C_{19}-Azomethine (54 mg) in acetone was treated with excess methyl iodide in acetone. The product, after three crystallizations from acetone, formed needles, m.p. 326–328°; $[\alpha]_D$ −27° (*c*, 1.19); $[M]_D$ −112°; pK_a ~12.5 (95% EtOH). Found: C, 58.01; H, 7.62. Calc. for $C_{20}H_{32}NI$ (413): C, 58.11; H, 7.75. Infrared spectrum: ν_{max} 1685 cm^{-1} ($>C=\overset{+}{N}<$).

Isomethiodide VII from the C_{19}-Azomethine

C_{19}-Azomethine (70 mg) was converted to methiodide as above, and the solvent evaporated. The crystalline residue was refluxed for 7 hours under nitrogen with 5 ml of a solution of 400 mg of potassium hydroxide in 7 ml of methanol. (The conversion was not complete after 3 hours.) The methanol was removed under reduced pressure, the residue taken up in water and extracted into ether which was washed and dried. The pale yellow gum from the ether was dissolved in methanol and exactly neutralized with hydriodic acid in methanol. The solvent was removed under reduced pressure and the residue taken up in methanol to which charcoal was added. The solution was filtered through a short celite column and the methanol evaporated. The crystalline residue was recrystallized four times from acetone–hexane and formed needles, m.p. 273° (evacuated capillary); $[\alpha]_D$ −24° (*c*, 1.43); $[M]_D$ −99°; pK_a 10.65 (95% EtOH). Found: C, 57.87; H, 7.45. Calc. for $C_{20}H_{32}NI$ (413): C, 58.11; H, 7.75. Infrared spectrum: ν_{max} 1697 cm^{-1} ($>C=\overset{+}{N}<$).

Lactam VIII from Isocarbinolamine VI

The isomethiodide (85 mg) was dissolved in 4 ml of dioxane–water (3:1) and treated with an excess of freshly precipitated silver oxide. After 1 hour the material was filtered and the residue washed with a little

[15]*Further proof of the correctness of the structure and stereochemistry has now been provided (J. ApSimon and O. E. Edwards, in preparation) by partial synthesis from podocarpic acid of the mirror image of an N-acetyl phenol derived from atisine (4).*

dioxane–water. (There appeared to have been some reduction of the silver oxide.) A solution of potassium permanganate (22 mg, 1 equiv.) in 3 ml of water was added dropwise to the filtrate. The first few drops were decolorized slowly but then decolorization became more rapid and manganese dioxide separated. After half of the permanganate solution had been added, the purple color persisted for 0.5 hour and so the addition was stopped. Sodium bisulphite was added to decolorize the solution, which was then percolated through celite to remove manganese dioxide. The filtrate was evaporated to dryness *in vacuo* and the residue taken up in ether. The ether solution was washed with 6 *N* sulphuric acid to remove any basic material, and then with water. The ether extract furnished 30 mg of neutral material of which 22.7 mg was pentane soluble and crystalline with m.p. 129–132°. Recrystallization from pentane gave the lactam VIII as prisms, m.p. 134.5–136°; $[\alpha]_D$ −56° (*c*, 0.81); $[M]_D$ −170°. Found: C, 79.91; H, 10.20. Calc. for $C_{20}H_{31}ON$ (301): C, 79.67; H, 10.37. Infrared spectrum: ν_{max} 1649 cm^{-1} (δ-lactam).

The lactam was recovered quantitatively after 2 hours at 200° in a solution of potassium hydroxide in trimethylene glycol.

N-Methyl Base IX

Azomethine methiodide (220 mg) was dissolved in aqueous methanol (80%, 10 ml) and a large excess of sodium borohydride (130 mg) was added. The solution became cloudy and an oil was gradually precipitated. After 3 hours the solvent was evaporated and the residue taken up in ether, washed with aqueous sodium carbonate, then water, and the ether dried with sodium sulphate. The ether extract was evaporated to give a clear gum (163 mg) which solidified. After four recrystallizations from acetone the product formed prisms, m.p. 59–60°; $[\alpha]_D$ −71° (*c*, 0.93); $[M]_D$ −211°. Found: C, 83.74; H, 11.36. Calc. for $C_{20}H_{33}N$ (287): C, 83.56; H, 11.57.

Lactam VIII from N-Methyl Base IX

A solution of the N-methyl base (85 mg) in pyridine (4 ml) was added to a solution of chromic oxide (138 mg) in pyridine (4 ml) and kept for 20 hours at room temperature. Sulphur dioxide was passed in with cooling until the solution was clear blue-green. The solvent was removed under reduced pressure, and the residue taken up in ether and washed with dilute aqueous hydrochloric acid, then water. The dried ether extract was evaporated to give a clear gum (51 mg) which solidified easily on seeding with the isolactam. The gum was chromatographed on neutral alumina (Grade IV, 1.5 g) and eluted with hexane (20 ml) to give 31 mg of crystalline lactam as prisms from pentane, m.p. 134–136°; $[\alpha]_D$ −57° (*c*, 0.69); $[M]_D$ −171°. It did not depress the melting point of the lactam from the isocarbinolamine and their infrared spectra (mulls) were identical.

Oxidation of N-Methyl Carbinolamine V

The methiodide from 108 mg of azomethine was dissolved in aqueous dioxane and stirred with excess freshly prepared silver oxide. The solid was removed by filtration. A solution of 0.7 g of sodium hydroxide in 4 ml of water was added to the filtrate, followed by dropwise addition over 20 minutes of a solution of 90 mg of potassium permanganate in 8 ml of water. The manganese dioxide was removed by filtration and the filtrate was acidified with dilute sulphuric acid and extracted with methylene chloride. The methylene chloride solution yielded 52 mg of neutral product. This was adsorbed from pentane solution onto 500 mg of alumina (Grade II). One component of the mixture was rapidly eluted with pentane. Chloroform then eluted a fraction from which was obtained, after recrystallization, 15 mg of lactam, m.p. 134.5–136°. This did not depress the melting point of lactam VIII, and their infrared spectra were identical.

Action of Nitrous Acid on the C_{19}-Azomethine III

A solution of azomethine (250 mg), sodium acetate (625 mg), and sodium nitrite (625 mg) in a mixture of dioxane (37.5 ml) and water (25 ml) was treated dropwise with a solution of acetic acid (1.25 ml) in dioxane (2.5 ml) over 6 hours. Nitrogen was passed over the solution continuously and during the addition of the acid the mixture was agitated vigorously. After standing for a further 12 hours, the solvents were evaporated at 30° and the residue taken up in ether. The ether extract was washed with aqueous potassium carbonate, water, 6 *N* sulphuric acid, and then again with water. On evaporation of the dried ether extract, 265 mg of a neutral yellow gum was obtained, $[\alpha]_D$ −48° (*c*, 1.05, $CHCl_3$). Adsorption on alumina (Grade III neutral, 8 g) and eluting with hexane gave the following fractions:

(1) mobile liquid (7.2 mg),
(2) material which crystallized from pentane (17.3 mg),
(3) non-crystalline yellow gum,
(4) yellowish solid, very soluble in pentane (20 mg).

Benzene and benzene–chloroform (3:2) eluted 208 mg of nearly pure hemiacetal (78%) which crystallized spontaneously.

This yield of hemiacetal was exceptional, and on repetition under apparently identical conditions the yield could drop to 60% or less of hemiacetal. The sodium acetate was added with the thought of trapping the primary carbonium ion before it could rearrange. However, no acetate ester was formed, and it appears that this may be useless.

Hemiacetal XIII and its Reduction

After recrystallization from pentane the hemiacetal had m.p. 164–165°, $[\alpha]_D$ −56° (*c*, 1.09). Its infrared spectrum had ν_{max} 3350 (OH) and 1050 (O—C—O—C) cm^{-1}. Found: C, 78.83; H, 10.37. Calc. for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41.

The hemiacetal was inert to sodium borohydride in aqueous methanol. However, in a refluxing solution of lithium aluminum hydride in ether it was quantitatively converted in 1 hour to the corresponding diol. This crystallized from aqueous alcohol as fine needles, m.p. 169°. For analysis this was sublimed at 140° at 5×10^{-4} mm. Found: C, 78.11; H, 11.08. Calc. for $C_{19}H_{32}O_2$: C, 78.03; H, 11.03.

Oxidation of Hemiacetal XIII to a Lactone

(*a*) Hemiacetal (20 mg) in dioxane (3 ml) was treated dropwise with bromine water. The first few drops were decolorized rapidly. The reaction mixture containing a small excess of bromine was left overnight. The solvent was evaporated and the white solid taken up in ether, washed with water, and dried. Evaporation of the ether gave the lactone as a white solid (19 mg). This was purified by percolating a benzene solution through neutral alumina (Grade III). Recrystallization from methanol–water afforded plates, m.p. 162.5–164°, $[\alpha]_D$ −37° (*c*, 0.91). Found: C, 79.03; H, 9.77. Calc. for $C_{19}H_{28}O_2$ (288): C, 79.12; H, 9.79%. Infrared spectrum: ν_{max} 1725 cm^{-1} (δ-lactone).

(*b*) A solution of 80 mg of hemiacetal in 4 ml of acetic acid was oxidized during 0.5 hour by 31 mg of sodium dichromate dihydrate in 1.25 ml of acetic acid. The excess reagent was destroyed by sodium sulphite, then the acetic acid removed under reduced pressure. The residue was taken up in methylene chloride, and this washed with dilute acid and sodium carbonate solution. The 79 mg of product was chromatographed on 1.7 g of neutral alumina (Grade II). Benzene and 1:1 benzene–ether eluted 55 mg of lactone. After recrystallization from aqueous methanol this melted at 163°; mixed m.p. with the lactone from oxidation by bromine–water 164°. The lactone was reduced by lithium aluminum hydride in refluxing ether to the same diol, m.p. 169°, obtained on reduction of the hemiacetal.

Primary Alcohol from XIII

Hemiacetal XIII (150 mg) and hydrazine (95%, 2 ml) in triethylene glycol (4 ml) were warmed overnight on a water bath. A further portion of hydrazine (1 ml) was added and the mixture refluxed at 140° for 1 hour. Potassium hydroxide pellets (1 g) were added gradually and the temperature raised to 200° for 6 hours. Water was added to the cooled mixture, which was then extracted with ether, washed with water, and dried. Evaporation of the ether gave a white solid (138 mg). Chromatography on neutral alumina (Grade III, 5 g) and elution with hexane–benzene mixtures gave a pentane-soluble solid (122 mg) which when crystallized from methanol gave prisms, m.p. 96°, $[\alpha]_D$ −38° (*c*, 1.00). Found: C, 82.30; H, 11.50. Calc. for $C_{19}H_{32}O$: C, 82.54; H, 11.66%. Infrared spectrum: ν_{max} 3260, 1017 cm^{-1} (OH).

Oxidation of Primary Alcohol to Aldehyde

The primary alcohol (88 mg) in acetic acid (4 ml) was treated dropwise with a solution of sodium dichromate dihydrate (31 mg) in acetic acid (1 ml). A small excess of reagent was present for 3 hours. Excess reagent was destroyed with sodium bisulphite and the solvents were evaporated. The solid was taken up in ether, washed with dilute aqueous sodium hydroxide (1%), water, and then dried. Evaporation of the ether gave a neutral solid (81 mg) which was chromatographed on neutral alumina (Grade III, 2 g). Elution with pentane gave the aldehyde, which crystallized from methanol as plates, m.p. 129–131°, $[\alpha]_D$ −94° (*c*, 0.84). Found: C, 82.99; H, 10.75. Calc. for $C_{19}H_{30}O$ (274): C, 83.15; H, 11.02%. Infrared spectrum: ν_{max} 2760, 2680, 1696 cm^{-1} (—CHO).

Oxidation of Aldehyde to Acid XV

Aldehyde (45 mg) in acetic acid (8 ml) was kept with a slight excess of a modified Kiliani reagent (600 mg of sodium dichromate, 800 mg of concentrated H_2SO_4, 1.35 g of water, and 1.35 g of acetic acid) for 2 hours. Excess reagent was decomposed with methanol and a small amount of sodium bicarbonate was added to neutralize the sulphuric acid. The solvents were evaporated and the solid was taken up in ether. The ether solution was extracted with aqueous sodium hydroxide (5%), washed with water, and dried. On evaporation the ether layer gave 37 mg of 'neutral' material. The alkaline extract, on acidification and extraction with ether, afforded 3 mg of gummy material. The 'neutral' material was chromatographed on neutral alumina (Grade III, 1 g). Hexane eluted a trace of aldehyde, while chloroform–methanol eluted the acid (32 mg), which crystallized from methanol–water as plates, m.p. 217°, $[\alpha]_D$ −45° (*c*, 1.43). Found: C, 78.63; H, 10.26. Calc. for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41%. Its pK_a' in 70% alcohol was 9.6 and in 80% dimethyl cellosolve was 9.42 (16). Its infrared spectrum (nujol mull) had peaks at 1695 cm^{-1} (medium) and 1675 cm^{-1} (strong) and a characteristic band for carboxylic acids at 1256 cm^{-1} (medium). In rather concentrated chloroform solution (9.7 mg/ml) its infrared absorption had peaks at 3560, 3480 cm^{-1} (OH) and 1730 (medium), 1690 (strong) cm^{-1} (C=O). In dilute solution in chloroform a new band appeared at 1715 cm^{-1} and the 1730 cm^{-1} band increased in intensity at the expense of the one at 1690 cm^{-1}.

The sodium salt of the acid was prepared in methanol. After removal of the solvent under reduced pressure the residual solid was washed with dry ether. Its infrared spectrum (nujol mull) had no absorption between 1600 and 1800 cm^{-1}, but had typical carboxylate anion absorption at 1565 (medium) and 1545 (strong) cm^{-1}.

1β-Methoxycarbonyl-1α,12β-dimethyl-7-hydroxy-trans-anti-trans-perhydrophenanthrene (XIX)

The α,β-unsaturated ketone from agathenedicarboxylic acid (17) (200 mg) in dry ether was slowly added to a vigorously stirred solution of lithium (300 mg) in liquid ammonia (100 ml). After 40 minutes the stirring was stopped, ammonium chloride (1 g) was carefully added, and the ammonia allowed to evaporate. Water (50 ml) was added to the residual slurry and the mixture was continuously ether-extracted for 36 hours. The extract was dried and evaporated, yielding a yellow oil (170 mg), which was distilled under reduced pressure. The main fraction (120 mg) distilled at 130–140° at 10^{-3} mm and crystallized on treatment with ethyl acetate. Recrystallization from the minimum volume of ethyl acetate yielded colorless prisms (95 mg), m.p. 107–108°, $[\alpha]_D$ +55.5° (*c*, 0.46). Found: C, 73.41; H, 10.30. Calc. for $C_{18}H_{30}O_3$: C, 73.43; H, 10.27. Infrared spectrum: ν_{max} 3550 cm^{-1} (hydroxyl), 1710 cm^{-1} (ester).

1β-Methoxycarbonyl-1α,12β-dimethyl-trans-anti-trans-perhydro-7-phenanthrone (XX)

The above alcohol (100 mg) in benzene (10 ml) and acetic acid (5 ml) was mixed with a solution of sodium dichromate dihydrate (75 mg) in acetic acid (10 ml) and allowed to stand at room temperature for 4 hours. The mixture was poured into water (50 ml) and the benzene layer separated. The aqueous layer was further extracted with benzene (3×25 ml) and the combined extracts washed well with 2 *N* sodium carbonate solution and water. The extract was dried and evaporated, yielding a pale yellow oil (83 mg) which crystallized on treatment with ether. Sublimation at 155° at 5×10^{-4} mm yielded colorless needles, m.p. 196°. Found: C, 73.64; H, 9.42. Calc. for $C_{18}H_{28}O_3$: C, 73.93; H, 9.65. Infrared spectrum: ν_{max} at 1720 cm^{-1}, strong and broad (ketone and ester). Its optical rotatory dispersion curve showed a single positive Cotton effect, λ_{max} 306 mμ, $[\alpha]_{max}$ +1000°; λ_{min} (approx.) 272 mμ, $[\alpha]_{min}$ −625°.

1β-Carboxyl-1α,12β-dimethyl-trans-anti-trans-perhydrophenanthrene (XXI)

The keto ester XX (50 mg) in hydrazine hydrate (100%) (1.5 ml) and triethylene glycol (2 ml) was heated to 140° during 1 hour, potassium hydroxide (600 mg) was added, and the temperature was raised to 200°±5° for a further 4 hours. The reaction mixture was cooled, acidified with 2 *N* sulphuric acid, and ether-extracted. The ether extract was washed well with water, dried, and evaporated to yield a pale yellow oil (35 mg). The product was chromatographed on silica (3 g) in pentane–benzene (50:50) to yield colorless needles, m.p. 130–140°. Sublimation at 120° at 10^{-4} mm yielded the analytical sample (20 mg), m.p. 150–154°, $[\alpha]_D$ +34° (*c*, 0.36). Found: C, 77.07; H, 10.74. Calc. for $C_{17}H_{28}O_2$: C, 77.22; H, 10.67. Infrared spectrum: ν_{max} 1697 cm^{-1} (—COOH); pK_a in 80% ethanol 8.4.

The same acid (XXI) (mixed melting point, infrared, and n.m.r. spectra) was also obtained by a similar Wolff–Kishner reduction of 1β-carboxyl-1α,12β-dimethyl-*trans*-anti-*trans* perhydro-6-phenanthrone (XXIV), kindly supplied by Dr. R. H. Bible, Jr.

1β-Carboxyl-1α,12β-dimethyl-trans-anti-cis-perhydrophenanthrene (XVIII)

1β-Carboxyl-1α,12β-dimethyl-*trans*-anti-*cis*-perhydro-6-phenanthrone (510 mg) (kindly supplied by Dr. R. H. Bible, Jr.), 100% hydrazine hydrate (4 ml), and triethylene glycol (4 ml) were heated to 140° during 1 hour. Potassium hydroxide (4 g) was added and the temperature raised to 200°±5° for a further 4 hours. The reaction mixture was cooled, acidified with 2 *N* sulphuric acid, and ether-extracted. The ether extract was washed well with water, dried, and evaporated to yield a colorless crystalline product (415 mg), m.p. 140–158°. Sublimation at 118° at 10^{-4} mm yielded colorless prisms of the acid XVIII, m.p. 171°, $[\alpha]_D$ +89° (*c*, 0.33). Found: C, 77.31; H, 10.84. Calc. for $C_{17}H_{28}O_2$: C, 77.22; H, 10.67. Infrared spectrum: ν_{max} 1695 cm^{-1} (—COOH); pK_a in 80% ethanol 8.2.

Attempted Synthesis of XVIII from Agathenedicarboxylic Acid

The α,β-unsaturated ketone from agathenedicarboxylic acid (600 mg) in triethylene glycol (5 ml) and hydrazine hydrate (100%) (3 ml) were heated to 140° during 1 hour. Potassium hydroxide (3 g) was added and the temperature raised to 200° for 5 hours. The mixture was cooled, acidified with 2 *N* H_2SO_4, and thoroughly ether-extracted. Drying and evaporation yielded a semicrystalline oil (650 mg) which was chromatographed on silica (10 g). Elution with pentane removed triethylene glycol while benzene–pentane (50:50) gave colorless prisms, m.p. ca. 140°. Recrystallization from *n*-pentane yielded colorless prisms, m.p. 140–145°, $[\alpha]_D$ +128° (*c*, 0.47). Found: C, 77.67; H, 9.76. Calc. for $C_{17}H_{26}O_2$: C, 77.82; H, 9.99. Infrared spectrum: ν_{max} 1698 cm^{-1} (—COOH). Proton resonance was observed at 8.80, 9.16, and 9.35. More than one vinyl hydrogen signal was present, indicating contamination with XXIII.

Hydrogenation of Wolff–Kishner Product

The acid produced above (25 mg) in acetic acid (10 ml) was hydrogenated in the presence of prereduced platinum oxide (24 mg). In 1 hour the uptake of 2.4 ml of hydrogen was observed (calc. for 1 mole 2.3 ml). The solution was filtered and the catalyst washed well with alcohol. Removal of the solvents under vacuum left a colorless oil (25 mg) which crystallized on treatment with ethyl acetate, m.p. 118–132°. Sublimation at 120° at 10^{-4} mm yielded colorless prisms, m.p. 130–136°, $[\alpha]_D$ +32° (*c*, 0.42). Found: C, 77.35; H, 10.54. Calc. for $C_{17}H_{29}O_2$: C, 77.22; H, 10.67. Infrared spectrum: ν_{max} at 1695 cm^{-1} (—COOH). Proton resonance observed at 8.78, 9.025, 9.27, corresponding to a mixture of XVIII and XXI.

The 16,17-Diol

To a solution of 493 mg of hemiacetal XII in 25 ml of dry ether was added 490 mg of lithium aluminum hydride. The solution was refluxed for 2 hours, then the excess reagent destroyed using ethyl acetate. Dilute sulphuric acid was cautiously added, the layers separated, and the aqueous layer extracted three times with ether. The spontaneously crystalline product weighed 540 mg. It was recrystallized from acetone–hexane to a constant melting point of 169°, then sublimed at 110° at 5×10^{-4} mm for analysis. It had $[\alpha]_D$ −28° (*c*, 1.25). Found: C, 78.11; H, 11.08. Calc. for $C_{19}H_{32}O_2$: C, 78.03; H, 11.03. Under less vigorous conditions some hemiacetal remained unreduced.

Lactone XXVII

The 16,17-diol (171 mg) was dissolved in 3 ml of acetic acid. To this was added, with stirring, a solution of 160 mg of sodium dichromate dihydrate in 2 ml of acetic acid. The oxidation was rapid until nearly the equivalent of two atoms of oxygen had been added. After completion of the addition (2 minutes) the reaction mixture was left for 0.5 hour at room temperature. The excess reagent was reduced with sodium bisulphite solution, then the solvent removed under reduced pressure. The residue was taken up in dilute acid and methylene chloride. The methylene chloride was washed with dilute sodium carbonate solution, dried, and the solvent evaporated. The 159 mg of neutral product was adsorbed from hexane on 5 g of neutral alumina (Grade II). After a small non-crystalline forerun (4 mg), hexane and benzene eluted 64 mg of pure lactone. Benzene–ether, 1:1, eluted a mixture of lactones (50 mg), and ether and methanol in ether eluted hydroxylic product. The combined early eluates were crystallized to a constant melting point of 168°, $[\alpha]_D^{25}$ −16° (*c*, 1.49), then sublimed for analysis. Found: C, 78.99; H, 9.94. Calc. for $C_{19}H_{28}O_2$: C, 79.12; H, 9.79. The more strongly adsorbed lactone mixture was separated by careful chromatography into the above lactone and a lactone identical with the one from oxidation of the hemiacetal. The hydroxylic products could not be resolved into pure substances by further chromatography.

Reduction of Lactone XIV to Hemiacetal

Pure lactone (32 mg) was dissolved in 2 ml of dry ether. To this was added a solution of approximately 4 mg of lithium aluminum hydride in 2 ml of ether. After 12 minutes at room temperature the reagent was destroyed with one drop of methanol. The solvent was removed under reduced pressure, and the residue distributed between methylene chloride and dilute acid. The 32 mg of product gave 27 mg of pure hemiacetal XIII.

Reduction of Lactone XXVII

The lactone was inert to sodium borohydride in hot aqueous dioxane. A solution of 14 mg of the lactone in dry ether containing 40 mg of lithium aluminum hydride was completely reduced to the 16,17-diol, m.p. and mixed m.p. 165°, in 15 minutes at room temperature.

A solution of 31 mg of the lactone, m.p. 167°, in 5 ml of ether was prepared. To this was added 2 ml of ether containing approximately 3 mg of lithium aluminum hydride. After 3 minutes at room temperature the excess reagent was destroyed with two drops of methanol and the solvent removed under reduced pressure. The residue was taken up in methylene chloride and dilute sulphuric acid. The methylene chloride layer and washings yielded 31 mg of product. This was dissolved in ca. 2 ml of hexane. After standing overnight the solution had deposited 8 mg of diol. The soluble product was adsorbed from hexane onto 530 mg of neutral alumina, activity II. Hexane, benzene, and ether eluted unchanged lactone (11 mg). Methanol in ether and ethanol in chloroform eluted 10 mg of a mixture of hemiacetal and diol, which were separated by crystallization from hexane. The hemiacetal after three recrystallizations from hexane melted at 164° (crystal form fine matted needles changing slowly to tiny cubes). It did not depress the melting point of hemiacetal XIII, and their infrared spectra (nujol mull of fine needles) were identical.

A reduction for 10 minutes of 48 mg of lactone in 6 ml of ether containing 7 mg of lithium aluminum hydride gave 35 mg of diol, 9 mg of unchanged lactone, and 2 mg of hemiacetal.

Action of Nitrous Acid on the C_{20}-Azomethine Acetate (XXXIV)

A solution of azomethine acetate (500 mg), sodium acetate (1.3 g), and sodium nitrite (1.25 g) in a mixture of dioxane (75 ml) and water (50 ml) was treated dropwise with a solution of acetic acid (2.5 ml) in dioxane (5.0 ml) during 5 hours. Nitrogen was passed over the solution continuously and during the addition of the acid, the mixture was agitated vigorously. The mixture was allowed to stand at room temperature overnight and the solvents were then removed at 50° under reduced pressure. The residue was dissolved in ether and washed with potassium carbonate, water, 6 *N* sulphuric acid, and then again with water. The dried extract was then evaporated, yielding a yellow gum (470 mg) which could not be induced to crystallize. It had infrared absorption at 3400 (OH), 1735 (acetate), and 1640 ($\rangle C{=}CH_2$) cm^{-1}.

The above oil was warmed with methanol and evaporated to small bulk and diluted with water, yielding colorless needles (390 mg). The analytical sample was sublimed at 160° at 10^{-3} mm, m.p. 175°, $[\alpha]_D^1$ −78.5° (*c*, 0.96). Infrared maximum at 1730 cm^{-1} (acetate), 1657 cm^{-1} ($\rangle C{=}CH_2$), and complex ether absorption in the region 1000–1100 cm^{-1}. Found: C, 73.47; H, 9.36; OMe, 8.25. Calc. for $C_{23}H_{36}O_4$: C, 73.36; H, 9.64; OMe, 8.07.

ACKNOWLEDGMENTS

We thank Mr. A. Knoll for the technical assistance, Mr. R. Lauzon for the infrared spectra, and Mr. J. Nicholson for the n.m.r. spectra. We are grateful to Dr. R. Bible for generous gifts of podocarpic derivatives.

THE RAMAN SPECTRA OF SULPHURIC, DEUTEROSULPHURIC, FLUOROSULPHURIC, CHLOROSULPHURIC, AND METHANESULPHONIC ACIDS AND THEIR ANIONS

R. J. GILLESPIE AND E. A. ROBINSON[1]
Department of Chemistry, McMaster University, Hamilton, Ontario
Received October 27, 1961

ABSTRACT

The Raman spectra of sulphuric acid, deuterosulphuric acid, chlorosulphuric acid, and methanesulphonic acid have been redetermined, and the spectrum of fluorosulphuric acid measured for the first time. The spectra of fluorosulphuric acid – sulphuric acid, chlorosulphuric acid – sulphuric acid, and fluorosulphuric acid – arsenic trifluoride mixtures have also been measured. The spectra of the hydrogen sulphate, deutero sulphate, fluorosulphate, chlorosulphate, and methanesulphonate anions have been obtained in various solvents. Frequencies are assigned to the normal modes of vibration of all these acids and their anions and the assignments are compared with those of previous workers.

During the investigation of the Raman spectra of the systems H_2SO_4–SO_3, D_2SO_4–SO_3, HSO_3F–SO_3, and HSO_3Cl–SO_3 reported in the following papers it became clear that the spectra of the acids H_2SO_4, D_2SO_4, HSO_3F, HSO_3Cl and their anions were not all known with certainty, either because all the expected lines had not been observed or because no complete assignment of the observed frequencies to the normal modes of vibration had been made. Therefore the Raman spectra of these acids and their anions, and the spectra of methanesulphonic acid and the methanesulphonate ion, were redetermined and in each case the observed frequencies have been assigned to the normal modes of vibration.

SULPHURIC ACID AND DEUTEROSULPHURIC ACID

The results of our measurements of the Raman spectra of H_2SO_4 and D_2SO_4 and the infrared spectrum of H_2SO_4 in the sodium chloride region are given in Table I together with the results of some of the earlier workers (1–5). Our Raman spectra are also shown in Fig. 1. Table I does not include the results of all the previous studies since there is generally good agreement between the various sets of measurements and much of the earlier work has recently been discussed by Walrafen and Dodd (2) and by Giguère and Savoie (4). Some workers have observed additional Raman shifts at 740 and 1050 cm^{-1} and additional weak bands in the infrared at 332, 675, 1050, and 1240 cm^{-1} that we did not observe in our Raman spectrum of H_2SO_4. Also, lines at 711 and 1050 cm^{-1} and at 305 and 475 cm^{-1} have been reported in the Raman and infrared spectra of D_2SO_4 that were not observed by us.

The 1050 cm^{-1} line, which increases in intensity on addition of water to sulphuric acid, is undoubtedly due to the HSO_4^- ion. Giguère and Savoie (4) observed this line in their infrared spectrum of sulphuric acid and claimed that it was due to HSO_4^- ions formed in the autoprotolysis of sulphuric acid,

$$2H_2SO_4 \rightleftarrows H_3SO_4^+ + HSO_4^-.$$

However, it has been shown by other methods that the concentrations of the autoprotolysis ions in 100% sulphuric acid are very small (e.g. at 25° $[H_3SO_4^+] = 0.013$ molal; $[HSO_4^-]$

[1]*Present address: Department of Chemistry, University of Toronto, Toronto 5, Ontario.*

= 0.018 molal (6)), and it is therefore most unlikely that any frequencies due to these ions could be detected in the pure acid by either infrared or Raman spectroscopy. Giguère and Savoie's observation of the 1050 cm^{-1} line in their infrared spectrum was undoubtedly due to HSO_4^- ions formed by the ionization of water impurity in their sample. The same explanation doubtless applies in other cases where the 1050 cm^{-1} has been reported as a line of sulphuric acid. The line observed by Leckie (3) at 740 cm^{-1} is probably due to H_3O^+ impurity since lines near this frequency have been observed in the infrared spectra of hydroxonium salts (7).

In the H_2SO_4 molecules, nine of the normal modes can be described approximately as a symmetric and an asymmetric stretch and a bending mode of the SO_2 group, three similar vibrations of the $S[OH(D)]_2$ group, SO_2 and $S[OH(D)]_2$ rocking modes, and a torsion. In addition there are six vibrations of the OH(D) groups. A reasonably complete assignment of the frequencies to the fundamental modes of H_2SO_4 has been given by Giguère and Savoie (4) and a partial assignment has also been suggested by Walrafen and Dodd (2).

NOTE: (*a*) This work; (*b*) Giguère and Savoie (4); (*c*) Walrafen and Dodd (2).
*Walrafen and Dodd gave a different description of the normal modes of the sulphuric acid molecule based on the four modes of the sulphate ion.

differ from those given by these authors. In the spectrum of SO_2F_2 the SO_2 bend and SO_2 rock have approximately the same frequency of 545 cm^{-1} and are not resolved in the Raman spectrum of the liquid (8). Similarly, in the spectrum of H_2SO_4 it appears that the SO_2 bend and SO_2 rock have approximately the same frequency of 563 cm^{-1}

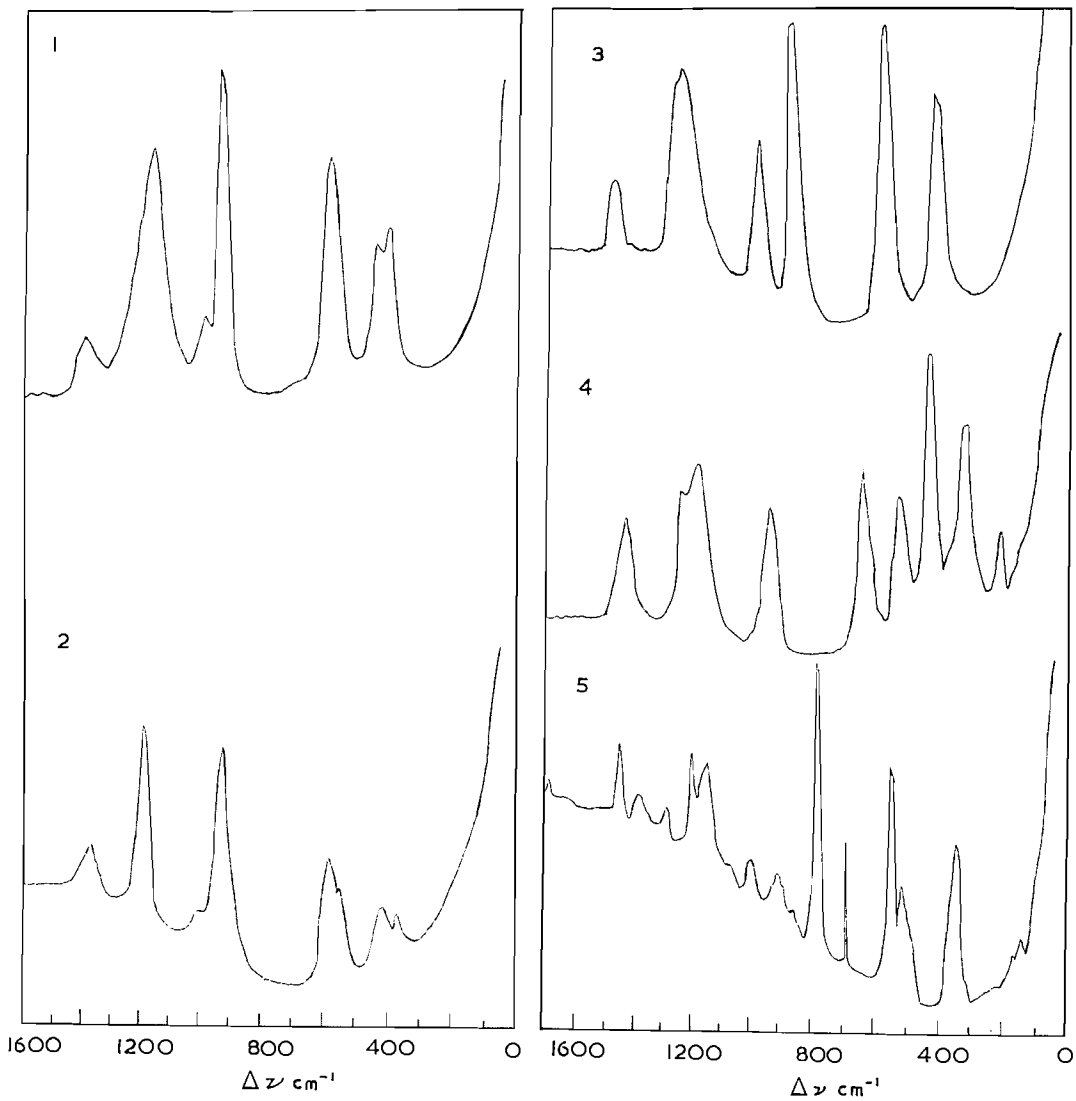

FIG. 1. Raman spectra: (1) H_2SO_4, (2) D_2SO_4, (3) HSO_3F, (4) HSO_3Cl, (5) CH_3SO_3H.

and are not resolved in the Raman spectrum. We agree with Venkateswaren (1) in finding that this line is weakly polarized whereas Walrafen and Dodd (2) found it to be depolarized. If it is indeed weakly polarized this is consistent with it actually consisting of two lines, one of which is polarized and one of which is depolarized. In the spectrum of D_2SO_4 the two lines expected in this region of the spectrum are in fact observed at 560 cm^{-1} (depolarized?) and 522 cm^{-1} (polarized). The latter is assigned to the SO_2 bend and the 560 cm^{-1} line to the SO_2 rock.

In the Raman spectra of H_2SO_4 and D_2SO_4 the lines at 422 and 395 cm^{-1}, respectively, are assigned to the $S(OH)_2$ and $S(OD)_2$ rocking modes and the lines at 392 and 356 cm^{-1}, respectively, to the $S(OH)_2$ and $S(OD)_2$ bending modes. The 392 cm^{-1} line has been reported by Venkateswaren (1) and by Walrafen and Dodd (2) to be weakly polarized.

Although we failed to observe any polarization of either the 392 or the 356 cm^{-1} line it seems probable that both lines are very weakly polarized. The apparent weak polarization of the 392 cm^{-1} line may be due to the depolarized line arising from the torsional mode also having a frequency of approximately 392 cm^{-1} in both H_2SO_4 and D_2SO_4 (cf. 360 cm^{-1} for the torsional mode in SO_2F_2 (8)). It seems probable that the line due to the torsional mode is in fact coincident with some other line in the spectrum since the torsional mode (a_2) should be active in the Raman and inactive in the infrared spectrum and no lines are observed in the Raman spectrum which do not have their counterparts in the infrared spectrum.

It is difficult to make any comparison of our assignment with that of Walrafen and Dodd (2) since these authors assume that the spectrum of sulphuric acid may be related to that of the sulphate ion in crystalline calcium sulphate, for which nine frequencies have been observed. Although they admit that the interactions which remove the degeneracies of the four fundamental frequencies of the sulphate ion to give the nine observed frequencies, are probably considerably different from those arising from the formation of S—OH bonds they assume that the frequencies of crystalline $CaSO_4$ may be used as a guide to the assignment of the frequencies of sulphuric acid, and of the HSO_4^- ion. This does not seem to us to be as reasonable a basis for making assignments as our comparison with other SO_2X_2 molecules and SO_3X^- ions.

Of the six vibrational frequencies (two stretches, two bends, and two wagging or torsional modes) which are theoretically expected to be associated with the O—H(D) groups we have only observed one, a bend at 1137 cm^{-1}, for sulphuric acid. The rather high frequency of this vibration is presumably to be attributed to strong hydrogen bonding between the O—H groups and other oxygen atoms. The O—H(D) stretches were not observed in our Raman spectra presumably due to the insensitivity of the photographic plates in the 1800–3000 cm^{-1} region. However, Giguère and Savoie (4) observed bands in the spectrum of H_2SO_4 at 2450 and 2970 cm^{-1} and in the infrared spectrum of D_2SO_4 at 1860 and 2200 cm^{-1}, which they assigned as the symmetric and asymmetric O—H(D) stretches, respectively. Similar bands were also reported by Walrafen and Dodd (2). Other very weak and somewhat doubtful lines in the infrared spectrum at 1240, 675, and 332 cm^{-1} for H_2SO_4 and at 475 and 305 cm^{-1} for D_2SO_4 may possibly be due to other OH(D) bending or torsional modes.

FLUOROSULPHURIC, CHLOROSULPHURIC, AND METHANESULPHONIC ACIDS

The results of our measurements of the Raman and infrared spectra of HSO_3F, HSO_3Cl, and CH_3SO_3H are given in Table I and Fig. 1. The Raman spectra of HSO_3Cl and $MeSO_3H$ have been reported previously by other workers but there has been no previous study of fluorosulphuric acid. Our measurements are in good agreement with the earlier work except for a few details which are discussed later. The Raman spectra of the systems HSO_3F–H_2SO_4 and HSO_3Cl–H_2SO_4 were also studied and the results are given in Table III. The spectra contain only the lines of the component acids, indicating that there is no extensive ionization or any other reaction in these systems (9).

The nine fundamental vibrations of a molecule of the type SO_2XY may be approximately described as SO_2 symmetric and asymmetric stretches, an SO_2 bending mode, SX and SY stretches, an SO_2 rock, an S—X wag, and S—Y wag, and a torsion. In the molecules HSO_3F, HSO_3Cl, and CH_3SO_3H there are, in addition, three vibrations of the O—H group and in the latter compound nine vibrations of the CH_3 group. Our assignments for these molecules are given in Table IV.

NOTE: (*a*) Present work; (*b*) Simon, Kriegsmann, and Dutz (25); (*c*) Vogel-Högler (27); (*d*) Gerding and Maarsen (10); (*e*) Simon and Kriegsmann (11).

The assignment of the line at 1174 cm^{-1} to the SO_2 symmetric stretch in CH_3SO_3H differs from the assignment of previous workers (10, 11) who assigned this frequency to the O—H wag and gave 1128 cm^{-1} as the SO_2 symmetric stretch. Our assignment of the SO_2 symmetric stretch in HSO_3Cl also differs from that given previously by Simon *et al.* (25). These authors did not observe a separate line at 1209 cm^{-1} but only a broad band centered at 1153 cm^{-1}, which they assigned to the SO_2 symmetric stretch. In our spectrum two separate lines were observed in this region at 1209 and 1150 cm^{-1}. The former is assigned to the SO_2 symmetric stretch and the latter to an O—H bend. In sulphuric acid we have assigned the analogous vibrations at 1195 and 1137 cm^{-1}, respectively. Two lines are also observed at similar frequencies in the spectrum of fluorosulphuric acid; one at 1230 cm^{-1} is assigned to the SO_2 symmetric stretch and the other at 1178 cm^{-1} to an O—H wag. In the spectrum of a 50 mole% solution of HSO_3F in AsF_3 the band at 1178 cm^{-1} is absent, although that at 1230 cm^{-1} appears strongly (Fig. 2); this supports the assignment of the 1178 cm^{-1} line as an O—H bend. Presumably

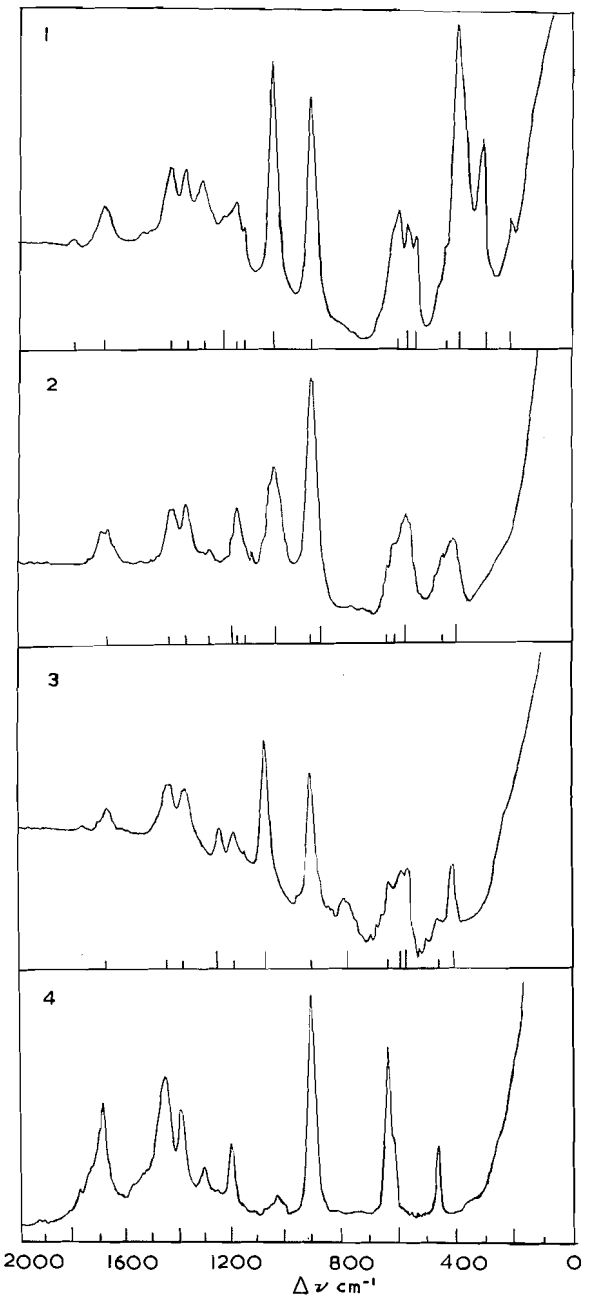

FIG. 2. Raman spectra of 1:1 mixtures of some acids with acetic acid: (1) HSO_3Cl–CH_3CO_2H, (2) H_2SO_4–CH_3CO_2H, (3) HSO_3F–CH_3CO_2H, (4) CH_3CO_2H. ¦ anion lines, | solvent lines.

the change in the nature and extent of hydrogen bonding caused by diluting the HSO_3F with AsF_3 shifts this band to some other region of the spectrum, probably to a lower frequency where it is obscured by another line. In other respects this spectrum is simply a superposition of the Raman spectra of arsenic trifluoride and fluorosulphuric acid, showing that there is no appreciable reaction or ionization in this system. This result is

in agreement with conductimetric measurements on dilute solutions of arsenic trifluoride in fluorosulphuric acid which show that AsF_3 is only slightly ionized (12).

It is interesting to note that the S—OH stretching frequencies HSO_3F, 960 cm^{-1}; HSO_3Cl, 920 cm^{-1}; CH_3SO_3H, 904 cm^{-1} decrease in the order of decreasing acid strength (9). The frequency of the O—H bend also apparently decreases as the acid strength decreases.

The assignments of the SO_2 bend and rocking vibration in these molecules were made by comparison with the assignment of the similar modes of SO_2Cl_2 and SO_2F_2 (8) and they are also consistent with the assignments made above for H_2SO_4 and D_2SO_4.

In fluorosulphuric acid the SF stretch is identified as the line at 850 cm^{-1} by comparison with the frequency of the similar vibration in related molecules. The remaining lines in the Raman spectrum of HSO_3F at 405 and 395 cm^{-1} can be reasonably assigned to the S—F wag and to the torsional mode. The only remaining vibration to which a frequency has to be assigned is the S(OH) bend. We presume that this also contributes to the band at 560 cm^{-1} on the grounds that the frequency of this vibration is probably greater than 482 cm^{-1}, which we assign below to the analogous vibration in HSO_3Cl, since the S(OH) stretch has a higher frequency in HSO_3F than in HSO_3Cl.

In the spectrum of HSO_3Cl the strong polarized band at 416 cm^{-1} is assigned to the S—Cl stretch and the low-frequency line at 200 cm^{-1} to the S—Cl wag. The line at 312 cm^{-1} is assigned as the torsion as this is the only low-frequency depolarized line. This assignment is also reasonably consistent with the frequencies assigned to this torsion in other related molecules. Only the S—OH wag remains to be considered and the weak line at 482 cm^{-1} must be assigned to this vibration.

In the spectrum of methanesulphonic acid the line at 772 cm^{-1} can without doubt be assigned to the C—S stretch. The frequency of 338 cm^{-1} (polarized) then seems reasonable for the S—CH_3 wag, leaving the line at 420 cm^{-1} as the torsion and that at 480 cm^{-1} (polarized) as the S—OH wag. The frequency of the S(OH) bend is very similar to that in HSO_2Cl, which is consistent with the similarity of the frequencies of the S(OH) stretches of these two molecules. The remaining lines may be assigned to C—H vibrations: 985 cm^{-1} as a CH_3 wag, 1265 and 1420 cm^{-1} as CH_3 bends, and 3032 and 2945 cm^{-1} as CH_3 stretches (11). The O—H stretch has apparently not been observed.

THE ANIONS HSO_4^-, DSO_4^-, SO_3F^-, SO_3Cl^-, $CH_3SO_3^-$

These ions have all been studied previously, although, in some cases, only a few of the strongest lines were observed or a limited region of the spectrum only was investigated, especially in the case of infrared studies. The results obtained in the present work are shown in Table V together with those of other investigators.

Siebert studied the Raman spectrum of a solution of sodium fluorosulphate in water (13). The infrared spectra of solid alkali metal, ammonium, silver, and triphenyl carbonium fluorosulphates have been investigated by Sharpe (14). A single line at 1080 cm^{-1} due to the fluorosulphate ion was observed by Millen (15) in the Raman spectrum of solid nitronium fluorosulphate. In the present work the following solutions containing the fluorosulphate ion were examined:

(i) Sodium fluorosulphate in water.

(ii) Solutions of sodium chloride and of sodium sulphate in fluorosulphuric acid. In these solutions fluorosulphate ion is formed according to the equations

$$Na_2SO_4 + 2HSO_3F = 2Na^+ + 2SO_3F^- + H_2SO_4,$$

$$NaCl + HSO_3F = Na^+ + SO_3F^- + HCl.$$

NOTE: (*a*) Present results, water in sulphuric acid (85% H_2SO_4) (Raman).
(*b*) Present results, sulphuric acid in acetic acid (Raman). Lines due to CH_3COOH and $CH_3COOH_2^+$ observed at 452, 629, 914, 1179, 1283, 1370, 1425, and 1676 cm^{-1}.
(*c*) Present results, $KHSO_4$ in sulphuric acid (Raman).
(*d*) $NaHSO_4$ in water (Raman) (Siebert (13)).
(*e*) Water in sulphuric acid (infrared) (Walrafen and Dodd (2)).
(*f*) Present results, $KFSO_3$ in water (Raman).
(*g*) $KFSO_3$ in water (Raman) (Siebert (13)).
(*h*) Present results, fluorosulphuric acid in acetic acid (Raman). Lines also appear in the spectrum at 461, 671, 908, 1192, 1380, 1448, and 1678 cm^{-1} due presumably to CH_3COOH and $CH_3COOH_2^+$.
(*i*) Present results, water in HSO_3F (Raman). Lines also appear in the spectrum at 844, 970, 1185, and 1408 cm^{-1} due to non-ionized HSO_3F, and at 910 cm^{-1} due to H_2SO_4.
(*j*) $KFSO_3$ (infrared) (Sharpe (14)).
(*k*) $Ph_3C^+.SO_3F^-$ (infrared) (Sharpe and Sheppard (29)).
(*l*) Present results, water in menthanesulphonic acid. Lines which were observed at 484 and 912 cm^{-1} are presumably due to non-ionized CH_3SO_3H.
(*m*) $CH_3SO_3.Na$ (infrared) (Siebert (13)).
(*n*) $CH_3SO_3.K$ (infrared) (Gerding and Maarsen (10)).
(*o*) $CH_3SO_3.Na$ (infrared) (Gerding and Maarsen (10)).
(*p*) $CH_3SO_3.Na$ (infrared) (Simon and Kriegsmann (19)).
(*q*) Present results, deuterium oxide in D_2SO_4 (12% D_2O) (Raman).
(*r*) Present results, $NaSO_3Cl$ in dimethyl sulphoxide (Raman). Lines due to the solvent were observed at 311, 337, 384, 602, 671, 703, 901, 931, 955, 1043, 1149, 1228, 1312, 1335, and 1420 cm^{-1}.
(*s*) Present results, KSO_3Cl in dimethyl sulphoxide (Raman). Lines due to the solvent were observed at 309, 384, 602, 671, 703, 901, 931, 953, 1044, 1149, 1230, 1314, 1340, and 1422 cm^{-1}.
(*t*) Present results, HSO_3Cl dissolved in acetic acid (Raman). Lines due to CH_3COOH and $CH_3COOH_2^+$ were observed at 603, 910, 1159, 1303, 1370, 1430, and 1676 cm^{-1}. The line observed at 313 cm^{-1} is presumably due to non-ionized chlorosulphuric acid.
(*u*) $PCl_5.SO_3$ (infrared) (Waddington and Klanberg (16)).
(*v*) $[(CH_3)_4N]Cl.SO_3$ (infrared) (Waddington and Klanberg (16)).
*Actually observed as a triplet at 1050, 1060, and 1073 cm^{-1}.

The hydrogen chloride was removed by warming the solutions. In the Raman spectra of these solutions only one new Raman shift, a strong line at 1080 cm^{-1}, was observed, and the intensity of the solvent line at 1230 cm^{-1} was enhanced. Other lines due to the fluorosulphate ion are obscured by the spectrum of the solvent.

(iii) Mixtures of acetic acid and fluorosulphuric acid. In addition to the lines due to the component acids several new lines which could be attributed to the SO_3F^- ion were observed (Fig. 3).

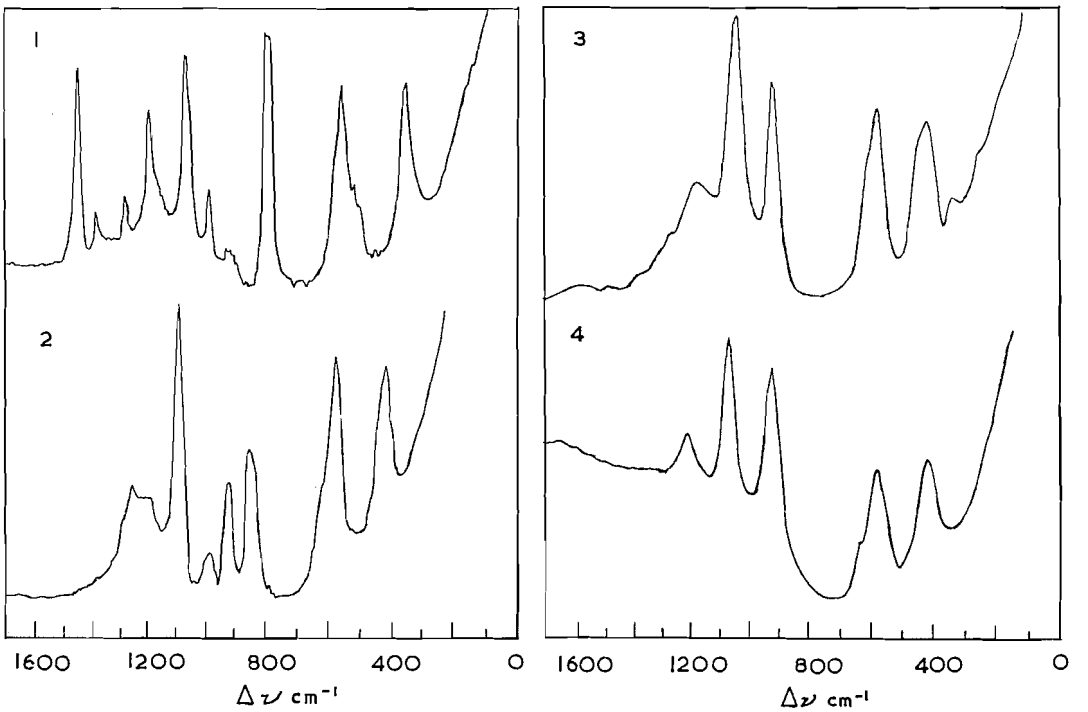

FIG. 3. Raman spectra of solutions of water in some acids: (1) 15% H_2O in CH_3SO_3H, (2) 10% H_2O in HSO_3F, (3) 15% H_2O in H_2SO_4, (4) 12% D_2O in D_2SO_4.

(iv) Solutions of water in fluorosulphuric acid. Fluorosulphate ion is formed by the ionization

$$H_2O + HSO_3F \rightleftharpoons H_3O^+ + SO_3F^-,$$

although there is also slow hydrolysis,

$$HSO_3F + H_2O \rightleftharpoons HF + H_2SO_4.$$

Lines due to the FSO_3^- ion and the 910 cm^{-1} line of sulphuric acid were observed in addition to those of fluorosulphuric acid (Fig. 2).

Simple metal chlorosulphates have not been studied previously, although Waddington and Klanberg (16) have attributed some of the bands of the infrared spectra of the 1:1 complexes of $[(CH_3)_4N]Cl$ and PCl_5 with sulphur trioxide, which they formulated as the chlorosulphates $(CH_3)_4N^+SO_3Cl^-$ and $PCl_4^+SO_3Cl^-$, to the chlorosulphate ion.

The following solutions containing the chlorosulphate ion were studied:

(i) Solutions of sodium and potassium chlorosulphates in dimethyl sulphoxide.

(ii) Mixtures of acetic acid and chlorosulphuric acid. In addition to the lines due to the component acids several new lines which could be attributed to the SO_3Cl^- ion were observed (Fig. 3).

(iii) Solutions of potassium chloride and potassium sulphate in chlorosulphuric acid in which the chlorosulphate ion is formed by the reactions

$$K_2SO_4 + 2HSO_3Cl = 2K^+ + 2SO_3Cl^- + H_2SO_4,$$
$$KCl + HSO_3Cl = K^+ + SO_3Cl^- + HCl.$$

The spectrum of the SO_3Cl^- ion is partially obscured by that of the acid. However, a strong line is observed at 1054 cm^{-1}, the 1209 cm^{-1} line of the acid is enhanced, and a weak line is found at 538 cm^{-1}.

The vibrational spectrum of HSO_4^- has been obtained previously from studies of solutions of water in sulphuric acid (e.g. ref. 2), from an aqueous solution of sodium hydrogensulphate (13), and from infrared studies of crystalline ammonium, sodium, and potassium hydrogensulphates (17). In the present work the Raman spectrum of the hydrogensulphate ion was obtained from the spectrum of three different solutions:

(i) Solutions of water in sulphuric acid in which hydrogensulphate ion is formed according to the equation

$$H_2O + H_2SO_4 = H_3O^+ + HSO_4^-.$$

The spectra obtained (Fig. 3) were somewhat more complex than would be expected from this equation and a detailed interpretation of the spectra gives evidence for some additional species, probably the hydrogen-bonded "ion-pair" $H_3O^+.HSO_4^-$. These measurements will be discussed in more detail in a later paper.

(ii) A solution of sulphuric acid in acetic acid (Fig. 2). The low intensities of the characteristic lines of sulphuric acid in the spectrum of an approximately equimolal mixture of sulphuric and acetic acids shows that ionization is extensive:

$$CH_3CO_2H + H_2SO_4 = CH_3CO_2H_2^+ + HSO_4^-.$$

This is consistent with the conclusion from previous cryoscopic and conductimetric measurements that ionization is essentially complete in dilute solutions of acetic acid in sulphuric acid (18).

(iii) A solution of potassium sulphate in sulphuric acid.

There is generally good agreement between our different sets of measurements and earlier work with respect to the frequencies that may be attributed to the hydrogensulphate ion. The infrared spectra of solid hydrogen sulphates (17) are rather more complex than the spectra of the ion in solution: this is presumably to be attributed to crystal-field splitting of the three degenerate modes of the HSO_4^- ion. Because of their complexity these spectra have not been given in Table V; they lend general support to our assignment of the six fundamentals.

The fundamental frequencies of the deuterosulphate ion were obtained from the spectra of solutions of D_2O in D_2SO_4. Similar measurements have previously been reported by Leckie (3), although he did not interpret his spectra in detail.

The spectrum of the methanesulphonate ion was obtained similarly from measurements on solutions of water in methanesulphonic acid. The infrared spectra of some salts of methanesulphonic acid have been reported previously by Gerding and Maarsen (10), by Siebert (13), and by Simon and Kriegsmann (19). The present spectrum is in good agreement with the previous work.

The ions XSO_3^- have tetrahedral structures and belong to the C_{3v} point group. They therefore have six normal modes of vibration which should all be active in both the Raman and the infrared spectrum. It is convenient to describe the three totally symmetric (a) vibrations as an SO_3 symmetric stretch, an SX stretch, and an SO_3 symmetric bend, and the asymmetric (e) vibrations as an SO_3 asymmetric stretch, an SX wag (or XSO_3 deformation), and an SO_3 asymmetric bend. Our assignments and those of previous workers are given in Table VI.

TABLE VI

Assignment of the fundamental vibrations of the anions XSO_3^- (frequencies in cm^{-1})

Approximate description	HSO_4^-*		DSO_4^-	SO_3Cl^-		SO_3F^-			$CH_3SO_3^-$			
	(*a*)	(*b*)	(*a*)	(*a*)	(*c*)	(*a*)	(*b*)	(*d*)	(*a*)	(*e*)	(*b*)	(*f*)
SO_3 sym. stretch (*a*)	1040	1051	1050	1050	1044	1082	1082	1073	1050	1054	1055	1049

SX wag (*e*)	411	429	411	220	—	405	409	—	344	346	348	346

NOTE: (*a*) Present results; (*b*) Siebert (13); (*c*) Waddington and Klanberg (16); (*d*) Sharpe (14); (*e*) Simon and Kriegsmann (11); (*f*) Gerding and Maarsen (10).
*Walrafen and Dodd (2) also assign the frequencies of HSO_4^- to normal vibrations of the ion but only group them as (*a*) or (*e*) vibrations, i.e. 1341, 1050, and 885 cm^{-1} (*a*); 1230, 593, and 417 cm^{-1} (*e*).

The SO_3 symmetric and asymmetric stretches and bends are easily assigned by comparison with the frequencies of the corresponding SO_2 vibrations. It is found that frequencies of the symmetric and asymmetric stretching modes fit the same linear relationship that has been shown to hold for the SO_2 symmetric and asymmetric stretches of sulphuryl compounds (20). They have lower frequencies than the corresponding SO_2 stretches in the parent acids, which is consistent with the reduced double-bond character of the SO bonds.

The SX stretches have frequencies that are very similar to those of the SX stretching modes in the parent acids. The somewhat lower frequency of the SF stretch in the fluorosulphate ion compared with that for the analogous vibration in fluorosulphuric acid is interesting and probably indicates that the partial double-bond character of the S—F bond in the fluorosulphate ion is appreciably less than in fluorosulphuric acid.

The spectrum of the SO_3F^- ion is very similar to that of the isoelectronic species perchloryl fluoride, ClO_3F, for which the Raman spectrum has been obtained by Powell and Lippincott (21) and the infrared spectrum by Lide and Mann (22). The assignment for SO_3F^- given in Table VI receives strong support from the fact that it is closely paralleled by Powell and Lippincott's assignment for ClO_3F, as is shown in Table VII.

TABLE VII

Comparison of the Raman spectra of ClO_3F and SO_3F^- (frequencies in cm^{-1})

SO_3F^-	ClO_3F		
	Assignment (21)		
408	405	Cl—F rock	$\nu_6(e)$
566	549	ClO_3 deformation	$\nu_3(a_1)$
592	589	ClO_3 deformation	$\nu_5(e)$
786	704, 714*	Cl—F stretch	$\nu_2(a_1)$
1082	1061	ClO_3 symmetric stretch	$\nu_1(a_1)$
1230	1315 or 1175	ClO_3 asymmetric stretch	$\nu_4(e)$

NOTE: ν_4 was assigned the frequency of 1315 cm^{-1} by Powell and Lippincott (21). It could be reassigned the frequency of 1175 cm^{-1}, which was interpreted by these workers as $2\nu_6$, in which case the 1312 cm^{-1} line could be reassigned to $\nu_2+\nu_6$.
*Two lines due to $Cl^{37}F$ and $Cl^{35}F$ respectively.

Waddington and Klanberg (16) did not observe the lines at 220 and 416 cm^{-1} in the spectrum of SO_3Cl^-, since their measurements did not extend to this region of the

spectrum. They assigned 540 cm^{-1} as the S—Cl stretch, 1275 cm^{-1} (in $(CH_3)_4N.SO_3Cl$) as the SO_3 asymmetric stretch, and 1150 cm^{-1} as a combination of the S—Cl stretch and asymmetric SO_3 bend ($\nu_2(a_1)+\nu_5(e)$ = 580+540 = 1120). We reassign the band at 1150 cm^{-1} in their spectrum, which corresponds to the line at 1195 cm^{-1} in our spectrum, to the SO_3 asymmetric stretch in which case the line at 1275 cm^{-1} in their infrared spectrum can be interpreted as a combination of the symmetric SO_3 stretch and S—Cl wag ($\nu_1(a_1)+\nu_6(e)$ = 1050+220 = 1270 cm^{-1}). We assume that the line at 565 cm^{-1} in the infrared spectrum, which we did not observe in the Raman spectrum, is due to the removal of degeneracy by the crystal field.

The line at 960 cm^{-1} in the spectrum of the methanesulphonate ion may be assigned as a CH_3 wag and those at 1268 and 1435 cm^{-1}, and 2943 and 3020 cm^{-1}, as CH_3 bends and CH_3 stretches by comparison with the similar lines in the spectrum of methanesulphonic acid. The line at 1368 cm^{-1} is presumably also a CH_3 wag and an analogous line may be present in the spectrum of methanesulphonic acid but it almost coincides with the line at 1350 cm^{-1}, which is the SO_2 symmetric stretch in this molecule. It is of interest to note that the frequencies of the CH_3 vibrations are very similar in both the acid and its anion.

EXPERIMENTAL

Sulphuric acid was prepared by adjustment of the freezing point of A.R. grade acid to 10.37° (30) by addition of A.R. grade oleum. Fluorosulphuric acid and chlorosulphuric acid were purified by distillation of the commercial products in a dry atmosphere, and had b.p.'s 161–162° and 152°, respectively. Methanesulphonic acid (Eastman Kodak) was purified by fractional crystallization (m.p. = 19.6°). Deuterosulphuric acid was prepared by slowly distilling sulphur trioxide into cooled deuterium oxide (ca. 97% D_2O) until the increase in weight indicated that a weak deutero-oleum had been produced. Then deuterium oxide was added to the weak oleum until the maximum freezing point of 14.2° was reached (23). Potassium fluorosulphate was prepared by the reaction between potassium chloride and fluorosulphuric acid. Fluorosulphuric acid was distilled onto the chloride and then the mixture heated under reflux until the reaction was complete. Excess fluorosulphuric acid was removed under reduced pressure. Sodium and potassium chlorosulphates were prepared by a similar method except that in this case only slightly more than the stoichiometric amount of chlorosulphuric acid was used and the excess removed by washing with acetonitrile and nitromethane. Acetic acid was purified by fractional crystallization. Dimethyl sulphoxide was 99.9% pure "Baker analyzed" solvent.

The Raman spectrometer and the method for obtaining depolarization factors have been described previously (24). Specimens for infrared spectra were thin films of liquid pressed between silver chloride disks. The infrared spectra were obtained with a Perkin-Elmer (model 21) spectrometer.

ACKNOWLEDGMENTS

We thank Dr. Sharda Dasgupta for carrying out the infrared measurements and Dr. R. H. Tomlinson for a gift of deuterium oxide.

The National Research Council and the Ontario Research Foundation are thanked for financial assistance.

RAMAN SPECTRA OF THE H_2SO_4–SO_3 AND D_2SO_4–SO_3 SYSTEMS: EVIDENCE FOR THE OCCURRENCE OF POLYSULPHURIC ACIDS

R. J. GILLESPIE AND E. A. ROBINSON[1]

Received October 27, 1961

ABSTRACT

The Raman spectra of oleums, i.e. mixtures of sulphur trioxide and sulphuric acid, have been re-examined. Similar measurements on the sulphur trioxide – deuterosulphuric acid (D_2SO_4) system are also reported. The experimental results and conclusions of previous similar work on oleums are discussed. By comparison of the spectra of oleums with those of the polysulphuryl halides it is shown that the polysulphuric acids $H_2S_2O_7$ and $H_2S_3O_{10}$ are present in this system. The increase in the frequency of the SO_2 stretching vibrations with increasing concentration of sulphur trioxide gives evidence for the existence of higher polysulphuric acids such as $H_2S_4O_{13}$ at high concentrations of sulphur trioxide. In relatively concentrated oleum, sulphur trioxide monomer and trimer are also present. It is shown that the self-dissociation of liquid $H_2S_2O_7$ gives mainly molecular $H_2S_2O_{10}$ and H_2SO_4 and not ionic species. The conclusions reached from the interpretation of the Raman spectra of the D_2SO_4–SO_3 system are similar to those arrived at for sulphuric acid oleums. The spectra of solutions of $NaHSO_4$ in oleums were also examined, and are discussed.

INTRODUCTION

The constitution of oleum solutions has been examined by several workers using Raman spectroscopy. The early work is surveyed by Millen (1) and more recently the system has been examined by Walrafen and Young (2). The infrared spectra of oleums have also been reported very recently by Giguère and Savoie (3). The previous workers are agreed that the spectra give evidence for the formation of $H_2S_2O_7$. Millen (1) claimed that the spectra also provide evidence for the formation of higher polysulphuric acids such as $H_2S_3O_{10}$ and $H_2S_4O_{13}$. The occurrence of such species in the H_2SO_4–SO_3 system has been disputed by Walrafen and Young (2), who claim that the Raman spectra can be explained in terms of H_2SO_4, $H_2S_2O_7$, ions derived from $H_2S_2O_7$ (e.g. $HS_2O_7^-$ and $H_3SO_4^+$), SO_3 monomer, and SO_3 polymer only. Giguère and Savoie (3) claim that their spectra also indicate the formation of higher polysulphuric acids such as $H_2S_3O_{10}$ in addition to $H_2S_2O_7$. In fact neither Millen's interpretation of the earlier Raman spectra (1) nor the work of Giguère and Savoie (3) gives direct proof for the existence of polyacids higher than $H_2S_2O_7$ and their arguments are not conclusive. Thus, although salts such as $K_2S_3O_{10}$ (4) and $(NO_2)_2S_3O_{10}$ (5) are well established, the existence of the parent acid has been less certain. The present work provides conclusive evidence for the occurrence of $H_2S_3O_{10}$ and strong evidence for higher acids such as $H_2S_4O_{13}$, although it is not possible to deduce the exact chain lengths of the higher polyacids. By comparison of the Raman spectra of oleums with those of $S_2O_5F_2$ and $S_3O_8F_2$, which have been shown to be linear acyclic polymers (6), the occurrence of $H_2S_2O_7$ and $H_2S_3O_{10}$, which are isoelectronic with $S_2O_5F_2$ and $S_3O_8F_2$, respectively, is proved. Although comparison of the oleum spectra with that of $S_4O_{11}F_2$ (7), with which $H_2S_4O_{13}$ is isoelectronic, is inconclusive, the variation of the frequency of the SO_2 symmetric stretching vibration with SO_3 concentration gives strong evidence for higher polysulphuric acids, such as $H_2S_4O_{13}$, at high sulphur trioxide concentrations.

SOLUTIONS OF SULPHUR TRIOXIDE IN SULPHURIC ACID

The Raman spectra of 14 oleum solutions with compositions intermediate between H_2SO_4 and SO_3 are given in Table I and some of the spectra are shown in Fig. 1, together

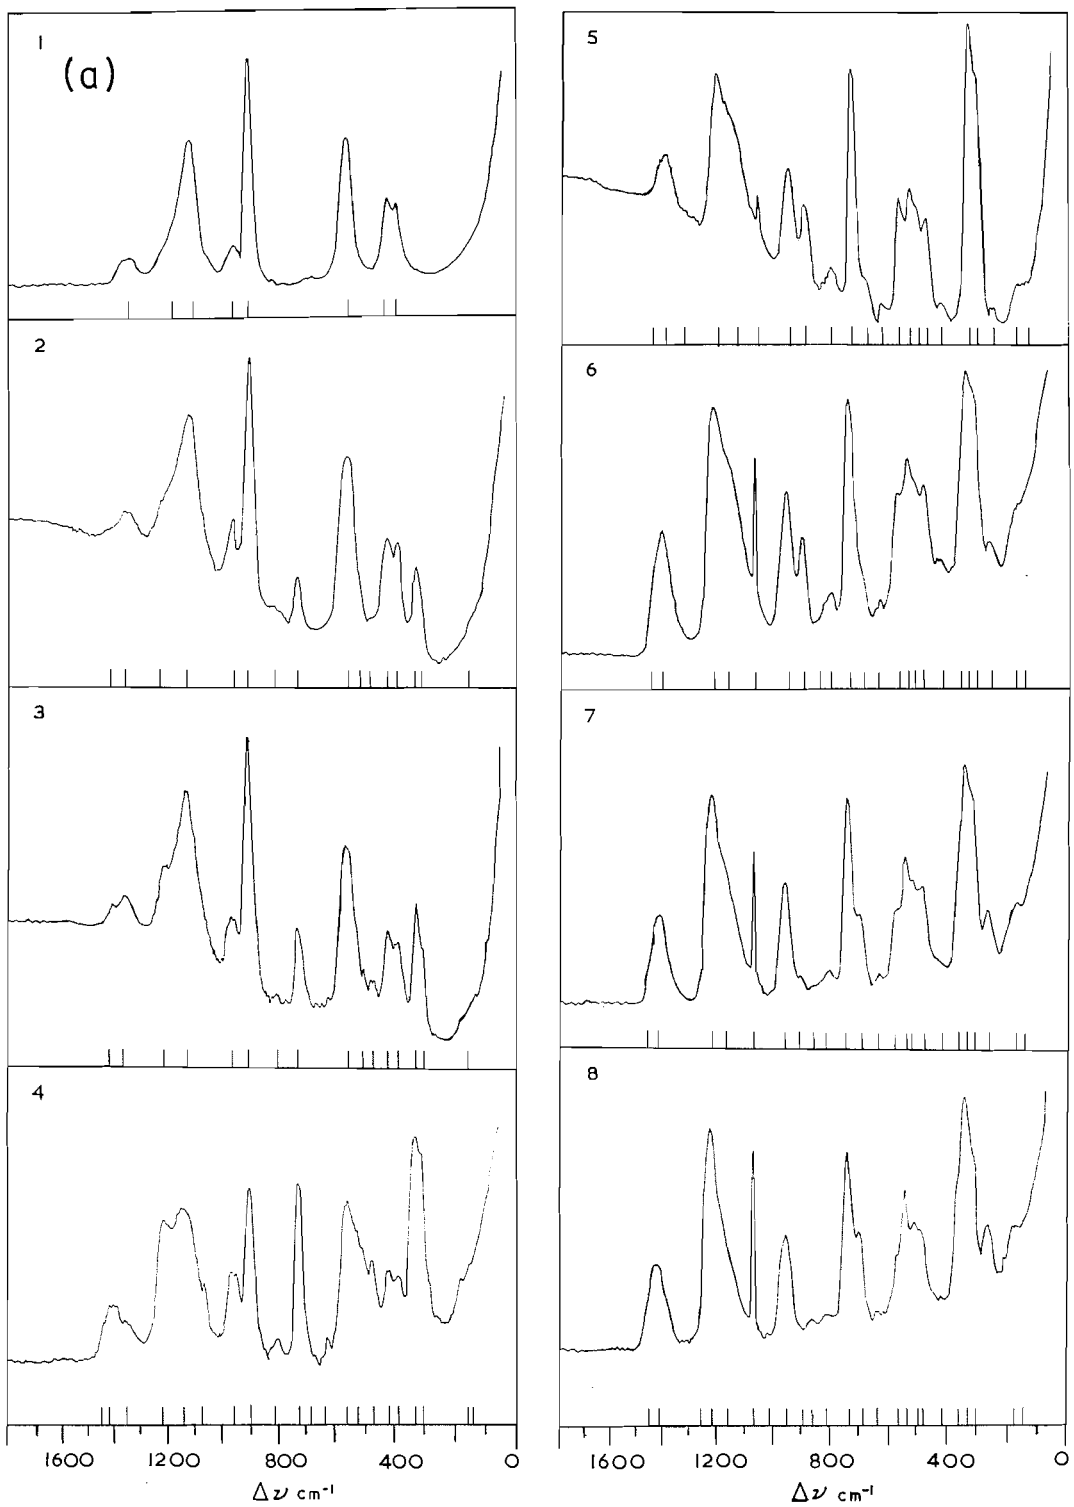

FIG. 1(*a*).

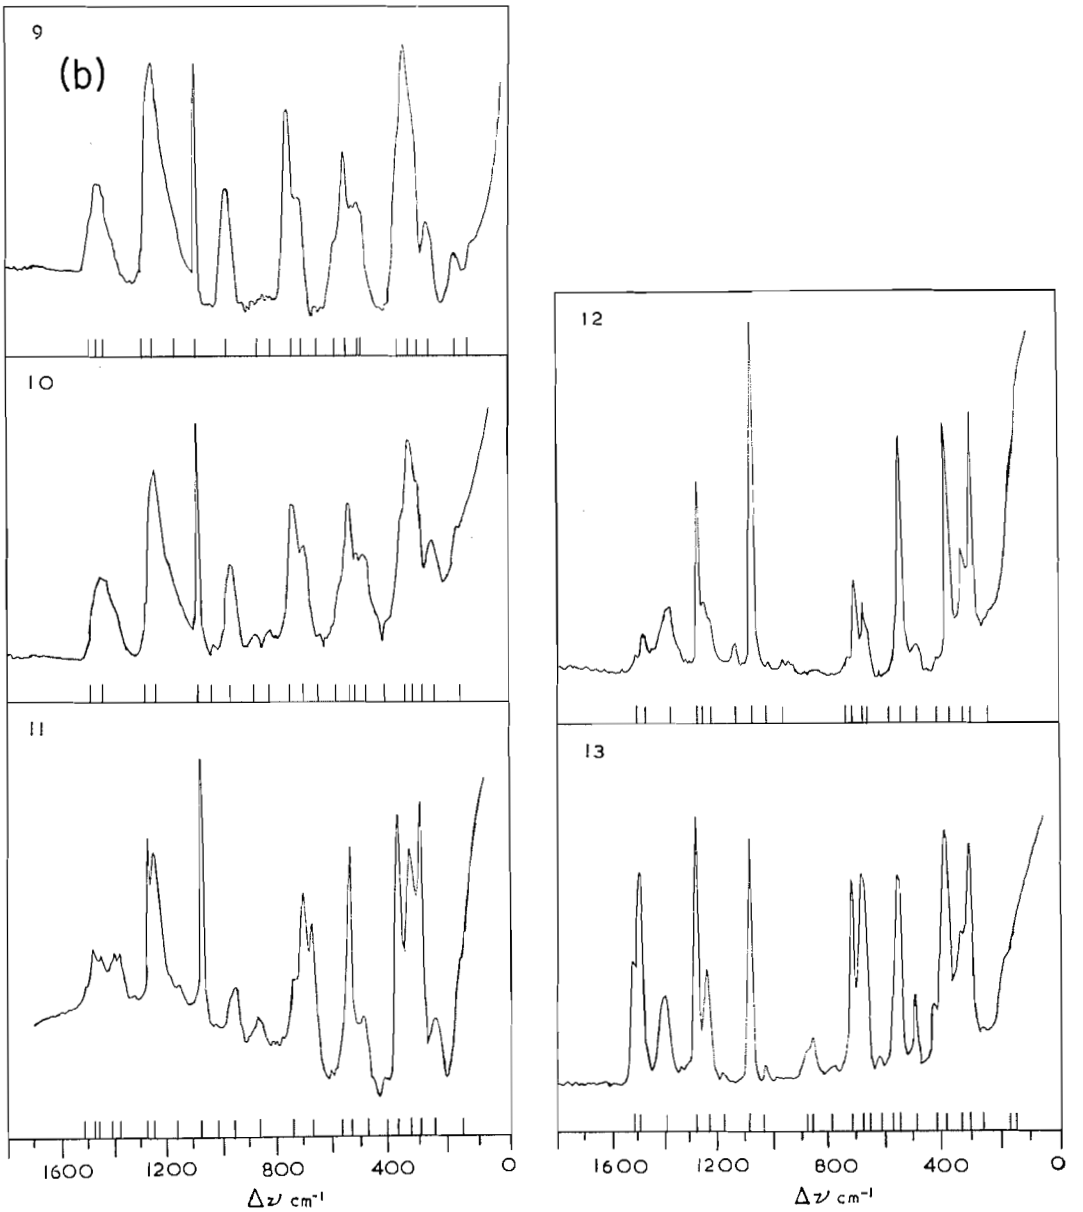

FIG. 1(*b*).

FIG. 1 (*a* and *b*). Raman spectra of oleums: (1) H_2SO_4, (2) 7.2% SO_3, (3) 11.1% SO_3, (4) 26.6% SO_3, (5) 35.8% SO_3, (6) 45.9% SO_3 ($H_2S_2O_7$), (7) 51.2% SO_3, (8) 56.5% SO_3, (9) 60.3% SO_3, (10) 68.8% SO_3, (11) 82.2% SO_3, (12) 92.2% SO_3, (13) 100% SO_3.

with the spectra of H_2SO_4 and liquid sulphur trioxide taken from previous publications (8, 9). These spectra are in good agreement with those obtained by previous workers except that we observed a number of additional lines and some lines were found in less concentrated oleums than previously.

Region 0 to 11.6% SO_3

When sulphur trioxide is added to 100% sulphuric acid several new frequencies appear in the Raman spectra of the solutions which are not observed in the spectrum of sulphuric acid itself and most of the lines due to sulphuric acid begin to diminish in intensity. New lines are observed at 152, 302, 323, 472, 506, 729, 800, and 1422 cm^{-1}. The sulphuric acid line at 563 cm^{-1} shifts slightly (to approximately 557 cm^{-1}) but does not change appreciably in intensity as the stoichiometric concentration of SO_3 increases, and the lines at 976 cm^{-1} and 1137 cm^{-1} increase in intensity while the sulphuric acid frequency at 1195 cm^{-1} gradually shifts to 1215 cm^{-1}. The new lines in the oleum spectra have their counterparts at very similar frequencies in the spectrum of $S_2O_5F_2$ except for the lines at 977, 1215, and 1422 cm^{-1} (Table II). This provides strong evidence that $H_2S_2O_7$ has a structure similar to that of $S_2O_5F_2$, i.e. $HO.SO_2.O.SO_2.OH$.

The lines at 1215 and 1422 cm^{-1} are obviously due to stretching vibrations of the SO_2 group and their occurrence at lower frequencies in the spectrum of $S_2O_5(OH)_2$ than the corresponding vibrations in disulphuryl fluoride but at higher frequencies than in sulphuric acid (8) is consistent with the established correlation of the SO_2 stretching frequencies with the electronegativities of the attached groups (10). A pair of symmetric stretching frequencies and a pair of asymmetric stretching frequencies are expected theoretically but it appears that the two lines expected for the symmetric stretches are not resolved. The expected separation of the two lines is approximately 20 cm^{-1}, which is of the same order as the width of the observed line at 1215 cm^{-1}. The slight change in the position of the sulphuric acid line at 1137 cm^{-1}, which has been assigned as an O—H bend (8) is consistent with the similar vibration in $H_2S_2O_7$ having a similar frequency. This also explains why its intensity changes little in *dilute* oleums, since on adding SO_3 to sulphuric acid the concentration of O—H bonds changes only slowly at low concentrations of sulphur trioxide.

In the Raman spectrum of $S_2O_5F_2$ an SF stretching vibration gives a strong line at 872 cm^{-1} and no analogous line is observed in the oleum spectra as expected. However, as the line at 977 cm^{-1} in the oleum spectrum is not present in the spectrum of $S_2O_5F_2$ it is reasonable to assign this line to the S—OH stretch of $S_2O_5(OH)_2$. At low concentrations of sulphur trioxide in sulphuric acid this line is at 977 cm^{-1}, and is not resolved from the asymmetric $S(OH)_2$ stretching frequency due to sulphuric acid, but in stronger oleums where sulphuric acid is no longer present its frequency can be more accurately determined as 968 cm^{-1}. In fluorosulphuric acid, which has been shown to be a stronger acid than sulphuric acid (11), the S(OH) stretch has been observed at 960 cm^{-1} (8). The shift of the SO_2 vibrations in $H_2S_2O_7$ to higher frequencies as compared to the SO_2 vibrations in H_2SO_4 is also consistent with $H_2S_2O_7$ being a stronger acid than H_2SO_4 (10). The other vibrations are assigned frequencies by comparison with the spectra of sulphuric acid (8) and disulphuryl fluoride (4), as shown in Table II.

The freezing-point depressions and conductivities of dilute solutions of SO_3 in sulphuric acid are consistent with the formation of $H_2S_2O_7$, which behaves as a weak acid of the sulphuric acid solvent system (11),

$$K_1 = [H_3SO_4^+][HS_2O_7^-]/[H_2S_2O_7][H_2SO_4] = 0.0014.$$

Thus a 1 molal solution of $H_2S_2O_7$ in sulphuric acid (7% SO_3) is only 12% ionized, and a 5 molal solution (21% SO_3) is only 5% ionized. It is shown later that a strong line at 1080 cm^{-1} is diagnostic of the $HS_2O_7^-$ ion, and no line at this frequency is detected in the oleum spectra, which is consistent with the concentration of $HS_2O_7^-$ being small.

*These lines are probably also common to higher polysulphuric acids.

There are in fact no lines which can be assigned to any of the ions $H_3SO_4^+$, $HS_2O_7^-$, and $S_2O_7^=$. The sulphuryl stretches of the anions of the acids $XSO_2.OH$ have frequencies in the range 1030 to 1090 cm^{-1} (8), and in the oleum spectra the only lines which occur in this range are the very sharp line at 1075 cm^{-1}, which is diagnostic of SO_3 monomer, and a weak line at 1020 cm^{-1}, which is found only at very high concentrations of SO_3 and is due to SO_3 trimer (9).

Region 11.6 to 41.2% SO_3

In this region the lines assigned to the species $H_2S_2O_7$ increase in intensity and those due to H_2SO_4 decrease in intensity. At 20.9% SO_3 new lines appear at 633 cm^{-1}, 685 cm^{-1}, and 1450 cm^{-1}. At a slightly higher concentration a new line appears at 140 cm^{-1} and at 35.8% SO_3 further low-frequency lines are observed at 176 cm^{-1} and 257 cm^{-1}. Also, in 26.6% SO_3 a sharp line appears at 1075 cm^{-1} and in 35.8% SO_3 a further line is found at 530 cm^{-1}. These latter lines are due to monomeric SO_3 (9), although the 530 cm^{-1} line is probably common to other species as well. The presence of free sulphur trioxide is also indicated by the high SO_3 vapor pressure of these solutions. The weak line at 630 cm^{-1} can be attributed to an SO_2 rocking mode of $H_2S_2O_7$, by comparison with the assignment of a line of the same frequency in the spectrum of $S_2O_5F_2$ (4).

It has been shown that the line at 150 cm^{-1} in the spectra of the disulphuryl halides, which has been assigned to the S—O—S bend, is replaced by several (theoretically five) lines in the spectra of trisulphuryl halides which are also due to skeletal bends (4). Thus the replacement in the most dilute oleums of the single line at 155 cm^{-1}, which is assigned to the S—O—S bend of $H_2S_2O_7$, by lines at 140, 176, and 257 cm^{-1} in the more concentrated oleums is considered to be due to the formation of trisulphuric acid, $H_2S_3O_{10}$. The line at approximately 700 cm^{-1} in the spectra of the disulphuryl halides (4) is replaced by two lines at approximately this frequency in the spectra of the trisulphuryl halides (699 and 724 cm^{-1} in the spectrum of $S_3O_8F_2$). Hence the appearance of a new line at 685 cm^{-1} in stronger oleums in addition to the 730 cm^{-1} line which occurs in weaker oleums also is ascribed to the formation of $H_2S_3O_{10}$. It has similarly been observed that a peak near 730 cm^{-1} in the infrared spectra of diphosphates is replaced by two peaks near 680 and 730 cm^{-1} in the infrared spectra of triphosphates and this has been used as a diagnostic test for these compounds (12).

The new line at 1450 cm^{-1} is interpreted as the SO_2 asymmetric stretch of $H_2S_3O_{10}$. As expected, it is weak and the non-appearance of the symmetric stretch as a separate line, which according to the straight-line relationship between SO_2 symmetric and asymmetric stretching frequencies (10) should occur near 1230 cm^{-1}, is probably due to overlap with the 1215 cm^{-1} line of $H_2S_2O_7$. In fact the band assigned to the symmetric stretch in $H_2S_2O_7$ gradually shifts to higher frequencies as the concentration of SO_3 increases.

The spectrum of dilute oleum is very similar to that of $S_2O_5F_2$, which is isoelectronic with $H_2S_2O_7$, but with increasing concentration of SO_3 the spectra become more similar to those of $S_3O_8F_2$, which is isoelectronic with $H_2S_3O_{10}$.

Liquid Disulphuric Acid (45.9% SO_3)

Cryoscopic studies have shown that $H_2S_2O_7$ undergoes extensive self-dissociation (13, 14). In the spectrum of liquid $H_2S_2O_7$ we assign the line at 900 cm^{-1} to the S—OH symmetric stretch in H_2SO_4 and the line at 965 cm^{-1} to the S—OH stretch in $H_2S_2O_7$. The two lines at 690 and 735 cm^{-1} and the low-frequency lines at 145, 175, and 252 cm^{-1} are all diagnostic of $H_2S_3O_{10}$. The line at 1075 cm^{-1} is due to sulphur trioxide monomer.

In addition the SOS symmetric stretch of $H_2S_2O_7$ at 328 cm^{-1} is accompanied by a weak line at 350 cm^{-1} and the SOS asymmetric stretch of $H_2S_2O_7$ at 809 cm^{-1} is accompanied by a weak line at 850 cm^{-1}. It has been shown previously that each of the two lines in the spectra of disulphuryl halides that are due to skeletal stretches splits into two lines in the spectra of the trisulphuryl halides (4). Thus we attribute the weak lines at 350 and 850 cm^{-1} in the spectrum of liquid $H_2S_2O_7$ to the species $H_2S_3O_{10}$. We conclude that the main self-dissociation process in liquid disulphuric acid is

$$2H_2S_2O_7 = H_2S_3O_{10} + H_2SO_4. \quad [1]$$

Since the strong sharp line at 1075 cm^{-1}, which is diagnostic of SO_3 monomer, is also present in the spectrum, the dissociation

$$H_2S_2O_7 = H_2SO_4 + SO_3 \quad [2]$$

must be of some importance. No lines are present in the spectrum of liquid disulphuric acid which can be attributed to ionic species. The low specific conductance of liquid $H_2S_2O_7$ ($\kappa = 3.7\times10^{-3}$ ohm^{-1} cm^{-1}) is consistent with the absence of appreciable concentrations of self-dissociation ions (15).

Region 45.9% to 100% SO_3

Comparison of the Raman spectra of concentrated oleums with the spectrum of $S_4O_{11}F_2$ (7) does not give conclusive evidence for the occurrence in the oleum system of higher polysulphuric acids such as $H_2S_4O_{13}$. Further splitting of lines in the spectrum of a trisulphuryl compound is to be expected on going to a tetrasulphuryl compound but these were not resolved in the spectrum of $S_4O_{11}F_2$ (7), presumably due to extensive overlapping of the lines resulting from the 45 normal vibrations of this molecule. Thus we have not been able to find characteristic diagnostic frequencies for tetrasulphuryl compounds. However, the SO_2 symmetric stretch, which has a frequency of 1195 cm^{-1} in H_2SO_4, 1224 cm^{-1} in oleum of the composition $H_2S_2O_7$, and 1230 cm^{-1} at the composition $H_2S_3O_{10}$, gradually moves to even higher frequencies as the concentration of SO_3 in oleum increases until at very high stoichiometric concentrations of SO_3, e.g. 92.2% SO_3, it is at 1260 cm^{-1}. The weak line attributed to the SO_2 asymmetric stretch also shifts to higher frequencies, although its low intensity makes this shift more difficult to observe. We interpret the continuous shift of the SO_2 stretching frequencies with increasing SO_3 concentration to the presence of increasing amounts of higher polysulphuric acids such as $H_2S_4O_{13}$. It is noteworthy that the SO_2 symmetric stretch has a frequency of 1260 cm^{-1} in the solid, acyclic, polymeric, α, and β forms of sulphur trioxide. The 1260 cm^{-1} line that is observed in 92.2% oleum cannot be due to S_3O_9 since this has symmetric SO_2 stretching frequencies at 1230 and 1270 cm^{-1} (9) and lines are observed at 1224 and 1270 cm^{-1} in the spectrum of 92.2% oleum *in addition* to the well-resolved line at 1260 cm^{-1}. This latter line also cannot be due to monomeric SO_3, which has SO stretching frequencies of 1070 and 1390 cm^{-1} (16). It is, moreover, not likely that the shift in frequency from 1220 to 1260 cm^{-1} is merely a solvent shift since over the same composition range the symmetric SO stretch of monomeric SO_3 has a constant frequency of 1070 cm^{-1}. We conclude therefore that the polysulphuric acids $HO.SO_2.(SO_3)_nOH$ have SO_2 symmetric stretching frequencies of 1230 cm^{-1} for $n = 1$, and higher frequencies for higher values of n up to a limiting value of 1260 cm^{-1} when n becomes rather large.

The 1270 cm^{-1} line which first appears in the 56.5% oleum and increases in intensity up to 100% SO_3 has been previously assigned as the in-phase symmetric SO_2 stretch of S_3O_9 (9). As it is the strongest line of this species none of the other lines in the spectrum of 56.5% oleum can be due to S_3O_9; they would be too weak to be observed.

Discussion of Previous Work

Millen (1) attributed lines in the oleum spectra at 480 and 530 cm^{-1} to $H_2S_3O_{10}$ and at 245 and 688 cm^{-1} to $H_2S_4O_{13}$ on the grounds that the first two appeared in the spectra at higher concentrations of SO_3 (36%) than other lines attributed to $H_2S_2O_7$, and the latter two at still higher concentrations (51%). However, we find a line at 471 cm^{-1} even in the weakest oleum studied (7.2%), and as there is a line at 487 cm^{-1} in the spectrum of $S_2O_5F_2$ the 471 cm^{-1} line can be assigned with some certainty to $H_2S_2O_7$. Similarly we find a line at 257 cm^{-1} in a 35.8% oleum and a line at 685 cm^{-1} in a 20.9% oleum. Comparison with the spectrum of $S_3O_8F_2$ shows that these lines can in fact be attributed with some certainty to $H_2S_3O_{10}$ rather than uniquely to $H_2S_4O_{13}$, although they are likely to occur in its spectrum also. The appearance of a new Raman line as the concentration of SO_3 is increased cannot be reliably correlated with the appearance of a new species at that concentration since it may arise from a line of weak intensity of a species that is present at considerably lower concentrations but not in sufficient amount to give an observable line.

Giguère and Savoie's interpretation of their infrared spectra (3) agrees reasonably well with our interpretation of the Raman spectra. Thus they assigned lines at 550, 970, 1185, and 1368 cm^{-1} as being common to both H_2SO_4 and $H_2S_2O_7$ while lines at 732 and 806 cm^{-1} were regarded as characteristic of $H_2S_2O_7$ and higher polysulphuric acids and were assigned to SOS skeletal vibrations. We assign the 806 cm^{-1} line to a skeletal vibration but according to our assignment the 732 cm^{-1} line is due to an SO_2 rocking mode. Using the same type of argument as Millen (1), Giguère and Savoie (3) have assigned a line at 688 cm^{-1}, which they first observed in a 25% oleum, and a line at 1430 cm^{-1}, which they first observed in a 23% oleum, to $H_2S_3O_{10}$. This is in agreement with our assignment for the 688 cm^{-1} line, but we find a line at 1420 cm^{-1}, which we assign to $H_2S_2O_7$, in the most dilute oleums studied that gradually shifts to higher frequencies in the higher polysulphuric acids. In agreement with the present work these authors were unable to find any conclusive evidence for the ions $H_3SO_4^+$ and $HS_2O_7^-$ in the oleums studied nor did they find any infrared bands that could be unambiguously assigned to $H_2S_4O_{13}$ or higher polysulphuric acids. The frequencies of the lines observed in the infrared spectra generally agree well with those observed in the Raman spectra. The infrared spectra contain two lines at approximately 618 and 640 cm^{-1} that are not observed in the Raman spectra.

Our conclusions are in more serious disagreement with the recent work of Walrafen and Young (2), who used a photoelectric method in an attempt to obtain estimates of the concentrations of species in the H_2SO_4–SO_3 system. Unfortunately, although the relative intensities of the lines that they observed are undoubtedly more accurate than could be obtained from our photographic work, they obtained many fewer lines and several closely spaced groups of lines are very poorly, if at all, resolved in their spectra. Because they found that the only lines in the Raman spectra of oleums that were not present in the spectra of either H_2SO_4 or liquid sulphur trioxide reached a maximum intensity at approximately the composition $H_2S_2O_7$ they assumed that this acid and its ions are the only new species formed in H_2SO_4–SO_3 mixtures. However, we find a number of lines that cannot be attributed to either H_2SO_4 or to SO_3 and its polymers that continue to increase in intensity in solutions containing more SO_3 than corresponds to the composition $H_2S_2O_7$ and which by comparison with the spectra of the polysulphuryl halides may be assigned to $H_2S_3O_{10}$ and higher polysulphuric acids. Young and Walrafen's quantitative interpretation of their results rests on their assumption that the only poly-

sulphuric acid that is formed is $H_2S_2O_7$ and on the further assumption that this acid is extensively ionized. This latter assumption is in direct contradiction to evidence from the results of extensive studies of the freezing points (11), conductivities (11), and acidity functions (17) of the H_2SO_4–SO_3 system, which show that $H_2S_2O_7$ is only a rather weak acid of the sulphuric acid system and is only very incompletely ionized even in the most dilute oleum studied in the Raman work.

Walrafen and Young found, as we have, that the intensity of the 910 cm^{-1} line does not decrease in intensity in proportion to the expected decrease in the concentration of H_2SO_4. They assumed therefore that one of the ions formed in the ionization of $H_2S_2O_7$ (i.e. $H_3SO_4^+$ or $HS_2O_7^-$) must also contribute to the intensity of the 910 cm^{-1} line. Our explanation for the persistence of this frequency at concentrations of SO_3 greater than that required for the stoichiometric formation of $H_2S_2O_7$ is, however, that free H_2SO_4 is in fact still present in the system as a consequence of the self-dissociation of $H_2S_2O_7$ into H_2SO_4 and $H_2S_3O_{10}$. Moreover, as is discussed later, it is unlikely that either of the ions $H_3SO_4^+$ or $HS_2O_7^-$ could contribute to the 910 cm^{-1} line.

Walrafen and Young also make the arbitrary assumption that "Raman radiation having a frequency of 300–325 cm^{-1} contains energy from two sources, $H_2S_2O_7$ and $HS_2O_7^-$". Our results on the other hand show two distinct lines in this region of the spectrum at 302 and 323 cm^{-1} which have been assigned to a torsional mode and a skeletal stretch, respectively, of $H_2S_2O_7$ and the higher polysulphuric acids.

It is unfortunate that the inadequate sensitivity and resolution of the photoelectric method used by Walrafen and Young and the unjustified assumptions made in the interpretation of their spectra and also the inaccuracy of their titration method of determining the concentrations of their oleums invalidate what would otherwise be useful information on the concentrations of the various species present in oleums. Although the present work establishes the nature of the species present with some certainty it gives only qualitative information on their relative concentrations.

SOLUTIONS OF SODIUM SULPHATE IN OLEUM

An important point in Walrafen and Young's discussion of their results is the assumption that the $HS_2O_7^-$ ion contributes to the intensity of the 910 cm^{-1} line. We have suggested above that this ion is not present in sufficient concentration in oleums to give rise to any characteristic lines in the spectrum. It seemed important therefore to attempt to obtain the spectrum of the $HS_2O_7^-$ ion and accordingly the Raman spectra of solutions of sodium sulphate in some oleums of different strengths were measured. The results of these measurements are given in Table III and Fig. 2. Some similar measurements have been reported previously by Millen (1). The compositions of the solutions are expressed in terms of the ratio $n_b/n_a{}^i$ where n_b is the number of moles of $NaHSO_4$ added to $n_a{}^i$ moles of $H_2S_2O_7$. The $HS_2O_7^-$ ion is formed in these solutions by the reaction

$$H_2S_2O_7 + NaHSO_4 = Na^+ + HS_2O_7^- + H_2SO_4. \quad [3]$$

At high concentrations of $NaHSO_4$ substantial quantities of $S_2O_7^=$ are also formed according to the equation

$$HS_2O_7^- + NaHSO_4 = Na^+ + S_2O_7^= + H_2SO_4. \quad [4]$$

The concentrations of all the species in a solution for various values of $n_b/n_a{}^i$ may be calculated from the following data (11) using a similar method to that outlined in a previous publication (18):

TABLE III

$$K_{ap}' = [H_3SO_4^+][HSO_4^-][H_2SO_4]^2 = 2.4\times10^{-6}$$
$$K_1 = [H_3SO_4^+][HS_2O_7^-]/[H_2S_2O_7][H_2SO_4] = 1.4\times10^{-3}$$
$$K_2 = [H_3SO_4^+][S_2O_7^=]/[HS_2O_7^-][H_2SO_4] = 1\times10^{-4}.$$

This value of K_2 is an estimate based on the assumption that $K_1/K_2 = 10$, as is the case for the first two dissociation constants of diphosphoric acid in water for which $K_1 = 1.4\times10^{-1}$ and $K_2 = 1.1\times10^{-2}$. The results of these calculations are shown in Fig. 3. No allowance has been made for probable non-ideal behavior of the solutions

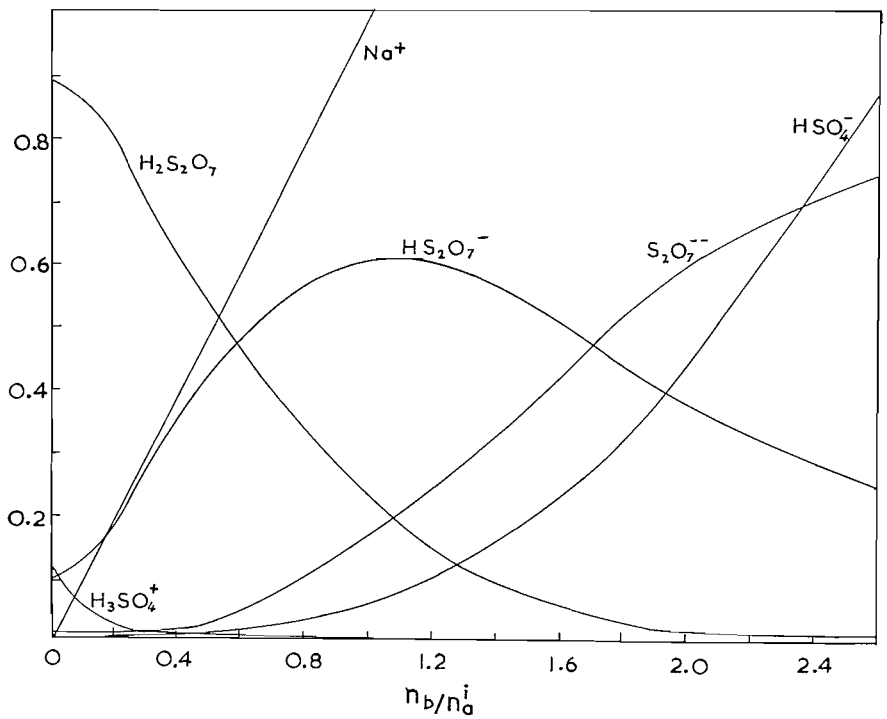

FIG. 3. Approximate concentrations of species in solutions of $NaHSO_4$ in oleum (1 molal $H_2S_2O_7$ in H_2SO_4).

or for the possibility of the conversion of the $HS_2O_7^-$ and $S_2O_7^=$ ions to higher polymeric forms such as $S_3O_{10}^=$ but Fig. 3 indicates at least approximately the manner in which the relative concentrations of species change as $NaHSO_4$ is added to an oleum, which is adequate for our present purpose.

It is possible to predict frequencies for some of the more important characteristic vibrations of $HS_2O_7^-$ and $S_2O_7^=$ by utilizing correlations derived from observations on related molecules and ions (8). Thus the following frequencies have been found for the S—OH stretching mode: HSO_4^-, 895 cm^{-1}; H_2SO_4, $(\nu_{sym}+\nu_{asym})/2$ = 944 cm^{-1}; HSO_3F, 960 cm^{-1}; $H_2S_2O_7$, 968 cm^{-1}. There seems to be an increase in the frequency of this vibration with increasing acid strength, and a frequency of between 944 and 968 cm^{-1}, probably close to 968 cm^{-1}, would be expected for the S—OH stretching frequency in the $HS_2O_7^-$ ion. It is rather unlikely that this vibration (or any other vibration of the $HS_2O_7^-$ ion) could contribute to the intensity of the 910 cm^{-1}, as was assumed by

Walrafen and Young (2). The SO_2 stretching vibrations also show a similar increase in frequency with increasing acid strength. Thus the following frequencies have been found for the SO_2 symmetric stretch: HSO_4^-, 1040 cm^{-1}; SO_3F^-, 1080 cm^{-1}; H_2SO_4, 1195 cm^{-1}; $H_2S_2O_7$, 1224 cm^{-1}; HSO_3F, 1230 cm^{-1}; and for the SO_2 asymmetric stretch: HSO_4^-, 1195 cm^{-1}; SO_3F^-, 1228 cm^{-1}; H_2SO_4, 1368 cm^{-1}; $H_2S_2O_7$, 1425 cm^{-1}; HSO_3F, 1445 cm^{-1}. The close similarities in the frequencies of the SO_2 stretching vibrations for HSO_3F and $H_2S_2O_7$ make it very probable that the vibrations of the —O.SO_3^- part of the $HS_2O_7^-$ ion will have frequencies close to those in SO_3F^-, i.e. 1080 and 1230 cm^{-1}, while the frequencies for the HO.SO_2.O— part of the ion should be close to those in $H_2S_2O_7$ itself, i.e. 1225 and 1425 cm^{-1}.

Sodium hydrogensulphate was added to 1 molal $H_2S_2O_7$, (7% SO_3) to give solutions with $n_b/n_a{}^i = 0.29$, 0.56, 1.00, and 2.00. There is little change in the spectrum compared with that of the original oleum until the composition $n_b/n_a{}^i = 0.56$ is reached. A solution of this composition has a minimum conductivity, the concentrations of $H_3SO_4^+$ and HSO_4^- are very small, and the most important ionic species are Na^+ and $HS_2O_7^-$ (19). At this composition a new, relatively sharp line is observed at 1080 cm^{-1} and its intensity increases as further $NaHSO_4$ is added. We therefore attribute this line, as Millen (1) did, to the $HS_2O_7^-$ ion, and we assign it to the SO_2 symmetric stretch of the O.SO_3^- part of the ion: its frequency agrees well with that predicted above. The corresponding asymmetric stretch is not observed as a separate line as it almost certainly has a very similar frequency to the symmetric SO_2 stretch of $H_2S_2O_7$. Although at the composition $n_b/n_a{}^i = 1.00$, molecular $H_2S_2O_7$ has been substantially replaced by $HS_2O_7^-$ ions the intensities of the lines at approximately 1210 and 1420 cm^{-1} do not diminish very greatly and therefore we assign these frequencies to the SO_2 stretching vibrations in the HO.SO_2.O— part of the ion in addition to the similar vibrations in the $H_2S_2O_7$ molecule.

At the composition $n_b/n_a{}^i = 2.00$, $HS_2O_7^-$ ion has been substantially converted to $S_2O_7^=$. Since the 1080 cm^{-1} remains in the spectrum with about the same intensity it must also be a frequency of the $S_2O_7^=$ ion: this is reasonable as not much change in the SO_2 symmetric stretch of the —O.SO_3^- part of $HS_2O_7^-$ would be expected when the second hydrogen is ionized to give $S_2O_7^=$.

The S—OH stretch of the $HS_2O_7^-$ ion is difficult to detect in the spectra because the S—OH stretch of $H_2S_2O_7$ and the asymmetric S—OH stretch of H_2SO_4 give lines at 960 cm^{-1}. However, in the 7% and 11% oleums solutions with $n_b/n_a{}^i = 1.00$ a new line may be present in the spectra at 940–950 cm^{-1}, since the line at 960 cm^{-1} appears to broaden and to merge into the 910 cm^{-1} line due to the symmetric S—OH stretch of sulphuric acid, whereas in the spectra of the original oleums and also of solutions containing larger quantities of $NaHSO_4$ the 960 cm^{-1} line is well resolved from the 910 cm^{-1} line. The above conclusions are confirmed by the spectra of solutions of $NaHSO_4$ in 26% and 45% oleum.

The spectra of these solutions are difficult to interpret in detail because of the considerable overlapping of the lines due to different molecular and ionic species. However, it seems clear that the 1080 cm^{-1} line is diagnostic of the $HS_2O_7^-$ and probably the $S_2O_7^=$ ions as well and the fact that this line is not observed in oleums, but appears and increases in intensity on the addition of $NaHSO_4$, is consistent with other strong evidence that disulphuric acid is a rather weak acid of the sulphuric acid system and not a strong acid as assumed by Walrafen and Young. It is unlikely therefore that the $HS_2O_7^-$ ion

contributes substantially to the intensity of the 910 cm^{-1} line in oleums as claimed by these authors, particularly as the S—OH stretch of this ion almost certainly has a frequency in the range 940–960 cm^{-1} and this is the only vibration that is likely to give rise to a line in this region of the spectrum.

SOLUTIONS OF SULPHUR TRIOXIDE IN DEUTEROSULPHURIC ACID

We have not studied the D_2SO_4–SO_3 system as extensively as the H_2SO_4–SO_3 system but the Raman spectra (Table IV) are very similar to the spectra of protosulphuric

acid oleums. The observed lines may be assigned by comparison of the spectra with the spectra of the polysulphuryl fluorides and the protosulphuric acid oleums as shown in Table V. This comparison clearly demonstrates the formation of $D_2S_2O_7$. Earlier cryoscopic and conductimetric measurements on the D_2SO_4–SO_3 system have been interpreted in terms of the formation of $D_2S_2O_7$, which behaves as a very weak acid (20). The absence of any lines in the Raman spectra which can be assigned to ions confirms the behavior of $D_2S_2O_7$ as a weak acid in D_2SO_4.

*These lines are probably also common to higher polyacids.

As the concentration of sulphur trioxide increases most of the Raman frequencies of D_2SO_4 (8) diminish in intensity and those due $D_2S_2O_7$ increase in intensity. The strong diagnostic frequency at 1075 cm^{-1} due to monomeric SO_3 is first observed in a relatively dilute oleum (27.1% SO_3) and this line grows in intensity as the concentration of the oleum increases. The band at 1270 cm^{-1}, which is diagnostic of the trimer S_3O_9, does not appear until the strength of the oleum is increased to approximately 80% SO_3. The formation of higher deuteropolysulphuric acids, e.g. $D_2S_3O_{10}$, is indicated both by the splitting of the 730 cm^{-1} line into two lines at 685 and 730 cm^{-1} and by the shift of the SO_2 symmetric stretch to higher frequencies with increasing stoichiometric concentration of SO_3. In dilute oleums the line at 1230 cm^{-1} is attributed to an SO_2 symmetric stretch of $D_2S_2O_7$. This line shifts to 1225 cm^{-1} in the strongest oleums and this is attributed to the formation of higher polyacids such as $D_2S_3O_{10}$ and $D_2S_4O_{13}$.

EXPERIMENTAL

Sulphuric acid (100%) was prepared, as has been described elsewhere (21), from analytical grade concentrated sulphuric acid and 30% oleum, by adjustment to the maximum freezing point of 10.37°. Deuterosulphuric acid was prepared by distilling sulphur trioxide into cooled deuterium oxide until there was a slight excess of sulphur trioxide. The 100% acid was then obtained by adjustment of the freezing point to 14.42° by addition of small amounts of deuterium oxide (20). The oleum solutions were prepared by weight by distillation of pure sulphur trioxide into the 100% acid. Sulphur trioxide was obtained by distillation of 65% commercial oleum to which potassium persulphate had been added to oxidize any sulphur dioxide present to the trioxide.

In the recent work of Giguère and Savoie (3) and of Walrafen and Young (2) the compositions of the oleums studied were obtained by titration with sodium hydroxide solution. As the latter workers point out this method of determining the compositions of solutions of sulphur trioxide in sulphuric acid is very inaccurate, particularly for strong oleums. Our method of preparing oleums of known composition is simple and the concentrations of the solutions were obtained very accurately.

The Raman spectra were measured with the photographic apparatus described previously using exposures of approximately 2 to 4 minutes. The spectra were measured by comparison with a standard iron arc using a Leeds and Northrup microphotometer (4). The frequencies of the lines reported are probably accurate to ± 5 cm^{-1}.

ACKNOWLEDGMENTS

Dr. R. H. Tomlinson is thanked for a gift of deuterium oxide, and the National Research Council and the Ontario Research Foundation for financial support.

SOLUTIONS OF SULPHUR TRIOXIDE IN FLUOROSULPHURIC ACID AND CHLOROSULPHURIC ACID: RAMAN AND N.M.R. SPECTROSCOPIC EVIDENCE FOR THE FORMATION OF HALOGENOPOLYSULPHURIC ACIDS

R. J. GILLESPIE AND E. A. ROBINSON[1]
Department of Chemistry, McMaster University, Hamilton, Ontario
Received October 27, 1961

ABSTRACT

The Raman spectra of solutions of sulphur trioxide in fluorosulphuric acid and chlorosulphuric acid have been examined. By comparing the spectra with those of the polysulphuryl halides and the polysulphuric acids the formation of the halogen-substituted polysulphuric acids HS_2O_6F, HS_3O_9F, HS_2O_6Cl, and HS_3O_9Cl is proved and some evidence is obtained for higher polyacids such as $HS_4O_{12}F$ and $HS_4O_{12}Cl$. The fluorine n.m.r. spectra of solutions of sulphur trioxide in fluorosulphuric acid have also been investigated: they provide supporting evidence for the formation of fluoropolysulphuric acids. Vibrational frequencies diagnostic of the ions $S_2O_6F^-$ and $S_2O_6Cl^-$ have been obtained from the Raman spectra of fluorosulphuric acid solutions containing both sulphur trioxide and sodium fluorosulphate, and chlorosulphuric acid solutions containing both sodium chlorosulphate and sulphur trioxide.

The preceding paper gives an analysis of the spectra of solutions of sulphur trioxide in sulphuric acid in terms of the formation of the polysulphuric acids $H_2S_2O_7$, $H_2S_3O_{10}$, and higher polyacids (1). This paper presents the results of a similar investigation of the Raman spectra of solutions of sulphur trioxide in fluorosulphuric acid and chlorosulphuric acid.

THE FLUOROSULPHURIC ACID – SULPHUR TRIOXIDE SYSTEM

Raman Spectra

Cryoscopic and conductimetric measurements have shown (2) that sulphur trioxide behaves as a non-electrolyte in dilute solution in fluorosulphuric acid. There has been no previous Raman spectroscopic investigation of this system. Our results are shown in Table I and Fig. 1.

The spectrum of the most dilute solution studied (4.6% SO_3) has new lines at 300, 311, 325, 458, 721, 1074, 1202, 1394, 1412, and 1489 cm^{-1}, which are not present in the spectrum of fluorosulphuric acid (3). The lines at 1074 and 1394 cm^{-1} can be assigned to sulphuric trioxide monomer (4). The five lines from 300 to 721 cm^{-1} may be compared with similar lines in the spectrum of $S_2O_5F_2$ at 290, 301, 323, 455, and 733 cm^{-1} (5). The spectra of relatively dilute solutions of SO_3 in fluorosulphuric acid are also very similar to the spectra of dilute solutions of sulphur trioxide in sulphuric acid (Table II), in which the formation of the compound $H_2S_2O_7$ (I) is well established. The new lines in the spectra are thus consistent with the formation of a disulphuryl compound. The high-frequency lines at 1212, 1243, 1412, and 1489 cm^{-1} are undoubtedly due to SO_2 valency vibrations. For a disulphuryl compound of the type $S_2O_5X_2$ or S_2O_5XY four valency vibrations of the SO_2 groups are expected (5) (two symmetric stretches and two asymmetric stretches), and thus the above lines may be assigned to two symmetric stretches (1212 and 1241 cm^{-1}), and two asymmetric stretches (1412 and 1489 cm^{-1}), of a disulphuryl compound. By comparison with the SO_2 valency vibrations in the spectrum of $S_2O_5F_2$ at 1249, 1264, 1490, and 1511 cm^{-1} it is clear that the high-frequency lines

observed in the spectrum of the $HFSO_3$–SO_3 system are not due to $S_2O_5F_2$ (II), although this might have been formed by the reaction

$$2HFSO_3 + SO_3 = S_2O_5F_2 + H_2SO_4.$$

Moreover, none of the characteristic vibrational frequencies of H_2SO_4 are found in these spectra.

IV

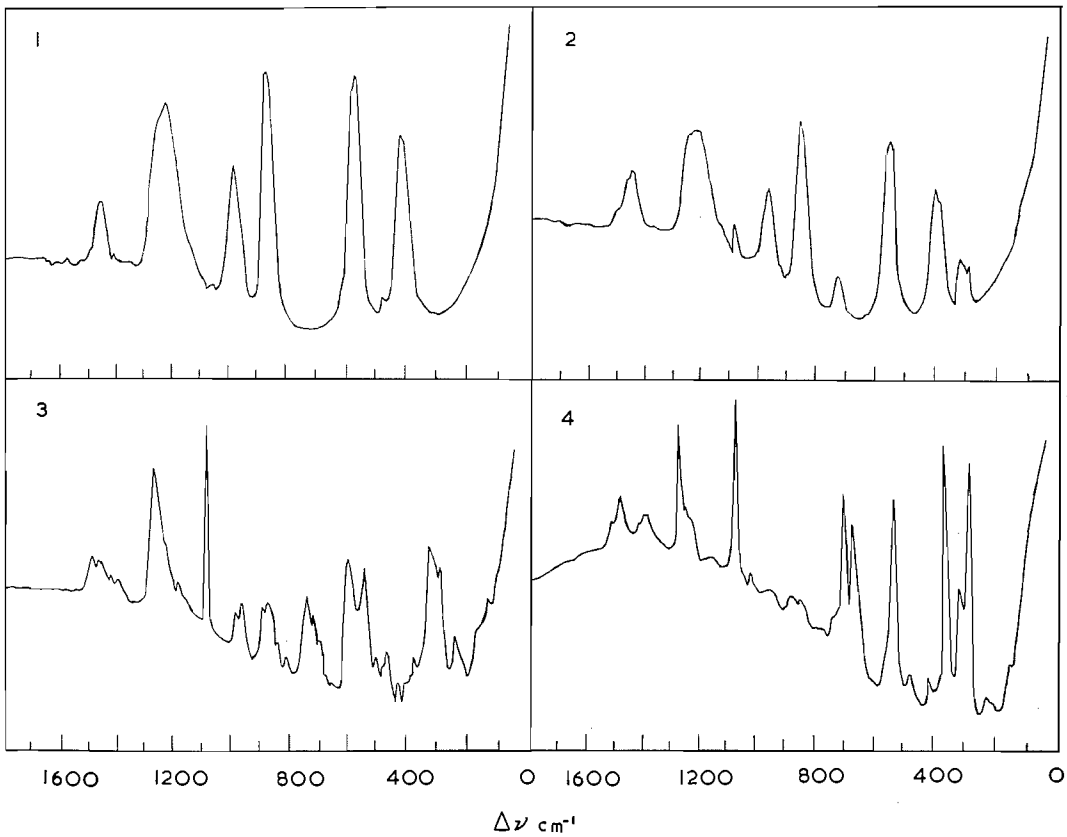

FIG. 1. Raman spectra of the HSO_3F–SO_3 system: (1) HSO_3F, (2) HSO_3F – 4.8% SO_3, (3) HSO_3F – 32.6% SO_3, (4) HSO_3F – 89.4% SO_3.

We conclude therefore that sulphur trioxide reacts with fluorosulphuric acid to form fluorodisulphuric acid, $S_2O_5F(OH)$ (III), in much the same manner as SO_3 reacts with sulphuric acid to form disulphuric acid. The comparison in Table III of the frequencies of the SO_2 stretching vibrations observed in the SO_3–HSO_3F system with those of $S_2O_5F_2$, S_2O_5FCl, $S_2O_5Cl_2$, and $S_2O_5(OH)_2$ provides strong support for attributing them to the new species $S_2O_5F(OH)$.

The S—OH stretch of $S_2O_5F(OH)$ would be expected to have a frequency close to 960 cm^{-1}, the frequency of the analogous vibration in fluorosulphuric acid. Therefore the new line which first appears at 973 cm^{-1} in the spectrum of the 7.9% SO_3 solution may be assigned to the S—OH stretch of fluorodisulphuric acid. In the spectrum of this solution another new line appears at 140 cm^{-1}, which can be assigned to the S—O—S bend of HFS_2O_6 by comparison with the line at 157 cm^{-1} in the spectrum of $S_2O_5F_2$. At slightly higher concentrations of stoichiometric sulphur trioxide further new lines appear in the spectra at 215, 232, 352, 364, 505, 530, and 705 cm^{-1}. The multiplicity of lines at low frequencies and in particular the replacement of the line at approximately 724 cm^{-1} by two lines at 724 and 705 cm^{-1} is diagnostic of a trisulphuryl compound (4) and thus we conclude that as the concentration of SO_3 increases the higher polyacid $S_3O_8F(OH)$ (IV) is also present in the system. At relatively high concentrations of sulphur trioxide

*Mean frequency of two unresolved lines.

in fluorosulphuric acid only a few new lines appear in the spectra. However, as was found to be the case for solutions of sulphur trioxide in sulphuric acid (1) at very high concentrations of SO_3, a line appears at 1270 cm^{-1} which is indicative of the presence of sulphur trioxide trimer, S_3O_9, in these solutions. The SO_2 symmetric stretch at 1250 cm^{-1} (which is well resolved from the adjacent line due to sulphur trioxide trimer) shifts slightly to approximately 1258 cm^{-1}. This small but real shift in frequency may possibly be ascribed to the formation of higher polysulphuric acids such as $S_4O_{11}F(OH)$. Table II gives our assignment of the observed spectral lines of two dilute solutions of sulphur trioxide in fluorosulphuric acid.

N.M.R. Spectra

Further evidence for the formation of fluoropolysulphuric acids in this system was obtained from a study of the variation of the chemical shift in the fluorine n.m.r. spectra of the fluorosulphuric acid – sulphur trioxide system (Fig. 2). As the stoichiometric concentration of sulphur trioxide increases the single fluorine resonance peak shifts to lower field. The fact that a separate resonance is not observed for each polyacid indicates that there is some rapid exchange process which averages the chemical environment of

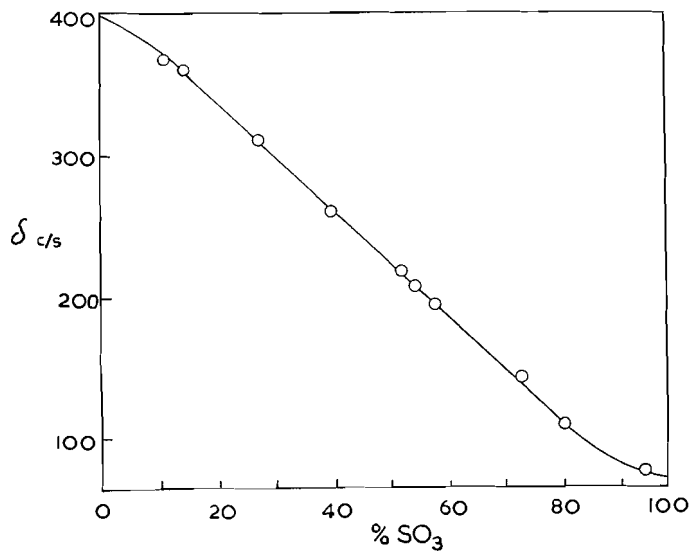

FIG. 2. F^{19} chemical shifts in the HSO_3F–SO_3 system. δ, chemical shift from internal $S_2O_5F_2$ (c/s at 56.4 Mc).

the fluorine atoms. Since the presence of free SO_3 in the system is indicated by the occurrence of the 1074 cm^{-1} line even at low SO_3 concentrations, the exchange process is most probably the exchange of SO_3 between the various polyacids:

$$H(SO_3)_nF + SO_3 \rightleftharpoons H(SO_3)_{n+1}F.$$

It is of interest to compare the relative chemical shifts in the fluorosulphuric acid – sulphur trioxide system with the corresponding shifts of the polysulphuryl fluorides (6). Figure 3 shows such a comparison for the purpose of which we have interpolated the

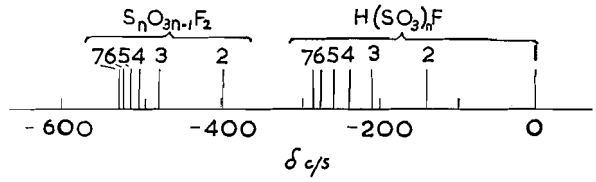

FIG. 3. Comparison of the F^{19} chemical shifts of the fluoropolysulphuric acids and the polysulphuryl fluorides. δ, chemical shift from internal $S_2O_5F_2$ (c/s at 56.4 Mc).

chemical shifts in the $HFSO_3$–SO_3 system at the stoichiometric compositions corresponding to complete formation of the acids HS_2O_6F, HS_3O_9F, $HS_4O_{12}F$, $HS_5O_{15}F$, etc., although, in fact, at these compositions the system undoubtedly contains several of these species in equilibrium. There is a striking similarity between the spectrum of the polysulphuryl fluoride resonances and those of the fluoropolysulphuric acids.

Addition of a polysulphuryl fluoride such as $S_2O_5F_2$ to a solution of SO_3 in fluorosulphuric acid gave an additional line in the n.m.r. spectrum, showing that these species were not present in the original system—a conclusion which agrees with our deduction from the Raman spectra that polysulphuryl fluorides are not formed from the reaction between fluorosulphuric acid and sulphur trioxide at room temperature. Polysulphuryl fluorides were formed, however, when sulphur trioxide and fluorosulphuric acid were heated to 100° in sealed tubes for several hours (Fig. 4).

The Raman and n.m.r. spectra of solutions of sulphur trioxide in fluorosulphuric acid at room temperature therefore indicate the formation of the fluoropolysulphuric acids HS_2O_6F, HS_3O_9F, and perhaps higher polyacids such as $HS_4O_{12}F$, although at higher temperatures polysulphuryl fluorides are also formed.

The $S_2O_6F^-$ Ion

When potassium fluorosulphate was added to a dilute solution of sulphur trioxide in fluorosulphuric acid the only marked change in the spectrum was the appearance of a strong line at 1080 cm^{-1}. The frequency of this line is the same as that of a characteristic frequency of the hydrogen disulphate ion (1). This is consistent with the formation of the fluorodisulphate ion, $FS_2O_6^-$, according to the equation

$$KFSO_3 + HFS_2O_6 = FS_2O_6^- + HFSO_3.$$

No line is observed at 1080 cm^{-1} in the spectrum of the fluorosulphuric acid – sulphur trioxide system. We conclude that the ion $FS_2O_6^-$ is not present in solutions of SO_3 in $HFSO_3$ and that therefore the acid HFS_2O_6 is a very weak acid of the fluorosulphuric acid system. This is in agreement with cryoscopic and conductimetric measurements (2) which show that SO_3 is a non-electrolyte in fluorosulphuric acid, although these measurements do not distinguish between the possibilities that the solution contains monomeric SO_3 or the non-ionized acid HS_2O_6F.

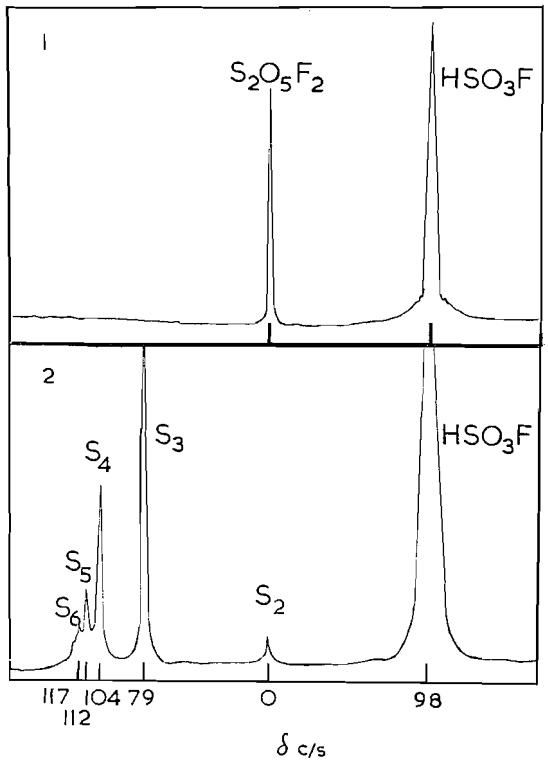

FIG. 4. Nuclear magnetic resonance spectra illustrating the formation of polysulphuryl fluorides in the HSO_3F–SO_3 system at elevated temperatures: (1) HSO_3F – 37% SO_3 at room temperature ($S_2O_5F_2$ was added to provide a reference signal); (2) HSO_3F – 37% SO_3 after 4 hours at 100° (S_n denotes the polysulphuryl fluoride $S_nO_{3n-1}F_2$).

Complexes are known between ionic fluorides and sulphur trioxide, e.g. $KF.2SO_3$ (7); these compounds may be formulated as salts of fluorodisulphuric acid.

THE CHLOROSULPHURIC ACID - SULPHUR TRIOXIDE SYSTEM

Solutions of sulphur trioxide in chlorosulphuric acid have received some attention previously due to their use in aromatic sulphonation and as smoke gases in war. The densities and viscosities of solutions of sulphur trioxide in chlorosulphuric acid have been examined by McCallum and Tollefson (8), who also found that no solid phase exists in such solutions up to 60% SO_3 by weight at room temperature. Vapor pressure measurements have been reported by Balson and Adam (9), and the Raman spectrum of a 1:1 mixture of SO_3 and chlorosulphuric acid has been discussed by Gerding (10), who did not report the spectrum but only his conclusion that a complex is formed, which he regarded as a loosely bound addition compound $SO_3.HSO_3Cl$.

The Raman spectra of several solutions of SO_3 in chlorosulphuric acid are shown in Table IV and Fig. 5. The analysis of these spectra follows very much the same pattern as that given above for solutions of sulphur trioxide in fluorosulphuric acid.

At relatively low concentrations of sulphur trioxide in chlorosulphuric acid, e.g. 12.8% SO_3, many new lines appear in the spectrum which cannot be attributed to either component. These occur at 148, 218, 232, 275, 289, 301, 360, 595, 720, 803, 950, 1075, 1235, and 1452 cm^{-1} in the spectrum of the 12.8% SO_3 solution. The line at 1075 cm^{-1}

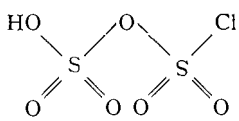
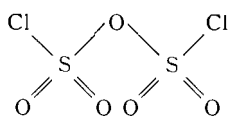
is due to SO_3 monomer (4) and the other lines are to be compared with lines in the spectrum of $S_2O_5Cl_2$ (5) at 147, 235, 273, 298, 370, 593, 716, 760, 1189, 1209, 1442, and 1462 cm^{-1} (Table V). This comparison clearly indicates the formation of a disulphuryl compound in the $HClSO_3$–SO_3 system. The spectra are also very similar to those of dilute solutions of SO_3 in sulphuric acid, where the formation of disulphuric acid (I) is well established. Again it is necessary to distinguish between the possible formation of chlorodisulphuric acid (V) or disulphuryl chloride (VI). The spectra support the forma-



V



VI

tion of the former rather than the latter since the new line at 950 cm^{-1} can be assigned to the S—OH stretch in this species (compare 920 cm^{-1} for the S—OH stretch in chlorosulphuric acid (3), and 960 cm^{-1} for the S—OH stretch in $H_2S_2O_7$ (1)). The new lines

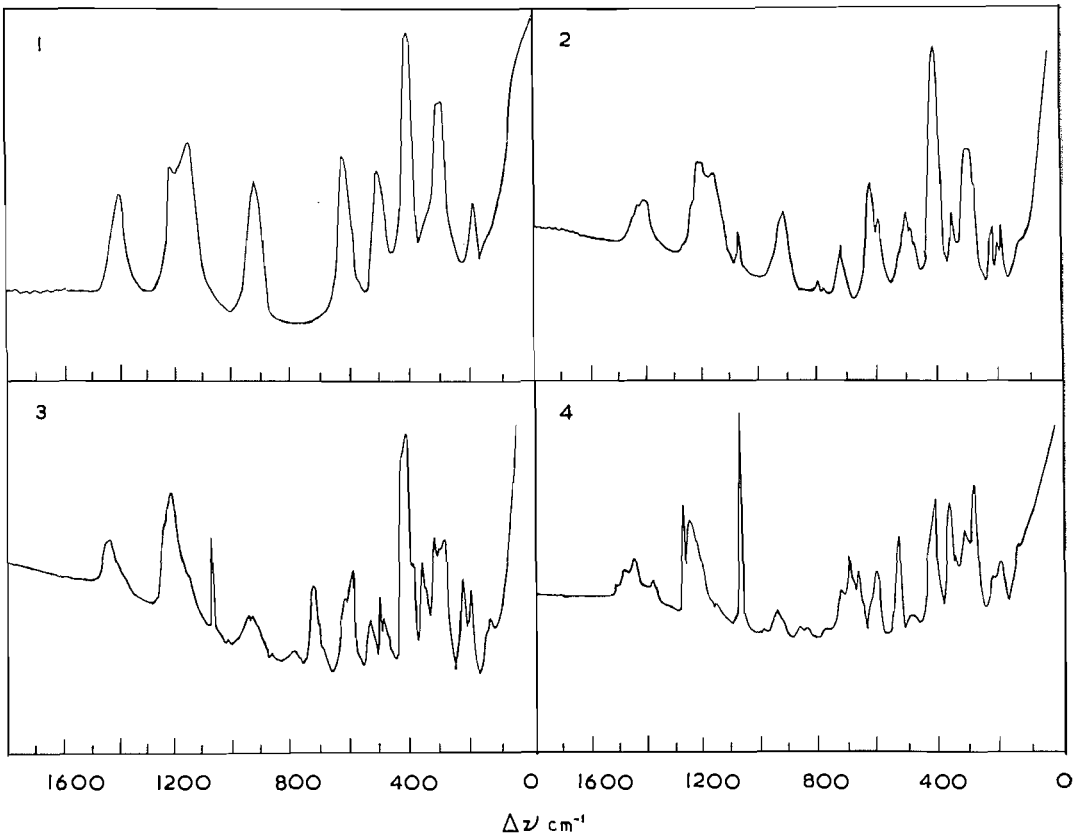


FIG. 5. Raman spectra of the HSO_3Cl–SO_3 system: (1) HSO_3Cl, (2) HSO_3Cl – 12.8% SO_3, (3) HSO_3Cl – 36.7% SO_3, (4) HSO_3Cl – 70% SO_3.

at 1235 and approximately 1450 cm^{-1} can be assigned, respectively, as a symmetric and an asymmetric stretching frequency of the SO_2 group. Since the intensities of the lines at approximately 1209 and 1408 cm^{-1}, which are the symmetric and asymmetric SO_2 vibrations of chlorosulphuric acid, change little even in solutions of high SO_3 content we conclude that these lines are also common to the spectrum of the new disulphuryl compound. Thus the new species has two symmetric stretches at approximately 1209 and 1235 cm^{-1} and two asymmetric stretches at approximately 1408 and 1452 cm^{-1}. The comparison of these frequencies with those of the SO_2 stretches of the other disulphuryl compounds shown in Table III strongly suggests that the new species is $S_2O_5Cl(OH)$.

As the concentration of SO_3 in chlorosulphuric acid increases, the spectra become increasingly similar to the spectrum of a trisulphuryl compound. In particular the line at 720 cm^{-1} is replaced by two lines in the same region of the spectrum at approximately 700 and 723 cm^{-1}. This is diagnostic of the formation of a trisulphuryl compound (5), i.e. $S_3O_8Cl(OH)$. As the concentration of SO_3 increases the symmetric stretch originally at 1235 cm^{-1} moves to higher frequencies, e.g. in 92.8% SO_3 the symmetric stretch is at 1258 cm^{-1}. There is also a line at approximately 1480 cm^{-1} which can be assigned as the corresponding SO_2 asymmetric stretch. This may be taken as evidence for the formation of higher polysulphuric acids such as $HS_4O_{12}Cl$.

On addition of sodium chlorosulphate to a dilute solution of SO_3 in chlorosulphuric acid the principal change in the spectrum is the appearance of a new line at 1080 cm^{-1}. Since this frequency is very similar to that of one of the SO_2 stretches of the $HS_2O_7^-$ ion we assign it to one of the SO_2 vibrations of the $ClS_2O_6^-$ ion. As this line is not present in the original chlorosulphuric acid oleum solutions we conclude that chlorodisulphuric acid is very little ionized in solution in chlorosulphuric acid.

The Raman spectra of solutions of sulphur trioxide in chlorosulphuric acid are consistent with the formation of the chloropolysulphuric acids HS_2O_6Cl, HS_3O_9Cl, and probably $HS_4O_{12}Cl$ and higher polyacids. As was the case for the corresponding fluoroacids the sharp line in the spectra at 1075 cm^{-1} indicates the presence of some free sulphur trioxide even at low stoichiometric concentrations of SO_3 and there is probably rapid exchange according to the equation

$$H(SO_3)_nCl + SO_3 \rightleftharpoons H(SO_3)_{n+1}Cl.$$

It is known that simple ionic chlorides such as sodium chloride form addition compounds with sulphur trioxide, e.g. $NaCl.SO_3$, $NaCl.2SO_3$, $NaCl.3SO_3$ (11). These compounds may be formulated as the salts of chlorosulphuric acid and the chloropolysulphuric acids, i.e. $NaClSO_3$, $NaClS_2O_6$, and $NaClS_3O_9$.

EXPERIMENTAL

Fluorosulphuric acid and chlorosulphuric acid were purified by distillation of the commercial products and had boiling points of 161° and 153°, respectively. Solutions were made up by weight by distilling sulphur trioxide into the acid. Sulphur trioxide was obtained by distillation from 65% fuming sulphuric acid or from commercial stabilized sulphur trioxide "Sulfan B".

The Raman spectroscopic measurements were carried out as has been described previously (5) using a Hilger E 612 spectrometer in conjunction with a water-cooled "Toronto" mercury arc lamp. The spectra were recorded photographically and measured by means of a Leeds and Northrup microphotometer.

The n.m.r. measurements were carried out using a Varian Associates n.m.r. spectrometer, operating at 56.4 Mc/sec. The spectra were calibrated using the side-band technique and shifts were measured with respect to disulphuryl fluoride as an internal reference.

ACKNOWLEDGMENTS

Dr. J. V. Oubridge is thanked for preliminary work on the n.m.r. spectra and Mr. J. Bacon for experimental assistance. The Ontario Research Foundation, the Defence Research Board, and the Allied Chemical Company are thanked for financial support.

THE KINETICS OF THE REACTION OF ACTIVE NITROGEN WITH ETHYLENE[1]

E. M. LEVY[2] AND C. A. WINKLER

Upper Atmosphere Chemistry Research Group, Physical Chemistry Laboratory, McGill University, Montreal, Que.

Received December 1, 1961

ABSTRACT

A comparison has been made of five methods for terminating the reaction of active nitrogen with ethylene in the temperature range 295° to 673° K. These were based on deactivating the active nitrogen by low-temperature trapping, by addition of nitric oxide, and by passing it over copper oxide or cobalt catalysts. With the nitric oxide and cobalt catalyst techniques, which appeared to be the most reliable of those used, an activation energy of 400 ± 200 cal/mole, with a P factor of about 10^{-5}, have been determined for the reaction.

INTRODUCTION

Although the reactions of active nitrogen with a large number of organic and inorganic compounds have been studied, most of the earlier investigations were of a semiquantitative nature, in which the extents of product formation were determined as functions of reactant flow rates, and plausible mechanisms suggested on the basis of this formation. In some cases, rate constants, of doubtful reliability, were calculated from such data, while, in one study, the rate constant of the active nitrogen – ethylene reaction was roughly determined by a diffusion flame technique (1). Recently, rate constants have been reported for the reactions of active nitrogen with atomic oxygen (2), molecular oxygen (3, 4), ozone (5), nitric oxide (4, 6), nitrogen dioxide (6), ethylene (7, 8, 9), and hydrogen bromide (8), but, with one exception (7), reaction time has not been a controlled parameter in these investigations.

In the present study, a comparison has been made of several experimental techniques by which the reaction of active nitrogen with ethylene might be terminated, so as to enable the reaction time, and hence the rate constant, to be estimated. By comparing the techniques for a range of reaction temperatures between 295° K and 673° K, it has been possible to select two methods that appear to be reliable for terminating such reactions, and it is now intended to apply these to evaluating the kinetic constants for other active nitrogen reactions.

EXPERIMENTAL

Materials

"Bone-dry" nitrogen was obtained from the Linde Company, and passed over copper turnings at 425° C, and through a liquid air trap to remove traces of oxygen, water, and carbon dioxide.

U.S.P. ethylene was obtained from the Ohio Chemical Company, and was subjected to two trap-to-trap distillations, only the middle two-thirds of each distillate being retained.

Nitric oxide, obtained from the Matheson Chemical Company Ltd., was purified by condensing it into a bulb containing Caroxite, which adsorbed the nitrogen dioxide. The nitric oxide was then allowed to evaporate from a dry ice – acetone bath which retained the N_2O_3, and the whole procedure was repeated.

Apparatus and Experimental Methods

The apparatus differed significantly from that previously described (10) and is shown in Fig. 1.

Nitrogen was passed through the dibutyl phthalate manostat, H, through a furnace, F, containing copper

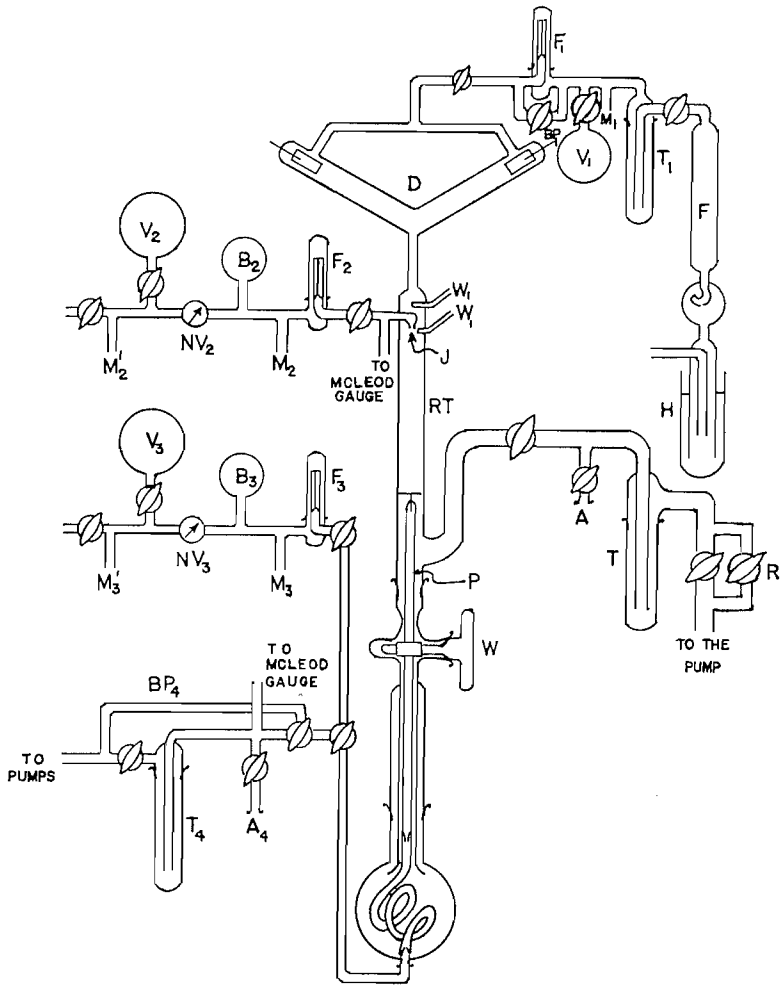

FIG. 1. Diagram of the apparatus.

turnings, and a trap, T_1, into the capillary flowmeter, F_1, which had been previously calibrated by the rate of evacuation, through it, of the known volume, V_1. The gas then entered the discharge tube, D, the construction and operation of which were similar to those described previously.

The reactant was metered by a flow system (subscripts 2) consisting of a known volume, V_2, a ballast volume, B_2, manometers, M_2 and M_2', a fine control needle valve, NV_2, and a capillary flowmeter, F_2. The reactant entered the reaction tube, RT, through the fixed reactant jet, J. Thermocouple wells, W_1, were placed 1 cm above and below the reactant jet. The reactions occurred in a Pyrex U-tube with an internal diameter of 22 mm. From there, the gas stream passed through a large liquid air trap, T, in which the condensable gases were retained. Continuous pumping was provided by a Cenco Hypervac 23 rotary oil pump.

In several of the techniques used to terminate the reactions, the reaction tube was provided with a movable probe mechanism, P (11), constructed from 10-mm Pyrex tubing, and sufficiently long to explore the entire length of the reaction tube. Its upper tip carried various contrivances to terminate the reaction. It was raised or lowered, under vacuum, by rotating the ground-glass joint, W. A friction drive between the probe and the projection of the joint was provided by a sleeve of rubber tubing. The bottom of the probe was connected with rubber tubing to either a second flow system (subscripts 3), or to a pumping system (subscripts 4). Through the former arrangement, gases were introduced into the reaction tube at any desired position, whereas the latter permitted the removal of samples of the reaction mixture after various reaction times.

Briefly, the experimental procedures were as follows:

(*a*) In a low-temperature technique for terminating the reaction between active nitrogen and ethylene, the reaction was stopped by immersing the U-shaped reaction tube in liquid air. (No probe mechanism was needed in these experiments.) The recombination of the nitrogen atoms was greatly enhanced (12), and the ethylene was condensed, at the low temperature, to deprive both reactants of their abilities to react.

In these experiments, the inner surface of the reaction tube was coated with disodium hydrogen phosphate (13), to retard the recombination of the nitrogen atoms on the walls of the reaction tube, and to stabilize the wall conditions. The reaction tube was heated to 400° C.

With the reaction tube immersed to the desired level in liquid air, purified nitrogen was passed through the apparatus, and the discharge operated until the temperature attained a constant and reproducible value, as an indication of a constant and reproducible initial active-nitrogen flow rate. Ethylene was then admitted, at a constant flow rate, to the stream of active nitrogen for a period of 100 seconds. The discharge and the flows of gases were stopped, the apparatus evacuated and isolated from the pump, and the condensable gases transferred to an absorber at A containing frozen, degassed water, where the hydrogen cyanide was later titrated with standard silver nitrate.

Experiments were made with flow rates of ethylene ranging from 0.9 to 14.8 μmoles per second, at a constant initial active-nitrogen flow rate, and with liquid air levels maintained at distances of 18.0, 23.5, and 29.0 cm from the fixed reactant jet, corresponding to reaction times of 19, 24, and 30 mseconds respectively. Experiments were also made, in which the reaction was permitted to proceed to completion, over a distance of 140 cm, as a basis for estimating the total initial active-nitrogen flow rate (7), which proved to be 14.0 μmoles per second.

(*b*) In a second technique for terminating the reaction between active nitrogen and ethylene, unreacted nitrogen atoms in the reaction mixture were consumed rapidly by flooding the reaction mixture with nitric oxide (7), introduced through the movable probe at any desired level. For this purpose, the probe was equipped with a 14-mm hemispherical bulb containing six small holes in its periphery, in a plane perpendicular to the gas stream in the reaction tube. Nitric oxide, at a flow rate in excess of that required to consume the active nitrogen completely, was passed into the reaction tube through this bulb, with the conditions of pressure and linear velocity of the gases selected so that the nitric oxide emerged radially from the bulb with no diffusion upstream, and a sharp plane of demarcation between the Lewis–Rayleigh afterglow and the nitric oxide reaction flame was obtained. Ethylene was passed into the stream of active nitrogen through the fixed reactant jet for a period of 100 seconds, and the products were trapped and analyzed as before. The nitrogen atom flow rate in these experiments was 7.0±0.3 μmoles per second, the ethylene flow rates were in the range 2.8 to 4.6 μmoles per second, the reaction times ranged from 2.1 to 55.8 mseconds, and reaction temperatures from 295° K to 671° K.

(*c*) A third method for studying the reaction of active nitrogen with ethylene was to remove a portion of the reaction mixture through the movable probe. The reaction was stopped at the tip of the probe by a small amount of oxidized copper turnings, an efficient catalyst for the recombination of nitrogen atoms (14). After a 2-minute period, during which the probe was flushed through the bypass, BP_4, the aliquot was diverted to the trap, T_4, for a period of 30 minutes. The hydrogen cyanide was treated as before. The extent of the reaction as a function of time was established by taking aliquots at various positions along the axis of the reaction tube. Separate experiments were made to determine the fraction of the total gases in the aliquot, from which the total extent of reaction was readily calculated. Nitrogen atom flow rates of 4.2 and 8.8 μmoles per second were used, with flow rates of ethylene between 1.1 and 3.0 μmoles per second, and reaction times that ranged from 1.6 to 40.2 mseconds. Reaction temperatures were 297° K and 543° K.

(*d*) The catalytic properties of copper oxide were utilized in still another way to promote the recombination of the nitrogen atoms, and hence to terminate the reaction of active nitrogen with ethylene. A fresh layer of copper was electrodeposited from a copper sulphate solution upon 45-mesh copper gauze, and a 21-mm disk of this gauze fastened with silver solder to a platinum wire, which was sealed into the end of the probe. The copper was oxidized by heating it in an oxygen-rich flame. The Lewis–Rayleigh afterglow was completely extinguished at the surface of the target, which was in a plane perpendicular to the flow of gases in the reaction tube. Again, the experiments were of 100 seconds' duration, and were made in the manner described previously. The nitrogen atom flow rate was 6.1 μmoles per second, the ethylene flow rate was 3.6 μmoles per second, the reaction time ranged from 3 to 45.5 mseconds, and the temperatures used were 295° K and 536° K.

(*e*) In a variation of the target procedure of section (*d*), above, the probe was equipped with a circular piece of 45-mesh platinum gauze which was electroplated with a black, spongy layer of cobalt, from an ammoniacal cobalt sulphate solution (15). In addition, three small holes were blown in the tube of the probe at a distance of 3 cm downstream from the cobalt target. This permitted "blank" experiments to be made, in which ethylene was passed into the gas stream after the active nitrogen had impinged on the target. The hydrogen cyanide from these experiments was limited entirely by the amount of active nitrogen that failed to be deactivated by the target, and provided a convenient means for checking the efficiency of the catalyst for deactivating the active nitrogen. In practice, it was found that reproducible results could be obtained only if the experiments were made at progressively shorter reaction times. Moving the cobalt target along the reaction tube apparently left behind traces of the catalyst on the walls. By working at

successively shorter reaction times, i.e. always moving the probe upward, the wall of the reaction tube in the region where the reaction occurred did not come in contact with the catalyst prior to the reaction, and contamination of it was thereby avoided.

For these experiments the ranges of conditions were: nitrogen atom flow rate, 2.9 to 9.8 μmoles per second; ethylene flow rate, 1.9 to 8.8 μmoles per second; reaction time, 5.2 to 47.6 mseconds; temperature, 298° K to 672° K.

RESULTS AND DISCUSSIONS

Rate constants were calculated on the assumption that the rate-determining step is a second-order process of the type

$$N + C_2H_4 \rightarrow HCN + \text{other products}$$

followed by fast reactions between nitrogen atoms and the free radicals formed in the initial step. The consumption of nitrogen atoms by the homogeneous and heterogeneous recombination of nitrogen atoms was neglected, since it was expected that these reactions would be insignificant in competition with the ethylene reaction. Rate constants for the disappearance of hydrocarbon may then be evaluated from the usual second-order rate expression

$$k = \frac{2.303}{t(a-2b)} \log \frac{b}{a} \frac{(a-2x)}{(b-x)},$$

where x = the concentration of ethylene consumed, which was found, for the flow rates used, to be approximately 1/2 of the HCN produced;
t = the duration of the reaction;
a = the initial active-nitrogen concentration, determined from the maximum production of HCN in the reaction with ethylene;
b = the initial ethylene concentration.

The reaction times were calculated from the linear velocity of the gas, and the distance between the point of injection of the reactant and the plane of termination of the reaction. Flow rates were converted to concentrations in the customary manner. The effect of temperature was considered in both these calculations.

Typical values of the second-order rate constant are shown in Table I, and the averages of a number of determinations of the rate constant at various temperatures, and by the various experimental methods, are listed in Table II.

In the low-temperature technique for terminating the active nitrogen – ethylene reaction, the main experimental uncertainty lies in the effectiveness of the low temperature for stopping the reaction, and the time required for the transfer of heat. These would tend to yield a conical, rather than a planar, region of termination, with a corresponding uncertainty in the calculation of the reaction time, and hence in the rate constants.

In the aliquot and copper oxide target techniques, the main uncertainty was in the behavior of the catalyst. At temperatures above 536° K, the copper oxide appeared to undergo some reduction, either by thermal decomposition at the low pressure, or by a reaction with one or more components of the gas stream that passed over the catalyst. As a consequence, rate constants determined by this method, at the higher temperatures, are uncertain. At the lower temperatures, however, where the catalyst was stable, the method seemed to be satisfactory, and the rate constants should be reliable.

The rate constants obtained by termination with nitric oxide and by the cobalt target are in close agreement. Such good agreement of the rate constants, over such a wide range

of temperature, seems quite improbable unless these methods not only terminate the active nitrogen–ethylene reaction with some precision, but also do not interfere appreciably with the production or recovery of hydrogen cyanide from the reaction. The cobalt target method has some advantage over the nitric oxide method, in that a check can be

made on the efficiency of the catalyst for stopping the reaction. By introducing ethylene through the probe, below the target, it was shown that deactivation of the active nitrogen, hence the termination of the reaction with ethylene, was virtually complete at the surface of the cobalt target (not more than 0.20% of the total initial active nitrogen ever survived its encounter with the target). Using this as a basis for comparison, it might then be concluded that the nitric oxide method was equally effective for terminating the reaction.

The rate constants for the active nitrogen–ethylene reaction, obtained with the nitric oxide and cobalt target techniques, are in reasonable agreement with those obtained by Greenblatt and Winkler (1) in their application of a diffusion flame technique, but are only about 1/10th as large as the value determined by Milton and Dunford (8), who also used a diffusion flame method. In view of the different experimental techniques employed, and the errors involved in each, this discrepancy is probably of the order to be expected. Similarly, the factor of about 5 between the present results and those obtained by mass spectrometry by Herron (9) is probably due mainly to experimental errors, since, for the conditions used, the N atom concentrations estimated by HCN production and by the NO titration differ by a factor of less than 2 (6). More significant than the difference between the data from these two studies is their similarity in showing practically no effect of temperature on the rate constant for the ethylene reaction, corresponding to a very low activation energy. The present value, 2.0×10^{-14} cc molecule^{-1} sec^{-1}, at 400° K, is in good agreement with a value of 3.0×10^{-14} cc molecule^{-1} sec^{-1}, at 423° K, obtained by Wright and Winkler (7) with the nitric oxide method for terminating the reaction.

From the data obtained with the nitric oxide and cobalt target techniques, activation energies of 250 and 600 cal/mole, respectively, may be calculated. It would seem reasonable, therefore, to assume a value of 400 ± 200 cal/mole for the activation energy of this reaction. This gives a P factor of the order of 10^{-5} for the reaction. The low steric factor is probably associated with the spin-disallowed reaction previously assumed (16) for the initial attack,

$$N + C_2H_4 \rightarrow HCN + CH_3.$$

Since it would appear that confidence may be placed in terminating the active nitrogen–ethylene reaction by the nitric oxide and the cobalt target techniques, these two techniques are now being used to evaluate the kinetic constants for the reactions of active nitrogen with other hydrocarbons and hydrocarbon derivatives.

THE EFFECT OF ADDED ELECTROLYTE ON HYDROGEN-BONDING EQUILIBRIUM IN DILUTE SOLUTIONS OF *t*-BUTYL ALCOHOL IN CARBON TETRACHLORIDE[1]

J. B. HYNE AND R. M. LEVY[2]
Department of Chemistry, University of Alberta, Calgary, Alberta

Received December 11, 1961

ABSTRACT

The effect of added tetra-*n*-butyl ammonium bromide on the hydrogen-bonding equilibrium of *t*-butyl alcohol in 0.0 to 0.08 *M* solution in carbon tetrachloride has been studied by infrared investigation of the spectral range 2.5–3.5 μ. The observations have been interpreted in terms of specific interaction between the alcohol and the more polar species of the salt which are present in the complex electrolyte equilibria (for example, ions and ion pairs). It is suggested that these species function as nucleation centers for aggregates of alcohol molecules, the enhanced degree of hydrogen bonding permitted in these aggregates being reflected in the infrared spectral response.

INTRODUCTION

It has been repeatedly demonstrated that the equilibrium between monomeric and polymeric forms of alcohols in non-polar solvents is very sensitive to concentration. Systems of alcohols in benzene or carbon tetrachloride have been extensively studied in recent years by both infrared (1–6) and n.m.r. techniques (7–11), all results being consistent with the predicted increase in association of the monomeric alcohol to higher *n*-mers with increasing concentration. In the infrared spectral studies, the increasing association is reflected in increased absorption in the region of 2.9 to 3.0 μ, normally assigned to a hydrogen-bonded hydroxyl, with a concomitant decrease in absorption at lower wavelengths characteristic of unassociated hydroxyl. In such binary systems, the problem is now one of establishing the distribution among various associated species (dimers, trimers, tetramers, etc.) rather than establishing the existence of the association phenomenon.

Recently Bufalini and Stern reported (12) that addition of tetra-*n*-butyl ammonium salts to methanol solutions in benzene resulted in a marked enhancement of the infrared absorption characteristic of associated hydroxyl over that corresponding to free hydroxyl. In their brief report these authors suggested that these results might be indicative of specific interaction between the added electrolyte and the alcohol component of the binary solvent mixture. In connection with our studies of specific solvation phenomena, we have carried out a preliminary quantitative investigation of the effect of added tetra-*n*-butyl ammonium bromide on the infrared spectral response of the hydroxyl function of *t*-butyl alcohol in dilute solution in carbon tetrachloride. Our choice of this system was based on the fact that detailed studies have been made of association in the binary *t*-butyl alcohol – carbon tetrachloride system (7, 4, 11) and on the electrical (13) and dielectric (14, 15) properties of tetra-*n*-butyl ammonium bromide in low dielectric solvents.

EXPERIMENTAL

Materials

Carbon tetrachloride: Matheson, Coleman, and Bell spectral grade used without further purification. *t*-Butyl alcohol: stock material purified as reported previously (7). Tetra-*n*-butyl ammonium bromide: prepared by the method of Accasina, Petrucci, and Fuoss (16).

Solution

Stock solutions of various concentrations of salt in carbon tetrachloride were prepared and *t*-butyl alcohol added volumetrically to obtain various concentrations over the range studied. Each salt solution was freshly prepared before each run and *t*-butyl alcohol dilutions made sequentially for each set of points at a given salt concentration.

Spectra

All spectra were run on a Perkin–Elmer Model 21 double beam spectrometer with scale expansion. Solvent compensation was made in matched 1-mm sodium chloride cells.

RESULTS

The spectra presented in Figs. 1(*a*) and 1(*b*) illustrate the effect of added tetra-*n*-butyl ammonium bromide(0.04 *M*) on the hydroxyl absorption region of various concentrations

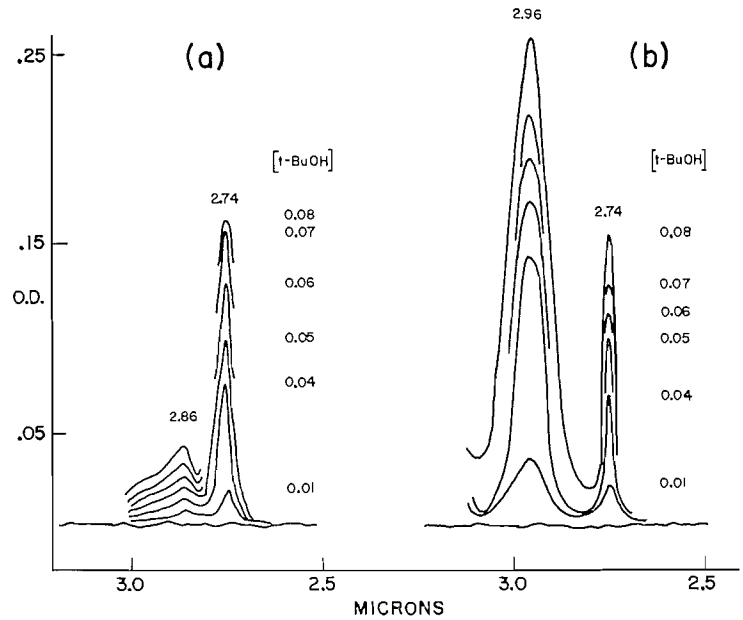

FIG. 1. The 2.5–3.5 μ region for various concentrations of *t*-butyl alcohol in carbon tetrachloride (*a*) without salt, (*b*) with added 0.04 *M* tetra-*n*-butyl ammonium bromide.

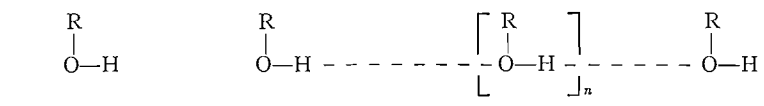
(0.0 to 0.08 *M*) of *t*-butyl alcohol in carbon tetrachloride. In the absence of salt (Fig. 1(*a*)), the two principal absorptions are at 2.74 μ and 2.86 μ, with an indication of the development of a peak at 2.96 μ at higher alcohol concentrations. These absorptions have been previously assigned (1) to various free and hydrogen-bonded hydroxyl O—H stretching vibrations as indicated below.



As a consequence of these assignments, the 2.74 μ absorption may be associated with monomer alcohol species, the 2.86 μ principally with dimeric species and the 2.96 μ absorption of the internal hydrogen-bonded hydroxyl groups with higher polymeric

alcohol species. The spectra in Fig. 1(*a*) indicate that the degree of polymerization to higher *n*-mers in the concentration range 0.0 to 0.08 *M* alcohol is very small, and it was with the intention of avoiding complications due to this polymer absorption that the alcohol concentration in this work was restricted to the range below 0.08 *M*. It is also noteworthy that over this same concentration range the change in n.m.r. chemical shift

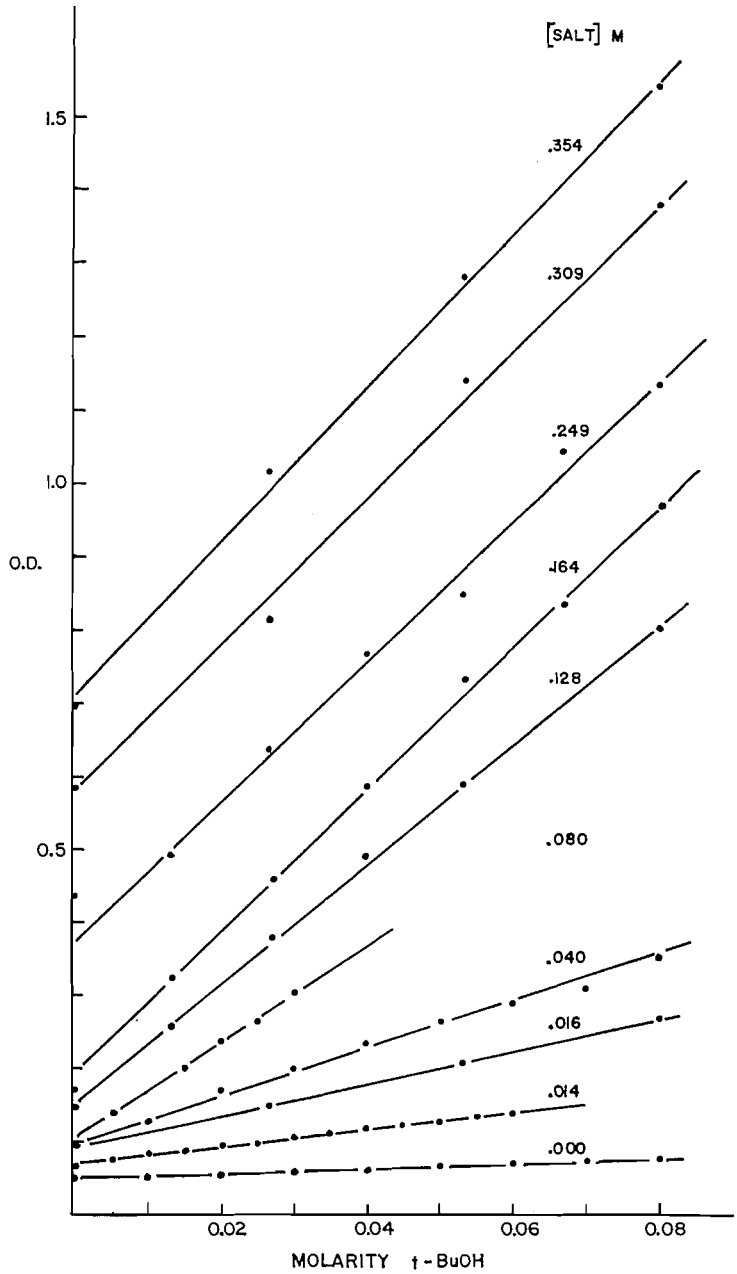


FIG. 2. Optical density at 2.96 μ versus *t*-butyl alcohol concentration for various fixed concentrations of added tetra-*n*-butyl ammonium bromide.

associated with the hydroxyl hydrogen has been found (7, 11) to be small, an observation in keeping with the assumption that higher polymer formation is minimal in this concentration range.

A very marked enhancement of the absorption at 2.96 μ is seen in Fig. 1(*b*) for the same concentration range of alcohol but in the presence of a fixed concentration (0.04 M) of tetra-*n*-butyl ammonium bromide. One of the most significant facts revealed by the comparison of Figs. 1(*a*) and 1(*b*) is that the dependence of absorption at 2.74 μ (free hydroxyl) on total concentration of alcohol is not as sensitive to the presence of salt as the absorption at 2.96 μ.

The dependence of the 2.96 μ absorption on alcohol concentration (0.0 to 0.08 M) has also been studied as a function of added salt concentration. Sets of spectra similar to that in Fig. 1(*b*) were obtained for various fixed salt concentrations (0.0 to 0.35 M). These data are presented in Fig. 2 as a plot of $\Delta \log I_0/I$ (2.96 μ) versus concentration of alcohol (total); $\Delta \log I_0/I$ represents the difference between absorbance at 2.96 μ at that particular alcohol concentration and the absorbance at 2.96 μ with no alcohol present. The optical density scale is an arbitrary one for the sake of clarity. The scale for any line can be reconstructed, however, by taking the intercept at zero alcohol concentration as the zero of the optical density scale.

DISCUSSION

Two important features are apparent in the comparison of Figs. 1(*a*) and 1(*b*). The absorption at 2.86 μ, characteristic of the terminal hydrogen-bonded hydroxyl in the dilute alcohol solutions without salt, is completely swamped by the very intense absorption at 2.96 μ, which characterizes the spectra with salt added. However, the intense absorption at 2.96 μ does not *appear* to occur at the expense of the absorption at 2.74 μ since this absorption differs only slightly, as a function of total alcohol concentration, from that in the system without added salt. In Fig. 3, the optical density of the various wavelengths for both systems (with and without salt) is plotted against the total alcohol concentration. Within the experimental uncertainty of the points, there is only a small difference between the dependence of the 2.74 μ absorption on total alcohol concentration in the two systems. This difference, however, is in the correct sense, indicating slight depletion of the 2.74 μ absorption in the system with salt as a result of the appearance of high absorption at 2.96 μ. The explanation which suggests itself is that the extinction coefficient associated with the 2.96 μ absorption is very much larger than that for the 2.74 μ absorption, the ratio indicated by the data in Fig. 2 being of the order of 20 to 1.

