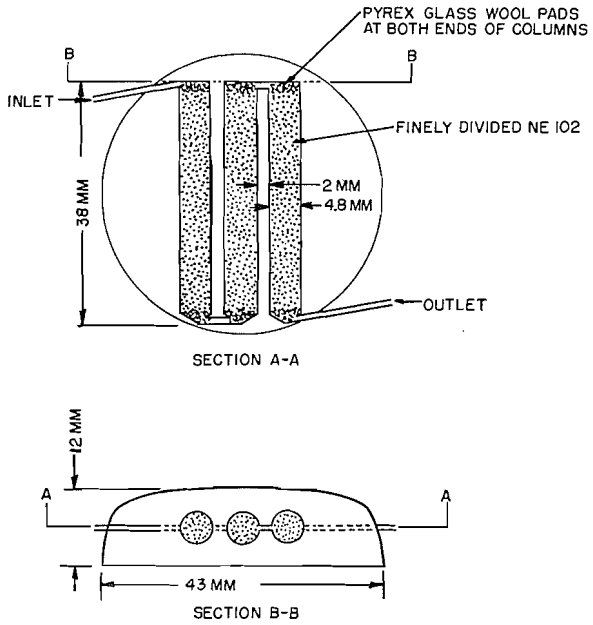

FIG. 1. Cross-sectional views of the flow detector.

Connections to the inlet and outlet of the detector were made with 22 gauge Teflon tubing (Pennsylvania Fluorocarbon Co., Philadelphia, Pa., U.S.A.), and the tubing was wired into place with copper wire. The whole assembly was checked for leaks by filling with water and then applying at least 100 p.s.i. pressure with a small hypodermic syringe. The detector was mounted with silicone fluid (Dow Corning 200, 60,000 centistokes) on a 2 inch diameter EMI 9536S multiplier tube inside a 2 inch thick lead castle. The detector was kept centered on the multiplier tube with the aid of a thick disk of pliable polystyrene foam. To prevent stray light from reaching the multiplier tube, the castle top was taped to the body of the castle with black opaque electrical tape, and the Teflon tubing connections leading to the detector were encased with black opaque spaghetti tubing. A small, easily replaceable filter, constructed from a piece of polyethylene tubing and Pyrex glass wool, was inserted into the inlet in order to remove the small amounts of suspended material that are usually found in solutions. The multiplier tube was kept at a constant temperature by running tap water through a coil incorporated in the castle body. The temperature of the multiplier tube during the winter months was approximately 7°.

Apparatus Used with the Detector

The detector was used with a white cathode follower-preamplifier (NE 5202A), a stabilized high-voltage supply (NE 5302), a non-blocking linear pulse amplifier (NE 5202), a single-channel differential pulse-height selector (NE 5102S), a rate meter (NE 5401), a Phillips scaler (PW 4032), a Baird-Atomic preset timer, and a Minneapolis-Honeywell Type 153 Electronik adjustable-span, adjustable-suppression recorder.

A liquid scintillation detector (NE 5503) was used to check the reliability of some of the measurements obtained with the flow detector. A 1000-watt Rayetheon Voltage Regulator was used to supply power for the whole system, which was enclosed in a grounded steel cabinet.

The above detection system was susceptible to some spurious interference from electrical relays and switches which were in the same room housing the detection system. The latter interference added approximately 0.5–3 c.p.m. to the background. The detector itself contributed approximately 14 c.p.m. to the background of the whole counting system. It was observed that occurrences of high humidity (or condensing moisture) gave rise to excessive spurious noise. This noise was eliminated by placing a drying agent, such as silica gel or Drierite, both in the castle compartment containing the multiplier tube and in the castle base which housed the preamplifier.

Labelled Materials

The gliadin-C^{14} was isolated from wheat which had been injected with acetate-2-C^{14} (4). C^{14}-Labelled amino acids were obtained by placing gliadin-C^{14} in a Pyrex test tube, adding 6 *N* redistilled HCl, freezing the mixture, evacuating to less than 0.5 μ pressure, sealing the tubing, and hydrolyzing for 22 hours at 120°. After hydrolysis, the HCl was removed by placing the tube, with its contents previously frozen, into a desiccator containing NaOH pellets and evacuating. Water was added to the residue, the humin removed by filtration, and the filtrate made up to volume with 0.2 *N* Na^+, pH 2.2 sodium citrate buffer containing BRIJ-35 detergent (Atlas Powder (Canada) Co., Brantford, Canada), and octanoic acid. S^{35}-Labelled amino acids were similarly obtained from wheat flour, the latter obtained from wheat injected with carrier-free $H_2S^{35}O_4$. S-(N-Ethylsuccinimido-1-C^{14})-cysteine was obtained by reacting N-ethylmaleimide-1-C^{14} (Schwarz Bioresearch, Inc.) with cysteine. A certified standard solution of C^{14} was obtained in the form of sodium carbonate from the Radiochemical Centre, Amersham, England.

RESULTS AND DISCUSSION

The effective scintillation-sensitive volume of the detector was determined by two different methods. In the first one, aliquots of S-(N-ethylsuccinimido-1-C^{14})-cysteine were successively introduced into the detector with an hypodermic syringe and the radioactivity noted. Plots of the activity versus the volume injected, as illustrated in Fig. 2, indicated that the volume was 1.02 ± 0.03 ml. In the second method, the activity of a solution occupying the whole detector volume was compared with the activity of the same solution passing through the detector at 0.500 ± 0.001 ml/min. The latter experiments indicated that the detector volume was 1.03 ± 0.08 ml. A value 1.02 ml was therefore used for the detector volume.

A representative integral bias curve for C^{14} is shown in Fig. 3, at the following operating conditions: multiplier tube voltage, 1000; amplifier gain, 5000; and temperature, 11.1°. The limiting efficiency was found to be 49%. At the lower bias setting of 7.50 v, which was chosen for routine counting of samples, the efficiency was 36.1% with a background of approximately 28 c.p.m.

The absolute efficiency of the detector for C^{14} was determined by injecting aliquots of a standard sodium carbonate-C^{14} solution into the detector with an hypodermic syringe and noting the resulting activity. The results, as illustrated in Fig. 4, indicated that the efficiency for C^{14} was 36.1%. The straight-line portion of the curve in Figs. 2 and 4 indicates that there is a linear relationship between the observed activity and the volume of activity injected into the detector. Higher efficiencies may be obtained by tighter packing of the plastic scintillator into the detector. The tighter packing, however, results in higher pressures necessary to introduce the sample into the detector. For example, to introduce a sample into a detector with an efficiency of 55% at the above operating conditions, a pressure of 100 p.s.i. was required for several minutes.

Repeated counts of the same aqueous C^{14}-solution over a period of several months gave an average count of 2129 ± 127 c.p.m. All the obtained counts were included in the latter average. When an equal volume of absolute ethanol was added to the above C^{14}-solution, the expected count was obtained.

Experiments with C^{14}-labelled wheat proteins and sodium carbonate-C^{14} indicated that

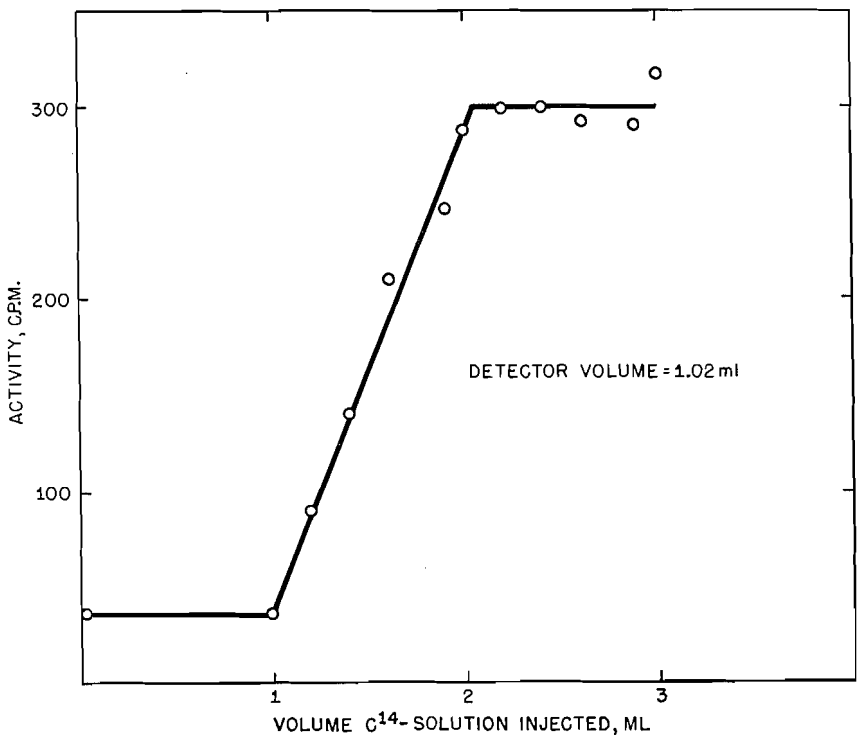

FIG. 2. Determination of detector volume by introduction of increments of a C^{14}-solution into the detector and determining the activity.

there was some retention of these substances on the detector. However, they were easily removed with weakly basic and acidic solutions respectively. The retention of sodium carbonate-C^{14} is illustrated by the skewed peak shown in Fig. 4, and the absence of a "flat top" to the curve (as in Fig. 2). When aqueous S^{35}-solutions containing sulphate-S^{35} were counted, however, the background usually increased from 5 to 15 c.p.m. The amount retained seemed to be a function of the amount of sulphate-S^{35} present and of the time the sample was kept in the detector. S^{35}-Activity retained could not be removed from the detector. It could be that under the acidic conditions of pH 2.2–3.5, at which most of solutions were counted, sulphonation of the polyvinyltoluene plastic scintillator might occur.

The quenching effects that are observed with this detector seem to be associated with the presence of those substances which have absorption spectra in the same region as the emission spectrum of the NE 102 plastic scintillator, which has a maximum at 4300 Å. Affirmative evidence for this assumption was obtained by counting $CuSO_4$ and $FeCl_3$ solutions containing the same amount of C^{14}. The data is given in Table I. These results are in agreement with those obtained by Steinberg, who used 2,4-dinitrophenol as a color quencher.

The efficiency of the detector for Sr^{90}–Y^{90} was determined by counting a solution of $SrCl_2$ made from a $Sr^{90}CO_3$ standard. An integral bias curve is illustrated in Fig. 5. At an amplifier gain of 5000, the limiting efficiency is 76%, and at a lower bias voltage of 7.5 v the efficiency is 72% with a background of 30 c.p.m.

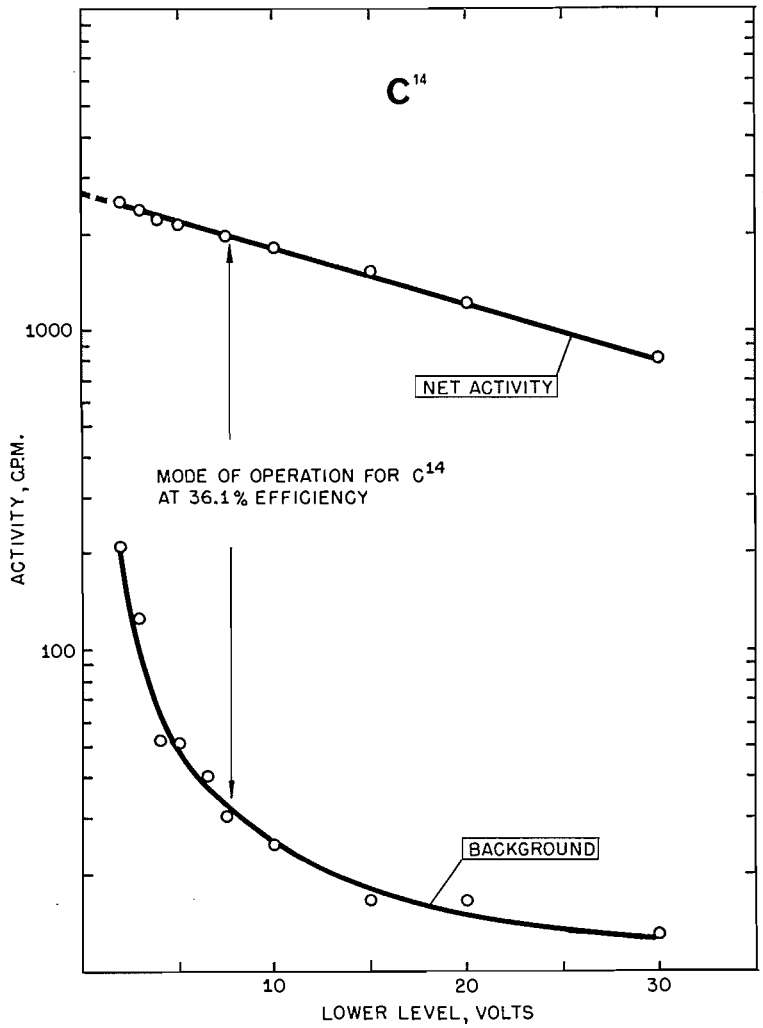

FIG. 3. Integral bias curve for a C^{14}-solution, with the 1.02 ml volume detector containing a total absolute activity of 5545 d.p.m. A multiplier tube voltage of 1000 v and an amplifier gain of 5000 was used. The temperature was 7°.

TABLE I

Activity of colored solutions

	Transmittance at 430 mμ (%)	Observed activity (c.p.m.)
Control solution	99.9	675
$CuSO_4$ solution	99.2	714
$FeCl_3$ solution	38.6	403

The detector efficiency for K^{40} was determined by counting a solution of naturally occurring KCl. The integral bias curve is illustrated in Fig. 6. It is seen that at an amplifier gain of 5000, the limiting efficiency is 93 and 83%, depending on whether the detector

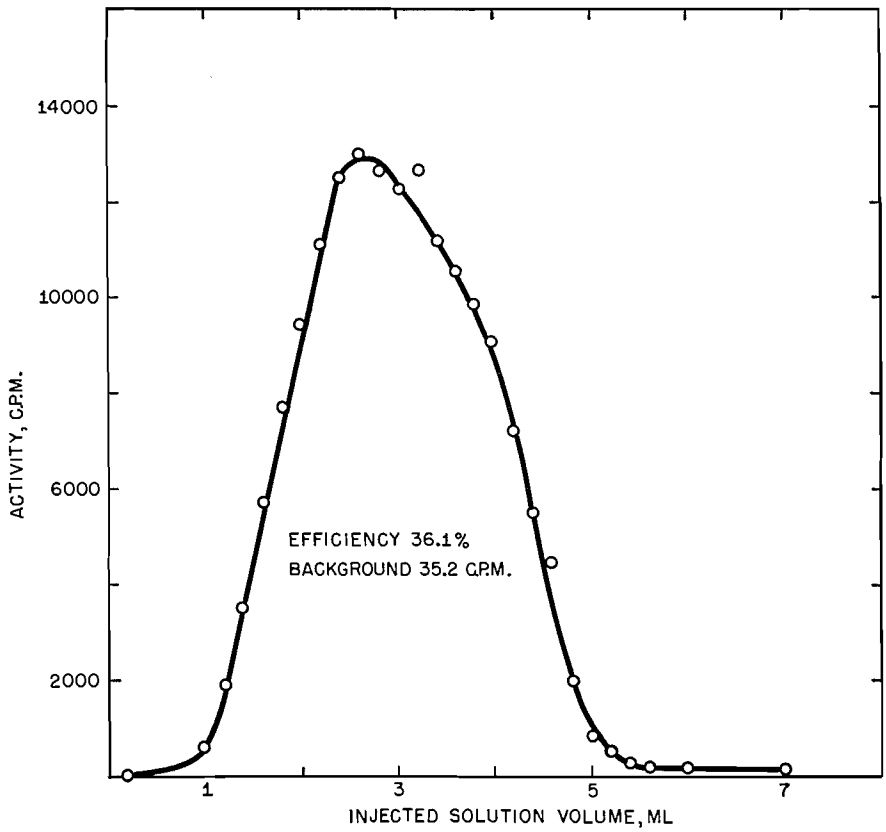

FIG. 4. Determination of detector efficiency by introduction into the detector of approximately 2 ml of a sodium carbonate-C^{14} standard solution (25,750 d.p.m./ml) followed by increments of water. The efficiency was calculated from the slope of the rising straight-line portion of the curve.

is sensitive only to the K^{40} β's or to K^{40} β's and γ's. It is unlikely that the detector would be sensitive to all of the 1.46 Mev γ's, because of the relatively low stopping power of the plastic phosphor. Evidence for this view was obtained by observing that a 5 μc Cs^{137} gamma source, when placed 3.8 cm from the geometrical center of the detector, gave a net count of only 1996 c.p.m. This activity is equivalent to an efficiency of approximately 2% for the 0.662 Mev γ's being emitted from this source. The absolute decay rate of 1692 and 209 d.p.m./g K was used for the K^{40} β- and γ-emission (5).

In the continuous flow experiments, effluents from ion exchange columns on a Spinco amino acid analyzer were monitored for their C^{14}- or S^{35}-activity. The detector was inserted into the effluent stream as it emerged from the ion exchange columns, by the use of encased Teflon tubing as described above for single sample operation. The use of the detector in conjunction with normal amino acid analyzer operation caused an increase of pressure of 4 p.s.i. on the buffer being pumped through the ion exchange columns at a rate of 30 ml/hr. Results from the analysis of a gliadin-C^{14} hydrolyzate are shown in Fig. 7. It is observed that the use of a detector with a 1.02-ml sample volume does not affect the resolution of the amino acids, nor cause any retention of the 18 C^{14}-labelled amino acids. These results are in agreement with those obtained independently, where the analysis of the above C^{14}-labelled amino acids was carried out with a vibrating reed

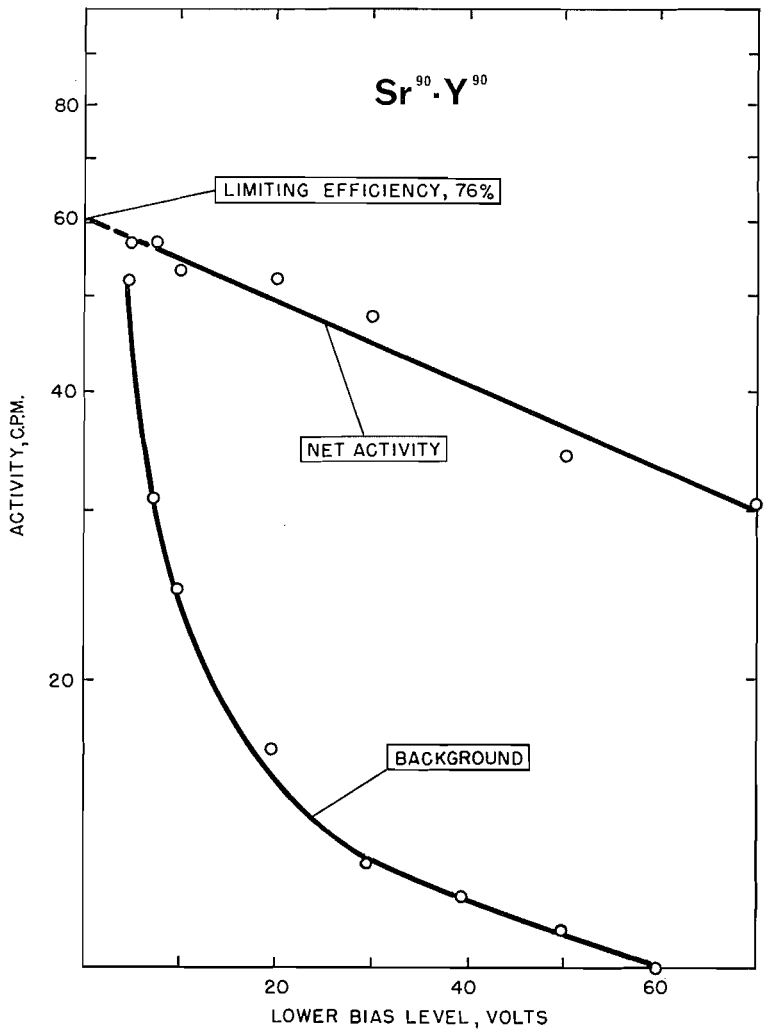

FIG. 5. Integral bias curve for a Sr^{90}–Y^{90} standard solution. The 1.02 ml volume detector contained a total absolute activity of 79.41 d.p.m. due to a mixture of Sr^{90}–Y^{90} at equilibrium. The multiplier tube voltage was 1000 v, the amplifier gain was 5000, and the temperature 6.9°.

electrometer. An analysis of an hydrolyzate from wheat flour labelled with S^{35} is illustrated in Fig. 8.

The reproducibility of the detector in the continuous flow mode of operation was checked by chromatography of a solution of S-(N-ethylsuccinimido-1-C^{14})-cysteine at various times over a period of several months. The activity was noted on the scaler and also from the size of the peak traced out by the recorder on the scintillation counter. The latter determination was done by tracing the peak from the chart paper onto bond paper and cutting out the traced peak and weighing it. The results were an average count of 4501 $\pm$136, equivalent to an average peak weight of 48.0$\pm$3.8 mg.

A single detector has been extensively used for a period of approximately 6 months. During the period, which included approximately 1 month of continuous operation, it gave constant and reproducible results. It would thus seem to be a fairly stable counting

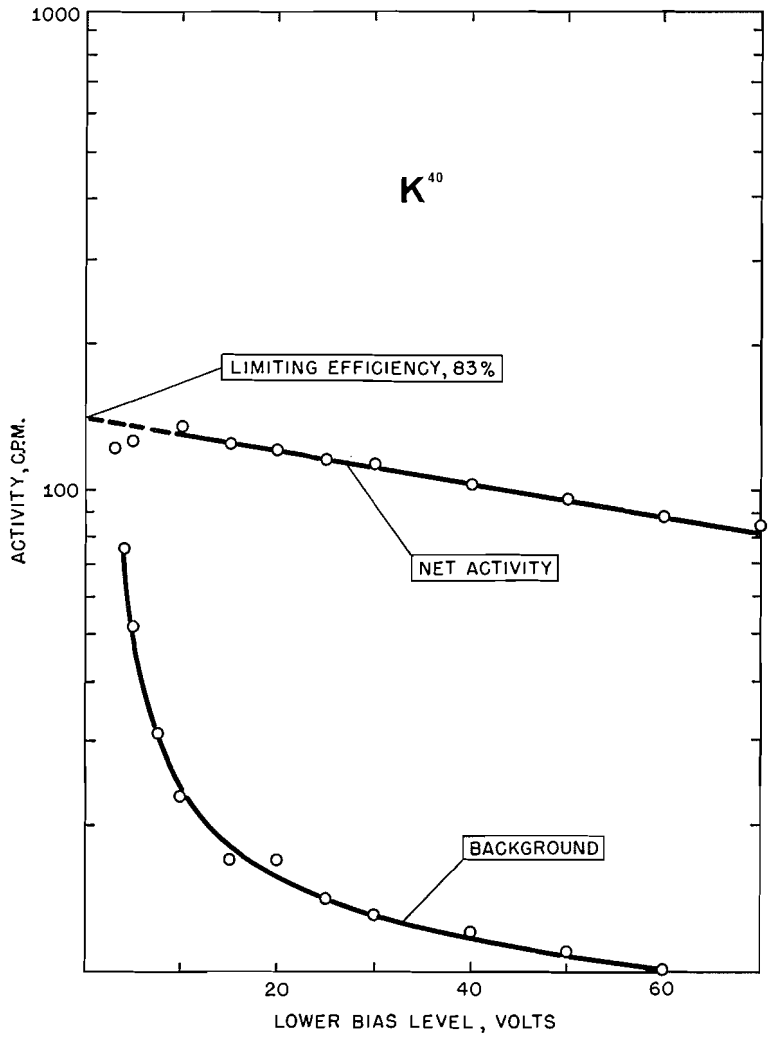

FIG. 6. Integral bias curve for K^{40}. The source of activity was 16.244 g of reagent grade KCl in 100 ml solution. Using the absolute decay rate of 1692 and 209 d.p.m./g K for K^{40} β's and γ's respectively, the limiting efficiencies are 93 and 83%, on the assumption that the detector is only sensitive to the 1.34 Mev K^{40} β's in the first instance, and sensitive both to the K^{40} β's and 1.46 Mev K^{40} γ's in the second instance. An efficiency of 100% under the present conditions is equivalent to 147 and 18 d.p.m. for the K^{40} β- and γ-emission. The multiplier tube voltage was 1000 v, the amplifier gain was 5000, and the temperature 6.9°.

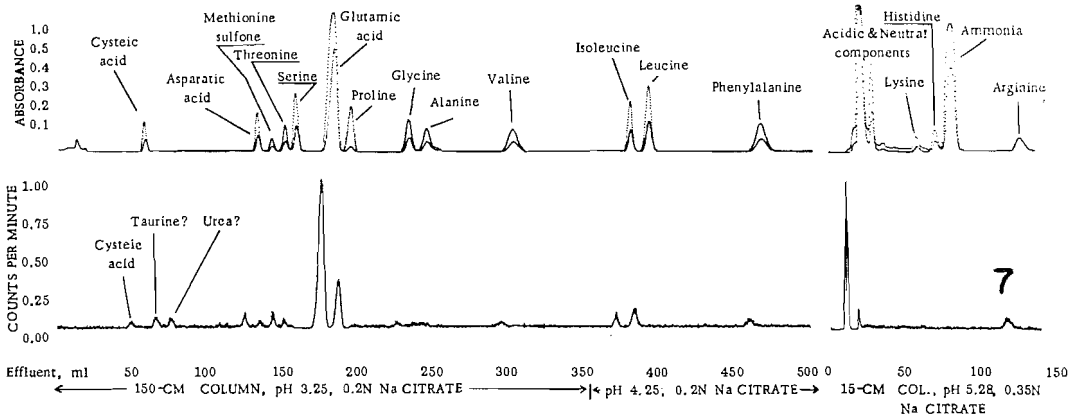
device. Assuming that the detection limit is given by a net sample count equal to background, then its limit is approximately 35 $\mu\mu$c C^{14} per ml in the single sample and 70 $\mu\mu$c C^{14} per ml solution in the continuous flow mode of operation.

When the present work had been essentially completed two reports appeared dealing with an anthracene detector (6, 7), and in addition three commercial anthracene detectors have recently become available (Atomic Accessories Inc., New York, N.Y., U.S.A.; Nuclear-Chicago Corp., Des Plaines, Ill., U.S.A.; Packard Instrument Co., Inc., La Grange, Ill., U.S.A.). With the lack of sufficient detail, it is difficult to make a comparison of the two different detectors at the present time. It would seem, however, that the anthracene detector is slightly more efficient and may not retain sulphate ion. On the



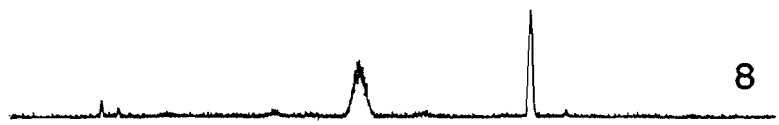


FIG. 7. Chromatographic (upper curve) with simultaneous C^{14}-radioactivity (lower curve) analysis record of a mixture of amino acids from a hydrolyzate of gliadin-C^{14}. The chromatographic analysis was obtained automatically in approximately 22 hours.

FIG. 8. S^{35}-Radioactivity record of a chromatographic separation of a hydrolyzate of wheat protein labelled with S^{35}. The two main peaks are due to cystine-S^{35} and methionine-S^{35}. The conditions are identical with those for the 150 cm column analysis illustrated in Fig. 7.

other hand, the anthracene will probably have to be replaced more often than the plastic scintillator in the detector because of solubility, and surface oxidation effects. The reported anthracene detector backgrounds have been slightly higher than observed for the present detector; however, this difference is probably not due to the detector but to the associated counting equipment.

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Dr. A. J. Finlayson, Prairie Regional Laboratory, Saskatoon, for providing a sample of gliadin-C^{14} where C^{14} activity of the constituent amino acids had been previously determined by a vibrating reed electrometer; to Dr. I. H. Harley, Health and Safety Laboratory, New York, for providing the Sr^{90}–Y^{90} standard; to Dr. B. L. Funt, University of Manitoba, and Dr. W. Reid, Nuclear Enterprises, Winnipeg, for many helpful discussions; and to Nuclear Enterprises, Winnipeg, for providing a sample of NE 102 plastic scintillator.

ABSTRACT

In experiments with C^{14}-labelled compounds, shikimic acid, phenylalanine, phenyllactic acid, and metatyrosine were found to be precursors of the terphenylquinone pigment volucrisporin. It is suggested that the pigment is biosynthesized by the self-condensation of two molecules of an unbranched phenylpropanoid intermediate, and that hydroxylation of the phenyl rings in the meta position occurs before the condensation step.

Several speculative schemes have been proposed for the biogenesis of terphenylquinone pigments. Kögl (1), as early as 1926, suggested that polyporic acid is formed from phenylacetic and oxalic acids. More recently Mittal and Seshadri (2) proposed that two branched C_6C_3 units such as 2-C-phenylglyceraldehyde might be involved in the formation of this pigment. Straight-chain phenylpropanoid compounds related to the common aromatic amino acids were considered to be more plausible intermediates by Read and Vining (3), who suggested that condensation of suitable pairs of such compounds would provide a general route to the terphenylquinones. The discovery of volucrisporin in saprophytic cultures of the hyphomycete *Volucrispora aurantiaca* Haskins (4) and elucidation of its structure as the terphenylquinone (III) (5) have provided the first practical opportunity to test these theories. Compounds of this class had previously been found only in the fruiting bodies of fungi growing in their natural environment, or in the slow-growing lichens (6).

V. aurantiaca has now been grown in the presence of various C^{14}-labelled substrates and the incorporation of radioactivity into the pigment examined. The results are shown in Tables I and II. The efficient utilization of the labelled carbon from D-glucose-1-C^{14},

‡Activity found in samples was not outside the limits of accuracy of the counting method.

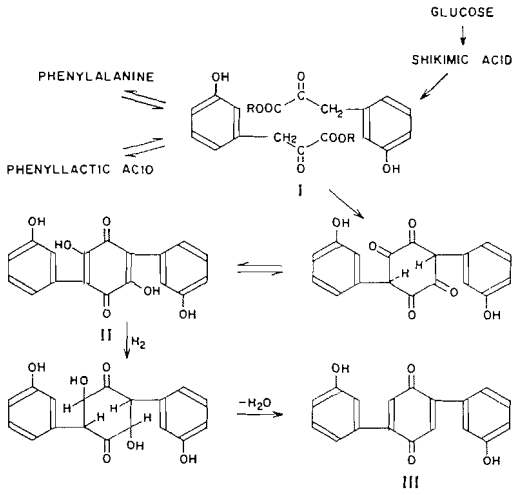
shikimic acid-G-C^{14}, L-phenylalanine-G-C^{14}, L-phenylalanine-1-C^{14}, and DL-phenyllactic acid-2-C^{14} strongly supports the view that unbranched phenylpropanoid compounds are intermediates in the biosynthesis of volucrisporin. The results suggest further that these intermediates are formed via the shikimic acid pathway and that the whole phenylpropanoid skeleton is utilized. Since acetate and glycine were relatively poor precursors of the pigment, formation of the phenylpropanoid unit by the condensation of a benzaldehyde with glycine to give the corresponding α-amino-β-hydroxy acid, as has been demonstrated in some mammalian cells (7), does not appear to be involved to an appreciable extent.

Two schemes which have been put forward (3, 8) to account for the meta hydroxylation in volucrisporin involve reactions subsequent to the formation of the terphenyl skeleton. In view of the relatively low dilution of radioactivity in the pigment produced in the presence of labelled metatyrosine, it appears more probable that hydroxylation occurs before the terphenyl skeleton is formed. Only one other instance where metatyrosine has been found to participate in a biosynthetic pathway appears to have been recorded. Winstead and Suhadolnik (9) observed that the tritium-labelled amino acid is an effective precursor of the antibiotic gliotoxin in *Trichoderma viride*. Meta-hydroxylated compounds are produced from caffeic acid and its derivatives in some mammalian tissues (10). A similar process, in which the para hydroxyl is eliminated from a 3,4-dihydroxylated intermediate, does not seem to occur in *V. aurantiaca* since neither L-tyrosine nor DL-3,4-dihydroxyphenylalanine labelled with C^{14} were found to be incorporated into volucrisporin. It would appear that certain microorganisms may be capable of the direct meta hydroxylation of phenylalanine, or a closely related compound.

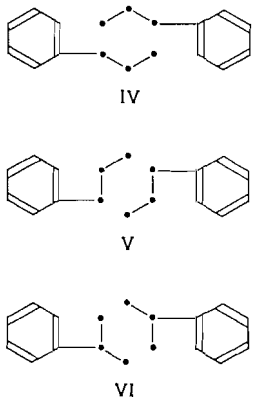
Cinnamic acid and its 3- and 3,4-hydroxy derivatives do not serve as precursors of volucrisporin. Although negative evidence of this kind must be accepted with reserve, it appears unlikely that they are biosynthetic intermediates. Phenyllactic acid, on the other hand, is incorporated almost as readily as phenylalanine. A reversible interconversion of phenyllactic acid, phenylalanine, and phenylpyruvic acid might be expected to occur (11) and, of these three compounds, it is suggested that phenylpyruvic acid is likely to be the most direct precursor of volucrisporin. Presumably it is converted to a suitably activated form of metahydroxyphenylpyruvic acid before dimerization. Derivatives of phenylpyruvic acid are more attractive as candidates for the condensing unit since, besides possessing a more highly activated methylene group, they might be expected to give rise more easily to other known terphenylquinone pigments, which all possess a 2,5-dihydroxylated quinone ring. Thus in the biosynthetic sequence for volucrisporin outlined in Scheme 1, polyporic acid (1), atromentin (12), leucomelone (13), and probably



SCHEME 1.

thelephoric acid (14) would be derived from appropriately substituted phenylpropanoid compounds by a similar pathway terminating at an earlier stage corresponding to structure II.

Degradation of the volucrisporin produced when DL-phenyllactic acid-α-C^{14}, carboxyl-labelled L-phenylalanine, and DL-metatyrosine were fed to *V. aurantiaca* gave inactive metaacetoxybenzoic acid. It is concluded that the β-carbons in the phenylpropanoid precursors remain attached to the aromatic ring during formation of the pigment, becoming carbons 2 and 5 of the benzoquinone ring. There are two ways (Scheme 2, IV and V) by which unbranched phenylpropanoid units might condense to yield a terphenyl



SCHEME 2.

skeleton. Moreover, a prior rearrangement of the carbon chain to give a branched intermediate (Scheme 2, VI) cannot be excluded, although this cannot take place by a migration of the phenyl group from the β- to the α-carbon, as in the biosynthesis of isoflavones (15). However, a rearrangement in which the carboxyl group migrates to the β-carbon as in the biosynthesis of tropic acid (16) is possible and would be difficult to detect by

degradation of the pigment since the labelling pattern would be the same as that for IV. Further work on the details of the biosynthetic process is in progress.

EXPERIMENTAL

C^{14}-Labelled Compounds

DL-Metatyrosine labelled in the carboxyl group was prepared from metahydroxybenzaldehyde and glycine-1-C^{14} by an azlactone synthesis using the procedure described by Sealock and co-workers (17). The crude product was purified by chromatography on a column of Dowex-1×8 (200–400 mesh) in the acetate form, developed with 0.1 *N* acetic acid. Crystallization of the amino acid from aqueous ethanol gave an analytically pure specimen in an overall yield of 50% based on glycine.

Metahydroxycinnamic acid-α-C^{14} was prepared by condensing metahydroxybenzaldehyde with malonic acid-2-C^{14} in the presence of pyridine as described by Pandya and Vahidy (18). The product after two crystallizations from aqueous ethanol was obtained in an analytically pure state, m.p. 197–198.5° C. The yield, based on malonic acid, was 94%.

DL-Phenyllactic acid-α-C^{14} was obtained in a yield of 65% by the action of nitrous acid on DL-phenylalanine-α-C^{14} using the method described by Wright and co-workers (19).

Shikimic acid-G-C^{14}, caffeic acid-β-C^{14}, cinnamic acid-β-C^{14} and DL-3,4-dihydroxyphenylalanine-α-C^{14} were prepared in this laboratory and kindly donated by Dr. A. C. Neish. The remaining compounds were purchased from the Atomic Energy Agency of Canada.

Culture

Experiments were carried out with two strains of PRL 1554 *V. aurantiaca*. Both were descendants of the original isolate (4). One strain was maintained in this laboratory and is referred to as PRL 1554; the other was maintained, probably under more constant conditions, in the American Type Culture Collection as ATCC 13128. It showed differences in pigmentation and manner of growth and is referred to as PRL 1952.

PRL 1554 was used in the early studies. The method of inoculation, nutrient medium, and conditions of growth were as described in a previous publication (5), except for the addition of the C^{14}-labelled compound to be tested. In a typical experiment a solution of glucose (10 g), peptone (1 g), soluble starch (0.2 g), soil extract (20 ml), and distilled water (180 ml) was dispensed in eight equal portions into 250-ml Erlenmeyer flasks and sterilized by autoclaving. Each flask was then supplemented aseptically with an aliquot (2 ml) of a filter-sterilized solution of the labelled compound,* and inoculated with a blended suspension in distilled water of *V. aurantiaca* grown on Difco potato-dextrose agar. Cultures were incubated at 25° C on a rotary shaker for 6 to 7 days.

PRL 1952 was used in later work after difficulty was encountered in obtaining adequate production of volucrisporin by PRL 1554. It gave appreciable yields of pigment on a simplified medium. In a typical experiment glucose (10 g) and peptone (1 g) were dissolved in distilled water (200 ml) and the C^{14}-labelled compound, dissolved in water (5 ml), was added. A small aliquot (2 ml) was removed for determination of the radioactivity, then aliquots of 25 ml were dispensed into 250-ml Erlenmeyer flasks, sterilized by autoclaving and inoculated with a suspension (1 ml) of washed, blended mycelium from a culture of *V. aurantiaca* grown in a glucose–peptone medium. Cultures were incubated on a rotary shaker for 11 days at 25° C.

Isolation of Volucrisporin

Appropriate cultures were pooled and filtered. The residual mycelium was washed, freeze-dried, and transferred to a Soxhlet thimble. After a preliminary Soxhlet extraction with petroleum ether (b.p. 30–60° C), it was extracted with acetone until the pigment was completely removed (3 to 6 hours). The acetone extract was dried by evaporation *in vacuo* and the residue washed successively with several portions of petroleum ether (b.p. 30–60° C), ether, and then water. The remaining deep red pigment was dried and then heated under reflux with acetic anhydride (2 ml) until completely dissolved. The orange-yellow solution was filtered while hot and water (0.5 ml) added. On cooling, yellow needles of volucrisporin diacetate separated. These were removed and recrystallized from acetic acid or a chloroform–ethanol mixture to constant melting point (219° C). Yields from 200 ml of culture medium varied between 5 and 40 mg. Measurement of radioactivity was carried out by total combustion of samples and estimation of the activity in the residual carbon dioxide in an electrometer.

Degradation of Volucrisporin

Volucrisporin acetate (2 mg) from experiments where L-phenylalanine-carboxyl-C^{14}, DL-metatyrosine-

**It was noted that glycerol, acetate, cinnamate, and phenylalanine at concentrations of 0.5 mg per ml of nutrient medium or higher severely depressed pigment formation and in some cases also the growth of the organism. Tests with various concentrations of phenylalanine showed growth to be unaffected at 1 mg per ml, but normal pigmentation was not obtained until the concentration was reduced to 0.25 mg per ml. Cinnamate gave normal growth and pigmentation at 0.08 mg per ml. At 0.25 mg per ml and above, growth was limited and no pigment was produced. The large variation in pigment yield in experiments where other C^{14}-labelled compounds were used may be attributed, at least in part, to their inhibitory effect.*

carboxyl-C^{14}, and DL-phenyllactic acid-α-C^{14} were used as precursors (Table II) was diluted with inactive carrier (60 mg) and dissolved in boiling acetic acid (5 ml). Chromium trioxide (200 mg) was added; the reaction mixture was heated under reflux for 10 minutes, then diluted with water and extracted with ether. Metaacetoxybenzoic acid (20 mg), m.p. 134° C, was obtained from the extract by sublimation, followed by crystallization from an ether – petroleum ether (b.p. 60–80° C) mixture.

In each instance the metaacetoxybenzoic acid contained no radioactivity.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Miss M. J. A. Gates and Mr. L. R. Nesbitt for expert technical assistance, and to Mr. J. Dyck for determining the radioactivity of numerous samples.

THE INFRARED SPECTRA OF N-ACYLTRIALKYLAMMONIUM HALIDES, IN RELATION TO THOSE OF AMIDE SALTS*†

DENYS COOK
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received July 19, 1962

ABSTRACT

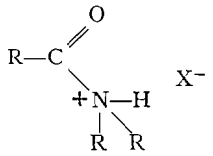
N-Acyltrialkylammonium halides have been prepared from the trialkylamine and acid halides. The ionic solids so produced can be easily handled in inert atmospheres but are easily attacked by moisture. Their infrared spectra have strong carbonyl bands near 1800 cm^{-1}, showing that the R_3N^+ group, when attached to an acyl group, has strong electron-withdrawing characteristics, to a rather greater extent than the halogens in acid halides.

Structurally, the N-acyltrialkylammonium halides would be similar to protonated (or alkylated) amides, if such protonation (or alkylation) occurred at the nitrogen atom. Since all amide salts examined hitherto have carbonyl frequencies over 100 cm^{-1} lower than 1800 cm^{-1} it is concluded that this work offers further evidence that protonation in amides occurs at the oxygen atom.

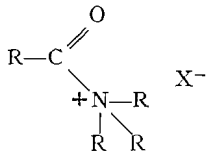
INTRODUCTION

The N-acyltrialkylammonium halides can be isolated and examined by techniques which prevent contamination by moisture. Structurally they are interesting as they represent a class of carbonyl compounds RCOX where the X group contains a formal positive charge. The effect of this charge upon the vibrational spectrum, particularly the carbonyl frequency, a group frequency very sensitive to electronic and mechanical factors, is of wide interest (1, 2).

The N-acyltrialkylammonium halides would be very similar to protonated (or alkylated) amides if such protonation (or alkylation) occurred at the nitrogen atom, as has been claimed (3–5). The structure of an N-protonated amide would be as in I. If this



I



II

nitrogen hydrogen atom were replaced by a methyl group, structure II would result. Several compounds like II have been made by low-temperature reaction of an acyl halide and a trialkylamine or a pyridine derivative. It is not possible to make compounds like I by the same method since the dialkylamine reacts to form the amide, releasing hydrogen halide, which forms the amine hydrohalide rather than the amide hydrohalide, since the amine is usually more basic. The electronic or mechanical effect of replacing hydrogen in I with methyl as in II would not be expected to be significant.

Contribution No. 70.
†*Presented, in part, at the 45th Conference of the Chemical Institute of Canada, Edmonton, Alberta, May 29, 1962.*

EXPERIMENTAL

Trimethylamine was taken from a freshly opened bottle of Distillation Products Industries anhydrous material and was used without further purification, except for bulb-to-bulb distillation from anhydrous Na_2SO_4 on a high-vacuum line. Triethylamine, from the same source, was distilled, after standing over anhydrous Na_2SO_4, and a center cut boiling at 89.7° C was taken. Pyridine, from the Fisher Scientic Company, was dried over anhydrous Na_2SO_4 several weeks, then distilled in a Todd column at a reflux ratio of 50:1, the portion boiling at 115.4° C being collected. Acetyl chloride from the J. T. Baker Company and propionyl chloride from Distillation Products Industries were both distilled as above: their boiling points were 50.3 and 77.7° C respectively.

The procedure for making the compounds was as follows. Glass cells fitted with stopcocks were filled with the appropriate amount of each component in a dry box. These cells were then attached to a high-vacuum system and the liquids outgassed in the conventional manner. Freon 113, from a previously dried and outgassed stock contained in a flask on the vacuum line, was condensed onto the less volatile component, then the more volatile component was condensed onto that, by the use of liquid nitrogen. On warming to room temperature the solid compound was precipitated and excess Freon 113 removed by evacuation. Emulsions of these solids, in Nujol and Fluorolube, were prepared in a dry box. Small samples were sealed in tubes at the same time for melting point determination.

RESULTS

Tables I and II show the bands in the various spectra, and Fig. 1 shows a spectrum of the N-acetylpyridinium chloride and of the N-acetyltrimethylammonium chloride. Spectra of N,N-dicyclohexylacetamide hydrochloride and hydrobromide are shown in Fig. 2. Some of the bands from these materials and their deuterated analogues are shown in Table III.

DISCUSSION

A strong band in the spectra of the N-acyltrialkylammonium halides at about 1800 cm^{-1} is attributed to the carbonyl stretching vibration in the salt. Its high frequency is an indication that the electron-withdrawing ability of the quaternary nitrogen atom is somewhat larger than that of the chlorine atom. Although the Taft sigma values (6)

(inductive effect alone) are not equal, $NMe_3^+ = +0.86$, and $Cl = +0.47$, the diminution in the CCCl angle in the acid halide from the theoretical sp^2 hybridization value of 120° to about 110° (2) would account for an elevation of about 30 cm^{-1} in the carbonyl frequency. Similarly, in the N-acylammonium salts some slight hindrance between the nitrogen methyl group and that on the acyl group would be relieved by enlarging the angle CCN^+, which has the effect of lowering the carbonyl stretching frequency. When rough estimates are made for these effects, the frequencies and sigma values become reasonably proportional.

Very small differences are noted between the carbonyl frequencies of N-acylpyridinium and N-acyltrialkylammonium halides. It is likely then that formal charge on the nitrogen atom blocks the transmission of mesomeric effects from the rest of the molecule to the carbonyl group.

By contrast with the high carbonyl frequency in the N-acyltrialkylammonium halides, the amide salts have no band in this region at all. Instead, most amide salts show a strong band at a frequency between 1630 and 1730 cm^{-1} depending on the amide (5, 7–10). A medium band in the region of 1750 cm^{-1} in the HCl salts only should not be confused

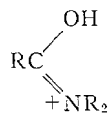
with a carbonyl vibration frequency, as this is some combination band associated with the strong band between 2000 and 2400 cm^{-1} due to the hydrogen bond. Both these bands shift in the DCl salt, and the lower-frequency band is not seen in salts with other acids. These combination bands are well known but in some cases the very high intensity of this band occurring in a region where other bands are expected could be confusing.

In the N,N-dicyclohexylacetamide salts chosen as models for discussion, the combination band is at 1764 cm^{-1}, and another strong band is present at 1626 cm^{-1}. The next strong band at lower frequency is at 1400 cm^{-1}. In the past the 1626 cm^{-1} band has been assigned to the carbonyl group stretching vibration, and since it occurred at a lower frequency than the same band in the free amide at 1647 cm^{-1}, protonation was said to occur at the carbonyl oxygen atom. In a few amide hydrochlorides studied the new band attributed to the carbonyl group absorbed at a frequency higher than the carbonyl vibration in the free amide (5, 9, 10). For example, in acetamide hydrochloride the carbonyl vibration was assigned to a band at 1718 cm^{-1} in the solid (5), whereas the free amide absorbed at 1684 cm^{-1} in the solid state. This low value is due to hydrogen bonding, and in CCl_4 solution it absorbs at 1714 cm^{-1}. On this account, the protonation was said to take place at the nitrogen atom, and it became the fashion thereafter to attribute carbonyl frequencies in the salts at a higher frequency than in the free amide to N protonation, and at a lower frequency to O protonation.

This distinction is unrealistic, as the present work on the N-acyltrialkylammonium halides shows. The absence of the 1800 cm^{-1} bands in these amide salts definitely excludes the possibility of N-protonation. As stated earlier, the difference in effect between a $HN(CH_3)_2^+$ group (in the alleged N-protonated amide) and a $N(CH_3)_3^+$ (in the N-acyltrialkylammonium halide) on the carbonyl frequency (from a purely inductive or mesomeric viewpoint) should be small. Compare, for example, the carbonyl stretching frequencies of methyl isopropyl ketone, 1722 cm^{-1}, and methyl *tert*-butyl ketone, 1711 cm^{-1}, which are isoelectronic with the compounds just discussed.

Part of the confusion in interpretation of these amide salts also arose from the habit of assuming that the highest-frequency band in the carbonyl region came from the carbonyl stretching vibration. It has recently been shown that in 2,6-dimethyl-4-pyrone the higher-frequency band of a pair at 1678 and 1639 cm^{-1} arose from a ring mode (11), while the lower-frequency band was due to the true carbonyl stretching vibration. The same situation arises in the 4-pyridones (12, 13) and probably in many others. This situation is particularly likely to arise when the carbonyl group is attached to a system containing mobile π electrons, as in the compounds just mentioned. The amides afford another example of such a system, for the NR_2 group in the amide has electrons of π symmetry which can form an extended molecular orbital over the NCO atoms. All amides whose structures have been determined by the methods of X-ray or electron diffraction have been found to have a planar or nearly planar arrangement of heavy atom, with long CO bonds and short NC (O) bonds.

It is now quite reasonable to look for carbonyl bands at much lower frequencies than hitherto thought possible, and a likely assignment is the strong band at 1400 cm^{-1}. This is in a very similar place to that found in 4-pyrone (11) and 4-pyridone (13) salts, namely, about 1490 cm^{-1}. In different amide salts it has been recorded at a range of frequencies from 1395 to 1450 cm^{-1}. This low frequency indicates that the carbonyl group has a much lower force constant, and therefore bond order, in the salt than in the free amide, and that in valence bond language a large contribution from a structure III would be expected. An equivalent statement would be that binding due to π electrons was now much greater



III

in the CN bond than in the CO bond. This leads very naturally to consideration of the assignment of the CN vibration. This must then be the band at between 1630 and 1730 cm^{-1} previously described, which is in keeping with our knowledge of the vibrational frequency of CN double bonds. In the amide salts, therefore, there is a reversal of assignments from the free amide. The amide I band is primarily CO stretching but contains some contribution from the CN stretching mode. The CN stretching vibration amide III is made up of contributions from the CO stretching mode and in secondary amides from the NH in-plane bending mode (14).

Corroborative evidence that these are the proper assignments comes from a consideration of the in-plane hydrogen bending mode of the protonated species. By replacement of HX with DX when preparing the amide salt, or by exchange with D_2O after preparation, new bands in the spectrum of the deuterated material were connected with bands which disappeared from the HX salt. Thus the band near 1280 cm^{-1} in the H salt is found near 1090 cm^{-1} in the D salt, the ratio of these frequencies being about 1.17. This low ratio indicates that a good deal of coupling takes place, probably with the CO stretching vibration. The shift of the absorption band due to this CO stretching vibration from 1400 to 1300 cm^{-1} is good evidence that these two are the coupled vibrations, though other coupling partners may also be present. Similar difficulties have been encountered in certain alcohols and phenols, and these have not yet been entirely resolved.

A comparison of the in-plane hydrogen bending frequency in the amide salts and in 4-pyrone salts (11) reveals some similarities. In 4-pyrone salts a band at 1340 cm^{-1} moves to about 1000 cm^{-1} in the deuterated species, and in the 2,6-dimethyl-4-pyrone salts the two frequencies are about 1300 and 1000 cm^{-1}. The band attributed to the carbonyl vibration is at 1490 cm^{-1}, which hardly shifts on deuteration. The ratio of the bending modes is about 1.30:1.35 and shows a fairly pure vibration. Absence of coupling is therefore inferred in the pyrone salts, and this is understandable since the two vibrations are further apart in frequency. Tertiary amine salts (15, 16) on the other hand have a hydrogen bending mode near 1420 cm^{-1} and the isotopic shift shows relative freedom from coupling in that the ratio is about 1.37.

Additional support for the assignment of the 1400 cm^{-1} band to the carbonyl stretching vibration was published recently (10). In an infrared study of propionamide hydrochloride containing O^{18}, the only band listed in the carbonyl region to show an isotopic shift was at 1487 cm^{-1} in the normal salt, and at 1480 cm^{-1} in the O^{18} salt. One other band showed a shift of 2 cm^{-1}, all others having zero shift. In the hydrobromide similar but not quite as clear-cut changes took place. In particular, a band at 1484 cm^{-1} shifted to 1479 cm^{-1} in the O^{18} salt. While these values may be slightly in doubt because of the possibility of confusion with NH bending modes, they do prove that the higher-frequency band near 1700 cm^{-1} does not move on isotopic substitution, and is therefore not associated with the oxygen atom.* They also strengthen the assignment of the protonated carbonyl group to bands in the 1400–1500 cm^{-1} region.