The similarity between the wavelength of the intense absorption with salt added (2.96 μ) and that associated with the higher polymeric alcohol forms in more concentrated alcohol solutions (2.96 μ) raises the question of whether the effect of the added salt is merely one of stabilizing the higher polymeric forms. That is to say, the 2.96 μ absorption with added salt is due to the same molecular vibration as is observed in higher concentration alcohol solutions without salt. Liddel and Becker (4) have reported integrated molar absorption coefficients per OH bond for the monomer and polymer forms of *t*-butyl alcohol in carbon tetrachloride as being in the ratio of 1:16. This ratio is sufficiently close to the required 1:20 ratio predicted from Fig. 2 to support an argument that the 2.96 μ absorption observed with added salt is due to a polymeric form similar to that found at higher alcohol concentrations without salt. If this argument is valid, however, it implies that the association equilibrium constant for monomers to polymers is very much higher in the presence of salt compared with the value in the absence of salt. This is

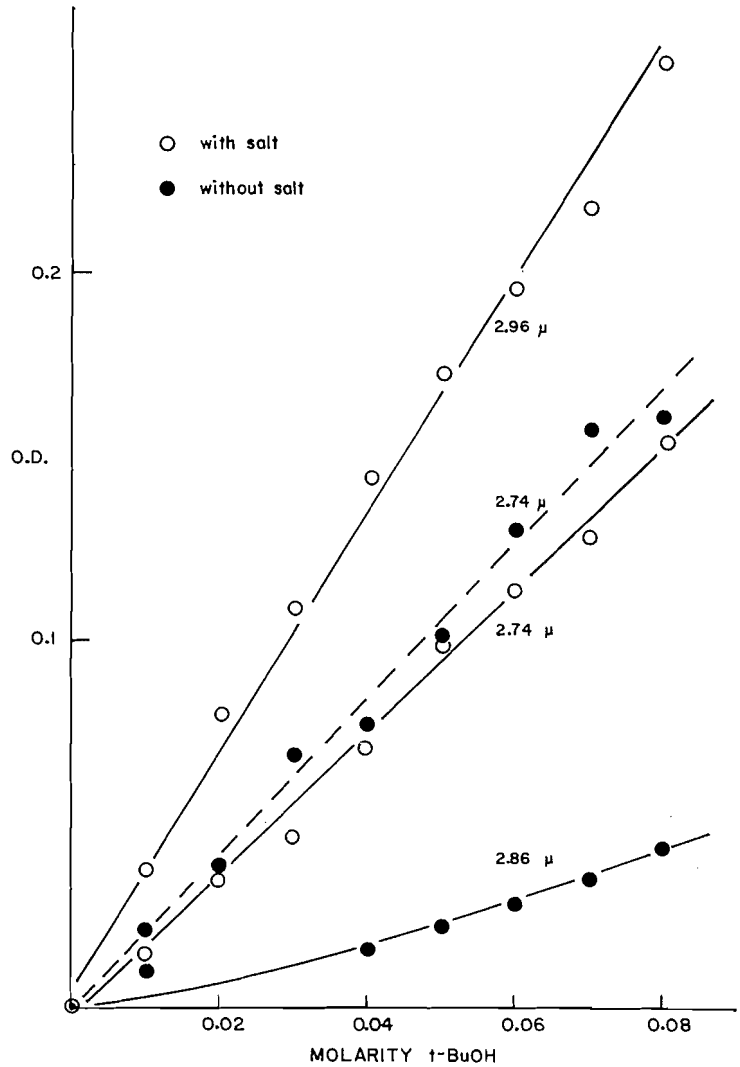

FIG. 3. Comparison of optical density dependence on alcohol concentration at various wavelengths for *t*-butyl alcohol in carbon tetrachloride with and without added salt.

tantamount to the statement made above that the polymeric form is more stable in the presence of the salt. An approximate calculation based on the optical densities of Fig. 1 and the 1:16 ratio for molar absorption coefficients indicates that the association constant for monomer to polymer association is a factor of 10 greater in the presence of salt compared with that in the absence of salt.

It must be emphasized, however, that it is only on the basis of similar λ_{max} values and similar absorption coefficient ratios that the conclusion is drawn that the same type of polymer OH vibration makes a major contribution to the absorption at 2.96 μ in the two cases.

The higher value of the association constant in the presence of salt can be rationalized by a model envisaging specific organization of the alcohol molecules about polar salt

entities in the solution. It is not unreasonable to assume that salt ions or ion pairs will favor the more polar alcohol hydroxyl groups in their immediate solvation shell with the low polarity methyl groups turned outward toward the non-polar carbon tetrachloride bulk solvent. In such a structure, there will exist a very favorable opportunity for internal hydrogen bonding of the type generally assigned a $\lambda_{max} = 2.96\ \mu$ (1). The polar salt species therefore serve as a nucleation center for the aggregation of alcohol molecules into a "micellar" structure in which hydrogen bonding will be favored. A difference of a factor of 10 in the monomer–polymer association constant is not unreasonable in the presence of such a polymer structure stabilizer as the salt species. It should also be noted, however, that in the proposed model there exists an equally favorable situation for hydrogen bonding of the type R—O—H---Br^-. It is not unreasonable to assume that the molar absorption coefficient of a hydroxyl group bonded in this manner will also be high and could be close to the same λ_{max} as that for internal hydrogen bonding (2.96 μ). The total absorption at 2.96 μ may therefore be due to both types of hydrogen-bonded hydroxyl. Since both phenomena are conditional upon specific interaction between the alcohol hydroxyl and the polar salt entities the breakdown into one form of bonding or the other is not critical at this stage of the argument.

The equilibrium proposed to account for the dramatic effect of added salt may be formalized as:

$$\mathrm{ROH} + (\mathrm{salt}) \overset{K}{\rightleftharpoons} \mathrm{R\overline{OH}}\ (\mathrm{salt}) \qquad [1]$$

where $\mathrm{R\overline{OH}}$ (salt) represents a hydrogen-bonded alcohol molecule in the aggregation around the salt species. Therefore

$$[\mathrm{ROH}] = \frac{1}{[(\mathrm{salt})].K} \cdot [\mathrm{R\overline{OH}(salt)}] \qquad [2]$$

or

$$(\mathrm{O.D.})_{2.96\,\mu} = C.K[(\mathrm{salt})].[\mathrm{ROH}], \qquad [3]$$

where the constant C contains the various constants of the Beer's law relationship. At a fixed concentration of salt a plot of [ROH] versus $(\mathrm{O.D.})_{2.96\mu}$ should therefore be linear, as is found in the plots of experimental data in Fig. 2. If the effect of the added salt was simply a medium effect then the slope of the plots of equation [3] should be a linear function of the salt concentration as this is varied for each set of points since

$$\text{slope [3]} = \frac{(\mathrm{O.D.})_{2.96\,\mu}}{[\mathrm{ROH}]} = C.K[(\mathrm{salt})]\ . \qquad [4]$$

In Fig. 4, it is seen that this linear relationship does not hold, indicating that the total salt concentration is not a direct linear measure of the effect of the salt on the hydrogen-bonding equilibrium. The curvature of the plot suggests that some particular species of the salt in solution, the concentration of which is determined by the total salt concentration, is primarily responsible for the observed effect of the added salt on the hydrogen-bonding equilibrium.

It is only to be expected that, in such low dielectric media as carbon tetrachloride, the salt will be present very largely as ionic aggregates. Although the bulk dielectric constant of the medium will change as alcohol is added, the change will be very small. The difference

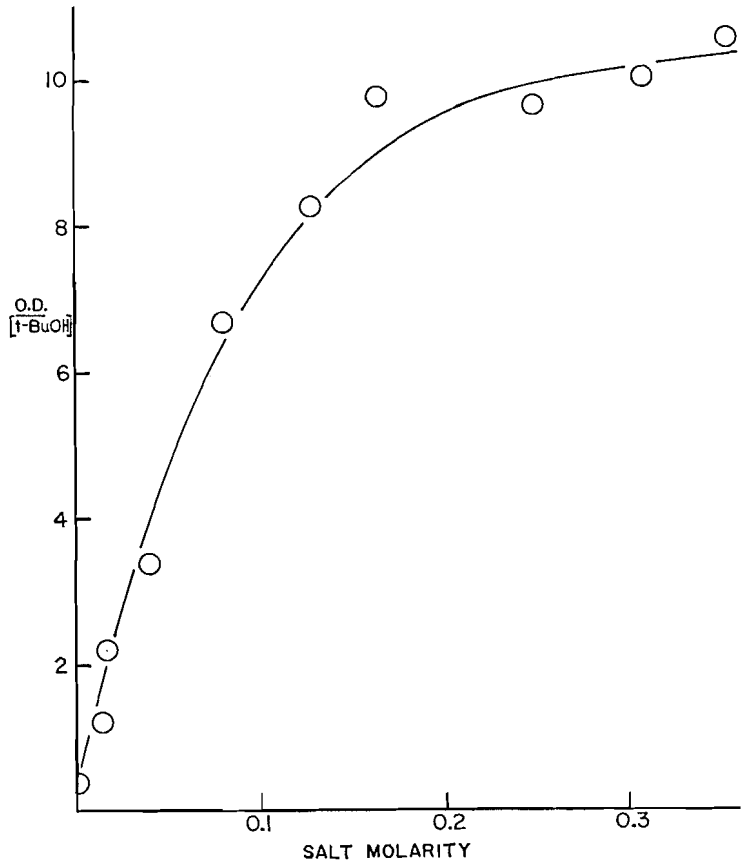

Fig. 4. Plot of slope of equation [3] versus concentration of tetra-*n*-butyl ammonium bromide.

between the bulk dielectric constant of pure carbon tetrachloride and carbon tetrachloride with 0.08 *M* added *t*-butyl alcohol cannot be greater than 0.5 (see, for example, ref. 14). It may therefore be assumed that there can be little if any *bulk* effect on the electrolyte equilibria as a result of varying the *t*-butyl alcohol concentration. The electrolyte equilibria involved may be represented as

$$(n\mathrm{Bu})_4\mathrm{N}^+ + \mathrm{Br}^- \overset{K_{ip}}{\rightleftharpoons} (n\mathrm{Bu})_4\mathrm{N}^+\mathrm{Br}^- \overset{K_{qp}}{\rightleftharpoons} (n\mathrm{Bu})_4\mathrm{N}^+\ \mathrm{Br}^- \cdots \mathrm{Br}^-\mathrm{N}^+(n\mathrm{Bu})_4$$

Ions — Ion pairs — Ion quadrupoles and higher aggregates

As the total salt concentration is increased, the coupled equilibria shown above will lead to a limiting value for the fraction of salt present as ions or ion pairs. Accordingly the concentration of these species in solution will not be a linear function of the total salt concentration. If the observed effect of added salt on the hydrogen-bonding equilibrium is due in large part to the nucleating action of the ions and ion pairs, this would account for the curvature in the plot of Fig. 4. It is furthermore reasonable to assume that the ions and ion pairs will have the greatest effect in terms of specifically solvating them-

selves with alcohol molecules. In the higher electrolyte aggregates, the bulky *n*-butyl groups provide the hydrocarbon shell between the charged nitrogen and bromine atoms and the carbon tetrachloride solvent. Indeed, it might be said that the formation of these electrolyte aggregates is itself a manifestation of specific solvation, one ion pair being specifically solvated by another. In the case of ion pairs, the bromide end of the ion pair is not well shielded by the four *n*-butyl groups of the ammonium ion and hence will tend to orient around itself *t*-butyl alcohol molecules with the polar hydroxyl group in the immediate vicinity of the charged center. In the case of the very few free ions present in such low dielectric solvents, the bromide ion would exert a highly specific ordering effect on the alcohol and would be expected to surround itself with a screen of alcohol molecules oriented with the polar hydroxyl groups pointing inward toward the bromide ion. The ammonium ion carries its own hydrocarbon low polarity screen and would probably be less effective as a nucleating center for specific alcohol aggregations. It is of interest to note that Bufalini and Stern (12, 17) reported considerable dependence of the hydrogen-bonding equilibrium response in the infrared on the nature of the salt *anion*.

A detailed quantitative analysis of the form of the plot shown in Fig. 4 does not appear to be possible at this time. Although Sadek and Fuoss (13) have reported the dissociation constants for tetra-*n*-butyl ammonium bromide in alcohol – carbon tetrachloride solvent mixtures, the limitations of the conductance method they used dictated a minimum dielectric constant for the solvent of 15. This is far above the bulk dielectric constant of the carbon tetrachloride – alcohol mixtures used in this work. However, using Sadek and Fuoss's results we can extrapolate to lower dielectric constant to obtain an approximate value for K(dissoc.) = 10^{-5} in carbon tetrachloride. It should be noted that this value is for the dissociation of ion pairs to free ions and does not take into account the equilibrium between ion pairs and higher aggregates. Furthermore, the value 10^{-5} would appear to be the upper limit for the dissociation constant in view of the considerably lower values of K found by Fuoss and Kraus (18) for alkylammonium nitrates in dioxane–water mixtures of low dielectric constant. A dissociation constant of this order of magnitude or less predicts a levelling off in the fractional dissociation to ions at concentrations below 0.2 M. This is qualitatively in keeping with the observed form of the plot in Fig. 4. Even if an accurate value for the ion-pair dissociation constant were available, however, the problem is complicated by the sensitivity of the ion quadrupole – ion pair equilibrium to alcohol concentration. Richardson and Stern (14, 15) have recently reported the results of dielectric studies on tetra-*n*-butyl ammonium bromide in benzene–methanol mixtures. These authors interpret their results as indicative of the great sensitivity of the quadrupole–pair equilibrium to added small amounts of the more polar alcohol. Although the bulk dielectric constant of the solvent changes by only 0.04 on adding 0.01 mole fraction of methanol to benzene, the quadrupole–pair equilibrium constant changes by a factor of 200 in favor of the ion pairs. Clearly the role of the alcohol molecules is highly specific and this may indeed be further evidence of the specific solvation role of the polar alcohol molecules in stabilizing the ion pairs. Since the experimental data presented in Fig. 2 are for fixed salt concentrations but over a range of 0.0 to 0.08 M *t*-butyl alcohol, the observed linear increase in optical density with alcohol concentration may be due to both increasing alcohol concentration and changes in the relative distribution of the total salt in the form of ions, ion pairs, and quadrupoles.

In the very recent paper of Bufalini and Stern (17), similar findings with a series of tetra-*n*-butyl ammonium salts in several alcohol–benzene systems are reported. Although these results differ in detail from those reported here, there is little question that both sets

of evidence support the concept of selective solvation of the electrolyte species by the more polar alcohol component of the binary solvent mixture. Comparison of Bufalini and Stern's data in benzene with those reported here in carbon tetrachloride indicates some significant differences in the stability of monomeric alcohol species relative to associated forms and also in the relative values of apparent extinction coefficients. Although it is somewhat premature to attempt a detailed explanation of the effect of changing the "inert" low dielectric component of the solvent, it is not surprising that replacing benzene with carbon tetrachloride should bring about significant changes in the quantitative aspects of the phenomenon. Davis, Pitzer, and Rao have reported (11) an n.m.r. study of hydrogen bonding of ethanol in both carbon tetrachloride and benzene at 22° C. The dependence of the hydroxyl proton shift on alcohol concentration is quite different in these two systems. These authors also point out that the presence of a minimum in the molar polarization curve for ethanol in carbon tetrachloride and the absence of such a minimum in the ethanol–benzene system may be interpreted as a reflection of significantly different distributions among possible associated structures in the two "inert" solvents. Bufalini and Stern's data on several electrolytes with varying cation provide some evidence in favor of the alcohol-to-cation hydrogen bond rather than the alcohol-to-alcohol hydrogen bonding in the alcohol aggregates around the electrolyte. As suggested previously in this paper, the precise molecular nature of the vibration responsible for the enhancement of absorption in the 3 μ region is not critical to the specific solvation argument and further work will be needed to elucidate this point. It is worth noting, however, that in benzene, Bufalini and Stern report the absorption maximum at 3.03 μ while, in carbon tetrachloride, the value observed was 2.96 μ. This difference may be significant in terms of structural changes between the two systems.

ACKNOWLEDGMENT

The authors are indebted to Dr. P. J. Krueger of this department for his helpful comments on, and discussion of, this work.

DEUTERIUM ISOTOPE EFFECTS IN ABSTRACTION OF HYDROGEN ATOMS FROM PHENOLS

R. A. BIRD, G. A. HARPELL, AND K. E. RUSSELL
Department of Chemistry, Queen's University, Kingston, Ontario
Received December 11, 1961

ABSTRACT

The effect of six deuterated phenols on the rate and degree of polymerization of styrene has been studied. The rate and degree of polymerization are decreased by deuterated phenols to a much less extent than by the corresponding phenols. Approximate transfer constants are estimated, and it is found that the transfer constant for hydrogen abstraction from the deuterated phenol is less than 0.2 of the transfer constant for the normal phenol. The rates of reaction of 2,2-diphenyl-1-picrylhydrazyl with three deuterated phenols have been determined. The rate constants for deuterated 2,6-di-*t*-butylphenol and 4-bromophenol are less than 0.15 of those for the corresponding phenols, but the isotope effect appears to be small with 4-nitrophenol.

In a recent study (1) it was shown that phenols lower both the rate and degree of polymerization of styrene and that the magnitude of the decrease depends on the nature and position of substituents in the phenol. The results are interpreted in terms of an attack by polystyryl radicals on the OH group of the phenol. Support for this suggestion comes from the observation that certain O-methyl phenols do not significantly alter the rate and degree of polymerization of styrene. In an attempt to obtain more positive evidence, the effect of six deuterated phenols on the polymerization of styrene has been determined, and the derived transfer constants compared with those estimated for the normal phenols.

In a separate study (2) the rates of reaction of 2,2-diphenyl-1-picrylhydrazyl (DPPH) with a wide range of substituted phenols were obtained. The rate-determining step was considered to be the abstraction by DPPH of a hydrogen atom from the OH group of the phenol since O-methyl phenols are relatively weak hydrogen donors, and deuteration of 2,6-di-*t*-butyl-4-methylphenol decreases the rate constant for hydrogen abstraction at 20° by a factor of 1.95 (3). Strong supporting evidence has now been obtained using deuterated 2,6-di-*t*-butylphenol and 4-bromophenol as donors. A surprisingly small isotope effect was observed with 4-nitrophenol.

EXPERIMENTAL

Styrene, a gift of Dow Chemical of Canada, Ltd., was distilled at reduced pressure and then degassed and subjected to two distillations on the vacuum line. It was stored at −78.5°. The phenols were normally recrystallized twice and dried in a vacuum desiccator. Deuteration was effected by adding about 4 g of heavy water or deuterated methanol to 1.5 g of the phenol and leaving overnight at 60° or refluxing for 2 hours. The water and methanol were removed on the vacuum line and the procedure was twice repeated. The extent of deuteration was estimated by taking infrared spectra of the deuterated phenols in chloroform solution. The purified chloroform was dried over calcium chloride and the sodium chloride cells were filled in a dry box. The general experimental procedure for studying the effect of phenols on the polymerization of styrene at 60° has been described elsewhere (1).

For the DPPH reactions the normal procedure was followed (2) except for the making up of the reaction mixtures. Benzene was stirred with calcium chloride on the vacuum line and distilled into a reaction tube containing weighed amounts of DPPH and the phenol. The tube was sealed and the rate of disappearance of DPPH determined at 30°. Concentrations of phenols were in the range 0.04–0.08 *M*

RESULTS AND DISCUSSION

Infrared analysis of the deuterated phenols showed that deuterium was substituted only at the OH group, and the extent of deuteration varied from 85% to 93%. These are probably minimum values since exchange may occur during the preparation of the chloroform solutions and in the filling of the sodium chloride cells. No attempt has been made to correct for undeuterated material in the samples used in this work. Table I

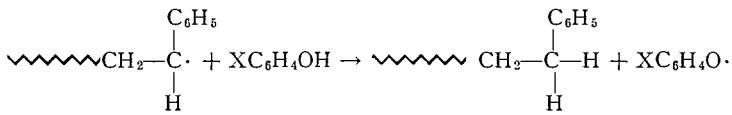
TABLE I

Extent of retardation and transfer constants at 60°

Phenol	Retardation		k_{tr}/k_p	
	Phenol	Deuterated phenol	Phenol*	Deuterated phenol
1-Naphthol	28% (0.2 *M*)	3% (0.2 *M*)	0.048±0.017	0.007
4-Benzyloxyphenol	20% (0.2 *M*)	2% (0.2 *M*)	0.029±0.014	0.001
2,3,4,6-Tetramethylphenol	39% (0.2 *M*)	2% (0.2 *M*)	0.058±0.024	0.002
Catechol	53% (0.2 *M*)	5% (0.2 *M*)	0.13 ±0.058	0.026
4-*t*-Butylcatechol	23% (0.02 *M*)	26% (0.2 *M*)	0.36 ±0.19	0.037
Pyrogallol	37% (0.006 *M*)	9% (0.006 *M*)	1.04 ±0.47	0.16

*Mean values. The limits shown are the standard deviations of six estimated values.

shows the effect of ordinary and deuterated phenols on the rate of polymerization of styrene at 60°. The results are given as the decrease in rate of polymerization for a 0.2 *M* solution of the phenol in styrene except for ordinary 4-*t*-butyl catechol where a 0.02 *M* solution was used and for ordinary and deuterated pyrogallol where 0.006 *M* solutions were used. It is seen that at equivalent concentrations the deuterated phenols all lower the rate of polymerization to a far less extent than the corresponding phenols. A similar conclusion applies to the effect of deuterated phenols on the degree of polymerization of the polystyrene. These qualitative conclusions can be explained if the phenols react with polystyryl radicals in the transfer step of reaction [1].



[1]

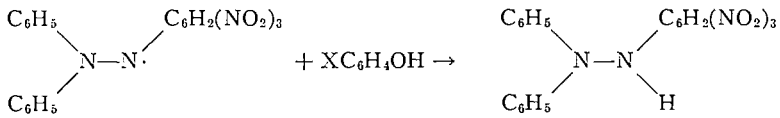
The phenoxy radical may cause retardation of polymerization by reacting with a polystyryl radical or with another phenoxy radical, and if the rate of formation of phenoxy radicals by reaction [1] is lower with the deuterated phenols, the extent of retardation will be smaller. Similarly the effect of the deuterated phenol on the degree of polymerization is smaller than with the normal phenol if reaction [1] proceeds at a relatively low rate.

Quantitative analysis of both the rate and degree of polymerization data leads to estimates of the transfer constant k_{tr}/k_p, where k_{tr} is the rate constant of reaction [1] and k_p is the rate constant for propagation of the polymerization of styrene. Since k_p is probably independent of the added phenol, the transfer constants are proportional to the rate constants for hydrogen abstraction, k_{tr}. Transfer constants for retarders may be estimated from rate data by the method of Jenkins (4). Three values of the transfer constant were obtained for each phenol assuming (*a*) that all phenoxy radicals disappear by cross termination with polystyryl radicals, or (*b*) that all phenoxy radicals disappear by mutual termination with other phenoxy radicals, or (*c*) that the rate constant for

cross termination is the geometric mean of rate constants for mutual termination of polystyryl and phenoxy radicals. Transfer constants were also estimated from the degree of polymerization data. For the retarders, three values of the transfer constant were obtained using (*a*) the simple chain transfer equation developed for non-retarders, (*b*) an equation developed on the assumption that the geometric mean assumption applies to the termination reactions of phenoxy and polystyryl radicals, and (*c*) an equation developed on the assumption that mutual termination of phenoxy radicals can be neglected (1). In the absence of reliable information concerning the exact fate of the phenoxy radicals, mean values of the six estimates for each retarding phenol were determined. These mean values for the retarders are given in Table I. The individual values vary by an average of about 40% from the mean. For those deuterated phenols which show no significant retardation, the transfer constants were obtained using the simple chain transfer equation. The transfer constants for deuterated 4-benzyloxyphenol and 2,3,4,6-tetramethylphenol may be low because the method of analysis tends to give low results for weakly retarding phenols (1). The values for the catechols and pyrogallol are calculated from the total effects which they and their reaction products exert on the rate and degree of polymerization.

The transfer constants given in Table I show that the rate constant for abstraction of deuterium from a deuterated phenol is probably less than 0.2 of the rate constant for abstraction of hydrogen from the corresponding phenol. The ratio of rate constants calculated on the assumption of a simple zero-point energy effect (5) with $\nu_{O-H} = 3620$ cm^{-1} and $\nu_{O-D} = 2660$ cm^{-1} is 0.126 at a temperature of 60°.

The rate-determining step in the reaction of DPPH with phenols is assumed to involve the abstraction of a hydrogen atom from the phenol (2):



[2]

Rate constants k_2 for reaction [2] are obtained from the rate of loss of DPPH and the stoichiometry of the overall reaction. The rate constants at 30° for normal and deuterated di-*t*-butylphenol, 4-bromophenol, and 4-nitrophenol are given in Table II. In the first

TABLE II

Rate constants k_2 for reaction [2] at 30°

Phenol	k_2 (cc/mole sec)	
	Phenol	Deuterated phenol
2,6-Di-*t*-butylphenol	19.8	2.44
4-Bromophenol	41.8	5.94
4-Nitrophenol	0.43	0.28

two cases, the ratios of rate constants for deuterated and normal phenols are 0.123 and 0.143. These results compare with a value of 0.102 calculated for a temperature of 30° on the assumption of a simple zero-point energy effect. The experimental ratio for 4-nitrophenol is 0.66 but it is not certain whether the small isotope effect is real or is due to difficulties in working with this particular phenol. Fairly high concentrations of the three relatively unreactive phenols were used in these studies so that any exchange

which occurred between the deuterated phenols and reactive impurities, such as water, would have a small effect. However, at these relatively high concentrations, some phenols do not show a simple kinetic behavior; there is frequently a rapid initial drop in optical density of the solution and the overall rate of reaction is not proportional to the concentration of phenol. 4-Nitrophenol behaves in this manner and the so-called second-order rate constant is dependent on the concentration of the nitrophenol. It is possible that the smaller isotope effect observed with 4-nitrophenol is connected with this complex behavior.

The observed ratios of rate constants for deuterated and normal phenols are presumably maximum values, because any normal phenol present in the deuterated phenol would increase the observed rate constant. The isotope effects strongly support the suggestion that hydrogen is abstracted from the O—H group of the phenol in the rate-determining step of the reaction with DPPH. McGowan, Powell, and Raw (6) suggest that DPPH abstracts a hydride ion rather than a hydrogen atom as in reaction [2], but a radical mechanism is probably to be preferred. Boozer, Hammond, Hamilton, and Sen (7) have concluded that the reaction of alkyl-peroxy radicals with phenols proceeds through an intermediate complex between radical and phenol and that an isotope effect should not necessarily be observed. Caldwell and Ihrig (8) have interpreted the kinetics of polymerization of methyl methacrylate in the presence of phenols in terms of a complex between a polymethyl methacrylate radical and a phenol molecule. Intermediate complexes may possibly be formed in the reactions of DPPH with phenols, or less likely of polystyryl radicals with phenols, but, if so, they do not prevent the observation of large kinetic isotope effects in most of the reactions studied.

ACKNOWLEDGMENTS

The authors are grateful to the National Research Council for generous financial help. They acknowledge the assistance of Mr. John Myher in the kinetic experiments involving DPPH.

THE CRYSTAL STRUCTURE OF Ag_3Ca_5[1]

R. P. RAND AND L. D. CALVERT
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received November 30, 1961

ABSTRACT

Ag_3Ca_5 is tetragonal, $a = 8.039 \pm 5$ Å, $c = 15.011 \pm 15$ Å, $c/a = 1.87$, space group $I4/mcm$. The structure is of the $D8_l$ type with 4 Ag_I in 4(*a*); 8 Ag_{II} in 8(*h*), $x = 0.378 \pm 5$; 4 Ca_I in 4(*c*); and 16 Ca_{II} in 16(*l*), $x = 0.164 \pm 5$ and $z = 0.150 \pm 5$. The structure is characterized by sheets of closely linked Ag and Ca atoms parallel to (001). An indexed powder pattern is given. $NH_4Pb_2Br_5$, $RbPb_2Br_5$, and KPb_2Br_5 also have the same structure and should be included together with B_3Cr_5, Ge_3Ta_5, Si_3Ta_5, and Si_3Nb_5 in the $D8_l$ group.

INTRODUCTION

Little is known about the binary compounds of the relatively inert metals of Group IB with the strongly electropositive elements of Group IIA but they are of interest because of the possibility of forming strongly directed bonding systems or showing charge transfer effects. The Ag–Ca phase diagram has been studied by Baar (1) using thermal techniques exclusively. He reported a compound tentatively given the formula $AgCa_2$ in the region 66–71 at.% Ca. Subsequently Degard (2) examined alloys of the compositions of all the compounds and eutectics reported by Baar. He reported only mixtures of AgCa and Ca in the region 50–100 at.% Ca.

EXPERIMENTAL

Ag_3Ca_5 has been obtained as small fragments chipped from ingots prepared by Dr. W. A. Alexander for use in a cooling curve apparatus. The metals were of high purity. Spectrographic analysis of the silver showed the following impurities (in p.p.m.): Pb 10, Fe 4, Si 5, Cd 20, Ca < 1, Mg < 1; Cu, Sn, Na not visible. The calcium was six times distilled before use and analysis gave Mg 2, Fe 2.5, Mn 1, Si 2, Ba 2.5, Sr 2.5 p.p.m.; Cu, Pb, Zn, Cd, Ni, Sb, Li, Cr, Al, Ag all not visible. Typical analyses for nitrogen in the calcium ranged from 140 to 260 p.p.m. To avoid air contamination of the alloys the calcium was distilled from a side arm of the mild steel cooling curve apparatus directly onto the silver at 950–960° C. The X-ray samples were taken after the cooling curves had been observed. Tests of impurity pickup in the alloys after the cooling curves had been observed showed Fe 110–200 p.p.m., and N_2 in the range 100–110 p.p.m. for an alloy that had been melted six times. It is believed that the iron is largely mechanically included in the ingots and that this accounts for the variation in the analyses. The three ingots from which Ag_3Ca_5 was obtained ranged in nominal composition from 62 to 70 at.% Ca. The best chemical analysis for Ag_3Ca_5 was made on a 0.5-mg sample ($D_m = 3.6 \pm 1$ g/cm^3) used for recording a major portion of the X-ray data. This sample had only a few weak powder lines corresponding to some surface decomposition. The analysis gave 59.0 wt.% Ag, 37.3 wt.% Ca, which on correcting to 100%, assuming the difference to be O_2 or H_2O, gives Ag 61.3 wt.% and Ca 38.7 wt.%; calculated for Ag_3Ca_5: 38.2 wt.% Ca. The empirical formula was established from the structure analysis before the chemical analysis was available.

Ag_3Ca_5 is a silver-white, brittle compound, stable in an inert atmosphere. It decomposes moderately quickly in dry air and rapidly in moist air. Since the formula of the compound was unknown, samples were taken from all ingots as they became available. Likely looking fragments (1–50 mg) were selected and their densities were determined on a microbalance. While most of the density values lay randomly between the possible limits, a few clustered near certain modal values. X-Ray photographs of these were then taken in a powder camera. Eight samples were found to be single crystals and were examined using a precession camera; four were examined in some detail. The samples were handled under liquids dried over sodium and protected during exposure by a coating of an acetone-soluble vinylidene chloride copolymer (Saran Resin F220, Dow Chemical Co., Sarnia, Ontario) or by sealing into glass capillaries. The reflections *hk*0, *hk*1, *hk*2, *hk*3, *hhl*, *h*0*l*, and those in the [3$\bar{1}$0] zone were recorded using Mo radiation.

[1]*Issued as N.R.C. No. 6715.*

CRYSTALLOGRAPHIC DATA

The crystals were tetragonal with good to excellent cleavage parallel to (001), diffraction symbol $4/mmm$. I—c—, $a = 8.039 \pm 5$ Å, $c = 15.011 \pm 15$ Å, $c/a = 1.87$, $D_m = 3.6 \pm 1$ g/cm³, $D_x = 3.59$ g/cm³, $V = 970.1$ Å³, F.W. = 524.04, $Z = 4$, $Fooo = 964$, μ_l for Mo $K_\alpha = 90.7$ cm^{-1}, $B = 1.23$ Å². Within the limits of the precession method there were no variations in the axial lengths of the samples examined. The complete X-ray powder pattern is given in Table I. The indexing is listed only to $d = 1.6$ Å since beyond this

there are too many ambiguities. It should be noted that powder patterns of this material may show strong absorption effects with the larger d-values, in error by 1–2% if the samples are unduly large. This pattern was obtained from samples having nominal compositions close to Ag_3Ca_5, whereas samples on either side of this composition showed mixed patterns.

STRUCTURE DETERMINATION

The original attempts to solve this structure were based on partial data obtained from two crystals extracted from a diffusion couple. One crystal, on chemical analysis, gave the formula $Ag_2Ca_{5.06}$; the other decomposed before being analyzed. No satisfactory solution for the structure was achieved by simple trial and error methods so fresh samples were obtained from the cooling curve ingots which had just become available. Care was taken to examine a number of samples in order to avoid possible difficulties due to twinning or other sample variations. The intensities for the reflections $hk0$ and hhl were obtained from timed precession photographs and corrected for Lorentz-polarization effects. The appropriate temperature factor and absolute scaling factor were obtained by Wilson's method (3). The possible space groups are $I4cm$ (C_{4v}^{10}), $I\bar{4}c2$ (D_{2d}^{10}), and $I4/mcm$ (D_{4h}^{18}). A comparison of the average intensities of the axial rows with those of the axial zones and the general zones (4) indicated the space group $I4/mcm$ as the most

probable. The fact that all zones were centric was taken to confirm this hypothesis. A consideration of atomic volumes together with the possible space group positions gave Ag_3Ca_5 as a likely formula and a trial structure of the $D8_l$-type was readily established. The optimum values for the individual parameters were obtained by varying each parameter systematically and calculating $R = \sum |F_{obs}| - |F_{calc}| / \sum |F_{obs}|$ for selected groups of planes particularly sensitive to the parameter in question. Shifts of 0.005 from the optimum positions gave markedly worse values of R. The reflections $00l$, $33l$, and $44l$ were used for the Ca_{II} z parameter; $11l$, $55l$, and a group of eight $hk0$ reflections were used to derive the Ag_{II} x parameter. The final structure has 4 Ag_I in 4(a), $0,0,\frac{1}{4}$; 8 Ag_{II} in 8(h), $x,\frac{1}{2}+x,0$ with $x = 0.378\pm5$; 4 Ca_I in 4(c) 0,0,0; and 16 Ca_{II} in 16(l), $x,\frac{1}{2}+x,z$ with $x = 0.164\pm5$ and $z = 0.150\pm5$. This structure gave $R = 0.07$ for all observed $hk0$ and $R = 0.20$ for all observed hhl planes. As a final check calculations of a few hkl reflections from the $[3\bar{1}0]$ zone gave $R = 0.09$. Subject to the limitations involved a rough estimate of the accuracy of the coordinates may be obtained from Luzzati's formula (12). This gives $|\overline{\Delta r}| \approx 0.05$ Å, corresponding to 0.003 for z and 0.006 for x. The agreement is generally good except for 004 where $F_c = 326$. Extinction may perhaps account for this disagreement. The crystals used were mostly multiple, with the various portions having the c-axis parallel. For the $hk0$ reflections the multiple spots were spread out but in the hhl reflections they are overlapped to an unknown degree and it is assumed that this accounts for the larger R value for these reflections (Table II).

DISCUSSION

The $D8_l$ structure was reported by Bertaut and Blum in 1953 for B_3Cr_5 (5). It has since been observed for Ge_3Ta_5 (6), Si_3Ta_5, and Si_3Nb_5 (7). Not previously noted is the fact that the same structure was reported for the ionic compounds $NH_4Pb_2Br_5$, $RbPb_2Br_5$, and KPb_2Br_5 by Powell in 1937 (8). (The origin used by Powell is removed $\frac{1}{2},\frac{1}{2},0$ from

that used in this paper.) All these compounds, although isostructural, are not isomorphous in the sense that their powder patterns are directly comparable since the wide variations in atomic sizes and scattering power obscure the fundamental similarity.

This structure can be most conveniently discussed in terms of slabs of atoms parallel to (001). Fig. 1(*a*), which is a full cell projection onto (010), shows the atoms arranged in layers at $z = 0$ (A), 0.15 (B), 0.25 (C), 0.35 (B), 0.50 (A), and so on. The interatomic distances corresponding to contacts are listed in Table III, and representative pairs of

TABLE III

Calculated interatomic distances (Å) for Ag_3Ca_5

Ag_I—$8Ca_{II}$	3.36	Ag_{II}—$1Ag_{II}$	2.77	Ca_{II}—$2Ag_{II}$	3.24
		—$2Ca_I$	3.19	—$1Ag_{II}$	3.32
Ca_I—$4Ag_{II}$	3.19	—$4Ca_{II}$	3.24	—$2Ag_I$	3.36
—$8Ca_{II}$	3.76	—$2Ca_{II}$	3.32	—$1Ca_{II}$	3.58
				—$1Ca_{II}$	3.73
				—$2Ca_I$	3.76

atoms corresponding to these distances are indicated by dotted lines in Fig. 1. The atoms lying in layers BCB are shown projected onto (001) in Fig. 1(*b*). This arrangement is the Al_2Cu structure (C16 type). The Ag_I atom lies in the center of eight Ca_{II} atoms arranged at the vertices of a square antiprism, 3.36 Å away from the Ag. For a coordination of eight the Ag—Ca distance is calculated to be 3.37 Å on the basis of the radii observed in the metals corrected for eight coordination.

The short Ca_{II}—Ca_{II} distance of 3.58 Å deserves attention. A calculation of the interatomic distance between the same pair of atoms in the 20 or so known C16-type structures shows that some apparent contraction occurs frequently but that it is most marked when the large atom is relatively "open", i.e. with a small ion core in respect to its metallic radius. For example, in Na_2Au the ratio rAu/rNa is 0.73 and the observed Na—Na distance is 3.30 Å as compared to 3.80 Å in the metal; in the present case rAg/rCa is 0.75 and the observed Ca—Ca distance is 3.58 Å as compared to 3.96 Å for the metal. The position marked H in Fig. 1(*b*) is at the center of a tetrahedral hole of radius 2.39 Å, about the size of a carbon or nitrogen atom.

The atoms in the layers BAB are projected onto (001) in Fig. 1(*c*). This layer, which forms the most striking feature of the structure, is identical with the structures of Th_3Al_2 (9) and U_3Si_2 (10). The Ca_I atoms are linked to four Ag_{II} atoms (3.19 Å) at the corners of a square while each Ag_{II} atom is linked to two Ca_I and one Ag_{II} (2.77 Å), the whole array forming a sheet of closely linked atoms parallel to (001). The relatively tight linkage in this layer probably accounts for the observed cleavage on (001). In addition to the contacts within the layer each Ca_I is connected to eight Ca_{II} (3.76 Å) at the corners of a square prism while each Ag_{II} is connected to six Ca_{II} at the vertices of a right triangular prism (four at 3.24 Å plus two at 3.32 Å). The Ca_I—Ag_{II} distance of 3.19 Å within the layer corresponds to a value somewhat larger than that calculated for 4-fold coordination but on the other hand the Ca_I—Ca_{II} distance of 3.76 Å is somewhat less than that calculated for CN = 8 (3.92 Å) or CN = 12 (3.96 Å), so that the coordination around Ca_I is intermediate in character between 4- and 12-fold. Similarly the short Ag_{II}—Ag_{II} distance (2.77 Å) and Ag_{II}—Ca_I distance (3.19 Å) are actually rather longer than that estimated for 3-fold coordination (~2.5 Å, ~3.0 Å), whereas the average Ag—Ca distance (3.25 Å) is somewhat shorter than that calculated for total 8-fold coordination (3.37 Å), leading to the conclusion that the bonding shows some evidence of an "electrochemical" effect, i.e. some degree of ionic character.

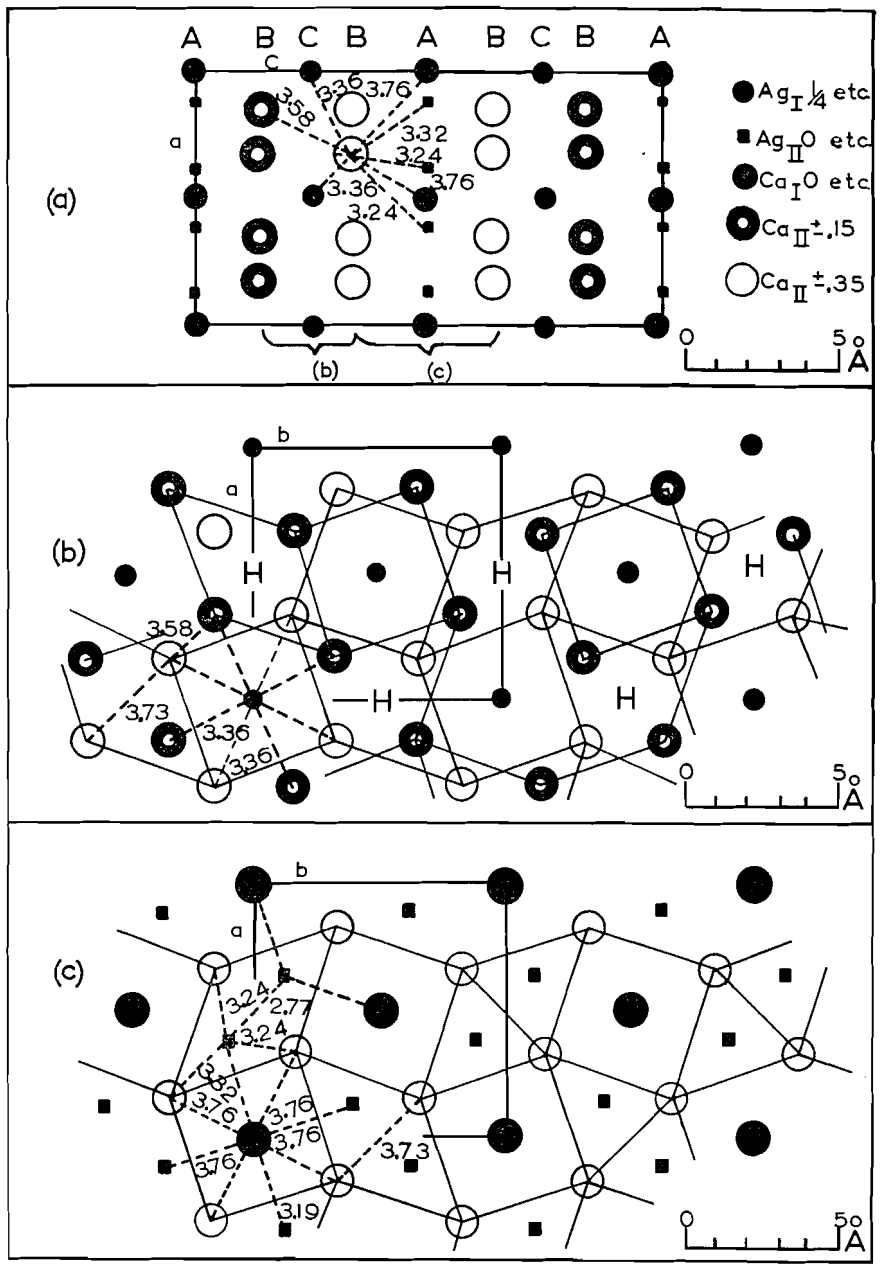

FIG. 1. Projections of the Ag_3Ca_5 structure. (*a*) Full cell projection onto (010); (*b*) layers BCB projected onto (001); (*c*) layers BAB projected onto (001).

The coordination of the Ca_{II} atom is complex and not easily pictured. The interatomic distances corresponding to contacts are indicated in Fig. 1(*a*) by dotted lines. The average of the nine distances is 3.48 Å whereas a weighted average of Ag—Ca (CN = 8) is ~3.6 Å.

This structure may be considered as being primarily determined by the relative sizes of the atoms concerned and not by their normal group valencies, metallic nature, or

electron/atom ratio, as may be seen by studying the formulae and radius ratios of the isostructural compounds listed in Table IV, in which metallic radii for CN = 12 have

TABLE IV

Compounds crystallizing with the $D8_l$ structure

Compound	Radius ratio	Compound	Radius ratio
Ag_3Ca_5	0.76	Ge_3Ta_5	0.90
B_2Cr_5	0.72	$RbPb_2Br_5$	0.77
KPb_2Br_5	0.68 (0.8?)	Si_3Ta_5	0.79
$NH_4Pb_2Br_5$	0.77 (0.8?)	Si_3Nb_5	0.77

been compared except for $NH_4Pb_2Br_5$, KPb_2Br_5, and $RbPb_2Br_5$, where the appropriate ionic radii have been used. A similar conclusion with respect to the Al_2Cu (C16) structure which comprises layers BCB (Fig. 1(*b*)) of the present structure has been proposed by Raynor (11). Secondly, the average interatomic distances are somewhat shorter and the average coordination numbers are somewhat smaller than might be expected on a purely metallic basis. This suggests that the bonding, although primarily metallic, is modified by a noticeable "electrochemical" effect. A more detailed discussion of the bonding is reserved until the results from other Ag–Ca compounds are available.

STEREOCHEMICAL STUDIES

IV. ACID-CATALYZED EQUILIBRATION OF α- AND β-FORMS OF 3-ALKOXY-4-OXA-5α-CHOLESTANES. THE ANOMERIC EFFECT

J. T. EDWARD AND I. PUSKAS[1]
Department of Chemistry, McGill University, Montreal, Que.

Received November 28, 1961

ABSTRACT

The α- and β-anomers of 3-methoxy-, 3-isopropoxy-, 3-cyclohexyloxy-, and 3-phenoxy-4-oxa-5α-cholestane were separated by chromatography on alumina. The configurations of the anomers were assigned from a consideration of their optical rotations. Acid-catalyzed equilibration of the 3-alkoxy anomers favored formation of the axial isomer, the proportions of α- to β-forms being about 7:3. 2α-Phenoxy-4-oxa-5α-cholestane in acid solution was in equilibrium with phenol and 4-oxa-5α-cholest-2-ene.

The reaction of benzyl alcohol with 3α-chloro-4-oxa-5α-cholestane in the presence of base, or with 4-oxa-5α-cholestan-3α-ol in the presence of acid, has been shown to yield a mixture from which 3α- and 3β-benzyloxy-4-oxa-5α-cholestane could be separated by chromatography on alumina. On the other hand, the corresponding reactions of methanol yielded mixtures from which only 3α-methoxy-4-oxa-5α-cholestane could be isolated in a pure state (1).

We have now found that by using a larger chromatographic column it is possible to separate 3β-methoxy-4-oxa-5α-cholestane from these mixtures. This chromatographic method was also used to separate the isomeric 3-isopropoxy-, 3-cyclohexyloxy-, and 3-phenoxy-4-oxa-5α-cholestanes, produced by reaction of 3α-chloro-4-oxa-5α-cholestane with the appropriate alcohol or phenol.

For each pair of isomers, the configuration at the 3-position was determined by a comparison of molecular rotations. According to Hudson's rules of isorotation (2), for aldopyranosides the molecular rotation of an α-D-glycoside should be about 350–400° more positive than that of the β-D-anomer. This rule has been rationalized by Whiffen (3) and Brewster (4) in their more general treatments of the effect of structure upon optical rotation. Since 3-substituted 4-oxa-5α-cholestanes have the C-1 conformation of the majority of D-pyranosides (5), about the same difference between the molecular rotations of α- and β-anomers should be observed. The results in Table I show this expectation to be confirmed. As anticipated, the molecular rotation difference is significantly greater for α- and β-forms of 3-phenoxy-4-oxa-5α-cholestane (+678°); phenyl α-D-glycopyranosides generally differ from phenyl β-D-glycopyranosides in molecular rotation by about +600° (6, 7).

According to these configurational assignments, the isomer more strongly adsorbed on alumina is in every case that having an equatorial alkoxy group. This is in line with the effect on adsorption of the configuration of the hydroxyl groups of steroidal alcohols (8). The differences in melting points of the pairs of isomers (Table II) are also those expected from their configurations. While the melting points of methyl α- and β-D-glycopyranosides vary in an irregular fashion, the melting points of phenyl (7) and higher alkyl (9) β-D-glycopyranosides are generally above those of the α-anomers, probably because of the better packing in the crystal possible for molecules with the bulky anomeric group equatorial.

TABLE II

Melting points of 3-substituted 4-oxa-5α-cholestanes

3-Substitutent	α-Anomer m.p. (°C)	β-Anomer m.p. (°C)
Methoxy	98–99.5 (1)	78
Isopropoxy	Syrup	90
Cyclohexyloxy	Syrup	109–110
Benzyloxy	42–51 (1)*	131–132 (1)
Phenoxy	112–117*	141

*Melting points of slightly impure compounds.

Both α- and β-forms of the 3-alkoxy-4-oxa-5α-cholestanes underwent mutarotation in acid solution, the same equilibrium value of the optical rotation being obtained starting with either isomer. Some typical results are shown in Fig. 1. Previously this type of change had been observed with 3α- and 3β-benzyloxy-4-oxa-5α-cholestane, and shown to be due to the formation of an equilibrium mixture of the α- and β-isomer (1). The same is true for the changes now under consideration. In the case of the 3-methoxy derivatives,

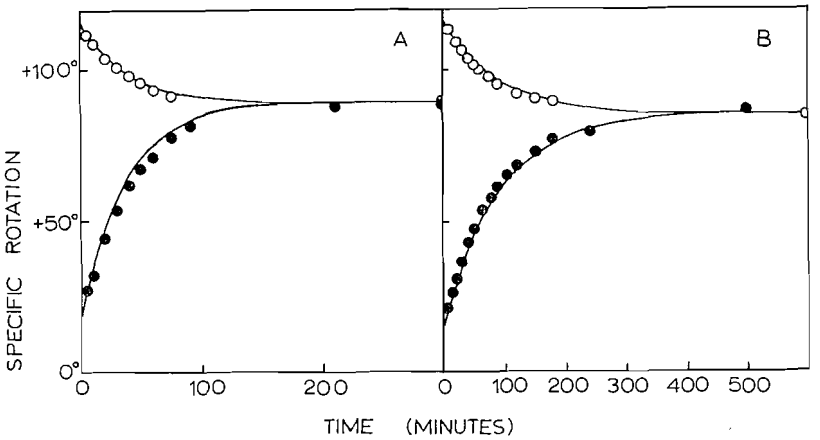

FIG. 1. Mutarotation of 3-alkoxy-4-oxa-5α-cholestanes; experimental values shown as points, and theoretical values for first-order reactions (having rate constant k) as curves. (A) 3α- (○) and 3β- (●) methoxy compounds in absolute methanol – tetrahydrofuran, 1:1 (v/v), 0.013 N with respect to hydrogen chloride, at 27±1.5° C; k = 0.027 min^{-1} (natural logs). (B) 3α- (○) and 3β- (●) isopropoxy compounds in absolute isopropanol, 0.084 N with respect to hydrogen chloride, at 22±0.5° C; k = 0.0115 min^{-1}.

the equilibrium mixture was recovered from solution and separated by chromatography into the 3α- and 3β-isomers; in the case of the 3-isopropoxy and 3-cyclohexyloxy derivatives, the equilibrium mixture was shown by qualitative infrared spectroscopy to be made up practically completely of 3α- and 3β-isomers. The equilibrium distributions of the isomers obtained from polarimetric measurements at 25±4°, assuming the equilibrium mixture to be made up solely of the 3α- and 3β-isomers, are shown in Table III.

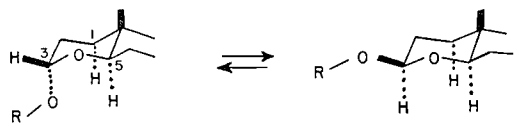
TABLE III

Anomeric equilibrium of 3-substituted 4-oxa-5α-cholestanes

	By polarimetry		By chromatography	
3-Substituent	Solvent	% α-form	Solvent	% α-form
Methoxy	MeOH	73±2	MeOH	67
Isopropoxy	Pr^iOH	71±2	Pr^iOH	75
Cyclohexyloxy	Cyc–THF, 3:2	69±2	Cyc	66
Benzyloxy (1)	$PhCH_2OH$–THF, 3:2	73±3	$PhCH_2OH$	85

These distributions are in rough agreement with those obtained by actual chromatographic separation of equilibrium mixtures (Table III). (The values for the isopropoxy and cyclohexyloxy derivatives in this table are derived from the experiments in which 3α-chloro-4-oxa-5α-cholestane was solvolyzed in the appropriate alcohol to give the alkoxy derivative and hydrogen chloride.) Better agreement could not be expected, because of the possibility of changes in composition during the removal of the solvent from the mixtures at reduced pressures and slightly elevated temperatures prior to chromatography; this (in part) may account for the presence of small amounts of 4-oxa-5α-cholest-2-ene and of other unidentified products in the chromatographic fractions.

The equilibrium distribution of isomeric 3-alkoxy-4-oxa-5α-cholestanes are about the same, regardless of the nature of the alkyl group, the axial (α) isomer being favored (Table III). Evidently the "anomeric effect" (1, 10, 11) outweighs the effect of steric interactions between an axial oxygen atom and the axial hydrogen atoms at the 1- and 5-positions; the latter effect is apparently approximately independent of the size of the alkyl group, as would be expected if the alkoxyl group has the conformation shown in formula I. The equilibrium constants K (= concentration of α-isomer/concentration of



(I) (II)

β-isomer) of 2.4±0.2 for the four isomerization reactions correspond to free energy differences (ΔF) of 520±50 cal/mole between the α- and β-isomers. This compares with a ΔF of 715 cal/mole between the corresponding α- and β-anomers of methyl D-glucoside (77% α-anomer at equilibrium in acidic methanol (12)). For all of these compounds ΔF may be considered as made up of the difference between the anomeric effect and the interaction energy for an axial oxygen and two axial hydrogen atoms. The greater ΔF for the sugar may be due in part to a greater value of the anomeric effect in this compound because of the inductive effects of the many hydroxyl groups (1, 11). However, it may

also be due in part to differing values of interaction energies of axial groups in glucosides and in 4-oxa-5α-cholestanes because of a stiffening of ring A in the latter through fusion with ring B (13). Thus ΔF between axial and equatorial hydroxyl groups of 4-*t*-butylcyclohexanol in isopropanol at 90° is 0.96 kcal/mole (14), and of cholestan-3-ol in boiling propanol is 2.0 kcal/mole (13).* Consequently, any attempt to estimate the separate contributions to ΔF made by the anomeric effect and by non-bonded repulsions in these compounds must be regarded as highly speculative until independent estimates of the interaction energies are available.

In any one equilibration experiment the changes in rotation followed the expected first-order kinetics with reasonable accuracy, as shown by the examples in Fig. 1. However, while the equilibrium constants obtained in different experiments were reasonably reproducible, the rate constants differed sometimes by factors of 2–3. Similar difficulties in reproducing rate constants for the acid-catalyzed mutarotation of glycosides have been reported, and attributed to the effect of traces of water in the alcohol (11).

In acidic solution in the presence of a large molar excess of phenol, 3α-phenoxy-4-oxa-5α-cholestane eliminated phenol by a first-order reaction (Fig. 2) to give an equili-

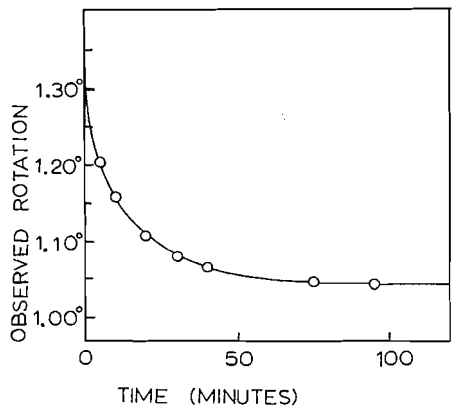


FIG. 2. Change in rotation, on standing, of a solution of 3α-phenoxy-4-oxa-5α-cholestane in acidic phenol–tetrahydrofuran, 1:4 (v/v) at 28.5±0.5° C. Circles: experimental values; curve: theoretical for a first-order reaction having rate constant = 0.054 min^{-1}.

brium mixture made up of about 2 moles of the phenoxy compound per mole of 4-oxa-5α-cholest-2-ene. This indicates a much smaller thermodynamic stability for the 3-phenoxy as compared with 3-alkoxy compounds: the latter may also be in equilibrium with 4-oxa-5α-cholest-2-ene in acidic alcohol (see above), but the quantity of the latter at equilibrium must be very much smaller, and not enough to affect appreciably the calculated equilibrium distributions shown in Table III. The lesser thermodynamic stability of the 3α-phenoxy compound was shown more directly in an equilibration experiment starting with 3α-methoxy-4-oxa-5α-cholestane and a large excess of phenol in acidic tetrahydrofuran. The products (3α-methoxy-, 3α-phenoxy-, 3β-phenoxy-4-oxa-5α-cholestane, etc.) were isolated by chromatography on alumina. Bearing in mind the limitations of such a method, discussed above, the constants calculated from these results can be considered only very approximate. However, for the reaction

3α-methoxy-4-oxa-5α-cholestane + phenol $\rightleftarrows$ 3α-phenoxy-4-oxa-5α-cholestane + methanol

an equilibrium constant ≈ 0.05 may be calculated, and for the equilibrium between 3α- and 3β-phenoxy-4-oxa-5α-cholestane, $K > 6$.

**We are grateful to a referee for bringing this point to our attention.*

EXPERIMENTAL

Intensities of infrared absorption are indicated after the frequencies either by the semiquantitative notation used previously (15) or by molecular extinction coefficients (in parentheses). Chromatography was on Woelm alumina; Brockmann activity grades shown. Melting points are uncorrected.

3β-Methoxy-4-oxa-5α-cholestane

3α-Methoxy-4-oxa-5α-cholestane (1) (235 mg) was dissolved by gentle warming in a solvent prepared previously by addition of acetyl chloride (0.5 ml) to absolute methanol (20 ml) and absolute tetrahydrofuran (5 ml). After solution was complete, excess silver carbonate (about 3 g) (16) was added with stirring. The insoluble silver salts were removed by filtration and washed with anhydrous ether. The filtrate and washings evaporated at reduced pressure left a solid which was chromatographed on alumina (50 g, basic, grade III). Elution with ligroin (200 ml) brought down the starting material (156 mg), identified by infrared spectrum and mixed melting point, while ligroin–benzene, 4:1, v/v (140 ml) washed down the *3β-methoxy isomer* (76 mg), m.p. 74–76° C. Recrystallization from methanol raised the m.p. to 78° C, depressed by admixture with the α-isomer; $[\alpha]_D^{26}$ +15.8° (*c*, 1.35 in chloroform); $[\alpha]_D^{26}$ +18.6° (*c*, 1.26 in tetrahydrofuran–methanol, 1:1, v/v); $\nu_{max}^{CCl_4}$ in cm^{-1}: 2920 (525), 2842 (288), 2725 (23), 2620 (17), 1469 (160), 1457 (138), 1448 (152), 1387 (180), 1368 (77), 1345 (71), 1326 (42), 1203 (50), 1169 (192), 1142 (115), 1132 (109), 1123 (132), 1098 (124), 1093 (120), 1072 (400), 1048 (230), 1027 (90), 936 (106), 928 (sh 65), 902 (48), 865 (34). Calc. for $C_{27}H_{48}O_2$: C, 80.20; H, 11.95; OMe, 7.68%. Found: C, 80.30; H, 11.90; OMe, 7.65%.

In a similar experiment in which 3α-methoxy-4-oxa-5α-cholestane (155 mg) was isomerized in acidic absolute ether – absolute methanol (1:1, v/v), 108 mg of α- and 47 mg of β-methoxy isomer were isolated by chromatography.

3α- and 3β-Isopropoxy-4-oxa-5α-cholestane

A solution of 3α-chloro-4-oxa-5α-cholestane (325 mg) in isopropanol (7 ml, spectro grade, water content less than 0.5%) was refluxed for 3 hours. The solvent was removed under reduced pressure and the residual syrup (342 mg) chromatographed on alumina (32 g, basic, grade III). Elution with the volumes of ligroin shown below afforded the following fractions:

(*a*) 30 ml: nothing;

(*b*) 10 ml: crystals of 4-oxa-5α-cholest-2-ene (6 mg), identified by m.p. and infrared spectrum;

(*c*) 50 ml: a syrup (202 mg) which proved to be 3α-isopropoxy-4-oxa-5α-cholestane, shown by its infrared spectrum to be contaminated with carbonyl-containing impurities;

(*d*) 60 ml: nothing;

(*e*) 35 ml: sticky crystals (14 mg) of an unidentified material; $\nu_{max}^{CCl_4}$ in cm^{-1}: 2950 (vs), 2870 (s), 1470 (s), 1450 (s), 1382 (s), 1370 (m), 1335 (w), 1261 (w), 1126 (m), 1101 (s), 1087 (s), 1049 (m), 1023 (s), 952 (w), 933 (w), 907 (w), 870 (w);

(*f*) 200 ml: impure crystals (67 mg) of 3β-isopropoxy-4-oxa-5α-cholestane.

Further elution with 25 ml benzene–ether (1:1, v/v) brought down a glassy solid (47 mg) which could not be identified, and with 25 ml benzene–methanol (3:2, v/v), crystals of 4-oxa-5α-cholestan-3α-ol (3 mg).

Chromatographic fraction *c* was dissolved in hot methanol and filtered under suction on a hot funnel. The solvent was evaporated from the filtrate, and the residual syrup stirred with small amount of hot methanol. The methanol was decanted from the syrup. Repetition of this process removed the carbonyl-containing impurities, although with an appreciable loss of the main product. The residual syrupy liquid, which appeared to be *3α-isopropoxy-4-oxa-5α-cholestane*, resisted all attempts at crystallization; $n_D^{22.8}$ 1.4938; $[\alpha]_D^{21}$ +112.3° (*c*, 1.42 in chloroform); $[\alpha]_D^{22}$ +115° (*c*, 1.51 in isopropanol); $\nu_{max}^{CCl_4}$ in cm^{-1}: 2925 (608), 2860 (337), 1470 (188), 1449 (135), 1382 (185), 1369 (148), 1335 (84), 1129 (214), 1098 (123), 1080 (67), 1038 (319), 956 (70), 932 (98), 899 (61), 873 (35). Calc. for $C_{29}H_{52}O_2$: C, 80.49; H, 12.11%. Found: C, 80.41; H, 12.00%.

Fraction *e* was dissolved in hot methanol and filtered under suction through a hot funnel. The precipitate separating in the filtrate redissolved on warming. On slow cooling, a syrup separated. The solution was decanted from the syrup, and on standing at 4° C deposited crystals which, on recrystallization from methanol, gave pure *3β-isopropoxy-4-oxa-5α-cholestane* (16 mg), m.p. 90° C; $[\alpha]_D^{23}$ +12.5° (*c*, 1.085 in chloroform); $[\alpha]_D^{23}$ +14° (*c*, 1.37 in isopropanol); $\nu_{max}^{CCl_4}$ in cm^{-1}: 2935 (595), 2680 (330), 1470 (192), 1458 (149), 1450 (146), 1384 (208), 1372 (160), 1337 (104), 1313 (55), 1192 (66), 1166 (255), 1138 (180), 1121 (225), 1093 (155), 1066 (470), 1045 (314), 944 (76), 933 (106), 902 (53). Calc. for $C_{29}H_{52}O_2$: C, 80.49; H, 12.11%. Found: C, 80.57; H, 12.05%.

On concentration of the combined mother liquors a further 24 mg of slightly impure crystals of 3β-isopropoxy-4-oxa-5α-cholestane was obtained (total yield 11.5%).

3α- and 3β-Cyclohexyloxy-4-oxa-5α-cholestane

A solution of 3α-chloro-4-oxa-5α-cholestane (167 mg) in cyclohexanol (3 ml, m.p. 22–24°) was heated to 120° C for 2 hours. The solvent was then removed under reduced pressure and the residual syrup chromatographed on alumina (32 g, basic, grade III). Elution with the solvents indicated gave the following fractions:

(*a*) 25 ml ligroin: nothing;
(*b*) 15 ml ligroin: crystals of 4-oxa-5α-cholest-2-ene (7 mg), identified by m.p. and infrared spectrum;
(*c*) 40 ml ligroin: syrup (123 mg), shown below to be 3α-cyclohexyloxy-4-oxa-5α-cholestane;
(*d*) 30 ml ligroin–benzene, 9:1, v/v: syrup (13 mg) having characteristic absorption peaks in CCl_4 at 1103, 1089, 1062, 1049, and 1024 cm^{-1} which are absent in the spectrum of both 3α- and 3β-cyclohexyloxy isomers (see below); the fraction must be a mixture of at least two compounds, since in another run the corresponding fraction showed the 1103 and 1089 cm^{-1} peaks only;
(*e*) 45 ml ligroin–benzene, 3:2, v/v: crystals (62 mg) shown below to be impure 3β-cyclohexyloxy-4-oxa-5α-cholestane.

Fraction *c* was dissolved in 20 ml hot methanol, treated with charcoal, and filtered, but all attempts to obtain crystals from the filtrate failed. Removal of the solvent left a syrup which appeared to be *3α-cyclohexyloxy-4-oxa-5α-cholestane*; $[\alpha]_D^{20}$ +103° (*c*, 1.23 in chloroform); $[\alpha]_D^{26}$ +108° (*c*, 1.78 in cyclohexanol–tetrahydrofuran, 3:2, v/v); $\nu_{max}^{CCl_4}$ in cm^{-1}: 2920 (780), 2845 (400), 1468 (166), 1450 (186), 1374–1379 (110), 1368 (114), 1233 (52), 1120 (202), 1098 (100), 1057 (182), 1035 (410), 931 (102), 910 (66), 888 (50). Calc. for $C_{32}H_{56}O_2$: C, 81.29; H, 11.94%. Found: C, 81.34; H, 11.94%.

Fraction *e* was dissolved in ligroin and decolorized with charcoal. The crystals left by evaporation of the solvent dissolved partially in hot methanol – ethyl acetate (9:1, v/v), leaving behind some undissolved syrup. On cooling, the solution gave colorless prisms of *3β-cyclohexyloxy-4-oxa-5α-cholestane* (22 mg), micro m.p. 108–110° C, unchanged by further recrystallization from methanol; $[\alpha]_D^{25}$ +8.5° (*c*, 1.34 in chloroform); $[\alpha]_D^{25}$ +8.1° (*c*, 1.15 in cyclohexanol–tetrahydrofuran, 3:2, v/v); $\nu_{max}^{CCl_4}$ in cm^{-1}: 2920 (685), 2840 (397), 1468 (164), 1454 (186), 1385 (120), 1368 (136), 1343 (82), 1166 (211), 1137 (175), 1120 (172), 1092 (159), 1068 (365), 1044 (330), 932 (100). Calc. for $C_{32}H_{56}O_2$: C, 81.29; H, 11.94%. Found: C, 81.08; H, 11.84%.

3α- and 3β-Phenoxy-4-oxa-5α-cholestane

(*a*) *From 3α-Chloro-4-oxa-5α-cholestane*

A solution of 3α-chloro-4-oxa-5α-cholestane (120 mg) and freshly distilled phenol (94 mg) in absolute tetrahydrofuran (4 ml) was refluxed gently overnight. The solvent was removed under reduced pressure and the residual syrup stirred with distilled water. The water was decanted and the syrup dried in a vacuum desiccator and chromatographed on alumina (20 g, basic, grade III) to give the following fractions:
(*a*) 20 ml ligroin: 4-oxa-5α-cholest-2-ene (2 mg);
(*b*) 25 ml ligroin: crystals (25 mg);
(*c*) 25 ml ligroin: unidentifiable syrup (11 mg);
(*d*) 20 ml ligroin; sticky crystals (19 mg);
(*e*) more ligroin, followed by more polar solvents: differing syrupy, foamy, and glassy fractions (60 mg).

Fraction *b*, twice recrystallized from ethyl acetate – ethanol (1:1, v/v), gave shining needles of *3α-phenoxy-4-oxa-5α-cholestane* (17 mg), m.p. 141° C; $[\alpha]_D^{25}$ +162° (*c*, 1.38 in chloroform); $\lambda\lambda_{max}$ 264, 270, 276 mμ; $\epsilon\epsilon_{max}$ 1120, 1590, 1360 (in cyclohexane); $\nu_{max}^{CCl_4}$ in cm^{-1}: 3053 (24), 3025 (29), 2926 (565), 2850 (304), 1597 (130), 1495 (255), 1469 (159), 1462 (125), 1448 (128), 1383 (124), 1367 (117), 1290 (49), 1226 (278), 1175 (76), 1160 (172), 1112 (202), 1102 (139), 1078 (82), 1038 (360), 963 (156), 948 (308), 935 (174), 921 (220), 890 (54), 690 (96). Calc. for $C_{32}H_{50}O_2$: C, 82.35; H, 10.80%. Found: C, 82.28; H, 10.61%.

Fraction *d*, recrystallized from ethyl acetate – ethanol at 0° C, gave colorless needles on the side of the flask and a syrup on the bottom. The crystals (2.8 mg) were separated, washed with methanol, and dried, and appeared to be slightly impure *3β-phenoxy-4-oxa-5α-cholestane*; micro m.p. 112–117° C; $[\alpha]_D^{25}$ +8.2° (*c*, 0.766 in chloroform); $\lambda\lambda_{max}$ 263, 269, 276 mμ; $\epsilon\epsilon_{max}$ 830, 1140, 975 (in cyclohexane; values of extinction coefficients uncertain because of weighing errors with small sample used); ν_{max}^{KBr} in cm^{-1}: 3050 (w, sh), 3030 (w, sh), 2925 (vs), 2845 (s), 1600 (m), 1582 (m), 1497 (s), 1468 (m), 1455 (m), 1446 (sh), 1393 (m), 1384 (m), 1367 (w), 1244 (s), 1227 (m), 1205 (w), 1179 (w), 1162 (w), 1139 (w), 1104 (w), 1070 (vs), 1051 (m), 1028 (w), 1001 (w), 994 (w), 960 (w), 939 (m), 910 (w), 904 (w), 885 (m), 832 (m), 819 (m), 755 (vs), 690 (s).

(*b*) *From 3α-Methoxy-4-oxa-5α-cholestane*

3α-Methoxy-4-oxa-5α-cholestane (140 mg) and freshly distilled phenol (2 g) were dissolved in absolute tetrahydrofuran (15 ml), and some dry hydrogen chloride was blown into the solution. The flask was stoppered and left to stand at room temperature for 2 hours. The acid was then neutralized by the addition of freshly prepared silver carbonate. The insoluble inorganic salts were removed by filtration and washed with ether. The combined filtrate and washings were concentrated *in vacuo*, and the residual syrup was dissolved in ether. The ether solution was washed with 5% sodium hydroxide solution and with water, and partially dried by washing with saturated sodium chloride solution. The ether was removed under vacuum and the residual syrup (163 mg) chromatographed on alumina (30 g, basic, grade III) to give the following fractions, identified by infrared spectroscopy:
(*a*) 40 ml ligroin: crystals of 4-oxa-5α-cholest-3-ene (10 mg);
(*b*) 35 ml ligroin: crystals of 3α-phenoxy-4-oxa-5α-cholestane (92 mg);
(*c*) 35 ml ligroin: crystals of 3α-methoxy-4-oxa-5α-cholestane (21 mg);
(*d*) 25 ml ligroin–benzene, 4:1, v/v: differing syrupy fractions, containing aromatic groups as revealed by their spectra (14 mg);
(*e*) 25 ml ligroin–benzene, 4:1, v/v: impure crystals of 3β-methoxy-4-oxa-5α-cholestane (14 mg).

Fraction *b* was purified by recrystallization from ethyl acetate – ethanol (1:1, v/v) to give pure needles of 3α-phenoxy-4-oxa-5α-cholestane, m.p. 141°, mixed m.p. 141°.

In fraction *d* there was infrared evidence for the presence of 3β-phenoxy-4-oxa-5α-cholestane accompanied by much impurity.

Acid-catalyzed Equilibration of 3α- and 3β-Alkoxy-4-oxa-5α-cholestanes

A solution of hydrogen chloride in the requisite alcohol was prepared by addition of a small amount of acetyl chloride, and the acid concentration determined by titration. An aliquot (0.02–0.06 ml) of this solution was added (at zero time) to a solution of 3-alkoxy-4-oxa-5α-cholestane (14–18 mg) in about 0.9 ml of the alcohol or alcohol–tetrahydrofuran mixture (Table III) contained in a 1.00-ml volumetric flask. The solution was made up to 1.00 ml and mixed, and polarimetric measurements were made as quickly as possible.

Acid-catalyzed Elimination of Phenol from 3α-Phenoxy-4-oxa-5α-cholestane

An aliquot (0.02 ml) of 0.0186 *N* hydrogen chloride in tetrahydrofuran was added to 3α-phenoxy-4-oxa-5α-cholestane (15.55 mg) in about 0.9 ml of phenol–tetrahydrofuran (20%, v/v). The solution was made up to 100 ml with the same solvent and mixed, and polarimetric measurements were taken (Fig. 2). After reaction the solution was treated with anhydrous sodium carbonate and the solvent removed under reduced pressure. The residue in ether was extracted with water, 5% aqueous sodium carbonate, and water, and dried. The solid, after removal of the ether, was analyzed by infrared spectroscopy and found to contain 3α-phenoxy-4-oxa-5α-cholestane and 4-oxa-5α-cholest-2-ene in approximately 2:1 ratio. The ratio from polarimetric measurements (Fig. 2) at equilibrium was 1.87:1, assuming only 3α-phenoxy-4-oxa-5α-cholestane and 4-oxa-5α-cholest-2-ene (and no 3β-phenoxy-4-oxa-5α-cholestane) to be present, and the specific rotation of 4-oxa-5α-cholest-2-ene to be the same in the present solvent as in chloroform (1): both assumptions are only approximately true (cf. Table I).

DETERMINATION OF THE ACTIVITIES OF MAGNESIUM IN LIQUID MAGNESIUM–TIN ALLOYS BY VAPOR PRESSURE MEASUREMENTS[1]

S. ASHTAKALA[2] AND L. M. PIDGEON[3]

Department of Metallurgical Engineering, University of Toronto, Toronto, Ontario

Received December 4, 1961

ABSTRACT

The vapor pressure of liquid magnesium–tin alloys has been measured between 780° C and 1010° C using the isopiestic method.

Activities of magnesium were obtained at 800° C, 910° C, and 940° C. Activities of tin showed a negative departure from ideality, and those of magnesium, both negative and a slight positive departure.

Partial heats and entropies of mixing were calculated, and values are negative for most of the composition range. Partial free energies of mixing for the entire composition range showed negative values. Integral heats, entropies, and free energies were calculated from the partial quantities. These values were negative, indicating an ordered liquid alloy.

INTRODUCTION

The measurement of vapor pressures in reactive metal systems presents special difficulties owing to the reactivity of the volatile metal, and many established techniques are unsuitable. Static isopiestic methods offer advantages which more than offset the objection that the results must be based on the work of others. The method is particularly applicable to systems consisting of but one volatile component. This paper describes measurement of the vapor pressure of magnesium over liquid magnesium–tin alloys using an elaboration of the method of Herasymenko (7). The changes adapted the technique to the treatment of liquid alloys, and at the same time achieved a more reliable system for the measurement of alloy temperature.

DESCRIPTION OF METHOD

Metallic magnesium was heated at a constant temperature T_1 at one end of a long tube. The magnesium vapor was allowed to come to equilibrium with the samples of tin kept at different temperatures, along the length of the tube, the temperature of the alloys being higher than that of magnesium. The composition of the alloys reached at equilibrium is established by quenching and subsequent analysis. Knowing the vapor pressure of magnesium from published data (1), and the temperature of the alloy, the activity of magnesium could be calculated from the formula

$$a_{Mg} = P^\circ/P_1^\circ,$$

where P° is the vapor pressure of pure magnesium at the temperature of the magnesium chamber, and P_1° is the vapor pressure of pure magnesium at the temperature of the alloy.

The basic limitation of this method is that the vapor pressures of the volatile component should be known accurately, and its accuracy is dependent on the accuracy of the work of others. On the other hand, the values obtained can easily be recalculated, if different values are subsequently accepted for the vapor pressure data of the volatile component.

EXPERIMENTAL PROCEDURE

(1) Assembly of the Reaction Tube

The reaction tube consisted of two parts—the magnesium chamber and the alloy chamber, connected by a small diameter tube, as shown in Fig. 1. The reaction tube was made of mild steel.

The magnesium chamber contained about 55 g of pure magnesium. The alloy chamber contained 10 thermocouple wells at equal distances. Inside the alloy chamber, the thermocouple wells were fitted with high-temperature porcelain tubes.

Tin samples were placed in graphite boats which were placed on the thermocouple wells. The boats were prevented from touching the steel tube by porcelain insulators. After positioning the tin boats, the assembly was connected to the vacuum system by a small tube and pumped down to about 0.001 mm Hg. The vacuum offtake was then "hot pressure welded" and sealed.

The furnace was provided with silicon carbide resistors controlled in two sections so that a suitable temperature gradient could be produced. It contained an inner "Inconel" tube, as shown in Fig. 2, in which the reaction tube was placed. The thermocouple wires were passed through the water-cooled copper end plate to the outside of the furnace, sealed by means of Pliocene cement. The end plate was made vacuum-tight by means of an O-ring.

The materials used in the experiments consisted of zone-refined tin of 99.999% Sn and silico-thermic magnesium of 99.96% Mg (courtesy of Dominion Magnesium Limited).

The "Inconel" tube was placed under slight vacuum in order to minimize the pressure differential inside and outside the reaction tube. The two sections of the furnace were heated and controlled separately, and power input was so manipulated that the temperatures of the alloys were always higher than that of magnesium.

At the end of the run, argon was introduced into the "Inconel" tube, the end plate was removed, and the reaction tube pulled out on rails and quenched by means of water sprayed on all the sides of the tube. The whole operation took about a minute.

(2) Precision and Accuracy of Experiments

(a) Temperature Measurement

The temperature of the chamber containing the magnesium "boiler" was constant to $\pm 0.5°$, and an exploratory thermocouple in the boiler itself indicated barely detectable changes.

In the part of the system containing the deliberate temperature gradient, it is of utmost importance that temperature of the alloy chambers be constant longitudinally and radially, and that the temperature as read by the thermocouple be that of the liquid alloy.

At the beginning of the experiments, the temperatures of the magnesium and alloy chambers, as read by thermocouples inside the thermocouple wells, were compared with a second set of thermocouples inserted into the melt directly.

As a result of these experiments, the shape and size of the graphite boats for the alloys and that of the magnesium chamber were established. It was also observed that, as long as the temperature difference between the hot and cold ends of the alloy chamber was less than 120° C and above a minimum of 750° C, the temperature as recorded by thermocouples in the wells agreed with the temperature inside the melt within $\pm 0.5°$ C.

(b) Alloy Analysis

Alloy analysis indicated an accuracy of $\pm 0.5\%$ by weight of magnesium. This resulted in an error of ± 1 mole% Mg in the lowest magnesium concentrations and ± 0.2 mole% Mg in the highest magnesium concentrations.

In most cases, each magnesium chamber was used for one experiment and occasionally for two experiments. At the end of the run, magnesium in the chamber was analyzed for tin content, which was found to be negligible.

(c) Quenching

Care is taken to quench the magnesium chamber faster than the rest of the tube. If the magnesium pressure is high during quenching, magnesium would condense on the relatively colder reaction tube than in the alloy. If the alloy pressure is high, magnesium would also condense on the tube. At no time was a condensate in evidence. It is considered that this effect, if any, was of a negligible proportion.

(d) Equilibrium

It would be expected that the time taken to reach equilibrium would be longest for an alloy of high magnesium content at the lowest magnesium pressure. Once the time required for such an alloy to come to equilibrium is established, all other alloys can safely be assumed to reach equilibrium in this time.

Experiments were conducted at low pressures for different periods of time, between 48 and 72 hours, and they showed similar results within the experimental error. In one experiment, instead of using pure tin in the alloy chambers, alternate samples were mixed with magnesium such that the equilibrium was approached from opposite sides in alternate cases, and results were within the accepted error. The various experimental points plotted on the log P vs. $1/T$ curves were obtained from different experiments, and all fell on a straight line within the experimental error, indicating that the equilibrium had been established. All experiments were conducted for 2 days or more.

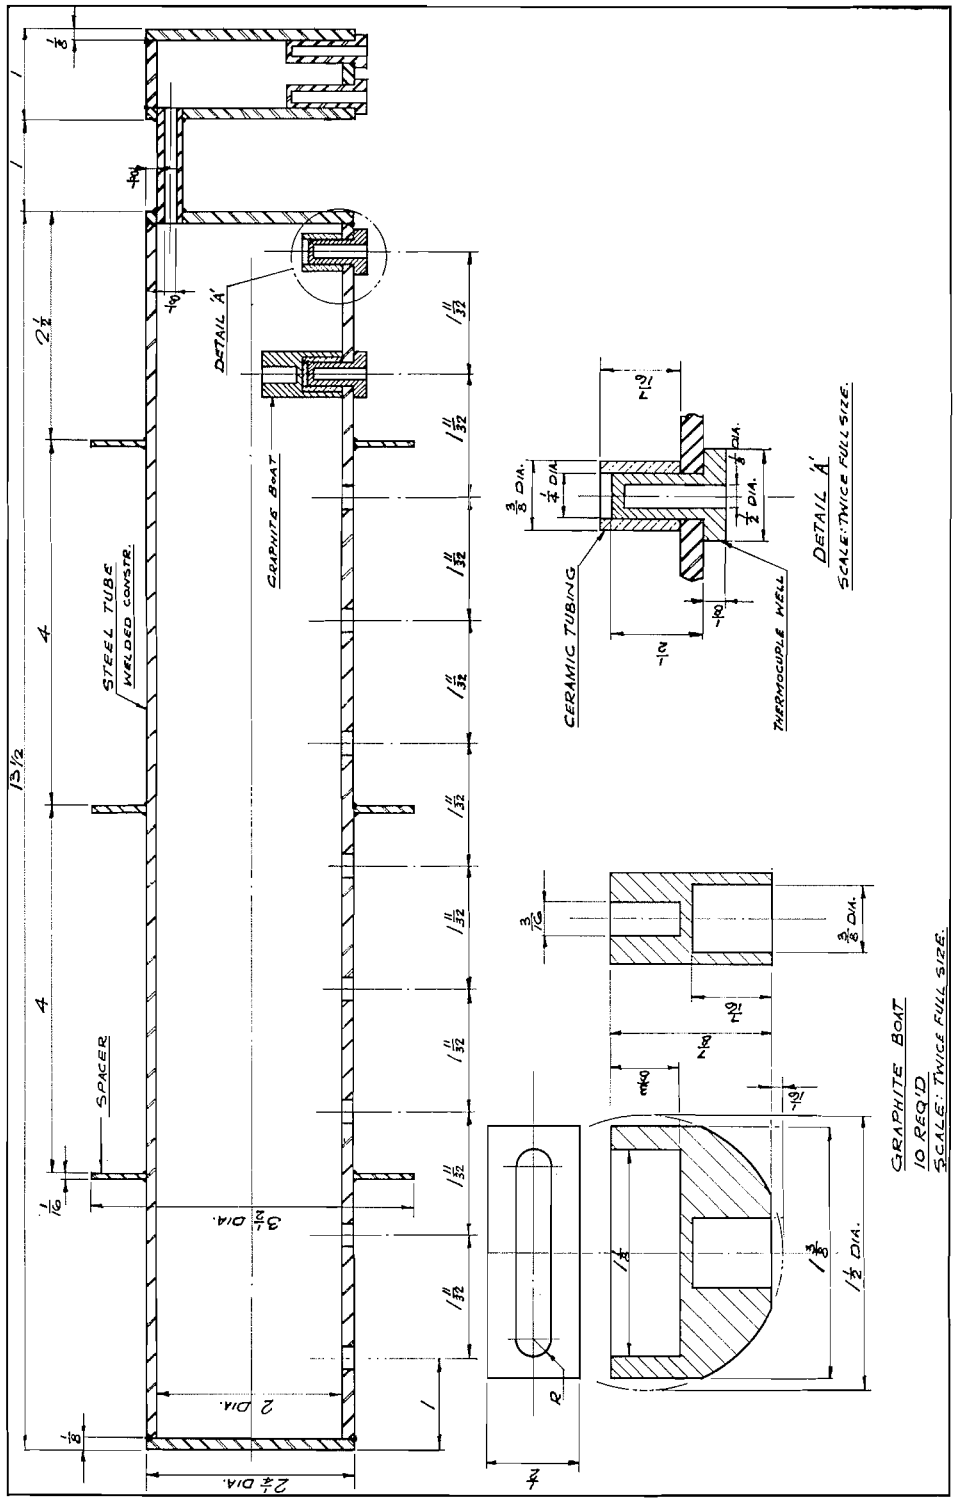

FIG. 2. Reaction tube (dimensions are in inches).

EXPERIMENTAL RESULTS AND DISCUSSION

For the calculation of the vapor pressure of liquid magnesium, the data of Kubaschewski (1) were employed; the vapor pressures are given by the formula

$$[1] \qquad \log P_{Mg}\ (\text{mm Hg}) = -7550/T - 1.41 \log T + 12.79.$$

The magnesium content of the tin–magnesium alloys was measured as a function of temperature at various pressures of magnesium. The experimental results are shown in Table I.

At the pressures used, it was only possible to obtain a variation in composition ranging from about 0.9 N_{Mg} to 0.3 N_{Mg}. In order to measure the activities at 910° C below this limit, the temperature gradient between the hot and the cold ends of the reaction tube would have to be about 300° C, well above the 120° C limit of the apparatus. Hence, activities below 0.3 N_{Mg} were not obtained.

(1) Magnesium Pressure Over the Alloys

From the results obtained, log P vs. $1/T$ curves were plotted for different compositions of Sn–Mg alloys, as shown in Fig. 3.

The magnesium pressures of these alloys are expressed in the form

$$[2] \qquad \log P_{Mg} = -A/T + B,$$

where the pressures are expressed in atmospheres and the temperature in degrees absolute. The vapor pressures of magnesium given in equation [1] are also expressed in this form for the same temperature range. The values obtained for the constants A and B are shown in Table II.

(2) Activities of Magnesium

The activities of magnesium at three temperatures, i.e., 880° C, 910° C, and 940° C, were calculated from the experimental data and shown in Fig. 4. The curve is extrapolated below 0.3 N_{Mg}. The α function of magnesium is expressed by the following formula:

$$[3] \qquad \alpha_i = \frac{\ln \gamma_i}{(1-N_i)^2},$$

where γ_i is the activity coefficient of component i and N_i is the mole fraction of the same component. The α function of magnesium is plotted against N_{Sn}, and the linear segment thus obtained from 0.7 N_{Sn} to 0.3 N_{Sn} is extrapolated to higher concentrations of tin. The calculated activities of magnesium from the α function gave added confidence to the extrapolation of the activity curve.

P_{Mg} values at low concentrations of magnesium were calculated from the activities thus obtained at the three temperatures. From plots of P_{Mg} vs. $1/T$ the values of the constants A and B in equation [2] were calculated and are shown in Table II.

(3) Activities of Tin

The activities of tin at the three temperatures 880° C, 910° C, and 940° C are calculated by the graphical integration of Gibbs–Duhem equation,

$$[4] \qquad \ln \gamma_{Sn} = \int_{N_{Sn}=1}^{N_{Sn}} \frac{N_{Mg}}{N_{Sn}}\, d \ln \gamma_{Mg}.$$

*$\Delta\bar{F}_{Mg} = \Delta_M\bar{H}_R - T\Delta\bar{S}_{Mg}$.
†$\Delta\bar{F}_{Mg} = RT \ln a_{Mg}$.

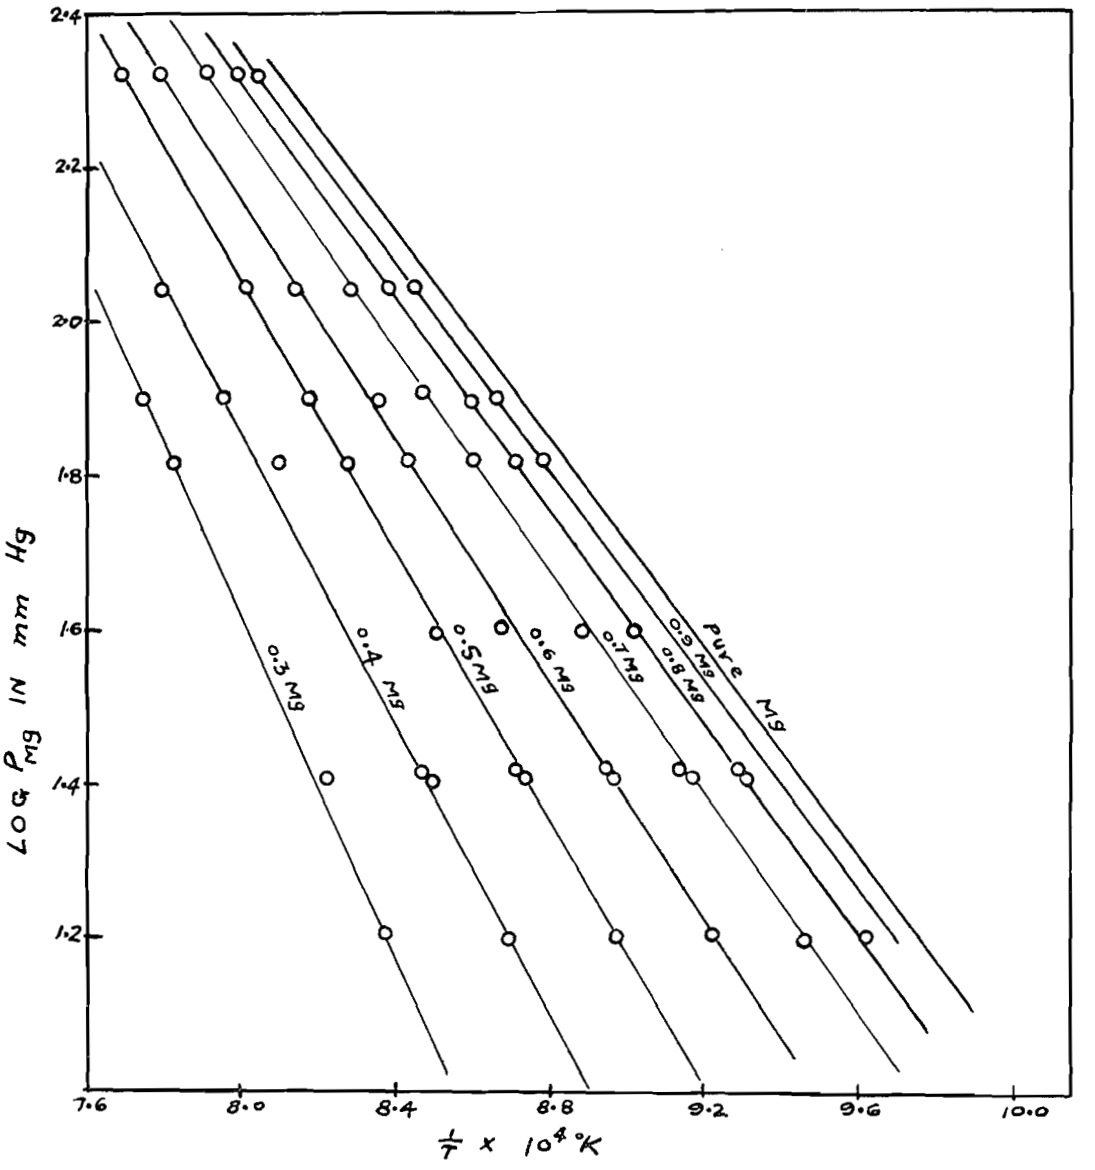

FIG. 3. Log P_{Mg} vs. $1/T$ magnesium–tin alloys.

The results obtained are shown in Fig. 4.

It can be seen from Fig. 4 that, for the most part, the activity curve of magnesium has a negative deviation from ideality, as can be expected in a system exhibiting intermetallic compounds. (The magnesium–tin system has an intermetallic compound, Mg_2Sn.) A negative departure is associated with a tendency for one atom to group with the other type, and a positive departure indicates a tendency for each type of atom to group with similar atoms. If this reasoning is pursued in the present case, it must be concluded that such tendencies change with the composition, since a positive departure exists above 0.7 N_{Mg}.

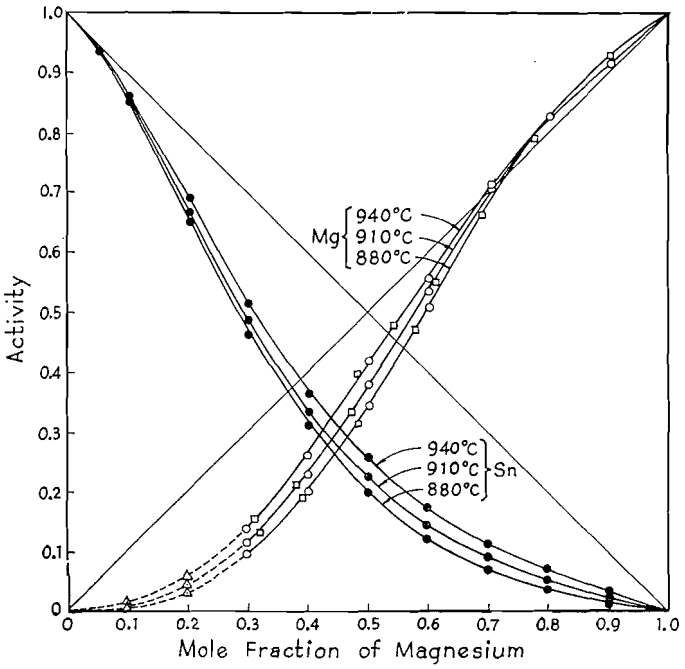

FIG. 4. Activity vs. mole fraction of magnesium: □, experimental data; ○, interpolated from Fig. 3; △, extrapolated from plot of α function; ●, calculated from tables.

It is of interest to note that the composition at which the deviation changes from positive to negative occurs at about the composition of the intermetallic compound Mg_2Sn.

Unlike magnesium, the activities of tin are negative throughout the composition range. The activity measurements of the magnesium–tin system were carried out by Schneider and Esch (2) using boiling point methods. In the range 93.9–66.7 mole% of magnesium at 1100° C, it was found to behave ideally. As can be seen from the present work, the activities of magnesium are approaching ideality in this range of composition. It can also be seen that the curves approach ideality at the higher temperatures. The maximum deviation from ideality in this range, even at 910° C, is of the order of 0.2 N_{Mg}. These observations of Schneider and Esch corroborate the present work.

(4) Partial Molal Properties

From the values of the constants A and B shown in Table II, it can be shown that

$$\Delta\bar{H}_{Mg} = 4.576\ (A^\circ - A) \quad [5]$$

$$\Delta\bar{S}_{Mg} = 4.576\ (B^\circ - B), \quad [6]$$

where A° and B° refer to pure magnesium and A and B refer to different alloys. The partial free energies are calculated from the activities of magnesium from the formula

$$\Delta\bar{F}_{Mg} = RT \ln a_{Mg}. \quad [7]$$

The values of the three partial molal quantities thus obtained at 910° C are shown in Table II.

(5) Integral Quantities

The integral quantities can be calculated from the partial quantities by the graphical

0.1	−1.18	−3.37		−1.85	−2.2	−0.27	+0.23	−2.08

NOTE: (1) Obtained from graphical integration of $\Delta F = N_{Sn} \int_0^{N_{Mg}} \bar{F}_{Mg} d(N_{Mg}/N_{Sn})$.

(2) Obtained by graphical integration of $\Delta H = N_{Sn} \int_0^{N_{Mg}} \bar{H}_{Mg} d(N_{Mg}/N_{Sn})$.

(3) Results of Kawakami (38) at 880° C.

(4) Obtained from the equation $\Delta F = \Delta H - T\Delta S$.

(5) Obtained by graphical integration of $\Delta S = N_{Sn} \int_0^{N_{Mg}} \Delta\bar{S}_{Mg} d(N_{Mg}/N_{Sn})$.

(6) Obtained from the equation $\Delta F_{ideal} = RT(N_1 \ln N_1 + N_2 \ln N_2)$.

(7) Obtained from the equation $\Delta S_{ideal} = -R\,(N_1 \ln N_1 + N_2 \ln N_2)$.

(8) Obtained from the equation $\Delta S^M = \Delta S^{id}_{ideal} + \Delta S^{Ex}_{excess}$.

integration of the Duhem–Margules equation. For a two component system, the integral quantities can be expressed as

$$[8] \qquad \Delta X^{M} = N_B \int_0^{N_A} \Delta \bar{X}_A d\frac{N_A}{N_B},$$

where ΔX^{M} may be the heat, entropy, or free energy of formation.

Each of the three integral quantities are obtained by graphical integration of the above equation.

The integral values thus obtained are shown in Table III, along with the ideal entropies and free energies of mixing.

The ideal entropies and free energies are expressed by the equation

$$\Delta S^{id} = -R(N_1 \ln N_1 + N_2 \ln N_2),$$

$$\Delta F^{id} = RT(N_1 \ln N_1 + N_2 \ln N_2).$$

The values of excess entropies are also tabulated in Table III, obtained from the equation

$$\Delta S^{M} = \Delta S^{id} + \Delta S^{Ex}.$$

From the results obtained, it can be seen that the magnesium–tin system does not behave as a regular solution. It may be said that the magnitude of the integral quantities thus obtained indicates that the liquid magnesium–tin alloy forms non-ideal solutions and that some degree of order is present.

It is of interest to note here that Boltaks (3) concluded from electrical and magnetic studies of Mg_2Sn that the bonding must be a mixture of metallic and polar types.

(6) Comparison of Heats of Formation with Literature Values

Heats of formation of liquid Mg–Sn system at 800° C were obtained by Kawakami (4) by direct combination of the constituent metals at various compositions in a calorimeter. His results are shown in Table III. It can be seen that his results are less negative than those obtained in the present work. The heat of formation of solid Mg_2Sn is given by Kubaschewski (5) as -6100 ± 400 cal/g-atom at 20° C. Biltz and Holverschiet (6) also measured the heat of formation of solid Mg_2Sn at 20° C calorimetrically from the heats of solution in HCl $FeCl_3$/aq., and reported a value of $-20{,}000$ cal/g-atom. Kawakami's results give a value of -3.3 kcal for the formation of liquid Mg_2Sn at 800° C. From the values of Kubaschewski for the heat of formation of solid Mg_2Sn and that of Kawakami for liquid Mg_2Sn, the value of heat of transformation of solid Mg_2Sn to liquid Mg_2Sn at 800° C can be calculated to be $+2.6$ kcal.

Using Biltz's results, a heat of formation of liquid Mg_2Sn of -17.4 kcal is found. The present work shows a value of -7.5 kcal for the heat of formation of liquid Mg_2Sn at 910° C. Thus, the present value lies between that of Kawakami and Biltz.

It is estimated that the ΔF_{Mg} values are correct to about ± 100 cal at low concentrations of magnesium to ± 50 cal at high concentrations. ΔH_{Mg} values are correct to ± 600 cal at low concentrations of magnesium to ± 100 calories at high concentrations. The error in ΔS_{Mg} values is of the order of ± 0.5 to ± 0.05 cal/deg mole.

OXYGEN EVOLUTION FROM SODIUM HYPOCHLORITE SOLUTIONS

ABSTRACT

The rates of oxygen evolution from carefully purified solutions of sodium hypochlorite have been measured. Methods of purification are described, and it is found that substantially the same rate is observed regardless of the method of purification. The rate of oxygen evolution is proportional to the square of the concentration of hypochlorite ions. The effect of temperature and ionic strength are examined. The rate constant is 7.5×10^{-6} $(\text{g-mol/l.})^{-1}(\text{min})^{-1}$ at 60° C and an ionic strength of 3.5; the activation energy is 26.6 kcal/g-mol. These results are compared with the corresponding quantities for the reaction of hypochlorite ions to form chlorite and chloride ions, and some tentative explanations are offered.

In an earlier paper (1), one of the present authors examined the decomposition of aqueous sodium hypochlorite solutions, particularly the rate of decomposition to sodium chlorate and chloride. The accompanying reaction giving sodium chloride and oxygen was examined more superficially. Rates of oxygen evolution were observed on a number of solutions at that time, but it was never proved that the oxygen evolution could not be ascribed to the presence of traces of catalyst. The reasons for this uncertainty were as follows. Firstly, measurements on the catalyzed reaction (2) showed that the observed rates could be accounted for by the presence of copper in concentrations of the order of a μg/l. Secondly, the rates were somewhat variable. Thirdly, it was found that the observed rates were roughly proportional to the concentration of hypochlorite, and it is difficult to suggest a simple first-order mechanism for the uncatalyzed reaction. However, relatively low orders of dependence on hypochlorite concentration are observed for the catalyzed reaction, which suggests that these earlier solutions contained traces of catalyst. Finally, and perhaps the most convincing reason for believing some catalyst to be present, it was found that the apparent activation energy for oxygen evolution was 21 kcal/g-mol, less than the 24.8 kcal/g-mol found for the reaction giving chlorate and chloride; yet the latter is the predominant reaction.

Other workers have also examined this decomposition, though they usually did not separate the rates of the two reactions. Giordani (3) found a second-order gas evolution; but his conclusions about the reaction to chlorate had not been confirmed, so it seemed worth while to investigate the reaction in more detail.

EXPERIMENTAL PART

The main problem was to obtain sodium hypochlorite free from traces of catalyst. At present only cobalt, nickel, and copper are known to catalyze this decomposition, so that the methods of purification were directed towards the removal or complexing of these metals. It seemed much more promising to purify the sodium hypochlorite solution as opposed to the chlorine and sodium hydroxide solution from which it was made. The following general methods of purification, or at least of removal of catalyst, were employed:

(1) precipitation of a compound in the solution in the hope that any catalyst would coprecipitate with it;

[1]*Present address: Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Mass., U.S.A.*

(2) deactivation of the catalyst by means of a complexing agent;
(3) a combination of these methods, by precipitation of sodium periodate.
The details of the methods were as follows:

(1) Coprecipitation.—It was already known that precipitation of calcium carbonate in a sodium hypochlorite solution would carry down a considerable fraction of any copper, nickel, or cobalt present. In a typical run, 10 ml of 1.0 *M* sodium carbonate solution was added to about 1 liter of sodium hypochlorite solution, and an equivalent amount of calcium chloride solution was then added slowly with vigorous stirring. After standing of the solution for a short time, the precipitate was filtered off on a sintered-glass filter. In many runs this procedure was repeated, usually five times in all. Other precipitates were examined: magnesium hydroxide, lanthanum hydroxide, calcium fluoride, and barium sulphate. In each case the metal ion (i.e. barium, etc.) was added last. The amounts used were much the same as described above for calcium carbonate; i.e. 10 ml of 1.0 *M* solution of the metal being precipitated was added to 1 liter of sodium hypochlorite. Magnesium and lanthanum hydroxides were chosen because they might be similar to the chemical form of the catalytic metals; calcium fluoride and barium sulphate because they are very insoluble salts of fairly simple structure. In fact, magnesium hydroxide and lanthanum hydroxide were fairly efficient, but none of them was superior to calcium carbonate.

(2) Complexing agents.—A number of organic complexing agents were examined, the substances chosen all having the stability constant for the copper (II) complex greater than 10^4, and having chemical structures which would not be too easily attacked by hypochlorite ions. The complexing agents were tested by adding about 4 g to 1 liter of sodium hypochlorite. As it turned out, few resisted attack by the sodium hypochlorite for long, particularly if the solution was not very alkaline. Most of these compounds generate acid on oxidation, and as the pH fell the rate of gas evolution rose. Sulphosalicyclic acid acted as a moderately efficient complexing agent as long as the solution was alkaline. O-Phenanthroline behaved similarly. Salicyclic acid, ethylenediaminetetraacetic acid, acetylacetone, and 8-hydroxyquinoline were tested, but found to be useless. Consequently none of these provide a satisfactory method of purifying the solution.

(3) Precipitation of sodium periodate.—Since periodate ions form stable complex salts with copper, nickel, and cobalt, and since sodium periodate is relatively insoluble, the following method of purification was tried. Sodium iodate solution (containing some sodium hydroxide) was added to the sodium hypochlorite solution. This was then rapidly warmed to 80° C, when sodium periodate precipitated. The solution was cooled and filtered. This procedure could be repeated for more efficient purification. It was found that the solutions so treated gave relatively low rates of gas evolution, showing that this was an effective method. In a typical run 10 ml of 0.25 *M* sodium iodate was added to about 1 liter of approximately 1.5 *M* sodium hypochlorite, to which had been added enough sodium hydroxide to replace that used up in the precipitation of sodium periodate, $Na_2H_3IO_6$. The solution was heated, cooled, and filtered, as described above. This was done five times in all; however, the sodium hydroxide was only added once, but in sufficient quantity to keep the solution alkaline throughout.

Measurement of Oxygen Evolution

The rates of evolution of gas were measured simply by keeping a weighed amount (about 900 ml) of the solution at constant temperature, and measuring the rate of evolution of gas in a gas burette. This held up to 50 ml, and could be read to 0.05 ml. In calculating the rate of oxygen evolution, it was assumed that the gas was always saturated with water vapor at the temperature of the water jacket of the gas burette. The concentration of sodium hypochlorite was found at intervals by analysis of samples, and the initial solutions were completely analyzed so that the ionic strength could be computed. The methods of analysis were the same as those given in an earlier paper (4). The solution was stirred throughout the run, and no readings of gas volume were used in the calculations until the gas had been found to be coming off at a constant rate. The solutions had been largely freed of dissolved gas during the filtrations, and oxygen must build up to a certain degree of supersaturation before a steady rate is reached. This took a surprisingly long time, usually several hours, or even a day at lower temperatures. This initial retention of oxygen in the solution can lead to results which make the oxygen evolution appear to be first order, at least approximately, since the gas rate is lower than it should be in the early part of a run when the concentration of hypochlorite ions is high.

The results are given in Tables I and II. The results are presented in the form of the calculated rate constants. The second-order rate constant is obtained from the equation

$$d[O_2]/dt = 1/2K_0[OCl^-]^2$$

and the first-order constant from

$$d[O_2]/dt = 1/2K_0^*[OCl^-].$$

The factor of one half arises, as two hypochlorite ions produce one oxygen molecule. It is evident from an examination of Table I that the second-order rate constant stays constant, while the first-order does not. The rate constants quoted in Tables I and II are slightly approximate since it is impossible to obtain, in practice, an instantaneous value of the rate of gas evolution. The oxygen must be collected over a period

of time so that an average rate is obtained. The concentration of hypochlorite used in the calculation was obtained by plotting $[ClO^-]^{-1}$ against time, which gives a linear plot, and by using the value of $[ClO^-]^{-1}$ at the midpoint of the period of gas collection. It follows from the rate equations that the approximate value of K_0 (2nd order) is related to the true value by the equation

$$K_0(\text{approx.}) = K_0.\frac{[1+(3K_1/4+K_0/2)X_0t]^2}{[1+2(3K_1/4+K_0/2)X_0t]},$$

where t is the time interval during which gas was collected, K_1 is the rate constant of the reaction giving sodium chlorate, and X_0 is the initial concentration of hypochlorite ions. In no run did this approximation cause an error of more than 0.07%.

DISCUSSION OF RESULTS

The first point to note from Table I, as mentioned above, is that gas evolution from carefully purified sodium hypochlorite is in fact second order in hypochlorite ions. The method of purification is indicated in Table I, and purification by calcium carbonate or by sodium periodate precipitation gave the same result. The average value of K_0 at 60° C and 3.5 ionic strength is 7.5×10^{-6} (g-mol/l.)$^{-1}$min^{-1}. The concentrations of sodium hydroxide are given in Table I. These varied from about 0.1 M to 0.01 M, and within these limits there is no drift of rate with hydroxide ion concentration. This indicates that the reaction is one of hypochlorite ions, and not hypochlorous acid.

Measurements were made at other ionic strengths and other temperatures and these are given in Table II. The effect of ionic strength is as would be expected: it causes little change in K_0 at low ionic strengths, but a rise at high ionic strengths. A plot of log K_0 against $1/T$ is reasonably linear, and gives an activation energy of 26.6 kcal/g-mol at an ionic strength of 3.5. A slightly higher value is obtained at lower ionic strengths. This value (26.6 kcal) is larger than the activation energy of 24.8 kcal/g-mol found for the reaction

$$2ClO^- \rightarrow ClO_2^- + Cl^-.$$

If K_1 is the rate constant of this reaction, then

$$K_1 = 1.76 \times 10^{12} e^{-24,800/RT},$$
$$K_0 = 2.10 \times 10^{12} e^{-26,600/RT}, \text{ time in minutes.}$$

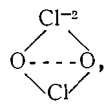
This is equivalent to saying that the entropy of activation of the two reactions is much the same (for K_0, $\Delta S^{\ddagger} = -12.5$ cal/deg, and for K_1, $\Delta S^{\ddagger} = -12.8$ cal/deg). This presumably indicates that the activated complex for the two reactions is somewhat the same sort of species in both cases: one might speculate that it consists of two ions close together but differently oriented; i.e.

[1] reaction to chlorite: $O^-—Cl—O^-—Cl$

[2] reaction to oxygen: $Cl—O^-—O^-—Cl$.

If the negative charge on the hypochlorite ion resides chiefly on the oxygen atom, this would make the second species less stable, as is required by experiment; in fact a simple model like this could account for a much larger difference in activation energy than is observed.

Another possibility is that the activated complex might have a cyclic structure and



this in fact could be the intermediate for either reaction. This would imply that the very small difference in the entropies of activation was due to experimental error. However, a compact structure like this seems less probable than one in which the atoms have not had to come so close together.

Some tentative calculations were also made on the relative energies of $OClOCl^{-2}$ and $ClOOCl^{-2}$ as intermediates. If it is assumed that the four electrons that previously formed the bonds in the two ions have become delocalized in σ-bonds extending over all four atoms, then application of Hückel's molecular orbital method (5) makes $OClOCl^{-2}$ more stable than $ClOOCl^{-2}$: the difference, using plausible values for the electronegativities of the atoms, is 0.35β. This difference will be offset to some extent by the greater proximity of the larger effective nuclear charges on the chlorines in $OClOCl^{-2}$. This conclusion is not dependent on the exact choice of values for the electronegativities, and hence for the Coulomb integrals for these atoms; provided chlorine and oxygen are different in this respect, $OClOCl^{-2}$ will be more stable. Consequently, if this picture of the activated intermediate state is correct, it explains the preferential formation of chlorite and chloride ions, as opposed to chloride ions and oxygen.

HEATS OF DILUTION OF POLYISOBUTYLENE SOLUTIONS

M. SENEZ[1] AND H. DAOUST
Department of Chemistry, University of Montreal, Montreal, Que.

Received December 18, 1961

ABSTRACT

The measurements of heats of dilution of polyisobutylene solutions in benzene, toluene, and chlorobenzene have been carried out with a Tian–Calvet microcalorimeter at 25° C. The dilution technique previously described has been improved and the extrapolated enthalpy parameter κ_1^* for each system has been corrected for the excluded volume effect using the Krigbaum–Carpenter–Kaneko–Roig formulation for the second virial coefficient A_2. No detectable variation in κ_1^* was found for high molecular weights ($\geqslant$43,000); but a definite increase in κ_1^* was found for very low molecular weights.

INTRODUCTION

In a preceding paper (1), a comparative study was made of the different treatments dealing with the effect of polymer–solvent interaction on viscosity. In this paper, statistical thermodynamic theory will be applied to calorimetric data of heats of dilution of the same systems.

It is now well known that lattice theories of polymer solutions fail to represent the behavior of thermodynamic functions, particularly for dilute solutions, where, contrary to experiment, they predict the chemical potential of the solvent to be practically independent of molecular weight; the necessary microscopic discontinuity of polymer concentration at high dilution is, of course, primarily responsible for this. The agreement is also not perfect in the case of concentrated solutions due to the inadequacy of a rigid lattice as a model for polymer solution theory.

Flory (2) was the first to propose a statistical mechanical calculation for the variation of the second virial coefficient A_2 with molecular weight, while Zimm (3), using the molecular distribution function formalism and Gaussian statistics for the configuration of a single chain, was able to calculate the molecular weight dependent double contact term in the expansion of the integral for A_2. Calculations of the higher-order contact terms of the series, taking into account the departure from purely Gaussian statistics, have been attempted (4, 5), and the results show that the series is slowly converging. Thus, several authors (6, 7) have tried to improve the original model of a uniform density equivalent sphere first used by Flory to represent the interacting molecules. Recently, a rather simple but ingenious theory was given by Krigbaum *et al.* (8) and was shown to predict very well the variation of A_2 with molecular weight.

Unfortunately, the calculation of the higher virial coefficients is not feasible. Fixman, in his recent theory (9), makes the parameters in the Gaussian potential of Flory and Krigbaum agree with the exact coefficient of the double contact term of A_2 and uses it to calculate the variation of osmotic pressure with concentration. This theory is certainly an improvement, but it is not in very good agreement with experiments (10), except with very good solvents. At present, it is rather difficult to predict the values of the thermodynamic functions except in infinitely dilute solutions. Also, it must not be forgotten that the theory is applicable only to high-polymer and not to short-chain solutions, although an important increase of the heat of dilution is observed in going from a high polymer to the dimer (see below).

[1]*Present address: Department of Chemistry, University of Manchester, Manchester, England.*

In this paper, we shall present our calorimetric data and show that the application of the new Krigbaum dilute solution theory gives results which are in good agreement with those of the intrinsic viscosity theory of Kurata and Yamakawa (5).

EXPERIMENTAL

The Tian–Calvet microcalorimeter and the dilution cell used have been previously described in the literature (11, 12). Originally, the partition cell was designed to have no vapor space and has been used accordingly as such at first. However, in this way the solution in the cell is stirred only in the bottom compartment and an important part of the heat of dilution is lost due to an incomplete dilution. To improve the mixing process, it is preferable to fill only half of the solution and solvent compartments. Since the variation of solvent activity is not rapid for polymer concentrations below 50%, the effect of vapor space is far less important than that of an incomplete dilution. The vapor pressure of the solvent above a high-polymer solution can be approximately calculated with the semiempirical Flory–Huggins equation

$$p_1/p_1^0 = \phi_1 \exp(\phi_2+\chi_1\phi_2^2), \qquad [1]$$

where p_1 and p_1^0 are the vapor pressures of the solvent above the solution and the pure solvent respectively, ϕ_1 and ϕ_2 are the volume fractions of solvent and polymer, and χ_1, an interaction parameter. The limits of the vapor phase correction, $\Delta H'$, are given by

$$K[(a_1'-1)V_U + (a_1'-a_1)V_L] < \Delta H' < K(1-a_1)V_L,$$

where $K = L_v^0 p_1^0/RT$, L_v^0 being the molar heat of vaporization of the pure solvent, V_U and V_L are the vapor phase volumes above the solvent and the solution respectively, and a_1 and a_1', the solvent activities before and after dilution. Since $V_U = V_L$ and $(a_1'-1) \cong -(a_1'-a_1)$, we have simply

$$0 < \Delta H' < K(1-a_1)V_L.$$

For example, in diluting a benzene solution from $\phi_2 = 0.4$ to 0.2, with $K = 0.042$ cal cm^{-3}, $V_L = 2$ cm^3, and $\chi_1 = 0.5$, we find $\Delta H' < 0.0006$ cal, whereas the heat of dilution is about 0.5 cal. Thus the vapor phase correction is not only small (for ϕ_2 below 0.5, of course) but also insensitive to the exact value of χ_1, so that it is necessary to have only a rough idea of the values of the solvent activities. That correction is evidently still smaller for less volatile solvents.

The heat of stirring is the most important correction, being of the order of 50% of the measured heat effect, but can be determined with surprising precision. Measurements were also performed using a stainless steel mesh cage, by a method previously described (13).

Materials

The polymer fractions used were obtained by a double fractional precipitation using the benzene–acetone pair at 25° C and originated from samples of "Vistanex" supplied by Enjay Co. Inc. Molecular weights were determined from viscosity measurements of their cyclohexane solutions.

The solvents used were reagent grade, which were distilled in a 30-theoretical-plate column and kept over "Drierite".

RESULTS AND DISCUSSION

If one assumes that the heat of dilution can be expressed as a power series of the volume fraction

$$\Delta\bar{H}_1 = RT\kappa_1^*\phi_2^2+RT\kappa_2^*\phi_2^3+\ldots, \qquad [2]$$

where the κ^*'s are the uncorrected enthalpy parameters for the chosen temperature (and molecular weight), then the integral heat of dilution is given by

$$\Delta H_d = (RTm_2\bar{v}_2/V_1)\,[\kappa_1^*(\phi_2-\phi_2')+\kappa_2^*(\phi_2^2-\phi_2'^2)/2+\ldots], \qquad [3]$$

where m_2 is the mass of polymer, $\bar{v}_2$ its specific volume, and V_1 the molar volume of the solvent. It is customary (12) to rewrite equation [3] and plot the results in terms of an apparent enthalpy parameter κ_a^* as a function of the average concentration $\bar{\phi}_2$:

$$\kappa_a^* = \Delta H_d V_1/RT\bar{v}_2 m_2(\phi_2-\phi_2') = \kappa_1^*+\kappa_2^*\bar{\phi}_2+\ldots. \qquad [4]$$

The third and higher coefficients of the power series in $\bar{\phi}_2$ are slightly higher than those defined in equation [2], the difference being greater the greater is $(\phi_2-\phi_2')$.

According to the dilute solution theory of Krigbaum *et al.* (8), the second virial coefficient can be given by the following equation:

$$A_2 = (\bar{v}_2/V_1)\psi_1(1-\theta/T)F(X,\rho), \qquad [5]$$

where ψ_1 and $\psi_1\theta/T$ are entropy and enthalpy parameters respectively. The factor $F(X,\rho)$ is related to the excluded volume effect, ρ^3 being the ratio of the number of long-range contacts to the total number of intramolecular contacts. It can be shown from equation [5] that κ_1^*, as actually extrapolated from heats of dilution measurements carried out at definite concentrations, is related to the real enthalpy parameter κ_1, by

$$\kappa_1^* = \kappa_1[F(X,\rho)+(T-\theta)(T/\theta)\partial F(X,\rho)/\partial T]. \qquad [6]$$

It can be seen from the results shown in Fig. 1 that, in concentrated solutions, κ_a^* is practically independent of molecular weight (if it is sufficiently large) in accordance with calorimetric measurements of heats of mixing on the same systems (14) and also

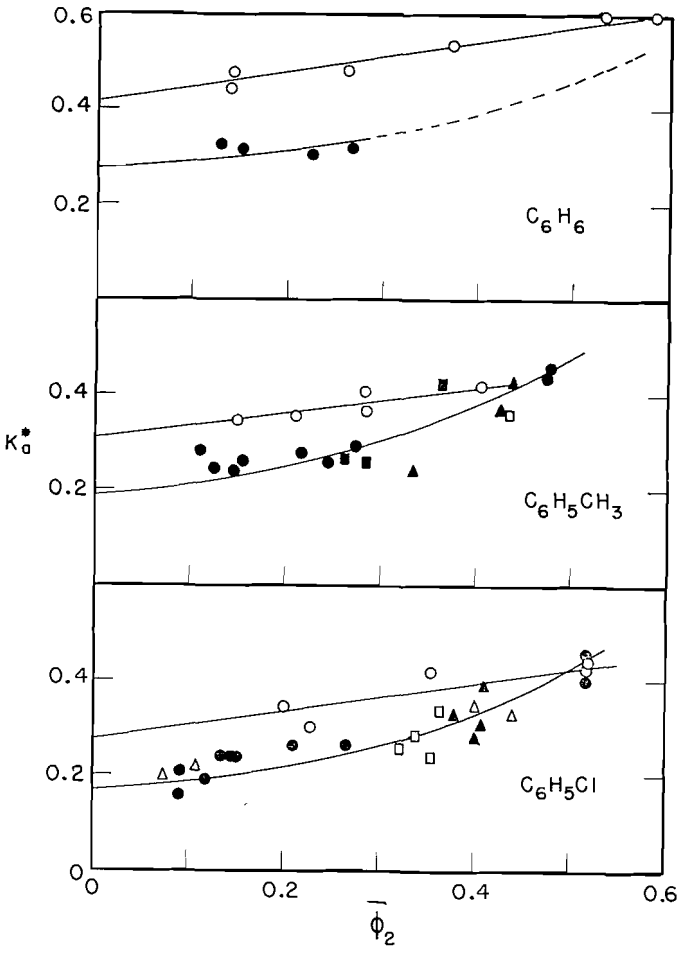

FIG. 1. The variation of the apparent heat parameter with the average volume fraction of polyisobutylene at 25° C. (Molecular weights: ○ 8,000; ● 43,000; △ 157,000; ▲ 270,000; □ 440,000; ■ 780,000.) The broken part of the curve for benzene has been drawn through the data obtained by the cage method; the data were taken from ref. 12.

with the predictions of the lattice theory. However, lattice theories cannot account quantitatively for the observed variation of thermodynamic functions. For instance, if one looks at the results covering the whole concentration range, the ratio $(\Delta\bar{S}_1 - R\phi_2/x)/\phi_2^2$ for polyisobutylene–benzene system obtained from the combined osmotic pressure data of Flory and Daoust (15) and vapor pressure data of Bawn and Patel (16), one sees that it is impossible to fit the results, because for small ϕ_2, the coordination number is smaller than 6 and for ϕ_2 larger than 0.5, it goes up to infinity. This is no doubt due to some kind of "melting" process in either component, and this has been observed before (17). Similarly, the enthalpy function cannot be fitted with a constant value for the coordination number. In dilute solution, a value of $\Delta\bar{S}_1$ or $\Delta\bar{H}_1$ corresponding to a coordination number smaller than 6 has been ascribed to back-coiling of the chain (18), but, since the theory ignores the important feature of discontinuity in polymer concentration in dilute solution (where it claims to apply), it cannot explain satisfactorily the thermodynamic functions. Fixman's theory predicts a variation of κ_a^* with concentration, but with a curvature in opposite sign to the observed one.

Turning now to the dilute solution theory, we observe first that the experimental value of κ_1^* for polyisobutylene–benzene at 25° C is around 0.28 and that it is equal to κ_1 or ψ_1 since the θ-temperature is 24.5° C and $F(X,\rho) = 1$ at θ. There is certainly a significant difference between the value 0.21 found previously (12) with no vapor space but insufficient stirring and the value 0.28 actually reported. This revised value 0.28 for ψ_1 agrees better than the value of 0.34 from osmotic measurements of Flory and Krigbaum (19) near the θ-temperature and also with that estimated from the Kurata–Yamakawa theory of viscosity (1). The value of κ_1 at the θ-temperature for polyisobutylene–benzene system can also be evaluated from the osmotic data of Flory and Daoust (15) at 25° C and 50° C. The calculated value at 37.5° C is 0.19 and it can be shown (20) that $d\kappa_1^*/dT$ for that system near the θ-temperature is given by

$$d\kappa_1^*/dT = -2\times10^{-5}M^{\frac{1}{2}}. \qquad [7]$$

With $M = 84{,}000$, $d\kappa_1^*/dT = 0.006$; then $\kappa_1^* = 0.26$ at 25° C, a value in agreement with those given above.

The General Case: Polyisobutylene in Chlorobenzene and in Toluene at 25° C

It has been shown in the preceding paper (1) that for these two systems θ and ψ_1 are almost the same. Since at 25° C, these systems are 37° C above θ, κ_1 should be estimated through the use of equation [6]. For weak interactions, i.e. for temperature ranging from θ to $\theta+16°$, $F(X,\rho)$ can be replaced by the $F(z)$ factor given by the Kurata–Yamakawa theory where $z = X\alpha^3/3^{3/2}$, but in the present case, it is better to use the tabulated values of $F(X,\rho)$ of Krigbaum *et al.* with $\rho = 0.3$ and X being computed according to a semiempirical method described previously (1). The estimated calorimetric values for κ_1 are 0.29 and 0.31 for PIB–chlorobenzene and PIB–toluene respectively.

Variation of κ_1^* with Molecular Weight

Since $F(X,\rho)$ is molecular weight dependent, κ_1^* should decrease with increasing molecular weight. However, it is difficult to detect this variation experimentally because of the difficulty of using molecular weights higher than about 2×10^5 in the calorimetric method due to the rapid increase in the viscosity of the solutions. For instance, the theoretically predicted decrease in κ_1^* for molecular weights between 43,000 and 157,000 is 0.02 and that variation is comparable with the experimental error in κ_1^*. However, Fig. 1 and Table I show that κ_1^* really increases when one goes to very low molecular weights and to the dimer.

TABLE I

Heat of dilution parameters κ_1* for polyisobutylene solutions at 25° C

Molecular wt.	Benzene	Toluene	Chlorobenzene
Dimer*	1.18	0.77	0.83
8,000	0.42	0.31	0.28

DERIVATIVES OF MONOGERMANE

PART II. PREPARATION AND PROPERTIES OF GERMYL PSEUDOHALIDES AND RELATED COMPOUNDS[1, 2]

ABSTRACT

Germyl isocyanate, isothiocyanate, and acetate have been prepared in almost quantitative yield by the interaction of germyl bromide with silver cyanate, thiocyanate, and acetate, respectively. Some of the physical properties of these new germyl derivatives are reported, and their thermal decompositions at moderate temperatures are described. The reaction of germyl bromide with silver oxide or carbonate produces germanium(II) hydride and water instead of digermoxane. Germyl bromide reacts with silver nitrite, forming germane, nitrous oxide, and nitric oxide as the only volatile products.

INTRODUCTION

Only 24 volatile compounds containing the germyl group (GeH_3—) have been reported up to the present time. These are of three main types: (i) binary hydrides, Ge_nH_{2n+2}, with $n = 1$ up to 5 (1–5), (ii) monohalides GeH_3X, with X = F, Cl, Br, I (6–9), and (iii) monoalkylgermanes (10–12). Vinylgermane (13), germyl cyanide (14), and digermthian (8) have also been prepared. By contrast, about 50 silyl (SiH_3—) compounds were known up to 1956 when MacDiarmid (15) reviewed their chemistry. Several of these were first obtained by the action of silyl halides on silver salts. In this paper we describe the reactions of germyl chloride and bromide with some silver salts. Our object has been the preparation of new compounds containing the germyl group and to compare their properties with analogous silyl derivatives.

RESULTS AND DISCUSSION

Preparation of Germyl Derivatives

In our attempts to prepare new germyl compounds we followed the pattern suggested by the following silver salt conversion series for silyl compounds, as proposed by MacDiarmid (15):

$$(SiH_3)_2Te \rightarrow SiH_3I \rightarrow (SiH_3)_2Se \rightarrow (SiH_3)_2S \rightarrow SiH_3Br \rightarrow$$
$$SiH_3Cl \rightarrow SiH_3CN \rightarrow SiH_3NCS \rightarrow SiH_3NCO \rightarrow (SiH_3)_2O \rightarrow SiH_3F.$$

By reaction with the appropriate silver salt, any compound in this series can be converted into any other following it but not into one preceding it. This conversion series is similar to those described earlier for trialkylsilyl (16) and trialkylgermyl (17) compounds.

Contrary to the above series, we found that neither germyl chloride nor germyl bromide reacted with silver carbonate or oxide to yield digermoxane, $(GeH_3)_2O$. However, this

[1]*Financial assistance for this work was received from the National Research Council. Parts of this work were described at the 42nd Annual Conference of the Chemical Institute of Canada, Halifax, N.S., May 25–27, 1959, and at the Annual Meeting of the Royal Society of Canada, Montreal, June 3–7, 1961.*

compound might have been an unstable intermediate in the following observed reactions:

$$2GeH_3Br + Ag_2CO_3 \rightarrow [(GeH_3)_2O] + 2AgBr + CO_2$$
$$\downarrow$$
$$2GeH_2 + H_2O$$
$$\uparrow$$
$$2GeH_3Br + Ag_2O \rightarrow [(GeH_3)_2O] + 2AgBr.$$

Sujishi (8) reported that germyl iodide reacts with silver oxide or mercuric oxide to produce digermoxane, but it decomposes during purification into germane and water as the only volatile products. More recently, Sujishi and Goldfarb (18) claimed the detection of digermoxane by infrared spectral measurements on the hydrolysis products of germyl cyanide, but they could not isolate pure digermoxane. The apparent instability of germyl ethers containing Ge—H bonds is further evident from the recent observations that (i) hydrolysis of *n*-butylbromogermane does not yield the expected 1,1′-di-*n*-butyldigermoxane (19) and (ii) interaction of methylbromogermane with silver carbonate does not give 1,1′-dimethyldigermoxane (20). By contrast, stable silyl ethers with Si—H bonds are easily obtained by the reaction of silyl halides with either water or silver carbonate (15, 21, 22).

In agreement with the silyl conversion series, we found that germyl bromide reacted with silver cyanide to produce germyl cyanide, GeH_3CN. However, we could not isolate a pure sample due to its decomposition at 25° in the presence of an unidentified impurity. Sujishi and Keith (14) obtained pure germyl cyanide from the reaction of germyl bromide with silver cyanide. The infrared spectrum of pure germyl cyanide reveals that, like silyl cyanide (23), it exists mainly in the normal form at room temperature (24, 25).

The fact that germyl bromide is more reactive than the chloride toward silver salts is evident from our observation that germyl bromide but not germyl chloride reacted with silver cyanate to produce germyl isocyanate, GeH_3NCO. The iso structure, confirmed by its infrared spectrum (24), is not surprising because cyanic acid and its esters have the iso structure. Covalent normal cyanates have not yet been detected, presumably because they are thermodynamically unstable with respect to their iso forms. Interestingly, silyl isocyanate, SiH_3NCO, has not yet been isolated, though MacDiarmid tried to prepare it by the reaction of silyl iodide with silver cyanate; he obtained silicon tetraisocyanate instead (26).

As expected, germyl bromide reacted with silver thiocyanate to form germyl isothiocyanate, GeH_3NCS, in high yield. This is similar to the preparation of silyl isothiocyanate from silyl iodide and silver thiocyanate. Infrared spectra of germyl and silyl isothiocyanates confirm their iso structures (24, 27).

We found that other silver salts, such as silver acetate and nitrite, reacted with germyl bromide. Thus, germyl acetate was obtained conveniently by the reaction of germyl bromide with silver acetate. Germyl nitrite was probably an unstable intermediate in the reaction between germyl bromide and silver nitrite which produced germane, nitrous oxide, and nitric oxide as the only volatile products.

Thermal Decomposition of Germyl Derivatives

Germyl isocyanate, isothiocyanate, and acetate were stable at ambient temperatures, but they decomposed at higher temperatures (50–200°) into polymeric germanium(II) hydride and the corresponding hydroacid, as represented by the equation

$$xGeH_3X \rightarrow (GeH_2)_x + xHX,$$

where X = NCO, NCS, or $OCOCH_3$. Germanium(II) hydride decomposes in a complex manner, yielding hydrogen, germane, germanium, and $(GeH)_x$, in amounts which depend on the temperature and duration of heating (28, 29). Germyl fluoride, like silyl halides (15), disproportionates at 25°, yielding germane and difluorogermane in equimolar quantities (6):

$$2GeH_3F = GeH_4 + GeH_2F_2.$$

Germyl chloride, however, decomposes at room temperature as follows (7):

$$2GeH_3Cl = GeH_4 + 2HCl + Ge.$$

As yet there is no quantitative data for the thermal decomposition of germyl bromide and iodide.

The fact that germyl halides and pseudohalides are less stable than the corresponding silyl compounds might be attributed to a difference in the polarities of the Ge—H and Si—H bonds in these compounds. Germanium and silicon have almost identical electronegativities, 1.90 and 2.00 respectively (30, 31), and their tetracovalent radii are not appreciably different, 1.17 and 1.22 Å, respectively (32). In spite of these similarities, the dipole moments of germyl chloride (2.12 D) and silyl chloride (1.30 D) differ significantly (33). These values suggest that the Ge—Cl bond is more polar than the Si—Cl bond. This might be due, in part, to the lesser tendency of germanium to use its vacant 4*d*-orbitals in d_π–p_π partial double bonding with the chlorine atom. If this is true, the electron-withdrawing effect of the chlorine atom might make the hydrogen atoms, also bonded to germanium, electropositive with respect to germanium and hence more susceptible to nucleophilic attack than the hydrogen atoms bonded to silicon, which are electronegative with respect to silicon. We believe that this protonic (or acidic) nature of the hydrogen atoms in germyl halides and pseudohalides accounts for their lesser thermal stability compared with their silicon analogues. Replacement of all hydrogen atoms in germyl halides and pseudohalides with electron-releasing methyl groups gives trimethylgermyl halides and pseudohalides which are known to be more stable thermally than the corresponding germyl derivatives (34, 24).

EXPERIMENTAL

Apparatus and Methods

The apparatus, techniques, and measurements of vapor pressure, molecular weight (M), and melting point have been described in a previous paper (20). In each reaction of germyl chloride or bromide with a silver salt, the vapor of the halide was passed slowly through a column loosely packed with a mixture of the dry salt and powdered glass wool.

Materials

Germane was prepared by the reduction of an aqueous acidic solution of germanium dioxide with sodium borohydride. Piper and Wilson (35), who first described this method, reported yields of germane in the range 60–75%. We obtained yields of 90–95% by allowing the reduction to occur at 35° instead of at 0°.

Germyl chloride was obtained by the reaction of germane with hydrogen chloride in the presence of aluminum(III) chloride as catalyst (7). It was separated from the mixture of products by several distillations at −96° (20% yield). (Found: M, 110.5; v.p. 69.7 mm at −23.6°; lit. (7) v.p. 70.2 mm at −23.6°. Calc. for GeH_3Cl: M, 111.1.)

Germyl bromide can be prepared by the reaction of germane with hydrogen bromide using aluminum(III) bromide as catalyst (7), but the yield is usually less than 10%. Yields of 60–90% were obtained by the reaction of germane with bromine, using a method similar to that described by Sujishi and Witz (36) for the preparation of silyl bromide. In one of our typical preparations bromine (7.9 mmole) was condensed in successive small portions onto germane (8.1 mmole) cooled to −196°. After each addition of bromine the mixture was warmed slowly until the color of bromine just disappeared, then the mixture was frozen again before the next addition of bromine. Germyl bromide was recovered from the product mixture by several distillations at −78° (91% yield). (Found: M, 156.0; v.p. 25.7 mm at −23°; lit. (7) v.p. 25.0 mm at −23°. Calc. for GeH_3Br: M, 155.5.)

The silver salts Ag_2O, Ag_2CO_3, AgOCN, and AgSCN were prepared by treating aqueous solutions of silver nitrate with equivalent amounts of aqueous NaOH, Na_2CO_3, KOCN, and NH_4SCN, respectively. Commercial samples of AgCN, $AgC_2H_3O_2$, and $AgNO_2$ were used. All silver salts were dried in a high vacuum for several days before they were used.

Reactions of Germyl Chloride

(a) With Silver Cyanide

Upon reaction with germyl chloride (1.50 mmole) at 25°, silver cyanide changed from white to brown, and a volatile material, which sublimed without melting, resulted. This volatile product was separated by distillation at −80° into: (i) a distillate (0.78 mmole) (found: M, 49.2) which was mainly hydrogen cyanide (calc. M, 27.0), as evident from its infrared spectrum and (ii) a residue which was crude germyl cyanide (0.62 mmole) (found: M, 100.1; calc. for GeH_3CN: M, 101.6). The molecular weight of the crude germyl cyanide decreased from 100.1 to 48.4 after it had been kept at 25° for 16 hours, and its vapor pressure became 89.1 mm at −22.9°, slightly higher than that of pure hydrogen cyanide (lit. (37) v.p. 85.2 mm at −22.9°). A non-volatile, yellow amorphous powder, undoubtedly germanium(II) hydride, remained on the walls of the storage bulb after the hydrogen cyanide had been removed. Evidently the crude germyl cyanide contained impurities, probably germyl chloride and hydrogen cyanide, which catalyzed its decomposition at 25° into hydrogen cyanide and germanium(II) hydride, as represented by

$$x\mathrm{GeH_3CN} \rightarrow (\mathrm{GeH_2})_x + x\mathrm{HCN}.$$

(b) With Silver Carbonate

Silver carbonate changed gradually from greenish-yellow to black when it reacted with germyl chloride (1.91 mmole). The condensable products consisted of carbon dioxide (0.28 mmole) (found: M, 44.3; calc. for CO_2: M, 44.0) and unchanged germyl chloride (1.43 mmole) (found: M, 106.9; calc. for GeH_3Cl: M, 111.1). Digermoxane $(GeH_3)_2O$, the expected product, was not obtained. The ratio of consumed germyl chloride to carbon dioxide produced was 1.72:1, rather than 2:1, as would be expected if the reaction

$$2\mathrm{GeH_3Cl} + \mathrm{Ag_2CO_3} \rightarrow \mathrm{GeH_2} + \mathrm{H_2O} + \mathrm{Ag_2O} + \mathrm{CO_2}$$

had occurred exclusively. Additional carbon dioxide probably resulted from thermal decomposition of some silver carbonate.

(c) With Silver Oxide

There was no noticeable change when germyl chloride (2.18 mmole) was passed 12 times through a column of dry silver oxide. Hydrogen was not produced and the recovery of germyl chloride (2.07 mmole) was almost quantitative. Therefore, no reaction occurred between germyl chloride and silver oxide.

Reactions of Germyl Bromide

(a) With Silver Cyanate

An exothermic reaction between germyl bromide (2.63 mmole) and dry silver cyanate produced germyl isocyanate in almost quantitative yield (2.43 mmole, 93% yield). (Found: M, 116.7; v.p. 27.7 mm at 0°. Calc. for GeH_3NCO: M, 117.6.) This new compound melts at $-44.0\pm0.5°$ and its vapor pressures in the range −23° to 23° are given by $\log_{10} p_{mm} = 8.369-(1891/T)$, which gives an extrapolated boiling point of 71.5°, a latent heat of vaporization of 8651 cal mole^{-1}, and a Trouton constant of 25.1.

Germyl isocyanate (2.24 mmole) did not decompose when heated for 40 hours at 110°, but after 12 hours at 200–220°, a lustrous silvery mirror of metallic germanium appeared uniformly on the walls of the flask. The volatile products were: (i) hydrogen (0.20 mmole), (ii) cyanic acid (0.21 mmole) (found: M, 44.1; v.p. 18.7 mm at −45°; lit. (38) v.p. 18.4 mm at −45°; calc. for HNCO: M, 43.0), and (iii) unchanged germyl isocyanate (1.99 mmole). Only 10% of the original germyl isocyanate decomposed and the ratio of hydrogen to cyanic acid was approximately 1:1; the ratio of decomposed germyl isocyanate to either hydrogen or cyanic acid was also about 1:1. These facts indicate that decomposition of germyl isocyanate occurred according to the equation

$$\mathrm{GeH_3NCO} \rightarrow \mathrm{Ge} + \mathrm{H_2} + \mathrm{HNCO}.$$

(b) With Silver Thiocyanate

Germyl bromide (2.08 mmole) and dry silver thiocyanate gave an exothermic reaction which yielded germyl isothiocyanate almost quantitatively (2.01 mmole, 97% yield). (Found: NCS, 43.6%. Calc. for GeH_3NCS: NCS, 43.33%.) This new germyl derivative has a melting point of $18.6\pm0.3°$ and its vapor pressures in the range 19 to 50° are given by $\log_{10} p_{mm} = 8.268-(2280/T)$, which indicates a latent heat of vaporization of 10.4 kcal mole^{-1}, an extrapolated boiling point of 150°, and a Trouton constant of 24.6. After germyl isothiocyanate (3.13 mmole) was heated for 20 hours at 55°, it decomposed completely into germane (1.07 mmole) (found: M, 77.2; calc. for GeH_4: M, 76.6) and a yellow, non-volatile residue. This residue did not dissolve in carbon disulphide, indicating that it did not contain free sulphur. The residue was non-homogeneous and could not be analyzed. It probably consisted of polymeric thiocyanic acid and solid germanium hydrides.

The ratio of decomposed germyl isothiocyanate to germane was approximately 3:1, as one might expect if decomposition had occurred according to the following scheme:

$$GeH_3NCS \rightarrow GeH_2 + HNCS,$$
$$3GeH_2 \rightarrow GeH_4 + 2GeH,$$
$$xHNCS \rightarrow (HNCS)_x.$$

(c) With Silver Oxide

Germyl bromide (4.20 mmole) reacted completely with silver oxide, producing carbon dioxide (0.27 mmole) (found: M, 44.7; calc. for CO_2: M, 42.0) and water (2.63 mmole) (found: M, 19.0; v.p. 12.6 mm at 15°; lit. (39) v.p. 12.8 mm at 15°; calc. for H_2O: M, 18.0), but no digermoxane. Evidently the main reaction was

$$2GeH_3Br + Ag_2O \rightarrow 2GeH_2 + 2AgBr + H_2O,$$

and the additional water (0.53 mmole) probably came from the silver oxide, which may not have been completely dry even though it had been evacuated for several days.

(d) With Silver Carbonate

Germyl bromide (2.31 mmole) was completely consumed in a highly exothermic reaction with silver carbonate. Digermoxane, the expected product, was not found among the products, which were carbon dioxide (7.46 mmole) and water (2.01 mmole). The reaction appeared to be

$$2GeH_3Br + Ag_2CO_3 \rightarrow 2GeH_2 + 2AgBr + CO_2 + H_2O.$$

The excess carbon dioxide undoubtedly resulted from the thermal decomposition of silver carbonate and the additional water probably came from the incompletely dry silver carbonate.

In another experiment the reaction between germyl bromide (1.84 mmole) and silver carbonate was allowed to occur at −28° for 5 hours. Again carbon dioxide (2.36 mmole) and water (0.90 mmole) were the only products. This time, the ratio of consumed germyl bromide to water was almost exactly 2:1, in accord with the above equation for the overall reaction.

(e) With Silver Acetate

Germyl bromide (3.20 mmole) reacted completely with dry silver acetate to form germyl acetate (3.07 mmole, 96% yield). (Found: M, 136.1; $C_2H_3O_2$, 43.6%; v.p. 9.7 mm at 0°. Calc. for $GeH_3C_2H_3O_2$: M, 134.7; $C_2H_3O_2$, 43.85%.) This new compound has a melting point of 12.8±0.1° and vapor pressures in the range −10 to 40° expressed by $\log_{10} p_{mm} = 9.227 - (2256/T)$, which gives a latent heat of vaporization of 10.3 kcal mole^{-1}, an extrapolated boiling point of 82.4°, and a Trouton constant of 30.0.

The yellow deposit which appeared after germyl acetate (1.80 mmole) was heated for only 10 minutes at 100–110° became orange-red after 16 hours of heating. The volatile products were: (i) hydrogen (1.09 mmole) and (ii) a mixture (1.38 mmole) (found: M, 95.6) of acetic acid (calc. M, 60.0) and germyl acetate (calc. M, 134.7) which could not be separated by fractional distillation. Assuming ideal gaseous behavior, we estimated that this mixture contained 0.72 mmole acetic acid and 0.66 mmole undecomposed germyl acetate. These results indicate that decomposition occurred to an extent of about 60%, probably according to the following scheme:

$$GeH_3C_2H_3O_2 \rightarrow GeH_2 + HC_2H_3O_2,$$
$$2GeH_2 \rightarrow 2GeH + H_2.$$

(f) With Silver Nitrite

The interaction of germyl bromide (1.87 mmole) with dry silver nitrite for 5 hours at −28° resulted in darkening of the silver nitrite and in complete consumption of germyl bromide. The volatile product mixture consisted of: (i) a fraction (0.69 mmole) (found: M, 65.4) which was shown by infrared measurements to be a mixture of germane (calc. M, 76.6) and nitrous oxide (calc. M, 44.0), (ii) nitric oxide (1.31 mmole) (found: M, 31.5; calc. for NO: M, 30.0), and (iii) water (0.88 mmole). There was no evidence of the expected germyl nitrite.

ACKNOWLEDGMENTS

We thank the National Research Council for a Postdoctorate Fellowship (to T. N. S.), two Studentships (to J. E. G.), and an Annual Grant (to M. O.). We are grateful to Mrs. P. Hayden (née Hilary Thomas) for technical assistance.

COMPLEXES BETWEEN LAMELLAR STRUCTURES AND BROMINE, IODINE CHLORIDE, AND CHROMYL CHLORIDE[1]

J. G. HOOLEY

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received May 12, 1961

ABSTRACT

Isotherms of Br_2 on four sizes of natural graphite crystals were measured with a recording vacuum balance. For 0.02- to 2-mm crystals, capillary condensation near saturation was small but significant, surface adsorption was negligible, and the composition $C_{16}Br_2$ was independent of pressure from 0.9 to 0.5. For the 0.002- to 0.01-mm crystals capillary condensation near saturation and surface adsorption were much greater, there was less intercalation than in the larger crystals, and there were no pressure-independent compositions. These effects of crystal size on the isotherm are believed to account for many of the variations in the reported compositions of lamellates in general and show that the complete isotherm on natural crystals at least 0.02 mm across should be determined. When this was done, there were pressure-independent compositions of $C_{16}Br_2$, $C_{16}ICl$, C_8ICl, and about $C_{40}CrO_2Cl_2$. In the latter case the longer the intercalated material remained in the structure the less of it diffused out on reducing the pressure to zero, until finally, none left. For these three adducts there were threshold partial pressures below which no intercalation occurred of 0.05 for Br_2, 0.03 for ICl, and 0.25 for CrO_2Cl_2 at 20° C. The adsorption curves above these pressures gave isosteric heats of 11, 12, and 13 kcal mole^{-1}. For a mixture of 0.02- to 2-mm crystals the rate of absorption of Br_2 or ICl at saturation was inversely proportional to composition for the first third of the reaction and was reproduced in subsequent runs on the same sample. The diffusion coefficient for this initial portion for ICl was three times the value for Br_2.

Isotherms of the three adducts on BN and MoS_2 showed no conclusive evidence for intercalation.

INTRODUCTION

Various workers have reported the intercalation of graphite by these three materials. The evidence for separation of the carbon layers has been X-ray data and exfoliation on rapid heating of the "compound" or lamellate. Compositions are usually reported as atomic ratios and these will be used in the following discussion although it is realized that proof of compound formation is often lacking. The reported composition in the saturated vapor varies. Thus, in Br_2 the usual value is C_8Br (1) but Herold (2) reports $C_{10}Br$ with an Acheson artificial graphite and Reyerson (3) reports 33% bromine (same as in $C_{13}Br$) with a purified natural graphite. Intercalation by ICl was first reported by Hennig (4), who found a 73% weight increase in Acheson pitch bonded artificial graphite suspended in vapor over the liquid at room temperature. He did not report it as an atomic ratio because the ICl was probably not stoichiometric. Rüdorff (5) reported $C_{5.4}ICl$ in graphite powder in saturated vapor at 30° C. Intercalation by CrO_2Cl_2 was first reported by Croft (6, 7), who heated the liquid with 65–100 mesh natural graphite for 4 hours at 100° C and obtained $C_{17}CrO_2Cl_2$, which exfoliated on heating. This was confirmed by Rüdorff (5), who found a maximum composition of $C_{12}CrO_2Cl_2$ if liquid were used but only $C_{130}CrO_2Cl_2$ for the vapor.

The purpose of the present work was to study the complete isotherms of these three adducts on graphite crystals of various sizes in the hope that variations of the above sort could be explained. These results were then to be applied to the interpretation of the isotherms on two other lamellar structures—BN and MoS_2. Thus, Croft (7) reported intercalation of BN by $FeCl_3$ and certain other compounds but not by Br_2 at 75° C. Rüdorff (8) was unable to verify any of these intercalations and confirmed the non-

[1]*Financial assistance from the National Research Council of Canada was received for this work.*

intercalations by Br_2. Rüdorff (9) has reported intercalation of MoS_2 by alkali metals.

Finally, rate measurements of some of the above processes were planned to help interpret the mechanism of intercalation.

MATERIALS

Natural graphite.—The four sizes will be designated.

Gr I—flakes of 1–2 mm from a deposit near Willsboro, N.Y., U.S.A.;

Gr II—spectroscopic carbon SP–1 from the National Carbon Co., Cleveland, Ohio. These are purified natural flakes 0.02–0.10 mm across;

Gr III—Gr II ball milled 37 hours in air to flakes of 0.01 mm;

Gr IV—Gr II ball milled 112 hours in air to flakes of 0.002 mm.

The porcelain mill contained a single flint pebble rolling in a groove of the same size. The flake sizes are those of the specks in a slurry with ethanol between two slide covers viewed through a microscope with a 0.01-mm scale.

Carbon blacks.—These were from G. Cabot Inc., Cambridge, Mass., U.S.A. Spheron 6 2700°—80-Å crystals in 300-Å blocks. Sterling MT 3100°— >200-Å crystals in 5000-Å blocks. The crystal sizes were estimated from X-ray line broadening and the sizes of the blocks of crystals from electron microscopy by the supplier (10).

Boron nitride.—A white powder supplied by the Norton Co. of Niagara Falls, Canada, with the following data (11) was used: a bulk density of 0.1 g ml^{-1} with particles 0.001 mm in average diameter plus some thin plates up to 0.026 mm across and rods 0.0005 mm in diameter×0.020 mm long. It had been fired at 2000° C and was 98% BN by their N analysis.

Molybdenum disulphide.—A powder, designated Moly-Paul No. 3, was supplied by K. S. Paul Ltd. of London, England, with the following analysis: Mo 59.0%, S 39.3%, plus less than 0.1% of each of Fe, Cu, and SiO_2. The particle size was determined in ethanol suspension to be 0.002 mm. Also, 3-cm chunks from Climax Molybdenum Co., New York, U.S.A., were used.

Bromine.—Reagent grade bromine was used and the middle fraction from a distillation was redistilled under vacuum into the balance reservoir.

Iodine chloride.—Commercial material was distilled and the middle 50%, which came over at 101° C at 760 mm, was redistilled under vacuum into the balance reservoir.

Chromyl chloride.—Chromyl chloride was supplied by the Allied Chemical and Dye Corp. of New York. It was distilled, the middle 50% being collected at 116° C and 760 mm and redistilled under vacuum into the balance reservoir. Its measured vapor pressure at 20° C was 1.7 cm and at −1.2° C, 0.45 cm. The reported m.p. is −96.5° C.

METHOD

The recording vacuum thermobalance and spoon gauge developed in this laboratory (12, 13) were used to determine the isotherms and rates of absorption. The sensitivities used were 1 to 5 mv mg^{-1} for weight and 50 mv cm^{-1} for pressure. The sample weight was chosen so that the expected change would be within the 300 mv linear output range of the balance and was therefore usually about 0.2 g for graphite. The weighed sample was sealed in the balance, the system was evacuated with a mercury diffusion pump, and liquid N_2 was placed around the trap next to the pump. After several hours or when the weight was steady the tap between the balance and the trap was closed and adduct was admitted to the desired pressure from the reservoir. Pressure was reduced at any stage by opening the tap to the trap. At the end of a run this trap, which was connected

by a tapered joint, was removed and cleaned. All taps in contact with adduct were greased with Kel F and held a vacuum of 10^{-5} cm for at least a week.

For temperatures above 20° C the reactor tube was immersed in an oil bath thermostated to 0.1° C. For temperatures from 20 to −27° C a special reactor tube was used with a jacket through which ethylene glycol was pumped from an Aminco low-temperature thermostated bath, again 0.1° C. An improved method of quickly damping spring oscillations was developed. It consisted of an arc-shaped glass fiber attached to a small glass tube resting in a side arm. An iron core was sealed in this glass tube so that an external magnet would move the fiber horizontally to or from the vertical suspension fiber to the sample bucket.

Because CrO_2Cl_2 is said to be light sensitive the whole apparatus was shielded with black cloth when used with that substance. After 2 months of use no decomposition products could be seen inside the system.

The graphite chromyl chloride lamellates were analyzed for Cl by first oxidizing the sample with pure O_2 in a 500-ml Schoniger flask (14) using 10 ml H_2O, 1 ml 2 *N* NaOH, and 3 drops 30% H_2O_2 as an adsorbent. Combustion was complete for samples less than 20 mg. The solution was boiled, acidified to Methyl Red with HNO_3, and boiled with 0.2 g $CaCO_3$. The cold solution plus 1.5 ml 1 *M* K_2CrO_4 was titrated with 0.01 *N* $AgNO_3$. The observation of the red end point in the yellow solution was found to be much easier if a pair of glassblower's goggles was worn during the titration. The didymium glass absorbs the yellow only. All runs were in triplicate.

RESULTS AND DISCUSSION

I. Bromine

1. Graphite and Carbon Black

a. High Relative Pressure

Previous workers refer to compositions in a vapor close to or at saturation without specifying all the experimental conditions. Accordingly, the following studies were made to evaluate the various factors that determine partial pressures near unity. Reproducible high partial pressures that could be roughly estimated were obtained by suspending the sample 1 cm from the bottom of a 2-cm diameter reaction tube which was thermostated over the bottom 12 cm at some temperature between 20° C and −27° C in a room at 22 to 24° C. The system was evacuated to 10^{-5} cm and bromine was admitted until a layer of liquid was present. Now although liquid is present only 1 cm below the sample, the partial pressure of vapor in the sample is not necessarily unity. The following data are presented to show the extent to which it approaches this value when the temperature differential between the room and the jacket is decreased or when the length of the jacketed portion is increased or when visible radiation is excluded. These are all variations that decrease the heat transfer to the bromine or to the sample and which therefore increase the partial pressure in the sample.

Temperature differential.—For the usual 12 cm of jacket length and with the reactor tube in darkness, the bromine uptake is plotted in Fig. 1 against jacket temperature for two carbon blacks and graphite Gr I. The measured bromine pressure is also marked along the abscissa. The degree of saturation at the lower temperatures can be estimated by reference to the actual isotherms of the two carbon blacks at 20° C, assuming that at a given partial pressure the uptake is the same at 20° as at, say, −10° C. These approximate values are marked on the abscissa. Although they are not known precisely,

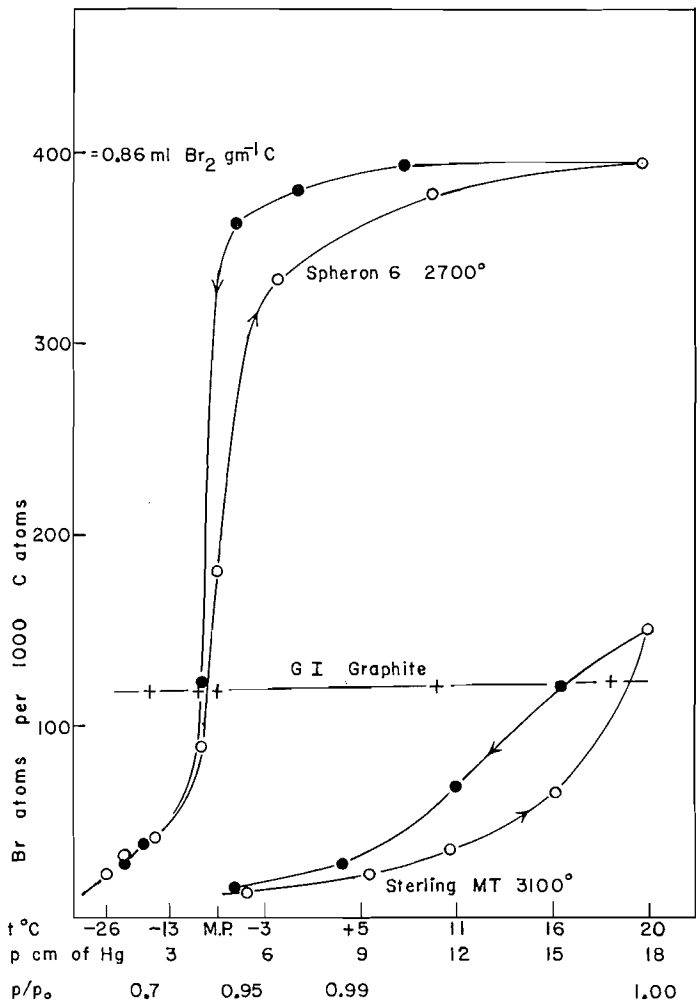

FIG. 1. Absorption of Br_2 near saturation.

they can be exactly reproduced by controlling the three conditions listed above. In practice, room temperature remains close to 22° C, so that the differential is controlled by the jacket temperature. If that is 20° C the vapor is as close to saturation as is feasible. Above that, condensation may occur in the balance system when bromine is admitted from the reservoir.

The compositions in Fig. 1 are believed to be equilibrium values. They were reached in 24 hours or less and many were shown to remain constant for an additional 48 hours. The hysteresis loops for the two carbon blacks were reproducible and show much more hysteresis than in the pressure range 0 to 0.9 of previous work (15). The small hysteresis at those lower pressures, which does not show up on the scale of Fig. 1, was believed to be the result of intercalation in some of the small graphite crystals of the carbon black (15). The large hysteresis at high pressure is believed to be the result of capillary condensation of bromine in the interparticle voids for the following reasons. First, it is known (10) that the carbon black particles are approximately spheres of nonuniform size, and de Boer (16) has shown that the voids in such a system will condense vapor

below saturation and give rise to hysteresis of the kind observed. Furthermore, the small voids in the fine Spheron 6 should and do condense a greater proportion of liquid at a low partial pressure than do the larger voids in the coarser Sterling MT 3100°. Finally, the range of particle sizes is known to be less for Spheron 6 (10) and so it should and does condense its bromine over a shorter pressure range than does Sterling MT 3100°.

The case of graphite Gr I is of special interest because it is a natural graphite of the sort used in lamellar studies. In Fig. 1 the loss of 0.005 Br/C units in going from a partial pressure of 1 to 0.9 is believed to be loss of bromine condensed between the crystals. The amount is considerably less than from the carbon blacks because of the very different shape and size distribution of the particles. For the smaller crystals of Gr II—also a natural graphite—the loss is 0.020 in the same pressure range (Fig. 2). For these two

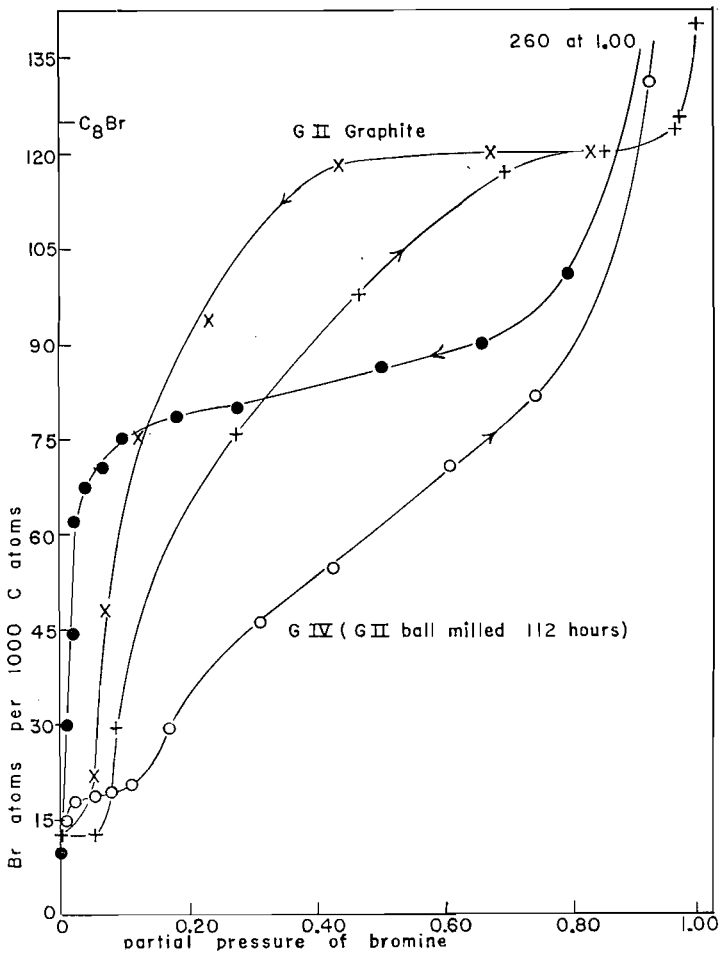

FIG. 2. Isotherms of Br_2 for two particle sizes of graphite.

graphites then, the composition near saturation is governed partly by the size distribution of the interparticle voids. This could be the cause of some of the variations in reported compositions of lamellates in general and shows that only from the complete isotherm can the existence of stoichiometric compounds be postulated.

Length of thermostated jacket.—This was held constant at 12 cm in the above experiments. In one run, however, when 38 cm was thermostated the amount absorbed by Sterling MT 3100° was the same as in Fig. 1 at 20° C but was 100 at 0° C. This increase by a factor of four in the amount condensed at 0° C when the jacket length was increased is caused by a higher partial pressure in the sample. This in turn is caused by a decreased heat leak to the sample along the suspension fiber and through the vapor. If the heat leak was reduced still further by using a longer tube the pressure would become still closer to unity and the amount condensed would approach that at 20° C. The fact that the change in jacket length did not change the absorption at 20° C shows that within experimental error the heat leak was zero at 20° C and that the partial pressure was unity for both lengths of jacket at that temperature.

Visible radiation.—This was held constant at zero in the above experiments by wrapping the reactor tube and section above it in opaque cloth. The following observations were made of the effect of visible radiation on the amount absorbed. A 60-watt bulb 22 cm from the jacketed tube lowered the value for Spheron 6 2700° at 20° C from 400 down to 100. Daylight or even the rather weak ceiling lights also decreased the value below that for a darkened tube. The effect is believed to be a decrease in partial pressure caused by the rise in temperature of the bromine vapor as it absorbs visible light. It could be the cause of some of the variations in reported compositions at high partial pressure.

b. Isotherms for Various Sizes of Graphite Crystals

For the 0.02- to 0.10-mm crystals of graphite Gr II surface adsorption is negligible with the techniques used, and capillary condensation occurs only above a partial pressure of 0.9. Hence below that pressure only lamellar absorption is being measured in the 20° C isotherm for Gr II in Fig. 2. This isotherm is reproducible and starts with the so-called residue compound (17) which remains after the first run to saturation and back to zero pressure. The initial adsorption curve from zero composition lies below the one shown and reaches the same composition at saturation. Both it and the one in Fig. 2 show the threshold pressure for intercalation of 0.05 (1 cm at 20° C), which has been observed in previous work (15). The desorption branch shows a lamellar composition of 0.120 or C_8Br persisting from a pressure of 0.9 to 0.5. This refutes the statement one sometimes sees that this compound or lamellate is stable only in saturated vapor.

The 1- to 2-mm crystals of Gr I show the same general shape of isotherm as do the smaller crystals of Gr II, although the residue composition is twice as great and capillary condensation at saturation is less. The critical pressure for intercalation and the maximum lamellar composition were, however, the same.

The 0.002-mm crystals of Gr IV made by grinding Gr II show a very different isotherm. In Fig. 2 adsorption begins at the lowest pressure used and continues until a monolayer is formed with a composition about 0.010 above that of the residue. The area calculated from this is 26 $m^2 g^{-1}$ (15). Then the isotherm levels off somewhat until the threshold pressure is reached, and although the exact value cannot be read off as precisely as for Gr II, it is close to the Gr II value. At high pressure there is much more capillary condensation and on the desorption branch there is no indication of any lamellate, even at C_8Br. The steepness of the final desorption to zero pressure is curious and no explanation is offered.

The 0.01-mm flakes of Gr III show the same isotherm as for Gr IV except that the residue composition is half as great and the saturation value is 6% less.

It thus appears that variations in the size of the graphite crystals used by different workers could explain some of the discrepancies in composition and in the reported

existence of lamellates in general. The above results show that crystals larger than 0.02 mm give a uniform composition with Br_2.

c. Rates of Absorption

These were measured in saturated vapor at 20° C by admitting bromine to the darkened, evacuated, and thermostated system until liquid condensed in the reactor. The resultant spring oscillations were then stopped as described under Method. The whole procedure required about 1 minute, after which a smooth record of weight versus time was available. It was found that for the first 25 to 50% of the absorption the composition was proportional to the square root of time. Hence, in that region the rate is inversely proportional to the composition and the rate or diffusion constants in Table I were calculated from the

TABLE I

Bromine diffusion coefficient D, $(Br_2/C)^2\ min^{-1} \times 10^4$

Sample	Temp., °C	Pressure, cm	D
Gr I graphite	20	17.6	0.062, 0.062
Gr II graphite	20	17.6	0.65, 0.65, 0.60
"	9.4	10.0	0.60
"	9.4	10.0	0.65, 0.60
"	0.3	6.0	0.55
"	−12.0	3.5	0.40, 0.40
Gr IV graphite	20	17.6	0.72
Sterling MT 3100°	20	17.6	0.025 then 0.045
Spheron 6 2700°	20	17.6	0.55 then 0.90
"	0	5.9	0.020 then 0.21

initial slopes of plots such as Figs. 3 and 4. These coefficients are really the averages for a variety of crystal sizes and hence they cannot be interpreted in terms of a reaction mechanism. In the following two sections, however, certain conclusions are drawn from other aspects of the data.

Particle type and reproducibility.—Two kinds of behavior were observed and found to depend on the type of particle in the powder. In the first kind, the diffusion coefficient D decreases after the initial linear portion and finally becomes zero, as in Fig. 3. This occurs for those powders in which the individual particle is a graphite crystal. Gr I is in this category and shows an initial D of 0.062 both for the original sample and for subsequent runs on the residue compound formed from it. This reproducibility shows that the residual bromine does not interfere with diffusion into the crystal and is therefore probably trapped toward the center of the crystal. It also shows that the formation and decomposition of the lamellate C_8Br does not change the lattice or edges in any way that would affect diffusion into the structure. Similar results were obtained with the smaller crystals of Gr II, the D being about 10 times as large and reproducible with the same or different samples. For the even smaller Gr IV the initial D was 0.72—about the same as for the coarser Gr II. However, in Gr IV considerable condensation occurs along with the intercalation and it was not possible to separate the two processes.