**This difficulty with* NH *modes was one of the reasons behind the choice of fully alkylated amides for this work.*

ACKNOWLEDGMENTS

The assistance of Miss C. D. Anderson in preparing some of the compounds and recording their spectra is gratefully acknowledged.

THE KINETICS OF THE REACTION OF ORGANIC ISOTHIOCYANATES WITH 1-OCTANOL IN *o*-DICHLOROBENZENE

YOSHIO IWAKURA AND HISAO OKADA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-Ku, Tokyo, Japan

Received June 25, 1962

ABSTRACT

The kinetics of the reaction of organic isothiocyanates with a large excess of 1-octanol in *o*-dichlorobenzene was examined at 90–140°. The rate of the reaction was first order with respect to the concentration of isothiocyanate, but the apparent second-order rate constants calculated varied according to the initial 1-octanol concentration. These facts can be explained by a reaction mechanism involving two molecules of 1-octanol in the transition state for the slow step of the reaction. The relative rate of the reaction of isothiocyanates with 1-octanol at 120° decreased in the order of benzyl, phenyl, allyl, ethyl, *n*-butyl, *n*-hexyl, isobutyl, and cyclohexyl isothiocyanate. The apparent energies of activation and log *A* were obtained as 13.5–16.5 kcal/mole and 4.65–6.46 (*A* in liter/mole min), respectively. Tributylamine had a slight catalytic effect, but dibutyltin dilaurate and ferric acetylacetonate had a strong catalytic action in these reactions.

INTRODUCTION

The addition reaction of organic isothiocyanates with alcohols gives thiourethanes:

$$R{-}N{=}C{=}S + R'{-}OH \rightarrow R{-}\overset{H}{N}{-}\overset{S}{\overset{\|}{C}}{-}O{-}R'. \quad [1]$$

Browne and Dyson (1, 2) compared the reactivity of various aromatic isothiocyanates with ethanol at its boiling point by isolating and weighing the products at different times. Zahradnik has studied the reaction of alkyl isothiocyanates with OH^- ions or alkylamines by using polarography (3, 4). It was an interesting problem for us to study the reactivity of organic isothiocyanates in the reaction with alcohols, to elucidate the mechanism of the reaction, and to determine the effective catalyst for this addition reaction.

In the present work, the kinetics of the reaction of organic isothiocyanates with a large excess of 1-octanol in *o*-dichlorobenzene at 90–140° has been studied, the reaction mechanism has been discussed, and the effect of catalysts on these reactions has been studied.

EXPERIMENTAL

Materials

Organic isothiocyanates, with the exception of commercial reagents, were synthesized in the following reactions, starting from the corresponding primary amines (5):

$$R{-}NH_2 + CS_2 + NaOH \rightarrow RNHCS_2Na + H_2O \quad [2]$$

$$RNHCS_2Na + ClCO_2C_2H_5 \rightarrow RNHCS_2CO_2C_2H_5 + NaCl \quad [3]$$

$$RNHCS_2CO_2C_2H_5 \rightarrow R{-}NCS + COS + C_2H_5OH. \quad [4]$$

The purification of the products was accomplished by fractional distillation. The boiling points observed are summarized in Table I.

Reagent grade 1-octanol was purified by fractional distillation, b.p. 87–91°/9 mm. *o*-Dichlorobenzene was dried over phosphorus pentoxide and distilled under reduced pressure, b.p. 68–75°/23 mm. Reagent grade tributylamine was dried over potassium hydroxide and fractionally distilled, b.p. 98–99°/19 mm. Free carboxylic acid was removed from commercial dibutyltin dilaurate by extraction of the latter three times with an equal volume of methanol. The slight amount of methanol remaining in the dilaurate was

TABLE I

then removed under reduced pressure at room temperature. Dibutyltin dilaurate was obtained as a slightly pale yellow liquid, m.p. 10–15°, n_D^{30} 1.4662. Ferric acetylacetonate was prepared from acetylacetone by the action of an aqueous solution of ferric chloride and sodium acetate. The product was obtained as a precipitate. On recrystallization from 60% methanol, the product was recovered as red needle-shaped crystals, m.p. 184–185°.

Procedure

The reaction vessel used was a long-necked, round-bottomed flask of approximately 50-ml capacity. A thermostat containing silicone oil (KF-96, Shin-etsu Chemical Industry Co. Ltd.) was controlled at 90–140 ±0.1° through the use of a decalin–mercury thermoregulator. Isothiocyanate or isothiocyanate–catalyst solution was prepared using a volumetric flask at a specified reaction temperature. After 1-octanol was brought to a specified temperature, a definite weight of 1-octanol was introduced into the reaction vessel. A kinetic run was initiated by adding isothiocyanate or isothiocyanate–catalyst solution to the reaction vessel and mixing rapidly. The total volume of the reaction mixture was about 30 ml in all cases. Disappearance of the isothiocyanate group was followed by a modification of the Stagg method (6) using di-*n*-butylamine in place of piperidine and titrating with 0.05 *N* hydrochloric acid – ethanol solution in the presence of bromphenol blue as indicator. Periodically 2-ml samples were pipetted from the reaction mixture and added to the 10-ml dibutylamine–acetone solution in a 100-ml glass-stoppered Erlenmeyer flask, and allowed to stand for about 30 minutes to react completely with the remaining isothiocyanate in the vessel. A blank determination on the dibutylamine solution was made at the beginning of each run.

RESULTS AND DISCUSSION

The reaction of benzyl isothiocyanate with a large excess of 1-octanol was carried out in *o*-dichlorobenzene at 100–120°. The apparent first-order rate constants were obtained by the method of least squares using the following equation:

$$\log [\text{concn. of R—NCS at time } t] = \log [\text{init. concn. of R—NCS}] - (k/2.303)t. \qquad [5]$$

The typical plot of equation [5] is shown in Fig. 1. From these plots the rate of reaction was shown to be apparently first order with respect to the concentration of isothiocyanate, and these results are summarized in Table II. If the reaction velocity is first order with respect to the concentration of isothiocyanate and 1-octanol respectively, the apparent second-order rate constants which were calculated by dividing the apparent first-order rate constants by the concentration of 1-octanol should show a constant value regardless of the concentration of 1-octanol. The second-order rate constants obtained in this experiment, however, varied according to the initial concentration of 1-octanol (see the last column in Table II). To compare the reactivity of several isothiocyanates, the reaction of the isothiocyanate (1 mole) with 1-octanol (35 moles) in *o*-dichlorobenzene was examined at 90–140°. The results are listed in Table III as the apparent second-order rate constants.

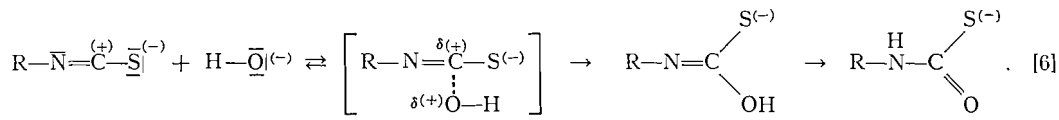
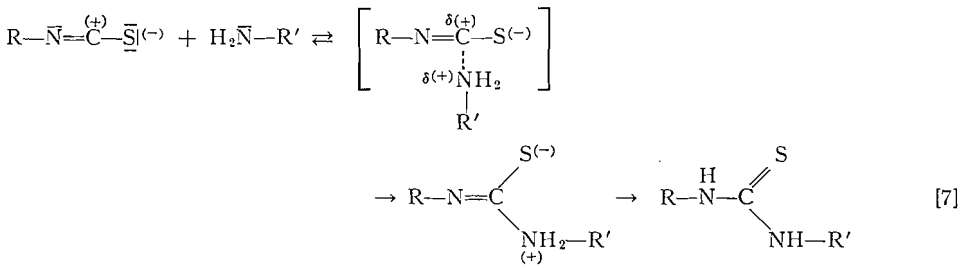
1-octanol at 120° decreased in the order of benzyl, phenyl, allyl, ethyl, *n*-butyl, *n*-hexyl, isobutyl, and cyclohexyl isothiocyanate. Reproducible results could not be obtained for the reaction of 1-octanol with *t*-butyl isothiocyanate.

In the reaction of isothiocyanates with a large excess of OH^- ion, the second-order rate constants which were calculated by dividing the apparent first-order rate constants obtained by the concentration of OH^- ion became almost constant, and a first-order decomposition mechanism of the complex has been proposed (3):



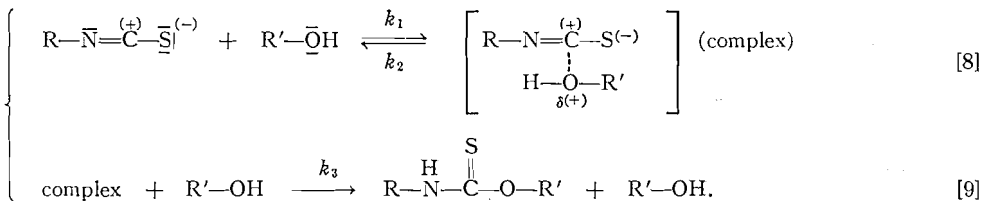
[6]

In the case of the addition reaction with a large excess of alkylamines, a similar reaction mechanism has been proposed (4):



[7]

In the reaction of isothiocyanates with 1-octanol in *o*-dichlorobenzene, however, the simple second-order rate equation was not applicable. The values which were obtained as second-order rate constants did not become constant and varied according to the initial concentration of 1-octanol. Accordingly, the most probable mechanism is considered to be a bimolecular decomposition of the complex, that is, the reaction proceeds through the interaction of the complex with the 1-octanol molecule:



[8]

[9]

This reaction mechanism is similar to that of the reaction between organic isocyanates and alcohols (7, 8). Assuming a steady-state concentration of the complex in this kinetic scheme, the following equation was obtained:

$$\frac{d[\mathrm{RNHC(S)OR'}]}{dt} = \frac{k_1k_3[\mathrm{R{-}NCS}][\mathrm{R'{-}OH}]^2}{k_2+k_3[\mathrm{R'{-}OH}]}. \qquad [10]$$

The apparent second-order rate constants (k_{obs}) may now be related to the initial concentration of 1-octanol by the equation

$$k_{obs} = \frac{k_1k_3[\mathrm{R'{-}OH}]}{k_2+k_3[\mathrm{R'{-}OH}]}, \qquad [11]$$

$$\frac{1}{k_{obs}} = \frac{1}{k_1} + \frac{k_2}{k_1k_3[\mathrm{R'{-}OH}]}. \qquad [12]$$

If the assumed mechanism of equations [8] and [9] is consistent with the experimental results, a linear relationship between the values of $1/k_{obs}$ and $1/[\mathrm{R'{-}OH}]$ should be realized. The results of Table II are plotted in Fig. 2. As shown in Fig. 2, the linear

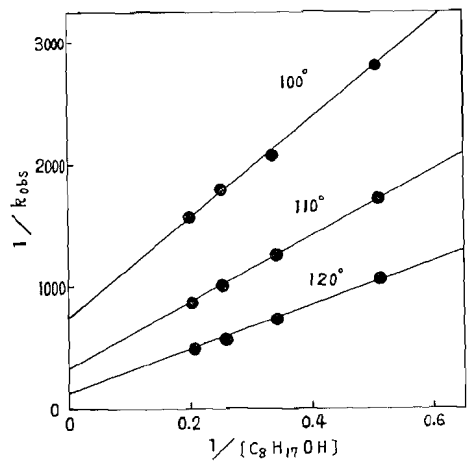


FIG. 2. Relationship between the apparent second-order rate constant and the initial concentration of 1-octanol in the reaction of benzyl isothiocyanate with 1-octanol in *o*-dichlorobenzene.

relationship is suitable, and this fact indicates that the presumed kinetic scheme and the derived kinetic equations are adequate. The individual rate constants k_1, and k_2/k_3, can be obtained as the intercept and the slope of these lines. The results are summarized in Table V. In the reaction of benzyl isothiocyanate with 1-octanol, the rate constant k_2 is larger than k_3 within the observed temperatures.

To examine the catalytic effect of tertiary amines and organometallic compounds in the reaction of isothiocyanates with alcohols, first the reaction of phenyl isothiocyanate with 1-octanol in the presence of tributylamine and then the reaction of ethyl isothiocyanate with 1-octanol in the presence of dibutyltin dilaurate or ferric acetylacetonate were investigated in *o*-dichlorobenzene at 120°.

coefficient is generally expressed in the following way:

$$k_{obs} = k_{0,\,obs} + k_c[\text{tributylamine}], \qquad [13]$$

where $k_{0,\,obs}$ is the apparent second-order rate constant in the absence of tributylamine and k_c is the catalytic coefficient. The values of k_c obtained are not constant, and decrease

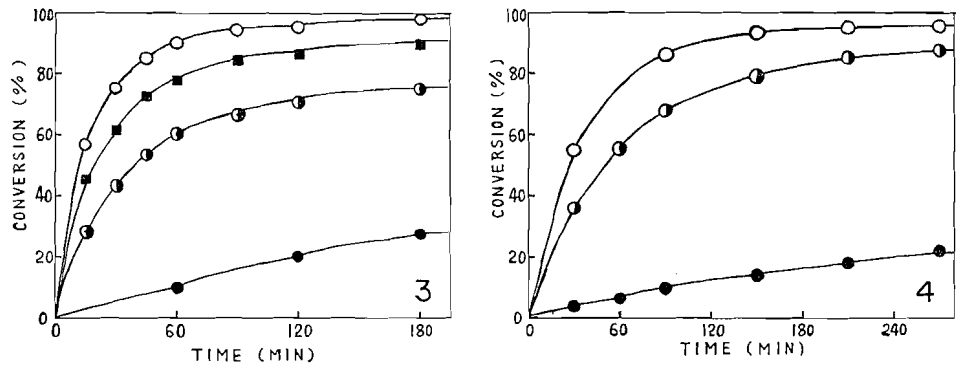

FIG. 3. Catalytic effect of dibutyltin dilaurate in the reaction of ethyl isothiocyanate with 1-octanol in *o*-dichlorobenzene at 120°. Initial concentration of ethyl isothiocyanate: 0.105 mole/liter; initial concentration of 1-octanol: 4.845 mole/liter; concentration of dibutyltin dilaurate: ● None, ◑ 0.0020, ■ 0.0040, ○ 0.0060 mole/liter.

FIG. 4. Catalytic effect of ferric acetylacetonate in the reaction of ethyl isothiocyanate with 1-octanol in *o*-dichlorobenzene at 120°. Initial concentration of ethyl isothiocyanate: 0.105 mole/liter; initial concentration of 1-octanol: 2.907 mole/liter; concentration of ferric acetylacetonate: ● None, ◑ 0.000269, ○ 0.000538 mole/liter.

as the concentration of tributylamine increases. This phenomenon may be explained by the Burkus hypothesis (9). The result shows that tributylamine had a slight catalytic effect in this reaction.

The catalytic actions of dibutyltin dilaurate and ferric acetylacetonate in the reaction of ethyl isothiocyanate with excess 1-octanol in *o*-dichlorobenzene at 120° were investigated. As shown in Figs. 3 and 4, these organometallic compounds have a strong catalytic action in this reaction; however, equation [5] was not applicable. More detailed kinetic evidence has not been obtained up to the present, and further work in this direction is in progress with a number of organometallic compounds.

THE PREPARATION OF SUCROSE MONOESTERS*

R. U. LEMIEUX† AND A. G. MCINNES‡
Department of Chemistry, University of Ottawa, Ottawa, Ontario

Received July 16, 1962

ABSTRACT

The Snell procedure for the preparation of sucrose monoesters of the higher saturated fatty acids by transesterification of sucrose and methyl esters in N,N-dimethylformamide was found to yield variable results due to the use of solid potassium carbonate as catalyst and to impurities in the solvent. A kinetic study of the reaction revealed that yields of sucrose ester and rates of reaction were reproducible when conditions for homogeneous catalysis were established. The reaction followed first-order kinetics in methyl ester and sucrate ion and the rate of reaction was essentially independent of the sucrose concentration, the molecular weight of the fatty acid, and the nature of the metal sucrate used to catalyze the reaction. The activation energy for the reaction was 9.9 kcal mole^{-1}. Equilibrium constants for the principal reactions were determined, and it was established that only the thermodynamic product prevailed at any time throughout the transesterification reaction. A preparative method for the synthesis of sucrose monoesters was developed that gave yields of sucrose ester, based on the amount of methyl ester which had reacted, which were essentially quantitative. The product contained about 20% of di- and 80% of mono-ester.

INTRODUCTION

In 1954 Snell and co-workers developed a process for the preparation of fatty acid esters of sucrose (1) using the transesterification reaction, which was subsequently published in 1956 (2). The procedure was based on the reaction of sucrose with the methyl ester of a fatty acid, in N,N-dimethylformamide (DMF) solution, using solid potassium carbonate as a catalyst. The methanol formed in the reaction was removed *in vacuo* under conditions for fractional distillation. This process attracted considerable interest from industry as a means for the preparation of sucrose monoesters of the higher fatty acids for use as low-cost, non-ionic detergents (3, 4).

The elucidation of the structures of the sucrose monoesters formed and the determination of their relative amounts in the products obtained first attracted our attention to this process. However, when an attempt was made to prepare samples of sucrose monoester, by the original Snell procedure (2), for structural analysis, it soon became apparent that the product did not warrant such an investigation since it could not be prepared under fully controlled and reproducible conditions. For unknown reasons, highly variable yields were obtained and the products differed considerably in the degree of substitution, solubility, and color even when the reaction was performed under apparently identical experimental conditions (5). Although other workers have claimed more success in this respect a critical assessment of their results clearly indicates that they have been equally unsuccessful in preparing reproducibly a product in high yield (2, 6–8). Furthermore, the conclusions which the various workers have drawn (2, 6–11) from their experimental results are often in conflict, and in direct opposition to modern concepts on the mechanism of transesterification reactions. Snell and co-workers, for example, have claimed that sucrose monoester was esterified so much faster than sucrose that higher-substituted esters of sucrose accumulated in the first stage of the reaction and subsequently reacted with the excess sucrose to re-form sucrose monoesters (2). They also concluded that the concentration of sucrose monoester in the final product was

*This paper was submitted by A. G. McInnes as a portion of a thesis for the Ph.D. degree.
†Present address: Department of Chemistry, University of Alberta, Edmonton, Alberta.
‡Present address: Atlantic Regional Laboratory, National Research Council, Halifax, Nova Scotia.

dependent on the amount of solvent (DMF) in which the reaction was carried out (2), and on the concentration of water in the reaction solution (6). Moreover, their results indicated that the only effect of increasing the catalyst concentration was to increase the soap content in the product of reaction (2). Workers at the Herstein Laboratories (7, 8), on the other hand, have claimed that the sucrose monoester content was dependent on the catalyst concentration and was independent of the moisture content in the reaction solution. The latter workers also claimed that the cation of the catalyst chelates with the sucrose molecule, and that it was this chelate complex which was the effective catalyst in the reaction. They concluded that different cations produced a product with different sucrose mono- to di-ester ratio, and have suggested that this is in some way related to the ionic radius of the cation (7). For example, it was claimed that lithium produced only sucrose monoester whereas potassium produced sucrose diester also. This specificity was attributed to the fact that lithium, which has a smaller ionic radius than potassium, cannot form a chelate with two hydroxyl groups at the same time, in contrast to potassium (7). Furthermore, the sucrose diester concentration was found to increase with increasing cation–sucrose complex concentration (7, 8), at least for those catalysts with the necessary ionic radius. Herstein and his co-workers have also claimed that an equilibrium exists between sucrose, sucrose diester, and sucrose monoester in the reaction solution (7). In spite of this observation, however, they evaluated the optimal conditions for the transesterification reaction by orthogonal statistical design (7, 8), and reached the conclusion that although an equilibrium existed between sucrose, sucrose diester, and sucrose monoester, the concentration of the latter passed through a maximum with increasing sucrose concentration and then decreased with a further increase in the sucrose concentration. Komori and co-workers (9, 11) have reported that the rate of transesterification was dependent on the sucrose concentration.

In contrast to the above conclusions, mechanistic studies have established that transesterifications are reversible reactions (12) which exhibit first-order kinetics in ester and alkoxide ion (13). In view of the apparent contradictions and the important role the conditions for transesterification by the Snell procedure promise to have in carbohydrate chemistry, it was decided to conduct a careful kinetic study of the reaction and to determine the equilibrium constants for the principal reactions.

EXPERIMENTAL AND RESULTS

Materials

In all experiments the DMF was distilled from phosphorus pentoxide, and only the fraction boiling at 153–154° at atmospheric pressure was used. The sucrose, $[\alpha]_D$ +66.50 (*c*, 22; water), was stored over phosphorus pentoxide under reduced pressure. The methanol was dried by distillation from magnesium methoxide. The methyl myristate, methyl palmitate, and *n*-octadecane each had a purity greater than 99.5 mole% when analyzed by gas–liquid partition chromatography (GLPC). The methyl stearate contained 9.0 mole% of methyl myristate, methyl palmitate, and an unidentified ester having a retention volume corresponding to that expected for a C_{17} fatty acid methyl ester. Since these methyl esters contained no free fatty acid they were used without further purification. *n*-Octadecane was soluble to the extent of 4.5 g/300 ml of reaction solution at 80°. All other solvents were reagent grade.

Methyl myristate was used in all reactions unless otherwise specified.

Rate Measurements

All rates of reaction were determined by following the decrease in concentration of the methyl ester of a fatty acid by GLPC (14) using *n*-octadecane as an internal standard. The apparatus used for the analyses was a "Pye Argon Chromatograph", and some of the pertinent characteristics are listed below:

Column size, 4 ft, 5-mm I.D.	Resolution, up to 1000 theoretical plates/ft
Detector, ionization (80 μc radium D)	Limit of detection, 0.01 γ
Carrier gas, argon	Column packing, Celite 545:Apiezon 17 (9:1, w/w)
Sample size, 3–6 γ	Column temperature, 200° C

The calibration of apparatus is shown in Fig. 1 and the retention volumes at 200° of the methyl esters of myristic, palmitic, and stearic acids, relative to that (1.0) of *n*-octadecane, were 0.57, 1.38, and 3.22, respectively.

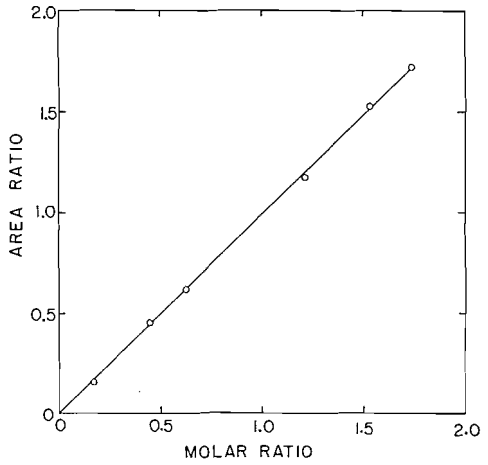

FIG. 1. The plot of the ratio of the areas obtained for standard mixtures of methyl-myristate and *n*-octadecane when analyzed by gas–liquid partition chromatography against the known molar ratio.

Standard Transesterification Reaction Conditions

The transesterification apparatus is shown in Fig. 2.

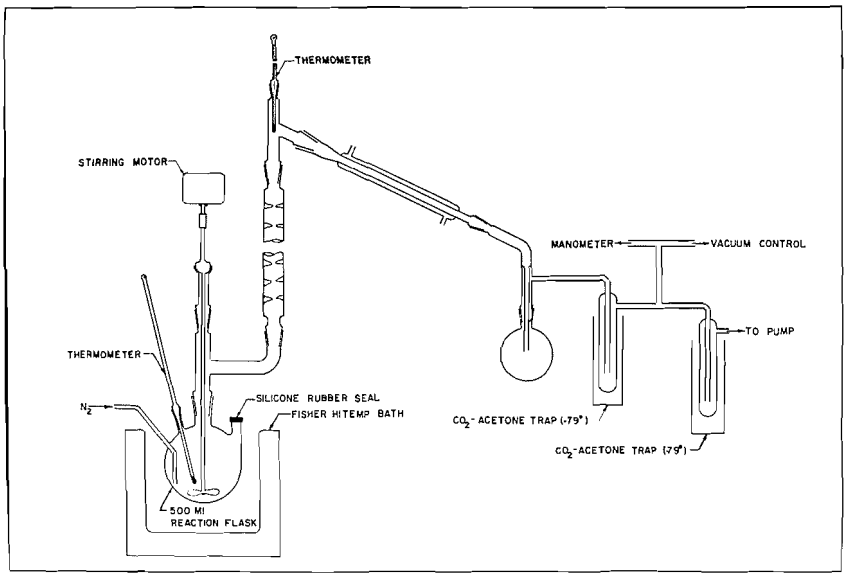

FIG. 2. The transesterification apparatus.

An attempt was made to remove the last traces of water from the reaction solution by conditioning the reactants in the following manner. Sucrose, 60 mmole, was dissolved in 300 ml of anhydrous DMF and conditioned at 80±0.5° at 75 mm pressure for 30 minutes. The oil-bath temperature was 89±1°, and the reaction solution was stirred mechanically and had a fine stream of dry nitrogen passing through it. A 50-ml volume of petroleum ether containing 20 mmole of methyl ester and 12.75 mmole of *n*-octadecane was then added to the DMF solution, and the petroleum ether was removed rapidly under reduced pressure. After 30 minutes the reaction solution temperature was again constant at 80° at 75 mm pressure. A

0.6-ml aliquot of the DMF solution was then taken and analyzed by GLPC (see below). The catalyst was then added to the reaction solution as a solid or as a methanolic solution at atmospheric or 75 mm pressure, respectively. In the former case a reaction temperature of 80° at 75 mm pressure was established as quickly as possible, and in the latter case the catalyst solution was injected into the reaction solution with a hypodermic syringe through the silicone rubber seal on the reaction vessel (see Fig. 2) while the apparatus was under reduced pressure. During the course of the transesterification reaction the temperature at the top of the Vigreaux column remained constant at 29±1°. The reaction solution had a total volume of 320 ml.

The progress of the reaction was followed by withdrawing at intervals of time 0.6-ml aliquots of the reaction solution, by means of a hypodermic syringe fitted with a 3-inch needle, through the silicone rubber seal (see Fig. 2) without disturbing the vacuum in the apparatus. These solutions were diluted with 0.6 ml of a 5% sodium chloride solution and the methyl ester and *n*-octadecane were extracted with 0.5-ml amounts of a 3:1 petroleum ether/ether solution. A 0.1-μl aliquot of the latter was then analyzed by GLPC. When standard mixtures of methyl myristate and *n*-octadecane in a 0.2 *M* solution of sucrose in DMF were analyzed in this manner the results were identical with those obtained using petroleum ether solutions of the compounds for calibration (see Fig. 1).

The yields of sucrose ester at the end of the reaction period were obtained, in duplicate, on 25-ml aliquots of the reaction mixture. Each aliquot was first cooled to 20° by the addition of solid carbon dioxide, and the *n*-octadecane and unreacted methyl ester were removed quantitatively by extracting the DMF solution with three 50-ml aliquots of petroleum ether. The DMF solution was then taken to dryness at 70° under reduced pressure and the residue was dissolved in 25 ml of *n*-butanol. The latter was washed with two 25-ml volumes of 5% sodium chloride solution to remove the catalyst (in the form of a metal carbonate) and unreacted sucrose, and the combined aqueous phase was re-extracted with 15 ml of *n*-butanol. Any sodium chloride in the combined *n*-butanol phase was precipitated by the addition of 40 ml of chloroform. After drying of the chloroform/*n*-butanol solution with 10 g of anhydrous sodium sulphate overnight the salts were removed by filtration, the latter being washed with a further 40 ml chloroform. The filtrate was taken to dryness under reduced pressure. Ethanol was then added and the mixture was evaporated in order to remove the last traces of *n*-butanol and DMF. The white residue of sucrose ester was dried under reduced pressure over phosphorus pentoxide.

The percentage yields of sucrose ester were based on the complete conversion of 20 mmole of methyl ester to sucrose monomyristate (denoted P) or on the amount of methyl myristate which had reacted (denoted P_I).

Routine Tests for the Presence of Impurities in the Sucrose Ester

The sucrose ester, 50 mg, was dissolved in 1 ml chloroform at room temperature. In the absence of sucrose and sodium chloride a clear solution free of insoluble residue was obtained. A 0.1-μl aliquot of the above chloroform solution was analyzed by GLPC for methyl ester and *n*-octadecane. An infrared spectrum of the above chloroform solution was taken. The presence of DMF or the anion of a fatty acid could be detected since they have characteristic absorptions, for the C=O stretching vibration, at approximately 1680 and 1560 cm^{-1}, respectively. An aqueous solution of the sucrose ester was also tested for chloride ion with silver nitrate.

All the samples of sucrose ester prepared using the above standard procedure gave negative results for these tests.

The Transesterification Reaction Using Solid Potassium Carbonate

The standard transesterification reaction conditions were used, and 4 meq of solid potassium carbonate were added to catalyze the reaction. Furthermore, the reaction was carried out (*a*) without mechanical stirring or nitrogen passing through the solution, (*b*) without mechanical stirring and with nitrogen passing through the solution, (*c*) with mechanical stirring and nitrogen passing through the solution, and (*d*) with the same reaction conditions as (*c*) except that the potassium carbonate had been impregnated on 1 g of Celite by admixing a 1-ml aliquot of an aqueous solution of potassium carbonate with 1 g of acid-washed Celite and drying the mixture at 180° for 48 hours before use.

Results for single experiments satisfying the above experimental conditions are given in Fig. 3. Reaction solutions (*a*), (*b*), (*c*), and (*d*) gave values of 41.2, 70.7, 87.8, and 79% for P after 7, 24, 7, and 4 hours, respectively. The corresponding values for P_I were 71.1, 70.5, 87.8, and 82.8%. Considerable variations in the rates of reaction and yields of sucrose ester were obtained when attempts were made to reproduce these results in duplicate experiments. Moreover, it was observed that all the solid potassium carbonate did not dissolve in any of the experiments. It was apparent that variable amounts went into solution.

The Effect of Water on the Transesterification Reaction at 80° using Solid Potassium Carbonate as Catalyst

The reaction conditions in (*c*) above were used.

The initial concentration of water in the reaction solutions were 0.01, 0.05, 0.25, and 1.25%, which corresponded to the addition of 0.42, 2.10, 10.5, and 52.5 mmole of water per meq of solid potassium carbonate. The water was added to the reaction solution after the usual 1-hour conditioning period, and

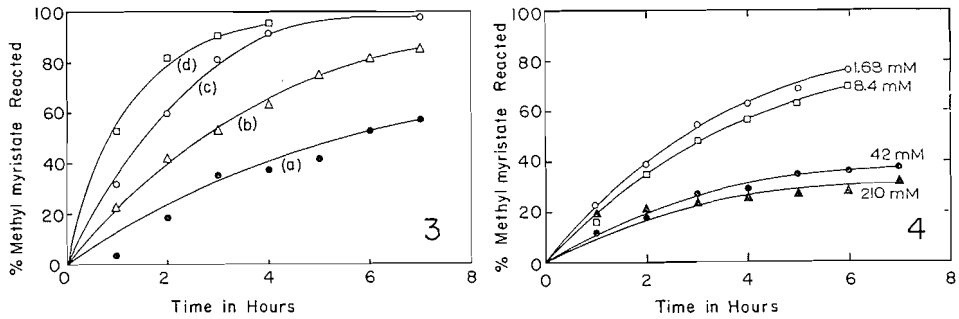

FIG. 3. Rates of transesterification at 80° using 4 meq of solid potassium carbonate as the catalyst. The reaction solutions were stirred mechanically in (*c*) and (*d*). A stream of nitrogen was passed through the solution in (*b*), (*c*), and (*d*). The catalyst in (*d*) was impregnated on Celite.

FIG. 4. The effect of adding 1.68, 8.4, 42, and 210 mmole of water on the rate of transesterification at 80°, using 4 meq of solid potassium carbonate as the catalyst. The reaction solutions were stirred mechanically, and scrubbed with a stream of nitrogen.

at the same time as the catalyst. The potassium carbonate did not dissolve completely in any of these experiments.

The effect of water on the rate of reaction is shown in Fig. 4. Yields of sucrose myristate of 82.2, 81.5, 31.0, and 32.3% for P, and 93.8, 87.7, 66.5, and 93.5% for P_I were obtained for the experiments containing 0.42, 2.10, 10.5, and 52.5 mmole of water, respectively.

Transesterification Reactions using Sodium Hydride and Saturated Solutions of Potassium Carbonate

The transesterification reaction was carried out in the usual manner using DMF or DMF plus sucrose solutions saturated with potassium carbonate. These solutions were prepared by heating 300 ml of DMF, or 300 ml of DMF containing 60 mmole of sucrose, with 4 meq of solid potassium carbonate at 80° for 18 and 6 hours, respectively. After removal of any solid material, by filtration, under anhydrous conditions, the filtrate was used for the transesterification reaction. Titration of aliquots of the DMF solution containing only potassium carbonate revealed that it was 0.0014 N in potassium ion. The latter solution gave only 9.9% reaction in 4 hours, and gave sucrose myristate values of 9.5 and 96.2% for P and P_I, respectively. The DMF plus sucrose solution of potassium carbonate, on the other hand, gave 56.0% reaction in 6 hours, and gave yields of sucrose myristate of 48.4 and 86.3% for P and P_I, respectively.

Another transesterification reaction carried out using 300 ml DMF, 60 mmole sucrose, 20 mmole methyl myristate, and 4 meq sodium hydride at 80°, at 190 mm pressure, on a rotary evaporator, gave 52% reaction in 6 hours, and sucrose myristate yields of 40.8 and 78.5% for P and P_I, respectively.

The Transesterification Reaction under Conditions for Homogeneous Catalysis

The yields of sucrose myristate as well as the rates of reaction are given in Table I.

All of the reactions reported in Table I were carried out in homogeneous solution at 80° under identical conditions of pressure and mechanical stirring, and with nitrogen bubbling through the reaction solution. In order to obtain homogeneous reaction conditions the catalyst (4 meq) was added to the reaction solution as a dilute solution in 5 ml anhydrous methanol or as a saturated methanolic or aqueous solution. Potassium carbonate, potassium methoxide, lithium methoxide, sodium methoxide, and potassium hydroxide were all used to catalyze the reaction.

The Effect of Sucrose Concentration on the Rate of Reaction at 80°

The rates for the standard transesterification reaction together with the yields of sucrose myristate are given for three concentrations of sucrose, namely 60, 40, and 20 mmole, respectively, in Table II. A saturated methanolic solution of potassium methoxide containing 4 meq of the latter in 0.68 ml solution was used as catalyst.

The Effect of Fatty Acid Chain Length on the Rate of Reaction at 80°

Potassium methoxide, 4 meq, in 5 ml anhydrous methanol was used to catalyze the reactions. The data for the three methyl esters are given in Table III. The pseudo first-order rate constants for the standard transesterification reaction using methyl myristate, methyl palmitate, and methyl stearate were found to be 3.33, 3.17, and 2.96×10^{-4} sec^{-1}, respectively.

The Effect of Gaseous Carbon Dioxide on the Rate of Transesterification at 80°

The standard transesterification reaction conditions were used except that gaseous carbon dioxide was passed through the solution for 150 minutes, and then replaced by a stream of nitrogen for a further 130

minutes. Potassium carbonate, 4 meq, in 5 ml of anhydrous methanol was used as catalyst under conditions for homogeneous catalysis. After 150 minutes the sucrose myristate yield was 19.3 and 89.0% for P and P_I, respectively, whereas after 280 minutes the corresponding values for P and P_I were 84.7 and 88.6%, respectively.

The depression of the rate of reaction by gaseous carbon dioxide is shown graphically in Fig. 5.

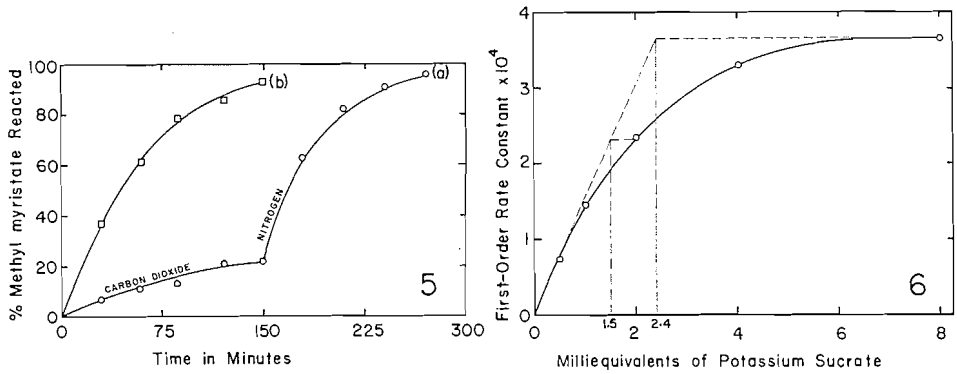

FIG. 5. Rates of transesterification reaction at 80° using 4 meq of potassium carbonate under conditions of homogeneous catalysis. In (*a*) streams of carbon dioxide and nitrogen were passed successively through the solution, whereas in (*b*) only nitrogen was used.

FIG. 6. The plot of the pseudo first-order rate constants for the standard transesterification reaction at 80° against the potassium sucrate concentration in 320 ml of reaction solution.

The Effect of Catalyst Concentration on the Rate of Transesterification at 80°

The standard transesterification reaction conditions were used except that 0.5, 1.0, 2.0, 4.0, and 8.0 meq of potassium methoxide in 5 ml of anhydrous methanol were used as catalyst, respectively. A precipitate of potassium sucrate was present during the entire reaction when more than 4 meq of potassium ion were used.

The plot of the pseudo first-order rate constants for the reactions at the different catalyst concentrations versus the catalyst concentrations is given in Fig. 6.

The Effect of Temperature on the Rate of Transesterification

The standard transesterification reaction was carried out at 80° (at 75 mm pressure) and 97° (at 140 mm pressure), respectively. Potassium methoxide, 2 meq, in 5 ml methanol was used as a source of catalyst. The pseudo first-order rate constants calculated for the data obtained at 80° and 97° and plotted in Fig. 7 were 2.36×10^{-4} and 4.51×10^{-4} sec^{-1}, respectively. Calculation by means of the Arrhenius equation (15) gave a value of 9.9 kcal $mole^{-1}$ for the energy of activation.

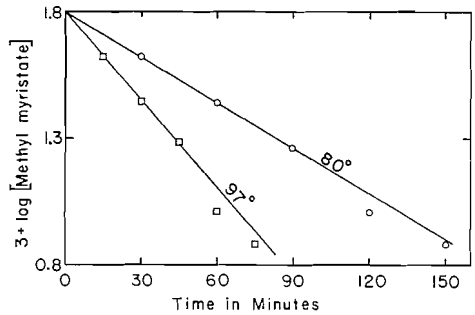

FIG. 7. The plot of the logarithm of the methyl myristate concentration against time for the standard transesterification reaction, at 80° and 97°, using 2 meq of potassium sucrate as catalyst.

Isolation of Sucrose Mono- and Di-myristate

Three standard transesterification reactions were carried out at 80° in the absence of *n*-octadecane and the sucrose myristate from the experiments combined. Four milliequivalents of potassium methoxide in 0.68 ml of anhydrous methanolic solution was used as catalyst. The products of the reaction were isolated by taking each reaction solution to dryness, at 70°, on a rotary evaporator, at the end of the reaction period of 150 minutes. The residue was then partitioned between *n*-butanol and 5% sodium chloride and the crude sucrose ester isolated as described above. The combined crude product weighed 26.57 g. The latter was then chromatographed on 250 g silicic acid (Mallinckrodt) using graded elution with methanol/

chloroform solutions. As the chromatogram developed the constituents were visible against a translucent background. The separation was also followed by taking infrared spectra of aliquots of the eluant. In this way it was possible to isolate three fractions containing methyl myristate, sucrose dimyristate, and sucrose monomyristate, as shown in Table IV.

TABLE IV

Chromatographic separation of sucrose myristates on silicic acid

Fraction	Solvent	Volume of solvent (ml)	Weight of fraction (g)	Compound*
I	Chloroform	2000	0.80	Methyl myristate
II	10% methanol/chloroform	250	7.95	Dimyristate
III	10% methanol/chloroform	1400	17.60	Sucrose monomyristate

*The residue from fraction I was actually collected in the first 700 ml of eluant and its infrared spectrum was identical with that of an authentic sample of methyl myristate.

The sucrose monomyristate (17.6 g) was precipitated from 100 ml acetone at −5° to yield 15.6 g of pure sucrose monomyristate as a white amorphous solid, m.p. 180–186°; $[\alpha]_D$ +36.7° (*c*, 4.8% in chloroform); saponification equivalent, 549 (theory, 552). Anal. calc. for $C_{28}H_{48}O_{12}$: C, 56.50%; H, 8.70%. Found: C, 56.36%; H, 8.63%.

The sucrose dimyristate (7.95 g) was precipitated first from methanol and then from acetone to yield 6.05 g sucrose dimyristate as a white amorphous solid, m.p. 139–145°; $[\alpha]_D$ +29.7° (*c*, 5.2% in chloroform); saponification equivalent, 376 (theory, 381). Anal. calc. for $C_{40}H_{74}O_{13}$: C, 63.0%; H, 9.77%. Found: C, 63.39%; H, 9.91%.

The infrared spectra for sucrose mono- and di-myristate were consistent with those expected for a mono- and di-fatty acid ester of a polyhydric alcohol. The two esters showed considerable differences in the relative intensities of the OH stretching and C=O stretching vibrations at 3500 and 1725 cm^{-1}, respectively, which could be used as a means of identification.

Determination of the Equilibrium Constant K_1

The equilibrium constant K_1 for the reaction

$$\text{sucrose} + \text{sucrose dimyristate} \rightleftarrows 2 \text{ sucrose monomyristate}$$

was estimated as follows at two different concentrations of sucrose.

Sucrose, 1 mmole, was dissolved in 15 ml anhydrous DMF at 80°, and 0.2 meq of potassium methoxide in 0.2 ml methanolic solution was added. The potassium sucrate which precipitated was redissolved by the addition of 5 ml anhydrous methanol and the solution was taken to dryness under reduced pressure. The residue was dried, under reduced pressure over phosphorus pentoxide, for 2 hours. Pure sucrose monomyristate, 1 mmole, was then added to the residue of sucrose and potassium sucrate, and the mixture was dissolved in 15 ml anhydrous DMF. The homogeneous reaction solution was at a temperature of 80° for 90 minutes. Care was taken at all times to exclude moisture from the reaction solution. At the end of t is period the catalyst was neutralized by the addition of 1 ml of a DMF solution containing 0.2 meq of potassium hydrogen phthalate. After taking the solution to dryness under reduced pressure, the sucrose myristates were isolated in the manner described above. Chromatography of the sucrose myristates (466.9 mg) on 10 g silicic acid using graded elution with methanol/chloroform solutions yielded 336.9 mg (0.61 mmole) of sucrose monomyristate, and 124.7 mg of sucrose "dimyristate". The separation was followed by comparing the infrared spectra of the sucrose ester in 5-ml fractions of the eluant from the chromatographic column with the infrared spectra of pure sucrose mono- and di-myristate. Seventeen fractions of 5% methanol/chloroform and 15 fractions of 10% methanol/chloroform were collected. The first 20 fractions contained sucrose dimyristate and the last 10 fractions contained sucrose monomyristate. The two intermediate fractions contained no sucrose ester, indicating that a complete separation of sucrose monomyristate from sucrose di- and higher myristates was achieved. On the assumption that only mono- and di-esters were formed, the yield of ester was 94%.

A second experiment, carried out under identical experimental conditions except that only 0.5 mmole of sucrose was used initially, yielded 434.0 mg of sucrose myristate. Chromatography of a sample of the latter (420.0 mg) on 10 g silicic acid, as described above, yielded 152.0 mg (0.199 mmole) of sucrose dimyristate and 267.0 mg (0.483 mmole) of sucrose monomyristate. The relative intensities of the hydroxyl and carbonyl stretching vibrations clearly indicated the product to contain some tri- and higher esters. On the assumption that only mono- and di-esters were formed, the yield of ester was 88%.

An estimate of the equilibrium constant, K_1, for the reaction

$$\text{sucrose} + \text{sucrose dimyristate} \rightleftarrows 2 \text{ sucrose monomyristate}$$

can be made using the above results and the assumption that only mono- and di-esters were formed. On this basis, the yields of the esters are corrected to 100% in order to use the following expression to calculate the equilibrium constant:

$$K_1 = [\text{sucrose monomyristate}]^2/[\text{sucrose}][\text{sucrose dimyristate}]$$
$$= 4M^2/(2Y-Z-M)(Z-M), \quad [1]$$

where M = moles of sucrose monomyristate at equilibrium, Y = total moles of sucrose in the system, and Z = total myristoyl groups in the system.

In the first experiment, $M = 0.61\times100/94 = 0.65$, $Y = 2$, and $Z = 1$; therefore $K_1 = 2.0$. In the second experiment, $M = 0.483\times100/88 = 0.55$, $Y = 1.5$, and $Z = 1$; therefore, $K_1 = 1.8$.

In all subsequent calculations a value of $K_1 = 2$ was assumed, since the error, introduced by ignoring the presence of higher-substituted sucrose myristates, was less for this value.

The Rate of Equilibration of C^{14}-Labelled Sucrose with Sucrose Mono- and Di-myristate

Uniformly C^{14}-labelled sucrose, 0.495 mmole, was equilibrated with 0.466 mmole of pure sucrose monomyristate, at 80°, in anhydrous DMF using 0.1 meq of potassium methoxide as catalyst. The reaction solution had a total volume of 5.5 ml and the procedure for preparation of the solutions was identical with that described above for the solutions used to determine the equilibrium constant K_1. Aliquots, 1 ml, of the reaction solution were taken at intervals of 10, 30, 45, and 65 minutes and the solvent removed rapidly (3 minutes) under reduced pressure. The residue was extracted with three 2-ml aliquots of chloroform and the combined chloroform extract was transferred quantitatively to a small chromatographic column containing 1 g silicic acid in chloroform. Elution with 25 ml 10% methanol/chloroform followed by removal of the solvent, under reduced pressure, yielded C^{14}-labelled sucrose myristates uncontaminated with C^{14}-labelled sucrose. The chromatographic procedure for isolating the C^{14}-labelled sucrose myristates was established by taking synthetic mixtures of sucrose monomyristate and sucrose di-myristate with C^{14}-labelled sucrose in anhydrous DMF, but in the absence of potassium sucrate, and recovering the corresponding sucrose ester in quantitative yield, and uncontaminated with C^{14}-labelled sucrose.

Another equilibration experiment using 0.475 mmole of sucrose dimyristate and 0.505 mmole sucrose in the presence of 0.1 meq of potassium sucrate was carried out under identical experimental conditions.

The specific activities of the C^{14}-labelled sucrose and sucrose myristates were determined by converting the compounds to barium carbonate by the apparatus and method of Calvin (16) except that a 0.2 M solution of barium hydroxide was used instead of sodium hydroxide. All samples were counted at infinite thickness, using a "Tracerlab (SC-50B) Automatic Flow Counter", and required 123.5 mg of barium carbonate for a planchet having an area of 4.94 cm^2. Under the experimental conditions used it was found that mock combustions gave a negligible blank of less than 0.3 mg of barium carbonate. All specific activities were calculated from the time taken for 10^4 disintegrations. However, since the composition of the sucrose myristates was not determined, the specific activities were calculated as the number of counts per minute per milligram of barium carbonate (c.p.m./mg $BaCO_3$). The C^{14}-labelled sucrose was found to have a specific activity of 8.475 c.p.m./mg $BaCO_3$.

The theoretical specific activities of the sucrose myristates, isolated after equilibration, were calculated in the following manner. The concentrations of sucrose monomyristate (M) and sucrose dimyristate were calculated by substituting the values for Y, Z, and K_1 into equation [1]. For example, these values were 0.961, 0.466, and 2.0, respectively, for the experiment using 0.495 mmole of C^{14}-labelled sucrose and 0.466 mmole of sucrose monomyristate. The calculated equilibrium concentrations of sucrose mono- and di-myristate were found to be 0.39 and 0.038 mmole, respectively. The theoretical specific activity was then calculated from the equation

$$A = 12fss^*/(d+m), \quad [2]$$

where A was the theoretical specific activity; s^* was the specific activity of the original C^{14}-labelled sucrose; s was the total moles of sucrose in the sucrose mono- and di-myristate; f was the fraction of the total moles of sucrose in the original reaction solution, whether present as sucrose myristate or free sucrose, which was C^{14}-labelled; d was the moles of barium carbonate obtained on combustion of the sucrose dimyristate; and m was the moles of barium carbonate obtained on combustion of the sucrose monomyristate.

The values of d, m, f, s, s^* in the above experiment were 1.52 mmole, 10.14 mmole, 0.5236, 0.428 mmole, and 8475, respectively. Substitution of these values into equation [2] gave a value for the theoretical specific activity, A, of 1950 c.p.m./mg $BaCO_3$ assuming random distribution of the sucrose molecules in the sucrose myristate.

A similar calculation for the experiment using 0.505 mmole of C^{14}-labelled sucrose and 0.475 mmole of sucrose dimyristate gave values for d, m, f, s, and s^* of 11.0 mmole, 10.40 mmole, 0.515, 0.675 mmole, and 8475, respectively, and a value of 1650 c.p.m./mg $BaCO_3$ for the theoretical specific activity A. The sucrose mono- and di-myristate concentrations at equilibrium were calculated to be 0.4 and 0.275 mmole, respectively.

The theoretical weight yields of the C^{14}-labelled sucrose myristates in 1 ml of the reaction solutions were calculated, assuming complete equilibration of the C^{14}-labelled sucrose and sucrose ester, from the

equilibrium concentrations of C^{14}-labelled sucrose mono- and di-myristate. The calculated yields were 44.4 and 78.1 mg/ml as compared with the highest experimental yields after 65 minutes' reaction of 38.3 and 72.2 mg/ml, respectively (see Table V).

The results of the equilibration studies are given in Table V.

The Effect of Methanol Concentration on the Extent of Reaction at 80°

A standard transesterification reaction was carried out at 80° using 0.68 ml of a saturated methanolic solution containing 4 meq of potassium methoxide as catalyst. Two aliquots of the reaction mixture were taken at intervals and the percentage of methyl myristate which had reacted in one aliquot (0.6 ml) was determined by GLPC using *n*-octadecane as an internal standard. The other aliquot (2.0 ml) was transferred to a small, stoppered test tube (total volume 2.2 ml) and allowed to equilibrate at 80°. At the end of the equilibration period the percentage of methyl myristate which had reacted was determined once more. Care was taken at all times to exclude moisture from the reaction solutions. The results are given in Table VI.

TABLE VI

Effect of methanol concentration on the extent of reaction at 80°

Sample No.	1	2	3	4	5	6	7
Time (min)*	5	10	20	40	80	120	150
% methyl myristate reacted	11.0	24.7	44.2	65.8	84.2	90.2	94.5
Time (min) for the reaction to reach equilibrium	145	140	130	110	70	30	
% methyl myristate reacted	55.4	62.2	69.8	78.1	90.0	94.5	

*Samples were withdrawn from the reaction mixture at this time both for analysis and for storage at 80° in a closed system to achieve equilibrium.

Determination of the Equilibrium Constant K_2

The equilibrium constant K_2 for the reaction

$$\text{sucrose} + \text{methyl myristate} \rightleftarrows \text{sucrose myristates} + \text{methanol}$$

was determined by approaching the equilibrium from both sides of the reaction.

A transesterification reaction solution containing 3.18 mmoles of sucrose, 1.06 mmole of methyl myristate, 0.676 mmole of *n*-octadecane, 1 mmole of methanol, and 0.116 mmole of potassium sucrate in 17 ml of anhydrous DMF solution was brought to equilibrium at 80° in a 17.2-ml test tube fitted with a rubber serum cap. The rate of equilibration was determined by taking, at intervals, through the serum cap, with a calibrated microsyringe, 0.1-ml aliquots of the reaction solution and analyzing for methyl myristate by GLPC using the *n*-octadecane as an internal standard. It was assumed that the equilibrium condition had been reached when there was no further decrease in the concentration of methyl myristate. At the end of the equilibration period 10 mmole of methanol was added to the reaction solution and the solution analyzed for methyl myristate once more after an interval of 30 minutes. Since the concentration of methyl ester showed a significant increase this established that the catalyst was not destroyed during the equilibration period. It should be noted that care was taken to exclude moisture at all times from the reaction solution. The rate at which equilibrium was reached is shown in Fig. 8.