In the second kind of behavior, D increases after the initial linear portion and later falls to zero, as in Fig. 4. This occurs for carbon blacks in which the particles are aggregates of graphite crystals and for which nearly all of the absorption is by capillary condensation. The increase in D may mark the establishment of a continuous liquid layer after which spreading and therefore condensation can occur more rapidly. Whereas the D for a graphite was reproducible and independent of sample weight over a factor

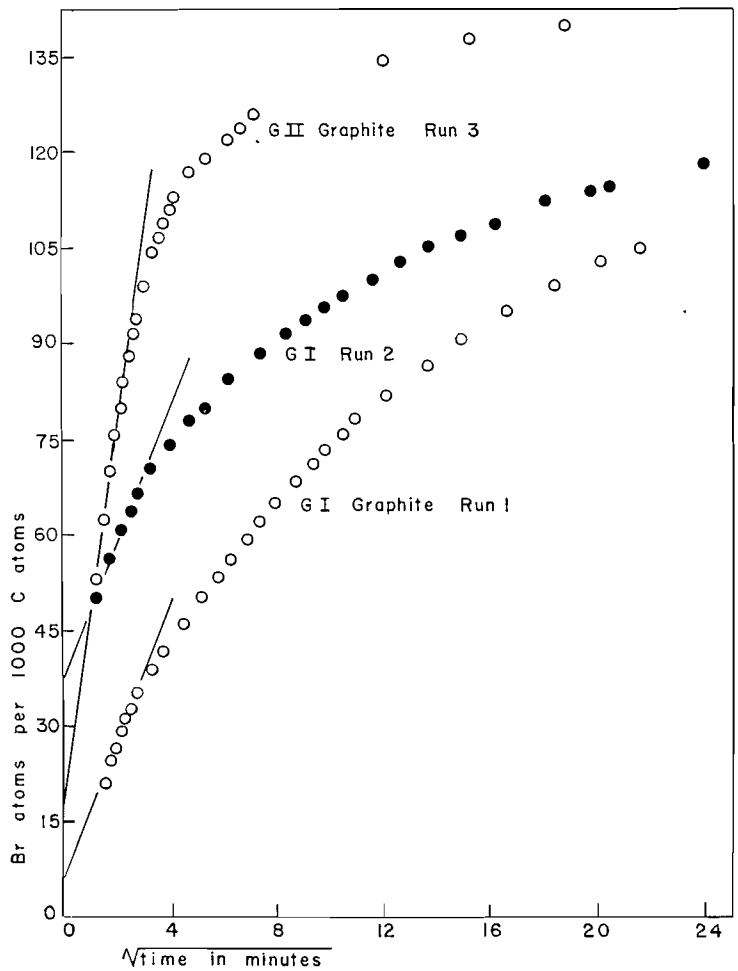

FIG. 3. Rate of absorption of Br_2 in graphite.

of at least three, that for a carbon black was not. This could be the result of variations in packing.

Rate as a function of temperature.—The above rates were all measured at 20° C and the final composition was that for the saturated vapor. At lower temperatures, however, the partial pressure is less than 1 even though liquid is present in the reactor. The effect on the final composition can be seen in Fig. 1. It is negligible for Gr I and Gr II but not for a carbon black. It will be noticed, however, that for Spheron 6 2700° at 0° C the final composition is only about 20% less than at 20° C. The rate for this black at 0° C was therefore determined along with rates at even lower temperatures for Gr II. The general behavior was the same as at 20° C. The lower values of D are listed in Table I and give for Gr II an energy of activation of 2.4 kcal mole^{-1}. For the carbon blacks, D was much more temperature dependent than for graphite and even less reproducible than at 20° C.

2. Boron Nitride

This powder resembles graphite Gr IV in particle size but its isotherm in Fig. 5 is very different. The only evidence for intercalation is the hysteresis to low pressure. However,

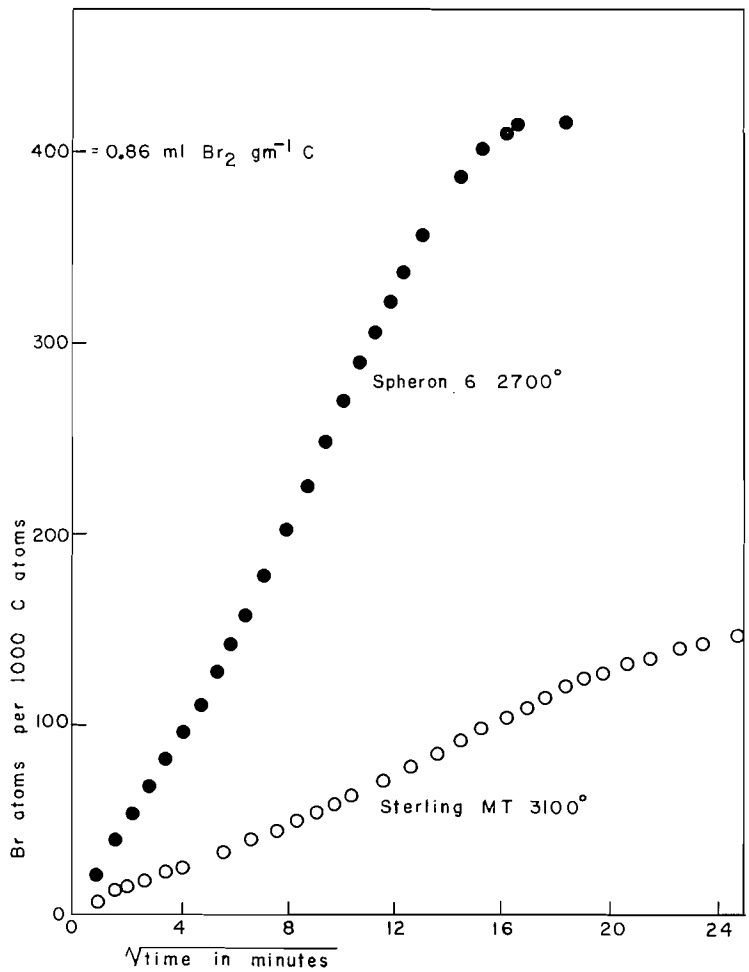

FIG. 4. Rate of absorption of Br_2 in carbon black.

the amount of hysteresis and of absorption at, say, a pressure of 0.5 is only about 5% as much as for Gr IV and there is no bromine residue at zero pressure. The isotherm could be accounted for by capillary condensation between platelets of BN.

3. Molybdenum Disulphide

The isotherm on Moly Paul No. 3 powder is shown in Fig. 6 and a run was also made on 1-mm flakes of MoS_2 shaved from a chunk. The latter absorbed no Br_2 at 20° C until the pressure reached saturation, at which point 0.020 ml g^{-1} condensed and, on slight reduction of pressure, evaporated, leaving no residue at zero pressure. There was apparently only capillary condensation between the flakes. The MoS_2 powder for Fig. 6 resembled graphite Gr IV in particle size and the isotherms of the two in Figs. 6 and 2 have certain features in common. Thus, there is hysteresis, a steep desorption curve at low pressure, a residue at zero pressure, and the amounts absorbed at an intermediate pressure, say 0.4, differ only by a factor of two when expressed in atomic ratio units. These features of Fig. 6 are, however, not necessarily caused by intercalation. Thus, the hysteresis and absorption at low pressure could be the result of condensation between

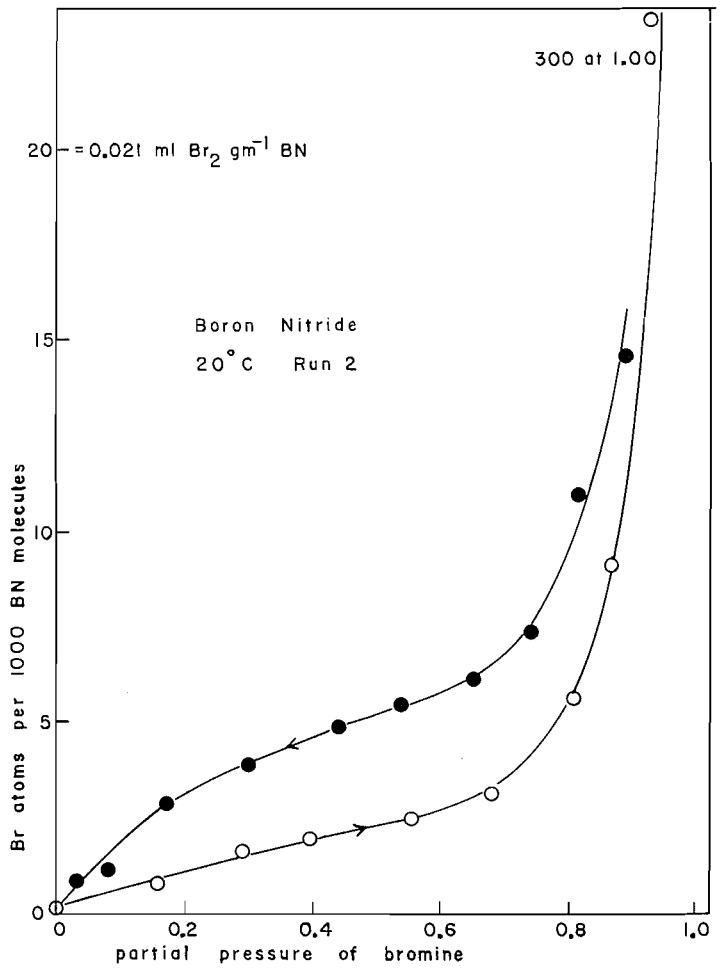

FIG. 5. Isotherm of Br_2 on BN powder.

MoS_2 platelets. The amount involved at a pressure of 0.4 is only 0.006 ml g^{-1}. This is the same as for the BN powder in which intercalation is very unlikely. The residue at zero pressure could be the result of edge atom reaction with bromine. In view of the non-intercalation of large MoS_2 crystals this latter interpretation of Fig. 6 is preferred.

II. Iodine Chloride

1. Graphite Gr II

In the 20° C isotherm of Fig. 7 those points above a partial pressure of 0.65 scattered badly in spite of several attempts to obtain a reproducible curve. At saturation, four values varied from 0.150 to 0.195. Below that pressure, however, the values were reproduced in subsequent runs on the same or different samples. Compositions that were nearly independent of pressure occurred at $C_{16}ICl$ for both adsorption and desorption and at C_8ICl for desorption. The only indication of Rüdorff's lamellate (5) is at saturation. Thus, if the maximum value of 0.195 is reduced by the amount condensed between the particles, one obtains 0.184 or $C_{5.4}ICl$—exactly his composition. The amount condensed is assumed to be 0.045 ml g^{-1}—the same as for Br_2.

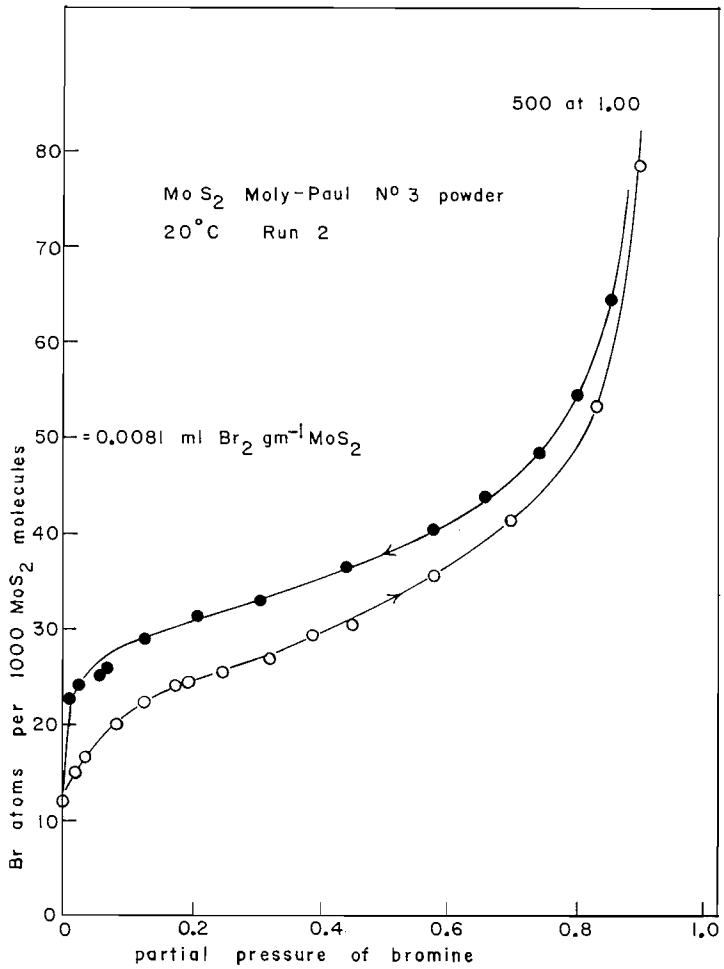

FIG. 6. Isotherm of Br_2 on MoS_2 powder.

Isotherms at 35 and 50° C were also determined, although the maximum partial pressures attainable were 0.5 and 0.3 respectively. The adsorption curves approached $C_{16}ICl$ as at 20° and on desorption there was hysteresis. From the adsorption curves at the three temperatures Arrhenius plots at compositions 0.03, 0.04, and 0.05 were made. Linearity was excellent and the three slopes gave an isosteric heat of 11.6 ± 0.5 kcal $mole^{-1}$.

For the isotherms at 35° and 50°, a threshold pressure of about 0.03 was noted below which no absorption occurred. If there was a similar critical pressure at 20° it was missed and would be below the 0.15 cm of the first point in Fig. 7.

The kinetic behavior in saturated vapor resembled that in bromine. Thus, in the plot of ICl/C against the square root of time at 20° C the initial linear portion extended to 0.050 and from its slope a diffusion coefficient D of 1.8×10^{-4} $(ICl/C)^2$ min^{-1} was calculated. This is about three times the value for bromine in the same graphite at the same temperature.

Finally, there was a residue "compound" whose composition reached a steady 0.010 after several days in saturated vapor. This is about the same as for bromine.

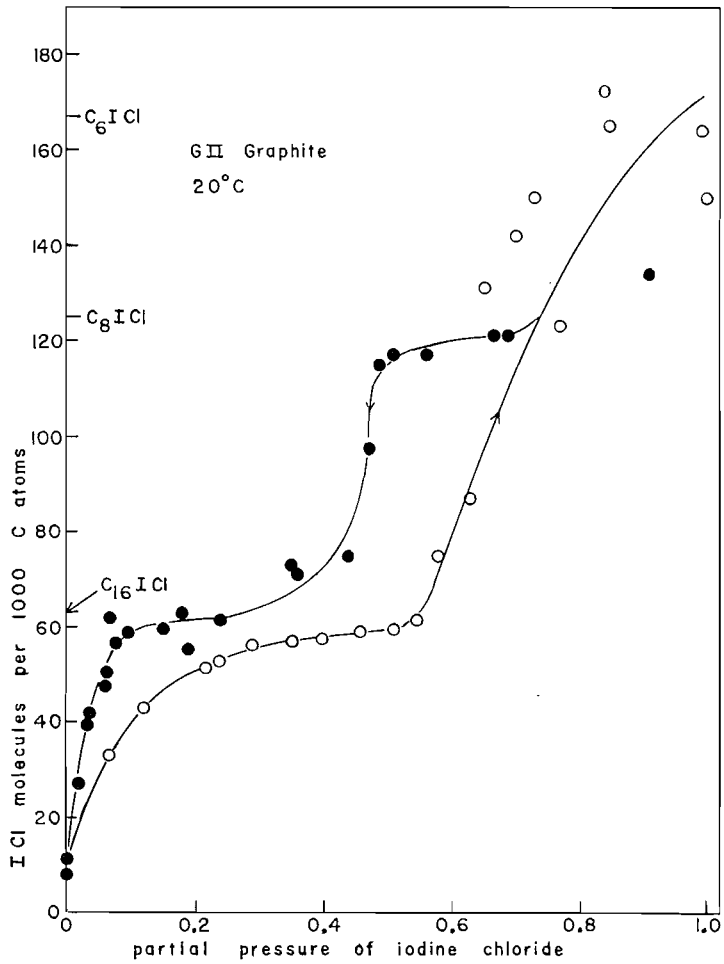

FIG. 7. Isotherm of ICl on graphite.

2. Carbon Black—Spheron 6 2700°

The 20° isotherm in Fig. 8 resembles that for Br_2, although the amount of hysteresis is about 15 times as great. Now it has been shown for Br_2 that hysteresis increases with the size of the graphite crystal in the black (15). If ICl behaves similarly, its isotherms would be more useful than those of Br_2 in estimating crystal size.

3. Boron Nitride

For the isotherm at 20° in Fig. 9 adsorption always occurred along path I. Desorption followed path II if there had been no previous desorption and path I if there had been. Furthermore, the effect of a previous desorption could be wiped out if the reactor tube was opened and the powder stirred and shaken down with a few sharp taps to the holder. Then path II would be followed during the next desorption. The desorption of ICl therefore affects the packing of this particular powder in such a way as to eliminate hysteresis. There is apparently no intercalation of ICl.

4. Molybdenum Disulphide

The 20° isotherm on Moly Paul No. 3 powder in Fig. 10 was reproducible although the values are somewhat scattered. As in the case of the Br_2 isotherm on this powder

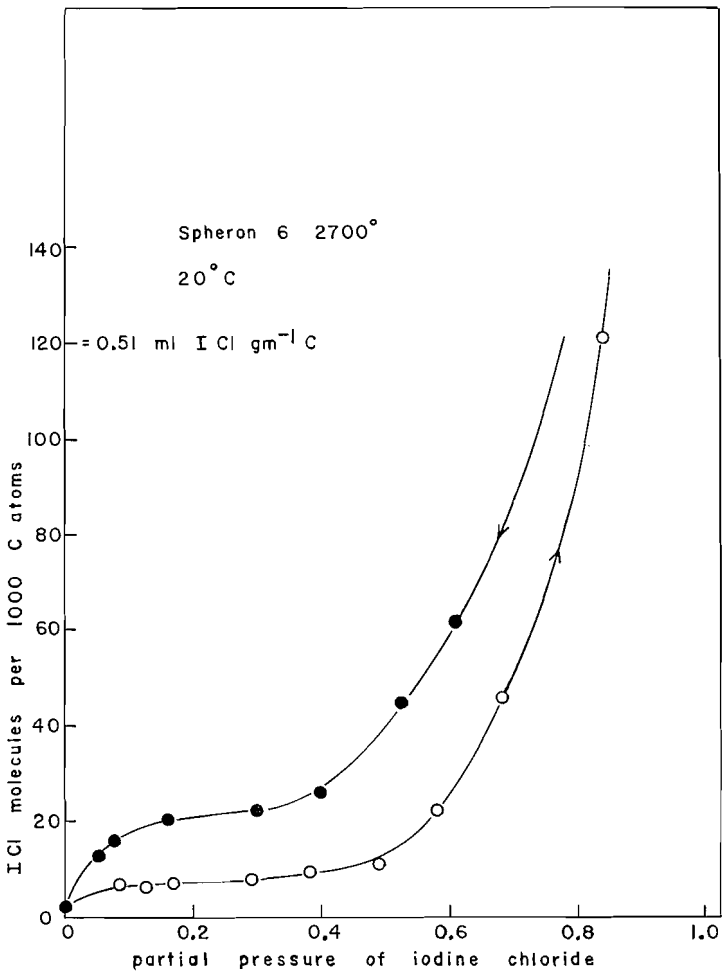

FIG. 8. Isotherm of ICl on a carbon black.

there are certain features compatible with intercalation. Thus the atomic ratio at an intermediate pressure—say 0.4—is comparable with that for Br_2 in graphite Gr IV and there is hysteresis to a low pressure and a residue. The first two features, however, can be explained by capillary condensation and the third by edge atom reaction, as in the case of Br_2. The amount of condensation at pressure 0.4 is 0.022 ml g^{-1}—the same as for ICl in the initial desorption from BN powder. In this latter case there was only condensation and the data proves no more than this for ICl on MoS_2 powder.

III. Chromyl Chloride

1. Graphite

The 20° isotherm for the 0.02- to 0.10-mm crystals of Gr II is shown in Fig. 11. The threshold pressure below which no absorption occurs is 0.4 cm or a partial pressure of 0.25, whereas for Br_2 and ICl the values were 0.05 and 0.03 respectively. Above that pressure the adsorption branch resembles that for Br_2 but levels off at $C_{37}CrO_2Cl_2$ as compared with $C_{16}Br_2$. The steep rise just below saturation was also noted in the Br_2 isotherm and is interparticle condensation. On lowering the pressure to 0.9 this condensed

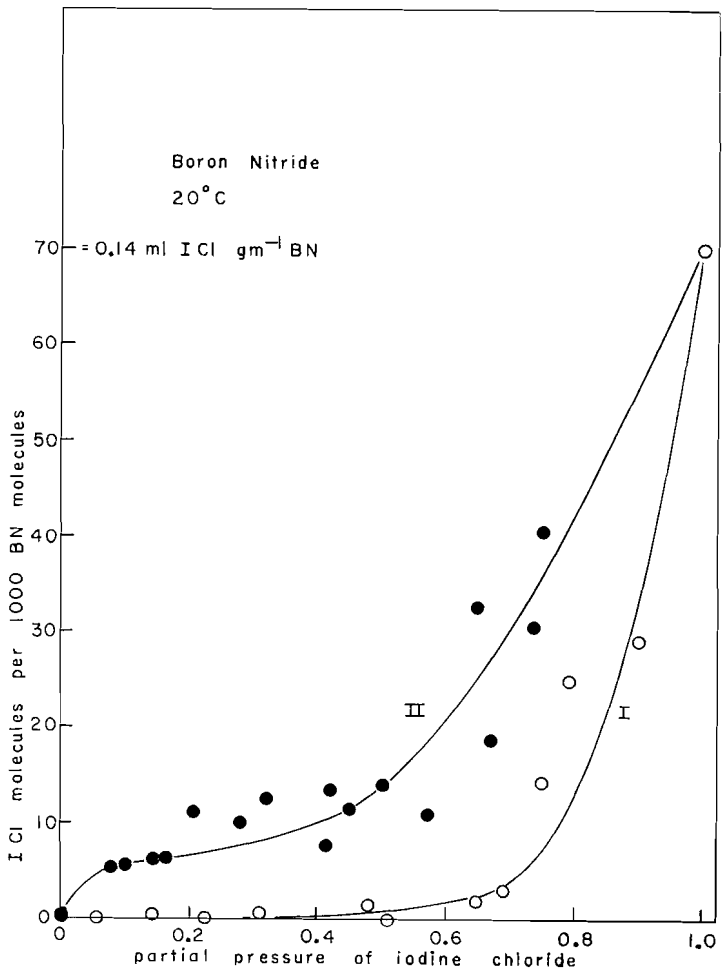

FIG. 9. Isotherm of ICl on BN powder.

material was lost and from there to zero pressure there was no further weight change. A repeat run to saturation and back duplicated the horizontal line and steep rise above pressure 0.9. The 1- to 2-mm crystals of Gr I graphite behaved similarly, although there was less condensation at saturation and the final CrO_2Cl_2 content was somewhat less. That the weight increase on forming these residues may be represented as CrO_2Cl_2 was shown by the fact that the Cl content calculated on this assumption is nearly the same as the analytical value. Thus for three samples the Cl percentages calculated from the weight increases were 10.7, 10.9, and 7.9 and from analysis 10.5 ± 0.6, 10.1 ± 0.2, and 7.1 ± 0.2 respectively.

After one of the runs on Gr II in which 0.261 g of graphite formed 0.353 g of residue, the latter was heated in a vacuum with a liquid N_2 trap in the line. The weight first changed at 300° C and after 1 hour at 330° had dropped to a steady 0.327 g and remained constant even after 2 hours at 500° C. This final product contained $5.7\pm0.2\%$ Cl, whereas the value would be 9.2% if pure CrO_2Cl_2 had been lost during heating. If, however, only Cl was lost and the amount was 1 atom per molecule of CrO_2Cl_2, the Cl content would have dropped to 6.3%. Loss of somewhat more chlorine per molecule

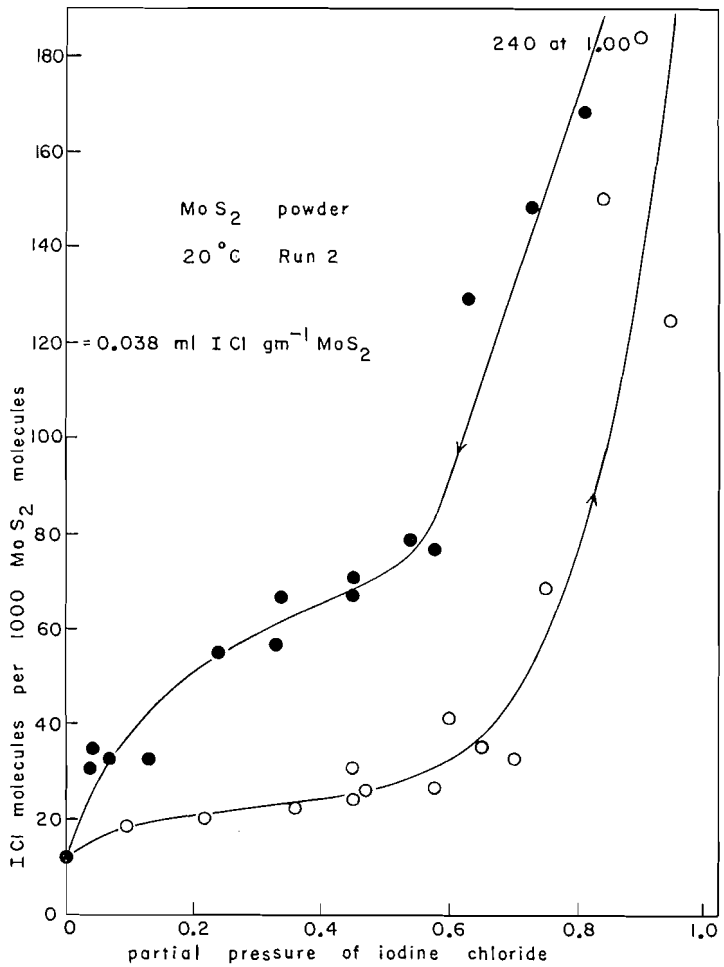

FIG. 10. Isotherm of ICl on MoS_2 powder.

has been reported when CrO_2Cl_2 is heated in a sealed tube (18). The reaction claimed is

$$3CrO_2Cl_2 \rightarrow (CrO_2)_3Cl_2 + 2Cl_2.$$

If this were the amount lost in the above case, the final Cl content would have been 4.3%. It therefore appears that graphite retains the intercalated material as CrO_2Cl_2 unless heated above 300° C, in which case about half the chlorine is lost to give a product that is not volatile at 500° C.

The small crystals of Gr IV, which are Gr II ground to 0.002 mm, gave an entirely different isotherm. The one shown in Fig. 11 is for the second run on a given sample. In the first run the desorption rose from 0 to 0.002 at a pressure of 0.2 and then gradually approached the curve shown, reaching it near saturation. The features to be explained are the small residue, the hysteresis, and the large absorption near saturation. Now in the case of Br_2 on Gr IV (Fig. 2) there was much less intercalation than in the large Gr II crystals. In the present case of CrO_2Cl_2 this is apparently also true. Furthermore, if the smaller amount intercalated behaves as it did in Gr II it will not be lost at zero pressure and will therefore account for the smaller residue of 0.004. The isotherm on this residue exhibits hysteresis which must be associated with the capillary condensation

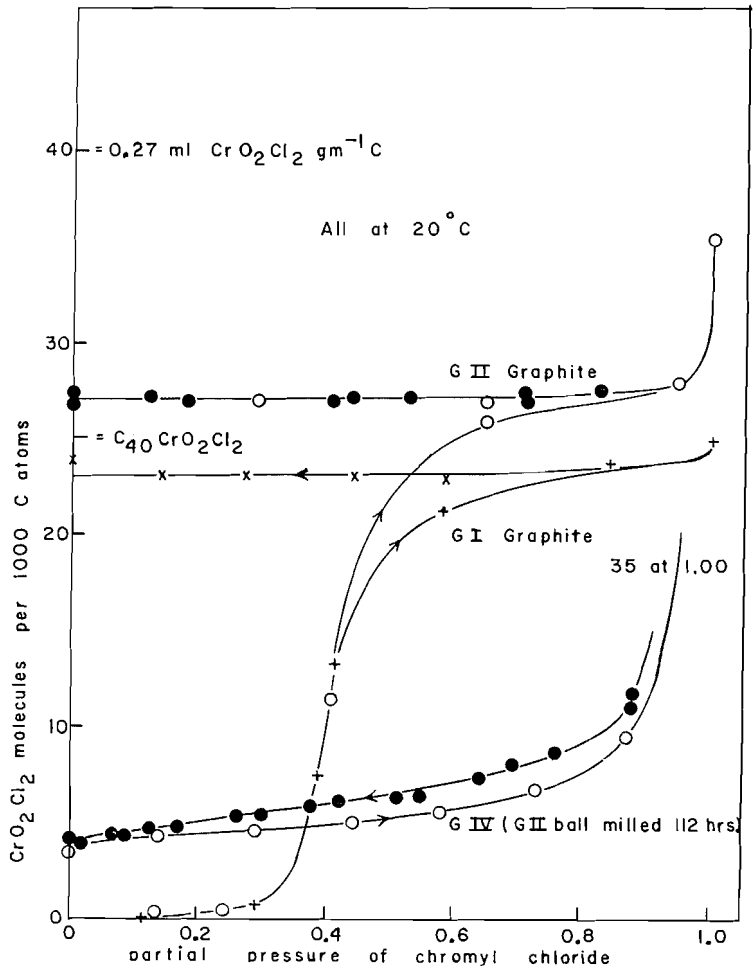

FIG. 11. Isotherms of CrO_2Cl_2 on graphite.

between crystals. In the case of the coarser Gr II there was less condensation at saturation and any hysteresis associated with it was too small to be observed.

There is an interesting time and temperature effect for Gr II that does not show up in Fig. 11 but which is illustrated in Fig. 12. It is that the residue composition increases with the time spent in CrO_2Cl_2 vapor and finally reaches the composition observed in the vapor at a pressure of about 0.9. The increase with time is much slower at the $-1.2°$ C of Fig. 12 than at 20° and so the residue composition is still below the high-pressure value after three runs—a total of 3 days in saturated vapor. The reason for the slight decrease in the high-pressure value after the first run is unknown. Again, at higher temperature the rate of fixing of CrO_2Cl_2 is higher, as shown by the three runs in Fig. 13. For the initial one at 44° C the desorption is horizontal after only 1 hour at 1.7 cm—a partial pressure of 0.45. For the next run, which uses this residue but at 30° C, the desorption is horizontal after 12 hours or less at 1.7 cm. An additional run at the same temperatures duplicated the horizontal desorption line. In the third run at 20° C the desorption branch did fall off toward zero pressure because only 4 hours was spent at saturation. The above behavior could be explained by the production of a nonvolatile

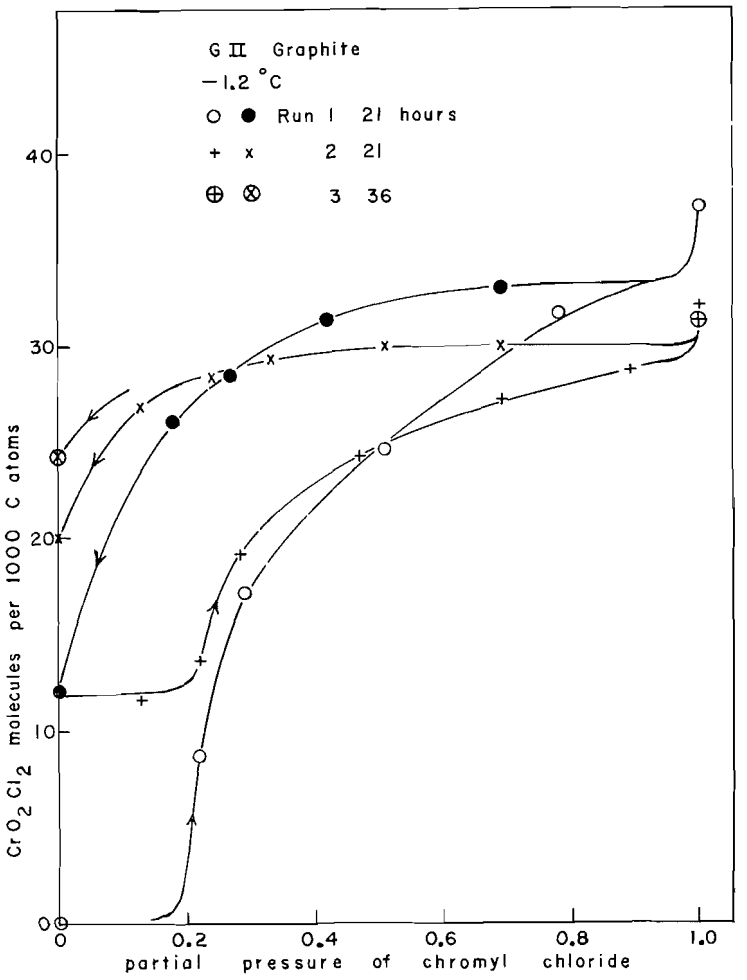

FIG. 12. Isotherm showing increased retention of CrO_2Cl_2 with time.

product either by a slow reaction of CrO_2Cl_2 with the carbon layers or by a slow polymerization of the intercalated CrO_2Cl_2.

From the three initial adsorption curves on Gr II at −1.2, 8.6, and 20° C Arrhenius plots at six compositions from 0.005 to 0.030 were made. Linearity was excellent and from the slope an isosteric heat of intercalation of 13±0.9 kcal mole^{-1} was calculated.

2. Carbon Black

The 20° C isotherm for Spheron 6 2700° resembled that for graphite Gr IV in Fig. 11. It showed the same amount of hysteresis and the same residue composition. The saturation composition was 0.81 ml g^{-1}—about the same as for Br_2.

3. Boron Nitride

The 20° C isotherm showed negligible adsorption and no hysteresis below a pressure of 0.6 and capillary condensation with some hysteresis at high pressure. The saturation absorption of 0.34 ml g^{-1} equals the value for Br_2. There was no residue and no evidence for intercalation.

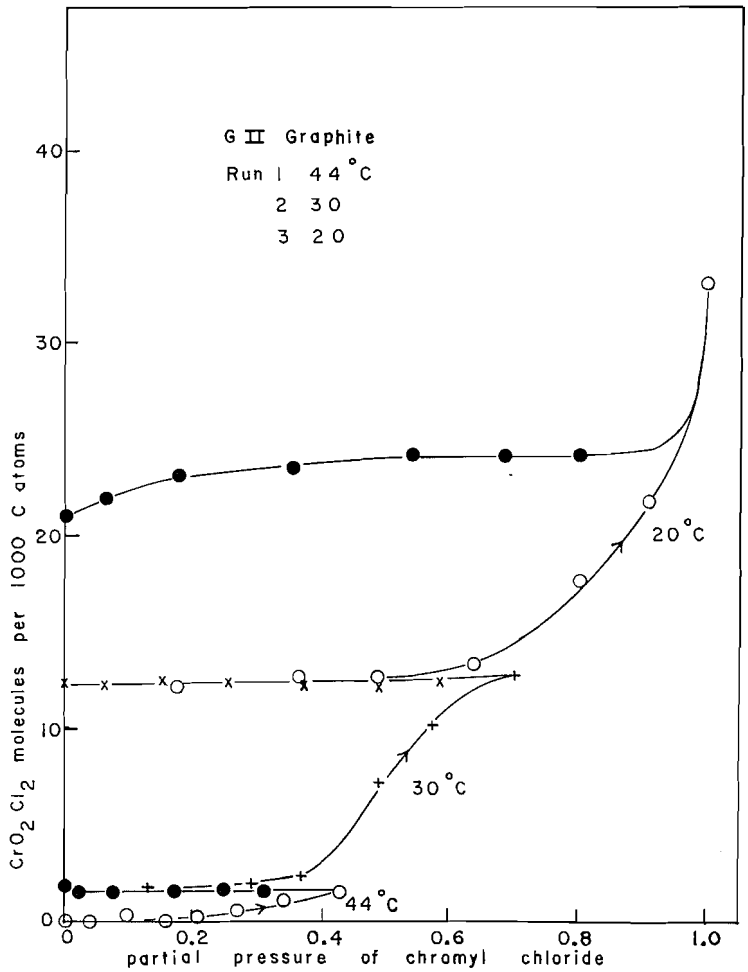

FIG. 13. sotherms showing effect of temperature on retention of CrO_2Cl_2.

4. Molybdenum Disulphide

The 20° C isotherm of the Moly Paul powder resembled that for graphite Gr IV in Fig. 11. There was even less hysteresis, a residue of 0.008, and a saturation absorption of 0.07 ml g^{-1}. There is therefore no definite evidence for intercalation.

CONCLUSIONS

The work with Br_2 on the four sizes of natural graphite crystals shows that measurement of the composition while in the vapor above liquid Br_2 is insufficient for reporting the stoichiometric ratios of lamellar compounds. Not only must the complete isotherm be determined with special attention to experimental conditions at saturation but also the effect of particle size on the isotherm must be studied. Thus, surface adsorption is negligible only for crystals over about 0.05 mm across. Capillary condensation is also less for larger crystals but even for the 0.1- to 2-mm range is not negligible at saturation and for 0.002-mm crystals it is greater than the amount intercalated. Indeed, for these small crystals the amount intercalated is, for some unknown reason, considerably less

than for the 0.02- to 2-mm range. Hence, in studying intercalation it is necessary to determine the complete isotherm for natural crystals over about 0.02 mm across.

When this is done, it is evident that there is a threshold partial pressure for intercalation at 20° C in graphite which is 0.05 for Br_2, about 0.03 for ICl, and 0.25 for CrO_2Cl_2. When more of these are known their significance may become apparent.

The 20° isotherms of Br_2 and ICl show the following compositions to be independent of partial pressure over the ranges indicated: $C_{16}Br_2$ (1.00 to 0.5), $C_{16}ICl$ (0.3 to 0.1), and C_8ICl (0.7 to 0.5). The isotherm of CrO_2Cl_2 was different in that the desorption curve was time dependent. That is, the amount leaving on pressure reduction decreased for longer times spent in the saturated vapor until, finally, none left even at zero pressure. This could be the result of a slow polymerization of intercalated CrO_2Cl_2 to produce a nonvolatile product. The limiting composition was about $C_{40}CrO_2Cl_2$, which is about three times as much as Rüdorff (5) found in the vapor and one third as much as he found in the liquid.

The rate of intercalation in the saturated vapor of Br_2 or ICl was inversely proportional to composition for about the first third of the process and had an energy of activation of about 2 kcal $mole^{-1}$. The significance of this relationship is lost, however, because the graphite used was a mixture of crystal sizes. The fact that the rate was, however, reproduced in subsequent runs on a sample is interesting because it shows that neither the process of intercalation and its reverse nor the existence of residual Br_2 or ICl in the graphite affects the initial rate. The residual material is therefore probably stored near the center of the crystal. The initial diffusion rate for ICl was three times as great as for Br_2. The lower threshold pressure and the existence of the more concentrated C_8ICl also show that this adduct enters graphite more readily than does Br_2.

If one considers hysteresis to be one of the characteristics of intercalation then the isotherms on BN and MoS_2 powders can, with one exception, be explained either by a small amount of intercalation or by a combination of surface adsorption and capillary condensation. The exception is ICl on BN for which only the initial cycle shows hysteresis. Subsequent cycles show negligible absorption below saturation and no hysteresis. This and the fact that hysteresis could be restored by stirring the powder show that it must have been associated with the packing of the powder and not with intercalation. Although this curious effect was not observed for the other isotherms on BN and MoS_2, it does show that the hysteresis to low pressures in those cases could be the result of capillary condensation and is not proof of intercalation. Another characteristic of intercalation, in graphite at least, is a residue at zero pressure. Now BN powder does not show this characteristic but MoS_2 powder does for all three adducts. Neither result is conclusive of course but they do suggest that BN powder is not intercalated and that MoS_2 powder either is intercalated or reacts at its edges with adduct to give a nonvolatile product. The latter conclusion is in agreement with the behavior of massive MoS_2. These large crystals absorb adduct only at saturation and leave no residue. This definitely shows capillary condensation and no intercalation. The residue formed by reaction of adduct with the relatively smaller number of edge atoms in this case was apparently too small to be detected. The conclusion, then, is that BN and MoS_2 are not intercalated by these three adducts.

ACKNOWLEDGMENTS

Grateful acknowledgment is made to Professor R. M. Barrer and his staff for their hospitality during my study leave at Imperial College, London, where this was written.

A CALCULATION OF THE H_2O_2 MOLECULE BY THE LCAO–MO–SCF METHOD

YOSHITO AMAKO[1] AND PAUL A. GIGUÈRE
Department of Chemistry, Laval University, Québec, Que.

Received October 16, 1961

ABSTRACT

The electronic structure of the hydrogen peroxide molecule in three different configurations, namely the cis, the trans, and the non-planar or skew forms, were calculated according to the LCAO–MO–SCF approximation. All the electrons were considered except those of the K-shell of the oxygen atoms. The orbitals of these atoms are essentially of the sp^3 hybrid type. It was shown that the skew form of the molecule with an azimuthal angle Φ of about 120° is the most stable, due mainly to conjugation of the σ_5 and σ_6 orbitals of the oxygen atoms with the other molecular orbitals. On the contrary, in the cis and trans forms these two orbitals are non-bonding. Because of the approximate nature of the treatment, especially as regards the screening effect of the K-electrons, the calculated orbital energies are definitely too large. However, the heights found for the cis and the trans barriers are in a reasonable mutual ratio. Numerical values were also obtained for the ionization potentials and the dipole moment of the skew model; the latter result, 2.05 D, agrees well with the experimental data.

INTRODUCTION

The first computation of the electronic structure of the H_2O_2 molecule was done in 1934 by Penney and Sutherland (1, 2) using the electron pair method and taking into account only the $2p$ electrons of the oxygen atoms. This first approximation was sufficient to prove that, somewhat contrary to expectation, a skew configuration of the molecule (Fig. 1*c*) with an azimuthal (or dihedral) angle Φ of the order of 100° should be more stable than either the trans or the cis configurations. Because of interaction of the unshared electron pairs on the oxygen atoms, free rotation of the OH groups about the O—O bond is opposed presumably by a high cis and a low trans energy barrier (Fig. 2). The same conclusion was reached later by Lassettre and Dean (3) from calculation of the electrostatic forces between various electron configurations of the molecule. Depending on the assumed values for the quadrupole moments, they arrived at azimuthal angles Φ ranging from 94° to 113°, but their barrier heights were appreciably different from those of Penney and Sutherland. In fact a wide variety of estimates have been made so far for these energy barriers, based either on calculations or on experimental data (Table I). It was thought that a treatment of this molecule after the molecular

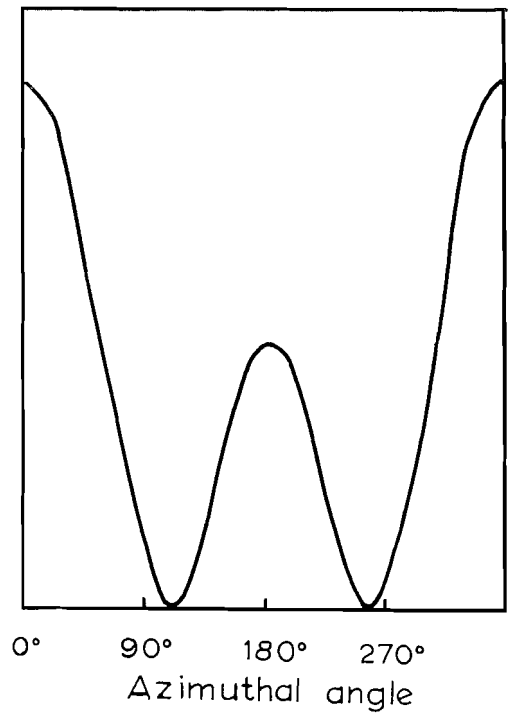

FIG. 2. Potential barriers hindering internal rotation in the H_2O_2 molecule.

orbital approximation—more precisely, the one known as "linear combination of atomic orbitals, molecular orbitals, self-consistent field"—would add to our knowledge, particularly on the type of hybridization of the oxygen atom orbitals and the true configuration of the ground state. Because of limited time and computation facilities, numerous approximations had to be made, the most serious of which was the neglect of the K-shell electrons of the oxygen atoms. Largely because of that, the calculated orbital energies turned out to be too large. Nevertheless, it is of interest that the MO method places the three possible forms of the H_2O_2 molecule not only in the correct order of stability, namely skew > trans > cis, but also on a plausible relative scale.

DETAILS OF THE CALCULATIONS

The method followed here was first outlined by Roothan (11). Throughout the calculations Slater's atomic wave functions were used:

$$h_1, h_2 = \frac{1}{\sqrt{\pi}} \exp(-Z_1 r_{1,2}),$$

$$s_{1,2} = \sqrt{\frac{Z_2^5}{3\pi}}\, r_{1,2} \exp(-Z_2 r_{1,2}),$$

$$x_{1,2} = \sqrt{\frac{Z_2^5}{\pi}}\, r_{1,2} \sin\theta_{1,2} \cos\phi_{1,2} \exp(-Z_2 r_{1,2}),$$

$$y_{1,2} = \sqrt{\frac{Z_2^5}{\pi}}\, r_{1,2} \sin\theta_{1,2} \sin\phi_{1,2} \exp(-Z_2 r_{1,2}),$$

$$z_{1,2} = \sqrt{\frac{Z_2^5}{\pi}}\, r_{1,2} \cos\theta_{1,2} \exp(-Z_2 r_{1,2}),$$

where h_1, h_2 indicate the $1s$ atomic orbitals of the two hydrogen atoms, $s_{1,2}$, $x_{1,2}$, $y_{1,2}$, and $z_{1,2}$, the $2s$, $2p_x$, $2p_y$, and $2p_z$ atomic orbitals of the oxygen atoms. $Z_{1,2}$ corresponds to the Slater effective nuclear charge, namely $Z_1 = 1$ and $Z_2 = 2.257$.

The three structural parameters, $r_{O-O} = 1.49$ Å, $r_{O-H} = 0.97$ Å, and $\theta_{OOH} = 100°$ (Fig. 1), selected for these calculations were taken from a critical compilation (12) of all the experimental data available at the time. The latest investigations (10, 13) seem to indicate a trend towards slightly smaller values for both bond lengths as well as for the angle θ. Since the same parameters were used for the three configurations, it follows that the results for the cis and trans forms are less correct than those for the skew form. As for the azimuthal angle Φ, its value had to be assumed a priori because it was not feasible to repeat the calculations for more than one skew model. The original estimate of Penney and Sutherland, namely 90° from interaction of the lone pair electrons plus some 5° or 10° due to repulsion of the hydrogen atoms, was based on the premise of pure p orbitals for the oxygen atoms. However, by analogy with the case of H_2O, it is more likely that the orbitals of the oxygen atoms in H_2O_2 are of the sp^3 hybrid type. Therefore, the major interaction between the two OH groups in that molecule should have near-threefold symmetry and, accordingly, the azimuthal angle was taken as 120°.

For simplicity the y axis was chosen as coincident with the O—O bond and one of the OH groups was considered as fixed in space. (Cf. Fig. 3 for the coordinate system.) Then the atomic wave functions for the skew and the trans forms were written down as follows, for example,

$$[1] \qquad (z_2)_{skew} = -\cos(\pi - \Phi) \cdot (z_2)_{cis} + \sin(\pi - \Phi) \cdot (x_2)_{cis},$$

$$[2] \qquad (z_2)_{trans} = -(z_2)_{cis},$$

so that the integrals for these two forms could be derived from those for the cis form.

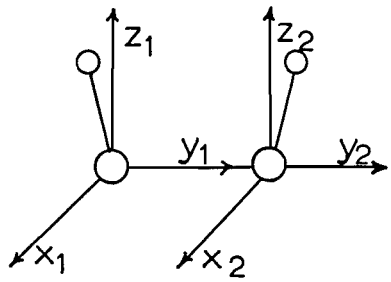

FIG. 3. System of coordinates used for the calculations.

Symmetry Orbitals

It was convenient to transform each atomic wave function into symmetry orbitals according to the point-group symmetry of the three forms of the molecule considered here, these being C_{2v} for the cis, C_2 for the skew, and C_{2h} for the trans forms. These symmetry orbitals can be classified as follows:

I. Cis form (C_{2v})

$$A_1: \quad \sigma_1 = \frac{1}{\sqrt{2}}(h_1+h_2),$$

$$\sigma_2 = \frac{1}{\sqrt{2}}(s_1+s_2),$$

$$\sigma_3 = \frac{1}{\sqrt{2}}(y_1-y_2),$$

$$\sigma_4 = \frac{1}{\sqrt{2}}(z_1+z_2);$$

$$A_2: \quad \sigma_5 = \frac{1}{\sqrt{2}}(x_1-x_2);$$

$$B_1: \quad \sigma_6 = \frac{1}{\sqrt{2}}(x_1+x_2);$$

$$B_2: \quad \sigma_7 = \frac{1}{\sqrt{2}}(h_1-h_2),$$

$$\sigma_8 = \frac{1}{\sqrt{2}}(s_1-s_2),$$

$$\sigma_9 = \frac{1}{\sqrt{2}}(y_1+y_2),$$

$$\sigma_{10} = \frac{1}{\sqrt{2}}(z_1-z_2).$$

II. Skew form (C_2)

$$A: \quad \sigma_1, \sigma_2, \sigma_3, \sigma_4, \sigma_5;$$

$$B: \quad \sigma_7, \sigma_8, \sigma_9, \sigma_{10}, \sigma_6.$$

III. Trans form (C_{2h})

$$A_g\colon\ \sigma_1, \sigma_2, \sigma_3, \sigma_4;$$

$$A_u\colon\ \sigma_5;$$

$$B_g\colon\ \sigma_6;$$

$$B_u\colon\ \sigma_7, \sigma_8, \sigma_9, \sigma_{10}.$$

These symmetry orbitals made it possible to reduce the 10×10 determinant into smaller ones, namely, two 4×4 and two 1×1 for each of the cis and the trans forms, and two 5×5 for the skew form of the molecule. The general procedure followed was the same as used by Mulligan (14) for his study of the CO_2 molecule. In the present case the bare nuclear field potentials are written thus:

$$[3] \qquad H = -\frac{\nabla^2}{2} - \frac{1}{r_{H_1}} - \frac{1}{r_{H_2}} - \frac{6}{r_{O_1}} - \frac{6}{r_{O_2}},$$

the nuclear charge on the oxygen atoms being arbitrarily taken as 6 because of exclusion of the K-shell electrons. Therefore, the energy values calculated refer to that hypothetical state.

DISCUSSION

Molecular Orbitals and Energies

The various orbital energies found for each form of the molecule are shown schematically in Fig. 4 and are listed below along with the corresponding wave functions. Each MO is denoted by the symbol of irreducible representation to which it belongs preceded by a running number which identifies the orbitals of the same symmetry. The σ_n terms are the symmetry orbitals defined above.

One obvious conclusion from these results is the fact that the s orbitals of the oxygen atoms share in the bonding in each and every MO. Therefore, the valence state of oxygen in H_2O_2 must be nearer to the sp^3 hybrid than to the pure p state, as we assumed originally by analogy with the case of H_2O, and the electron distribution must be approximately tetrahedral. Another significant conclusion relates to the behavior of the σ_5 and σ_6 orbitals, which are non-bonding in the cis and trans forms, but take part in conjugation with the other MO in the skew form. The increased stability of the latter stems mainly from this unique property. Recently, Pauling (15) has assumed sp hybridization for the oxygen atoms in H_2O_2 which, as in the treatment of Penney and Sutherland, leads to an azimuthal angle Φ close to 90°.

The Azimuthal Angle

Since in the MO approximation the interaction of the non-bonding orbitals of oxygen with the hydrogen orbitals is the major factor in stabilizing the skew form of H_2O_2, it follows that maximum overlap between them will occur for an azimuthal angle of about 120° as shown in Fig. 1*d*. A number of values have been found or proposed for this parameter following the original estimate of Penney and Sutherland (Table II). The first pertinent spectroscopic evidence (16) showed that the H_2O_2 molecule is in fact a slightly asymmetric top; from this it was predicted that Φ could not be in the range 85°–95°. Because it is unlikely a priori that Φ be much smaller than a right angle, a larger value seemed favored. In a recent neutron diffraction study of the H_2O_2 single crystal (13) where the hydrogen atoms could be located, Φ was found nearly equal to

− 6.766	$\psi(3\,a_g) = 0.0345\,\sigma_1 + 0.1411\,\sigma_2 - 0.8075\,\sigma_3 - 0.4977\,\sigma_4$
15.235	$\psi(3\,b_u) = 0.3780\,\sigma_7 - 0.3841\,\sigma_8 - 0.9941\,\sigma_9 - 0.4837\,\sigma_{10}$
21.769	$\psi(4\,a_g) = 0.0818\,\sigma_1 + 0.0644\,\sigma_2 - 0.8671\,\sigma_3 - 0.3411\,\sigma_4$
40.973	$\psi(4\,b_u) = 1.0333\,\sigma_7 - 0.3742\,\sigma_8 + 0.6062\,\sigma_9 - 0.8025\,\sigma_{10}$

a right angle. However, this result in no way conflicts with the present conclusion since the two correspond in fact to different physical states of the molecule. In the crystal, packing conditions and intermolecular forces are sufficient to distort the azimuthal angle appreciably from its value in the free molecule, because the restoring force involved is certainly small (low barriers to internal rotation). This is borne out by the rather wide range of values reported for Φ (from 90° to 130°) in various crystals (Table II). A high-dispersion study of the rotational structure of several infrared bands of H_2O_2 has been carried out lately (10) from which it was possible to get very accurate rotational constants of the molecule. It is gratifying that the azimuthal angle thus found agrees exactly with our conclusion.

Ionization Potentials

The above results for the ionization potentials refer to an hypothetical energy state since the *K*-shell electrons were not included in the calculations. In order to translate these data into the actual state of the molecule, we assume that the energy of the highest filled orbital is equal to the one experimentally known ionization potential, 11.26 ev (20). Addition of this *ad hoc* constant, 4.83 (= 11.26 − 6.43), yields the values shown in Fig. 4. Experimental data with which to compare the above are lacking unfortunately. Nevertheless, it is of interest that they agree nicely with the theoretical estimates of Mulliken (21) for levels 3 and 2 (Fig. 4, last column).

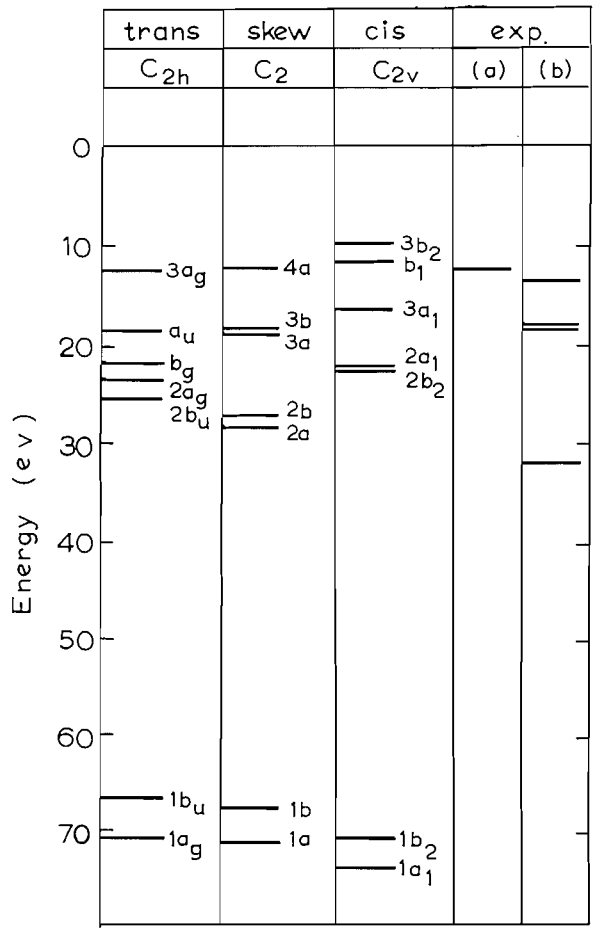

FIG. 4. Schematic energy levels for the three configurations of the H_2O_2 molecule. Experimental data: (*a*) Lindeman and Guffy (20), (*b*) Mulliken's estimates (21).

TABLE II

Previous estimates of the azimuthal angle in H_2O_2

Method	Φ	Reference

Dipole Moment

Using the well-known equation

$$\mu = \int \psi_\epsilon \sum_i r_i \psi dv \qquad [4]$$

the dipole moment of the skew form of H_2O_2 with $\Phi = 120°$ was calculated to be 2.05 D. The necessary integrals, listed below in Table III, refer to the C_2 axis of the molecule.

TABLE III

Dipole moment integrals

$(h_1 z_m h_1)$ =	0.85951	$(h_1 z_m s_2)$ =	0.02047
$(h_1 z_m s_1)$ =	0.06310	$(h_1 z_m y_2)$ =	0.00187
$(h_1 z_m z_1)$ =	0.13595	$(h_1 z_m z_2)$ =	0.00107
$(h_1 z_m y_1)$ =	−0.02397	$(h_1 z_m x_2)$ =	−0.00093

Experimental values of 2.13 D for dilute solutions in dioxane and, more recently, of 2.26 D from the Stark effect in the microwave spectrum of the vapor, have been reported in the literature (12).

Total Energy

The total electronic energy is given by the equation

$$E_n = \sum_{i}^{\text{occup}} 2H_i + \sum_{i}^{\text{occup}} \sum_{j=1} (2J_{ij} - K_{ij}) \qquad [5]$$

and the orbital energy, by

$$\epsilon_i = H_i + \sum_{j=1}^{\text{occup}} (2J_{ij} - K_{ij}). \qquad [6]$$

Then the total energy is expressed as

$$E_n = \sum_{i}^{\text{occup}} (H_i + \epsilon_i) \qquad [7]$$

where

$$H_i = \int \psi_i H \psi_i dv$$

and

$$\psi_i = \sum b_{ip} \chi_p.$$

The calculated values of H_i are listed in Table IV from which the relative stability of the three forms of the H_2O_2 molecule appear in the expected order, namely, skew > trans > cis. The differences between them are in the ratio 3 to 1, which seems quite

*In atomic units. Contribution of the *K*-shell electrons not included.

plausible, although the actual figures are certainly too large for the corresponding barrier heights. As pointed out above these exceedingly large orbital energies are due mainly to the exclusion from our calculation of the K-electrons of the oxygen atoms, and the uncertainty as to their screening effect on the outer electrons. Indeed, for lack of a more reliable estimate a screening factor of one was assumed. This, and a number of other approximations, had to be resorted to in evaluating the many integrals involved, nearly one thousand in all.

ACKNOWLEDGMENTS

The authors are grateful to the National Research Council for a generous research grant, to the "Centre de Calcul de l'Université Laval", and to the IBM Company for assistance in carrying out the computations.

RÉSUMÉ

On présente les résultats de calculs par la méthode LCAO–MO–SCF de la structure électronique de la molécule H_2O_2 dans trois configurations possibles, soit cis, trans et oblique. On prouve que cette dernière, dans laquelle l'angle dièdre est d'environ 120°, est plus stable que les deux autres à cause de la conjugaison des orbitales σ_5 et σ_6 des atomes d'oxygène avec les autres orbitales moléculaires. Au contraire, dans les formes cis et trans ces deux orbitales demeurent non-liantes. On montre que les orbitales de l'oxygène sont dans l'état hybride sp^3 et on calcule les potentiels d'ionisation et le moment dipolaire de la molécule. Les résultats sont en bon accord avec les données de la littérature. Par contre les différences entre l'énergie totale calculée pour les trois formes conduisent à des valeurs trop fortes pour les barrières de potentiel qui gênent la rotation libre dans la molécule H_2O_2.

APPENDIX

The calculations for the cis and the trans forms were made manually but for the skew model an IBM 605 computer was used. For the program of the latter, the secular determinant is written as follows

$$|(H+G)-S\epsilon| \equiv 0, \qquad [8]$$

where the terms containing the energy parameters appear in the non-diagonal elements. These terms are usually missing in the eigenvalue problems for which programs are available at present. Therefore a special program had to be set up, which required finding out the inverse matrix S^{-1}

$$S^{-1}S = \delta. \qquad [9]$$

Through multiplication of the above secular determinant by the inverse matrix

$$|S^{-1}(H+G)-\delta\epsilon| \equiv 0 \qquad [10]$$

we revert to the usual eigenvalue problem.

MANGANESE(III) COMPLEXES WITH ETHYLENEDIAMINETETRAACETIC ACID[1]

ABSTRACT

Manganese(III) ethylenediaminetetraacetic acid complex has been prepared by various methods. The solid having a composition of $KMnY.2.5H_2O$ is obtained as deep red crystals when the manganese dioxide suspension reacts with free ethylenediaminetetraacetic acid (H_4Y). The manganese was shown to be trivalent from its redox equivalent in its reaction with acidified iodide solution, and its magnetic moment, which was 4.89 Bohr magnetons, corresponding to four unpaired electron spins. The complex ion has an absorption maximum at 500 mμ ($\log \epsilon = 2.67$) in a slightly acidic medium. The variation of the visible spectra with pH has been studied by the spectrophotometric method, the value $pK \simeq 5.3$ being obtained between the red and the yellow species. Observations have been made on the type of bond between the metal and carboxylate groups by the infrared spectral method. From its ion-exchange and pH titration behavior a formula, $K[Mn(OH_2)EDTA].1.5H_2O$, was suggested.

INTRODUCTION

The formation of manganese(III)–EDTA complex in solution was utilized by Přibil *et al.* for the photometry and redox titration of manganese (1, 2, 3). They oxidized divalent manganese to the trivalent state by means of lead dioxide, sodium bismuthate, etc. in the presence of excess EDTA. However, since the manganese(III)–EDTA complex solution thus obtained contains reaction products of the oxidizing agents, their methods for the formation of the manganese(III)–EDTA complex was found to be unsuitable for studying the nature of the complex. In the course of study on the stabilization of less familiar oxidation states of metals by coordination (4, 5), the present authors have found that the manganese(III)–EDTA complexes could be formed by the reaction of EDTA with manganese compounds of higher oxidation states, such as manganese dioxide or potassium permanganate. The critical examination of stoichiometry of the complex formation reaction revealed that the manganese dioxide or permanganate ion was reduced by EDTA itself, giving a reddish-purple solution of the manganese(III)–EDTA complex. After a number of attempts, we have been able to prepare a crystalline solid. The present paper describes the preparation and properties of the complex of this sort.

EXPERIMENTAL

Materials

Inorganic salts, acids, and bases were all the JIS[3] special-class grade. Free acid (H_4Y) and disodium salt ($Na_2H_2Y.2H_2O$) of ethylenediaminetetraacetic acid were also the JIS special-class grade. Fe(III)–EDTA chelate, $NaFe(C_{10}H_{12}N_2O_8).2H_2O$, purchased from Daiichi Pure Chemicals Co., was of reagent grade. Co(III)–EDTA chelate, $KCo(C_{10}H_{12}N_2O_8).2H_2O$, was prepared according to the method of Dwyer *et al.* (6). Organic solvents of the JIS first-class grade were used after distillation.

As ion-exchange resins, strongly acidic cation-exchange resin Diaion SK-1 of 100–200 mesh (sulphonated polystyrene-divinyl-benzene copolymer, purchased from Mitsubishi Kasei Co., Tokyo) and strongly basic anion-exchange resin, Dowex 1-X8, 100–200 mesh, were employed in a column method.

Instruments

Magnetic measurements were made on the solid complex using a Goüy apparatus of conventional type. An X-ray diffractometer, "Geigerflex" of Rigaku Denki Co., was used for examining powder diffraction patterns of the chelate using Cu K_{α_1} ray. For thermal analysis, the "Tokoshi type" thermobalance was used. The infrared spectra were recorded with a recording spectrophotometer of Nihon Bunko Co., type DS-301, equipped with a sodium chloride prism. As the sample, which was handled as a potassium bromide pellet, decomposed gradually, a Nujol mull technique was employed. Visible and ultraviolet spectra were measured with the EPS II recording spectrophotometer and the EPU II spectrophotometer, both from Hitachi Co. The pH of the solution was measured by a glass electrode pH-meter of Iio Denki Co., model 43.

PREPARATION OF COMPLEXES

(i) Formation of Manganese(III)–EDTA Complex in Solution

In preliminary attempts, various methods for the preparation of the manganese(III)–EDTA complex in solution were tried.

(*a*) Freshly prepared manganese dioxide suspended in water was mixed with solid EDTA (H_4Y) under vigorous stirring. The resultant reddish purple complex in the filtrate was determined by both spectrophotometry and iodometric titration. The relation between the mole ratio EDTA to MnO_2 and that of produced Mn(III)–EDTA complex was shown in Fig. 1. During the reaction the evolution of carbon dioxide was observed

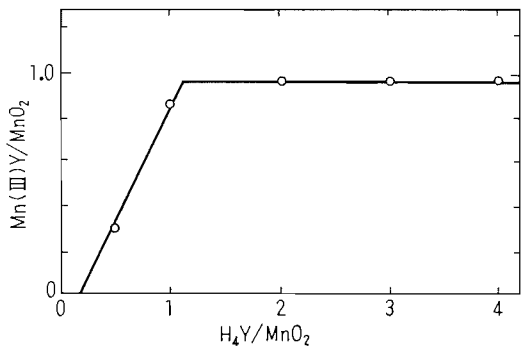

FIG. 1. Relation between the mole ratio of EDTA to manganese dioxide and the mole ratio of produced Mn(III)Y to manganese dioxide (MnO_2: 2.69×10^{-3} mole).

and a little of EDTA was lost; this may be due to the oxidation of EDTA by manganese dioxide. However, the mole ratio of Mn(III) to EDTA in the complex was found to be close to 1:1.

(*b*) In the above-mentioned case, H_4Y could be replaced by a mixed solution of Na_2H_2Y and acetic acid (pH 2.5–3). In this case, however, the yield, i.e., the ratio of Mn(III)–EDTA to MnO_2, showed a maximum at EDTA/$MnO_2 \simeq 1$, and then gradually decreased as the ratio EDTA/MnO_2 was increased. This is presumably ascribed to the partial decomposition of Mn(III)–EDTA by the excess of EDTA in the solution.

(*c*) It was also found that potassium permanganate could be used in place of manganese dioxide. The maximum yield was obtained at the point where the mole ratio EDTA/MnO_4^- was a little larger than 1, although the reaction sometimes did not proceed smoothly, depending upon the conditions employed, and the yield and the purity of the products were not always high.

(*d*) The manganese(III)–EDTA complex was also formed by oxidizing manganese(II)–EDTA complex with manganese dioxide. The relation between the obtained Mn(III)–EDTA and the used Mn(II)–EDTA is illustrated in Fig. 2. For a fixed amount of MnO_2, the amount of Mn(III)–EDTA increased until Mn(II)–EDTA/MnO_2 reached ca. 1.7,

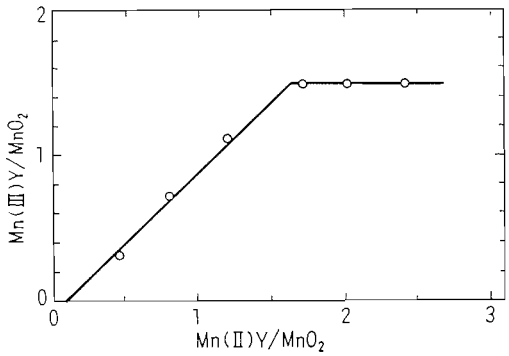

FIG. 2. Relation between the mole ratio of Mn(II)Y to manganese dioxide and the mole ratio of produced Mn(III)Y to manganese dioxide (MnO_2: 2.69×10^{-3} mole).

and then the yield remained nearly constant (Mn(III)–EDTA/$MnO_2 \simeq 1.5$). It seems that the EDTA chelated to Mn(II) is easily decomposed by oxidation, but, in the above case, the main reaction may be

$$2Mn(II)Y + Mn(IV) \rightarrow 2Mn(III)Y + Mn(II).$$

(ii) Preparation of Solid Complex

After a number of attempts, it was found that an extension of the method described above in (*a*) was most suitable for preparing a solid complex. One of the typical methods of preparation of potassium salt is as follows:

Six grams of finely powdered potassium permanganate were added to a mixed solution of 40 ml of water and 10 ml of ethanol. The mixture was shaken and then carefully warmed. After the vigorous reaction had ended, the mixture was warmed repeatedly in order to expell the excess ethanol and aldehyde. To the mixture of manganese dioxide and potassium hydroxide so obtained, 10 g of EDTA (H_4Y) was added. With vigorous stirring, a reaction took place, evolving carbon dioxide, and a deep cherry-red solution was obtained. After the excess manganese dioxide was filtered off with a glass filter, an equal volume of cold ethanol was added to the filtrate. The mixture was allowed to stand for 3–4 hours in a cold, dark place. The precipitated crystals were then filtered off with a glass filter and washed with 90%, then absolute ethanol and ether. Finally they were dried in the air in a cold, dark place. The yield based on the used EDTA (H_4Y) was 45–60%.

When more diluted solution of manganese(III)–EDTA was mixed with an equal volume of ethanol, large, needle-like crystals were obtained after standing of the solution for 1 or 2 days in a refrigerator.

(iii) Analysis

The manganese was separated as hydroxides by the addition of sodium hydroxide and hydrogen peroxide to the complex solution. After the hydroxides were dissolved in dilute sulphuric acid with the aid of sodium sulphite, the manganese was weighed as manganese sulphate, or back-titrated with EDTA and zinc chloride solutions at pH 10 using Eriochrome Black T as indicator. A check on the manganese content was made by iodometric titration: the sample was added to acidified potassium iodide solution, and then liberated iodine was titrated with thiosulphate solution. The results of these separate determinations were in good agreement, and this means that the

manganese in the complex is in a trivalent state. To determine potassium, the solid sample was ignited at red heat and the residue was dissolved in hydrochloric acid. From the solution so obtained, potassium was determined gravimetrically by its weight as potassium sulphate after separation from other constituents. Carbon and hydrogen were determined through microchemical analysis, with special care being taken for the presence of potassium by the addition of tungsten trioxide to the sample. The nitrogen analysis was made by micro-Dumas method.

The results of a typical analysis follow: Found: K, 9.41%; Mn, 12.70%; C, 28.73%; H, 3.85%; N, 6.67%. Calculated for $KMn(III)(C_{10}H_{12}O_8N_2).2.5H_2O$: K, 9.14%; Mn, 12.88%; C, 28.13%; H, 3.91%; N, 6.56%.

That the solid has a 1:1 mole ratio of manganese to EDTA was checked by the EDTA titration method after reducing the complex with ascorbic acid.

PROPERTIES OF COMPLEX

The potassium salt of the manganese(III)–EDTA complex is a deep red crystal. Its X-ray diffraction pattern is shown in Fig. 3. It is very soluble in water, slightly soluble

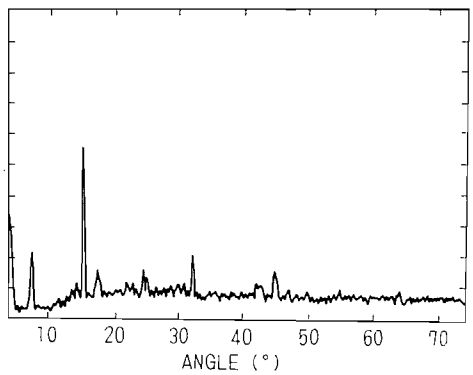

FIG. 3. X-Ray powder diffraction pattern of potassium salt of Mn(III)–EDTA complex (Cu K_{α_1}, λ = 1.54050 Å).

in glacial acetic acid, but insoluble in most organic solvents, such as absolute ethanol, ethyl ether, or acetone. At 0° C, in dark and dry air, the complex can be preserved even after a month, but at room temperature and especially in the daylight, it decomposes rapidly, leaving a colorless mass (probably Mn(II)–EDTA). Such characteristics are quite similar to those of oxalate complexes of trivalent manganese (7).

(i) Magnetic Measurement

As is to be expected the complex is paramagnetic, and the observed susceptibility was 9996×10^{-6} at 21° C. After allowing for the diamagnetic susceptibility of the various atoms the magnetic moment was calculated as 4.89 Bohr magnetons. The calculated value for "spin only" atom with four unpaired electron spins is 4.90. Hence these results support a formula with Mn(III).

(ii) Thermal Analysis

The thermal decomposition behavior of the solid complex was examined from 20° C to 300° C by using a thermobalance. The result is illustrated in Fig. 4. At about 80° C, the weight loss equivalent to ca. 0.5 mole of water per mole of the complex was observed

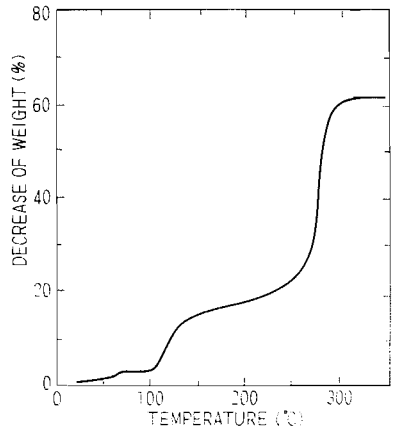

FIG. 4. The thermal analysis of potassium salt of Mn(III)–EDTA complex.

but the oxidation power of the products remained almost unchanged in this range. Hence the decrease of weight at this stage may correspond to the water of crystallization or some form of loosely bound water. At 100–200° C, 12–13% of the weight loss took place. The products at this state were still soluble in water, but the mole ratio of manganese to EDTA was greater than 1. Therefore, the decrease in weight at 100–200° C may correspond to the sum of the weight of the coordinated water and that of decomposed EDTA. The remaining EDTA was completely decomposed at 260–300° C; the residue, ca. 38% of the original sample, is probably a mixture of potassium carbonate and a compound similar to manganese oxycarbonate($MnO.MnCO_3$).

(iii) Infrared Spectra

A typical spectrum of the solid complex was shown in Fig. 5. As is seen in many trivalent transition metal – EDTA chelates (8), a characteristic strong absorption of

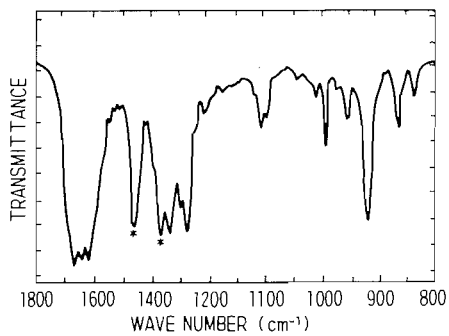

FIG. 5. Infrared spectra of potassium salt of Mn(III)–EDTA complex by Nujol method (*: absorption of Nujol).

the carboxylate group was observed in the 1600–1700 cm^{-1} region, but its fine structure was rather complicated; the complex exhibited three peaks due to antisymmetric vibration of carboxylate group at 1660, 1640, and 1600 cm^{-1}. Assignments for these frequencies would not be easy, but according to the extensive studies by Sawyer *et al.* (8), one possible interpretation would be that at least one of the COO^- groups is not bonded

to the manganese ion. Another factor which should be taken into consideration is a stereochemical one. It has been known that the distortion of octahedron of Mn^{3+} ion gives four short bonds and two long ones (9). In view of this, four carboxylate groups may be bonded to the metal in two ways.

(iv) Visible and Ultraviolet Spectra

Visible absorption spectra of the complex in acetic acid – sodium acetate buffer solutions of various pH were measured, and the results are shown in Fig. 6. Between

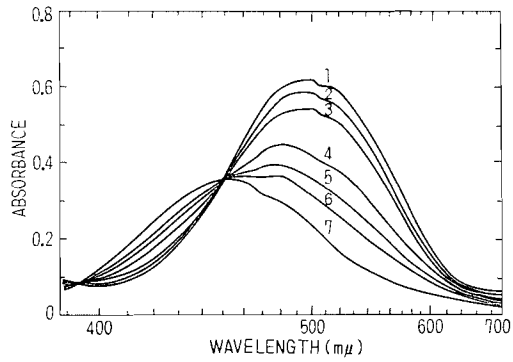

FIG. 6. The absorption spectra of Mn(III)–EDTA complexes in acetic acid – sodium acetate buffer solutions (μ = 0.1, Mn(III)Y: 9.34×10^{-4} mole/l.). The pH values of the solutions are: (1) 2.70, (2) 4.53, (3) 5.00, (4) 5.50, (5) 6.07, (6) 6.57, (7) 9.71.

pH 2.5–4.0 the maximum absorptions were observed at 500 mμ (log ϵ = 2.67), while in the higher pH region the color turned yellow and the maximum shifted to 450 mμ (log ϵ = 2.41). The spectra of the red species are very similar to those of manganese-(III)–trioxalato complex (λ_{max} at 500 mμ, log ϵ = 2.41) (7). As has been interpreted by some authors (10, 11), the absorption at 500 mμ may be due to $t_{2g} \rightarrow e_g$ transition for one 3*d* electron of the Mn^{3+} ion. In the series of these spectra isosbestic points were observed at about 390 mμ and 450 mμ.

Figure 7 illustrates the relation between the extinction at 500 mμ and the pH of the solutions. From this, the p*K* value between red and yellow species was evaluated as 5.3.

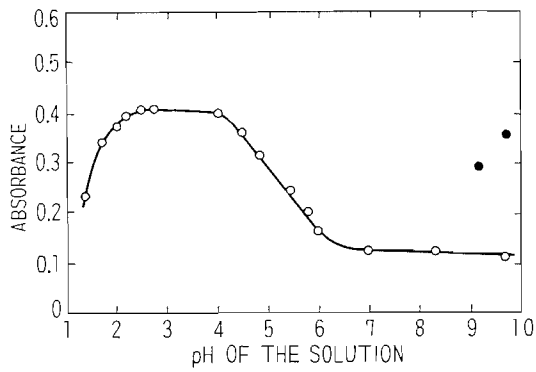

FIG. 7. The absorbance of Mn(III)–EDTA complexes at 500 mμ in acetic acid – sodium acetate buffer solutions (μ = 0.1, Mn(III)Y: 5.90×10^{-4} mole/l.) (●: absorbance of MnO_2 colloidal solution).

The yellow species was more unstable and readily decomposed in aqueous solution, giving manganese dioxide precipitation. However, when its solution was acidified immediately after its formation, the spectra and oxidation equivalent of the reproduced red species was nearly the same as those of the original red species. Yet, the attempts to produce the yellow species directly from manganese dioxide and alkaline EDTA solution or to obtain the solid yellow species have not been successful.

In the ultraviolet region, no remarkable absorption maximum was recognized but the absorption increased rapidly as the wavelength decreased.

(v) Acid–Base Titrations and Ion-exchange Behavior

Although the Mn(III)–EDTA complex is not stable enough in alkaline solution, it was found possible to follow its general behavior in acid–base titrations. Curve (A) in Fig. 8 was obtained when an aqueous solution of the solid complex was titrated with

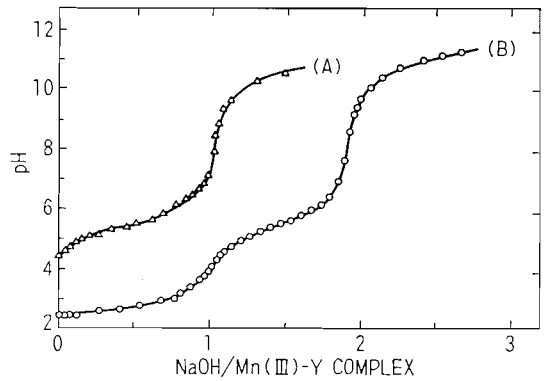

FIG. 8. Titration curves of Mn(III)–EDTA complexes with 0.1 *N* sodium hydroxide at 4±1° C. (A) 1.09×10^{-3} mole of KMn(III)Y; (B) 4.02×10^{-3} mole of HMn(III)Y.

standard sodium hydroxide solution. The curve has a single inflection point at a neutralization point (pH = 8.0) with approximately 1 mole of sodium hydroxide per mole of the complex. The pH of the half-neutralized solution is 5.5, which agrees fairly well with the pK value obtained from the spectral measurement.

In another run, a solution of the free complex acid was prepared by passing the potassium salt through the hydrogen form of a cation-exchange resin. On titration of the free acid with sodium hydroxide the curve (B) in Fig. 8 was obtained. This has inflection at 1 mole and ca. 1.9 mole of sodium hydroxide added per mole of the complex. The deviation of the second inflection point from 2 moles of NaOH may be due to the partial decomposition of the complex throughout the process.

For the purpose of comparison, similar acid–base titrations were carried out using Fe(III)–EDTA (Na salt) and Co(III)–EDTA (K salt). These results are plotted in Figs. 9 and 10. In the case of Co(III)–EDTA chelate in which EDTA is covalently bonded to the metal as a sexadentate ligand (12, 13), the pH of the solution of the potassium salt rises rapidly, showing no inflection point, while the free complex acid acts as a fairly strong monobasic acid. On the other hand, Fe(III)–EDTA complex behaves just in the same way as Mn(III)–EDTA complex, giving a single inflection point for sodium salt and two inflection points for its free acid. As was pointed out

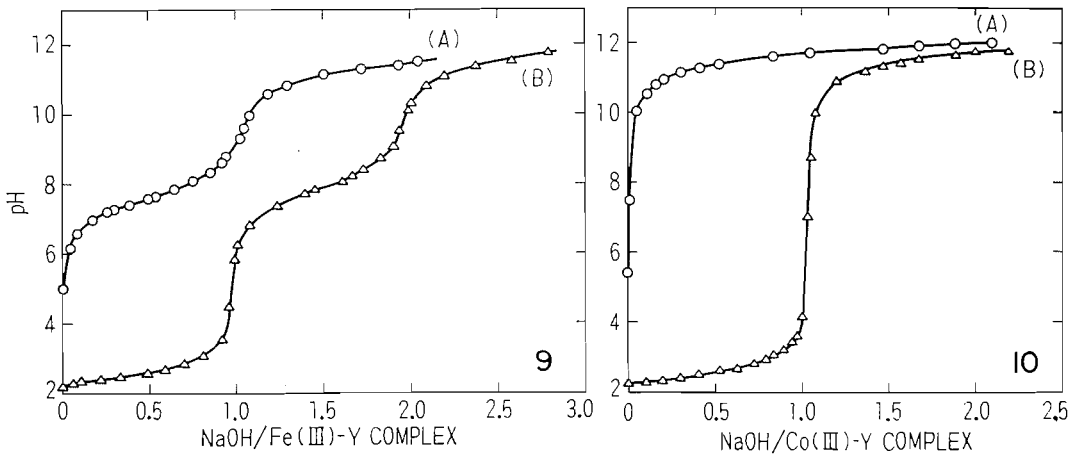

FIG. 9. Titration curves of Fe(III)–EDTA complexes with 0.1 *N* sodium hydroxide at 25±1° C. (A) 4.00×10^{-4} mole of $Na[Fe(OH_2)Y]$; (B) 4.00×10^{-4} mole of $H[Fe(OH_2)Y]$.

FIG. 10. Titration curves of Co(III)–EDTA complex with 0.1 *N* sodium hydroxide at 25±1° C. (A) 5.10×10^{-4} mole of K[Co(III)Y]; (B) 5.10×10^{-4} mole of H[Co(III)Y].

by Schwarzenbach (14), the Fe(III)–EDTA complex hydrolyzes strongly in higher pH region, forming a hydroxo complex, thus

$$[Fe(OH_2)EDTA]^- \rightleftarrows [Fe(OH)EDTA]^{2-} + H^+. \quad \text{(i)}$$

Analogously, the pH behavior of the free acid of Mn(III)–EDTA complex may be conveniently expressed in the following way:

$$H[Mn(OH_2)EDTA] \rightleftarrows H^+ + [Mn(OH_2)EDTA]^-, \; pK_1 \simeq 2.7 \quad \text{(ii)}$$

$$[Mn(OH_2)EDTA]^- \rightleftarrows H^+ + [Mn(OH)EDTA]^{2-}, \; pK_2 \simeq 5.5. \quad \text{(iii)}$$

That the Mn(III)–EDTA complex resembles the Fe(III)–EDTA rather than the Co(III)–EDTA complex could be checked by an anion-exchange experiment. When a solution of potassium salt of Co(III)–EDTA complex was passed into a column of Dowex 1-X8 in its chloride form, the complex anion displaces the chloride ion into the effluent. By the use of 4.08×10^{-4} mole of the complex it was found that 4.25×10^{-4} mole of chloride was displaced by the complex (Cl^-/complex = 1.04). However, similar experiments gave a displacement ratio Cl^-/complex of 1.4 for the Fe(III)–EDTA and 1.3 for the Mn(III)–EDTA complex. Moreover, by further washing of the columns with water the chloride ions continued to appear in the effluents and the flow rate became extremely slow. Such behavior for Fe(III)–EDTA and Mn(III)–EDTA complexes may be interpreted by assuming that the Fe(III)–EDTA and Mn(III)–EDTA complexes hydrolyze partially in the resin phase, as represented by equations (i) and (iii), and this hydrolysis is followed by a subsequent increase in the negative charges of complex anions.

(vi) General Remarks

From the results described above, there can be little doubt that the solid is a 1:1 chelate of the trivalent manganese with EDTA, but it is not yet possible to write a detailed formula for the potassium salt of the manganese(III) complex. At the present state, the following two formulae would fit the experimental facts:

(A) $K[Mn(III)(C_{10}H_{12}O_8N_2)(H_2O)].1.5H_2O$

(B) $K[Mn(III)(C_{10}H_{12}O_8N_2)(H_2O)_2].0.5H_2O$.

The result of the thermal analysis, which suggests the presence of $0.5H_2O$, supports the formula (B). Recently Hoard *et al.* (15) reported on the X-ray evidence for the seven coordination for $[Fe(III)(OH_2)Y]^-$ and $[Mn(II)(OH_2)Y]^{2-}$. In view of the close resemblance between the Fe(III) and Mn(III) ions there might also be a possibility of seven coordination for the Mn(III)–EDTA complex, but at present we do not have any direct evidence for it.

ACKNOWLEDGMENTS

The authors would like to express their thanks to their colleagues, to Dr. K. Imahori for infrared measurements, to Dr. Y. Takano for X-ray measurements, to Mr. M. Kinoshita for magnetic measurements, to Mr. S. Masuda for elementary analyses, and to Professor D. McCoy of the Sophia University for helping with the manuscript.

THE RAMAN SPECTRUM OF THE SULPHURIC ACIDIUM ION: THE CONSTITUTION OF CONCENTRATED SOLUTIONS OF TETRA(HYDROGENSULPHATO)BORIC ACID IN SULPHURIC ACID

R. J. Gillespie and E. A. Robinson[1]
Department of Chemistry, McMaster University, Hamilton, Ontario
Received December 15, 1961

ABSTRACT

The Raman spectra of sulphuric acid solutions of tetra(hydrogensulphato)boric acid and its sodium and hydronium salts have been examined. Frequencies are assigned to some of the vibrations of the sulphuric acidium ion, $H_3SO_4^+$, and are compared with the frequencies of the analogous vibrations of H_2SO_4 and HSO_4^-. Evidence is presented that elimination of disulphuric acid occurs between molecules of $HB(HSO_4)_4$ to give polymers containing B—O—B linkages.

No frequencies have been observed in either the infrared or Raman spectra of sulphuric acid oleums that can be attributed to the $H_3SO_4^+$ ion (1, 2), presumably because disulphuric acid and the higher polysulphuric acids are not strong enough acids to give a concentration of the $H_3SO_4^+$ ion that is sufficiently large to be detected by these methods (3). It was decided, therefore, to examine the Raman spectra of solutions of the relatively strong tetra(hydrogensulphato)boric acid, $HB(HSO_4)_4$, in the hope of obtaining frequencies for some of the vibrations of the $H_3SO_4^+$ ion.

When boric acid is dissolved in dilute sulphuric acid oleum, tetra(hydrogensulphato)-boric acid, $HB(HSO_4)_4$, is formed:

$$H_3BO_3 + 3H_2S_2O_7 = HB(HSO_4)_4 + 2H_2SO_4. \quad [1]$$

The conductivities of this acid in sulphuric acid show that it is a relatively strong acid of the sulphuric acid solvent system ($K_a = 0.2$ mole kg^{-1} (3)). Cryoscopic measurements on solutions of the acid (4), conductimetric titrations with various bases (5), and measurements of the Hammett acidity function, H_0 (6), all confirm the extensive ionization of tetra(hydrogensulphato)boric acid in sulphuric acid:

$$HB(HSO_4)_4 + H_2SO_4 = H_3SO_4^+ + B(HSO_4)_4^-. \quad [2]$$

In order to interpret the Raman spectra it was necessary to also have information on the spectra of solutions of the salts $NaB(HSO_4)_4$ and $H_3O.B(HSO_4)_4$; these were obtained by neutralizing the acid with an equivalent amount of the base $NaHSO_4$, and by dissolving boric acid in sulphuric acid:

$$H_3BO_3 + 6H_2SO_4 = 3H_3O^+ + B(HSO_4)_4^- + 2HSO_4^-. \quad [3]$$

The Raman spectra are given in Table I. In the spectrum of a 0.35 molal solution of $HB(HSO_4)_4$ in sulphuric acid most of the observed frequencies are due to the solvent sulphuric acid but, in addition, new lines were observed at 730, 985, 1100, 1260, and 1480 cm^{-1}.

In the spectrum of a 0.4 molal solution of H_3BO_3 in sulphuric acid all the observed frequencies can be assigned to sulphuric acid except for a strong line at 1040 cm^{-1} and a line at 588 cm^{-1}, both of which are undoubtedly due to the hydrogen sulphate ion

—	—	1480	$H_3SO_4^+$	—	—

NOTE: (*a*) 0.4 molal H_3BO_3 in H_2SO_4; (*b*) 0.35 molal $HB(HSO_4)_4$ in H_2SO_4; (*c*) 0.35 molal $NaB(HSO_4)_4$ in H_2SO_4.

(8), and a relatively weak line at 1100 cm^{-1}, which also occurs in solutions of the acid. This latter line is assigned to the symmetric stretch of the SO_2 group in the $B(O.SO_2.OH)_4^-$ ion. The corresponding asymmetric stretch, according to the linear relationship between SO_2 symmetric and asymmetric stretches (9), should occur at ~1260 cm^{-1}. A very weak line of this frequency appears to be present in the spectrum. The frequency of 1100 cm^{-1} for the SO_2 symmetric stretch in the $B(HSO_4)_4^-$ ion seems reasonable in view of the frequency of ~1200 cm^{-1} for this vibration in the acids $X.SO_2.OH$ and of ~1050 cm^{-1} in their anions $X.SO_2.O^-$ (8).

Although the SO_2 asymmetric stretch of the $B(HSO_4)_4^-$ ion probably contributes to the line at 1260 cm^{-1} in the spectrum of the 0.35 molal solution of $HB(HSO_4)_4$, the intensity of this line is much greater than in the spectrum of the 0.4 molal solution of H_3BO_3 in sulphuric acid. Thus we assign the frequency 1260 cm^{-1} also to the SO_2 symmetric stretch of the sulphuric acidium cation. The very weak line at 1480 cm^{-1} in the spectrum of the acid can then be assigned to the asymmetric SO_2 stretch of the $H_3SO_4^+$ ion: the pair of frequencies 1260 and 1480 cm^{-1} fit the straight-line relationship reasonably well. The new line at 985 cm^{-1} can be very reasonably assigned to the S—OH symmetric stretch of the $H_3SO_4^+$ ion, by comparison with the frequencies of this vibration in H_2SO_4 and HSO_4^- (Table II), and the 730 cm^{-1} line assigned to the $B(HSO_4)_4^-$ ion, probably to an SO_2 rocking mode.

In the molecules XSO_2OH the frequencies of the SO_2 and S(OH) stretching vibrations have been found to increase with increasing electronegativity of the group X (8). The

TABLE II

Comparison of the SO_2 and S—OH stretching frequencies of HSO_4^-, H_2SO_4, and $H_3SO_4^+$ (frequencies in cm^{-1})

Species	SO_2 (sym.)	SO_2 (asym.)	S—OH
HSO_4^-	1040	1195	895
H_2SO_4	1195	1368	910
$H_3SO_4^+$	1260	1480	985

frequencies which we have assigned to the stretching vibrations of the $H_3SO_4^+$ ion are compared in Table II with the frequencies of these vibrations in H_2SO_4 and HSO_4^- (8). It may be seen that the frequencies increase in the order $\nu_{HO.SO_2.O^-} > \nu_{HO.SO_2.OH} > \nu_{HO.SO_2.OH_2^+}$, which is quite consistent with the increasing electronegativity of the groups $-O^-$, $-OH$, and $-OH_2^+$.

When a 0.35 molal solution of $HB(HSO_4)_4$ was neutralized with an equivalent amount of $NaHSO_4$,

$$HB(HSO_4)_4 + NaHSO_4 = NaB(HSO_4)_4 + H_2SO_4, \quad [4]$$

the lines at 985 and 1480 cm^{-1} disappeared from the spectrum but the lines at 730, 1100, and 1260 cm^{-1}, which are assigned to the $B(HSO_4)_4^-$ ion, remained. Additional weak lines were also observed at 590, 625, 700, and 1040 cm^{-1}. The lines at 590 and 1040 cm^{-1} are due to the HSO_4^- ion (8), and the lines at 625 and 700 cm^{-1} may be due to vibrations of the $B(HSO_4)_4^-$ ion. Lines at these frequencies are also found in the more concentrated solutions of $HB(HSO_4)_4$.

The spectra of the concentrated solutions of $HB(HSO_4)_4$ in sulphuric acid are rather complex (Table III). Apart from the frequencies that can be reasonably assigned to

1480 (1)	1480 (2)	$H_3SO_4^+$

NOTE: (*a*) 1.4 molal $HB(HSO_4)_4$ in H_2SO_4; (*b*) 5 molal $HB(HSO_4)_4$ in H_2SO_4.
*Many of the lines assigned to $H_2S_2O_7$ are probably common also to $H_2S_3O_{10}$ (1).

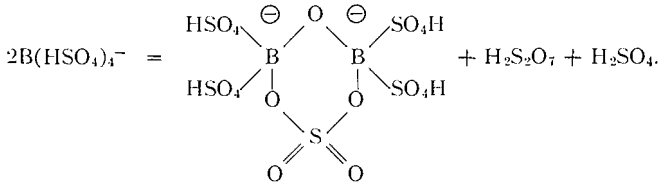
H_2SO_4 and $B(HSO_4)_4^-$ there are many other lines, some of which are obviously due to $H_2S_2O_7$ and $H_2S_3O_{10}$ (1). Tentative assignments are given in Table III. In a 5 molal solution of $HB(HSO_4)_4$ the intensities of the H_2SO_4 lines, in particular the 910 cm^{-1} line, relative to the lines of $H_2S_2O_7$, in particular the 327 cm^{-1} line, are approximately

the same as in a 20% oleum (1) in which the mole ratio $H_2S_2O_7/H_2SO_4 = 0.3$. Although some $H_2S_2O_7$ is formed by the reaction

$$H_3SO_4^+ + H_2SO_4 = H_3O^+ + H_2S_2O_7, \qquad [5]$$

this occurs only to the extent of a few percent in a 5 molal solution (7). Evidently the concentration of $H_2S_2O_7$ is much greater than can be accounted for in this way.

The most reasonable explanation for the occurrence of relatively large concentrations of disulphuric acid in concentrated solutions of $HB(HSO_4)_4$ is that it is eliminated in a condensation process between $B(HSO_4)_4^-$ ions giving polymeric anions containing B—O—B linkages. Evidence is presented in a following paper that these B—O—B linkages are generally contained in a six-membered ring which also contains a sulphate group, e.g.



Quantitative elimination of $H_2S_2O_7$ according to the above equation would in the case of a 5 molal solution of $HB(HSO_4)_4$ give a solution in which the mole ratio of $H_2S_2O_7$ to H_2SO_4 is equal to 0.3. This agrees with the estimate given above from the comparison of the spectrum with that of a 20% oleum. Evidently this polymerization reaction is extensive if not complete.

EXPERIMENTAL

The Raman spectra were obtained as previously described (10). The preparation of solutions of tetra-(hydrogensulphato)boric acid has been described in a previous publication (4).

TERPENOIDS

I. THE CONSTITUTION AND STEREOCHEMISTRY OF CEANOTHIC ACID[1]

P. DE MAYO AND A. N. STARRATT
Department of Chemistry, University of Western Ontario, London, Ontario
Received November 27, 1961

ABSTRACT

Ceanothic acid, a substance previously isolated by Julian, Pikl, and Dawson (J. Am. Chem. Soc. **60**, 77 (1938)), has been shown to be a triterpenoid related to the lupeol–betulin group, but in which ring A is five-membered. It has been degraded to the keto ester A norbetulonic acid methyl ester, a substance of defined constitution and stereochemistry. The hydroxyl and carboxyl groups attached to ring A have been shown by spectroscopic studies to be trans, the stereochemistry of ceanothic acid being that represented by (XII).

By the extraction of the root bark of *Ceanothus americanus* (Jersey Tea) Julian, Pikl, and Dawson (2) isolated a crystalline acid which was termed ceanothic acid. This substance, which had not been reported by other investigators of the root bark (3), was characterized by the American workers as a hydroxy dicarboxylic acid and attributed the formula $C_{29}H_{44}O_5$. It was characterized by the preparation of a dimethyl ester and of a dimethyl ester acetate.

They reported, further, that on heating to the melting point 1 mole each of water and carbon dioxide were evolved. The major fragment they concluded, for unspecified reasons, but probably on the basis of alkaline non-solubility, was a lactone, and hence proposed that ceanothic acid was a γ-hydroxy acid.

Attempted repetition of the method of isolation used by Julian, Pikl, and Dawson did not lead, in our hands, to the isolation of any ceanothic acid. These authors remark on the variability of the plant, and subsequent workers (4) have also made similar observations. A modified procedure was evolved and is described in the experimental section of this paper. The acid so isolated had the properties ascribed to it by the early workers, but, as will be seen in the sequel, the empirical formula requires modification to $C_{30}H_{46}O_5$, a point difficult of determination from analyses alone.

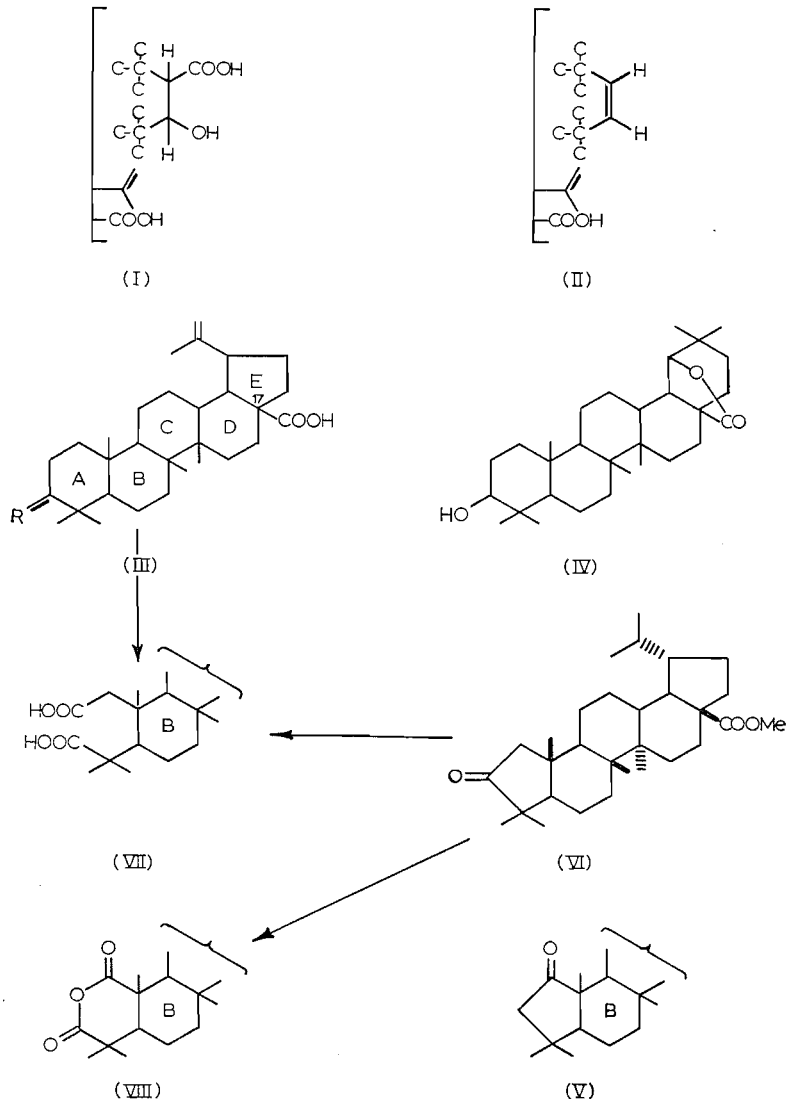
The infrared spectra of ceanothic acid and of its dimethyl ester showed bands at 833 (nujol mull) and 889 cm^{-1}, respectively, indicative of the presence of an exo methylene group. This interpretation was supported by the disappearance of this band on catalytic hydrogenation both of the acid and of the ester to their respective saturated dihydro compounds. The n.m.r. spectrum of the ester showed a doublet at τ 5.37 ($J \sim 7.7$ c.p.s.) (2 hydrogens) attributed to the methylene group and a singlet (3 hydrogens) at τ 8.36 attributed to a vinylic methyl group (5, p. 61). These observations, in the absence of any other double bond, indicated the presence of an isopropenyl group.

The n.m.r. spectrum, further, showed singlets (1 hydrogen) at τ 5.98 and τ 7.51. It thus seemed probable that both the hydroxyl group and one of the carboxyl groups were attached to carbon atoms bearing one hydrogen atom: these bands are in appropriate places for the respective methine hydrogens (5, pp. 55, 57).

Evidence for the proximity of the hydroxyl group and the secondary carboxyl group was obtained by an examination of the "lactone" obtained by Julian, Pikl, and Dawson (2). This substance was, in fact, an unsaturated acid, as evinced by its conversion, with

[1]*Part of the material reported herein formed the substance of a preliminary communication (1).*

diazomethane, to the corresponding ester. In addition to the bands at τ 5.40 and τ 8.46 in the n.m.r. spectrum, indicative of the continuing presence of the isopropenyl group, two hydrogens producing an AB pattern (doublets at τ 4.16 and τ 4.66; $J_{AB} \sim 5.4$ c.p.s.) were present. The formation of this pattern is evidence for the transformation indicated in the conversion of (I) to (II), that is, the dehydration–decarboxylation of a β-hydroxy acid.



This was confirmed, as follows. Dimethyl ceanothate was converted into the benzoate (isolated only as an oil) and the latter pyrolyzed at 330° to eliminate benzoic acid. The isolated anhydroacid showed the expected ultraviolet end absorption for an isolated isopropenyl group and an α,β-unsaturated ester. Furthermore, a band (singlet, 1 hydrogen) at τ 3.9 in the n.m.r. spectrum indicated the presence of the expected vinyl hydrogen in addition to those of the isopropenyl group (5, p. 61).

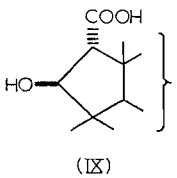
Since dihydroceanothic acid and its dimethyl ester showed no absorption in the ultraviolet spectrum in the 200–210 mμ region, they were, presumably, saturated. It followed that ceanothic acid was, therefore, pentacarbocyclic. Some relationship to the lupeol – betulin – betulinic acid (III, R = H, OH) series seemed probable in view of the presence of the isopropenyl group and this view was strengthened by the presence of betulinic acid itself amongst the root constituents.

One of the characteristic transformations of the lupeol–betulin group of substances is the ready acid-catalyzed expansion of the terminal, E, ring to give derivatives of the β-amyrin series (6). In those substances having a carboxyl function at C_{17} concomitant lactonization occurs: betulinic acid (III, R = H, OH), for instance, is converted into (IV). When subjected to suitable conditions—refluxing formic acid for 3 hours—ceanothic acid was converted into a γ lactone (bands at 1696 (carboxyl) and 1762 cm^{-1} (γ lactone)) with the simultaneous disappearance of the isopropenyl group. The resulting monocarboxylic acid lactone was further characterized as the acetate, indicating the nonparticipation of the hydroxyl group in the lactonization process, and as the methyl ester.

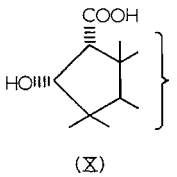
Some modification of the betulinic acid skeleton in ceanothic acid was, however, necessary since the functions indicated in (I) cannot otherwise be accommodated. The grouping in (I) was suggestive of the occurrence of a 'biogenetic' pinacolic rearrangement at some stage in the genesis of ceanothic acid, such as may take place in the formation of gibberellic acid (7) and of the aldehyde in magnamycin (8).

Oxidation of methyl dihydroceanothate with sodium dichromate gave the corresponding ketone. Alkaline hydrolysis resulted in the loss of carbon dioxide expected of a β-keto ester and the formation of a ketonic monoester. This substance showed an unresolved band in the infrared spectrum (at 1738 cm^{-1}) for the cyclopentanone and ester, while its precursor showed bands (CCl_4) at 1750 (cyclopentanone) and 1727 cm^{-1} (ester).

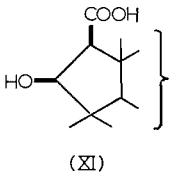
Two possible structures, (V) and (VI), were possible for this ketone, but its properties suggested that it was (VI), a substance previously prepared by Ruzicka *et al.* (9, 15) from betulonic acid by hydrogenation, nitric acid oxidation to (VII), followed by pyrolysis and esterification. Direct preparation of this substance from methyl dihydrobetulonate and comparison of it, the derived 2:4-dinitrophenylhydrazone, and anhydride (VIII) (obtained by selenium dioxide oxidation) showed them to be identical in every respect. Four possible structures, (IX), (X), (XI), and (XII), followed for ceanothic acid.



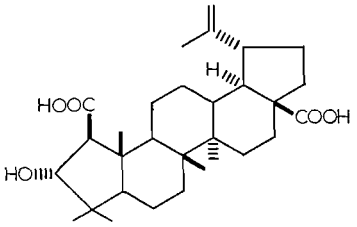
(IX)



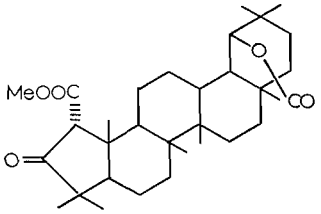
(X)



(XI)



(XII)



(XIII)

It has already been noted that, in dimethyl ceanothate, the methine hydrogens adjacent to the carbomethoxyl and hydroxyl groups were singlets; that is, although the hydrogens were on contiguous carbon atoms, the coupling constant was close to zero. In contrast, the ketone (XIII), derived from methyl ceanothate lactone, on reduction with sodium borohydride gave an epimeric alcoholic lactone, methyl isoceanothate lactone. This substance showed, in its n.m.r. spectrum, a doublet at τ 7.0, the methine hydrogens being coupled, and a quartet at τ 5.9 (5, pp. 55, 57), the hydrogen on the carbon bearing oxygen being split by the adjacent methine hydrogen and by the hydroxyl hydrogen. This would suggest that in dimethyl ceanothate the hydrogen atoms are at an angle of about 90° (10, 11) and, therefore, in the trans relationship.

Further evidence supporting this view was obtained from a study of infrared spectra. Treatment of methyl dehydroceanothate lactone, (XIII), with sodium methoxide resulted in a rapid epimerization of the carbomethoxyl group—which must, therefore, be in the unstable configuration—and the formation of the isomeric methyl dehydroepiceanothate lactone. Reduction of this with sodium borohydride then gave methyl epiceanothate lactone. Three of the four epimeric hydroxy esters were now in hand. The infrared spectra of these substances in solution were determined in the carbonyl and hydroxyl regions. The results are recorded in Table I. Methyl dihydroceanothate shows a normal

TABLE I

Compound	ν_{ester} (cm^{-1})*	$\nu_{hydroxyl}$ (cm^{-1})*	Concentration (%)†
Dimethyl dihydroceanothate	1733	3634 (sharp), ~3510 (broad)	2.5
		3634 (sharp)	1.2
		3640 (sharp)	0.2
Methyl isoceanothate lactone	1718	3582 (sharp)	0.7
		3580 (sharp)	0.1
Methyl epiceanothate lactone	1717	3632 (sharp), 3508 (broad)	1.9 ($CHCl_3$)‡
		3634 (sharp), 3508 (broad)	0.3

*Spectra taken in CCl_4 (Fisher Spectranalyzed) unless specified otherwise.
†Maximum concentration limited by compound solubility.
‡Chloroform washed and dried to remove alcohol.

unbonded ester and, in agreement, the hydroxyl group shows bonding (intermolecular) only in the most concentrated solution. In contrast, the epimeric methyl isoceanothate lactone shows a bonded ester group and a bonded hydroxyl band even in dilute solution. These results support the trans and cis configurations, respectively, allocated. It seems probable that methyl epiceanothate lactone is, also, cis.

Structures (IX) and (XII) remain for ceanothic acid, and inspection of models suggests that the β-carbomethoxyl group is under more severe non-bonded interaction than the α epimer. In view of the ready epimerization of methyl dehydroceanothate lactone, stereostructure (XII) is preferred for ceanothic acid.[2]

An attempt was made to confirm this from optical rotatory dispersion measurements. An amplitude of 200, 203, and 228 for methyl dehydroepiceanothate lactone, methyl dehydroceanothate lactone, and (VI) respectively was recorded. The differences are too small to be interpretable, particularly since slight changes in the conformation of the cyclo-

[2]*We understand that Dr. J. J. H. Simes (University of New South Wales) has independently arrived at the same stereochemical conclusions with regards to ceanothic acid. We wish to thank Dr. Simes for this information.*

pentanone ring are likely to be of considerable significance (12). It is interesting, however, that the proposed stereochemistry of the keto esters is that predicted by Bose's empirical rule (13).

The substance emmolic acid, recently isolated by Boyer, Eade, Locksley, and Simes (14) from *Emmenospermum alphitonioides* F. Muell. has constants comparable with those of ceanothic acid, and, where the same derivatives have been prepared, there is good agreement. We have been informed[3] that these substances are identical: the name used by Julian, Pikl, and Dawson (2) should therefore be that retained.

After the preparation of this manuscript a recent publication (16) by Mechoulam became available. This author concurs in the allocation of the β configuration to the carboxyl group of ceanothic acid, but concludes that the hydroxyl group is cis. The reasons advanced are that, first, lithium aluminum hydride reduction of the ketone derived from dimethyl ceanothate and of dimethyl ceanothate itself gives the same triol. It is proposed that the hydroxyl produced by ketonic reduction is that which is more hindered, i.e. β, and that this configuration is, therefore, that present in ceanothic acid itself. Secondly, it is reported that in dilute (unspecified) solution in carbon tetrachloride the triol exhibits hydrogen bonding of the hydroxyl group, again apparently supporting the cis allocation of configuration.

We do not find these results persuasive. The prediction of the configuration of the hydroxyl produced by ketonic reduction is quite uncertain in the presence of a nearby function with which the lithium aluminum hydride can chelate and direct the stereochemical course of reduction. It cannot thence be concluded that the alcohol produced is the more hindered. The assignment of the configuration rests solely, therefore (assuming no epimerization of the carbomethoxyl group during the reduction), on a single observation with regard to hydrogen bonding. We believe that such observations are only relevant if the appropriate epimer is available for comparison. Since, in the triol, the situation is complicated by a third (primary) hydroxyl group, the conclusion is rendered yet more dubious.

EXPERIMENTAL

Infrared spectra and rotations were determined in chloroform solution and ultraviolet spectra in ethanol unless otherwise stated. Melting points were uncorrected and determined on the Köfler hot stage. Nuclear magnetic resonance spectra were determined at 60 Mc/s on the Varian V-4304 spectrometer in carbon tetrachloride solution with 1% tetramethylsilane as an internal reference. Alumina was Woelm neutral, standardized according to Brockmann. Light petroleum refers to the fraction of b.p. 60–80°.

Extraction of Ceanothus americanus

Extraction and isolation in the manner described by Julian, Pikl, and Dawson (2) was not successful in our hands. By different procedures, different proportions of the various acid constituents were obtained. That leading to ceanothic acid is described below; other procedures will be described in a forthcoming publication.

The ground root bark (2 kg, supplied by S. B. Penick and Co.) was extracted continuously with ether in a Soxhlet apparatus for 33 hours. The residue (35 g) was extracted with light petroleum under reflux for 3 hours, the light petroleum then being replaced, and the process repeated four times. The residue, in ethereal solution, was extracted exhaustively with potassium hydroxide solution (2%). A solid (A), which separated at the interface, was removed by filtration. Acidification of the alkaline solution and isolation with ether gave the crude acid mixture (11 g), which was further defatted by extraction with light petroleum.

The acid mixture (10.4 g) was added, in benzene solution, to a column of silica (B.D.H.; 300 g). Elution with benzene–ether (20:1) gave an *acid* (538 mg), which, after recrystallization from ether–methanol, had melting point 350–354° (decomp.), $[\alpha]_D$ +39° (*c*, 1.23; pyridine). Found: C, 76.45; H, 9.23; O, 14.43%.[4]

[3]*We wish to thank Dr. T. G. Halsall (Oxford) for this information.*

[4]*Further work on this substance, ceanothenic acid, and better methods of isolation will be reported in due course.*

Further elution with the same solvent mixture then gave betulinic acid (232 mg), m.p. 270–285°, identified as described below. Elution with benzene–ether (10:1) then gave material which after two crystallizations from ether–benzene gave ceanothic acid (350 mg), m.p. 330–340° (with evolution of gas). Further recrystallization from ether–methanol gave pure ceanothic acid, m.p. 356–357° (gas evolution), $[\alpha]_D$ +38°: (*c*, 1.20; ethanol). Julian, Pikl, and Dawson (2) report m.p. 354°. The substance showed ν_{max} at 3480, 1720, 1641, and 883 cm^{-1} (nujol mull).

Identification of Betulinic Acid

The salt (A) was acidified and the acid isolated with ether. It was identical with the crude betulinic acid isolated during chromatography. It was reduced in ethereal solution with excess lithium aluminum hydride, the crude diol acetylated, and the diacetate, m.p. 215–216°, $[\alpha]_D$ +14° (*c*, 0.90) was identical in infrared spectrum and gave no melting point depression on admixture with an authentic specimen of betulin diacetate.

Dimethyl Ceanothate

Methylation with diazomethane gave the dimethyl ester, m.p. 221–223° (Julian, Pikl, and Dawson (2) report 223°), $[\alpha]_D$ +41° (*c*, 1.00). Acetylation gave the acetate, m.p. 157–160° (Julian, Pikl, and Dawson (2) report 157°), $[\alpha]_D$ +29° (*c*, 1.07).

Dimethyl Dihydroceanothate

Dimethyl ceanothate (53 mg) in ethanolic solution was hydrogenated over palladized charcoal (35 mg, 5%). After chromatography on alumina the material eluted with benzene–ether (20:1) was crystallized from ether–methanol, when the dimethyl dihydroceanothate obtained had m.p. 262–263°, $[\alpha]_D$ +21° (*c*, 1.36). Calc. for $C_{32}H_{52}O_5 . 0.5MeOH$: C, 73.31; H, 10.15%. Found: C, 73.06; H, 9.91%.

The same substance was obtained by hydrogenation in glacial acetic acid solution over platinum oxide catalyst; 1.0 mole hydrogen was absorbed.

Dihydroceanothic Acid

Ceanothic acid (199 mg) was hydrogenated in acetic acid solution over platinum oxide. Crystallized from ether–methanol, the acid had melting point above 350°, $[\alpha]_D$ +11° (*c*, 0.97; ethanol). Calc. for $C_{30}H_{48}O_5$: C, 73.73; H, 9.90%. Found: C, 73.94; H, 10.04%.

Pyrolysis of Dimethyl Ceanothate Benzoate

Dimethyl ceanothate (89 mg) was converted into the benzoate (benzoyl chloride – pyridine). After extensive chromatography it was obtained only as an oil (77 mg). This oil (69 mg) was heated at 330° under a slow stream of nitrogen. The crude product was refluxed for 1 hour with methanolic potassium hydroxide (5%) and the neutral material was isolated with ether and chromatographed on alumina (Grade 1; 2 g). Elution with light petroleum – benzene (1:1) and crystallization from ether–methanol gave dimethyl anhydroceanothate (19 mg), m.p. 166–168°, $[\alpha]_D$ −16° (*c*, 1.51), λ_{inf} 215 mμ (ϵ 7500). Calc. for $C_{32}H_{48}O_4$: C, 77.37; H, 9.74; OMe, 12.5%. Found: C, 77.65; H, 9.63; OMe, 12.39%.

On catalytic hydrogenation in acetic acid solution over platinum oxide 2 moles of hydrogen were absorbed.

Ceanothic Acid Lactone

Ceanothic acid (60 mg) was refluxed in formic acid (98%) for 3 hours, the formic acid removed *in vacuo*, and the residue refluxed with methanolic potassium hydroxide (5%) for 30 minutes. Isolation with ether and crystallization from ether – light petroleum gave the lactone, m.p. 190–205° and 303–305°, $[\alpha]_D$ +90° (*c*, 0.91), ν_{max} 1760, 1695 cm^{-1}. Calc. for $C_{30}H_{46}O_5 . 0.5H_2O$: C, 72.72; H, 9.49%. Found: C, 72.24; H, 9.55%.

The acid lactone, on methylation with ethereal diazomethane, gave the methyl ester, m.p. 256–257°, $[\alpha]_D$ +90° (*c*, 0.98). Calc. for $C_{31}H_{48}O_5$: C, 74.36; H, 9.66%. Found: C, 74.08; H, 9.66%. The lactone, prepared from ceanothic acid (296 mg), was acetylated (acetic anhydride – pyridine) and the crude acetate chromatographed on silica gel (15 g). Elution with benzene–ether (20:1) afforded, after crystallization from ether–methanol, the acetate, m.p. 309–311° (decomp.), $[\alpha]_D$ +70° (*c*, 1.19). Calc. for $C_{32}H_{48}O_6$: C, 72.69; H, 9.15%. Found: C, 72.64; H, 9.16%.

Methyl Dehydroceanothate Lactone

Methyl ceanothate lactone (70 mg) in acetic acid (6 ml) containing sodium dichromate (44 mg) was allowed to stand overnight at room temperature. Isolation in the usual way gave, after crystallization from chloroform–methanol, the ketone, m.p. 220–225° and 319–324°, $[\alpha]_D$ +178° (*c*, 0.63). Calc. for $C_{31}H_{46}O_5$: C, 74.66; H, 9.30%. Found: C, 74.76; H, 9.25%.

Decarboxyanhydroceanothic Acid

Ceanothic acid (47 mg) was heated in a Wood's metal bath under nitrogen until the temperature rose to 350°. The product was taken up in ether, washed with dilute potassium hydroxide solution, and, after evaporation of the ether, was crystallized from ether – light petroleum, when it has m.p. 238–244° (Julian, Pikl, and Dawson (2) record 234°), $[\alpha]_D$ +27° (*c*, 0.79), ν_{max} 1697, 1643, 881 cm^{-1} (CCl_4). Calc. for $C_{29}H_{44}O_2$: C, 82.02; H, 10.44%. Found: C, 81.97; H, 10.62%.

Methyl Dehydrodihydroceanothate

Methyl dihydroceanothate (45 mg) in acetic acid (5 ml) containing sodium dichromate (18 mg) was allowed to stand overnight at room temperature. Isolation and crystallization from ether–methanol gave the keto ester, m.p. 183–184°, $[\alpha]_D$ +94° (*c*, 1.25), ν_{max} 1750 cm^{-1}. Calc. for $C_{32}H_{50}O_5 . 0.5MeOH$: C, 73.59; H, 9.81%. Found: C, 73.77; H, 9.45%.

Methyl Decarboxydehydrodihydroceanothate

Methyl dehydrodihydroceanothate (59 mg) was refluxed 2 hours in methanolic potassium hydroxide (10 ml; 10%). Isolation and crystallization from ether–methanol afforded the decarboxy ester, m.p. 180.5–181.5°, $[\alpha]_D$ +72° (*c*, 1.11). Calc. for $C_{30}H_{48}O_3$: C, 78.89; H, 10.59%. Found: C, 78.32; H, 10.67%. The melting point was undepressed on admixture with A-nor-dihydrobetulonic acid methyl ester of the same melting point prepared as described by Ruzicka and Isler (15). Ruzicka, Brenner, and Rey (9) record $[\alpha]_D$ +84.6°. It was also prepared as described below. The infrared spectra were superposable. The 2:4-dinitrophenylhydrazone, crystallized from chloroform–methanol, had melting point 261–263° and gave no depression in melting point on admixture. Calc. for $C_{36}H_{52}N_4O_6$: C, 67.89; H, 8.23; N, 8.80%. Found: C, 67.94; H, 8.19; N, 9.03%.

The ceanothic keto ester (28 mg) was heated in a sealed tube with selenium dioxide (120 mg) and dioxan (4 ml) at 200° for 11½ hours. The anhydride, isolated as described by Ruzicka and Isler (15), had m.p. 271–272°, $[\alpha]_D$ +40° (*c*, 1.32), ν_{max} 1800, 1755, 1720 cm^{-1}. These authors report m.p. 269–270° (cor.), $[\alpha]_D$ +42.5°.

The Oxidation of Methyl Dihydrobetulonate

The keto ester (255 mg) was added to a precooled mixture of fuming nitric acid (11 ml; 90%) and glacial acetic acid (10 ml), and stirred for ¾ hour at 0°, when the ester had dissolved, and allowed to stand for a further ¾ hour. After dilution with water the collected material was chromatographed on silica gel (11 g). Elution with benzene afforded some starting material after which elution with benzene–ether (20:1) gave A-secodihydrobetulinic acid tricarboxylic acid monomethyl ester, m.p. 160–163°, $[\alpha]_D$ +8° (*c*, 1.08). Calc. for $C_{31}H_{50}O_6 . 0.5H_2O$: C, 70.59; H, 9.67%. Found: C, 70.72; H, 9.46%. Methylation (diazomethane) gave the known trimethyl ester, m.p. 147–149°, $[\alpha]_D$ −18° (*c*, 1.2). Ruzicka and Isler report 145° (15).

Pyrolysis of the diacid ester at 260° (12 mm Hg) gave a mixture of anhydride and cyclopentanone. Hydrolysis with alcoholic potassium hydroxide (5%) and isolation of the neutral material gave the A-nor ketone identical in melting point and mixed melting point with the material described above.

Epimerization of Methyl Dehydroceanothate Lactone

The lactone (13.6 mg) in methanol (5 ml) had $[\alpha]_D$ +153°. Methanolic sodium methoxide (5%; 0.5 ml) was added and the rotation redetermined immediately and found to be $[\alpha]_D$ +113°. It was not changed on further standing. Repetition of the above experiment on a larger scale (101 mg) on isolation of the product gave, after crystallization from chloroform–methanol, methyl dehydroepiceanothate lactone, m.p. 328–330° (decomp.), $[\alpha]_D$ +117° (*c*, 0.71). Calc. for $C_{31}H_{46}O_5$: C, 74.66; H, 9.30%. Found: C, 74.83; H, 9.33%.

Methyl Epiceanothate Lactone

To methyl dehydroepiceanothate lactone (40 mg) in dioxan (5 ml), methanol (5 ml), and water (1 ml) was added sodium borohydride (40 mg). After 45 minutes the product was isolated with ether and, after evaporation of the solvent, chromatographed on alumina (Grade 3; 2 g). Elution with benzene – light petroleum (1:1) followed by crystallization of the product from chloroform–methanol gave the alcohol, m.p. 301–303°, $[\alpha]_D$ +31° (*c*, 1.19). Calc. for $C_{31}H_{48}O_5$: C, 74.36; H, 9.66%. Found: C, 74.44; H, 9.47%.

Methyl Isoceanothate Lactone

Methyl dehydroceanothate lactone (129 mg) in dioxan (13 ml), methanol (15 ml), and water (4 ml) was treated with sodium borohydride (50 mg). After 35 minutes the product was isolated and chromatographed on alumina (Grade 3; 12 g). Elution with benzene – light petroleum (1:1) gave, after crystallization from chloroform–methanol, the alcohol, m.p. 239–240°, $[\alpha]_D$ +85° (*c*, 0.84). Calc. for $C_{31}H_{48}O_5$: C, 74.36; H, 9.66%. Found: C, 74.17; H, 9.52%.

ACKNOWLEDGMENTS

We wish to thank Dr. J. B. Stothers for the n.m.r. spectra, Dr. J. E. D. Levisalles, Miss H. Herrmann, and Miss L. Ohnimus (Strasbourg) for the optical rotatory dispersion measurements, and Dr. C. J. W. Brooks (Glasgow) for an informative discussion. We also wish to thank Dr. R. A. Abramovitch (Saskatoon) for a generous supply of crude acids.

The authors are indebted to the National Research Council of Canada and to the Research Corporation for financial support.

A KINETIC STUDY OF THE METATHETICAL AND ADDITION REACTIONS CHARACTERISTIC OF ALLYL POLYMERIZATION

A. C. R. Brown and D. G. L. James
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received September 25, 1961

ABSTRACT

The rate constants of the reactions

$$CH_3CH_2\cdot + CH_2{=}CH{-}CH_2OH \rightarrow CH_3CH_2{-}CH_2{-}\dot{C}H{-}CH_2OH, \quad [7]$$

$$CH_3CH_2\cdot + CH_2{=}CH{-}CH_2OH \rightarrow CH_3CH_3 + CH_2{=}CH{-}\dot{C}H{-}OH \quad [6]$$

have been measured in the gas phase between 50° and 142° C:

$$k_7/k_2^{1/2} = (5.5\pm2.7)\times10^{-8}\exp(-7750\pm350)/RT \text{ cm}^{3/2}\text{ molecule}^{-1/2}\text{ sec}^{-1/2},$$

$$k_6/k_2^{1/2} = (2.5\pm1.0)\times10^{-8}\exp(-7600\pm300)/RT \text{ cm}^{3/2}\text{ molecule}^{-1/2}\text{ sec}^{-1/2},$$

where k_2 is the (known) rate constant for the reaction

$$2CH_3CH_2\cdot \rightarrow C_4H_{10}. \quad [2]$$

The significance of these values is discussed in relation to the propagation and chain transfer processes in the polymerization of allyl alcohol. A consideration of the rates of addition of free radicals to a series of monomers of diverse reactivity reveals that a correlation exists between the rate constants for the addition of the ethyl radical in the gas phase and of certain polymer radicals in the liquid phase.

An application of the general equation proposed by Bamford, Jenkins, and Johnston for radical reactivity leads to the conclusion that $k_p \approx 2k_7$ and that $k_p/k_f \approx k_7/k_6 = 1.8$ for allyl alcohol at 60° C. Predictions based upon these relationships are compared with experimental data for the propagation and degree of homopolymerization of allyl alcohol and for inhibition and propagation in copolymerization; reasonable agreement is found in all cases.

INTRODUCTION

The polymerization of allyl alcohol appears to offer the clearest example of allylic kinetics (1); but the kinetic study is rendered difficult by the low reactivity of the monomer (2). In this paper we offer a new approach to problems of this kind, and suggest that our method may be of general use in the study of the energetics of the elementary reactions of polymerization.

Allyl polymerization owes its distinctive character to a delicate balance between the rates of two competing reactions: addition and metathesis. Each of these alternatives involves the same reactants: a growing polymer radical, vinylic in nature, and an allylic monomer molecule:

$$M_j\cdot + CH_2{=}CH{-}CH_2X \rightarrow M_j{-}CH_2{-}\dot{C}H{-}CH_2X \text{ (addition)},$$

$$M_j\cdot + CH_2{=}CH{-}CH_2X \rightarrow M_jH + CH_2{=}CH{-}\dot{C}HX \text{ (metathesis)}.$$

Addition forms another vinylic polymer radical, equal in reactivity to its parent, and is thereby a step in the propagation of polymerization. Metathesis produces a new class of radical, the allylic radical $CH_2{=}CH{-}CHX\cdot$. The allylic radical is stabilized by resonance (3) and has a reactivity decisively lower than the vinylic radical (4); indeed, the allylic radical is characteristically too unreactive to add to the monomer molecule, and so cannot propagate the chain (5). Instead, it may terminate the chain by combining with a growing polymer radical, or it may be removed by dimerization. In either case, metathesis results in both structural and kinetic chain termination, whereas addition is the

essential reaction of propagation in both allyl and vinyl polymerization. The experimental evidence for these views has been derived largely from kinetic studies of the polymerization of allyl acetate (5–8), and a comprehensive kinetic scheme has been proposed by Litt and Eirich (7).

The ideal allyl monomer for this study is one which reveals most clearly the competition between metathesis and addition. Certain allyl monomers are unsuitable because they display either vinylic reactivity (allyl chloride (9)), effective chain transfer (allyl acetate (10, 11)), or radical displacement reactions (allyl trimethyl acetate (10)). Allyl alcohol was chosen for this study because the OH group is neither reactive in itself nor does it confer abnormal reactivity upon the double bond (12). Thus, allyl alcohol can be polymerized very slowly by peroxidic catalysts, but only an oil with a degree of polymerization of five is obtained, and fresh catalyst must be added frequently to the system (13, 14).

Our aim is the comparison of the rates of the metathetical and addition reactions of allyl alcohol, chosen as a typical allylic monomer. To eliminate inessentials, we have chosen the simplest vinylic radical, $CH_3CH_2\cdot$, to attack the monomer, and have studied the reaction in the gas phase. In this way we avoid the variable influences of chain length and configuration of the vinylic polymer radical, and other problems arising from interactions in the liquid phase.

EXPERIMENTAL METHODS

The apparatus and method have been described in two earlier papers (15, 16). Certain improvements in the techniques of purification of reactants and analysis of products have been adopted in this investigation. The diethyl ketone and the allyl alcohol, both White Label grade materials of the Eastman Kodak Company, were purified by gas chromatography, using the 6-ft "Ucon polar" column of the Beckmann Megachrom instrument at 110° C. The 2,3-dimethyl butadiene-1,3, the cyclohexadiene-1,3 and the 2,5-dimethyl hexadiene-2,4 were purified in the same way.

The analysis followed the original pattern of fractionation into CO, C_2, and C_4 samples, supplemented by analysis by gas chromatography. The CO fraction was found to be pure and free from traces of hydrogen and methane. The C_2 fraction was analyzed in a stream of helium at 80° C on a 2-m silica gel column, and consisted entirely of C_2H_4 and C_2H_6. Mixtures of C_2H_4 and C_2H_6 of known composition were used to calibrate the apparatus for the analysis of the C_2 fractions. The C_2H_4/C_2H_6 ratio could then be measured by a comparison of peak areas, if the area of the C_2H_4 peak was multiplied by 1.08. For reaction temperatures below 145° C it was found that the C_4 fraction sometimes contained a trace of 1-pentene, but this did not exceed 0.5% of the butane, and was usually much less than this. The proportion of 1-pentene formed was greater for reactions above 145° C and consequently this temperature was not exceeded in quantitative studies.

THE KINETICS OF THE REACTIONS OF THE ETHYL RADICAL

The photolysis of pure diethyl ketone conforms to the established mechanism (17–20):

$$CH_3CH_2—CO—CH_2CH_3 + h\nu \rightarrow 2CH_3CH_2\cdot + CO \quad [1]$$

$$2CH_3CH_2\cdot \rightarrow C_4H_{10} \quad [2]$$

$$2CH_3CH_2\cdot \rightarrow C_2H_6 + C_2H_4 \quad [3]$$

$$CH_3CH_2\cdot + CH_3CH_2—CO—CH_2CH_3 \rightarrow CH_3CH_3 + CH_3\dot{C}H—CO—CH_2CH_3. \quad [4]$$

At higher light intensities and below 250° C the pentanonyl radical is removed by the reaction

$$CH_3CH_2\cdot + CH_3\dot{C}H—CO—CH_2CH_3 \rightarrow CH_3CH(CH_2CH_3)—CO—CH_2CH_3. \quad [5]$$

One molecule of carbon monoxide is equivalent to two ethyl radicals and hence to one molecule of either ethane or butane. The material balance may be defined by the ratio

$$M = \frac{R_{C_2H_6} + R_{C_4H_{10}}}{R_{CO}},$$

where the symbol R_Z represents the rate of formation of the product Z in molecule sec^{-1} cm^{-3} of illuminated volume. The quantity M was found to have the value 0.997 ± 0.03 over a wide range of temperature and light intensity, showing that reactions [1] to [5] account for all the products (15).

If a gaseous mixture of allyl alcohol and diethyl ketone is illuminated, the metathetical and addition reactions of the ethyl radical with allyl alcohol will take place. At higher light intensities the metathetical reaction will take the course

$$CH_3CH_2\cdot + CH_2{=}CH{-}CH_2OH \rightarrow CH_3CH_3 + CH_2{=}CH{-}\dot{C}HOH, \qquad [6]$$

$$CH_3CH_2\cdot + CH_2{=}CH{-}\dot{C}HOH \rightarrow CH_2{=}CH{-}CH(CH_2CH_3)OH. \qquad [6a]$$

The rate of reaction [6] is given by the following equation, which remains valid even if [6*a*] does not represent the exclusive fate of the allylic radical:

$$\frac{k_6}{k_2^{1/2}} = \left(\frac{R_{C_2}}{R_{C_4}} - \frac{2k_3}{k_2}\right)\frac{R_{C_4}^{1/2}}{[B]} - \frac{[D]}{[B]}\frac{k_4}{k_2^{1/2}},$$

where [D] and [B] represent the concentration of diethyl ketone and allyl alcohol, respectively, in molecule cm^{-3}.

The addition of the ethyl radical to allyl alcohol will form a vinylic radical:

$$CH_3CH_2\cdot + CH_2{=}CH{-}CH_2OH \rightarrow CH_3CH_2{-}CH_2{-}\dot{C}H{-}CH_2OH. \qquad [7]$$

The adduct will react with a second ethyl radical, either directly,

$$CH_3CH_2\cdot + CH_3CH_2{-}CH_2{-}\dot{C}H{-}CH_2OH \rightarrow CH_3CH_2{-}CH_2{-}CH(CH_2CH_3){-}CH_2OH, \qquad [7a]$$

or through some intermediate process (such as metathesis with diethyl ketone followed by reaction [5]).

In all such cases ethyl radicals disappear from the system without the formation of C_2H_6 or C_4H_{10}, and so the value of M falls below unity. Since two ethyl radicals are equivalent to one allyl alcohol molecule in the addition reaction, the rate equation is given by

$$\frac{k_7}{k_2^{1/2}} = \frac{R_{CO} - (R_{C_2H_6} + R_{C_4H_{10}})}{[B](R_{C_4H_{10}})^{1/2}} = \frac{(1-M)}{[B]}\frac{R_{CO}}{(R_{C_4H_{10}})^{1/2}}.$$

The rate equation for addition is not rigorous if ethane or ethylene is formed by reactions of the type

$$CH_3CH_2\cdot + CH_2{=}CH{-}\dot{C}HOH \rightarrow CH_2{=}CH_2 + CH_2{=}CH{-}CH_2OH \qquad [6b]$$

or

$$CH_3CH_2\cdot + CH_3CH_2{-}CH_2{-}\dot{C}H{-}CH_2OH \rightarrow CH_3CH_3 + CH_3CH_2{-}CH{=}CH{-}CH_2OH. \qquad [7b]$$

These reactions would lead to an increase in M and erroneously small values of k_7. We have shown elsewhere on the basis of experimental evidence that such reactions will have no more than a negligible effect upon the validity of the rate equation (16).

RESULTS

The results obtained from the photolysis of diethyl ketone in the presence of allyl alcohol are presented in Fig. 1.

Statistical analysis of the data give us the results of Table I; values for 1-heptene (16) and for vinyl acetate (22) have been added for comparison. Allyl alcohol is significantly more reactive than 1-heptene at 100° C with respect to both addition and metathesis. The greater reactivity of allyl alcohol may be attributed to the greater electrophilic

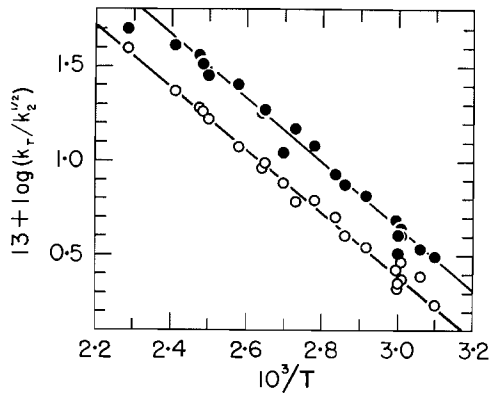

FIG. 1. Addition and metathetical reactions of the ethyl radical with allyl alcohol: ●, addition, $E_7 - \frac{1}{2}E_2 = 7.8$ kcal mole^{-1}; ○, metathesis, $E_6 - \frac{1}{2}E_2 = 7.6$ kcal mole^{-1}.

character of the OH group—considerably mitigated by its distance from the double bond.

The 1-pentene found in the butane fraction for reactions above 145° C may arise from a radical displacement reaction:

$$CH_3CH_2\cdot + CH_2{=}CH{-}CH_2OH \rightarrow CH_3CH_2{-}CH_2{-}CH{=}CH_2 + OH\cdot. \quad [8]$$

This is equivalent to stating that the product of addition is unstable, and may decompose in the period normally elapsing between its formation and its combination with an ethyl radical. By the nature of the rate equations we would expect k_7 to be affected at a lower temperature than k_6, and in Fig. 1 the point corresponding to k_7 at the highest temperature employed shows a negative deviation from the straight line.

The values of $k_4/k_2^{1/2}$ calculated from preliminary photolyses with pure diethyl ketone were in full agreement with the earlier values (15). The ratio of the disproportionation and combination constants of the ethyl radical, k_3/k_2, was found to be 0.134 ± 0.01 in this study, indistinguishable from the value of 0.136 ± 0.02 reported previously (15), and of 0.135 in the most recent work (20). This concordance establishes a basis for comparing the results of this study with the earlier data.

DISCUSSION

The Relevance of k_6 and k_7 to Polymerization Kinetics

Allyl polymerization owes its distinctive quality to the restriction of the values of k_p/k_t to a narrow range of about 2 to 20. We have found that $k_7/k_6 = 1.8$ for allyl alcohol at 60° C, but this ratio is relevant to the polymerization of allyl alcohol only if $k_p/k_t \approx k_7/k_6$. Here we shall present the evidence for this equation, and we begin by showing that k_p and k_7 are of the same order of magnitude, and, indeed, that $k_p \approx 2k_7$ for allyl alcohol at 60° C.

The value of the addition constant k_7 may be calculated using the value of k_2 measured by Shepp and Kutschke (21): $k_2 = 5.06 \times 10^{-10} \exp(-2000 \pm 1000)/RT$ cm^3 molecule^{-1} sec^{-1}. Values of k_7 are compared with k_p for vinyl acetate at 60° C, and for this monomer $k_p = 1.8\, k_7$:

allyl alcohol:	$k_7 = 2.2 \times 10^{-18}$ cm^3 molecule^{-1} sec^{-1},
vinyl acetate (22):	$k_7 = 3.5 \times 10^{-18}$ cm^3 molecule^{-1} sec^{-1},
vinyl acetate (23):	$k_p = 6.3 \times 10^{-18}$ cm^3 molecule^{-1} sec^{-1}.

TABLE I

Reactions of the ethyl radical with unsaturated molecules

Substrate	Nature of reaction	Number of runs	C	B	$13+\log (A_r/A_2^{1/2})$	$E_r-\frac{1}{2}E_2$ (kcal mole^{-1})	$13+\log (k_r/k_2^{1/2})$ (at 100° C)
Allyl alcohol	Addition	18	5.739	1.695	5.7±0.2	7.75±0.35	1.20
1-Heptene (16)	Addition	34	5.156	1.530	5.2±0.1	7.0±0.2	1.06
Vinyl acetate (22)	Addition	22	5.300	1.485	5.3±0.3	6.8±0.4	1.32
Allyl alcohol	Metathesis	17	5.385	1.665	5.4±0.2	7.6±0.3	0.92
1-Heptene (16)	Metathesis	22	5.605	1.825	5.6±0.3	8.3±0.5	0.71

NOTE: The constants B and C are the coefficients of the straight lines $13+\log (k_r/k_2^{1/2}) = C-10^3B/T$ fitted to the experimental results. The symbol k_r represents either k_6 or k_7, expressed in units of cm^3 molecule^{-1} sec^{-1}. The limits of error are calculated at the 5% probability level.

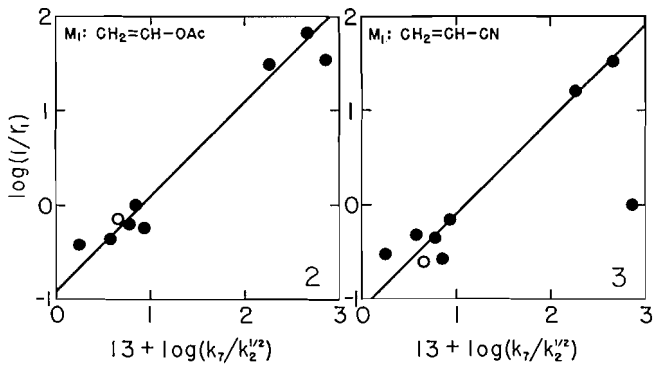
Acrylonitrile (26)	2.86	+1.53	0.00	−2.7	+0.34	Acrylonitrile

Vinyl acetate has been introduced because it resembles allyl alcohol both in its reactivity towards the ethyl radical, and also in degree of resonance stabilization and electron-donor power in polymerization. In Fig. 2 we demonstrate the correlation between the rate



FIGS. 2 and 3. Correlation of rate constants for addition: of the ethyl radical in the gas phase and (2) the polyvinyl acetate radical, or (3) the polyacrylonitrile radical, in solution. The open circle represents allyl alcohol.

constants for the addition of the ethyl and polyvinyl acetate radicals respectively to a series of monomers. The diversity of these monomers is evident from the range of the values (24) of q and ϵ given in Table II. A reference line of unit slope has been drawn; the small degree of scatter about this line supports the validity of the correlation. The values of the reactivity ratios r_1 were calculated from the revised equation of Schwan and Price (24):

$$RT \ln (1/r_1) = (q_1 - q_2) + 7.23 \times 10^{20} \epsilon_1(\epsilon_1 - \epsilon_2);$$

unfortunately their data do not include allyl alcohol, but the point for the closely related monomer allyl acetate is shown by the open circle. Figure 3 is the corresponding correlation diagram for the ethyl and polyacrylonitrile radicals; here allyl alcohol is marked by an open circle. This is a far more severe test of correlation, as the polyacrylonitrile radical differs markedly from the ethyl radical in its resonance stabilization and its electrophilic nature (27); yet the scatter of points about the line of unit gradient is small, the only significant deviation being for acrylonitrile monomer. As the ethyl and polyvinyl acetate radicals are much more nearly matched in reactivity, it seems reasonable to assume that the point for allyl alcohol would lie close to the straight line of Fig. 2. On this basis we may estimate that $k_p \approx 2k_7$ for allyl alcohol, giving $k_p = 4 \times 10^{-18}$ cm^3 molecule^{-1} sec^{-1} at 60° C, similar to the value of k_p for vinyl acetate.

In support of the proposition that $k_p/k_t \approx k_7/k_6$ for allyl alcohol we shall apply the general equation proposed by Bamford, Jenkins, and Johnston for radical reactivity (28):

$$\log k_S = \log k_T + \alpha\sigma + \beta.$$

The rate constants k_S and k_T refer respectively to the reaction of a given radical $R.CH_2CHX\cdot$ with a substrate S and to metathesis of the same radical with toluene; σ is the Hammett constant for the group X, and α and β are constants for the substrate S. The parameter σ is zero for the ethyl radical and very small for the polyallyl alcohol radical; it therefore follows that

$$\log \left(\frac{k_p}{k_t} \Big/ \frac{k_7}{k_6} \right) = (\alpha_A - \alpha_M)\sigma_X,$$

where the subscripts A, M, and X refer to addition, metathesis, and the polymer radical respectively. Since α gives a measure of the intrinsic polarity of the reaction, which is small in each case, it follows that the difference $(\alpha_A - \alpha_M)$ is very small, and the product $(\alpha_A - \alpha_M)\sigma_X$ is negligible. We may therefore write $k_p/k_t \approx k_7/k_6$, and expect the latter ratio to predict the behavior of allyl alcohol in polymerizing systems. In the next section we shall show that this expectation is fulfilled.

The Application of k_6 and k_7 to the Polymerization of Allyl Alcohol

High polymer is readily formed from both vinyl acetate and methyl acrylate by the action of a trace of free radical catalyst; whereas allyl alcohol is so unreactive that Staudinger originally believed that no polymer could be obtained from this monomer (29). This reluctance to polymerize is not due to the low reactivity of the double bond of allyl alcohol. It is clear from the following rate constants, from Table I, and from the relationship $k_p \approx 2k_7$, that the double bond of vinyl acetate is only slightly more reactive:

allyl alcohol: $k_7 = 12.4\times10^{-13} \exp(-8800/RT)$ cm^3 molecule^{-1} sec^{-1},
vinyl acetate (23): $k_p = 4.0\times10^{-13} \exp(-7300/RT)$ cm^3 molecule^{-1} sec^{-1},
methyl acrylate (30): $k_p = 1.7\times10^{-13} \exp(-7100/RT)$ cm^3 molecule^{-1} sec^{-1}.

The essential difference is the presence of a site for rapid metathesis in allyl alcohol, which causes degradative chain transfer to dominate the polymerization. No such site exists in vinyl acetate (22) and its polymerization proceeds unchecked by significant chain transfer.

The number-average molecular weight of polyallyl alcohol may be estimated from our results. This quantity is given by k_p/k_t, the ratio of the propagation and transfer constants (31), and therefore approximately by k_7/k_6, which has the value of 1.9 at 100° C. This is considerably lower than the value of 5 reported for a mixture of 155 parts of allyl alcohol and 2 parts of hydrogen peroxide, held at 100° C for 116 hours with frequent replenishment of the hydrogen peroxide (13). However, in such a system we may expect extensive reactivation of the "dead" polymer by metathesis with the hydroxyl radicals present. By this means new reactive polymer radicals would be formed, and, in principle, the degree of polymerization could be increased indefinitely.

The approximate equality of k_6 and k_7 for allyl alcohol explains the powerful inhibiting action of this substance upon the polymerization of certain other monomers. Allyl alcohol inhibits the polymerization of butadiene so effectively that the corresponding copolymer must be prepared indirectly (1). Reactivity in this system rapidly becomes transferred to the $CH_2{=}CH{-}\dot{C}HOH$ radical, which is too unreactive to add to allyl alcohol or to the stabilized butadiene ($q = -3.6$ kcal mole^{-1}) (24).

In contrast, allyl alcohol does form high copolymer with acrylonitrile (14); clearly it must be possible for the $CH_2{=}CH{-}\dot{C}HOH$ radical to add to the double bond of acrylonitrile. This difference in behavior may be explained in terms of the lowering of the energy of activation for the addition by contribution of ionic forms to the stability of the activated complex (27). The $CH_2{=}CH{-}\dot{C}HOH$ radical will behave as a weak electron donor. Acrylonitrile ($\epsilon = +0.34\times10^{-10}$ e.s.u. (24)) is strongly electrophilic; it is reduced at the dropping mercury electrode at the low half-wave potential of -1.94 volt (S.C.E.) (32), and is very readily polymerized by an anionic chain mechanism by such catalysts as butyl lithium (33) and a solution of sodium and naphthalene in tetrahydrofuran (34). The polar effect should therefore be pronounced for acrylonitrile and very weak for butadiene ($\epsilon = -0.24\times10^{-10}$ e.s.u. (24)). This situation closely resembles

that of Fig. 3, where the apparently anomalous behavior of acrylonitrile is also due to its electrophilic nature.

CONCLUSIONS

We have tested the relevance of values of k_6 and k_7 to the study of the polymerization of allyl alcohol in such varied aspects as the magnitude of the propagation constant, the competition between propagation and chain transfer, the degree of polymerization, and propagation and inhibition in copolymerization. In each case the observed behavior of the propagating system is consistent with predictions based upon the values of k_6 and k_7. The measure of success renders it probable that the polymerization of other monomers may be interpreted in terms of the reactions of the monomer with the ethyl radical in the gas phase (22).

ORGANIC PEROXIDES

IV. CATALYSIS OF AROYL PEROXIDE REACTIONS BY ALUMINUM CHLORIDE: THE DIRECT INTRODUCTION OF *O*-AROYL GROUPS INTO AROMATIC NUCLEI

J. T. EDWARD, H. S. CHANG, AND S. A. SAMAD[1]
Department of Chemistry, McGill University, Montreal, Que.

Received December 13, 1961

ABSTRACT

In inert solvents in the presence of aluminum chloride, aroyl peroxides decompose to esters and carbon dioxide. In highly nucleophilic solvents such as anisole or mesitylene, *p,p'*-dinitrobenzoyl peroxide effects a Friedel–Crafts type of substitution of the solvent molecule. Both decomposition and substitution reactions probably depend on a heterolytic fission of the peroxide linkage catalyzed by aluminum chloride.

Reynhart (1) claimed that in the presence of aluminum chloride benzoyl peroxide reacted with benzene at 0° C to give a 90% yield of phenyl benzoate and 92% yield of benzoic acid:

$$ArH + (ArCO_2)_2 \rightarrow ArCO_2Ar + ArCO_2H. \quad [1]$$

At higher temperatures the yield of ester was said to drop, and the amounts of diphenyl formed to increase (1, 2).

In a reinvestigation of this reaction we obtained much lower yields of phenyl benzoate, which did not seem to be much affected by temperature. Furthermore, the compound was obtained when solvents other than benzene were used, seemingly from the overall reaction

$$(ArCO_2)_2 \rightarrow ArCO_2Ar + CO_2, \quad [2]$$

as shown by the concomitant formation of carbon dioxide (Table I). This mode of decomposition had already been observed by Reynhart (1) when benzoyl peroxide in

TABLE I

$AlCl_3$-catalyzed decomposition of benzoyl peroxide in different solvents

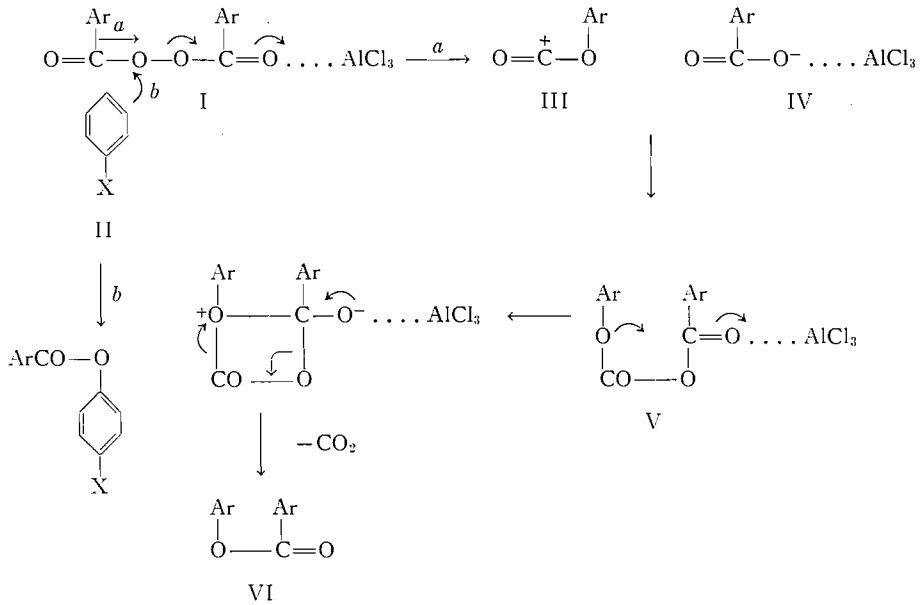
‖4,4'-Dimethoxy diphenyl (22–23% yield) also formed.

[1]*Holder of Colombo Plan Fellowship, 1957–1960.*

petroleum ether was treated with antimony pentachloride. However, the peroxide may be diverted from this mode of decomposition by suitable solvents. Thus from a reaction in a mixture of nitrobenzene and anisole, 4,4′-dimethoxydiphenyl was isolated in 22–23% yield; other bianisyls were also probably formed, but not obtained crystalline. From a reaction in 1,3-dimethoxybenzene a very small amount of 2,4-dimethoxyphenyl benzoate was isolated. This was the only crystalline product resulting from a Friedel–Crafts attack on solvent following equation [1]; it is possible that mesitylene also reacted partially in this fashion, but no crystalline benzoate could be isolated.

With boron trifluoride etherate in place of aluminum chloride, no decomposition of the peroxide in benzene took place.

It seems likely that aluminum chloride, like Brønsted acids (3), promotes the ionic fission of the peroxide linkage of aroyl peroxides. The electron deficiency of the developing oxygen cation may then be relieved either by synchronous migration of an aryl group (4) (route *a*, Scheme I) to give the aryloxyformyl cation (III), or by synchronous electron donation from an external aromatic nucleus (II) (route *b*), after the fashion of many Friedel–Crafts acylations (5). Evidently the latter route is possible only with highly reactive aromatic nuclei such as 1,3-dimethoxybenzene. The ions III and IV



SCHEME I

formed by route *a* can recombine to form the carboxylic–carbonic anhydride (V): Leffler (3) has already obtained an anhydride of this type by rearrangement of *p*-methoxy-*p*′-nitrobenzoyl peroxide in thionyl chloride. Benzoic–phenylcarbonic anhydride (V; Ar = Ph) was reported by Windholz (6) to decompose to give a 10% yield of phenyl benzoate (equation [3]) and 80% yields of benzoic anhydride and diphenyl carbonate (equation [4]):

$$PhCO.O.CO.OPh \rightarrow PhCOOPh + CO_2 \quad [3]$$

$$2PhCO.O.CO.OPh \rightarrow (PhCO)_2O + CO(OPh)_2 + CO_2. \quad [4]$$

However, it seems likely that in the presence of aluminum chloride, decomposition

would take place mainly according to equation [3]. Thus benzoic–ethylcarbonic anhydride, which is stable at room temperature, decomposes at 175–185° to give 50% of ethyl benzoate and 50% of benzoic anhydride; however, in the presence of boron trifluoride etherate, decomposition takes place at room temperature to give ethyl benzoate almost exclusively (6). Similarly we have found benzoic–ethylcarbonic anhydride in benzene decomposes at room temperature in the presence of aluminum chloride to give a 48% yield of ethyl benzoate and 14% yield of benzoic acid (presumably from benzoic anhydride). The mechanism for the catalyzed decomposition of benzoic–phenylcarbonic anhydride (V; Ar = Ph) shown in Scheme I is suggested by the fact that the uncatalyzed decomposition is greatly facilitated by electron-withdrawing groups in the acyl portion of the anhydride (6–9).

An alternative mechanism was considered in which the phenoxyformyl cation (III; Ar = Ph) lost carbon dioxide to form the phenyl cation (a reaction for which analogies exist (9–11)), followed by union of the latter with benzoate ion (IV; Ar = Ph) to give phenyl benzoate. However, the reaction of the phenyl cation with $PhCO_2^- \ldots . AlCl_3$ would be expected to give also some chlorobenzene; none of this compound could be detected by gas chromatography in the products of the aluminum-chloride-catalyzed decomposition of benzoyl peroxide in toluene.

The heterolysis of the peroxide linkage leading to phenyl benzoate (route *a*) probably receives anchimeric assistance from the migrating phenyl group. It was expected that *p,p'*-dinitrobenzoyl peroxide would rearrange by this route less readily than benzoyl peroxide because of the lesser migratory aptitude of the *p*-nitrophenyl group (12), so that in this case route *b* might compete successfully with route *a*. This expectation was realized when sufficiently reactive aromatic compounds were used as solvents in the reaction, direct substitution of *p*-nitrobenzoyloxy groups into solvent molecules taking place. The results are listed in Table II. It is obvious from the 54–77% yields of *p*-nitrobenzoic acid that competing reactions are taking place, since the maximum yield of this acid can be only 50% if the reaction path is defined by equation [1]. Oxidation of solvent molecules to biaryls could give *p*-nitrobenzoic acid in a maximum yield of 100%; however, in no case were biaryls isolated.

TABLE II

Products of $AlCl_3$-catalyzed reactions of *p,p'*-dinitrobenzoyl peroxide in aromatic solvents

	p-Nitrobenzoate		*p*-Nitrobenzoic acid
Solvent	Aryl group	Yield (%)	Yield (%)*
m-Xylene	2,4-Dimethylphenyl	5	72
Mesitylene	Mesityl	34	68
Anisole	*o*-Methoxyphenyl	7	57
	p-Methoxyphenyl	21	
Phenetole	*o*-Ethoxyphenyl	10	54
	p-Ethoxyphenyl	12	
Veratrole	3,4-Dimethoxyphenyl?	trace	77
1,3-Dimethoxybenzene	2,4-Dimethoxyphenyl	20	59

*Based on $(O_2N.C_6H_4.CO_2)_2 \rightarrow 2O_2N.C_6H_4.CO_2H$.

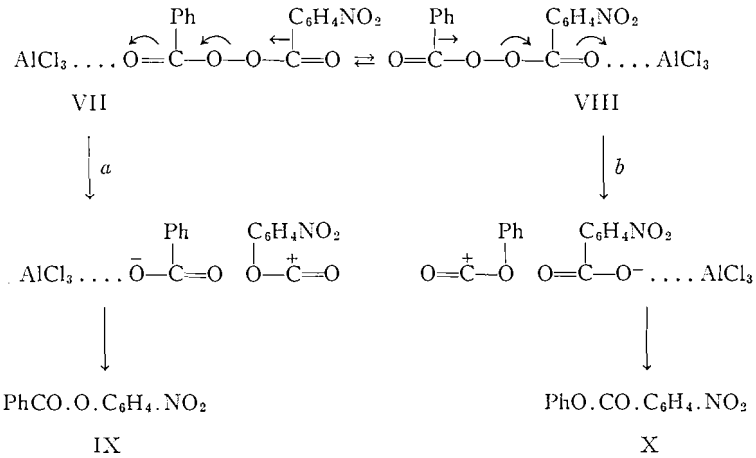
Except for *o*- and *p*-methoxyphenyl *p'*-nitrobenzoates, the esters of Table II are new compounds. The identities of the compounds obtained from *m*-xylene, anisole, and phenetole were established by comparison with authentic specimens prepared from the appropriate phenols. The ester obtained from 1,3-dimethoxybenzene was shown to be 2,4-dimethoxyphenyl *p'*-nitrobenzoate because it differed from the other two possible isomers,

3,5-dimethoxyphenyl and 2,6-dimethoxyphenyl *p'*-nitrobenzoates, both of which were synthesized. The orientation of the substitution reaction revealed by the products in Table II is in accord with an electrophilic attack on the aromatic nucleus, as postulated in Scheme I.

Without fairly strongly electron-releasing substituents, the benzene ring is insufficiently reactive to effect this type of Friedel–Crafts reaction. A suspension of *p,p'*-dinitrobenzoyl peroxide in benzene in the presence of aluminum chloride reacted only very slowly at room temperature, 21% of *p*-nitrobenzoic acid and 70% of recovered peroxide being obtained after 48 hours. The neutral residue after removal of benzene showed weak absorption at 1748 cm^{-1} indicative of a *p*-nitrobenzoyl group, but no crystalline product could be isolated. On the other hand, in methylene dichloride a 65% yield of the rearrangement product, *p*-nitrophenyl *p'*-nitrobenzoate, was obtained after reaction overnight at 0°. The more rapid reaction in this solvent may be due to the greater solubility of aluminum chloride and the peroxide in it.

A serious limitation on the usefulness of this Friedel–Crafts method for introducing the *p*-nitrobenzoyloxy group directly into aromatic nuclei lies in the fact that no suitable solvent for the reaction has been found. Attempts to bring about the reaction of naphthalene with *p,p'*-dinitrobenzoyl peroxide in nitrobenzene or nitromethane solvents gave only gummy and intractable products. Even 1,3-dimethoxybenzene gave an intractable product when the reaction was carried out in methylene chloride solution. It is to be expected that the bimolecular reaction of peroxide with an aromatic compound (route *b*), as compared with unimolecular decomposition of the peroxide (route *a*), will be disfavored by dilution with an inert solvent. However, it was not possible to isolate any *p*-nitrophenyl *p'*-nitrobenzoate (from route *a*) from the reaction with 1,3-dimethoxybenzene in methylene chloride, so that the course of the reaction in this solvent mixture remains unknown.

Finally, the aluminum-chloride-catalyzed decomposition of the unsymmetrical *p*-nitrobenzoyl peroxide was studied. This reaction was of interest because the nature of the product should be determined by the rates of two competing reactions *a* and *b* (Scheme II). Reaction *a* should be favored by the greater basicity of the benzoyl carbonyl group,



SCHEME II

and hence by a greater concentration of the complex VII than of VIII; on the other hand, the heterolysis of the latter should take place more readily because the anchimeric

assistance of a phenyl group is superior to that of a *p*-nitrophenyl group. In the event, the latter effect is predominant, as evidenced by the isolation in 81% yield of phenyl *p*-nitrobenzoate (X), but of no *p*-nitrophenyl benzoate (IX), when the reaction was carried out in methylene chloride. The aluminum-chloride-catalyzed decomposition thus follows the rearrangement pattern found by Leffler (3, 7) for the uncatalyzed decomposition of unsymmetrical peroxides. A small yield (12%) of *p*-nitrobenzoic acid probably came from the anhydride, produced by a reaction similar to that of equation [4]. In benzene and in nitrobenzene the catalyzed decomposition of this peroxide followed a less clear-cut path. The yield of *p*-nitrobenzoic acid was considerably larger, and of neutral material considerably smaller. From the latter a gummy material was obtained which appeared from its infrared spectrum to contain phenyl *p*-nitrobenzoate, but which could not be purified further.

EXPERIMENTAL

Materials

Commercial benzoyl peroxide was crystallized by addition of methanol to a concentrated solution of the peroxide in chloroform, and dried by several days standing at room temperature in an evacuated desiccator. *p,p'*-Dinitrobenzoyl peroxide was prepared from *p*-nitrobenzoyl chloride and sodium peroxide by the method of Price and Krebs (13). *p*-Nitrobenzoyl peroxide was prepared according to Wieland and Rasuwajew (14), and crystallized from ethanol, m.p. 113° (decomp.).

Reactions of Benzoyl Peroxide

Benzoyl peroxide dissolved in about four times its weight of organic solvent was added under nitrogen slowly with stirring to an equimolar quantity of aluminum chloride suspended in about the same volume of the same solvent. The nitrogen passing slowly over the reaction mixture was led through a known volume of standard alkali, which was subsequently titrated for carbon dioxide (15). Reaction was allowed to proceed for 7 hours or more, except for the reaction in nitrobenzene (4 hours at 0°, 5 hours at 50°: Table I). The reaction mixture was then treated with dilute aqueous hydrochloric acid and filtered from a solid residue. The solid residue and the organic layer in the filtrate were both extracted with aqueous sodium bicarbonate to remove benzoic acid. The neutral organic solution was then washed with water, dried, and distilled: phenyl benzoate came over at 162° at 13 mm and solidified, m.p. and mixed m.p. 69°. A considerable amount of intractable resinous solid was left behind in the distillation flask (about 30% of weight of peroxide; b.p. > 230° at 0.5 mm).

For the reactions in nitrobenzene–toluene and nitrobenzene–anisole, benzoyl peroxide (24.2 g; 0.1 mole) dissolved in toluene or anisole (125 ml) was added to aluminum chloride (13.5 g; 0.1 mole) dissolved in nitrobenzene (125 ml). From the latter experiment 4,4'-dimethoxydiphenyl (5.0 g; 23%) was isolated by distillation of the organic layer obtained as described above, b.p. 154° at 0.5 mm. Crystallized from ethanol, it had m.p. 169°, undepressed by admixture with an authentic specimen.

From the reaction in 1,3-dimethoxybenzene, the neutral fraction on distillation gave no phenyl benzoate but a gum (2.1 g), b.p. 195° at 1 mm, having strong absorption at 1743 cm^{-1}. The gum was chromatographed on alumina, using petroleum ether as eluent, to give an oily solid which crystallized from petroleum ether in colorless rods (0.24 g), m.p. 89° (reported m.p. 2,4-dimethoxyphenyl benzoate 90° (16)); $\nu_{max}^{CCl_4}$ in cm^{-1}: 3030 (m), 2960 (m), 2840 (m), 1740 (s), 1600 (s), 1470 (s), 1443 (s), 1318 (s), 1270–1245 (s, broad), 1180 (s), 1162 (s), 1125 (s), 1080 (s), 1062 (s), 1030 (s), 925 (m). Calc. for $C_{15}H_{14}O_4$: C, 69.76; H, 5.42%. Found: C, 69.95; H, 5.50%.

From the reaction of benzoyl peroxide (4.82 g) in mesitylene, the neutral fraction gave a liquid (2.5 g), b.p. 156–166° at 1 mm, having strong absorption at 1740 cm^{-1}.

Reactions of p,p'-Dinitrobenzoyl Peroxide

Because of its very small solubility in most organic solvents, this peroxide was slowly added as a solid to a suspension of aluminum chloride in an organic solvent at room temperature. The reaction mixture was kept overnight at 0° C unless otherwise noted, and then worked up in the general fashion described above for benzoyl peroxide reactions. Results with the different solvents are given in Table II and below.

(a) Methylene Dichloride

Evaporation of the neutral fraction gave a solid which crystallized from ethanol as colorless needles, m.p. 159°, identified as *p*-nitrophenyl *p'*-nitrobenzoate by mixed melting point (recorded m.p. 159° (17)).