In another experiment, 1 mmole of sucrose monomyristate, 0.638 mmole of *n*-octadecane, 1 mmole of methanol, and 0.116 mmole of potassium sucrate were equilibrated at 80° in 15 ml of DMF solution contained in 15.1-ml test tube. The rate of equilibration was followed as described above, and is shown graphically in Fig. 8.

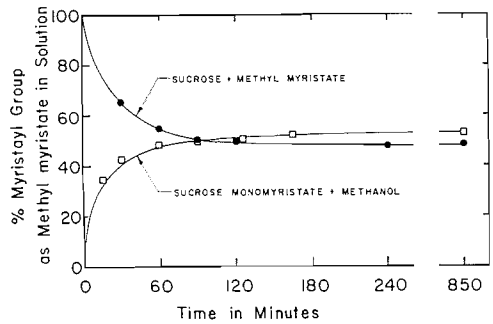

FIG. 8. The rate of equilibration of sucrose and methyl myristate with sucrose monomyristate and methanol in DMF solution at 80°. For the curve denoted by ● the reaction solution was 18.75, 6.25, 6.25, and 0.7×10^{-2} M in sucrose, methyl myristate, methanol, and alkoxide ion, respectively, whereas for the curve denoted by □ the solution was 6.25, 6.25, and 0.7×10^{-2} M in sucrose monomyristate, methanol, and alkoxide ion, respectively.

The data for the first experiment in Fig. 8 shows that 51.8% (0.549 mmole) of the methyl myristate had reacted at equilibrium to form sucrose myristates. If it was assumed that only sucrose mono- and di-myristate were formed in the reaction the equilibrium concentration of the former (0.468 mmole) could be calculated by substituting values for Y (3.18 mmole), Z (0.549 mmole), and $K_1 = 2$ into equation [1]. Setting R and X as the equilibrium and initial molar amounts of methanol and myristoyl group in the reaction solution, respectively, the molar amounts of the reactants and products in the reaction at equilibrium are, sucrose monomyristate = M, sucrose dimyristate = $(Z-M)/2$, methanol = R, sucrose = $(2Y-Z-M)/2$, and methyl myristate = $X-Z$. The other variables (Y, Z, and M) were defined previously in connection with equation [1]. The equilibrium constant, K_2, can be calculated from the expression

$$K_2 = \text{[sucrose myristates][methanol]/[sucrose][methyl myristate]}$$
$$= R(M+Z)/(2Y-Z-M)(X-Z).$$

A value of 0.577 for K_2 is obtained on substituting values (in mmole) for Y (3.18), X (1.06), M (0.468), R (1.549), and Z (0.549).

In the same way, the values (in mmole) of Y (1), X (1), M (0.31), R (0.472), and Z (0.472) which were obtained in a second experiment gave a value of 0.576 for K_2. In this experiment 52.8% (0.528 mmole) of the myristoyl group was converted to methyl myristate (see Fig. 8). Consequently, the methanol concentration (R) at equilibrium was 0.472 mmole, and 47.2% of methyl myristate had reacted to form sucrose myristate (see Fig. 8).

A solution of 60 mmole sucrose, 20 mmole methyl myristate, and 12.75 mmole *n*-octadecane in 300 ml DMF was maintained at 80° and 75 mm pressure, for 6 hours, with nitrogen passing through the solution. No catalyst was added to the reaction mixture. Analysis of the reaction solution by GLPC at 30-minute intervals revealed that the methyl myristate concentration remained constant over the entire reaction period.

The Preparation of Sucrose Myristates on a Preparative Scale

As a consequence of the kinetic studies of the reaction the following preparative procedure was developed.

Sucrose (60 mmole) was dissolved in anhydrous DMF at 80° and 65 mm pressure with vigorous and continuous stirring, and with a stream of nitrogen passing through the solution. After about 15 minutes the sucrose was completely dissolved and the solvent refluxed to a point in the Vigreaux column about 2 inches from the neck of the flask. Sodium methoxide solution (4 ml containing 4 meq) was added below the surface of the solution using a hypodermic syringe, in the usual manner. The evolution of methanol was rapid but caused no difficulties. After equilibrium was re-established, the oil-bath temperature was raised to 100°, whereupon the solution achieved a temperature of 80° and refluxed about half way up the Vigreaux column. The still head temperature was about 50°. The system was kept under these conditions for a further 15 minutes and then the methyl myristate (20 mmole) was added using a hypodermic syringe. The solution was then maintained at 80° for 150 minutes. During this reaction period approximately 50 ml of the DMF distilled over slowly.

At the end of the reaction period, glacial acetic acid (0.5 ml) was added to the stirred reaction solution, at atmospheric pressure, to stop the reaction. The solution was then taken to dryness at 70°, under reduced pressure, in 30 minutes, and the sucrose myristate isolated by partitioning the residue between *n*-butanol and 5% sodium chloride solution as described above. The residue of sucrose myristate (9.6 g) was then precipitated from acetone to yield sucrose myristates (9.2 g) as a white powder. Theory for pure sucrose monomyristate is 11.0 g.

DISCUSSION

Before the kinetic study of the transesterification reaction could be carried out it was first necessary to develop analytical methods for determining the rates and extents of the reaction, and the sucrose mono- and di-ester content in the product of the reaction.

The rates of reaction were determined by following the concentration of the methyl esters of the higher fatty acids in the reaction solution by GLPC using *n*-octadecane as an internal standard of constant concentration. In this way it was established that the concentration of methyl ester could be determined to within ±2% from 10 to 100% of the range of concentrations encountered (see Fig. 1). Methyl myristate was used for most of the kinetic studies since it had been used in this laboratory for previous investigations (5) and had a convenient retention volume relative to *n*-octadecane. Although Lovelock (17) had shown that the response of the ionization detector was not the same for hydrocarbons and methyl esters of fatty acids, due to differences in the magnitude of their ionization potentials, the methyl esters of myristic, palmitic, and stearic acids gave the same molar response as *n*-octadecane under our experimental conditions.

Although the catalyst was not neutralized before the product of reaction (sucrose ester) was isolated, the simple routine procedure which was developed gave high, reproducible yields of sucrose ester for reactions carried out under identical experimental conditions (see Table I). It was found, however, that the addition of an equivalent amount of acetic acid or potassium hydrogen phthalate neutralizes the catalyst without causing any significant inversion of sucrose or sucrose ester.

Of the other analytical methods used, one worthy of mention is the separation of sucrose monoester from higher esters of sucrose by chromatography on silicic acid using methanol/chloroform solutions as the developing phase. The recoveries were quantitative.

Equipped with these experimental procedures and analytical tools, we undertook a kinetic investigation of the reaction. It seemed desirable to begin with an examination of the procedure recommended by the Snell Laboratories (2, 6). Reactions performed by this procedure at 80° and initiated by the addition of solid potassium carbonate proceeded at unpredictable rates and to variable extents (see Fig. 3). It became evident that this situation was to an important degree dependent on the rate of dissolution of the catalyst since the rate of reaction was substantially increased (about twofold) by using very finely divided potassium carbonate distributed over Celite (see Fig. 3). Also, although the solid potassium carbonate did not dissolve completely in any of our experiments, it was apparent that variable amounts went into solution. The observations suggested that the rate and extent of dissolution of potassium carbonate were related to the presence of traces of water. In fact, the rate of reaction and yields of sucrose ester were influenced by the addition of water to the reaction solution (see Fig. 4). The exact nature of this effect was not established since it was later observed that homogeneous solutions of potassium carbonate in DMF or DMF containing sucrose could catalyze the formation of sucrose ester. These results suggested that a satisfactory solution to the problem would require conditions for homogeneous catalysis. Furthermore, identical specimens of the reagents were used for all experiments dealing with one reaction variable, since it was realized that different specimens of the reagents would be used during the investigation, which could affect the reproducibility of the results. In this way it was possible, for example, to compare the rates of reaction, even if they were not the absolute reaction rates, within a selected group of experiments.

It was decided, therefore, to add the potassium carbonate as a solution in methanol. At this point a surprising (to us) observation was made. When a saturated methanolic solution of potassium carbonate was prepared, under reflux, the titration of the solution revealed the presence of strong base. Furthermore, the amount of strong base increased the longer the solution was heated. It was apparent, therefore, that heating led to the loss of acid through the evolution of carbon dioxide. By analogy the reaction of sucrose with potassium carbonate should lead to the formation of potassium sucrate in high concentration. The formation of sucrose myristate using solid sodium hydride as the catalyst suggested, moreover, that sucrate ion was the reactive species which catalyzed the reaction. Consequently potassium methoxide should serve to initiate the catalysis at least as efficiently as potassium carbonate.

The procedure for the transesterification reaction was therefore modified to enable methanolic solution of the catalyst to be added to the reaction mixture. The methanol was then removed by distillation, under reduced pressure, to leave a homogeneous reaction solution. It was now found that the reaction proceeded at highly reproducible rates, and these were independent of the base used (see experiments 1–6, Table I). Furthermore, the infrared spectra of samples of sucrose ester (see experiments 1–4, Table I) were identical, indicating that the product composition was the same. The rates of reaction using the conditions for homogeneous catalysis were much superior to those obtained by other workers (2, 5, 6, 8, 9).

It was also demonstrated that aqueous solutions of potassium carbonate and hydroxide, or methanolic solutions of potassium hydroxide, led to the formation of detectable amounts of potassium soap, resulting in lower rates of reaction and yields of sucrose ester (see experiments 7, 8, 10, and 11, Table I). Superior initial rates of reaction were observed when a saturated solution of potassium methoxide was used (see experiments 9, 12; Tables I and II, respectively) instead of a dilute methanolic solution of potassium methoxide (see Table III) to catalyze the reaction. These results indicate that dry methanol is the solvent of choice for the preparation of potassium sucrate solutions, and that the discrepancy in the initial rates of reaction was related to the efficiency with which methanol was being removed from the reaction solution. This latter effect will, of course, be more critical in the initial stages of the reaction when the methanol concentration is highest, and is consistent with the observation of Komori and his associates (9) that the rate of transesterification increased when the pressure in the system was decreased. Under our experimental conditions a rapid and reproducible rate of removal of methanol could not be achieved by distillation alone. However, the introduction of a rapid rate of stirring, combined with a continuous stream of nitrogen as a carrier gas, was found to positively solve this problem, and this use resulted in highly reproducible rates of reaction. Moreover, the viscous nature of saturated methanolic solutions of potassium methoxide made them difficult to handle. Consequently, most of our experiments were carried out using dilute methanolic solutions.

The effectiveness of the procedure for the removal of the methanol from the reaction solution was tested by taking samples, at intervals, from a transesterification reaction and equilibrating them in sealed glass tubes at the reaction temperature. The data in Table VI clearly illustrate the necessity for efficient removal of methanol from the reaction solution. Furthermore, in view of the high rates of reaction obtained using our standard transesterification conditions it can be concluded that methanol was being removed rapidly in all of our experiments in which conditions for homogeneous catalysis prevailed.

Experiments directed at obtaining a direct measure of the equilibrium constant for the reaction

$$\text{sucrose} + \text{methyl myristate} \rightleftarrows \text{sucrose ester} + \text{methanol}$$

were carried out by approaching the equilibrium from both sides (see Fig. 8). The equilibrium constant, K_2, for this reaction was found to have a value of 0.57 in both cases. The close agreement is probably fortuitous, although it is not considered likely that the actual value will differ significantly from this value. This result is consistent with the observations of Fehland and Adkins (18) and Juvet and Wachi (19) that the formation of methyl ester is favored in reactions in which aliphatic alcohols are equilibrated with the methyl esters of fatty acids using base (18) or acid (19) catalysis.

It became obvious, early in the investigation, that the transesterification reaction followed pseudo first-order kinetics in the methyl ester of the fatty acid (see Fig. 7). Evidence that sucrate ion was the reactive species which catalyzed the reaction was provided when it was observed that sodium hydride catalyzed the reaction, and when the extent and rate of reaction, using a methanolic solution of potassium carbonate as catalyst, was strongly depressed when a stream of carbon dioxide was passed through the solution instead of the usual nitrogen (see Fig. 5). This requires that sucrose (SOH) and potassium carbonate react according to the following scheme,

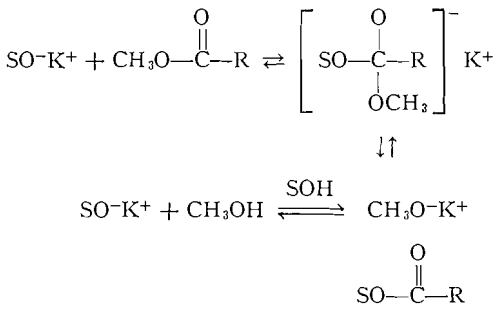
$$\text{SOH} + \text{K}_2\text{CO}_3 \rightleftarrows \text{K.OS} + \text{KHCO}_3,$$

$$\text{SOH} + \text{KHCO}_3 \rightleftarrows \text{K.OS} + \text{H}_2\text{CO}_3,$$

$$\text{H}_2\text{CO}_3 \rightleftarrows \text{CO}_2 + \text{H}_2\text{O},$$

to form potassium sucrate (K.OS). Furthermore, the fact that equivalent amounts of potassium carbonate, potassium methoxide, sodium methoxide, and lithium methoxide gave identical rates of reaction can only be explained satisfactorily if sucrate ion is the effective catalyst for the reaction (see Table I).

The transesterification reaction must therefore be bimolecular and involve nucleophilic attack of the methyl ester by sucrate ion, as would be expected from the earlier studies (13) on the mechanism of base-catalyzed transesterifications.



In view of this mechanism, the rate of the transesterification reaction should be dependent only on the concentrations of sucrate ion and methyl ester. However, the actual rate of reaction would also depend on the rate of re-formation of the methyl ester in the reverse direction, and this will depend on the efficiency with which the methanol is removed from the reaction solution. Since the methanol is kept at an insignificant low level under our experimental conditions (see above), the sucrate ion concentration should remain at virtually constant level throughout the course of the reaction.

Thus, the rate of reaction should be directly proportional to the sucrate ion concentration. It can be seen from Fig. 6 that this is the case for reaction solutions which were up to 3.125×10^{-3} M in potassium sucrate (1 meq of potassium sucrate per 320 ml of reaction solution). At higher concentrations of potassium sucrate the reactions behave in a non-ideal manner, and solid potassium sucrate precipitates from solution at concentrations in excess of 12.5×10^{-3} mole liter^{-1} (4 meq of potassium sucrate per 320 ml of reaction solution).

The downward drift may result from the association of the ionic substance at high concentrations in such a manner as to reduce the effective concentration.

In view of the above considerations the rate of reaction should be independent of the concentration of sucrose as long as methanol is being removed effectively. This was found to be the case and no appreciable rate difference was observed by doubling or halving the initial sucrose concentration (see Table II). Although the rate and extent of reaction was somewhat lower at the lowest concentration of sucrose (see experiment 13, Table II), it was observed that a precipitate of potassium sucrate was present during the entire reaction period. In view of the high rate of reaction, however, it is felt that if all the catalyst had been in solution the rates of reaction of the three concentrations of sucrose would have been identical. This is in contrast to the results of Komori and co-workers (9, 11), who claim that the rate of reaction was dependent on the sucrose concentration.

The chain length of the fatty acid (see Table III) and the nature of the cation have little effect on the rate of reaction. In the latter case, equivalent amounts of potassium carbonate, lithium methoxide, sodium methoxide, and potassium methoxide, as potential sources of sucrate ion, gave essentially the same rates of reaction (see Table I). The only possible gain that could be obtained by changing the cation would be in the solubility of the metal sucrate in the reaction solution. It was observed that lithium sucrate was the only catalyst which did not give an initial precipitate when it was added to the reaction mixture. The saturation levels of the metal sucrates, other than potassium sucrate, were not determined. These results are in contrast to the cation–sucrose complex theory of workers at the Herstein Laboratories, which must necessarily predict different rates of reaction for the different cations (7, 8).

Inspection of Fig. 6 reveals that the effective sucrate ion concentration is only 1.5 meq per 320 ml of reaction solution (4.96×10^{-3} mole liter^{-1}) when the pseudo first-order rate constant has a value of 2.36×10^{-4} sec^{-1} at the 2 meq level of potassium sucrate. Consequently, the corresponding second-order rate constant (k_r) for the reaction at 80° has a value of 5.03×10^{-3} mole liter^{-1}. From this value for k_r and the energy of activation (9.9 kcal mole^{-1}), the Arrhenius frequency factor (0.7×10^5 liter mole^{-1} sec^{-1}) was calculated (15). Using the transition-state theory (20), the following constants were calculated, $\Delta F^{\ddagger} = 22$ kcal mole^{-1}, $\Delta H^{\ddagger} = 9$ kcal mole^{-1}, and $\Delta S^{\ddagger} = -38$ entropy units. The low frequency factor and large negative entropy is usually associated with reactions in which there is electrorestriction of the solvent molecules due to the formation of a highly polar activated complex (21, 22). Reactions which exhibit this behavior also have negative volumes of activation, and the rates of reaction are accelerated by pressure (22). These phenomena are observed in the acid and base hydrolysis of esters and amides (23–25), and in the transesterification of esters with an alcohol using base catalysis (13, 26).

Using chromatographically pure samples of sucrose monomyristate, it was possible to establish the equilibrium constant K_1 for the reaction

$$\text{sucrose} + \text{sucrose dimyristate} \rightleftarrows 2 \text{ sucrose monomyristate}$$

to be approximately 2. Although the equilibrium was not approached from both sides, the values of K_1 were obtained at two different sucrose concentrations. The above expression neglects the formation of tri- or higher myristoyl sucroses. Our chromatographic analyses definitely indicate that such compounds are formed. However, their concentrations seemed negligible when two or more moles of sucrose were used per mole of myristoyl group.

The theoretical yield of sucrose monomyristate (M) corresponding to any initial concentration of sucrose (Y) and methyl myristate (Z) could be determined from a knowledge of K_1 provided it was assumed that there was quantitative conversion of the methyl myristate to sucrose mono- and di-myristate. Using a value of $K_1 = 2$, the quadratic equation [1] gave two solutions for M, only one of which was positive, namely,

$$M = \sqrt{(Y^2+2YZ-Z^2-Y)}.$$

If Y and M were expressed as multiples of Z (i.e., $Z = 1$), the above equation reduced to

$$M = \sqrt{(Y^2+2Y-1-Y)}.$$

Since this equation was satisfied by all values of Y from 0.5 to ∞, the effect of sucrose concentration on the yield of sucrose monomyristate could be shown graphically by plotting M/Z versus Y/Z. It should be noted, however, that this equation is only valid when an equilibrium exists exclusively between sucrose, sucrose dimyristate, and sucrose monomyristate. At concentrations of sucrose which are low relative to myristoyl group content substantial amounts of higher-substituted myristoyl esters of sucrose will be formed in their equilibrium proportions. Therefore, this equation can only be given values for $Y/Z \geqslant 2$ for which the concentration of sucrose esters with more than two myristoyl groups is not significant. Finally, the plot of M/Z against Y/Z must necessarily pass through the origin, as shown in Fig. 9.

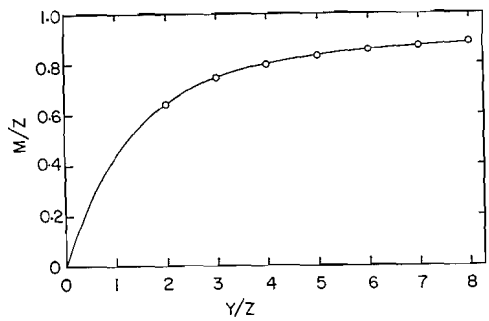


FIG. 9. The plot of the molar ratio of sucrose monomyristate/methyl myristate (M/Z) expected by calculation for the standard transesterification reaction conditions at 80° against the initial molar ratio of sucrose/methyl myristate (Y/Z).

From Fig. 9, it can be seen, for example, that 0.74, 0.80, and 0.83 mole of sucrose monomyristate are formed when 3, 4, and 5 moles of sucrose are used per mole of methyl myristate in the transesterification reaction. This corresponds to a 92, 93.7, and 95% yield of sucrose myristate (sucrose mono- and di-myristates), respectively, at the three sucrose concentrations. Thus, it is clear that little is gained by the use of a sucrose to methyl ester ratio greater than 3. However, in all of our experiments carried out under conditions for homogeneous catalysis (see Table I, experiments 1–4) the methyl myristate

had reacted to the extent of approximately 92% and gave a yield of sucrose myristates of approximately 83% by weight. From equation [1] it can be calculated that, under our standard conditions, 92% reaction would give 0.80 and 0.06 mole of sucrose mono- and di-myristates, respectively, corresponding to a theoretical weight yield of sucrose myristates of 87%, and a yield based on the amount of methyl myristate which had reacted of 94%. Furthermore, the preparative procedure which was developed as a result of our kinetic studies gave a yield of sucrose myristate of 84%. The experimental yields obtained during our investigations are therefore in excellent agreement with the predicted yield of 87%.

It was also established, using uniformly C^{14}-labelled sucrose, that the rate of the exchange reactions

$$\text{sucrose}^* + \text{sucrose dimyristate} \rightleftarrows \text{sucrose myristates}^*$$

and

$$\text{sucrose} + \text{sucrose monomyristate} \rightleftarrows \text{sucrose myristates}^*$$

was too rapid to expect any product control through kinetic control. In other words, at any time during the transesterification reaction, the product prevailing is the thermodynamic product under the conditions which prevail. From Table V it can be seen that approximately 65–80% of the theoretical activity was present in the isolated sucrose myristates after only 10 minutes' reaction. The discrepancy between the specific activity of the sucrose ester isolated after 65 minutes and the theoretical value is undoubtedly due to the presence of polysubstituted esters of sucrose. It is clear from these results that the sucrose esters formed in the transesterification reaction will have a higher sucrose monoester content in the initial stages of the reaction than at the completion of the reaction. We have not tested this prediction but make it with confidence. This is in direct contrast to the claims of other workers (2, 5–8) that the reaction proceeds by way of the rapid formation of sucrose diester. Furthermore, any claims that water (6) and the catalyst concentration (7, 8) influence the product composition are clearly not justified.

The fact that the rate constants for the transesterification remain virtually constant over the reaction period would suggest that little or no catalyst is used up in side reactions. The absence of soap in our reaction products is consistent with this observation. This is in contrast to the results of other workers who report that the catalyst is used up during the reaction, and that soap is formed in significant amounts (2, 5–8). The reason for this apparent discrepancy in the experimental results undobutedly lies in the fact that anhydrous conditions prevailed during this investigation, whereas the reaction solutions of other workers contained moisture.

THE COMPOSITION OF THE SUCROSE MONOMYRISTATE PREPARED BY TRANSESTERIFICATION[1]

R. U. LEMIEUX[2] AND A. G. MCINNES[3]
Department of Chemistry, University of Ottawa, Ottawa, Ontario
Received July 16, 1962

ABSTRACT

The composition of the sucrose monomyristate which is obtained by reaction of sucrose with methyl myristate in dimethylformamide and in the presence of a basic catalyst was established by application of gas–liquid partition chromatography and nuclear magnetic resonance spectroscopy to appropriate derivatives. The substance is a mixture of 6′-myristoyl sucrose, 6-myristoyl sucrose, and unidentified isomeric esters in the relative proportions of 0.62:0.28:0.10, respectively.

INTRODUCTION

The first attempt to establish the structure of a fatty acid monoester of sucrose was made by Snell and co-workers (1) in 1956. Sucrose monolaurate, prepared by the transesterification reaction (2), was hydrolyzed with refluxing aqueous acid and a fraction containing glucose and fructose monolaurate was isolated. After deacylation, the ratio of the two hexoses was determined by visual inspection of the intensities of the spots developed on a paper chromatogram. Furthermore, 1 mole of sucrose monolaurate consumed 2.9 moles of periodate to yield 0.68 mole of formic acid. When sucrose monolaurate 3.15-tosylate was reacted with sodium iodide in acetone more than 71% of the tosyloxy groups were replaced by iodine. On the basis of these experimental observations, Snell concluded that at least 80% of the ester group was present at the 6-position of sucrose. It should be noted, however, that this work did not take into account the possibility that ester groups substituted on different positions in the sucrose molecule may undergo hydrolysis at very different rates in acid media. Also, no attempt was made to provide an explanation for the low yield of formic acid (68% of theory) obtained in the periodate oxidation. Moreover, Snell assumed that tosyloxy groups substituted on the three primary hydroxyl groups of sucrose would all react with iodide ion whereas it was established in this laboratory (3) that although tosyloxy groups at the 6- and 6′-positions of sucrose are replaceable by iodine, a tosyloxy group at the 1′-position is unreactive (3). A reinterpretation of Snell's results, on the basis that only the 6- and 6′-positions reacted, would require that none of the ester groups occupied either of these positions in sucrose.

Gee and Walker (4) also examined the structure of fatty acid monoesters of sucrose. A commercial sample of sucrose monostearate was methylated, the product was saponified, the solution was deionized, and the residue on evaporation was subjected to molecular distillation. Analysis of the distillate by gas–liquid partition chromatography (GLPC) revealed that it was a mixture of isomeric hepta-*O*-methyl sucroses and octa-*O*-methyl sucrose. The distillate was then subjected to methanolysis to yield a mixture of fully and partially methylated methyl fructosides and glucosides, which were subsequently analyzed by GLPC. It was concluded, on the basis of the analysis, that the stearoyl group was predominantly at the 6-position although appreciable substitution of stearate

[1]*This paper was submitted by A. G. McInnes as a portion of a thesis for the Ph.D. degree.*

at the 6′-position of sucrose was considered to be relatively unimportant. No attempt was made to explain the presence of octa-*O*-methyl sucrose in the distillate and analytical data to support the identification of the hepta-*O*-methyl sucroses were not provided. Since octa-*O*-methyl sucrose could only have formed during the methylation procedure by hydrolysis of sucrose monostearate, and the relative rates of hydrolysis of ester groups located on different positions in the sucrose molecule are not known, the composition proposed could not be accepted without reservation.

The failure of previous attempts to unambiguously establish the structure of a sucrose monester led us to reinvestigate the problem. The purpose of this communication is to report on the structure of an analytically pure sample of sucrose monomyristate.