(b) Benzene

To a stirred suspension of aluminum chloride (1.35 g; 0.01 mole) in benzene (75 ml) was added the peroxide (3.32 g; 0.01 mole) at 22°. The mixture was left at room temperature for 48 hours and then worked

up in the usual way to give 0.69 g (21%) of *p*-nitrobenzoic acid. The residue of insoluble material was unreacted peroxide; further crops were obtained from the neutral benzene solution on concentration, giving a total recovery of 2.30 g (70%). Complete evaporation of the benzene gave a tar (0.57 g), which was chromatographed on alumina using light petroleum (b.p. 66–75°) and benzene as eluents. No crystalline product was obtained, but several fractions showed a weak infrared peak at 1748 cm^{-1}.

(c) m-Xylene

Removal of xylene from the neutral fraction left a gum, which was chromatographed on alumina using petroleum ether (b.p. 66–75°) and benzene as eluents. A few semisolid fractions were obtained which were triturated with ethanol and then recrystallized from this solvent (charcoal) as colorless needles of 2,4-dimethylphenyl *p*-nitrobenzoate, m.p. 112°. The same compound (m.p. and mixed m.p.) was obtained from 2,4-dimethylphenol and *p*-nitrobenzoyl chloride in pyridine. Calc. for $C_{15}H_{13}NO_4$: C, 66.42; H, 4.79; N, 5.16%. Found: C, 66.21; H, 4.92; N, 5.11%.

(d) Mesitylene

The gummy residue from the neutral fraction was chromatographed as above to give a few solid fractions, obtained on crystallization from ethanol as slightly brownish plates, m.p. 122°, of mesityl *p*-nitrobenzoate. Calc. for $C_{16}H_{15}NO_4$: C, 67.37; H, 5.26; N, 4.91%. Found: C, 67.30; H, 5.33; N, 5.00%. Infrared spectrum: $\nu_{max}^{CCl_4}$ in cm^{-1}: 3030 (m, sh), 2940 (s), 2870 (m), 1743 (s), 1610 (s), 1525 (m), 1487 (s), 1350 (s), 1322 (m), 1275–1240 (s), 1195 (m), 1140 (s), 1080 (s), 1010 (w), 870 (m), 695 (w, sh).

(e) Anisole

A stirred suspension of aluminum chloride (1.35 g) and peroxide (3.32 g) in anisole (35 ml) was allowed to react at 22° for 7 hours. From the neutral fraction anisole was removed by distillation at 15 mm. The gummy residue (0.87 g) was chromatographed on alumina using, successively, petroleum ether (b.p. 66–75°), benzene, and ether as eluents. The first few fractions gave pale yellowish needles of *o*-methoxyphenyl *p'*-nitrobenzoate (0.19 g; 7%), m.p. 102° alone or admixed with an authentic specimen (recorded m.p. 102° (18)). Later fractions gave almost colorless needles of *p*-methoxyphenyl *p'*-nitrobenzoate (0.57 g; 21%), m.p. 112° alone or admixed with an authentic specimen (recorded m.p. 113–115° (18)).

(f) Phenetole

This reaction was carried out under the same conditions as described above for anisole. Removal of phenetole from the neutral fraction at 44° at 1 mm left a residue (1.15 g), which was chromatographed on alumina. The solid from the first few fractions, after crystallization from ethanol, was obtained as yellowish plates (0.31 g; 10%), m.p. 114°, and was identified as *o*-ethoxyphenyl *p'*-nitrobenzoate by comparison (m.p. and mixed m.p.) with the compound prepared by reaction of *o*-ethoxyphenol with *p*-nitrobenzoyl chloride in pyridine. Calc. for $C_{15}H_{13}O_5N$: C, 62.72; H, 4.53; N, 4.88%. Found: C, 62.90; H, 4.66; N, 4.82%. Infrared spectrum: $\nu_{max}^{CCl_4}$ in cm^{-1}: 3040 (w), 2980 (m), 2925 (m), 2872 (w), 1740 (s), 1700 (w), 1600 (s), 1490 (s), 1470 (s), 1450 (m), 1405 (m), 1340 (s), 1275–1225 (s), 1175 (s), 1110 (m), 1060 (s), 1035 (m), 920 (w), 835 (m).

The next few fractions (0.31 g) had unsharp melting points (ca. 92–99°) and were evidently mixtures. However, later fractions could be crystallized from ethanol to give plates (0.37 g; 12%) melting sharply at 118°. This compound was identified as *p-ethoxyphenyl p-nitrobenzoate* by comparison (m.p. and mixed m.p.) with the compound prepared from *p*-ethoxyphenol and *p*-nitrobenzoyl chloride in pyridine. Found: C, 62.63; H, 4.56; N, 4.98%. Infrared spectrum: $\nu_{max}^{CCl_4}$ in cm^{-1}: 3055 (w), 2985 (m), 2940 (w), 1740 (s), 1478 (m), 1345 (s), 1275–1225 (s), 1185 (m), 1105 (w), 1070 (m), 1042 (m).

(g) Veratrole

From a reaction using 3.32 g of peroxide, the neutral fraction on distillation gave a very small quantity of solid product, b.p. 150° at 1 mm, which crystallized from ethanol in colorless rods, m.p. 135°. Infrared spectrum: $\nu_{max}^{CCl_4}$ in cm^{-1}: 3030 (w), 2960 (m), 2840 (m), 1742 (s), 1605 (m), 1495 (s), 1475 (m), 1347 (s), 1275–1225 (s), 1165 (m), 1090 (s), 1000 (w), 870 (m), 690 (w).

(h) 1,3-Dimethoxybenzene

The neutral fraction on distillation gave a solid, b.p. 225° at 1 mm, which crystallized from ethanol as colorless rods of *2,4-dimethoxyphenyl p'-nitrobenzoate*, m.p. 128°. Calc. for $C_{15}H_{13}NO_6$: C, 59.41; H, 4.29; N, 4.63%. Found: C, 59.65; H, 4.39; N, 4.65%. The melting point was depressed by admixture of the compound with 3,5-dimethoxyphenyl *p'*-nitrobenzoate and with 2,6-dimethoxyphenyl *p'*-nitrobenzoate (see below). Infrared spectrum: $\nu_{max}^{CHCl_3}$ in cm^{-1}: 3030 (w), 2940 (m), 2840 (m), 1740 (s), 1609 (s), 1495 (w), 1460 (m), 1350 (s), 1320 (m), 1157 (m), 1120 (m), 1070 (s), 1015 (w), 865 (w).

2,6-Dimethoxyphenyl *p'*-nitrobenzoate, prepared from 2,6-dimethoxyphenol, crystallized from ethanol as pale yellowish needles, m.p. 164°. Found: C, 59.57; H, 4.33; N, 4.55%. 3,5-Dimethoxyphenyl *p'*-nitrobenzoate, prepared from 3,5-dimethoxyphenol, crystallized from ethanol as pale yellowish needles, m.p. 141°. Found: C, 59.51; H, 4.26; N, 4.59%.

(i) 1,3-Dimethoxybenzene in Methylene Chloride

From a mixture of aluminum chloride (1.35 g; 0.01 mole), *p,p'*-dinitrobenzoyl peroxide (3.32 g; 0.01 mole), and 1,3-dimethoxybenzene (4 ml; 0.03 mole) in methylene chloride (50 ml), mixed at 20° and left overnight at 0°, *p*-nitrobenzoic acid (1.04 g; 31%) was obtained by the usual work-up. The methylene

chloride solution was washed and dried. On slow concentration of the solution *p*-nitrobenzoic anhydride separated and was recrystallized from benzene as colorless flakes (0.5 g; 16%), m.p. and mixed m.p. 191° (recorded m.p. 189–190° (19)). The mother liquor on further concentration afforded a gum which did not distill at temperatures up to 270° at 1 mm, and which did not give any crystalline fraction on chromatography on alumina.

Reactions of p-Nitrobenzoyl Peroxide in Different Solvents

(a) Methylene Chloride

To a stirred suspension of aluminum chloride (1.35 g) in methylene chloride (50 ml), the peroxide (2.87 g) was added at 8–10°. The mixture was stirred a further 2 hours, left overnight at 0°, and then worked up as usual. After removal of *p*-nitrobenzoic acid (0.35 g; 12%), m.p. 236–237°, the methylene chloride solution was washed with water, dried, and evaporated. The residue on crystallization from petroleum ether (b.p. 55–75°) gave colorless flakes of phenyl *p*-nitrobenzoate (1.97 g; 81%), m.p. and mixed m.p. 129–130°.

(b) Benzene

This experiment was carried out as in the previous one, except that benzene (60 ml) was used in place of methylene chloride. Extraction with bicarbonate, in the usual work-up, removed a mixture (0.83 g) of *p*-nitrobenzoic and benzoic acids, m.p. 227–232°. The residue from the neutral fraction, after removal of solvent, was chromatographed on alumina. Elution with petroleum ether (b.p. 65–75°) and benzene gave a series of fractions of impure solid (0.41 g), which crystallized from ethanol as colorless flakes melting over the range 100–115°. The range was not diminished by further crystallization.

(c) Nitrobenzene

A similar experiment using nitrobenzene (50 ml) as solvent gave a mixture (0.82 g) of *p*-nitrobenzoic and benzoic acids, m.p. 230–234°, and a neutral product (0.36 g), m.p. 100–120°, similar to the neutral product of the previous experiment.

Decomposition of Benzoic–Ethylcarbonic Anhydride by Aluminum Chloride in Benzene

To aluminum chloride (4.05 g; 0.03 mole), suspended in dry benzene (50 ml) under a nitrogen atmosphere, was added with constant stirring at room temperature benzoic–ethylcarbonic anhydride (5.82 g; 0.03 mole) prepared according to Tarbell and Leister (20). The mixture was left overnight, and then worked up in the usual way to yield benzoic acid (0.51 g; 14%). The neutral solution was washed, dried, and distilled. A liquid (2.26 g; 48%), b.p. 78–80° at 1 mm, was collected and identified as ethyl benzoate by comparison of its refractive index (n_D^{23} 1.5046) and infrared spectrum with those from an authentic specimen.

ACKNOWLEDGMENTS

We are grateful to Professors D. H. R. Barton, D. J. Cram, and D. L. de Tar for helpful comments, to Dr. W. F. Hemmens for preliminary experiments, to Dr. T. Vrbaski for gas chromatographic analyses, and to the National Research Council for financial support.

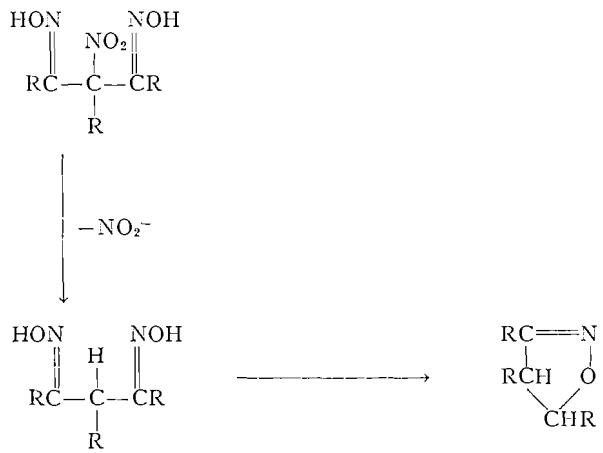
NOTES

SOME PROPERTIES OF BETA-NITROPROPIONIC ACID

A. M. UNRAU

Beta-nitropropionic acid is one of the three naturally occurring organic nitro compounds. In a recent review, Pailer (1) has presented a thorough discussion of the chemistry of chloramphenicol (chloromycetin) and aristolochic acid I and II, and of the occurrence of beta-nitropropionic acid, either as the free acid or in the form of a glycoside, in a number of plants and fungae. The significance of the occurrence of this nitro acid in plants is not understood and up to this time, very little has been reported regarding its chemical properties. In a recent communication, Birch *et al.* (2) have presented evidence that beta-nitropropionic acid may be formed from aspartic acid in a *Penicillium* species.

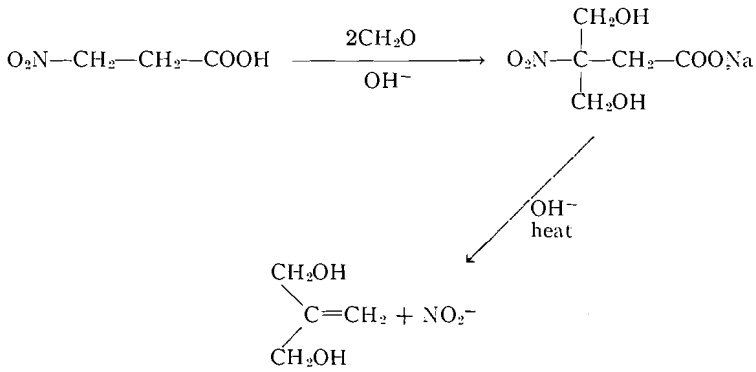
Beta-nitropropionic acid may be prepared by the reaction of nitrite with beta-iodopropionic acid and beta-iodopropionitrile or in a 30–40% yield by treating beta-propiolactone with sodium nitrite (3). Treatment of the nitro acid with aqueous alkali (saturated sodium borate or sodium bicarbonate) in an autoclave at 15-lb pressure yields relatively small quantities of nitrite ion which, however, can be quantitatively determined (4). A possible mechanism for the formation of relatively small quantities of nitrite ion rests in the observation that homologous nitroparaffins yield trialkylisoxazoles upon reaction with alkali (5). Lippincott (6) has proposed that the nitro group in an intermediate shown below is lost to yield a dioxime which was isolated when an organic base was used.



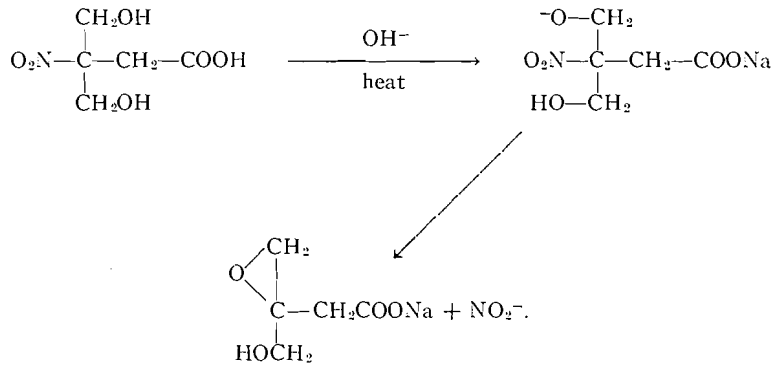
Hydrolysis of the dioxime gave the final cyclic compound. In the above sequence, one nitro group per 3 moles of original nitroparaffin is lost as nitrite ion.

The observation was made that the alkali-catalyzed condensation of formaldehyde (7) with beta-nitropropionic acid resulted, upon alkaline hydrolysis, in a 3- to 4-fold increase in nitrite ion formation. Vanderbilt and Hass (8) have shown that a variety of bases may be used to catalyze this aldol-type condensation involving primary nitroparaffins. The condensation of beta-nitropropionic acid with 2 moles of formaldehyde apparently

results in the formation of 3-nitro-3,3-dihydroxymethyl propionic, acid which cannot react with base as illustrated for the unsubstituted nitro compound. It is postulated that the nitro group may be lost by a beta elimination, as illustrated.



An alternative mechanism whereby the nitro group may be eliminated from the substituted nitro acid finds its analogy in the reaction of halohydrins with alkali to yield epoxides.

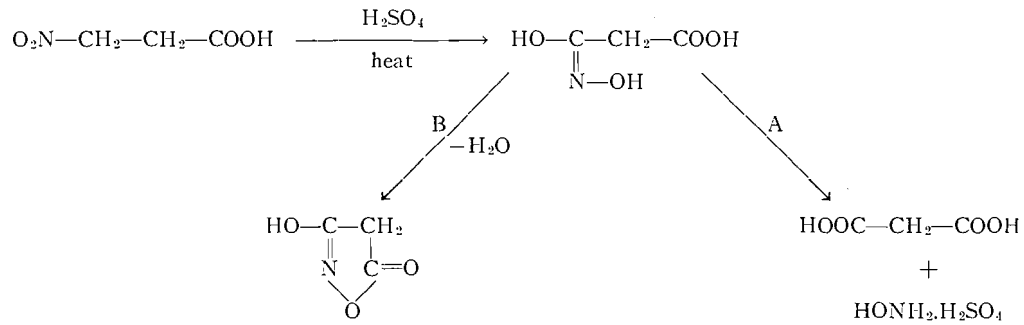


When the reaction sequence was applied to nitropropane, approximately three to four times as much nitrite ion was detected in the reaction mixture compared to the case in which no formaldehyde was added. In this case, a beta elimination of the type suggested for the fully substituted beta-nitropropionic acid is not possible and the elimination of the nitro group is believed to proceed by the formation of epoxides.

In both instances when beta-nitropropionic acid and nitropropane were subjected to the reaction series, a very marked dependence was observed with respect to nitrite ion formation on the strength of the alkali used. Hass and Riley (5) have stressed that the addition of aldehydes to nitroparaffins must compete with at least two other reactions, namely (*a*) aldol condensation of the aldehyde with itself and (*b*) the conversion of the nitroparaffin to the isoxazole. Since low yields of nitrite ion were observed when strong (8–25%) solutions of NaOH were used, one or both of the above reactions was dominant. The greatest removal of the nitro group from beta-nitropropionic acid was observed when sodium bicarbonate or sodium borate buffers were used. Organic bases have not been tried.

Since primary aliphatic nitro compounds are known to give hydroxylamine in high yield when boiled with 88% sulphuric acid or concentrated hydrochloric acid (9), an

attempt was made to utilize this reaction as an analytical method for the determination of beta-nitropropionic acid. The reaction was entirely unsuccessful regardless of how vigorously the nitro acid was treated. It is believed that the reaction proceeds normally to give, in this case, the carboxyhydroxamic acid but that the latter probably forms an anhydride, as represented in reaction B.



Whereas the usual red solutions of the corresponding nitrolates were obtained when nitropropane and nitroethane were treated with nitrous acid and alkali in that order, beta-nitropropionic acid gave instead a pale yellow color. Using the procedure described by Altschuler and Cohen (10) which involves the above reaction sequence, a prominent absorption maximum was observed at 333 to 335 mμ. Preliminary trials indicated that in the absence of interfering substances microamounts of the nitro acid may be detected in this manner.

EXPERIMENTAL

Reagents

(1) Sulphanilic acid: to a 1:2 (v/v) mixture of water and concentrated hydrochloric acid was added 0.5 g sulphanilic acid;

(2) naphthylamine: naphthylamine hydrochloride (0.5 g) was dissolved in ethanol (20 ml), and water (75 ml) and concentrated hydrochloric acid (5 ml) were added;

(3) formaldehyde: 8–9% aqueous solution;

(4) sodium acetate buffer: 2 *M*;

(5) buffers for alkaline hydrolysis: (A) sodium borate, 0.2 *M*, (B) sodium bicarbonate, 2 *M*, (C) sodium hydroxide, 2, 5, and 10% solutions;

(6) standard solutions: (A) beta-nitropropionic acid, 0.05 mg per ml (aqueous solution), (B) 1-nitropropane, 0.5 mg per ml (aqueous solution);

(7) sulphuric acid: 88%;

(8) sodium nitrite solution, approximately 7%.

Alkaline Hydrolysis of Nitro Compounds

Into beakers or Erlenmeyer flasks (150 ml) were transferred standard solutions of nitro compound (1 ml) and sodium borate buffer (5 ml). The mixture was autoclaved at 15 p.s.i. pressure for 1 hour. After the solutions were cooled in an ice bath, water (10 ml) and sulphanilic acid (3 ml) were added. After about 4 minutes, naphthylamine reagent (3 ml) and 95% ethanol (10 ml) were added and the pH of the solution adjusted to about 2.5 with sodium acetate buffer. The solutions were made to volume (50 ml) and the absorbance determined in a colorimeter at 520 mμ.

In a similar manner, alkaline hydrolyses of the two nitro compounds were performed using alkaline buffers B and C. Alternative procedure: Into matched borosilicate glass colorimeter tubes were transferred (1 ml) standard solutions of nitrocompounds and alkaline buffers A, B, or C (5 ml). The tubes were capped with aluminum foil and placed in a boiling-water bath for 1.5 hours. After the tubes were cooled in an ice bath, sulphanilic acid (3 ml) was added and the contents mixed. After the mixture had stood for about 4 minutes, naphthylamine (3 ml) and 95% ethanol (10 ml) were added, the contents mixed, and without adjusting the pH, the absorbance of the solutions measured at 520 mμ.

Addition of formaldehyde:—To a mixture of alkaline buffer and nitro compound as described above was added (1 ml) 8–9% aqueous formaldehyde, and the solutions were treated as above.

Acid Hydrolysis of Compounds

Into a 50-ml round-bottomed flask fitted with a condenser was transferred an aliquot (1 ml) of standard solution of nitro compound and 88% sulphuric acid (10 ml). The solution was refluxed for 3.5–4 hours, after which time the extent of formation of hydroxylamine was determined colorimetrically by a standard procedure (4).

Conversion of Nitro Compounds to Nitrolates

To an aliquot (2 ml) of the nitro compound was added (3 ml) sodium nitrite solution and concentrated hydrochloric acid (2 ml) in that order. The solutions were made alkaline with 10% sodium hydroxide solution and the color formation observed. Nitropropane gave the expected red-colored solution while beta-nitropropionic acid gave a pale yellow solution with an absorption maximum at 334–340 mμ.

TRANSITION METAL ARSENIDES

V. A NOTE ON THE RHODIUM/ARSENIC SYSTEM AND THE MONOCLINIC DIARSENIDES OF THE COBALT FAMILY*

J. Claire Quesnel and R. D. Heyding

Identification of the compounds Rh_2As, RhAs, $RhAs_2$, and $RhAs_3$ in the rhodium/arsenic system was reported in an earlier note (1). Using sealed quartz tube techniques to prepare the specimens, phase relations in this system have been examined in the temperature region 300° to 1000° C. Powdered specimens were allowed to approach equilibrium for 3 months at 300° C, and progressively shorter times at higher temperatures, to 24 hours at 1000° C. The samples were quenched in ice water and examined by Debye–Scherrer patterns obtained in 11.46-cm cameras with Cu K_α radiation.

Two additional compounds have been recognized, the first at $Rh_{1.7}As$, and the second in a homogeneous field from $Rh_{1.6}As$ to $Rh_{1.3}As$. The homogeneity limits of the latter phase are only slightly temperature dependent. The patterns of both of these compounds are comparatively complex, and as yet no symmetry elements have been recognized. Apparently neither is isostructural with known transition metal pnictides.

No liquid phases were observed in the system to 1000° C in the metal-rich region, or to 900° C in the arsenic-rich region. From 300° to 1000° C the phase diagram is featureless except for a polymorphic transition in Rh_2As. The low-temperature modification described earlier (α-Rh_2As) with the cubic C1 (Ir_2P, Rh_2P) structure transforms at 650–700°

*Issued as N.R.C. No. 6702.

With the structure determinations of RhP_2 and IrP_2 by Rundqvist (2), and of $CoSb_2$, $RhSb_2$, and $IrSb_2$ by Zhuravlev *et al.* (3), the existence of a new class of monoclinic MX_2 pnictides has been established. Obviously the diarsenides of cobalt, rhodium, and iridium would be expected to be isostructural with the diphosphides and diantimonides. We have compared the powder diffraction patterns of the arsenides with those of RhP_2 and $RhSb_2$. Rundqvist recorded the pattern of the phosphide, but none has been published for the antimonide. Accordingly $RhSb_2$ was synthesized and its powder diffraction pattern indexed using, initially, the unit cell dimensions given by Zhuravlev.

Diffraction patterns for $RhAs_2$, $IrAs_2$, and $RhSb_2$ were obtained in a Guinier – de Wolff focusing camera with Cu K_α radiation using As_2O_3 as an internal standard. The pattern of $CoAs_2$ was obtained with a 19-cm Debye–Scherrer camera with Co K_α radiation, again using As_2O_3 as an internal standard.

The patterns were indexed by direct comparison of the five or six most intense reflections with those of the phosphide and antimonide. Refinement gave the monoclinic unit

cell dimensions recorded in Table III. The diffraction patterns of the arsenides and of $RhSb_2$ are given in Tables IV–VII.

TABLE III

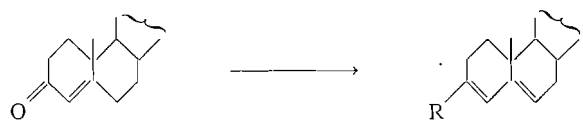
STEROIDAL 3-CHLORO-3,5-DIENES

R. Deghenghi and R. Gaudry

In some cases the modification of the Δ^4-3 ketone moiety (I) of the natural steroidal hormones has led to biologically active analogues, particularly in the anabolic–androgenic field (1, 2).

The 3-enol-ether analogues (3), for instance, (II) R = O-alkyl, of methyltestosterone



I II

were found to be more active, by the oral route, than their parent compound (4).

We chose to modify the Δ^4-3 keto portion of the molecule by forming a 3-chloro-3,5-diene (II, R = Cl), which thus had the same geometry (II) of ring A and B, with concomitant increased stability of the diene system.[1]

Previous examples of steroidal 3-chloro-3,5 dienes were one prepared by Ruzicka by the action of benzoyl chloride at 100° C (5,6) on 4-cholestene-3-one and a 3-chloro-3,5-androstadien-17-one that was described in 1937 by Kuwada (7), but was not completely characterized and was without any mention of its biological activity.

The observation (8) that the action of oxalyl chloride on some Δ^4-3-keto-etianic acids in order to form the corresponding acid chlorides, according to the method of Wilds (9), resulted, in absence of pyridine, in an attack of the Δ^4-3-keto moiety, with the formation of a 3-chloro-3,5-diene,[2] prompted us to employ this reagent to transform a number of steroidal Δ^4-3 ketones into new analogues (II, R = Cl).

The acid-catalyzed reaction proceeds smoothly at room temperature and in most cases is completed in 1 hour in yields of 50–70% of theory.

[1]*The 3-enol-ether analogues were assumed to be active "per se" and not as precursors of the conjugated 3-keto steroids by endogenous hydrolysis (4).*

[2]*Reichstein et al. (10) have noted a decrease in the yield of a similar reaction from 83% to 75% when pyridine was omitted. They could isolate minor unidentified by-products which, in our opinion, may well be the corresponding chlorodienes. Oxalic acid is, of course, a product of the reaction and was therefore chosen by us to catalyze our transformations.*

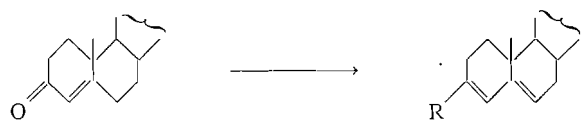
STEROIDAL 3-CHLORO-3,5-DIENES

R. Deghenghi and R. Gaudry

In some cases the modification of the Δ^4-3 ketone moiety (I) of the natural steroidal hormones has led to biologically active analogues, particularly in the anabolic–androgenic field (1, 2).

The 3-enol-ether analogues (3), for instance, (II) R = O-alkyl, of methyltestosterone



I II

were found to be more active, by the oral route, than their parent compound (4).

We chose to modify the Δ^4-3 keto portion of the molecule by forming a 3-chloro-3,5-diene (II, R = Cl), which thus had the same geometry (II) of ring A and B, with concomitant increased stability of the diene system.[1]

Previous examples of steroidal 3-chloro-3,5 dienes were one prepared by Ruzicka by the action of benzoyl chloride at 100° C (5,6) on 4-cholestene-3-one and a 3-chloro-3,5-androstadien-17-one that was described in 1937 by Kuwada (7), but was not completely characterized and was without any mention of its biological activity.

The observation (8) that the action of oxalyl chloride on some Δ^4-3-keto-etianic acids in order to form the corresponding acid chlorides, according to the method of Wilds (9), resulted, in absence of pyridine, in an attack of the Δ^4-3-keto moiety, with the formation of a 3-chloro-3,5-diene,[2] prompted us to employ this reagent to transform a number of steroidal Δ^4-3 ketones into new analogues (II, R = Cl).

The acid-catalyzed reaction proceeds smoothly at room temperature and in most cases is completed in 1 hour in yields of 50–70% of theory.

[1]*The 3-enol-ether analogues were assumed to be active "per se" and not as precursors of the conjugated 3-keto steroids by endogenous hydrolysis (4).*

[2]*Reichstein et al. (10) have noted a decrease in the yield of a similar reaction from 83% to 75% when pyridine was omitted. They could isolate minor unidentified by-products which, in our opinion, may well be the corresponding chlorodienes. Oxalic acid is, of course, a product of the reaction and was therefore chosen by us to catalyze our transformations.*

Progesterone, testosterone acetate, methyltestosterone acetate, and cortisone acetate were readily transformed by this method. A hindered alcoholic function (like the 17-hydroxyl group in cortisone) was not affected by the reagent.

The resulting chlorodienes were stable, crystalline substances, with a characteristic ultraviolet absorption at 242 mμ with two shoulders at 236 and 250 mμ and a log ε of 4.4. The infrared absorption in chloroform reveals a single $\Delta^{3,5}$ band at 1621 cm^{-1}. The molecular change in the rotation from the parent Δ^4-3 keto steroid is −850.

The 3-chlorodiene IV, obtained from cortisone, was devoid of appreciable glucocorticoid activity (liver glycogen deposition) but caused sodium excretion; the adduct III from progesterone was inactive in the Clauberg test. 17β-Acetoxy-3-chloro-3,5-androstadiene V (from testosterone acetate) showed a favorable anabolic–androgenic activity ratio (levator ani and seminal vescicles weight test).

EXPERIMENTAL[3]

3-Chloro-3,5-pregnadiene-20-one III

A solution of 10 g of progesterone in 100 ml of dry benzene was stirred at room temperature for 2 hours in the presence of 30 cc oxalyl chloride and 0.5 g oxalic acid. The organic solvent was evaporated at reduced pressure and the residue was taken up in ether, washed with $NaHCO_3$ solution, and water. The solvent was dried and evaporated to give crude 3-chloro-3,5-pregnadiene-20-one, 10 g, which was recrystallized from ether. Colorless needles, m.p. 126–128° C, $[\alpha]_D$ −61°, λ_{max} 242 mμ, log ε 4.4. Calc. for $C_{21}H_{29}OCl$ (332.9): C, 75.77; H, 8.78; Cl, 10.65%. Found: C, 75.86; H, 8.76; Cl, 10.56%.

3-Chloro-3,5-androstadiene-17β-ol Acetate V

A quantity of 1 g of testosterone acetate was dissolved in 25 cc dry benzene and stirred with 5 cc oxalyl chloride and 0.1 g oxalic acid for 1 hour. The usual working up gave 0.6 g *17β-acetoxy-3-chloro-3,5-androstadiene*, m.p. 148–152° C, $[\alpha]_D$ −172°, λ_{max} 242 mμ, log ε 4.4. Calc. for $C_{21}H_{29}O_2Cl$ (348.9): C, 72.29; H, 8.38; Cl, 10.16%. Found: C, 72.19; H, 8.30; Cl, 10.10%.

17α-Methyl-3-chloro-3,5-androstadiene-17β-ol Acetate VI

A quantity of 6 g of 17α-methyltestosterone acetate was dissolved in 100 ml dry benzene and stirred with 20 ml of oxalyl chloride and 0.3 g oxalic acid at room temperature for 1½ hours. The reaction mixture was worked up as in the previous examples to give 3.5 g *17α-methyl-17β-acetoxy-3-chloro-3,5-androstadiene*, m.p. 127–128° C after crystallization from methanol, $[\alpha]_D$ −148°, λ_{max} 242 mμ, log ε 4.4. Calc. for $C_{22}H_{31}O_2Cl$ (362.9): C, 72.80; H, 8.61; Cl, 9.77%. Found: C, 73.01; H, 8.45; Cl, 9.90%.

21-Acetoxy-17α-hydroxy-3-chloro-3,5-pregnadiene-11,20-dione IV

A quantity of 3 g of cortisone acetate in 100 ml dry benzene was stirred with 0.4 g oxalic acid and 20 cc oxalyl chloride for 18 hours at room temperature. The usual working up gave needles of *21-acetoxy-17α-hydroxy-3-chloro-3,5-pregnadiene-11,20-dione*, 1.6 g, m.p. 195–197° C from methanol–water, $[\alpha]_D$ ±0, λ_{max} 242 mμ, log ε 4.4. Calc. for $C_{23}H_{29}O_5Cl$ (420.9): C, 65.63; H, 6.94; Cl, 8.42%. Found: C, 65.29; H, 6.76; Cl, 8.43%.

[3]*Melting points were determined in evacuated capillaries and corrected. Rotations measured at 23° C in 1%* $CHCl_3$ *solution.*

A PHOTOCHEMICAL PREPARATION OF SOME HALOGENATED CYCLOPROPANES

EDWARD L. DEDIO, PETER J. KOZAK, SERGE N. VINOGRADOV, AND HARRY E. GUNNING

The photochlorination of cyclopropane was first reported by Gustavson (1). Roberts and Dirstine (2) attempted a flow photochlorination in their investigation of the thermal chlorination of cyclopropane. Using high flow rates, of the order of moles per hour, and a 4:1 ratio of cyclopropane to chlorine, they obtained a yield of monochlorocyclopropane of only 7.6% of the cyclopropane consumed, even with partial recycling of the reaction mixture. Slabey (3), using essentially the same apparatus as Roberts and Dirstine, and similar conditions, but without recycling of the cyclopropane, obtained a yield of about 10%.

In our investigations of the formation and behavior of cycloalkyl radicals in the gas phase, in particular, of the photolysis and mercury-photosensitized decomposition of monohalocyclopropanes, we were led to explore means of preparing these compounds quickly and conveniently. It has been found that cyclopropane can be photochlorinated and photobrominated in a simple flow system without recycling the cyclopropane. In the former case, we were able to obtain yields of monochlorocyclopropane up to 20–30% of the cyclopropane consumed, with flow rates much lower than those used by previous investigators. In the case of photobromination, nitrogen was used as the carrier of bromine, and chlorine served to initiate the photobromination. The yields of monobromocyclopropane were correspondingly lower, usually not exceeding 10% of the cyclopropane consumed. Photobromination, in the absence of chlorine, resulted in the opening of the cyclopropane ring. Attempts to photoiodinate cyclopropane, again with nitrogen as the carrier gas, and chlorine as the initiator, were unsuccessful.

Table I shows some representative results of the photochlorination of cyclopropane. It is seen that the ratio of monochlorocyclopropane to 1,1-dichlorocyclopropane varies directly, while the total yield varies inversely, with the cyclopropane-to-chlorine ratio.

A PHOTOCHEMICAL PREPARATION OF SOME HALOGENATED CYCLOPROPANES

EDWARD L. DEDIO, PETER J. KOZAK, SERGE N. VINOGRADOV, AND HARRY E. GUNNING

The photochlorination of cyclopropane was first reported by Gustavson (1). Roberts and Dirstine (2) attempted a flow photochlorination in their investigation of the thermal chlorination of cyclopropane. Using high flow rates, of the order of moles per hour, and a 4:1 ratio of cyclopropane to chlorine, they obtained a yield of monochlorocyclopropane of only 7.6% of the cyclopropane consumed, even with partial recycling of the reaction mixture. Slabey (3), using essentially the same apparatus as Roberts and Dirstine, and similar conditions, but without recycling of the cyclopropane, obtained a yield of about 10%.

In our investigations of the formation and behavior of cycloalkyl radicals in the gas phase, in particular, of the photolysis and mercury-photosensitized decomposition of monohalocyclopropanes, we were led to explore means of preparing these compounds quickly and conveniently. It has been found that cyclopropane can be photochlorinated and photobrominated in a simple flow system without recycling the cyclopropane. In the former case, we were able to obtain yields of monochlorocyclopropane up to 20–30% of the cyclopropane consumed, with flow rates much lower than those used by previous investigators. In the case of photobromination, nitrogen was used as the carrier of bromine, and chlorine served to initiate the photobromination. The yields of monobromocyclopropane were correspondingly lower, usually not exceeding 10% of the cyclopropane consumed. Photobromination, in the absence of chlorine, resulted in the opening of the cyclopropane ring. Attempts to photoiodinate cyclopropane, again with nitrogen as the carrier gas, and chlorine as the initiator, were unsuccessful.

Table I shows some representative results of the photochlorination of cyclopropane. It is seen that the ratio of monochlorocyclopropane to 1,1-dichlorocyclopropane varies directly, while the total yield varies inversely, with the cyclopropane-to-chlorine ratio.

TABLE I

The photochlorination of cyclopropane

Flow rate (moles/hr)		Molar ratio	Total yield		%yield*
$\widehat{C_3H_6}$	Cl_2	$\frac{\widehat{C_3H_6}}{Cl_2}$	(g/hr)	$\frac{\widehat{C_3H_5Cl}}{\widehat{C_3H_4Cl_2}}$	$\widehat{C_3H_5Cl}$
0.26	0.05	4.3	2.7	2.7	9.8

0.13	0.07	1.9	4.5	0.8	20
0.11	0.07	1.6	4.5	0.6	20
0.13	0.11	1.2	7.0	0.8	31
0.13	0.17	0.8	6.6	0.7	27
0.07	0.13	0.5	10.0	0.2	29 (22)
0.07	0.34	0.2	12.0	0.05	11

*Calculated as mole % of the $\widehat{C_3H_6}$ consumed using the values given in column 5. The values in parentheses were calculated, taking into consideration the areas of the remaining peaks in the chromatograms.

It is seen that, contrary to expectations, the best yield of monochlorocyclopropane is obtained when the molar ratio of cyclopropane to chlorine in near unity.

Table II shows some typical results of the photobromination of cyclopropane. Here, as in the case of the photochlorination, there was no difficulty in separating the monobrominated cyclopropane from the rest of the products by distillation. While the yields

*Using nitrogen as carrier. The amount of bromine was determined in separate experiments by condensing it at dry-ice temperature and weighing.

of the monobromocyclopropane were only about 10% of the cyclopropane consumed, the simplicity of the method presents some advantage over the conventional method of preparing the monobromo derivative from the silver salt of the cyclopropylcarboxylic acid (4). It should also be stressed that, in both cases, the photochemical method produced, albeit in small quantities, several higher halogenated cyclopropanes which can be isolated by temperature-programed gas–liquid partition chromatography (G.L.P.C.). It is thus a convenient method of simultaneously preparing several related compounds.

EXPERIMENTAL

The flow apparatus is shown in Fig. 1. The spiral cells were of pyrex tubing and 100 to 200 cm long, the diameter of each loop being about 10 cm. The lamp was a General Electric, H85-C3, medium-pressure mercury arc. The flow was regulated by needle valves on each cylinder, and measured with a soap-bubble flowmeter, prior to each photohalogenation. Total flow rates varied between 50 and 200 ml/min at S.T.P. The collector was kept immersed in ice during a run.

The cyclopropane (U.S.P. Ohio Chemical Co., and The Matheson Co.), chlorine (The Matheson Co.), bromine (reagent grade, Allied Chemical Co.), and nitrogen (purified grade, The Matheson Co.) were used

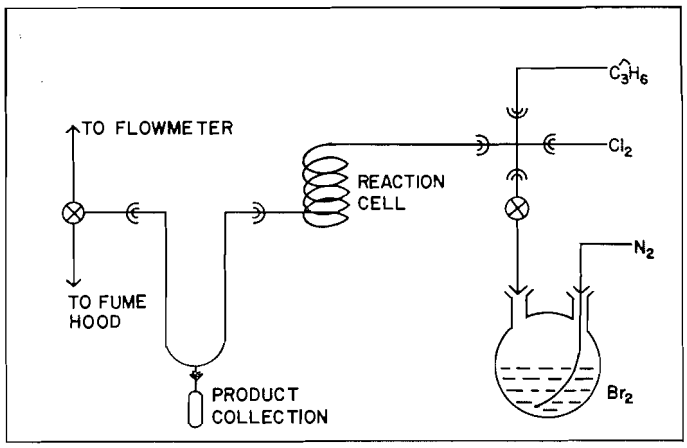

FIG. 1. Diagram of flow photohalogenation of cyclopropane.

without purification. The liquid products were washed twice with equal volumes of aqueous sodium sulphite solution (8%) and twice with equal volumes of aqueous sodium carbonate solution (8%). Initial separation of the products was performed by distillation and the final purification achieved with temperature-programed gas–liquid partition chromatography in columns packed with di-(2-ethyl)-hexyl sebacate or silicone rubber on firebrick.

The total yield of crude products was obtained by weighing, while estimates of individual yields were calculated from the G.L.P.C. data.

The monochlorocyclopropane, 1,1-dichlorocyclopropane, and the monobromocyclopropane were identified by their physical properties, and by comparison of their infrared spectra to previously published results (2–5). In addition, the following microanalyses were obtained.

Monochlorocyclopropane: Found: C, 46.3%; H, 7.1%; Cl, 45.1%. Calc.: C, 47.0%; H, 6.5%; Cl, 46.3%.
1,1-Dichlorocyclopropane: Found: C, 31.6%; H, 3.5%; Cl, 64.9%. Calc.: C, 32.5%; H, 3.6%; Cl, 63.9%.
Monobromocyclopropane: Found: C, 29.7%; H, 4.9%; Br, 64.8%. Calc.: C, 29.8%; H, 4.1%; Br, 66.1%.

Finally, in the case of the monohalocyclopropanes, the formation of cyclopropane during a photolytic decomposition in the presence of a saturated hydrocarbon was considered as additional evidence that the compound was a cyclopropane derivative.

COORDINATION COMPOUNDS OF NICKEL (II)
PART III. FURTHER MAGNETIC STUDIES OF SOLUTIONS

H. C. CLARK, K. MACVICAR, AND R. J. O'BRIEN

There has recently been much interest in the so-called "magnetically anomalous" complexes of nickel (II). Apart from recent work on some aminotroponeimine-nickel (II) chelates (1), attention has been centered on the behavior of substituted nickel (II)

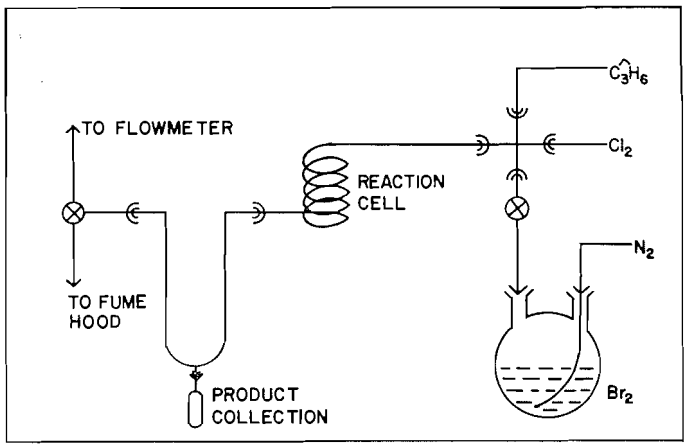

FIG. 1. Diagram of flow photohalogenation of cyclopropane.

without purification. The liquid products were washed twice with equal volumes of aqueous sodium sulphite solution (8%) and twice with equal volumes of aqueous sodium carbonate solution (8%). COORDINATION COMPOUNDS OF NICKEL (II)
PART III. FURTHER MAGNETIC STUDIES OF SOLUTIONS

H. C. CLARK, K. MACVICAR, AND R. J. O'BRIEN

There has recently been much interest in the so-called "magnetically anomalous" complexes of nickel (II). Apart from recent work on some aminotroponeimine-nickel (II) chelates (1), attention has been centered on the behavior of substituted nickel (II)

salicylaldimine complexes. Current views on possible interpretations of the magnetic and spectroscopic behavior of these complexes have been summarized in the previous paper of this series (2) and by Ferguson (3). It now seems clear that the appearance of paramagnetism in solutions of these complexes (e.g. bis-N-methyl-salicylaldimine nickel (II)) in non-coordinating solvents such as chloroform, carbon tetrachloride, etc. is due to association of the solute, rather than to solvent perturbation. Such solute interaction must give some type of distorted octahedral configuration about the nickel atoms, thereby decreasing the singlet–triplet separation so as to make the triplet state thermally accessible. There is, however, no evidence which indicates the mode of association and, indeed, two different models for association are required in view of the very different properties of the two paramagnetic species of bis-N-methyl-5-chloro-salicylaldimine nickel (II) (2). Although earlier magnetic measurements (4–6) of solutions of these salicylaldimine complexes gave little indication of concentration dependence of the magnetic susceptibility, such dependence must clearly occur in those cases where solute association takes place. To clarify this point and in an attempt to gain information concerning the associated species, we have made a further series of magnetic measurements.

EXPERIMENTAL

The compounds studied were bis-N-methyl-salicylaldimine nickel (II) and bis-N-*n*-butyl-salicylaldimine nickel (II); their preparations are described elsewhere (4, 7). Solvents were carefully purified and dried by standard methods, and magnetic measurements were made using the apparatus described previously (2). The results obtained are shown in Table I and Figs. 1 and 2.

TABLE I

(A) Concentration and temperature variation of the molar susceptibility ($\times 10^3$) of bis-N-methyl-salicylaldimine nickel (II) in $CHCl_3$ solution

Temperature (°K)	221	239	253	263	273	283	294
3.1% (w/w) ≡ 0.146 *M*	5.285	4.426	3.662	3.267	2.810	2.381	2.123
Temperature	220.5	239	254	264	271.5	283	293
2.00% (w/w) ≡ 0.0936 *M*	4.448	3.731	2.920	2.550	2.146	1.845	1.402
Temperature	218	237	253	263	272	281.5	294
1.00% (w/w) ≡ 0.0468 *M*	3.800	3.146	2.336	1.797	1.127	0.866	0.601

(B) Solvent dependence of the molar susceptibility ($\times 10^3$) of bis-N-*n*-butyl-salicylaldimine nickel (II)

Temperature	215	239	253	263	271	282	293
3.00% (w/w) ≡ 0.113 *M* in 100% $CHCl_3$	2.986	1.893	1.228	0.883	0.686	0.509	0.219
Temperature	231	245	258	279	291		
9.0% (w/w) ≡ 0.37 *M* in 10% pyridine – 90% $CHCl_3$	4.451	4.194	4.014	3.742	3.532		

(C) Concentration dependence of the magnetic susceptibility ($\times 10^3$) of bis-N-*n*-butyl-salicylaldimine nickel (II) in chloroform and pyridine–chloroform at 298° K

Concentration (*M*)	0.407	0.371	0.318	0.269	0.233
$\chi_M \times 10^3$ in 100% $CHCl_3$	0.464	0.306	0.216	0.176	0.150
$\chi_M \times 10^3$ in 10% C_5H_5N – 90% $CHCl_3$	3.370	3.380	3.420	3.350	3.510

Molecular weights were determined cryoscopically in benzene solution; the following results (Table II) were obtained.

DISCUSSION

Contrary to earlier reports, the present results show that the magnetic susceptibilities are in fact concentration dependent except for solutions where a strongly coordinating base, such as pyridine, is present. This concentration dependence, giving a greater degree

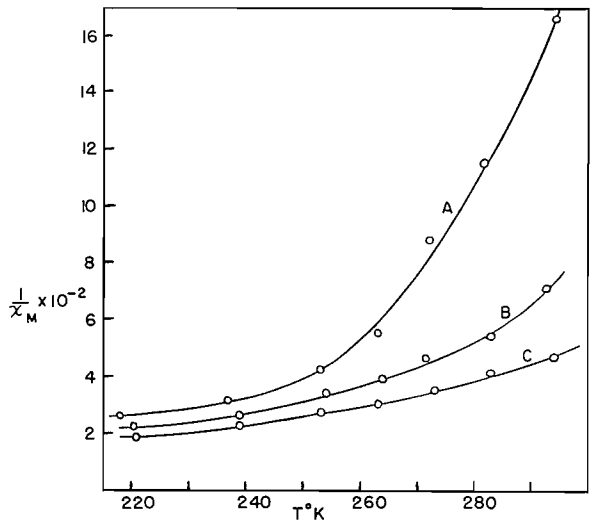

FIG. 1. Magnetic susceptibility of the N-methyl complex in $CHCl_3$ solution: A, 1.0%; B, 2.0%; C, 3.1%

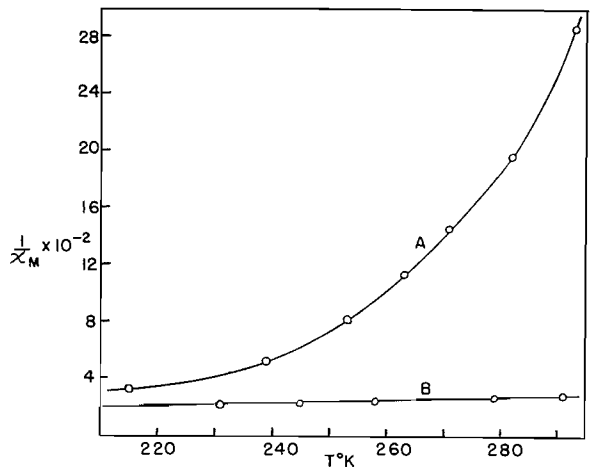

FIG. 2. Magnetic susceptibility of the N-butyl complex: A, in $CHCl_3$; B, in 10% pyridine – 90% $CHCl_3$.

TABLE II

Molecular weight determinations

Concentration (% by weight)	0.50	0.75	1.0	2.0	3.0	4.0
N-Methyl complex	357	415	540			
N-*n*-Butyl complex		447	465	512	570	683

of paramagnetism with increasing concentration, together with the observed increases in molecular weight with increasing concentration, provides excellent evidence that solute association occurs in these solutions of both the complexes. Since our measurements were made, the results of similar experiments by Holm have been published (8). Our results are in general agreement with Holm's in that both confirm the suggestion, originally made by Ferguson (3), as to the occurrence of association. However, the

present extension of measurements to low temperatures allows an important difference in interpretation to be made. Holm considers the low paramagnetism at room temperature of all the *n*-alkyl complexes (other than methyl) to be insignificant and he hence concludes (9) that these complexes are monomeric in solution. The measurements of Holm and McKinney were, however, made at only one concentration, or over a very restricted concentration range, and at only one temperature. The present magnetic measurements show clearly, when examined over the temperature and much wider concentration ranges, and particularly below room temperature, that there is ample evidence for association of the *n*-butyl complex. This is also supported by the molecular weight measurements. We therefore conclude that association occurs in non-coordinating solvents for all substituted salicylaldimine nickel (II) complexes so far investigated. When a strong base, such as pyridine, is present rapid solvation to octahedral, paramagnetic ($\mu \sim 3.2$ B.M.), dipyridine adducts (5, 10) occurs. The magnetic susceptibility then follows the Curie–Weiss law, as shown by Fig. 2.

Of the possible modes of solute association, that involving Ni—O intermolecular interactions to give an approximately octahedral arrangement about each nickel atom has been considered previously (2, 8, 11). An obvious alternative is that involving Ni—N intermolecular interactions to give the same type of arrangement. Miller and Sharpe (12) have rejected the possibility of coordination of the benzene rings of one molecule of bis-salicylaldehyde nickel (II) to the nickel atoms of adjacent molecules. An examination of the infrared spectra of the various forms of bis-N-methyl-5-chloro-salicylaldimine nickel (II) (2) likewise makes this type of interaction unlikely for the salicylaldimine complexes, since no frequency shifts are observed for absorptions associated with the phenyl groups (13).

Holm (8) has interpreted his results as indicating that, for the *n*-alkyl complexes (other than methyl), rotational motion of the alkyl groups must introduce a definite steric barrier so as to strongly inhibit association. Since our present results show that appreciable association occurs for these higher alkyl complexes, it seems that such steric effects are probably not the factors determining the occurrence or non-occurrence of association, although they apparently influence the degree of association. Detailed crystallographic studies are probably necessary to gain any reliable indication of the manner of association.

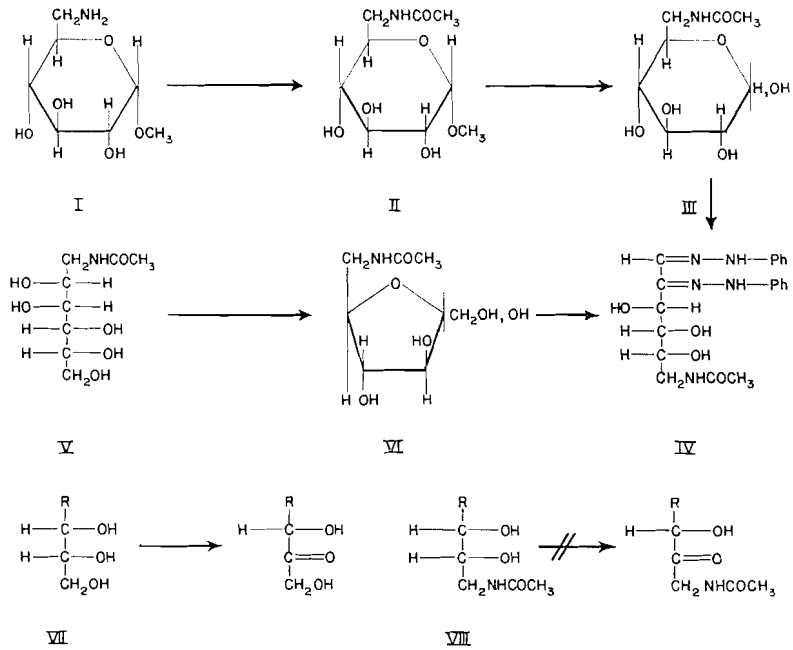
THE SYNTHESIS OF ACETAMIDO-DEOXY KETOSES BY ACETOBACTER SUBOXYDANS. PART IV

J. C. TURNER

Methyl 6-amino-6-deoxy-α-D-glucoside (I) was prepared by the method of Cramer *et al.* (1) and *N*-acetylated with aqueous acetic anhydride (2) to give methyl 6-acetamido-6-deoxy-α-D-glucoside (II). Acid hydrolysis of the methyl glucoside (II) then gave 6-acetamido-6-deoxy-D-glucose (III) (1,3), from which a crystalline phenylosazone (IV) was prepared.



1-Acetamido-1-deoxy-D-mannitol (V) (4) was oxidized by *Acetobacter suboxydans* under conditions described in a previous publication (5) to give an 84% yield of a syrupy ketose sugar (VI). The ketose (VI) gave a crystalline phenylosazone (IV) which was identical with that obtained from 6-acetamido-6-deoxy-D-glucose (III). The ketose (VI) was therefore epimeric with 6-acetamido-6-deoxy-D-glucose (III) and thus possessed the D-fructose or D-*arabo*-hexulose configuration, and was therefore 6-acetamido-6-deoxy-D-*arabo*-hexulose.

As no other ketose was detected in the oxidation medium, it was concluded that oxidation of a polyhydric alcohol possessing the D-*erythro* configuration of hydroxyl groups according to the Bertrand–Hudson rules (VII) (6, 7) does not occur when the hydroxyl group of the primary alcohol group is replaced by an acetamido-deoxy group (VIII).

EXPERIMENTAL

Methyl 6-amino-6-deoxy-α-D-glucoside

Methyl 6-*O*-*p*-toluenesulphonyl-α-D-glucoside (5 g) (m.p. 116–118° C, $[\alpha]_D$ +106° (*c*, 2.2 in ethanol); lit. values: m.p. 124° C, $[\alpha]_D$ +98.5° (ethanol) (1)) was dissolved in absolute methanol (180 ml) and cooled

to 0° C. The solution was saturated with anhydrous ammonia, then heated in an autoclave at 120° C for 16 hours. After cooling, the dark solution was boiled with charcoal and filtered, and the filtrate was passed through Amberlite IRA 400 (OH^-) anion-exchange resin. The eluate was evaporated to dryness to give syrupy methyl 6-amino-6-deoxy-α-D-glucoside (3 g) (1).

Methyl 6-acetamido-6-deoxy-α-D-glucoside

Syrupy methyl 6-amino-6-deoxy-α-D-glucoside (3 g) was *N*-acetylated with aqueous acetic anhydride (2) to give crystalline methyl 6-acetamido-6-deoxy-α-D-glucoside. The product was recrystallized three times from methanol–ether to give needles (2.0 g) which had m.p. 163–164° C, $[\alpha]_D$ +133° (*c*, 2.0 in water) and gave absorptions in the infrared (potassium bromide disk) at 3500 cm^{-1} (OH), 3300 cm^{-1} (NH), 1640 cm^{-1} (amide I), and 1565 cm^{-1} (amide II).

Anal. Calc. for $C_9H_{17}O_6N$: C, 46.0%; H, 7.2%; N, 6.0%. Found: C, 46.0%; H, 7.7%; N, 6.2%.

6-Acetamido-6-deoxy-D-glucose

Methyl 6-acetamido-6-deoxy-α-D-glucoside (600 mg) was hydrolyzed with *N* sulphuric acid (15 ml) at 100° C for 3.5 hours. The solution was cooled to room temperature and passed through Duolite A4 (OH^-) anion-exchange resin and the eluate was evaporated to dryness. The residue was *N*-acetylated with aqueous acetic anhydride (2) as some de-*N*-acetylation had been observed in trial experiments under the same hydrolysis conditions. The product, which was obtained as a pale yellow syrup, contained unhydrolyzed methyl 6-acetamido-6-deoxy-α-D-glucoside and 6-acetamido-6-deoxy-D-glucose. The latter was separated by chromatography on Whatman 3MM paper using butan-1-ol–ethanol–water, 3:1:1, as solvent, and obtained as a clear, colorless syrup (100 mg), which crystallized on the addition of ethanol. When recrystallized from aqueous ethanol the 6-acetamido-6-deoxy-D-glucose (65 mg) had m.p. 203–205° C (decomp.), $[\alpha]_D$ +35±3° → +44±4° (18 hours) (*c*, 0.7 in water). (Lit. values: m.p. 182–183° C (decomp.), $[\alpha]_D$ +42° (in water, after 2 hours) (1) and m.p. 196–198° C (decomp.), $[\alpha]_D$ +44° → +35° (in water, after 24 hours) (3).)

6-Acetamido-6-deoxy-D-glucose gave absorptions in the infrared (potassium bromide disk) at 3300 cm^{-1} (OH and NH), 1625 cm^{-1} (amide I), and 1570 cm^{-1} (amide II).

*6-Acetamido-6-deoxy-*D-arabo-*hexose Phenylosazone*

The phenylosazone was prepared by the usual method using freshly distilled phenylhydrazine and glacial acetic acid. The phenylosazone was recrystallized from aqueous ethanol to give needles, m.p. 207–209° C (decomp.). The phenylosazone gave absorptions in the infrared (potassium bromide disk) at 3300 cm^{-1} (OH, NH) 3040 cm^{-1} (aromatic CH), 2900 cm^{-1} (aliphatic CH), 1635 cm^{-1} (amide I), 1580 cm^{-1} (amide II), and 1600, 1495, 745, 690 cm^{-1} (phenyl group).

*6-Acetamido-6-deoxy-*D-arabo-*hexulose*

1-Acetamido-1-deoxy-D-mannitol was oxidized by *Acetobacter suboxydans* under conditions described in a previous publication (5) and oxidation was complete after 21 days. The oxidation product was separated by chromatography on a cellulose column using butan-1-ol half-saturated with water as irrigant, and was obtained as a pale yellow syrup, $[\alpha]_D$ −8±2° (*c*, 1.94 in water). The ketose gave one spot on paper chromatography in several different solvent systems and gave a pink color with the orcinol – trichloroacetic acid spray reagent (8), changing to green on prolonged heating. The ketose gave absorptions in the infrared at 3300 cm^{-1} (OH, NH), 1725 cm^{-1} (saturated carbonyl group), 1640 cm^{-1} (amide I), and 1565 cm^{-1} (amide II). The infrared spectrum was obtained by smearing a little of the syrupy ketose on the surface of a potassium bromide disk.

The carbonyl peak at 1725 cm^{-1}, which was very weak, indicated that some of the ketose (ca. 5%) existed in the acyclic form and this was also suggested by the fact that the ketose slowly reduced Fehling's solution at room temperature (4).

*6-Acetamido-6-deoxy-*D-arabo-*hexose Phenylosazone*

The phenylosazone was prepared from the ketose under the same conditions as those used for 6-acetamido-6-deoxy-D-glucose. The phenylosazone was obtained as needles, m.p. 211–215° C (decomp.) and had a mixed melting point with the phenylosazone from 6-acetamido-6-deoxy-D-glucose of 206–209° C (decomp.). The infrared spectra of the two phenylosazones were identical over the range 4000–600 cm^{-1} and the two phenylosazones moved at identical rates on paper chromatograms in several different solvents.

Anal. Calc. for $C_{20}H_{25}O_4N_5$: C, 60.1%; H, 6.3%; N, 17.6%. Found: C, 60.3%; H, 6.9%; N, 17.5%.

*Periodate Oxidation of 6-Acetamido-6-deoxy-*D-*glucose and 6-Acetamido-6-deoxy-*D-arabo-*hexulose*

6-Acetamido-6-deoxy-D-glucose and 6-acetamido-6-deoxy-D-*arabo*-hexulose were each oxidized with an excess of sodium metaperiodate in unbuffered aqueous solution. The oxidation solutions were allowed to stand for 2 hours at room temperature, then tested for formaldehyde using the chromotropic acid method (9). 6-Acetamido-6-deoxy-D-glucose gave no formaldehyde, while 6-acetamido-6-deoxy-D-*arabo*-hexulose gave a strongly positive test for formaldehyde.

HYPERFINE STRUCTURE IN THE ELECTRON SPIN RESONANCE SPECTRUM OF THE DIPHENYLENE RADICAL ANION

C. A. MCDOWELL AND K. F. PAULUS

The electron spin resonance spectra of the positive and negative radical ions of diphenylene were previously studied by McDowell and Rowlands (1). In that work it was mentioned that the observed five-line spectra could not be further resolved into the expected complete spectra of 25 lines. We now wish to report that we have been able to resolve completely the e.s.r. spectrum of the diphenylene radical anion. The radical anion was prepared by reacting the parent hydrocarbon with metallic potassium in purified, degassed, 1,2-dimethoxyethane as a solvent. The solvent had previously been carefully dried by allowing it to stand in contact with excess sodium anthracenide.

The spectra were recorded on a Varian e.s.r. spectrometer with 100 kc/s modulation and using a 12-in. Varian magnet. All the spectra were run at very low concentrations ($\sim 10^{-4}$ molar). The magnetic field calibrations were obtained by measuring the field with a proton resonance magnetometer, a 3-mm probe coil containing glycerol being inserted in the magnet gap. The associated marginal oscillator was frequency-modulated at 20 c/s and the proton resonance signal was displayed on an oscilloscope. A signal generator was loosely coupled and tuned for zero beat on the oscilloscope; the generator frequency and also the kystron frequency were measured with a Hewlett Packard 524/525/540 frequency counter which was standardized periodically against the WWV radio station.

Figure 1 shows the typical e.s.r. spectrum observed for the diphenylene radical anion in dimethoxyethane. The complete spectrum is shown in the upper portion of the figure while the detail of one of the five main bands is shown in the lower portion of the diagram. From the spectra we obtain the coupling constants for the two types of protons in diphenylene (see Fig. 2) to be $a^{H}_{(2)} = 2.76 \pm 0.01$ gauss, and $a^{H}_{(1)}$ to be 0.206 ± 0.008 gauss.

As is well known, the coupling constants for hyperfine splitting, a^{H}_{i}, due to protons are related to the average spin density, ρ_i, on the adjacent carbon atoms by the equation $a^{H}_{i} = Q\rho_i$. Q is a constant, negative in sign, which has been given various values such as

HYPERFINE STRUCTURE IN THE ELECTRON SPIN RESONANCE SPECTRUM OF THE DIPHENYLENE RADICAL ANION

C. A. MCDOWELL AND K. F. PAULUS

The electron spin resonance spectra of the positive and negative radical ions of diphenylene were previously studied by McDowell and Rowlands (1). In that work it was mentioned that the observed five-line spectra could not be further resolved into the expected complete spectra of 25 lines. We now wish to report that we have been able to resolve completely the e.s.r. spectrum of the diphenylene radical anion. The radical anion was prepared by reacting the parent hydrocarbon with metallic potassium in purified, degassed, 1,2-dimethoxyethane as a solvent. The solvent had previously been carefully dried by allowing it to stand in contact with excess sodium anthracenide.

The spectra were recorded on a Varian e.s.r. spectrometer with 100 kc/s modulation and using a 12-in. Varian magnet. All the spectra were run at very low concentrations ($\sim 10^{-4}$ molar). The magnetic field calibrations were obtained by measuring the field with a proton resonance magnetometer, a 3-mm probe coil containing glycerol being inserted in the magnet gap. The associated marginal oscillator was frequency-modulated at 20 c/s and the proton resonance signal was displayed on an oscilloscope. A signal generator was loosely coupled and tuned for zero beat on the oscilloscope; the generator frequency and also the kystron frequency were measured with a Hewlett Packard 524/525/540 frequency counter which was standardized periodically against the WWV radio station.

Figure 1 shows the typical e.s.r. spectrum observed for the diphenylene radical anion in dimethoxyethane. The complete spectrum is shown in the upper portion of the figure while the detail of one of the five main bands is shown in the lower portion of the diagram. From the spectra we obtain the coupling constants for the two types of protons in diphenylene (see Fig. 2) to be $a^{H}_{(2)} = 2.76 \pm 0.01$ gauss, and $a^{H}_{(1)}$ to be 0.206 ± 0.008 gauss.

As is well known, the coupling constants for hyperfine splitting, a^{H}_{i}, due to protons are related to the average spin density, ρ_i, on the adjacent carbon atoms by the equation $a^{H}_{i} = Q\rho_i$. Q is a constant, negative in sign, which has been given various values such as

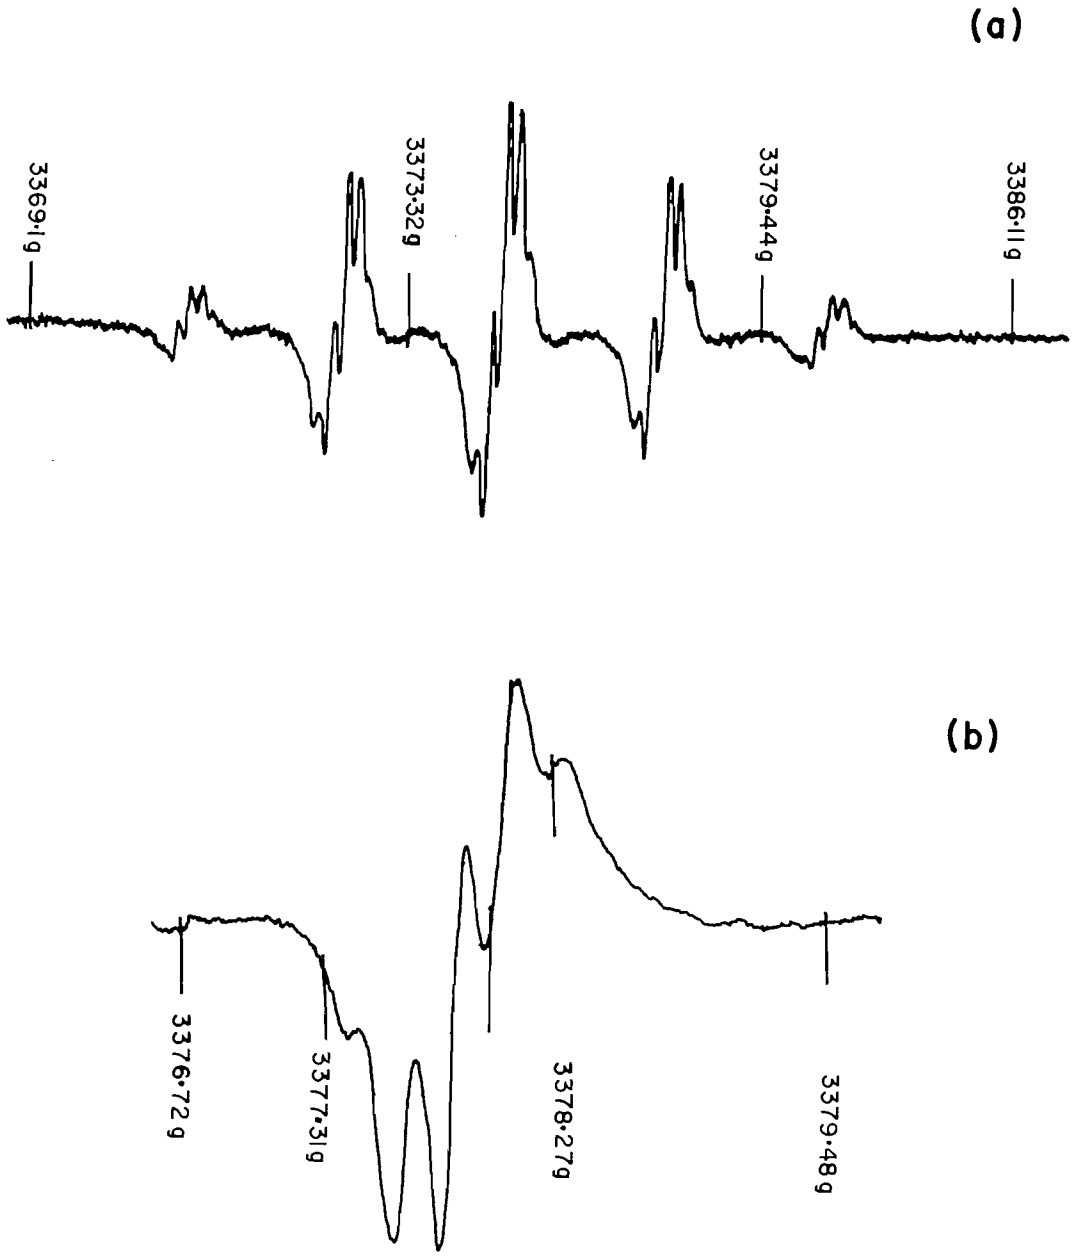

FIG. 1. A typical electron spin resonance spectrum for the diphenylene radical anion in dimethoxyethane; (*a*) complete spectrum, (*b*) one of the main bands shown in greater detail.

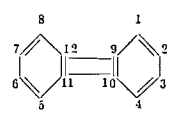

FIG. 2. Numbering system for the diphenylene molecule.

-22.5 gauss for the benzene negative ion (2), -25.67 gauss for the cyclooctatetraenyl radical anion (3), and values of about -30, which are necessary to fit the observed electron spin resonance spectra of polynuclear hydrocarbon radical ions, assuming the electron densities are given by the simple Hückel LCAO approximation (4). McLachlan (5) has analyzed most of the accurate data on these radical ions and concluded that the best value was $Q = -24.2$ gauss. Karplus and Fraenkel (6) have recently used a variation-perturbation method to calculate for the CHC_2 fragment, a value of $Q = -23.72$ gauss. Because of the success of McLachlan's treatment of the e.s.r. spectra of polynuclear hydrocarbon radical ions we shall adopt his value of $Q = -24.2$ gauss. Our experimental values for the hyperfine interaction constants then give the spin densities at carbon atoms 1 and 2 in the diphenylene radical anion to be $\rho_1 = 0.0085$, and $\rho_2 = 0.1140$. It also follows that the spin densities at carbon atoms 9, 10, 11, and 12 are $\rho_9 = \rho_{10} = \rho_{11} = \rho_{12} = 0.1275$. These values may be compared with those predicted by the simple Hückel LCAO approximation as given in Table I of reference 1. There it is shown that the Hückel theory gives $\rho_1 = 0.0269$, $\rho_2 = 0.0873$, and $\rho_9 = 0.1360$. However, altering the Coulombic integral for the four central carbon atoms so that it becomes equal to the normal carbon Coulombic integral *plus one-fifth* the carbon–carbon resonance integral, i.e. we take $\alpha_{C_9} = \alpha_C + 1/5\beta$, we obtain the following results: $\rho_1 = 0.032$, $\rho_2 = 0.0853$, and $\rho_9 = 0.1274$. For this latter set of parameters the calculated values for ρ_1 and ρ_2 do not agree well with the experimental values, but there is remarkably good agreement between the calculated and experimental values for ρ_9.

Because of the high spin density at the two sets of four equivalent carbon atoms C_9, C_{10}, C_{11}, and C_{12}, and also C_2, C_3, C_6, and C_7, and the nature of the spectrum shown in Fig. 1, it seemed that it might be possible to observe the hyperfine splittings due to C^{13}. The magnitude of this C^{13} hyperfine splitting can be calculated from two recent theories of C^{13} hyperfine interactions (6, 7). We choose to follow the more recent theory of Karplus and Fraenkel (6) as it seems to be somewhat more complete and gives good agreement with the known experimental values. The expected hyperfine splitting constants for $a^{C^{13}_{(2)}}$ was calculated to be 2.35 gauss and this would lie beneath the main lines in the spectrum of the diphenylene radical anion. For C_{11}, etc. the value calculated from the Karplus and Fraenkel theory for the case of the diphenylene radical anion depends on the nature of the interactions chosen. If the interaction parameters are chosen to represent C_1, C_9, and C_{10} the value calculated for $a^{C^{13}_{(9)}}$ is 2.64 gauss. If, however, the interaction path is taken to be C_9, C_{10}, C_{12}, C_1, then there results the value of 0.98 gauss for $a^{C^{13}_{(6)}}$. None of these C^{13} hyperfine interactions would be observable for the natural abundance of C^{13} in the diphenylene radical anion.

We wish to thank the National Research Council of Canada for generous grants in aid of this research work.

5-BROMOPENTANOIC ACID AND 2,5-DIBROMOPENTANOIC ACID

N. ISENBERG, J. B. LEIBSOHN, AND V. E. MEROLA

We wish to report a convenient synthesis of 5-bromopentanoic acid and 2,5-dibromopentanoic acid from cyclopentanone. 5-Bromopentanoic acid has been synthesized from diethyl phenoxypropylmalonate (1), from 5-phenoxypentanoic acid (1), and from dihydropyran (2) in reasonable yields. Attempts to convert cyclopentanone to δ-valerolactone with hydrogen peroxide and to obtain 5-bromopentanoic acid from the lactone with hydrobromic acid (3) resulted in a low yield (18%). Using the method of Sager and Duckworth (4) we were able to prepare 5-bromopentanoic acid from cyclopentanone in 49% yield.

5-Bromopentanoic acid was also prepared from pentanediol in 25% yield by converting the diol to the lactone in the presence of copper chromite (5). The crude lactone was then treated with hydrobromic acid.

2,5-Dibromopentanoic acid was prepared from 5-bromopentanoic acid according to the method of Merchant, Wickert, and Marvel (1) in 85% yield.

EXPERIMENTAL

Synthesis from Cyclopentanone

Cyclopentanone (37.5 g) was oxidized with peroxytrifluoroacetic acid (4) to yield 42.8 g of crude δ-valerolactone. The crude material was refluxed with 100 ml of 48% hydrobromic acid for 3 hours and the two layers were separated. The upper aqueous layer was diluted with 200 ml of water and was extracted with several portions of ether. The organic layers were combined and dried over anhydrous sodium sulphate. The ether was removed by distillation and the product was distilled at reduced pressure. 5-Bromopentanoic acid was obtained (39.4 g; 49%).

Synthesis from 1,5-Pentanodiol

1,5-Pentanodiol (52 g) was heated under reflux in the presence of copper chromite to yield 35 g of crude δ-valerolactone. The crude material was refluxed with 100 ml of 48% hydrobromic acid for 3 hours and the product was separated and purified as described before. 5-Bromopentanoic acid was obtained (22.5 g; 25%).

5-Bromopentanoic Acid.—Neutralization equivalent: 181.48; found, 181; melting point: 38°–39° (1); observed, 38°–39°; boiling point: 142°–145° at 13 mm (1); observed, 104°–106° at 1.5 mm.

Synthesis of 2,5-Dibromopentanoic Acid from 5-Bromopentanoic Acid

5-Bromopentanoic acid (10 g) was converted to 2,5-dibromopentanoic acid with bromine and phosphorus tribromide (1). 2,5-Dibromopentanoic acid was obtained (12.2 g; 85%). The overall yield starting with cyclopentanone is 42%.

2,5-Dibromopentanoic Acid.—Neutralization equivalent: 260.40; found, 261; boiling point: 150°–152° at 5 mm (1); observed, 134°–136° at 2 mm; n_D^{25}, 1.5347 (1); observed, 1.5338.

THE HALF-LIFE OF Ca^{41} [1]

J. R. S. DROUIN[2] AND L. YAFFE

Department of Chemistry, McGill University, Montreal, Que.

Received November 22, 1961

ABSTRACT

Ca^{41}, a nuclide decaying by orbital electron capture, has been again identified and its half-life measured. The activity of the source, a highly irradiated sample of calcium carbonate, had decayed for 10 years so that competing activities were non-existent. The measurement was made with a gas-flow proportional counter with well-determined characteristics. A value of $(7.5\pm1.1)\times10^4$ years has been obtained.

INTRODUCTION

The nuclide Ca^{41} has previously been prepared and measured by only one group of workers, viz. Brown, Hanna, and Yaffe (1). Richards, Smith, and Browne (2) had shown by measurements on the threshold of the reaction $K^{41}(p,n)Ca^{41}$ that an energy of only 0.44 ± 0.02 Mev is available for the decay of Ca^{41}. Thus the decay to K^{41} would be by electron capture with the simultaneous emission of potassium X rays.

Brown, Hanna, and Yaffe prepared Ca^{41} by a 15-week irradiation, in a high neutron flux, of calcium depleted 200-fold in the isotope of mass 44. The material was subjected to a rigorous chemical purification and the X rays emitted by the source measured by an argon-filled proportional counter equipped with a thin window.

The identification of the nuclide and the measurement of its half-life were both rendered exceedingly difficult because of the β^--activity due to Ca^{45} (153 days), produced by the reaction $Ca^{44}(n,\gamma)Ca^{45}$, even in this highly depleted source. This caused the production of calcium X rays by ionization of the material in the source. Hence a composite X-ray peak composed of the fluorescent calcium X rays and potassium X rays due to Ca^{41} was superimposed over a background of the same intensity as the composite peak. The use of a potassium 'critical' absorber helped to discriminate against the calcium X rays. The rigid chemical purification, and the fact that the potassium X-ray activity being detected was proportional to neutron flux in several samples, ruled out possibilities other than Ca^{41}.

The half-life determination rested on the resolution of a composite peak and was found to be $(1.1\pm0.3)\times10^5$ years.

We were fortunate in having available a highly irradiated sample of calcium,* the activity of which had decayed for about 10 years, so that the Ca^{45} contribution was now negligible. This communication reports the remeasurement of the half-life of Ca^{41} under more favorable conditions and reaffirms its identity.

**We wish to express our appreciation to Dr. R. H. Betts, Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario, who helped greatly in making this sample available to us.*

EXPERIMENTAL AND RESULTS

(a) Irradiation

A sample of 'spec-pure' calcium carbonate was irradiated in the NRX nuclear reactor at Chalk River for a period of about 10 months, along with a small amount of cobalt wire, which was used as a flux monitor. Measurement of the monitor showed that the sample had been subjected to a total integrated flux of 8.1×10^{20} neutrons cm^{-2}. The activity of the calcium sample was allowed to decay for about 10 years, after which time it showed no activity measurable by highly sensitive β- and γ-counters.

(b) Determination of Calcium Content

The calcium carbonate was purified, evaporated to dryness with nitric acid, and made up to volume with distilled water. The calcium content of the 'master solution' was determined by a method described by Welcher (3) which consisted of an EDTA titration using an indicator made of *o*-cresolphthalein complexes. The EDTA solution was standardized against a standard calcium nitrate solution. The calibration curve is shown in Fig. 1.

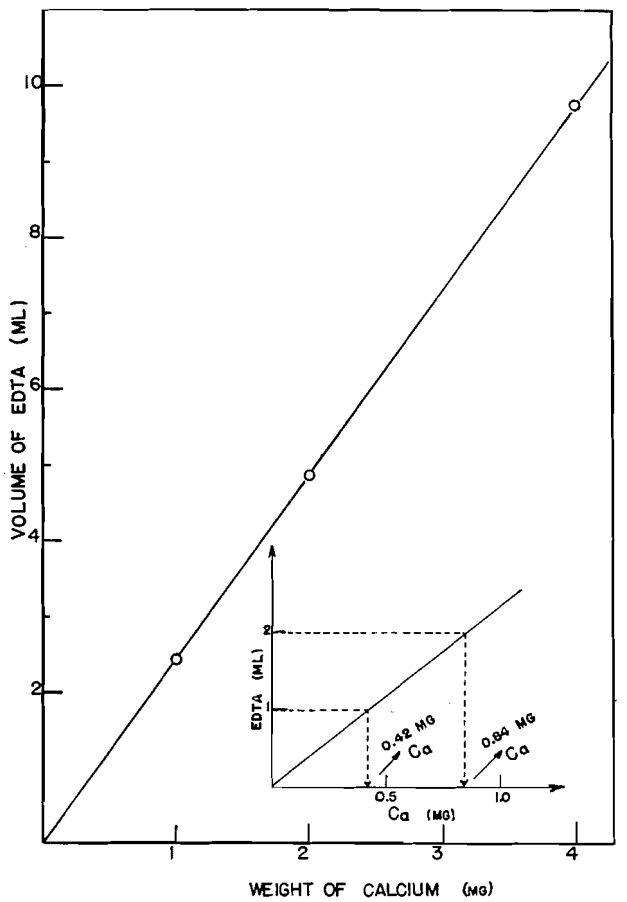

FIG. 1. Analysis of calcium 'master solution'.

Two aliquots, namely 100 and 200 μl, were withdrawn from the solution and analyzed. The results are shown in the bottom of Fig. 1, giving a value of $0.42 \pm .01$ mg of Ca per 100 μl of the solution. A great deal of care was taken with the above analysis, since, in the previous measurement, the determination of the Ca content of the source introduced an error of $\pm 15\%$.

(c) Specific Activity Determination

The disintegration rate of the sample was determined using a gas-flow proportional counter. A sketch of this is shown in Fig. 2. The counter pulses were fed into a cathode follower, amplifier, and pulse height analyzer. A detailed description of the operating characteristics of such a counter has been given previously (4).

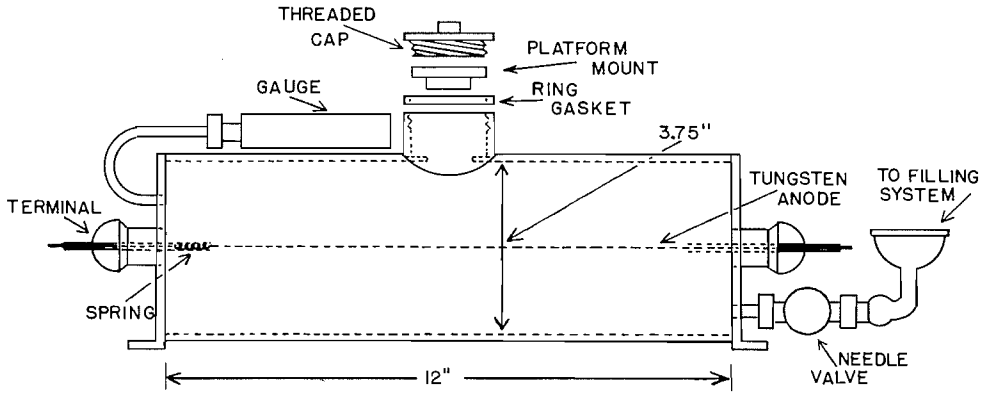

FIG. 2. Gas-flow proportional counter.

The sample was mounted internally in the counter on a platform. The source mount, prior to the evaporation of the sample, was treated with a 5% insulin solution which was removed as completely as possible. A sample of 100 μl was deposited on an area of 1 cm^2. During the process of evaporation the mounted source was continually rocked in order to keep all parts of the area, originally covered, wet until the last possible moment. When the sample was completely dry, it was covered with an aluminum absorber thick enough (0.8 μ) to absorb all the Auger electrons emanating from the source (5).

The source was placed in the counter, and characteristic K X rays of potassium were identified as shown in Fig. 3. The characteristic K X rays from Cr^{51}, Fe^{55}, and Zn^{65} were used to calibrate the energy response of the counter as shown in this figure and verify that the measured activity corresponded to potassium K X rays.

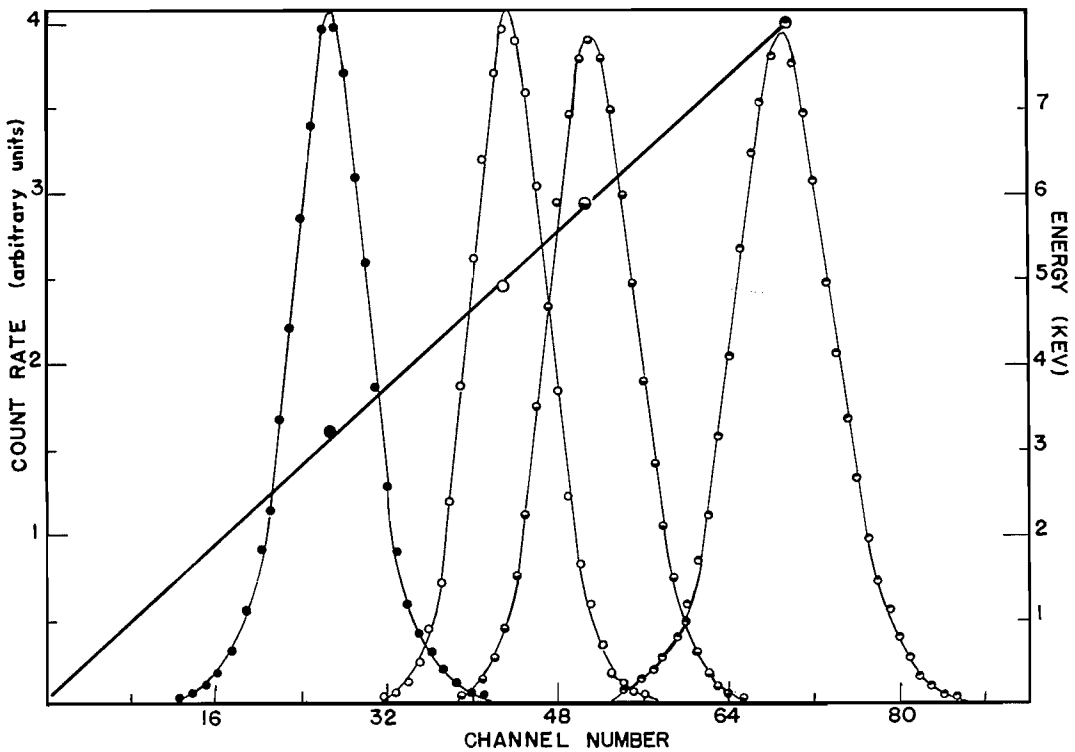

FIG. 3. Energy calibration of the counter: ● Ca^{41}, ○ Cr^{51}, ◒ Fe^{55}, ◓ Zn^{65}.

In Fig. 4 is shown the photopeak due to the potassium K X rays from which the half-life measurement data were taken. The background during this measurement was slightly less than 1 count per minute per channel

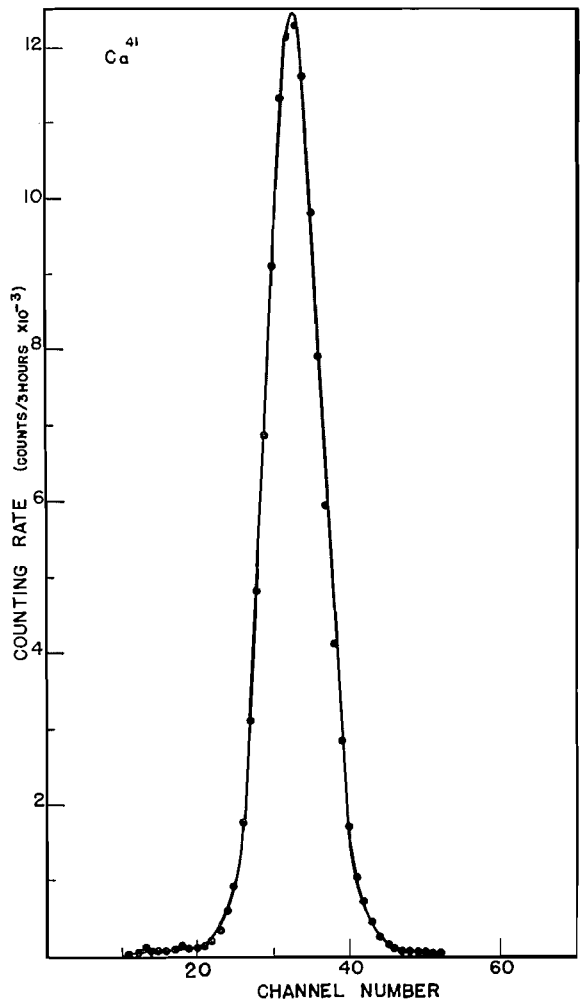

FIG. 4. Photopeak due to Ca^{41}.

and of course no calcium fluorescent X rays were detectable. The instrumental arrangement enabled the background to be subtracted automatically.

When the counter was operated at pressures of 1 and 2 atm, the counting rates were reproducible within the standard deviation, showing that the X rays were completely absorbed in the counter.

To change the measured counting rate into a disintegration rate, the following corrections had to be employed:

(i) Self-absorption: This factor is exceedingly important for such low-energy X rays (3.2 Kev). This was determined experimentally in the following way. The source was diluted with known amounts of inactive calcium nitrate and the counting rate measured. The area of the source was kept constant. The results are shown in Fig. 5. From this the decrease in count rate due to self-absorption was determined to be 14% for the sample used.

(ii) Transmission of the characteristic X rays by the Auger electron absorber: The transmission of the potassium K X rays was obtained by inserting into an equation derived by Campion and Merritt (6) the proper mass absorption coefficient and thickness for the aluminum absorber (7). The above equation is applicable in the present case, i.e. an uncollimated beam of radiation. The Auger electron absorber was found to transmit 67% of the potassium K X rays.

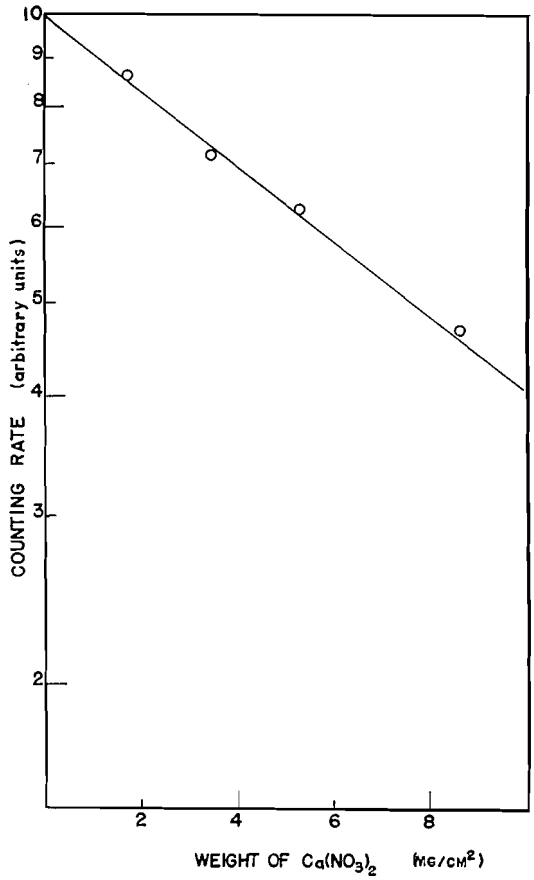

FIG. 5. Self-absorption of potassium K X rays in calcium nitrate.

(iii) Fluorescence yield: The K-fluorescence yield of potassium, W_k, has been semiempirically calculated by Hagedoorn and Wapstra (8) to be 0.120, and this value has been used. Brown *et al.* used an interpolated value of 0.13 ± 0.01, which agrees very well with the recent work quoted above.

(iv) L-capture contributions: From the theoretical results of Brysk and Rose (9), the L/K capture (including L_{II}- and L_{III}-capture contributions) was evaluated as 0.089.

(v) Geometrical efficiency of the counter: The geometrical efficiency of the counter has previously (4) been determined to be 50%.

From Fig. 4, the number of potassium K X rays beneath the peak was manually integrated and found to be 594 ± 6 counts min^{-1} for 0.42 mg Ca.

From the irradiation data and the cross section, one obtained the number of Ca^{41} atoms, N_{41}, formed by irradiating a known number of Ca^{40} atoms, N_{40}, as follows:

$$N_{41} = N_{40}\sigma(nv)t,$$

where nv = integrated neutron flux = 8.07×10^{20} neutrons cm^{-2}, σ = cross section = 0.22 barns (10). Therefore, in 1 mg of naturally occurring Ca (97% Ca^{40}), there were produced

$$N_{41} = \frac{6.02\times10^{20}}{40}\times0.97\times0.22\times10^{-24}\times8.07\times10^{20} = 2.59\times10^{15} \text{ atoms.}$$

The disintegration rate, obtained by applying the corrections discussed above, is

$$594\times\frac{1}{0.86}\times\frac{1}{0.67}\times\frac{1}{.12}\times1.089\times2$$

$$= 1.87\times10^{4} \text{ disintegrations } min^{-1} \text{ for 0.42 mg Ca}$$
$$= 4.45\times10^{4} \text{ disintegrations } min^{-1} mg^{-1} \text{ Ca.}$$

The disintegration rate = $N_{41}\lambda$, where

$$\lambda = \frac{0.693}{\text{half-life}}.$$

Therefore

$$\text{half-life} = \frac{2.59\times10^{15}\times0.693}{4.45\times10^{4}\times365\times1440}$$

$$= 76{,}700 \text{ years.}$$

The errors involved in the actual measurement itself are small (~1%). Other errors in the absorption corrections, flux determination, etc., impose limits of ±15% on the measurement, yielding a final value of $(7.7\pm1.1)\times10^{4}$ years.

This agrees remarkably well, within the errors quoted, with the value of Brown, Hanna, and Yaffe. The latter calculated theoretically the half-life one would predict assuming that this is an α-type first-order forbidden transition. This is possible since the ft values of β-emitters of this type are closely grouped. Their results gave an upper limit of 6×10^{4} years, just outside the experimental limits of error. Our value brings this half-life into closer agreement with the prediction.

CONDUCTANCES OF AQUEOUS SOLUTIONS OF SODIUM OCTANOATE AT 25° AND 35° AND THE LIMITING CONDUCTANCE OF THE OCTANOATE ION

A. N. CAMPBELL, E. M. KARTZMARK, AND G. R. LAKSHMINARAYANAN
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received January 3, 1962

ABSTRACT

Equivalent conductances, densities, and viscosities of aqueous solutions of sodium octanoate have been determined at 25° and 35° C, at concentrations ranging from 0.0002 *M* to 2.8 *M*. The limiting equivalent conductances of the octanoate ion have been determined as 23.08 mhos and 29.09 mhos, at 25° and 35° C respectively.

Comparison has been made of our experimental conductances with those calculated, using the equations of Robinson–Stokes, of Falkenhagen–Leist, and of Fuoss.

No evidence has been found of micelle formation in solutions of sodium octanoate.

The work here described on the conductance of sodium octanoate is part of our general project of measuring the electrical conductance of sodium salts of higher fatty acids over a wide range of concentration. It might be supposed a progressive increase of anion size would eventually lead to an anion so large that it would be virtually motionless and non-conducting but it is known that, after a certain number of carbon atoms in the chain is reached, micelle formation occurs and it is known that micelles are conducting. Why this should be so is not immediately obvious, since though the charge is increased the mass is increased in the same ratio, but presumably some alignment occurs after the manner of liquid crystals, so that the resistance to movement is reduced.

We continue to endeavor to fit the conductance equations of Wishaw–Stokes (1) and Falkenhagen–Leist (2) to our experimental results, although we now admit that these equations must be considered to be empirical in the concentrated range. We have also used Fuoss' latest equation (3) for the same purpose.

EXPERIMENTAL PROCEDURE

n-Octanoic acid, otherwise known as caprylic acid, obtained from the Eastman Kodak Company, was redistilled. The acid was neutralized with the equivalent quantity of sodium hydroxide, dissolved in alcohol, and the solution concentrated by slow evaporation. A mixture of acetone and alcohol, in the ratio of 2 to 1, was added to the concentrated solution, when the sodium salt was thrown out of solution. The filtered salt was dried in a vacuum oven, ground, and stored over barium oxide.

The salt was analyzed by conversion to sodium sulphate, a method given in Stock, Staehler, Patnode, and Dennis (4). The method, the only one available, is somewhat crude. Four analyses gave the purity as 99.5%. The presence of alkali, as an impurity, would give a high, not a low, result. Direct pH measurements on the aqueous solution of the salt gave a value in good agreement with that calculated for the hydrolysis of sodium octanoate.

Conductance water, having a specific conductance at 25° C of $2\text{–}3\times10^{-7}$ mhos, was obtained by bubbling nitrogen through distilled water. We have found this method to be more satisfactory than more complicated methods. The more concentrated solutions were prepared by direct weighing of salt and solution, the very dilute solutions by the technique of Shedlovsky (5), using a duplicate of his large silica conductance cell. In calculating the constant of this cell we used the equation of Fuoss (6) for the equivalent conductance of potassium chloride solutions of varying concentration, at 25° C.

The methods of measuring viscosity and density require no description. The method of Campbell and Bock (7) was used to correct the equivalent conductance for the effect of hydrolysis. The ionization constant of octanoic acid was obtained from the data given by Dippy (8).

EXPERIMENTAL RESULTS

The experimental results are given in Tables I and II.

*The viscosities corresponding to the first six low concentrations were not determined experimentally: they were obtained by linear interpolation.

DISCUSSION OF RESULTS

The overall error in the equivalent conductance measurements amounts to 0.1%. The first six measurements in the dilute region were used to calculate the limiting conductance. The methods of Kohlrausch, of Shedlovsky (5), and of Fuoss (3) were used.

The value of Λ_0 obtained by the three methods, at 25° and at 35°, are as follows:

	Λ_0 at 25° (mhos)	Λ_0 at 35° (mhos)
Kohlrausch	73.18	90.63
Shedlovsky	73.30	90.90
Fuoss	73.34	90.92

Using the Kohlrausch values for Λ_0 and the values 50.10 mhos at 25° and 61.54 mhos at 35° for the ionic conductance of the sodium ion (9), the ionic conductances of octanoate ion at 25° and 35° respectively result as 23.08 mhos and 29.09 mhos.

The Arrhenius equation applied to the conductance figures at the two temperatures, and to the corresponding viscosities (fluidities), for the same concentrations and temperatures, yielded the figures of Table III, for the activation energies of conductance and of viscosity, respectively.

TABLE III

Activation energy of conductance and viscosity between 25° C and 35° C

Concentration (mole/liter)	Activation energy of conductance (kcal/mole)	Activation energy of fluidity (kcal/mole)
0.0	3.897	3.880
0.25	4.103	4.027
0.50	4.110	4.080
1.00	4.116	4.016
1.50	4.228	4.162
2.00	4.439	4.339
2.50	4.721	6.080

As usual, the figures of activation energies of conductance and of viscosity are very similar, suggesting a fundamental resemblance between the mechanisms of the two processes in aqueous solution. The sudden increase in the energy of viscosity at the highest concentration indicates a change in the nature of the flow, perhaps on approach to micelle formation. In anhydrous melts, the activation energies of conductance and of viscosity are generally far from equal.

It is well known that Walden's rule does not apply to different concentrations of the same electrolyte in the same solvent but it is always interesting to work out the values of Λ_η and to plot these values against concentration in the form of $\sqrt{c}$. This has been done in Fig. 1.

As usual, we applied the Robinson–Stokes and the Falkenhagen–Leist equations to our work. To these we have now added the Fuoss equation. The method of using this latest equation is detailed in Chap. XV of "Electrolytic Conductance" by Fuoss and Accascina (10).

As with sodium hexanoate (11), we found that the agreement with the equations of Robinson–Stokes and Falkenhagen–Leist was not good. We therefore reproduce here only the calculations for dilute solution (Tables IV and V). Although the experimental values agree in general within 0.65 mhos in the case of the Robinson–Stokes and Falkenhagen–Leist equations up to a concentration of nearly 0.1 M at 25° C and 0.075 M at

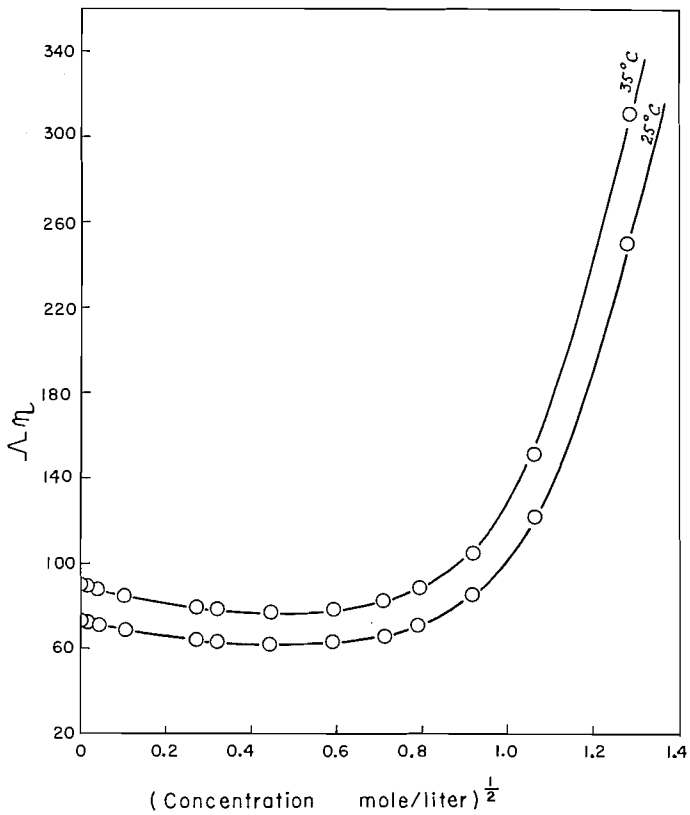

FIG. 1. $\Lambda\eta$ vs. $\sqrt{c}$.

0.1970	67.63	64.90	67.02	63.93	65.26	—
0.3472	60.91	55.93	58.28	55.14	56.23	—

of concentration. It is claimed that the Fuoss equation can reproduce the experimental results as long as $K\mathring{a} < 0.2$; because of the high $\mathring{a}$ value (7–8 Å) this corresponds to a concentration not greater than 0.01 *M*.

Admitting that the equations of Robinson–Stokes and Falkenhagen–Leist are to some extent empirical, it is still surprising that, for example, in the case of lithium chlorate (12), the agreement between calculated and observed results is so good. Perhaps the "distance of closest approach" cannot be expressed in terms of a single parameter when dealing with a long-chain ion.

It has been stated by Smith and Robinson (13) that micelle formation occurs in solutions of sodium octanoate but, judging by the behavior of the conductance and viscosity curves, we think it unlikely. Certainly, micelle formation must set in when a certain number of carbon atoms in the ion has been attained but we think this number is greater than eight. To investigate this point we determined the apparent molecular weight at different concentrations by the vacuum flask freezing point depression techniques. In this method finely shaved ice and a solution of sodium octanoate are thoroughly stirred until equilibrium is established. The temperature is noted and an analysis then made by evaporation of water from a sample. The results are contained in Table VI. They show no evidence of enhanced molecular weight.

TABLE VI

Concentration (g of salt/100 g H_2O)	Apparent molecular weight
2.464	100.4
5.496	96.5
7.553	93.1
10.575	88.7

Work is continuing on the acid containing 10 carbon atoms.

THE HETEROGENEOUS AND HOMOGENEOUS THERMAL DECOMPOSITIONS OF NICKEL CARBONYL[1]

R. K. CHAN[2] AND R. MCINTOSH[3]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received January 5, 1962

ABSTRACT

The homogeneous thermal decomposition of $Ni(CO)_4$ between 35° C and 80° C and over a pressure range of 15 mm to 80 mm of Hg has been distinguished from the heterogeneous reaction occurring on the freshly deposited nickel surface. The activation energy of the homogeneous reaction was found to be 19.1 kcal $mole^{-1}$ and of the heterogeneous reaction, 14.3 kcal $mole^{-1}$. The activated complex for the heterogeneous reaction is $Ni(CO)_4$, which is physically adsorbed. The heat of adsorption of $Ni(CO)_4$ is 7.4 kcal $mole^{-1}$. Carbon monoxide is also adsorbed upon the same sites with a heat of adsorption of 13.3 kcal $mole^{-1}$, which is much greater than its latent heat of vaporization. The homogeneous reaction may be inhibited by a surface of sodium chloride. Nickel deposited upon rutile behaves in the same way catalytically as nickel deposited upon glass wool.

INTRODUCTION

The thermal decomposition of $Ni(CO)_4$ was first reported by Mittasch (1). Mechanisms have been suggested for the homogeneous reaction by Bawn (2) and Garrat and Thompson (3). Bawn noted that the reaction was partially heterogeneous, about 20% of the decomposition occurring by a heterogeneous mechanism under some conditions. Tonosaki and Suginuma (4), on the other hand, concluded that the reaction was completely heterogeneous. As the heterogeneous reaction would be similar to those reported by Taylor and his associates in the studies of the decomposition of germane, arsine, and stibine (5), in the sense that reaction occurs upon a freshly deposited, and hence clean, metallic surface, an attempt has been made to examine the reaction more fully, and to pay particular attention to the heterogeneous reaction. The heterogeneous part of the reaction was exaggerated by packing the vessel with glass wool (up to the amount of 1 g). This procedure sufficed to permit the separation of the composite reaction into its two parts. The homogeneous part was found to obey the mechanism proposed by Bawn (2) and by Garrat and Thompson (3). The heterogeneous part was explicable if the rate was assumed proportional to adsorbed $Ni(CO)_4$, which competes for adsorption sites with CO. The $Ni(CO)_4$ is physically adsorbed, while the CO has a sufficiently high heat of adsorption to suggest chemisorption.

Additional experiments were performed with finely divided rutile suspended in glass wool, and with finely divided sodium chloride. The latter substance could not be effectively dispersed throughout the glass wool. These experiments showed two things: first, the rate of the heterogeneous reaction is not dependent upon the substrate upon which the nickel layer forms; second, a salt surface of appreciable area will reduce the initial composite rate very substantially below the rate for the homogeneous reaction. This is explained by assuming that the intermediate $Ni(CO)_3$ is adsorbed and recombination with CO occurs on the ionic surface. Further study of the influence of polar and non-polar surfaces is thus warranted.

EXPERIMENTAL

The experimental assembly was conventional except for the pressure gauge (see Fig. 1). As Mittasch (1) had shown that the presence of Hg accelerated the reaction, and as this was confirmed in preliminary experiments, a metal bellows gauge was constructed which had a sensitivity of 0.15 mm of Hg per mm

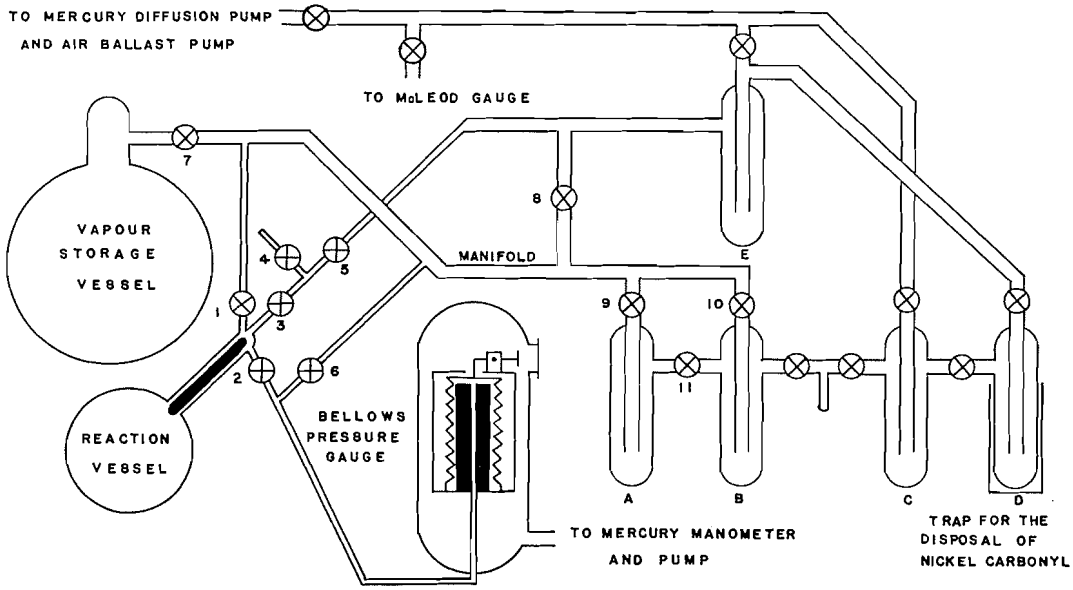

FIG. 1. Apparatus for decomposing nickel carbonyl: A and B, traps for vacuum distillation; C and B, liquid air traps.

deflection. The temperature range studied was 35° C to 80° C, and the pressure range about 15 mm to 80 mm. The $Ni(CO_4)$ was obtained from the City Chemical Corporation of New York. It was freed of dissolved air by trap-to-trap distillation and by vigorous pumping of the frozen material. Dry ice was used as the refrigerant as Mittasch and Kuss (6) have reported violent explosions when liquid air was used as the coolant.

The reaction vessel was pumped at 100° C for, at least, 5 hours before use. Several decompositions had to be carried out before the reaction rate became reproducible. The rate was then reproducible for many runs until the thickness of the deposited nickel was estimated to be 5000 layers of nickel. Thereafter the rate began to accelerate and the nickel was no longer deposited as a coherent metallic film but as an apparently fine powder. The reaction vessel was then cleaned and the surface again conditioned for further experiments.

The glass fibers used to increase the surface were obtained from the Corning Glass Works, Corning, New York. The average diameter of the fibers was reported as $8.6\pm0.7\times10^{-4}$ cm on the basis of an examination of 24 fibers (7). The surface area per gram was thus taken to be 0.2 m^2. The estimated area of the quartz reaction vessel was 200 cm^2. (Quartz was employed because the removal of nickel films by washing with dilute nitric acid brought about changes of the rate of reaction in a clean vessel.)

Rutile powder having a specific surface of 80 m^2/g was also used, dispersed in a known amount of glass wool. Only amounts below about 15 mg could be suspended in the glass wool. Similarly, sodium chloride of specific surface up to 90 m^2/g was employed. The preparation of the sodium chloride has been described in earlier publications (8–10).

PROCEDURES FOR EVALUATING THE RATE OF DECOMPOSITION AT $t = 0$

As the time of admission of the $Ni(CO)_4$ to the reaction vessel is finite, and because some oscillation of the gauge was observed initially, care was exercised in the evaluation of the initial composite rate. Three procedures were tested and compared. These were:

(*a*) A plot of x/t versus $1/t \ln p/(p-x)$ was made arising from the equation

$$\frac{x}{t} = \frac{1+pb_c}{b_c}\frac{1}{t}\ln\frac{p}{p-x} - \frac{k_c}{b_c},$$

which is the integrated form of the assumed rate equation

$$\frac{dx}{dt} = \frac{k_c(p-x)}{1+b_c x}.$$

This method is sensitive to the value of the gauge reading at zero time.

(*b*) A cubic equation of the form $x = \alpha_0+\alpha_1 t+\alpha_2 t^2+\alpha_3 t^3$ was fitted to the experimental data. The coefficient α_1 gives the initial composite rate. α_0 gives the value of the gauge reading at zero time required in (*a*) above.

(*c*) A solution of the equation $1/t = (\alpha/x)-\beta$ for α,β was made on the basis of the finding that an expression of the form $x = (\alpha t)/(1+\beta t)$ fitted the experimental data quite well.

These three procedures were made into a program suitable for the I.B.M. 650 computer. The results were within $\pm 2\%$ for the three methods of expressing the data.

The uncertainty caused by an error in selecting zero time was also examined. The timer was normally started at a value of -2 seconds as the $Ni(CO)_4$ was admitted to the vessel, since Bawn (2) had established that this was a reasonable time for the admission and warming of the gas to be completed. The value of zero time was then arbitrarily shifted between -2 seconds and $+2$ seconds and several values of the initial rate of decomposition were re-evaluated. The error introduced was always less than $\pm 5\%$, depending upon the temperature and initial pressure. The choice of the origin for the time axis was, therefore, relatively unimportant because the pressure increase in the first few seconds was almost linear with time.

EVALUATION OF THE CONSTANTS OF THE RATE EQUATIONS OF THE HOMOGENEOUS AND HETEROGENEOUS REACTIONS

The rate of the homogeneous reaction was assumed to obey the equation given by Garratt and Thompson (3), namely:

$$\left(\frac{dx}{dt}\right)_{\text{homo}} = \frac{K_1(p-x)}{1+4(K_3/K_2)x} = \frac{k_2(p-x)}{1+b_2 x},$$

where p is the initial pressure of $Ni(CO)_4$, the amount decomposed at time t is x (in units of pressure), and K_1, K_2, K_3 are the respective specific rate constants of the reactions

$$Ni(CO)_4 \xrightarrow{K_1} Ni(CO)_3 + CO,$$

$$Ni(CO)_3 \xrightarrow{K_2} Ni + 3CO,$$

$$Ni(CO)_3 + CO \xrightarrow{K_3} Ni(CO)_4.$$

The rate of the heterogeneous reaction was assumed to be given by

$$\left(\frac{dx}{dt}\right)_{\text{heter}} = \frac{k_1 A b(p-x)}{1+b(p-x)+b_1 x},$$

based upon the view that the rate depends upon the surface area and the fraction of the surface covered by reactant molecules. It is implicit also in the expression that CO competes with $Ni(CO)_4$ for adsorption sites. The constant $b_1/4$ is the Langmuir constant for adsorption of CO and the constant b that for $Ni(CO)_4$.

The observed composite rate was then assumed to be formed according to the relation

$$\left(\frac{dx}{dt}\right)_{\text{comp}} = \left(\frac{dx}{dt}\right)_{\text{homo}} + \left(\frac{dx}{dt}\right)_{\text{heter}} = \frac{k_2(p-x)}{1+b_2 x} + \frac{k_1 A b(p-x)}{1+b(p-x)+b_1 x}.$$

Moreover, the composite rate was found, by observation, to be suitable for representation in the form

$$\left(\frac{dx}{dt}\right)_{\text{comp}} = \frac{k_c(p-x)}{1+b_c x}.$$

At $t = 0$

$$\left(\frac{dx}{dt}\right)_{\substack{\text{comp}\\ t=0}} = k_c p = \frac{k_1 A b p}{1+bp} + k_2 p.$$

A plot of initial composite rate versus surface area for fixed temperature and initial pressure should yield $(k_1 bp)/(1+bp)$ from its slope and $k_2 p$ from its intercept (see Fig. 2).

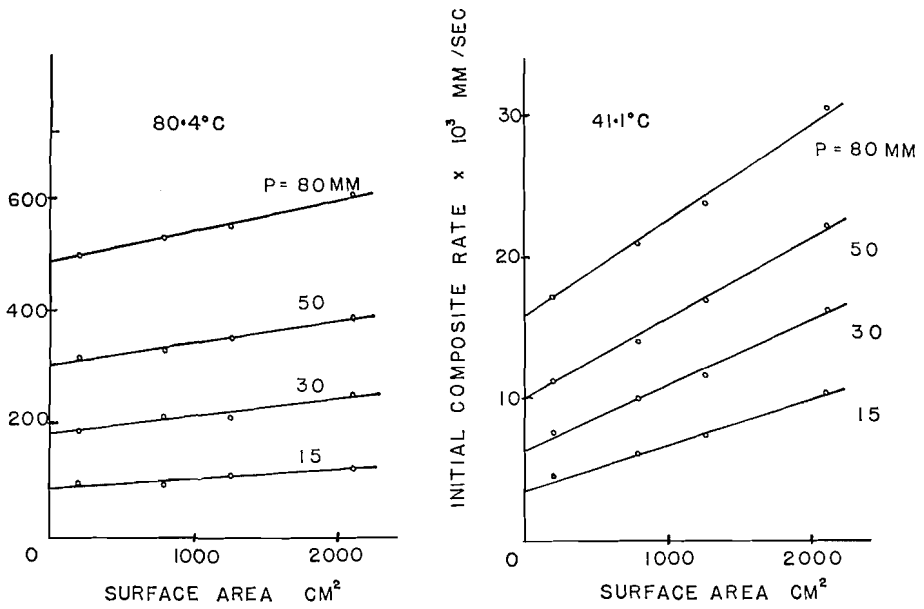

FIG. 2. Initial composite rate versus surface area.

Intercepts of similar plots for a given temperature but different initial pressures give the initial homogeneous rates from which k_2 may be obtained.

The heterogeneous rate constant k_1 and b may be solved in the following way:

$$k_c p - k_2 p = \frac{k_1 A b p}{1+bp} = \left(\frac{dx}{dt}\right)_{\substack{\text{heter}\\ t=0}}$$

and

$$1 \Big/ \left(\frac{dx}{dt}\right)_{\substack{\text{heter}\\ t=0}} = \frac{1}{k_1 A b}\frac{1}{p} + \frac{1}{k_1 A}.$$

Thus, from the appropriate plot, $k_1 A$ and $k_1 A b$ are obtained, and so a value of b, since A is known. Thus far, k_1, k_2, and b are known. The remaining constants, b_1 and $4K_3/K_2 = b_2$, are obtained in the following way. Since the observed composite rate equation is to

be accounted for on the assumption of the homogeneous and heterogeneous equations for all values of x and t, it can be shown that

$$k_c = \frac{k_1 A b}{1+bp} + k_2$$

and

$$b_1 = b_c(1+bp)+b$$
$$b_2 = b_c.$$

Because $b_1/4$ and b are constants in Langmuir's adsorption isotherm, they are expected to be constant for a given temperature. In order to fulfill this requirement b_c must increase as p decreases. Experiment confirms this prediction. However, it is not clear why b_2 should also increase with decreasing p, and this question will be discussed later.

Thus all five constants can be evaluated for a given temperature, provided A is known.

CHARACTERISTICS OF THE HOMOGENEOUS REACTION

On the basis of the mechanism outlined above, and first given by Garratt and Thompson (3), it follows that the homogeneous reaction at zero time should be first order in the pressure of $Ni(CO)_4$. This is adequately demonstrated in Fig. 3 for the entire range of

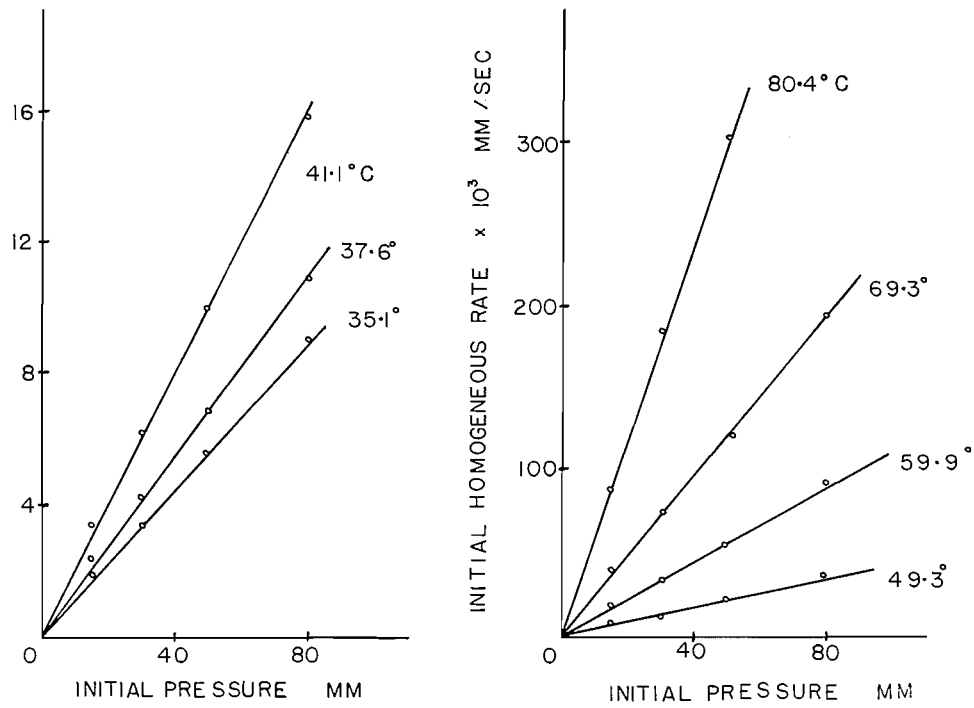

FIG. 3. Initial homogeneous rate versus initial pressure.

temperature. The initial homogeneous rate and the specific rate constant k_2 are given in Table I. From the variation of k_2 with temperature, plotted in the usual way in Fig. 4, the activation energy of this primary step was determined to be 19.1 kcal mole^{-1}. The

TABLE I

Initial homogeneous rate and homogeneous rate constant

	Temp. (°C)	Initial pressure of $Ni(CO)_4$ (mm Hg) 15	30	50	80
$k_2p\times10^3$	35.1	1.8	3.4	5.5	9.1

NOTE: k_2p in mm/sec and k_2 in sec^{-1}.

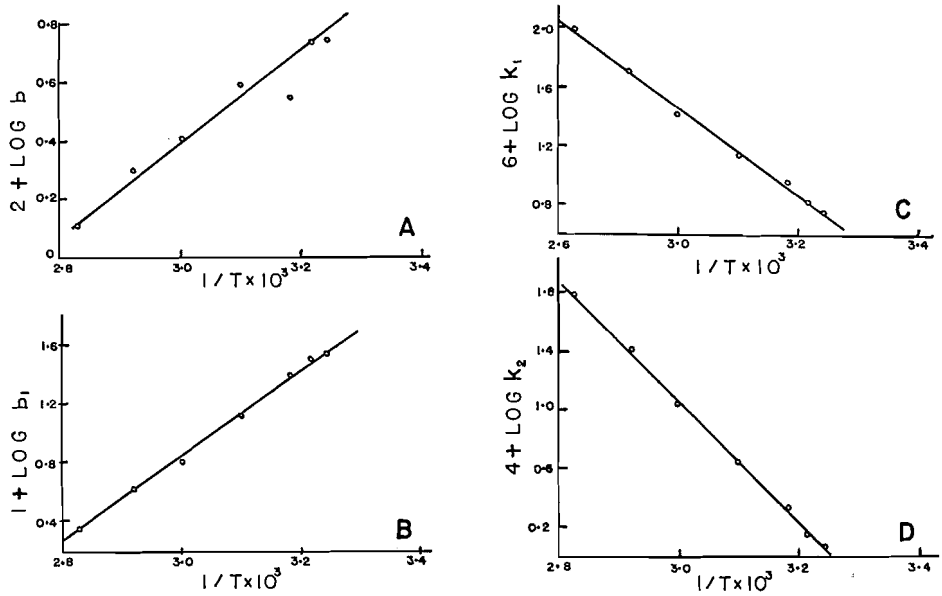

FIG. 4. (A) Heat of adsorption of $Ni(CO)_4$ = 7.4 kcal $mole^{-1}$; (B) heat of adsorption of CO = 13.3 kcal $mole^{-1}$; (C) activation energy of heterogeneous reaction = 14.3 kcal $mole^{-1}$; (D) activation energy of homogeneous reaction = 19.1 kcal $mole^{-1}$.

activation energy determined by Garratt and Thompson (3) was 12 kcal $mole^{-1}$, and by Bawn 10.3 kcal $mole^{-1}$ (2) for temperatures in the neighborhood of 100° C and on the assumption that the reaction is essentially homogeneous at this and higher temperatures. (This assumption is supported by our observations.) Tonosaki and Suginuma (4) give a value of 18.7 kcal $mole^{-1}$. They employed a rate expression identical with Bawn's and also with Garratt's and Thompson's, although the reaction was considered to be entirely heterogeneous. Their value cannot be compared directly with the values obtained

in this work for the individual reactions, but a comparison was made for the activation energy of the composite reaction in an unpacked vessel at 50 mm pressure. The apparent activation energy for this set of conditions was 18.9 kcal mole^{-1}. This is practically indistinguishable from the value given by Tonosaki and Suginuma, but considerably higher than those reported by the other authors.

CHARACTERISTICS OF THE HETEROGENEOUS REACTION

Since the initial heterogeneous rate is proportional to the surface area, its value per unit surface should be the same for all amounts of glass wool. Somewhat serious errors occur for the empty vessel because of the small contribution of the heterogeneous reaction. Thus, in Fig. 5, only the data involving glass wool are plotted.

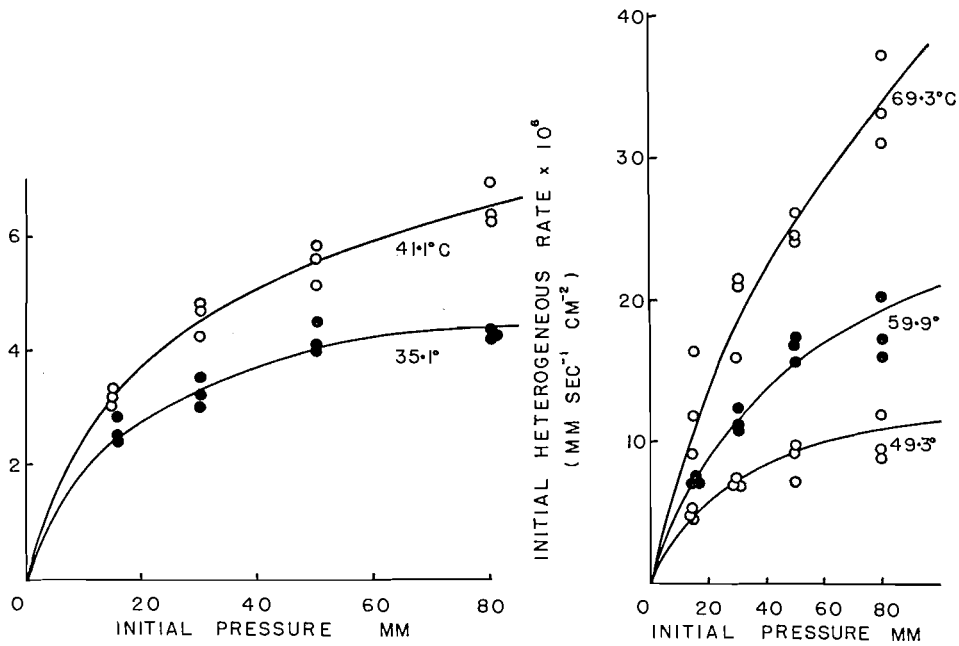

FIG. 5. Initial heterogeneous rate per unit surface area versus initial pressure.

The two constants k_1 and b were evaluated from these data and are given in Table II. Included are values given by employment of the equation $b = 3.52\times10^{-7} \exp(7400/RT)$.

TABLE II

Heterogeneous rate constant and Langmuir's adsorption isotherm constants for $Ni(CO)_4$ and CO

Temperature (°C)	$k_1\times10^6$ (mm sec^{-1}cm^{-2})	$b\times10^2$ (mm^{-1})	b (calc)$\times10^2$ (mm^{-1})	b_1 (mm^{-1})
35.1	5.52	5.51	6.28	3.44
37.6	6.41	5.38	5.70	3.11

49.3	13.6	3.91	3.72	1.32
59.9	26.3	2.57	2.57	0.646
69.3	51.3	2.00	1.91	0.414
80.4	100	1.28	1.35	0.226

(This equation was utilized to provide values of b required to obtain b_1.) From the variations of these constants with temperature the activation energy of the heterogeneous reaction, E_{heter}, and the heat of adsorption of $Ni(CO)_4$ upon the fresh nickel surface were obtained (see Fig. 4). E_{heter} is 14.3 kcal mole^{-1} and $Q_{Ni(CO)_4}$ is 7.4 kcal mole^{-1}. The latter figure may be compared with the reported value of 6.5 kcal mole^{-1} given by Dewar and Jones for the latent heat of vaporization of $Ni(CO)_4$ (11). The agreement is sufficiently close to warrant the conclusion that the $Ni(CO)_4$ is physically adsorbed upon the nickel films. This view is also consistent with the entropy of the activated complex, which is recorded in a later section.

It has been assumed in the equation describing the course of the heterogeneous reaction that carbon monoxide is also adsorbed upon the nickel film and uses up sites which would otherwise be available for the adsorption of $Ni(CO)_4$. The Langmuir constant for the adsorption of carbon monoxide is $b_1/4$, and its variation with temperature provides a value of the heat of adsorption. These data are also recorded in Fig. 4 and Table II, from which a value of Q_{CO} = 13.3 kcal mole^{-1} is obtained. This value is so greatly in excess of the latent heat of vaporization, 1.44 kcal mole^{-1}, at its normal boiling point (12), that the CO is chemisorbed upon the nickel. Tonosaki and Suginuma (4) were also of the view that CO is strongly adsorbed compared with $Ni(CO)_4$.

If b_1 has the significance attributed to it, b_c must, according to the equation $b_1 = b_c(1+bp)+b$, increase with diminishing pressure. The trend is illustrated in Fig. 6.

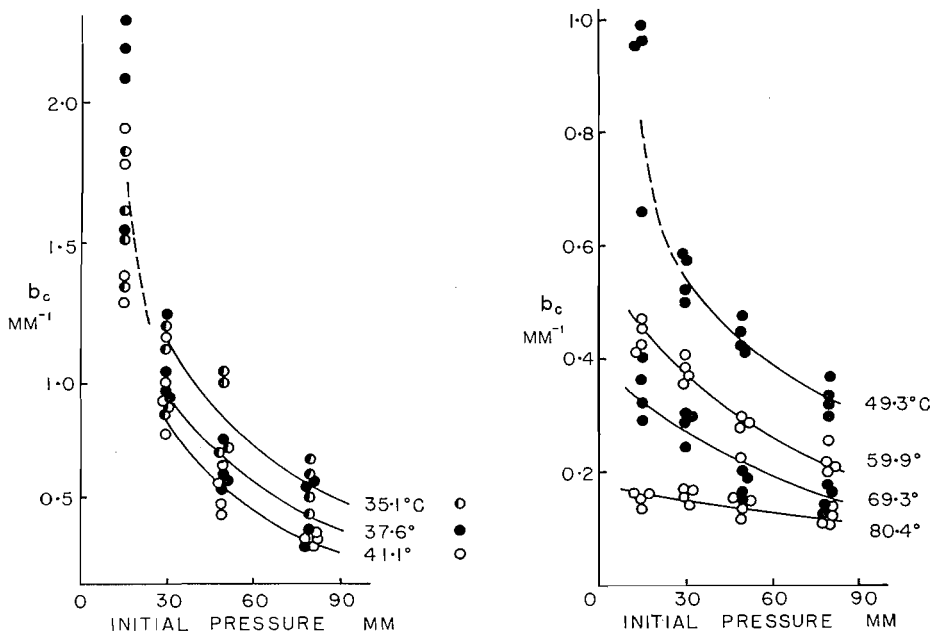

FIG. 6. Variation of b_c with pressure of $Ni(CO)_4$ at different temperatures.

THE VARIATION OF b_2 WITH PRESSURE

On the basis of the equations resulting from the assumed mechanisms, it has been shown that $b_2 = b_c$, and that b_c increases with diminishing pressure of $Ni(CO)_4$. This finding presents difficulties which require discussion. In the first place, if b_c is a function

of pressure of $Ni(CO)_4$, then it should not be possible to represent the course of a reaction by means of the equation

$$\left(\frac{dx}{dt}\right)_{comp} = \frac{k_c(p-x)}{1+b_c x}.$$

In the second place, b_2 is $4K_3/K_2$, and there is no obvious reason why this ratio should vary with pressure.

The answer appears to be that b_c becomes less dependent upon pressure as the temperature is increased. For a low-temperature run, say in the vicinity of 40° C, the rate of decomposition is slow, and an experiment was normally concluded when about 5% of the $Ni(CO)_4$ had decomposed. The variation of b_c would not be easily detected in this circumstance. At a high temperature, say 80° C, the decomposition was carried to about 10%, but for this temperature the variation of b_c with pressure is small. Thus the empirical equation appeared valid under all the experimental conditions employed. A more complicated expression of the composite rate would presumably remove the contradictions.

EXPERIMENTS USING RUTILE AND SODIUM CHLORIDE PACKINGS

The experiments in which these powders were employed need not be described extensively. Rutile could be dispersed and suspended to the extent of about 15 mg in a small amount of glass wool. Up to this amount of suspended rutile, the heterogeneous reaction rate increased linearly with amount of rutile. The absolute value of the rate agreed with expectation on the basis of the known behavior of the nickel film formed upon glass wool when the respective surface areas of rutile and glass wool were taken into account. Thus one concludes that the surface properties of the nickel deposited upon rutile are the same as those of nickel deposited upon glass wool.

In the course of these experiments with rutile, it was further established that exposure of the deposited nickel film to oxygen decreases the rate of the heterogeneous reaction. After the deposition of further layers of nickel (only a few partial decompositions are required), the rate was re-established. Thus oxygen inhibits the heterogeneous reaction, contrary to its effect on a germanium surface when germane is thermally decomposed (13). Its effect also differs in that the inhibition is eliminated on further deposition of nickel, whereas the oxygen had a persistent effect with germanium films and was therefore considered to diffuse to the surface on addition of further germanium.

The experiments with sodium chloride were less informative. The powder could not be satisfactorily dispersed, and showed little specific surface due to clumping. An attempt to avoid this clumping led to the deposition of sodium chloride upon the quartz wall by allowing a smoke of salt to deposit on the flask. After the usual pumping procedure, it was found that reaction was slow, appreciably less than that of the homogeneous reaction at the same temperature. This finding was established conclusively in repeated experiments.

To rationalize this result, it was postulated that $Ni(CO)_3$ is readily adsorbed upon the polar surface, and there reacts with CO to reform $Ni(CO)_4$. Therefore, two extra steps have to be added to the mechanism offered by Garratt and Thompson (3):

$$Ni(CO)_3 + S \xrightarrow{K_4} Ni(CO)_3\text{-}S$$

$$Ni(CO)_3\text{-}S + CO \xrightarrow{K_5} Ni(CO)_4 + S,$$

where S is adsorption site on the salt surface and $Ni(CO)_3$-S represents the adsorbed

$Ni(CO)_3$. The modified homogeneous decomposition may be expressed through the equation

$$\frac{-dNi(CO)_4}{dt} = \frac{K_1 Ni(CO)_4}{1+\frac{K_3}{K_2}CO+\frac{K_4}{K_2}S}.$$

If the term $(K_4/K_2)S$ is large as compared to $1+(K_3/K_2)CO$, the rate can be reduced appreciably. The effect has not been extensively investigated, but it is clear that a study of this inhibition, and inhibition by other surfaces, is warranted.

ENTROPIES OF THE ACTIVATED COMPLEXES

On the basis of the reaction rates which have been determined experimentally and the theory of absolute reaction rates of Glasstone, Laidler, and Eyring (14), the entropy of activation of the homogeneous reaction is found to be −16.2 e.u. From this the effective collision frequency is determined to be about 10^{10} per second. This is abnormally low. Even lower results would be obtained using the activation energies reported by Bawn (2) and by Garratt and Thompson (3). From this standpoint the decomposition reaction is somewhat unusual.

On the other hand, the entropy change on formation of the activated complex of the heterogeneous reaction, assumed to be adsorbed $Ni(CO)_4$, is calculated to be −16.7 e.u. at 40° C. The standard state for the gaseous $Ni(CO)_4$ is 1 atm and that for the adsorbed $Ni(CO)_4$ is taken as $\theta = \frac{1}{2}$ (15). The entropy change is about what would be expected if one degree of translational freedom had been lost, but no appreciable change had been suffered in the rotational and vibrational freedom (−18.3 e.u.). This is consistent with the statement made earlier that $Ni(CO)_4$ is physically adsorbed upon the nickel films.

SUMMARY

The activation energy of the homogeneous decomposition of $Ni(CO)_4$ has been shown to be 19.1 kcal mole^{-1}, and the reaction is first order in $Ni(CO)_4$. In the presence of an ionic surface such as sodium chloride, the intermediate postulated in the homogeneous reaction, namely $Ni(CO)_3$, appears to be adsorbed, and recombines with CO, so that the rate of reaction is appreciably reduced.

The activation energy of the heterogeneous reaction has been determined to be 14.3 kcal mole^{-1}. The activated complex is adsorbed $Ni(CO)_4$, which is physically adsorbed and mobile. The heat of adsorption upon the nickel substrate is 7.4 kcal mole^{-1}. The sites of the nickel surface also adsorb CO, which is more firmly bound. The heat of adsorption of CO is 13.3 kcal mole^{-1}, which suggests chemical rather than physical binding.

BIOSYNTHESIS OF SUGARS FOUND IN BACTERIAL POLYSACCHARIDES

PART I. BIOSYNTHESIS OF L-RHAMNOSE

J. K. N. JONES, M. B. PERRY, AND R. J. STOODLEY

Received November 30, 1961

ABSTRACT

Azotobacter indicum was grown on media which contained D-glucose-1-C^{14}, D-glucose-2-C^{14}, D-glucose-6-C^{14}, D-mannose-1-C^{14}, or D-galactose-1-C^{14}. The radioactive polysaccharides produced were hydrolyzed and the specific activities of the isolated D-glucose and L-rhamnose were measured. The sugars were degraded and the distribution of activity in the individual carbon atoms was determined.

The results suggest that some L-rhamnose is formed from D-glucose by a pathway which involves the breakdown of the glucose carbon skeleton.

INTRODUCTION

The conversion of D-glucose to deoxy sugars of the L-series has received considerable attention. For example, using isotopic tracer techniques the biosynthesis of L-fucose has been studied in bacteria (1–3) and in man (4). The results favor a direct conversion of D-glucose to L-fucose. A similar conclusion (5) has been reached in the case of colitose (3-deoxy-L-fucose). The biosynthesis of L-rhamnose has been investigated in bacteria (6–9) and in plants (10), and again a direct conversion of D-glucose to L-rhamnose is indicated.

Bacterial extracts can transform guanosine diphosphate D-mannose to guanosine diphosphate L-fucose (11) and thymidine diphosphate D-glucose to thymidine diphosphate L-rhamnose (12–14). Intermediates in these interconversions have recently been characterized (15, 16) and they provide strong evidence for the existence of direct pathways, although they do not preclude the existence of alternative pathways in vivo.

Azotobacter indicum produces an extracellular polysaccharide when grown in suitable media containing sugar substrates (17, 18). Studies in this department (19) have shown that, when a peptone medium is used, the polysaccharide contains D-*glycero*-D-*manno*-heptose, D-glucose, D-mannose, D-glucuronic acid, L-rhamnose, and arabinose.

In the present paper the results of growing the organism in a peptone medium, containing a variety of C^{14}-labelled hexoses, are reported. The polysaccharides were hydrolyzed and the distribution of activity in the carbon atoms of D-glucose and L-rhamnose was determined. The possible origin of the heptose sugar will be discussed in a future communication.

EXPERIMENTAL

Materials

The radioactive sugars were purchased from Merck and Co., Montreal, Que. *A. indicum*-446 was kindly supplied from the Culture Collection of the National Research Laboratories, Ottawa, Ontario.

Determination of Radioactivity

Carbon dioxide was precipitated as barium carbonate. Hydrazones, dimedon derivatives, iodoform, and barium carbonate were plated in triplicate on sintered-glass planchets (6–12 mg per plate). The samples were counted in a proportional methane gas flow counter. The barium carbonate self-absorption curve was used to correct all solid samples to their activity at "infinite thickness" (20).

Liquid samples containing radioactive sugars were evaporated on aluminum plates and counted at "infinite thinness". The activity was converted to microcuries (μc), assuming 50% counting efficiency. The values are not absolute and should not be directly compared with the activities of solid samples.

Growth of A. indicum and Isolation of Polysaccharide

The culture medium contained dipotassium hydrogen phosphate (12 mg), magnesium sulphate (5 mg), calcium carbonate (500 mg), peptone (25 mg), sugar (1.00 g with 100 μc activity), and distilled water (25 ml). The suspension was autoclaved and inoculated with *A. indicum*, growing in a similar liquid medium. Sterile, carbon dioxide free air was slowly drawn through the medium; the evolved carbon dioxide was collected in a trap containing 2 *N* sodium hydroxide (200 ml). The specific activity of the carbon dioxide was determined.

Generally, the medium became quite viscous after 7–10 days. After about 2 weeks the medium was diluted with water (25 ml) and shaken to dissolve the slime which accumulated on the flask wall. The suspension was centrifuged (12,000 r.p.m. for 90 minutes) and the clear supernate was poured into ethanol (2 vol.). The gel-like precipitate was collected by centrifugation, washed with 60% ethanol (4×), absolute ethanol (2×), acetone, and ether, and dried in a vacuum desiccator containing silica gel. The supernate and ethanol washings were combined and evaporated to a syrup, which was dried.

In a control experiment radioactive glucose was added to a non-radioactive solution of polysaccharide. When the polysaccharide was isolated in the above manner it contained no appreciable activity.

The yields of extracellular polysaccharide and carbon dioxide produced, when *A. indicum* was grown in media containing C^{14}-labelled sugars, are shown in Table I.

TABLE I

Yields of extracellular polysaccharide and evolved carbon dioxide

Sugar substrate	Weight of sugar (g)	Time of growth (days)	Weight of polymer isolated (g)	Weight of substrate recovered (g)	Yield of polymer (%)	Yield of CO_2 (%)
D-Glucose-U-C^{14}	1.00	12	0.149	0.585	36	65
D-Glucose-1-C^{14}	1.00	22	0.150	0.480	29	58
D-Glucose-2-C^{14}	1.00	14	0.095	0.591	23	85
D-Glucose-6-C^{14}	1.00	18	0.174	0.461	32	74
D-Mannose-1-C^{14}	1.00	14	0.224	0.415	38	65
D-Galactose-1-C^{14}	1.00	14	0.156	0.507	32	73

The specific activities of the sugar substrates and evolved carbon dioxide are shown in Table II.

TABLE II

Specific activities of evolved carbon dioxide, hydrolyzates, and isolated sugars

Sugar substrate	Specific activity of sugar (μc/mmole C)	Specific* activity of CO_2 (μc/mmole C)	Specific activity of hydrolyzate (μc/mmole C)	Specific activities of sugars (μc/mmole C)	
				Glucose	Rhamnose
D-Glucose-U-C^{14}	3.00	1.73	2.36	—	—
D-Glucose-1-C^{14}	3.00	1.46	1.80	3.12	2.73
D-Glucose-2-C^{14}	3.00	1.42	1.88	3.09	2.80
D-Glucose-6-C^{14}	3.00	1.08	1.94	2.89	2.05
D-Mannose-1-C^{14}	3.00	1.60	2.05	3.03	2.93
D-Galactose-1-C^{14}	3.00	1.62	2.09	3.04	2.86

*The average molecular weight of the sugars in the hydrolyzate was taken to be 180.

Hydrolysis of Polysaccharide

The polysaccharide was hydrolyzed with 90% formic acid for 7.5 hours at 100° C in a sealed tube. After evaporation, *N* sulphuric acid was added to the syrup. The solution was heated on a boiling-water bath for 5 hours, neutralized (barium carbonate), filtered, and passed through Amberlite IR 120 (H^+) ion-exchange resin. The eluate was evaporated to a syrup, which was dried in a vacuum desiccator containing silica gel. Usually 50–60% by weight of the polysaccharide was recovered as monosaccharides. The specific activity of the hydrolyzate was measured and is shown in Table II.

Isolation of Radioactive Sugars

The No. 3 MM Whatman paper on which the hydrolyzates were fractionated was prewashed with the developing solvent—butan-1-ol–pyridine–water (10:3:3, v/v). Sugars were fractionated by multiple development (21) using developing times of 16, 12, 12, and 17 hours. The chromatograms were placed in contact with X-ray films for 8 days and the areas containing radioactive sugars were eluted with water. The eluates

which contained glucose and rhamnose were diluted to known volumes. The concentration of these sugars was estimated on triplicate samples by the phenol – sulphuric acid method (22). The specific activities of these sugars are recorded in Table II.

"Carrier" D-glucose and L-rhamnose were added to their respective solutions, which were then evaporated to syrups. Glucose was crystallized from aqueous ethanol, and rhamnose from moist acetone.

Degradation of L-*Rhamnose*

L-Rhamnose was degraded by the reactions outlined in Fig. 1.

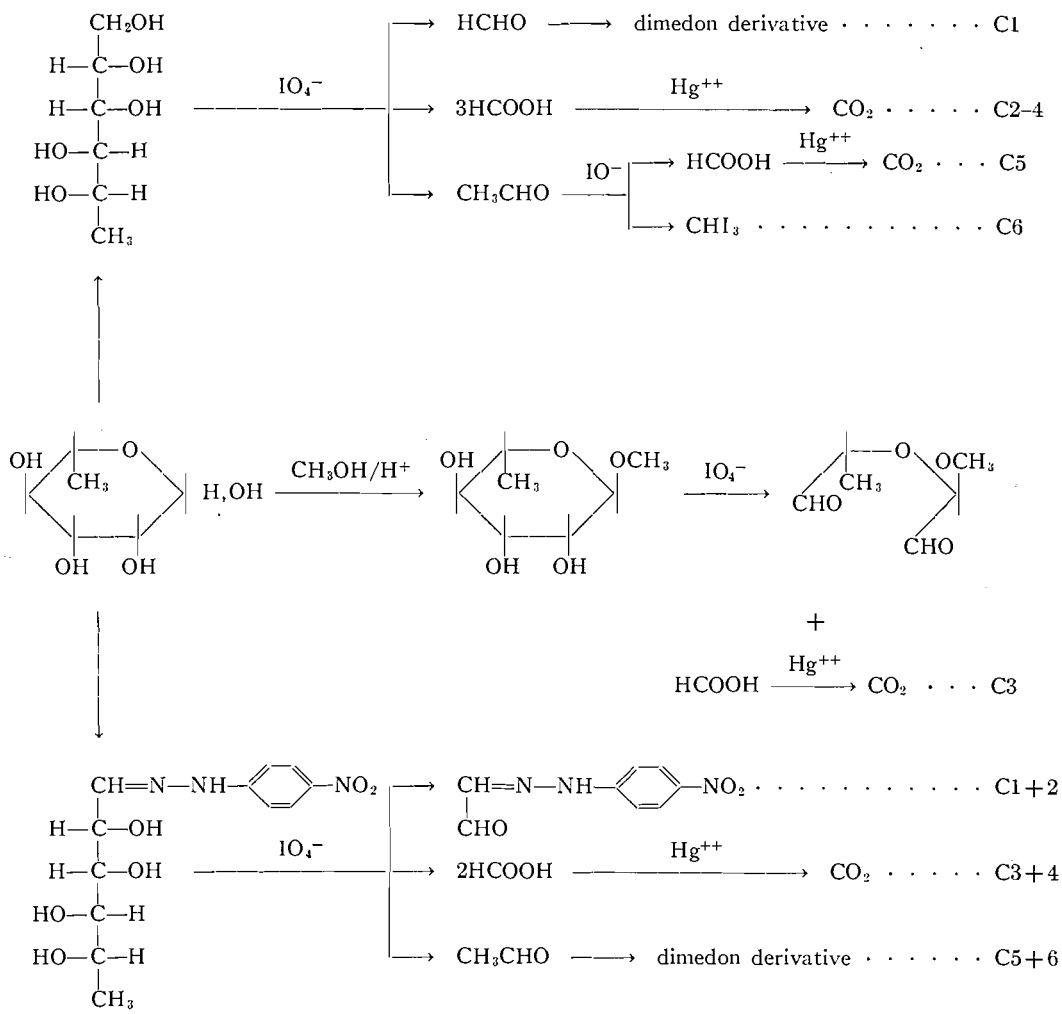

FIG. 1. Degradation of L-rhamnose-C^{14}.

Determination of C^{14} *in C1, C2–4, C5, and C6*

L-Rhamnitol was prepared *in situ* by reducing L-rhamnose (20 mg) with 1% sodium borohydride (2 ml). Excess borohydride was destroyed after 12 hours by the addition of 2 *N* sulphuric acid. The rhamnitol was oxidized by the procedure developed by Nicolet and Shinn (23). Phosphate buffer at pH 8 (10 ml) was added to the solution together with glycine (200 mg) and 0.3 *M* sodium metaperiodate (1.5 ml). Nitrogen was bubbled through the solution to remove acetaldehyde (C5+6), which was collected in 2% sodium metabisulphite. The bisulphite solution was concentrated *in vacuo* to a small volume and potassium carbonate (1.0 g) was added (24) followed by 9 *N* potassium hydroxide (0.05 ml) and 0.1 *M* iodine in 20% potassium iodide (2 ml). The iodoform (C6) was collected by filtration after 15 minutes, washed well with water,

and plated. The plates were dried *in vacuo* over silica gel and their specific activities determined. The material, m.p. 117–118° C, was obtained in 30–35% yield. The filtrate and washings were acidified with 2 *N* sulphuric acid and iodine was destroyed by the addition of dilute sodium thiosulphate. The solution was neutralized and the formic acid (C5) was oxidized to carbon dioxide with mercuric acetate (25) in about 30% yield.

The solution obtained after removal of acetaldehyde contained formaldehyde (C1) and formic acid (C2–4); it was acidified with acetic acid, and dimedon was added. The formaldehyde dimedon was collected after 20 hours and was obtained in about 70% yield, after recrystallization from aqueous ethanol; m.p. 188° C. The derivative was dried in a vacuum desiccator containing silica gel and its specific activity determined. The formic acid in the filtrate was oxidized to carbon dioxide (25) in about 70% yield, and its specific activity was determined.

Determination of C^{14} in C1–6

L-Rhamnose *p*-nitrophenylhydrazone was prepared in the usual manner in yields of 80–85%; m.p. 190–192° C. Portions of the hydrazone (ca. 8 mg) were ground to a fine powder in ether and the suspensions were plated. The plates were dried in an oven at 100° C for 15 minutes and their specific activities were determined.

Determination of C^{14} in C1+2 and C5+6

The *p*-nitrophenylhydrazone (50 mg) was dissolved in pH 8 phosphate buffer (8 ml), and 0.3 *M* sodium metaperiodate (1.5 ml) was added to the chilled solution. Glyoxal *p*-nitrophenylhydrazone (C1+2), which precipitated within a few seconds, was removed by centrifugation and recrystallized from aqueous acetone. The material was obtained in 50–60% yield; m.p. 198–200° C; it was plated and dried in a vacuum desiccator prior to the determination of its specific activity.

Nitrogen was bubbled through the supernate and the acetaldehyde was collected in an ice-cold solution of dimedon at pH 4.3 (26). The precipitated derivative was collected after 20 hours by filtration, and, after recrystallization from aqueous ethanol, was obtained in 30–40% yield; m.p. 139–140° C. The specific activity of C5+6 was determined.

Determination of C^{14} in C3

L-Rhamnose (50–100 mg) was dissolved in methanolic hydrogen chloride (2 ml concentrated hydrochloric acid in 100 ml methanol) and the solution refluxed for 10 hours. The solution was diluted with water and passed through Duolite A4 (OH^-) resin. The eluate was concentrated to a syrup and fractionated chromatographically on Whatman No. 3 MM paper using a neutral solvent—butan-1-ol–ethanol–water (3:1:1, v/v). End strips of the chromatogram were sprayed with silver nitrate (27) and the area of paper containing methyl α-L-rhamnopyranoside was eluted with water. The solution was concentrated, and the syrup allowed to crystallize. When a sufficient quantity of glycoside was available it was recrystallized from ethyl acetate; m.p. 100–101° C.

The glycoside (30–40 mg) was dissolved in water (1 ml) and oxidized with 0.3 *M* periodic acid (1 ml). After 2.5 hours the solution was passed through Duolite A4 (OH^-) resin, which was then washed with water (100 ml). The column was washed with 0.2 *M* barium hydroxide (15 ml) and water (30 ml). The eluate was neutralized with 3 *N* sulphuric acid and the formic acid (C3) oxidized to carbon dioxide in the usual manner (25).

Degradation of D-*Glucose*

Determination of C^{14} in C1+6 and C2–5

D-Glucitol was prepared *in situ* by reducing D-glucose (15 mg) with 1% sodium borohydride (2 ml). Excess borohydride was destroyed after 12 hours by the addition of 2 *N* sulphuric acid. Phosphate buffer at pH 8 was added to the solution together with 0.3 *M* sodium metaperiodate (1.5 ml). Barium acetate was added after 2 hours and the insoluble barium salts were removed by filtration. The solution was acidified with acetic acid and dimedon was added. The formaldehyde dimedon was collected after 20 hours and recrystallized from aqueous ethanol; m.p. 188° C. The material was obtained in 70% yield and was used to determine the specific activity of C1+6. The specific activity of C2–5 was measured by oxidizing the formic acid in the filtrate to carbon dioxide (25).

Determination of C^{14} in C1–6

Glucose (4–6 mg) was oxidized to carbon dioxide by Van Slyke's procedure (28) and its specific activity determined. Glucose *p*-nitrophenylhydrazone was prepared in 70–75% yield; m.p. 188–189° C. The specific activity of C1–6 was determined by directly counting the hydrazone.

Determination of C^{14} in C1+2 and C6

Glucose *p*-nitrophenylhydrazone was oxidized in a manner similar to that described for rhamnose *p*-nitrophenylhydrazone. Glyoxal *p*-nitrophenylhydrazone (C1+2) was recrystallized from aqueous acetone and its specific activity was determined. Dimedon was added to the filtrate and the formaldehyde dimedon was collected after 20 hours. The derivative, after recrystallization from aqueous ethanol, was obtained in about 50% yield; it was used to determine the specific activity of C6.

The specific activities of the fragments obtained during the degradation of rhamnose are recorded in Table III.

TABLE III

Specific activities of rhamnose fragments (c.p.m./mmole C)

Rhamnose carbons	Sugar substrate				
	G-1-C^{14}	G-2-C^{14}	G-6-C^{14}	M-1-C^{14}	Gal-1-C^{14}
C1–6	10,170	20,010	19,380	22,060	18,940
C1+2	23,780	46,900	5,250	45,670	39,080
C5+6	4,350	6,560	46,170	12,460	5,490
C1	44,610	13,780	13,610	91,840	—
C2–4	1,310	31,540	0	1,860	2,570
C5	2,300	—	0	2,300	3,120
C6	6,230	0	97,250	24,270	8,690
C3	1,970	7,870	—	2,460	3,940

NOTE: G = glucose, M = mannose, Gal = galactose.

The specific activities of the fragments obtained during the degradation of glucose are shown in Table IV.

TABLE IV

Specific activities of glucose fragments (c.p.m./mmole C)

Glucose carbons	Sugar substrate				
	G-1-C^{14}	G-2-C^{14}	G-6-C^{14}	M-1-C^{14}	Gal-1-C^{14}
C1–6*	8,730	18,600	25,440	31,590	13,320
C1–6†	—	19,140	26,100	29,250	11,970
C1+2	21,960	50,760	6,390	80,100	34,020
C6	4,140	2,340	159,840	32,000	13,500
C1+6	21,690	7,200	79,020	84,060	36,720
C2–5	1,000	25,250	590	2,570	2,610

NOTE: G = glucose, M = mannose, Gal = galactose.
*Determined by Van Slyke oxidation (28) of glucose.
†Determined by directly counting glucose *p*-nitrophenylhydrazone.

The percentage distribution of activity in the carbon atoms of L-rhamnose and D-glucose is shown in Table V. The specific activities shown in Tables III and IV were multiplied by the number of carbon atoms they represented to give total activities. The total activity of the rhamnose molecule was calculated by summing the activities of C1, C2–4, C5, and C6. Generally, this value corresponded (±7%) with the activity of C1–6, determined by an independent method. The total activity of the glucose molecule was calculated by summing the activities of C1+6 and C2–5. The value corresponded (±7%) with the activity of C1–6, determined by two independent methods. When D-glucose-6-C^{14} was the substrate the value obtained for C6 was slightly greater than that of C1+6. In this case the total activity was compounded from the sum of the activities of C1+2, C2–5, and C6.

TABLE V

Distribution of C^{14} in individual carbon atoms of isolated sugars

Sugar substrate	Sugar isolated	C^{14} as % total in monosaccharide					
		C1	C2	C3	C4	C5	C6
G-1-C^{14}	Rhamnose	78	←——	7	—→	4	11
	Glucose	83	←————	8	———→		9
G-2-C^{14}	Rhamnose	11	66	7	5	11	0
	Glucose	10	77	←———	11	——→	2
G-6-C^{14}	Rhamnose	12	←————	0	———→		88
	Glucose	7	←————	1	———→		91
M-1-C^{14}	Rhamnose	74	←——	4	—→	2	20
	Glucose	76	←————	6	———→		18
Gal-1-C^{14}	Rhamnose	80	←——	8	—→	3	9
	Glucose	72	←————	12	———→		16

NOTE: G = glucose, M = mannose, Gal = galactose.

DISCUSSION

A. indicum was grown in aerated, buffered media which contained C^{14}-labelled sugar substrates. Generally about 30% of the sugar utilized was converted to extracellular polysaccharide and most of the remainder was oxidized to carbon dioxide.

The specific activity of the evolved carbon dioxide was substantially lower than that of the sugar substrate, even when D-glucose-U-C^{14} was the substrate. This isotope dilution may be due to peptone in the medium serving as an additional carbon source. Also, acidic materials may be liberated into the medium by the bacteria, displacing inactive carbon dioxide from calcium carbonate. Furthermore an exchange reaction between metabolic carbon dioxide and inactive carbonate may occur. Nevertheless, the specific activity of carbon dioxide evolved during the D-glucose-6-C^{14} growth was noticeably lower than in the other cases, indicating that the hexose monophosphate shunt is probably operating in the organism.

The isolated polysaccharides were hydrolyzed and usually 50–60% of their weight was recovered. However, although the specific activities of the hydrolyzates were quite similar, they were lower than those of the original substrates, indicating that they contained inactive materials.

The specific activities of the isolated glucose and rhamnose were determined. They were usually quite similar to each other and to the specific activities of the original substrates. However, the specific activity of L-rhamnose isolated from the D-glucose-6-C^{14} growth was approximately 30% lower than in the other cases. This result is believed to be significant and indicates that C6 of D-glucose contributes only about 70% as much to the L-rhamnose skeleton as does C1 or C2 of D-glucose or C1 of D-mannose and D-galactose.

A number of degradations of L-rhamnose have been reported in the literature. In this work rhamnose of low specific activity was occasionally isolated and it was necessary to devise a procedure which required less than 1 mmole of sugar. Quite often the majority of the activity is found in the terminal carbon atoms and it is then unnecessary and time consuming to use a procedure which gives the activity of each carbon atom. It is an advantage, therefore, to use a procedure which initially gives the activity of the terminal carbon atoms.

Hauser and Karnovsky (6) oxidized potassium rhamnonate to carbon dioxide (C1), formic acid (C2–4), and acetaldehyde (C5+6). However, about 0.5 mmole of rhamnose is required for this degradation, and in one case (8) poor recoveries of activity were reported. The same information can be readily obtained by oxidation of rhamnitol, using the procedure of Nicolet and Shinn (23), and only about 0.12 mmole of sugar is required.

Rhamnose phenylosazone has been used (6) to determine the activity of C1–3, C4, and C5+6. However, on a 0.5-mmole scale the present authors were unable to obtain better than 25% yield of recrystallized osazone. Rhamnose *p*-nitrophenylhydrazone could be prepared in over 80% yield and was therefore used to determine the specific activities of C1+2 and C5+6.

The isotope content of C3 was determined by periodate oxidation of methyl α-L-rhamnopyranoside. Watkin and Neish (10) have recently described a method for degrading rhamnose which involves the periodate oxidation of its glycopyranosides. The specific activities of C2, C3, C4, C5, and C6 were determined directly while that of C1 was calculated by difference, about 1 mmole of rhamnose being required for the degradation.

The degradative studies revealed that about $77 \pm 6\%$ of the activity was retained in C1 of the isolated monosaccharides, when D-glucose-1-C^{14}, D-mannose-1-C^{14}, or D-galactose-1-C^{14} were substrates. The majority of the remaining radioactivity was located in C6 of the hexoses.

When D-glucose-6-C^{14} served as substrate most of the activity was recovered in C6 of the hexoses (90±2%). The remaining activity was found in C1 of these sugars.

Approximately 72±6% of the activity was recovered in C2 and 10% in C5 of D-glucose and L-rhamnose, when D-glucose-2-C^{14} was substrate. In addition about 10% of the activity was found in C1 of these sugars. The latter result further indicates that C1 decarboxylation is occurring and suggests that some of the pentose formed by the hexose monophosphate shunt is reutilized for hexose synthesis. Apparently about 10% of hexose is resynthesized by this route and it can presumably equilibrate with substrate hexose.

About 10% of activity was detected in C6, C5, or C1 of D-glucose and L-rhamnose, when D-glucose-1-C^{14}, D-glucose-2-C^{14}, or D-glucose-6-C^{14} were the respective substrates.

These results suggest that there is a hexose pool which at equilibrium contains about 20% of hexose resynthesized from equilibrated trioses (formed from D-fructose 1,6-diphosphate via the Embden–Meyerhof pathway) and about 10% of hexose resynthesized from pentose (produced by the hexose monophosphate shunt) by the action of transketolase.

The specific activity of L-rhamnose derived from D-glucose-6-C^{14} was about 30% lower than that derived from 1-C^{14}-labelled precusors, and so it will be assumed that 70% of L-rhamnose is synthesized directly from D-glucose. This transformation probably proceeds via the thymidine diphosphate derivatives (12–14) and requires three epimerizations and a reduction of $—CH_2OH$ to $—CH_3$. An intermediate in this interconversion, the thymidine diphosphate derivative of 6-deoxy-4-oxo-D-glucose, has recently been isolated from a cell-free enzyme system of *Pseudomonas aeruginosa* (16). Presumably a second pathway, involving scission of the glucose carbon skeleton, contributes to rhamnose biosynthesis in *A. indicum*. A possible route, which has not been demonstrated experimentally, may involve the transfer of a dihydroxy acetone unit from D-fructose 6-phosphate to L-pyruvaldehyde (produced by glycolysis) by the action of transaldolase. The resultant 6-deoxy-L-sorbose might then be converted to L-rhamnulose.

It is interesting to note that the same sugar can form different nucleotides. For example, glucose can form uridine diphosphate glucose and thymidine diphosphate glucose, which presumably results in a channelling of the sugar to different metabolic pathways. If glucose 1-phosphate and the glucose nucleotides can act as glycosyl donors in polysaccharide synthesis, then different linkages may be produced in the polysaccharide chain.

There are a number of other studies on the biosynthesis of L-rhamnose using isotopic tracer techniques. Hauser and Karnovsky (6, 7) have studied the biosynthesis of the rhamnolipide produced by *P. aeruginosa*. They found that glycerol and propanediol could serve equally well for L-rhamnose synthesis. Degradation of L-rhamnose indicated that it was formed by the combination of two triose units. When D-glucose-6-C^{14} in the presence of inactive glycerol was the substrate, the rhamnose contained 35% of its activity in C1 and 48% in C6. On the other hand, with D-fructose-6-C^{14} as substrate, 83% of the activity was recovered in C6 of L-rhamnose. These results presumably reflect fundamental metabolic differences of the two sugars. Although the results indicate that L-rhamnose is formed from two triose units, it is possible that a hexose precursor is first formed which is then directly transformed to L-rhamnose.

Southard and co-workers (8) have investigated the conversion of D-glucose-1-C^{14} and D-glucose-6-C^{14} to L-rhamnose of streptococcal cell walls. Although only 60–80% of the total activity was recovered in their degradations, the majority of activity was retained in the terminal carbon atoms. However, the specific activity of the L-rhamnose isolated

from D-glucose-6-C^{14} was about 30% higher than that derived from D-glucose-1-C^{14}. It would be necessary to isolate and degrade bacterial glucose to determine the significance of this result.

Taylor and Juni (9) have studied the biosynthesis of D-glucose and L-rhamnose in a bacterial capsular polysaccharide. Unlabelled polysaccharide was isolated when D-glucose-1-C^{14} and D-glucose-2-C^{14} were the substrates. However, with D-glucose-6-C^{14}, the isolated D-glucose and L-rhamnose contained twice the initial specific activity. The bacterial D-glucose was not degraded but the L-rhamnose contained 50% of its activity in C1 and 43% in C6. The results indicated that the polysaccharide was derived only from C4, C5, and C6 of D-glucose. It was not possible to decide whether L-rhamnose arose directly from trioses or from a six-carbon sugar which was synthesized from the trioses.

Recently, Watkin and Neish have studied the biosynthesis of L-rhamnose from D-glucose in buckwheat (10). These authors showed that the isolated D-glucose and L-rhamnose possessed similar specific activities and distributions of activity, suggesting a direct conversion of D-glucose to L-rhamnose.

Whatever interpretation is placed upon the results presented in this paper, there appears to be a pathway for L-rhamnose biosynthesis which involves the breakdown of the glucose carbon skeleton.

ACKNOWLEDGMENTS

The authors are grateful to Dr. G. B. Krotkov and Dr. C. D. Nelson of the Biology Department of Queen's University for making available the counting apparatus. They are indebted to the National Research Council for grants (T-39 and N.R.C. 706) and for the award of a Studentship (to R. J. S.).

TRYPTAMINES, CARBOLINES, AND RELATED COMPOUNDS

PART X. AN ALTERNATIVE SYNTHESIS, AND THE NITRATION, OF δ-CARBOLINE[1]

R. A. ABRAMOVITCH AND K. A. H. ADAMS
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received January 10, 1962

ABSTRACT

δ-Carboline, together with β-carboline, has been synthesized in reasonably good yield by the Fischer cyclization of cyclohexanone 3-pyridylhydrazone followed by dehydrogenation of the separated tetrahydro derivatives. The isomer ratios of products formed in this and similar reactions are discussed. Nitration of δ-carboline gives a mixture of the 6- and 8-nitro derivatives, the latter being the predominant product. The magnitude of the dipole moment of δ-carboline is appreciably higher than that predicted from molecular orbital calculations (15).

The first unambiguous synthesis of δ-carboline* (I) was described in Part VIII of this series (1), in which the cyclization of 3-azido-2-phenylpyridine was reported to give variable yields of (I). In order to study the substitution reactions of this ring system a synthesis giving more reproducible yields was required. An alternative method of obtaining the δ-carboline ring system was sought and found in the Fischer cyclization of cyclohexanone 3-pyridylhydrazone (II).

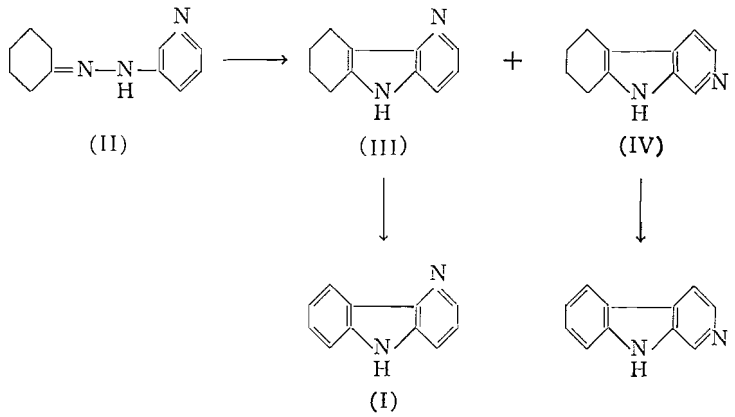
The Fischer cyclization of pyridylhydrazones has been found by a number of workers to take place with greater difficulty than the cyclization of the corresponding phenylhydrazones. Perkin and Robinson were unable to effect the cyclization of acetone 2-quinolylhydrazone (2), and Fargher and Furness (3) and Okuda and Robison (4) obtained similar negative results using a number of 2-pyridylhydrazones. Clemo and Holt prepared 1-methyl-5,6,7,8-tetrahydro-β-carboline in low yield from cyclohexanone 2-methyl-3-pyridylhydrazone and zinc chloride (5). A moderate yield of 5,6,7,8-tetrahydro-α-carboline was obtained by heating cyclohexanone 2-pyridylhydrazone with polyphosphoric acid (4). Ficken and Kendall have recently examined the cyclization of the pyridylhydrazones of isopropylmethyl ketone to give the corresponding azaindole derivatives (6). They found that heating with zinc chloride to a relatively high temperature (210–250°) was necessary to effect ring closure. It is interesting to note, as well, that isopropylmethyl ketone 3-pyridylhydrazone was reported by these authors to give exclusively 2,3,3-trimethyl-3H-4-azaindole; i.e. cyclization had occurred at the α-position of the pyridine ring only. Similarly, Takahashi, Saikachi, Goto, and Shimamura (7) obtained 5-chloro-2-methyl-4-azaindole from acetone 2-chloro-5-pyridylhydrazone.

3-Hydrazinopyridine reacted with cyclohexanone to give the required cyclohexanone 3-pyridylhydrazone (II), which was somewhat unstable in air but could be kept for long periods in a closed container in the refrigerator. Cyclization was effected by fusion of (II) with zinc chloride at 250° and gave a high yield (94%) of a mixture of 6,7,8,9-tetrahydro-δ-carboline (III) (63%) and 5,6,7,8-tetrahydro-β-carboline (IV) (37%). The structures of (III) and (IV) were established by dehydrogenation to the corresponding fully aromatic structures. The dehydrogenations were carried out by heating the compound with 10% palladium–charcoal in boiling mesitylene; the catalyst became poisoned

[1]*Part IX: R. A. Abramovitch and K. A. H. Adams. Can. J. Chem.* **39**, *2516 (1961).*

**The trivial names α-, β-, and δ-carboline have been used throughout this paper and in previous papers in this series. They are acceptable according to the Definitive I.U.P.A.C. 1957 Rules for Nomenclature, and refer to 9H-pyrido[2,3-b]indole, 9H-pyrido[3,4-b]indole, and 5H-pyrido[3,2-b]indole (Ring Index), respectively.*

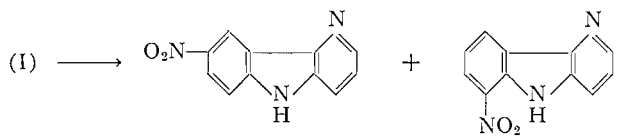
after about half the reaction had occurred and a second batch had to be added. The mixture of tetrahydro derivatives could be separated by chromatography on a column of alumina, when the δ-carboline derivative was eluted first, followed by the β-compound. The order of elution is similar to that reported by Abramovitch (8) for the separation of mixtures of *ind-N*-methyl-δ-carboline and *ind-N*-methyl-β-carboline. The cyclization of cyclohexanone 3-pyridylhydrazone was found to give very reproducible yields, thus providing a good route to the δ-carboline ring system.



The observation that ring closure at the 2-position of the pyridine ring predominates is in agreement with the results of Ficken and Kendall (6) but differs in that these authors did not observe any cyclization to the 4-position of the pyridine nucleus. In pyridine derivatives possessing an electron-releasing group in the 3-position electrophilic attack generally leads to substitution in the 2-, rather than the 4-, position (9). This has been discussed by Schofield (10), who suggested that protonation and some form of chelation may be responsible. In the present study, attack at C_2 was favored over attack at C_4 to the extent of about 2:1. In contrast, the Graebe–Ullmann cyclization of 1-β-pyridylbenztriazole apparently results in exclusive substitution at C_4 of the pyridine nucleus (11). Molecular orbital calculations on the pyridine ring itself indicate that the π-electron density in the ground state is greater at the 4- than at the 2-position whereas the atom localization energies (A_e) for a Wheland-type transition state indicate (for pyridine but not pyridinium salts) that electrophilic substitution should be easier at the 2- than at the 4-position (12). A 3-amino substituent may well activate the 2- and 4-positions to different extents. Also, in the case of the Fischer cyclization, particularly that catalyzed by zinc chloride, there is no doubt that the pyridine nitrogen is coordinated with the metal atom. It would seem safe to suggest, however, that "strong" electrophilic reagents which do not make a large electron demand upon the substrate could well substitute into the pyridine ring according to the order of the ground-state π-electron densities at the nuclear carbons, whereas "weak" electrophilic reagents would probably follow the pattern suggested by the atom localization energies, with various shades possible in between, depending upon whether the transition state resembled more the starting materials or a Wheland-type intermediate structure.

The nitration of α- and β-carboline has already been studied. Thus, in the case of α-carboline it has been reported that 6-nitro-α-carboline is obtained exclusively (13), whereas mononitration of β-carboline gives mainly 6-nitro-β-carboline together with a

lesser amount of what was suggested to be the 8-nitro derivative (14). Paoloni (15) has carried out some simple Hückel molecular orbital calculations of the ground-state π-electron densities for the four carbolines. These indicate that, in all cases, C_8 has the highest π-electron density, with C_6 the next highest.* As it is believed that in nitrations the transition state is somewhat closer in electron distribution to the unperturbed ground state than to the Wheland-type intermediate (16) it might have been expected from Paoloni's calculations that substitution at the 8-position* would have been favored (17), which is not the case. The nitration of δ-carboline with concentrated nitric acid has now been studied, and was found to lead to a mixture of two isomeric mononitro derivatives. The major product (56% after recrystallization) separated from the reaction mixture in the form of its salt. The free base did not melt below 360°. The second nitro compound (17% yield) had m.p. 232–233°.

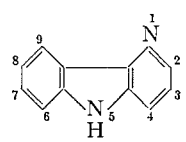


(V) (VI)

By analogy with the nitration of carbazole (18) and of α- and β-carboline, it was initially assumed that the high-melting major product was probably 8-nitro-δ-carboline† (V) while the low-melting isomer was 6-nitro-δ-carboline† (VI). Tentative confirmation of the assignment of structure (VI) to the low-melting isomer was obtained from a study of its infrared and ultraviolet absorption spectra. It was hoped, in particular, that the infrared spectrum would show evidence of the hydrogen bonding possible between the nitro group and the indolic N—H group. The N—H group of the low-melting isomer absorbed at 3420 cm^{-1} (dilute $CHCl_3$ solution), which is a lower frequency than is the N—H stretching band of δ-carboline (3450 cm^{-1}, $CHCl_3$ solution). The N—H group of *N*-methyl-*o*-nitroaniline absorbs at 3415 cm^{-1}. Unfortunately, the extreme insolubility in solvents suitable for infrared studies of the high-melting isomer made it impossible to determine its N—H stretching frequency under the same conditions. Spectra of the nitro compounds measured by the KBr disk technique did not give sharp N—H bands, so that the frequencies could not be accurately determined. The asymmetric and symmetric NO_2 frequencies could, however, be compared in this way. The bands for the low-melting isomer were at 1518 and 1320 cm^{-1} respectively, whereas the corresponding ones for the high-melting isomer appeared at 1528 and 1328 cm^{-1}. The lower frequencies for the low-melting nitro compound could be due to hydrogen bonding, a conclusion similar to that drawn by Hathway and Flett, who studied the infrared spectra of some *o*-nitronaphthylamines (20). It has been reported that *o*-nitroaniline absorbs at longer

Numbering here applies to the α- and β-carbolines. See also the following footnote.

†*Note that the numbering in the γ- and δ-carboline ring systems is different from that in the α- and β-isomers (19).*



(I)

wavelengths in the ultraviolet than do the para and meta isomers (21). Also, 1-nitrocarbazole absorbs in the visible region at 403 mμ (22). The ultraviolet absorption spectrum of the low-melting nitro-δ-carboline has a band at 385 mμ which tails into the visible region, whereas the high-melting compound does not absorb appreciably in the visible. Finally, the hydrogen-bonded structure is supported by the *relatively* low melting point of (VI).

The structure of the high-melting nitro-δ-carboline as (V) was confirmed by reducing it to the corresponding amine, which gave a positive test for a *p*-phenylenediamine with a primary amino group (23).

An attempt was made to study the pattern of nucleophilic substitution in δ-carboline. When (I) was treated with phenyllithium an insoluble *ind-N*-lithium salt was formed and no further reaction occurred. The reaction was repeated using the very small quantity of *ind-N*-methyl-δ-carboline on hand instead of (I); a low yield of a basic product exhibiting bands at 690 and 765 cm^{-1} (monosubstituted phenyl) was obtained, but in insufficient quantities to permit characterization. Reduction of δ-carboline with sodium and butanol proved to be difficult and in most cases starting material was recovered. Under more vigorous conditions over half of the δ-carboline was unchanged but the crude mixture (from which no other product could be isolated in a pure state) gave a positive Ehrlich test. Acetylation of the crude reaction mixture did not lead to the isolation of any pure reduction product. Catalytic reduction of δ-carboline was also attempted using 5% ruthenium on charcoal at 100° and 1350 p.s.i. of hydrogen; unchanged δ-carboline was recovered. It is not clear why δ-carboline should be more difficult to reduce than the other carbolines.

Paoloni (15) has estimated the dipole moments of the four carbolines from his molecular orbital calculations. His predicted value for δ-carboline is 3.90 D. The dipole moment of δ-carboline in benzene at 20° was kindly determined for us by Dr. G. F Wright and found to be 4.92 D, slightly more than 1 D greater than the calculated value. This result, together with the fact that there is a lack of correspondence between the calculated (15) and measured (1) ultraviolet absorption bands of δ-carboline, point to the limitations of the simple molecular orbital calculations in this case.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured with a Perkin–Elmer Model 21 instrument equipped with sodium chloride optics. Ultraviolet absorption spectra were measured on a Cary Model 14 recording spectrometer.

Cyclohexanone 3-Pyridylhydrazone

3-Hydrazinopyridine (3.91 g) was heated under reflux with a solution of cyclohexanone (2.8 ml) and pyridine (4 ml) in ethanol for 4 hours. The reaction mixture was poured into water and the crystalline precipitate filtered. Recrystallization of the crude product (4.82 g) from aqueous ethanol (charcoal) gave the *hydrazone* as pale yellow-brown crystals, m.p. 139–141° (decomp.). Calc. for $C_{11}H_{15}N_3$: C, 69.81; H, 7.99. Found: C, 69.73; H, 7.88.

Fischer Cyclization of Cyclohexanone 3-Pyridylhydrazone—6,7,8,9-Tetrahydro-δ-carboline and 5,6,7,8-Tetrahydro-β-carboline

Cyclohexanone 3-pyridylhydrazone (2 g) was intimately mixed with zinc chloride dihydrate (7 g) and the mixture heated in a metal bath at 250–260° (bath temperature) with occasional stirring. After the initial vigorous reaction was over (6 minutes) heating was continued for an additional 5 minutes. The cooled melt was dissolved in 10% hydrochloric acid, filtered to remove a small amount of brown solid, basified with 2 *N* sodium hydroxide, and extracted with ether. The dried (Na_2SO_4) ether solution was evaporated and left behind a brown oil which solidified (1.7 g).

The crude mixture (3.1 g) was chromatographed on a column of neutral alumina. Elution with benzene – light petroleum (b.p. 60–80°) (5:1) gave *6,7,8,9-tetrahydro-δ-carboline* (1.66 g) which, after recrystallization from benzene or from aqueous ethanol, melted at 199–200°. Calc. for $C_{11}H_{12}N_2$: C, 76.71; H, 7.02. Found:

C, 76.71; H, 7.16. λ_{max} 230, 260, 290 mμ; $\epsilon \times 10^{-3}$ 28.30, 9.54, 9.32. Elution with ether–benzene (1:1) gave a brown solid (1 g) which, on recrystallization from aqueous alcohol, gave *5,6,7,8-tetrahydro-β-carboline* as white leaflets, m.p. 197–198°. Found: C, 76.86; H, 7.17. λ_{max} 229, 267, 300 mμ; $\epsilon \times 10^{-3}$ 29.00, 7.45, 5.85.

δ-Carboline

6,7,8,9-Tetrahydro-δ-carboline (1.43 g) was dissolved in hot mesitylene (15 ml), and 10% palladium–charcoal (225 mg) added. The suspension was boiled under reflux for 8 hours, a second lot of catalyst (225 mg) was added, and heating was continued for an additional 10 hours. The reaction mixture was diluted with benzene, the catalyst filtered, and the cooled filtrate saturated with dry hydrogen chloride. The crystalline hydrochloride was filtered, washed with ether, dissolved in water, and the solution made alkaline to give δ-carboline (1.2 g), m.p. 207–208°, after recrystallization from benzene. The melting point was not depressed on admixture with an authentic sample (1) of δ-carboline. The infrared spectra of the two samples were identical. The melting point of the methiodide (249–250°) was not depressed on admixture with an authentic sample of *py-N*-methyl-δ-carbolinium iodide (1).

β-Carboline

Prepared similarly from 5,6,7,8-tetrahydro-β-carboline (300 mg), β-carboline (290 mg) was obtained as fine white needles, m.p. 197–198°. The melting point of the methiodide was not depressed on admixture with an authentic sample (1) of *py-N*-methyl-β-carbolinium iodide.

Nitration of δ-Carboline

δ-Carboline (0.570 g) was stirred with concentrated nitric acid (6 ml) at room temperature for 2 hours, during which time the color of the solution changed to greenish-yellow and a precipitate separated. The precipitate was filtered, washed with water, and stirred with concentrated ammonium hydroxide. The solid was filtered, washed with water and with methanol, and recrystallized from pyridine to give *8-nitro-δ-carboline* (410 mg), m.p. above 360°. An analysis sample was purified by sublimation at 250° at 0.07 mm and recrystallization from pyridine. Calc. for $C_{11}H_7N_3O_2$: C, 61.97; H, 3.31. Found: C, 61.94; H, 3.50.

The acidic filtrate from the nitration mixture was basified with ammonia and extracted with chloroform. The dried (Na_2SO_4) chloroform solution was evaporated to give a bright yellow solid (202 mg), which was purified by chromatography on a column of alumina. Elution with benzene – light petroleum (b.p. 60–80°) gave *6-nitro-δ-carboline* (122 mg) which, after recrystallization from methanol, had m.p. 232–233°. Calc. for $C_{11}H_7N_3O_2$: C, 61.97; H, 3.31. Found: C, 61.66; H, 3.44. The compound was initially obtained in the form of yellow needles. On being kept under cold methanol these gradually changed to prisms having the same melting point.

8-Amino-δ-carboline

8-Nitro-δ-carboline (410 mg) was suspended in concentrated hydrochloric acid (4 ml), and a solution of stannous chloride dihydrate (2.15 g) in concentrated hydrochloric acid (6 ml) was added. The mixture was heated on the steam bath with stirring for 1.5 hours, cooled, and basified. Extraction with ether gave the crude amine (347 mg), which was difficult to purify and which was discolored on standing. It gave a blue-black precipitate when oxidized with potassium persulphate in the presence of aniline, a test characteristic of a *p*-phenylenediamine derivative with a free primary amino group (23). Attempted acetylation of the amine using a procedure described in Vogel's "Practical organic chemistry" (24) led, instead, to the analytically pure *amine monohydrochloride*, m.p. above 300° (from methanol). Calc. for $C_{11}H_9N_3$,HCl: C, 60.14; H, 4.56. Found: C, 60.22; H, 4.20.

ACKNOWLEDGMENTS

This work was carried out during the tenure (by K. A. H. A.) of a C.I.L. Scholarship (1960–1961). Financial support from the National Research Council is gratefully acknowledged. The authors wish to thank Dr. G. F Wright (Toronto) for the determination of the dipole moment of δ-carboline.

ENERGY BARRIERS AND STRUCTURE OF *cis*-, MUCO-, AND ALLO-INOSITOL HEXAACETATES IN SOLUTION[1]

S. BROWNSTEIN
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received September 29, 1961

ABSTRACT

The proton resonance spectra of *cis*-, muco-, and allo-inositol hexaacetates as a function of temperature yield enthalpies of activation and Arrhenius factors for some of the skeletal oscillations of the six-membered ring.

INTRODUCTION

When the location of substituents on a cyclohexane ring is such that one conformation is strongly favored, proton resonance spectroscopy may often be used to determine axial and equatorial substituents and the conformation of the ring (1–4). In those cases where rapid inversion of the chair form of the cyclohexane ring exchanges the substituents between axial and equatorial positions only an averaged signal is observed. However, by lowering the temperature to reduce the rate of inversion it is often possible to observe the individual conformations and determine the rate of inversion (5–9). When the rate of exchange of a substituent between an axial and equatorial position is comparable to the difference in chemical shift between them, the spectral lines corresponding to the individual positions merge to a single averaged line. This yields a single rate measurement, and an Arrhenius factor of 10^{13} has been assumed to obtain the enthalpy of activation. Quantitative calculations of line shape as a function of exchange rate have been made (10–12), enabling exchange rates to be determined over a temperature range. In the cyclohexane system for those cases where the Arrhenius factor was obtained by nuclear magnetic resonance methods values of $10^{10.1}$, $10^{14.3}$, and $10^{16.6}$ were found (6, 9).

The results obtained in the present study also indicate that the "normal" Arrhenius factor may be a poor approximation in the cyclohexane system.

An investigation of ring inversions for some monosubstituted cyclohexanes by ultrasonic relaxation yields "normal" Arrhenius factors (13). The activation energies are in agreement with those obtained by proton resonance measurements (7). From the limited results available it is difficult to determine under what circumstances "normal" Arrhenius factors may be assumed. It is also proposed that the ring inversion may occur via a chair–planar–chair pathway analogous to the Alg vibrational mode in cyclohexane (13). The limited data presently available suggest that a solution of the problem of ring inversions in the cyclohexane system will require careful examination of many more compounds. The results for a few compounds are presented in this paper.

DISCUSSION

The geometrical relationship of the substituents in *cis*-, allo-, and muco-inositol hexaacetate as a planar model and in the chair forms is shown in Fig. 1. The acetate groups are shown but the protons attached to the cyclohexane ring are not indicated. In these three isomers an inversion of the chair form of the cyclohexane ring causes the three

[1]*Issued as N.R.C. No. 6742.*

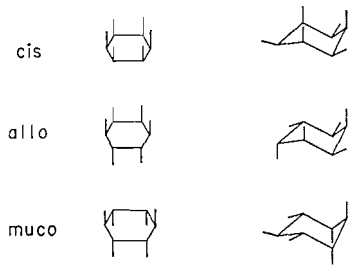

FIG. 1. The relationship of the substituents in *cis*-, allo-, and muco-inositol hexaacetates.

axial substituents to become equatorial and vice versa, resulting in an identical conformation. Therefore changes in the proton resonance spectrum with temperature will only reflect a change in the inversion rate since contributions from varying amounts of two conformations cannot occur.

In Fig. 2 some representative spectra of these compounds are shown. The rate constants are obtained by fitting the observed spectra with those theoretically calculated in the

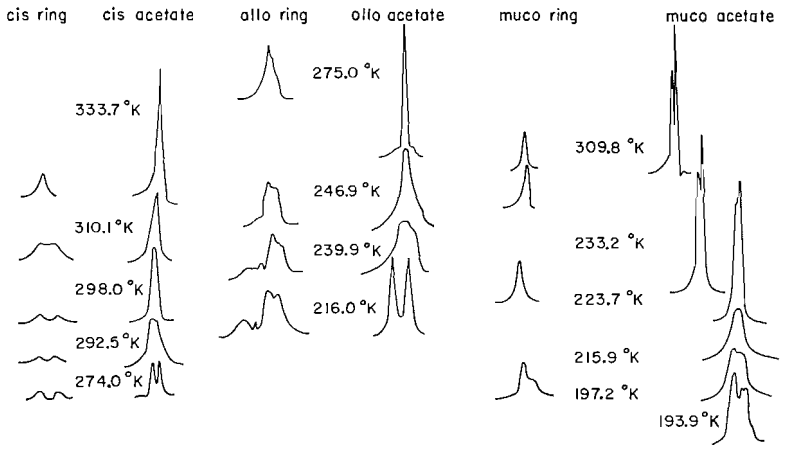

FIG. 2. Proton resonance spectra of inositol hexaacetates.

case of the cis and allo isomers (12, 14). For the muco isomer two magnetic averaging mechanisms are occurring. The one which is observed at low temperatures yields a complex pattern of overlapping lines which cannot be rigorously analyzed. However, the rate of this averaging process can be estimated as 12.5 sec^{-1} at 197.2° K from the coalescence of the individual peaks at this temperature. If the assumption is made that the Arrhenius factor for this averaging process is the mean of those observed for the cis and allo isomers an enthalpy of activation of 4.7 kcal/mole is obtained. There will be considerable uncertainty in this value because of the approximate nature of the rate and the assumption of a value for the Arrhenius factor. The magnetic averaging which is observed at high temperatures causes the merging of the two sharp peaks due to the acetate protons.

It was not possible to obtain sufficiently high temperatures to cause complete merging of the separate acetate peaks in the muco isomer. The rates were calculated from the decrease in separation of the lines, assuming they had a negligible width (15). The results

are plotted in Fig. 3 and the thermodynamic quantities are listed in Table I. These were derived from a least-squares fit of the experimental points except for the low-temperature

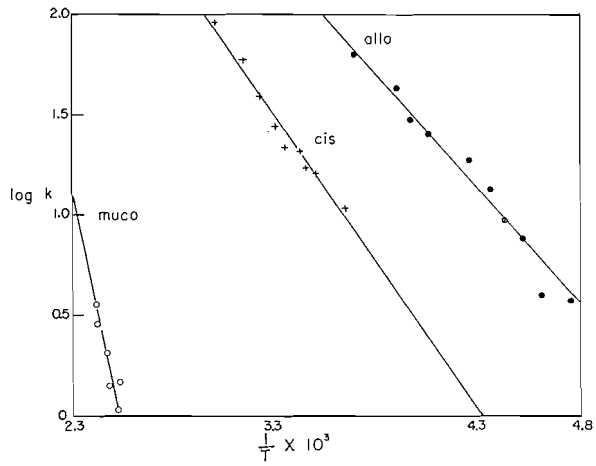

FIG. 3. Temperature dependence of the inversion rate.

TABLE I

Activation enthalpies and Arrhenius factors for ring oscillations of some inositol hexaacetates

Isomer	ΔH^*	log A
cis	6.60±0.05	6.24
allo	5.48±0.05	6.26
muco	4.7	6.25
	20.2±2	11.2

averaging for the muco isomer, as described previously. The greater uncertainties for the high-temperature averaging for the muco isomer are readily explained by the error inherent in measuring the separation of two lines which are at most 1.91 cycles apart. The assumption of negligible line width may also be expected to introduce an error.

In the chair form of the cis isomer there are two groups of three geometrically identical acetate substituents and a similar arrangement of hydrogens attached to the cyclohexane ring. The proton resonance spectrum, when inversion is sufficiently slow, has two peaks of equal intensity for both the acetate groups and the ring protons, which agrees with this structure. For the chair form of the allo isomer there are three equatorial and three axial acetate groups but all those in a given group are no longer identical. Nevertheless two peaks of equal intensity may be observed for the acetate protons. A complex trace is obtained for the ring protons which indicates the variety of environments. This too agrees with the chair structure for the allo isomer.

In the chair form of the muco isomer there are also three equatorial and three axial acetate groups, with those in a given group not identical. Therefore when inversion is slow one would expect either two peaks of equal intensity or more than two peaks. Similarly for the ring protons a complex trace might be expected. If inversion between the two chair forms of the cyclohexane ring is rapid this still does not average all the acetate groups. In a given conformation there is one equatorial acetate group which has an

equatorial acetate on each side of it. There is also an axial group with axial acetate groups on each adjacent ring carbon atom. When inversion to the other chair conformation occurs these two groups exchange environments and appear in an average magnetic environment if the rate of exchange is sufficiently rapid. Similarly there are two equatorial and two axial acetate groups, each of which is situated between an axial and an equatorial group. Inversion of the cyclohexane ring can also average the environment of these four acetate groups. However, the environments of the two and the four acetate groups remain unique. This can be visualized by inspection of the chair conformation of muco-inositol hexaacetate shown in Fig. 1.

The observed spectra agree with this interpretation. At the lowest temperature a complex spectrum containing at least three peaks is observed, as shown in Fig. 2. A total of four peaks with intensity ratio 1:2:2:1 might occur. However, overlap of two of these would give rise to the observed spectrum. As the temperature is raised a two-line pattern is eventually obtained, with intensity ratio of 2:1. This corresponds to rapid inversion of the chair form of the cyclohexane ring. At still higher temperatures the separation between the lines decreases from 1.9 to 1.4 cycles at the highest temperature reached. This requires an additional averaging mechanism. Conversion to the boat form might possibly be such a mechanism.

In Fig. 4 are shown four possible conformations when the ring is in a boat configuration.

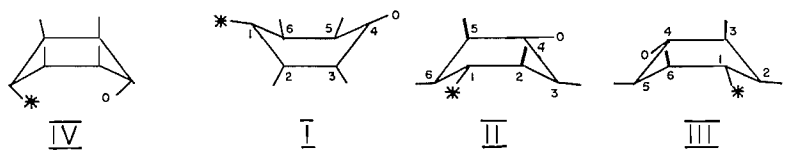

FIG. 4. Boat conformations of muco-inositol hexaacetate.

In conformation I all six acetate groups are in a pseudoequatorial location. However, the two distinguished by marks are not equivalent to the other four. If the ring inverts conformation IV is obtained. This is not equivalent to conformation I since now all six acetate groups are in pseudoaxial positions. A great deal of steric repulsion may reasonably be expected between the acetate groups, causing this conformation to have a much higher energy than conformation I. The ring protons in conformation I will all be axial and will have the same configuration as shown for the acetate groups in conformation IV. Another mode of motion for the boat form of the cyclohexane ring allows an infinite number of intermediate configurations without altering the carbon–carbon bond angles (16). When substituents are placed on the cyclohexane ring to give the stereochemistry of muco-inositol hexaacetate the possibilities are reduced to those shown by conformations I–III. Conformation II may be generated from conformation I by a rotation about all the carbon–carbon bonds of the cyclohexane ring. Atoms 3 and 6 are now at the prows of the boat instead of 1 and 4. By a further rotation atoms 2 and 5 take up this position as shown in conformation III. Conformations II and III are identical, except for a mirror image transformation because labels are on two of the acetate groups. However, they are not the same as conformation I.

The two acetate groups which are averaged by chair–chair inversion of the cyclohexane ring correspond to those at the prows of the boat. They will still be different from the other four acetate groups. Even though the same groups of two and four remain non-equivalent

during a chair–boat conversion magnetic averaging will still occur provided that the magnetic environment of the two acetate groups is different in the boat conformation I than in the average of the two chair conformations. A similar situation will apply for the four equivalent acetate groups. An averaging of all six acetate groups could occur by transformations among conformations I, II, and III. Since conformations II and III contain two axial acetate groups they might be of higher potential energy than conformation I and the extent of this type of magnetic averaging is difficult to estimate.

In the chair–chair inversion of *cis*-inositol hexaacetate all six acetate groups have to pass by each other. In the allo isomer four pairs are adjacent during inversion and in the muco isomer only two pairs. The observed enthalpies of activation also decrease in this order. Since a chair–chair inversion is presumably involved in all three of these averaging processes it may be safe to assume a similar Arrhenius factor for the muco isomer. The magnetic averaging observed at high temperatures for the muco isomer must occur by a different mechanism, resulting in a very different Arrhenius factor.

EXPERIMENTAL

The proton resonance spectra were obtained on a Varian Associates high-resolution nuclear magnetic resonance spectrometer operating at 56.4 Mc/sec. The spectra were calibrated using side-band modulation, with the modulating frequency altered during recording of the spectra. The modulating frequencies were determined to 0.1 cycle/sec by counting with a Hewlett Packard Model 521C frequency counter. By averaging many determinations peak positions were determined to an accuracy of 0.1 cycle/sec for muco-inositol hexaacetate. This accuracy was not necessary for the other isomers since line shapes rather than peak positions were used to calculate the inversion rates. Since the widths of the resonance lines due to the inositol acetates were often temperature dependent they could not be used as a criterion of instrument resolution. The width at half height of a modulation sideband from the solvent signal was used to determine resolution. This width was between 0.5 and 1.1 cycle/sec in all the measurements.

The thermostated probe assembly has been described previously, but was modified by using polyurethane-foam-jacketed glass tubes to introduce the thermostating gas, and by attaching the outlet to a water aspirator to increase the pressure differential across the probe assembly (17). A temperature range of $\pm 140°$ C could be obtained. Chloroform solutions of the acetates were used. Purity of the inositol acetates was determined by vapor phase chromatography to be 97% for the allo isomer, 99% for the cis isomer, and 99.8% for the muco isomer.

ACKNOWLEDGMENTS

The author is indebted to Professor S. J. Angyal for kindly supplying the inositol hexaacetates and a description of their purity. A referee suggested the low-temperature measurements of the muco isomer.

THE PROTON MAGNETIC RESONANCE SPECTRA OF CHRYSANTHEMUM ETHYL ESTER AND THE RELATED *cis*- AND *trans*-CHRYSANTHEMUMIC ACIDS

H. M. Hutton and T. Schaefer
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received November 24, 1961

ABSTRACT

The high-resolution proton magnetic resonance spectra of a mixture of the cis and trans isomers of chrysanthemum monocarboxylic acid ethyl ester have been studied. The *cis*-chrysanthemumic and *trans*-chrysanthemumic acids spectra were obtained to facilitate the interpretation of the complex spectra of the ester. The percentage of the trans isomer in the chrysanthemum ester was measured to be 62.0±1.1%. The cyclopropane proton spin coupling constants were found to be $J_{cis} = 8.7$ c.p.s. and $J_{trans} = 5.4$ c.p.s., in reasonable agreement with Karplus' calculations of the dependence of coupling constants on the dihedral angle.

INTRODUCTION

There have been no unequivocal measurements of the cis and trans proton coupling constants in the cyclopropane ring. In the present work the analyses of the *cis*- and *trans*-chrysanthemum ester and the corresponding acids were used to obtain these values. The chrysanthemum ester sample was a mixture of both the cis and the trans isomers, making a complete assignment of spectra lines difficult. It was found more convenient to analyze the *cis*- and *trans*-chrysanthemumic acids separately in order to identify the resonance peaks. Since the two ring protons interact only with the isobutenyl proton the analysis was that of an ABX-type system.

It was necessary to use solvents which preferentially shifted the proton signals in such a manner that the resonance peaks of the ring protons were not obscured by the other peaks. Carbon disulphide was used for the *cis*-chrysanthemumic acid and benzene for the trans acid.

EXPERIMENTAL

The spectra were obtained on a Varian V4302 DP 60 Mc/s spectrometer at room temperature. The line separations were measured by the side-band technique, using a Hewlitt and Packard 521c frequency counter. The chrysanthemum ester (min. 95%), the *cis*-chrysanthemumic acid (99.9%), and the *trans*-chrysanthemumic acid (100%) were of known purity as supplied by Benzol Products Co., and were not purified further. Since the acids were of limited solubility saturated solutions were used; the ester concentrations were approximate by volume since the solvents were only used to obtain preferential proton shifts. Internal benzene was used as the reference point in the measurement of the shifts.

ANALYSIS

I. cis-Chrysanthemumic Acid in CS_2

The spectrum of the *cis*-chrysanthemumic acid is shown in Fig. 1 together with the calculated spectrum for the ring protons corresponding to the AB part of an ABX system. The X part of the spectrum, at 114 c.p.s. with respect to internal benzene, consists of two doublets whose components are further split by the two isobutenyl methyl groups. The peaks of the latter occur at 324 c.p.s. and 328 c.p.s. The methyl groups attached to the cyclopropane ring have the same shift and occur at 357 c.p.s. The carboxyl proton peak is situated at −287 c.p.s. and is not shown in Fig. 1. The results of the ABX analysis gave J_{AB} (cis) = 8.7 c.p.s., $J_{AX} = 8.1$ c.p.s., $J_{BX} \approx 0$ c.p.s. The coupling constant of the X proton to the isobutenyl methyl group protons was about 1.4 c.p.s.

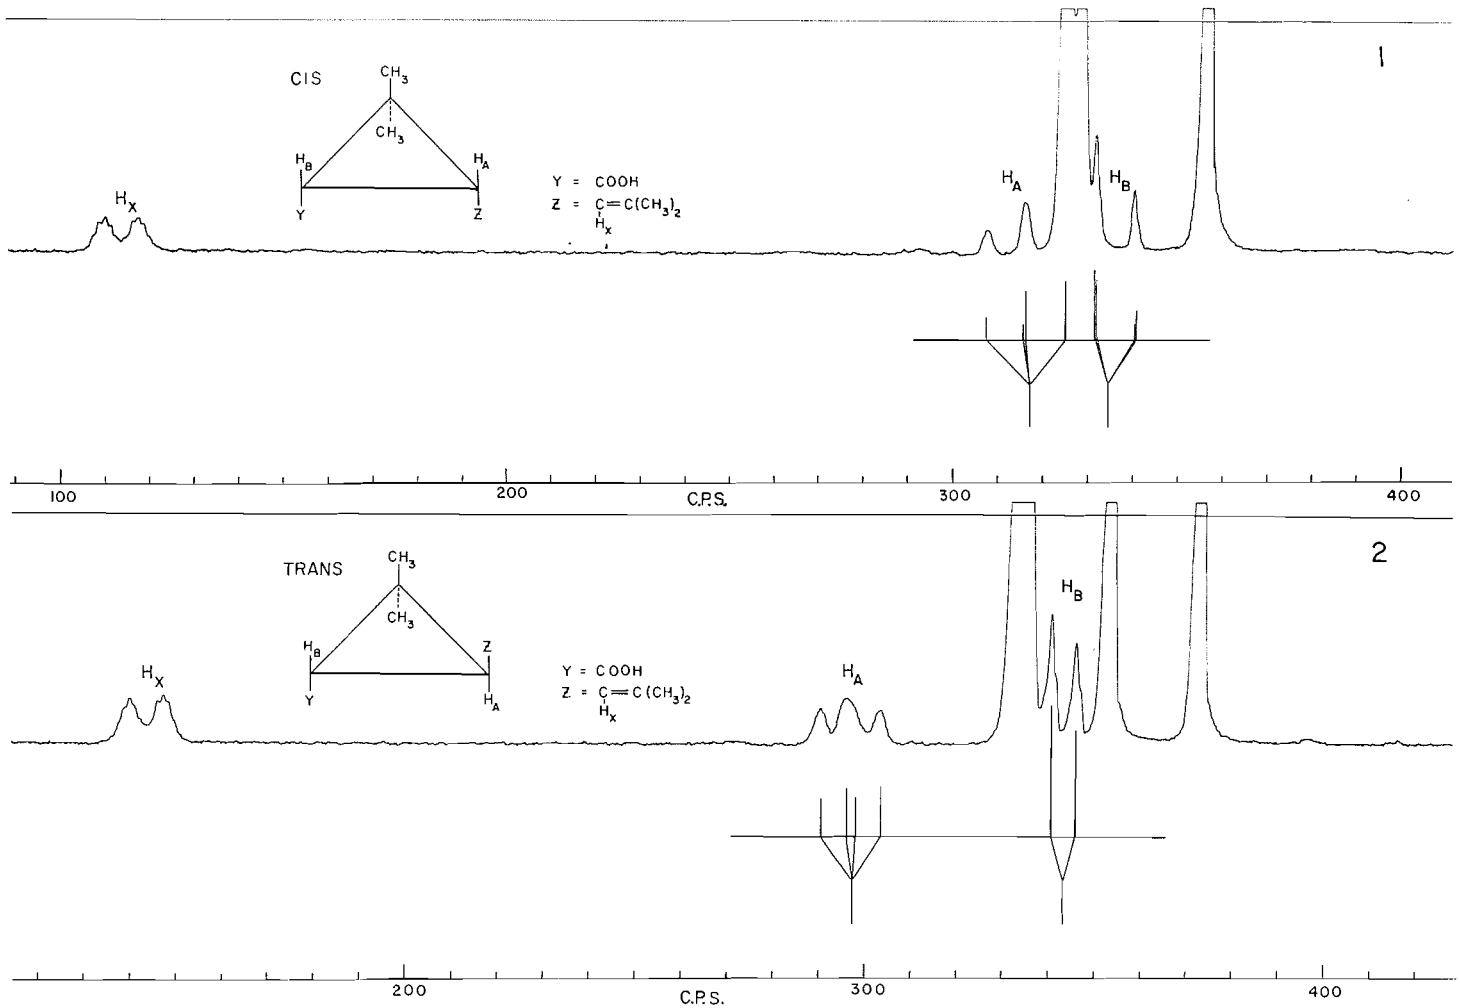

FIG. 1. Proton resonance spectrum at 60 Mc/s of *cis*-chrysanthemumic acid saturated in CS_2; calibration is with respect to internal benzene.
FIG. 2. Proton resonance spectrum at 60 Mc/s of *trans*-chrysanthemumic acid saturated in benzene; calibration is with respect to internal benzene.

II. Trans-Chrysanthemumic Acid in Benzene

The proton spectrum is shown in Fig. 2 together with the calculated spectrum for the ring protons corresponding to the AB part of an ABX system. The X part of the spectrum, at 144 c.p.s. from internal benzene, consists of two doublets whose components are further split by the isobutenyl methyl groups by about 1.4 c.p.s. The isobutenyl methyl group peaks occur at 335 c.p.s. The two methyl group peaks attached to the ring occur at 353 c.p.s. and 373 c.p.s. The results of the ABX analysis gave J_{AB} (trans) = 5.4 c.p.s., J_{AX} = 7.6 c.p.s., $J_{BX} \approx 0$ c.p.s.

III. Chrysanthemum Ester

The spectra of the chrysanthemum ester is given in Fig. 3 with the interpretation and the assignment of peaks relative to internal benzene in Table I. The coupling constants have been included in Table II.

*Measurements are with respect to internal benzene.

Since the ethyl group in the cis isomer is in a different magnetic environment than the ethyl group in the trans isomer, the cis and trans CH_3 resonance peaks are slightly shifted from each other. Similarly the —CH_2 peaks are displaced from each other as is shown in Fig. 3. From spectra of the ester mixture the percentage of the *trans-* and *cis-*chrysanthemum isomers was readily calculated by taking advantage of this displacement of the CH_2 lines in the cis and trans esters. A comparison of the heights of corresponding

resonance peaks gave the percentage of the trans isomer. A more accurate method would be the comparison of peak areas but since the peak widths are no doubt very nearly the same this first method was thought to be sufficient for our purpose. Within experimental error the same percentage, 62.0±1.1% trans isomer, was obtained for the ester neat, in benzene, and in carbon disulphide. A previous infrared study gave 65% trans ester (1).

DISCUSSION

(a) Cyclopropane

Karplus has expressed the coupling constant between protons *a* and *b* in the fragment H_a—C—C—H_b as a squared cosine function of the dihedral angle (2). A consideration of the electron-diffraction results of Hassel and Viervoll for cyclopropane yield 0° and about 147° for the dihedral angle between the cis-vicinal and trans-vicinal protons, respectively (3). Karplus then predicts 8.2 c.p.s. and 6.4 c.p.s. for the cis and trans coupling constants, respectively, compared to 8.7 c.p.s. and 5.4 c.p.s. found experimentally. It is not impossible that the large groups in our substituted cyclopropanes distort the dihedral angles somewhat. It is, however, gratifying to see a rough agreement between calculated and observed values.

It had been thought that Karplus' calculation did not apply to the cyclopropane ring (4). Jackman found $J_{cis} = J_{trans} = 6.3$ c.p.s. from an analysis of *trans*-1,2-dibromocyclopropane (4). The triplet proton resonances observed for the CHBr groups in this A_2X_2 system was taken as evidence that J_{cis} and J_{trans} are equal. It is perhaps possible that J_{gem} is large enough to obscure differences in J_{cis} and J_{trans} and that the value of 6.3 c.p.s. actually represents an average of J_{cis} and J_{trans}. There may also be a small effect depending on the electronegativity of the substituent. Small effects have been observed in substituted ethanes for which the H—C—C—H coupling constant is given by $8.4-0.4\,E$, where E is the electronegativity of the substituent (5). The smaller value of 6.3 c.p.s. found by Jackman as compared to our average of 7.0 c.p.s. is in the right direction. From data on over 100 substituted ethylenes a definite correlation has been established between the electronegativity of the *atom in the substituent group attached to the vinyl carbon* and the values of the proton coupling constants (6, 7). Such electronegativity effects are larger for unsaturated systems such as the ethylenes than for the ethanes.

The proton coupling constants for cyclopropane itself have been measured from the C^{13} satellites of its proton spectrum (8). The value of 7.5±0.5 c.p.s. quoted for both the

cis and trans coupling constants is, no doubt, an average value for reasons which are now well known (9).

A recent publication gives the proton spectrum of thujopsene and hinokiic acid (10). Only the X part of the spectrum is visible and one obtains only the sum of J_{cis} and J_{trans}. This is 14.0 c.p.s., a value entirely in keeping with our sum of 14.1 c.p.s.

(b) Comparison with Other Ring Systems

In Table III there are collected the calculated and observed proton coupling constants for eight different values of the dihedral angle. They are taken from data given for

three-, five-, and six-membered rings and include the judicious measurements of Anet (11, 12). The six-membered rings are assumed to exist in one conformation only (12). A certain amount of distortion from the assumed dihedral angle is possible for most of these rings but the overall agreement between theory and experiment is encouraging.

On the other hand, values of proton coupling constants in three-membered rings containing the heteroatoms oxygen, nitrogen, and sulphur do not agree very well with Karplus' predictions (13, 14) although the ratios of cis to trans coupling constants are roughly those predicted by Karplus. It is interesting to note that the deviation from the predicted values increases with the difference in electronegativity between the heteroatoms and carbon. The deviation is in the same direction as for the substituted ethylenes mentioned above. For sulphur, with an electronegativity similar to that of carbon, the coupling constants are close to the value we have found for our cyclopropanes. The geometries of these molecules show relatively small changes (13), and it seems reasonable to assume that the couplings in these heterocyclic propanes depend not only on angular factors but also on the electronegativity of the heteroatom.

CONCLUSION

Unequivocal values for cis and trans proton coupling constants in the same cyclopropane ring have been observed. They fall reasonably well into the scheme devised by Karplus. A consideration of the proton coupling constants in heterocyclic propanes suggests that both angular factors and electronegativities are important in determining their magnitudes. It was also shown that the measurements of relative concentrations of geometrical isomers of substituted cyclopropanes can be measured rapidly in favorable cases by n.m.r. methods. Further work is needed to determine the gem coupling constant in cyclopropane derivatives. This is being done and a knowledge of all these types of couplings constant will facilitate the interpretation of quite complex spectra.

ACKNOWLEDGMENTS

We thank Dr. W. F. Ringk of Benzol Products Company for the compounds used in this work. One of us (H. H.) would like to thank Canadian Industries Limited for fellowship support. This work was supported by the National Research Council and the Research Corporation.

THE BASE-CATALYZED REARRANGEMENT OF N-ALKYL TRIPHENYLISOXAZOLIUM SALTS

J. F. KING AND T. DURST[1]
Department of Chemistry, University of Western Ontario, London, Ontario
Received January 17, 1962

ABSTRACT

The action of base on trisubstituted N-alkyl isoxazolium salts, first described by Kohler and co-workers (1, 2), has been reinvestigated. On the basis of photochemical and spectroscopic studies it is concluded that the reaction of the N-methyl triphenylisoxazolium ion (I*a*) with aqueous sodium hydroxide leads to 4,5,6-triphenyl-2*H*-1,3-oxazine (III), a derivative of a heterocycle previously known only in benz-fused systems.

In 1928, Kohler and Blatt (1) described the action of alkali on N-methyl triphenylisoxazolium "ferric chloride double salt" (I*a*). Among the materials produced was one obtained most readily by shaking the isoxazolium salt with dilute aqueous alkali and

ether for a few minutes and then separating and evaporating the ether layer. This they called the "anhydro compound" because of a presumed relation with some hydrated "pseudo bases". As possible representations of the "anhydro compound" they discussed structures II*a*, III, and IV, tentatively adopting II*a*; later Kohler and Richtmyer (2) considered II*a* as "definitely established". In the final communication of the series, Kohler and Bruce (3) described the preparation of an "anhydro compound" from the benzisoxazolium salt VI*c*, and assigned structure VII*c* to this compound.

Aliphatic Schiff bases are known to be reactive species readily undergoing polymerization and other addition reactions (4, 5). Those derived from formaldehyde are, in fact, apparently unstable under the usual conditions of their formation and only

VII*c*, R = CH_3

hydrolysis or—in the absence of water—trimerization products have been isolated. It seemed to us that the comparative stability of the "anhydro compound" from the triphenylisoxazolium ferrichloride (I*a*) was not compatible with structure II*a* and, further, it was felt that the nature of this and the other "anhydro compounds" could be shown by the use of modern physical and chemical methods not available to Kohler and his co-workers.

Accordingly, we have prepared compounds I*a*, VI*a*, and VI*b* (as the ferric chloride or perchlorate salts) and obtained crystalline "anhydro compounds" by what is essentially Kohler's procedure. In Table I are listed the ultraviolet maxima, infrared peaks in the

TABLE I

The "anhydro compounds" and model compounds: spectroscopic data

	ν_{max} (cm^{-1})	$\lambda\lambda_{max}$ (mμ) (ϵ, in parentheses)	δ (p.p.m.) from tetramethylsilane
"Anhydro compound" from I*a*	1626	239 (15,700) 338 (6,200)	5.58
"Anhydro compound" from VI*a*	1616	238 (10,900) 325 (1,700)	5.54
"Anhydro compound" from VI*b*	1610	240 (12,400) 329 (1,700)	6.39
Benzalaniline	1628	—	8.35

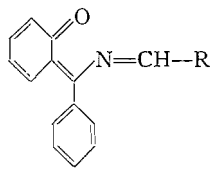
‡*AB* quartet, j = 11 cycles/sec.

carbonyl region, and the chemical shifts of hydrogens attached to the non-aromatic carbon atoms; unless otherwise noted the n.m.r. peaks are singlets.

In addition to structures II*a*, VII*a*, and VII*b*, which correspond to Kohler's proposals, structures III, VIII*a*, and VIII*b* for these three "anhydro compounds" are a priori possible. Structure IV in which the nitrogen has 10 valence electrons is, of course, not possible and the related ylide (V) would be much too unstable to be isolated under these conditions.

The single infrared maximum around 1620 cm^{-1} shown by each of the compounds is in accord with the cyclic structures III, VII*a*, and VII*b* being well within the range 1660–1480 cm^{-1} quoted by Bellamy (6) and similar to the C=N maxima of benzophenone anil (1623 cm^{-1}) and benzyliminobenzophenone (1626 cm^{-1}). The open-chain structures II*a*, VIII*a* and VIII*b*, on the other hand, would be expected to show two bands in this region.

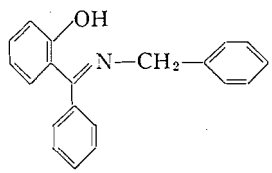


VIII*a*, R = H

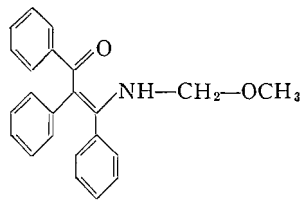
VIII*b*, R = ϕ

The observation of only one band can be rationalized only by assuming that the carbonyl and azomethine absorptions coincide, an assumption that is extremely tenuous since the absorption occurs outside the normal range of carbonyl groups not involved in hydrogen bonding.

The ultraviolet data also agree well with the cyclic structures. The long wavelength bands of the "anhydro compounds" derived from the benzisoxazoles (at 325 and 329 mμ, respectively) are very close to that of benzylimino-*o*-hydroxybenzophenone (IX), which is found at 328 mμ. The close similarity between the ultraviolet spectra of the two



IX



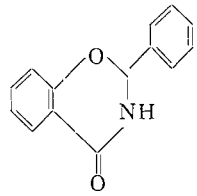
X

"anhydro compounds" derived from the benzisoxazole also argues in favor of the cyclic structures. In the open-chain structure VIII*b*, the "new" phenyl group is conjugated with the main chromophoric system, which would be expected to result in distinct differences in the spectrum. The ultraviolet spectrum of the "methanol adduct" (X) (the formation of which is discussed below) is of interest in connection with the structure of the triphenyl "anhydro compound". The long wavelength of band X is found at *longer* wavelengths (by 12 mμ) than the corresponding band in the "anhydro compound". Though on the basis of the cyclic structure (III) for the "anhydro compound" this is unremarkable, on the basis of structure II*a* it would mean that the conjugation of another double bond with the chromophore of X yields a distinct hypsochromic shift.

Though the nuclear magnetic resonance spectra of comparatively few model systems have been reported, again the cyclic structures are much more satisfactory for their interpretation than the acyclic. Protons bonded to an azomethine carbon evidently absorb at rather low field. Aliphatic aldoximes have been found at 6.3–7.0 p.p.m. (7), aliphatic aldehyde semicarbazones at 7.4–7.8 p.p.m. (8), and aliphatic aldehyde 2,4-dinitrophenylhydrazones at 6.8–7.2 p.p.m. (8). We have found that the azomethine proton of propyliminoacetaldehyde (XI) absorbs at 7.63 p.p.m and the corresponding protons of formaldehyde 2,4-dinitrophenylhydrazone at 6.73 and 7.12 p.p.m. The methylene protons of the "anhydro compounds" derived from the N-methyl isoxazolium salts (I*a* and VI*a*), however, are found at 5.58 and 5.54 p.p.m. The corresponding methine proton of the "anhydro compound" from the N-benzyl isoxazolium salt (VI*b*) absorbs at 6.39 p.p.m.; the azomethine proton of benzalaniline absorbs at 8.35 p.p.m.; the methine proton of the model compound XII (9) on the other hand is found at 6.22 p.p.m.

$CH_3CH{=}NCH_2CH_2CH_3$

XI



XII

It is evident that the n.m.r., infrared, and ultraviolet data individually agree—on the basis of expectations derived from the study of model systems—far better with the cyclic structures III, VII*a*, and VII*b* for the "anhydro compounds" than with the open-chain structures II, VIII*a*, and VIII*b*. In addition the data show a measure of agreement with one another which, independent of the model systems, strongly supports the same conclusion. The C=N bands in the infrared are in the same region, the ultraviolet spectra of the two benz-fused compounds are very similar, and the chemical shift of the methylene protons of the two "anhydro compounds" derived from N-methyl isoxazolium salts are virtually identical; the shift to lower field accompanying the replacement of one proton by a phenyl group is as expected.

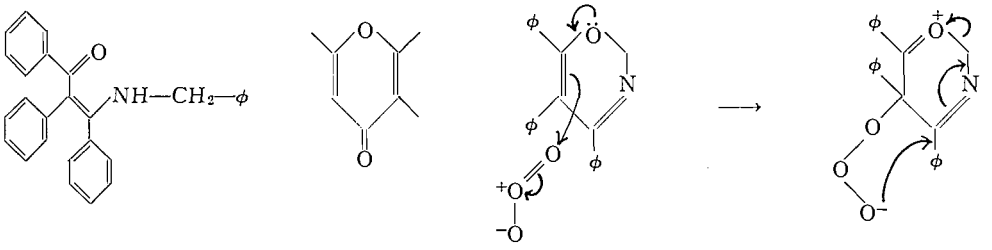
Following the conclusions from the physical data just discussed and anticipating those of the discussion of the chemical reactions of the compounds, we shall, for simplicity, describe the reactions in terms of the cyclic structures III, VII*a*, and VII*b*, and shall refer to the compounds by the corresponding names.

Kohler and Blatt (1) reported that the triphenyloxazine (III), on being refluxed with methanol for an hour, was converted to a "methanol adduct" to which he ascribed structure X. We have prepared this compound and have measured its infrared, ultraviolet, and n.m.r. spectra, which, coupled with Kohler's observation that the "methanol adduct" (like the oxazine (III) itself) hydrolyzes readily to dibenzoylphenylmethane, comprise good support for the structure (X) proposed by Kohler. The formation of X from the "anhydro compound" is readily rationalized on the basis of the oxazine structure (III) by assuming that under the conditions of the reaction the oxazine (III) is reversibly converted into the open-chain compound (II*a*); such a transformation is, formally at least, merely a variant on the familiar ring–chain tautomerism of oxazolidines, tetrahydrooxazines, and similar compounds.

Kohler and Blatt also reported (1) that the oxazine (III) reacts with phenyl magnesium bromide, giving the vinylamine XIII. Again this reaction probably proceeds via an open-chain intermediate, though it is likely that the ring opening is accelerated by complexing with the metal. The action of Grignard reagents on carbinolamine ethers to yield products derived from the corresponding Schiff bases has been frequently observed (10).

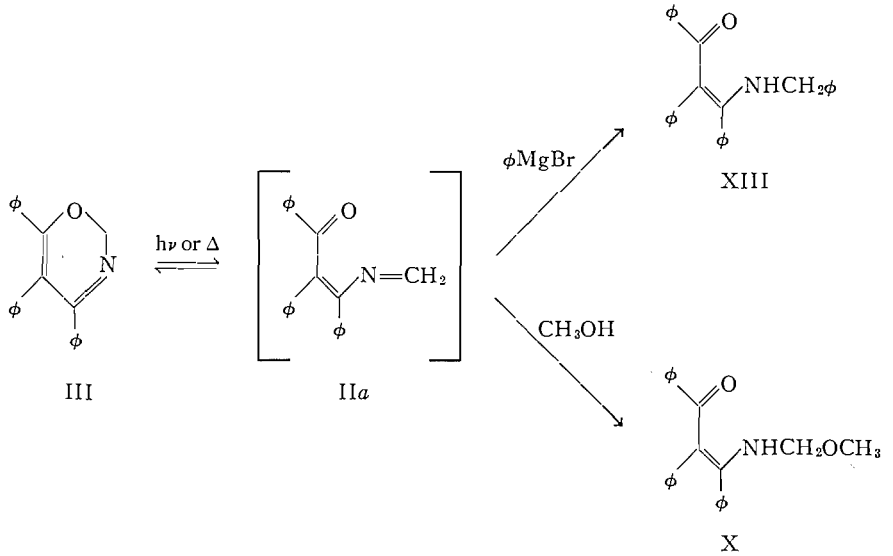
Kohler and co-workers (1, 2) described the action of ozone on the triphenyl "anhydro compounds"; most notably, ozonolysis of the "anhydro compound" from I*b* (in ethyl bromide solution at room temperature) gave *p*-bromobenzil and benzamide. They considered that the results of these experiments established the open-chain structures (II*a* and II*b*) for these compounds. It has already been shown, however, that structure II*a* for the "anhydro compound" derived from I*a* is far from satisfactory in explaining the spectroscopic data, and since ozone is a highly reactive species which may yield so-called abnormal products by a number of different mechanisms (11, 12), it is much more reasonable to propose that the root of the apparent anomaly lies with the ozonolysis rather than the physical data. The double bond in III bears an oxygen and a carbon–nitrogen

double bond; it is notable that a formally similar system in 2,3,6-trimethyl-4-pyrone (XIV) leads to "abnormal" ozonolysis products, methylglyoxal and biacetyl (13). The process XV → XVI (or its one-step equivalent) illustrates a possible mode of ozone addition which would yield abnormal cleavage products. It is, of course, also conceivable that the ozone is reacting with the small equilibrium concentration of the open-chain tautomer under the conditions of the reaction.



XIII XIV XV XVI

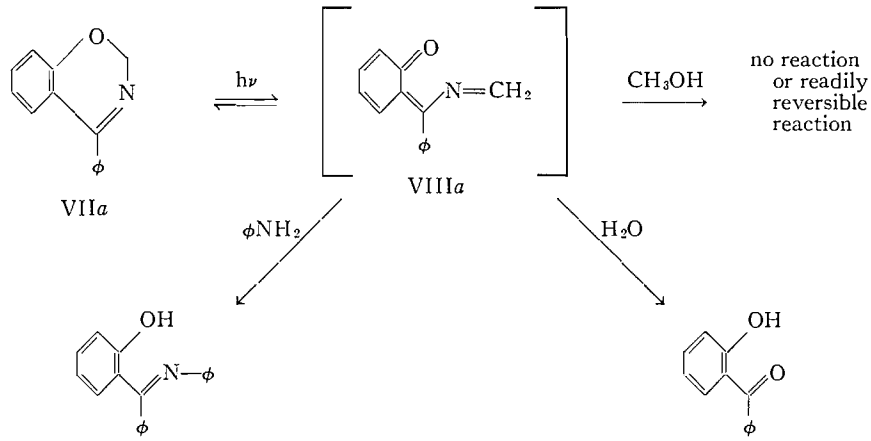
To provide further information about the nature of the "anhydro compounds" we have investigated some photochemical reactions of these compounds. Barton (14) has recently suggested that it is a general property of any ring of $2n$ members containing $(n-1)$ conjugated double bonds, when irradiated with light of the appropriate wavelength, to form an open-chain compound having n conjugated double bonds. It would be expected then that ultraviolet irradiation of III would yield II*a* and that if formation of the methanol adduct takes place via II*a*, the reaction might be accelerated by ultraviolet irradiation. We have, in fact, found that irradiation of a solution of the oxazine (III) in methanol at −60° leads to complete conversion to the methanol adduct (X) within 2 hours. The thermal reaction, which takes place rapidly in refluxing methanol and slowly at room temperature, is completely suppressed at −60°. These results are in accord with Scheme 1.



III II*a* XIII X

SCHEME 1

Irradiation of VII*a* and VII*b* would also be expected to yield the open-chain species VIII*a* and VIII*b*, respectively, though since the ring opening disrupts the aromatic system, it would be anticipated that these compounds would cyclize very readily, giving back starting materials. When a solution of VII*a* in dry methanol was irradiated, only starting material was isolated. When irradiated in methanol–ether (reagent grades) *o*-hydroxybenzophenone was obtained. Irradiation in dry methanol in the presence of aniline yielded the anil of *o*-hydroxybenzophenone. Without irradiation no reaction was observed either after refluxing with methanol–ether or on standing in the methanol–aniline mixture. These results agree with Scheme 2, analogous to Scheme 1.

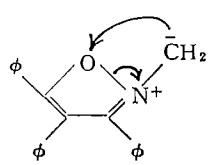


SCHEME 2

In addition to allowing ready rationalization and correct prediction of the thermal and photochemical addition reactions, the oxazine structures predict that the triphenyl compound (III) should be more reactive than the benz-fused compounds (VII*a* and VII*b*). On the other hand, reactions involving additions to structures VIII*a* and VIII*b* would lead to aromatic systems and hence should proceed more readily than the corresponding reactions with II*a*. The observed order of reactivity is that predicted on the basis of the oxazine structures III, VII*a*, and VII*b*.

From this study of the spectroscopic properties and a number of chemical reactions of Kohler's "anhydro compounds", we conclude that they are best represented by the oxazine structures III, VII*a*, and VII*b*. It appears that a "bare" (i.e. not fused to a benzene ring) 2*H*-1,3-oxazine, though a simple heterocyclic system, has not been reported previously; the "anhydro compound" (III) is evidently the first example of this type of heterocycle.

As reasonable mechanisms for the formation of the oxazine we suggest that an ylide (V), formed by abstraction of a proton by base, may either rearrange as indicated by the arrows in structure XVII (a process which is formally analogous to the Stevens rearrangement) or, alternatively, the ring of the ylide (V) may open to form II*a*, which then equilibrates with III.



XVII

EXPERIMENTAL

Infrared and nuclear magnetic resonance spectra were determined in dilute carbon tetrachloride solution using, respectively, a Beckman IR-7 grating spectrophotometer equipped with sodium chloride optics, and a Varian DP-60 spectrometer. Chemical shifts are reported in parts per million from internal tetramethylsilane. Ultraviolet spectra were determined in cyclohexane solution using a Beckman DK-1 instrument. Petroleum ether refers to the fraction of b.p. 35–60°. Melting points were determined on a Kofler block and are uncorrected.

*4,5,6-Triphenyl-2*H*-1,3-oxazine (III)*

This compound was prepared from N-methyl triphenylisoxazolium ferrichloride (I*a*) (m.p. 161–162°) as described by Kohler and Blatt (1) and melted at 140–141°; reported m.p. 140–141° (1).

3-Phenyl-1,2-benzisoxazole

The following procedure was found to be more satisfactory than that of Kohler and Richtmyer (2). *o*-Chlorobenzophenone oxime (15) (4.42 g) was dissolved in a mixture of 50% aqueous potassium hydroxide solution (30 ml) and ethylene glycol monomethyl ether (10 ml). The solution was refluxed and after about 1 hour had separated into two phases. After being heated for a further 6 hours, the mixture was cooled, yielding a crystalline product. Recrystallization from methanol gave 3.1 g (80%) of material melting at 82–83°.

N-Methyl-3-phenyl-1,2-benzisoxazolium Ferrichloride (VIa)

3-Phenyl-1,2-benzisoxazole (3.3 g) was added to freshly distilled dimethyl sulphate (15 ml) and heated at 125° for 24 hours. The solution was cooled and treated with 6 *N* hydrochloric acid. Ferric chloride solution (2 parts $FeCl_3$ to 1 part water) was added until the yellow salt precipitated; yield 6.25 g (90%); m.p. 117–119°. Calculated for $C_{12}H_{12}ONFeCl_4$: C, 41.22%; H, 2.97%; N, 3.35%. Found: C, 41.36%; H, 3.12%; N, 3.43%.

*3-Phenyl-2*H*-1,3-benzoxazine (VIIa)*

N-Methyl-3-phenyl-1,2-benzisoxazolium ferrichloride (5.25 g) was shaken for 15 minutes with ether (15 ml) and a 5% aqueous solution of sodium hydroxide (15 ml). The ether layer was washed with water, dried over anhydrous sodium sulphate, and evaporated, yielding a yellow oil (1.35 g, 50%). Addition of a solution of picric acid in ether gave a dimorphous yellow picrate, m.p. 103–104° (from methylene chloride – ether) and 158–160° (from glacial acetic acid). A solution of the picrate in methylene chloride was poured onto a column of basic alumina (Woelm, grade I); on elution with benzene a white solid was obtained which recrystallized from ether – petroleum ether as white needles, m.p. 49–50°. The infrared spectra of the crystalline and crude oily materials were virtually identical. Calculated for $C_{14}H_{11}ON$: C, 80.37%; H, 5.30%; N, 6.81%. Found: C, 80.64%; H, 5.28%; N, 6.69%.

N-Benzyl-3-phenyl-1,2-benzisoxazolium Perchlorate (VIb)

3-Phenyl-1,2-benzisoxazole (440 mg) was dissolved in benzyl chloride (3 ml), and a saturated solution of silver perchlorate (500 mg) in ether added. A white precipitate formed immediately, which was filtered off and triturated with methylene chloride. The mixture was filtered (to remove the silver chloride) and the filtrate evaporated to about 2 ml. Addition of ether gave white crystals (275 mg, 30%) which, after four recrystallizations from methylene chloride – ether, melted at 164–165°. Calculated for $C_{20}H_{16}O_5NCl$: C, 62.26%; H, 4.18%; N, 3.63%. Found: C, 61.86%; H, 4.26%; N, 3.41%.

*2,4-Diphenyl-2*H*-1,3-benzoxazine (VIIb)*

The perchlorate (VI*b*) (145 mg) was dissolved in methanol (5 ml) and a 5% aqueous sodium hydroxide solution (15 ml) added with stirring during 15 minutes. On work-up a crystalline material (89 mg, 84%) was obtained which recrystallized from methylene chloride – petroleum ether as white needles melting at 97–99°. Calculated for $C_{20}H_{15}ON$: C, 84.18%; H, 5.30%; N, 4.91%. Found: C, 83.87%; H, 4.90%; N, 5.19%.

*Irradiation of 4,5,6-triphenyl-2*H*-1,3-oxazine*

4,5,6-Triphenyl-2*H*-1,3-oxazine (III) (50 mg) was dissolved in a mixture of ether (20 ml) and methanol (2 ml). The solution was divided into two equal portions and each half placed in a glass-stoppered, 50-ml round-bottomed Pyrex flask. One flask was wrapped carefully with aluminum foil to allow as little light as possible to reach the inside, the other flask was not wrapped. The flasks were immersed in cold methanol contained in a stainless steel beaker cooled in a dry ice – methanol bath. The temperature of the methanol surrounding the reaction flasks was kept at $-60\pm5°$ during the experiment. A Hanovia C-H-3 ultraviolet lamp was placed in a Pyrex test tube and immersed in the methanol bath so that the light source was the same distance (ca. 2 cm) from each flask. After 90 minutes' irradiation both samples were removed from the bath and the solvent removed *in vacuo*. The infrared spectrum of the crude irradiated material indicated that it consisted largely of the "methanol adduct" (X); recrystallization gave X (17 mg), identified by comparison of the melting point and infrared spectrum with that of an authentic sample obtained by Kohler and Blatt's procedure (1). The infrared spectrum of the crude material from the shielded sample indicated it to be almost pure starting material, which, after recrystallization, was identified as III by melting point and infrared spectrum.

In a second experiment ultraviolet spectroscopy showed that the irradiated sample was converted to the methanol adduct in less than 2 hours and that no significant change took place with the shielded sample in 6 hours.

*Irradiation of 4-phenyl-2*H*-1,3-benzoxazine (VIIa)*

(a) In Methanol–Ether

4-Phenyl-2*H*-1,3-benzoxazine (450 mg) was dissolved in a mixture of ether (Mallinckrodt anhydrous, 85 ml) and methanol (Fisher Spectranalyzed, 85 ml), and the solution irradiated for 10 hours in a quartz immersion apparatus (16) using a Hanovia C-H-3 lamp. The solvent was evaporated and the material soluble in ether chromatographed on silica gel. Elution with petroleum ether – benzene (20:1) gave a yellow oil (200 mg), identified by its infrared and n.m.r. spectra as *o*-hydroxybenzophenone.

(b) In Dry Methanol

When the irradiation was carried out under the same conditions as in (*a*) but using as solvent methanol carefully dried by the magnesium methoxide procedure, only starting material was obtained.

(c) In Methanol–Aniline

4-Phenyl-2*H*-1,3-benzoxazine (450 mg) and freshly distilled aniline (1 ml) were dissolved in methanol dried by the magnesium methoxide procedure (170 ml), and the solution irradiated in the immersion apparatus. After about 10 minutes the solution began to redden and within ½ hour was a dark red. The irradiation was continued for 10 hours. The solvent was then evaporated and the residue triturated with methylene chloride. The methylene chloride solution was filtered through a silica gel column and the solvent evaporated, leaving yellow needles (205 mg), identified by melting point, mixed melting point, and infrared spectrum as the anil of *o*-hydroxybenzophenone (17). The proton magnetic resonance spectrum of the anil showed a singlet (due to hydrogen-bonded O—H) at 13.80 p.p.m. and a broad absorption at 6.7 to 7.3 p.p.m. due to the aromatic hydrogens.

*Treatment of 4-Phenyl-2*H*-1,3-benzoxazine (VIIa) with Methanol–Ether*

4-Phenyl-2*H*-1,3-benzoxazine (25 mg) was dissolved in a mixture of methanol (Fisher Spectranalyzed, 5 ml) and ether (Mallinckrodt anhydrous, 5 ml), and the solution refluxed for 12 hours. The solvent was evaporated; the infrared spectrum of the residue showed it to be unchanged starting material.

*Treatment of 4-Phenyl-2*H*-1,3-benzoxazine (VIIa) with Methanol–Aniline*

Aniline (0.2 ml) was added to a solution of 4-phenyl-2*H*-1,3-benzoxazine (10 mg) in dry methanol (15 ml), and the solution allowed to stand at room temperature for 16 hours. The infrared spectrum of the product showed it to be unchanged starting material.

ACKNOWLEDGMENTS

Valuable preliminary experiments in this study were carried out by Mr. R. S. Bernier. The n.m.r. spectrum of 4,5,6-triphenyl-2*H*-1,3-oxazine was obtained through the courtesy of Professor K. Wiesner, University of New Brunswick, Fredericton, N.B. Other n.m.r. spectra were determined in this department by Mr. R. E. Klinck and Dr. J. B. Stothers; we are especially grateful to Dr. Stothers for aid in the interpretation of the n.m.r. spectra.

The National Research Council of Canada has supported this work by grants-in-aid and a bursary.

THE CONDUCTANCE OF MOLTEN LITHIUM CHLORATE AND THE EFFECT OF ADDITIONS OF TRACES OF NONELECTROLYTES ON THE CONDUCTANCE

A. N. CAMPBELL, E. M. KARTZMARK, AND D. F. WILLIAMS[1]
Chemistry Department, University of Manitoba, Winnipeg, Manitoba
Received November 30, 1961

ABSTRACT

The specific conductance of pure molten lithium chlorate between 130 and 145° C was determined and an activation energy of conductance deduced. Additions of substances having various dielectric constants were made to molten lithium chlorate and the conductances determined. These additions were: (*a*) water, 0–6% by weight; (*b*) nitrobenzene, 0–0.4% by weight; (*c*) methyl alcohol, 0–1.25% by weight. The results are discussed.

Although much experimental work has emanated from this and other laboratories on the conductance and viscosity of concentrated aqueous solutions, over the last dozen or so years, a satisfactory theoretical treatment is still lacking. It is contended by many that the Debye–Hückel–Onsager treatment has been pushed to its limit when κa $(= (50.29\mathring{a}\sqrt{c})/(\epsilon T)^{1/2})$ becomes greater than 0.2, corresponding in most cases to a concentration not greater than 0.05 *M*. According to Fuoss, "It therefore seems futile to look for a solution to the problem of higher concentrations by an extension of the present theory which is, however, valid for low concentrations." (1)

Since the original great advances in the theory of conductance were made by the study of what has been called "slightly impure distilled water", it seemed to us that interest might now well shift to the study of molten salts, to which traces of impurity were added, more especially as we had at our disposal, in the form of lithium chlorate, a very low melting salt. The melting point of this salt lies at 127.8° C, and this is about 150° lower than that of any other simple salt. The present paper deals with the conductance of molten lithium chlorate, at a temperature slightly above its melting point, both pure and in the presence of trace addition. The theoretical treatment of the problem of conductance in melts is extensive, though somewhat inconclusive; it therefore seems to us best to limit this paper largely to an account of results obtained.

The electrical conductivities of aqueous solutions of lithium chlorate, ranging in concentration from dilute aqueous solutions to molten salt, were most recently determined by Campbell, Kartzmark, and Paterson (2), but for experimental reasons, there was a gap in the measurements between 90 and 100% lithium chlorate. This gap has now been filled.

EXPERIMENTAL

Lithium chlorate was prepared by the method of Kraus and Burgess (3), as modified by Campbell and Griffiths (4). Lithium chlorate is extremely hygroscopic and must be handled in a nitrogen-filled dry box. We used barium oxide to dehydrate the dry-box atmosphere. The final product ($LiClO_3$) was heated at 100° C, under high vacuum, for 6–8 weeks. The melting point obtained was 127.8° C.

Since we intended to admit, at first, only traces of water to the lithium chlorate, it was important that the lithium chlorate should be truly anhydrous. After abortive attempts at detection of water by infrared absorption, we were finally successful with gas chromatography. The method was as follows:

[1]*Holder of a Cominco Fellowship*, 1960–61.

A Precision Chromofrac VP-7 instrument was used: argon was the carrier gas. The instrument was calibrated for water by injecting samples of 0.01 ml ethyl alcohol containing known amounts of water. The lower limit of detection was found to be 1 part of water in 500 parts of alcohol, by volume. Lithium chlorate (31.101 g), mixed with dry sand, was heated in a hard-glass tube. Under the catalytic action of the sand, the lithium chlorate decomposed to chloride. The evolved oxygen, together with any moisture it might contain, was trapped in liquid nitrogen. A test of the residual showed that decomposition was complete.

The trapped gases were allowed to warm up slowly to 0° C and a measured quantity of ethyl alcohol then added. The solution was then allowed to warm up to room temperature and then passed through the chromatograph. The result showed that our preparation of lithium chlorate contained less than 0.006% water by weight.

For the conductance determinations we used a large double-jacketed thermostat containing 18 gal of Marcol GX oil. The temperature of the thermostat was 131.8° C±0.06° C; this fluctuation occurred over a cycle of steady rise and fall, as the heater went on and off. Temperatures were read on a Beckmann thermometer which had been calibrated against a platinum resistance thermometer. The method of conductance determination was identical with that used in dilute solution work. It is sufficient to say that the bridge used was a Leeds and Northrup Jones conductivity bridge. The input signals were provided by an audio oscillator. The output from the bridge was coupled through a three-stage amplifier to an oscilloscope. This circuit proved capable of detecting changes of less than 0.1 ohm in 3000 ohms. The conductance cell is represented in Fig. 1. Powdered anhydrous lithium chlorate was introduced into the weighed cell, in the dry box, and

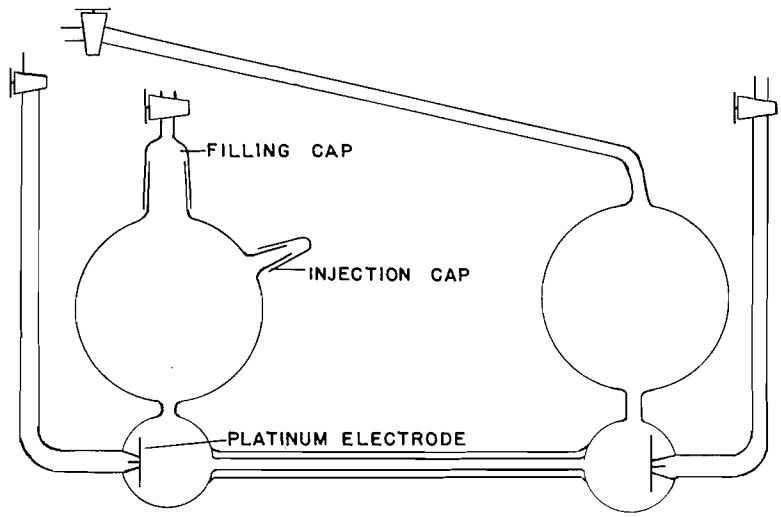

FIG. 1. The conductance cell.

the whole reweighed. When the cell was placed in the thermostat, the salt melted, leaving air bubbles along the capillary and attached to the electrodes. These were removed by causing the melt to flow into the bulbous compartments. After thermal equilibrium had been reached, the resistance of the cell was measured at the maximum and minimum temperatures of the bath fluctuation, using signal frequencies of 1,000, 5,000, and 10,000 cycles/sec. An oscilloscope was used as null point detector. A graph of temperature against resistance was then plotted for each of the frequencies used and the resistance corresponding to 131.8° C was then plotted against $1/\sqrt{(\text{frequency})}$ (Fig. 2). Extrapolation of this graph to infinite frequency gave the resistance of the cell in the absence of ionic polarization.

A calibrated syringe was used to introduce the addition reagents. The cell constant was determined after the completion of each experiment: no change was detectable.

In addition to the isothermal experiments at 131.8° C, the conductance of pure (molten) lithium chlorate was determined over the range of temperature 130°–140° C. The activation energy was obtained from a plot of $\log_{10} \kappa_{sp}$ vs. $1/T$. The slope of this straight line is equal to $-\Delta E_\kappa/R$.

EXPERIMENTAL RESULTS

The experimental results are summarized in Tables I and II. The activation energy derived from the data in Table I is 6.3 kcal/mole, between 130 and 140° C.

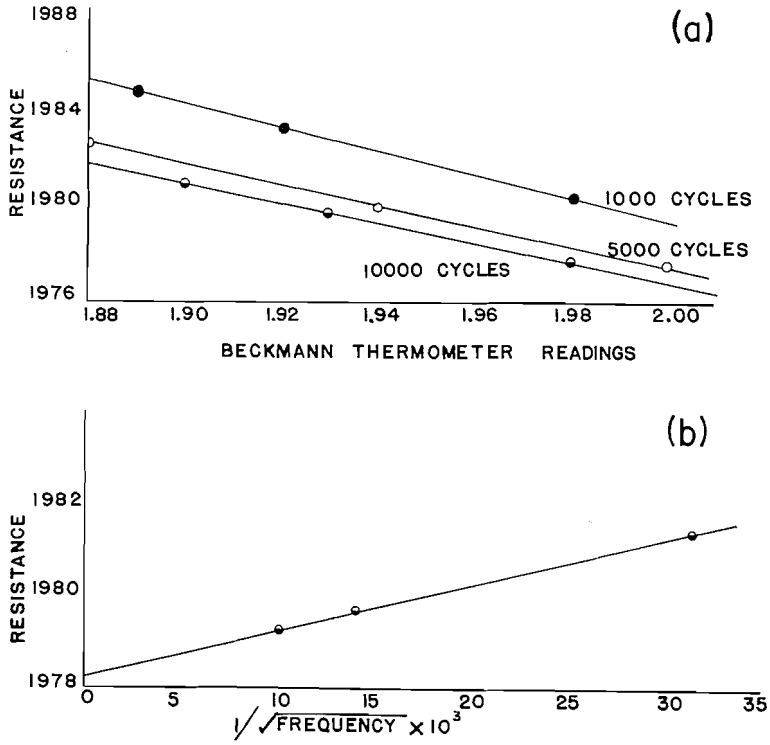

FIG. 2. (*a*) Resistance vs. Beckmann temperature. (*b*) Resistance at 131.8° C vs. $(1/\sqrt{F})\times 10^3$: an example showing the calculation of a resistance at infinite frequency.

TABLE I

Temperature, resistance, and specific conductance of pure molten lithium chlorate

Temperature (°C)	Resistance at infinite frequency (Ω)	Specific conductance	$(1/T)\times 10^4$	$\log_{10} \kappa_{sp}$
131.80	2350.0	0.1150	24.70	−0.9389
143.01	1903.0	0.1420	24.04	−0.8477
140.78	1973.0	0.1370	24.17	−0.8623
136.49	2149.0	0.1258	24.42	−0.8993
135.69	2222.8	0.1231	24.47	−0.9098
131.80	2347.4	0.1152	24.70	−0.9385

DISCUSSION OF RESULTS

The conductances with small additions of water are in good agreement with the figures of Campbell, Kartzmark, and Paterson (2), for solutions of 93.98 and 100 weight% lithium chlorate.

Nitrobenzene Additions

Nitrobenzene was found to have a very limited solubility in molten lithium chlorate. The maximum amount of nitrobenzene in a one-phase system at 131.8° was only 0.4 weight%.

NOTE: Dielectric constants of additives: water, 78.54 at 25°; nitrobenzene, 34.82 at 25°; methyl alcohol, 32.63 at 25°.

Methyl Alcohol Additions

The solubility of methyl alcohol in lithium chlorate is large but a practical limit is set, at 131.8° C, by the fact that chemical decomposition of the methyl alcohol occurs at a concentration of methyl alcohol greater than 5% by weight; at least, gas bubbles are evolved, which adhere to the electrodes and block the capillary, rendering the resistance readings uncertain.

In order to compare the conductance of lithium chlorate in methyl alcohol as solvent with a corresponding concentration in water, a value of the specific conductance, at 25° C, of a solution of lithium chlorate in methyl alcohol, containing 55.8 weight% lithium chlorate, was determined. The value found was $\kappa_{sp} = 0.00939$. This should be compared with the corresponding figure for 55.71 weight% lithium chlorate in water of 0.1189 (2).

The specific conductance, related to the mole ratio of additive to lithium chlorate, is given in Table III. (The results are represented graphically in Fig. 3.)

The Arrhenius equation, when applied to the present results, gives:

$$\kappa_{sp} = A_\kappa \exp(-\Delta E_\kappa/RT).$$

Over the small temperature range of 130–140° C, the graph of $\log_{10} \kappa_{sp}$ vs. $1/T$ is essentially linear, giving an activation energy of 6.3 kcal/mole. This value is rather high and is comparable with those of mercuric chloride (5) and mercuric bromide (6), viz. 6.15 and 6.2 kcal respectively, but in the latter cases complex ion formation is known

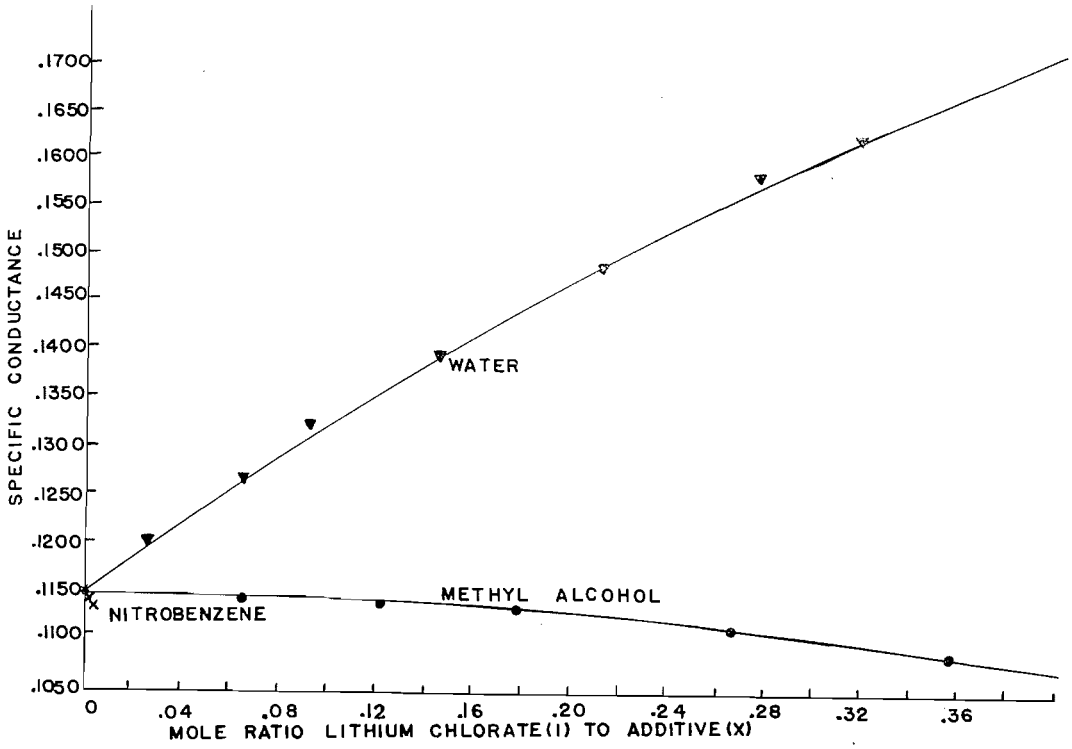

FIG. 3. Specific conductance vs. mole ratio of additive.

to occur. Yaffe and van Artsdalen (7) have shown that the value of ΔE increases considerably as the melting point is approached from a higher temperature, and it may be that the value of ΔE for lithium chlorate between 130° and 140° should not be considered as the true activation energy. Further experiments will determine the activation energy at higher temperatures.

The addition of a small amount of water increased the specific conductance considerably. The conductance of the pure melt at 131.8° C is 0.1150 ± 0.0002 mhos. The addition of 2% of water increases the specific conductance to 0.1336, an increase of 16%. This initial rate of increase of conductance is slightly greater than that found for additions of water between 2 and 6% (12%). This may indicate that the role played by the initial water molecules is not entirely the same as that of water molecules entering the system at higher dilution. It is possible that the effect of the addition of water is twofold, on the one hand causing an increase in the number of Li^+ ions available for conduction, on the other an increase in the effective size of the lithium ion, caused by its combination with water molecules. The first effect will increase the conductivity, whereas the latter will do the reverse. It can be assumed that the effect of the chlorate ion on conductance, under these conditions, is small and constant, because of its large size and consequent small mobility, compared with that of the (naked) lithium ion.

The second additive investigated was methyl alcohol. Little change in the conductivity is noticed until a mole ratio of 1:0.18 or 0.63% by weight of methyl alcohol is present. The tendency is towards a slow decrease in specific conductance. Thus a methyl alcohol/lithium chlorate solution of mole ratio 1:0.26 has a specific conductance of 0.1125 whereas

a comparable water/lithium chlorate solution has a specific conductance of 0.1560. The difference is presumably due to the much greater ionizing power of water; a fact substantiated when the conductance of a 55.8% lithium chlorate solution in methyl alcohol, specific conductance at 25° C 0.0094, is compared to an equivalent aqueous solution, specific conductance 0.115. Partial ionization of the lithium chlorate by the methyl alcohol present can be seen when the comparison is made with the effects of the third additive investigated, nitrobenzene. Though only a small addition is possible, the more rapid decrease in conductance for comparable mole ratios is immediately noticed.

These results suggest that in the case of lithium chlorate the predominating influence exerted by traces of nonelectrolytes upon the conductance may be that affecting the degree of ionization. Further experiments, which will involve determinations of density, viscosity, and conductance, will furnish us with a more complete study of the thermodynamic principles involved.

A NEW PHOTOCHEMICAL REACTION: THE STRUCTURE AND ABSOLUTE STEREOCHEMISTRY OF ATISINE[1]

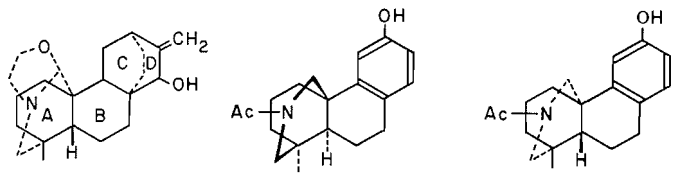
J. W. ApSimon[2] and O. E. Edwards
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received February 5, 1962

ABSTRACT

Irradiation of azides of diterpenoid acids with 1α- and 1β-carboxyl groups gave the corresponding isocyanates and ca. 25% yields of lactams. The azide of hexanoic acid under comparable conditions gave 8% of hexanamide. The reaction has been used to convert podocarpic acid to the enantiomer of the phenol III derived from atisine. This completes the structure proof of the atisine family of alkaloids, the Garrya alkaloids, and related diterpenes, and proves the absolute stereochemistry of these substances.

There is extensive evidence that the alkaloid atisine contains the features shown in rings B, C, and D of formula I (2, 3, 4). The evidence for the structure of ring A and the nitrogen-containing bridge was indirect, resting on the products of selenium dehydrogenation and superficial oxidation (3, 4) and on interpretation of n.m.r. spectra (3). Considerable evidence had been obtained for the relative and absolute stereochemistry shown in I (2, 3, 4). Very recently interrelation of the Garrya alkaloids, steviol, and kaurene, and extensive rotatory dispersion observations have provided confirmation of this absolute stereochemistry (5). However, since the structure of steviol and kaurene have not been rigorously proved, the ring A and hetero ring structure needed confirmation. We have now provided very direct proof of the correctness of the structure and absolute stereochemistry shown in I by partial synthesis of the N-acetyl phenol II from podocarpic acid. This proved to be the mirror image of the N-acetyl phenol III,



which had been prepared earlier from atisine (2).

For partial synthesis of II a method was sought of substituting the angular methyl (C-17) of resin acid derivatives. A very direct possibility of doing this and immediately forming the heterocyclic system IV common to all diterpenoid alkaloids of known structure suggested itself. Thermal decomposition of acid azides leads via electron-deficient nitrogen to the isocyanate. It seemed possible that if the intermediate were generated in close proximity to a saturated carbon the nitrene or diradical might substitute this carbon. We were encouraged in this conception by the report of attack of thermally generated nitrenes from aryl azides on methyl groups, giving rise to heterocyclic rings (6), i.e. V → VI (after oxidative aromatization).

[1]*Issued as N.R.C. No. 6791.*
A preliminary report of some of this work has been published (1).

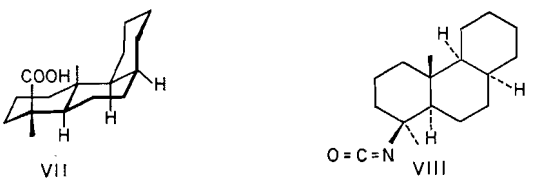
IV V VI

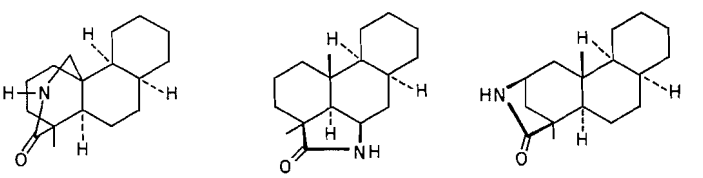
It seemed probable that the chance of attack on saturated carbon in the case of acid azides would be increased if the energy for decomposition was supplied by ultraviolet irradiation. Not only might the electron-deficient nitrogen then be more energetic, but it might be in a different electronic state (triplet rather than singlet), thus enabling the substitution reaction to compete favorably with the rearrangement.[3]

Previous work on the photolysis of acid azides had shown that isocyanates were produced as in the thermal reaction (7). It thus appeared imperative to have the saturated carbon exceptionally close to the electron-deficient nitrogen if we were to observe the desired reaction. We hence chose for study the azide of the trans-anti-cis acid VII available to us from other work (8). In this acid, ring C should provide steric compression of the angular methyl group, forcing it unusually close to the axial carboxyl.



VII VIII

The azide of VII was prepared via the acid chloride and hydrazide. Because of its sensitivity it was not isolated, but merely characterized by its infrared absorption at 2145 and 1700 cm^{-1}. When a dry hexane solution of this was refluxed for 1 hour only the corresponding isocyanate VIII was produced. When the same solution was irradiated in a 1-cm quartz cell using a Hanovia ultraviolet lamp, at room temperature, there was steady evolution of nitrogen. After completion of the reaction the products were separated using chromatography on alumina. The isocyanate VIII, which was the main product (65%), was very readily eluted. The more strongly adsorbed products were a δ-lactam (9) ($\nu_{max}^{CHCl_3}$ 1665 cm^{-1}), in 25% yield, and a trace of γ-lactam (10) ($\nu_{max}^{CHCl_3}$ 1685 cm^{-1}), both of which gave correct analyses for $C_{18}H_{27}NO$. The δ-lactam could unambiguously be assigned the desired structure IX since the n.m.r. signal for the angular methyl group (C-17) which appeared at $\tau = 9.03$ in the spectrum of the parent acid and $\tau = 9.09$ in that of the hydrazide was missing from its spectrum (n.m.r. spectra of carbon tetrachloride solutions with tetramethylsilane as internal standard). The γ-lactam was either

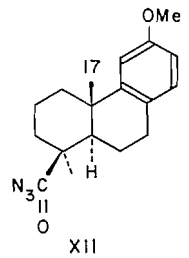


IX X XI

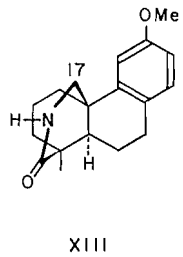
[3]*The rearrangement most likely involves migration of the alkyl group with its full complement of electrons, and hence requires a singlet state of nitrogen (nitrene).*

X or XI, but insufficient evidence was available to distinguish between these possibilities.

In order to pursue the potentialities of the substitution and to assess the importance of the steric compression discussed above we next examined the azide of the methyl ether of podocarpic acid (XII). With the flattened ring C, this should have the methyl and carboxyl functions at a more normal 1,3 diaxial distance. The photolysis of XII in hexane proceeded smoothly. To our surprise a 25% yield of a mixture of lactams was



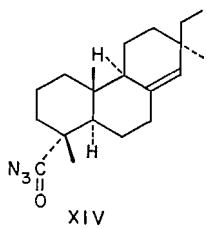
XII



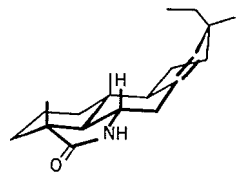
XIII

again produced. The δ-lactam which predominated crystallized on the walls of the photolysis cell. It analyzed for $C_{18}H_{23}NO_2$ and had ν_{max}^{nujol} 1655 cm^{-1}. Since the high-field signal expected for an angular methyl group (C-17) was absent from its n.m.r. spectrum it clearly had structure XIII. A 5% yield of γ-lactam (ν_{max}^{nujol} 1695 cm^{-1}) was also produced.

In order to examine the reaction under conditions where only secondary carbon could be substituted the azide (XIV) from dihydropimaric acid was prepared. When this was irradiated in hexane a lactam again crystallized on the walls. This analyzed for $C_{20}H_{31}NO$ and had $\nu_{max}^{CHCl_3}$ 1685 (γ-lactam). In view of the geometric limitations this can only be XV. The yield was similar (26%) to that in the methyl substitution. The



XIV



XV

reaction thus provides a new[4] and potentially valuable method for introducing substituents on ring B of the resin acids.

Finally, in an attempt to observe the proportion of γ- and δ-lactams formed when equivalent methylenes were available for substitution, the azide of hexanoic acid was irradiated. An 8% yield of hexanamide was produced, probably by hydrogen abstraction from the solvent. The other products besides isocyanate were a complex mixture, which will be the object of further study.

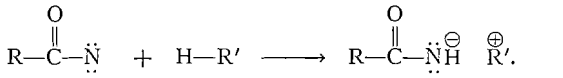
As discussed by Smolinsky for the thermal decomposition of aryl azides (4, 11) the photolysis of acid azides could involve the singlet nitrene XVI or the corresponding

[4]*Chromic acid oxidation has been used to place oxygen on ring B of resin acids with an aromatic ring C (12), and in the case of one pimaric acid isomer (Ukita's acid) (13) selenium dioxide has been used to introduce oxygen on* C-9.

triplet diradical XVII (unpaired spins of two of the unshared electrons). He produced evidence for the triplet character of the nitrogen in the thermal reaction (11).

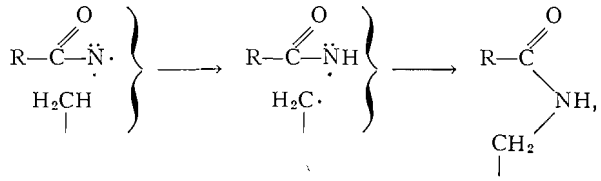
XVI XVII

We consider that the formation of the hexanamide from the azide proves the diradical nature of the nitrogen doing the hydrogen abstraction in this photolysis. Had the nitrene state done the hydrogen abstraction the first stage would be as in (*a*):



(*a*)

The charged particles in the non-polar solvent would form an ion pair which would collapse to uncharged RCONHR′. While it seems probable by analogy that the lactam formation also involves a triplet nitrogen as shown:



the product could equally well arise from nitrene as in (*a*) or by insertion of nitrene into the C—H bond. An attempt to decompose the azide of dihydropimaric acid by energy transfer from triplet benzophenone (14), and hence get information about the mechanism, produced no change in product ratio or yield over photolysis without the benzophenone.

This reaction takes its place with the Hofmann–Loffler–Freytag reaction (15, 16) and the recently developed photolysis of aliphatic azides (17) as a means of forming nitrogen-containing rings by substitution on saturated carbon. The latter two reactions seem to preferentially form pyrrolidine rather than piperidine rings (six-membered cyclic transition state for hydrogen abstraction). The formation predominantly of piperidone in the compounds with a 1β-carboxyl when two possibilities for pyrrolidone formation were present is remarkable. This is particularly so if hydrogen is abstracted as hydride ions or hydrogen atoms, since this should be easier from secondary than from primary carbon. The proximity of the 1β-carboxylic function and the angular methyl is the most probable cause of this preferential δ-lactam formation.

With lactam XIII readily available we were now in a position to synthesize phenol II. Hydrolysis of XIII with hot constant-boiling hydrobromic acid gave the phenolic lactam, which was then reduced by lithium aluminum hydride in refluxing dioxane to the secondary aminophenol. This was acetylated, then partially hydrolyzed to the N-acetyl phenol II. This melted at 279–280° and its infrared spectrum (nujol mull) was identical with that of the N-acetyl phenol from atisine (2). However, its rotation was +112°, compared to −105° for the atisine degradation product. This proves decisively that the latter is correctly represented by III and that atisine has the structure and

stereochemistry illustrated in I. Since podocarpic acid has been synthesized (18), this work opens a way to total synthesis of the mirror images of diterpenoid alkaloids.

EXPERIMENTAL

Rotations were of ethanol solutions, infrared spectra were of Nujol mulls, unless otherwise stated, and melting points were taken on a Kofler hot stage.

Azide of VII

1β-Carboxy-1α,12β-dimethyl-*trans*-anti-*cis*-perhydrophenanthrene (8) (850 mg) in dry ether (25 ml) and pyridine (3 drops) was allowed to react with thionyl chloride (2 ml) for 2 hours at room temperature. The precipitated pyridine hydrochloride was removed by filtration and the solution evaporated *in vacuo*, yielding a pale yellow oil (870 mg) which crystallized on standing. This product showed infrared absorption at 1795 cm^{-1} (acid chloride) but none at 1695 cm^{-1} (COOH). The acid chloride was readily hydrolyzed to the parent acid.

The acid chloride (800 mg) in ether (50 ml) was added to 100% hydrazine hydrate (2 ml) in absolute ethanol (10 ml) at 0° C. The mixture was vigorously shaken for 3 minutes, poured into water, and extracted with ether. The ether extract was washed well with water, dried, and evaporated, yielding a crystalline product forming colorless needles (780 mg) from ether/*n*-hexane, m.p. 160°, $[\alpha]_D$ +47° (*c*, 0.34). Found: C, 73.14; H, 10.71; N, 10.28. Calc. for $C_{17}H_{30}N_2O$: C, 73.33; H, 10.86; N, 10.06. Infrared spectrum: ν_{max} 3400 cm^{-1}, 1600 cm^{-1} (amide).

The above hydrazide (500 mg) was dissolved in acetic acid (20 ml) and cooled to 0° C. A saturated solution of sodium nitrite (250 mg) in water was added and the mixture vigorously shaken for 1 minute. The mixture was diluted with water and extracted several times with *n*-hexane. The extract was washed with ice-cold water, 5% sodium bicarbonate, and water again, then dried with anhydrous sodium sulphate. The infrared spectrum of this hexane solution showed absorption at 2145 cm^{-1} and 1700 cm^{-1} (acid azide).

Photolysis of the Azide of VII

The hexane solution of the azide was irradiated using a Hanovia ultraviolet lamp, at room temperature, in a 1-cm quartz cell. The photolysis cell had a capacity of ca. 150 ml and was fitted with a circulating device. A similar quartz cell, through which cold water was passed, was placed between the light source and the photolysis cell to keep the reaction cool. A steady evolution of nitrogen was observed and the disappearance of the azide bands in the infrared spectrum was complete after 6 hours. The reaction mixture was evaporated, yielding a pale yellow oil (260 mg) which was chromatographed on alumina (Grade IV, 7 g) in hexane. The following fractions were obtained.

Eluant	Fraction No.	Wt. (mg)	Infrared indicates
Hexane	1, 2	163	Isocyanate
Hexane/benzene (70/30)	3–5	5	γ-Lactam
Benzene/chloroform (30/70)	10–15	62	δ-Lactam

The isocyanate (VIII) was sublimed at 90° at 10^{-4} mm, yielding colorless prisms, m.p. 64–66°, $[\alpha]_D$ +36°, (*c*, 1.07). Found: C, 78.26; H, 10.39; N, 5.56. Calc. for $C_{17}H_{27}NO$: C, 78.11; H, 10.41; N, 5.36. Infrared spectrum: ν_{max} 2250 cm^{-1} (isocyanate).

The next eluted product was the γ-lactam (X or XI), m.p. 182°, $[\alpha]_D$ +27° (*c*, 0.33), forming colorless needles from ethanol. Sublimation at 170° at 10^{-4} mm yielded the analytical sample. Found: C, 78.38; H, 10.13. Calc. for $C_{17}H_{27}ON$: C, 78.11; H, 10.41. Infrared spectrum: ν_{max} 1680 cm^{-1} (γ-lactam). The more strongly absorbed δ-lactam (IX) was crystallized twice from ether/pentane and sublimed at 120° at 10^{-3} mm to yield colorless needles, m.p. 183°, $[\alpha]_D$ +23° (*c*, 2.02). Found: C, 78.37; H, 10.13; N, 5.25. Calc. for $C_{17}H_{27}NO$: C, 78.11; H, 10.41; N, 5.36. Infrared spectrum: ν_{max} 3200 cm^{-1} (>NH), 1650 cm^{-1} (δ-lactam); 1665 cm^{-1} in CCl_4.

Thermal Rearrangement of the Azide of VII

The hexane solution of the azide from a comparable run was refluxed for 1 hour, cooled, and evaporated to yield quantitatively the isocyanate (VIII) described above.

Photolysis of O-Methyl Podocarpic Acid Azide (XII)

A hexane solution of this azide (XII) was readily prepared using the previous procedure. The hydrazide prepared during this sequence readily crystallized from ethyl acetate as colorless needles, m.p. 166°, $[\alpha]_D$ +124° (*c*, 0.38). Found: C, 71.39; H, 8.62; N, 9.51. Calc. for $C_{18}H_{26}O_2N_2$: C, 71.49; H, 8.67; N, 9.26. Infrared spectrum: ν_{max} 3350 cm^{-1} (>NH), 1615 cm^{-1} (amide), 1600 cm^{-1} and 1560 cm^{-1} (aromatic).

A hexane solution of XII (ν_{max} 2150 cm^{-1} and 1700 cm^{-1}) from 1 g of hydrazide was irradiated as described for VII. After 2 hours a colorless crystalline product was observed forming on the windows of the photolysis cell. After 16 hours the disappearance of the azide absorption was observed in the infrared spectrum of the solution. The hexane solution was decanted and chromatographed on alumina (Grade IV). The isocyanate was eluted with hexane as a colorless oil (500 mg) which slowly crystallized. Sublimation at 80° at 10^{-3} mm gave colorless prisms, m.p. 62°, $[\alpha]_D$ +89° (*c*, 1.32). Found: C, 75.93; H, 8.10; N, 5.05. Calc. for $C_{18}H_{23}NO_2$: C, 75.75; H, 8.12; N, 4.91. Infrared spectrum: ν_{max} 2260 cm^{-1} (isocyanate), 1600 cm^{-1} and 1560 cm^{-1} (aromatic). Elution with benzene/hexane (1/1) yielded a crystalline product (45 mg) forming needles from acetone, m.p. 284°. This was too insoluble for a rotation determination. Found: C, 75.92; H, 8.08; N, 4.88. Calc. for $C_{18}H_{23}NO_2$: C, 75.75; H, 8.12; N, 4.91. Infrared spectrum: ν_{max} 1695 cm^{-1} (γ-lactam), 1600 cm^{-1} and 1560 cm^{-1} (aromatic).

The product which crystallized on the window of the photolysis cell was collected and recrystallized from ethanol, yielding colorless prisms of XIII (190 mg), m.p. 274°, $[\alpha]_D$ +41° (*c*, 0.33). Found: C, 76.03; H, 8.14; N, 4.96; OMe, 10.80. Calc. for $C_{17}H_{20}NO(OMe)$: C, 75.75; H, 8.12; N, 4.91; OMe, 10.88. Infrared spectrum: ν_{max} 3300 cm^{-1} (>NH), 1655 cm^{-1} (δ-lactam), 1600 cm^{-1} and 1560 cm^{-1} (aromatic).

Thermal Rearrangement of XII

The hexane solution of the acid azide (XII) was refluxed for 1 hour and evaporated to yield quantitatively the isocyanate, $[\alpha]_D$ +89° (*c*, 0.73), described above.

Synthesis of Phenol II

A solution of the lactam (XIII) (200 mg), obtained from O-methyl podocarpic acid, in acetic acid (3 ml) and 48% hydrobromic acid (10 ml) was refluxed for 3 hours. The cooled mixture was evaporated to dryness *in vacuo*, yielding a colorless product (160 mg) which was crystallized from ethanol to yield needles, m.p. 347°. This was too insoluble for a rotation determination. Found: C, 74.97; H, 7.82. Calc. for $C_{17}H_{21}NO_2$: C, 75.24; H, 7.80. Infrared spectrum, ν_{max} 3300 cm^{-1} (>NH), 3140 cm^{-1} (—OH), 1650 cm^{-1} (amide), 1600 cm^{-1} and 1560 cm^{-1} (aromatic).

The phenolic lactam (150 mg) was dissolved in hot dioxane (75 ml), and lithium aluminum hydride (100 mg) in ether (10 ml) was added at such a rate that the ether distilled off. The mixture was refluxed for 2 hours, cooled, and the excess lithium aluminum hydride was decomposed with ethereal methanol. Evaporation to dryness *in vacuo* yielded a colorless product, which was extracted several times with warm ethanol. The ethanol extract yielded a secondary amine (110 mg) which exhibited no infrared absorption in the carbonyl region but complex absorption in the 3500 cm^{-1}–3300 cm^{-1} region (amine + phenol).

This amine was dissolved in pyridine (5 ml) and acetic anhydride (5 ml). The solution was refluxed for 40 minutes, cooled, and poured into 2 *N* hydrochloric acid (50 ml). The product was extracted into ether. The ether solution was washed well with water and 2 *N* hydrochloric acid, dried, and evaporated, yielding a pale yellow oil (91 mg) which showed no absorption in the hydroxyl region of its infrared spectrum but had absorption at 1738 cm^{-1} (acetate) and 1610 cm^{-1} (amide). This product was dissolved in methanol (15 ml) and water (5 ml). Potassium hydroxide (10 ml, 5%) was added and the mixture refluxed for 3 minutes. The solution was cooled and extracted with ether. The aqueous layer was acidified with 2 *N* hydrochloric acid and extracted with chloroform. The chloroform extract was dried and evaporated to yield a crystalline residue (53 mg). Recrystallization from acetone gave small colorless prisms, m.p. 279–280°, $[\alpha]_D$ +112° (*c*, 0.45). Found: C, 76.40; H, 8.34. Calc. for $C_{19}H_{25}NO_2$: C, 76.22; H, 8.42. The infrared spectrum of this N-acetyl phenol (II) was identical with that of the phenol (III) obtained from the degradation of atisine.

Photolysis of Dihydropimaric Acid Azide (XIV)

A hexane solution of the above azide (XIV) was prepared using the described procedure. The hydrazide formed colorless needles from aqueous ethanol (900 mg), m.p. 156–157°, $[\alpha]_D$ 7° (*c*, 0.76). Found: C, 75.64; H, 10.60; N, 8.88. Calc. for $C_{20}H_{34}N_2O$: C, 75.42; H, 10.76; N, 8.80. Infrared spectrum: ν_{max} 3380 cm^{-1} (>NH), 1620 cm^{-1} and 1590 cm^{-1} (amide). The hexane solution of the acid azide prepared from this hydrazide (850 mg), which showed infrared absorption at 2130 cm^{-1} and 1700 cm^{-1}, was irradiated as described for VII. After 12 hours the disappearance of azide absorption was observed and the solution was then evaporated to dryness and chromatographed on alumina (Grade IV). Hexane eluted the isocyanate (520 mg) as a colorless oil, b.p. 130–140° at 10^{-1} mm. Found: C, 79.82; H, 10.48. Calc. for $C_{20}H_{31}NO$: C, 79.67; H, 10.37. Infrared spectrum: ν_{max} 2245 cm^{-1} (isocyanate). The benzene eluates yielded a crystalline product, XV (153 mg), forming needles from aqueous methanol with m.p. 209°. The analytical sample sublimed at 162° at 10^{-4} mm as colorless prisms, m.p. 210°, $[\alpha]_D$ 7° (*c*, 0.9). Found: C, 79.82; H, 10.51; N, 4.81. Calc. for $C_{20}H_{31}NO$: C, 79.67; H, 10.37; N, 4.65. Infrared spectrum: ν_{max} 3250 cm^{-1} (>NH), 1690 cm^{-1} and 1640 cm^{-1} (γ-lactam), 1685 cm^{-1} (in $CHCl_3$, γ-lactam). Dihydropimaric acid (250 mg) in hexane (150 ml) was unchanged after photolysis for 12 hours.

Photolysis of Hexanoic Azide

Hexanoyl chloride (2 g) in dioxane (25 ml) and sodium azide (2.5 g) in water (10 ml) were vigorously shaken for 5 minutes and extracted with cyclohexane. The organic layer was well washed with water, 5% sodium bicarbonate, and water again, then dried with anhydrous sodium sulphate. This solution, which exhibited infrared absorption at 2130 cm^{-1} and 1710 cm^{-1} (acid azide), was irradiated as described for VII during 12 hours. The only product that could be readily separated from the resulting mixture was the amide of hexanoic acid (230 mg), m.p. and mixed m.p. 99–100° after sublimation at 70° at 10^{-4} mm and having the requisite infrared spectrum. Found: C, 62.90; H, 11.23; N, 12.09. Calc. for $C_6H_{13}ON$: C, 62.57; H, 11.38; N, 12.16.

KINETICS OF FORMATION OF ANODIC OXIDE FILMS ON BISMUTH

L. MASING[1] AND L. YOUNG
British Columbia Research Council, University of British Columbia, Vancouver, British Columbia
Received January 3, 1962

ABSTRACT

The steady-state and transient kinetics of formation of thin insulating anodic oxide films on bismuth have been investigated. The thickness of the films was determined by the spectrophotometric method. No dependence on the crystal face of the substrate was detected (sensitivity better than 1% with thicker films). The transient behavior was found to be somewhat different from that of tantalum. The activation distances were found to be unusually large. The dielectric properties were also investigated.

INTRODUCTION

Anodic polarization of bismuth electrodes immersed, for example, in dilute sodium hydroxide solution produces uniform, insulating oxide films which show bright interference colors, and which behave, in many ways, analogously with anodic oxide films on tantalum, aluminum, titanium, and similar more reactive metals (1, 2). Bismuth was chosen for the present study because it was thought that the comparison of the behavior of bismuth with that of materials which are so different in most other respects might be expected to help to show which aspects of the kinetics of anodic film growth are essentially characteristic of the process and which are special to the particular metal. In addition there is, of course, the possibility that some application may be found for the films, particularly since there have been only two or three papers on the subject since the exploratory work of Güntherschulze and Betz in 1931. Bismuth is obtainable in rather pure state, single crystals are easily grown, and, though this technique was not used, it is of interest, in view of recent trends, that thin layers of the metal are easily fabricated by evaporation.

EXPERIMENTAL PROCEDURES

The metal was obtained from the Consolidated Mining and Smelting Co. of Canada and was of 99.999% purity. Spherical single crystals about 2 cm in diameter were grown for us by K. G. Davis of the Physical Metallurgy Department of the University of British Columbia. Faces corresponding to (100), (110), and (111) on the pseudocubic description were prepared. These were abraded with metallurgical papers down to 4×0 paper and were then electropolished in a bath due to Hare and Mallon (3) containing 10 volumes ethanol, 10 volumes orthophosphoric acid (S.G. 1.75), and 3 volumes concentrated hydrochloric acid (S.G. 1.19) at a current density of approximately 100 ma cm^{-2} and cell voltage of around 2.5 volt using a tubular tantalum cathode. The bath was stirred. It was at an initial temperature of about 20° C. The specimens were washed in ethanol and water. They were then dipped into a 1:4 mixture by volume of concentrated hydrochloric acid and water and, finally, washed again in water before placing in the cell. Anodic oxide films were removed in the above acid solution and the specimens were reused several times before repolishing.

Electrical contact to the specimens was made with a metal rod screwed into the bismuth crystals and insulated with apiezon-type waxes or epoxy resin. Various other stopping-off materials were tried in preliminary work. The technique was also tried of using a tantalum rod as connector, anodized to provide insulation and screwed in tightly either with or without a Teflon gasket.

Various cells were used. The kinetic work reported here was obtained with a cell similar to that used previously with tantalum (4). The reference electrode in the work quoted was a hydrogen electrode in the same solution. The whole cell was immersed in a water thermostat. It was not practical to bring the tip of the Luggin capillary very close to the specimen. In some experiments no capillary was used. In most of the

[1]*Present address: Sprague-T.C.C. (Canada) Ltd., 50 Bertal Road, Toronto 15, Ontario.*

work the ohmic drop of potential in the solution did not matter since it was independent of the thickness of the film at constant current and was eliminated in calculating such quantities as $\Delta V/\Delta D$. When it was necessary to correct for it, the electrolyte resistance R_e between anode and cathode was determined by extrapolating plots of series equivalent resistance against reciprocal frequency to infinite frequency; the ohmic fall was then taken as IR_e, where I denotes the total current.

The electrolyte used in the work quoted was 0.1 M sodium hydroxide in distilled water. The specimen was immersed for 5 minutes before starting formation in order to let it take up the temperature of the bath. The solution was circulated rapidly during formation.

The formation was at constant current and was controlled using the automatic electronic device used previously for tantalum (e.g., ref. 4). This terminates the current when a preset voltage is reached with respect to the reference electrode, and exhibits the times required to traverse successive 1- or 10-volt intervals during formation. Other equipment, such as the a-c. bridge and the spectrophotometric apparatus, were also as previously described.

RESULTS

General Behavior

The initial questions to which answers should be sought were clear from previous work on tantalum (e.g., refs. 4–8). The difficulty is, of course, that bismuth does not behave as ideally as does tantalum. With tantalum, for example, the current efficiency for the production of oxide is very close to 100% over a wide range of current density and temperature in a wide variety of solutions. With bismuth, oxygen evolution occurs more readily. However, under favorable conditions, the reduction in current efficiency due to this side reaction is not excessive. Numerical values are given later. Another difference from tantalum is that the film material is appreciably soluble. The films are also shown to be unstable by increases in the dielectric losses with time on standing in the solution. Possibly, as with aluminum (9), a non-aqueous or partly non-aqueous solution could be found that would give more ideal behavior, but experiments made with various common non-aqueous solvents that have been used for anodizing did not uncover any preferable alternative. In preliminary experiments various forms of non-ideal behavior were encountered. In the final experiments, quoted here, the behavior was very reasonably reproducible. The chief limitation was that we were able to obtain accurate kinetic data only over a rather limited range of temperature.

The field in the oxide required to produce a given ionic current density of the order of a few ma cm^{-2} is roughly of the order of one sixth of the value for tantalum. In other words, films formed at a few ma cm^{-2} to 10 volt on bismuth are of the same order of thickness as films formed to 60 volt on tantalum. However, the total maximum thickness that can be produced before breakdown occurs is of the same order as with tantalum. This is perhaps not without significance. Under the conditions of the present experiments the current efficiency fell off quickly at a little over 50 volt, more or less, according to whether the current density was higher or lower.

Except following breakdown, the films were structureless under the light microscope. They can be removed by attaching adhesive tape and pulling.

The experimental results to be presented are as follows. First, the dielectric properties of the film are discussed. The determination of thickness and derived quantities is then reviewed. The kinetic results are then described, first for steady-state conditions and then for transient conditions. The significance of the results in deciding the mechanism of the process is dealt with in the discussion section.

Dielectric Properties of the Oxide Film

Since the size of the specimens used for the kinetic studies gave capacitances that were too high for the accurate measurement of their frequency dependence, measurements were made with a smaller polycrystalline specimen of 99.999% material, about 0.86 cm^2

in area, of dimensions about 6 mm×3 mm×3 mm. This was stopped off with picien wax and etched in 70% nitric acid. It was immersed symmetrically in a large platinum tube electrode.

Figure 1 shows the reciprocal of the series equivalent capacity C_s (normalized to unity at 1 kc/s), and the loss tangent (tan δ) plotted against the logarithm of the frequency f

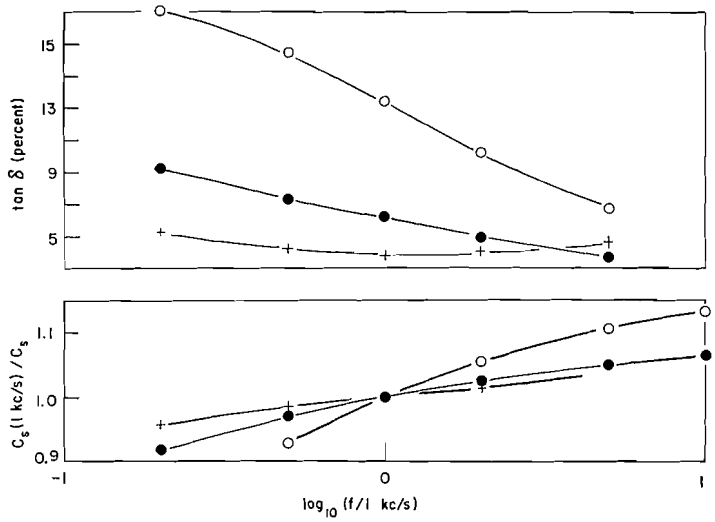

FIG. 1. Loss tangent (tan δ) and reciprocal series equivalent capacity (normalized) for three thicknesses of oxide (formed to voltages of 30 v (○), 10 v (●), and 3 v (+) at 2 ma cm^{-2} and 1.4° C) as function of frequency f of measurement.

for a series of films formed to 3, 10, and 30 volt respectively at 2.0 ma cm^{-2} and 1.4° C. To eliminate the time dependence, the measurements at the various frequencies were made first in order of increasing frequency and then back. The plotted values are the means. The figure shows that the dielectric losses are very much larger than would be found with non-porous films on tantalum or aluminum. The losses increase with increasing thickness of oxide.

Similar high dielectric losses with anodic oxide films on zirconium (10) may satisfactorily be explained by assuming that the films contain a comparatively high density of microfissures. The alternative would be that the dielectric losses of the flawless film material were unusually high. The electrolyte solution is supposed to penetrate into these cracks and to provide a parallel leakage conductance. The theory may be tested by varying the conductivity of the electrolyte. Figure 2 shows the effects with bismuth of reducing the concentration of the solution. The losses were, as expected, markedly decreased.

The increase in the losses with increasing thickness is also typical of films on zirconium and other metals. It appears that as the film thickens, stresses accumulate which cause cracking.

Reciprocal Capacity and Formation Potential

Figure 3 shows the reciprocal capacity at 1 kc/s plotted against the successive potentials to which the specimen was formed at the indicated current densities. The film was removed after each separate formation (see Experimental Procedure), and the next film then formed starting from the "bare" metal. The significance of such plots is as follows.

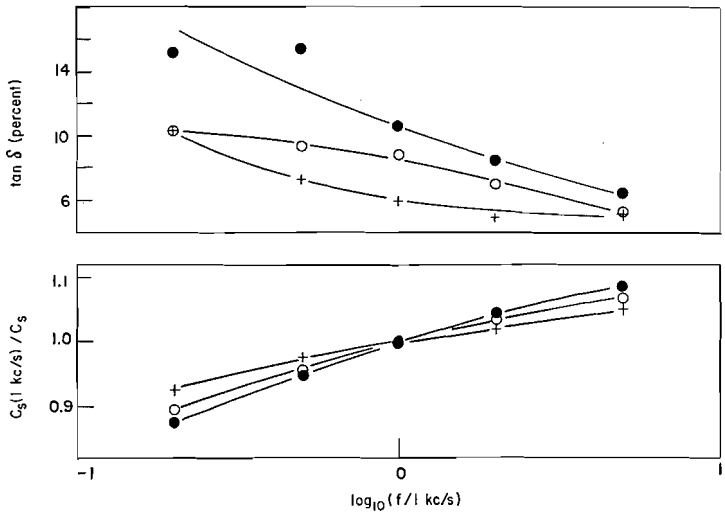

FIG. 2. Loss tangent and reciprocal capacity for a single film measured in 0.1 *M* NaOH (○), in 0.01 *M* NaOH (+), and remeasured in 0.1 *M* NaOH (●).

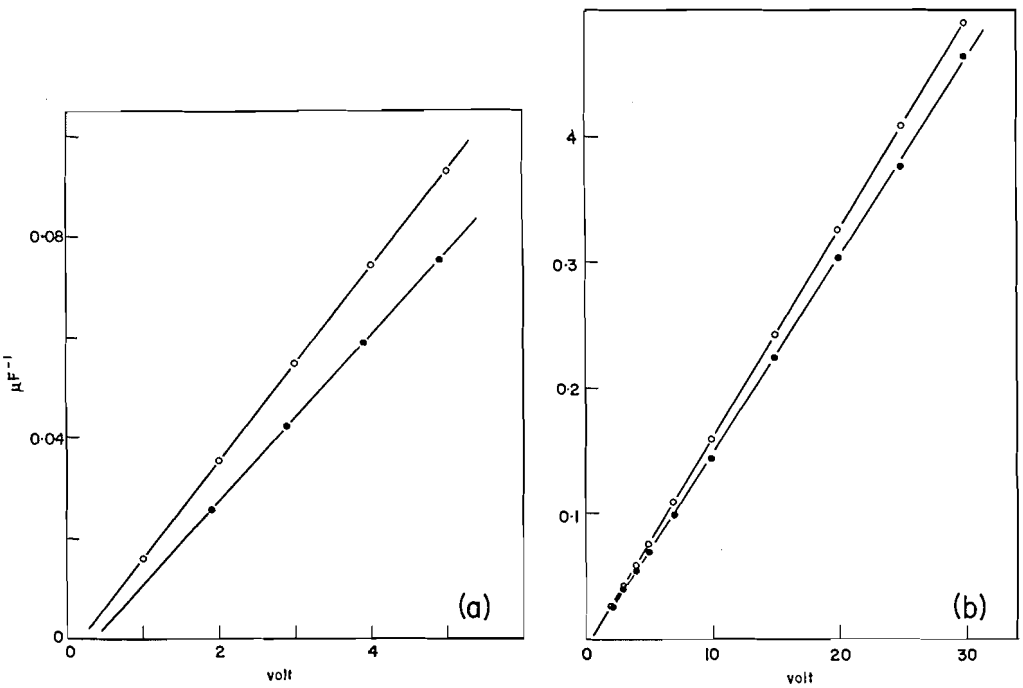

FIG. 3. (*a*) Reciprocal series equivalent capacity at 1 kc/s versus potential against hydrogen electrode in same solution to which the specimen was formed in 0.1 *M* NaOH at 0° C with current densities 0.2 ma cm^{-2} (○) and 2 ma cm^{-2} (●).
(*b*) Reciprocal capacity at 100 c.p.s. (●) and at 1 kc/s (○) versus potential (larger scale than (*a*)), for film formed at 2 ma cm^{-2} and 0° C.

The E.M.F. which causes the electrochemical formation of oxide is the oxide overpotential, defined as the actual potential of the electrode with respect to some reference electrode less the reversible potential for the oxide-producing reaction (in this case

assumed to be $2Bi + 3H_2O = Bi_2O_3 + 3H_2$, $E^0 = 0.37$ volt). The overpotential V may formally be considered to be made up of a possible contribution V_i from the interfaces oxide/metal and oxide/solution plus a term ED, where E is the mean overfield in the oxide (defined analogously with the overpotential) and D is the thickness of the film. The interfacial contribution will be expected to be independent of D but possibly to be dependent on the current density and the temperature. Thus

$$\begin{aligned} V &= ED + V_i \\ &= E\epsilon A/4\pi C + V_i, \end{aligned}$$

where ϵ is the dielectric constant, A is the area, and C is the capacity. Thus the slope of the plots is a measure of the field E and its constancy indicates either that ϵ and E are inversely correlated, or, more probably, that ϵ and E are independent of D. The deviation of the intercept on the voltage axis at zero $1/C$ from the calculated reversible potential is a measure of V_i. Clearly, V_i was of the same order as the experimental error, the observed deviation being within about 0.2 volt. Thus we expect differential measures of the field strength (of the form $\Delta V/\Delta D$) to equal integral measures (of the form V/D).

Thickness, Dielectric Constant, and Related Quantities

Principles of Method

There are several types of measurement that purport to give a measure of the thickness of the films. Each type involves one or more parameters, such as the density of the oxide, the refractive index, or the dielectric constant. By comparing the data from the various types of measurement, first a check is obtained that thickness is indeed being measured and that the films are uniform, and, secondly, various relations are obtained among the parameters. If sufficient of these may be taken as known, the values of the others may be deduced. The charge to form an increment of thickness x is expected to be

$$Q = xA\rho 6F/M, \qquad [1]$$

where A denotes true area; ρ, the density; F, the Faraday; M, the molecular weight (the oxide being presumed to be Bi_2O_3). The consequent change in reciprocal capacity is expected to be

$$\Delta(1/C) = x4\pi/\epsilon A, \qquad [2]$$

where ϵ denotes the dielectric constant. Minima in the specular reflectivity at a wavelength λ are expected to occur with successive increments of thickness,

$$x = \lambda/2n\cos\theta, \qquad [3]$$

where n is the refractive index, assumed constant, and θ is the angle of refraction. In previous work with tantalum and niobium, it was shown that it was not necessary to assume that the true area is equal to the measured macroscopic area, since the area may be eliminated between [1] and [2]. With bismuth, however, it seemed preferable to assume that the true area was equal to the apparent area. The calculation was done by first determining the field strength at various temperatures and current densities in terms of the optical thickness (involving n). Values of the fields were also obtained with the thickness calculated from the charge to form the films, using a method by which it was hoped to allow for current efficiencies below 100%. Comparison gave n/ρ. A similar procedure using the capacity to estimate the thickness gave ϵn. The refractive index here was for $\lambda = 4000$ Å. By also determining the field at one current density and temperature only in terms of n for $\lambda = 5890$ Å, the ratio of the refractive indices at these two

wavelengths was determined. Finally, a value of the index in sodium light was assumed. Corresponding numerical values for ϵ, ρ, and the field strengths could then be deduced. If a preferable value of any of these should later become available, it would be a simple matter to recalculate the data given here to fit the new value.

Optical Thickness

Figure 4 shows tracings of the spectrophotometer records of the minima in reflectivity, shown as maxima in "optical density," for specimens giving destructive interference at

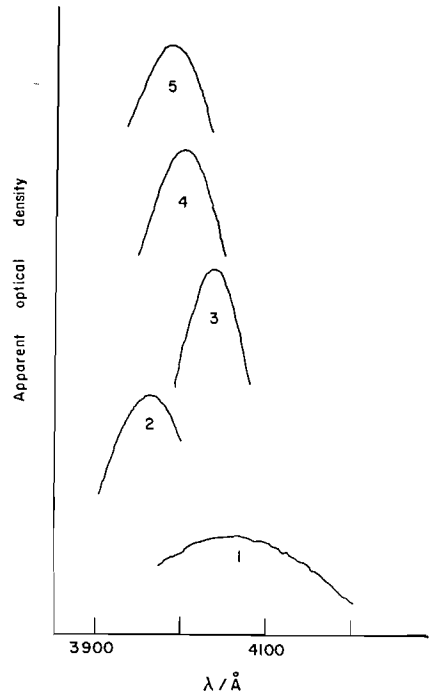

FIG. 4. Tracings of spectrophotometer recordings (apparent optical density) of minima in specular reflectivity (maximum in optical density) at near-normal incidence for films giving minima near 4000 Å in successive orders of interference.

successive orders at wavelengths near 4000 Å. The peaks are flattest in the first order, but are then the most sensitive to the thickness of oxide (cf. Fig. 5). The wavelength (λ) of the peak may be determined (excluding calibration errors of the instrument) to about 10 Å with thin films and 5 Å with thick films, giving a thickness (D) sensitivity of a few Å of oxide (see Table IV for $dD/d\lambda$).

Figure 5 shows plots of the wavelengths of the peaks versus voltage for specimens formed at a given current density and temperature. Such plots were interpolated to obtain estimates of the potentials corresponding to the thicknesses giving interference in successive orders at precisely 4000 Å for each current density and temperature. Numerical data are given in Table I. In all such experiments, each film was formed on "bare" metal, the previous film being first dissolved away.

Figure 6 shows the voltages giving interference at successive orders at 4000 Å plotted against order of interference (i.e., thickness in units of $\lambda/2n\cos\theta$ with arbitrary zero) for formation at a given current density and temperature. The plot is linear. This was

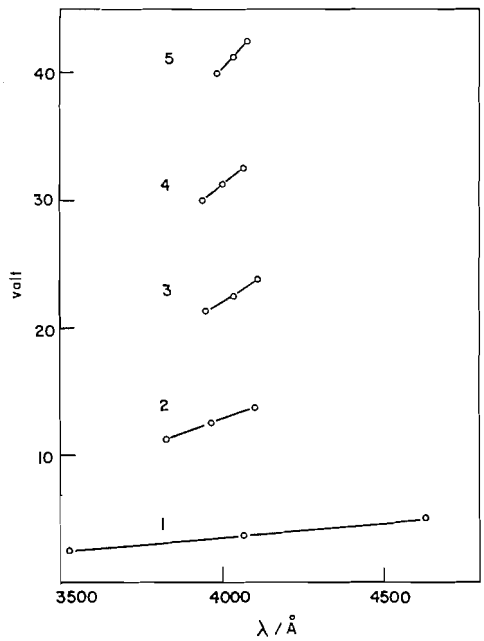

FIG. 5. Potential (against hydrogen electrode in the same solution) to which film was formed at 2 ma cm^{-2} and 25° C plotted against wavelength of interference for films giving interference at wavelengths close to 4000 Å in successive orders.

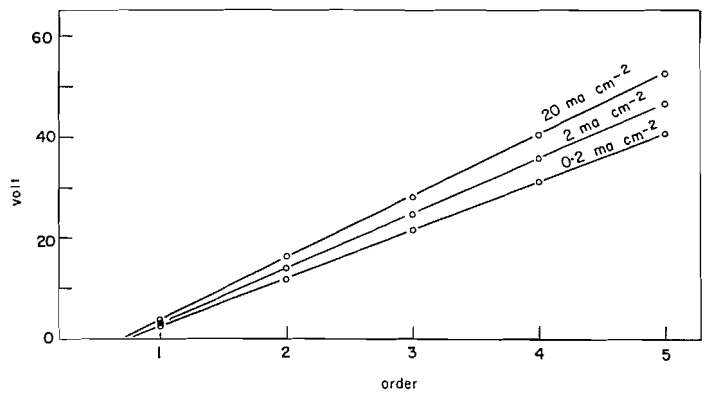

FIG. 6. Oxide overpotential (formation at 0.2, 2, and 20 ma cm^{-2} and 0° C) for films giving interference at 4000 Å in successive orders plotted against order of interference (i.e., thickness in arbitrary units with arbitrary zero).

typical and indicates the absence of detectable variation of field with thickness at constant current.* The slope of such plots, estimated graphically, was taken as a measure of the field strength for the conditions of the plot.

To obtain the dispersion of the refractive index between 4000 Å and 5890 Å, the slopes of two such plots were compared, one plot for each wavelength of interference. The ratio of the refractive indices was $n(4000\ \text{Å})/n(5890\ \text{Å}) = 1.19$ (estimated accuracy, ± 0.02). Thus if the (rather old) published (11) value of the index for white light is assumed as

*The unlikely alternative is that compensation occurs in that the various methods suggest constant field but that parameters such as the refractive index vary to compensate for an actual change in field.

TABLE IA

Potentials (in volts) against hydrogen electrode in the same solution (ohmic p.d. eliminated) corresponding to the thicknesses D_1, D_2, . . . giving interference at 4000 Å in successive order for various current densities and temperatures

	Total current density (ma cm^{-2}):

4–3						9.3
5–4						9.2

n(5890 Å) = 1.91, we have n(4000 Å) = 2.27. The value 1.91 was obtained using a prism of metal converted to oxide by heating in air and cannot be considered reliable though it is the same as the mean of one pair of values tabulated by Larsen (12) for bismite. It is assumed quite arbitrarily and all the other numerical values of field, etc. are derived from this value. Furthermore, it is assumed that the refractive index is independent of the current density and temperature of formation.

Data on the capacities at 1 kc/s of films formed at 2 ma cm^{-2} at 0° C gave $\epsilon n = 140$, i.e. $\epsilon = 62$ for n(4000 Å) = 2.27.

The Charge to Form the Films

Figure 7 shows statistical plots illustrating the variations of the charge required to increase the potential by 1 volt during formation at a given current density and temperature. The individual values are grouped into successive 5-volt ranges. The plots are of the

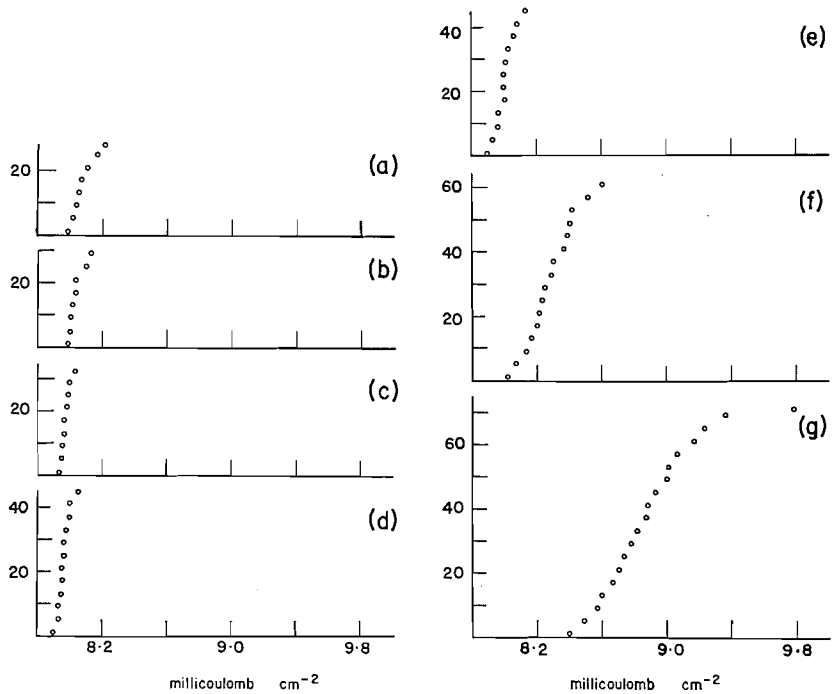

FIG. 7. The ordinate shows the number of specimen trials in which less than the charge/cm² indicated in the abscissa was required to form through 1 volt in the voltage intervals indicated at 2 ma cm⁻² and 25° C. The abscissa scale is common to the whole set of plots. (*a*) 31–36 v, (*b*) 26–31 v, (*c*) 21–26 v, (*d*) 16–21 v, (*e*) 11–16 v, (*f*) 6–11 v, (*g*) 1–6 v.

integrated type (13) instead of the usual distribution function type. The number of specimen trials which required less than a given amount of charge is plotted against the charge.

To use these plots, we rely on the principle that the charge can never be less than corresponds to 100% current efficiency* but that it can exceed this amount without limitations. Thus the estimated values of the charge can be less than the theoretical minimum only by the small measuring error.

To obtain an estimate of the theoretical charge, the plots of Fig. 7 are extrapolated to zero specimens and the intercept on the charge axis is taken as the required value. This gives an estimate of

$$\frac{dQ}{dV} = \frac{dQ}{dD}\cdot\frac{dD}{dV} = \frac{(A\rho 6F)}{M}\frac{1}{E}.$$

**To avoid misunderstandings, we note that references are occasionally made in the literature to current efficiencies greater than 100%. Such statements usually mean that the actual reaction was not that being assumed. In some cases the experimental result was really that the weight increase had been found to be greater than expected. This can occur, for example, if components of the solution have been absorbed by the oxide.*

Figure 8 shows how the results tended to vary with the potential. The charge was in all cases high at the beginning of the formation, then decreased as the thickness increased,

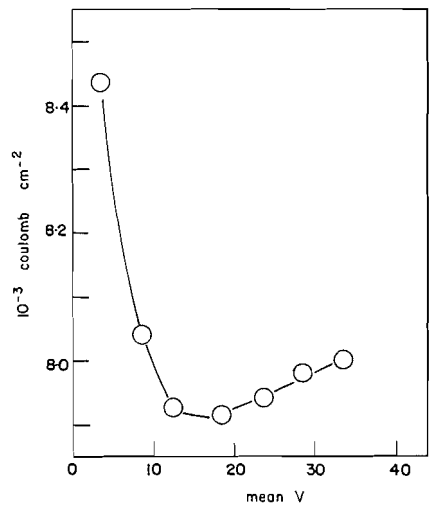

FIG. 8. Estimated minimum charge/cm² to form through 1 volt at 2 ma cm^{-2} and 25° C plotted against mean voltage (from intercepts in Fig. 7).

and finally rose slowly with further increase in thickness. Since the field calculated from the optical thickness showed no such variation over the same range of thickness, these variations appear to be without significance. A mean was taken of the values for each current density and temperature, excluding the values for voltages less than 10. The scatter of the data was least for the conditions of Fig. 8, i.e., 2 ma cm^{-2} and 25° C. Other data are given in Fig. 9.

Together with the fields from the optical thickness, the data gave an overall mean value of $n/\rho = 0.333$ (accuracy believed to be a few percent). With $n(4000\ \text{Å}) = 2.27$, this gives $\rho = 6.8$ g cm^{-3}. Published values of the bulk density fall in the range 8.2–8.9 g cm^{-3}. Evidently if the assumed index is correct, the films differ somewhat in properties from chemically prepared Bi_2O_3.

Current Efficiency

The field strengths obtained from the optical thickness refer to total applied current density. To estimate the ionic current density a mean was taken of the times required to traverse the last 1 volt (or 10 volt at the highest current density) before the current was terminated for all the specimens in the various orders of interference which were used to determine the field at a given applied current and temperature. This gave a mean dV/dt for these conditions. The ionic current density i was calculated from

$$i = \frac{1}{E}\frac{dV}{dt}\frac{6F\rho}{M},$$

where E was the optically determined field. A value of n/ρ is required and the value determined above was used. A value of n itself is not required. This gave the results for the current efficiency reproduced in Table II.

2	97	96	—
0.2	86	92	—

Zero of Thickness

Unless values of the optical constants of the metal are assumed, the spectrophotometric method gives a measure of increments of thickness rather than of absolute thickness. Three methods may be used to obtain a zero point. First, as shown above, the plots of reciprocal capacity versus potential (Fig. 3) suggest that if a plot is made of thickness with unknown zero against oxide overpotential (for a given current density and temperature), the intercept at zero overpotential would indicate the zero of thickness. Thus, in Fig. 6, this would give the thickness D_1 (say) of the film giving first-order interference at 4000 Å as a fraction 0.29 ($\pm 10\%$ spread) of the increment between orders (i.e., of $\lambda/2n \cos\theta = 884$ Å if $n(4000 \text{ Å}) = 2.27$). This gives $D_1 = 255$ ($\pm 10\%$ or more) Å. The second method is to plot the charge-to-form against the order of interference. This neglects the film present before anodization (with tantalum the thickness of this preexisting film can be estimated from the charge-to-form, with certain assumptions). The

plot shown in Fig. 10 is for 2 ma cm^{-2} at 25° C and, clearly, gave good agreement within the accuracy of the data. Thirdly, the increase in voltage that is required to produce a

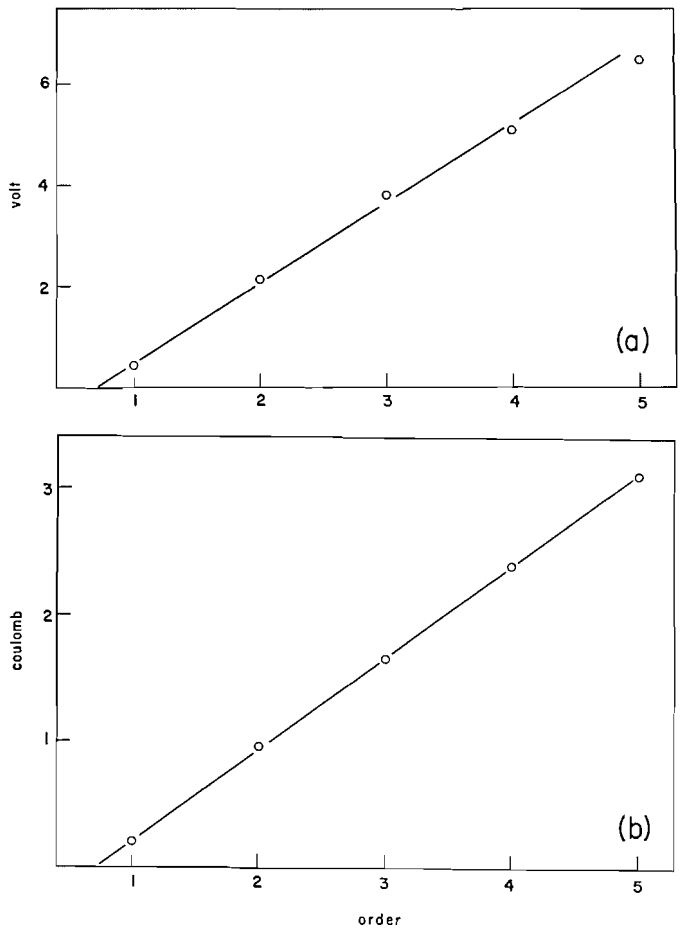

FIG. 10. (*a*) Increase in potential required to increase steady-state current density at 25° C by a factor of 10 plotted against order of interference. Mean values using all points available at each thickness.
(*b*) Total charge required to form at 2 ma cm^{-2} and 25° C to thicknesses giving destructive interference at 4000 Å in successive orders plotted against order of interference.

10-fold increase in current may also be plotted against the order of interference, as shown in Fig. 10. In drawing the line shown, the zero has been taken in agreement with that given by the above methods. This method involves fewer assumptions but is less precise.

Steady-State Kinetics

Figure 11 shows data on the field from the optical thickness versus $\log_{10}$ (ionic current density). The field and the ionic current density were determined as explained in previous sections. The difference between the total and the ionic current density is quite small on the logarithmic plot. The plots are linear within experimental error, but it is perhaps doubtful whether small deviations from linearity of the type observed with tantalum would have been detected, the accuracy being less than with tantalum.

With tantalum and niobium a mean value of $dE/d \log_e i$ (the equivalent of the Tafel slope in the kinetics of non-film-forming electrode processes) over a fixed range of i has

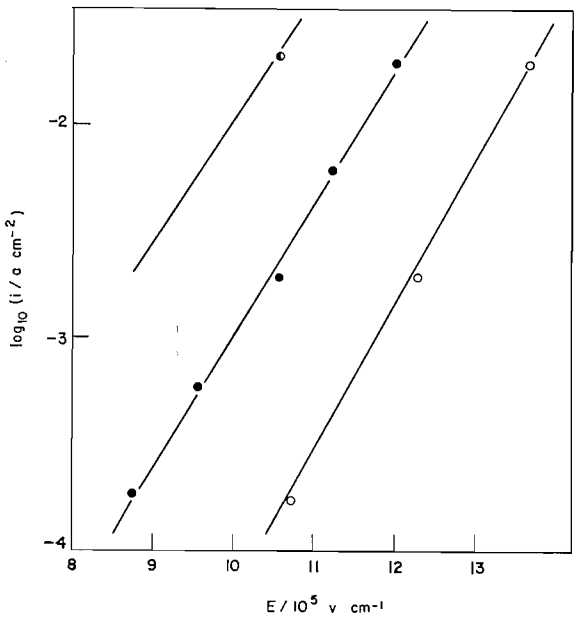

FIG. 11. Log_{10} (ionic current density) versus field strength at 0° C (○), 25° C (●), and 50° C (◐) in 0.1 *M* NaOH. The points are experimental, the continuous lines are calculated from the fitted equation (see text). The ionic current density was derived from dV/dt. The fields are differential values ($\Delta V/\Delta D$) derived from the slopes of plots such as Fig. 6.

been found to be nearly independent of temperature instead of proportional to temperature as expected on simple theory. With bismuth, as with aluminum, it has not proved possible to obtain accurate results over a wide enough range of temperature to obtain a real test of the temperature dependence of $dE/d \log_e i$. We, therefore, have chosen to fit the data with the expression $i = i_0 \exp \{-(W-qaE)/kT\}$. The constants are given with the number of digits needed to reproduce closely the experimental data. They are, of course, individually known to much lower accuracy. The values are $\log_{10} (i_0/\text{a cm}^{-2}) = 10.09$, $W = 1.14$ ev, and $a = 12.2$ Å, q being assumed to be $3e$, where e is the charge on the proton. The lines in Fig. 10 are calculated from the above expression with these values of the constants.

Transient Kinetics

As with other "valve metals," the system adjusts slowly to a sudden change in field or current. The field–current relations that have been reported above refer to the situation where a constant current has been applied for a long enough time to achieve steady-state conditions. Two types of experiment were made under transient conditions.

The first type of experiment consisted in applying a constant current until a steady state was set up and then suddenly changing the potential (i.e., the field). The current immediately after the change was determined by the method (4) described elsewhere (involving cathode ray oscilloscope photography). The "transient" Tafel slope defined as $\Delta E/\Delta \log_e i$ was then calculated. Results are given in Fig. 12 and Table III.

In the second kind of experiment, the current was recorded during the period after the field had been suddenly increased to a new value. Tracings of photographs are given in Fig. 13, which also contains the result of a similar experiment with tantalum. With

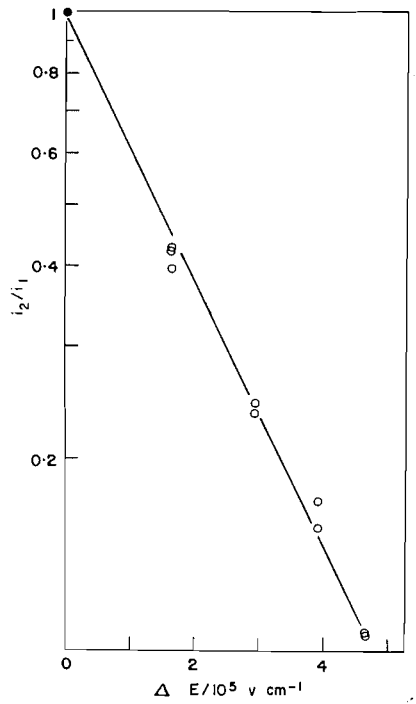

FIG. 12. Change in $\log_{10} i$ (shown as ratio i_2/i_1 of final to initial current with logarithmic scale) for sudden decrease ΔE in field (50° C, initial current $i_1 = 20.9$ ma cm^{-2}).

0	2.0	2.34	3.35
0	20.9	2.19	3.59
50	20.9	2.08	4.46

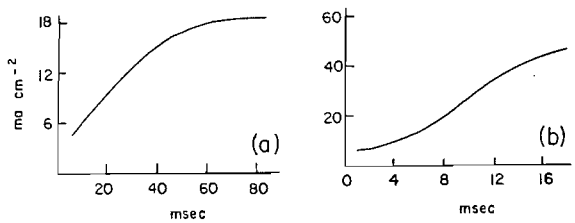

FIG. 13. (*a*) Tracing of oscilloscope photograph showing current versus time following sudden change as potential reached 20 volt from formation at constant current density (2 ma cm^{-2}) to formation at constant voltage (28 volt) for bismuth. Temperature 4° C.
(*b*) Similar but not identical experiment with tantalum. Initial formation at 4 ma cm^{-2} to 90 volt. After 1 minute on open circuit, 100 volt was suddenly applied.

tantalum (4), the current (after its initial sudden jump) increased slowly at first and then more rapidly. With bismuth, the current increased rapidly at first and then more slowly. It would have been preferable to have been able to check this result by working at lower

fields with specimens with a very low initial concentration of mobile ions. This experiment, however, is difficult because of the lower current efficiencies at lower current densities.

Dependence of Kinetics on Crystal Face

With tantalum no variation with crystal face of the substrate metal in the field required to produce a given ionic current has been detected. Probably a variation of 1% would have been found. On the other hand, with indium antimonide a difference was found by Dewald (14), though only at the low end of the range of field studied. Differences occur with titanium (15) and with zirconium and hafnium (16, 17), but only under circumstances that are not fully established. Differences have been found with thin anodic films on cadmium (18), but these are probably a special case, since the oxide is crystalline and epitaxial.

With spherical single crystals of bismuth, no variation in interference color could be seen by eye. To obtain numerical data, films were prepared on a single crystal on which three contiguous faces ((100), (111), and (110)) had been prepared. The specimen was formed at 0.2 ma cm^{-2} in one set of experiments, and at 20 ma cm^{-2} in another set, to a series of potentials giving interference near 4000 Å in successive orders. The wavelengths of the peaks were measured on the three crystal faces. The wavelengths of interference for the films on the three crystal faces were not entirely consistently in the same order but showed some tendency to be so. The maximum difference between any two faces at each formation voltage was calculated. The quantities $dD/d\lambda$ (i.e., the variation in film thickness corresponding to unit change of wavelength) were determined from the data of Fig. 5 for the successive thicknesses (say D_1, D_2, D_3, D_4) giving interference at 4000 Å. From the differences in λ and the $dD/d\lambda$, the corresponding maximum variation in oxide thickness between any two faces was calculated. The results are given in Table IV. The

TABLE IV

Test of possible variation of kinetics with crystal face of substrate metal

Order of interference	Maximum difference in λ between any two faces (Å)	$dD/d\lambda$	Maximum difference in D (Å)	D (Å)	Maximum percent variation in field
Formation at 20 ma cm^{-2} and 25° C					
1	67	0.18	12	250	5
2	19	0.66	12	1170	1
3	11	1.0	11	2080	0.5
4	7	1.4	10	2910	0.3
Formation at 0.2 ma cm^{-2} and 25° C					
1	19	0.17	3	190	2
2	28	0.67	19	990	2

maximum percentage change in field was about 5% at D_1, falling to 0.3% at D_4. Probably the small differences observed were due to slight variation between crystal faces in the ohmic potential fall in the solution. Variations in optical constants of the metal from face to face will not affect the above test.

Although no appreciable change was detected between crystal faces, the kinetic data given here were, as a precaution, obtained for a specific face, (111). It should be mentioned that in preliminary work with polycrystalline material, different crystal faces were sometimes found to show different colors. The reason for this was not discovered—possibly the effect is due to some variation in the state of the surface produced during its preparation prior to anodization, perhaps because the etching process was sensitive to the crystal face.

DISCUSSION

The discussion of the significance of the results as regards the fundamental mechanisms involved can only be tentative. The experimental results do not provide answers to all the questions that one would wish to ask and the possible alternative theories cannot be said to have been fully explored. Despite the recent intensive study of tantalum, the behavior even of this metal is not well understood.

As a preliminary point, we note that the evidence seems consistent with a uniform film though, of course, narrow transitional layers near the interfaces are not excluded.

The constancy of the field with thickness does not mean, as is sometimes stated, that there is no space charge present. It may mean either that the films are so thin and the space charge density so small that the change in field across the film is negligible or it may mean that the films are so thick that the space charge layers required to adjust the rate of entry of ions to the rate of passage through the oxide are complete and yet occupy only a small fraction of the total thickness. The second case means that we have the same conditions as with macroscopic-sized conductors. The first case is that dealt with by the theory of Cabrera and Mott. In this case, the field required to give a particular ionic current is entirely determined by the properties of the metal/oxide interface. It is not wholly certain but it appears likely that in this case the kinetics should depend to a detectable extent on the crystal face of the substrate metal. Since no such dependence was found and since, also, it is difficult to explain convincingly the transients on this theory, one is led to conclude that the results refer to the second case, that is to ionic conduction by an electrically neutral slab of oxide, the interfaces playing no part.

The most striking difference from tantalum, aluminum, zirconium, and similar metals is that the field strengths required to give the observable range of ionic currents are comparatively very low, though still sufficiently high to give "high-field conduction" (i.e., an exponential dependence of current on field). It has been suggested in connection with work on niobium (19) that an inverse correlation seems possible between the dielectric constant and the ionic resistivity. The present results are in accord with this idea.

One might expect that the lowness of the fields would lead to differences in mechanism, but this is no more than an expectation since the fields are low only because ionic movement is relatively easy, so that effects requiring high fields with tantalum might well be expected at lower fields with bismuth.

The best approach to the explanation of the transients involves the idea that the concentration of mobile ions is a function of the field but adjusts only slowly to a sudden change in the field. Since electroneutrality is being postulated, this must be taken to mean that a background of negative space charge is a function of the field and only adjusts slowly to change in the field. The concentration of mobile ions is supposed to be in itself variable, but to take up the value giving electroneutrality. It is perhaps difficult to envisage that electroneutrality should be maintained at all times, even after a sudden change in the field, but this simplifying assumption has been made in several recent papers and is difficult to avoid if one is to have a simple mathematical treatment of the model to be discussed. Space charge effects would be more in line with the usual, rather vague, explanations of similar effects with bulk materials.

An idea first proposed by Bean, Fisher, and Vermilyea (20) to account for certain reported features of the steady-state kinetics with tantalum was applied by Vermilyea (5) and by Dewald (6) to the transients with this and other metals with some initial success. The idea is that the high fields directly produce Frenkel defects. (A Frenkel

defect is the electrically neutral combination of vacant lattice site and interstitial metal ion.) The process is equivalent to the ordinary process of ionic mobility except that here the ion moves from a lattice to an interstitial site rather than from one interstitial site to the next. The interstitial ions are supposed to be mobile but (to avoid complications) the vacant sites are supposed to be immobile. The rate of production of defects was supposed to be given by the usual form of expression for ionic mobility, $N\nu_1 \exp\{-(W_1 - qa_1E)/kT\}$, where N = concentration of filled cation sites, ν_1 = vibration frequency, W_1 = activation energy at zero field, q = charge on ions, a_1 = activation distance, and the rate of destruction is given by $i\sigma m$, where i = current, σ = cross section for the capture of interstitial ions by vacant sites, and m = concentration of vacant lattice sites. Thus,

$$dm/dt = N\nu_1 \exp\{-(W_1 - qa_1E)/kT\} - i\sigma m$$
$$i = 2a_2\nu_2 m \exp\{-(W_2 - qa_2E)/kT\}.$$

Thus for a sudden increase in field, $(\Delta E/\Delta \log_e i) = kT/qa_2$, and for steady-state conditions, $dE/d \log_e i = 2kT/q(a_2+a_1)$. Furthermore, on suddenly increasing the field, the current after the initial sudden change should increase rapidly at first and then more slowly. With tantalum (4), the current actually builds up slowly and then more rapidly, thus suggesting the existence of some sort of cascade process involving the production of Frenkel defects by the moving ions instead of by the field alone. With bismuth, on the other hand, the behavior found is qualitatively as expected.

With tantalum and niobium, which are the only metals which behave sufficiently ideally for it, so far, to have been proved possible to obtain unequivocal evidence on the point, the Tafel slope, for steady-state conditions, shows an unexpected form of temperature dependence. With tantalum the Tafel slope for transient conditions has been shown to exhibit a similar anomalous temperature dependence. According to the most recent work (4), which happens to be by one of us, the behavior may be explained by the necessity to include a higher power of the field, so that $(\alpha - \beta E)$ replaces a in the above equations. With the lower fields with which we are here concerned one might anticipate that, if the explanation is correct, the simple form of temperature dependence would be shown. Unfortunately, we were not able to obtain experimental data over a wide enough range of temperature to settle the point. The data on the transient Tafel slope (Table III) obtained at 0° C and 50° C (with initial current about 20 ma cm^{-2}) show the same absence of the expected temperature dependence as would be found with tantalum (with fixed initial current). The data are probably statistically significant on this point but we do not consider them to be decisive. Significant values of the steady-state Tafel slope could be obtained at 0° C and 25° C only. They were, as it happens, consistent with proportionality to temperature.

The values of the activation distances (obtained from the Tafel slopes, see earlier) are unusually large. Thus with tantalum a_2 is of the order of 1 Å and a_1 of the order 5 Å (varying with temperature and current density). With bismuth a_2 is of the order 4 Å and a_1 of the order 22 Å.

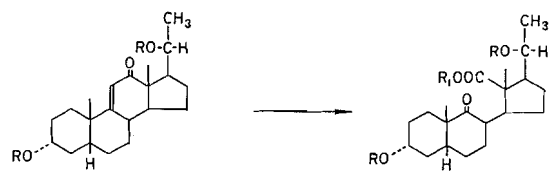
ABSTRACT

It is shown that the ozonolysis of $\Delta^{9(11)}$-12-keto steroids with a trans fusion of rings A and B proceeds in better yields than the corresponding opening of ring C in the sterically more hindered A/B-cis series. The syntheses of 23ξ-bromo-3β-hydroxy-9-oxo-9,12-*seco*-25-iso-5α,22β-spirostan-12-oic acid and some of its derivatives as well as of 3β,20α-dihydroxy-9-oxo-9,12-*seco*-12-pregnanoic acid and some of its ester derivatives are reported. It is demonstrated that the reduction with lithium aluminum hydride in tetrahydrofuran of a 12,20-diketone leads predominantly to a 12β,20α-dihydroxy derivative, in contradistinction to the reduction of a 12α-acetoxy-20-ketone, which affords mostly the 20β-alcohol.

In Part I of this study (1), we described an opening of ring C of the steroid nucleus, in the presence of protected alcohol functions in positions 3 and 20, leading to a 9-oxo-9,12-*seco*-12-acid derivative of type II. The fission of ring C was effected by ozonolysis of a $\Delta^{9(11)}$-12-ketone (compare I), a reaction which gave only a low yield of the desired *seco* product.



I, R = acyl

II, R = H, acyl
R_1 = H, alkyl

An inspection of models (compare Fig. 1) suggests that this reaction should proceed in better yields in the case of steroids with a trans fusion of rings A and B. It can be

seen that even though a 9,11-double bond is also shielded in the case of an A/B-trans fused system (Fig. 1*b*), particularly by the hydrogen substituents of carbon atom 1, the attack, especially from the α-side of the molecule, is far more hindered in the case of a cis fusion of rings A and B. In that instance, ring A (which is perpendicular to the plane of the rest of the ring system), the equatorial hydrogen atom in position 1, and the axial 2α- and 4α-hydrogen atoms protect the double bond in a cage-like manner (see Fig. 1*a*). In this publication we endeavor to show that the stereochemistry of the fusion of rings A and B indeed influences the yield of ozonolysis of a 9,11-unsaturated 12-keto steroid.

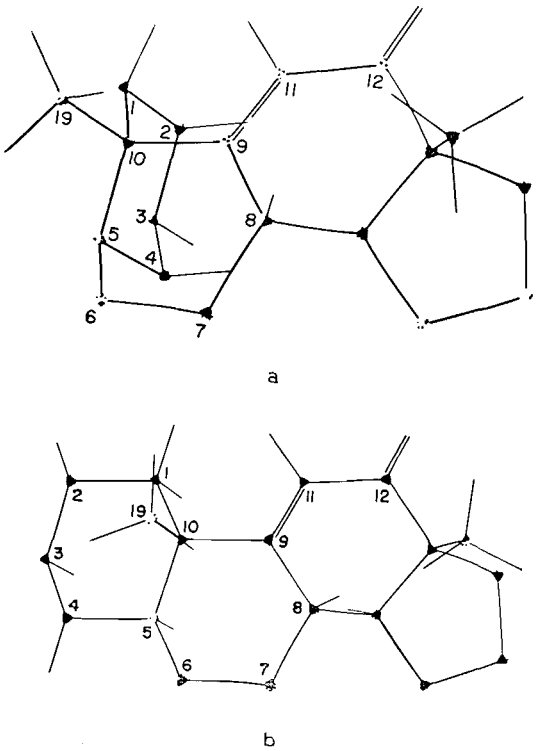

FIG. 1. Models of $\Delta^{9(11)}$-12-keto steroids: (*a*) with cis fusion of rings A and B; (*b*) with trans fusion of rings A and B.

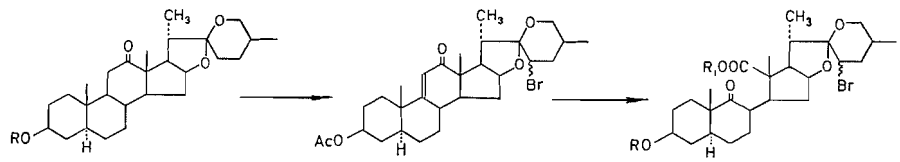
In a first series of experiments, we transformed hecogenin acetate (III*a*), according to Djerassi's method (3), to 23ξ-bromo-9(11)-dehydrohecogenin acetate (IV), which we ozonized under conditions similar to those employed in our experiments in the A/B-cis series (1). The usual working up of the ozonide with aqueous hydrogen peroxide gave a 52% yield of acidic material. Methylation and reacetylation afforded a product which gave, upon chromatography, crystalline acetoxy methyl ester V*b* in an overall yield of 13% (from III*a*). Reozonization of the neutral fraction isolated from the ozonolysis product gave a 71% yield of acidic material from which a further 14% of pure ester V*b* was obtained. These yields are significantly higher than those achieved in the A/B-cis series (1). The structure of the *seco* derivatives (V, V*a*, V*b*) was ascertained by infrared and elemental analyses of the acetoxy methyl ester V*b*.



III, R = H
IIIa, R = Ac

IV

V, R = R$_1$ = H
Va, R = H; R$_1$ = CH$_3$
Vb, R = Ac; R$_1$ = CH$_3$

After this preliminary set of experiments, which already seemed to confirm our assumption of a more facile opening of the 9,11-double bond in the A/B-trans series, we wished to compare the yield of the formation of a 9-oxo-9,12-*seco*-12-acid of the A/B-trans series in the instance of a compound truly analogous to the derivatives which we had studied in the A/B-cis series. This endeavor was of particular interest to us since our goal was the synthesis of 3,20-dioxygenated 9-oxo-9,12-*seco*-12-acids (compare ref. 1).

We chose hecogenin (III) as starting material and degraded its acetate III*a*, according to the experimental procedure of Wall and co-workers (4, compare also refs. 5 and 6), to Δ^{16}-5α-pregnen-3β-ol-12,20-dione (VI), which we isolated as the acetate VI*a* (6, 7). The unsaturated diketone VI*a* was reduced in the usual fashion, with palladium on charcoal, to the saturated acetoxy diketone VII (6).

We decided to transform the 3β-acetoxy-12,20-diketone VII to the 3,20-diacetoxy-12-keto derivative IX (and thence to the unsaturated 12-ketone VIII) by metal hydride reduction of the keto functions with concomitant hydrolysis at position 3 (compare X), followed by partial esterification of the 3- and 20-hydroxy groups (compare X*a*), and by subsequent oxidation of the unprotected 12-hydroxy function.[7]

The reduction of the diketo acetate VII with lithium aluminum hydride in tetrahydrofuran gave a crystalline product from which a homogenous trihydroxy adduct was isolated in high yield; we assign to this compound the structure of 3β,12β,20α-trihydroxy-5α-pregnane (X).

Indeed, the diacetate obtained by careful selective acetylation of the triol must be a 3,20-diacetate (compare X*a*), since its oxidation yields a keto diacetate (compare IX), which can be readily dehydrogenated with selenium dioxide to an α,β-unsaturated ketone; such a reaction is possible in the case of a 12-ketone but not in the case of a 20-ketone. Furthermore, the infrared carbonyl absorption of the α,β-unsaturated ketone (ν_{max}^{KBr} 1675 and 1604 cm^{-1}) is in accord with structure VIII but not with that of a Δ^{16}-20-ketone.[8] Upon diacetylation of the trihydroxy derivative X to the hydroxy diacetate X*a*, a decrement of molecular rotation of 45° is observed. A compilation of data from the literature (compare also ref. 8) indicates that the decrement due to acetylation of a 3β-alcohol of the A/B-trans series averages 30°. Hence, acetylation of the 20-hydroxy function of triol X resulted in a decrement of rotation of approximately 15° (or, in the case of an exceptionally strong negative contribution of the acetylation in position 3, in a

[7] *Another pathway will be described in a subsequent paper of this series.*

[8] *The diacetate cannot be a 12,20-diacetate since a 3β-hydroxy function is esterified faster than hydroxy functions in 12 and 20. Also, the ultraviolet absorption maximum of the above-mentioned α,β-unsaturated ketone (compare VIII) (λ_{max}^{EtOH} 238 mμ) agrees with that of a $\Delta^{9(11)}$-12-ketone but not with that of a Δ^{1}-3-ketone, which would have been formed if a 12,20-diacetoxy-3-hydroxy derivative of the A/B-trans series had been subjected to the above-described sequence of transformations.*

very small increment). This is in excellent agreement with an α-configuration of the 20-hydroxy function, but not with a β-configuration, which results invariably in a marked increment of molecular rotation (9).

The β-configuration of the 12-hydroxy group of compound X follows from the facile triacetylation of this product, at room temperature; under analogous conditions a 12α-hydroxy group is not acetylated. Furthermore, the molecular rotation of the resulting triacetate X*b* exceeds that of the diacetate X*a* by 15° only; acetylation of a 12α-alcohol results invariably in a strong increment (averaging 150–190°) of molecular rotation (compare refs. 10, p. 179; 11–15, and, for extreme values, 16–18).