EXPERIMENTAL AND RESULTS

The Tosylation of Sucrose Monomyristate

Pure sucrose monomyristate (0.6023 g) was reacted with *p*-toluenesulphonyl chloride (2.80 g) in anhydrous pyridine (20 ml) for 12 hours at room temperature. The excess *p*-toluenesulphonyl chloride was then destroyed by adding water (1 ml) to the reaction solution. After the latter was left standing at room temperature for 30 minutes, it was poured into ice water (50 ml) and extracted with five aliquots (20 ml) of chloroform. After being washed first with 2 *N* hydrochloric acid, then with sodium bicarbonate solution (20% w/v), and finally with distilled water, the chloroform solution was dried by filtration through paper wetted with chloroform. Removal of the chloroform under reduced pressure yielded a substance (1.48 g) which contained the amount of sulphur (12.28%) expected for a sucrose monomyristate containing 5.18 tosyl groups per sucrose unit.

Reaction of Sucrose Monomyristate "5.18-Tosylate" with Sodium Iodide

The sucrose monomyristate with a degree of tosylation of 5.18 (0.5396 g) was reacted with sodium iodide (0.6 g) in acetone (6 ml) for 15 hours at 105° in a sealed glass tube. After the reaction was complete, the sodium *p*-toluenesulphonate (0.1424 g) which had precipitated from the solution was collected. The filtrate was taken to dryness and the residue was extracted with three 15-ml amounts of chloroform. After extraction with sodium thiosulphate solution (10% w/v) and then with distilled water, the chloroform solution was dried. Evaporation under reduced pressure yielded sucrose 1.84-iodo, 3.34-tosylate (0.4474 g). Anal. Calc. for sucrose monomyristate 1.84-iodo, 3.34-tosylate: S, 8.43; I, 18.42%. Found: S, 8.30; I, 18.90%.

Methylation of Sucrose Monomyristate

Pure sucrose monomyristate (2.03 g) was methylated in anhydrous *N*,*N*-dimethylformamide (DMF) (60 ml) (5, 6) using methyl iodide (60 ml) and freshly prepared silver oxide (22 g). Finely divided anhydrous calcium sulphate (20 g) was added to the reaction solution to ensure anhydrous conditions for methylation and to reduce the possibility of ester hydrolysis. The reaction was assisted by vigorous agitation of the reaction solution on a mechanical shaker for 15 hours. At the end of the reaction period the solution was filtered free of solids and the clear filtrate was diluted with 150 ml of chloroform to precipitate silver iodide. The silver iodide was removed by filtration and the chloroform/DMF solution was taken to dryness *in vacuo* on a rotary evaporator. Drying under reduced pressure over phosphorus pentoxide left 2.39 g of crude methylated sucrose ester (quantitative yield). Since GLPC analysis revealed the presence of methyl myristate, a sample (2.35 g) was chromatographed on silicic acid (40 g) using graded elution with methanol/chloroform solutions as shown in Table I. Fraction 1 was shown (infrared and GLPC) to be pure methyl

TABLE I

Chromatography of methylated sucrose monomyristate on silicic acid

Fraction	Solvent	Volume (ml)	Weight of Residue (g)
1	Chloroform	150	0.0442*
2	"	100	0.1068
3	"	225	1.4985
4	10% methanol/chloroform	200	0.6909
5	Methanol	150	0.0030
		Total weight recovered	2.3434 (99.7% recovery)

*This material was collected in the first 100 ml of chloroform.

myristate and represented 1.9% of the total weight of the sample. Fraction 2 had an infrared spectrum virtually identical with those of fractions 3 and 4. Only the latter two fractions (2.1894 g, 91.6% theory) were combined for further examination. Their infrared spectra showed no absorption in the O—H stretching region and were consistent with that expected for hepta-*O*-methyl sucrose monomyristate.

Preparation of Hepta-O-methyl Sucrose

A sample (1.1200 g) of hepta-*O*-methyl sucrose monomyristate was transesterified with 10 ml of anhydrous methanol under reflux for 5 hours, using potassium methoxide (2 mmole) as catalyst. At the end of the reaction period the catalyst was converted to potassium carbonate by the addition of solid carbon dioxide and the methanol was removed under reduced pressure. The residue was extracted with 50 ml of chloroform and the extract was taken to dryness under reduced pressure. The residue was chromatographed on 10 g of silicic acid. Elution with 100 ml of chloroform yielded 0.3958 g of an oil (98.0% of theory) the infrared spectrum of which was identical with that of methyl myristate. Further elution with 5% methanol–chloroform (100 ml) yielded 0.6958 g of hepta-*O*-methyl sucrose (92% of theory) as a colorless oil. Anal. Calc. for $C_{19}H_{36}O_{11}$: methoxyl, 49.3%. Found: 48.4%. The infrared spectrum in carbon tetrachloride (0.0025 *M*) showed absorption in the O—H stretching region at 3485 cm^{-1}. The n.m.r. spectrum (Fig. 1) in carbon

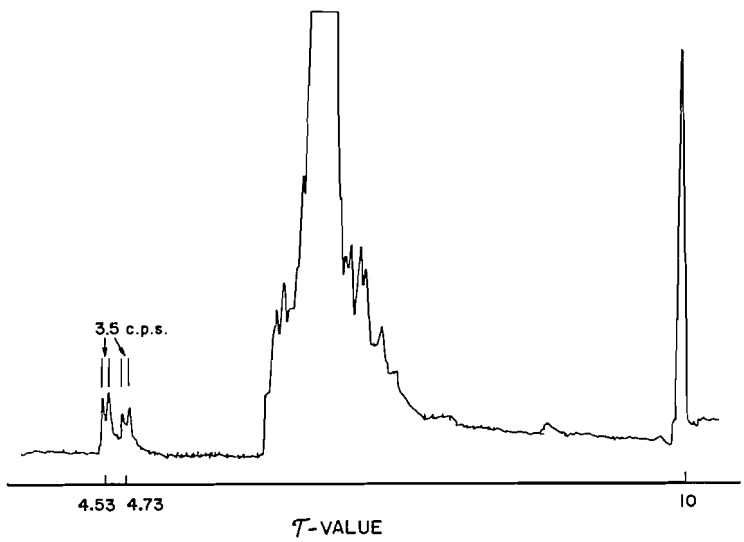

FIG. 1. The proton magnetic resonance spectrum of the mixture of hepta-*O*-methyl sucroses.

tetrachloride (20% w/v) had two doublets for two anomeric hydrogens (8, 9) with τ-values (7) of 4.73 and 4.53. Each doublet had a spacing of 3.5 c.p.s. and their relative intensities were 0.65 to 0.35, with the doublet at lower field having the greater intensity. All n.m.r. spectra were measured on a 60 Mc/s high-resolution Varian spectrometer.

Tosylation of Hepta-O-methyl Sucrose

Hepta-*O*-methyl sucrose (0.1566 g) was reacted with 0.27 g of *p*-toluenesulphonyl chloride in 2 ml of anhydrous pyridine for 12 hours. The hepta-*O*-methyl sucrose monotosylate (0.2172 g) was isolated in quantitative yield. Anal. Calc. for $C_{26}H_{42}SO_{13}$: S, 5.39%. Found: S, 5.15%. The infrared spectrum in chloroform (5% w/v) was consistent with that expected for a tosyl ester of a methylated sugar. The n.m.r. spectrum (Fig. 2) in carbon tetrachloride (20% w/v) possessed a quartet at an average τ-value of 2.55 for four aromatic protons (7). Two doublets with a combined intensity corresponding to one proton were in the region expected for signals from anomeric hydrogens. The relative intensities of the two doublets was 0.65:0.35.

The Preparation of Hepta-O-methyl Deoxysucrose from Hepta-O-methyl Sucrose Monotosylate

The hepta-*O*-methyl sucrose monotosylate (0.1019 g) was reacted with 0.6 g of sodium iodide in 6 ml of acetone at 105° for 15 hours. Hepta-*O*-methyl iododeoxysucrose (0.0916 g, 97% of theory) was isolated as an oil. The n.m.r. spectrum showed that only 10% of the tosyloxy groups had not been lost in the reaction with sodium iodide. The hepta-*O*-methyl iododeoxysucrose was dissolved in 6 ml of methanol containing 24 mg of diethylamine and the solution was reduced with hydrogen at atmospheric pressure for 4 hours using palladium on charcoal as catalyst. After clarification and deionization, the product was dried under reduced pressure. The yield based on hepta-*O*-methyl deoxysucrose was 0.061 g (87% of theory). Anal.

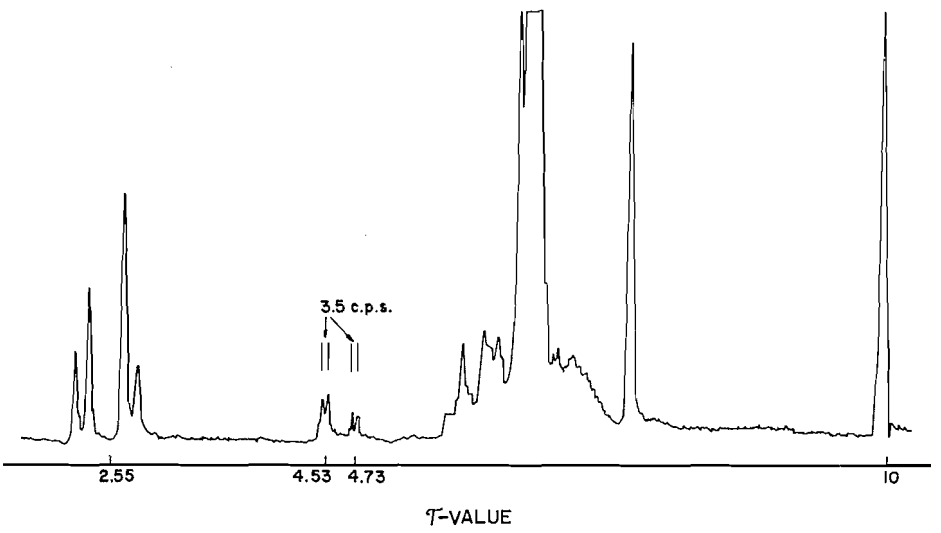

FIG. 2. The proton magnetic resonance spectrum of the mixture of the mono-*O*-tosyl hepta-*O*-methyl sucroses.

Calc. for $C_{19}H_{36}O_{10}$: C—CH_3, 6.37%. Found: 5.80%. The n.m.r. spectrum (Fig. 3) in carbon tetrachloride (20% w/v) showed that the aromatic protons (τ = 2.55) (7) had an intensity corresponding to only 0.4

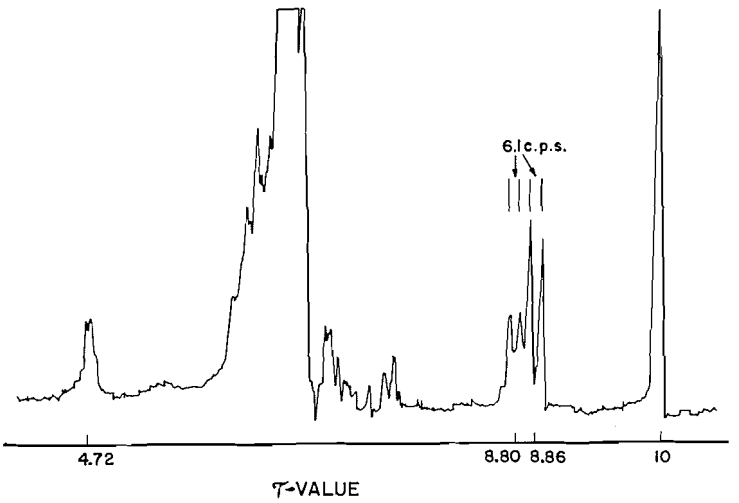

FIG. 3. The proton magnetic resonance spectrum of the mixture of deoxy hepta-*O*-methyl sucroses.

proton, and the anomeric hydrogens were present as an ill-defined quartet with an average τ-value of 4.72. Two doublets with a common spacing of 6.1 c.p.s. were present for the protons of methyl groups (7) at τ-values of 8.80 and 8.86, respectively. The total intensity of the two doublets corresponded to 2.8 protons (theory 3 protons) and the ratio of the intensities of the doublets was 0.65:0.35. The signal at highest field had the greater intensity.

Chromatography of Hydrolysis and Methanolysis Products of Hepta-O-methyl Sucrose

The method of Hayward (10) was used for the hydrolysis of 10 mg of hepta-*O*-methyl sucrose in 1 ml of 0.05 *N* sulphuric acid on a steam bath for 2 hours. At the end of the reaction period, the sulphuric acid was neutralized with solid barium carbonate and the aqueous solution was clarified by centrifugation. Aliquots of the supernatant solution were spotted on Schleicher and Schuell, orange ribbon 289, chromatographic

paper. The chromatogram was developed with *n*-butanol–ethanol–water, 5:1:4 (11), for 18 hours, using 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3,4-tri-*O*-methyl-D-glucose as standards. Two spray reagents were used, namely, 3% *p*-anisidine hydrochloride in moist *n*-butanol to detect both ketoses and aldoses and 3% resorcinol in *n*-butanol containing hydrochloric acid to detect ketoses only (11). Only three spots were present, with R_{TG} values (R_f value relative to that of 2,3,4,6-tetra-*O*-methyl glucose) of 0.81 (red-brown), 0.89 (yellow), and 1.00 (red-brown), when the *p*-anisidine hydrochloride spray was used. Two pink spots were present, with R_{TG} values of 0.89 and 1.00, when the resorcinol spray was used. Clearly, both 2,3,4,6-tetra-*O*-methyl-D-glucose and 1,3,4,6-tetra-*O*-methyl-D-fructose were present. 2,3,4-Tri-*O*-methyl-D-glucose produces a red-brown spot with $R_{TG} = 0.81$. For reasons which will become clearly apparent later on, the substance with $R_{TG} = 0.89$ must be 1,3,4-tri-*O*-methyl-D-fructose.

Hepta-*O*-methyl sucrose (13.2 mg) was reacted with 3% methanolic HCl (0.20 ml) for 5 hours at room temperature. Aliquots of the reaction mixture (0.1 μl) were analyzed by GLPC, on a "Pye Argon Chromatograph", using a Celite – butanediol succinate polyester (20% w/v) column (12) at 160° and using a flow rate of 60 ml of argon per minute. The analysis showed the presence of 10 methyl glycosides. The retention volumes of these compounds were calculated relative to that of methyl 2,3,4,6-tetra-*O*-methyl-α-D-glucopyranoside as shown in Table II. Only those compounds with relative retention volumes of 0.68, 0.73, 0.88, 1.00, 1.33, and 2.66 were present in significant amounts. The molar ratio of the pentamethyl glucosides to pentamethyl fructosides was found to be 0.69:0.31 as determined by their area ratios. Furthermore, the molar ratio of methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranoside to that of the compounds with relative retention volumes of 1.33 and 2.66 (see Table II) was 0.34:0.66. The methanolysis products of octa-*O*-methyl sucrose are also shown in Table II.

TABLE II

Retention volumes of the products of methanolysis of hepta-*O*-methyl and octa-*O*-methyl sucrose relative to methyl 2,3,4,6-tetra-*O*-methyl-α-D-glucopyranoside

Compound	Standards	Octa-*O*-methyl sucrose	Hepta-*O*-methyl sucrose
Methyl 2,3,4,6-tetra-*O*-methyl-β-D-glucopyranoside	0.68	0.68	0.68
Methyl 1,3,4,6-tetra-*O*-methyl-β(?)-D-fructofuranoside		0.73	0.73
Methyl 1,3,4,6-tetra-*O*-methyl-α(?)-D-fructofuranoside		0.88	0.88
Methyl 2,3,4,6-tetra-*O*-methyl-α-D-glucopyranoside	1.00	1.00	1.00
Methyl 1,3,4-tri-*O*-methyl-β(?)-D-fructofuranoside*			1.33
Methyl 1,3,4-tri-*O*-methyl-α(?)-D-fructofuranoside*			1.49
Methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranoside	1.81		1.81
Methyl 1,3,4-tri-*O*-methyl-β(?)-D-fructopyranoside*			1.91
Methyl 2,3,4-tri-*O*-methyl-α-D-glucopyranoside	2.38		2.38
Methyl 1,3,4-tri-*O*-methyl-α-(?)-D-fructopyranoside*			2.66

*These compounds were provisionally assigned these structures after the structure of hepta-*O*-methyl sucrose was known.

DISCUSSION

Sucrose monomyristate (6) was methylated using silver oxide and methyl iodide in dimethylformamide solution (5, 7(*a*)) and finely divided calcium sulphate as a drying agent. The crude yield was quantitative. However, chromatography on silicic acid showed the product to contain about 2% of the original myristoyl content as methyl myristate (see Table I). Pure hepta-*O*-methyl sucrose monomyristate was obtained in 92% yield from the chromatogram and the material was transesterified quantitatively to hepta-*O*-methyl sucrose with a methoxyl content, 48.2%, in good agreement with the theoretical value of 49.3%. Hydrolysis with 0.5 *N* sulphuric acid gave a product which was shown by chromatography to contain three components when sprayed with *p*-anisidine hydrochloride. Two of these spots (reddish brown), with R_{TG} values of 1.0 and 0.81, corresponded to 2,3,4,6-tetra-*O*-methyl glucose and 2,3,4-tri-*O*-methyl glucose. The third spot, with an R_{TG} value of 0.89, was yellow (ketose) and agreed with the reported value for 1,3,4-tri-*O*-methyl fructose (13). Therefore, it was evident that the hepta-*O*-methyl sucrose was almost entirely a mixture of only 2,3,4,1′,3′,4′,6′- and 2,3,4,6,1′,3′,4′-hepta-*O*-methyl sucroses.

Methanolysis of the mixture of hepta-*O*-methyl sucroses and GLPC analysis of the methyl glycosides revealed the presence of 10 compounds. The theoretical number of methyl glycosides which can be formed from the above mixture is 10 (see Table II). The relative amounts of the fully methylated D-glucopyranosides and D-fructofuranosides was 0.69:0.31. Since experience has shown that the methyl furanosides of fully, or partially, methylated hexoses have smaller retention volumes than the corresponding methyl pyranosides (12, 14), the compounds with relative retention volumes of 1.33 and 2.66 (see Table II) are probably the methyl furanoside and pyranoside of 1,3,4-tri-*O*-methyl-fructose, respectively. The relative amounts of these compounds to that of methyl 2,3,4-tri-*O*-methyl-β-D-glucopyranoside was found to be 0.66:0.34.

The nuclear magnetic resonance spectrum (Fig. 1) for the mixture of hepta-*O*-methyl sucroses showed two signals (doublets) for the anomeric hydrogen, at low field (16), with a common spacing of 3.5 c.p.s. The relative intensities of the two doublets was 0.65:0.35 and the doublet at lowest field had the greater intensity.

Reaction of the mixture of hepta-*O*-methyl sucroses with *p*-toluenesulphonyl chloride in pyridine produced hepta-*O*-methyl sucrose monotosylate in quantitative yield. The n.m.r. spectrum (Fig. 2) again showed the presence of two doublets for the anomeric hydrogen with a relative intensity of 0.65:0.35. When this monotosylate was treated with sodium iodide in acetone, at 105°, for 15 hours, hepta-*O*-methyl iododeoxysucrose was obtained in 97% yield. The nuclear magnetic resonance spectrum of this compound revealed that 90% of the tosyloxy groups had been replaced by iodine. Hydrogenolysis of the iodocompound produced in 87% yield an iodine-free compound the n.m.r. spectrum of which (Fig. 3) showed two signals in the form of doublets for C-methyl groups. The total intensity of these doublets relative to the total signal for anomeric hydrogen was 2.8 protons (theory 3 protons). The doublets had a spacing of 6.1 c.p.s., which is characteristic for methyl groups substituted on a carbon carrying one hydrogen (7(*b*)). The relative intensities of these signals were once again in the ratio of 0.65:0.35. Therefore, the methyl groups must be at the 6- and 6′-positions of sucrose since these are the only two positions in which a methyl group could be attached to a carbon atom bearing a hydrogen. Furthermore, the GLPC analysis of the products of methanolysis of the hepta-*O*-methyl sucroses showed that more pentamethyl glucoside was formed than pentamethyl fructoside. This can only mean that the myristoyl group was to a greater extent at the 6′- than at the 6-position of sucrose. It can be concluded, therefore, that sucrose monomyristate has about 0.62 of the myristoyl group at the 6′-position, 0.28 at the 6-position, and 0.10 at the other positions. It is likely that most of the latter fraction is on the third primary hydroxyl, namely, the 1′-position of sucrose. This is in direct contrast to the claims of other workers (1, 4) that sucrose monoester is substituted almost exclusively at the 6-position of sucrose.

The results obtained on the structure of sucrose monomyristate by first tosylating the ester and then reacting the tosylated product with sodium iodide in acetone were very misleading. A reaction sequence of this type revealed that 1.84 tosyloxy groups were replaced by iodine in sucrose monomyristate 5.18-tosylate. Since previous work in this laboratory had shown that only the 6- and 6′-positions in polysubstituted tosyl esters of sucrose were replaced by iodine (8), the above result would require 90% of the myristoyl groups to be at the other positions of sucrose. Since such an interpretation is erroneous, clearly secondary tosyloxy groups were replaced by iodine. Furthermore, it is apparent that the presence of the myristoyl group is required for the facile replacement. It is conceivable that the myristoyl groups at the 6- and 6′-positions participate in replacement at the 4- and 4′-positions. It is noteworthy in this respect that Helferich and Gnüchtel

(15) replaced the mesyloxy group in 4-*O*-mesyl-1,2,3,6-tetra-*O*-acetyl-β-D-glucose on heating the compound with sodium iodide in acetone. Methyl α-D-glucopyranoside tetramesylate underwent quantitative replacement of the 6-mesyloxy group (15). The relative amounts of the two isomeric mono-*O*-myristoyl sucroses together with the evidence (6) that they were formed as an equilibrium mixture requires the equilibrium constant, K_e, for the reaction

6-myristoyl sucrose $\rightleftarrows$ 6′-myristoyl sucrose

to be

$$K_e = \frac{0.62}{0.28} = 2.2.$$

This corresponds to a difference in standard free energy of approximately 0.6 kcal mole^{-1} at 80°, which likely arises mainly from the difference in the non-bonded interactions about the ester groupings. The pyranose ring of the glucose moiety of sucrose exists in the chair form wherein the atoms on neighboring carbons in the ring are in the staggered

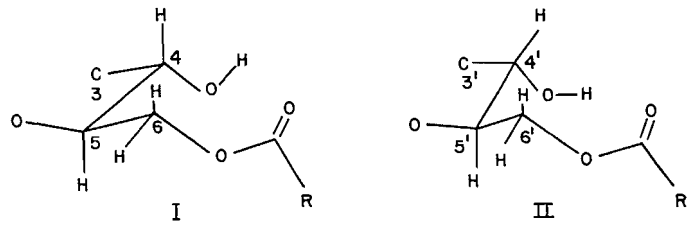

FIG. 4. The conformations of groups or atoms attached to the fourth and fifth carbon atoms in the glucose (I) moiety of 6-myristoyl sucrose, and the fructose (II) moiety of 6′-myristoyl sucrose.

relationship. Therefore, a staggering of the substituents on the 6-carbon with the substituents on the 5-carbon of the glucose molecule will cause an eclipsing of two of the substituents on the 6-carbon with the hydrogen and oxygen on the 4-carbon. This relationship is depicted in the conformational formula I (Fig. 4). On the other hand, the atoms on neighboring carbons in the furanose ring of the fructose moiety can only be in a partially staggered relationship. Therefore, in this case, a staggering of the substituents on carbons 5 and 6 will *not* eclipse the substituents on the 6-carbon with the hydrogen and the oxygen on the 4-carbon (see conformational formula II, Fig. 4). Thus, an acyloxy group at the 6′-position of the sucrose molecule will be in a less congested region of the sucrose molecule than an acyloxy group at the 6-position.

METAMECONINE AS A MODEL COMPOUND IN THE STUDY OF AROMATIC REACTIONS[1]

S. SAFE, MARJORIE ALLEN,[2] AND R. Y. MOIR

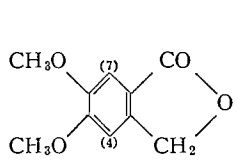
Department of Chemistry, Queen's University, Kingston, Ontario

Received August 9, 1962

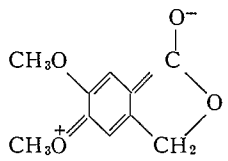
ABSTRACT

Previous work had shown the somewhat unexpected course of nitration, bromination, and demethylation reactions of metameconine and its derivatives. The discovery that metameconine could easily be dinitrated enabled us to bring to light equally interesting results in the relative rates of reduction of the nitro groups, in the course of certain nucleophilic substitution reactions, in the activation of the methylene group, and in certain physical properties. Much of the work, past and present, now holds as its main interest the somewhat special character of a nitro group in the 7-position.

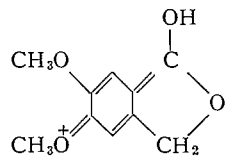
Metameconine (I), because its contrasting methylene and carbonyl groups are equivalently situated with respect to a pair of vacant positions and with respect to a pair of methoxyl groups, is beautifully adapted to the study of competing factors in aromatic reactions. Rây and Robinson (1) were the first to employ it in this way; we have followed their example, and the work of this paper, together with our previously reported experimental work, amounts to a qualitative survey of the possibilities of the system.



I



II



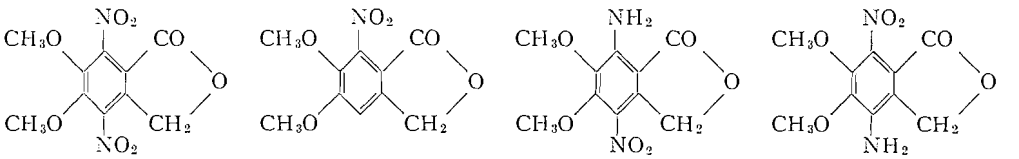
III

In one of the earliest tests of the new "electronic" theory of reactions, Rây and Robinson (1) predicted that metameconine should undergo nitration at position 7 (because of the depression of the directing influence of the methoxyl at position 5 by contributor II to the overall structure of metameconine) rather than at position 4 (suggested by the simple summation of the effects of the separate groups). This prediction was later verified (1–4). Ingold (5) generalized somewhat similar situations as characteristic of systems having a $+E$ group meta to a $-I-M$ group; his generalization has been applied to the present series by Blair and Newbold (6). Such systems often show differences between the directions of nitration and bromination, attributed by Ingold (5) to the greater steric requirements of bromination. Metameconine in particular is brominated at the 4-position (3), but Ingold's explanation is sufficiently less convincing for it than for the experimental examples cited by him to encourage consideration of other effects. Other differences between nitration and bromination are of course known; their importance is recognized and we hope to investigate them later, but in the absence of more quantitative data, only one is worth mentioning here because of its simplicity and because of its application in the quite different reaction of demethylation. Metameconine is much more likely to have its carbonyl protonated under the conditions of nitration than under those of

[1]*Presented in part at the Annual Meeting of the Chemical Institute of Canada in Montreal, August 4, 1961.*
[2]*Holder of a Scholarship from the National Research Council of Canada, 1960–61.*

bromination; the contributor III (more available in nitration than in bromination) would, of course, be more effective than the contributor II in suppressing the influence of the methoxyl at position 5.

This interest in the implications of our previous work on the electrophilic substitution reactions of metameconine was reawakened by a new observation. It was found that metameconine could easily be dinitrated in good yield to give 4,7-dinitrometameconine (IV) under conditions not much more severe than those required to produce high yields

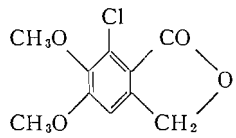


of easily purified 7-nitrometameconine (V) (1–3). Well-separated stages of nitration are commonplace, but few of the known examples involve insertion of the second nitro group para to the first. In fact, a moment's thought will show that, regardless of the course assumed for the dinitration, it is difficult to reconcile the experimental results with the great deactivation of the 4-position of V to be expected from the para nitro group. The existence of two unusual features in 7-nitrometameconine (V) is therefore of interest: (i) conjugation between the methoxyl at position 6 and the nitro group at position 7 is incompatible with the contributors corresponding to II and III, which also repress the activation of position 4; in the extreme limit, this effect would produce the delightful paradox of the *activation* for electrophilic substitution of position 4 by the insertion of a nitro group in the para position; (ii) the nitro group may be less deactivating than expected because of its lack of coplanarity with the ring. The existence of the second feature is confirmed in the discussion of the infrared spectra given later; because of this, the first effect is probably small.

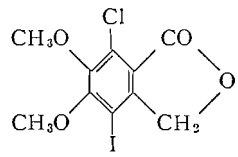
The position of the two methoxyls in metameconine (I) permits the study of competitive effects in demethylation. Coordination with a proton (or some approximately equivalent association with an acid) is undoubtedly the first step in demethylation. Clearly, on account of the contribution of either II or III, coordination should be easier with the methoxyl at position 6 than with that at position 5, and if this is the determining step, demethylation of metameconine should occur preferentially at position 6. Previous work showed that metameconine is preferentially demethylated at position 6 (4), and the same argument may be extended to other demethylations. However, our further experimental work on the demethylation of halogenated metameconines (4, 7) showed that the second step is the determining step in still other reactions of this kind, and it is likely that further progress can be made only by more quantitative methods.

The discovery of the dinitration of metameconine enabled us to consider new types of competitive reactions. For example, which nitro group in 4,7-dinitrometameconine (IV) should be more subject to reduction? One current theory of the effect of substituents stresses that reduction is aided by electron withdrawal from the center to be reduced, and the obvious (but incautious) application of this theory suggests that 7-amino-4-nitrometameconine (VI) should be formed preferentially. The experimental result is the direct contrary: 7-amino-4-nitrometameconine (VI) is formed only in traces, and its isomer, 4-amino-7-nitrometameconine (VII), is formed in very high yield when IV is reduced with iron and acetic acid.

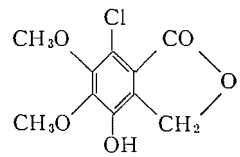
The remarkable substance VII forced several other unexpected results upon our attention. For example, diazotization of VII in hydrochloric acid, followed by reduction with hypophosphorous acid, gave 7-chlorometameconine (VIII) rather than the expected 7-nitrometameconine (V). Nucleophilic substitution of the nitro group by chlorine had,



VIII



IX



X

therefore, preceded the reduction of the diazonium group; other examples of this are, of course, known (8). We sought to avoid the nucleophilic reaction by the use of an acid with a less nucleophilic anion, but diazotization with nitrosylium bisulphate gave a diazonium salt whose great resistance to decomposition is recorded in the experimental part.

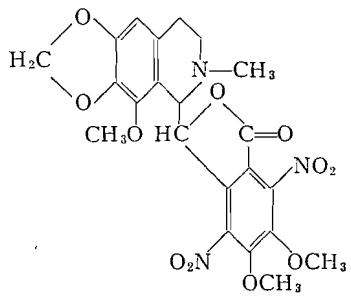
The easy displacement of the 7-nitro group made possible the formation of 7-chloro-4-iodometameconine (IX) by diazotization of VII in hydrochloric acid, followed by the addition of potassium iodide. The structure of the product was proved by its preferential reduction (4, 7) to the known 7-chlorometameconine (VIII) (7). One more surprise remained. The Ullmann reaction of IX with aqueous potassium hydroxide and copper gave only 7-chlorometameconine (VIII) in place of the expected 4-hydroxy-7-chlorometameconine (X). Reductive dehalogenation is a known side reaction of the Ullmann reaction (9, 10), but with the related 4-iodometameconine the normal substitution reaction predominated under similar conditions (10).

The unusual character of a nitro group in the 7-position of the metameconine system was further exemplified by the infrared spectra. A nitro group in the 7-position possessed a higher, sometimes a very much higher, stretching frequency than did a nitro group in the 4-position, suggesting that, in the solid state at least, the 7-nitro group was very far from being coplanar with the ring (11). Thus the dinitro compound IV showed peaks at 1547 and 1530 cm^{-1}, the minor isomer (VI) at 1512 cm^{-1}, and the major isomer (VII) at 1567 cm^{-1}; the conjugation between the nitro group and the amino group was, therefore, very much more effective in VI than in VII, in agreement with the assumed lack of coplanarity of the nitro group at position 7. Other bands in the infrared served to confirm the chemical proofs of structure. Thus hydrogen bonding should be more effective with the amino group of VI than of VII, whether one considers the greater opportunities for internal bonding in VI, the steric blocking of intermolecular bonding to the carbonyl in VII (7), or the greater effect of the nitro group in VI in reducing the shielding of the protons. In fact, the minor isomer from the reduction (VI) had its N—H stretching bands at 3466 and 3353 cm^{-1}, much lower than those of the major isomer (VII) at 3500 and 3402 cm^{-1}. Finally, whether due to resonance, or to the greater opportunities for hydrogen bonding, the compound assigned to VI should have a carbonyl stretching frequency lower than that of the compound thought to be VII; the experimental values were 1749 and 1758 cm^{-1}, respectively. The dinitro compound (IV) showed a band at 1772 cm^{-1}.

Hydroxyl groups do not appreciably bond with phthalide carbonyl groups ortho to them (7, 12), but the fact that VI has a much lower melting point than its geometrically

very similar isomer VII suggests strongly that the amino group in VI is internally bonded to carbonyl. At any rate, this analysis of the situation led one of us (S. S.) to suggest that VI might be more soluble than VII in water. There proved to be a large difference in the solubilities, and extraction of the mixed isomers with hot water led to a rapid separation of the isomers when previously the use of organic solvents had permitted only a very laborious separation of them.

The final item in our qualitative survey of competitive effects in metameconine concerned the activation of the methylene group by nitro groups. Rây and Robinson (1) reported that cotarnine readily condensed with 7-nitrometameconine (V), in which the nitro group is meta to the methylene. Hope and Robinson (13) had long before shown that in similar condensations the activating nitro group might be in any of the ortho, meta, or para positions. Our series of compounds seemed to provide us with the means for a further study of this interesting indifference to position. After a great deal of effort we succeeded in condensing cotarnine and 4,7-dinitrometameconine (IV) to the phthalide–isoquinoline derivative (XI). This proved to be a very labile compound indeed,



XI

easily reverting to its constituents. Clearly, the success of the condensation depended more upon the management of a mobile equilibrium than it did upon the increasing of the activation of the methylene to increase the rate of reactions. We feel, however, that this work has pointed to a new series of compounds interesting both for their relation to the natural phthalide–isoquinoline alkaloids and for the variety of steric effects possible in them.

EXPERIMENTAL

Infrared spectra were determined using potassium bromide disks containing 0.8% by weight of sample. The spectrometer was a Perkin–Elmer Model 21, with a sodium chloride prism; frequencies below 2000 cm^{-1} were corrected by repeated recalibrations with a polystyrene standard, but frequencies above 2000 cm^{-1} were not corrected. Melting points otherwise unspecified were determined on the Kofler Micro Hot Stage, and lowered 3–5° to agree with the precision capillary melting points of standard compounds. Melting points marked (P) were determined on the precision capillary apparatus (7); two interesting examples of large differences in the two melting points appear below.

4,7-Dinitrometameconine (IV)

Metameconine (I) (28 g, m.p. 154–157°) was added over a period of 1 hour to a mechanically stirred mixture of fuming nitric acid (80 ml, *d* 1.5) and concentrated sulphuric acid (20 ml) which had previously been cooled to 0°; though cooling was continued during the addition, the temperature at times rose as high as 8°. After stirring had been continued for 5 hours longer at 0°, the very dark, reddish reaction mixture was slowly poured onto ice with stirring. Next morning, the yellow precipitate was recovered, very thoroughly washed with water, and dried over sodium hydroxide in the desiccator, yield 25.3 g, m.p. 147.8–151.5°. Recrystallized with slow cooling from 50% aqueous acetic acid, the product was obtained as pale yellow flat plates, yield 22.3 g, or 54%; m.p. 153–154°.

In preliminary experiments, with the use of smaller proportions of the acids, 7-nitrometameconine (V) (1–3) was obtained from the crude nitration product by recrystallization from glacial acetic acid; dilution of the mother liquors with water gave a much larger crop of impure material, m.p. 134–151°. Part of this material was recrystallized six times from 50% aqueous acetic acid to give the analytical sample, m.p. 150.4–151.1° (P). Found: C, 42.51, 42.40; H, 2.88, 2.63; N, 10.68, 10.61; 10.10, 9.88% (repeat). Calc. for $C_{10}H_8O_8N_2$: C, 42.26; H, 2.84; N, 9.86%. The rest was nitrated again, giving after one recrystallization from dilute acetic acid a product of m.p. 153–154° in excellent yield.

Reduction of 4,7-Dinitrometameconine

Recrystallized 4,7-dinitrometameconine (22.5 g, m.p. 150–151°) was mechanically stirred with glacial acetic acid (500 ml) and iron powder (10 g). After 1 hour, the temperature had risen to 48°; after 3 hours, more iron powder (3 g) and acetic acid (100 ml) were added; stirring was then continued for another 11 hours. The red mixture was evaporated *in vacuo* on the rotary evaporator, the residue freed from acetic acid by two evaporations with water *in vacuo*, and then treated with water (200 ml). The insoluble residue was recovered, boiled with water, and filtered hot (the 7-amino-4-nitrometameconine passing into the filtrate). The material insoluble in the hot water was recrystallized from butanol with charcoal; slow cooling gave long bright yellow needles of pure *4-amino-7-nitrometameconine (VII)* in a yield of 15.3 g, or 76%; m.p. 230–231°. The analytical sample, obtained from an earlier run in which water extraction of the isomer was not used, after six recrystallizations from butanol (two with charcoal) had a melting point of 228.6–229.1° (P) (with slight decomposition). Found: C, 47.22, 47.05; H, 4.21, 4.01; N, 11.11, 10.95%. Calc. for $C_{10}H_{10}O_6N_2$: C, 47.24; H, 3.94; N, 11.02%.

The hot water extract of the crude reaction product deposited yellow crystals when cooled and concentrated; m.p. 165–171°. Two more recrystallizations from water gave small amounts of not quite pure *7-amino-4-nitrometameconine (VI)*. The analytical sample was recovered from an early run performed before the discovery of the efficient separation by water. The major isomer was isolated by recrystallization of the mixture from butanol; concentration of the mother liquors gave fractions, one of which was rich in the minor isomer. This fraction was recrystallized once from butanol, and then three times from water to give pure *7-amino-4-nitrometameconine (VI)*, m.p. 177.9–178.5° (P), yield 0.065 g (from 7.5 g of the dinitro compound). Found: C, 47.49, 47.19; H, 4.34, 4.12; N, 11.10%. Calc. for $C_{10}H_{10}O_6N_2$: C, 47.24; H, 3.94; N, 11.02%.

7-Chloro-4-iodometameconine (IX)

Concentrated hydrochloric acid (150 ml) and water (110 ml) were added to 4-amino-7-nitrometameconine (6 g) and the mixture stirred and warmed to 90° to dissolve as much solid as possible. With continued stirring, the mixture was cooled to 0° and kept at 0° during the diazotization. Sodium nitrate (2.7 g) in water (25 ml) was added over a period of 1 hour, the stirring continued for a further 2.5 hours, and the mixture then poured, with stirring, into a solution of potassium iodide (18 g) and urea (15 g) in water (35 ml). After the reaction had subsided, more urea was added, and then sulphur dioxide was passed in for about 1 hour to destroy the iodine formed. The yellow precipitate was recovered, washed with water, and dried; yield 4.0 g, or 48%; m.p. 148–150°. The analytical sample, made in a run in which the diazotization was allowed to proceed 10 hours to ensure the prior extrusion of the nitro group, was recrystallized twice from butanol with charcoal, and then four times from methanol; its melting point was 150.5–151.0° (P). Found: C, 33.89, 34.00; H, 2.29, 2.28; I, 35.69, 35.52%. Calc. for $C_{10}H_8O_4ClI$: C, 33.88; H, 2.28; I, 35.80%.

Under the microscope the analytical sample appeared to exhibit dimorphism, one set of crystals melting at 146° and another at 151°. The precision capillary method, in which the crystals were bathed in their own melt, gave the sharp melting point recorded above. Prolonged attempts to isolate one of the forms did not succeed in changing this behavior.

7-Chlorometameconine (VIII)

(a) By Reduction of the Iodo Compound

An aqueous solution of potassium hydroxide (36 ml, 10%) was heated with 7-chloro-4-iodometameconine (0.36 g) until the solid had dissolved. Zinc dust (1.44 g) was added and the mixture stirred and heated under reflux for 4.5 hours. The zinc was removed by filtration, the filtrate brought almost to boiling, and then slowly acidified with hydrochloric acid. The white crystals were recovered, washed, and dried in a desiccator; their yield was 0.205 g, or 88%, and their melting point (196.5–197.5°) was not depressed by admixture with known 7-chlorometameconine (7).

(b) By Ullmann Reduction of the Iodo Compound

Potassium hydroxide (5 g) dissolved in water (105 ml) was heated under reflux for 3 hours with 7-chloro-4-iodometameconine (1.1 g) and Kaulbaum's copper bronze catalyst (0.96 g). The solution was filtered hot, the filtrate reheated with charcoal, again filtered, and acidified cautiously with hydrochloric acid; after the solution had cooled, the resulting white precipitate was recovered and dried; yield 0.57 g, m.p. 190–197°. The crude material was recrystallized six times (once with charcoal) from water containing a little methanol; the pure sample had a melting point of 196.9–197.6° (P). Its infrared spectrum was identical with that of known 7-chlorometameconine. Found: C, 52.85, 52.58; H, 3.98, 3.85; Cl, 15.99%. Calc. for $C_{10}H_9O_4Cl$: C, 52.55; H, 3.94; Cl, 15.51%.

(c) From 4-Amino-7-nitrometameconine (VII)

Water (50 ml) and concentrated hydrochloric acid (10 ml) were heated to boiling, and 4-amino-7-nitrometameconine (crude, 0.67 g) was slowly added with stirring; the mixture was then cooled and kept at 0° during the addition of a solution of sodium nitrite (0.243 g) in water (15 ml). The addition required 50 minutes; hypophosphorous acid (5.4 ml of 50%) was then added dropwise during 30 minutes. Cooling and stirring were continued 90 minutes longer; the mixture was then kept 6 days in the refrigerator, the resulting precipitate recovered and recrystallized four times from aqueous acetic acid (50%), charcoal being used once. The purified material had a melting point of 195.2–195.8° (P) undepressed by admixture with known 7-chlorometameconine (7); the yield of pure material was 0.262 g, or 44%. Its infrared spectrum was identical with that of authentic material. Found: C, 52.50, 52.79; H, 4.21, 4.21 (N, 0.15%). Calc. for $C_{10}H_9O_4Cl$: C, 52.55; H, 3.94 (N, 0.00%).

Three other preparations gave the same compound in about the same yield.

Diazotization of VII in Absence of Chloride

Sodium nitrite (0.735 g) was added to concentrated sulphuric acid, the mixture warmed, then cooled to 0°. Glacial acetic acid (7.5 ml) was stirred with 4-amino-7-nitrometameconine (1.5 g) while concentrated sulphuric acid (3.9 ml) was slowly added; the clear yellow viscous paste was cooled to 0° and then added over a period of 2 hours to the cooled and stirred solution of the "nitrite". The following experiments showed the great stability of the diazonium group in this system. After excess "nitrous acid" had been destroyed with sulphamic acid, cold absolute ethanol (50 ml) was added slowly to the reaction mixture. There was some initial frothing. The stirrer was then removed and the mixture heated under reflux for 1.5 hours, then evaporated *in vacuo* to about one third its original volume, and poured onto ice with stirring. The yellow precipitate was twice crystallized from ethyl acetate – ligroin with charcoal, and dried; a small sample of the crystals decomposed at 171–172°, but without any violence. The infrared spectrum showed the very sharp, intense peak of the diazonium group at 2200 cm^{-1}.

An attempted diazotization in dilute aqueous sulphuric acid eventually gave back the unchanged amino compound.

Anhydrocotarnine-4,7-dinitro-5,6-dimethoxyphthalide (XI)

Cotarnine (2 g, m.p. 116–118°), purified 4,7-dinitrometameconine (2 g, m.p. 153–154°), and absolute ethanol (200 ml) were stirred together for 2 days at room temperature; the crystals which had deposited were then recovered and dried; their melting point of 152–154° was considerably depressed by admixture with the dinitro compound. The crystalline product was then treated with a mixture of methanol and chloroform (1:1), and filtered from insoluble plate-like crystals which did not melt below 250°. After being chilled in a bath of acetone and solid carbon dioxide, the filtrate yielded bright yellow crystals, m.p. 135–138°. Four more somewhat similar recrystallizations from methanol–chloroform (not above room temperature) gave the analytical sample, m.p. 135.8–136.4° (under the microscope; consistent melting points were obtained on the hot stage, but not in the capillary apparatus). The substance was very sensitive to light. Found: C, 53.04, 52.94; H, 4.65, 4.57; N, 8.19, 8.10%. Calc. for $C_{22}H_{21}O_{11}N_3$: C, 52.49; H, 4.21; N, 8.35%.

The product was very labile. An attempt to bring about the above condensation in boiling ethanol resulted in the recovery of nearly all of the 4,7-dinitrometameconine (identified by m.p. and mixture m.p.). The crude product obtained from condensations performed at lower temperatures suffered extensive decomposition when attempts were made to recrystallize it from boiling solvents (e.g. methanol). In one experiment, the very facile reversal of the condensation was shown. The crude product (m.p. 155–157°, giving a marked depression on admixture with 4,7-dinitrometameconine) was dissolved in acetic acid and the solution cautiously neutralized with ammonia. Long yellow needles separated; they were identified as pure 4,7-dinitrometameconine by their melting point (152–153°) and mixture melting point with authentic material. We did not succeed in isolating cotarnine from the decomposition product. The curious sharp drop in melting point attendant on purification of the condensation product was observed several times.

Two attempts to repeat the work of Rây and Robinson on the condensation of 7-nitrometameconine (V) with cotarnine gave only the original nitro compound, and in high yield; compare refs. 2–4.

ACKNOWLEDGMENTS

The work was made possible by Research Grant A-618 of the National Research Council of Canada. We wish to thank the Howard Smith Paper Company of Cornwall, Ontario, for the generous gift of the vanillin used as the raw material for our work.

NOTES

HYDROGEN ATOM RECOMBINATION IN THE FLOW SYSTEM ATTACHED TO A MASS SPECTROMETER AND USED FOR THE STUDY OF MERCURY-SENSITIZED REACTIONS

P. KEBARLE AND M. AVRAHAMI*

A flow system for the study of mercury-photosensitized reactions with a mass spectrometer has been developed by Lossing (1, 2). The primary decomposition of the compounds studied often leads to the formation of hydrogen atoms. An uncertainty has existed as to the fate of these atoms. The hydrogen atoms could be recombining in the flow system or could be reaching the ion source. In the ion source the atoms could be: (*a*) detected as hydrogen atoms, (*b*) adsorbed on the wall and not detected, (*c*) recombining on the wall and detected as hydrogen.

Experiments in which the sensitized decomposition of hydrogen and deuterium was studied in apparatus similar to that of Lossing were made so as to clear up some of these questions. The hydrogen at 1–10 μ Hg was added to the helium carrier gas (10 mm Hg). The reaction zone is defined by an annular resonance lamp of 3.5-cm length. In the flow tube, below the lamp, is a pinhole leading to the mass spectrometer ion source. The lamp could be moved relative to the sampling leak. When the lamp was 1 cm above the leak, the hydrogen decomposition measured at the leak was 7%. After the lamp was moved 12 cm† upstream the decomposition was only 0.9%. In order to demonstrate that the effect was due to downstream recombination, experiments with a 1:1 hydrogen–deuterium mixture were made. In a typical run, with the lamp in the low position, 16% of the hydrogen had disappeared; however, 19% HD was formed. Thus the unrecombined hydrogen was 6.5%, close to the value observed with hydrogen alone. When the lamp was in the upper position, the hydrogen decomposition was 13%, the HD 25%, i.e. the unrecombined hydrogen was 0.5%. These results clearly show that recombination occurs in the flow system.

A series of runs was made in which the position of the lamp was changed stepwise and the missing hydrogen determined. The results are summarized in Fig. 1. The missing hydrogen was multiplied by 2 and given as H atom concentration. The logarithmic plot gives reasonable straight lines, showing that the recombination is first order and thus occurs on the wall (3). The rate constant obtained is 490 ± 200 sec^{-1}. The error is estimated. The rate constant independent of the reactor tubing radius (3) is $k' = kr/2$ and for $r = 0.4$ cm $k' = 98$ cm/sec. It has been shown by Herzfeld (4) that the recombination coefficient γ does not depend on the presence of a carrier gas when the tubing is not too wide. Using, then, the general formula (3) $\gamma = 2kr/\bar{v}$ we obtain $\gamma = 1.5 \times 10^{-3}$ (silica). This agrees reasonably well with $\gamma = 0.75 \times 10^{-3}$ (pyrex) found by Wise (5) by an entirely different technique. Linnet (6) in a more comprehensive study of the recombination on clean silica and pyrex has shown that γ may be as low as 10^{-4}, depending on the pretreatment of the surface. Therefore the rate constant determined in the present experiments may be expected to give only order of magnitude estimates on the recom-

bination of hydrogen atoms in the flow system, but from the results it is at least clear that the recombination is appreciable.

One still has to inquire about the fate of the hydrogen atoms in the ion source. It is evident that, in the experiments where the lamp was closest to the leak, hydrogen atoms were present in sufficient concentration to be detectable with the mass spectrometer. No positive detection could be achieved at mass 1. Since the sensitivity of the instrument at mass 1 could be quite low, while it was known to be adequate at mass 2, an experiment was made in which deuterium was decomposed. A small increase of the mass 2 peak was observed when the lamp was put on. A search of the upper mass range, with the lamp on, revealed no species which could make a contribution to mass 2. The appearance potential of the mass 2 species could not be measured since the concentration was too small, but it could be established that it was lower than that of hydrogen. Therefore, very probably, the peak was due to D atoms. Assuming that the sensitivity of D atoms was equal to half the sensitivity of hydrogen, a balance with the missing D_2 showed that at most 10% of the D atoms was detected. For a D atom pressure of 1 μ, on the high-pressure side of the leak, about 10^{13} atoms/sec enter the mass spectrometer. The instrument has an open ion source (2) and the surface area of the container is larger than 100 cm^2. If each atom were adsorbed on the first collision, it would take many hours before a monolayer (10^{15} atoms/cm^2) could build up. Thus the atoms would be missing, unless an appreciable part was ionized before colliding with a wall. Considering the particle beam, ion source, and pumping geometry, one can estimate that only about 1% of the particles is ionized before collision. Since in the experiment deuterium atoms could be detected, but incompletely, adsorption must occur after a few collisions. In contrast, alkyl radicals are known to withstand hundreds of collisions before adsorption or reaction (7, 8).

REACTIONS OF THE DIMER OF 2,4-TOLYLENE DIISOCYANATE

PRITAM SINGH AND JEAN L. BOIVIN

INTRODUCTION

In a previous paper (1) the uretidine-dione ring in 1,3-bis(4-methyl-3-*n*-butyl-carbamylphenyl)uretidine-2,4-dione was shown to change to an ureylene link by alkaline reduction. With hydrazine hydrate an unsymmetrically monosubstituted urea was obtained, while with hydroxylamine an oxime of the corresponding formamide was formed. Ammonium formate appeared to give the N-substituted amide with the ring unaffected. Further experiments are reported to verify the above reactions, using 1,3-bis[4-methyl-3-(N,N-dibenzylureido)phenyl]uretidine-2,4-dione (1).

DISCUSSION OF RESULTS

As expected, the reduction of 1,3-bis[4-methyl-3-(N,N-dibenzylureido)phenyl]uretidine-2,4-dione, I, by magnesium and methanol gave the symmetrically substituted urea, II. The uretidine-dione ring in the presence of alkali seemed to dissociate and one of the isocyanate groups might be hydrolyzed into an amino group, this latter reacting with the other isocyanate group to form a symmetrically substituted urea.

With ammonium formate, 1,3-bis(4-methyl-3-*n*-butyl-carbamylphenyl)uretidine-2,4-dione was cleaved to form a substituted biuret, by the addition of ammonia, rather than to form the 2,4-bis(N-formamido)uretidine as reported earlier. Although both compounds have the same carbon and hydrogen analysis and the presence of the ring cannot be detected by the carbonyl absorption in the infrared, the latter structure was arrived at when ammonia was found to give the same compound as ammonium formate. It appears that ammonium formate under the conditions used might be dissociating to give ammonia and formic acid, ammonia reacting with the ring.