The predominant formation of a 20α-alcohol (compare X) by reduction of the acetoxy diketone VII with lithium aluminum hydride in tetrahydrofuran is of interest. In the majority of cases (compare ref. 10, pp. 568, 622, and the relevant references therein) metal hydride reduction of a 20-ketone leads mainly to 20β-alcohols. As we reported in the first part of this study (1), reduction of 3α,12α-diacetoxypregnan-20-one with lithium aluminum hydride affords predominantly the 20β-alcohol. However, Just and Nagarajan (19) showed recently that reduction of the corresponding 3α,12α-dihydroxy-20-ketone, with the same reagent, gives a high yield of the 20α-alcohol; these authors suggest that this is due to a bridging of the 12- and 20-oxygen functions by an intermediate complex with the aluminum hydride ion; the formation of this complex would force the side chain into a conformation inducive to reduction to a 20α-alcohol. The reduction of the 20-ketone to a 20α-alcohol in the presence of a 12-keto function could be explained in a similar manner.[9]

The formation in high yield of the equatorial 12β-alcohol (compare X) by metal hydride reduction of the 12-ketone VII is in accord with conformational and configurational expectations and confirms the results obtained by Hirschmann *et al.* (20) in the reduction of hecogenin acetate (III*a*) with lithium aluminum hydride; according to these authors, the 12α- and 12β-alcohols are formed in approximate yields of 25 and 75%, respectively.[10] Reduction of an 11α-halo-12-ketone (compare for instance ref. 21) and of a 9,11-unsaturated 12-ketone (22) with metal hydrides also yields predominantly the 12β-alcohols. Only Pataki, Meyer, and Reichstein (23) report that reduction of methyl 3α-acetoxy-12-oxoetianate with sodium borohydride affords the two 12α- and 12β-epimeric alcohols in 41 and 31% yields, respectively.

As mentioned above, 3β,12β,20α-dihydroxy-5α-pregnane (X) can be partially acetylated in positions 3 and 20. Treatment of the triol with approximately three equivalents of acetic anhydride in pyridine, at 0°, gave a 50% yield of diacetate X*a*. The remainder of the product consisted mainly of triacetate X*b*. After separation of the diacetate X*a* from the reaction product, the rest of the mixture was hydrolyzed, with methanolic potassium hydroxide, to the triol X. Thus, the effective yield of diacetylation could be raised to approximately 80%. Oxidation of the hydroxy diacetate X*a* with chromic acid in acetic acid gave the diacetoxy ketone IX in over 80% yield. Conversion of this product

[9]*We shall discuss the stereochemical course of the reduction of 20-keto steroids with metal hydrides, in relation to the conformation of the side chain, in more detail in a forthcoming paper of this series.*

[10]*In their discussion of the stereochemical course of the reduction of steroid ketones with metal hydrides, Fieser and Fieser (10, pp. 268–270) indicate that the reduction of a 12-ketone gives a 1:1 ratio of the two 12-hydroxy epimers; they refer to the above-quoted article by Hirschmann et al. (20). These authors mention indeed that after methylsuccinylation of the reduction product the two 12-epimeric 3β-monomethylsuccinates were isolated in approximately equal amounts; but they also indicate that there remained, after the separation of the crystalline epimers from the crude reaction product, an amorphous mixture, amounting to more than 50% of the total product; this amorphous material was largely succinylated in both the 3- and 12-positions and afforded, upon hydrolysis, rockogenin, the 12β-hydroxy epimer. Thus, the actual yield of the 12β-alcohol amounts approximately to 75% and the yield of the 12α-epimer to approximately 25%, as indicated above.*

to the 9,11-unsaturated diacetoxy ketone VIII, with selenium dioxide (24, 25), proceeded in almost 70% yield.

Ozonolysis of the 9,11-unsaturated 12-ketone VIII under conditions equivalent to those described in the first part of this investigation (1) gave a 63% yield of acidic material (compare XI), which afforded upon methylation (compare XI*a*) and acetylation, in an overall yield (from VIII) of 11%, crystalline methyl 3β,20α-diacetoxy-9-oxo-9,12-*seco*-5α-pregnan-12-oate (XI*b*), characterized by elemental analysis and by its infrared and ultraviolet absorption spectra, as well as by the spectra of the intermediates XI and XI*a*. Reozonization of the neutral fraction isolated from the product of ozonolysis gave a 47% yield of an acid fraction which afforded another 7% of pure diacetoxy methyl ester XI*b*. The yields of both the crude acid fractions (compare XI) and of pure diacetoxy methyl ester XI*b* were significantly higher than those obtained with the 3,20-diacetoxy-9,11-unsaturated 12-ketone of the A/B-cis series (1). The yield of crude acid material obtained upon ozonolysis was raised from 25–30% to 50–60%, the yield of pure diacetoxy methyl ester (XI*b*), after reozonization of the neutral ozonolysis fraction, from 5 to 18%. Thus, the results of both the ozonolysis of 23ξ-bromo-9-dehydrohecogenin acetate (IV) and of $\Delta^{9(11)}$-3β,20α-diacetoxy-5α-pregnen-12-one (VIII) confirm our postulate that the 9,11-double bond of an A/B-trans steroid is opened more readily than that of a product with an A/B-cis configuration.

EXPERIMENTAL[11, 12, 13]

Methyl 23ξ-Bromo-3β-acetoxy-9-oxo-9,12-seco-25-iso-5α,22β-spirostan-12-oate (Vb) from 23ξ-Bromo-9(11)-dehydrohecogenin Acetate (IV)

A quantity of 900 mg of 23ξ-bromo-9(11)-dehydrohecogenin acetate (IV), prepared from hecogenin acetate (III*a*), according to the method of Djerassi *et al.* (3), was dissolved in a mixture of 13.5 cc of acetic acid and 13.5 cc of ethyl acetate. At −10°, a stream of oxygen, containing 8% of ozone and flowing at an approximate rate of 160 cc per minute, was passed through the solution for the period of 4.5 hours (approximately 85 equivalents of ozone). Water (3.5 cc) and 30% hydrogen peroxide (0.35 cc) were added and the mixture was stored for 18 hours at room temperature. The product was dissolved in 2 l. of ether and the solution was washed with water and extracted with a 1.5 *N* sodium hydroxide solution. The ethereal solution was washed until neutral and dried over sodium sulphate; evaporation of the solvent gave 451 mg of neutral product.

The aqueous alkaline solution was acidified with sulphuric acid to the Congo-blue reaction and the resulting mixture was extracted with chloroform. The organic layer was washed until neutral and dried over sodium sulphate and the solvent was removed. Thus, 458 mg (52%) of crude *hydroxy keto acid V* was obtained. This product could not be crystallized. The material was dissolved in 5 cc of absolute methanol and treated at 0° with 26 cc of a 2.7% ethereal diazomethane solution. After 10 minutes the solution was allowed to warm to room temperature and was stored at 25° for another 16 hours. The excess diazomethane was destroyed with acetic acid and the solvent was removed *in vacuo*. The residue (454 mg), representing crude *hydroxy keto methyl ester Va*, could not be crystallized. The material was acetylated in the usual fashion with 4 cc of acetic anhydride in 7 cc of pyridine and the resulting crude acetoxy keto ester V*b* (461 mg) was dissolved in 4 cc of benzene and absorbed on 14 g of slightly alkaline aluminum oxide. Benzene–ether mixtures (4:1 and 1:1) eluted 122 mg (12.7%) of crystalline methyl *23ξ-bromo-3β-acetoxy-9-oxo-9,12-seco-25-iso-5α,22β-spirostan-12-oate (Vb)*, which melted after one recrystallization from methanol–water at 99–101°. The bromine-containing product was recrystallized twice from methanol–water for analysis; short prisms, m.p. 100–101°, $[\alpha]_D^{22}$ 5° (*c*, 0.985 in $CHCl_3$), λ_{max}^{EtOH} 282 mμ, ν_{max}^{KBr} 1720 cm^{-1} (broad ester band), 1707 cm^{-1} (9-ketone), 1251 and 1242 cm^{-1} (double ester band). Anal. Calc. for $C_{29}H_{43}O_7Br$: C, 59.68; H, 7.43. Found: C, 59.43; H, 7.46.

The neutral fraction of the ozonolysis experiment (451 mg) was dissolved in 14 cc of a 1:1 mixture of acetic acid and ethyl acetate and treated at −10° with ozone for 2.5 hours, as described above. The ozonide

[11] *The melting points were taken in evacuated capillaries and the temperatures were corrected.*

[12] *We are indebted to Mr. J. F. Alicino, Metuchen, N.J., and to Mr. A. Bernhardt, Mülheim (Ruhr), Germany, for the microanalyses, and we extend to them our sincere appreciation.*

[13] *If not otherwise stated, Merck's aluminum oxide was used for chromatography. The alkaline reagent was treated as described in footnote 18 of reference 26. We sincerely thank Merck and Company, Montreal, for the generous gift of this material.*

was decomposed with 2 cc of water and 0.2 cc of a 30% hydrogen peroxide solution. The usual working up (see above) gave 118 mg of neutral product and 304 mg (71%) of acidic material. The acid fraction was methylated and acetylated according to the method described above. Chromatography of the resulting product gave 113 mg (13.9%) of crystalline acetoxy methyl ester V*b*, which yielded, after one recrystallization from methanol–water, 98 mg of ester V*b*, melting at 99–100°.

Δ^{16}-3β-Acetoxy-5α-pregnene-12,20-dione (VIa)

A quantity of 25 g of hecogenin acetate (III*a*) was converted according to the procedure of Wall *et al.* (4) to *Δ^{16}-3β-hydroxy-5α-pregnene-12,20-dione (VI)*. The crude amorphous product (21.3 g) was dissolved in 80 cc of pyridine and treated for 16 hours with 40 cc of acetic anhydride, at room temperature. The usual working up afforded 21.5 g of a yellow oil which was chromatographed on 650 g of aluminum oxide Woelm (activity II–III). Petroleum ether – benzene (1:1 and 1:4) and benzene eluted 12.2 g (58.6%) of *Δ^{16}-3β-acetoxy-5α-pregnene-12,20-dione (VIa)*, m.p. 169–173°. Recrystallization from ether–ethanol afforded 10.4 g (45%) of pure acetate VI*a*; m.p. 178–180°, $[\alpha]_D^{25}$ 126° (*c*, 1.00 in $CHCl_3$), λ_{max}^{EtOH} 227 mμ (log ε 3.94). Recrystallization from ether gave a product melting between 176 and 177°, $[\alpha]_D^{25}$ 128° (*c*, 1.00 in $CHCl_3$), λ_{max}^{EtOH} 227 mμ (log ε 3.92). Anal. Calc. for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66. Found: C, 74.02; H, 8.60.

3β-Acetoxy-5α-pregnane-12,20-dione (VII)

A solution of 9.5 g of Δ^{16}-3β-acetoxy-5α-pregnene-12,20-dione (VI*a*), m.p. 174–174.5°, in 500 cc of 95% ethanol was hydrogenated with 1 molecular equivalent of hydrogen over 950 mg of 5% palladium on charcoal at room temperature and at atmospheric pressure. The solution was filtered over sodium sulphate and taken to dryness. Recrystallization of the crude product (9.55 g) from ethanol gave 9.3 g (97% yield) of crystalline acetoxy diketone VII, m.p. 183–184°. The product showed no ultraviolet absorption at 227 mμ. A sample was recrystallized twice from ethanol, for analysis; prisms, m.p. 186–187°, $[\alpha]_D^{22}$ 138° (*c*, 0.981 in $CHCl_3$). Anal. Calc. for $C_{23}H_{34}O_4$: C, 73.76; H, 9.15. Found: C, 73.69; H, 9.00.

3β,12β,20α-Trihydroxy-5α-pregnane (X)

A solution of 1.0 g of 3β-acetoxy-5α-pregnane-12,20-dione (VII) in 80 cc of absolute tetrahydrofuran was added over a period of 15 minutes to a slurry of 1.23 g of lithium aluminum hydride in 80 cc of absolute tetrahydrofuran. The mixture was refluxed for 1 hour and was kept at room temperature for another 16 hours. The excess lithium aluminum hydride was decomposed with ethyl acetate and ice, and the product was poured into iced 2 *N* sulphuric acid. The mixture was extracted with ether, the ethereal solution was washed with iced dilute sulphuric acid, cold sodium bicarbonate solution, and water and was dried over sodium sulphate. Removal of the solvent afforded 950 mg of a semicrystalline solid, m.p. 205–210°, which showed no carbonyl absorption in the infrared. Recrystallization from ethanol afforded 820 mg (91%) of 3β,12β, 20α-trihydroxy-5α-pregnane (X), m.p. 219–221°. A sample was recrystallized three times from ether–methanol, for analysis; prisms, m.p. 225–226°, $[\alpha]_D^{24}$ 1.1° (*c*, 1.000 in $CHCl_3$), $[\alpha]_D^{22}$ 0.7° (*c*, 0.991 in methyl cellusolve). Anal. Calc. for $C_{21}H_{36}O_3$: C, 74.95; H, 10.78. Found: C, 75.04, 74.98; H, 10.65, 10.88.

Diacetate (Xa)

A solution of 10 g of 3β,12β,20α-trihydroxy-5α-pregnane (X) in 28 cc of pyridine was treated at 0° with 9 cc of acetic anhydride. The mixture was kept for 16 hours at 0° and was worked up in the usual manner. The resulting amorphous product (12.964 g) was dissolved in 25 cc of benzene and chromatographed on 370 g of aluminum oxide (activity II–III). Petroleum ether – benzene (1:1 and 1:4), benzene, and benzene–ether (4:1) gave 3.44 g of crystalline *triacetate Xb* (see below); benzene–ether (1:1) eluted an oil, and ether washings afforded 6.264 g (50.1%) of crystalline *diacetate Xa*, m.p. 181–185°. Ethyl acetate and methanol eluted oils. Recrystallization of the diacetate X*a* from ether – petroleum ether gave 4.011 g of fluffy, long needles, m.p. 188–190°. A sample was recrystallized three times for analysis; m.p. 192–193°, $[\alpha]_D^{22}$ −9.2° (*c*, 0.649 in $CHCl_3$).[14] Anal. Calc. for $C_{25}H_{40}O_5$: C, 71.39; H, 9.59. Found: C, 71.40; H, 9.56.

The mother liquors of the crystallization of X*a* (1.831 g) were combined with the amorphous chromatogram fractions and with the crude triacetate X*b*, isolated from the chromatogram (see above). This product (8.641 g) was dissolved in 455 cc of methanol and refluxed for 6 hours with 282 cc of an 8.1% methanolic potassium hydroxide solution. The mixture was kept for another 16 hours at room temperature, and was subsequently poured into 3 l. of water. The precipitate was extracted with ether, the organic solution was washed until neutral and dried over sodium sulphate. Evaporation of the solvent gave 7.03 g of a crude product, which yielded upon crystallization from acetone 6.09 g of starting material, *3β,12β,20α-trihydroxy-5α-pregnane (X)*, m.p. 217.5–219°. Considering this recovery of the triol X, the yield of diacetate X*a* was 82%.

In another run, 750 mg of the triol X was acetylated to 647 mg of crude diacetate X*a*, m.p. 170–180° (69% yield, not taking into account the recovery of starting material).

[14]*We sincerely thank Professor G. Just and Dr. G. R. Nagarajan, McGill University, Montreal, for taking this rotation in their microtube.*

Triacetate Xb

A solution of 150 mg of 3β,12β,20α-trihydroxy-5α-pregnane (X) in 2 cc of pyridine was treated at room temperature for 16 hours with 0.8 cc of acetic anhydride. The usual working up gave 215 mg of a foam which afforded, upon filtration over aluminum oxide, 195 mg (95% yield) of crystalline triacetate X*b*, m.p. 162–164°. A sample was recrystallized three times from acetone–hexane and was subsequently sublimed for analysis in high vacuum, at 110°; small prisms, m.p. 167–169°, $[\alpha]_D^{24}$ −4.9° (*c*, 1.000 in $CHCl_3$). Anal. Calc. for $C_{27}H_{42}O_6$: C, 70.09; H, 9.15. Found: C, 69.84; H, 9.23.

3β,20α-Diacetoxy-5α-pregnan-12-one (IX)

To a solution of 500 mg of 3β,20α-diacetoxy-5α-pregnan-12β-ol (X*a*), m.p. 191–192°, in 21 cc of acetic acid, a solution of 131 mg of chromic oxide in 1.25 cc of 90% acetic acid was added, at 17°. The mixture was kept at the same temperature for 17 hours, was then treated with 3 cc of methanol, and was finally poured into 250 cc of water. The product was extracted with ether and worked up in the usual fashion. Thus, 496 mg of crystals, m.p. 148–154°, were obtained. Recrystallization from ether–hexane gave 385 mg of diacetoxy ketone IX, m.p. 164–167°. Chromatography of the mother liquors afforded another 35 mg of the diacetoxy ketone IX, m.p. 164.5–166.5° (total yield 84%). A sample was recrystallized twice from ether–hexane for analysis; fine needles, m.p. 168–170°, $[\alpha]_D^{22}$ 58.2° (*c*, 1.00 in $CHCl_3$). Anal. Calc. for $C_{25}H_{38}O_5$: C, 71.74; H, 9.15. Found: C, 71.72; H, 9.09.

$\Delta^{9(11)}$-3β,20α-Diacetoxy-5α-pregnen-12-one (VIII)

To a solution of 600 mg of 3β,20α-diacetoxy-5α-pregnan-12-one (IX) in 8.04 cc of 0.0006 *N* hydrogen chloride in acetic acid, 450 mg of selenium dioxide was added. The mixture was refluxed for 20 hours, cooled, and poured into 500 cc of ether. After filtration over sodium sulphate, the solution was washed with water, cold dilute hydrochloric acid, iced sodium bicarbonate solution, and again with water and was dried over sodium sulphate. Removal of the solvent gave 605 mg of a product which crystallized from ether–hexane. A solution of this material in 3 cc of benzene was absorbed on 18 g of aluminum oxide. Benzene–ether (4:1) eluted crystalline $\Delta^{9(11)}$-3β,20α-diacetoxy-5α-pregnen-12-one (VIII), m.p. 174–179°, which gave upon one recrystallization from ether–hexane 409 mg (67.5%) of the unsaturated ketone VIII, m.p. 184–185°, $[\alpha]_D^{23}$ 42.5°(*c*, 0.99 in $CHCl_3$), λ_{max}^{EtOH} 238 mμ (log ε 4.1), ν_{max}^{KBr} 1740 and 1254 cm^{-1} (3β,20α-diacetate), 1685 and 1604 cm^{-1} ($\Delta^{9(11)}$-12-keto doublet). Anal. Calc. for $C_{25}H_{36}O_5$: C, 72.08; H, 8.71. Found: C, 72.19; H, 8.57.

Methyl 3β,20α-Diacetoxy-9-oxo-9,12-seco-5α-pregnan-12-oate (XIb)

At −10°, a stream of oxygen, containing 7.8% of ozone, was passed through a solution of 1.5 g of $\Delta^{9(11)}$-3β,20α-diacetoxy-5α-pregnen-12-one (VIII) in 29.7 cc of acetic acid and 29.7 cc of ethyl acetate, at a flow rate of 140 cc per minute, for the period of 105 minutes. There was added 7 cc of water and 0.7 cc of a 30% hydrogen peroxide solution, and the mixture was allowed to stand overnight at room temperature. The product was extracted with 2 l. of ether, the ethereal solution was washed with water, six times with iced 1.5 *N* sodium hydroxide solution, and again with water and was dried over sodium sulphate. Removal of the solvent gave 603 mg of a neutral product.

The alkaline washings were combined and acidified with sulphuric acid to the Congo-blue reaction. The product was extracted with chloroform and the organic solution was washed until neutral and was dried. Removal of the solvent gave 803 mg (63%) of amorphous acid (compare XI) which resisted all attempts of crystallization.

A solution of this acid (803 mg), in 4 cc of absolute methanol and 8 cc of absolute ether, was treated at 0° with 43 cc of a 1.5% ethereal diazomethane solution. The product was kept for 20 hours at room temperature and the excess diazomethane was destroyed with acetic acid. Evaporation of the solvent *in vacuo* gave 820 mg of an amorphous neutral product (compare XI*a*). Acetylation at room temperature with 4 cc of acetic anhydride in 10 cc of pyridine gave 843 mg of amorphous material, which was dissolved in 5 cc of benzene and absorbed on 24 g of aluminum oxide. Benzene–ether (4:1 and 1:1) eluted crystalline fractions contaminated with oils. Recrystallization from aqueous methanol gave 182 mg (11.2%, from VIII) of colorless, fine, short needles, m.p. 147–148°, representing the diacetoxy keto methyl ester XI*b*. A sample was recrystallized four times for analysis; m.p. 153–154°, $[\alpha]_D^{22}$ 101° (*c*, 1.060 in $CHCl_3$), λ_{max}^{EtOH} 280 mμ. Anal. Calc. for $C_{25}H_{38}O_7$: C, 66.64; H, 8.50. Found: C, 66.47; H, 8.50.

The neutral fraction (603 mg) isolated after ozonolysis (see above) was dissolved in 12 cc of acetic acid and 12 cc of ethyl acetate and reozonized at −10° with a 7.9% ozone stream, for 67 minutes (flow rate 180 cc per minute). The product was treated as described above with 2.8 cc of water and 0.28 cc of a 30% hydrogen peroxide solution. The material was worked up as described above and there was obtained 286 mg of a neutral fraction and 301 mg (47%) of an acid fraction (compare XI) which was methylated in 1.5 cc of absolute methanol and 3 cc of absolute ether with excess diazomethane (16.5 cc of a 1.5% ethereal solution). The reaction product (307 mg) was acetylated in the usual fashion. Chromatography of the amorphous material thus obtained (314 mg) afforded 111 mg (13.6% yield from the neutral product of the first ozonolysis, 6.9% yield calculated from the total starting material) of *seco* ester XI*b*, m.p. 147.5–148.5°. The total yield of the *seco* ester XI*b*, after one reozonization, amounted to 18%.

ACKNOWLEDGMENTS

We extend sincere thanks to Mr. R. W. White, Science Service Laboratory, London, Ontario, for a number of infrared analyses, and to Mrs. J. Capitaine and Mr. D. Capitaine for their valuable assistance. We are greatly indebted to The National Research Council of Canada, The Federal–Provincial Departments of Health and Welfare, Ottawa and Toronto, to Ayerst, McKenna and Harrison, Ltd., Montreal, the Schering Corporation, Bloomfield, N.J., the Schering Corporation Ltd., Montreal, and to the Canadian Life Insurance Officers Association, for financial support. We appreciated the kind encouragement of Dean J. B. Collip and of Professor J. A. Gunton, in whose departments part of this work was carried out at the University of Western Ontario, and the cooperation of the authorities of Laval University, in particular of Director P. A. Giguère.

THE THERMAL DECOMPOSITION OF HEXAFLUOROAZOMETHANE[1]

ELIZABETH LEVENTHAL, CHARLES R. SIMONDS,[2] AND COLIN STEEL[3]
Chemistry Department, University of Toronto, Toronto, Ontario

Received December 18, 1961

ABSTRACT

The pyrolysis of hexafluoroazomethane has been studied in a static system between 0.3 mm and 73 mm and 572° K and 634° K by measuring the rate of nitrogen formation. The rate constant of the high-pressure homogeneous reaction is given by $k = 10^{16.17\pm0.15} \exp(-55{,}200 \pm 400/RT)$ sec^{-1}.

INTRODUCTION

There has recently been interest in the thermal decomposition of azo compounds in connection with the problem of frequency factors in unimolecular reactions (1, 2). Most azo compounds possess high-frequency factors and the reported data for the simple members are shown in Table I. Hexafluoroazomethane appeared to be somewhat out of

TABLE I
Decomposition of azo compounds in the gas phase

Compound	Reference	log A (sec^{-1})	E (kcal mole^{-1})
$CF_3N{=}NCF_3$	3	13.9	48.5
$CF_3N{=}NCF_3$	This work	16.2	55.2
$CH_3N{=}NCH_3$	6	15.7	51.2
$C_2H_5N{=}NC_2H_5$	9	15.7	48.5
i-$C_4H_9N{=}N$$i$-$C_4H_9$	13	16.3	42.8

line, since the entropy of activation is significantly lower than the entropy of activation of the other compounds. The decomposition of hexafluoroazomethane has been studied by the toluene carrier technique (3), and as has been emphasized elsewhere (1, 2), this method gives low results for the high-pressure frequency factor A_∞, and for the high-pressure activation energy E_∞, if the system is in the pressure-dependent region. For these reasons we have reinvestigated the reaction using a static system similar to the one used for the pyrolysis of azomethane.

EXPERIMENTAL

Materials

Hexafluoroazomethane was prepared after the manner of Ruff and Willenberg (4). Gas chromatographic and mass spectrometric analyses showed the presence of 3% of higher-boiling impurities, which were probably perfluorotetramethylhydrazine and perfluorohexamethyltetrazine (5). The propylene was Phillips Research Grade.

Apparatus

A 460-ml Pyrex reaction vessel was contained in an electric furnace kept constant to ±0.05° C by means of a platinum resistance thermometer proportional controller. The output from the bridge was amplified and fed onto a recorder so that a record of the temperature variation throughout the reaction was obtained. The temperature was read to 0.05° C by means of a two-junction thermocouple contained within an axial well in the reaction vessel.

Procedure

In the experiments with hexafluoroazomethane alone the reactant was measured in a gas burette and the gas transferred quantitatively to the reaction vessel by freezing it into a small side thimble which was attached to the vessel. For the runs with added gas (propylene), the latter was quickly added to the vessel immediately after the azo compound had been flash-vaporized from the thimble, the positive propylene pressure ensuring that no hexafluoroazomethane diffused out of the reaction vessel. At the end of the run the products were pumped through two liquid nitrogen traps, by means of a diffusion pump and a Toepler pump working in series, into calibrated volumes where the pressure and volume of the non-condensable fraction were measured. The sample was then analyzed by gas chromatography or mass spectrometry. In the experiments with hexafluoroazomethane alone analyses showed that the non-condensable sample was pure nitrogen. In the runs with excess propylene, however, impurities were detected. A typical analysis was: N_2, 97½%; CH_4, 2½%; ethane, ½%; propylene, ½%.

RESULTS AND DISCUSSION

Variation in the Experimental First-order Rate Constant with Percentage Decomposition

The first step in the decomposition is undoubtedly

$$CF_3N{=}NCF_3 \rightarrow 2CF_3 + N_2. \qquad [1]$$

The trifluoromethyl radicals will then add to the parent compound so that the latter can no longer undergo reaction [1]. These addition reactions have been observed by Young and Dacey (5). Thus we should expect the experimental first-order rate constant to decrease with increasing percentage reaction. This can be seen from the data given in Fig. 1. In the subsequent experiments, therefore, we limited the decomposition to not

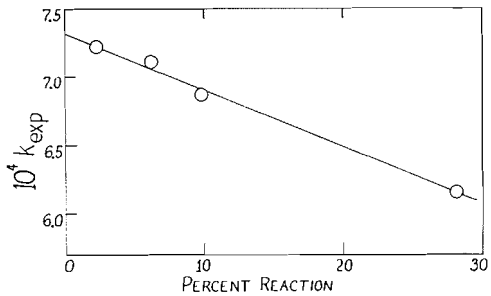

FIG. 1. Variation in experimental first-order rate constant (sec^{-1}) with percentage decomposition. Pressure of hexafluoroazomethane 4.9±0.5 cm Hg; temperature 594.8° K.

more than 20% (it was in fact generally less than 10%) and corrected all the rates to 0% decomposition. Such corrected rate constants are designated k to distinguish them from the original experimental rate constants $k_{expt.}$

Effect of Packing and Seasoning the Reaction Vessel

The pyrolysis of azomethane has been shown to be complicated by a surface effect which could be effectively removed by seasoning the surface of the reaction vessel with allyl bromide for 12 hours at 500° C (6). The results given in Table II for the decomposition of hexafluoroazomethane show that there is no significant difference between the rates obtained using packed and unpacked vessels. Furthermore, seasoning had no effect on the reaction. We may conclude that the decomposition proceeds homogeneously in the gas phase.

Effect of Pressure on the Reaction

Slater's theory (7, 8) indicates that the various vibrational modes contribute to different extents to the reaction coordinate. Thus, for example, the fast motions associated with

TABLE II

Effect of packing and seasoning the reaction vessel

No. of runs	10^4k (sec^{-1})	P_{azo} (cm Hg)	$\frac{\text{Surface area}}{\text{volume}}$ (cm^{-1})
7	1.60±0.10	0.20±0.01	8.27*
4	1.61±0.20	0.15±0.02	0.98†
4	1.54±0.15	0.17±0.02	0.98*

NOTE: All rate constants corrected to 611.0° K.

†Surface seasoned with allyl bromide at 500° C for 12 hours.

light hydrogen atoms can have little effect on the slower motion associated with a C—N stretching vibration. If we therefore substitute fluorine for hydrogen in azomethane we should expect the number of effective normal mode vibrations to increase. In terms of the Kassel model we should expect hexafluoroazomethane to be associated with a larger value of s (the number of effective oscillators) than is azomethane. Thus the pressure-dependent region should be shifted towards lower pressures, and for any pressure range the variation in rate constant with pressure should be less for hexafluoroazomethane than for azomethane. This can be seen in Fig. 2; here we have compared the results for both

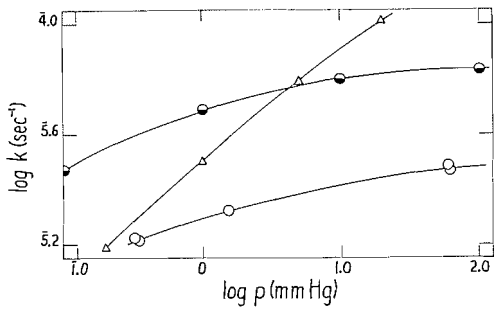

FIG. 2. Variation in rate constant with pressure: △ azomethane 563° K (6); ◒ azoethane 533° K (9); ○ hexafluoroazomethane 584° K.

systems. We have also added the curve for azoethane for comparison (9). The limited rate–pressure curve obtained here for hexafluoroazomethane was fitted by a Kassel (10) model having $s = 23\pm3$. The apparatus used was incapable of yielding data for higher or lower pressures. However, we hope to investigate the pressure dependence over a wide range using a newly designed apparatus. Tentatively we may state that the rates at very high pressures will not be very much greater than those obtained at 6–7 cm Hg, so that the latter results, to a good approximation, give the limiting high-pressure rates.

The Effect of Propylene on the Reaction

In the thermal decomposition of azomethane, propylene acted both as an energy transfer agent and as a chain inhibitor. In the former role it tended to increase the rate of reaction, in the latter it decreased the rate of reaction. As can be seen from Fig. 3 and from equations (*a*) and (*c*) below, for hexafluoroazomethane, propylene acts simply as an energy transfer agent, there being no evidence of any chain inhibition.

Arrhenius Parameters

In Fig. 3 we have given Arrhenius plots for three sets of experimental conditions.

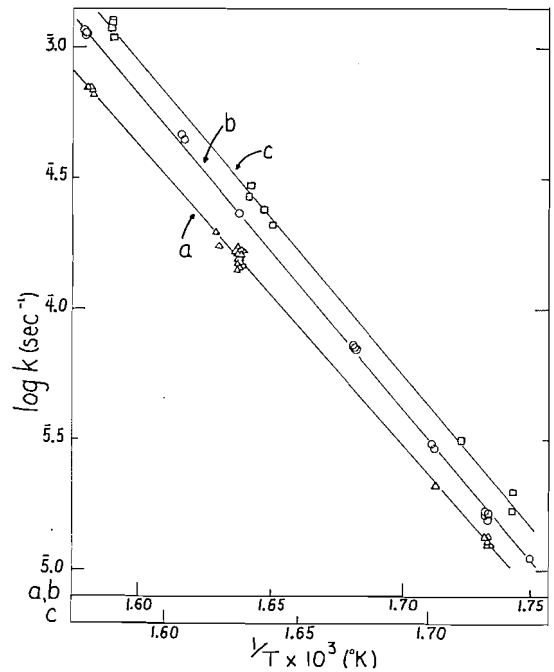

FIG. 3. Arrhenius plots for the thermal decomposition of hexafluoroazomethane. (*a*) P_{azo} 1.7±0.2, P_{prop} 0; (*b*) P_{azo} 63±7, P_{prop} 0; (*c*) P_{azo} 1.7±0.2, P_{prop} 66±7 mm Hg.

The corresponding equations determined by the method of least mean squares are:

$$k_{1.5\text{ mm}} = 10^{15.1\pm0.20} \exp(-52{,}700\pm600/RT)\ (\text{sec}^{-1}) \qquad (a)$$

$$k_{63\text{ mm}} = 10^{16.17\pm0.15} \exp(-55{,}200\pm400/RT)\ (\text{sec}^{-1}) \qquad (b)$$

$$k_{1.5\text{ mm, prop}} = 10^{15.93\pm0.20} \exp(-54{,}600\pm600/RT)\ (\text{sec}^{-1}) \qquad (c)$$

CONCLUSION

This study indicates that hexafluoroazomethane decomposes by a homogeneous non-chain mechanism with a frequency factor which is similar to those of the other simple azo compounds. Thus the reactivity of these compounds is governed by their activation energies. This can be seen in Table I. Azoisopropane affords an apparent exception to this regular trend, since Ramsperger (11) has reported that the rate constants are best fitted by the equation $k = 10^{13.7} \exp(-40{,}900/RT)$ sec^{-1}. However, Cohen and Zand (12) have recently reinvestigated the reaction and have shown that the decomposition is complicated by rearrangement to the isomeric hydrazone. The decomposition of azoisopropane, which merits more detailed study, is a complex process, accounting for the exceptional entropy and energy of activation.

ACKNOWLEDGMENT

The authors wish to thank Dr. J. R. Dacey for his generous provision of materials and facilities for the preparation of hexafluoroazomethane.

ABSTRACT

A series of carbamates of the dimer of 2,4-tolylene diisocyanate was prepared from different alcohols, leaving the uretidine-dione ring unaffected. Di-*sec*-butylamine and dibenzylamine did not affect the dimer ring and reacted only with the two free isocyanate groups. However, di-*n*-propylamine, di-*n*-butylamine, and di-*n*-amylamine ruptured the ring, and diureas of the monomer were obtained. Alkaline reduction changed the dimer ring into a ureylene link and a N-substituted amide was formed by the Leuckart reaction. Hydrazine hydrate gave an unsymmetrical monosubstituted urea whereas hydroxylamine broke the ring and gave the corresponding oxime of the formamide.

INTRODUCTION

In the manufacture of polyurethanes, polymeric diols are chain-extended with diisocyanates such as 2,4-tolylene diisocyanate (TDI) (1). Since commercial TDI contains a dimer it is of interest to study the stability of the uretidine-dione ring of the dimer (TDID), which shows isocyanate activity at relatively higher temperatures than the monomer. This property is being used to modify elastomers, plastics, and foams (2).

RESULTS

When the dimer of 2,4-tolylene diisocyanate was reacted with alcohols at about 90°, the corresponding diurethanes were formed, giving only traces of allophanates. The diurethanes prepared are listed in Table I. Higher temperatures in the range of 125 to 160° and catalysts such as triethylamine and N-methyl morpholine appeared to be necessary for the formation of allophanates (3) and triphenyl isocyanates (4).

TDID did not react with the *tert*-butyl alcohol probably because of its easy dehydration. Benzyl alcohol gave a reaction product which analyzed for a compound made from 1 mole of TDI and 2 moles of benzoic acid. However, this compound could not be prepared from TDI and benzoic acid. Under milder conditions only 1 mole of benzoic acid reacted with the isocyanate group in para position, which was due to the high reactivity of the para group compared to the ortho group (5).

The failure to dimerize 3-methylcarbamyl-2-isocyanatotoluene in pyridine was probably due to the fact that the *o*-isocyanate is hindered (6). Heating under reflux with benzene or ethyl acetate in excess changed TDID to an amorphous powder which was insoluble in all common organic solvents, but soluble in dimethylformamide. On heating the product to 215° for 45 minutes a yellow, hard-setting resin was obtained which was soluble in dimethylformamide.

Some of the dialkylamines used, such as di-*n*-propyl, di-*n*-butyl, and di-*n*-amylamines, ruptured the uretidine-dione rings of TDID very easily (Table II). In *o*-dichlorobenzene, the dimer ring was found to react with di-*n*-butylamine at an appreciable rate even at

50° (7, 8). Diisobutylamine and dibenzylamine, however, left the ring unaffected and reacted with the *o*-isocyanate groups to yield substituted ureas (Table III). Both compounds showed characteristic infrared absorption bands for CO stretching frequency of the four-membered uretidine-dione ring.

For the oxidation, reduction, and carbonyl activity studies the two free isocyanate groups in TDID were blocked by forming the *n*-butyl urethanes (V). The structure of the new diurethane derivative of TDID was derived from its analysis and infrared spectrum. The blocking of the two isocyanate groups seemed to enhance the stability of the uretidine-dione ring. Heating a solution of the compound in benzene or ethyl acetate under reflux did not affect the ring, which was found to be moderately stable toward oxidation by potassium persulphate, lead tetraacetate, and selenium dioxide in dioxane.

Alkaline reduction by various reagents such as sodium methylate, magnesium methylate, ammonium sulphide, or zinc and alcoholic ammonia all readily changed the ring into the ureylene link, with the appearance of CO and NH absorption bands at 1630 and 1602 cm^{-1} respectively. In alkaline medium, it seems that the ring was dissociated and that one of the isocyanate groups was hydrolyzed to amino group, which in turn reacted with the other isocyanate group to give symmetrical ureas. Hydrazine hydrate, on the other hand, reduced the ring to form an unsymmetrical monosubstituted urea.

The Leuckart reaction seems to give the corresponding N,N-substituted amide, according to infrared spectra determination. The new absorption for CO stretching (formyl group) at 1662 cm^{-1} (m) coupled with the appearance of free NH stretching vibration at 3410 cm^{-1} (m) and 3010 cm^{-1} (w) provide evidence for the presence of formyl derivatives of the primary amine (9). The failure to isolate any carbamate from the alcoholic solvent further lent credence to the conclusion that the uretidine-dione ring was intact. There was evidence that the CO group in the uretidine-dione ring acted as a true carbonyl, since hydroxylamine gave the oxime in poor yield. The elemental analysis corresponded to that of a N-substituted formamide oxime obtained from the monomer. This was also supported by the appearance of C—N and N—OH absorption bands and the absence of —N=C=N— absorption bands.

EXPERIMENTAL

General

The reactions with alcohols and diamine were performed in a 100-ml three-necked flask fitted with a mercury sealed stirrer. The condenser carried a $CaCl_2$ tube. Alcohols and diamines were taken in excess (2–3 ml) for 0.001 mole (1.0 g) of the dimer. The solvent used for the reactions was petroleum ether, A.R. (B.D.H.), b.p. 80–100° (40 ml). After the reaction was over the mixture was cooled, the compound filtered, washed, and dried in vacuum before crystallization.

All the melting points reported are uncorrected and most of them depend on the rate of heating. The infrared spectra were recorded with a Beckman IR–4 spectrophotometer using KBr pellets containing 0.5% by weight of sample, and reported spectra are all calibrated. Ultraviolet spectra were all recorded with a Beckman DK1-A spectrophotometer using 95% ethanol as solvent. Analyses were performed by Micro Tech Laboratories, Skokie, Ill.

2-Isocyanato-4-benzoylcarbamyl Toluene

A solution of 2,4-tolylene diisocyanate (5.0 g, 0.03 mole) and benzoic acid (3.65 g, 0.03 mole) in petroleum ether (100 ml, b.p. 80–100° C) was heated on a steam bath for half an hour. The solution was stirred with a stream of nitrogen to exclude moisture. On cooling of the solution, a compound melting at 84–85° C was obtained which upon crystallizing twice from petroleum ether (b.p. 80–100° C) gave an analytical sample of m.p. 85° C. Yield, 5.8 g (67%). If an excess of benzoic acid was used, the same compound was obtained under the same experimental conditions. Calc. for $C_{16}H_{12}O_4N_2$: C, 64.8%; H, 4.05%. Found: C, 64.8%; H, 4.09%.

2,4-Bis(benzylcarbamyl) Toluene

The dimer of 2,4-tolylene diisocyanate (1.0 g, 0.003 mole) and benzyl alcohol (2 ml) were heated under reflux in petroleum ether (40 ml, b.p. 80–100° C) for 5 hours. The reaction mixture was cooled and the solid filtered, washed with petroleum ether, and dried. The solid was crystallized twice from cellosolve to give an analytical sample of m.p. 217.5° C. Yield, 0.8 g (50%). Ultraviolet absorption spectrum in dimethyl formamide: λ_{max}: 2650 Å, E_{max}: 10,323; inflection point: 2780 Å. The infrared absorption spectrum showed two carbonyl absorption bands of the mixed anhydride at 1775 cm^{-1} (s), 1697 cm^{-1} (s) and C—O—C stretching vibration at 1065 cm^{-1} (s). Calc. for $C_{23}H_{18}O_6N_4$: C, 66.0%; H, 4.30%. Found: C, 66.7%; H, 4.43%.

Attempted Dimerization of 2-Isocyanato-4-methylcarbamyl Toluene

A solution of 2-isocyanato-4-methylcarbamyl toluene (2.0 g, 0.009 mole) in pyridine (10 ml) was kept at room temperature for 24 to 240 hours. No dimer was obtained. A drop of triethyl phosphate as catalyst at elevated temperature (80–100° C) did not give any dimer either.

1,3-Bis(4-methyl-3-n-butyl-carbamylphenyl)-2,4-bis(N-formamido) Uretidine (I)

To a stirred solution of ammonium formate (3.0 g) in ethanol (30 ml), 1,3-bis(4-methyl-3-*n*-butylcarbamylphenyl) uretidine-2,4-dione (1.0 g), m.p. 197°, was added. The mixture was refluxed for 2 hours

with constant stirring. The clear solution obtained on vacuum evaporation and dilution gave a precipitate, which was filtered and washed with water. Yield, 0.8 g; m.p. 160–162°. Two crystallizations from ethanol gave the analytical sample with a melting point of 164–165°, molecular weight (Rast) 525. λ_{max}: 2250 Å, E_{max}: 8310. Free NH stretching modes, 3410 cm^{-1} (m), 3050 cm^{-1} (w); amide I band, 1720 cm^{-1} (s); amide II band, 1662 cm^{-1} (m). Calc. for $C_{28}H_{38}O_6N_6$: C, 60.6%; H, 6.85%; N, 15.1%. Found: C, 60.5%; H, 6.62%; N, 14.9%.

N-(4-Methyl-3-n-butyl-carbamylphenyl) Urea (II)

To a solution of 1,2-bis(4-methyl-3-*n*-butyl-carbamylphenyl) uretidine-2,4-dione (1.0 g), m.p. 197°, in 95% ethanol (30 ml) was added hydrazine hydrate (85%, 5 ml). After the reaction mixture was refluxed for half an hour with constant stirring, alcohol (20 ml) was removed *in vacuo*. The residue on cooling gave a compound melting at 201–202°. Yield, 0.7 g. Three crystallizations from acetonitrile gave a pure compound of m.p. 208–209°. λ_{max}: 2830 Å, E_{max}: 13,515; λ_{max}: 2400 Å, E_{max}: 11,130; λ_{max}: 2180 Å, E_{max}: 1325. CO and NH absorptions of the monosubstituted ureas are 1692 cm^{-1} (s), 1610 cm^{-1} (s) respectively. Calc. for $C_{13}H_{19}O_3N_3$: C, 58.8%; H, 7.16%; N, 15.8%. Found: C, 58.7%; H, 6.88%; N, 16.0%.

N,N'-Di(4-methyl-3-n-butyl-carbamylphenyl) Urea (III)

To a stirred suspension of 1,3-bis(4-methyl-3-*n*-butyl-carbamylphenyl) uretidine-2,4-dione (2.0 g), m.p. 197°, in absolute methanol (50 ml), magnesium turnings (1.0 g) were added in small portions while temperature was maintained at 60° for 40 minutes. The reaction mixture was filtered through glass wool and evaporated under reduced pressure. Hydrochloric acid (10%, 50 ml) was then added and the mixture warmed, cooled, filtered, and washed free from acid with water. Crystallization from ethanol–water gave the compound of m.p. 180–181°. Yield 1.6 g. λ_{max}: 2180 Å. E_{max}: 35,720; λ_{max}: 2590 Å, E_{max}: 38,070; inflection point: 2950 Å. CO and NH absorption for disubstituted urea partial structure, 1630 cm^{-1} (m), 1602 cm^{-1} (m) respectively. Calc. for $C_{25}H_{34}O_5N_4$: C, 63.8%; H, 7.23%; N, 11.9%. Found: C, 63.5%; H, 7.23%; N, 12.1%. Reduction with sodium and methanol or with hydrazine hydrate plus 5% solution of sodium in methanol gave the above compound in identical yield. Alkaline reduction with ammonium sulphide at 60° for 4 hours or by zinc and alcoholic ammonia likewise gave the same compound in excellent yields of 80–90%. Mixed melting point determinations showed no depression and the infrared spectra were superimposable.

N-(4-Methyl-3-n-butyl-carbamylphenyl) Formamide Oxime (IV)

To a suspension of 1,3-bis(4-methyl-3-*n*-butyl-carbamylphenyl) uretidine-2,4-dione (m.p. 197°, 1.0 g) in a mixture of ethanol (25 ml) and water (25 ml), hydroxylamine hydrochloride (2.5 g) and sodium acetate (4.0 g) were added, and the reaction mixture refluxed with stirring for 1 hour. After the reaction mixture was evaporated to 30 ml and cooled, a precipitate was obtained, m.p. 169–170° C. Yield, 0.40 g. Two crystallizations from acetonitrile gave the analytical sample of m.p. 170–171°. λ_{max}: 2850 Å, E_{max}: 2630; λ_{max}: 2400 Å, E_{max}: 23,670; λ_{max}: 2180 Å, E_{max}: 31,560. C—N absorption of oxime, 1660 cm^{-1} (s). Free OH stretching frequencies for N—OH group, 3460 cm^{-1} (s) and 3400 cm^{-1} (s). Calc. for $C_{13}H_{19}O_3N_3$: C, 58.8%; H, 7.16%; N, 15.9%. Found: C, 58.7%; H, 7.0%; N, 16.4%.

HYDRODESULPHURIZATION OF THIOPHENE

II. REACTIONS OVER A CHROMIA CATALYST[1, 2]

P. J. OWENS[3] AND C. H. AMBERG
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received November 17, 1961

ABSTRACT

The hydrodesulphurization of thiophene to butane and H_2S over chromia has been studied by flow and microreactor techniques. The sulphided, i.e. mixed oxide–sulphide, catalyst showed improved desulphurization activity compared to pure chromia, while butene hydrogenation activity was reduced by a factor of at least 10^3. The apparent activation energy of the flow reaction was 24–25 kcal/mole. No organosulphur compounds were found among the products. The reaction proceeded predominantly via butadiene and butene intermediates, with a preference for 1-butene; their rates of hydrogenation as well as the rates of isomerization of the butenes have been compared as a function of temperature. The reaction also partly went to completion at the original desulphurization site, without the desorption of intermediates, presumably by a series of analogous steps on the surface.

INTRODUCTION

In a previous publication (1) a microreactor method first described by Kokes, Tobin, and Emmett (2) was further developed to study the desulphurization of thiophene over a presulphided cobalt molybdate catalyst supported on alumina. With hydrogen acting as both reactant and carrier gas, continuous flow as well as pulse techniques showed that the reaction to butane and H_2S proceeds, in the main, in steps through butadiene and butene and not, as has also been suggested, through butyl mercaptan, thiolane, or other sulphur compounds. Approximate relative rates were assigned to the various steps.

By making use of the catalyst bed also as a gas–solid partition column it was possible to examine adsorption–desorption behavior of reactants and products under reaction conditions, and hence the influence of the adsorbates on the course of the reaction. Thus, for instance, it was found that adsorbed H_2S modifies the surface so as to suppress butene hydrogenation in contrast to its much weaker effect on thiophene conversion.

Some preliminary data using an unsupported chromia catalyst, again in a presulphided state, were also presented. These have now been extended by a more thorough search for reaction intermediates as well as by measurements of the relative rates of the reaction steps over a range of temperatures. Pertinent adsorption studies will be submitted as Part III of this series.

EXPERIMENTAL

The microreactor and associated apparatus have already been described (1). The reactor was operated only at atmospheric pressure. The catalyst employed was an unsupported chromia, prepared by the method of Burwell *et al.* (3) and activated by heating slowly to 400° in hydrogen. It was then stabilized as a desulphurization catalyst by passage of a thiophene–hydrogen mixture over it for several hours at 400°. The catalyst tended to oxidize and was resulphided from time to time whenever injected H_2S samples showed, by generating water peaks observable on the chromatogram, that such oxidation had occurred. The freshly sulphided catalyst contained 14.2% sulphur, and was therefore a mixed oxide–sulphide. In this it is similar to catalysts made from supported cobalt molybdate (1) and the oxides of iron (4) and molybdenum (5). The sulphided chromia was amorphous to X rays. It had a B.E.T. surface area of 118 m^2/g, decreased from 223 m^2/g for freshly prepared chromia.

RESULTS AND DISCUSSION

Effect of Temperature

The effect of temperature on catalyst activity for both the shot and flow reactions is shown in Fig. 1. The activity per square meter of catalyst surface was nearly identical in

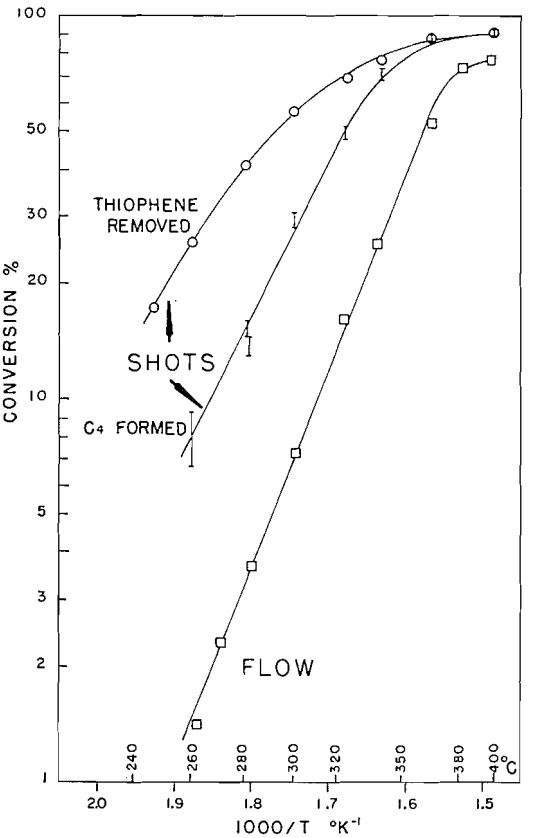

FIG. 1. Effect of temperature on thiophene conversion for flow and shot reactions (2.5 g chromia; 5.7 l./hr H_2; thiophene used: shots 5μl, flow 6.6% in H_2).

both cases with that of cobalt molybdate, provided allowance is made for the lower thiophene-to-hydrogen ratio used in the earlier flow experiment.

The apparent activation energy of the flow reaction was 24–25 kcal/mole, the same value that was obtained on supported cobalt molybdate (1) and supported chromia (6). The shot experiments gave two different curves, C_4 formed and thiophene removed (Fig. 1), due presumably to irreversible adsorption or polymerization of one of these, as discussed before (1). The lines are closer together in this case, probably because the weight of catalyst used was smaller and therefore the losses reduced. In both the flow and shot reactions the apparent rate constant fell off at high-percentage conversions, as one might expect from this type of plot.

Shot conversions were higher than flow conversions at the same temperature (Fig. 1), but were found to vary considerably with sample size. There is no a priori reason to

suppose that the reaction pattern in flow and shot experiments was fundamentally different. This is supported by the fact that the temperature coefficients for C_4 formation from shots and in steady flow appear to be nearly the same (see slopes, Fig. 1), though the former can only be measured approximately.

Reaction Products

The reaction products were examined for traces of butyl mercaptan or tetrahydrothiophene, but neither could be found. In addition, the rate of reaction of each of these compounds was checked at 400°. The conversion obtained using tetrahydrothiophene was only twice the conversion of thiophene at this temperature, so that if any had been formed almost all of it should have been present in the products. We conclude that none was formed. Butyl mercaptan was approximately 30 times as reactive as thiophene, but as little as 0.03% in the reaction products would have been clearly visible on the chromatogram. This is the amount that should have remained if 5% of the thiophene which reacted had done so by the mercaptan route.

The reaction scheme already presented (1), which involves intermediate formation of butadiene and the *n*-butenes as well as stepwise hydrogenation of these to butane, was further investigated by measuring the rates of the various hydrogenation and isomerization steps over a range of temperatures, using pure C_4 shots in hydrogen carrier gas. The results are shown in Figs. 2 and 3, and Arrhenius coefficients calculated from the slopes are listed in Table I.

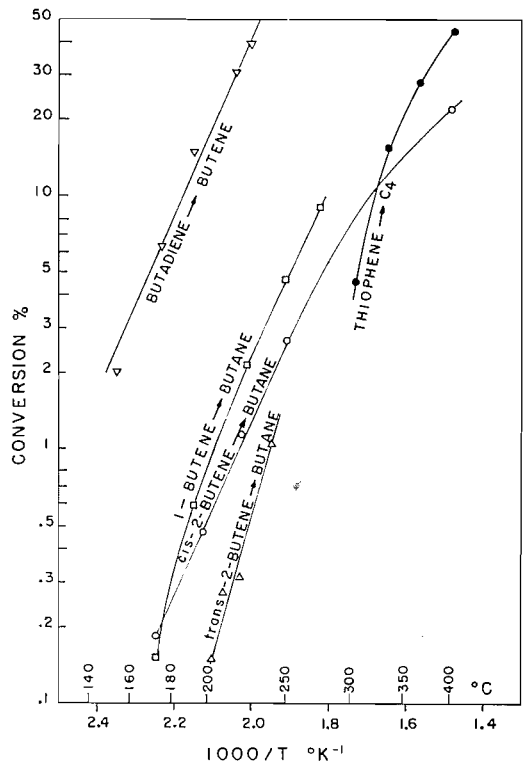

FIG. 2. Hydrogenation rates (0.113 g chromia; 1.3 l./hr H_2; shots 0.2 cc at N.T.P., or 0.7 μl).

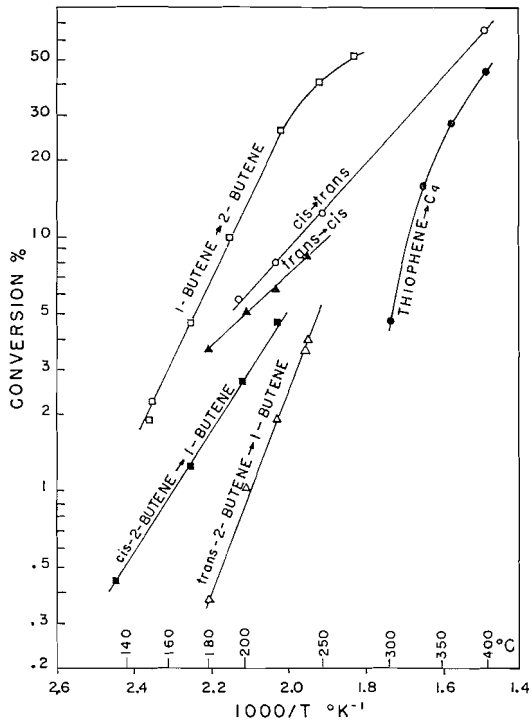

FIG. 3. Isomerization rates (0.113 g chromia; 1.3 l./hr H_2; shots 0.2 cc at N.T.P.; data on conversion of 0.7 μl thiophene shots included for comparison).

TABLE I

Apparent activation energies of various reactions

Reaction	Temp. range (°C)	E (kcal/mole)
Thiophene → C_4	260–330	24
Butadiene → butene	170–230	16
1-Butene → butane	190–270	15.5
cis → butane	170–250	15.5
trans → butane	310–360	15.5
	200–250	~25
1-Butene → 2-butene	150–225	14.5
trans → 1-butene	180–280	~17
cis → 1-butene	135–220	~11
trans → *cis*	180–240	6.5
cis → *trans*	250–400	8.5
	190–250	6.5
	120–180	0

At low temperatures (i.e. at 150° and below) the reactions were relatively simple (see Table II). 1-Butene isomerized to a mixture of *trans*- and *cis*-2-butene (about 64% *cis*-2-butene); pure *cis*-2-butene isomerized almost exclusively to *trans*-2-butene, and vice versa. Butadiene hydrogenation yielded all three isomers, but with a high preponderance of 1-butene.

Above 200° these were still the dominant reactions, but isomerization of 2-butene to 1-butene and hydrogenation of all three butene isomers to butane also occurred. There

was no evidence of a simple reaction scheme (for example with a single intermediate in isomerization and hydrogenation of all the isomers) even though there was a tendency of the catalyst to yield excess *cis*-2-butene. The ratio of *cis*- to *trans*-2-butene in the products of 1-butene was high, and similar to that obtained by Cvetanović and Foster with KOH-impregnated chromia (7), but different from the ratio they obtained with pure chromia. It is tempting to speculate that the initial sulphiding treatment of our catalyst had an effect on its acidity similar to that of KOH impregnation.

The sulphided catalyst was different from pure chromia also in its olefin hydrogenation activity. Though its activity for olefin isomerization was similar to that of pure chromia activated at the same temperature (8), its hydrogenation activity was less than that of pure chromia (8) by a factor of 10^3–10^4. Littlewood and Burwell (8) have presented evidence to show that isomerization and hydrogenation occur on different sites on pure chromia. If this is so, it suggests that sulphiding of the catalyst practically eliminates one of these two types of site. It is noteworthy, however, that the activity of chromia for thiophene desulphurization rose appreciably during sulphiding, so that while catalyst activity was destroyed for one reaction it increased for another. The effect of H_2S on subsequent butene hydrogenation over sulphided chromia was small (see Part III); therefore the hydrogenation rates in Fig. 2 and Table I, unlike those in the earlier work, were not measured in the presence of H_2S.

Initial Products from Thiophene at 400°

The C_4 products obtained from thiophene at 400° showed a non-equilibrium distribution of isomers when small amounts of catalyst were used. Isomerization and hydrogenation of the individual pure hydrocarbons were found to be incomplete at this temperature. Now if one assumes the same changes to occur in a hydrocarbon formed from thiophene as occur in the hydrocarbon injected as such, then the composition of the initial C_4 mixture formed from thiophene can be calculated. (This assumption would not be strictly correct if large concentration gradients were set up in the catalyst pores; however, we consider this to be unlikely.) The result of such a calculation is shown in Table III, together with the composition actually found. A comparison of the butane figures in the table shows that the reaction is only partially stepwise via intermediates free in the gas phase, and to the extent of 27.8%, goes to completion at the original desulphurization site. Furthermore, the data probably correspond to a low hydrogen-to-thiophene ratio; with smaller shot sizes (higher H_2/thiophene ratio) no butadiene at all

TABLE III

Composition of C_4 product from thiophene at 400° C
(2 μl shot over 0.113 g chromia; H_2 flow: 2.4 cc/sec)

	Found (%)	Corrected for subsequent reaction (%)
n-Butane	33.9	27.8
1-Butene	21.6	30.3
trans-2-Butene	23.9	15.5
cis-2-Butene	18.4	18.3
Butadiene	2.2	8.1

was found, even at the highest flow rates used. It is conceivable that in flow reactions using a high hydrogen-to-thiophene ratio about half the butane product is formed directly at the desulphurization site, and the other half via the hydrogenation of butene.

In consequence, the most plausible picture of the reaction is that of a series of hydrogenation steps on the surface, in which the sulphur atom is eliminated first and desorption is possible at any subsequent stage, i.e. as butadiene, butene, or butane. The second of these surface steps, butadiene hydrogenation, must be relatively fast if such a reaction is to yield the product distribution shown in Table III; from Fig. 2 it seems likely that this is so.

CONCLUSIONS

The activity of sulphided chromia for desulphurization was similar to that of sulphided cobalt molybdate when compared on a surface area basis. Initial sulphiding of the chromia increased its desulphurization activity, but decreased its activity for butene hydrogenation by a factor of 10^3–10^4. Neither reaction was much affected by H_2S, in contrast to the earlier results (1). Butene isomerization activity was probably not altered by sulphiding.

The apparent activation energy for the continuous flow reaction between thiophene and hydrogen over chromia was 24–25 kcal/mole, the same value that applies to cobalt molybdate and supported chromia catalysts.

Conversion of thiophene to butane was essentially a stepwise reaction. The only intermediates free in the gas phase were butadiene and the three butenes, especially 1-butene; there was no evidence for the formation of organosulphur compounds at any stage of the reaction. To a considerable extent butane formation occurred at the original desulphurization site. The butadiene hydrogenation step was very rapid compared with any of the others at all temperatures.

HYDRODESULPHURIZATION OF THIOPHENE

III. ADSORPTION OF REACTANTS AND PRODUCTS ON CHROMIA[1, 2]

P. J. OWENS[3] AND C. H. AMBERG
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received November 17, 1961

ABSTRACT

The adsorption of thiophene, butene, hydrogen, and H_2S on sulphided chromia was studied by a chromatographic method. Results were similar to those obtained earlier with a cobalt molybdate catalyst (P. J. Owens and C. H. Amberg, Advances in Chem. Ser. No. 33, 182 (1961)), showing strong interaction of the surface with H_2 and H_2S at reaction temperatures and weaker interaction with thiophene and butene. The main difference lay in the effect of adsorbed H_2S on butene hydrogenation, the suppression being far less marked on chromia. Thiophene adsorption or product desorption are unlikely to be rate controlling in the desulphurization reaction, but neither hydrogen adsorption nor surface reaction could be ruled out as possible slow steps.

INTRODUCTION

A grasp of the relevant adsorption processes is essential to an understanding of either the mechanism or the kinetics of a catalytic process. High-temperature adsorption is difficult to study with conventional volumetric apparatus where reaction occurs, so that until the recent introduction of chromatographic adsorption studies little such knowledge had accumulated (1). The present work surveys the interactions of thiophene, hydrogen, butene, and H_2S with a modified chromia catalyst, alone and in various combinations, and also attempts to draw some conclusions regarding the possible effect of such interactions on the overall reaction rate.

EXPERIMENTAL

Adsorption was studied mainly by the chromatographic techniques already described (2). The catalyst column was connected straight to the katharometer in all experiments, so that eluted bands were recorded directly and peak retardation occurred only on the catalyst. The flow rates of the various carrier gases were measured at the katharometer exit by water displacement. A small amount of tracer—helium, argon, or nitrogen—was added to the sample shot, and the separation between the peak maxima was taken as a measure of the delay time of the adsorbed gas.

RESULTS

Adsorption of Thiophene and Butene

The retention volumes of product butene and thiophene on sulphided chromia were similar to those measured earlier on cobalt molybdate, but had slightly different temperature coefficients (Fig. 1). The values obtained from the slopes in Fig. 1, after making appropriate corrections for the temperature at which flow rates were measured, were 7.0 and 8.0 ± 0.5 kcal/mole for thiophene and butene respectively, compared with 9.5 ± 1.0 and 8.5 ± 0.5 on cobalt molybdate. In this temperature range, the retention volumes on chromia were exactly the same in both helium and hydrogen carrier gases, and as before (2), the effect of adsorbed H_2S on the retention volume was slight.

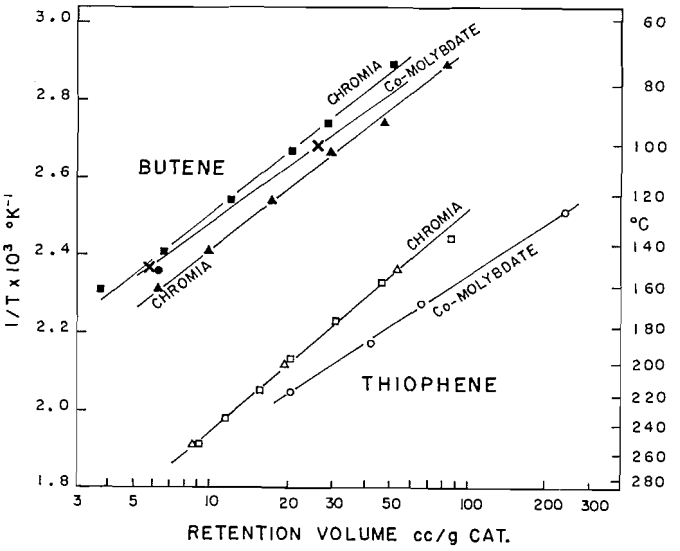

FIG. 1. Thiophene and butene adsorption. Peak retention volumes vs. temperature. Open symbols for thiophene, others for butene: □ chromia, 0.35 cc/g catalyst shots, H_2 carrier gas; △ chromia, He carrier gas; ○ cobalt molybdate, 0.40 cc/g catalyst shots, H_2 carrier gas; ■ chromia, 0.34 cc/g catalyst shots, H_2 carrier gas; ● chromia, He carrier gas; ▲ chromia, 0.031 cc/g catalyst shots, H_2 carrier gas; × cobalt molybdate, 0.39 cc/g catalyst shots, H_2 carrier gas.

The method of peak integration recently suggested by Cremer (3) was used to construct the isotherms shown in Fig. 2 from the chromatograms, and these were then used to

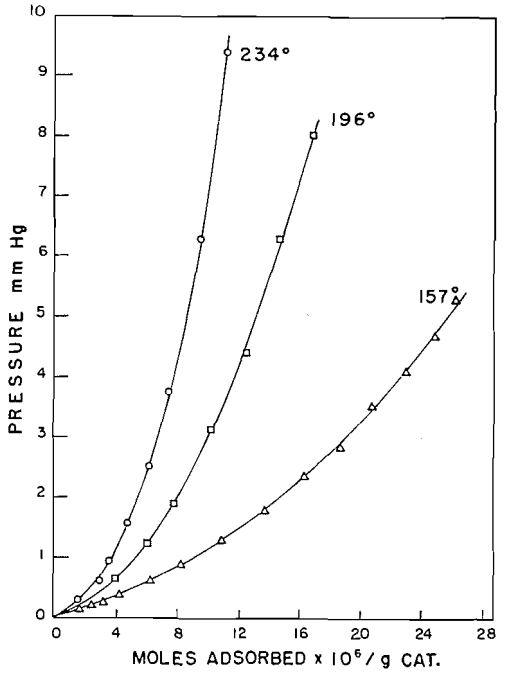

FIG. 2. Adsorption isotherms of thiophene on chromia catalyst. Estimated from the chromatograms in H_2 carrier gas by the method of Cremer (3), allowing for diffusion.

calculate isosteric heats of adsorption for thiophene. The results were in the range 8–11 kcal/mole, but were somewhat uncertain, because a small amount of irreversible adsorption as well as peak tailing always took place. Nevertheless, the figures are interesting as approximate values to compare with the temperature coefficients obtained above, which under ideal conditions should equal heats of adsorption. Chromatographic theory cannot strictly be applied to systems with curved isotherms, and even at very small shot sizes may give low results (4); however, the results taken together reinforce the view that high-temperature thiophene adsorption on chromia is relatively weak and rapid when compared, for example, with hydrogen adsorption (see below).

Another effect of irreversible adsorption can be seen in Fig. 3, where it causes the thiophene retention volumes to tend to infinity at small shot sizes. The amount of

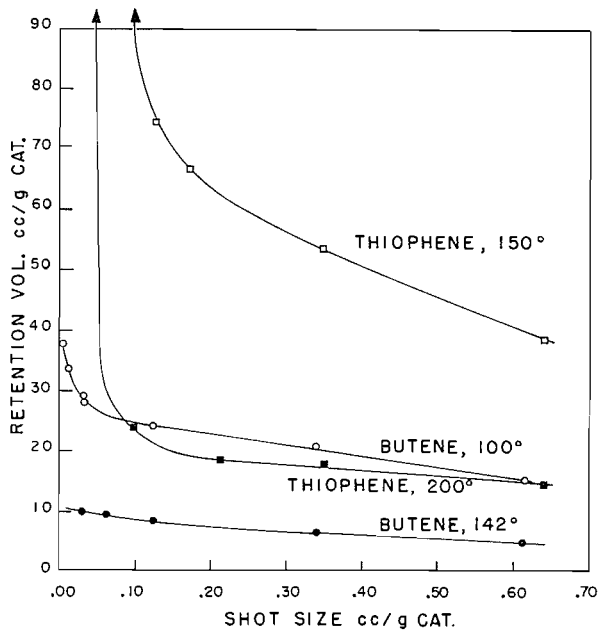

FIG. 3. Effect of sample size on retention volume. Thiophene and butene on chromia catalyst, in H_2 carrier gas.

thiophene irreversibly adsorbed varied, but was seldom more than 0.5 μl, and it appeared to be independent of shot size or catalyst temperature. It could have been due to some side reaction, such as polymerization or carbon formation; it was apparently unconnected with the main reaction and small compared with the amount of thiophene converted at high temperature. The phenomenon could be the explanation for the discrepancy in thiophene converted and products eluted over both cobalt molybdate and chromia catalysts (2, 5).

At lower temperatures (e.g. 250°) it is unlikely that the relatively weak, reversible thiophene adsorption could be rate controlling. It is unfortunately not possible to calculate a rate of adsorption from the chromatographic data to compare with the measured rate of reaction. On the other hand it is possible to find from the chromatogram the minimum number of adsorption–desorption steps that a thiophene molecule undergoes in travelling through the column; this is given by the plate number. (The true number of steps on a

porous catalyst is presumably much higher.) At 250°, approximately 5% conversion occurred per plate or equilibrium stage, so that less than 5%—and probably very much less—would have converted at each of the actual adsorption steps. Thiophene adsorption is thus rapid compared with the overall rate of reaction at least up to 250°. However, with a temperature coefficient of only 7 kcal/mole it increases in rate much more slowly than the overall process, which has a temperature coefficient of approximately 25 kcal/mole (5); so that without knowing the number of adsorption steps which occur within the catalyst pores in each equilibrium stage, one cannot be certain that adsorption remains relatively rapid at higher temperatures. The only indication that it does so is given by the temperature coefficient of the flow reaction, which remains at 25 kcal/mole up to at least 360–370° (5); any change in the rate-controlling step would have caused a change in the overall temperature coefficient.

From Fig. 1, the adsorption–desorption process is an order of magnitude faster for butene than it is for thiophene, at all temperatures. This makes it extremely unlikely that butene desorption could be the slowest step at any temperature, unless it desorbed from reaction sites in an entirely different way from that observed at 80–160°. This also is unlikely, because over cobalt molybdate, butene formed from thiophene had a retention volume between those of butene alone and thiophene, as might be expected (2), and there is no reason to suspect that it would behave differently over chromia.

There is one important reservation to be made, however, about the conclusions drawn from the above results. At present we are unable to calculate the number of adsorption–desorption steps made by the average molecule within one plate of the catalyst. If this number was very large, and if the proportion of the surface occupied by "active" sites was small, it would be quite possible for most of the thiophene or butene adsorptions to occur on inactive parts of the surface and for the observed conversion per plate to occur on only a few sites. In this case the above measurements would reflect the inactive rather than the active adsorption steps, and the possibility of the significant thiophene adsorption or butene desorption being slow would remain.

Hydrogen

Hydrogen chemisorption has been extensively studied on pure chromia, but never, so far, on sulphided chromia. On the former it occurs at all temperatures from −195° (6) up to at least 500° (7), and in amounts up to 0.1 cc/m² of surface at the higher temperatures (7). Activation energies of 13–21 kcal/mole have been reported for adsorption (8–10), as well as an increase in the activation energy of desorption from 15 to 45 kcal/mole with decreasing coverage (10). The rate of adsorption increases with temperature (11) and pressure (10); it decreases with amount adsorbed according to the Elovich equation (9).

Our results suggest that hydrogen chemisorption on sulphided chromia is similar. In chromatographic experiments using helium carrier gas, hydrogen peaks behaved in the same way as on cobalt molybdate. The first few shots were adsorbed rapidly and completely, until the catalyst reached a certain hydrogen content. Thereafter the peak height and delay obtained depended both on shot size and on the time interval between shots, i.e. on the amount of hydrogen still adsorbed on the catalyst. As before, curves of peak height or delay vs. shot size could be corrected for hydrogen already adsorbed, so that all the data lay on one line.

During the further course of a series of constant-volume injections the peak heights gradually tended to increase; this was attributed to slow adsorption at high coverages.

Large shot sizes seemed to increase both the rate of this drift and the rate of attainment of equilibrium: in other words the rate of the slow chemisorption was increased by pressure as in static experiments on pure chromia (10).

The peaks had very small delay times and plate numbers, showing again that equilibrium was not reached during the time of passage of one shot. As the temperature rose, the peak heights for a given shot size dropped, demonstrating that adsorption was more rapid at higher temperatures.

Variations in the rate of adsorption with coverage, pressure, and temperature were thus seen to be in the same direction as on pure chromia. However, it was not convenient to measure the extent of chemisorption chromatographically; therefore a few static measurements were made using a conventional volumetric apparatus (see Fig. 4). The amount

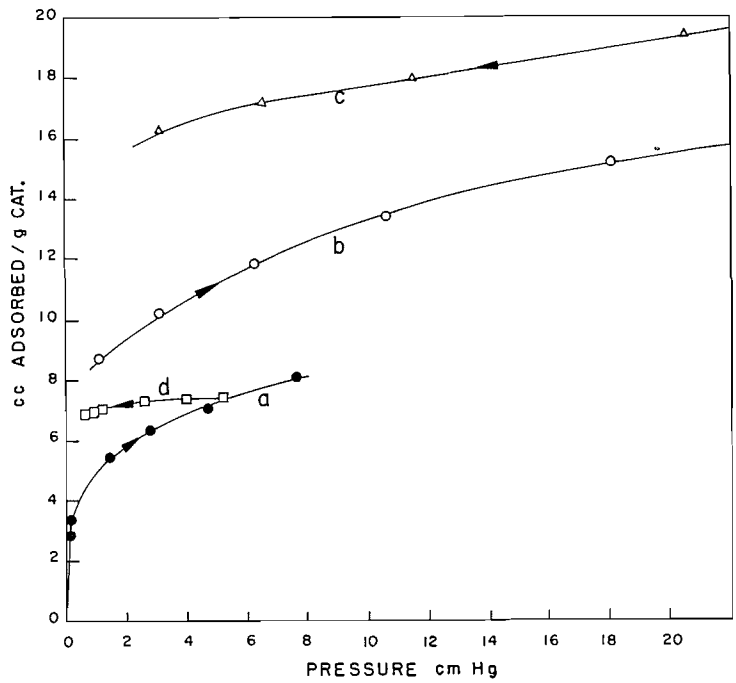

FIG. 4. Hydrogen adsorption, curves *a–c* at 330°, curve *d* at 350°.
a. Adsorption on chromia catalyst outgassed 18 hours at 400°; points at ½-hour intervals.
b. Adsorption after same treatment and 5 hours in 1 cm H_2; points at 1-hour intervals.
c. Desorption following adsorption at 36 cm H_2; points at 1-hour intervals.
d. Rapid desorption measured chromatographically; points at approximately 10-second intervals.

of hydrogen chemisorbed is seen to be similar to or larger than the amount adsorbing on pure chromia (7), with the extreme slowness of approach to equilibrium being quite evident.

One of the hydrogen chromatograms was used to calculate an isotherm by the Cremer method (3); this is also shown in Fig. 4 as curve *d*. It was obtained on a catalyst which had been brought apparently to equilibrium by repeated hydrogen injections at a point in the peak tail corresponding to 4.2 mm hydrogen pressure. For that reason it is drawn, somewhat arbitrarily, through a static point obtained after 2 hours' adsorption at a similar pressure. The amount of hydrogen adsorbed during passage of a shot which

raised the hydrogen pressure to at least 5.5 cm is clearly small (~0.28 cc/g) compared with equilibrium adsorption at 5.5 cm (4–5 cc/g). This is a measure of departure from equilibrium under chromatographic conditions, and shows again the relative slowness of hydrogen adsorption.

Since hydrogen chemisorption occurs at so low a rate, it is natural to ask whether it might be rate controlling in the desulphurization reaction. The hydrogen consumption in the flow reaction at 333° was 1.8 cc at N.T.P. min^{-1} (g catalyst)$^{-1}$. It is possible to make only very rough estimates of the rate of chemisorption at 76 cm pressure from the data in Fig. 4. If one uses for this purpose Kubokawa's result (10) that the rate of chemisorption is proportional to pressure to the power 0.8, the calculated rates of chemisorption appear to be of the right order of magnitude. An independent estimate from the amount of hydrogen completely adsorbed during the time of passage of a chromatographic peak gave a figure of 11 cc min^{-1} (g catalyst)$^{-1}$. Without a precise knowledge of the dependence of chemisorption rate on pressure and coverage even this higher estimate must be considered close enough to the reaction rate not to exclude hydrogen chemisorption as a possible rate-determining step.

Strongly (and more rapidly) chemisorbed hydrogen has been found relatively inactive in desulphurization and butene hydrogenation on cobalt molybdate (2) and in low-temperature exchange reactions on chromia (7). In the present work, conversions of butene and thiophene shots reacted with preadsorbed hydrogen were found to fall off very rapidly as the hydrogen eluted from the catalyst. In Fig. 5, *a* and *b*, these conversions are plotted against the partial pressure of hydrogen in the helium carrier gas leaving the

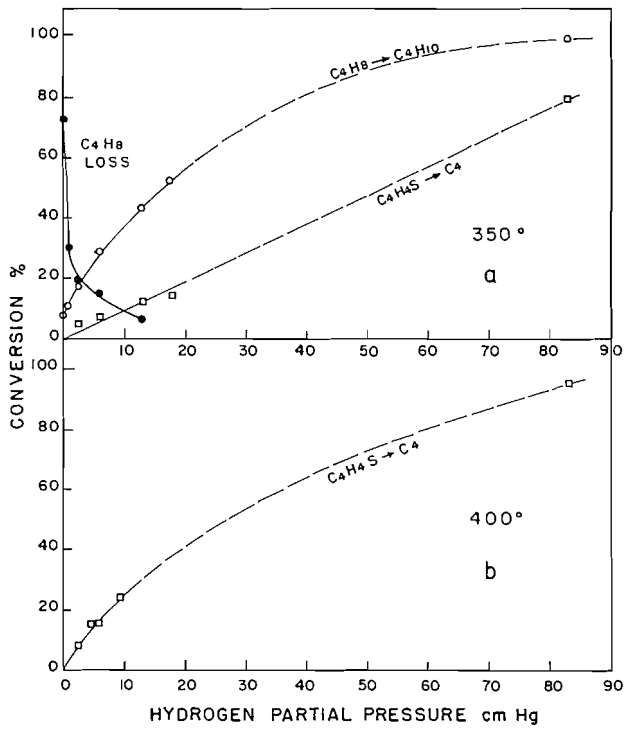

FIG. 5. Reaction of thiophene and butene with preadsorbed hydrogen. Shots injected at various points (i.e. partial pressures) in the tail of a desorbing hydrogen band, helium carrier gas.

catalyst. Conversions in hydrogen carrier gas at 83 cm are included. It is obvious from Fig. 4 (curve *d*) that the total amount of hydrogen chemisorbed would have changed very little during this rapid elution, so that the conversion was determined not by the total amount of hydrogen chemisorbed, but apparently by the partial pressure of hydrogen free in the gas phase. This means that strongly chemisorbed hydrogen is not reactive and that a much smaller amount of weakly sorbed hydrogen, which can establish equilibrium with the gas phase more rapidly, is solely responsible for the reaction.

The considerable loss from butene shots at low hydrogen partial pressures is interesting (Fig. 5*a*). It suggests that rapid carbon formation, which is well known to occur at low hydrogen partial pressures, might come about largely by the polymerization and coking of product butene rather than of thiophene itself. These large losses did not arise during the measurement of retention volumes (e.g. Figs. 1 and 3), no matter whether hydrogen or helium was used as a carrier gas, because of the lower temperatures involved.

Hydrogen Sulphide

Hydrogen sulphide adsorption was investigated by the chromatographic method only. The same type of behavior occurred as on cobalt molybdate (2): the peak shapes obtained were similar and the delay times at 300° were almost the same when corrected for catalyst weight and carrier gas velocity.

Both peak delay and peak height were found to depend largely on the total H_2S on the chromia, i.e. shot size plus preadsorbed H_2S. A typical result is shown in Fig. 6. Peak delays were longer at 400° than at 300°, and as before, there was an apparent change in base level of adsorbed H_2S with temperature. For example, catalyst heated to 400° in hydrogen adsorbed approximately 2.0 cc H_2S/g irreversibly at 300° before desorption commenced. The base level also appeared to be different in hydrogen and helium carrier

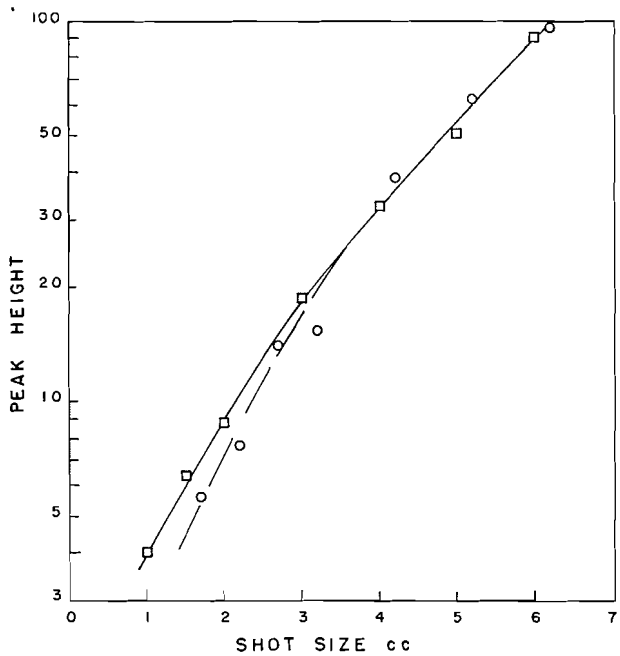

FIG. 6. Peak heights (arbitrary units) for H_2S shots injected while preadsorbed H_2S was emerging at different desorption rates: □ 0.20 cc/min; ○ 0.64 cc/min, shot sizes corrected by the 1.2 cc H_2S still present on the catalyst.

gases. Thus chromia saturated with H_2S and then flushed in a helium stream for 10 minutes (i.e. until desorption became very slow) released a total of 3.2 cc H_2S upon injection of three successive 3-cc hydrogen shots. Also, the low rate of removal of H_2S from the surface, as measured by the amount subsequently readsorbed, was higher in hydrogen than in helium (Table I), in contrast to the results with butene and thiophene, and the inverse delay time vs. shot size plots were quite different (Fig. 7). Hydrogen thus displaces H_2S, as well as eluting it, presumably by adsorbing on the same sites.

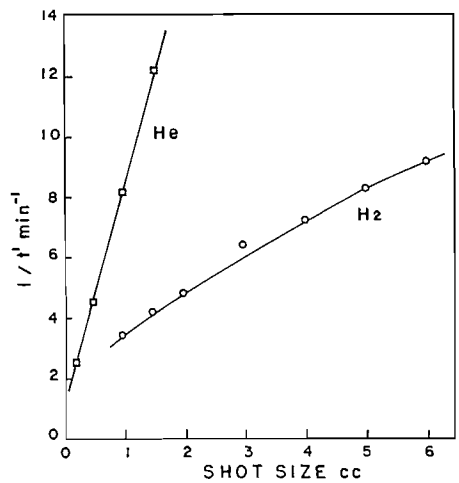

FIG. 7. Hydrogen sulphide breakthrough rates in H_2 and He carrier gases at 400°.

The hydrogenation of butene shots was reduced by preadsorbed H_2S to the small extent shown in Fig. 8, in sharp contrast to the earlier results (2). Similar amounts of H_2S had a similar effect on thiophene conversion. It has already been suggested (2) that H_2S acts on cobalt molybdate by poisoning fast hydrogenation sites, leaving only sites capable of both desulphurization and slow hydrogenation. It now seems likely (5) that the fast hydrogenation sites on chromia are permanently eliminated during presulphiding, so that further poisoning with H_2S has little effect.

Using the data for shot conversions of thiophene in the presence of H_2S over chromia, the percentage drop in conversion in a flow reaction due to H_2S produced was estimated to be 20, 10, and 0% at 400, 350, and 300° respectively. A similar calculation using our published data for cobalt molybdate indicated that conversion at 300° was 30% lower than it might have been in the absence of an H_2S effect. Adsorbed H_2S thus affects the overall reaction appreciably, but does not exert a controlling influence.

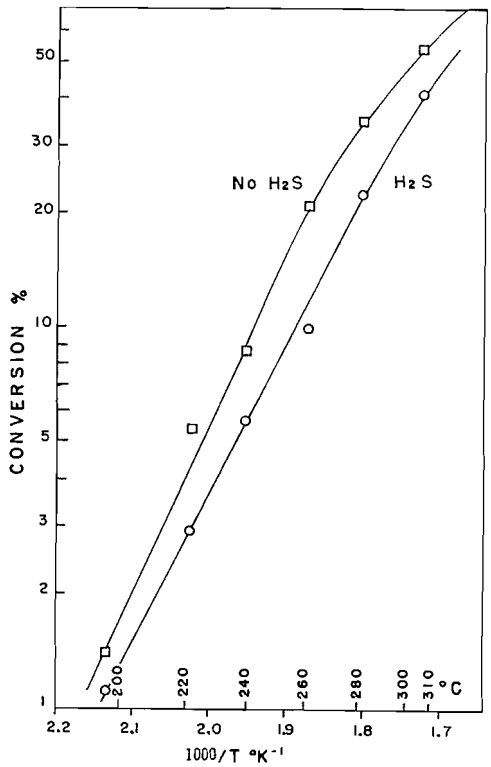

FIG. 8. Effect of H_2S on butene hydrogenation over chromia catalyst.

To calculate the effect of H_2S on flow conversion it was necessary to assume that the peak heights obtained from various samples of H_2S approximated the instantaneous desorption rates corresponding to the total H_2S contents of the catalyst (i.e. preadsorbed plus sample). Since data obtained at two different catalyst contents correlated tolerably well together (Fig. 6), there was some basis for this assumption. The rates of formation of H_2S in a flow experiment were known (5); these gave the H_2S desorption rates at various temperatures in a steady-state experiment; from this together with Fig. 6 the catalyst H_2S contents could be calculated. Then, by comparing the slug conversions in the absence of H_2S and in the presence of the amount calculated, the effect of H_2S on conversion in a steady-state experiment could be estimated.

Olefins

The effect of adding olefins to thiophene shots was investigated briefly, to gain some idea whether product butene was likely to have an inhibiting effect on the flow reaction by occupying desulphurization sites. Gaseous butene could not readily be handled in the same syringe as liquid thiophene. Therefore the liquid olefins hexene and cyclohexene were used; these had retention volumes intermediate between those of butene and thiophene. Adding 2 μl hexene to a 2-μl thiophene shot produced a negligible effect; adding 6 μl reduced thiophene conversion by 10–15%. The effects of cyclohexene and cyclohexane were slightly weaker, in that order; it is noteworthy in that connection that cyclohexene consumed as much hydrogen as thiophene itself. However, 15 μl of hexene

was found to cut the thiophene retention volume by 100%. We conclude that hydrocarbons are unable to compete for desulphurization sites, so that the butene produced should not inhibit the reaction significantly. Nevertheless, in the desulphurization of, say, low-sulphur cracked feedstocks the large proportion of hydrocarbons present could be expected to inhibit thiophene removal to an appreciable extent.

CONCLUSIONS

In view of the obvious chemical differences between chromia and supported cobalt molybdate catalysts, the close similarity in adsorption phenomena is striking. Moreover, Griffith, Marsh, and Newling (12) have shown that extensive hydrogen chemisorption and weaker thiophene adsorption occur also on sulphided molybdenum oxide and on pure nickel and molybdenum sulphides at high temperatures, so that this type of adsorption behavior appears to have some generality among desulphurization catalysts. (Hydrogen sulphide and butene adsorption were not included in this earlier study (12).) On the other hand, supported chromia is probably somewhat different, kinetic studies having shown that thiophene adsorption is more extensive than hydrogen adsorption on a catalyst of this type (13). Further work along these lines is being planned at present. The main difference between chromia and cobalt molybdate lay in the marked effect of adsorbed H_2S on butene hydrogenation over the latter.

The observed adsorption of thiophene and butene on chromia was relatively rapid and weak, and the effect of adsorbed H_2S on desulphurization was small, so that it appears unlikely that adsorption of thiophene, desorption of butene, or desorption of H_2S could constitute rate-determining steps under any conditions. Hydrogen adsorption on the other hand was slow and could be rate controlling, particularly since the strongly and more rapidly adsorbed hydrogen did not take part in the reaction, but the results do not exclude the possibility that the surface reaction might also be slow.

THE NUMBER-AVERAGE AND WEIGHT-AVERAGE MOLECULAR WEIGHT OF SOME NONIONIC SURFACE-ACTIVE AGENTS*

A. F. Sirianni, J. M. G. Cowie, and I. E. Puddington
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received January 12, 1962

ABSTRACT

Further evidence for the existence of large differences between the weight- and number-average molecular weight for nonionic surface-active substances in nonaqueous solvents has been found when the property is assessed by light-scattering and vapor-pressure-lowering measurements. Equilibrium ultracentrifuge measurements support the results obtained by vapor-pressure-lowering determinations. Sorbitan and glycerol monostearates have been examined in benzene solution.

INTRODUCTION

It has been noted by Debye (1) that number-average ($\bar{M}_n$) and weight-average ($\bar{M}_w$) molecular weights of nonionic detergents in nonaqueous solvents may differ considerably. Some of the difference may be due to the existence of heterogeneous clusters of molecules in solution (1). In the case of α-monoglycerides the presence of free fatty acid as an impurity magnified the difference by increasing the value obtained from light-scattering and decreasing the value obtained from vapor-pressure-lowering measurements.

In a previous communication it was indicated that solutions of pure hexaoxyethyleneglycol monoethers having an alkyl chain of 12 or of 14 carbon atoms consisted of monomers and dimers when examined by vapor pressure lowering in benzene at about 30° C (3). Light-scattering measurements on solutions of pure hexaoxyethylene *n*-tridecanol in benzene at 25° C indicated a micelle consisting of 99 monomers (4). This compound differs from the previous two by only one carbon atom in the alkyl chain, and the results suggest the probability of the two methods of examination yielding quite different answers for the state of aggregation of a number of dissolved polar molecules.

The present investigation was undertaken to assess the behavior of sorbitan monostearate (span 60†) in which the existence of nonequilibrium states in benzene solutions was reported by Becher using light scattering (5). Solutions were examined by light scattering at 25° and 45° C and by two methods depending on vapor pressure lowering in solution. Benzene was used as a solvent in most instances. Solution properties of a commercial sample of glycerylmonostearate are also included.

EXPERIMENTAL

The light-scattering measurements were carried out with a Brice–Phoenix light-scattering photometer using blue light at 436 mμ and a small semioctagonal cell in conjunction with a small slit system. The usual precautions to exclude dust and other foreign matter were taken.

The sample of commercial sorbitan monostearate was obtained purified to the extent that the free polyol had been removed by extraction rendering the detergent completely soluble in benzene. Solutions were made with reagent grade benzene freshly distilled over CaH_2. A commercial sample of glycerylmonostearate (Aldo 33, Glyco Product Company) was used without further purification other than evacuation at room temperature in order to remove volatile matter.

*Issued as N.R.C. No. 6787.

†*Obtained through the courtesy of Dr. Paul Becher, Chemical Research Department, Atlas Powder Co., Wilmington, Delaware.*

The experimental technique and the apparatus used to carry out differential vapor pressure measurements between pure solvent and solutions have been described elsewhere (6). Apparent molecular weights were calculated from Raoult's Law.

Some determinations were also carried out with a Mechrolab vapor pressure osmometer Model 301 at 37° C. Samples were prepared as described for the light-scattering experiments. The instrument was calibrated with solutions of recrystallized sucrose octaacetate (mol. wt. = 678), triphenylmethane (mol. wt. = 244), and benzil (mol. wt. = 210) over a concentration range of 0.01 to 0.1 molal. These limits are optimal since at higher and at lower concentrations reproducibility is considerably reduced (7). The solutions were shaken periodically and allowed to equilibrate by standing overnight prior to use. The syringes employed to feed the thermistor beads were thoroughly cleaned with benzene, then rinsed 8–10 times with the appropriate solution. ΔR readings for each solution were taken at 1-minute intervals for 5 minutes. Fresh drops of solvent and solution were then placed on the thermistors and the measurements repeated. Usually three to four sets of measurements were taken for each concentration. Although the readings were virtually constant after 1 minute, the average value after 3 minutes was used in the calculation.

The apparent molecular weight of an unknown was calculated using the molar constant from the calibration curve. Calibration solutions should not deviate from the ideal behavior over the concentration range used. The data obtained with benzene solutions used fitted very closely a common straight line having a slight negative slope when $\Delta R/C$ is plotted against ΔR, where ΔR = dial reading in ohms and C = molal concentration. Caution is necessary, however, when taking molar constants from a portion of the calibration curve lying beyond the last experimental points, particularly if a slight amount of curvature is indicated in the plot. A detailed account of the operating procedure of the Mechrolab osmometer is given in the instruction manual (7), and the theory by Brady, Huff, and McBain (8).

RESULTS AND DISCUSSION

The variation of the apparent molecular weight with solute concentration (g solute/100 g solvent) for sorbitan monostearate in benzene using the Mechrolab osmometer and in benzene and alcohol using a differential mercury micromanometer is shown in Fig. 1.

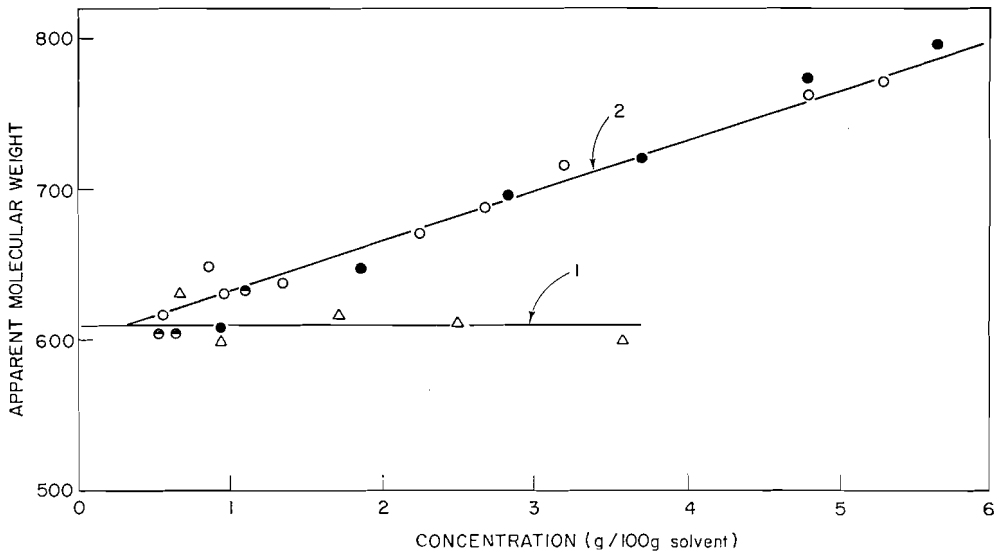

FIG. 1. Apparent molecular weight versus solute concentration for sorbitan monostearate. Curve 1, in alcohol. Curve 2, in benzene. The filled circles were obtained with the osmometer at 37° C. The open and semifilled circles were obtained by static vapor pressure determinations at 35 and 45° C respectively.

Curve 1 was obtained with alcohol at about 44° C and the molecular weight is virtually independent of concentration over the range examined. The sample contains about 5% free fatty acid of average molecular weight 275. The ester portion has a molecular weight of about 628. Thus the value of 610 indicated in alcohol is in good agreement with the analytical data for the compound (9). Curve 2 indicates the behavior in benzene. The

filled circles were obtained with the osmometer at 37°. The open and semifilled circles were obtained from static differential vapor pressure determinations in benzene at 35° C and 45° C respectively. In the concentration range 1–5% no large differences in apparent molecular weights are observed between these two methods of measurement. Below about 1% solute concentration, however, some deviation appears and the molecular weight obtained employing the osmometer is somewhat lower. The reason for this is not too clear but it might be caused by increases in the surface concentration of the unstirred drops due to slight surface activity of the solute or perhaps to insufficient lagging of the thermostat resulting in excessive evaporation from the drops. The tendency with the differential micromanometer is in the reverse direction and the apparent molecular weight can be slightly higher in the very dilute region, possibly owing to adsorption of solute on the container walls. In the static measurements the solutions are made with anhydrous solvents that are carefully freed from permanent gases and are continually stirred. This is not possible with the osmometer however.

The results of the light-scattering measurements on benzene solutions of sorbitan monostearate, summarized in Table I, are shown by Fig. 2. Curve 1 is obtained at 25° C

TABLE I

Concentration (%)	$\tau \times 10^{-3}$	$Hc/\tau \times 10^{5}$
At 25° C; refractive index increment = −0.0515 ml/g		
1.996	1.41	1.30
1.522	0.96	1.46
1.250	0.62	1.58
1.006	0.59	1.57
0.740	0.43	1.85
0.416	0.20	1.91
$\bar{M}_w$ = 48,500, second virial coefficient—negative		
At 45° C; refractive index increment = −0.0420 ml/g		
1.943	0.89	1.33
1.560	0.75	1.27
1.229	0.61	1.23
1.003	0.52	1.18
0.719	0.36	1.22
0.408	0.21	1.18
$\bar{M}_w$ = 89,300, second virial coefficient—positive		

and the data fit a line having a slight upward curvature. Curve 2 is obtained at 45° C and the experimental points fall on a curved line concave downwards. A micellar weight of about 48,500 is obtained at 25° C, which is in good agreement with the value calculated from the results reported by Becher with the same system (5). The critical micelle concentration (c.m.c.) is about 0.1 g/100 ml. A micellar weight of about 89,000 is indicated at 45° C. The larger aggregates at the higher temperature are consistent with the behavior of a number of surface-active materials in aqueous solution.

The large difference in micellar weight indicated between light scattering and vapor pressure lowering is similar to the observations with the hexaoxyethyleneglycol ethers (3). The latter method suggests slight association only, while agglomerates containing about 80 monomers are indicated by light-scattering measurements. It is unlikely that the low values from the vapor pressure measurements are due to small quantities of water in the benzene, since agreement between the static and the osmometric results,

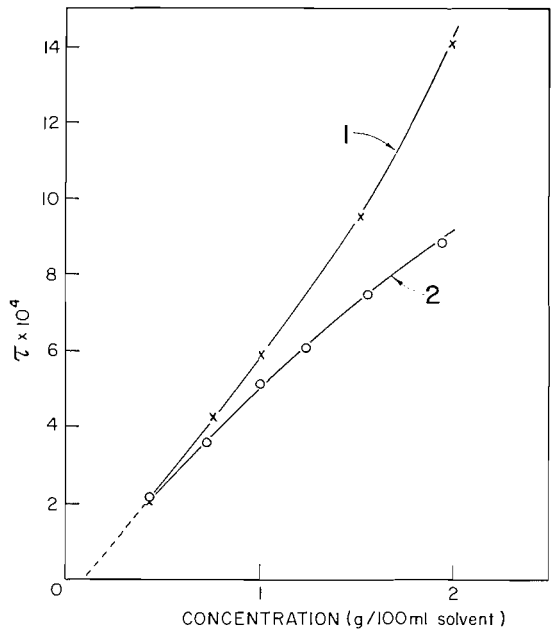

FIG. 2. Turbidity–concentration curves for sorbitan monostearate in benzene solution. Curve 1 and curve 2 were obtained at 25 and 45° C respectively.

where conditions are much less rigorously controlled, is good. It seems more probable that the micelle structure is sufficiently weak to allow the components to act individually in their effect on the vapor pressure of the solvent, while it behaves as a unit in scattering light.

The size of the sorbitan monostearate micelle was also estimated by measuring its molecular weight in the ultracentrifuge using the equilibrium method. A Spinco model E ultracentrifuge equipped with phase plate Schlieren optics and a rotor temperature control unit was used. A 2% solution of the material in benzene was examined in an Epon-filled, 12-mm double-sector cell which allows simultaneous photographing of the solvent base line and the solution pattern. The length of the solution column was 3 mm, and 0.05 ml of mercury was placed in the solution sector to provide the correct curvature at the cell bottom, thus reducing the possibility of convective disturbances. Rotor speeds were 50,740 r.p.m. and the temperature was controlled at 25° C.

Photographs were taken at a bar angle of 40° and magnified ×20 prior to measurements. The molecular weight at equilibrium was calculated from the equation (10)

$$M_w = \frac{1}{\bar{x}C_0}\left(\frac{dc}{dx}\right)_{x=\bar{x}} \frac{RT}{\omega^2(1-\bar{V}\rho)},$$

where (dc/dx) is the concentration gradient at the point $\bar{x}$ defined as $\bar{x} = (a+b)/2$. Here a and b are the distances from the center of rotation to the meniscus and base of the solution and C_0 is the initial concentration and was measured by means of a synthetic boundary cell.

The value of M_w obtained for a 2% solution was approximately 800. While this is somewhat higher than the 660 indicated by vapor pressure depression at this concentration,

it is far smaller than the micellar size suggested by light scattering. Since a point of inflection is frequently observed in the density vs. concentration relation at the c.m.c. for solutions of surface-active materials, some significance may be attached to the fact that the sample is under considerable pressure during the ultracentrifugal measurements. It seems unlikely, however, that heterogeneity in the sample can be affecting the light-scattering results seriously.

The commercial sample of glycerylmonostearate yielded no conclusive results when benzene solutions up to 1% concentration were examined by light scattering. However, an $\bar{M}_w$ of 4730 was estimated from measurements below 0.5% concentration for a pure α-glycerylmonostearate by Robinson, although the light scattered was so small that a c.m.c. was not measurable (11). Debye and Prins (2) obtained an $\bar{M}_w$ of 4000 and a c.m.c. of 0.14 g/100 ml for a similar pure compound in benzene at about room temperature.

The apparent molecular weight of the sample of glyceryl monostearate assessed by static vapor pressure lowering is indicated by Fig. 3. The filled circles were obtained with

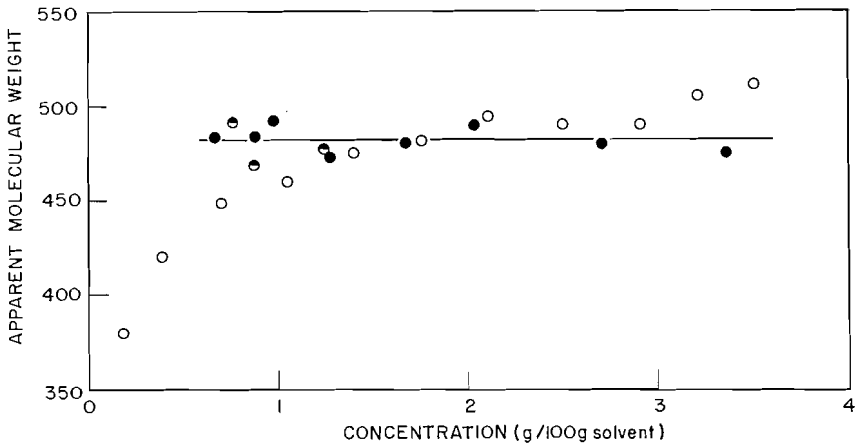

FIG. 3. Apparent molecular weight versus solute concentration for glycerylmonostearate. Filled and semifilled circles were obtained with alcohol at 39 and 45° C respectively by static vapor pressure measurements. Open circles with benzene at 37° C using the osmometer.

ethanol at 39°. A few of the measurements were made at 45° C (semifilled circles). Again the molecular weight appears reasonably constant over the concentration range examined. It is 35% higher than the calculated value for the pure compound. The open circles were obtained with solutions in benzene at 37° C employing the osmometer. The apparent molecular weight increases quickly with increasing solute concentration, reaching a nearly constant value at about 1.5%. Assuming a monomer weight of 358, solute aggregation does not appear to proceed beyond an equilibrium mixture of monomers and dimers. A c.m.c. of 0.12 g/100 g solvent agrees well with the value 0.14 g/100 ml obtained for the pure α-monostearin from light-scattering determinations by Debye and Prins (2). Considering that some impurities may be present in the commercial substance it is difficult to ascribe too much significance to the c.m.c. indicated by our measurements. However, the ratio of the size of the solute units indicated by light scattering and by vapor pressure depression is again large and suggests that quite different properties of the units are being measured by the two procedures.

ABSTRACT

Hydrogen bonding in phenol, aniline, and thiophenol has been investigated by n.m.r. spectroscopy and cryoscopy. While phenol shows evidence for the presence of monomer–dimer–polymer equilibrium, thiophenol only indicates low monomer–dimer equilibrium. The extent of association in these three systems decreases in the order phenol, aniline, thiophenol.

Hydrogen bonding in hydroxy compounds has been investigated in great detail by infrared (1–3) and n.m.r. (4–6) spectroscopy. Recently, association of phenol has also been investigated by ultraviolet spectroscopy (7–9). The hydrogen bonding of some heterocyclic amines has been investigated by Fuson *et al.* (10) by infrared spectroscopy. Although the hydrogen bonding in aniline has been studied by several workers (10–14) by infrared spectroscopy, the situation is not very clear (15). Fuson *et al.* (10) have concluded that the shift to lower frequencies in the NH stretching bands of aniline with increase in concentration is due to N—H - - - N bond formation. Recent ultraviolet spectroscopic studies show that hydrogen bonding in aniline is not very considerable (8). However, there has been no n.m.r. investigation on aniline. Hydrogen bonding in liquid thiols has been indicated by infrared studies (16, 17), but no n.m.r. studies have been reported. We have now studied hydrogen bonding in phenol, aniline, and thiophenol by n.m.r. spectroscopy. In addition, molecular weights of these compounds have also been determined as functions of concentration.

EXPERIMENTAL

The proton magnetic resonance spectra of solutions of anhydrous phenol, aniline, and thiophenol in carbon tetrachloride were recorded on a Varian high-resolution n.m.r. spectrometer operated at a fixed frequency of 40 Mc/sec. Sample tubes of 4.5-mm outer diameter were used. The chemical shifts have been calculated using the para ring proton (18) as the reference. The standard deviation in the chemical shifts varies between 0.5 and 2 cycle/sec.

Molecular weights of the compounds were determined in benzene solution as a function of concentration by the cryoscopic method.

Phenol, aniline, and thiophenol of high purity were used, care being taken to see that they were completely anhydrous. All the solvents were purified and fractionated before use.

RESULTS AND DISCUSSION

The chemical shifts of —OH, —NH_2, and —SH proton magnetic resonance of phenol, aniline, and thiophenol are shown as functions of concentration in Fig. 1. It can be clearly seen that there is considerable hydrogen bonding in the case of phenol and the results can be interpreted in terms of monomer–dimer–polymer equilibrium (5, 6). The

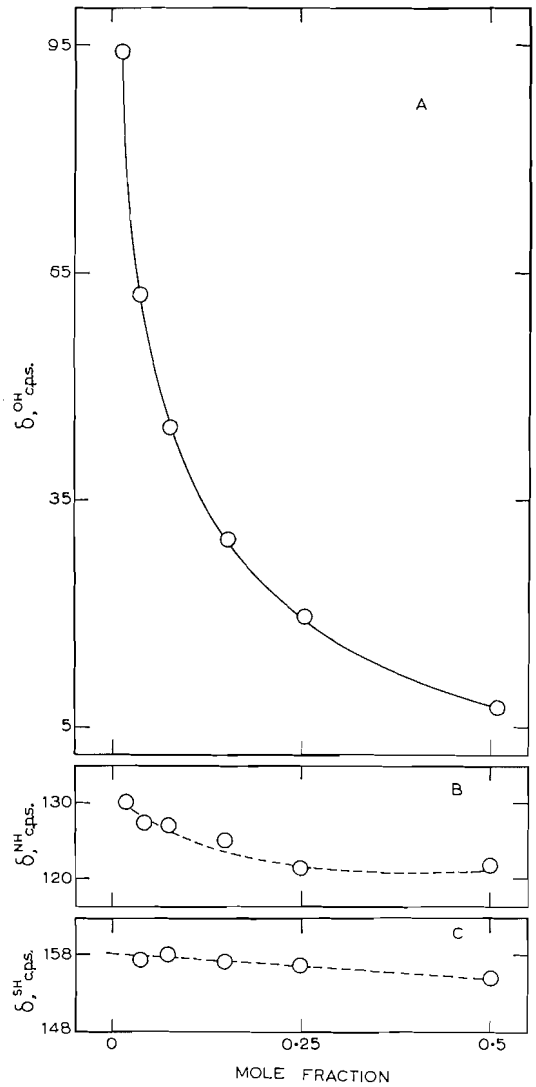

FIG. 1. Plots of proton chemical shifts versus mole fraction: A, phenol; B, aniline; C, thiophenol.

variation in the chemical shift in the case of aniline is considerably less than that of phenol, suggesting lower equilibrium constants for the monomer–dimer–polymer equilibrium in aniline. It might be expected that N—H - - - N hydrogen bonds are energetically less favorable than O—H - - - O hydrogen bonds.

The variation of δ_{SH} with concentration of thiophenol is nearly linear and is probably due to weak hydrogen bonding. It is also possible that the small changes in δ_{SH} may simply be due to solvent effects. It seems likely, however, that the linearity is due to a monomer–dimer equilibrium present over the entire range of concentrations. Monomer–dimer equilibrium in phenol can be realized only at very low concentrations. Our conclusion with regard to the monomer–dimer equilibrium in thiophenol is in agreement with the infrared studies of Spurr and Byers (17). The observation that there is negligible self-association in thiophenol compared to phenol is also consistent with the fact that thiophenol is a stronger acid than phenol.

In Fig. 2, the molecular weights of phenol, aniline, and thiophenol are shown as functions of concentration. It can be seen that phenol approaches the theoretical molecular

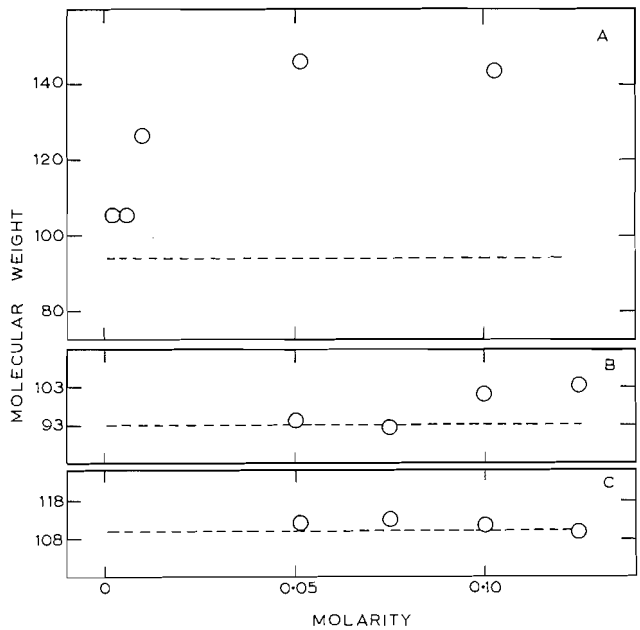

FIG. 2. Cryoscopic molecular weights as a function of concentration: A, phenol; B, aniline; C, thiophenol. Dotted lines represent theoretical molecular weights.

weight only at very low concentrations, while thiophenol gives the theoretical molecular weight throughout the range studied. Aniline falls in between these two cases. These results clearly point out that association due to hydrogen bonding decreases in the order phenol, aniline, thiophenol. Since the theoretical molecular weight of thiophenol is found throughout the range of concentrations investigated, it may be concluded that the equilibrium constant for dimerization (as indicated by n.m.r. studies) must be very low.

IONIZATION OF ORGANIC COMPOUNDS

III. BASICITIES OF PROPIONIC ACID AND PROPIONAMIDE

J. T. EDWARD AND I. C. WANG
Department of Chemistry, McGill University, Montreal, Que.

Received February 9, 1962

ABSTRACT

Protonation constants (pK_{BH^+}) of −6.8 and −0.9 have been determined for propionic acid and propionamide, respectively, from measurements of their ultraviolet absorption in various concentrations of sulphuric acid. The ionization ratio of propionamide and of other amides increases more slowly than the Hammett acidity function, h_0, with increase in acid concentration. This may be explained by assuming that in a given concentration of sulphuric acid the protonated amide is more heavily hydrated than the protonated Hammett indicator used to establish the h_0 scale for this region of acid concentrations.

The equilibria in aqueous sulphuric acid of many types of aromatic compounds (B) (1–4), assumed to ionize according to the equation

$$BH^+ \rightleftarrows B + H^+, \qquad [1]$$

have been investigated by Hammett's method (5) in which the ionization ratio $[BH^+]/[B]$ is determined spectrophotometrically. Ionizations of this type are assumed to follow the Hammett acidity function h_0 (6, 7), so that the protonation constants K_{BH^+} of the compounds, defined as

$$K_{BH^+} = [B]h_0/[BH^+] \qquad [2]$$

(the quantities in brackets being molar concentrations), may be calculated from the spectrophotometric results.

Aliphatic compounds absorb much more feebly in the spectral regions accessible with most spectrophotometers, and perhaps for this reason their ionizations have not been much studied by Hammett's method. Most investigations of the basicities of aliphatic amides have been carried out by titration (8) or indicator (9) methods using solutions in acetic or formic acids. However, it is not certain that the relative strengths of different Brønsted bases are the same in these solvents as in water (10). In one of the rare applications of Hammett's method, Goldfarb, Mele, and Gutstein (11) determined the basicities of a number of aliphatic amides by observing the change in their absorption at 200–210 mμ with changing acidity. The absorption curves of aliphatic amides have a shoulder or inflection in this region (12), due to a weak peak casued by an $n \rightarrow \pi^*$ transition (13, 14) buried in the edge of a more intense peak at about 190 mμ which has been attributed to a $\pi \rightarrow \pi^*$ transition (14, 15). Protonation of the amide group, if it takes place, as is now believed (16, 17), on the carbonyl oxygen, should cause a large blue shift of the $n \rightarrow \pi^*$ peak (18). In fact, Goldfarb *et al.* observed a decrease in absorption at 200–210 mμ with increasing acidity of the medium. However, the spectral data, according to their method of calculation, indicated two equilibria and two ionization constants. Since even in absolute sulphuric acid aliphatic amides are only monoprotonated (19), the interpretation of these results has remained puzzling.

Goldfarb and his co-workers (11) also calculated a pK_{BH^+} of −6.10 for acetic acid from the change with acidity of the $n \rightarrow \pi^*$ peak at about 203 mμ (12, 20).

In the present work we have studied, by Hammett's method, the ionization of propionamide and of propionic acid (whose pK_{BH^+} values were required in another connection) using a spectrophotometer which enabled us to measure absorption down to wavelengths of about 186 mμ. Attention was given to the interpretation of the spectral data in an attempt to discover whether it necessitated two pK_{BH^+} values for the amide. In the event, it was found that the calculation of two protonation constants was probably an error arising from the assumption (now known to be invalid (21)) that the ionization of *all* monoprotonated Brønsted bases must follow the h_0 acidity function according to equation [2].

EXPERIMENTAL

Materials

Propionamide (Eastman) was recrystallized from aqueous ethanol to a constant melting point of 80.7–82.0° (lit. m.p. 79.5° (22)). Propionic acid was distilled through a Vigreux column, the middle fraction boiling at 140–142°, n_D^{24} 1.3852, being taken (lit. b.p. 140.8°, n_D^{25} 1.3843 (23)). Sulphuric acid solutions were prepared and standardized as described previously (18).

Apparatus

A Unicam SP 500 spectrophotometer was used. There was no temperature control in the cell compartment, and the temperature of the solutions was 24±3° during measurements. Sulphuric acid of 10–30% concentration absorbs very strongly below 200 mμ, presumably because of the presence of sulphate ion (whose concentration is at a maximum in about 17% acid (24)), and consequently for solutions of this concentration matched silica cells having a 1-mm light path were used. For other concentrations of sulphuric acid quartz cells of 1-cm light path were used.

Procedure

Aliquots (1.00 ml) of an aqueous solution of propionamide or propionic acid of known concentration were diluted with aqueous acid to 25.00 ml in a volumetric flask. Extinction coefficients at different wavelengths were measured within 4–5 minutes; reproducibility of the measurements was within ±1%. Hydrolysis of propionamide in this time was negligible, as expected (11, 25); even after 15 minutes no change in absorption could be observed. Beer's law was valid for all the concentration ranges studied.

The concentration of acid in the solutions was determined by titration using phenolphthalein as an indicator, and correcting, where necessary, for the propionic acid present. Corresponding H_0 values were obtained from large-scale plots of H_0 against acid concentration constructed from the data of Paul and Long (7).

RESULTS AND DISCUSSION

Protonation of Propionic Acid

Propionic acid in aqueous solution has absorption peaks at 203 mμ (ε 46) and 189 mμ (ε 59). However, the latter peak is due to propionate ion, as shown by the absorption of sodium propionate in water (λ_{max} 188 mμ, ϵ_{max} 1410).[1] In 0.8% sulphuric acid, in which ionization to propionate is effectively suppressed, propionic acid has only one peak, at 206 mμ (ε 43.5).

As the sulphuric acid concentration is increased to 62.5%, this peak undergoes a progressive blue shift to 196 mμ (Fig. 1), which must be due to a medium effect. However, with further increase of acid concentration to 95.4% this peak disappears, presumably because of protonation of the carbonyl group (3). In absolute sulphuric acid propionic acid is known to be monoprotonated (27). While the spectral changes must be due mainly to protonation as the sulphuric acid concentration is increased from 62.5% to 95.4%, they must also be due in part to medium effects, as shown by the failure of the absorption curves (see Fig. 1) to pass through an isobestic point (5).

[1]*The maxima reported for acetic acid (10, 18) and other aliphatic acids (e.g., ref. 26) in water are probably very slightly in error because of a failure to take account of ionization.*

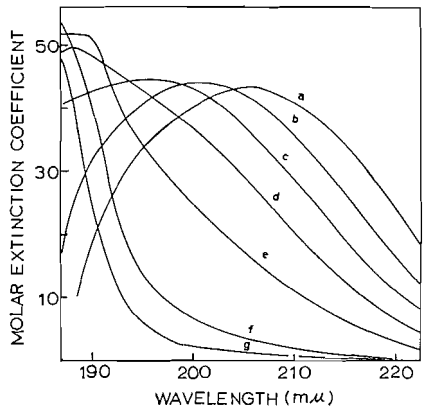

FIG. 1. Ultraviolet absorption of propionic acid in the following concentrations of aqueous sulphuric acid: *a*, 0.8; *b*, 50.2; *c*, 62.5; *d*, 72.1; *e*, 78.6; *f*, 86.8; *g*, 95.4%.

The $n \rightarrow \pi^*$ peaks of aliphatic ketones change with increasing acidity of medium in a very similar fashion; the reasons given for the medium effect as the acid concentration is raised to 65% (18) may apply in the present instance also.

Plots of the molar extinction coefficient ϵ at different wavelengths against the H_0 values of the solutions gave sigmoid curves, from which the inflection points were obtained by the graphical method of Stewart and Yates (2). The H_0 value at the inflection point then gave the pK_{BH^+} (method A, Table I). The experimental sigmoid curves were moderately close to those theoretically required by equation [3], derived from equation [2] by a consideration of Beer's law:

TABLE I

Protonation constants (pK_{BH^+}) of propionic acid and propionamide from absorption measurements at different wavelengths (λ)

	$-pK_{BH^+}$ of propionic acid		$-pK_{BH^+}$ of propionamide
λ(mμ)	Method A	Method B	Method A
190	—	—	0.7
192	—	—	0.8
194	—	—	0.9
196	7.1	—	0.9
198	7.1	7.0	1.0
200	6.9	6.8	0.8
203	6.6	7.0	—
205	6.8	6.9	—
210	6.6	—	—
215	6.5	—	—

$$pK_{BH^+} = H_0 - \log (\epsilon_{BH^+} - \epsilon)/(\epsilon - \epsilon_B), \quad [3]$$

ϵ_B, ϵ_{BH^+}, and ϵ being the molar extinction coefficients of the unprotonated acid, the protonated acid, and the mixture of protonated and unprotonated forms in a solution of acidity function H_0, respectively. This is shown in Fig. 2, in which the points represent experimental values and the curve has been calculated from equation [3] assuming $pK_{BH^+} = -7.0$, $\epsilon_B = 44.0$, and $\epsilon_{BH^+} = 3.0$.

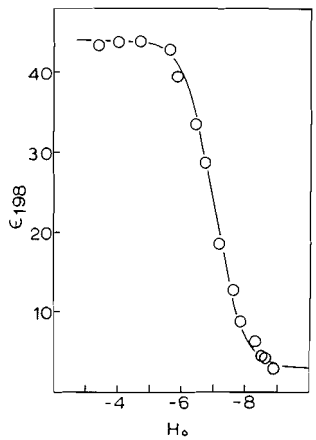

FIG. 2. Ionization of propionic acid in sulphuric acid.

Method A takes no account of the medium effect. It was thought that the pK_{BH^+} values obtained from measurements at different wavelengths might agree better if this effect were corrected by Hammett's method (5) of shifting absorption curves laterally to varying extents to make them all pass through an isobestic point, in this case at $\lambda = 192.5$ mμ, $\epsilon = 44.2$. The corrected values of ϵ, read from such a graph, were plotted against H_0, and pK_{BH^+} values obtained as before from such plots (method B, Table I). This method did not lead to significantly improved agreement of pK_{BH^+} values. It may be remarked that Hammett's assumption (5) about the medium effect—that it causes a lateral shift in absorption curves but no change in intensity—remains unproved.

By averaging the results in Table I, a pK_{BH^+} of -6.8 ± 0.3 is obtained for propionic acid.

Effect of Acidity on Spectrum of Propionamide

Aliphatic ketones exhibit three absorption peaks: a weak peak at about 280 mμ, a more intense peak at about 190 mμ, and a still more intense peak at about 150 mμ. These peaks have been assigned by McMurry (13), largely on the basis of their intensities, to $n \rightarrow \pi^*$, $n \rightarrow \sigma^*$, and $\pi \rightarrow \pi^*$ transitions respectively. The substitution of an amino for an alkyl group alters the energies of the orbitals of the ground state and the excited states, so that the weak peak of amides at about 220 mμ is attributed to a $n \rightarrow \pi^*$ transition and the intense peak at about 190 mμ to a $\pi \rightarrow \pi^*$ transition (14, 15).

The absorption curve for propionamide in water (Fig. 3) conforms to the general pattern in showing a shoulder at about 215 mμ ($\epsilon \sim 130$) which disappears in 33% sulphuric acid (Fig. 3B) presumably because of protonation of the carbonyl group (17, 28). However, the intense peak at 187 mμ (ϵ 6350) shows a shoulder at about 190 mμ (Fig. 3A),[2] and is most plausibly explained as being made up of two overlapping peaks: a peak at about 187 mμ ($\epsilon \sim 4500$) due to a $n \rightarrow \sigma^*$ transition and a peak at about 190 mμ ($\epsilon \sim 2800$) due to a $\pi \rightarrow \pi^*$ transition. This composite nature of the observed peak would explain the spectral changes observed as the solvent is changed from water to 33% sulphuric acid (Fig. 3A). Protonation of the carbonyl oxygen would be expected to cause a large blue shift of the $n \rightarrow \sigma^*$ peak (29), and a small red shift of the $\pi \rightarrow \pi^*$ peak (14, 30). The peak at 188 mμ remaining in 33% acid is accordingly attributed to a

[2]*We find, in agreement with Ley and Arends (12), that the absorption curve of acetamide in aqueous solution does not show a shoulder in this region.*

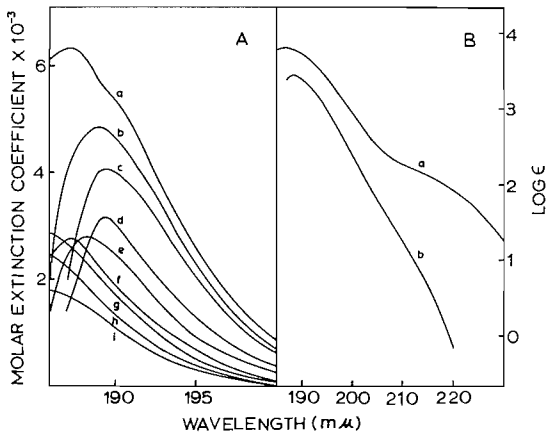

FIG. 3. Ultraviolet absorption of propionamide in the following concentrations of aqueous sulphuric acid: A: *a*, 0; *b*, 4.9; *c*, 11.3; *d*, 23.8; *e*, 33.0; *f*, 35.1; *g*, 55.2; *h*, 72.0; *i*, 96.4%; B: *a*, 0; *b*, 33.0%.

$\pi \rightarrow \pi^*$ transition of the protonated amide, and the shift of this peak to shorter wavelengths with further increase of acid concentration to a medium effect. The causes of shifts due to medium effects are often obscure.

This analysis of the absorption peak at 187 mμ is admittedly contentious and other interpretations of the changes in spectra with altering acidity are possible. Further work on the effect of solvents on the absorption of amides is planned.

Calculation of Protonation Constants of Propionamide

From plots of ϵ against H_0 (Fig. 4), the protonation constant of propionamide may be

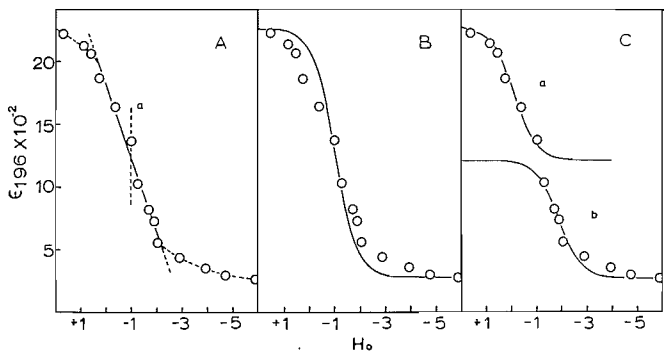

FIG. 4. Ionization of propionamide in sulphuric acid.

obtained by three different procedures:

1. The inflection point of the experimental sigmoid curve, and thence the pK_{BH^+} value, may be found by the method of Stewart and Yates (2). This is illustrated in Fig. 4A: the line *a* indicates the midpoint of the straight-line portion of the curve, and hence the inflection point.

For reasons made apparent in the sequel, we consider this the best method available. Values of the protonation constant obtained from measurements at different wavelengths are given in Table I, and indicate a pK_{BH^+} of -0.9 ± 0.1.

2. The theoretical curve is calculated from equation [3] using different values of ϵ_B, ϵ_{BH^+}, and pK_{BH^+}, the curve giving the best fit being found by trial and error. This is illustrated in Fig. 4B, in which the curve has been calculated assuming $pK_{BH^+} = -1.0$, $\epsilon_B = 2260$, and $\epsilon_{BH^+} = 260$.

It is found that the experimental points for propionamide deviate from the theoretical curve in a manner which is characteristic for all amides so far studied (4, 25, 31): in the neighborhood of the inflection point, the slope of the experimental curve is always less than theoretical (i.e. increase of h_0 produces a smaller increase in the ionization ratio than predicted by equation [2]). This has also been shown in plots of log $\{(\epsilon_{BH^+}-\epsilon)/(\epsilon-\epsilon_B)\}$ against H_0 for seven substituted benzamides having pK_{BH^+} ranging from -2.00 to -3.11 (32). According to equation [3], these plots should give straight-line curves of slope = 1; in fact, straight-line curves having slopes of 0.58–0.70 were obtained.

These discrepancies have hitherto been attributed to medium effects (25, 32). However, the deviation is always in the same direction regardless of the type of amide or of electronic transition ($n \rightarrow \pi^*$, $\pi \rightarrow \pi^*$, etc.) being considered, and it seems likely that it is due to a general failure of equation [2] when applied to the ionization of amides. This equation has been found inapplicable to the ionization of other types of Brønsted bases also (31), and the reason for its failure is given in the last section of this paper.

3. A better fit of theoretical values with the experimental results is obtained by assuming two equilibria and hence two curves calculated from equation [3]. This has been done in Fig. 4C, assuming $pK_{BH_1^+} = 0.1$, $\epsilon_B = 2260$, and $\epsilon_{BH_1^+} = 1200$ to calculate curve *a* and $pK_{BH_2^+} = -1.9$ and $\epsilon_{BH_2^+} = 260$ to calculate curve *b*. However, the two pK_{BH^+} values are not uniquely defined in this procedure: a reasonably satisfactory fit is obtained with two other pK_{BH^+} values (for example, $+0.2$ and -1.7 for Fig. 4C, with $\epsilon_{BH_1^+} = 1500$).

This procedure is the graphical equivalent of the method of calculation followed by Goldfarb, Mele, and Gutstein (11). Its only justification lies in the procrustean assumption that the experimental data for all compounds must fit equation [3]. Since we have grounds for rejecting this assumption, we may also reject this procedure because there is no evidence for the two equilibria which it postulates. If so, the pK_{BH^+} should lie somewhere between the $pK_{BH_1^+}$ and $pK_{BH_2^+}$ values of Goldfarb *et al.* On the assumption that the inflection point (i.e. the midpoint of the central straight-line portion of the experimental sigmoid curve (2)) lies somewhere on the straight-line curve between $H_0 = pK_{BH_1^+}$ and $H_0 = pK_{BH_2^+}$, pK_{BH^+} can be shown to be given by the equation

$$pK_{BH^+} = pK_{BH_1^+} + (pK_{BH_2^+} - pK_{BH_1^+})(\epsilon_{BH_1^+} - \epsilon_{BH^+})/(\epsilon_B - \epsilon_{BH_2^+}). \quad [4]$$

In Table II are given the values thus calculated from the recorded data of Goldfarb *et al.*

TABLE II
Protonation constants calculated from the experimental data of Goldfarb *et al.* (9)

Compound	$-pK_{BH^+}$	Compound	$-pK_{BH^+}$
Acetamide	0.59	N-*i*-Butylacetamide	0.61
N-Methylacetamide	1.25	Glycinamide	4.91
N-*n*-Butylacetamide	0.40	Aceturic acid	3.06

The value for acetamide is in good agreement with the protonation constant (-0.50) for aqueous solution recorded by Hall (8). It would appear, consequently, that propionamide is a weaker base than acetamide, and propionic acid a weaker base than acetic

acid. This may indicate that hyperconjugation is more important than inductive effects in stabilizing protonated amide and carboxylic acid groups.

Failure of the H_0 Acidity Function to Apply to the Protonation of Amides

The failure of equation [2] when applied to the protonation of amides may be attributed to the neglect of hydration effects in deriving this equation. The importance of these effects was first pointed out by Taft (21). The reasonable consistency of the H_0 scale as determined by Hammett using different indicators and different mineral acids (6, 7) was probably in part fortuitous: almost all the indicators used in the more dilute acid regions were substituted anilines, the conjugate acids of which should be hydrated to the same extent in a given acid solution (21). This is less than the hydration of the hydrogen ion (33), so that the ionization of a Hammett indicator (In) is given by

$$InH^+ + nH_2O \rightleftarrows In + H^+, \qquad [5]$$

the formulae representing the hydrated ions or molecules. The equilibrium constant K_{InH^+} for this equilibrium is

$$K_{InH^+} = ([In]a_{H^+}f_{In})/([InH^+]a_{H_2O}{}^n f_{InH^+}), \qquad [6]$$

where the a's represent activities and the f's molar-concentration activity coefficients. Operationally the acidity function h_0 of an acid solution is defined (6, 7) by

$$K_{InH^+} = ([In]h_0)/[InH^+] \qquad [7]$$

and hence

$$h_0 = (a_{H^+}f_{In})/(a_{H_2O}{}^n f_{InH^+}). \qquad [8]$$

This equation, differing from the original equation of Hammett (6) by taking account of water activities, has already been derived in slightly different form by Bascombe and Bell (33), who showed that for 0–8 M hydrochloric, sulphuric, and perchloric acid solutions $n \approx 4$.

The ionization of an acid BH^+ in a given concentration of aqueous mineral acid will also involve a number of water molecules, differing possibly from the number involved in the ionization of InH^+:

$$BH^+ + mH_2O \rightleftarrows B + H^+. \qquad [9]$$

The equilibrium constant K'_{BH^+} is then given by

$$K'_{BH^+} = ([B]a_{H^+}f_B)/([BH^+]a_{H_2O}{}^m f_{BH^+}), \qquad [10]$$

which combined with equation [8] gives

$$K'_{BH^+} = ([B]h_0 f_B f_{InH^+})/([BH^+]a_{H_2O}{}^{m-n} f_{In} f_{BH^+}). \qquad [11]$$

It is usually assumed (6, 7, 21) that the term $(f_B f_{InH^+})/(f_{In} f_{BH^+})$ is reasonably invariant with change of acidity; this assumption is supported by the work of Deno and his collaborators on the solubilities of neutral organic compounds (34) and of organic salts (34, 35) in different concentrations of sulphuric acid. Accepting this assumption, equation [11] becomes

$$K'_{BH^+} = ([B]h_0)/([BH^+]a_{H_2O}{}^h), \qquad [12]$$

where $(m-n)$, the difference in hydration numbers of InH^+ and BH^+, is termed the hydration parameter h.

This last equation reduces to equation [2] when $h = 0$, i.e. when BH^+ and InH^+ are hydrated to the same extent, if B and In are (as assumed by Bascombe and Bell (33)) unhydrated. This case is represented for a hypothetical base having $pK_{BH^+} = -2$ by curve *a* in Fig. 5, which gives the percentage protonation of the base for different H_0

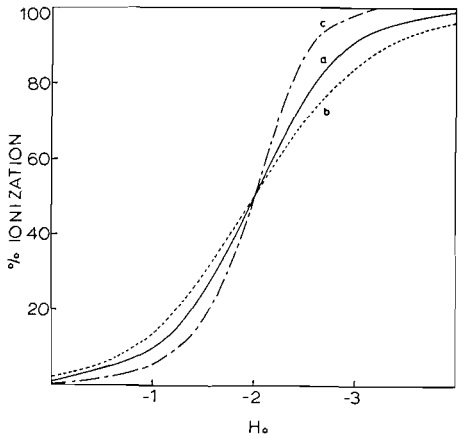

FIG. 5. Theoretical curves according to equation [12] for ionization of a base having $pK_{BH^+} = -2.0$ and *a*, $h = 0$; *b*, $h = -2$; *c*, $h = +2$.

values. When BH^+ has a greater hydration number than InH^+, $h < 0$ and the ionization ratio according to equation [12] is then proportional to $h_0 a_{H_2O}^{-h}$. Since a_{H_2O} (and hence $a_{H_2O}^{-h}$) decreases as the acid concentration (and h_0) increases (33), the ionization ratio will increase more slowly with increase of h_0 than indicated by equation [2]. This is the situation we have already found for amides. In curve *b* of Fig. 5 it is illustrated for a hypothetical base having $pK_{BH^+} = -2$ and $h = -2$; the curve has been calculated for ionization in aqueous sulphuric acid using the H_0 (7) and a_{H_2O} (36) values recorded in the literature for various concentrations of this acid. Similarly, the curve *c* has been calculated for the ionization in sulphuric acid of a base having $pK_{BH^+} = -2$ and $h = +2$. Curves of this last type have been found characteristic of the ionization of certain substituted thioureas (31); the significance of the positive value of h will be discussed in a later communication.

It should be noted that according to this treatment K_{BH^+} is not a true equilibrium constant except when $h = 0$ and $K_{BH^+} = K'_{BH^+}$. K_{BH^+} may be regarded as a constant operationally defined by equation [2], i.e. it is equal to the h_0 value at which the base is half ionized. K'_{BH^+} may then be calculated from K_{BH^+} by the equation

$$K'_{BH^+} = K_{BH^+}/a_{H_2O}{}^h, \qquad [13]$$

the a_{H_2O} in this case being the water activity of the acid solution of $H_0 = pK_{BH^+}$.

The hydration parameter required in equation [13] may be obtained from the slope of the plot of $\log\{(\epsilon_B - \epsilon)/(\epsilon - \epsilon_{BH^+})\} + H_0$ against $\log a_{H_2O}$, since equation [12] may be rewritten in the form

$$\log\{(\epsilon_B - \epsilon)/(\epsilon - \epsilon_{BH^+})\} + H_0 = -h \log a_{H_2O} + pK'_{BH^+}. \qquad [14]$$

Such a plot for propionamide is shown in Fig. 6. Unfortunately, it is seen that h is continually decreasing as a_{H_2O} decreases, i.e. as the acid becomes more concentrated (Table

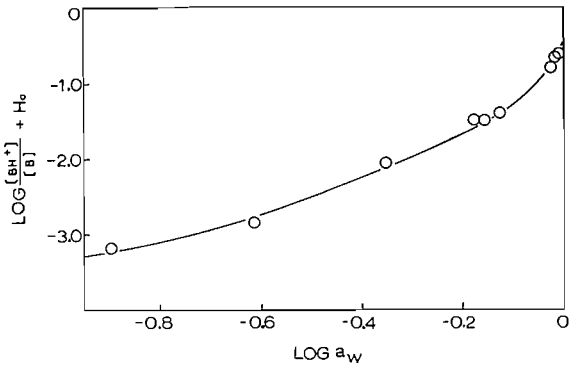

FIG. 6. Plot of {log (ionization ratio)$+H_0$} against log (water activity) for solutions of propionamide in aqueous sulphuric acid.

III). This trend, which has been noted by us for other amides (31) and by Taft (21) for other bases, greatly reduces the practical usefulness of equation [12]. It is to be expected,

TABLE III

Hydration parameter (h) of propionamide in sulphuric acid solutions of different acidities

$-H_0$	$-\log a_{H_2O}$	h
—	0	16.4
0.90	0.048	8.1
1.5	0.10	5.1
2.7	0.30	2.9
3.6	0.50	2.5
4.2	0.70	1.9
4.7	0.90	0.5

since with decreasing water activity the hydration numbers of all ions will tend towards zero. Consequently the difference in hydration numbers of InH^+ and BH^+, which defines h, should decrease.

The fact that in general h will be very small for ionizations in very strong acids means that in these acids the deviation of the ionization ratio from that given by equation [2] will be small. This is exemplified for propionic acid in Fig. 2. Furthermore, the continuous decrease in h with increase in acidity indicates that curve b of Fig. 5, calculated on the assumption of a constant h, is unrealistic. If $h = -2$ at $H_0 = -2$, then at lower acidities $h < -2$ and curve b should diverge more from curve a; at higher acidities $h > -2$ and curve b should be closer to curve a. However, in all cases (curves a, b, and c of Fig. 5) the inflection points of the curves indicate the H_0 value for half-ionization of the bases. Consequently, we consider the graphical method of Stewart and Yates (2) the best one for determining pK_{BH^+}, as redefined above.

ACKNOWLEDGMENTS

We are grateful to Professors N. C. Deno and R. Stewart for access to unpublished material, to Professors G. C. B. Cave and C. Sandorfy for the use of equipment, and to the National Research Council for financial assistance.

THE PHOSPHORYLATION OF 2-METHYL-Δ^2-OXAZOLINE*

R. GREENHALGH

Defence Research Chemical Laboratories, Ottawa, Canada

Received January 5, 1962

ABSTRACT

In common with other acylating agents, diisopropyl phosphorochloridate reacts with 2-methyl-Δ^2-oxazoline in aqueous and ethereal media to yield N-phosphoryl derivatives. In both media, phosphorylation is followed by ring opening between positions 1 and 5, as shown by the isolation of diisopropyl N-acetyl-N-2-chloroethylphosphoramidate and diisopropyl N-acetyl-N-2-hydroxyethylphosphoramidate. The latter compound undergoes further rearrangement, being slowly converted to diisopropyl N-2-acetoxyethylphosphoramidate in aqueous bicarbonate solution.

Nuclear magnetic resonance studies of 2-methyl-Δ^2-oxazoline in aqueous bicarbonate solution (pH 8.5) reveal that it is all transformed to N-acetylethanolamine within 23 hours. This short lifetime allows speculation regarding the origin of 2-acetamidoethyl diisopropyl phosphate isolated from the reaction of the base with diisopropyl phosphorofluoridate.

The normal products resulting from the action of acylating agents with 2-substituted-Δ^2-oxazolines in anhydrous or aqueous media are N-acyl derivatives (1, 2). The reaction of diisopropyl phosphorofluoridate (DFP) with 2-methyl-Δ^2-oxazoline (methyl oxazoline) appears to be an exception in that Porter *et al.* (3) obtained 2-aminoethyl dihydrogen phosphate.

Repetition of this reaction under their conditions (4) confirmed the result, since 2-aminoethyl diisopropyl phosphate and 2-acetamidoethyl diisopropyl phosphate were isolated in small yields. The isolation procedure was modified to avoid acidic conditions, under which N $\rightarrow$ O migration of phosphoryl groups is known to occur (5). This precaution eliminated one possible mode of formation of the O-phosphoryl derivatives.

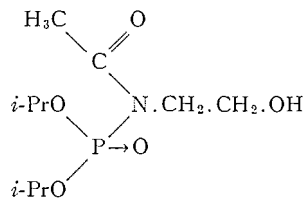
In order to determine whether phosphorylation and acetylation of methyl oxazoline proceed by different mechanisms the reaction between the chloro analogue of DFP, diisopropyl phosphorochloridate (DClP), and methyl oxazoline was studied. Wagner-Jauregg *et al.* (6) have shown that DClP is more reactive than DFP, readily reacting with primary and secondary amines to give N-phosphoryl derivatives.

Methyl oxazoline, when treated with DClP at room temperature for 24 hours in sodium bicarbonate solutions (pH 8.2), gave a 51% yield of diisopropyl N-2-acetoxyethylphosphoramidate together with a little N-acetylethanolamine. This reaction clearly indicates that phosphorylation of methyl oxazoline, like acylation, gives an N-acyl derivative. If the reaction was stopped after 1 hour, a neutral oily product was obtained which appeared to be isomeric with diisopropyl N-2-acetoxyethylphosphoramidate, having the same elemental analysis, including one acetyl group, but a different infrared spectrum. No N—H or C=O (ester) absorption was apparent; instead the compound showed absorption at 3400 cm^{-1}, 1690 cm^{-1}, and 1050 cm^{-1}, which were tentatively assigned to the O—H, C=O (amide I), and C—OH stretching vibrations (7). The existence of an hydroxyl group in the molecule was confirmed by acetylation, which gave a quantitative yield of an oil whose infrared spectrum showed no absorption at 3400 cm^{-1} and 1050 cm^{-1} but two new bands appeared at 1740 cm^{-1} and 1230 cm^{-1}, which were assigned to the C=O (ester) and C—OC (ester) stretching vibrations. The only location remaining for the acetyl group, to which the band at 1690 cm^{-1} is ascribed, is on the nitro-

**Issued as D.R.C.L. Report No. 363.*

gen atom, the lack of any N—H and amide II absorption being in keeping with a tertiary amide structure. The high frequency of the C=O stretching vibration is in agreement with the nitrogen atom being substituted with a diisopropyl phosphoryl group, since electrophilic groups substituted on the amide nitrogen increase the C=O frequency (8).

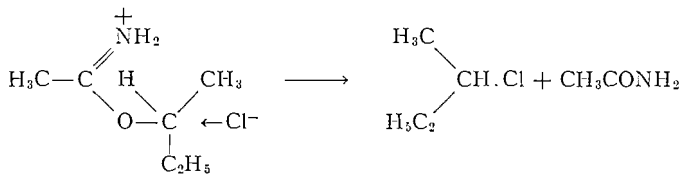
On the basis of these results, the product isolated from the reaction of methyl oxazoline with DClP after 1 hour was assigned structure I, with which the n.m.r. spectrum is in agreement. If this material is allowed to remain on an alumina column (ca. 1 hour) prior to elution, it is quantitatively converted to diisopropyl N-2-acetoxyethylphosphoramidate (II). The migration can also be effected by allowing the compound to stand overnight in aqueous sodium bicarbonate at pH 8.2.



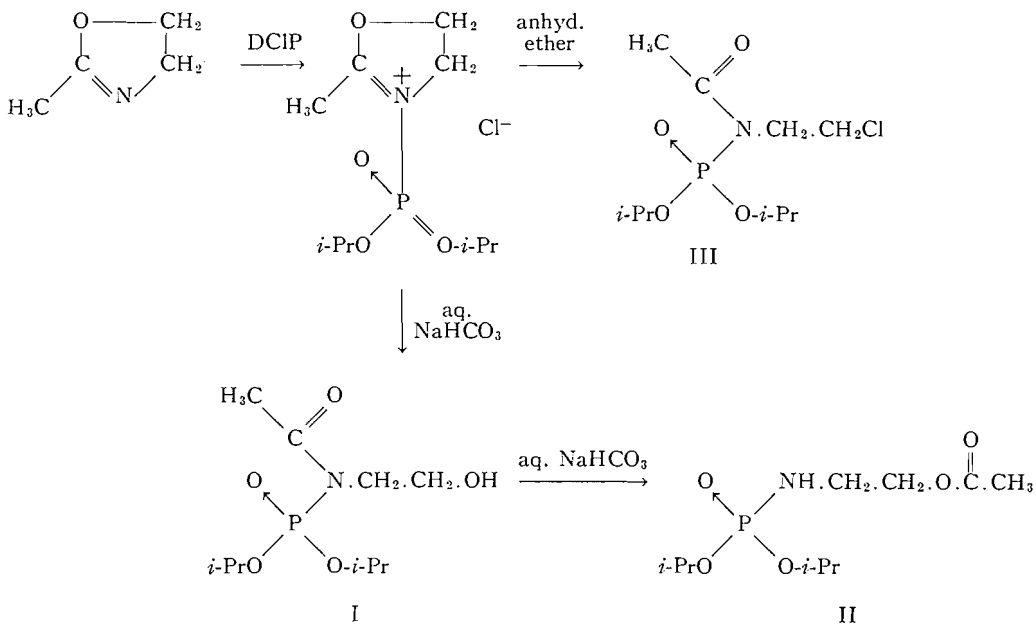
I

Treatment of methyl oxazoline with DClP in anhydrous ether in the absence of a base gives an oily product whose infrared spectrum, apart from absorption at 3400 cm^{-1} and 1050 cm^{-1}, is identical with that of I. Since elemental analysis revealed the presence of chlorine and an acetyl group the material was thought to be the chloro analogue of I, namely diisopropyl N-2-chloroethylphosphoramidate (III). Replacement of the hydroxyl by the chloro group stabilized the molecule to the extent that it could be chromatographed on alumina without undergoing migration.

Fry (1) considers the acylation of Δ^2-oxazolines to proceed by formation of a salt-like intermediate, followed by ring opening between positions 1 and 5 in ether and 2 and 3 in aqueous bicarbonate solution. This work elaborated the previous explanation by Goldberg and Kelly (9) of the ring opening of oxazolinium salts. They compared the 1/5 ring opening of phenyl oxazoline hydrochloride to give N-2-chloroethylbenzamide with the similar degradation of imidate hydrohalides to alkyl chlorides and amides. This decomposition of imidate hydrohalides was later shown to be first order with respect to the halide ion (10). Stevens *et al.* (11) confirmed the bimolecular nature of the reaction by isolating *sec*-butyl chloride with inverted configuration from the thermal decomposition of optically active *sec*-butyl acetimidate hydrochloride.



By analogy, the mode of phosphorylation of methyl oxazoline can be considered to give first a salt-like intermediate which cleaves between positions 1 and 5 under both anhydrous acidic and aqueous basic conditions. The last stage in aqueous bicarbonate is the migration of the acetyl group from the N to the O atom.



The transformation of methyl oxazoline in aqueous solution has been studied by Porter *et al.* (12) and very recently by Martin and Parcell (13). The first authors studied unbuffered solutions having initial pH values of 4.8, 5.4, and 6.2 whilst the latter employed buffered solutions in the pH range −1 to 7. Other work (14), which will be reported elsewhere, indicated that the expressions derived (12, 13) for the rate of disappearance of methyl oxazoline could not be extrapolated to higher pH values as used in our phosphorylation experiments (pH 8.5–9). This work involved a study of an aqueous solution of methyl oxazoline (2.5%) at controlled pH values in the range 0 to 10. Our results give excellent agreement with those of Martin and Parcell from pH 0 to 6, but discrepancies appear outside this range. Nuclear magnetic resonance spectroscopy was used to follow the reaction since it readily differentiates between the methyl protons of methyl oxazoline, O-acetylethanolamine, N-acetylethanolamine, and acetic acid. When this technique was applied to a control of methyl oxazoline (1% in 6% sodium bicarbonate), the triplet at 2.724, 2.746, and 2.770 p.p.m. up field from water resulting from methyl oxazoline disappeared in 23 hours. The only other signal detected was a single peak at 2.698 p.p.m. corresponding to N-acetylethanolamine (O-acetylethanolamine 2.563 p.p.m.). An infrared study (thin film, CaF_2 plates) of a similar solution of methyl oxazoline but in D_2O and using deuterated sodium bicarbonate confirmed the result.

Since methyl oxazoline is readily converted to N-acetylethanolamine under the conditions employed in the reaction of methyl oxazoline and DFP, a separate experiment was carried out with DFP and N-acetylethanolamine, and 2-acetamidoethyl diisopropyl phosphate was isolated.

It would therefore appear likely that under the conditions used for the phosphorylation of methyl oxazoline with DFP, 2-acetamidoethyl diisopropyl phosphate arises from the reaction of N-acetylethanolamine with DFP. However, the isolation of 2-aminoethyl diisopropyl phosphate remains unexplained.

EXPERIMENTAL

Infrared spectra were recorded on a Perkin–Elmer 221G spectrophotometer and the nuclear magnetic resonance spectra on a Varian V4300 spectrometer. Paper chromatograms were run on Whatman No. 1 paper using butanol:acetic acid:water, 4:1:5, as the developer.

2-Methyl-Δ^2-oxazoline was prepared by the method of Wenker (15), b.p. 109–110°.

Diisopropyl phosphorochloridate was prepared according to McIvor *et al.* (16), b.p. 74° at 10 mm.

Diisopropyl phosphorofluoridate was prepared by the method of Goldwhite and Saunders (17), b.p. 63° at 1 mm.

N-Acetylethanolamine was prepared according to Wenker (15), b.p. 140° at 0.1 mm.

Diisopropyl N-2-hydroxyethylphosphoramidate was prepared according to Plapinger and Wagner-Jauregg (5) and distilled at 95–98° at 0.1 mm. Infrared (film): 3375 cm^{-1}, OH; 3280 cm^{-1}, NH; 1230 cm^{-1}, P → O; 1178, 1140, 1107 cm^{-1}, C—OP (isopropyl); 1061 cm^{-1}, C—OH; 1018, 989 cm^{-1}, P—OC.

Diisopropyl N-2-Acetoxyethylphosphoramidate

Diisopropyl N-2-hydroxyethylphosphoramidate (800 mg) and triethylamine (395 mg) were dissolved in anhydrous ether, and acetyl chloride (305 mg) was slowly added. After standing for 72 hours, the solution was filtered and the filtrate evaporated to give an oil (845 mg) which distilled at 95–98° at 0.05 mm, n_{21}^{D} 1.435 (yield 86%). Calc. for $C_{10}H_{22}O_5NP$: N, 5.28; P, 11.68%. Found: N, 5.57; P, 11.34%. Infrared (film): 3250 cm^{-1}, NH; 1740 cm^{-1}, C=O (ester); 1232 cm^{-1}, P → O and C—OC (ester); 1170, 1135, 1108 cm^{-1}, C—OP (isopropyl); 1015, 985 cm^{-1}, P—OC.

Reaction of DClP with 2-Methyl-Δ^2-oxazoline in Aqueous Bicarbonate Solution

(*a*) DClP (1.71 g) was added over a period of 2 hours to a stirred solution of methyl oxazoline (500 mg) and sodium bicarbonate (1.5 g) in water (17 ml). The solution was stirred for 20 hours and then ether-extracted to give 823 mg (52%) of oil which distilled at 95–99° at 0.1 mm, n_{21}^{D} 1.434. Calc. for $C_{10}H_{22}O_5NP$: C, 45.2; H, 8.37; N, 5.28; P, 11.68%. Found: C, 45.36; H, 8.58; N, 5.04; P, 11.78%. Infrared (film): 3250 cm^{-1}, NH; 1740 cm^{-1}, C=O (ester); 1232 cm^{-1}, P → O and C—OC (ester); 1170, 1135, 1108 cm^{-1}, C—OP (isopropyl); 1015, 985 cm^{-1}, P—OC. The infrared spectrum was identical with that of an authentic sample of diisopropyl N-2-acetoxyethylphosphoramidate.

(*b*) Using the quantities of reactants mentioned above, DClP was added to the solution in 15 minutes and after an hour the solution was extracted with chloroform. The chloroform extract gave diisopropyl N-acetyl-N-2-hydroxyethylphosphoramidate, 910 mg (58%), as a yellowish oil, which was distilled at 95–100° at 0.01 mm. Calc. for $C_{10}H_{22}O_5NP$: C, 45.2; H, 8.37; N, 5.28; P, 11.68; CH_3CO, 16.22%. Found: C, 45.51; H, 8.34; N, 5.08; P, 11.82; CH_3CO, 16.01%. Infrared (film): 3400 cm^{-1}, OH; 1685 cm^{-1}, C=O (amide I); 1270 cm^{-1}, P → O; 1170, 1135, 1108 cm^{-1}, C—OP (isopropyl); 1050 cm^{-1} (sh), C—OH; 1010, 985 cm^{-1}, P—OC.

(*c*) A mixture of methyl oxazoline (2 g), DClP (11.49 g), sodium bicarbonate (12 g), and isopropanol (75 ml) was made up to 200 ml with water, maintained at 37° for 4 days, and then extracted with ether followed by chloroform. The ether extract contained 2.1 g of oil, of which 500 mg was chromatographed on Woelm IV neutral alumina; the main products were diisopropyl N-2-acetoxyethylphosphoramidate (289 mg), which was eluted with 2:1 benzene:ether, and N-acetylethanolamine (25 mg), eluted with 50:1 chloroform:methanol. All the chloroform extract (102 mg) was chromatographed on the same type of alumina; diisopropyl N-2-acetoxyethylphosphoramidate (59 mg) was eluted with 8:1 benzene:chloroform; diisopropyl N-2-hydroxyethylphosphoramidate (20 mg) was eluted with 20:1 chloroform:methanol and N-acetylethanolamine (16 mg) was eluted with 100:1 chloroform:methanol. The fractions were identified by comparison of the infrared spectra with those of authentic samples.

The total yields of diisopropyl N-2-acetoxyethylphosphoramidate and diisopropyl N-2-hydroxyethylphosphoramidate were 1.28 g (20%) and 20 mg (0.4%) respectively.

Reaction of DClP with 2-Methyl-Δ^2-oxazoline in Anhydrous Ether

DClP (1.16 g) in anhydrous ether was added to a stirred solution of methyl oxazoline (500 mg) in anhydrous ether. After the solution was stirred for 18 hours the solvent was removed and the residue freed of volatiles by pumping at 0.3 mm, yielding 1.62 g of yellow oil. A 500-mg aliquot was chromatographed on Woelm neutral alumina grade III and two main fractions were obtained. Elution with 4:1 benzene:pentane gave a colorless oil (340 mg) which distilled at 85–90° at 0.1 mm. Yield 68%. Calc. for $C_{10}H_{12}O_4NPCl$: N, 4.89; P, 11.19; Cl, 12.42%. Found: N, 4.61; P, 10.98; Cl, 12.65%. Infrared (film): 1690 cm^{-1}, C=O (amide I); 1270 cm^{-1}, P → O; 1174, 1138, 1095 cm^{-1}, C—OP (isopropyl); 1010 (sh), 986, 970 (sh) cm^{-1}, P—OC. From the n.m.r., infrared, and analytical data this compound was concluded to be diisopropyl N-acetyl-N-2-chloroethylphosphoramidate. A second fraction (128 mg) was eluted with 1:1 benzene:ether as a clear oil and had an infrared spectrum identical with that of N-2-chloroethyl-N-acetylethylamine. Infrared (film): 3280 cm^{-1}, NH; 1650 cm^{-1}, C=O (amide I); 1565 cm^{-1}, OCNH (amide II); 1260 cm^{-1} (amide III).

Acetylation of Diisopropyl N-Acetyl-N-2-hydroxyethylphosphoramidate

Acetyl chloride (300 mg) was slowly added to a solution of triethylamine (388 mg) and diisopropyl N-acetyl-N-2-hydroxyethylphosphoramidate (850 mg) in anhydrous ether. After the solution had stood overnight, the white precipitate of triethylamine hydrochloride was filtered off; evaporation of the ethereal filtrate gave 890 mg of yellow oil which distilled at 87–90° at 0.1 mm, giving diisopropyl N-acetyl N-2-acetoxyethylphosphoramidate (92%) as a clear oil. Calc. for $C_{12}H_{24}O_5NP$: N, 4.53; P, 10.02; CH_3CO, 23.90%. Found: N, 4.66; P, 9.75; CH_3CO, 23.66%.

Reaction of DFP with 2-Methyl-Δ^2-oxazoline

A solution of methyl oxazoline (2 g), DFP (11 g), and sodium bicarbonate (12 g) in water was homogenized by the addition of isopropanol (75 ml), and the volume was made up to 200 ml. The reaction was carried out in a fume hood, and the solution kept at 37° for 4½ days. After this time, the reaction mixture was extracted with ether and chloroform, which yielded 758 mg and 45 mg of oil, respectively.

A portion (500 mg) of the ether extract was chromatographed on Woelm neutral alumina grade IV (15 g) and three main fractions were obtained. The first fraction eluted was DFP (27 mg), with 2:1 benzene: pentane; followed by N-acetylethanolamine (110 mg), eluted with 80:1 chloroform:methanol; and finally sodium diisopropyl phosphate (221 mg), eluted with methanol. All the chloroform extract was chromatographed on 2 g alumina, giving two main fractions: N-acetylethanolamine (10 mg), eluted with 90:1 chloroform: methanol, and sodium diisopropyl phosphate (22 mg), eluted with 100:1 methanol:acetic acid. All these compounds were identified by comparison of their infrared spectra with those of authentic samples. Two small fractions from the chloroform extract eluted with 1:1 chloroform:ether showed positive ninhydrin and Hanes–Isherwood (18) spots at R_F 0.72 and 0.73 respectively, and also Hanes–Isherwood-positive spots at R_F 0.89 and 0.92 respectively.

These two fractions were combined (10 mg), and 5 mg streaked on a sheet of Whatman No. 3 paper 18×18 in. and separated electrophoretically in an E.C. Model 40 apparatus, using 1N formic acid as the buffer at 900 v for 1 hour. Three Hanes–Isherwood-positive bands were detected at −6, −1.5, and +2.6 cm using the print method (19). After air drying the paper, the bands were cut out and eluted with water (2 ml). The eluate was passed through a millipore filter and in the case of band 1, through 1 cc IRA 400 (OH^-) before evaporating to dryness. Band 1 gave 1.1 mg of oil, band 2, 2.5 mg, and band 3, 1.3 mg. These oils were shown to be pure by re-examination of chromatographic and electrophoretic properties. These values, together with the spectral data, are given in Table I.

TABLE I

Paper chromatographic, paper electrophoretic, and infrared absorption data of the three fractions from the chloroform extract

			Chromogenic reaction			
Band	R_F	Mobility* (cm)	Ninhydrin	Hanes–Isherwood	Chlorine (20)	Infrared spectra ($CHCl_3$) (cm^{-1})
1	0.72	−7.9	+	+	+	3470, 3200, 1580, 1250, 1178, 1150, 1105, 1000, 800
2	0.92	−1.4		+	+	3450, 3350, 1670, 1520, 1180, 1150, 1105, 1015
3	0.81	+3.3		+		2700, 2100, 1650, 1210, 1170, 1150, 1180, 1020

*Mobility is measured as the distance moved from the start line, and the sign denotes the electrode towards which migration occurred.

On the basis of these properties being identical with those of 2-aminoethyl diisopropyl phosphate in the case of band 1, 2-acetamidoethyl diisopropyl phosphate for band 2, and diisopropyl dihydrogen phosphate for band 3, the compounds were assigned these structures. The yield of 2-aminoethyl diisopropyl phosphate was 0.07% and 2-acetamidoethyl diisopropyl phosphate 0.08%.

Reaction of DFP with N-Acetylethanolamine

N-Acetylethanolamine (2.45 g) was mixed with DFP (11 g), sodium bicarbonate (12 g), and isopropanol (75 ml) and made up to 200 ml. The reaction was maintained at 37° for 4 days.

After 4 days at 37° the reaction was extracted with ether and chloroform. The ether extract gave a brown oil (908 mg), of which 500 mg was chromatographed on Woelm neutral alumina grade IV (15 g). The products isolated in order of elution were DFP (233 mg), triisopropylphosphate (7 mg), 2-acetamidoethyl diisopropyl phosphate (12 mg), N-acetylethanolamine (87 mg), and diisopropyl dihydrogen phosphate (141 mg). The chloroform extract gave 43 mg of oil which yielded on chromatography 2-acetamidoethyl

diisopropyl phosphate (9 mg) and N-acetylethanolamine (15 mg). All the products were identified by paper chromatography and infrared spectra by comparison with known samples. The main product was 2-acetamidoethyl diisopropyl phosphate, 30 mg (0.47%).

ACKNOWLEDGMENTS

The author is indebted to Mr. J. Legari for technical assistance and to Dr. M. A. Weinberger for interpretation of the n.m.r. spectra. Microanalyses were carried out by Mr. J. Helie, infrared absorption spectra by Mr. R. Gravelle, and n.m.r. spectra by Mr. K. Oikawa.

TOTAL SYNTHESIS OF STEROIDAL DERIVATIVES

I. SYNTHESIS OF HYDROCHRYSENE ANALOGUES AND RELATED COMPOUNDS

JAMES P. KUTNEY, WM. MCCRAE,[1] AND ARNOLD BY
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received December 6, 1961

ABSTRACT

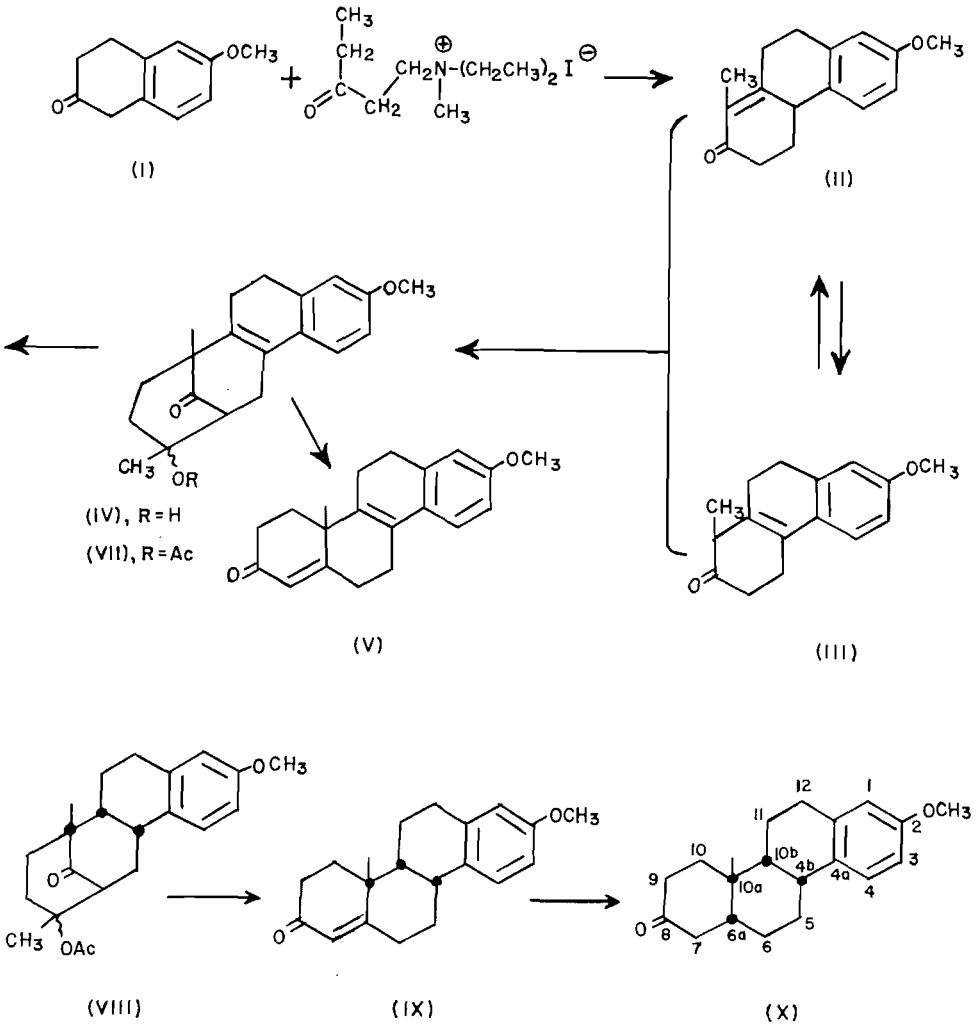
A synthetic sequence leading to the total synthesis of several hydrochrysene derivatives is described. It is noted that these derivatives may provide entry into the synthesis of various interesting steroidal analogues.

Recently a considerable effort has been put forth to study the effect of substituents attached to the steroid skeleton on the biological properties of these compounds. Indeed, dramatic effects have been obtained for substitutents such as methyl, hydroxyl, and halogen, particularly fluorine, when these groups are situated at rather specific positions on the nucleus. Related to these studies, the removal of angular methyl groups, as in 18-nor and 19-nor steroids, or of methylene groups from the ring skeleton to generate ring-contracted steroidal nuclei has also been accompanied with very important alterations in the biological activity of these molecules (1, 2).

All of the above studies have involved the use of the naturally occurring steroids as starting materials, and although these are obviously the logical choice in most cases, they offered certain limitations in synthesizing some of the steroidal derivatives which were of interest in our studies between structure and biological activity. For this reason, we initiated investigations directed toward the total synthesis of steroidal analogues, with particular emphasis on intermediates which would readily lend themselves to the introduction of substituents or alterations of the actual skeleton not conveniently possible from the natural steroids. This paper outlines the total synthesis of hydrochrysene derivatives which fulfill this aim.

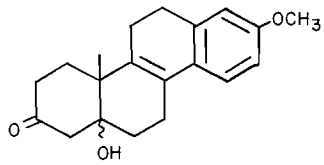
Of the various approaches which were available, the one utilizing the Robinson–Mannich base reaction originally developed by Robinson and co-workers (3) and so successfully applied in the elegant researches of Johnson and co-workers (4) was selected. Condensation of 6-methoxy-2-tetralone (I) with 1-diethylamino-3-pentanone methiodide, in the presence of sodium methoxide, provided an isomeric mixture of the tricyclic ketones (II and III). The arrangement of the double bond in the tricyclic ketone permits its migration into conjugation with either the aromatic ring or with the carbonyl function (II $\rightleftarrows$ III). It was not surprising, therefore, to find that our product was an oily mixture of both isomers. The ultraviolet spectrum of this mixture indicated a broad band in the 250–260 mμ region and the infrared spectrum indicated the presence of saturated and unsaturated carbonyl functions (5.86 and 6.05 μ). Careful chromatography of this mixture, first on alumina and then on silica gel, allowed the separation into the two respective isomers, II (λ_{max} 253 mμ, infrared 6.05 μ) and III (λ_{max} 275 mμ, infrared 5.85 μ). In general, this separation involved considerable losses, and for preparative purposes, in the subsequent condensation, the isomeric mixture was employed. It is pertinent to point out that a similar mixture was encountered by Johnson and co-workers in a similar reaction (5).

[1]*Holder of N.R.C. Postdoctorate Fellowship, 1960–1961.*

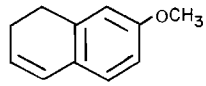


The common anion derived from either isomer II or III made it unnecessary to isolate each isomer in a pure state for the second Robinson–Mannich cyclization. Consequently, the tricyclic ketone mixture was treated with either 1-diethylamino-3-butanone methiodide or methyl vinyl ketone and the condensation was allowed to proceed, in the presence of sodium methoxide, to yield a tetracyclic product. In our hands, the use of methyl vinyl ketone instead of the Mannich base was more convenient and provided better results and we have utilized it in most of our condensations. It should be noted that a similar preference for the use of the parent ketone instead of the Mannich base methiodide is indicated by Woodward and co-workers in a related reaction (6). The nature of the tetracyclic product depended on the reaction conditions—the hydroxy ketone (IV) was formed at lower temperatures whereas the tetracyclic ketone (V) was the major product at refluxing methanol temperature. Since ketone V was readily obtained from the hydroxy ketone by treatment with base, and since the ketol IV allowed us to obtain some of the desired hydrochrysene derivatives, we concentrated our efforts on developing optimum conditions for the sequence II, III $\rightarrow$ IV $\rightarrow$ V.

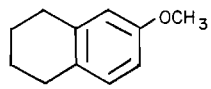
The nature of the ketol structure deserves some comment since at the outset, two formulations (IV or VI) are possible depending on the manner of the final cyclization. The structure IV was anticipated, since Johnson and co-workers (8) have recently



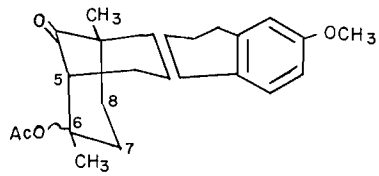
(VI)



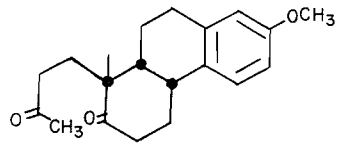
(XII)



(XIII)



(XI)



(XIV)

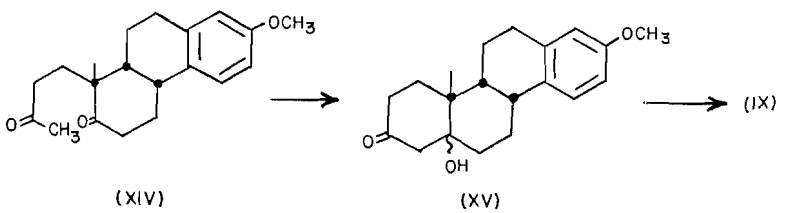
published a detailed paper indicating that the correct structure for their ketols, obtained in an analogous sequence, is represented by a formulation of type IV and not VI as originally proposed. Indeed, our hydroxy ketone, m.p. 216–218°, could be readily assigned the bridged structure IV on the basis of the following evidence. The infrared spectrum of the substance indicated the presence of a saturated carbonyl chromophore (5.88 μ) and a hydroxyl function, and the ultraviolet spectrum (λ_{max} 274 mμ; λ_{min} 236 mμ) was characteristic of a *p*-methoxystyrene chromophore. Subsequent comparison with the model compound, 3,4-dihydro-6-methoxynaphthalene (XII) (λ_{max} 269 mμ; λ_{min} 237 mμ), indicated that the ultraviolet spectra were virtually superimposable except for a slight shift of the maximum in IV, as expected for more substitution on the chromophore. This spectral data is obviously consistent for both IV or VI, but when we turned to consider the n.m.r. data, we could exclude VI very easily. The n.m.r. spectrum, run in pyridine (7), showed *two* sharp signals at high applied magnetic field characteristic of proton resonance from methyl groups (9.38 τ, $-\overset{|}{\underset{|}{C}}-CH_3$ and 9.22 τ, $HO-\overset{|}{\underset{|}{C}}-CH_3$)—a situation clearly consistent with structure IV but not VI. In addition the characteristic signals for the methoxyl group and the aromatic protons were present (see experimental portion). Acetylation of IV with isopropenyl acetate provided a good yield of the expected acetate, VII, m.p. 150–150.5°. Apart from the usual carbonyl absorption characteristic of the ketone and acetate functions (5.78, 5.85 μ) in the infrared, the n.m.r. spectrum of this substance, run in pyridine, also indicated some interesting features. Firstly, the presence of two high-field signals (9.42, 8.98 τ) confirmed the presence of two methyl groups. In addition it is to be noted that one of these signals is shifted downfield upon acetylation and this is expected in such a structure as IV. This evidence allows us to assign, with certainty, the highest-field signal to the angular methyl group. It is well known (7) that pyridine exerts a considerable solvent shift in the n.m.r. and in order to see what effect is noticed in this series of compounds, we also ran the acetate VII, under identical conditions with deuteriochloroform as the solvent. In general all the signals were shifted

downfield with some signals being shifted much more than others. For example, the high-field signals now occurred at 8.80 and 8.35 τ. In addition the resolution in pyridine was far superior to that in deuteriochloroform so that pyridine appears to be an excellent solvent for compounds of this type.

It has been known for some time (8) that catalytic hydrogenation of the acetates of ketols of type IV effects stereoselective reduction of the styrene double bond, with the hydrogen being absorbed from the β face of the molecule. This stereochemical course can be rationalized if one considers the conformational expression for the acetate VII (see XI). It becomes clear that β-side hydrogenation would be expected because approach of the catalyst to the α-side of the double bond is seriously hindered by the bridge containing carbons 6, 7, and 8. When the ketol VII was catalytically reduced by the use of palladium hydroxide on strontium carbonate, a good yield of the reduction product (VIII) was obtained. The ultraviolet spectrum of this substance (λ_{max} 278 and 286 mμ) was virtually superimposable upon the spectrum of an authentic sample of 1,2,3,4-tetrahydro-6-methoxynaphthalene (XIII), indicating that complete reduction had occurred. The infrared spectrum still retained the typical saturated carbonyl chromophore, and the acetate group (5.86, 5.80 μ) and the n.m.r. spectrum, with signals at high field (8.90 τ, $-\overset{|}{\underset{|}{C}}-CH_3$; 8.47 τ, $-\overset{|}{\underset{OAc}{C}}-CH_3$), were entirely consistent with the above formulation.

When the above reduction product (VIII) was refluxed in benzene in the presence of sodium methoxide, an excellent yield of the expected tetracyclic ketone IX was obtained. This substance, m.p. 158–159°, now exhibited a conjugated carbonyl absorption in the infrared spectrum (6.04 μ) and a new absorption occurred at 233 mμ in the ultraviolet apart from the usual aromatic absorption already mentioned in VIII. The n.m.r. spectrum of this substance was completely different from that of the starting material and, apart from a detailed description given in the experimental portion, may be mentioned the presence of only *one* signal at high field (8.53 τ, $-\overset{|}{\underset{|}{C}}-CH_3$) and a weak signal in the olefinic proton region (4.16 τ), which is clearly in support of structure IX. This interesting reaction, previously observed by Johnson and his co-workers, (8) may be rationalized as taking place via a reverse aldol reaction to give, in this case, the diketone XIV, followed by recyclization to the ketol structure XV, which then undergoes a base-catalyzed elimination of water to provide the product IX.

In order to provide further desirable derivatives in this series, the unsaturated ketone IX was catalytically reduced by the use of palladium on charcoal containing a trace of concentrated hydrobromic acid—reaction conditions known to provide ring A/B cis



fusions in compounds of this type (9). The reduction product, m.p. 76.5–77.5°, was assigned the cis-syn-cis structure X. The completeness of the reduction was indicated by the infrared spectrum of the product (5.86 μ) and its ultraviolet spectrum, which now showed a complete disappearance of the conjugated carbonyl chromophore and a retention of the typical aromatic absorption, making the spectrum superimposable on that of the methoxy tetralin, XIII. The n.m.r. spectrum was also instructive, indicating absence of olefinic signals and the presence of a sharp peak at 8.85 τ, attributable to one $-\overset{|}{\underset{|}{C}}-CH_3$ function. It is interesting to note that in X, where there are no ring olefinic bonds present to create a deshielding effect on the methyl signal, the peak now occurs at higher fields and in the region more normally attributable to methyl protons.

Finally, in the hope of providing hydrochrysene derivatives with different stereochemistry at the ring junctures, we have subjected the ketol IV to a more drastic methoxide treatment and have obtained, in high yield, the expected tetracyclic ketone, V. This material, m.p. 142–143°,* exhibited a strong carbonyl absorption in the infrared due to the conjugated chromophore in ring A (6.01 μ), and the ultraviolet spectrum of the material indicated two maxima (235 mμ (broad) and 270 mμ). The n.m.r. spectrum had, among its important features, a single band at high field (8.52 τ, $-\overset{|}{\underset{|}{C}}-CH_3$) and a weak signal due to the olefinic proton (4.13 τ). Other n.m.r. signals appearing in the spectrum are given in the experimental portion. The mode of formation of V is analogous to the one already given for IX.

It is pertinent to point out that although the substances described herein differ from the ones previously prepared only in the nature of the aromatic nucleus, this difference represents an important modification for the synthesis of many steroidal substances. The aromatic system in the above compounds lends itself readily to numerous interesting variations not conveniently obtainable previously. Indeed, Nagata and co-workers (11) have very recently described the preparation of various C-18-substituted steroids and related substances, utilizing such intermediates as V. We hope to present other interesting modifications in a forthcoming publication.

EXPERIMENTAL

All melting points were determined on a Fischer–Johns apparatus and are uncorrected. The ultraviolet spectra were recorded in 95% ethanol on a Cary 11 recording spectrophotometer. Infrared spectra were recorded as potassium bromide pellets on a Perkin–Elmer Model 21 spectrophotometer. The n.m.r. spectra were taken at 60 megacycles on a Varian A 60 instrument. In all cases tetramethylsilane was the external standard set at 0 c.p.s. In all cases integration of areas under the signals was carried out and the number of protons corresponding to each signal indicated in parentheses. The positions of the signals are recorded in the Tiers τ scale. The analyses were performed by Dr. A. Bernhardt and his associates, Mulheim (Ruhr) Germany, and by Mrs. Aldridge, University of British Columbia.

Reaction of 6-Methoxy-2-tetralone (I) with 1-Diethylamino-3-pentanone Methiodide

We have performed numerous experiments in order to obtain optimum reaction conditions. We have found that maximum yields are only obtainable if the reactions are conducted under absolutely anhydrous conditions and in the complete absence of oxygen. The apparatus described in *Org. Syntheses* (12) was used throughout the entire sequence.

**This substance has been independently mentioned in a recent communication (10). We found the ultraviolet data presented for this substance to be incorrect. We are very grateful to Dr. W. Nagata for providing us with a comparison sample and thereby allowing us to establish, beyond doubt, that their material is identical with ours.*

To a 250-ml 3-necked flask fitted with a drying tube, a dropping funnel, and a source of dry nitrogen, 1-diethylamino-3-pentanone (28.5 g) dissolved in dry benzene (83 ml) was added. The solution was chilled (ice bath) and dry nitrogen was passed into the flask over a period of 20 minutes. With nitrogen still passing into the flask, methyl iodide (13.5 g) was added dropwise, over a period of 1 hour, to the stirred pentanone solution. The temperature of the reaction mixture was kept at 0° during the addition, and after addition was complete, the reaction mixture was stirred at 0° for a further 3 hours, with a slow passage of nitrogen being maintained. In order to complete the reaction, the mixture was kept at 0° overnight and was then ready for use. This stock solution, containing the gummy methiodide, could be used for several condensations. Just before use, dry methanol (30 ml) was added to dissolve the methiodide and while still cold, aliquots of this solution were used in the various condensations.

A 1-liter 3-necked flask was equipped with a pressure-equalized dropping funnel, a stirrer, and a reflux condenser which was connected at the top through a 3-way stopcock to a vacuum source (water aspirator) and dry nitrogen (12). The system was evacuated, and with a rapid escaping stream of nitrogen passing through, the apparatus was flame dried. Anhydrous methanol (105 ml) was put into the flask and sodium (4.43 g) was added through an escaping stream of dry nitrogen. After the metal had dissolved, the methoxide solution was cooled to 0°, the system evacuated until the solvent began to boil, then filled with dry nitrogen, and the procedure repeated once more. To this stirred, cold basic solution, a solution of 6-methoxy-2-tetralone (23.11 g) in dry benzene (51 ml) was added rapidly through the dropping funnel. The dropping funnel was then charged with an aliquot (0.73 parts of the above stock solution) of the cold Mannich base methiodide (in an escaping stream of nitrogen) and the methiodide was then added over a period of 40 minutes with stirring and cooling to 0°. The reaction mixture gradually became green and stirring was continued for 1.75 hours at 0° in an atmosphere of nitrogen. Finally, the mixture was refluxed for 1 hour, during which time the solution developed an orange color. After cooling to 0°, the reaction was treated with 2 *N* sulphuric acid (147 ml) and then diluted with water (90 ml). The mixture was extracted with several portions of ether, the ethereal layer dried over anhydrous magnesium sulphate, and solvent evaporated *in vacuo* to yield a crude oily product. This oily product was partially distilled to yield a fraction (2.14 g) distilling in the range 100–119° at 0.1 mm which proved to be unreacted tetralone. The residual oil (28.42 g, 89.5% yield) consisted almost entirely of the desired tricyclic ketone mixture, although the infrared spectrum of this material showed the presence of a hydroxy-containing material. Chromatography of this oil on silica gel (330 g) and elution with benzene yielded the desired product as an isomeric mixture: II, III (23.3 g, 81% yield). Finally, elution with ether removed the hydroxy-containing material, which was not further characterized.

A small aliquot of the 23.3-g fraction was distilled at 230–250° (bath temp.) at 0.15 mm to yield an analytical sample of the tricyclic ketone. The ultraviolet spectrum indicated λ_{max} 225 (log ϵ 3.93), 254 mμ (log ϵ 4.06), λ_{min} 235 mμ (log ϵ 3.85); and the infrared spectrum showed 5.86 and 6.05 μ. Found: C, 78.97; H, 7.50; O, 13.65. Calc. for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49; O, 13.22.

In one experiment, a small portion (1 g) of the tricyclic ketone mixture was chromatographed on deactivated alumina (grade II–III). Elution with benzene and benzene–ether mixture yielded a poor recovery (600 mg) of a yellow gum. This gum was then further rechromatographed on silica gel (6 g). Elution with benzene – petroleum ether (1:1) yielded, in the initial fractions, a small amount of the isomer III, λ_{max} 275 mμ (log ϵ 3.93), λ_{min} 242 mμ (log ϵ 3.45); infrared 5.85 μ. Found: C, 79.10; H, 7.54; O, 13.31. Continued elution with the same solvent yielded a small amount of isomer II, λ_{max} 253 mμ (log ϵ 4.10); infrared 6.05 μ. Found: C, 79.24; H, 7.41; O, 13.12. Due to the poor recovery encountered in this experiment, this separation was abandoned.

For the subsequent condensation with methyl vinyl ketone, the tricyclic ketone mixture, as obtained from the silica gel chromatography, was always distilled immediately before reaction so as to remove traces of water etc.

Reaction of Tricyclic Ketone with Methyl Vinyl Ketone—Preparation of Ketol (IV)

In numerous experiments attempted wherein we used 1-diethylamino-3-butanone methiodide or methyl vinyl ketone we found the latter reagent to be much more convenient and better yields were realized. Consequently only the procedure with this reagent is outlined here.

A 250-ml 3-necked flask was fitted with a stirrer, a dropping funnel, etc., exactly as already indicated in the first condensation above. After any moisture or oxygen was eliminated from the system as above, the flask was charged with a solution of the tricyclic ketone mixture (15.33 g) in anhydrous methanol (28 ml) (in an escaping stream of nitrogen). The dropping funnel was now filled with a sodium methoxide solution prepared from sodium metal (1.09 g) in dry methanol (28 ml) and the entire system was evacuated until the solvent began to boil. Dry nitrogen was then admitted, the system evacuated, and the procedure repeated again. The sodium methoxide solution was now added (in an escaping stream of nitrogen) rapidly to the stirred tricyclic ketone mixture, kept at 0°. To this reaction mixture, kept at 0°, a solution of dry methyl vinyl ketone (6.66 g, obtained from Matheson, Coleman and Bell, dried over anhydrous potassium carbonate, and freshly distilled) in anhydrous methanol (20 ml) was added dropwise over a period of 25 minutes, with a slow nitrogen stream being maintained. During the addition, the reaction mixture gradually attained a dark green color and after the addition was complete, the mixture was stirred for a further 2

hours at 0°. During this period a precipitate started to form. To complete the reaction, the ice bath was removed and the stirring was continued for 18 hours at room temperature under a nitrogen atmosphere. The reaction mixture was cooled to 0° and glacial acetic acid (7 ml) was added. The solid product was filtered off, washed with a small amount of ethyl ether, cold water, a small amount of ethanol, and then dried. The yield of this white solid was 13.72 g (69.5%) and it had a melting point of 200–206°. On one or two occasions, the melting started as low as 180°.

A small portion of this product was recrystallized several times from methanol to yield the analytical sample, m.p. 216–218° (with some decomposition). λ_{max} 274 mμ (log ϵ 4.07), λ_{min} 236 mμ (log ϵ 3.24); infrared 5.88 μ; n.m.r. signals (pyridine): 9.38 (—C(—CH$_3$)—, area = 3 H), 9.22 (HO—C(—CH$_3$)—, area = 3 H), 6.92 (OCH$_3$, area = 3 H), 4.44 (OH, area = 1 H), remaining signals in region 7.0–9.0 τ (area = 11 H) due to ring CH$_2$'s etc. The aromatic region is masked by the solvent. Found: C, 76.76; H, 8.09; O, 15.61; mol. wt. (Rast) 310. Calc. for $C_{20}H_{24}O_3$: C, 76.89; H, 7.74; O, 15.36; mol. wt. 312.

Acetylation of Ketol

A mixture of the ketol IV (5.25 g), *p*-toluenesulphonic acid monohydrate (33.7 mg), and isopropenyl acetate (27 ml) was heated on a steam bath for 5 hours. The solid which was present at the beginning of the reaction dissolved after about 1 hour. The reaction mixture was cooled to room temperature, 2 drops of pyridine were added, and the solvent was removed in a current of air. The residue was dissolved in a small amount of hot 95% ethyl alcohol, the solution was filtered and then concentrated to a volume of 30 ml. Upon cooling of the solution, the first crop of crystals (4.56 g) separated and had a melting point of 146–149°. An additional 0.53 g (total 5.09 g, 85.4%) was recovered as a second crop, m.p. 139–146°. Recrystallization of a small portion from aqueous ethanol provided a pure sample of the acetate VII, m.p. 150–150.5°. λ_{max} 275 mμ (log ϵ 4.16), λ_{min} 237 mμ (log ϵ 3.54); infrared 5.78, 5.85 μ; n.m.r. signals (pyridine): 9.42 (—C(—CH$_3$)—, area = 3 H), 8.98 (—C(=O)—O—C(—CH$_3$)—, area = 3 H), 8.70 (O—C(=O)—CH$_3$, area = 3 H), 6.95 (OCH$_3$, area = 3 H), remaining signals in region 7.0–8.6 τ (area = 11 H) due to ring CH$_2$'s etc.; n.m.r. signals (deuteriochloroform): 8.80 (—C(—CH$_3$)—, area = 3 H), 8.35 (—C(=O)—O—C(—CH$_3$)—, area = 3 H), 8.02 (—C(=O)—CH$_3$, area = 3 H), 6.19 (OCH$_3$, area = 3 H), remaining signals in region 6.5–8.0 (area = 11 H) due to ring CH$_2$'s etc., multiplet centered at 3.05 τ (aromatic H, area = 3 H). Found: C, 74.06; H, 7.66; O, 18.04. Calc. for $C_{22}H_{26}O_4$: C, 74.55; H, 7.39; O, 18.06.

Catalytic Hydrogenation of Unsaturated Tetracyclic Acetate

A solution of the unsaturated acetate VII (4.56 g) in 95% ethanol (170 ml, the alcohol was pretreated with Raney nickel) was hydrogenated over 30% palladium hydroxide on strontium carbonate (1.47 g) at hydrogen pressure of 40 lb/in^2 and room temperature for 20 hours. The catalyst was removed by filtration and the clear filtrate was concentrated to a small volume. The first crop (3.5 g) of crystals which separated melted at 148–150°. An additional 0.14 g (total, 3.64 g) was recovered from the mother liquors. A small portion was recrystallized twice from aqueous ethanol to yield the desired syn-cis product, VIII, m.p. 152.5–153.5°. λ_{max} 277 (log ϵ 3.39), 286 (log ϵ 3.39), 226 mμ (log ϵ 3.96); λ_{min} 248 (log ϵ 2.79), 283 mμ (log ϵ 3.20) virtually identical with the ultraviolet spectrum of XIII, which shows λ_{max} 278 (log ϵ 3.38), 287 (log ϵ 3.32), 223 mμ (log ϵ 3.97); λ_{min} 247 (log ϵ 2.58), 284 mμ (log ϵ 3.30).

The infrared spectrum of VIII shows bands at 5.80 and 5.86 μ; n.m.r. signals (deuteriochloroform): 8.90 (—C(—CH$_3$)—, area = 3 H), 8.47 (—C(=O)—O—C(—CH$_3$)—, area = 3 H), 8.05 (—C(=O)—CH$_3$), 6.24 (OCH$_3$, area = 3 H), remaining signals in region 6.6–8.2 (area = 16 H, including 3 H of acetate), multiplet centered at 3.08 τ (aromatic H, area = 3 H). Found: C, 74.00; H, 7.86; O, 17.87. Calc. for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92; O, 17.96.

Synthesis of syn-cis-2-Methoxy-8-keto-10a-methyl-4b,5,6,8,9,10,10a,10b,11,12-decahydrochrysene (IX)

The apparatus used in this experiment was set up exactly as in the tricyclic ketone preparation in order to maintain anhydrous conditions and a nitrogen atmosphere at all times.

Into the 250-ml 3-necked flask, which was flame-dried and evacuated as before, dry methanol (70 ml) was added and then sodium (1.37 g) was added gradually in small pieces. After the sodium had reacted, the methoxide solution was cooled and the entire apparatus evacuated until the solvent began to boil; dry nitrogen was then admitted, the system evacuated, and the entire process repeated several times. To the stirred methoxide solution, a solution of the acetate VIII (3.5 g) in dry benzene (20 ml) was added through

a dropping funnel under a flow of escaping nitrogen. After the addition was complete, the system was evacuated again, dry nitrogen admitted, etc. to ensure complete removal of oxygen. The reaction mixture was then refluxed for 5 hours in this inert atmosphere. At the end of the refluxing period the reaction was cooled in ice, glacial acetic acid (4 ml) was added, and the mixture was swirled for several minutes. Some water and benzene were added to the reaction flask, the layers were then separated, and the aqueous layer was extracted with ether. The combined organic solutions were washed with a saturated solution of sodium chloride and dried over anhydrous magnesium sulphate. Concentration of the solvent under reduced pressure provided a first crop (1.83 g) of pale yellow needles, m.p. 155.5–158.5°. An additional 0.91 g (total 2.74 g, 94%) was recovered from the mother liquors. Two recrystallizations from ethanol provided an analytical sample of IX, m.p. 158–159°. λ_{max} 233 (log ϵ 4.23), 277 (log ϵ 3.35), 287 mμ (log ϵ 3.29); λ_{min} 274 (log ϵ 3.32), 284 mμ (log ϵ 3.24); infrared 6.04 μ; n.m.r. signals (deuteriochloroform): 8.53 (—C(CH$_3$)—, area = 3 H), 6.22 (OCH_3, area = 3 H), remaining signals in region 6.6–8.4 (area = 14 H), 4.16 (O=C—C(H)=C<, area = 1 H), multiplet centered at 3.12 τ (aromatic H, area = 3 H). Found: C, 80.68; H, 8.21; O, 10.84; Calc. for $C_{20}H_{24}O_2$: C, 81.04; H, 8.16; O, 10.80.

Synthesis of cis-syn-cis-2-Methoxy-8-keto-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (X)

A solution of the unsaturated tetracyclic ketone IX (2.6 g) in a 4:1 mixture of benzene – 95% ethanol (82 ml, benzene was refluxed with sodium, then with Raney nickel, while the ethanol was refluxed with Raney nickel) was treated with 10% palladium on carbon (0.33 g) and 1 drop of 48% hydrobromic acid. This mixture was hydrogenated at room temperature and atmospheric pressure for 5 hours, after which time 1 mole of hydrogen had been absorbed. The catalyst was removed by filtration and the solvent removed *in vacuo*, whereby a yellow gum was obtained. This gum was dissolved in benzene (10 ml) and chromatographed on deactivated alumina (29 g, approx. activity II–III). Elution with benzene yielded 2.38 g of a gum which crystallized nicely from a small volume of aqueous ethanol. Two further recrystallizations from the same solvent yielded pure X, as plates, m.p. 76.5–77.5°. λ_{max} 287 (log ϵ 3.15), 280 (log ϵ 3.16), 226 mμ (log ϵ 3.87); λ_{min} 284 (log ϵ 3.15), 248 mμ (log ϵ 2.14); infrared 5.86 μ; n.m.r. signals (deuteriochloroform): 8.85 (—C(CH$_3$)—, area = 3 H), 6.28 (OCH_3, area = 3 H), remaining signals in region 7.0–8.7 (area = 17 H), multiplet centered at 3.16 τ (aromatic H, area = 3 H). Found: C, 80.60; H, 8.98; O, 10.49. Calc. for $C_{20}H_{26}O_2$: C, 80.49; H, 8.78; O, 10.73.

Synthesis of 2-Methoxy-8-keto-10a-methyl-5,6,8,9,10,10a,11,12-octahydrochrysene (V)

(a) From the Ketol IV

Again the apparatus used was exactly the same as in the previous condensations wherein anhydrous and oxygen-free conditions are maintained.

Anhydrous methanol (280 ml) was put into a 1-liter 3-necked flask which had been previously dried and evacuated to remove air. Sodium (2.07 g) was then added gradually in small pieces, in an escaping stream of nitrogen. The apparatus was evacuated until the solvent began to boil, dry nitrogen admitted, etc., and to this methoxide solution, the dry ketol IV (17.7 g) was added. The mixture was refluxed for about 4 hours in this inert atmosphere. The ketol, which was not entirely soluble at the beginning, dissolved completely after about 2 hours and the solution attained a yellow coloration. The reaction mixture was cooled to 0°, glacial acetic acid (7 ml) was added, and the resulting pale yellow crystalline product was removed by filtration. This solid was washed with a small amount of ether, water, a small volume of ethanol, and then dried to yield crude tetracyclic ketone V (13.7 g), m.p. 140–142.5°. The filtrate was diluted with water and the aqueous layer extracted with ether. The ethereal layer was washed with a saturated solution of sodium chloride and dried over anhydrous magnesium sulphate. Evaporation of the solvent yielded a residual gum which upon seeding provided an additional 2.3 g (total 16 g) of the desired product. Several recrystallizations of the product from dimethyl cellosolve provided analytically pure V, m.p. 142–143°. λ_{max} 235 (broad, log ϵ 4.26), 270 mμ (log ϵ 4.25); λ_{min} 252 mμ (log ϵ 4.17); infrared 6.01 μ; n.m.r. signals (deuteriochloroform): 8.52 (—C(CH$_3$)—, area = 3 H), 6.19 (OCH_3, area = 3 H), remaining signals in region 6.5–8.0 (area = 12 H), 4.13 (O=C—C(H)=C<, area = 1 H), multiplet centered at 3.09 τ (aromatic H, area = 3 H). Found: C, 81.30; H, 7.30; O, 10.89; mol. wt. (Rast) 312. Calc. for $C_{20}H_{22}O_2$: C, 81.60; H, 7.53; O, 10.87; mol. wt. 294.

This preparation of V was, in our hands, superior to the one described in part (*b*) and we have used it in most of our preparations.

(b) Directly from Tricyclic Ketone

As before, the reaction was run under anhydrous conditions and in an inert atmosphere.

The methiodide of 1-diethylamino-3-butanone was prepared crystalline in the manner already described for the corresponding pentanone from 1-diethylamino-3-butanone (1.11 g) and methyl iodide (1.2 g). A solution of this methiodide (2.16 g) in anhydrous methanol (5 ml) was added dropwise over a period of 1 hour to the ice-cold mixture of the tricyclic ketone (1.9 g) in dry benzene (30 ml) and a sodium methoxide solution (from 0.278 g sodium in 10 ml methanol). After the addition was complete, stirring was continued for a further 30 minutes at 0°, and then the mixture was refluxed for 40 minutes. The reaction mixture was cooled, treated with 2 *N* sulphuric acid (15 ml), and extracted with benzene. The benzene layer was washed with water and dried over anhydrous magnesium sulphate. The solvent was evaporated *in vacuo* to yield a gummy product (2.5 g). This oil could not be conveniently crystallized, so it was then purified by chromatography on silica gel. Elution with benzene – petroleum ether (6:4) yielded a small amount of semicrystalline gum (0.7 g) which crystallized from dimethyl cellosolve. Several more recrystallizations from this solvent yielded the desired product, V, m.p. 142–143°. This product was shown to be identical with the one obtained in part (*a*).

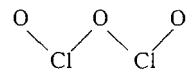
LE SPECTRE INFRAROUGE DE L'ANHYDRIDE PERCHLORIQUE Cl_2O_7

RODRIGUE SAVOIE[1] ET PAUL A. GIGUÈRE
Département de Chimie, Université Laval, Québec, Qué.

Reçu le 15 février 1962

RÉSUMÉ

Le spectre infrarouge de l'anhydride perchlorique gazeux mesuré entre 220 et 1500 cm^{-1} a révélé une dizaine de bandes. Dans le cristal on a observé jusqu'à 17 bandes distinctes. Ces spectres concordent bien avec le spectre Raman et la structure proposée par Fonteyne, soit deux groupes ClO_3 reliés par un pont d'oxygène. Des diverses configurations possibles selon cette structure celle qui contient la chaîne



dans un plan de symétrie semble la plus probable.

L'anhydride perchlorique a été isolé pour la première fois par Michael et Conn (1) par déshydratation de l'acide perchlorique. Quoique plus stable que les autres oxydes de chlore, et d'un pouvoir oxydant moindre, il peut cependant exploser violemment sous l'effet d'un choc ou d'un brusque changement de température. De plus, sa préparation entraîne parfois la formation d'autres oxydes de chlore, dont Cl_2O, ClO_2 ou Cl_2O_6, qui peuvent provoquer une explosion.

On sait peu de chose sur la structure moléculaire de ce composé. Fonteyne (2) a d'abord mesuré le spectre Raman d'une solution à 40% dans CCl_4. D'après la ressemblance avec le spectre de l'acide perchlorique, il en a déduit que la molécule doit contenir deux groupes ClO_3 reliés par un pont d'oxygène. Il a ensuite déterminé le moment dipolaire, 0.72 ± 0.02 debye, et il a évalué à 128° l'angle entre les valences Cl—O—Cl du pont central (3).

Au cours d'un travail récent sur le spectre infrarouge de l'acide perchlorique absolu (4) nous avons observé à quelques reprises des bandes d'absorption qui ne pouvaient appartenir à cet acide, mais qui, par contre, concordaient bien avec le spectre Raman de l'anhydride. Aussi, il nous a semblé à propos d'étudier systématiquement le spectre moléculaire de ce composé.

MÉTHODE EXPÉRIMENTALE

On trouve dans la littérature (5) plusieurs méthodes de préparation de l'anhydride perchlorique. Les échantillons employés ici ont été obtenus comme suit: quelque quatre ou cinq gouttes d'acide perchlorique anhydre (4) préalablement refroidi à −70° C étaient ajoutées à du pentoxyde de phosphore dans un petit ballon également refroidi dans de la glace sèche. En laissant réchauffer le mélange lentement jusqu'à la température ambiante l'anhydride gazeux se dégageait, et il était entraîné par un courant d'azote sec à travers trois colonnes de purification. La première et la dernière étaient remplies de pentoxyde de phosphore sur de la laine de verre afin de compléter la déshydratation de l'acide perchlorique, tandis que celle du centre contenait des tournures de cuivre fraîchement réduit en vue d'éliminer le chlore et ses autres oxydes. Le courant d'anhydride était ensuite introduit directement dans la cellule à absorption.

L'appareil, tout en verre, était assemblé au moyen de rodages normalisés. La lubrification de ces derniers, ainsi que des robinets, a posé un problème épineux. Les graisses du type "Fluorocarbon" (Halocarbon Products) conviennent bien à pression ordinaire, mais elles sont trop volatiles pour le travail sous vide. Dans ce cas, nous avons utilisé une quantité minimum de lubrifiant à base de silicone (Dow Corning) qui était légèrement attaqué au cours des expériences. Avant chaque préparation l'appareil était nettoyé avec un oxydant énergique (acide sulfurique fumant) puis assemblé et séché sous vide. Il fallait remplacer chaque fois le pentoxyde de phosphore sans quoi un peu de chlore était entraîné avec l'anhydride, ce qui avait un effet marqué sur le spectre du solide, en particulier.

[1]*Boursier du Conseil national des Recherches.*

Pour prendre le spectre du gaz, la cellule à absorption consistait en un tube de verre de 12 cm de long et 5 cm de diamètre fermé par des fenêtres de chlorure d'argent ou de Teflon selon la région à couvrir. En cas d'explosion la cellule était montée dans une cage de Plexiglass. Quant au solide, il a été étudié au moyen d'une cellule à vide conventionnelle munie de fenêtres de bromure de césium. Le gaz était condensé sous pression réduite à la température de l'air liquide, soit sur un disque de chlorure d'argent, soit—pour la région des basses fréquences au-delà de 400 cm^{-1}—sur une plaque de polythène. Les spectres ont été enregistrés sur spectrophotomètres de Perkin–Elmer: l'un (modèle 112-C) muni de prismes de chlorure de sodium ou de bromure de césium, l'autre, à réseaux (modèle 201-C) pour les basses fréquences (de 320 à 220 cm^{-1}).

DISCUSSION DES RÉSULTATS

De façon générale, les bandes infrarouges de Cl_2O_7 gazeux sont d'apparence un peu diffuse (Fig. 1) tant à cause de chevauchements multiples qu'à cause de la faible séparation

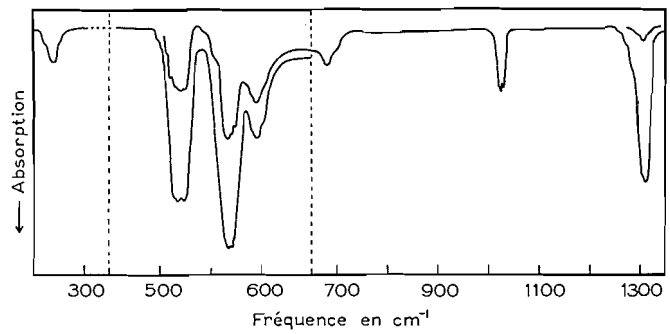


FIG. 1. Spectre d'absorption infrarouge de Cl_2O_7 gazeux.

(environ 8 cm^{-1}) des branches P, Q et R. En outre, il y a dans certains cas possibilité de décalages isotopiques appréciables, puisque les espèces $Cl^{35}OCl^{35}$, $Cl^{35}OCl^{37}$ et $Cl^{37}OCl^{37}$ sont présentes dans des concentrations relatives de 5:2:1. Dans le cristal (Fig. 2) les

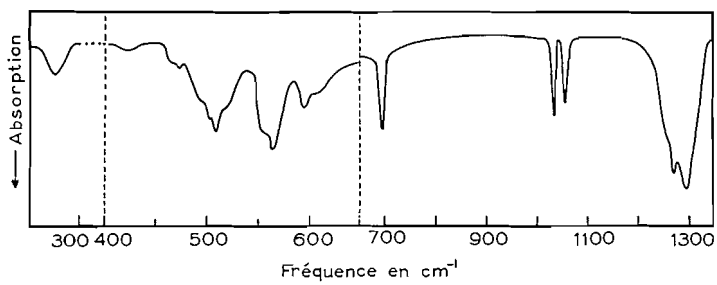

FIG. 2. Spectre infrarouge de Cl_2O_7 à l'état cristallin.

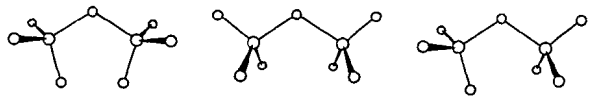
forces intermoléculaires conduisent à une séparation parfois assez marquée des modes semblables. Ces spectres confirment bien la structure proposée par Fonteyne; en particulier la présence des bandes caractéristiques du groupe ClO_3, comme dans l'acide perchlorique (4), ne laisse aucun doute à ce sujet.

Cependant, cette structure comporte plus d'une configuration spatiale selon l'orientation mutuelle des deux groupes ClO_3, laquelle peut être symétrique ou non. Dans le premier cas (formes *cis*, I*a* et I*b*, Fig. 3) la molécule aura deux plans de symétrie (C_{2v}), et 4 de ses 21 vibrations fondamentales (classe A_2) seront inactives en infrarouge. Dans



Ia Ib II

FIG. 3. Configurations possibles pour la molécule $ClO_3—O—ClO_3$.

le cas contraire (forme *trans*, II, Fig. 3) on n'aura qu'un plan de symétrie (C_s) et toutes les fondamentales seront actives. Les données actuelles ne permettant pas de trancher la question, nous avons choisi d'interpréter nos résultats d'après le modèle I*b* (Fig. 3) qui, comme nous le verrons plus loin, est le plus probable. La classification des divers modes de vibration de ce modèle est reproduite dans le Tableau I d'après la notation adoptée

TABLEAU I

Classification des fréquences fondamentales de Cl_2O_7

	A_1	A_2	B_1	B_2
ClO_3 valence asym.	ν_1	ν_8	ν_{12}	ν_{18}
ClO_3 valence sym.	ν_2	—	ν_{13}	—
Cl_2O valence asym.	—	—	ν_{14}	—
ClO_3 déform. asym.	ν_3	ν_9	ν_{15}	ν_{19}
ClO_3 déform. sym.	ν_4	—	ν_{16}	—
Cl_2O valence sym.	ν_5	—	—	—
ClO_3 balancement $\perp$	—	ν_{10}	—	ν_{20}
ClO_3 balancement $\parallel$	ν_6	—	ν_{17}	—
Cl_2O déform.	ν_7	—	—	—
ClO_3 torsion	—	ν_{11}	—	ν_{21}

par Herzberg (6) pour décrire une molécule analogue, $CH_3—O—CH_3$. Ici les indications symétriques et asymétriques pour les groupes ClO_3 se rapportent à leur axe ternaire, tandis que les notations $\parallel$ et $\perp$ se réfèrent au plan Cl—O—Cl (xz) de la molécule.

Les fréquences fondamentales

Les fréquences les plus élevées appartiennent naturellement aux vibrations de valence ClO_3. Des cinq modes actifs, les trois asymétriques ν_1, ν_{12} et ν_{18} coïncident aux environs de 1310 cm^{-1} dans le spectre du gaz (Tableau II), mais dans le cristal on peut les distinguer à 1260, 1272 et 1294 cm^{-1}. De même, les deux vibrations symétriques ν_2 et ν_{13} qui se superposent à 1025 cm^{-1} dans le gaz, sont largement séparées dans le solide (1034 et 1057 cm^{-1}). On s'attendrait à une distribution assez semblable pour les modes de déformation des groupes ClO_3. En pratique on observe trois régions de forte absorption vers 600, 570 et 520 cm^{-1} respectivement. La première, que nous attribuons à la vibration asymétrique ν_{19}, se résout en deux bandes distinctes (595 et 612 cm^{-1}) dans le solide. Il s'agit ici, croyons-nous, d'un dédoublement dû au champ de force du cristal plutôt que de deux modes distincts appartenant à une molécule de symétrie C_s.

Les deux autres fréquences de déformation asymétrique, ν_3 et ν_{15}, qui se situent probablement à 554 et 565 cm^{-1} dans le solide, se recouvrent en partie vers 560–570 cm^{-1} dans le gaz. Enfin, il reste pour les deux modes symétriques de ce groupe, ν_4 et ν_{16}, la bande à 510 cm^{-1} qui s'accompagne dans le cristal de deux pics satellites à 501 et 523 cm^{-1}. Comme le premier a son équivalent dans le spectre Raman, nous l'attribuons au mode totalement symétrique ν_4. Le second peut provenir, soit du dédoublement de ν_{16}, soit de quelque impureté; en effet son intensité semblait varier quelque peu d'un échantillon à l'autre.

		429 (1) P	ν_6 (a_1)
	(423)?		ν_{17} (b_1)
(281) 271 (261)	278	280 (2) P	ν_7 (a_1)

NOTE: P = polarisée.
*Intensités relatives entre parenthèses.

La molécule possède encore quatre modes de balancement (rocking) des groupes ClO_3, et deux de torsion interne (twisting), ν_{11} et ν_{21}. Ces derniers sont certainement de très basse fréquence, donc au-delà de la région couverte ici. Quant aux premiers, les deux de type $\perp$ devraient normalement être de fréquence un peu plus élevée que dans $HClO_4$, soit aux environs de 440 cm^{-1}, vu la double force de rappel sur l'oxygène médian. En fait un examen soigné de cette région n'a révélé qu'une très faible absorption vers 472 cm^{-1} dans la vapeur, tandis que dans le cristal, un doublet distinct apparaît à 464 et 472 cm^{-1} que nous assignons provisoirement à la vibration ν_{20}. Les deux autres modes, dits $\parallel$, ν_6 et ν_{17}, sont encore plus imprécis. La bande polarisée à 429 cm^{-1} dans le spectre Raman conviendrait bien pour le premier, et la faible bande infrarouge à 423 cm^{-1} pour le second.

Enfin il reste à identifier les trois vibrations caractéristiques du pont Cl—O—Cl. Fonteyne avait attribué au mode asymétrique ν_{14} l'une des deux fréquences 501 et 595 cm^{-1} plutôt que celle à 695 cm^{-1}, parce que cette dernière est polarisée en Raman. Cependant la comparaison avec le spectre infrarouge de l'acide perchlorique nous conduit à rejeter cette interprétation. La vibration de valence symétrique ν_5 est plus difficile à

localiser car elle tombe vraisemblablement dans une région de forte absorption due aux groupes ClO_3 vers 500 cm^{-1}. Pour le mode de déformation Cl—O—Cl la fréquence 280 cm^{-1} en Raman s'accorde parfaitement avec les fréquences infrarouges 270 cm^{-1} dans le gaz et 278 cm^{-1} dans le solide.

Structure moléculaire de Cl_2O_7

Vu la proximité de plusieurs fréquences fondamentales de Cl_2O_7 et de $HClO_4$ on peut conclure que les paramètres correspondants sont presque les mêmes dans les deux molécules (4), soit des longueurs de 1.70 Å et 1.45 Å respectivement pour les liaisons Cl—O simples et doubles, et des angles ∠OClO d'environ 105° entre liaisons doubles et 115° entre une liaison simple et une double. Quant à l'angle ∠ClOCl du pont d'oxygène, Fonteyne l'avait évalué à 128°, mais en se basant sur des fréquences de vibration incorrectes (501 et 429 cm^{-1}). Cette valeur est certainement trop grande; en fait on doit s'attendre ici à un angle de l'ordre de 111° comme dans la molécule triatomique Cl_2O (7).

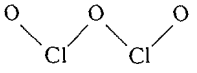
Reste à choisir entre les trois configurations possibles (Fig. 3). La première, I*a*, est sans doute à rejeter car elle rapproche deux des oxygènes sur les groupes ClO_3 adjacents à une distance beaucoup moindre (quelque 2 Å) que le double du rayon de van der Waals de cet atome, 1.4 Å d'après Pauling (8). Des deux autres, la configuration symétrique I*b* nous paraît la plus probable parce que l'orientation de chaque groupe ClO_3 y est décalée par rapport à l'axe ternaire O—Cl de l'autre groupe. Cette orientation alternée, qui est la plus fréquente, assure un meilleur équilibre des forces de répulsion entre les groupes ClO_3 ainsi qu'entre les doublets libres sur l'oxygène médian (hybridation sp^3 ?). Notons en outre, bien que des corrélations de ce genre ne soient pas tellement probantes, que dans les molécules analogues CH_3—O—CH_3 (9) et CH_3—S—CH_3 (10) c'est la forme I*b* qui est la plus stable. De toute façon il serait bon d'étudier la molécule Cl_2O_7 par quelque méthode directe pour trancher cette question.

REMERCIEMENTS

Ce travail a été rendu possible grâce à une subvention du Conseil national des Recherches.

SUMMARY

The infrared spectra of chlorine heptoxide Cl_2O_7 have been measured between 220 and 1500 cm^{-1}. In the gas 10 absorption bands, rather diffuse, were observed, and in the solid, some 17 bands. The frequencies, together with those of the Raman spectra, confirm the structure proposed by Fonteyne of two ClO_3 groupes linked by an oxygen bridge. From the spectroscopic data it cannot be decided which of the various configurations possible for such a structure is the correct one, although an arrangement with the chain



in one plane of symmetry seems the most likely.

THE FORMATION AND THE THERMODYNAMIC PROPERTIES OF K_2TiCl_6 IN KCl–LiCl MELTS[1]

J. H. MUI[2] AND S. N. FLENGAS[3]

Department of Metallurgical Engineering, University of Toronto, Toronto, Ontario

Received October 5, 1961

ABSTRACT

The reaction between gaseous titanium tetrachloride and the eutectic melt of potassium and lithium chlorides was investigated at various temperatures and pressures. It was found that, at an optimum temperature of 370° C, titanium tetrachloride vapor at a pressure of 1 atm reacts with the potassium chloride in the eutectic to yield K_2TiCl_6 as a solid mixture with lithium chloride.

The solubilities of K_2TiCl_6, and the partial molar properties of the solutions of K_2TiCl_6, and of potassium chloride, in the eutectic melt of potassium and lithium chlorides were obtained by vapor pressure measurements. It was found that the solubility of titanium tetrachloride increases from 1.5 weight% at 420° C to 5 weight% at 500° C. The activities of K_2TiCl_6, and of potassium chloride, indicate positive deviations from ideality.

INTRODUCTION

Many existing methods for the production of titanium metal involve the electrolytic reduction of titanium tetrachloride in solution in various molten salt mixtures of alkali chlorides or alkaline earth chlorides. However, in spite of the recent promising developments in this field (1, 2), the solubilities and the other thermodynamic properties of the solutions of titanium tetrachloride in molten salts are virtually unknown.

In a previous investigation (3), it was found that the solubility of titanium tetrachloride in the equimolar mixture of potassium and sodium chlorides at 690° C is 14% by weight. This solubility was attributed to the formation of the compound K_2TiCl_6. The thermal stability (4) and crystal structure (5) of K_2TiCl_6 prepared in the pure state were also determined.

The present work was undertaken to provide further information concerning the thermodynamic properties of K_2TiCl_6 in solution in the eutectic melt of potassium and lithium chlorides over the temperature range 350° C to 550° C.

Specifically, the problems investigated were (*a*) the extent of the chemical reaction between titanium tetrachloride vapor and the eutectic melt of potassium and lithium chlorides, and (*b*) the solubilities of K_2TiCl_6 in the melt. These two problems are closely associated with the recovery of titanium metal by fused salt electrolysis in a "low-temperature" cell that would employ titanium tetrachloride as the feed material, and would operate at temperatures of 500° C or less.

I. THE FORMATION OF K_2TiCl_6 IN THE KCl–LiCl EUTECTIC MELT

EXPERIMENTAL

The titanium tetrachloride for use in the experiments was obtained by purification of the commercially pure material. This was achieved by refluxing in the presence of copper filings for about 2 hours and by fractional distillation in a dry atmosphere. The front and end tailings of the distillate were rejected, and the middle portion was stored in sealed containers.

[1]*Paper presented at the 18th International Congress of Pure and Applied Chemistry, August 6–12, 1961, Montreal, Que.*

[2]*Present address: Department of Mining and Metallurgy, University of British Columbia, Vancouver, British Columbia.*

[3]*Department of Metallurgical Engineering, University of Toronto, Toronto 5, Ontario.*

The eutectic mixture of potassium and lithium chlorides was prepared from the reagent grade materials (41 mole% KCl, and 59 mole% LiCl). The melt was purified by using anhydrous hydrogen chloride following the method of Boston and Smith (6). The purified melt was transferred in Pyrex ampoules and was sealed under an argon atmosphere.

The reaction between titanium tetrachloride vapor and the eutectic melt of potassium and lithium chlorides was investigated by using the quartz spring balance apparatus described in a previous investigation (3). The method involved the direct measurement of the increase of the weight of a given quantity of the melt exposed to an atmosphere of titanium tetrachloride vapor at a given pressure.

Results and Discussion

The changes of length of the quartz spring, i.e., the corresponding change in weight of the sample, were measured as a function of time at various furnace temperatures and different pressures of titanium tetrachloride vapor.

From these measurements the percentage reaction of the initial potassium chloride in the eutectic, as a function of time, was calculated using the equation

$$2KCl + TiCl_4 = K_2TiCl_6.$$

The reaction between solid lithium chloride and titanium tetrachloride vapor was also investigated and, under similar experimental conditions, there was no evidence of any chemical reaction.

The results of these measurements at various temperatures and pressures are shown in Fig. 1.

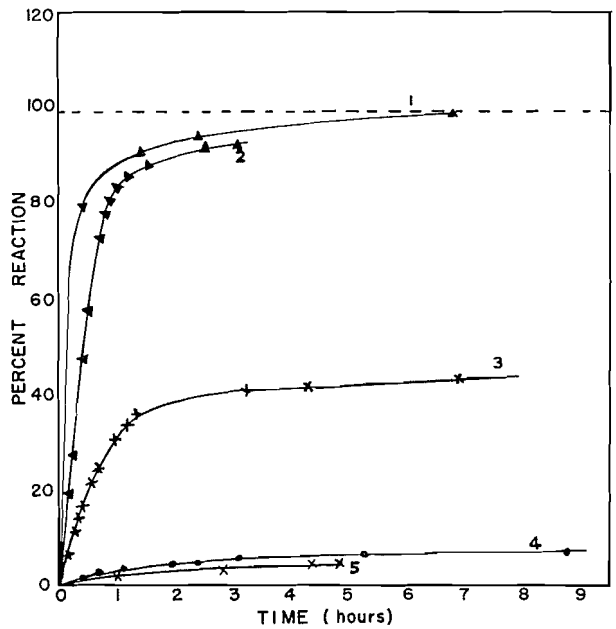

FIG. 1. Reaction between $TiCl_4$ vapor and the eutectic melt of KCl–LiCl at various temperatures and pressures:

Run No.	Temp. (°C)	P_{TiCl_4} (atm)
1	355	0.9
2	373	0.5
3	388	1.0
4	400	0.9
5	448	0.5

It is seen that at temperatures between 355° C and 375° C, the reaction is relatively slow and reaches completion within 7 hours. At higher temperatures, that is, between 390° C and 450° C, the apparent reaction rate decreases further, and the reaction does not reach equilibrium within the time of observation. By comparing curves 1 and 2 with curves 4 and 5 in Fig. 1, it becomes apparent that the reaction is not pressure dependent to any significant extent. On the contrary, the main controlling factor is temperature.

In an attempt to explain the anomalous behavior of the system, the course of the reaction was also investigated by a method involving the visual observation of the reaction site during the formation of K_2TiCl_6. The very simple apparatus consisted of a Pyrex tube of 1-in. diameter, bent at right angles and closed at one end. Purified titanium tetrachloride was introduced into the vertical closed-end arm, and was frozen with liquid air. A silica boat containing about 10 g of solid eutectic mixture was placed in the horizontal arm and the apparatus was evacuated and sealed under vacuum; the titanium tetrachloride was then heated to 136° C using a silicone oil bath, and the eutectic mixture was heated to 400° C using a tubular furnace fitted with an observation window.

The qualitative observations from the experiment may be described as follows: initially, titanium tetrachloride vapor dissolved into the transparent and colorless melt, and the solution acquired a deep yellow color. Subsequently, a solid layer gradually formed on the surface of the melt, this layer then thickened and eventually covered the entire surface. No liquid was found to remain after about 20 hours, and the reaction product was a yellow solid mass of uniform appearance. The solid was analyzed by X rays and the diffraction pattern indicated that K_2TiCl_6 and unreacted lithium chloride were the major components.

It is evident that the reaction takes place at the surface of a saturated solution of K_2TiCl_6 in the eutectic melt of potassium and lithium chlorides. The insoluble reaction products adhere to the surface of the melt by surface tension or density effects, and lithium chloride is codeposited as the eutectic mixture becomes depleted of its potassium chloride. Although the data available at present are quite insufficient to explain the kinetic mechanism of this reaction, it appears that the decrease of the overall reaction rate must be associated with the formation of the solid surface layer of K_2TiCl_6 + LiCl, which essentially separates the reactants. The study of the kinetic mechanism of this reaction is beyond the scope of the present investigation and will be the object of further study. However, these experiments indicate that titanium tetrachloride vapor reacts with the potassium chloride in the eutectic mixture of potassium and lithium chlorides. At about 400° C, the reaction is a driven one and the product K_2TiCl_6 has a limited solubility in the melt.

II. SOLUBILITIES AND PARTIAL MOLAR PROPERTIES OF K_2TiCl_6 IN THE KCl–LiCl EUTECTIC MELT

The solubilities of K_2TiCl_6, and the partial molar properties of the solutions of K_2TiCl_6 and of potassium chloride, in the eutectic melt of potassium and lithium chlorides, were investigated by measuring the pressure of titanium tetrachloride vapor in equilibrium with a melt containing K_2TiCl_6.

Experimental

Pure K_2TiCl_6 (99.9%) was prepared by the method described previously (4), and was analyzed both chemically and by means of its X-ray diffraction pattern.

The apparatus for the vapor pressure measurements, as shown in Fig. 2, consisted of a tubular furnace B fitted with an observation window, the reaction cell A, the pressure gauge D, and the pressure control train.

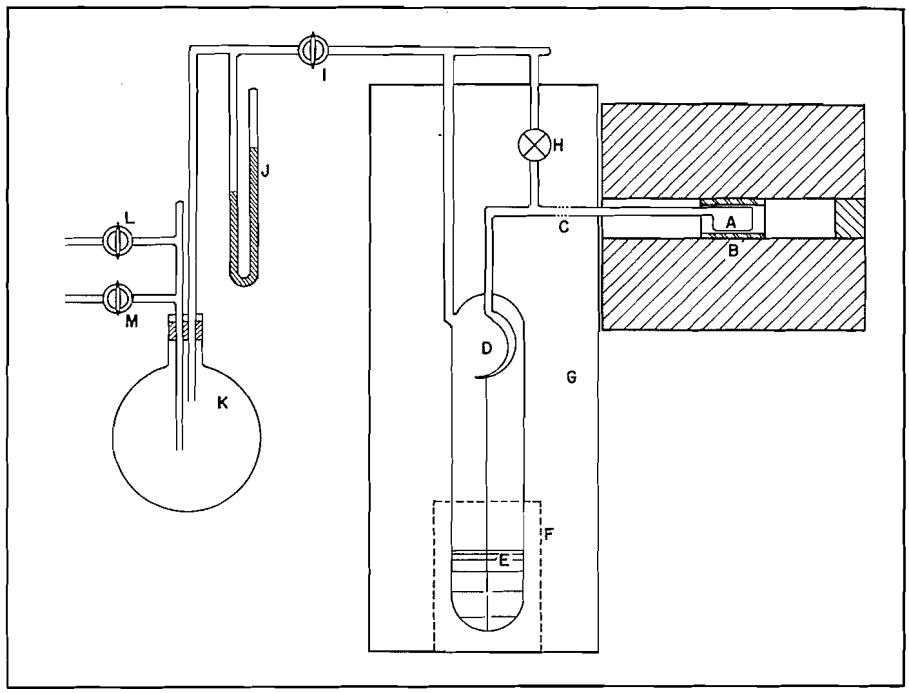

FIG. 2. Apparatus for the vapor pressure measurements.

A = sample cell	H = metal valve
B = furnace	I = stopcock
C = graded seal	J = mercury manometer
D = spoon gauge	K = air reservoir
E = damping fluid	L = to vacuum pump
F = observation window	M = to oxygen or air
G = air bath	

The reaction cell was heated in the tubular furnace, the temperature of which was kept constant to within ∓1° C by a thermocouple set in a well just beside the sample, and connected with a Honeywell proportional temperature controller. The quartz cell, $\frac{3}{4}$-in. diameter and $1\frac{1}{2}$-in. length, was connected to the spoon gauge through a quartz-to-Pyrex graded seal. The pressure gauge was a modified Bourdon "sickle" or "spoon gauge" constructed from thin Pyrex glass and having a sensitivity of about ∓1 mm of mercury. A glass pointer, about 8 in. long, attached to the tip of the spoon was used as a zero-point indicator. The gauge was enclosed in a glass tube closed at one end, and a small amount of silicone oil, Dow Corning Fluid 550, was also added to damp out the vibrations of the pointer and to act as a diffracting medium. The reaction cell and the gauge were connected to the pressure control train by using a Kovar, Pyrex-to-metal joint, and a stainless steel valve. The pressure control train included an air reservoir and the closed-end mercury manometer. The pressure in the system was regulated by manipulating the valves leading to the vacuum pump and to the air reservoir. During measurements, the gauge was used only as a "zero-point" indicator, and the reaction pressure at all times was balanced by changing the pressure in the outside jacket. A three-point technique was used to observe the neutral position, and the reaction pressure was read directly on the closed-end mercury manometer.

To avoid any condensation of titanium tetrachloride, all parts of the main apparatus outside the furnace were enclosed in an air bath at a temperature of about 145° C.

At the beginning of a run, 5 to 10 g of the various mixtures of K_2TiCl_6, and of the solid eutectic, were transferred into the quartz cell in a dry box. The cell was immediately connected to the apparatus, and the entire system evacuated. In order to melt the eutectic, the cell was heated to about 360° C, the system was then closed and allowed to stand for about 6 hours; the valve leading to the vacuum pump was then opened, and the system was evacuated for about 5 minutes at that temperature.

The decomposition pressures were measured at equilibrium as a function of temperature and composition of the melt. At temperatures up to 450° C, equilibrium was reached in about 2 to 3 hours, but the readings were taken after about 8 hours. At temperatures above 450° C, equilibrium was established in about 1 hour, but readings were taken after at least 5 hours. Equilibrium readings were taken for increasing and decreasing temperatures.

Thermodynamic Considerations

The thermal decomposition of (*a*) pure solid K_2TiCl_6, and (*b*) K_2TiCl_6 in solution in the eutectic melt of potassium and lithium chlorides may be represented by the following equilibria:

K_2TiCl_6 solid:

$$K_2TiCl_6\,(s) \rightleftharpoons 2KCl\,(s) + TiCl_4\,(g). \qquad [1]$$

K_2TiCl_6 in solution:

$$K_2TiCl_6\,(s) \rightleftharpoons (K_2TiCl_6)_{eut} \qquad [2]$$

and

$$(K_2TiCl_6)_{eut} \rightleftharpoons 2(KCl)_{eut} + TiCl_4\,(g). \qquad [2a]$$

By choosing as the standard states pure K_2TiCl_6 and pure potassium chloride at the temperature of the experiments, the activity equation may be readily derived as

$$\frac{a^2_{KCl}}{a_{K_2TiCl_6}} = \frac{P^0}{P}. \qquad [3]$$

For a "saturated" solution, the activity of K_2TiCl_6 in the solid phase is equal to the activity of K_2TiCl_6 in solution and this, by convention, may be taken as equal to unity. Therefore

$$a_{K_2TiCl_6} = 1,$$

and the activity of potassium chloride in the eutectic melt may be calculated. Thus, at a given temperature, equation [3] becomes

$$a^2_{KCl} = \frac{P^0}{P_1}, \qquad [4]$$

where P^0 is the pressure of titanium tetrachloride vapor in equilibrium with solid K_2TiCl_6, and P_1 is its pressure in equilibrium with a saturated solution of K_2TiCl_6 in the melt.

For a completely miscible system, the activity of K_2TiCl_6 may be calculated directly from equation [3], in the form

$$a_{K_2TiCl_6} = a^2_{KCl}\cdot(P_2/P^0), \qquad [5]$$

where P_2 is the pressure of titanium tetrachloride in equilibrium with a completely miscible system, P^0 has the same significance as before, and a_{KCl} is the activity of potassium chloride in the saturated solution at the same temperature. In making the above calculation, it is assumed that small amounts of K_2TiCl_6 of the order of 1 mole% would not have any significant effect on the activity of potassium chloride in the eutectic.

Results and Discussion

The decomposition pressures of solid K_2TiCl_6 at equilibrium have been measured previously by Flengas and Ingraham (4), and by Morozov and Toptygin (7). The equilibrium pressures reported in both these investigations were, however, significantly different. It was, therefore, decided to redetermine the equilibrium pressures of the system over the temperature range 350° C to 550° C.

The results, along with those of the previous two investigations, plotted as log P versus $1/T$, are shown in Fig. 3.

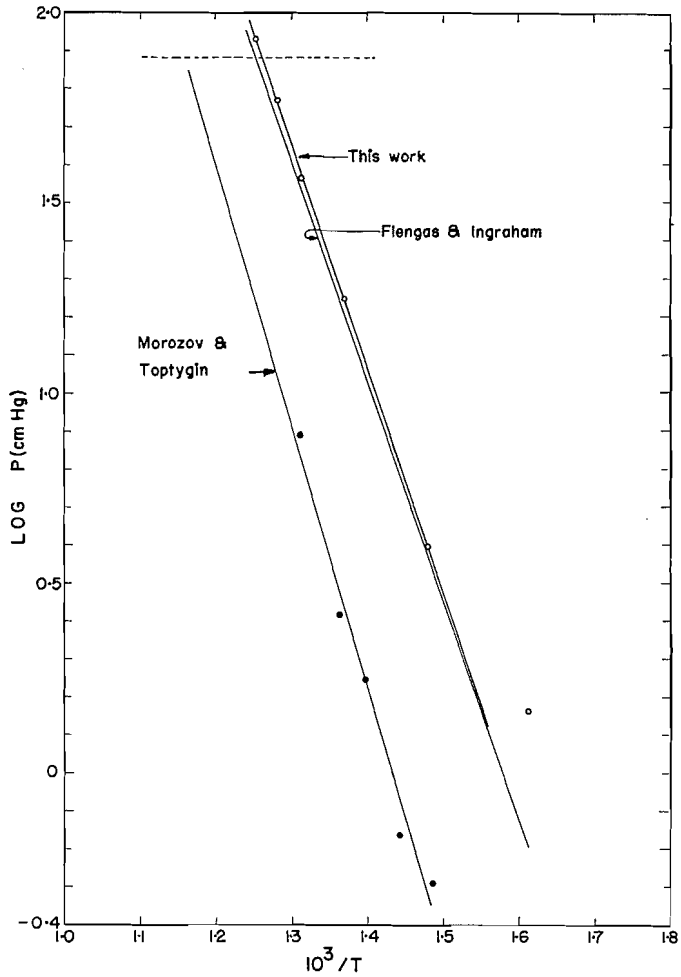

FIG. 3. Equilibrium decomposition pressures of solid K_2TiCl_6.

It is seen that these results are in good agreement with the original data of Flengas and Ingraham (4).

The pressures of titanium tetrachloride vapor in equilibrium with pure solid K_2TiCl_6 are represented by the equation

$$\log P^0_{(\text{cm of Hg})} = \frac{-5930}{T} + 9.3636, \qquad [6]$$

which is valid for the temperature range between 350° C and 550° C.

The heat of formation of K_2TiCl_6 from solid potassium chloride and titanium tetrachloride vapor can be calculated from the slope of the pressure curve by using the van't Hoff equation, and is -27.1 ± 0.4 kcal/mole, which is in good agreement with -26.4 ± 1.3 kcal/mole obtained previously (4).

The pressures of titanium tetrachloride in equilibrium with various mixtures of K_2TiCl_6, and of the eutectic melt, were then measured at temperatures between 350° C and 525° C. The results are given in Fig. 4.

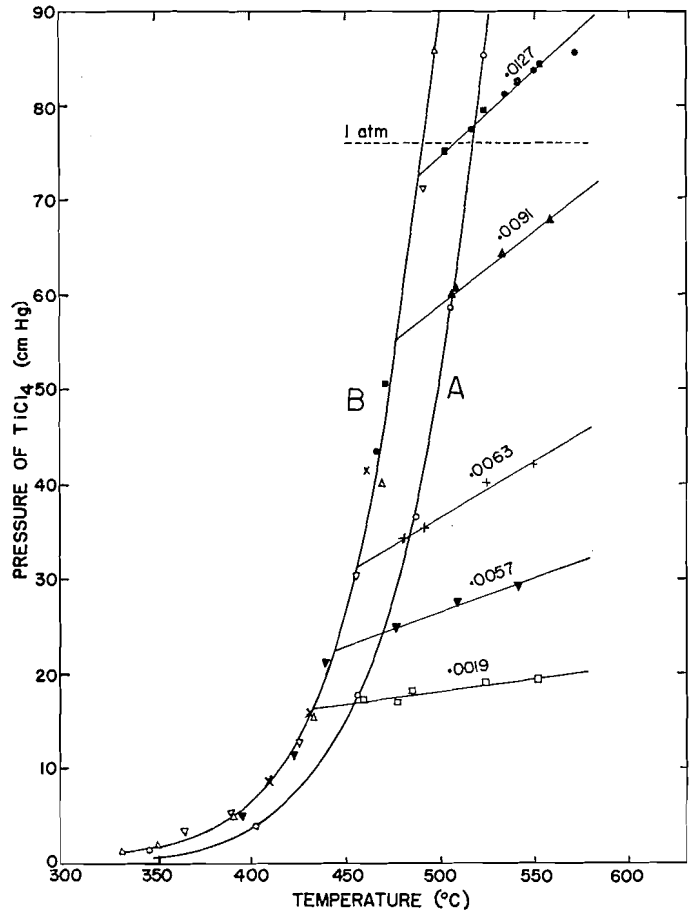

FIG. 4. Equilibrium decomposition pressures of K_2TiCl_6 in KCl–LiCl eutectic melts:

For the purpose of comparison, curves A and B represent respectively the results with pure K_2TiCl_6 and with the various mixtures. The decomposition pressures of the saturated solutions of K_2TiCl_6 in the eutectic melt are given by the continuous part of curve B. The horizontal branches of curve B represent the completely miscible systems. The corresponding mole fractions of K_2TiCl_6 are given also in the diagram.

The temperature of complete miscibility, that is, the liquidus temperature of the ternary, is found from the intercept of the horizontal and the vertical parts of curve B,

and the composition of the mixture at this temperature is the liquidus composition. The region to the left of curve B thus represents the two-phase systems of constant activity, and the region to the right of curve B represents the completely miscible one-phase system of changing activity. The pronounced change in slope between any two parts of the same curve reflects the sharp decrease of the activity of K_2TiCl_6 with increase in temperature, when K_2TiCl_6 becomes completely soluble.

From Fig. 4, it is seen that at a given temperature a saturated solution of K_2TiCl_6 has a higher decomposition pressure of titanium tetrachloride than the corresponding pure solid. Solutions, on the other hand, in the range of complete miscibility have lower decomposition pressures than pure solid K_2TiCl_6.

The pressures of titanium tetrachloride in equilibrium with the saturated solutions are well represented by the linear equation

$$\log P_{1(\text{cm of Hg})} = \frac{-6006}{T} + 9.7328, \qquad [7]$$

which is valid for the temperature range between 350° C and 500° C.

The behavior of the system of the eutectic melt in contact with titanium tetrachloride vapor can also be predicted from the pressure curves in Fig. 4. Thus, at a given temperature of the melt, it should be expected that titanium tetrachloride would dissolve until the decomposition pressure of the solution becomes equal to the applied pressure of the vapor. If the applied pressure is maintained constant while the temperature of the melt is reduced below the corresponding liquidus temperature of the ternary, then solid K_2TiCl_6 should be precipitated. The reaction under these conditions should be a driven reaction, and should continue indefinitely, provided that the composition of the eutectic does not change and that the supply of melt is unlimited. When the available amount of eutectic melt is limited, the formation of K_2TiCl_6 should take place and the composition of the melt should change until it reaches the liquidus composition of the binary mixture of potassium and lithium chlorides at the temperature of the experiment. Any further precipitation of K_2TiCl_6 would then be followed by the codeposition of solid lithium chloride and the composition of the melt would thus remain unchanged until the completion of the reaction. These conditions have been simulated in the experiments described in the first part of this paper.

The solubilities of titanium tetrachloride at various temperatures were obtained from the intercepts of the horizontal and the vertical parts of curve B in Fig. 4. The results are given in Fig. 5 as weight percent soluble titanium tetrachloride against temperature.

For the purpose of calculation, the composition of the melt was corrected for the amount of titanium tetrachloride in the gas phase, assuming that the system obeys the ideal gas laws. The correction factor was particularly significant for mixtures containing less than 1% titanium tetrachloride, and the solubilities in this range could not be obtained accurately. It was also found that, at temperatures above 500° C, the decomposition pressures of the more concentrated solutions exceeded 1 atm and could not be measured with the existing apparatus. However, the results obtained within the temperature and the composition ranges allowed by the system were well reproducible, and the average deviations which are shown in Fig. 5 represent the expected error which is introduced when the composition of the melt is corrected for the amount of titanium tetrachloride present in the gas phase of the non-isothermal system.

It is seen in Fig. 5 that the solubility of titanium tetrachloride in the eutectic melt of potassium and lithium chlorides is rather limited and increases with temperature from

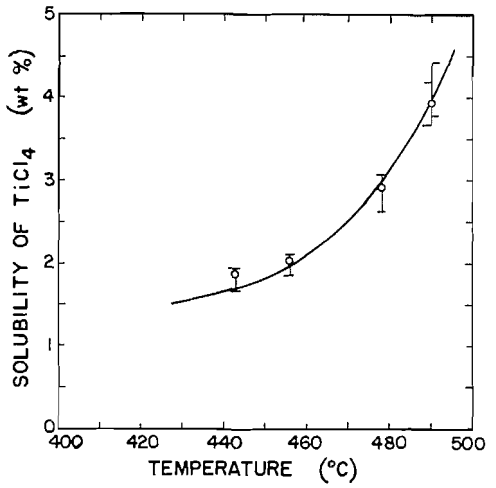

FIG. 5. Solubilities of $TiCl_4$ in KCl–LiCl eutectic melt.

about 1.5% at 420° C to 5% at 500° C. These results are much higher than the solubilities found by Smolinski and Leach (8) by the chemical analysis of a melt that had been previously saturated with titanium tetrachloride.

Activity Calculations

The activities of potassium chloride in the melt of potassium and lithium chlorides at the eutectic composition (0.41 mole% KCl, and 0.59 mole% LiCl) were calculated using equation [4], and the pressure data given by equations [6] and [7]. The results obtained regarding the activities are given in Fig. 6, and the experimental data are summarized in Table I. The excess partial molar properties of the solutions which are calculated from the data are given in Table II.

It is seen that, in the temperature range between 350° C and 500° C, the activity coefficients demonstrate slight positive deviations from ideality. However, the existence of a rather large excess partial molar entropy of mixing also indicates that the system cannot be treated as a regular solution. These results are in disagreement with the activities calculated by Aukrust *et al.* (9) from the phase diagram of the binary system of potassium and lithium chlorides. The latter calculations indicated rather small negative deviations from ideality, and that at the eutectic composition the system approaches regularity.

The derivation of activities from phase diagrams has been criticized by Kubaschewski and Evans (10) on the grounds of the many assumptions involved in the calculation, and the present work supports this view.

The activities, and the other thermodynamic properties of the solutions of K_2TiCl_6 in the eutectic melt of potassium and lithium chlorides, were calculated by using equation [5], and the data given in Table I. In order to calculate the activities of K_2TiCl_6 for temperatures as high as 550° C, for which the pressure data were available, it was necessary to extrapolate the activities of potassium chloride for about 50° C, as shown in Fig. 4. The results of the calculations are given in Fig. 7, and the excess partial molar properties of the solutions are listed in Table III. Despite the scatter of the points in Fig. 7, the activity coefficients are reasonably constant for each temperature. Also, due

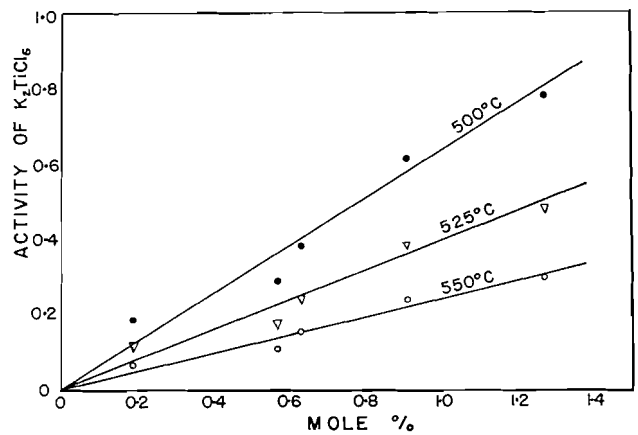

FIG. 7. Activities of K_2TiCl_6 in the eutectic melt of KCl–LiCl.

positive deviations from ideality, as expected from the tendency of the system to form saturated solutions. The large excess partial molar entropy of mixing, which is usually associated with the vibrational energy of the system, indicates a change in the bond type of the titanium ion in the melt. The change could be interpreted either in terms of a decrease of the coordination number of titanium or in terms of a weakening of the chemical bond. The decrease of the activity coefficients with increasing temperature indicates the tendency of the system to approach ideality at higher temperatures. At constant temperature, the activity is proportional to the mole fraction, which indicates that Henry's law is applicable to the system.

CONCLUSIONS

The results obtained in this investigation may be discussed with reference to electrolytic cells used for the recovery of titanium metal by fused salt electrolysis. The operation of experimental titanium cells in the region of 500° C has already been reported in the

literature (2). The common features of these cells were, the low operating temperatures of about 500° C, the use of potassium and lithium chlorides as the solvent melt, and the use of titanium tetrachloride vapor as the feed material.

The prerequisite of any high-temperature electrolytic reduction should be the existence of a suitable ionic solution. The properties of titanium tetrachloride, as determined in the present investigation, however, exclude the possibility of a true electrolytic process, at least on a large scale.

At low temperatures, that is, at or below 400° C, it should be possible to prepare relatively stable solutions of titanium tetrachloride, but the solubilities are extremely low. Under these conditions, any electrolytic cell would reach its limiting current densities at very low currents. Any attempt to increase the electrolytic current would lead to the buildup of a concentration overvoltage, and eventually to the reduction of the alkali metals in the solvent.

At temperatures higher than 500° C, it should be possible to prepare concentrated solutions of titanium tetrachloride. However, at such temperatures, the decomposition pressures are quite high, and "stable" solutions can only be realized in a completely closed or even a pressurized system by controlling the pressure of titanium tetrachloride vapour over the solutions.

It is felt that the various titanium cells which have been operated so far have not satisfied the conditions imposed by the system. In all probability, the primary step was the reduction of the alkali metal ions, the titanium metal being recovered as a by-product of the overall cell reaction.

ACKNOWLEDGMENTS

This work was carried out with financial assistance from the National Research Council of Canada. The authors wish also to thank N.R.C. for a maintenance grant to one of us (J. H. M.). The assistance in the analysis of the samples provided by the analytical section, Mineral Sciences Division, Mines Branch, Department of Mines and Technical Surveys, Ottawa, is also gratefully acknowledged.

THE SULPHURIC ACID SOLVENT SYSTEM

PART III. THE PREPARATION AND STRUCTURES OF SOME COMPLEX SULPHATOBORATES

R. J. GILLESPIE

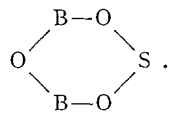
Received February 8, 1962

ABSTRACT

By neutralizing sulphuric acid solutions of tetra(hydrogensulphato)boric acid with various metal hydrogensulphates, sodium, potassium, ammonium, and strontium salts have been prepared. From the compositions of these salts, and from the results of cryoscopic and conductimetric measurements on their solutions in sulphuric acid, it is concluded that they are best formulated as polysulphatoborates containing the six-membered ring



It is shown that previously described sulphato compounds of boron can also be satisfactorily formulated on this basis.

Cryoscopic and conductimetric measurements on dilute solutions of boric acid and boric oxide in 100% sulphuric acid and in dilute oleums have been interpreted in terms of the formation of tetra(hydrogensulphato)boric acid, $HB(HSO_4)_4$, and its hydronium salt (1). Conductimetric titrations (2) and a comparison of the electrical conductivities of sulphuric acid solutions of $HB(HSO_4)_4$ with those of disulphuric acid (3) show that $HB(HSO_4)_4$ is a rather strong acid of the sulphuric acid solvent system which is extensively ionized in dilute solution according to the equation

$$HB(HSO_4)_4 + H_2SO_4 = H_3SO_4^+ + B(HSO_4)_4^-.$$

Further confirmation of this ionization has been obtained from the observation of lines in the Raman spectra of solutions of $HB(HSO_4)_4$ in sulphuric acid that may be assigned to the $H_3SO_4^+$ ion (4). The Raman spectra also showed that in concentrated solutions of $HB(HSO_4)_4$ disulphuric acid is formed.

The earlier work (1) showed that the hydronium salt of tetra(hydrogensulphato)boric acid is formed when boric acid is dissolved in 100% sulphuric acid:

$$B(OH)_3 + 6H_2SO_4 = 3H_3O^+ + B(HSO_4)_4^- + 2HSO_4^-,$$

and solutions of other salts were obtained by titrating the acid with various hydrogen sulphates (2), e.g.,

$$HB(HSO_4)_4 + KHSO_4 = KB(HSO_4)_4 + H_2SO_4.$$

It was the object of the present work to attempt to isolate solid tetra(hydrogensulphato)-borates from such solutions.

EXPERIMENTAL

Preparations

Solutions of tetra(hydrogensulphato)boric acid were prepared by dissolving the calculated quantity of recrystallized "Analar" boric acid in an oleum which had been prepared by distilling a weighed quantity of sulphur trioxide into 100% acid:

$$B(OH)_3 + 3H_2S_2O_7 = HB(HSO_4)_4 + 2H_2SO_4.$$

These solutions were neutralized by adding a sulphuric acid solution containing the equivalent quantity of a metal sulphate (K_2SO_4, Na_2SO_4, $(NH_4)_2SO_4$, $BaSO_4$, $SrSO_4$), or an organic base (2:4-dinitroaniline). White solids separated after a few hours from the solutions neutralized with K_2SO_4 and $(NH_4)_2SO_4$ but in the case of those neutralized with Na_2SO_4 and $SrSO_4$ precipitation did not occur until after several days and even then in some cases only when the solution was heated to 100° to 200°. It was not found possible to precipitate salts of barium, lead, or 2:4-dinitroaniline.

The salts were filtered in a dry box through a sintered-glass filter and washed with dry nitromethane to remove the last traces of sulphuric acid. Nitromethane was then removed by drawing dry air through the filter. The compounds were stored over sulphuric acid in a vacuum desiccator. The salts were white and slightly hydroscopic: they evolved sulphur trioxide on heating.

Analysis

The salts were hydrolyzed completely to metal sulphate, sulphuric acid, and boric acid on dissolving in water. Sulphuric acid was determined by titration with standard sodium hydroxide solution. Boric acid was determined by neutralizing the sulphuric acid with the required amount of sodium hydroxide and then continuing the titration after the addition of a large excess of mannitol (5). The results of the volumetric determinations are expressed in terms of the ratio, $r = n_{H_2SO_4}/n_{H_3BO_3}$, of the number of moles of sulphuric acid to the number of moles of boric acid produced on hydrolysis, e.g., $2KB(HSO_4)_4 + 6H_2O = K_2SO_4 + 2H_3BO_3 + 7H_2SO_4$, $r = 3.5$. Ammonium and strontium were determined by standard methods. The analytical results are given in Table I.

Cryoscopic and Conductimetric Measurements

The salts obtained were generally not very soluble in sulphuric acid but in some cases appreciable freezing-point depressions and electrical conductivities were obtained. The freezing-point depressions and conductivities were measured by methods that have been described previously (6, 7). A cryoscopic equivalent weight, defined as the weight of substance which, when dissolved in 1000 g of sulphuric acid, gives the molal freezing-point depression for a non-electrolyte of 6.12°, was calculated from the cryoscopic results (8). A conductimetric equivalent weight, defined as the weight of substance which, when dissolved in 1000 g of sulphuric acid, produces 1 mole of hydrogensulphate ion, was obtained by comparing the observed conductivities with the conductivities of potassium and hydronium hydrogensulphates (9). For example,

$$M_2B_2O(SO_4)(HSO_4)_4 + 4H_2SO_4 = 2M^+ + H_3O^+ + 2B(HSO_4)_4^- + HSO_4^-,$$

cryoscopic equivalent weight = (molecular weight)/6, conductimetric equivalent weight = molecular weight.

DISCUSSION

Comparison of the analytical results with the calculated values given in Table II for the tetra(hydrogensulphato)borates, $MB(HSO_4)_4$, and the corresponding sulphates, $MB(SO_4)_2$, shows that in no case did the salts obtained have either of these simple compositions. The observed cryoscopic equivalent weights are smaller than the values required for compounds with these compositions and the conductimetric equivalent weights are much smaller than the infinite values predicted for $MB(HSO_4)_4$ or $MB(SO_4)_2$. The analytical results are also not consistent with those expected for any polymeric compound of intermediate composition formed by the elimination of H_2SO_4 molecules between $B(HSO_4)_4^-$ ions.

Recently several authors (10) have discussed the principles underlying the structures of the hydrated polyborates. It appears that the basic structure is the six-membered ring I in which one, or at most two, of the boron atoms has a tetrahedral four-coordinated configuration, while the remainder have a trigonal three-coordinated configuration. Thus the ions II and III and condensed forms in which one or two boron atoms are shared between two rings, e.g. IV, V, VI, and VII, have been postulated to account for the

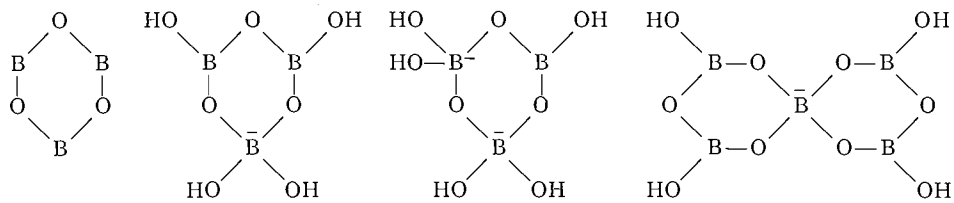
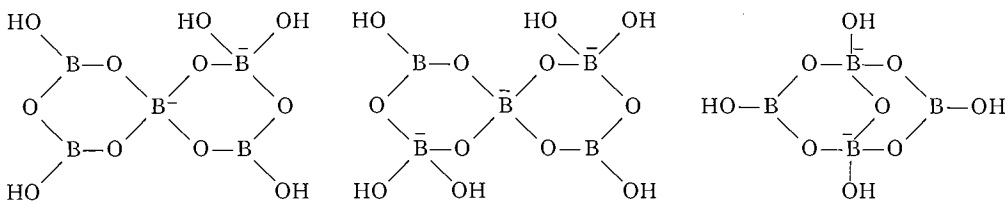
compositions of a large number of borates. These complex ions either occur as discrete units in the crystal or as larger polymeric structures in which these basic units are joined by oxygen bridges formed by the elimination of water between —OH groups. X-Ray diffraction and nuclear magnetic resonance studies have provided evidence for the existence of some of the postulated anions (10, 11).



I II III IV



V VI VII

It seemed reasonable, therefore, to attempt to explain the compositions of the sulphatoborates in terms of similar structures.

We first considered as possibilities structures corresponding to II to VII but with OH groups replaced by $—HSO_4$ groups (designated II′ to VII′ in Table III) and with SO_4

TABLE III

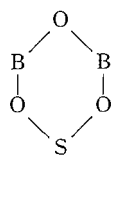
groups forming bridges between rings (designated II″ to VII″ in Table III). These polymers may be imagined as being formed by elimination of disulphuric acid from simple $B(HSO_4)_4^-$ anions, e.g.,

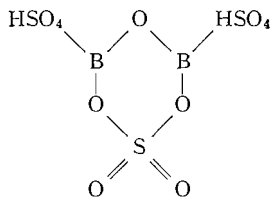
$$3B(HSO_4)_4^- \rightarrow B_3O_3(HSO_4)_4^- + H_2S_2O_7 + 2HS_2O_7^- + 2H_2SO_4.$$

II′

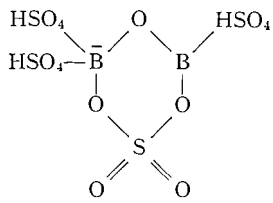
The corresponding values of the hydrolysis ratio r, the ratio of the number of moles of sulphuric acid to the number of moles of boric acid produced on complete hydrolysis of the salt, are given in Table III: in all cases they are smaller than the observed values. Consequently we next considered the possibility that the six-membered ring unit is retained but that one boron atom is replaced by a sulphur atom to give the basic ring structure VIII.



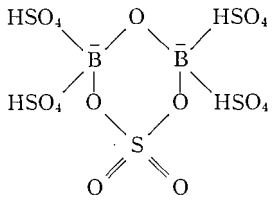
VIII



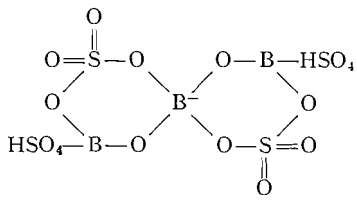
IX



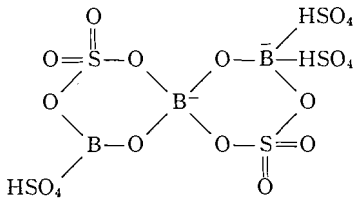
X



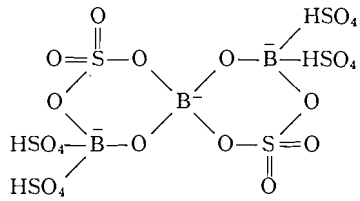
XI



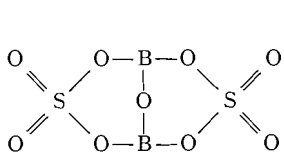
XII



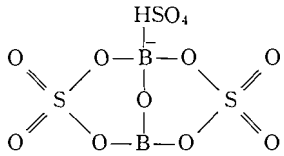
XIII



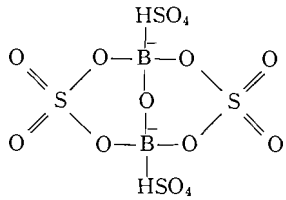
XIV



XV

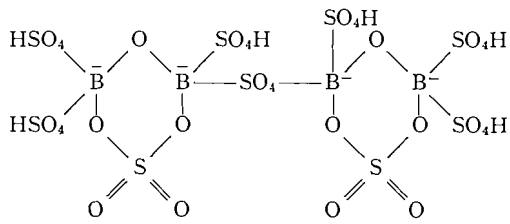


XVI

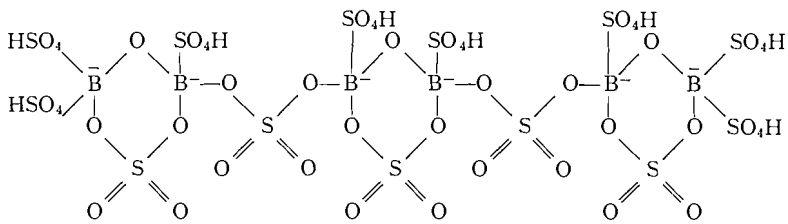


XVII

It may be seen from Table III that, of these structures, only X and XI have r values which agree reasonably well with the observed values. However, in order to account for r values as low as 1.6 it is necessary to postulate that, in some cases, further polymerization occurs by elimination of sulphuric acid between the $-SO_4H$ groups of the anions X or XI to form chains or other complex structures with sulphate bridges between six-membered rings. Titration ratios, r, for salts containing fully condensed polymeric anions in which elimination of sulphuric acid between all the $-SO_4H$ groups has taken place (X′–XVII′) are given in Table III. All the observed values of r fall between the limiting values for the simple anion XI and its fully condensed form XI′ but many of the observed values fall outside the limiting values for X and its fully condensed form X′. Since the observed r values are generally considerably larger than are required by the fully condensed form XI it seems reasonable to suppose that the salts consist mainly of polymers that contain only a few of the six-membered ring units, e.g. the "dimer" XVIII and the "trimer" XIX.



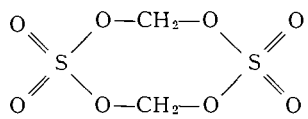
XVIII



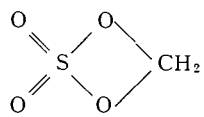
XIX

Calculated composition for the potassium and ammonium salts of these anions are given in Table II together with similar values for the corresponding "tetramer" and infinite polymer ($n = 8$ and $n = \infty$ in the general formula $M_nB_nO_{n/2}(SO_4)_{(3n-4)/2}(HSO_4)_{n+2}$). The analytical data for each of the salts can be explained by assuming that they contain the simple anion XI or its condensed forms such as XVIII and XIX with $n = 2$, 4, 6, or 8. For comparison the calculated compositions for X and some of its condensed forms are also given in Table II: the agreement between the observed and calculated compositions is not very good. We conclude, therefore, that the salts described in Table I are best considered as containing the anion XI and its condensed forms such as XVIII and XIX. However, it is probable that none of the products obtained was actually a pure salt containing a single anion, rather it is most likely that they were mixtures of salts of the simple anion XI and/or one or more of its condensed forms.

It seems more reasonable to formulate the condensed structures with bridging sulphate groups as in XVIII and XIX rather than with bidentate sulphate groups because of the very small size of the boron atom. In this connection it is of interest to compare the present structures with that of methylene sulphate, which has been shown (12) to be dimeric in benzene and therefore to have structure XX rather than XXI.

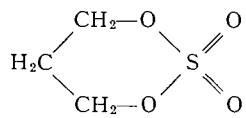


XX



XXI

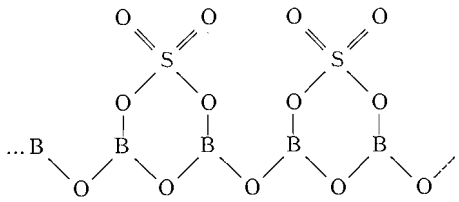
Comparison with trimethylene sulphate is also appropriate. This is monomeric in benzene (12) and can therefore presumably be formulated as in XXII with a six-membered ring analogous to VIII.



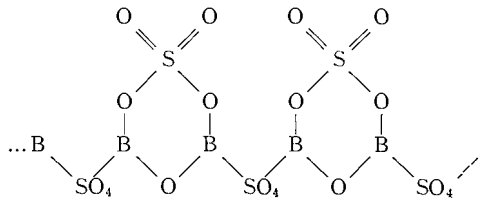
XXII

Early workers have reported several compounds as products of the reactions between boric acid or boric oxide and sulphuric acid, oleum, or sulphur trioxide. The reaction of BCl_3 with SO_3 has been reported (12) to give sulphuryl chloride and a boron compound having the composition $B_2O_3.SO_3$. A product of the same composition is also given by the reaction between BBr_3 and SO_3. The compounds $B_2O_3.SO_3$ and $B_2O_3.2SO_3$ were obtained by Pictet and Karl (14) by heating boric oxide and sulphur trioxide in sealed tubes at 115° and 250°, respectively. Merz (13) obtained a transparent glass having the composition $5B_2O_3.2SO_3.2H_2O$ and Schultz and Sellac (13) report a compound which their analysis showed to have the composition $B_2O_3.3SO_3.H_2O$, which they obtained by treating a solution of boric acid in sulphuric acid with SO_3 or by dissolving boric acid in sulphuric oleum and then evaporating to dryness. These compounds can all be formulated in terms of the six-membered ring VIII as the basic unit. The proposed structure for $B_2O_3.SO_3$ is based on structure IX and is formed by elimination of $H_2S_2O_7$ between such units to give the infinite polymer XXIII. The compound $B_2O_3.2SO_3$ may be formulated

as XV or as the infinite polymer XXIV with sulphate bridges between the following rings:

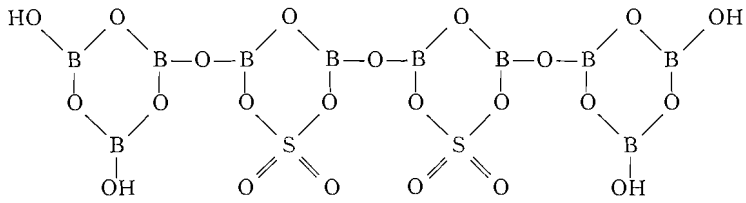


XXIII



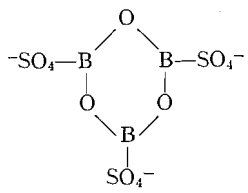
XXIV

The compound $B_2O_3.3SO_3.H_2O$ or $B_2O(SO_4)(HSO_4)_2$ probably has structure IX, and the compound $5B_2O_3.2SO_3.2H_2O$ can be formulated as the complex borate–sulphatoborate XXV.

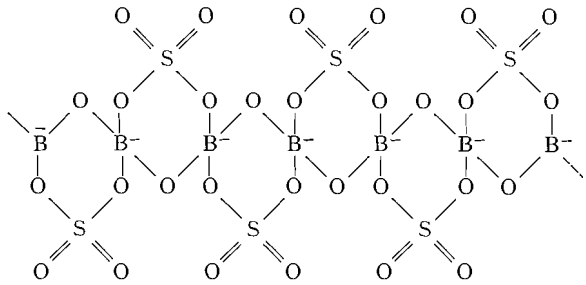


XXV

By heating potassium or sodium hydrogen sulphates with boric acid at 500° or by heating a mixture of sodium borate, sodium sulphate, and sulphuric acid, compounds corresponding to the composition $M(BO).SO_4$ have been obtained (13). These may be formulated as the salts of XXVI or XXVII.



XXVI



XXVII

d'Arcy (15) prepared a compound with composition $H_3BO_3.3SO_3$ or $B(HSO_4)_3$ from the reaction of sulphur trioxide with boric acid. We have also obtained a white, very hygroscopic compound corresponding very closely in composition to $B(HSO_4)_3$ by dissolving boric oxide in excess sulphur trioxide and then removing excess sulphur trioxide under vacuum. Greenwood and Thompson (16) obtained a similar compound from the reaction of boron trichloride with sulphuric acid:

$$BCl_3 + 3H_2SO_4 = B(HSO_4)_3 + 3HCl.$$

They also claim to have obtained the acid $HB(HSO_4)_4$ as a wet solid by the reaction between 1 mole of BCl_3 and 4 moles of sulphuric acid:

$$BCl_3 + 4H_2SO_4 = HB(HSO_4)_4 + 3HCl.$$

In view of the evidence from the Raman spectra of concentrated solutions of this acid in sulphuric acid that elimination of $H_2S_2O_7$ occurs to give B—O—B links (4) and in view of the complex structures of the salts discussed in this paper it seems unlikely that this wet solid was in fact the pure acid $HB(HSO_4)_4$. It is more likely that the product of this reaction is a mixture of polysulphatoboric acids with sulphuric acid and disulphuric acid with the overall composition $HB(HSO_4)_4$.

THE ACTION OF ANHYDROUS ACIDS ON ATP:CREATINE PHOSPHOTRANSFERASE*

FLORANTE A. QUIOCHO AND FELIX FRIEDBERG
Department of Biochemistry, Howard University Medical School, Washington, D.C.

Received December 19, 1961

ABSTRACT

Treatment of ATP:creatine phosphotransferase with anhydrous sulphuric acid permits transposition of 24% of the threonine residues and 69% of the serine residues. Treatment with anhydrous phosphoric acid yields similar results: 41% of the threonine residues and 60% of the serine residues are rearranged. Anhydrous formic acid does not induce an N- to O-acyl migration in the protein.

Non-specific hydrolysis of peptide bonds or destruction of certain amino acids that might have occurred simultaneously with rearrangement during the anhydrous sulphuric or anhydrous phosphoric acid appears to be very slight. When the protein is treated with anhydrous sulphuric acid, however, phenylalanine "disappears" almost completely from the chromatogram.

Following the suggestion by Bergmann and Miekeley (1) that serine displays a distinctive chemical reactivity through N-acyl to O-acyl transformation, Elliott (2) rearranged C-peptide bonds involving the beta-hydroxy amino acids serine and threonine with 97.5% anhydrous sulphuric acid. Such a N–O acyl migration frees the α-amino groups of the serine and threonine residues involved. Since nitrous acid reacts with these amino groups the difference in amino acid content after nitrous acid treatment in protein exposed to anhydrous acid and protein not exposed can be taken as a measure of transposition. In the experiments reported here this method was applied to ATP:creatine phosphotransferase (EC 2.7.3.2.).† A study was made of the comparative efficiency of anhydrous concentrated sulphuric acid, phosphoric acid, and formic acid. In addition, information was sought on the effect of these reagents on the other amino acids of the protein.

EXPERIMENTAL PROCEDURE

ATP:creatine phosphotransferase prepared by procedure B of Kuby *et al.* (3), crystallized twice, and lyophilized, showed a single peak on ultracentrifugation.

Treatment with Sulphuric Acid

To 100 mg of enzyme dried over P_2O_5 *in vacuo* at 60°, 4 ml of cold concentrated sulphuric acid were added. The flask was securely stoppered to prevent entry of moisture, gently shaken until the protein was dissolved, and then allowed to stand for 72 hours in a desiccator. The solution which was originally pale yellow turned somewhat darker. At the end of the specified time, the flask was cooled well below −40°, anhydrous ether, previously cooled below −40°, was added, and the mixture was thoroughly shaken. The resulting protein precipitate was washed several times with cold ether until the washings were free from $SO_4^=$ (as tested with $BaCl_2$) and then dissolved in distilled water (6 ml).

Treatment with Phosphoric Acid

ATP:creatine phosphotransferase (100 mg) was dried over P_2O_5 *in vacuo* at 60° and transferred to a glass-stoppered flask. H_3PO_4 (4g, 85%) and P_2O_5 (about 400 mg) were added. After incubation at 40° for

*This work was supported by a grant-in-aid (G-14363) from the National Science Foundation and an equipment grant from the Charles F. Kettering Foundation.

†*According to the "Report of the Commission on Enzymes of the International Union of Biochemistry", Pergamon Press, 1961, page 98, the name of the enzyme is ATP:creatine phosphotransferase. The associated trivial name is creatine kinase. The official number of the enzyme is 2.7.3.2.*

We believe that it will be useful to follow these recommendations in the Report of the Enzyme Commission, in order to achieve a common terminology among authors.

72 hours, a mixture of crushed ice and ice water was added to the flask to bring the total volume to approximately 100 ml, followed by a small excess of $CaCO_3$ to precipitate the phosphate. The supernatant liquid was dialyzed against distilled water and then lyophilized. The dry material was resuspended in 6 ml of distilled water.

Treatment with Formic Acid

To 100 mg of ATP:creatine phosphotransferase dried over P_2O_5 *in vacuo* at 60° and placed into a glass-stoppered flask 10 ml of 98% formic acid was added. After incubation for 72 hours at room temperature, the resulting solution was lyophilized. The dried protein was dissolved in 6 ml of distilled water.

Nitrous Acid Treatment of Proteins

The aqueous solution obtained as described above was dialyzed against 0.5 *N* acetate buffer (pH 4.0). It was then treated with 414 mg $NaNO_2$ and incubated for 16 hours at room temperature. The resulting solution was dialyzed against distilled water and lyophilized.

Hydrolysis and Amino Acid Analysis

Some of the dried material (10 mg) was hydrolyzed with 2 ml 6 *N* HCl for 22 hours at 110° in evacuated and sealed tubes. The hydrolyzate was taken to dryness *in vacuo* over NaOH pellets, dissolved in sodium citrate buffer, pH 2.2, and analyzed in the Spinco Amino Acid Analyzer (4).

Control runs were performed on ATP:creatine phosphotransferase hydrolyzed by 6 *N* HCl without prior treatment by anhydrous concentrated acid both with and without nitrous acid exposure.

RESULTS AND DISCUSSION

Table I shows that treatment of ATP:creatine phosphotransferase with anhydrous sulphuric acid permits transposition of 24% of the threonine residues and 69% of the serine residues. This limited conversion is in agreement with Elliott's study in silk fibroin, where 60% of the serine residues was rearranged (2). (There are few threonine residues in silk fibroin.) In lysozyme, however, he found nearly all serine residues affected, but only one-third of the threonine residues were converted (5). The extent of the induced

Phenylalanine	5.93	6.50	0.75	6.86	6.66

*Values given are averages of two determinations.

†The data here agree with those previously reported (12) except for the amino acids glycine and phenylalanine, which are considerably higher in the present paper. We believe that the automatic assay allows better separation of the glycine–alanine and phenylalanine–tyrosine pairs and yields more accurate results. Since the amino acid analyses were performed only after a single period of hydrolysis (22 hours) the absolute values for such amino acids as threonine, serine, or valine are not quantitatively reliable. The amount of cystine is small (about 3 moles/molecule), is destroyed by hydrolysis, and can only be determined by special means.

‡The large ammonia content in the hydrolyzates of the acid-treated protein might be due to ammonia in the mineral acids carried through to the hydrolysis stage. We have, however, no explanation for the high values of glutamic acid. The ratios of the height of the glutamic acid peaks yielded by the 570 and 440 mμ tracings remain constant. There is no evidence for another substance under the glutamic acid peak.

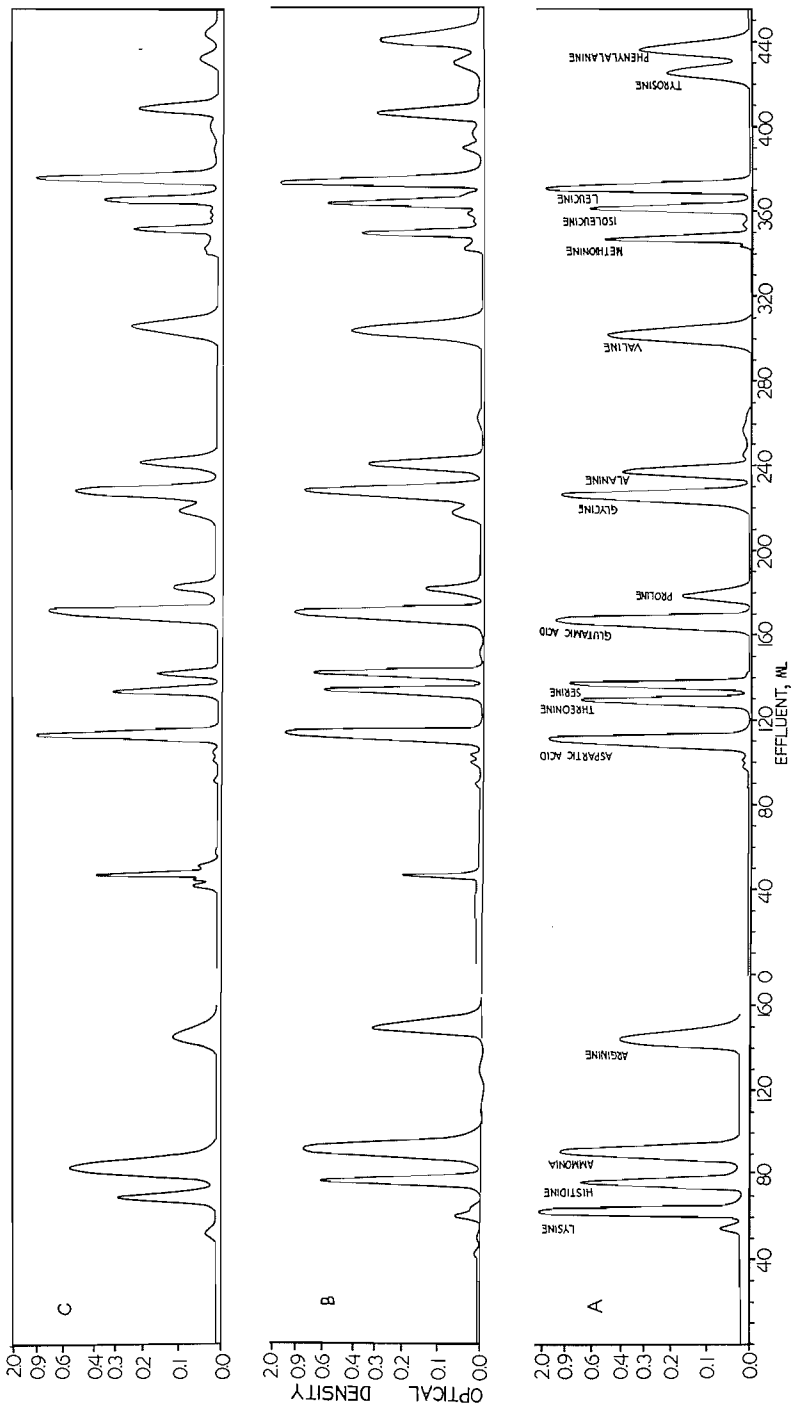

FIG. 1. Chromatograms for: A. Untreated ATP:creatine phosphotransferase. B. HONO-treated ATP:creatine phosphotransferase. C. H_2SO_4–HONO-treated ATP:creatine phosphotransferase. D. HONO-treated poly-L-lysine (upper curve), HONO-treated poly-L-tyrosine (lower curve). Leucine was added as a marker. There were no other peaks on the entire chromatogram. The lower curve is included because it shows that the peak midway between leucine and phenylalanine cannot be the result of a reacted tyrosine.

The basic amino acids and ammonia were separated on a 15-cm column operated at 50° and with the pH 5.28, 0.35 *N* sodium citrate buffer. The acidic and neutral amino acids were separated on a 150-cm column, which was also operated at 50°, starting with the pH 3.25, 0.2 *N* sodium citrate buffer, with a change to the pH 4.25, 0.2 *N* sodium citrate buffer at 260 ml (8 hours and 40 minutes). Since amounts of materials used in loading the columns varied, the table should be consulted for quantitative data.

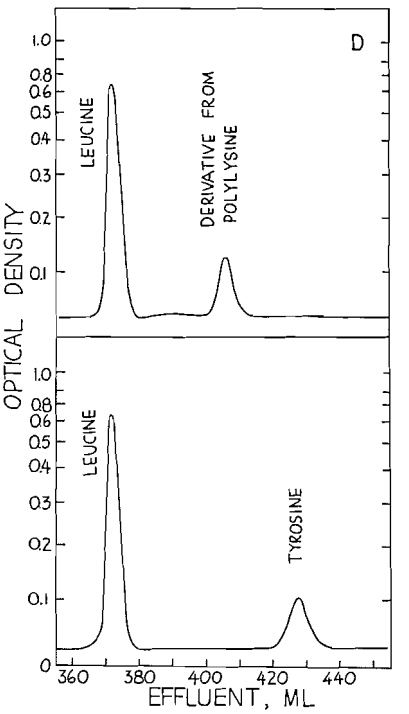

FIG. 1D.

shift was not increased on further standing of the reaction mixture. Wiseblatt *et al.* (6), who applied the method to wheat gluten also observed the preferential release of the amino groups of serine and Ramachandran and McConnell (7) reported 60–70% transposition of the peptide bonds of serine but none of those of threonine in gliadin. Hence, one may conclude that such transpositions are usually not complete and that threonine residues are more resistant than serine residues. The results for the treatment of ATP: creatine phosphotransferase by anhydrous phosphoric acid are similar: 60% of the serine residues and 41% of the threonine residues are rearranged (Table I). Fasman (8) demonstrated that concentrated sulphuric acid causes poly-DL-serine to rearrange to the polyester, to the extent of 70% of the original number of amide bonds. The remaining hydroxyls of the serine residues become sulphonated. Upon hydrolysis of serine-O-sulphate under the conditions of our experiments (22 hours hydrolysis) we observed 80% recovery of the free serine. Even though this incomplete hydrolysis of serine-O-sulphate could conceivably increase our values obtained for the transposition of the peptide bond of serine and probably also threonine, such an error should be slight. Whereas Josefsson and Edman (9) postulated that the increase in amino nitrogen during the reaction of ribonuclease with anhydrous formic acid is due to N-, O-acyl migration, more recent studies invalidate such a hypothesis (10, 11). Our results support the conclusion that anhydrous formic acid does not bring about an N- to O-acyl migration at the hydroxy-amino acid residues of ATP:creatine phosphotransferase.

That some non-specific hydrolysis of peptide bonds or destruction of certain amino acids might have occurred simultaneously with the rearrangement during the sulphuric or phosphoric acid treatment, but only to a very slight extent, is indicated by the lower

values for the amino acids arginine, alanine, and methionine after sulphuric acid treatment, and for alanine and arginine after phosphoric acid treatment. Only one major alteration in amino acid patterns can be deduced from the data: When the protein is treated with anhydrous sulphuric acid, phenylalanine "disappears" almost completely from the chromatogram (Fig. 1C). The sulphonated phenylalanine, migrating very rapidly on the Dowex resin, would be expected to emerge in front of the aspartic acid (the first amino acid in the effluent). Tyrosine-O-sulphate, for example, moves ahead of the aspartic acid. Anhydrous phosphoric acid treatment has no such effect.

Nitrous acid, itself, under the conditions employed in this study, induces nitrosation of tyrosine, besides deamination of the epsilon-amino group of lysine. In the chromatograms tyrosine and lysine are almost completely absent (Fig. 1B). A new peak appears in the effluent midway between leucine and phenylalanine which can also be obtained by exposing poly-L-lysine to the nitrous acid treatment (Figs. 1B and 1D). In addition there is a pronounced unidentified shoulder to the right of glycine (Fig. 1B).

NOTES

NEAR-INFRARED SPECTRA OF ALIPHATIC ALDEHYDES

J. F. KING AND B. VIG

It has been known for many years that numerous functional groups show characteristic absorption in the near-infrared region of the electromagnetic spectrum and that these absorption bands are most commonly overtones or combination bands involving hydrogen (see reference 1). Their use for the purposes of structural elucidation has been proposed in review articles on near-infrared spectra (1, 2), but remarkably few practical applications have been made to date. We have investigated the spectra of a number of aldehydes and wish to point out the utility of measurements in this region of the spectrum for confirming the presence of the aldehyde grouping and for providing information concerning its environment.

The bands arising from combination of the carbonyl stretching mode (around 1700 cm^{-1}) with each of the formyl C—H bands (around 2800 and 2700 cm^{-1}) would be expected to appear around 4500 and 4400 cm^{-1} respectively. It has previously been reported (1, 3) that aldehydes absorb in these regions, though except for a recent study of aromatic aldehydes (3), the specific basis of this generalization has not been disclosed. We have measured the near-infrared spectra of more than 30 aldehydes and find that all of the compounds show the two expected combination bands. These peaks are normally comparatively strong ($\epsilon \approx 1$) and in some of the simplest compounds are the strongest bands in the near-infrared spectrum. (Chloral, a possible exception, shows two bands but the low-frequency absorption, like the corresponding band in the infrared region, is of much lower intensity than the other: it is not certain that this band is due to the aldehyde function.) Examination of the near-infrared spectra of a substantial number of other compounds shows that absorption due to other functional groups (including saturated hydrocarbon units) may obscure the low-frequency band but that the region around 4500 cm^{-1} is comparatively free of absorption by other functions. What interference there is stems from double bonds bearing hydrogen, though these usually absorb at somewhat higher frequencies.

Though other carbonyl functions may absorb in the region of the C=O stretching mode of aldehydes, and other groups (e.g. certain other C—H groups, N-methyl groups, etc.) in the region of the formyl C—H bands, the combination band is unique to aldehydes. It would appear that the presence of the 4400 and 4500 cm^{-1} bands together with the 1700, 2700, and 2800 cm^{-1} absorptions is good circumstantial—if not absolute—proof of the presence of an aldehyde. In addition, the absence of the combination bands—notwithstanding the presence of bands at 1700, 2700, and 2800 cm^{-1}—would appear to exclude the possibility of the presence of an aldehyde.

In Table I are listed the aldehyde bands of a number of "α,β-saturated" and α,β-unsaturated aldehydes. The combination bands of the saturated aldehydes (excepting chloral) were found in the regions 4415–4445 cm^{-1} and 4525–4550 cm^{-1} and those of the α,β-unsaturated aldehydes in the regions 4360–4415 cm^{-1} and 4480–4510 cm^{-1}, respectively. The lower limit of the low-frequency band of the α,β-unsaturated compounds is

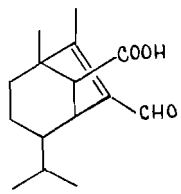
*Determined in chloroform solution. Control experiments indicate that the position of the aldehyde peaks is not significantly different in chloroform and carbon tetrachloride solutions.

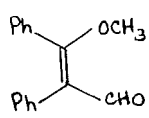
uncertain because absorption in this region due to other groups makes it difficult to determine the precise position of the aldehyde peak; the comparatively high extinction coefficient of these bands is almost certainly due to the presence of other absorption in this region. Included in the table also are the fundamental C=O and C—H frequencies and the sum obtained by adding the C=O frequency to each of the formyl C—H frequencies. Agreement between the near-infrared bands and the sums of the infrared frequencies is good, what differences there are being readily ascribable to anharmonicity and, to some extent, experimental uncertainty. Recently, Powers *et al.* (3) have confirmed the assignment of the 4500 and 4400 cm^{-1} bands in benzaldehyde as the combination of the C=O and C—H bands, by measuring the spectrum of benzaldehyde deuterated on the α-carbon. These authors also report the near-infrared frequencies of 11 other aromatic aldehydes. We have measured most of these compounds and a few other aromatic

aldehydes as well and find that all show the two combination bands. Our values for these compounds are in acceptable agreement with those of Powers *et al.*, and need not be duplicated here.

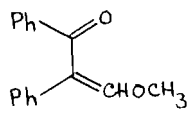
The usefulness of the near-infrared spectra of aldehydes has been shown in the study of the fungal sesquiterpene helminthosporal (4). This compound on oxidation yielded an acid in which the nature of the third oxygen was not clear. The absorption of the carboxyl group obscured the 2700 and 1700 cm^{-1} regions of the infrared spectrum, and attempts to remove this interference by esterification of the carboxyl group or to establish the nature of the oxygen by classical means led to intractable materials. The near-infrared spectrum, however, showed bands at 4480 and 4400 cm^{-1}, clearly indicating an α,β-unsaturated aldehyde as in I. The proton magnetic resonance spectrum confirmed the presence of the aldehyde group.



I



II



III

The near-infrared spectrum has been used in determining the structure of the crystalline product (m.p. 128°) obtained by methylating formyldesoxybenzoin with diazomethane (5). The near-infrared and infrared data (see Table I) together with the n.m.r. peak at 9.36 p.p.m. from tetramethylsilane show the structure to be II rather than III.

EXPERIMENTAL

The near-infrared spectra were determined with a Beckman DK-1 spectrophotometer using approximately 5% solutions in carbon tetrachloride in 1-cm quartz cells. With conventional cells, about 3 ml of solution is required; use of a semimicrocell reduces the volume necessary to less than 1 ml. Calibration indicates the error of the measurements to be less than ± 10 cm^{-1}. The values quoted represent the average of three or more measurements rounded to the nearest 5 cm^{-1}.

The infrared spectra were determined on a Beckman IR-7 grating spectrophotometer equipped with sodium chloride optics. The spectrum of each compound in carbon tetrachloride solution was determined using 0.1-mm sodium chloride cells.

Most of the compounds used in this study were commercial materials purified, in the case of solids, by recrystallization, and in the case of liquids, by washing with aqueous sodium bicarbonate, drying with Drierite, and distilling.

We are indebted to Dr. J. B. Stothers and Mr. R. E. Klinck for samples of 1-cyclohexene-1-carboxaldehyde and 1-cycloheptene-1-carboxaldehyde, and to Mr. Tony Durst for the spectrum of β-methoxy-α-phenylcinnamaldehyde.

THE ISOLATION OF A REPRESENTATIVE LIGNIN FRACTION FROM WOOD AND STRAW MEALS

J. M. PEPPER AND P. D. S. WOOD

Previous publications (1–3) have described the isolation of a representative lignin fraction by the acidolysis in a dioxane–water medium of spruce and aspen wood meals. The application of this procedure gave rise, in good yields, to a readily obtained lignin product, which on preliminary examination appeared to be only moderately changed from the protolignin of the original plant substance and hence quite amenable to fundamental chemical studies. This report deals with a study of the generality of the application of this procedure to the isolation of a lignin fraction from the sapwood of 11 deciduous and coniferous trees and from the straw of four cereals. The "dioxane-lignins" so obtained, were examined according to their yield (based on the original Klason lignin content of the plant materials), methoxyl content, and fundamental carbon and hydrogen analysis for representative samples of each group.

SOURCE AND PREPARATION OF PLANT MATERIAL

Deciduous woods.—The sapwood of aspen (*Populus tremuloides* Michx.), mountain ash (*Sorbus aucuparia* L.), willow (*Salix* sp.), and cherry (*Prunus* sp.) were separately cut first into small chips and then ground in a Wiley mill (ca. 20 mesh).* The milled wood meal was air-dried, then extracted continuously for 48 hours with a benzene – ethyl alcohol (95%, 1:1) mixture in a large Soxhlet extractor to remove the extractives. The resultant wood meal was air-dried before storage.

Coniferous woods.—The sapwood of each of alpine larch (*Larix laricina* (Du Roi) Koch), western red cedar (*Thuja plicata* D. Donn), black spruce (*Picea mariana* (Mill.) B. S. P.), white spruce (*Picea glauca* (Moench) Voss), jack pine (*Pinus banksiana* Lamb), and balsam fir (*Abies balsamea* (L.) Mill.) was treated as described for the deciduous woods.

Cereal straws.—Clean, hand-picked samples of straw, dry but in a slightly green condition, of wheat (*Triticum vulgare* (Thatcher variety)), oats (*Avena sativa* (Exeter variety)), barley (*Hordeum vulgare* (Parlsland variety)), and rye (*Secale cereale* (Prolific variety)) were first hammer-milled and then extracted and treated in the same fashion as were the wood meals.

EXTRACTION OF LIGNIN

Pre-extracted, air-dry wood or cereal meal (25 g) was used in each case. The general procedure of lignin extraction was that reported earlier by Pepper and Siddiqueullah (2) and modified by the same authors (3).

EXPERIMENTAL RESULTS

The lignin sample isolated from each of the 15 plant materials was examined for its yield (based on the original Klason lignin content), color, and methoxyl content. Samples of the lignin representative of each of the three plant divisions were analyzed for their carbon and hydrogen content. These data are summarized in Table I.

**For one sample of aspen, grinding was continued to pass 50 mesh but on subsequent extraction no significant increase in lignin yield was obtained.*

It is interesting to note that during the acidolysis of cherry and mountain ash wood meal, bright red dioxane–water solutions were formed compared with the yellow-brown solutions normally obtained; the residual meal was red instead of the usual tan color. The precipitated lignin was also red, the color increasing in intensity by adsorption from the supernatant solution. On treatment with sodium hydroxide or sodium carbonate the red color of the solution or the precipitate was changed reversibly to bright green.

Presumably in these two species leucoanthocyanins were present in the sapwood used, and were not removed by the 48-hour benzene–ethanol extraction. On treatment with the acid dioxane–water solution, conversion to the colored anthocyanidins occurred, the color being in part adsorbed on the lignin precipitate. The red color of the washed and dried lignin persisted, though the centrifugate faded to a yellow-brown color after a few days, even in the dark.

DISCUSSION

This study has indicated the applicability of the acidolysis procedure for the isolation of a representative lignin fraction from the three divisions of lignified material studied, namely the deciduous and coniferous woods and cereal straws. By this method it is apparent that lignin is most easily isolated from the cereal straws (40–50% yield) and least easily from the conifers (10–20% yield), with the deciduous woods occupying an intermediate position (20–35% yield). The known difference in the composition of these three species of lignin is supported by the analytical data of Table I. The deciduous woods and cereal straws give rise to similar yields (18–23%) of Klason lignin as opposed to the

much higher yields (25–31%) obtained from the conifers, and the former group has a carbon and hydrogen content of about 59 and 5.5% respectively as apposed to about 63 and 6.3% respectively for the latter group. There is, too, a slight but significant difference in the methoxyl content of the deciduous and straw lignins, the latter being about 1% greater than the former.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Dr. C. Riley of the Canadian Agriculture Research Station, Saskatoon, and to Mr. H. Gerrie, Department of Field Husbandry, University of Saskatchewan, Saskatoon, for their assistance in the provision of various wood and straw samples. UREA AND SODIUM CHLORIDE WHISKERS*

L. D. CALVERT, A. F. SIRIANNI, AND I. E. PUDDINGTON

INTRODUCTION

The growth of molybdena whiskers on a molybdenum trioxide – silicon dioxide substrate was reported by Callahan, Petrucci, and Brown (1). Sodium chloride whiskers possessing a visible twist and having a mean length of 180 mm and a thickness of 1–30 μ were obtained by Jeszenszky and Hartmann (2). Sodium chloride whiskers have also been reported by Fells and Firth (3). Alumina, zirconia, and silica whiskers have been observed by Cunningham (4). Twists on alumina whiskers have been described by Sears, De Vries, and Huffine (5).

While the behavior of finely divided silica in hydrocarbon oil was being investigated, an accidental observation led to the experiments described below in which urea whiskers of the order of 25 cm in length and very thin sodium chloride crystals of 2–3 cm in length were obtained. A few casual experiments suggested that other salts might be prepared in whisker form by similar procedures but this was not pursued.

EXPERIMENTAL

The silica aquagel was obtained by electrodialyzing solutions of N grade sodium silicate produced by the Philadelphia Quartz Co. containing 4–5% silicon dioxide. The system was dialyzed to a pH of about 5. On standing, the silica sol sets to a hard, almost transparent silica aquagel.

About 25 g of urea was added to 500 g of silica aquagel containing about 30 g of SiO_2, and thoroughly mixed until a syrupy texture was obtained. About 10 g of a semirefined hydrocarbon oil of 174 SUS viscosity at 210° F diluted with about 10 g of varsol was added, and a uniform emulsion prepared. About 50% of the water was boiled off at atmospheric pressure while the slurry was being stirred. The powdery residue

**Issued as N.R.C. No. 6733.*

much higher yields (25–31%) obtained from the conifers, and the former group has a carbon and hydrogen content of about 59 and 5.5% respectively as apposed to about 63 and 6.3% respectively for the latter group. There is, too, a slight but significant difference in the methoxyl content of the deciduous and straw lignins, the latter being about 1% greater than the former.

UREA AND SODIUM CHLORIDE WHISKERS*

L. D. CALVERT, A. F. SIRIANNI, AND I. E. PUDDINGTON

INTRODUCTION

The growth of molybdena whiskers on a molybdenum trioxide – silicon dioxide substrate was reported by Callahan, Petrucci, and Brown (1). Sodium chloride whiskers possessing a visible twist and having a mean length of 180 mm and a thickness of 1–30 μ were obtained by Jeszenszky and Hartmann (2). Sodium chloride whiskers have also been reported by Fells and Firth (3). Alumina, zirconia, and silica whiskers have been observed by Cunningham (4). Twists on alumina whiskers have been described by Sears, De Vries, and Huffine (5).

While the behavior of finely divided silica in hydrocarbon oil was being investigated, an accidental observation led to the experiments described below in which urea whiskers of the order of 25 cm in length and very thin sodium chloride crystals of 2–3 cm in length were obtained. A few casual experiments suggested that other salts might be prepared in whisker form by similar procedures but this was not pursued.

EXPERIMENTAL

The silica aquagel was obtained by electrodialyzing solutions of N grade sodium silicate produced by the Philadelphia Quartz Co. containing 4–5% silicon dioxide. The system was dialyzed to a pH of about 5. On standing, the silica sol sets to a hard, almost transparent silica aquagel.

About 25 g of urea was added to 500 g of silica aquagel containing about 30 g of SiO_2, and thoroughly mixed until a syrupy texture was obtained. About 10 g of a semirefined hydrocarbon oil of 174 SUS viscosity at 210° F diluted with about 10 g of varsol was added, and a uniform emulsion prepared. About 50% of the water was boiled off at atmospheric pressure while the slurry was being stirred. The powdery residue

*Issued as N.R.C. No. 6733.

was packed into crystallizing dishes with a spatula and the remaining water was evaporated under the following experimental conditions:

(*a*) at room temperature from open containers,
(*b*) in an oven at 110° C,
(*c*) under reduced pressure at room temperature,
(*d*) at a variety of constant relative humidities at room temerature.

The details of the whisker growth observed are given below. Sodium chloride whiskers were produced by substituting salt for urea in the silica aquagel – hydrocarbon oil mixture.

RESULTS

Extremely fine urea whiskers of the order of 10–12 cm in length appeared in various areas perpendicular to the surface of the packed substrate while it was left to stand overnight at room temperature. After about 6 days, a large number of fibers grew to a length of about 25 cm. Meanwhile, a very dense fibrous growth of short crystals swelled the substrate into a thick soft mat of about eight times its original volume. No further obvious change occurred on longer standing. The fibrous growth in the substrate and the appearance of the urea whiskers can be seen in Fig. 1. Short intertwined urea fibrils were produced by heating the mixture at 110° C. A somewhat similar type of growth appeared upon evacuating a warm suspension.

A longer time was required for crystal growth to occur in an enclosed system at a constant relative humidity at room temperature. Portions of the urea substrate were packed in Petri dishes to a depth of about 1 cm and placed in desiccators containing supersaturated solutions of zinc chloride, calcium nitrate, and ammonium chloride to give respective relative humidities of about 10, 51, and 79%. Each system was closed under a slight vacuum. After about 14 days, a sudden fibrous growth intermingled with a large number of longer crystals appeared in the desiccator over the $ZnCl_2$ solution. This is shown in Fig. 2. The elongated column of fibrous crystals shown in the right-hand side of the photograph was obtained by raising the temperature overnight to about 40° C. The upper portion of the column was contaminated with some silica and oil. When growth was resumed at room temperature the center portion remained white, and virtually free of contaminants. There was no evidence of crystal growth in the desiccator at about 79% relative humidity even after 4 months. After about 3 weeks, short, rather thick crystals appeared where the relative humidity was maintained at 51%. These were less voluminous than those which appeared at 10% relative humidity.

It was found that the long white crystals melted at 131° C, contained no ash, and gave a positive test for amine. An infrared spectrum identified the material as urea. X-Ray diffraction photographs corresponded to the known urea pattern. When the surface was coated with a dye and growth encouraged by raising the temperature of the material about 15° C above room temperature, dyed portions were completely lifted upwards by the growing fibers. There was no visible evidence of crystal growth above the dye level. Some fibers which had bent ends were noted to be at different angular positions during their early period of growth.

Morphology of the Whiskers

Urea

The rapidly grown silky fibrils (100–200 μ diam.) were found to be loosely connected bundles of heavily notched, "ribbon-like" fibers, as frequently curved as straight. Individual fibers showed perfect cleavage parallel and perpendicular to the fiber direction. The broken ends usually presented a stepped appearance with the cleavage faces perpendicular to each other. These faces are probably (011) and (001) since these are the

known cleavage faces for urea. The X-ray results show that the cleavage perpendicular to the fiber must be on (001). X-Ray rotation photographs of the silky fibrils gave typical fiber diagrams with the fiber axis as [001]; the arcing on the photographs corresponded to a variation of $\pm 15°$ from the mean fiber direction for individual fibers. A similar rotation photograph of a single 20-μ fiber, typical of the slowly grown fibers, showed it to be a single crystal with (001) as its fiber axis. Such individual fibers, which are typically uniform in diameter along their length, show extinction parallel to the fiber when examined in a microscope under crossed polars; if the fiber has a bend in it the direction of extinction follows the bend. Examination in an optical goniometer usually reveals continuous or streaky reflections extending over many degrees with maxima separated by 90°. The external appearance of these fibers is deceptive but most appear as spiral "ribbons". Goniometric measurement of the twist gives values in the range 12–20°/mm for long, straight fibers. One spiral "ribbon" with a twist of 12°/mm over a 10-mm length was found to be roughly triangular in cross section, rounded at the corners, with a single re-entrant right-angled notch on one side. The spiralling of this notch was apparently sufficient to create the observed spiral ribbon-like appearance. It is probable that the flat faces bounding the notches are responsible for the observed goniometer signals 90° apart while the rounded corners yield the continuous or streaky reflections. Such a cross section, though observed a number of times, was not as common as a strongly notched cross section, much wider in one cross dimension than the other. In no case was a central hole observed in a cross section, although many fibers appeared to be hollow on casual inspection.

Sodium Chloride

Very thin sodium chloride whiskers of the order of 2–3 cm in length were observed growing on the surface of a substrate after it had stood at room temperature for about 6 days. Many shorter fibrous crystals swelled the substrate to a thick soft mat. The longer crystals lying almost flat on the surface of the mat can be seen from Fig. 3. These fibers were identified as sodium chloride from their X-ray diffraction photographs.

The fibers of sodium chloride were generally fine (20 μ), with the thinnest bending easily in the draughts present in the room. While generally similar to the urea fibers, they were not so ribbon-like (diameters seldom differing by more than 3:2) and much more regular in form. They were distinguished by frequent kinks at right angles. One such fiber was observed with four kinks in a short distance forming a rectangular "spiral". X-Ray rotation photographs showed the fibers to be single crystals with [001] (i.e. any cubic axis) as the fiber axis. Optical goniometry usually gave faces separated by 90°, the most likely form being {011}. An exceptionally good fiber gave four reflections, tentatively identified as coming from the faces (110), ($1\bar{1}0$), ($\bar{3}\bar{2}0$), and ($\bar{3}20$). Many fibers showing a slight spiral twist were so fine that no satisfactory observations of their form could be made.

CONCLUSIONS

Although no final conclusions can be given at the present time, the evidence suggests that the growth proceeds from the base and that the conditions defining the diameter and twist of the fiber persist over fairly long periods of time. The formation of the whiskers seems to be dependent on some feature of the substrate and the rate of loss of water. Curiously, whiskers grew in relative humidities of 10 and 51% but not of 79%. As the total amount of water is depleted many surface imperfections occur and crystal growth can take place relatively unrestricted in many directions. The type of

PLATE II

FIG. 3. Sodium chloride whiskers and fibrous crystals grown at room temperature.

hydrocarbon oil seems to have little influence since very thin urea whiskers of the order 5–6 cm in length were obtained using medicinal oil instead of the less refined hydrocarbon oil.* Whiskers could not be produced using urea and oil alone. It may be remarked that needle growth of crystals is favored when crystallization is rapid and requires the dissipation of a large amount of energy. The factors governing the growth of these fibers are not yet understood and a series of experiments to define them is planned (6).

THE DECOMPOSITION OF *n*-PENTANE SENSITIZED BY ALLYL RADICALS

W. A. BRYCE AND M. S. HARDIMAN

The inhibition of the thermal decomposition of paraffin hydrocarbons by propylene has for many years been ascribed to the removal, from the system, of chain-propagating radicals such as CH_3 and C_2H_5 by hydrogen abstraction from the inhibitor (1, 2). It was assumed that the allyl radical formed was not sufficiently reactive to serve as a chain propagator and hence the rate of the overall decomposition was substantially reduced compared with the rate in the absence of propylene. The residual rate of the so-called "fully inhibited" reaction has, in the past, been ascribed to non-radical molecular processes.

Interest in the reactivity of the allyl radical has developed during the past few years. A reconsideration of its role in organic decompositions inhibited by propylene has been made necessary by the results of recent investigations (3–6) which have established that allyl radicals are capable of abstracting hydrogen at temperatures above 400° C. It can therefore no longer be argued that inhibition by propylene at these temperatures is a consequence of the inability of allyl to propagate decomposition chains. The role of allyl and of nitric oxide in the mechanism of inhibited decompositions has been discussed in general terms by McNesby and Gordon (5) and by Bryce and Ruzicka (6) and has been supported by recent results (7) on the pyrolysis of normal butane. Detailed theoretical treatments of the kinetics of inhibited decompositions have been presented recently by Laidler and Wojciechowski (8) and by Eyring (9). It is assumed in both of these discussions that molecular mechanisms play no significant part.

**Bundles of crystals 3–4 cm in length, thick at the base and tapering to a point at the tips, were obtained from silica aquagel alone after about 1 month's time.*

THE DECOMPOSITION OF *n*-PENTANE SENSITIZED BY ALLYL RADICALS

W. A. BRYCE AND M. S. HARDIMAN

The inhibition of the thermal decomposition of paraffin hydrocarbons by propylene has for many years been ascribed to the removal, from the system, of chain-propagating radicals such as CH_3 and C_2H_5 by hydrogen abstraction from the inhibitor (1, 2). It was assumed that the allyl radical formed was not sufficiently reactive to serve as a chain propagator and hence the rate of the overall decomposition was substantially reduced compared with the rate in the absence of propylene. The residual rate of the so-called "fully inhibited" reaction has, in the past, been ascribed to non-radical molecular processes.

Interest in the reactivity of the allyl radical has developed during the past few years. A reconsideration of its role in organic decompositions inhibited by propylene has been made necessary by the results of recent investigations (3–6) which have established that allyl radicals are capable of abstracting hydrogen at temperatures above 400° C. It can therefore no longer be argued that inhibition by propylene at these temperatures is a consequence of the inability of allyl to propagate decomposition chains. The role of allyl and of nitric oxide in the mechanism of inhibited decompositions has been discussed in general terms by McNesby and Gordon (5) and by Bryce and Ruzicka (6) and has been supported by recent results (7) on the pyrolysis of normal butane. Detailed theoretical treatments of the kinetics of inhibited decompositions have been presented recently by Laidler and Wojciechowski (8) and by Eyring (9). It is assumed in both of these discussions that molecular mechanisms play no significant part.

**Bundles of crystals 3–4 cm in length, thick at the base and tapering to a point at the tips, were obtained from silica aquagel alone after about 1 month's time.*

In an attempt to demonstrate directly the ability of allyl radicals to initiate the decomposition of paraffin hydrocarbons an investigation has been made of the pyrolysis of *n*-pentane in the presence of varying amounts of diallyl (1,5-hexadiene). The latter compound decomposes at a temperature substantially lower than that required for the pyrolysis of *n*-pentane and the kinetic and analytical evidence (5, 6) indicates that the primary dissociation results in the formation of two allyl radicals:

$$CH_2{=}CH{-}CH_2{-}CH_2{-}CH{=}CH_2 \rightarrow 2CH_2{=}CH{-}CH_2\cdot.$$

The effect of the allyl radicals thus generated on the rate of decomposition of *n*-pentane was observed by following the pressure change in the system and by obtaining a complete analytical mass balance for the components of the reaction mixture at the specified reaction time. All analyses were done by gas chromatography using conventional techniques.

The overall effect of the addition of diallyl to *n*-pentane is illustrated by the pressure–time curves presented in Fig. 1. It is recognized that there are limitations to the reliance

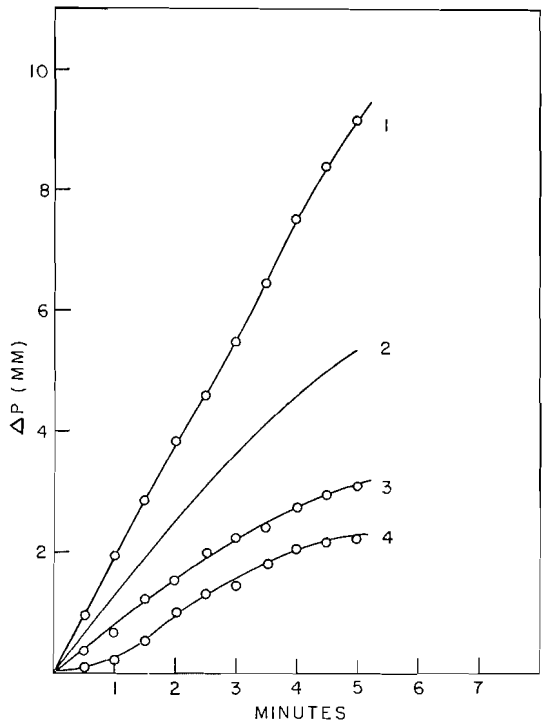

FIG. 1. The effect of the addition of diallyl on the rate of decomposition of *n*-pentane at 480° C: (1) 90 mm *n*-pentane plus 10 mm diallyl; (2) calculated assuming independent decomposition of *n*-pentane and diallyl; (3) 90 mm *n*-pentane; (4) 10 mm diallyl plus 90 mm Kr.

one can place on pressure measurements as a means of following gas-phase reactions, particularly when polymerizable materials are involved. However, this technique does provide a measure of reaction rate where the main process involves the decomposition of a paraffin. It is apparent from a comparison of curves 1 and 3 that the decomposition of *n*-pentane at 90 mm pressure is significantly accelerated by the addition of 10 mm of diallyl. The pressure change versus time curve for 10 mm of diallyl to which 90 mm

of krypton was added to maintain a total pressure of 100 mm is given in curve 4. The more rapid decomposition of diallyl than of *n*-pentane can be seen from the fact that the pressure increase for 10 mm of diallyl plus 90 mm Kr at 3 minutes is 22% while the corresponding figure for *n*-pentane alone is only 2.4%. If one were to make the extreme assumption that the *n*-pentane and diallyl were decomposing independently the total pressure increase would be merely the sum of curves 3 and 4. The resultant, curve 2, falls well below the results shown in curve 1. The effect of the diallyl in initiating the decomposition of *n*-pentane thus appears to be established.

Further indication of the initiation of *n*-pentane decomposition by allyl radicals is revealed by the analytical results for propylene and ethylene. These two compounds, which are formed in roughly the same proportions in the pyrolysis of *n*-pentane, together constitute about half of the decomposition products under normal conditions. In Fig. 2,

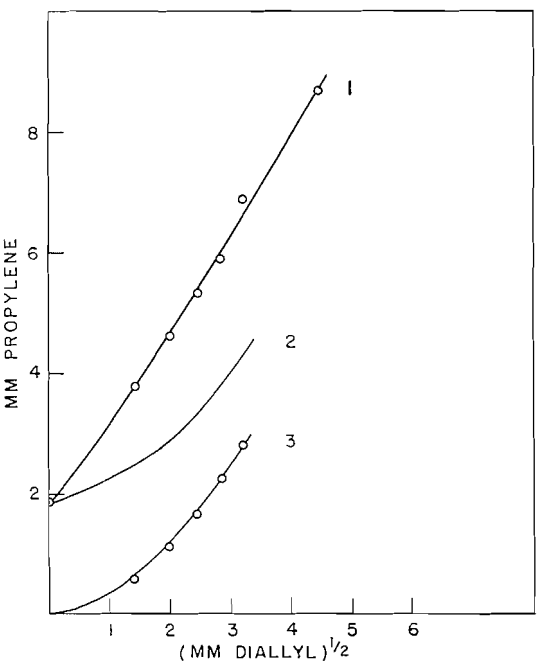

FIG. 2. Propylene yield at 5 minutes as a function of square root of diallyl pressure: (1) *n*-pentane plus diallyl; (2) calculated assuming independent decomposition of *n*-pentane and diallyl; (3) diallyl plus krypton. Total pressure, 100 mm.

curve 1, the partial pressure of propylene in the reaction mixture is plotted against the square root of the diallyl partial pressure for a reaction time of 5 minutes. The total initial pressure was kept constant at 100 mm. The temperature was again 480° C. The propylene pressure was plotted as a function of $(P_{\text{diallyl}})^{1/2}$ on the assumption that the latter quantity was a measure of allyl radical concentration in accordance with an equilibrium dissociation of diallyl:

$$\text{diallyl} \rightleftharpoons 2\text{allyl};$$

$$P_{\text{allyl}} = (KP_{\text{diallyl}})^{1/2}.$$

Curve 3 in Fig. 2 shows the variation of the partial pressure of propylene in the reaction mixture at 5 minutes' reaction time for the decomposition of diallyl in the presence of

krypton for the range of partial pressures of diallyl used in this investigation. If again one were to make the assumption that *n*-pentane and diallyl were decomposing independently in the pentane–diallyl mixtures, the partial pressure of propylene would be merely the sum of the propylene produced by each compound. The variation of this sum with square root of diallyl concentration is presented in curve 2. The fact that this curve falls well below curve 1 establishes that the decomposition of the diallyl sensitizes the decomposition of *n*-pentane to propylene and other products. The overall dependence of propylene production on the square root of the diallyl pressure is slightly greater than linear.

Results of the same kind for the production of ethylene are given in Fig. 3. The production of ethylene, which must involve secondary decomposition processes, is much

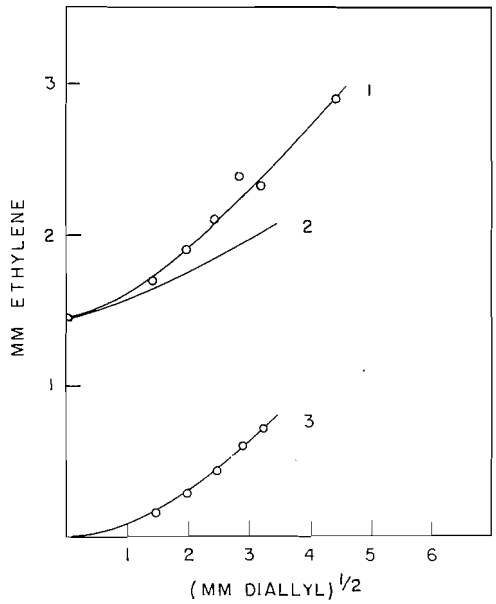

FIG. 3. Ethylene yield at 5 minutes as a function of square root of diallyl pressure: (1) *n*-pentane plus diallyl; (2) calculated assuming independent decomposition of *n*-pentane and diallyl; (3) diallyl plus krypton. Total pressure, 100 mm.

less dependent on the square root of the diallyl pressure than is the production of propylene, as is revealed by a comparison of the slopes of curves in Figs. 3 and 2. The production of ethylene by the decomposition of diallyl in the presence of krypton is shown in curve 3. The C_2H_4 which would be produced assuming the independent decomposition of *n*-pentane and diallyl is given by curve 2. It is thus apparent that the decomposition of diallyl has sensitized those processes in the *n*-pentane decomposition which result in the formation of ethylene.

A more complete account of this work will be published at a later date.

THE SYSTEM LITHIUM SULPHATE – MAGNESIUM SULPHATE – WATER AT 30° C

G. ARAVAMUDAN[1]

INTRODUCTION

The equilibrium relationships were studied in the system lithium sulphate – magnesium sulphate – water at 30° C and below in order to find out whether lithium sulphate would behave as the other alkali metal sulphates and ammonium sulphate, which are well known to form double salts with the magnesium salt. The binary system of the two salts is of the simple eutectic type and is devoid of any compounds, according to Bergman and Golubova (1).

EXPERIMENTAL

The complexes, comprised of the three components, were prepared by several different methods at 30° C so that the complete nature of the isotherm, inclusive of the metastable regions, if any, and of the kinetics of approach to equilibrium could be ascertained. In general, the complexes were prepared by the admixture of pairs of solid and liquid phases as follows: (i) lithium sulphate monohydrate and concentrated or supersaturated solutions of magnesium sulphate, (ii) anhydrous lithium salt and liquid phase as in (i), (iii) magnesium sulphate heptahydrate and saturated solutions of lithium salt, (iv) partially desiccated magnesium sulphate heptahydrate (containing 13–15% water by weight) and liquid phase as in (iii), (v) mixtures of $Li_2SO_4.H_2O$ and $MgSO_4.7H_2O$ crystals and water, and (vi) anhydrous lithium salt and solutions containing lithium and magnesium sulphate. Besides the above methods, controlled evaporation at 30° C of solutions containing various proportions of the lithium and magnesium salts was also carried out. The complexes were well agitated at 30±0.02° C for varying periods of time, after which the saturated solutions were quickly separated from the wet solid phase by conventional methods. Equilibrium was found to be attained within 24 hours in most cases. However, much longer periods of about 15 days or more were required in cases where the complexes were made by the method (iv). The scheme of analysis adopted in all cases consisted of the determination of the percentage of total anhydrous salt by drying to constant weight and of percentage of magnesium by the oxine method, which was found to give values accurate to 0.1%.

RESULTS AND DISCUSSION

A representative set of results of the experiments obtained under equilibrium conditions at 30° C is set forth in Table I. Extrapolation of tie lines in Fig. 1 shows clearly that three solid phases exist at 30° C, namely, $Li_2SO_4.H_2O$, $MgSO_4.7H_2O$, and $MgSO_4.6H_2O$, the last of which appears under metastable conditions only. Addition of lithium sulphate, in anhydrous or hydrated state, to supersaturated solutions of magnesium sulphate resulted in the crystallization of the magnesium sulphate hexahydrate in most cases. Two invariant points were realized, the first related to the cosaturation

SECONDARY ISOTOPE EFFECT IN THE ADDITION OF HYDROGEN ATOMS TO PROPYLENE-d_6[1]

M. Takahasi[2] and R. J. Cvetanović

In several recent studies the magnitudes and direction of the secondary deuterium isotope effects on reaction rates have been interpreted in terms of the configuration of the reaction centers in the transition complex (1–3). In particular Matsuoka and Szwarc (3) have found an increase of 7 to 11% in the rate of addition of methyl radicals to α,α,β-styrene-d_3 relative to styrene containing no deuterium, both carried out in isooctane solution. Although in the expected direction, the magnitude of the isotope effect was much smaller than that calculated (82%) on the assumption of a tetrahedral transition state. In view of this the authors concluded that the configuration of the transition state deviated only slightly from that of the initial state.

Recent work in this laboratory and elsewhere has shown important differences in the trends in reactivities of some free radicals. These are at least partly explainable in terms of the differences in the electron-seeking properties of the free radicals. The relative rates of addition of hydrogen atoms to a number of olefins in the gas phase have been recently determined in this laboratory (4, 5) and the trends in the rates are similar to those of methyl radicals in the corresponding reactions, although both are vastly different from the trends shown by oxygen atoms. Neither hydrogen atoms nor methyl radicals are likely to exhibit an appreciable electrophilic character and a similarity in their behavior is not unexpected. At the same time, besides a broad similarity, some significant quantitative differences in the reactivity trends of these two radical species have also been found. The latter are perhaps due to different steric requirements of the two reagents, although

of the phases $Li_2SO_4.H_2O$ and $MgSO_4.7H_2O$ and the second of the phases $Li_2SO_4.H_2O$ and $MgSO_4.6H_2O$. Experiments carried at lower temperatures down to 0° C did not reveal any new phases apart from the above ones. While this study was in progress, results on the ternary system at 25° C and 75° C were reported by Lepeshkov and Romashova (2, 3). The authors have missed the metastable existence of the hexahydrate at 25° C.

ACKNOWLEDGMENTS

The author wishes to thank Professor K. R. Krishnaswami for his keen interest in the work and the Government of India for financial assistance.

SECONDARY ISOTOPE EFFECT IN THE ADDITION OF HYDROGEN ATOMS TO PROPYLENE-d_6[1]

M. Takahasi[2] and R. J. Cvetanović

In several recent studies the magnitudes and direction of the secondary deuterium isotope effects on reaction rates have been interpreted in terms of the configuration of the reaction centers in the transition complex (1–3). In particular Matsuoka and Szwarc (3) have found an increase of 7 to 11% in the rate of addition of methyl radicals to α,α,β-styrene-d_3 relative to styrene containing no deuterium, both carried out in isooctane solution. Although in the expected direction, the magnitude of the isotope effect was much smaller than that calculated (82%) on the assumption of a tetrahedral transition state. In view of this the authors concluded that the configuration of the transition state deviated only slightly from that of the initial state.

Recent work in this laboratory and elsewhere has shown important differences in the trends in reactivities of some free radicals. These are at least partly explainable in terms of the differences in the electron-seeking properties of the free radicals. The relative rates of addition of hydrogen atoms to a number of olefins in the gas phase have been recently determined in this laboratory (4, 5) and the trends in the rates are similar to those of methyl radicals in the corresponding reactions, although both are vastly different from the trends shown by oxygen atoms. Neither hydrogen atoms nor methyl radicals are likely to exhibit an appreciable electrophilic character and a similarity in their behavior is not unexpected. At the same time, besides a broad similarity, some significant quantitative differences in the reactivity trends of these two radical species have also been found. The latter are perhaps due to different steric requirements of the two reagents, although

this point necessitates further study. In view of some difference in the behavior of hydrogen atoms and methyl radicals it was thought necessary to determine experimentally[3] the secondary isotope effect in the addition of hydrogen atoms to an olefinic double bond. For this purpose propylene and propylene-d_6 have been chosen as a representative pair of a light and a heavy olefin. With some modification in the design of the reaction vessel, the technique developed previously (4, 5) has been used for determination of the relative rate constants.

Hydrogen atoms are produced by mercury-photosensitized decomposition of *n*-butane and abstract another hydrogen atom from the *n*-butane to produce H_2 (reaction 1). When smaller amounts of an olefin are added, hydrogen atoms may also add to it (reaction 2) or abstract from it (reaction 3). Reactions have to be carried out with rigorously purified *n*-butane and at very small conversions. Under such conditions (4, 5),

$$[1] \qquad f(H_2) = \frac{R_{H_2}[1+\{q_2(Ol)/q_1(B)\}]}{R_{H_2}{}^* - R_{H_2}[1+\{q_2(Ol)/q_1(B)\}]} = \frac{k_3}{k_2} + \frac{k_1}{k_2}\frac{(B)}{(Ol)},$$

where $R_{H_2}{}^*$ and R_{H_2} are the rates of hydrogen formation in the absence and presence of the added olefin, respectively, (B) stands for *n*-butane and (Ol) for the olefin, and q_2/q_1 is the ratio of the quenching efficiencies of the olefin and *n*-butane. Since butane is always present in huge excess, q_2/q_1 does not have to be known too accurately and the previously employed (5) q_2/q_1 value of 8.2 has been also used in the present work. The same value was adopted for both C_3H_6 and C_3D_6 but even an appreciable difference in the quenching efficiencies of the two compounds could not have a significant effect on the results. The experimental $f(H_2)$ values are plotted against (B)/(Ol) and the slope of the linear plot gives k_1/k_2 and the intercept k_3/k_2.

The reaction system consisted of a 13.2-l. pyrex flask with a quartz window 5 cm in diameter attached to it through a large graded seal. The flask was provided with a glass stirrer on teflon bearings operated by an external rotating magnet and the gases were continuously stirred in the course of the reaction. The reactants were introduced through mercury cutoffs; they were then thoroughly degassed by repeated condensation and evaporation and saturated with mercury vapor by circulating with an all-glass plunger-type pump through a mercury saturator.

Phillips research grade *n*-butane was further purified to remove traces of olefin contaminants by passage through three wash bottles of concentrated H_2SO_4, over KOH pellets and through an activated silica gel column, followed by degassing and bulb-to-bulb distillation under reduced pressure. Phillips research grade propylene and propylene-d_6 obtained from Merck, Sharp & Dohme were thoroughly degassed in the usual manner. Mass spectrometric analysis of the deuteropropylene indicated 96% propylene-d_6 and 4% propylene-d_5. Reactions were carried out at 25±1° C, using 450 mm *n*-butane and varying small amounts of the olefin. The mercury resonance radiation was obtained from a low-pressure mercury vapor lamp, operated at a constant current of 100 ma supplied through a transformer from a voltage stabilizer. Exposure times of 20 minutes were used and the fluctuations in the lamp current remained less than 1% in these intervals. Hydrogen was collected through two liquid nitrogen traps by means of two mercury diffusion pumps and was measured on a constant volume burette.

The results of the measurements are given in Table I, where "Ratio" represents the ratio of the concentrations of *n*-butane and the added olefin, (B)/(Ol), and $f(H_2)$ is

[3]*No attempt has been made in the present work to estimate the expected theoretical values of the secondary isotope effects for different configurations of the transition state. The experimental value obtained is compared with the values reported in reference 3 for methyl radicals.*

TABLE I

The values of $f(H_2)$ at various n-butane/propylene ratios

Propylene							
Ratio	689	597	433	294	108		
$f(H_2)$	1.030	0.908	0.669	0.469	0.193		
Propylene-d_6							
Ratio	758	654	587	497	374	284	104
$f(H_2)$	1.108	0.955	0.828	0.660	0.578	0.464	0.209

defined in equation [1]. In the present work $R_{H_2}{}^*$ has not been corrected for finite conversion and residual olefin impurity (5). The values of the slopes and the intercepts of the plots of $f(H_2)$ vs. (B)/(Ol) have been calculated by the method of least mean squares and the k_2/k_1 and k_3/k_2 values thus obtained and their probable errors (6) are summarized in Table II. For comparison the previously determined (5) value for C_3H_6 is also given in the table and the agreement with the present result is seen to be satisfactory.

TABLE II

The values of k_2/k_1 and k_3/k_2

	k_2/k_1	k_3/k_2	Note
Previous result with propylene (5)	695±16	0.033±0.015	Circulating reaction system
Present result with propylene	692.3±3.8	0.0410±0.0037	Static reaction system (stirred reactor)
Present result with propylene-d_6	746±25	0.063±0.023	Static reaction system (stirred reactor)

The magnitude of the secondary isotope effect in the addition of H atoms to C_3D_6 and C_3H_6 is, on the basis of the results in Table II, $k_2(D)/k_2(H) = 1.078\pm0.037$. Thus the secondary isotope effect seems to be in the same direction as in the case of methyl radical addition to styrene and styrene-d_3 (3) and, as in this latter case, it is quite small.

The values of k_3/k_2 given in Table II indicate that $k_3(D)/k_3(H)$ is between 0.9 and 2.1. However, in view of the large extrapolations that have to be made, the intercepts of the $f(H_2)$-vs.-(B)/(Ol) plots may be considerably more uncertain than is suggested by the estimated limits of error in k_3/k_2 values in Table II. Consequently, much quantitative significance cannot be attached to these values. In agreement with this, direct mass spectrometric determinations of the HD-to-H_2 ratio in the hydrogen collected from the mixtures of n-butane and C_3D_6 give for $k_3(D)/k_1$ values of only 0.8–2.2. This would indicate some 20 times smaller rates of abstraction of D atoms from C_3D_6 than would have to be assumed on the basis of the mean value of the intercept of the $f(H_2)$-vs.-(B)/(C_3D_6) plot. The discrepancy may be entirely due to the large experimental uncertainties of the values of the intercepts. An alternative possibility is that a very small fraction (α) of the initial interaction of n-butane with the excited mercury atoms results in direct formation of H_2 (by molecular detachment) rather than giving H atoms and butyl radicals. In view of the experimental uncertainties and the smallness of this effect further, more extensive work is necessary to establish with certainty the cause of the apparent discrepancy. However, even if it should turn out that a small amount of molecular detachment of H_2 does occur in the mercury-photosensitized decomposition of n-butane, i.e. $\alpha > 0$, the present and the previously determined (5) relative rates of addition of hydrogen atoms to olefins will not be affected. The slope of the $f(H_2)$-vs.-(B)/(Ol) plots would in

this case be equal to $(1/1-\alpha)k_1/k_2$ and therefore the ratios of k_2 values for various olefins would remain unchanged.

The authors are grateful to Dr. A. W. Tickner for the mass spectrometric analysis.

A RADIOCHEMICAL METHOD FOR THE ESTIMATION OF THE SULPHYDRYL-TO-DISULPHIDE RATIO IN WHEAT GLUTEN

C. C. LEE AND E. R. SAMUELS

Considerable interest has been shown in our earlier note (1) on S-(N-ethylsuccinimido)-L-cysteine (I), the adduct formed between L-cysteine and N-ethylmaleimide (NEM), and the possible use of I as a carrier for the estimation of the relative amounts of sulphydryl and disulphide groups in proteins containing S^{35}. Since some unchanged I can be recovered from an acid hydrolyzate after hydrolysis of peptide bonds (1), if a S^{35}-labelled protein were allowed to react with NEM and then hydrolyzed, any sulphydryl groups originally present as cysteine residues would give rise to S^{35}-labelled I, which could then be isolated with the aid of ordinary I as carrier. The present communication reports some preliminary results on the application of this technique in a study with gluten of wheat flour in which S^{35} has been incorporated.

Gluten was chosen for investigation because of the possible involvement of sulphydryl groups in the action of flour improvers (2–4). Minute amounts of oxidizing agents, such as bromate or iodate, are known to have the capability of improving the bread-making quality of flour. Suggestions have been made that such an improver action may be due to the formation of disulphide cross-linkages from oxidation of sulphydryl groups of the gluten (2), or the inhibition of interchange reactions in the protein network between disulphide bonds and sulphydryl groups, presumably through the oxidative destruction of the sulphydryls (3, 4). Because of the very low sulphydryl contents of flour, it has been difficult to obtain a clearcut demonstration of a direct oxidation of flour sulphydryls by flour improvers (5). The application of the sensitive tracer technique may be of advantage; hence the present study was undertaken.

Carrier-free S^{35} as sulphate was injected into the stems of maturing wheat plants of the Thatcher variety about 20 days before harvest. The resulting kernels were milled to provide a radioactive flour. Fractionation studies (6, 7) showed that the protein fractions obtained do contain S^{35}. Dough samples were prepared, each from 15 g of active flour, 7 ml of distilled water, and no improver, 50 p.p.m.* potassium bromate, or 50 p.p.m.

**Throughout this note, p.p.m. refers to parts per million based on the weight of flour.*

this case be equal to $(1/1-\alpha)k_1/k_2$ and therefore the ratios of k_2 values for various olefins would remain unchanged.

A RADIOCHEMICAL METHOD FOR THE ESTIMATION OF THE SULPHYDRYL-TO-DISULPHIDE RATIO IN WHEAT GLUTEN

C. C. LEE AND E. R. SAMUELS

Considerable interest has been shown in our earlier note (1) on S-(N-ethylsuccinimido)-L-cysteine (I), the adduct formed between L-cysteine and N-ethylmaleimide (NEM), and the possible use of I as a carrier for the estimation of the relative amounts of sulphydryl and disulphide groups in proteins containing S^{35}. Since some unchanged I can be recovered from an acid hydrolyzate after hydrolysis of peptide bonds (1), if a S^{35}-labelled protein were allowed to react with NEM and then hydrolyzed, any sulphydryl groups originally present as cysteine residues would give rise to S^{35}-labelled I, which could then be isolated with the aid of ordinary I as carrier. The present communication reports some preliminary results on the application of this technique in a study with gluten of wheat flour in which S^{35} has been incorporated.

Gluten was chosen for investigation because of the possible involvement of sulphydryl groups in the action of flour improvers (2–4). Minute amounts of oxidizing agents, such as bromate or iodate, are known to have the capability of improving the bread-making quality of flour. Suggestions have been made that such an improver action may be due to the formation of disulphide cross-linkages from oxidation of sulphydryl groups of the gluten (2), or the inhibition of interchange reactions in the protein network between disulphide bonds and sulphydryl groups, presumably through the oxidative destruction of the sulphydryls (3, 4). Because of the very low sulphydryl contents of flour, it has been difficult to obtain a clearcut demonstration of a direct oxidation of flour sulphydryls by flour improvers (5). The application of the sensitive tracer technique may be of advantage; hence the present study was undertaken.

Carrier-free S^{35} as sulphate was injected into the stems of maturing wheat plants of the Thatcher variety about 20 days before harvest. The resulting kernels were milled to provide a radioactive flour. Fractionation studies (6, 7) showed that the protein fractions obtained do contain S^{35}. Dough samples were prepared, each from 15 g of active flour, 7 ml of distilled water, and no improver, 50 p.p.m.* potassium bromate, or 50 p.p.m.

**Throughout this note, p.p.m. refers to parts per million based on the weight of flour.*

potassium iodate. The dough was allowed to stand 3 hours, then thoroughly mixed with a solution of 400 p.p.m. NEM in 2 ml of distilled water, and then allowed to stand one more hour. The gluten was separated by washing off the starch (8) and dried at 100° C. A 1-g sample of pulverized, dry gluten was hydrolyzed by refluxing (100–103° C) for 18 hours in 50 ml of 6 *N* hydrochloric acid. The hydrolyzate was concentrated under reduced pressure, filtered, and made up to a volume of 25 ml. Twenty-five milligrams of ordinary NEM–cysteine adduct (I) was then added as carrier to aid in the subsequent development and separation of I by paper chromatography.

Although one-dimensional ascending paper chromatography was effective in separating I from cystine (1), it was necessary to use two-dimensional ascending paper chromatography, run at right angles to each other, in order to separate I from cystine and methionine. The solvent systems employed were 1-butanol, pyridine, acetic acid, water (BPAW) at the volume ratio of 30:20:6:24 and water-saturated phenol (WSP) (454 g phenol and 113.5 ml water). A number of 5-λ aliquots of each hydrolyzate were chromatographed on Whatman No. 1 filter paper, first in the BPAW system for about 18 hours, air dried, and then in the WSP system for about 20 hours. After air drying again, the chromatograms were developed with 0.1% ninhydrin in acetone. The spots corresponding to cystine, methionine, and adduct I were the only ones that showed activities significantly above background. The activity of the spot corresponding to cystine was of the order of 5000 c.p.m. The average values for the ratio of the activity of adduct I to the activity of cystine were 4.02:100, 3.67:100, and 0.86:100, respectively, for the chromatograms derived from doughs treated with no improver, with 50 p.p.m. potassium bromate, and with 50 p.p.m. potassium iodate. These decreases in the ratios of the activity of I to that of cystine indicate that some of the cysteine residues of the gluten were destroyed, likely by oxidation, after treatment with bromate or iodate. The data showed that under the conditions of the present experiments, the destruction of sulphydryls amounted to about 10% and 80%, respectively, when the dough was treated with 50 p.p.m. potassium bromate and with 50 p.p.m. potassium iodate.

For an absolute quantitative determination of the sulphydryl content of a protein by the measurement of the activity of I, it would be essential to have a complete recovery of I from the reaction of NEM with all of the sulphydryl groups of the protein. The use of an excess of NEM in the present experiments should facilitate its reaction with all the available sulphydryl groups of the dough. However, it is uncertain whether complete recovery of I from the gluten hydrolyzate was achieved because some decomposition of I might have occurred during the protein hydrolysis. On the other hand, if the fraction of I lost, if any, during protein hydrolysis were constant, as might be expected for hydrolyses carried out under identical conditions, relative comparisons of sulphydryl contents, as reported in this note, should still be valid. In order to demonstrate that the recovery of I after hydrolysis was constant, the following experiments were carried out. Radioactive adduct I was prepared from reaction of N-ethylmaleimide-1-C^{14} * with L-cysteine. It showed a single active spot after paper chromatography. This adduct was subjected to 10 replicate hydrolytic treatments in 6 *N* hydrochloric acid for 18 hours at 100–103° C, either with or without the presence of some ordinary gluten. Each hydrolyzate was chromatographed in the usual manner and the spot corresponding to adduct I was counted. The recovery of activity was essentially constant, amounting to 81±1% of the activity of I before hydrolysis. Thus the loss of I during hydrolysis under our experimental conditions is constant and the relative activities of I recovered after hydrolysis can be used as a measure of the sulphydryl content.

**Obtained from Schwarz Bio Research Inc., Mount Vernon, New York.*

To further establish the applicability of this radiochemical method, 1.0, 0.7, or 0.5 mmole of reduced glutathione in 10 ml of water was treated with 10 ml of solution containing 2.0 mmoles of C^{14}-labelled NEM. The resulting mixture was allowed to stand overnight, concentrated to a small volume, hydrolyzed in 6 *N* hydrochloric acid, and then chromatographed in the usual way. The spot corresponding to the recovered adduct I showed activities of 293, 211, and 150 c.p.m., respectively, for the original glutathione content of 1.0, 0.7, and 0.5 mmole. The activity ratio of 293:211:150 corresponds to 1.00:0.72:0.51, in excellent agreement with the known glutathione contents.

THIN LAYER CHROMATOGRAPHY OF CARBOHYDRATE ACETATES[1]

M. E. TATE[2] AND C. T. BISHOP

Division of Applied Biology, National Research Council, Ottawa, Canada

Received February 19, 1962

ABSTRACT

Thin layer chromatography on silica gel G with benzene–methanol mixtures is a rapid method for the analytical or semimicro preparative separation of low molecular weight carbohydrate acetates. Some mixtures of inositol acetates are also resolved by the same procedure. A sensitive spray reagent has been developed for the analytical detection of acetates on the chromatographic plates and is based on the formation of the ferric hydroxamate of acetic acid. Oligosaccharide acetates are easily detected on a semimicro preparative scale by spraying the chromatographic plates with water, a general, non-destructive method for detection of hydrophobic compounds. The chromatograms can be run in 40 minutes and multiple development can be carried out to improve resolution when necessary.

Thin layer chromatography has been reviewed in several recent articles (1–4). Its application to carbohydrates has so far been limited to the free sugars (5), which are strongly polar and, with the exception of certain specific conditions, are more conveniently separated by paper chromatography. The most spectacular applications of thin layer chromatography have been to the separation of slightly polar compounds, which are resolved only poorly or not at all by paper chromatography. The readily available carbohydrate acetates fall into this category and a study of their behavior on thin layer chromatograms was therefore undertaken and is described in the present paper.