Ammonium formate reacted in the same way with 1,3-bis[4-methyl-3-(N,N-dibenzylureido)phenyl]uretidine-2,4-dione to give the substituted biuret, IV. The compounds prepared by reaction with ammonia and ammonium formate showed no depression in a mixed melting point determination and the infrared absorption spectra were superimposable.

EXPERIMENTAL

N,N-Bis[4-methyl-3-(N,N-dibenzylureido)phenyl]urea, II

To a stirred suspension of 1,3-bis[4-methyl-3-(N,N-dibenzylureido)phenyl]uretidine-2,4-dione, I (1.0 g), in absolute methanol (30 ml), magnesium turnings (1.0 g) were added in small portions. Then the mixture was heated under reflux for 2 hours, cooled, and evaporated under reduced pressure. Hydrochloric acid (10%, 50 ml) was then added and the mixture warmed to 60° C; it was cooled, filtered, and washed free of acid with water. Crystallization from dimethylformamide–ethanol mixture gave a compound (0.62 g)

REACTIONS OF THE DIMER OF 2,4-TOLYLENE DIISOCYANATE

PRITAM SINGH AND JEAN L. BOIVIN

INTRODUCTION

In a previous paper (1) the uretidine-dione ring in 1,3-bis(4-methyl-3-*n*-butyl-carbamylphenyl)uretidine-2,4-dione was shown to change to an ureylene link by alkaline reduction. With hydrazine hydrate an unsymmetrically monosubstituted urea was obtained, while with hydroxylamine an oxime of the corresponding formamide was formed. Ammonium formate appeared to give the N-substituted amide with the ring unaffected. Further experiments are reported to verify the above reactions, using 1,3-bis[4-methyl-3-(N,N-dibenzylureido)phenyl]uretidine-2,4-dione (1).

DISCUSSION OF RESULTS

As expected, the reduction of 1,3-bis[4-methyl-3-(N,N-dibenzylureido)phenyl]uretidine-2,4-dione, I, by magnesium and methanol gave the symmetrically substituted urea, II. The uretidine-dione ring in the presence of alkali seemed to dissociate and one of the isocyanate groups might be hydrolyzed into an amino group, this latter reacting with the other isocyanate group to form a symmetrically substituted urea.

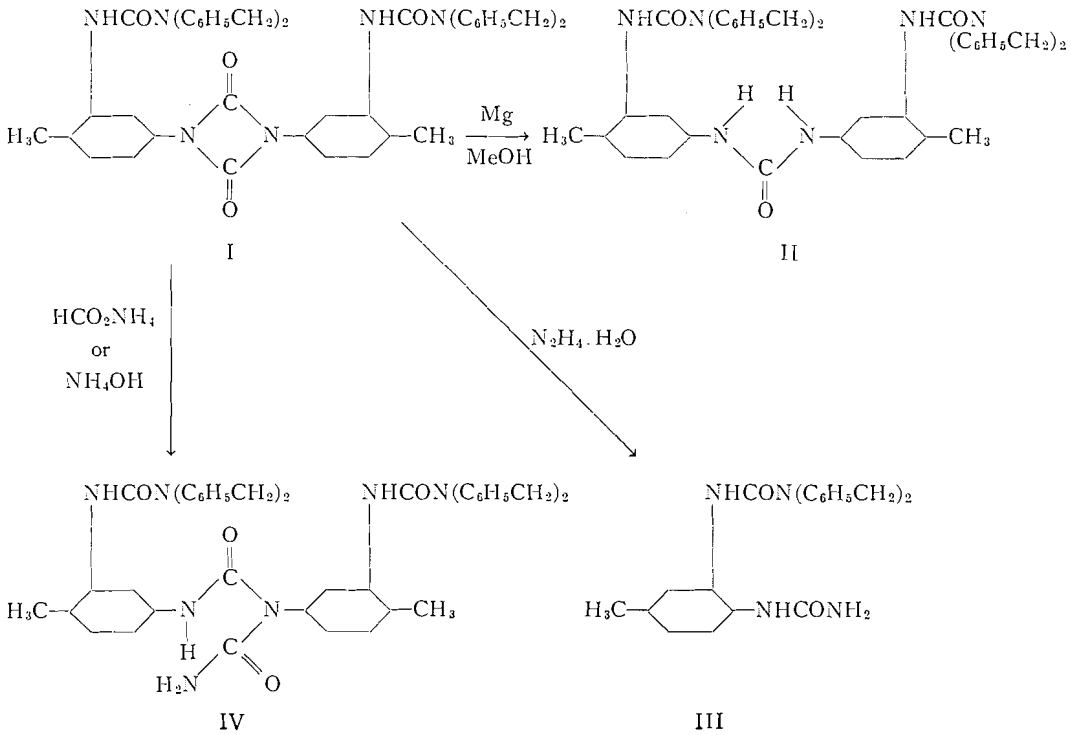
With ammonium formate, 1,3-bis(4-methyl-3-*n*-butyl-carbamylphenyl)uretidine-2,4-dione was cleaved to form a substituted biuret, by the addition of ammonia, rather than to form the 2,4-bis(N-formamido)uretidine as reported earlier. Although both compounds have the same carbon and hydrogen analysis and the presence of the ring cannot be detected by the carbonyl absorption in the infrared, the latter structure was arrived at when ammonia was found to give the same compound as ammonium formate. It appears that ammonium formate under the conditions used might be dissociating to give ammonia and formic acid, ammonia reacting with the ring.

Ammonium formate reacted in the same way with 1,3-bis[4-methyl-3-(N,N-dibenzylureido)phenyl]uretidine-2,4-dione to give the substituted biuret, IV. The compounds prepared by reaction with ammonia and ammonium formate showed no depression in a mixed melting point determination and the infrared absorption spectra were superimposable.

EXPERIMENTAL

N,N-Bis[4-methyl-3-(N,N-dibenzylureido)phenyl]urea, II

To a stirred suspension of 1,3-bis[4-methyl-3-(N,N-dibenzylureido)phenyl]uretidine-2,4-dione, I (1.0 g), in absolute methanol (30 ml), magnesium turnings (1.0 g) were added in small portions. Then the mixture was heated under reflux for 2 hours, cooled, and evaporated under reduced pressure. Hydrochloric acid (10%, 50 ml) was then added and the mixture warmed to 60° C; it was cooled, filtered, and washed free of acid with water. Crystallization from dimethylformamide–ethanol mixture gave a compound (0.62 g)



melting at 219–220° C. CO and NH absorptions for the disubstituted urea partial structure were obtained at 1660 cm^{-1} and 1620 cm^{-1} respectively. $\lambda_{max}^{HCON(CH_3)_2}$: 2660 Å, ϵ_{max}: 37,400, inflection point at 2900 Å. Calc. for $C_{45}H_{44}N_6O_3$: C, 75.4; H, 6.14; N, 11.7%. Found: C, 75.0; H, 6.77; N, 11.8%.

N-[4-Methyl-3-(N,N-dibenzylureido)phenyl]urea, III

To a solution of 1,3-bis[4-methyl-3-(N,N-dibenzylureido)phenyl]uretidine-2,4-dione (1.0 g), m.p. 197° C, in ethanol (95%, 20 ml) was added hydrazine hydrate (85%, 3 ml). After the reaction mixture was refluxed for 3 hours with constant stirring, it was cooled, and a crystalline material (0.8 g) melting at 147–150° C was obtained. Further purification by repeated crystallizations from cellosolve–alcohol gave a compound melting at 151–153° C. CO and NH absorption bands for the monosubstituted urea were at 1695 cm^{-1} (s) and 1635 cm^{-1} (s) respectively. Primary amine absorption was at 3340 cm^{-1} (m) and 3050 cm^{-1} (w). $\lambda_{max}^{HCON(CH_3)_2}$: 2860 Å, ϵ_{max}: 3140 and $\lambda_{max}^{HCON(CH_3)_2}$: 2660 Å, ϵ_{max}: 2340. Calc. for $C_{23}H_{24}N_4O_2$: C, 71.1; H, 6.16; N, 14.4%. Found: C, 71.1; H, 6.02; N, 14.6%.

1,3-Bis[4-methyl-3-(N,N-dibenzylureido)phenyl]biuret, IV

To a stirred solution of ammonium formate (1.0 g) in ethanol (30 ml) 1,3-bis[4-methyl-3-(N,N-dibenzylureido)phenyl]uretidine-2,4-dione (1.0 g) was added and the mixture refluxed for 2 hours with constant stirring. The clear solution obtained was evaporated to dryness and taken up with water. The solid was filtered, washed with water, and dried. Yield, 0.7 g. Further crystallization from ethanol gave an analytical sample, m.p. 118° C. CO and NH absorptions for the biuret were at 1720 cm^{-1} (s) and 1670 cm^{-1} (s) respectively. Primary amino group absorptions were at 3410 cm^{-1} (m), 3300 cm^{-1} (m), and 3050 cm^{-1} (m). λ_{max}^{EtOH}: 2300 Å, ϵ_{max}: 3470, inflection point at 2850 Å. Calc. for $C_{46}H_{45}N_7O_4$: C, 72.7; H, 5.9; N, 12.9%. Found: C, 72.5; H, 5.9; N, 13.0%. The same compound was also prepared in identical yield by substituting ammonium hydroxide (12 *N*, 2 ml) for ammonium formate, other reaction conditions being the same.

1,3-Bis[4-methyl-3-n-butyl-carbamylphenyl]biuret

To a solution of ammonium formate (3.0 g) in ethanol (30 ml) was added 1,3-bis[4-methyl-3-*n*-butylcarbamylphenyl]uretidine-2,4-dione (1.0 g) and the mixture refluxed for 2 hours with constant stirring. The solution was evaporated under reduced pressure and diluted with water to give a precipitate, which was filtered and washed with water. Yield, 0.8 g; m.p. 160–162° C. Three crystallizations from ethanol gave the analytical sample with a melting point of 164° C. Molecular weight by Rast method: 525. Free NH stretching frequencies for the primary amino group: 3410 cm^{-1} (m), 3250 cm^{-1} (m), and 3050 cm^{-1} (w). CO and NH absorptions were exhibited at 1720 cm^{-1} (s) and 1660 cm^{-1} (m). λ_{max}^{EtOH}: 2250 Å, ϵ_{max}: 75,900. Calc. for $C_{26}H_{35}N_5O_6$: C, 60.8; H, 6.82; N, 13.7%. Found: C, 60.5; H, 6.62; N, 13.9%.

The same compound was also prepared by substituting ammonium hydroxide (12 *N*, 2 ml) for ammonium formate. However, the yield in this case was lower (0.3 g). No depression of melting point was observed on a mixed melting point determination and the infrared spectra were superimposable.

KINETICS OF THE REACTIONS OF ATOMIC HYDROGEN
EFFECT OF DIFFUSION ON THE DETERMINATION OF H ATOM CONCENTRATION

W. R. Schulz and D. J. Le Roy

Voevodsky and Kondratiev (1) have recently criticized the results of Berlie and Le Roy (2) in their study of the kinetics of the reaction of atomic hydrogen with ethane, in which they used the method of Tollefson and Le Roy (3, 4). Their criticism is qualitatively correct, and it is the purpose of the present communication to make appropriate modifications in the theory of the method.

Briefly, the method consists in adding a reactant, say RH, to a gas stream containing about 1% H atoms and 99% H_2, and calculating the H atom concentration downstream from measurements of the rate of heat liberation on a detector which is operated as an isothermal calorimeter. As modified by Berlie and Le Roy (2), the detector is a flat spiral of tungsten or platinum wire extending over most of the cross section of the cylindrical reactor, so that all of the H atoms reaching that position combine on the detector. The difference between the wattage required to keep the detector at a given temperature (or resistance) in the absence of H atoms and in the presence of H atoms was defined as W_H. This can be related to the number of H atoms reaching the detector in unit time, n, by the expression

$$W_H = 4.184\Delta Hn/N, \qquad [1]$$

in which ΔH is the molar enthalpy of formation of atomic hydrogen and N is Avogadro's number. The quantity n was then related to the H atom concentration immediately in front of the detector by the expression

$$n = fA(H), \qquad [2]$$

in which f is the linear flow rate of the gas (almost pure H_2) and A is the cross-sectional area of the reactor.

Following this procedure, they measured W_H as a function of x_0, the distance of the detector from the RH inlet, and equated the rate of H atom consumption, $-d(H)/dt$, to $-(N/4.184\Delta HA)(dW_H/dx_0)$. It was necessary to assume that f remained constant (a reasonable assumption, since there is a negligible change in the total number of moles of gas) and that the H atom concentration between the inlet and the detector was not influenced by the diffusion gradient set up by the complete removal of H atoms at the detector.

The same compound was also prepared by substituting ammonium hydroxide (12 *N*, 2 ml) for ammonium formate. However, the yield in this case was lower (0.3 g). No depression of melting point was observed on a mixed melting point determination and the infrared spectra were superimposable.

KINETICS OF THE REACTIONS OF ATOMIC HYDROGEN
EFFECT OF DIFFUSION ON THE DETERMINATION OF H ATOM CONCENTRATION

W. R. Schulz and D. J. Le Roy

Voevodsky and Kondratiev (1) have recently criticized the results of Berlie and Le Roy (2) in their study of the kinetics of the reaction of atomic hydrogen with ethane, in which they used the method of Tollefson and Le Roy (3, 4). Their criticism is qualitatively correct, and it is the purpose of the present communication to make appropriate modifications in the theory of the method.

Briefly, the method consists in adding a reactant, say RH, to a gas stream containing about 1% H atoms and 99% H_2, and calculating the H atom concentration downstream from measurements of the rate of heat liberation on a detector which is operated as an isothermal calorimeter. As modified by Berlie and Le Roy (2), the detector is a flat spiral of tungsten or platinum wire extending over most of the cross section of the cylindrical reactor, so that all of the H atoms reaching that position combine on the detector. The difference between the wattage required to keep the detector at a given temperature (or resistance) in the absence of H atoms and in the presence of H atoms was defined as W_H. This can be related to the number of H atoms reaching the detector in unit time, n, by the expression

$$W_H = 4.184\Delta Hn/N, \qquad [1]$$

in which ΔH is the molar enthalpy of formation of atomic hydrogen and N is Avogadro's number. The quantity n was then related to the H atom concentration immediately in front of the detector by the expression

$$n = fA(\mathrm{H}), \qquad [2]$$

in which f is the linear flow rate of the gas (almost pure H_2) and A is the cross-sectional area of the reactor.

Following this procedure, they measured W_H as a function of x_0, the distance of the detector from the RH inlet, and equated the rate of H atom consumption, $-d(\mathrm{H})/dt$, to $-(N/4.184\Delta HA)(dW_H/dx_0)$. It was necessary to assume that f remained constant (a reasonable assumption, since there is a negligible change in the total number of moles of gas) and that the H atom concentration between the inlet and the detector was not influenced by the diffusion gradient set up by the complete removal of H atoms at the detector.

If the reactions removing atomic hydrogen are all first order in its concentration it is possible to take account of the diffusion effect in a fairly rigorous and simple manner for our experimental conditions. To treat the general case it would be necessary to extend the method of Wise and Ablow (5).

The recombination coefficient on the poisoned walls of the reactor is only of the order of 10^{-4} to 10^{-5} (4), and the total pressures used are of the order of 4 mm. It will therefore be assumed that the H atom concentration will be approximately uniform in any plane normal to the axis of the reactor (5). Equating the net rate of decrease in the H atom concentration in a volume element of cross section A and length dx at a distance x from the RH inlet to the rate of consumption, $k(\mathrm{H})$, it follows that

$$d^2(\mathrm{H})/dx^2-(f/D)d(\mathrm{H})/dx-(k/D)(\mathrm{H}) = 0, \qquad [3]$$

in which D is the diffusion coefficient of atomic hydrogen.

The general solution of [3] is

$$(\mathrm{H}) = C_1e^{-\beta_1 x}+C_2e^{\beta_2 x}, \qquad [4]$$

in which

$$\beta_1 = \frac{f}{2D}\left\{\left(1+\frac{4kD}{f^2}\right)^{1/2}-1\right\}, \qquad [5]$$

$$\beta_2 = \frac{f}{2D}\left\{\left(1+\frac{4kD}{f^2}\right)^{1/2}+1\right\}, \qquad [6]$$

and C_1 and C_2 are to be determined from the boundary conditions. It is convenient to set $(\mathrm{H}) = (\mathrm{H})_0$ at $x = 0$, the point at which the reactant RH is added, from which it follows that $C_1+C_2 = (\mathrm{H})_0$.

If the detector had no influence on H atom concentration one could set $(\mathrm{H}) = 0$ at $x = \infty$, from which it would follow that C_2 would be equal to zero and (H) would be equal to $(\mathrm{H})_0e^{-\beta_1 x}$. This was the procedure adopted by Dickens *et al.* (6) in dealing with the decay of oxygen atom concentration.

Since, in our method, the detector is designed to remove all H atoms reaching it we adopt the boundary condition $(\mathrm{H}) = 0$ at $x = x_0$. With this condition

$$(\mathrm{H}) = (\mathrm{H})_0\frac{e^{\beta_1(x_0-x)}-e^{-\beta_2(x_0-x)}}{e^{\beta_1 x_0}-e^{-\beta_2 x_0}}. \qquad [7]$$

The number of H atoms crossing any plane perpendicular to the axis per unit time is equal to $fA(\mathrm{H})-DAd(\mathrm{H})/dx$. In particular, the number reaching the plane of the detector per unit time will be equal to $-DA(d(\mathrm{H})/dx)_{x=x_0}$, since $(\mathrm{H}) = 0$ at $x = x_0$. Thus, from [1],

$$\frac{W_{\mathrm{H}}N}{4.184\Delta H} = -DA\,(d(\mathrm{H})/dx)_{x=x_0}, \qquad [8]$$

or

$$\frac{W_{\mathrm{H}}N}{4.184\Delta HDA} = (\mathrm{H})_0\frac{(\beta_1+\beta_2)e^{-\beta_1 x_0}}{1-e^{-(\beta_1+\beta_2)x_0}}. \qquad [9]$$

In general $(\mathrm{H})_0$ will depend on x_0 even when the rate of formation of H atoms in the dissociator and the flow rate are kept constant. However, if the values of x_0 are kept

large enough it seems reasonable to assume that $(H)_0$ will be relatively independent of x_0. In our previous procedure the slope of a plot of $-\ln W_H$ vs. x_0 was equated to the first-order rate constant divided by the flow rate. If we define the quantity obtained in this way as k^*, rather than the true rate constant k, then

$$[10] \qquad -\frac{d \ln W_H}{dx_0} \equiv k^*/f = \beta_1 + \frac{\beta_1+\beta_2}{e^{(\beta_1+\beta_2)x_0}-1} - \frac{d \ln (H)_0}{dx_0}.$$

The first approximation to β_1 will be k^*/f. The second term will be small compared to β_1; both it and the third term will vanish as x_0 increases and the two terms tend to cancel each other. It follows that β_1 can be equated to k^*/f if the values of x_0 are large enough for the slope of the $-\ln W_H$ vs. x_0 plot to become constant.

From [5] it is evident that the true rate constant, k, is related to β_1 by the expression

$$[11] \qquad k = \beta_1 f + \beta_1^2 D,$$

or, if the second and third terms of [10] can be neglected,

$$[12] \qquad k = k^* + (k^*)^2 D/f^2.$$

A test of [12] was made by carrying out a number of experiments over a range of values of D and f. No RH was added, so k is the rate constant for H atom consumption in the absence of reactant. The values of D were taken from Amdur (7), and are, of course, inversely proportional to the pressure. The pertinent data are given in Table I. The plots

TABLE I

Effect of flow rate and diffusion coefficient on $\beta_1 f$

Pressure (mm)	f (cm sec^{-1})	D (cm^2 sec^{-1})	$\beta_1 f$ (sec^{-1})	$\beta_1^2 D$ (sec^{-1})	D/f^2 (sec)
3.99	84.4	340.9	2.02	0.196	0.048
3.92	69.0	347.6	1.97	0.282	0.073
4.02	43.4	338.7	1.67	0.508	0.180
3.52	30.6	386.8	1.43	0.844	0.413
3.19	21.8	426.6	1.05	0.983	0.898

Least-squares value of $k = 2.27$ sec^{-1}

of $-\ln W_H$ vs. x_0 were linear over more than 20 cm but fell off close to the RH inlet, where the slope increased, indicating the importance of the second term in equation [10] for small values of x_0. The least-squares slopes of the linear portions of the curves were equated to β_1. In Fig. 1 is shown a plot of $\beta_1 f$ vs. $\beta_1^2 D$, i.e. k^* vs. $(k^*)^2 D/f^2$. The curve is linear, as predicted by the theory, and the least-squares slope of 1.15 is in good agreement with the predicted value of unity.

It should be emphasized that the present treatment is applicable to kinetic processes which are first order in the atom concentration. It has been assumed that W_H is dependent only on the H atom combination on the detector, i.e. that the H atom concentration is much greater than that of any radicals that might combine on the detector or of any excited molecules that might be deactivated on it (8). Gomer has pointed out (9) that any expansion or contraction occurring in a flow system may simulate a first-order reaction. However, under the conditions used in our experiments this effect would be negligible. The initial concentration of H atoms is only about 1%, and if they were completely removed, which is not the case, by combination or the conversion of a higher paraffin to methane the contraction would amount to about 0.5%.

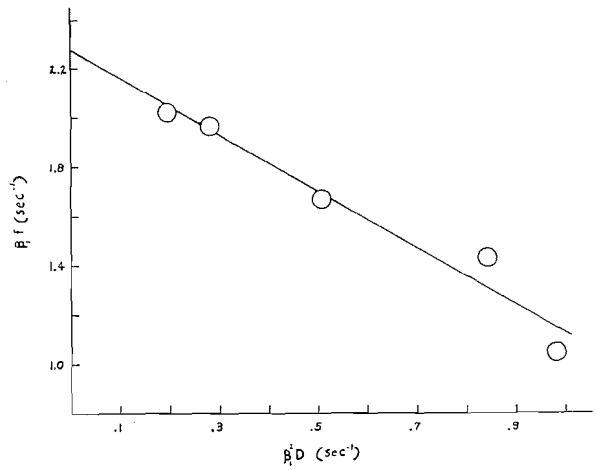

FIG. 1. Test of the relation $k = \beta_1 f + \beta_1^2 D$, or $k = k^* + (k^*)^2 D/f^2$.

The present treatment will be applied, in a forthcoming publication, to some recent work on the reaction of atomic hydrogen with propane.

THE STRUCTURE OF TUBEROSTEMONINE[1]

O. E. EDWARDS AND G. FENIAK[2]

The investigations of Götz, Bögri, and Gray (1) have established the structure of tuberostemonine as being either I or II. These formulations were consistent with the work of Professor Uyeo and his colleagues (2), and with the bulk of the evidence accumulated in these laboratories (3). We now present evidence that permits us to assign structure I to the alkaloid.

The n.m.r. spectrum of bisdehydrotuberostemonine (III or IV) in chloroform (3) had two apparent triplets at τ 5.45 and τ 6.9. These signals shifted to τ 6.1 and τ 7.65 in

I II III IV

pyridine but retained their structure, confirming their true triplet character. Because of its chemical shift and the fact that it is a triplet, the signal at τ 5.45 can unambiguously be assigned to the hydrogen on C_9.[3,4] The similarity in the splitting of the signals at τ 5.45 and τ 6.9 (J = 6.5 c.p.s. in each case) suggested that the hydrogens responsible for these signals were on adjacent carbon atoms. If this were so, the signal at τ 6.9 would clearly be that of the hydrogen attached to C_{10}, which would be deshielded by the pyrrole ring and nearby oxygen atoms. The simplicity of this signal would not be consistent with structure IV for bisdehydrotuberostemonine since the C_{10} hydrogen in structure IV would give rise to at least a four-line multiplet.

It appeared that the spin decoupling technique could be used to establish whether the hydrogens giving rise to the signals at τ 5.45 and τ 6.9 were actually on adjacent carbon atoms. The method described by Kaiser (4) was used. It proved necessary to use an audiomodulation frequency of 85 c.p.s. rather than 92 c.p.s. (which corresponds to the chemical shift between the two signals) to avoid overlap of signals. The intensity of the decoupling magnetic field had to be increased to compensate for this. Under these conditions the upper side band of the τ 5.45 signal and the lower side band of the τ 6.9 signal were reduced to doublets (J = 6.5 c.p.s. in both cases) and there was no sign of other decoupling occurring in the vicinity of these signals. This proved that the two hydrogens in question were indeed on adjacent carbons. It follows that bisdehydrotuberostemonine has structure III and that tuberostemonine is correctly represented by I.

We are grateful to Dr. F. A. L. Anet for the spin decoupled spectrum and advice on its interpretation.

[3]*From its chemical shift, the quartet at τ 4.6 must also be due to a hydrogen of the type* H—C(|)—O—. *Since this signal is not present in the n.m.r. spectrum of the methyl ester of the acid obtained by hydrogenolysis of bisdehydrotuberostemonine (3), it must be due to the allylic hydrogen on* C_{16}.

[4]*The numbering system is based on that given for azepino[3,2,1-hi]indole in Patterson et al. (A. M. Patterson, L. T. Capell, and D. F. Walker. The ring index. American Chemical Society Publications, Washington. 1960).*

ON PAOLONI'S NOTE ENTITLED: THE STRUCTURE OF CARBOLINES AND RELATED COMPOUNDS

R. A. ABRAMOVITCH

In a recent note (1), Paoloni has alleged that a phrase, quoted by Abramovitch and Adams (2) from his original paper (3), is not a *verbatim* translation of any sentence in that paper, "but is, on the best, the abstract of their interpretation of the last paragraph of p. 1532 of reference 2" (1). Both of these statements are incorrect. The phrase does indeed appear in Paoloni's original paper, on p. 1538, l. 16–18. The sentence, of which the phrase quoted is a part, appears in a discussion of the charge distributions as calculated by him, and reads as follows (my italics): "Su questa posizione si trova ora un eccesso negativo, che *illustra in maniera eloquente il compromesso tra la tendenza alla formazione del sestetto e quella al bilanciamento delle cariche*, sottolineata da R. Robinson[1] come una necessità strutturale" (3). The phrase italicized above was translated (2) as follows: "illustrate eloquently the compromise between the tendency to form the sextet and that to neutralize the charges".