This work constitutes an extension to thin layer chromatography of the separation of carbohydrate acetates on columns of Magnesol–Celite as described by McNeely, Binkley, and Wolfrom (6). The substitution of silica gel G for Magnesol–Celite was indicated when preliminary experiments showed the presence of ghost spots from pure, fully acetylated monosaccharides on thin layers of Magnesol–Celite after multiple development. Behavior of acid–base indicators on thin layer chromatograms of Magnesol–Celite showed that the adsorbent was alkaline. It was likely, therefore, that the ghost spots were a result of partial deacetylation of the compounds during the drying of plates between developments.

Good separations of carbohydrate acetates were obtained on thin layers of silica gel G using benzene–methanol mixtures containing 2–10% (v/v) of methanol. The mobilities of the various components were dependent on the concentration of methanol, within the above limits, and were presumably related to the strength of hydrogen bonding between the silicic acid and the compounds concerned. For example, with two developments, 4% of methanol in benzene is sufficient to resolve the acetylated lower members of the polymer homologous series of $1 \rightarrow 3$ linked β-D-glucose units obtained from laminarin.

[1]*Issued as N.R.C. No. 6799.*

[2]*National Research Council of Canada Postdoctorate Fellow 1960–1962.*

However, again with two developments, 10% of methanol in benzene is necessary to separate the acetates of a similar series of $1 \rightarrow 4$ linked β-D-N-acetylglucosamine units obtained from chitin.

Figure 1 shows the separation of the anomeric acetates of D-glucose, maltose, and cellobiose, and of the β-acetates of the polymer homologous series of oligosaccharides obtained from laminarin. These separations serve to illustrate the resolving power of this technique; the relative mobilities of anomeric pairs ($\beta > \alpha$) were the same as given by the Magnesol–Celite procedure (6) for the compounds used.

a weak spot that was not resolved from either *allo-* or *muco*-inositol. The weak intensity of the *scyllo*-inositol hexaacetate spot was caused, at least partially, by the low solubility of this compound; heavier applications merely resulted in a streak running to the origin. With the exception of *scyllo*-inositol hexaacetate, the order of mobilities of the inositol hexaacetates was remarkably similar to the inverse order of electrophoretic mobilities of the inositol–borate complexes reported by Angyal and McHugh (7). These data are shown in Table I and indicate that a complex formation similar to that in the borate complexes may be responsible for the adsorption of inositol hexaacetates in thin layer chromatography.

*Double development (2×17 cm) of thin layer chromatogram on silica gel G using 4% methanol in benzene (v/v).

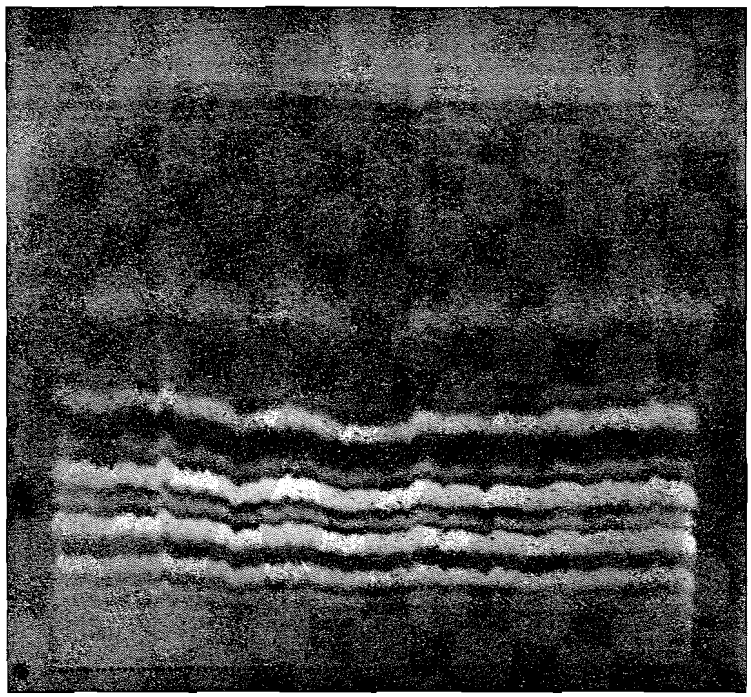

FIG. 3. Semimicro preparative thin layer chromatogram.
Adsorbent: silica gel G; solvent: 4% methanol in benzene (v/v); double development (2×17 cm).
Components: β-oligosaccharide acetates obtained by acetylation of partial acid hydrolysis products from commercial dextran.

applied until the plates were saturated; at that stage the background became translucent and the hydrophobic compounds appeared as white bands. This method of detection offers considerable advantages over other procedures, such as spraying guide strips or applying an indicating reagent as a streak. First, no material is sacrificed for detection purposes because the water spray is non-destructive. Second, the separated products can be recovered completely and with no mixing of closely neighboring components because the full bands are visible and any minor irregularities can be traced. The maximum load of the mixture of oligosaccharide acetates that could be resolved was 25 mg on a

20-cm plate. When an oligosaccharide acetate was run as a spot the minimum amount detectable by the water spray was 100 γ. Monosaccharide acetates are not sufficiently hydrophobic to be detectable by this technique, which is, however, applicable to any strongly hydrophobic compound and has also been applied to lipids in these laboratories.

High concentrations of carbohydrate acetates may also be detected on thin layer chromatograms by iodine vapor but the sensitivity is of the same order as the water spray, i.e. 100 γ. Detection of carbohydrate acetates in the range 5–100 γ required the development of a more sensitive procedure. Demole (1) has mentioned application of the ferric hydroxamate reaction to volatile esters and this has now been extended to the non-volatile acetates. Factors involved in this reaction have been thoroughly investigated by Goddu *et al.* (8) and have been developed for paper chromatographic procedures by other workers (9, 10). The procedures developed for paper chromatography were not directly applicable to thin layer chromatography and were therefore modified as described in the experimental section.

Thin layer chromatography thus offers a rapid and convenient method for analyzing hydrophobic derivatives of carbohydrates. Other procedures for the analysis of carbohydrate acetates include reverse phase chromatography on acetylated paper (11), paper chromatography in two-phase organic solvent systems (12), and the Magnesol–Celite column procedures (6). The present method offers advantages in speed, simplicity, and sensitivity over these other procedures. The method should prove useful for following the course of a reaction involving hydrophobic carbohydrates, e.g. acetolysis of polysaccharides or molecular rearrangements in the monosaccharide series, and for isolating identifiable amounts of closely related products.

EXPERIMENTAL

Analytical Separations

Smooth glass plates (20×20×0.37 cm) were coated with a uniform layer (250 microns thick) of silica gel G* (a standardized mixture of silicic acid and gypsum) using a commercial applicator.* The applicator was loaded with a well-mixed slurry prepared by addition of silica gel G (30 g) to distilled water (60 ml) with stirring. After application of the thin layer the plates were dried in an oven at 110° C for 30 minutes and allowed to cool. Samples were applied from a thin wire loop (ca. 1-mm diameter) with the aid of a numbered plastic template. Standard solutions of the carbohydrate acetates were made at 2% (w/v) concentration in chloroform. Spots were applied in a line 2 cm from one edge of the plate and were spaced at intervals of 1 cm. Marker dyes of Sudan III, methyl red, and methyl orange were applied to each plate as controls. Under the conditions used methyl orange remained at the origin, Sudan III moved near the solvent front, and, depending upon the methanol content of the solvent system, methyl red moved to an intermediate position approximating the mobility of a fully acetylated trisaccharide.

Chromatograms were developed by the ascending technique in rectangular tanks (25×25×7 cm) lined with filter paper for good equilibration and containing the solvent system to a depth of 1 cm. The edge of the plate along which the samples had been applied was placed in the solvent, the tank was closed, and the solvent was allowed to rise to within 2 cm of the top of the plate; this required approximately 40 minutes. Multiple development was used when high resolution was desired and was especially necessary for the separation of anomeric acetates. To do this, the developed chromatograms were removed from the tank, dried in a current of air, and replaced in the tank for a second development. This process could, of course, be repeated as many times as necessary.

The solvent system used must be varied in methanol content according to the compounds under investigation. Thus, the separations shown in Figs. 1, 2, and 3 were obtained with 4% of methanol in benzene. Separation of more-polar compounds, such as fully acetylated amino sugars, required an increase in methanol concentration to 10% but resolution of non-polar, low molecular weight acetates required only 2% of methanol in the solvent system. Solvent in the tank was replaced each day because the methanol content was gradually depleted by adsorption onto the silicic acid.

Detection of Acetates by the Ferric Hydroxamate Reaction

The solutions used were:

(A) 10% (w/v) aqueous hydroxylamine hydrochloride;

**Desaga–Brinkman, Brinkman Instruments Incorp., Great Neck, New York.*

(B) 20% (w/v) aqueous sodium hydroxide;
(C) ferric nitrate.$9H_2O$ (40 g), distilled water (600 ml), glacial acetic acid (400 ml);
(D) concentrated hydrochloric acid.

After the final development with solvent the plates were dried in a current of air and sprayed with a mixture containing equal volumes of solutions A and B until the surface was uniformly moistened. The plates were then heated in an oven at 100–110° C for 10 minutes, cooled to room temperature, and then sprayed with the ferric nitrate reagent (45 ml of solution C plus 6 ml of solution D). The acetates appeared as dark purple spots on a yellow background; a speckled, pink background indicated that further spraying with the ferric nitrate reagent was necessary. The spots remain visible for at least 1 week but gradually diminish in intensity after the first hour. For permanent records the plates may be photographed or traced on glassine paper. The spray reagents are stable for approximately 48 hours but for best results should be mixed just prior to use. *R* values have not been recorded because they have no valid significance when multiple development is used.

Semimicro Preparative Separation

The chromatographic plates were prepared as described for the analytical procedure. The crude mixture of acetates in chloroform (10–30%, w/v) was applied from a capillary or a wire loop as a band of contiguous spots 2 cm from one edge of the plate; each spot was approximately 2 mm in diameter. The plate was developed twice (2×17 cm) in benzene containing 4% (v/v) of methanol. After the second development the plate was dried and sprayed with water (see Fig. 3) and the bands were circumscribed with a sharp scalpel. The plate was then allowed to dry and individual bands were removed by holding the plate vertically on glassine paper and scraping the bands from the surface with a scalpel. The silica gel containing a single component was then transferred from the glassine paper to a numbered glass tube which had been constricted and plugged with cotton wool to form a miniature column. The product was then eluted with a mixture of methanol:chloroform (1:1, v/v) and the eluate was evaporated in a stream of air. The plate depicted in Fig. 3 yielded the following quantities: bands are numbered in order of decreasing mobility: band (1) 0.5 mg; (2) 0.3 mg; (3) 1.0 mg; (4) 0.6 mg; (5+6) 1.7 mg; (7) 1.8 mg; (8) 1.2 mg; (9) 0.9 mg. The homogeneity of each band was verified by deacetylation and examination of the products by paper chromatography in ethyl acetate:pyridine:water, 10:4:3. Under these conditions, components in the weaker bands were not resolved from those in the immediately following stronger bands. This result indicated that the pairs of weak and strong bands were perhaps anomers, although the possibility exists that they were different oligosaccharides that were not resolved by paper chromatography.

The mixture of acetylated oligosaccharides was obtained by hydrolysis of a commercial dextran according to the method of Barker *et al.* (13) and acetylation of the products by acetic anhydride and sodium acetate. The maximum load of this mixture of oligosaccharide acetates was 25 mg/20 cm of plate. The maximum volume of solution which can be spotted in a single application was approximately 0.06 ml, i.e. 3 μl/cm.

ACKNOWLEDGMENTS

The authors wish to thank Professor S. J. Angyal, The University of New South Wales, Broadway, N.S.W., Australia, for samples of the inositol hexaacetates. We are grateful to Dr. W. J. Whelan for the polymer homologous series of acetylated oligosaccharides from laminarin.

POTENTIAL CYTOSTATIC CARBOHYDRATE DERIVATIVES

PART II. N-MUSTARD PHOSPHATES

KITTY M. VAGI, VINCENT W. ADAMKIEWICZ, AND THOMAS NOGRADY[1]

Department of Physiology, University of Montreal, Montreal, Que.

Received January 22, 1962

ABSTRACT

2,3,4,6-Tetra-O-acetyl-D-glucosyl-(N-bis-β-chloroethyl)-phosphoramidate and ethyl-D-fructopyranoside-1-(N-bis-β-chloroethyl)-phosphoramidate have been synthesized. The first compound inhibited Adenocarcinoma 755 to 40–50%.

Many attempts were recently undertaken in the field of experimental chemotherapy of malignant tumors to enhance the selectivity of the chemotherapeutic agents, particularly that of the N-mustards. Many types of carriers were used, among them carbohydrates (cf. refs. 1–3). Other transport forms of "hidden" or "toxagenic" N-mustards were also designed, one of the most successful among them the phosphoramidate esters of the Cytoxan type, by Arnold and collaborators (4).

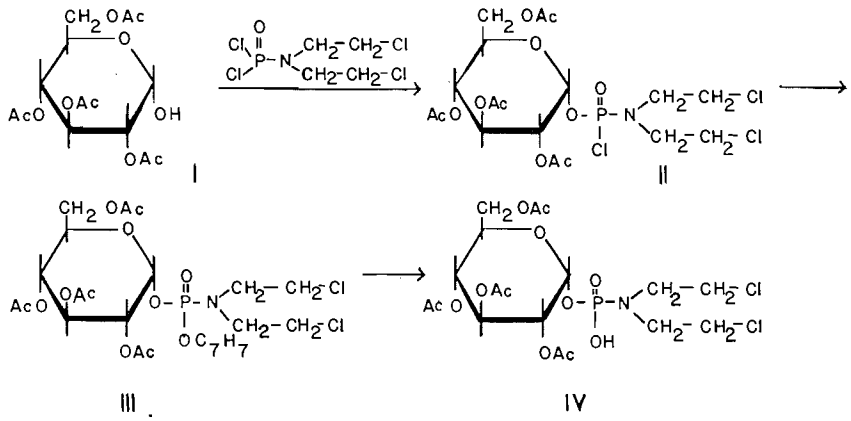
It seemed promising to combine the favorable transport characteristics of carbohydrates and phosphoramidate esters, particularly, because the carbohydrate phosphates are metabolites, with an already existing phosphatase and phosphoramidase enzyme system. It might be expected that the same enzyme system would be capable of splitting the sugar phosphate – N-mustard combination, liberating the N-mustard from its inactive transport form.

Therefore several series of carbohydrate-(N-bis-β-chloroethyl)-phosphoramidates were synthesized.

By reacting 2,3,4,6-tetra-O-acetyl-β-D-glucose (I) (5) with bis-(β-chloroethyl)-phosphoramidic dichloride (6) in the presence of triethylamine, 2,3,4,6-tetra-O-acetyl-1-glucosyl-(N-bis-β-chloroethyl)-phosphoramidic chloride (II) was obtained, either in 15 hours at room temperature or 45 minutes at 80°. Usually without isolating the chloride (II), it was then esterified with benzyl alcohol to III in a quantitative yield. This consumed the theoretical amount of H_2 on hydrogenation in ethanolic solution with Pd–C catalyst, yielding 2,3,4,6-tetra-O-acetyl-(α,β?)-D-glucopyranosyl-N-bis-(β-chloroethyl)-phosphoramidate (IV), an almost colorless, water-soluble, and strongly acidic syrup.

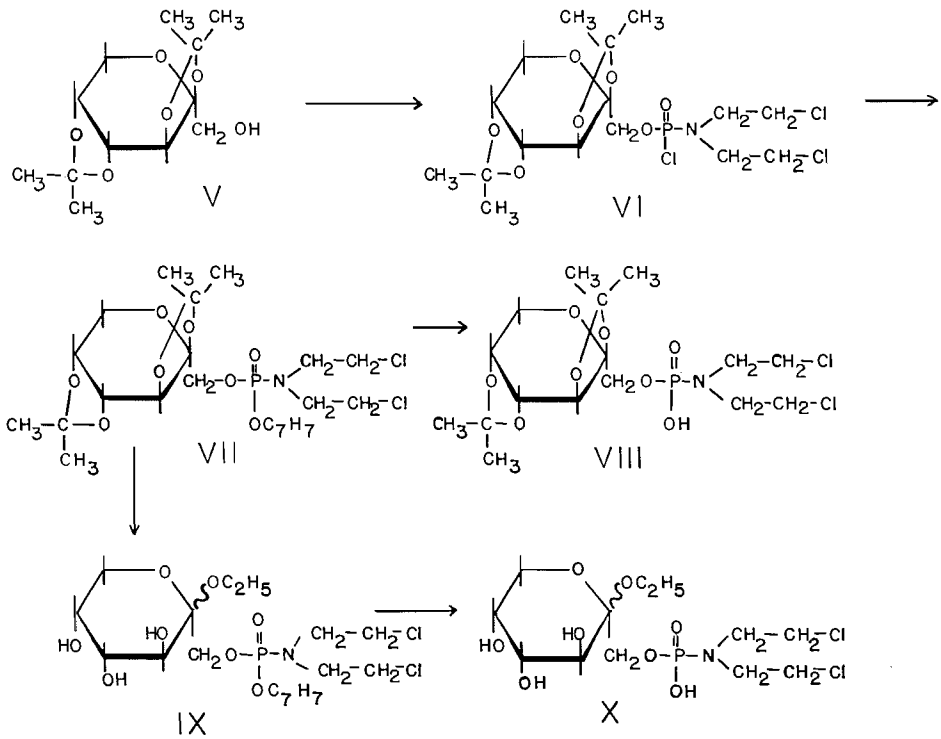
This behaved, however, quite peculiarly. It failed to crystallize, and could not be distilled. No salt formation could be achieved without splitting off the bis-(β-chloroethyl)-amine group. Organic bases such as cyclohexylamine, norephedrine, or even the weak novocain (pK_b 5.15) were able to decompose the molecule, and bis-(β-chloroethyl)-amine hydrochloride could be isolated. This was surprising, because according to known facts (7), the P—N bond in phosphoramidates is acid sensitive and alkali stable, although some diesters of phosphoric acid are known to be very unstable in alkali. This sensitivity towards bases in polar solvents was, however, a general characteristic in our series. Chromatography on acid-washed alumina caused the same splitting, basic ionic exchange resins in alcoholic solution even more so, as well as attempted catalytic deacetylation with sodium methylate.

[1]*Present address: Department of Chemistry, Loyola College, Montreal 28, Que.*



Deacetylation of IV was therefore attempted with cold ethanolic hydrochloric acid, which gave a crude, dark oil, with the approximate analysis. Not being able to purify it satisfactorily, we submitted the acetylated compound (IV) for cancerostatic screening, which did not show any activity against Sarcoma 180. It inhibitied, however, Adenocarcinoma 755 in doses of 250 mg per kg per day (for 7 days) to an extent of 40–50%.

The whole reaction sequence, starting from 2,3:4,5-di-O-isopropylidene-β-D-fructopyranose (V) (8), was repeated. The phosphoramidic chloride (VI) was obtained, and subsequent esterification with benzyl alcohol yielded the benzyl-phosphoramidate (VII), which, on catalytic hydrogenolysis, furnished the free phosphoramidate (VIII).



Attempted removal of the isopropylidene groups with ethanolic hydrochloric acid from VII gave a dark syrup, presumably IX. This, when hydrogenated, gave ethyl-(α,β?)-D-fructopyranoside-1-(N-bis-β-chloroethyl)-phosphoramidate (X) as a yellow oil, which, however, darkened in a matter of hours, and gave inconsistent analyses. The compound exhibited the same base sensitivity as the glucose derivatives II–IV, and presented the same difficulties regarding purification.

EXPERIMENTAL*

2,3,4,6-Tetra-O-acetyl-(α,β?)-D-glucopyranosyl-(N-bis-β-chloroethyl)-phosphoramidic Chloride (II)

N-Bis-(β-chloroethyl)-phosphoramidic dichloride (1.30 g) (8) and 2,3,4,6-tetraacetyl-glucopyranose (1.74 g) (7) stood with 0.72 ml triethylamine in 20 ml benzene at room temperature, until the theoretical amount of triethylamine hydrochloride precipitated, and the reaction mixture became neutral (15 hours). After the triethylamine hydrochloride was filtered off, the benzene solution was washed once with ice water, dried, and evaporated to dryness under reduced pressure, affording 2.85 g (100%) of yellow syrup. $[\alpha]_D^{20}$: +47.0°; n_D^{25}: 1.4791. Anal. Calc. for $C_{18}H_{27}Cl_3NO_{11}P$: C, 37.88; H, 4.77; N, 2.45. Found: C, 37.41; H, 4.93; N, 2.36.

2,3,4,6-Tetra-O-acetyl-(α,β?)-D-glucopyranosyl-(N-bis-β-chloroethyl)-benzyl-phosphoramidate (III)

Freshly prepared II (2.85 g) and 0.54 ml benzyl alcohol were refluxed with 0.72 ml triethylamine in 30 ml benzene for 40–60 minutes, until the reaction mixture became neutral. Then, the triethylamine hydrochloride was filtered off, and the benzene solution was washed once with ice water, dried, and evaporated under reduced pressure, yielding 3.2 g (100%) of yellow syrup. $[\alpha]_D^{20}$: +32.0°; n_D^{25}: 1.4959. Anal. Calc. for $C_{25}H_{34}Cl_2NO_{12}P$: C, 46.74; H, 5.33; N, 2.18. Found: C, 46.16; H, 5.38; N, 2.26.

2,3,4,6-Tetra-O-acetyl-(α,β?)-D-glucopyranosyl-(N-bis-β-chloroethyl)-phosphoramidate (IV)

Compound III (1.28 g), dissolved in 20 ml ethanol, was hydrogenated in the presence of 0.2 g of 5% Pd–C catalyst. It consumed the theoretical 48 ml of H_2 in 1 hour. After filtration and evaporation, 0.95 g (85%) of an almost colorless viscous syrup was obtained. $[\alpha]_D^{20}$: +42.9°; n_D^{25}: 1.4730. Anal. Calc. for $C_{18}H_{28}Cl_2NO_{12}P$: C, 39.14; H, 5.11; N, 2.54. Found: C, 39.60; H, 5.16; N, 2.62.

2,3:4,5-Di-O-isopropylidene-β-D-fructopyranose-1-(N-bis-β-chloroethyl)-phosphoramidic Chloride (VI)

N-Bis-(β-chloroethyl)-phosphoramidic dichloride (1.30 g) and 2,3:4,5-di-O-isopropylidene-β-D-fructopyranose (1.30 g) were refluxed with 0.72 ml triethylamine in 20 ml toluene for 6–8 hours, until the reaction mixture was neutral. The precipitated triethylamine hydrochloride was filtered off and washed with toluene. The combined toluene solutions were washed once with ice water, dried, and evaporated under reduced pressure, resulting in 2.35 g (97.5%) of yellow syrup. $[\alpha]_D^{20}$: −18.0°; n_D^{20}: 1.4900. Anal. Calc. for $C_{16}H_{27}Cl_3NO_7P$: C, 39.81; H, 5.64; N, 2.90. Found: C, 39.3; H, 5.8; N, 2.90.

2,3:4,5-Di-O-isopropylidene-β-D-fructopyranose-1-(N-bis-β-chloroethyl)-benzyl-phosphoramidate (VII)

Compound VI (7.42 g) and 1.67 ml benzyl alcohol were refluxed with 2.22 ml triethylamine in 40 ml toluene for 20–24 hours. After working up as above, the yield was 6.32 g (75%) of a yellow syrup. $[\alpha]_D^{20}$: −16.2°; n_D^{25}: 1.4982. Anal. Calc. for $C_{23}H_{34}Cl_2NO_8P$: C, 49.83; H, 6.18; N, 2.53. Found: C, 49.32; H, 6.26; N, 2.73.

2,3:4,5-Di-O-isopropylidene-β-D-fructopyranose-1-(N-bis-β-chloroethyl)-phosphoramidate (VIII)

Compound VII (1.1 g) was dissolved in 15 ml ethanol and hydrogenated in the presence of 0.2 g of 5% Pd–C catalyst. It consumed 46 ml hydrogen (calc. 48 ml) in 50 minutes. After filtration, it was evaporated under reduced pressure. The residue was a yellow syrup, 0.90 g (93%). $[\alpha]_D^{20}$: −18.0°; n_D^{25}: 1.4830. Anal. Calc. for $C_{16}H_{28}Cl_2NO_8P$: C, 41.39; H, 6.08; N, 3.02. Found: C, 41.8; H, 6.7; N, 3.10.

Ethyl-(α,β?)-D-fructopyranoside-1-(N-bis-β-chloroethyl)-phosphoramidate (XI)

Compound VII (1.05 g) was dissolved in 3 ml of 16% ethanolic hydrochloric acid. After standing for 2.5 hours at room temperature, the red reaction mixture was evaporated to dryness under reduced pressure, dissolved again in 10 ml ethanol, and hydrogenated in the presence of Pd–C catalyst. Worked up as usual, the resulting yellow syrup weighed 0.67 g (72.5%). $[\alpha]_D^{20}$: −8.3°; n_D^{25}: 1.493. Anal. Calc. for $C_{12}H_{24}Cl_2NO_8P$: C, 34.96; H, 5.87; N, 3.40. Found: C, 35.61; H, 6.04; N, 3.39.

THE PREPARATION OF SOME THIOSEMICARBAZONES AND THEIR COPPER COMPLEXES

PART III[1]

B. A. GINGRAS, T. SUPRUNCHUK, AND C. H. BAYLEY
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received February 7, 1962

ABSTRACT

Reactions of some diketones with thiosemicarbazide have been studied under various conditions. Monothiosemicarbazones, dithiosemicarbazones, and cyclization products can be obtained. It was found that dithiosemicarbazones form 1:1 complexes with Cu(II) but failed to react with Cu(I). Dithiosemicarbazones in which the N^2-hydrogen atom has been replaced by Me do not form complexes, confirming our views about the importance of this hydrogen atom in the thione ↔ thiol tautomerism necessary for complex formation. 4,4-Dimethyldithiosemicarbazones behave like the unsubstituted parent compounds in forming 1:1 complexes with Cu(II). Infrared spectra provide evidence for the structure of a cyclization product, 5,6-diphenyl-3-thio-1,2,4-triazine, which had been erroneously described by various authors as the thiol tautomer, 5,6-diphenyl-3-mercapto-1,2,4-triazine.

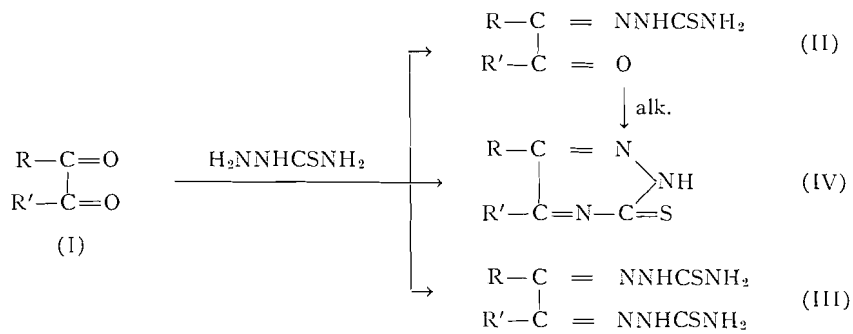
In previous publications (1, 2), the reactions of thiosemicarbazones (tscs) with Cu(I) and Cu(II) ions were reported. A polymeric structure was suggested for the insoluble 1:1 complexes obtained from these reactions (2), and the antifungal activity of both free tscs and their copper complexes was also reported (3). The present work describes the reactions of mono- and di-tscs with a number of metals. It was found that monotscs which form complexes readily with copper in alkaline or neutral solution fail to react similarly with the following metals: Ag(I), Hg(II), Ni(II), Mn(II), Zn(II), Sn(II), Co(II), Fe(II), and Fe(III). Guha-Sircar *et al.* (4) obtained solid precipitates from tscs and several of these metals at pH from 3 to 7, and suggested that this reaction could be used for the quantitative determination of cations. In the present work, precipitates were obtained with the cations mentioned above but no definite products were isolated. The high metal content (approx. 50%) indicated that these solid materials were mostly inorganic, consisting probably of the metal sulphides.

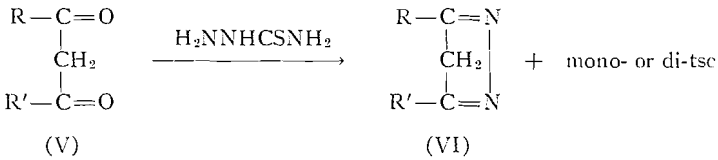
The fact that tscs form definite complexes with copper only, coupled with our previous finding that antifungal activity is usually limited to the free tscs, the complexes being inactive (3), is believed to be quite significant in the study of the mechanism of antifungal action of these compounds. The role and the nature of the metal in biological processes involving metal-binding substances is of great importance (5) and work is currently being carried out along this line and will be reported elsewhere.

A number of dithiosemicarbazones (ditscs) were prepared from dicarbonyl compounds in order to examine their reaction with metals and eventually to study their antifungal properties. The reaction of dicarbonyl compounds with thiosemicarbazide is not simple and mixtures of products are usually obtained. The separation of these mixtures is complicated by the low solubility of the various components and the discrepancies encountered in the literature concerning their melting points.

Glyoxal (I) (R = R′ = H) and diacetyl (I) (R = R′ = CH_3) gave readily the ditscs (III), but benzil (I) (R = R′ = C_6H_5) afforded a mixture of monotscs (II), ditscs (III), and the cyclization product 5,6-diphenyl-3-thio-1,2,4-triazine (IV) (R = R′ = C_6H_5).

[1]*Issued as N.R.C. No. 6795.*

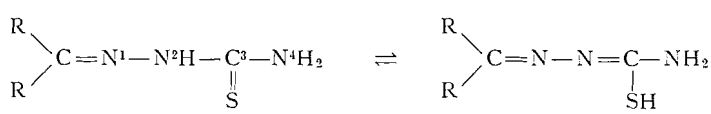




In the case of 1,3-diphenyl-1,3-propanedione (V) (R = R′ = C_6H_5), the monotsc and a cyclization product, 3,5-diphenyl pyrazole (VI) (R = R′ = C_6H_5), were obtained, while many attempts to isolate the ditsc were unsuccessful. Pyrazoles are usually obtained from reaction of 1,3-dicarbonyl compounds with hydrazine or semicarbazides (6), so it is not surprising that thiosemicarbazide should give rise to similar compounds. 1-Phenyl-1,3-butanedione (V) (R = CH_3, R′ = C_6H_5) gave the expected ditsc plus an unidentified product, $C_{20}H_{19}N_5S$. 2,5-Hexanedione, 2,3-heptanedione, and 2,3-octanedione gave the expected ditscs and no other tractable products. We failed to isolate the mono- or di-tsc from acetyl acetone, and part of the diketone must have been broken down since acetyl thiosemicarbazide was identified from the reaction mixture.

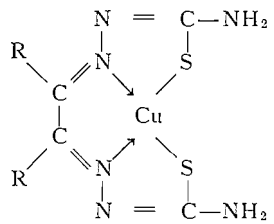
The preparation of Cu(II) and Ni(II) complexes with a few ditscs (diacetyl, 2,3-pentanedione, 2,3-hexanedione, 1-phenyl-1,2-propanedione ditscs) has been previously described (7–9). Later, Górski *et al.* (10) obtained metal complexes with the ditsc of the diethyl ester of 2,3-dioxobutane-1,4-dicarboxylic acid, but did not isolate the compounds. We found that ditscs examined in this work formed 1:1 complexes readily with Cu(II)* but no definite products were obtained using Cu(I) in ammoniacal solution, or with Fe(II), Fe(III), Zn(II), Sn(II), Co(II), Hg(II), or Ag(I) in neutral or alkaline solution.

Substituted ditscs were prepared from 2-methyl and 4,4-dimethyl thiosemicarbazide with glyoxal, and their reaction with copper was studied. The 2-methyl derivative did not form a complex, confirming our previous findings (2) that the N^2-hydrogen atom is a requirement of the tautomeric equilibrium illustrated below, which is necessary for the formation of complexes.



**2,5-Hexanedione and 2,3-heptanedione ditscs gave solid precipitates with Cu(II) but no definite products could be identified.*

On the other hand, both glyoxal and diacetyl di(4,4-dimethyl)tscs readily formed 1:1 copper complexes, as did the unsubstituted ditscs. Considering that ditscs contain two thiosemicarbazide residues, the 1:1 complexes described here may be regarded as 2:1 with respect to the thiosemicarbazide–copper ratio, for the important species here is the thiosemicarbazide residue, $=N—NH—CS—NH_2$, which alone is responsible for complex formation. On this basis, ditsc–copper complexes are quite different from monotsc–copper complexes, in which the ratio of thiosemicarbazide to copper is unity. The structure of ditsc–copper complexes is probably best represented by the conventional formula (VII), previously suggested by Bähr (7).



(VII)

The compounds discussed in this work are listed in Table I together with their infrared spectra. Only two regions of the spectrum are of particular interest, the 3500–3000 cm^{-1}

TABLE I

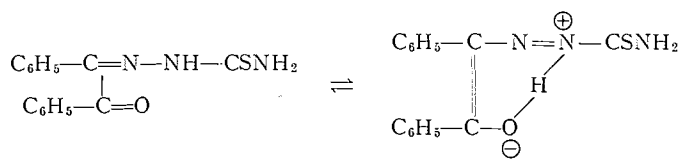
Compounds and their infrared spectra in two regions

Compounds		3500–3000 cm^{-1}	1700–1500 cm^{-1}
Glyoxal ditsc		3380 m, 3230 m, 3130 m	1650 w, 1605 s
Glyoxal di(2-methyl)tsc		3420 s, 3240 s, 3120 m	1685 w, 1675 w
Glyoxal di(4,4-dimethyl)tsc		3425 s, 3200 m, 3045 w	1575 m, 1550 m
Glyoxal ditsc-Cu(II)		3440 w, 3390 m, 3250 w	1655 m, 1630 m, 1570 m
Glyoxal di(4,4-dimethyl)tsc-Cu(II)		3420 m	1625 w, 1570 w
Diacetyl ditsc		3425 s, 3200 s, 3260 w, 3160 w	1695 w, 1600 w
Diacetyl di(4,4-dimethyl)tsc		3280 m	1525 s
Diacetyl ditsc-Cu(II)		3400 s, 3290 s, 3140 s	1630 s, 1595 s
Diacetyl di(4,4-dimethyl)tsc-Cu(II)		3410 m	1500 s
2,5-Hexanedione ditsc		3400 s, 3200 s, 3140 w	1585 s, 1515 s
2,3-Heptanedione ditsc		3440 m, 3280 m, 3160 m	1600 s
2,3-Octanedione ditsc		3400 m, 3240 w, 3140 w	1690 w, 1600 s
2,3-Octanedione ditsc-Cu(II)		3290 w, 3140 m	1615 m, 1585 m, 1530 m
1-Phenyl-1,3-butanedione ditsc		3410 w, 3220 m, 3120 w	1585 s, 1540 w
1,3-Diphenyl-1,3-propanedione monotsc		3440 m, 3300 s, 3150 w	1590 s, 1575 w
3,5-Diphenyl pyrazole		—	1610 w, 1590 w, 1575 w
Benzil monotsc		3150–3120 b	1555 s, 1500 w
Benzil ditsc		3420 w, 3220 m, 3140 m	1660 s, 1600 s
5,6-Diphenyl-3-thio-1,2,4-triazine	(KBr)	3120 m	1585 w, 1565 m, 1540 s
	(Soln.)	3380 m	1585 w, 1550–1500 b
5-6-Diphenyl-3-oxy-1,2,4-triazine	(KBr)	3400 m	1680–1650 b, 1600 m, 1585 m, 1565 s
	(Soln.)	3400 m	1700–1650 b, 1590 s, 1565 s
5,6-Diphenyl-3-thio-1,2,4-triazine-Cu(II)		3400 m, 3060 w	1625 w, 1600 m

NOTE: s, strong; m, medium; w, weak; b, broad. Unless otherwise noted, the spectra were taken from KBr pellets.

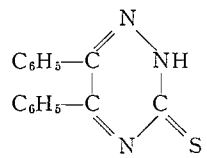
(N—H stretching) and the 1700–1500 cm^{-1} (double-bond region). The spectra of ditscs resemble those of monotscs discussed earlier (2). Due to the overlapping of the bands in the N—H region, it has not been possible to ascribe the various absorptions to definite vibrations. It can be seen that the copper complexes have one more band in the double-bond region than the original compounds and this is in agreement with the suggested formula for the complexes.

As can be seen from the table, the spectrum of benzil monotsc shows a broad NH absorption at 3120–3150^{-1} and the band at 1555 cm^{-1} is a little low for the free carbonyl group. Considering the spectrum of benzil ditsc, which has no carbonyl, the bands in the double-bond region due to C=N are at 1660 and 1600 cm^{-1}. The lack of a carbonyl absorption in the case of benzil monotsc can be explained by a conjugate chelation between the carbonyl and the NH group of the thiosemicarbazide residue:

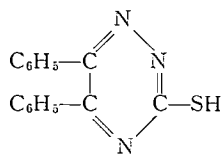


This phenomenon has been observed before with dicarbonyl compounds (11) and the presence of the broad NH band, due to the hydrogen bridge, lends support to this theory. This agrees with the findings of Sadler (12) that in α-diketone monotscs, strong intramolecular NH·····O=C bonds predominate.

The spectrum of 5,6-diphenyl-3-thio-1,2,4-triazine (IV*a*) is particularly interesting in that it shows one sharp NH band at 3120 cm^{-1} (KBr), 3380 cm^{-1} (chloroform solution), and no SH band could be observed in either media. This triazine has been described before (8, 13, 14) and its structure was assumed to be (IV*b*) and not (IV*a*). On the basis

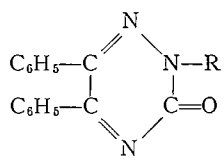


(IV*a*)



(IV*b*)

of its infrared spectrum, structure (IV*a*) is to be preferred and the tautomer (IV*b*) probably does not exist in the solid state nor in solution in chloroform. This is in agreement with similar findings that open-chain tscs exist only in the thiono form in the solid state (15), and 3-mercapto-5-oxo-1,2,4-triazines were recently shown to exist in the keto and thiono forms in neutral solution (16). However, there is little doubt that in the presence of a base, the thione ↔ thiol tautomerism takes place since both tscs and thiotriazine dissolve in alkali, and the S-Na salt of acetone tsc has already been described (17). As a comparison, the analogous 3-oxy-1,2,4-triazine (VIII) was prepared and its infrared



(VIII) R = H
(IX) R = CH_3

spectrum taken both in the solid state and in chloroform solution. The same behavior was found in this case and no OH bands were detected. The weak peak at 3450 cm^{-1} (KBr) and 3350 cm^{-1} (chloroform) is due to N—H stretching. Furthermore, there is no doubt about the strong carbonyl absorption at 1685 cm^{-1}, both in KBr and chloroform.

Chemical evidence also supports the ketonic structure of the oxytriazine, since all attempts to methylate the O atom failed, the product being the N-CH_3 derivative (IX) (18).

The structure of 3,5-diphenyl pyrazole (VI) (R = R′ = C_6H_5) is confirmed by its infrared spectrum, which is of requisite character, the lack of NH bands being its most significant feature.

EXPERIMENTAL

The diketones and thiosemicarbazide were reagent grade material. Glyoxal was a 30% aqueous solution. 2-Methyl and 4,4-dimethyl thiosemicarbazides were prepared in this laboratory as previously described (19, 20). All melting points were taken on a Fisher-John apparatus and are corrected.

Glyoxal ditsc

Glyoxal (30% aq. soln.) (20 g, 0.1 mole) was dissolved in ethyl alcohol (250 ml) and the solution heated on a steam bath. To this was added a solution of thiosemicarbazide (18.2 g, 0.2 mole) in water (600 ml) containing acetic acid (40 ml). A solid precipitated out and heating was continued for 15 minutes. The mixture was cooled and the solid was collected by filtration and washed with hot alcohol and hot acetone; m.p. > 300° C decomp.; lit. m.p. > 300° C (1), 17.2 g, 84.6%.

Glyoxal Di(2-methyl)tsc

Glyoxal (30% aq. soln.) (20 g, 0.1 mole) was added dropwise to a solution of 2-methyl thiosemicarbazide (4.75 g, 0.045 mole) in water (150 ml), and the mixture heated at 50° C for 10 minutes. A yellow solid precipitated out which, after cooling of the mixture, was separated by filtration, washed, and dried; m.p. 276° C, 1.83 g, 35%. Calc. for $C_6H_{12}N_6S_2$: C, 31.00; H, 5.17; N, 36.2; S, 27.6%. Found: C, 31.20; H, 5.11; N, 36.00; S, 27.6%.

Glyoxal Di(4,4-dimethyl)tsc

Glyoxal di(4,4-dimethyl)tsc was prepared similarly using glyoxal (11.83 g, 0.025 mole) in alcohol (100 ml) and 4,4-dimethyl thiosemicarbazide (5.95 g, 0.05 mole) in water (100 ml) containing acetic acid (10 ml). A yellow precipitate was collected and washed with boiling alcohol; m.p. 203° C, 5.05 g, 77%. Calc. for $C_8H_{16}N_6S_2$: C, 36.9; H, 6.16; N, 32.3; S, 24.6%. Found: C, 36.83; H, 6.13; N, 32.45; S, 25.0%.

Glyoxal ditsc-Cu(II)

To a gently refluxing solution of glyoxal ditsc (2 g, 0.01 mole) in N,N-dimethylformamide (100 ml) was added dropwise, with stirring, a hot solution of cupric acetate (2 g, 0.01 mole) in 40 ml of aqueous alcohol (50%). Heating was continued for 15 minutes and the black precipitate was collected; m.p. 236° C, 1.9 g, 71.4%. Calc. for $C_4H_6N_6S_2 \cdot Cu$: C, 18.07; H, 2.26; N, 31.62; S, 24.1; Cu, 23.96%. Found: C, 18.77; H, 2.87; N, 30.90; S, 24.3; Cu, 23.96%.

Glyoxal Di(4,4-dimethyl)tsc-Cu(II)

Cupric acetate (3.4 g, 0.017 mole) in alcohol (100 ml) was added to a hot solution of glyoxal di(4,4-dimethyl)tsc (4 g, 0.017 mole) in dimethyl sulphoxide (450 ml), and heating on the steam bath was continued for 15 minutes. The resulting purple solution was allowed to cool, and after addition of water, the crystals that formed were collected, washed with water and hydrochloric acid (3%), and recrystallized from alcohol. The 1:1 copper complex had m.p. 244° C, 3.86 g, 70%. Calc. for $C_8H_{14}N_6S_2 \cdot Cu$: C, 29.78; H, 4.65; N, 26.05; S, 19.84; Cu, 19.7%. Found: C, 30.12; H, 4.36; N, 26.10; S, 19.78; Cu, 19.9%.

Diacetyl ditsc

This was prepared by adding a warm solution of thiosemicarbazide (3.6 g, 0.04 mole) in water (120 ml) containing 6 ml of acetic acid to a warm solution of diacetyl (1.72 g, 0.02 mole) in ethyl alcohol (200 ml). The yellow precipitate obtained was collected and washed with boiling alcohol and acetone; m.p. 272° C, lit. m.p. 255° C (9), 4.5 g, 97%. Calc. for $C_6H_{12}N_6S_2$: C, 31.05; H, 5.18; N, 36.2; S, 27.6%. Found: C, 31.50; H, 5.35; N, 36.05; S, 27.24%.

Diacetyl Di(4,4-dimethyl)tsc

This was prepared as above using diacetyl (1.72 g, 0.02 mole) in ethyl alcohol (100 ml) and 4,4-dimethyl thiosemicarbazide in water (100 ml) and acetic acid (8 ml). The compound obtained had m.p. 198° C, 1.9 g, 32.9%. Calc. for $C_{10}H_{20}N_6S_2$: C, 41.7; H, 6.95; N, 29.2; S, 22.2%. Found: C, 42.3; H, 7.5; N, 28.8; S, 22.15%.

Diacetyl ditsc-Cu(II)

To a hot solution of diacetyl ditsc (2.4 g, 0.01 mole) in dimethylformamide (240 ml) was added copper acetate (2 g, 0.01 mole) in water (50 ml), and the mixture was heated and stirred for an additional 15 minutes. A dark colored precipitate was formed which, after cooling of the mixture, was collected and washed with hydrochloric acid (3%), water, hot alcohol, and acetone; m.p. 267° C decomp., 2.09 g, 71%. Calc. for $C_6H_{10}N_6S_2 \cdot Cu$: C, 24.55; H, 3.41; N, 28.63; S, 21.8; Cu, 21.6%. Found: C, 24.04; H, 3.59; N, 28.7; S, 21.8; Cu, 21.2%.

Diacetyl Di(4,4-dimethyl)tsc-Cu(II)

A solution of cupric acetate (1.04 g, 0.005 mole) in alcohol (100 ml) was added dropwise to a refluxing solution of diacetyl di(4,4-dimethyl)tsc (1.5 g, 0.005 mole) in chloroform (150 ml) and heating was continued for 15 minutes, during which time a solid precipitated out. After cooling of the mixture, the precipitate was collected, washed, and crystallized from acetone; m.p. 300° C, 0.32 g, 17.4%. Calc. for $C_{10}H_{19}N_6S_2 \cdot Cu$: C, 34.25; H, 5.43; N, 23.95; S, 18.25; Cu, 18.12%. Found: C, 35.17; H, 5.25; N, 24.2; S, 18.6; Cu, 17.93%.

2,5-Hexanedione ditsc

This was prepared by adding a warm solution of thiosemicarbazide (3.6 g, 0.04 mole) in water (120 ml) containing acetic acid (16 ml) to a solution of 2,5-hexanedione (2.28 g, 0.02 mole) in alcohol (200 ml). The white precipitate obtained had m.p. 272° C, 4.5 g, 86.5%. Calc. for $C_8H_{16}N_6S_2$: C, 36.95; H, 6.15; N, 32.3; S, 24.6%. Found: C, 37.13; H, 6.54; N, 32.0; S, 24.5%.

2,3-Heptanedione ditsc

This was obtained as above using 2,3-heptanedione (12.8 g, 0.1 mole) in alcohol (200 ml) and thiosemicarbazide (18.2 g, 0.2 mole) in water (600 ml) containing acetic acid (40 ml). The product, after recrystallization from aqueous ethyl cellosolve, had m.p. 218° C; lit. m.p. 222° C (9), 10.5 g, 40%.

2,3-Octanedione ditsc

This was made by the usual method starting with 2,3-octanedione (4.26 g, 0.03 mole) in alcohol (200 ml) and thiosemicarbazide (5.47 g, 0.06 mole) in water (200 ml) and acetic acid (10 ml). The product, 4.75 g, 55%, had m.p. 230° C. Calc. for $C_{10}H_{20}N_6S_2$: C, 41.7; H, 6.94; N, 29.15; S, 22.20%. Found: C, 41.93; H, 7.28; N, 28.6; S, 22.10%.

2,3-Octanedione ditsc-Cu(II)

Copper acetate (2 g, 0.01 mole) in water (80 ml) was added dropwise to a refluxing solution of 2,3-octanedione ditsc (2.88 g, 0.01 mole) in N,N-dimethylformamide (100 ml). The mixture was stirred and heating was continued for 15 minutes, during which time a brown precipitate was formed. This was collected, washed with water, and recrystallized from alcohol; m.p. 225° C, 0.65 g, 18.6%. Calc. for $C_{10}H_{18}N_6S_2 \cdot Cu$: C, 34.38; H, 5.16; N, 24.01; S, 18.3; Cu, 18.17%. Found: C, 34.81; H, 5.75; N, 23.95; S, 17.92; Cu, 17.9%.

1-Phenyl-1,3-butanedione ditsc

The usual procedure of adding an aqueous solution of thiosemicarbazide to the diketone in alcohol afforded only an unidentified product of m.p. 106° C: $C_{20}H_{19}N_5S$. The required ditsc was obtained by using the following method:

Thiosemicarbazide (1.9 g, 0.02 mole) in boiling alcohol (150 ml) was added to the previously molten 1-phenyl-1,3-butanedione (1.62 g, 0.01 mole). The resulting solution was refluxed for 30 minutes and allowed to cool. The ditsc crystallized out and, after recrystallization from *n*-hexane, had m.p. 131° C, 0.39 g, 12.6%. Calc. for $C_{12}H_{16}N_6S_2$: C, 46.7; H, 5.2; N, 27.28; S, 20.78%. Found: C, 46.85; H, 5.23; N, 27.20; S, 20.40%.

Reaction of 1,3-Diphenyl-1,3-propanedione with Thiosemicarbazide

A solution of thiosemicarbazide (1.8 g, 0.02 mole) in water (60 ml) and acetic acid (8 ml) was added to the diketone (4.49 g, 0.02 mole) in alcohol (110 ml), and the resulting mixture was heated for 15 minutes on the steam bath and allowed to cool. 3,5-Diphenyl pyrazole crystallized out, and after filtration, it was recrystallized from benzene–hexane; m.p. 197° C, 1.55 g, 35.4%; lit. m.p. 197–200° C (21). Calc. for $C_{15}H_{12}N_2$: C, 81.8; H, 5.45; N, 12.7%. Found: C, 82.0; H, 5.45; N, 12.55%.

The mother liquor, after addition of water, yielded the monotsc (0.85 g, 14.3%), which, after recrystallization from benzene–hexane, and from alcohol, had m.p. 128° C. Calc. for $C_{16}H_{15}N_3OS$: C, 64.6; H, 5.05; N, 14.13; S, 10.78%. Found: C, 64.57; H, 5.38; N, 14.78; S, 10.58%.

Reaction of Benzil with Thiosemicarbazide

As the conventional method of condensation gave mixtures of products, the following modified procedure was used:

Benzil (2.1 g, 0.01 mole) and thiosemicarbazide (1.8 g, 0.02 mole) were dissolved in N,N-dimethylformamide, and concentrated hydrochloric acid (3 ml) was added. After being heated on the steam bath for 4 hours, the solution was allowed to evaporate slowly until benzil ditsc had precipitated out. The product

was collected and washed with water followed by hot alcohol. It had m.p. 217° C, 1.15 g, 42.4%. Calc. for $C_{16}H_{16}N_6S_2$: C, 53.9; H, 4.49; N, 23.6; S, 17.99%. Found: C, 52.98; H, 4.58; N, 23.4; S, 17.40%.

5,6-Diphenyl-3-thio-1,2,4-triazine was obtained in a 67% yield by a method described previously (22). The compound, after recrystallization from acetone, had m.p. 220° C; lit. m.p. 233° C (22), 226° C (23). Calc. for $C_{15}H_{11}N_3S$: C, 67.9; H, 4.15; N, 15.84; S, 12.08%. Found: C, 67.31; H, 3.92; N, 16.12; S, 12.28%.

A small amount of benzil monotsc was identified as a by-product, and after recrystallization from acetone, had m.p. 190° C; lit. m.p. 188° C (23). Calc. for $C_{15}H_{13}N_3OS$: C, 63.7; H, 4.6; N, 14.84; S, 11.3%. Found: C, 64.14; H, 5.48; N, 14.50; S, 10.93%.

5,6-Diphenyl-3-thio-1,2,4-triazine-Cu(II)

A small amount (200 mg) of copper complex was obtained from the addition of copper acetate (10 g, 0.05 mole) in water (200 ml) to a boiling solution of the triazine (13.8 g, 0.05 mole) in a large excess of acetone (500 ml). The complex precipitated out and was separated by filtration, washed successively with water, hydrochloric acid (3%), alcohol, acetone, and finally recrystallized from pyridine, m.p. 302° C. There was not sufficient material for further purification, but the elementary analysis is in fair agreement with the calculated values. Calc. for $C_{15}H_{10}N_3S \cdot Cu$: C, 54.9; H, 3.06; N, 12.82; S, 9.77; Cu, 19.38%. Found: C, 53.2; H, 3.12; N, 13.19; S, 10.02; Cu, 18.1%.

ACKNOWLEDGMENTS

Our thanks are due Mr. E. C. Goodhue and Mr. R. Ironside, both of the Analytical Section, for carrying out the metal analyses and for taking the infrared spectra respectively.

ELECTRON SPIN RESONANCE OF X-RAY-IRRADIATED SINGLE CRYSTALS OF *dl*-ALANINE HYDROCHLORIDE

W. C. LIN AND C. A. MCDOWELL
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received January 18, 1962

ABSTRACT

The electron spin resonance of an X-ray-irradiated single crystal of *dl*-alanine hydrochloride indicates that the radical formed is probably the same as that produced by X- and γ-ray irradiation of alanine. The components of the hyperfine interaction tensor for the radical have been evaluated.

INTRODUCTION

The electron spin resonance (e.s.r.) spectra of X-ray-irradiated single crystals of α-alanine was first studied in detail by Miyagawa and Gordy (1). They identified the radical as CH_3—$\dot{C}$H—R. The odd electron was found to have a nearly isotropic hyperfine interaction with the three methyl protons, and an anisotropic hyperfine interaction with the α-proton.

Alanine crystals have orthorhombic symmetry and the unit cell contains four molecules. There are, therefore, four non-equivalent molecular sites for each crystal orientation. Only when the external field is parallel to a crystal axis do the four site spectra become coincident. This means that for the principal element, say A_1 of the hyperfine interaction tensor **A**, there are four different sets of values for the direction cosines. Neither the signs of these direction cosines nor those of principal values of **A** can be determined conveniently from the experimental data. Miyagawa and Gordy (1) made use of observed second-order effects to analyze their spectra, and calculated values for the components of the interaction tensor, which have been corrected recently by Morton and Horsfield (2), who made further studies on single crystals of alanine.

We here report the results we have obtained in studies of the e.s.r. spectra of irradiated single crystals of *dl*-alanine hydrochloride. The advantage of studying this compound is that the crystals are monoclinic and there are not so many complications as in the case of alanine. There are only two non-equivalent sites in such crystals. When the *b* axis of this type of crystal is placed vertical in the magnetic field, the two sites become equivalent.

EXPERIMENTAL

The crystals of *dl*-alanine hydrochloride were grown from aqueous solution. An idealized diagram of the monoclinic crystals of *dl*-alanine hydrochloride is shown in Fig. 1. The relevant crystallographic data (Dr. J. Trotter, personal communication) are: monoclinic, space group $P2_1/c$, $a = 9.20 \pm 0.02$ Å, $b = 9.04 \pm 0.02$ Å, $c = 7.31 \pm 0.02$ Å, $\beta = 95°21' \pm 5'$. There are four molecules per unit cell. Suitable specimens were irradiated at room temperature with 50 kv X rays for several hours. After irradiation the crystals were studied in our 9 Gc/sec e.s.r. spectrometer with 10 kc/sec modulation and using a 6-in. Varian magnet with pole shims to provide a homogeneous magnetic field (3). The error in measuring the angular rotation of the crystals was about ±2°, and the hyperfine splitting constants are probably correct to about ±0.5 gauss.

RESULTS AND DISCUSSION

The energy levels of an oriented radical in a single crystal (with orbitally quenched electron angular momentum) in external field can be calculated from the Hamiltonian

$$\mathcal{H} = g\beta\mathbf{H}.\mathbf{S} + \mathbf{S}.\mathbf{A}.\mathbf{I} - g_n\beta_n\mathbf{H}.\mathbf{I} \qquad [1]$$

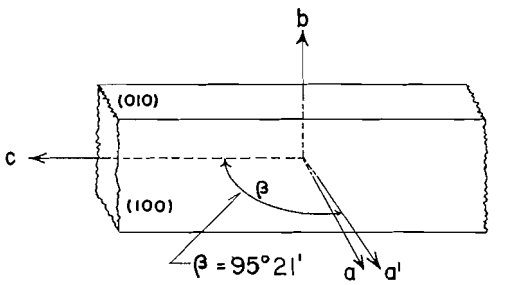

FIG. 1. An idealized sketch showing the relation of the form of the monoclinic crystals of *dl*-alanine hydrochloride to the crystal axes and the experimental reference axes.

and our data have been interpreted in terms of these levels.

The spectra observed were very similar to those of X-ray-irradiated alanine except for certain rather minor differences. In the example shown in Fig. 2 it will be seen that there is a further splitting of the lines into triplets with intensity ratios of 1:2:1. The main pattern in Fig. 2 is regarded as being a five-line spectrum with intensity ratios of 1:4:6:4:1, and that in Fig. 3 an eight-line spectrum with intensity ratios of 1:1:3:3:3:3:1:1. In Fig. 4 is shown a spectrum corresponding to the *c* axis $\perp \mathbf{H}_0$ and an orientation with direction cosines of $\sqrt{3}/2,1/2,0$, with respect to $\mathbf{H}_0$. This illustrates the separation of the two separate spectra due to the two non-equivalent radicals in the unit cell.

Using the hyperfine interactions measured from the spectra we have calculated the π-electron – σ-proton interaction tensor $\mathbf{A}_\sigma$ and the π-electron – methyl proton interaction tensor $\mathbf{A}_m$ with respect to an orthogonal system of axes *a*, *b*, *c*. The crystallographic *b* axis has been taken as our *b* axis but the *a* and *c* axes are chosen arbitrarily. Our *c* axis is along the elongated direction of the crystal. The components of the calculated tensors, in gauss, are:

$$\mathbf{A}_\sigma = \begin{bmatrix} 15.3 & \pm 5.4 & 2.5 \\ \pm 5.4 & 28.3 & 0 \\ 2.5 & 0 & 18.5 \end{bmatrix} \qquad \mathbf{A}_m = \begin{bmatrix} 23.7 & 0 & 0 \\ 0 & 28.3 & 0 \\ 0 & 0 & 21.8 \end{bmatrix} \qquad [2]$$

The direction cosines of the principal values of these tensors with respect to the *a*,*b*,*c* system of axes are given in Table I. In recording these data the principal values of the $\mathbf{A}_\sigma$ tensor have been written with the correct negative sign (4); the $\mathbf{A}_m$ tensor is known to be positive in sign (5).

TABLE I

Direction cosines of principal values of interaction tensors $\mathbf{A}_\sigma$ and $\mathbf{A}_m$ with respect to the *a*,*b*,*c*, system of axes

$\mathbf{A}_\sigma$				$\mathbf{A}_m$			
Principal values	Direction cosines			Principal values	Direction cosines		
	l	*m*	*n*		*l*	*m*	*n*
−12.4	∓0.880	+0.300	±0.360	+28.3	0	1	0
−19.4	∓0.316	+0.191	∓0.930	+23.7	1	0	0
−30.4	∓0.348	−0.934	∓0.074	+21.8	0	0	1

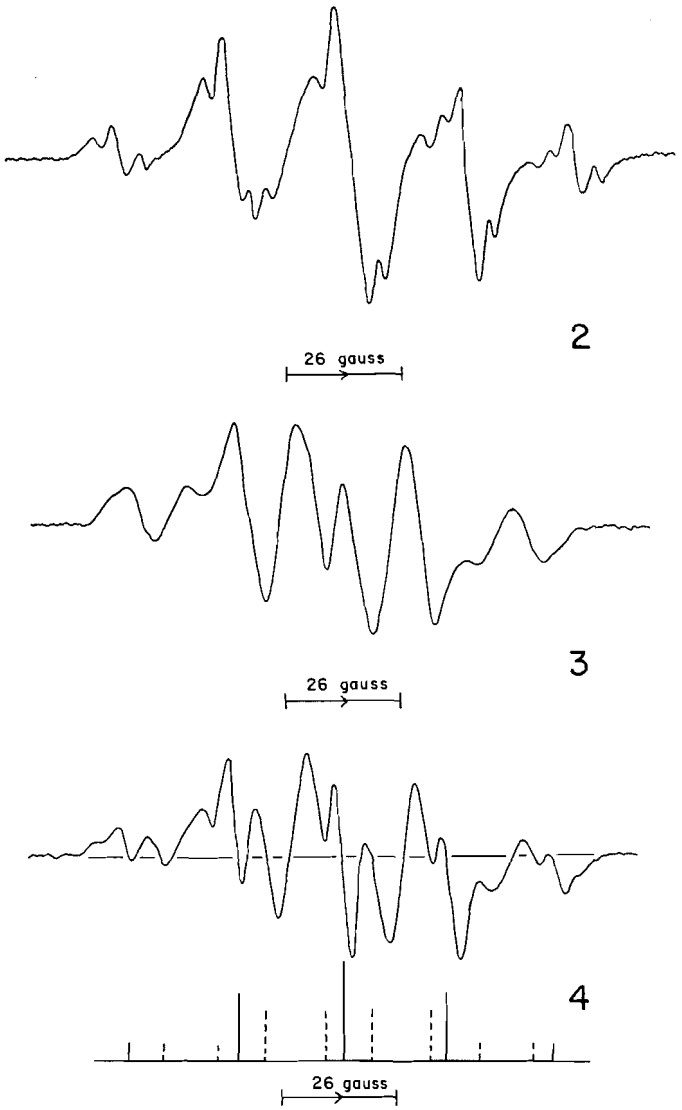

FIG. 2. Electron spin resonance spectrum of an X-ray-irradiated single crystal of *dl*-alanine HCl (H direction cosines: 0,1,0).
FIG. 3. Electron spin resonance spectrum of an X-ray-irradiated single crystal of *dl*-alanine HCl (H direction cosines: $1/2,0,-\sqrt{3}/2$).
FIG. 4. Electron spin resonance spectrum of an X-ray-irradiated single crystal of *dl*-alanine HCl (H direction cosines: $\sqrt{3}/2,1/2,0$).

The values in Table I agree well with those given for the radical produced by X-ray irradiation of alanine (2). The principal values for $\mathbf{A}_\sigma$ are quite similar to those for the $\cdot CH(COOH)_2$ radical (4) and indicate that the unpaired electron density at the α-carbon atom in the radical is approximately 0.9. The values resulting for the electron – methyl protons interaction tensor give an isotropic contribution of 24.6 gauss, which is quite close to the value of 25 gauss estimated for a freely rotating methyl group (5).* The

**This value also agrees well with the recently reported result for a freely rotating methyl group in the* $CH_3 \cdot C(COOH)_2$ *radical (see C. Heller, J. Chem. Phys. 36, 175 (1962)).*

principal values for anisotropic portion of $\mathbf{A}_m$, namely, +3.7, −0.9, −2.8 gauss, are not axially symmetric. Plotting the angular variation of the hyperfine splitting constants for the methyl group on polar diagrams indicates that they are nearly symmetrical (see Table I). There may be a small asymmetry; but in this crystal it is extremely difficult to resolve the small differences between the two nearly isotropic methyl proton hyperfine splittings corresponding to two non-equivalent sites and so one cannot readily determine the degree of anisotropy. This means that calculations of the angle between the C—CH_3 bond and the C—H bond are subject to large errors and for these reasons such calculations are not given here.

Earlier we mentioned that where the lines could be resolved, triplets with intensity ratios of 1:2:1 were found to have a separation of up to 4 gauss. It is likely that this triplet splitting is caused by interaction with protons belonging to a neighboring molecule in the host crystal.

THE PHOTOIONIZATION OF NITROGEN DIOXIDE

D. C. Frost, D. Mak, and C. A. McDowell
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received February 2, 1962

ABSTRACT

The ionization of nitrogen dioxide by photons has been studied using a photoionization mass spectrometric technique and also by the ordinary electron impact method. The photoionization results show a large variation in the relative ionization efficiency within the energy range 9–14 ev, and help to explain the differences between previously reported values for the first ionization potential of this compound. The photoionization efficiency curve indicates the first ionization potential to lie at 9.8 ev and inner ionization potentials to lie at about 11.1 and 12.7 ev.

The electron impact ionization efficiency curve for the NO_2^+ ion exhibits a low ion intensity near the threshold. This confirms the viewpoint that previous determinations of the first ionization potential have employed threshold energy measuring techniques not properly suited for the type of molecule such as nitrogen dioxide which radically changes symmetry on ionization.

INTRODUCTION

The values reported in the literature for the first ionization potential of nitrogen dioxide show a remarkable variation. Electron impact studies have led to the values of 11 ev (1), 11.3 ev (2), and 11.0 ev (3). Kandel (4) deduced a value of 9.91 ev from his studies on the ionization and dissociation of nitromethane. Spectroscopic studies by Price and Simpson (5) led to a value of 12.3 ev for an inner ionization potential based on the extrapolation of two probable Rydberg bands in the far-ultraviolet absorption spectrum of nitrogen dioxide. Further work by Weissler, Sampson, Ogawa, and Cook (6) using a combination of a photoionization monochromator and a mass spectrometer yielded a value of 11.3 ev for the first ionization potential. More recently, photoionization studies carried out by Nakayama, Kitamura, and Watanabe (7) have yielded a value of 9.78 $\pm$0.05 ev for the first ionization potential of nitrogen dioxide, and suggested the occurrence of a second ionization potential at 11.62 ev. It should be pointed out that Weissler *et al.* did not investigate the region below 11 ev in much detail and for this reason missed the first ionization potential of this compound. The work to be described, which included both electron impact and photoionization studies using a mass spectrometer, confirms the previous value obtained from photoionization measurements for the first ionization potential of nitrogen dioxide and also indicates why the other workers may have obtained some of the results quoted.

EXPERIMENTAL

The apparatus, to be fully described elsewhere, basically consists of a 60-deg sector field 6-in. magnetic radius mass spectrometer designed so that it can be used with an electron or a photon ionizing source. The light source was a gas discharge tube, containing mixtures of rare gases and H_2 or D_2, excited at a microwave frequency of 2460 Mc/s. A Seya–Namioka type monochromator was used to provide ionizing radiation. The resolution of the monochromator is about 6 Å, which means the photon energy spread is 0.07 ev at 12 ev. After traversing the mass spectrometer ion chamber, the radiation strikes a sodium-salicylate-coated photomultiplier, the output of which is taken to be proportional to the radiation intensity. The optical system is windowless, and the pressure is kept low through efficient differential pumping. An ion–electron multiplier is used to measure the resolved ion currents. The ratio of ion current to photon intensity is determined at as many wavelengths as possible and then plotted against photon energy (see refs. 6 and 8 for a description of similar instruments). The NO_2 was prepared by reacting oxygen with nitric oxide which had been purified by low-temperature distillation.

DISCUSSION

As mentioned in the Introduction, values reported in the literature for the first ionization potential of NO_2 show remarkable disagreements, and it is the purpose of this paper to present new measurements which help to explain the apparent discrepancies.

Figure 1 shows the photoionization efficiency curve for NO_2^+. It is seen that the threshold energy (9.80 ± 0.05 ev) agrees with the adiabatic value (7). However, the ion intensity

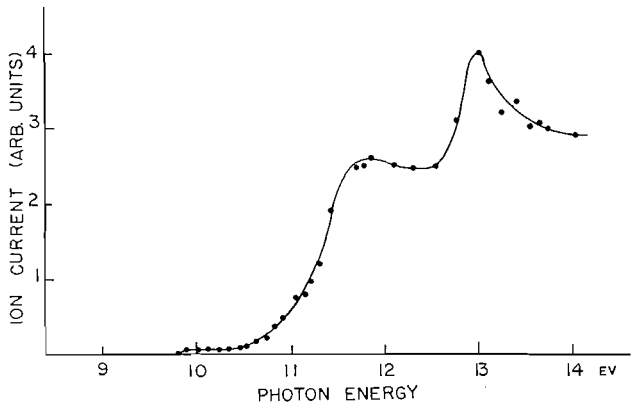

FIG. 1. Photoionization efficiency curve for nitrogen dioxide.

remains low (compared with that at much higher energies) and fairly constant up to about 10.5 ev. Here, an inner adiabatic ionization potential is indicated since the curve begins to rise. The photon energy at the point of greatest slope in this region, about 11.1 ev, should equal the corresponding vertical ionization potential provided ionization is occurring only through this second process. The electron impact measurements of Steuckelberg and Smyth (1), and Collin (2), seem to be associated with our vertical ionization potential at 11.1 ev.

Figure 2 shows the electron impact ion efficiency curves for NO_2^+ and Kr^+, which we obtained using a conventional ion source. Clearly the curved portion of the NO_2^+ ionization efficiency curve extends over a much greater energy range than that of Kr^+, and it

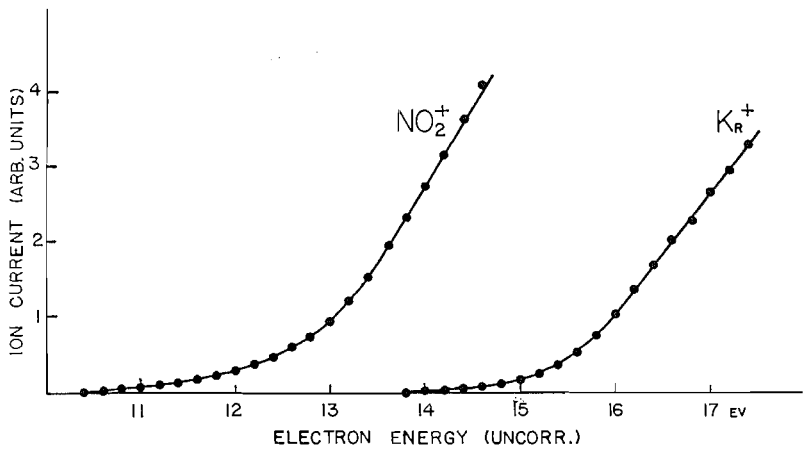

FIG. 2. Electron impact ionization efficiency curve for nitrogen dioxide.

is difficult to decide the threshold energy for NO_2^+ formation. It would seem therefore that in the case of nitrogen dioxide there is likely to be considerable uncertainty as to the interpretation of the first ionization potential from electron impact studies. We find this value to be about 10.5 ev, using the initial upward break method, and, since it lies between the first and second adiabatic ionization potentials, it should decrease as the ion current detector sensitivity is increased.

At photon energies greater than 12 ev the ion efficiency for NO_2^+ shows a slight decrease. Why this should be so is not clear, unless preionization is responsible for the maximum. The ionization increase at about 12.4 ev can be correlated with Price and Simpson's Rydberg series limit at 12.3 ev. The vertical ionization potential here would normally correspond to the photon energy where the photoionization curve has the greatest slope, but it is difficult to account for the peak at 13 ev unless preionization is involved.

We find no evidence to support the proposed ionization potential which Nakayama *et al.* claim to have observed at 11.62 ev. In view of the marked increase in ion current which we observe just below 11 ev, it may well be that the rise in total ionization seen by Nakayama *et al.* at 10.83 ev is only partially due to formation of the ion pair $NO^+ + O^-$ (theoretically formed at a minimum energy at 10.89 ev). We attempted to clarify this point by studying the formation of NO^+ from nitrogen dioxide by photoionization. It was extremely difficult, however, to obtain satisfactory results. Even with very pure nitrogen dioxide as a starting material there seemed to be more NO^+ present than would have been expected from the process under discussion. This extra nitric oxide could probably have been produced by the photolysis of the nitrogen dioxide in the ion chamber. Light of wavelength less than 4000 Å is well known (9) to cause the following reaction:

$$2NO_2 + h\nu = 2NO + O_2. \qquad [1]$$

It is possible that the occurrence of this reaction caused our experiments to be indefinite on this particular point.

Closer examination of the basis on which Nakayama *et al.* evaluated the second ionization potential of 11.62 ev makes it apparent that it may not be so well established as it might at first sight appear. Those authors assigned six absorption bands as Rydberg bands and fitted them to the Rydberg series

$$\nu_m = 93{,}695 - 2/(n+0.21)^2,$$

with $n = 3$, (?), 4, 5, 6, 7, 8 . . . . In Table 2 of their paper they compare the calculated and observed positions of the bands. The agreements for bands with $n = 4$ to 8 are fairly good but in the case of the band with $n = 3$ a discrepancy of 6334 cm^{-1} was found between the observed and the calculated frequencies. Presumably for this reason the authors labelled this band, $n = 3$, as being doubtfully assigned.

The electronic structure of the nitrogen dioxide molecule has been considered by many authors (9–14). Recent work has confirmed the earlier views that the unpaired electron can be regarded as being localized mainly on the nitrogen atom. This would mean that the first ionization potential at 9.8 ev would refer to the removal of an electron from the $4a_1$ molecular orbital. As the nitrogen dioxide molecule is bent in its ground state, it is expected that on ionizing to form NO_2^+ by the removal of an electron from the $4a_1$ orbital, this ion would be formed in its linear ground state. There is evidence that the NO_2^+ ion is, in fact, linear (15). None of the theoretical values for the ionization potentials

agree well with the experimental results. In this connection we may note that McEwen (12) has pointed out that the NO_2^+ ion can be formed in singlet and triplet excited states. It is important to realize that both the radical (NO_2) ground state and the three lowest singlet configurations of the positive ion are strongly stabilized by interaction with low-energy doubly excited configurations. The corresponding interactions with the $^3B_2$ and $^3A_2$ triplet configurations of the ion are much smaller. The difficulty in adequately taking these factors into account in the calculations makes the theoretical results less satisfactory than might have been expected.

ACKNOWLEDGMENTS

We wish to thank the National Research Council of Canada for grants in aid of this work. In earlier phases of this work we were greatly assisted by support from the Geophysical Research Directorate of the U.S. Air Force, Cambridge Research Centre, and we wish to extend our thanks to that body for its generosity.

LYCOPODIUM ALKALOIDS

XII. FLABELLIFORMINE

M. CURCUMELLI-RODOSTAMO AND D. B. MACLEAN
Department of Chemistry, McMaster University, Hamilton, Ontario
Received February 13, 1962

ABSTRACT

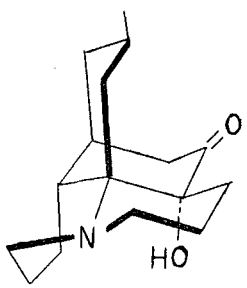
Evidence is furnished which establishes the structure of a new alkaloid isolated from *Lycopodium flabelliforme.*

In the present publication we wish to report evidence which enables the assignment of structure I to a new alkaloid obtained from *Lycopodium flabelliforme.*

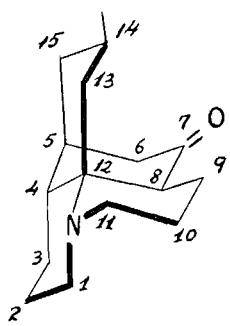
The alkaloid, for which the name flabelliformine seems appropriate, is sparingly soluble in cold ether. Advantage was taken of this property in its isolation from the bases obtained, after the separation of lycopodine from the crude alkaloid mixture.

Analysis of flabelliformine, I, fits the formula $C_{16}H_{25}O_2N$. The infrared spectrum of the alkaloid, measured in chloroform solution, shows ketonic carbonyl absorption at 1705 cm^{-1} and a hydroxyl band at 3560 cm^{-1}. Reduction of the carbonyl group with sodium borohydride affords the diol II, $C_{16}H_{27}O_2N$. The hydroxyl group appears to be attached to a tertiary carbon atom, since flabelliformine is recovered unchanged after treatment with chromium trioxide and its n.m.r. spectrum shows no absorption below a τ-value of 6.5.

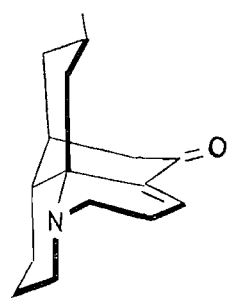
Treatment of the alkaloid with hydrogen iodide replaces the hydroxyl group with hydrogen; the reaction product is identical with lycopodine, III (1–4). Flabelliformine, therefore, is formally derived from lycopodine by replacement of a methine hydrogen by a hydroxyl group.



I



III



IV

Dehydration of I, effected by both phosphoric acid and *p*-toluenesulphonic acid, affords a non-crystalline product, IV, which was converted to a crystalline methiodide, V, $C_{17}H_{26}ONI$. Compound IV has the properties of an α,β-unsaturated ketone. The ultraviolet spectrum of this substance shows maximum absorption at 245 mμ and the infrared spectrum, measured in carbon tetrachloride solution, has bands of equal intensity at 1685 and 1617 cm^{-1}. The n.m.r. spectrum of IV has a triplet at a τ-value of 3.01 which is attributed to a proton on the β-carbon of the α,β-unsaturated carbonyl system (5, 6).

Compound IV is formed without alteration of the carbon skeleton present in the alkaloid, since on hydrogenation, over a platinum catalyst, it yields lycopodine. The double bond must occupy the 8,9 position, as shown. A double bond in the alternative conjugated position would result in a very large distortion of bond angles. The hydroxyl group in I is therefore attached to C_8.

The conversion of flabelliformine, I, to lycopodine, III, proves that both alkaloids have the same configuration at C_4, C_5, C_{12}, and C_{14}.

The configuration at C_8 can be deduced from spectral data. The absorption at 3560 cm^{-1}, in the spectrum of flabelliformine, shows that the hydroxyl group is hydrogen bonded. The bonding is intramolecular, for the peak is not displaced on dilution. A comparison of the infrared and ultraviolet spectra of lycopodine and flabelliformine indicates that the hydroxyl is not hydrogen bonded with the carbonyl oxygen. The infrared spectrum of lycopodine (chloroform solution) shows carbonyl absorption at 1693 cm^{-1}, while that of flabelliformine has a band at 1705 cm^{-1}. Their ultraviolet spectra have maxima at 284 and 303 mμ respectively (7). The hydrogen bonding appears, therefore, to involve the nitrogen lone pair. Structure I, alone, fulfills the spatial requirements for such an interaction.

EXPERIMENTAL

Isolation of Flabelliformine

The crude alkaloid mixture was obtained from *L. flabelliforme* by the method of Manske and Marion (8). Lycopodine was isolated by column chromatography as described by Barclay and MacLean (9). The other, more strongly adsorbed, alkaloids were eluted with chloroform and combined. The mixture of bases was shaken with cold ether and the ether-insoluble residue crystallized from acetone–methanol. The material obtained was dissolved in acetone and treated with 48% hydrobromic acid. Flabelliformine hydrobromide separated immediately. From the mother liquors dihydrolycopodine (2, 10) was obtained. Recrystallization of the hydrobromide from acetone, containing a small quantity of water, gave crystals melting over 337° with decomposition. The alkaloid (I) liberated from the hydrobromide salt melts at 210–211°. A change in crystalline form occurs at 150°. Calc. for $C_{16}H_{25}O_2N$: C, 72.96; H, 9.57; N, 5.32%. Found: C, 73.04; H, 9.68; N, 5.33%.

The infrared spectrum of flabelliformine, determined in chloroform, shows hydroxyl absorption at 3560 cm^{-1}, carbonyl absorption at 1705 cm^{-1}, and a band at 1415 cm^{-1} attributed to a methylene group adjacent to the carbonyl. The ultraviolet spectrum has $\lambda_{max}^{CH_3OH}$ at 303 mμ (ϵ, 50). The n.m.r. spectrum of the alkaloid shows no absorption below a τ-value of 6.5, indicating the absence of the group $\rangle$CH—OH.

Flabelliformine, when treated with methyl iodide in acetone solution, gave a crystalline methiodide which melted over 335° with decomposition. Calc. for $C_{17}H_{28}O_2NI$: C, 50.37; H, 6.96; N, 3.45%. Found: C, 50.75; H, 7.08; N, 3.35%.

Preparation of Compound II

A solution of sodium borohydride (0.20 g) in ethanol was added slowly to a stirred ethanolic solution of flabelliformine (0.15 g). After addition of the hydride solution, the mixture was stirred for 2 hours and then left to stand overnight. Excess reagent was destroyed with acetone and the reaction mixture evaporated to dryness. Water was added to the residue. The mixture was acidified with hydrochloric acid and heated briefly on a steam bath. It was then basified with ammonia and extracted with chloroform. From the chloroform extract a crystalline product (compound II) was obtained (0.12 g) which, on recrystallization from ether, afforded crystals melting at 217–217.5°. Calc. for $C_{16}H_{27}O_2N$: C, 72.41; H, 10.26; N, 5.28%. Found: C, 72.41; H, 10.28; N, 5.28%.

The infrared spectrum (Nujol mull) of compound II shows no carbonyl-group absorption but has two bands in the hydroxyl region at 3610 and 3460 cm^{-1}.

Treatment of Flabelliformine with Chromium Trioxide

A solution of chromium trioxide (0.10 g) in water was added dropwise over a period of 1 hour to a stirred solution of flabelliformine (0.040 g) in 10% aqueous acetic acid. The temperature was maintained at −5 to −10° during the addition, and the mixture was stirred at this temperature for a further 5 hours. The oxidant was destroyed with methanol and the reaction mixture kept in a refrigerator overnight. The solution was then concentrated, made strongly acidic with hydrochloric acid, and extracted with chloroform. It was then basified with ammonia and again extracted with chloroform. From the last extract flabelliformine (0.033 g) was recovered.

Treatment of Flabelliformine with Hydriodic Acid

Flabelliformine (0.05 g) was dissolved in hydriodic acid (4 ml, 47%). The solution was refluxed for 17 hours, then made basic with ammonia and extracted with chloroform. The compound isolated (0.03 g) from the chloroform extract was found to be identical with lycopodine: the melting point of the product was not depressed on admixture with an authentic sample of lycopodine and the infrared spectra of the two samples, measured both in Nujol mull and carbon tetrachloride, were superimposable.

Dehydration of I by Treatment with Phosphoric Acid

A solution of flabelliformine (I) (0.11 g) in 88% aqueous phosphoric acid (7 ml) was heated on a steam bath for 12 hours. The mixture was cooled, made basic with potassium hydroxide, and extracted with chloroform. Evaporation of the chloroform left an oil (IV) (0.09 g) which could not be induced to crystallize.

The infrared spectrum (film) of compound IV shows absorption at 1614 cm^{-1} (conjugated double bond) and 1678 cm^{-1} (conjugated carbonyl); the two bands are situated at 1617 and 1685 cm^{-1} when the spectrum is measured in carbon tetrachloride solution. Compound IV has $\lambda_{max}^{CH_3OH}$ at 245 mμ. The n.m.r. spectrum (in $CDCl_3$) exhibits a triplet at a τ-value of 3.01.

Dissolution of compound IV in acetone and treatment with an excess of methyl iodide afforded a crystalline methiodide, V, which melted over 285° with decomposition. Calc. for $C_{17}H_{26}ONI$: C, 52.71; H, 6.77; N, 3.62%. Found: C, 52.40; H, 6.86; N, 3.55%.

The infrared spectrum (Nujol mull) of compound V shows bands at 1620 and 1688 cm^{-1}.

Dehydration of I by Treatment with p-Toluenesulphonic Acid

A solution of flabelliformine and *p*-toluenesulphonic acid in *o*-xylene was heated under reflux for 12 hours. The reaction mixture was extracted with water. The extract was shaken with ether to remove completely the xylene, basified with ammonia, and extracted with chloroform. The product obtained from the chloroform solution was identical with compound IV described in the preceding section.

Hydrogenation of Compound IV

A solution of compound IV in methanol was shaken with hydrogen (35 p.s.i.g.) and platinum oxide for 16 hours.

The catalyst was removed by filtration and the solvent evaporated. The residue was dissolved in acetone and treated with methyl iodide. A crystalline methiodide separated which melted with decomposition at 315–318°. The methiodide was shown to be identical with lycopodine methiodide by a mixed melting point determination and comparison of infrared spectra.

ACKNOWLEDGMENTS

We wish to express our thanks to the National Research Council of Canada, and to the Ontario Research Foundation, for financial assistance. We are indebted to Mr. J. C. F. Young, who isolated the flabelliformine.

Received February 7, 1962

ABSTRACT

Chemical shift data for the formyl proton in some 30 aromatic aldehydes are reported. It was found that meta- and para-substituted benzaldehydes exhibited this peak in the range 9.65–10.20 δ, while ortho-substituted compounds appear at lower field, 10.20–10.50 δ; the former shifts show an approximate correlation with the Hammett sigma parameter. Evidence for steric inhibition of resonance is presented for some ortho-substituted compounds and some interesting solvent effects are discussed.

INTRODUCTION

Although it is well known (1, 2) that the aldehyde proton absorbs in a characteristic region of the N.M.R. spectrum (i.e., 9–11 p.p.m. from tetramethylsilane), no extensive survey of its resonance position has so far been reported. The present study was undertaken to determine those structural features which influence the chemical shift of this proton. While our investigation has included examples from the aliphatic, alicyclic, and aromatic series, only the latter is discussed in this paper. The results from the other series will be reported in the near future.

On the basis of the present theories of magnetic shielding (3) one can suggest the major structural features which would be expected to contribute to the chemical shift of the formyl proton in an aromatic aldehyde. The shielding of a specific nucleus is considered to be determined by two major factors: (*a*) the electron density about that nucleus, and (*b*) the presence of magnetically anisotropic groupings within the molecule. In this series of compounds, the anisotropic carbonyl group and the aromatic ring would be expected to have pronounced effects on the chemical shifts, as would variations in the electron density about the formyl proton.

For protons, the electron distribution about the nucleus is essentially isotropic and the local effect, (*a*) above, is diamagnetic and directly dependent on the electron density. Therefore, the greater the electron density, the greater will be the shielding, due to the circulations of the electrons surrounding a specific proton. In an aldehyde molecule, the electrophilic character of the carbonyl carbon will tend to polarize the C—H and C—C bonds attached thereto. The polarization of the C—H bond will reduce the electron density about the formyl proton and so must contribute to the low shielding observed for it. Electron-releasing groups bonded to the carbonyl group will reduce the electrophilic nature of the carbonyl carbon and so decrease the polarization of the C—H bond. Thus, it is suggested that formyl protons in conjugated systems would be shielded relative to those in analogous saturated cases. Support for this hypothesis is provided by the observation that, as a rule, carbonyl groups conjugated with ethylenic or phenyl groups are less reactive towards nucleophiles than are simple carbonyl compounds. The

[1]*These results were presented as part of a paper at the 44th Annual Conference of the Chemical Institute of Canada, Montreal, August 3–5, 1961.*

C^{13} chemical shifts of the carbonyl carbon in a number of aldehydes also furnish evidence for this view, since the carbonyl carbons in aromatic and α,β-unsaturated aldehydes appear at significantly higher field than those in related saturated cases (4). This shift is presumably due to the increased electron density about the carbon atom in the conjugated systems. Similar correlations have been presented for C^{13} chemical shifts and electron densities in aromatic molecules (5–7). Similarly, any other factors which affect the polarization of the carbonyl carbon could be expected to be reflected in the chemical shift of the formyl proton.

Pople (8) has shown that a major contribution to the low shielding observed for the formyl proton in aldehydes arises from the anisotropy of the carbonyl grouping. It has been shown that this group has a large diamagnetic anisotropy arising from electron circulations occurring when the applied field is normal to the plane of the trigonal carbon atom (9, 10). Since a detailed discussion of the influence of this grouping on neighboring nuclei has appeared (2) in terms of the point dipole approximation due to McConnell (11), it is sufficient to note that protons in the plane of the trigonal carbon would be subjected to a strong deshielding effect. The orientation of the proton in the formyl grouping cannot change relative to the carbonyl bond in any aldehyde, and so it seems reasonable to assume that this strong effect will be approximately constant in a series of aldehydes.

A third important factor in this series of compounds will be the contribution to the shielding by the aromatic nucleus whose ring current effects are well established (12–15). The anisotropy of the aromatic ring is such that the field induced by the circulation of the π electrons around the ring serves to accentuate the applied field in the plane of the ring and thus to deshield nuclei in this plane. This effect is maximal in the plane of, and close to, the ring and decreases as the orientation of a specific nucleus is changed therefrom. In the aromatic series, it is evident that the formyl proton will not be far removed from this plane at any time and so would experience a strong deshielding effect. In the case of polycyclic aromatics, this effect will be enhanced since the ring current contributions are larger (13).

From these considerations, it is suggested that the important factors which determine the chemical shift of a formyl proton in an aromatic aldehyde include the contributions by the anisotropic carbonyl bond and aromatic ring and the degree of polarization of the formyl C—H bond. It is found that this rather simple model accounts qualitatively for the observed results, although a quantitative evaluation of the relative contributions of these factors is not yet possible because of their interdependence.

EXPERIMENTAL

A Varian V-4302 spectrometer operating at 60 Mc/sec was employed for all measurements. The peak positions were determined using the usual audio side-band technique (16) by interpolation between two side bands of the reference signal placed on either side of the desired peak. An audio oscillator whose output was continuously monitored with a Hewlett-Packard 522B frequency counter was used throughout. In most instances, the compounds were examined in 20, 10, and 5% (w/v) solutions in carbon tetrachloride. If the compound was sparingly soluble in this solvent, a similar range of concentrations in deuterochloroform was measured. A few aldehydes were studied in both solvents to determine the effect of changing the solvent. Some substituted benzaldehydes were examined in acetone, methanol, cyclohexane, and benzene solutions as well. The tabulated data are those obtained for the most dilute solutions (5%) and are given in p.p.m. (δ) relative to internal tetramethylsilane with an estimated precision of ± 0.01 p.p.m. Each value is the mean of at least 10 separate measurements.

The compounds used in this study are commercially available and were purified by distillation or recrystallization before use. Spectrograde carbon tetrachloride (Fisher Scientific) was used throughout and the deuterochloroform was obtained from Merck, Sharpe and Dohme (min. 99% D).

RESULTS

The chemical shift data are collected in tabular form as follows: Table I, meta- and para-substituted benzaldehydes; Table II, ortho-substituted benzaldehydes and polycyclic aromatic aldehydes. For comparative purposes, the data for a few other aldehydes are given in the text below.

TABLE I

Chemical shifts of the formyl proton in some meta- and para-substituted benzaldehydes (in p.p.m. from tetramethylsilane; 5% solution (w/v))

Aldehyde	CCl_4*	$CDCl_3$*
Benzaldehyde	9.96 (+0.02)	10.02 (+0.02)
m-Tolualdehyde	9.90 (+0.03)	9.98 (+0.03)
p-Tolualdehyde	9.89 (+0.03)	9.96 (+0.03)
p-Anisaldehyde	9.81 (+0.02)	—
m-Nitrobenzaldehyde	—	10.13 (−0.03)
p-Nitrobenzaldehyde	—	10.18 (−0.01)
m-Hydroxybenzaldehyde	—	9.91 (—)
p-Hydroxybenzaldehyde	—	9.86 (—)
m-Chlorobenzaldehyde	9.94 (+0.02)	—
p-Chlorobenzaldehyde	9.94 (0.00)	—
3,4-Dichlorobenzaldehyde	9.91 (—)	—

TABLE II

Chemical shift data for the formyl proton in some ortho-substituted benzaldehydes and some polycyclic aldehydes (5% solutions (w/v) in p.p.m. from tetramethylsilane)

Aldehyde	CCl_4*	$CDCl_3$*
Salicylaldehyde	9.86 (+0.05)	9.89 (+0.03)
Benzaldehyde	9.96 (+0.02)	10.02 (+0.02)
o-Tolualdehyde	10.18 (+0.03)	—
o-Nitrobenzaldehyde	10.37 (+0.03)	10.43 (+0.03)
o-Anisaldehyde	10.39† (+0.01)	—
o-Chlorobenzaldehyde	10.45 (+0.04)	—
Mesitylaldehyde	10.49 (+0.04)	—
1-Naphthaldehyde	10.31 (+0.07)	10.38 (+0.07)
2-Naphthaldehyde	—	10.14 (+0.05)
9-Anthraldehyde	—	11.51‡ (+0.24)
Phenanthrene-9-carboxaldehyde	—	10.39‡ (+0.17)

*Bracketed quantity is dilution shift for 20–5% solution.
†This is the center of the observed doublet, $J = 0.8$ cycle/sec, due to coupling with one of the ring protons. This splitting has been noted previously (17).
‡2.5% solutions.

Although spin coupling of aldehydic hydrogen with the ring protons has been observed in a number of heterocyclic cases (17), it can be noted that, in general, the aromatic

formyl protons appear as singlets and spin coupling with the benzenoid protons is not resolved. In the present series, two exceptions were found: *o*-anisaldehyde exhibits a coupling constant of 0.8 cycles/sec for the formyl proton while *m*-fluorobenzaldehyde shows a splitting of 1.8 cycles/sec, but which other nucleus is involved was not established in either case.

DISCUSSION

General Considerations

For aromatic aldehydes, it has been suggested above that the chemical shift of the formyl proton will be determined by the relative magnitudes of two opposing factors since it may be assumed that the deshielding effect of the carbonyl group will be approximately the same in all cases. The local shielding contribution which depends on the polarization of the C—H bond will be opposed by the deshielding influence of the aromatic ring current. Since acetaldehyde absorbs at 9.73 δ and benzaldehyde at 9.96 δ (both in CCl_4 solution), it appears that the ring current effect outweighs the conjugative shielding. For comparative purposes, it may be noted that acrolein and crotonaldehyde absorb at 9.53 and 9.43 δ, respectively. In these two compounds, a conjugative effect would be opposed by the deshielding due to the anisotropic olefinic bond which tends to deshield in its plane, and since the shifts are to higher field relative to acetaldehyde one can conclude that the effect of conjugation is the stronger. Other evidence in support of a shielding effect by conjugation is provided by the C^{13} results mentioned above.

A further indication that the ring current contribution is a major factor affecting the shielding of the formyl proton in benzaldehyde is provided by the chemical shift of this proton in cinnamaldehyde, which absorbs at 9.64 δ (i.e., 0.32 p.p.m. to high field relative to benzaldehyde). There should be a substantial reduction in the ring current effect since the formyl proton is farther removed from the aromatic nucleus and, to a first approximation, the conjugative contribution may be considered to be comparable to that in benzaldehyde. Although this view may be oversimplified, the observed shift is consistent with the argument.

In a series of substituted benzaldehydes changes in the magnitudes of each of the shielding factors could be expected. As a first approximation, however, it seems reasonable to assume that the ring current effect remains virtually constant. Abraham (18) has suggested that the magnitude of the ring current in a given system is related to the resonance energy of that system and since large changes in the resonance energies of the members of this series are not expected, this assumption would appear to be rational. Variations in the polarization of the C—H bond therefore should be more important and the electronic effects of substituents should influence the formyl shifts in a predictable manner. Similar correlations have been discussed for a number of other systems (7, 19–22). Since an electron-releasing substituent would tend to decrease the positive nature of the carbonyl, the shift of the formyl proton in such a system would be expected to be towards higher field, while electron-withdrawing groups would tend to produce the opposite effect. One can consider the results in detail on the basis of these assumptions.

Meta- and Para-substituted Benzaldehydes

The data in Table I show that the formyl proton in this series absorbs in the region 9.65–10.18 δ, and that these shifts depend markedly on the substituent. Qualitatively the trend is as expected for the simple model and the observed shifts appear to be a measure of the electron supply to, or withdrawal from, the carbonyl grouping. Thus, one might

expect a linear correlation between the chemical shifts and the Hammett sigma parameter of the various substituents. Only a rough correlation, however, is observed, as shown in Fig. 1, which was plotted using the sigma values listed by McDaniel and Brown

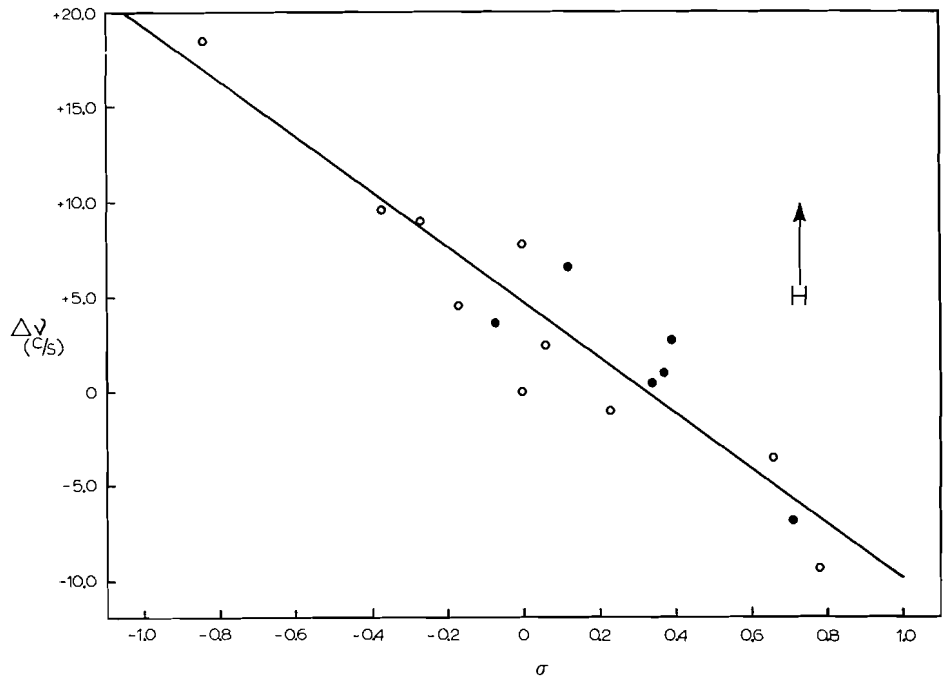

FIG. 1. Correlation of the formyl proton chemical shifts of *m*- and *p*-substituted benzaldehydes by Hammett's σ. The shifts are given in cycles/sec (at 60 Mc/sec) from the peak position of the formyl proton in benzaldehyde. (○ indicates *p*-isomer; ● indicates *m*-isomer.)

(23) and the chemical shifts relative to benzaldehyde. Since some of the samples are insufficiently soluble in carbon tetrachloride to allow measurements over the usual concentration range, the values obtained in deuterochloroform solution were compared to the chemical shift of benzaldehyde in that solvent. No better linear correlation could be obtained using the Taft parameters, σ_R and σ_I (24). The line indicated in Fig. 1 was obtained by a least-squares analysis of the data, considering the shift of benzaldehyde no more reliable than the others.

The largest deviation (ca. 5 cycles/sec) was found for benzaldehyde while other significant deviations (ca. 3.5 cycles/sec) are evident for the *m*-hydroxy-, *m*-bromo, and *p*-acetamido derivatives. It is interesting to find that the para-substituted examples appear to give the closest approach to a linear relation. This could be an indication that the meta substituents exert a small effect through space on the formyl proton. Since rather precise linear free-energy correlations have been obtained for fluorine chemical shifts in *m*- and *p*-substituted fluorobenzenes (19, 20), these results suggest that formyl protons, owing to their lack of inner shell electrons and hence a more exposed nucleus, are more susceptible to the effects of anisotropic meta substituents.

The influence of inductive effects on the chemical shift of the formyl proton is clearly demonstrated by the strong electron-withdrawing cyano and nitro groups, both of which

produce significant shifts to lower field. Presumably this is a result of polarization of the C—H bond via the strong inductive effect on the carbonyl carbon atom.

Ortho-substituted Benzaldehydes

The formyl proton in ortho-substituted benzaldehydes appears at lower field (10.18–10.49 δ) than the *m*- and *p*-substituted examples, with one exception, salicylaldehyde. This compound is a special case because of intramolecular hydrogen bonding of the ortho-hydroxyl group with the carbonyl oxygen atom. The observed shift for the aldehydic proton at 9.89 δ may be compared to that of the *p*-substituted isomer at 9.86 δ. In these two compounds the conjugative effect and the ring current contributions would be similar and, thus, it appears that the effect of hydrogen bonding is small. (It can be noted that a change in solvent from CCl_4 to $CDCl_3$ results in a smaller shift (2 cycles/sec) than in other examples.) It would appear, therefore, that hydrogen bonding involving the formyl oxygen produces a small shift to lower field, which is in the expected direction. (The effect on the chemical shift of the carbonyl carbon, however, is significant and is also to lower field.) Another factor which will contribute to the shielding of the formyl proton but which is difficult to estimate is the effect of the anisotropic hydroxyl group itself. This could conceivably mask the effect of hydrogen bonding (however, see below).

The other examples in this series do not show any correlation of chemical shift with substituent polarity. These observations indicate that the conjugative effect is markedly reduced. Other evidence bearing on this point has been provided by Wolfenden and Jencks (26) from a comparison of the reactivities of a series of ortho- and para-substituted benzaldehydes. These authors have concluded that electron donation by resonance is more effective from the para position than from the ortho for the methoxyl, methyl, and chloro groups. In the present series, since the shifts are all to *lower* field than benzaldehyde itself, the results indicate that the conjugative shielding contribution by the ring is also reduced. These observations suggest that the ortho substituents force the formyl group out of the plane of the ring and thus reduce the shielding effect due to conjugation. This would result in an increased polarization of the C—H bond and a reduction in the local shielding contribution. The net effect would be a shift to lower field. Since the formyl proton cannot be far from the plane of the aromatic ring even in the extreme (ca. 1 Å), the ring current effect would still be relatively strong. Inductive effects could still be operative and so the relative shifts of *o*-tolualdehyde and *o*-nitrobenzaldehyde appear to be reasonable. Again, the effect of the anisotropic substituents would be difficult to estimate, but it is interesting that these ortho-substituted compounds absorb over a rather narrow range.

An alternative explanation for these shifts would invoke a possible hydrogen bonding of the formyl proton with the polar ortho substituents. In fact, this interpretation has been advanced to account for the observed infrared absorption maxima for a number of ortho-substituted benzaldehydes (27, 28). One would have considerable difficulty, however, defending this view as a rational explanation for the observed chemical shifts for both *o*-tolualdehyde and mesitylaldehyde, which absorb at 10.18 and 10.49 δ, respectively. Since hydrogen bonding would be comparable in these cases, one would expect the chemical shifts to be similar. For comparison, *p*-tolualdehyde appears at 9.89 δ.

Polycyclic Aromatic Aldehydes

Four polycyclic compounds were included in this survey and the data are given in Table II. It is to be expected that the ring current effects of these larger aromatic systems would be greater than in the benzaldehydes, and the observed shifts are in qualitative

agreement with this expectation. Bernstein, Schneider, and Pople (13) have shown the effect of larger ring systems in a series of polycyclic aromatic hydrocarbons and were able to account for the enhanced shifts in a quantitative fashion. More recently, Abraham has applied the method to an analysis of the chemical shifts in porphyrins (18). In the present series, a similar approach appears worthwhile.

As a model for the evaluation of the ring current effect first used by Pople (12, 13) and since modified by Waugh and Fessenden (14) and, more recently, by Johnson and Bovey (15), the aromatic nucleus is considered to provide a closed loop around which the π electrons circulate under the influence of an applied field, H_0, normal to the plane of the ring. The circulation of these electrons produces an induced magnetic field which accentuates H_0 in the plane of the ring (i.e., deshields nuclei in this orientation) and opposes H_0 over the ring (i.e., a shielding effect). Between these two extremes the effect is intermediate. Johnson and Bovey have provided tables of the magnitude of this effect calculated for all orientations about a benzene nucleus (29), in terms of the distances a given nucleus is from the center of, and from the plane of, the ring. Using Dreiding models, these distances were measured for the formyl protons in benzaldehyde, 1- and 2-naphthaldehydes, 9-anthraldehyde, and phenanthrene-9-carboxaldehyde. As a first approximation, only planar conformations were considered and, in those cases in which there are two, equal populations in each were assumed. Furthermore, only the effect of the ring(s) in addition to that to which the formyl group is bonded is considered in order to compare the enhanced ring current with that of benzaldehyde. The additional deshielding contributions for the four examples are found to be (p.p.m.): +0.15, 2-naphthaldehyde; +0.38, 1-naphthaldehyde; +0.53, phenanthrene-9-carboxaldehyde; +0.75, 9-anthraldehyde, while the observed shifts relative to benzaldehyde are +0.12, +0.36, +0.37, and +1.51 p.p.m., respectively. A direct comparison of these figures, of course, assumes that the relative shifts are due entirely to the larger ring current. Differences in the electron-releasing characteristics of these aromatic groupings at the various points of attachment of the formyl groups will also be a factor which would tend to oppose the ring current contribution. This probably accounts in part for the differences observed in the first three examples. Furthermore, since the contributions of the additional ring(s) is not necessarily equal for both conformations, a difference in populations could also be reflected in the observed shifts. In the case of 9-anthraldehyde, however, the observed shift is much larger than that calculated. A steric effect of the two *peri*-hydrogens could be responsible for this result. If the formyl group were hindered from attaining coplanarity with the anthracene nucleus, the deshielding influence of the aromatic system would not be greatly reduced while the conjugative shielding factor would be substantially diminished.

Although evidence for steric inhibition of resonance in the case of 1-naphthaldehyde has been reported (25), the N.M.R. data do not definitely substantiate this point since the relative contributions of the various operative factors cannot be established.*

It is interesting that the contribution calculated for the aromatic nucleus by the method of Johnson and Bovey is +0.58 p.p.m. and since benzaldehyde absorbs at 0.23 p.p.m. to low field relative to acetaldehyde the conjugative contribution may be estimated to be −0.35 p.p.m. for this molecule. For comparative purposes, the value for the ring current effect on a formyl proton for a conformation in which the plane of the carbonyl

**It can be noted that the proton spectra could be used as an analytical method for mixtures of 1- and 2-naphthaldehydes since the formyl protons are well separated (0.24 p.p.m. in $CDCl_3$), whereas the carbonyl stretching modes are reported (30) to absorb at 1700 and 1702 cm^{-1}, respectively.*

group is at 90° to the ring is estimated, as above, to be +0.44 p.p.m., which indicates that the deshielding effect is still strong, while a conjugative effect would be markedly reduced.

Solvent Effects

As the data in Tables I and II show, there are no large shifts observed on dilution in either carbon tetrachloride or deuterochloroform solutions for most of the aldehydes. Usually the dilution shift is less than 2 cycles/sec (ca. 0.03 p.p.m.). Since some of the aldehydes could not be studied in CCl_4 solution, a few were examined in both solvents to determine whether or not an association was involved in $CDCl_3$. There is a small, but significant, shift to lower field of ca. 0.07 p.p.m., which is presumably due to hydrogen bonding of the carbonyl group with the solvent. Support for this conclusion is provided by the observation that salicylaldehyde exhibits a smaller shift to low field for this solvent change (0.03 p.p.m.). The effect of hydrogen bonding on the formyl shifts, therefore, appears to be small.

In two cases, however, the shift on dilution is marked. Both of the tricyclic aromatic examples undergo shifts to lower field upon dilution in $CDCl_3$ in the following way: 9-anthraldehyde: 30% solution, 11.18 δ; 20%, 11.27 δ; 10%, 11.41 δ; 5%, 11.47 δ; 2.5%, 11.51 δ; 1.25%, 11.53 δ; phenanthrene-9-carboxaldehyde: 30%, 10.15 δ; 20%, 10.22 δ; 10%, 10.31 δ; 5%, 10.37 δ; 2.5%, 10.39 δ. These results indicate that the tricyclic aldehydes tend to associate with each other in chloroform solution. It is interesting to note that the dilution shifts for these compounds in acetone or in benzene solution are much smaller (ca. 4 cycles/sec for a concentration range of 20–5%) and are comparable to the results discussed above. Further work is required to clear up the question of self-association in these two cases and this study is in hand.

To investigate solvent effects on the chemical shifts of formyl protons in more detail, a few substituted benzaldehydes were examined in cyclohexane, methanol, acetone, and benzene solutions as well. These results are presented in Fig. 2. For comparative purposes, propionaldehyde and crotonaldehyde were included in this series of experiments. The shifts are presented relative to those obtained in CCl_4 solution and a correction of −0.07 p.p.m. has been used for the nitro derivatives which were examined in $CDCl_3$. A slight inaccuracy in this correction would be without effect on the conclusions drawn below.

From these results, the following important general features can be noted: (1) Relative to carbon tetrachloride, the signals are shifted to lower field in acetone and higher field in benzene solution. (2) The solvent shifts in acetone are virtually independent of the substituent on the aromatic ring, while those in benzene are markedly dependent on it. (3) Methanol solutions do not exhibit appreciable shifts relative to carbon tetrachloride solutions. This observation provides further evidence that hydrogen-bonding effects are small. (4) Steric hindrance of the formyl group by bulky ortho substituents does not appear to produce a significant change in the solvent effects, as shown by the data for mesitylaldehyde. Points (1) and (2) are similar to observations reported by Schaefer and Schneider (31) from a study of solvent effects on aromatic proton shifts in some substituted toluenes and fluorobenzenes. Since these authors have presented a detailed discussion of the various factors involved it is sufficient to note that strong evidence for a specific solute–solvent association was presented for these two solvents. A similar conclusion appears to be justified in the present series.

The most striking effects are observed in benzene solution. For most cases the shift is to higher field and, in contrast to the trend observed in acetone, is markedly dependent on

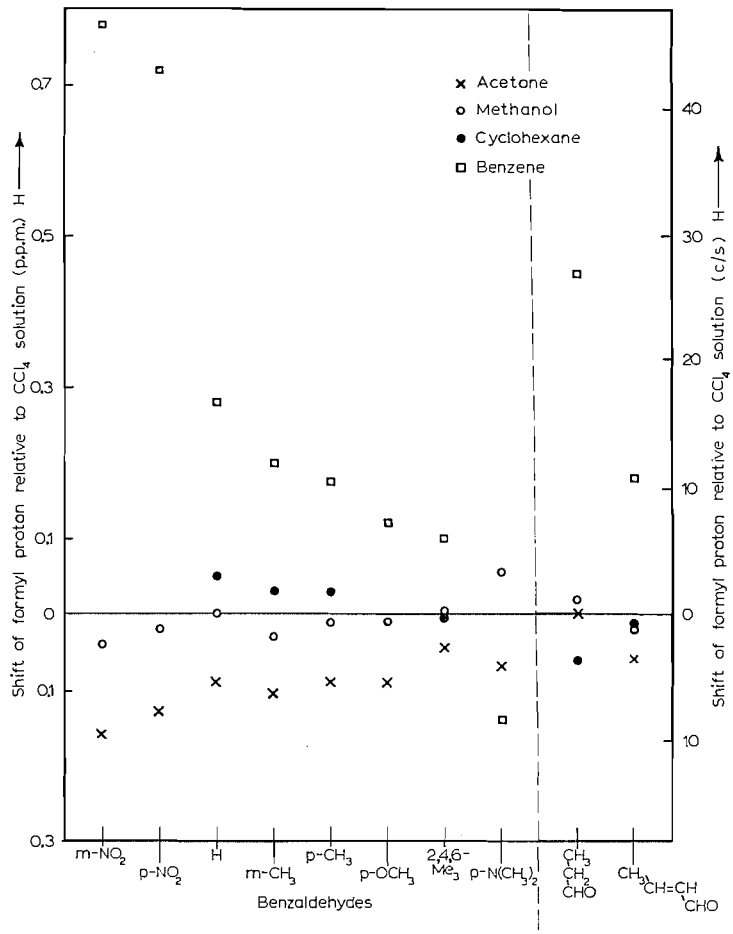

FIG. 2. Shifts of the formyl proton of various aldehydes in dilute benzene, acetone, methanol, and cyclohexane solutions relative to their resonance position for a dilute carbon tetrachloride solution. The shifts are given in p.p.m. and in cycles/sec for a fixed radio frequency of 60 Mc/sec.

the substituent. It is interesting that the shifts to higher field decrease with change in the substituent in the order NO_2, H, CH_3, CH_3O, $(CH_3)_2N$. These data indicate that the substituted benzaldehydes are associated with solvent molecules in a rather specific manner. It appears that this interaction depends markedly on the polarization of the molecule, such that the solvating benzene molecule(s) is most strongly associated with the relatively electron-deficient portion of the aldehyde molecule. One possible interpretation of these results is that the solvating molecule(s) tends to lie over the relatively planar solute molecule, as indicated in Fig. 3(*a* and *b*) and the variations in chemical shifts may be interpreted in terms of the benzene ring anisotropy, as discussed above. For example, in the case of *p*-nitrobenzaldehyde, it is suggested that the interaction involves the formyl grouping (Fig. 3(*a*)) while in the case of the *p*-dimethylamino derivative, the association involves the substituent (Fig. 3(*b*)). Further tests of this suggestion include a study of the solvent dependence of the chemical shifts of all protons in the solute molecule and this approach is being actively pursued.

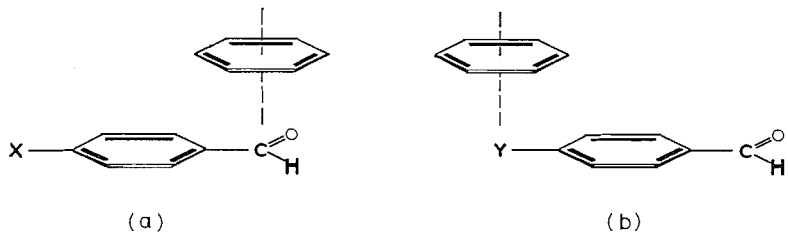

FIG. 3. Schematic representations of a possible solute–solvent interaction for substituted benzaldehydes in benzene: (*a*) electron-withdrawing substituent, (*b*) electron-releasing substituent.

CONCLUSIONS

The results of this survey indicate that, in addition to the strong deshielding effect of the carbonyl group, contributions by the aromatic ring current effect and change in the polarization of the carbonyl group constitute the major factors controlling the chemical shift of the formyl proton in aromatic aldehydes. At this stage, however, only a qualitative discussion of these effects is possible in the absence of quantitative evaluations of these various factors and since some of the assumptions may be valid only as first approximations. A knowledge of the chemical shift of the formyl proton, however, could assist in a structural elucidation, particularly for distinguishing ortho-substituted aldehydes.

Relatively minor effects are noted in hydrogen-bonded systems, and anisotropic meta substituents appear to affect the chemical shift of this proton slightly. In a number of cases in which a bulky ortho substituent could hinder the formyl group from attaining coplanarity with the ring, evidence for a steric inhibition of resonance was obtained for *o*-methyl, *o*-methoxyl, *o*-chloro, and *o*-nitro groups. Solute–solvent interactions are observed in acetone and benzene solutions and, in the latter case, depend upon the substitution of the aromatic ring.

Received November 9, 1961

ABSTRACT

A study has been made of the discrepancy between the N-atom content of active nitrogen as inferred from the maximum HCN production from the reaction of many hydrocarbons, and that indicated by the extent of NO destruction. The HCN production from several hydrocarbons was similar at high reaction temperatures in a spherical reaction vessel, and was independent of reaction temperature in a cylindrical reaction vessel. The ratio (NO destroyed)/(HCN produced) was found to be independent of the mode of excitation of the molecular nitrogen and of the N-atom concentration, and to be unaffected by the addition, upstream, of N_2O or CO_2. Although NH_3 was found to be a minor product of the hydrocarbon reactions, HCN accounted for at least 96% of the N-atom content of the products under conditions where its formation is considered a measure of the N-atom concentration. The NO "titration" value, the maximum extent of HCN production from C_2H_4, and the destruction of NH_3 after different times of decay of active nitrogen gave evidence that part of the NO reaction occurred, as does the NH_3 reaction, with excited nitrogen molecules. The long lifetime of the N_2^* species capable of reaction with NO or NH_3, as calculated from the above data, strongly favors its identification as low vibrational levels of the $N_2(A^3\Sigma_u^+)$ molecule. A consideration of the values for the NO/HCN, NH_3/HCN, and NH_3/NO ratios, after different times of decay, for poisoned and unpoisoned systems, suggested that the N_2^* responsible for the NH_3 reaction is formed only during homogeneous recombination of N atoms, while the N_2^* responsible for reaction with NO might be produced by wall recombination as well. Possible reactions of excited molecules present in the active nitrogen – NO system that might lead to decomposition of NO without consumption of N atoms are discussed.

INTRODUCTION

Although the chemical activity of active nitrogen appears to be due mainly to ground-state atoms (1), recent work indicates that excited molecules (2–5) might be important in at least some active nitrogen reactions. For example, there seems little doubt that the reaction of active nitrogen with NH_3 involves excited molecules (6–8). Verbeke and Winkler have also suggested (9) that the greater nitrogen atom content of active nitrogen indicated by the NO titration (10), in comparison with that inferred from the maximum production of HCN from ethylene, may be due to reaction of NO with excited nitrogen molecules, in addition to its very rapid reaction with nitrogen atoms. On the other hand, the discrepancy between the two estimates of nitrogen-atom concentration has been attributed (11, 12) to the complexity of the hydrocarbon reaction.

The destruction of NH_3 in measurable amounts has only been detected in active nitrogen produced by a condensed discharge (6, 9, 13) and it has been suggested (14) that this reaction occurs with a species that is produced only by this mode of excitation of the molecular nitrogen. It has been reported (14) that, in active nitrogen produced by a microwave discharge, the maximum yield of HCN and the NO titration technique both indicate the same nitrogen-atom concentration.

The purpose of the present work was twofold: (i) to examine more closely the discrepancy between the two chemical methods of estimating the nitrogen-atom concentration of active nitrogen, (ii) to study the relative extents of reaction of active nitrogen, after

different times of decay, with reactants that appear to involve mainly nitrogen atoms (e.g. C_2H_4), excited molecules (e.g. NH_3), or both (e.g. NO). Some of these interrelations have been examined previously as a function of pressure (13) and, in a preliminary way, as a function of decay of active nitrogen (9), but not as a function of time of decay of active nitrogen under controlled reaction conditions.

An investigation was first made of the effect of the shape of the reaction vessel on the temperature dependence of HCN production from hydrocarbons, in the region where this was independent of flow rate of the hydrocarbon, in active nitrogen produced by a condensed discharge and by a microwave system. Many of the preliminary results of the present investigation were reported at the Symposium on Some Fundamental Aspects of Atomic Reactions held at McGill University, Montreal, September 6 and 7, 1960.

EXPERIMENTAL

Nitrogen, nitric oxide, ammonia, and the hydrocarbons used were purified by methods similar to those described in previous papers from this laboratory. Nitrous oxide and carbon dioxide were freed from water by distillation at $-78°$ C.

The products of the reactions with hydrocarbons were trapped at liquid air temperature and distilled into an absorber that contained ice at liquid air temperature, and the aqueous solution analyzed after the absorber had been allowed to warm to room temperature. The amount of NH_3 in the products was estimated by titration with standard sulphuric acid, and this was followed by analysis for hydrogen cyanide by standard silver nitrate titration, in the presence of added ammonia, with potassium iodide as indicator. Ammonia was also qualitatively identified among the reaction products by infrared spectroscopy. Cyanogen has been shown, by previous workers, to be present in relatively insignificant quantities.

Excess NH_3 from the ammonia reaction was analyzed in the same way as the ammonia content of the products from the hydrocarbon reactions.

The products from the nitric oxide reaction consisted of nitric oxide and nitrogen dioxide (generally present as N_2O_3) and these were trapped quantitatively at about $-210°$ C, using liquid nitrogen under reduced pressure. Nitric oxide was separated, with a Toepler pump, from the nitrogen dioxide, maintained at $-64°$ C, and the amount of each gas was measured by pressure–volume methods at constant temperature. This technique gave good agreement with that used by Verbeke and Winkler (9). The reaction of nitric oxide with active nitrogen was also followed by the gas phase titration method (10).

The reactions of active nitrogen with nitrous oxide and carbon dioxide were followed by trapping unreacted nitrous oxide, or carbon dioxide, at liquid air temperatures and estimating their amounts by pressure–volume methods at constant temperature. No other products were observed, even with a trap at $-210°$ C.

The experiments described in this paper were made in two different types of apparatus, (I) and (II). To increase the reproducibility in the experiments, both types of apparatus were equipped with a stopcock between the reaction vessel and products trap. This minimized contamination of the reaction vessel and discharge regions by reaction products. Kel-F stopcock grease was used and was unaffected by active nitrogen. To obtain reproducible results, it was also necessary to operate the condensed discharge, in either apparatus, for at least 15 minutes prior to initiating a reaction.

Apparatus (I) was similar to that used by previous workers (6, 9, 13). The reaction vessels were of unpoisoned pyrex and the dimensions were varied in several of the experiments. Condensed and microwave discharges were used as alternative methods of obtaining active nitrogen. The condensed discharge operated between aluminum electrodes, 45 cm apart, and at a flash rate of about 10 sec^{-1}. The microwave discharge operated at 2450 Mc/sec and was supplied from a Raytheon 125-watt generator. The flow rate of molecular nitrogen, at a pressure of 2.45 mm Hg, was 133×10^{-6} mole/sec.

Apparatus (II) utilized a condensed discharge to produce a high concentration of nitrogen atoms, to facilitate the study of possible reactions of excited nitrogen molecules, which are probably produced by the recombination of nitrogen atoms (13). A large bulb was incorporated into the center of the discharge tube to reduce "pulsing" in the active nitrogen stream. The reaction vessel was a straight, pyrex tube of 25-mm diameter, which contained two fixed reactant jets, about 14 and 14.5 cm below the discharge tube. It was also provided with a mobile reactant jet that could be moved from 0.1 to 45 cm below the lower of the two fixed jets, by a stopcock arrangement (15) that provided a friction drive on the lower part of the mobile jet column. This column contained a glass-encased thermocouple, which permitted a measurement of temperature 3.0 cm below the outlet of the mobile jet. Both the fixed upper jets, and the mobile jet, contained six small holes placed symmetrically around their bulbous ends to produce an even flow of reactant into the active nitrogen stream.

All experiments in apparatus (II) were made in an unheated reaction vessel and at a pressure of 3 mm of Hg. The flow rate of molecular nitrogen was 378×10^{-6} mole/sec, corresponding to a linear flow rate of

478 cm/sec. Experiments were made in both an unpoisoned reaction vessel, and in the reaction vessel poisoned by water vapor ($<0.03\times10^{-6}$ mole/sec), introduced through a capillary leak into the molecular nitrogen before the discharge. This minute amount of vapor apparently has no measurable effect (16) on the course of the active nitrogen reactions but does poison the walls of the apparatus effectively against the decay of nitrogen atoms.

RESULTS

A Comparison of the Maximum Extent of Reaction of Active Nitrogen with Nitric Oxide and with Hydrocarbons

The extent of the reaction with NO was taken as the initial flow rate of NO minus the flow rate of total nitrogen oxides (i.e. $NO+NO_2$) analyzed in the products. Hydrogen cyanide production was taken as a measure of the reaction of nitrogen atoms with ethylene, ethane, *n*-butane, and but-2-ene. At the maximum extent of these reactions, the total of ammonia and cyanogen in the products never exceeded 4% of the hydrogen cyanide.

In Table I are shown the data obtained, using apparatus (I), when variations were made in reaction temperature, dimensions of the reaction vessel, and type of discharge

used to produce the active nitrogen. Values for NO consumption obtained by product analysis agreed well with results obtained by the gas phase titration with NO at the lower atom concentrations, but at higher atom concentrations (systems A and B) the titration gave results that were 10–20% lower than those reported in the table.

The Production of Ammonia from the Reaction of Active Nitrogen with Ethylene and Ethane

The relative amounts of HCN and NH_3 produced in these reactions in a spherical, unpoisoned reaction vessel, with a condensed discharge, are shown in Table II. Production of ammonia from *n*-butane and but-2-ene was found to be similar to that from ethylene at both temperatures.

*All units are mole/sec$\times 10^{-6}$.

The Influence of Nitrous Oxide and Carbon Dioxide on the Reactions of Active Nitrogen with Nitric Oxide and Ethylene

Apparatus (I) was used, with a reaction vessel consisting of two spherical bulbs, connected by a 10-cm pyrex tube of 20-mm i.d. Nitrous oxide or CO_2 entered the active nitrogen in the upper bulb (85-mm i.d.), while NO or C_2H_4 was admitted to the lower bulb (110-mm i.d.). A condensed discharge activated the nitrogen, and the vessel walls were not poisoned.

The admission of either N_2O or CO_2 to the active nitrogen in the upper vessel caused no significant change in the heat given off at any position in the system. Both N_2O and CO_2 were destroyed to a minor extent; the N_2O destruction appeared to increase with reaction temperature. The addition of these gases to the active nitrogen resulted in an increase in the maximum extents of reaction of both NO and C_2H_4, but the ratio $NO_{consumed}/HCN_{produced}$ remained essentially unchanged over a range of flow rates of N_2O or CO_2 from 2×10^{-6} to 30×10^{-6} mole/sec. Typical results, for a flow rate of N_2O or CO_2 of 6.7×10^{-6} mole/sec, are shown in Table III.

TABLE III

Effect of N_2O and CO_2 on the reactions of active nitrogen with NO and C_2H_4

	Maximum extent of HCN production from ethylene, mole/sec ($\times10^6$)	Maximum extent of decomposition of NO, mole/sec ($\times10^6$)	Ratio NO/HCN
Without N_2O	3.7	6.3	1.7
With N_2O	4.2	7.1	1.7
Without CO_2	3.6	6.4	1.8
With CO_2	4.4	7.7	1.7

A Comparison of the Plateau Values for HCN Production from C_2H_4 and of NH_3 Destruction and NO Destruction, after Different Times of Decay of Active Nitrogen

Apparatus (II) permitted the accurate determination of these plateau values (maximum extents of reaction) at four different levels, spaced 15 cm apart, of the mobile jet under otherwise similar conditions. These levels corresponded to 31.4, 62.7, and 94.3 milliseconds of decay of active nitrogen after the reference level, 0.1 cm below the lowest fixed jet. The temperature increases in the active nitrogen stream at these same positions were also determined before the reactant was introduced. The extent of NO destruction was estimated, at the different levels, by a visual gas phase titration (10). Since the results

obtained in apparatus (I) indicate that the HCN plateau values are independent of reaction temperature in a cylindrical vessel, and this has recently been confirmed by other workers (17) for the ethylene reaction, these values are considered to be a measure of the maximum HCN production from ethylene. Good linear relations, of which those in Fig. 1 are typical, were obtained between the plateau values for the reactions and the

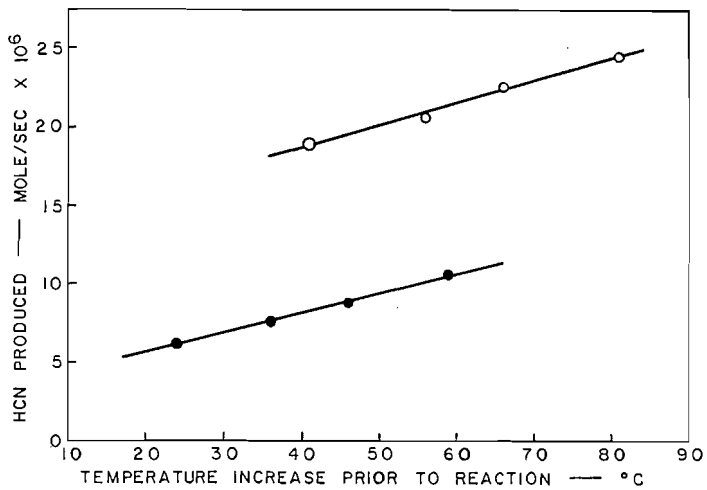

FIG. 1. Plot of HCN produced from ethylene against the temperature of the active nitrogen, above room temperature: ○, poisoned system; ●, unpoisoned system.

temperature increases in the active nitrogen in both the poisoned and unpoisoned systems. Unfortunately, the possibility of estimating the relative concentrations of active nitrogen from such relative temperature increases is applicable only to a given apparatus and given operating conditions. For example, for a temperature increase of 46° C prior to reaction, the destruction of NH_3, or production of HCN from C_2H_4, in the poisoned system, was more than double, while NO destruction was slightly less than double that observed in the unpoisoned system. Presumably, the condition of the system determines the N-atom concentration upstream, hence the extent of formation of excited nitrogen molecules, and both of these, in turn, may be reflected in the observed temperature increases and plateau values for the reactions.

A plot of NH_3 destroyed against HCN produced from C_2H_4, at the different levels in the reaction tube, is linear for both the poisoned and unpoisoned systems (Fig. 2). Extrapolation of the line for the unpoisoned system to zero HCN production gives an intercept on the axis of NH_3 destruction of 0.2×10^{-6} mole/sec, while a similar extrapolation of the line for the poisoned system gives an intercept on the axis of HCN production of 11×10^{-6} mole/sec.[4]

The ratios (NH_3 decomposed/HCN produced), (NO decomposed/HCN produced), and (NH_3 decomposed/NO decomposed), more simply referred to hereafter as the ratios NH_3/HCN, NO/HCN, and NH_3/NO, all decrease, at constant pressure, with time of decay of the active nitrogen in the poisoned system, while in the unpoisoned system the ratio NO/HCN increases markedly, and the ratio NH_3/HCN increases slightly. Verbeke

[4]*Extrapolation to zero value of* HCN *production yields values corresponding to reaction conditions where the* N*-atom concentration has fallen to a very low value, i.e., to long distances downstream. Of course, the extrapolated values are applicable only to the present system, wherein a large* N*-atom concentration existed upstream, and a relatively high concentration of excited nitrogen molecules may then exist at a distant position downstream, as a result of* N*-atom recombination upstream.*

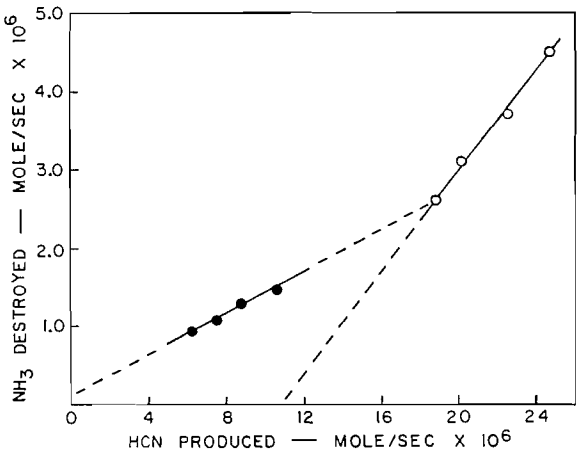

FIG. 2. Plot of NH_3 destroyed against HCN produced from C_2H_4 at the different levels: ○, poisoned system; ●, unpoisoned system.

and Winkler (9) had some indication of an increase in the NO/HCN ratio with decay time in a poisoned system.

Reasonably good straight lines are obtained if plots are made of NH_3/HCN against HCN (Fig. 3A), NO/HCN against HCN (Fig. 3B), and NH_3/NO against NO (Fig. 4)

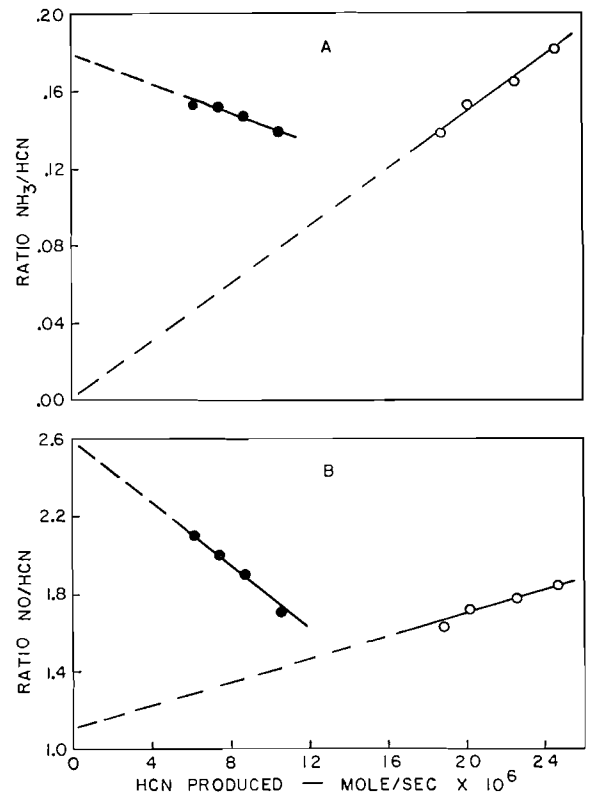

FIG. 3. (A) Plot of ratio NH_3 destroyed/HCN produced; (B) plot of ratio NO destroyed/HCN produced: ○, poisoned system; ●, unpoisoned system.

for different levels in the reaction tube. Extrapolation of these, as indicated in the figures, are certainly not accurate, but it is apparent that the lines of Fig. 3 are of opposite slopes for the poisoned and unpoisoned systems, and extrapolate to widely different intercepts, while the lines in Fig. 4 are of similar slope and extrapolate to similar values for the two systems. The significance of these relations will be discussed later.

Effect of Adding NH_3 Upstream from NO, C_2H_4, or NH_3; and C_2H_4 above NH_3

The experiments were made in apparatus (II).

(a) Effect of Adding NH_3 above NO

Since both the reactions of NO and NH_3 may be due, at least in part, to the reaction of excited nitrogen molecules, the addition of one upstream might be expected to decrease the extent of the reaction of the other. However, when NH_3 was introduced at a flow rate of 4.0×10^{-6} mole/sec through the fixed upper jet, the change in the end point of the NO titration was negligible in the poisoned system at all levels down to 45 cm. If anything, there was a slight increase in the end point, especially at the 45-cm level. In the unpoisoned system, the increase in the end point was more significant, e.g., 3.7×10^{-6} mole/sec at the 30-cm level, when NH_3 was added at a flow rate of 2.2×10^{-6} mole/sec.

(b) Effect of Adding NH_3 above C_2H_4

If the reaction of NH_3 with active nitrogen involves N atoms in any way, the HCN production from C_2H_4 might be expected to decrease when NH_3 is added upstream. In fact, addition of NH_3 at the fixed upper jet slightly *increased* the HCN production from C_2H_4 over that obtained at the various levels and flow rates when no NH_3 was added upstream. This increase was larger in the unpoisoned system. The results are given in Table IV.

In the poisoned system, the C_2H_4 reaction temperature at the 45-, 30-, and 15-cm levels, in the presence of NH_3, was about 3° C higher than in its absence, while, in the unpoisoned system, the corresponding increase was about 8° C at all three levels. In the unpoisoned system, an increase in the intensity of active nitrogen afterglow was observed at the lower levels, upon the introduction of the NH_3.

The addition of C_2H_4 downstream from NH_3 was found to decrease the extent of NH_3 decomposition and this decrease became larger as the C_2H_4 was added closer to the NH_3 jet. Since the addition of an excess of C_2H_4 below NH_3 appeared to terminate the NH_3 active nitrogen reaction, this method has been used (18) to obtain a rate constant for the NH_3 reaction.

TABLE IV

Effect of addition of NH_3 on HCN production from C_2H_4

Level at which C_2H_4 added, cm	C_2H_4 flow rate, mole/sec ($\times 10^6$)	NH_3 flow rate, mole/sec ($\times 10^6$)	Increase in HCN production, mole/sec ($\times 10^6$)

45	60	"	2.4
30	52	2.5	1.4
30	60	"	1.4
15	52	2.5	1.5
15	60	"	0.4
15	60	8.0	2.7
0	46	2.5	0.4
0	60	"	1.7
0	60	11.7	2.1
	Unpoisoned system		
45	46	2.5	3.9
45	"	7.7	4.2
30	46	2.5	4.5
15	46	2.8	2.6

(c) Effect of Adding C_2H_4 above NH_3

In the poisoned system, no decomposition of NH_3 was observed, after accounting for the slight NH_3 production from the C_2H_4 reaction, when 8.0×10^{-6} mole/sec of NH_3 was added at the 15- and 30-cm levels and 46×10^{-6} mole/sec of C_2H_4 added at the fixed upper jet. The extent of HCN production from the C_2H_4 reaction was slightly decreased. It may be noted that, at the 15-cm level, NH_3 was added in the region of the active nitrogen – C_2H_4 reaction flame, while at the 30-cm level, no reaction flame was visible.

(d) Effect of Adding NH_3 above NH_3

Ammonia was added through the fixed upper jet at flow rates lower than those corresponding to the plateau for destruction of NH_3. Most of the NH_3 that was added was therefore destroyed above the 30-cm level. If excited molecules, capable of destroying NH_3, were formed only during the decay of nitrogen atoms, in the presence of NH_3, the addition of excess NH_3 at the lower positions should result in a total NH_3 destruction almost equal to that obtained when the excess is added at the fixed upper jet. However, for successive additions in the poisoned system, the combined extent of NH_3 destruction was 0.5×10^{-6} mole/sec less at the 30-cm level, and 1.0×10^{-6} mole/sec less at the 45-cm level, than when a flow rate of NH_3 in the plateau region, e.g., 8.0×10^{-6} mole/sec, was added at the fixed upper jet. In the unpoisoned system, the total extent of NH_3 destruction was approximately the same (1.5×10^{-6} mole/sec) whether the reactant was introduced at the upper level only, or at both upper and lower levels.

DISCUSSION

Essentially equal yields of HCN from hydrocarbons have been obtained in apparatus (I), as follows: ethylene, *n*-butane, but-2-ene, and ethane at elevated temperatures in a spherical reaction vessel, and ethylene and *n*-butane in an unheated cylindrical reaction vessel. The maximum HCN production from the hydrocarbons, except from C_2H_6, does not vary, to any extent, with reaction temperature in a cylindrical vessel, with active nitrogen produced by either a condensed or microwave discharge. Consequently, any

uncertainty about having reached an HCN plateau that is independent of reaction temperature is eliminated, and there appears to be added justification for assuming that this value of HCN production corresponds to the N-atom concentration in the system. The reasons for the temperature dependence of HCN production observed in the present work, and in many previous studies (see, for example, ref. 13), in a spherical reaction vessel are not obvious, and further study of this problem is in progress.

The observed discrepancy between the estimations of active nitrogen concentration from NO destruction and from maximum HCN production, as reflected in the NO/HCN ratios of Table I, agrees well with that obtained previously (9) at similar reaction pressures, for active nitrogen produced by a microwave discharge: a value of about 1.7 at 2.45 mm, compared with a previous value of 1.6 at 2 mm, and a value of 2.0 at 3.7 mm, compared with the earlier value of 1.9 at 4.0 mm. Contrary to recent assumptions (19), the present data confirm the previous conclusion (9) that the NO/HCN ratio does not change appreciably with active nitrogen concentration at a constant total pressure, nor does it depend upon the mode of excitation of the nitrogen.

The lower N-atom concentration indicated by the extent of HCN production from hydrocarbons apparently cannot be due to the formation of N-containing products, other than HCN, in these reactions, since the total content of N atoms in the form of NH_3 or $(CN)_2$ recovered from the hydrocarbon reactions, under conditions of maximum HCN production, is less than 4% of that recovered as HCN.[5]

Similarly, it seems unlikely that the discrepancy between the NO and HCN estimates of atomic nitrogen concentration is due to catalyzed recombination of N atoms on the parent hydrocarbon, after initial formation of a complex of relatively long life (20),

$$N + N\cdot C_2H_4 \rightarrow N_2 + C_2H_4, \qquad [1]$$

since the NO/HCN ratio would then be temperature dependent, and possibly also dependent on the N-atom concentration (13). No dependence of the ratio on temperature was observed in a cylindrical reaction vessel (Table I), while, in the unpoisoned system of apparatus (II), the ratio *increased* (Fig. 3B) with decreasing N-atom concentrations after longer decay times of the active nitrogen.

Again, the suggestion of Zinman (11) that the formation of a complex of a substantial lifetime might explain the pressure dependence (9) of the NO/HCN ratio also appears untenable. In modified form, his scheme may be represented by

$$N + RH \rightarrow [N\cdot RH]^* \qquad [2]$$

$$[N\cdot RH]^* \rightarrow HCN + R' + --- \qquad [3]$$

$$R' + N \rightarrow HCN + --- \qquad [3']$$

$$[N\cdot RH]^* \xrightarrow{M} [N\cdot RH] \rightarrow \tfrac{1}{2}N_2 + RH. \qquad [4]$$

Reaction [3'] is necessary since the reaction of N atoms with free radicals, which may conserve spin, is probably faster (21) than the N-atom reaction with the parent hydrocarbon. If it is assumed that the NO titration measures the N-atom concentration, this mechanism gives

$$\frac{[\text{NO consumed}]}{[\text{HCN produced}]} = \frac{[N]}{[HCN]} = \frac{nk_3 + k_4[M]}{nk_3}, \qquad [5]$$

[5] *The yield of* NH_3 *from the* C_2H_6 *reaction in the unheated spherical reaction vessel (Table II) was a considerable fraction of the slight* HCN *yield. However, there is considerable evidence, as will be discussed in a later paper, that this reaction involves excited nitrogen molecules at low reaction temperatures.*

where n = number of carbon atoms in the hydrocarbon. On this basis, the NO/HCN ratio should depend on the molecular weight of the hydrocarbon, which is not borne out by the experiments described in Table I. Furthermore, experiments in apparatus (II) indicated that the NO/HCN ratio increased with time of decay of the active nitrogen in the unpoisoned system. Since the ratios involved plateau values for HCN production at the various levels for constant pressure conditions, an explanation for the discrepancy represented by the NO/HCN ratio must involve more than its pressure dependence.

Finally, it should be emphasized, perhaps, that a discrepancy, similar to that given by the NO/HCN ratio, has been observed when the active nitrogen concentration, estimated by the NO titration, was compared with the extent of reaction of active nitrogen with NO_2 (9) and, more recently, by the extent of its reaction with O_2, as given by the production of O atoms (22).[6] Among the widely different chemical methods studied, therefore, the NO reaction, whether followed by gas phase titration or by analytical methods, appears to be unique in indicating an exceptionally high atomic nitrogen concentration.

The observation that the NO/HCN ratio does not have a fixed value, even at a given pressure, but depends on the time of decay of the active nitrogen, suggests (since the HCN data are based on plateau values) that the extent of the NO reaction does not vary directly with the N-atom concentration, but involves excited molecules derived from atom recombination or directly from the discharge tube. This is suggested also by the similarity in the plots of NH_3/HCN and NO/HCN against HCN yield for the poisoned and unpoisoned systems (Fig. 3), since the NH_3 reaction is known to involve excited molecules. Again, the similarities in slopes of the NH_3/NO plots against NO (Fig. 4), for both the poisoned and unpoisoned systems, and in the extrapolation of the lines to a similar low value, strongly suggest that both reactions occur, at least in part, with species produced by a similar mechanism.

Since the NO/HCN ratio may increase with time of decay of the active nitrogen, it is not likely that NO reacts with some species of long life, other than N atoms, that may be produced in a particular type of discharge. Moreover, most of the excited species that might be produced during the excitation process are known to be of short life (2, 23), and can be expected to decay rapidly with time. If an excited molecular species is responsible for part of the NO reaction, it is probably formed during the recombination of $N(^4S)$ atoms. The decrease in the NO/HCN ratio with decay of the active nitrogen in the poisoned system may then be explained if the disappearance of N atoms in this system, which occurs at about twice the rate of the homogeneous recombination, is considerably slower than that of any N_2^* which might have been produced, mostly upstream in the region of relatively high N-atom concentration.[7] The same seems also to be true for the N_2^* that reacts with NH_3 in a poisoned system, since it appears, from the extrapolation in Fig. 2, that the decomposition of NH_3 falls to zero at rather high values of the N-atom concentration in such a system. In contrast, in the unpoisoned system, the extrapolated value for NH_3 destruction at zero HCN production suggests a considerable concentration of N_2^* in this system, even under conditions where the N-atom concentration has fallen to a low value. The small limiting extent of NH_3 destruction suggests further that N_2^* is produced during the relatively small homogeneous part of the overall decay of N atoms in the unpoisoned system.

[6]*It might be noted, however, that the analysis of* O*-atom concentration in this reaction by the* NO_2 *titration recently indicated a* N*-atom concentration similar to that inferred from the* NO *titration* (12).

[7]*This explanation suggests that a system poisoned with metaphosphoric acid (9) corresponds more closely with an unpoisoned system than with a system poisoned with* H_2O *vapor. For* O *atoms, at least, small amounts of water vapor have been shown (24) to be a most effective poison against surface recombination.*

The difference in slopes and intercepts (Fig. 3A) when the NH_3/HCN ratios are plotted against HCN, for the poisoned and unpoisoned systems, may also be explained if the N_2^* responsible for NH_3 decomposition is formed by homogeneous recombination and persists in significant concentrations, in the unpoisoned system, into the regions where the N-atom concentration has fallen to low values. The much higher extrapolated value of 2.6 for the plot of NO/HCN against HCN (Fig. 3B) in the unpoisoned system suggests that some N_2^* capable of NO destruction may be formed by wall decay of N atoms. The corresponding extrapolated value of 1.1 in the poisoned system indicates that the concentration of N_2^* responsible for NO destruction becomes negligible when the N-atom concentration has decreased to a very low value in this system.

In view of the preceding discussion, it seems reasonable to conclude that NO is destroyed not only by N atoms, but also by an excited molecular species of considerable lifetime produced by both homogeneous and surface decay of N atoms. The destruction of NH_3, on the other hand, appears to be due only to an excited molecule produced during homogeneous decay.

Nature of the Excited Molecular Species that might React with NO

A vibrationally excited, ground-state nitrogen molecule might contain sufficient energy to cause dissociation of NO during a collision process, and, at least in the lower vibrational levels, would be expected to be of long life (23, 25, 26). Quite high vibrational levels of the ground state may be populated directly by homogeneous recombination of N atoms, as pointed out by Polanyi (27) for atomic association reactions of this type. To contain sufficient energy to cause dissociation of NO after a collision of the Second Kind, the molecule would have to be in at least the 27th vibrational level (9). There is some experimental evidence (28) for the presence, in active nitrogen, of $N_2(X^1\Sigma_g^+)$ in vibrational levels as high as the 27th, but they would presumably be deactivated readily by collision processes because of their small vibrational level spacing. It is improbable, therefore, that such molecules would be present in sufficient concentration to account for the NO/HCN ratios.

Another possibility is that such molecules are *produced* in the excitation process. Kaufman and Kelso (25) found that the addition of N_2O or CO_2 removed energy from certain species, probably ground-state molecules in low vibrational levels, in active nitrogen emanating from a microwave discharge. In the present studies, the addition of either gas to discharged nitrogen made little difference to the NO/HCN ratio (Table III). Moreover, there was negligible temperature increase when these gases were introduced into active nitrogen formed in a condensed discharge, compared with that observed (25) in active nitrogen from a microwave discharge. This suggests that microwave excitation may be more effective than a condensed discharge in producing excited ground-state molecules of low-energy content, and that, if NO reacts with excited nitrogen molecules, as well as atoms, the N_2^* are certainly of higher energy than those removed by collision with N_2O or CO_2.

Production of vibrationally excited, ground-state molecules might be expected to be favored, through spin coupling (29) with the paramagnetic NO molecule, in the reaction

$$N(^4S) + NO(X^2\Pi) \rightarrow N_2(X)\dagger + O(^3P) \qquad [6]$$

in a manner analogous to that found for other reactions of atoms with molecules (e.g. ref. 30). In fact, there is evidence that this reaction does produce nitrogen in low-lying levels of the ground state (25). However, it is exothermic only to the extent of about 75 kcal, and the maximum energy that might be expected to remain as vibrational energy

in the newly formed bond would be between about 53 kcal, corresponding to $v = 8$ (31), and 75 kcal, corresponding to $v = 12$ (27). Hence, although reaction [6] occurs at almost the bimolecular collision rate (12, 32), and would provide vibrationally excited molecules almost immediately after the introduction of NO, such molecules could not directly decompose NO.

On the other hand, $N_2(A^3\Sigma_u^+)$, in the first or second vibrational levels, would have sufficient energy to decompose NO in a collision of the Second Kind. Such a molecule may be formed directly by recombination of N atoms, or by a cascade process after the N atoms recombine into a higher state. Since its transition to the ground state, the only lower-energy state available, involves a change in spin (the forbidden Vegard–Kaplan bands), it has a relatively long radiative lifetime, recently estimated (33) to be between 0.24 and 50 second. It has also been shown (23) that, although vibrational levels of the A state higher than $v = 1$ lose their energy in a number of collisions much less than 10^8, the $v = 1$ level can survive 10^9 collisions. Moreover, there is the possibility of a resonance energy transfer between low vibrational levels of the A-state molecule and NO, as pointed out previously (9). For these several reasons, it is suggested that NO might be decomposed in the following process, which may conserve spin:

$$N_2(A^3\Sigma_u^+)_{v = \text{low values}} + NO(X^2\Pi) \rightarrow N_2(X^1\Sigma_g^+) + N(^4S) + O(^3P). \quad [7]$$

It should be noted that, although the A-state molecule has recently been observed in absorption (34, 35), no direct evidence is available that its concentration in active nitrogen is sufficient to account for the NO/HCN discrepancy. There is little question, however, that its concentration is much greater than that of the B-state molecule, or other triplet-state molecules such as the precursor of the 'Y' bands in active nitrogen (36, 37), the $Y^3\Sigma_u^-$ (perhaps better referred to as the $B'^3\Sigma_u^-$ (38, 39)) state, or of the $^3\Delta_u$ state, all of which probably have very short lifetimes (33, 8). Process [7] is therefore favored over the analogous process, for which evidence has been obtained by Heath (40),

$$N_2(B^3\Pi_g) + NO(X^2\Pi) \rightarrow N_2(X^1\Sigma_g^+) + NO(^2\Sigma^-). \quad [8]$$

Heath observed that the active nitrogen afterglow, especially transitions from $v = 5$, 6, and 7 levels of the B state, was weakened at higher pressures (10 to 760 mm) in the presence of NO. He suggested, therefore, a resonance energy transfer in process [8], which conserves spin and may lead to the dissociation of NO, to explain the disappearance of the First Positive group in high-pressure air discharges. The $^4\Sigma^-$ state for NO correlates with the dissociation limit (41, 42) for NO into $N(^4S) + O(^1D)$.

The Lifetimes of the Excited Molecules Involved in the NO and NH_3 Reactions

The plateau values for NO and NH_3 destruction, after different times of decay of the active nitrogen, permit calculation of lifetimes for the excited molecular species that appear to be involved in these reactions, provided the rate constant of surface decay of the N atoms is known for the given experimental conditions. This was obtained, for the present study, from the equation

$$-d[N]/dt = k_1[N] + k_2[N]^2P, \quad [9]$$

where $k_1[N]$ represents the rate of heterogeneous decay, and $k_2[N]^2P$ represents the rate of homogeneous decay of N atoms. The value of k_2 may be taken to be 3×10^{-33} cc^2 molecule^{-2} sec^{-1} (43, 44).[8] Values of [N] were inferred from maximum HCN yields in the

[8]*This value was based on a* N*-atom concentration deduced from* HCN *production from* C_2H_4 *or* C_2H_6 *at high reaction temperatures, and consequently could be too high if values of* [N] *so obtained were too low.*

C_2H_4 reaction at various levels, and values of $d[N]/dt$ were obtained as slopes of the straight-line plots of HCN production against decay time of the active nitrogen at the 0-, 15-, and 30-cm levels (-1.57×10^{16} and -1.00×10^{16} molecules cc^{-1} sec^{-1} respectively in the poisoned and unpoisoned systems). The following reasonable values of k_1 (sec^{-1}) were obtained:[9]

Level, cm	Poisoned system	Unpoisoned system
0	1.4	3.5
15	1.7	4.4

The rate of decay of the N_2^* species, assumed capable of causing the decomposition of NO in reaction [7], may be represented by

$$d[N_2^*]/dt = \tfrac{1}{2}ak_2[N]^2P+\tfrac{1}{2}bk_1[N]-k_3[N_2^*], \qquad [10]$$

from which,

$$k_3 = \frac{k_1[N]}{2[N_2^*]} + \frac{k_2[N]^2P}{2[N_2^*]} - \frac{d\ln[N_2^*]}{dt}. \qquad [11]$$

The first term on the right-hand side of equation [10] represents the rate of production of N_2^* by homogeneous recombination, the second term its rate of possible production by heterogeneous recombination, and the last term its decay. The concentration of molecular nitrogen is approximated by the total pressure, P, in the system. Equation [11] is derived by arbitrarily taking the values of the constants a and b to be unity. This is a reasonable value for a if, for example, N_2^* represents the A state of nitrogen, since this state may be populated directly during the volume decay of N atoms, as well as from the end result of light emission in the First Positive system. Although the value of b is much more uncertain, the recent work of Harteck, Reeves, and Mannella (4, 48) supports the possibility that an excited molecular species may be formed during surface recombination.

Values of $d\ln[N_2^*]/dt$ were obtained from plots of $\ln\frac{1}{2}(NO-HCN)$ against time, on the assumption that $[N_2^*] = \frac{1}{2}(NO_{reacted}-HCN_{produced})$. Values of k_1, k_2, and [N] were taken as outlined previously, and the following values for k_3 were obtained:

$k_3 = 7.9$ sec^{-1}, poisoned system at 0-cm level;
$= 9.7$ sec^{-1}, poisoned system at 15-cm level;
$= 8.3$ sec^{-1}, unpoisoned system at 15-cm level.

Accordingly, the excited state of N_2, assumed capable of reacting with NO, is calculated to have a half-life, assuming its decay to be a first-order process, of about 8.4×10^{-2} second. This value is somewhat higher than the minimum lifetime of 10^{-2} second observed by Lichtin (49) and the value of 2.6×10^{-2} second recently observed by Wilkinson and Mulliken (50), but less than the value of 0.15 second inferred by Carleton (34), for the $v = 0$ level of the $N_2(A^3\Sigma_u^+)$ molecule. (The A state contains 142 kcal/mole of excess energy and low-lying vibrational levels of this electronic state would contain sufficient energy, 150 kcal/mole, to cause reaction [7].)

[9]*If values for k_1 are similarly calculated from the* NO *data, it is found that the value for the unpoisoned system (2.1 sec^{-1}) agrees well with that (2.5 sec^{-1}) previously reported (45) for such a system, but a larger, not a smaller, value is obtained for the poisoned system. If the larger value of k_2 obtained by other investigators (46, 47) from the* NO *titration are substituted into equation [9], along with the present* NO *data, the anomaly is accentuated. This suggests that the* N*-atom concentrations inferred from the* NO *titration are too high.*

The extents of NH_3 destruction at different levels enable a similar calculation of the rate constant, k_4, for the decay of the N_2^* species capable of destroying NH_3. However, recent measurements (18) on the rate of the active nitrogen – NH_3 reaction have given further indication that the N_2^* responsible for the NH_3 reaction is formed only during homogeneous decay of N atoms, in which case $b = 0$ in equations [10] or [11]. The values obtained for k_4 (sec^{-1}) are then:

Level, cm	Poisoned system	Unpoisoned system
0	10.6	6.7
15	9.6	7.3

The average value in the poisoned system of 10.1 sec^{-1} indicates a half-life for the N_2^* species of 6.9×10^{-2} second.

It is interesting, perhaps, that there is a definite trend towards higher values of the ratio of N_2^* responsible for NO destruction, given by $\frac{1}{2}(NO-HCN)$, to N_2^* responsible for NH_3 reaction, given by the extent of NH_3 destruction, at greater times of decay of the active nitrogen in the unpoisoned system:

Level, cm	Poisoned system	Unpoisoned system
0	2.24	2.52
15	2.35	3.15
30	2.32	3.24
45	2.23	3.58

This gives further evidence that NO may react with a N_2^* species produced at the wall as well as in volume decay of N atoms.

The Behavior of Reactions in the Presence of NH_3, N_2O, and CO_2

Herron *et al.* (14) have observed that the addition of NH_3 to active nitrogen produced by a microwave discharge, in which the destruction of NH_3 was immeasurably small, did not affect the value of the NO titration. The significant *increase* in the NO titration, observed in the present studies, when NH_3 was added to the unpoisoned system, may be attributed to a slower decay of N atoms in the presence of the polar NH_3 molecule, which may serve as a poison against the wall recombination of N atoms. Consequently, if NO reacts with N_2^*, it would seem that the N_2^* involved is different from that responsible for the decomposition of NH_3, *or*, that the products of the NH_3 decomposition react rapidly with NO. The latter alternative is quite possible, since Bamford has shown (51) that NO rapidly scavenges NH_2 radicals, even at room temperature, according to

$$NO + NH_2 \rightarrow N_2 + ---. \qquad [12]$$

Moreover, the reaction

$$NH_2 + NO \rightarrow N_2 + H_2O \qquad [12']$$

occurs (52) during the photolysis of NH_3 in the presence of NO, and in NH_3 flames (53), together, perhaps, with the reaction

$$NH + NO \rightarrow N_2 + OH. \qquad [13]$$

Since the addition of NH_3 upstream from C_2H_4 did not decrease the extent of HCN production (Table IV), the reaction of NH_3 with active nitrogen apparently does not consume N atoms. The slight increase in HCN production in the poisoned system is

difficult to explain, but might be due to additional wall poisoning by NH_3. The greater increase, proportionately, in HCN production in the unpoisoned system is almost certainly due to the efficient wall poisoning by small amounts of NH_3 in this system. The increased temperature of the C_2H_4 reaction, in both systems, in the presence of added NH_3, may then be explained by more extensive reaction in the presence of the higher N-atom concentration promoted by the poisoning effect of NH_3. The poisoning effect of NH_3 might also account for the visual increase in the afterglow intensity *downstream* when small amounts of NH_3 were added upstream in the unpoisoned system. A decrease in light intensity in the region where a low flow rate of NH_3 is added, accompanied by an increase at points further downstream in the unpoisoned system, has recently been confirmed quantitatively by measurements (54) with a photomultiplier tube. Since the total destruction of NH_3 was not affected by addition of small amounts of NH_3 upstream in the unpoisoned system, the slower decay of N atoms, due to NH_3 absorption on the walls, appears to compensate for any loss of N_2^* effective for the NH_3 reaction resulting from a low NH_3 concentration in the region between the fixed and mobile jets.

The small increase in HCN production from C_2H_4, and in the extent of NO decomposition, in the presence of N_2O or CO_2 (Table III), might also be attributed to poisoning of the walls against atom recombination by these molecules in the unpoisoned system of apparatus (I). This wall effect might also provide an explanation for the enhanced afterglow intensity observed downstream by Kaufman and Kelso (25) when N_2O was added upstream. These authors attributed the higher N-atom concentration downstream to a decreased rate of homogeneous recombination of N atoms in the region of higher temperature produced upstream by the absorption of energy by N_2O from excited nitrogen molecules of relatively low energy content. However, the rate of homogeneous recombination of N atoms has a small temperature dependence (14), and, although the temperature coefficient of this association reaction has generally been considered to have a negative value (55), there have been some indications (43, 44) that it may even have a small positive value.

Since no NH_3 decomposition was observed when C_2H_4 was added upstream, it is apparent that C_2H_4 may remove the N_2^* responsible for the NH_3 reaction. This is not surprising, in view of the many degrees of freedom of the ethylene molecule. However, although an excited C_2H_4 molecule formed during a collision of the Second Kind with N_2^* might suffer some decomposition, such fragments would consume N atoms (1) before producing HCN. In the opinion of the authors, the direct formation of HCN from hydrocarbons through chemical reaction with N_2^* is considerably less probable than the decomposition of NO induced by N_2^*.

A PROTECTED ANGIOTENSIN II

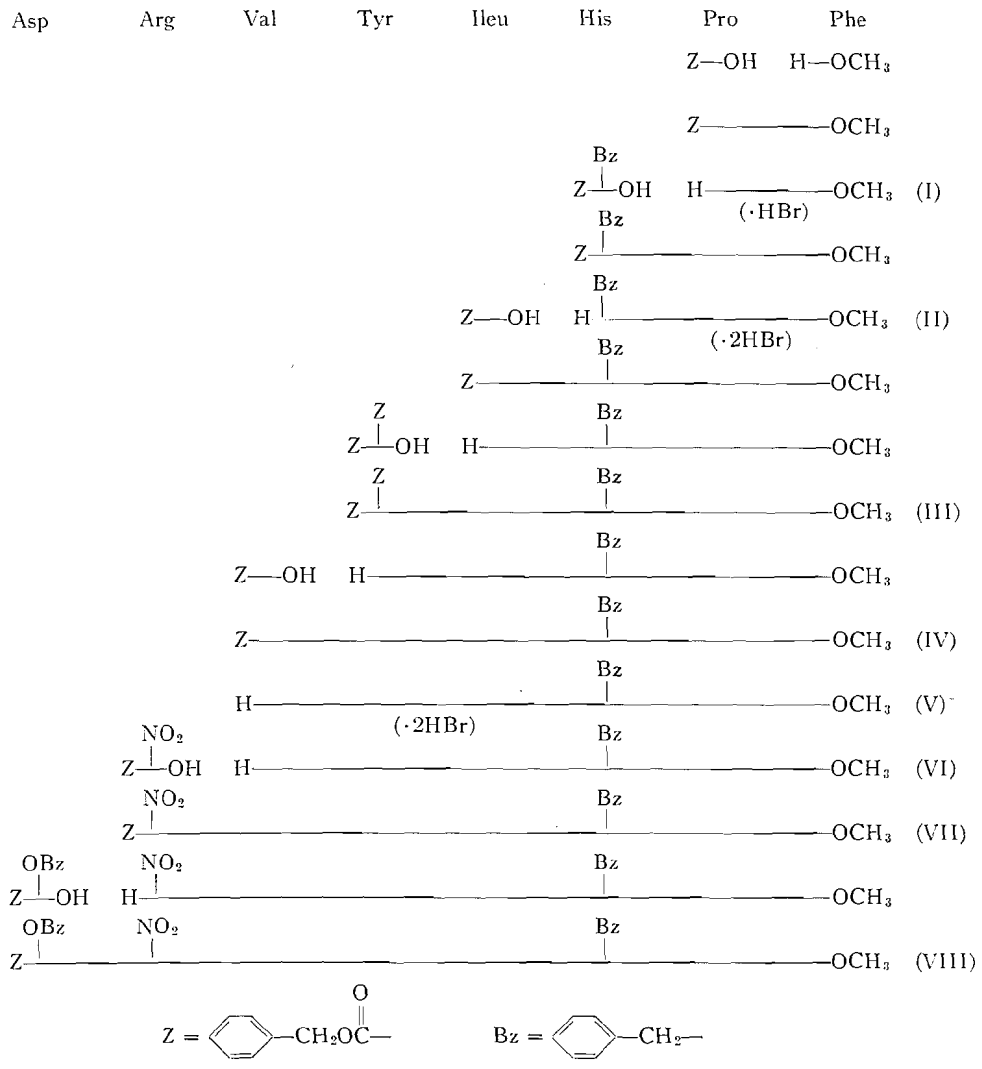
ROBERT H. MAZUR
Division of Chemical Research, G. D. Searle & Co., Skokie, Ill., U.S.A.

Received November 27, 1961

ABSTRACT

The preparation of an octapeptide, carbobenzoxy-(β-benzyl ester)-L-aspartyl-nitro-L-arginyl-L-valyl-L-tyrosyl-L-isoleucyl-(im)benzyl-L-histidyl-L-prolyl-L-phenylalanine methyl ester, a derivative of angiotensin II, is described.

We would like to report the synthesis of a protected angiotensin II, carbobenzoxy-(β-benzyl ester)-L-aspartyl-nitro-L-arginyl-L-valyl-L-tyrosyl-L-isoleucyl-(im)benzyl-L-histidyl-L-prolyl-L-phenylalanine methyl ester (VIII). The octapeptide was built up one



unit at a time beginning from the C-terminal end in order to minimize racemization (1). The ready purification of the intermediates and the final product indicated the absence of any substantial quantity of diastereomers. At each stage dicyclohexylcarbodiimide (2) was used to effect coupling. The synthesis was not carried through to angiotensin II itself as this material has already been reported (3, 4, 5) and also because our choice of protecting groups proved not to be especially felicitous from the standpoint of ready removal. Thus, we had expected to be able to debenzylate the imidazole ring of histidine by hydrogenation and, in fact, the reaction has been recently reported (6). In our hands, however, hydrogenolysis was erratic and unpredictable and usually stopped after partial debenzylation. Removal with sodium in liquid ammonia is undesirable as the powerful reducing system seems to cause side reactions with complex peptides (7, 8).

It might be anticipated that the C-terminal methyl ester would be difficult to remove without rearrangement in the presence of N-terminal aspartic acid. α-Aspartyl peptides in the presence of either strong acid or base gave mixtures containing varying amounts of β-aspartyl peptides,* presumably through a succinimide intermediate. This difficulty has been largely overcome recently by the introduction of the *p*-nitrobenzyl ester (10, 11, 12), which is reasonably stable to hydrogen bromide in acetic acid and can be removed by catalytic hydrogenation.

The structure of our angiotensin II derives from the method of synthesis and was confirmed by total hydrolysis of the product.

EXPERIMENTAL

We would like to thank R. T. Dillon and associates for analyses, rotations, and spectra. The rotations were carried out at 25±2° C. We are especially grateful to S. Eich and D. Malik for determination of the amino acid ratios. Certain peptide derivatives seemed to hold solvent tenaciously. The analytical samples were dried initially overnight at room temperature and approximately 100 mm pressure. When water of crystallization was indicated, the analysis was repeated after drying 4 hours at 100° under high vacuum.

L-Prolyl-L-phenylalanine Methyl Ester Hydrobromide (I)

L-Phenylalanine methyl ester hydrochloride (13) (54.0 g, 0.25 mole) and carbobenzoxy-L-proline (14) (61.5 g, 0.247 mole) were suspended in 600 ml methylene chloride, and 35.0 ml (0.25 mole) triethylamine was added. The clear solution was stirred in an ice bath and 53.5 g (0.26 mole) dicyclohexylcarbodiimide in 200 ml methylene chloride added. The mixture was allowed to stand overnight at 5°. The dicyclohexylurea was removed by filtration and the methylene chloride washed successively with 1 *N* hydrochloric acid, 10% sodium sulphate, and 1 *N* potassium bicarbonate. The organic phase was dried over sodium sulphate and concentrated to give 109 g of a viscous liquid.

The crude product was dissolved in 400 ml 2 *N* hydrobromic acid in acetic acid and allowed to stand 1½ hours at room temperature. The solution was concentrated to a small volume at 45° and the ester hydrobromide precipitated with ether. Purification was effected by dissolving the ester hydrobromide in 75 ml methanol and 750 ml ethyl acetate and concentrating until crystallization began. L-Prolyl-L-phenylalanine methyl ester hydrobromide was obtained as rectangular prisms, 57.7 g (66%), m.p. 171–172°, $[\alpha]_D^{25}$ −36° (*c* 2, water) (lit. (6), m.p. 169.5–170.5°, $[\alpha]_D^{19}$ −37° (*c* 2, water)).

(Im)Benzyl-L-histidyl-L-prolyl-L-phenylalanine Methyl Ester Dihydrobromide (II)

Carbobenzoxy-(im)benzyl-L-histidine (15, 16, 17) (31.0 g, 0.0815 mole) was dissolved in 100 ml dimethylformamide containing 11.6 ml (0.083 mole) triethylamine and the solution diluted with 300 ml methylene chloride. Finely powdered I (29.4 g, 0.082 mole) was added, followed by 17.3 g (0.084 mole) dicyclohexylcarbodiimide in 100 ml methylene chloride. The mixture was stirred in an ice bath for 1 hour and allowed to stand overnight at 5°. After removal of the dicyclohexylurea by filtration, the methylene chloride was washed successively with 1 *N* hydrochloric acid, 10% sodium sulphate, and 1 *N* potassium bicarbonate, dried over sodium sulphate, and the solvents distilled under vacuum.

The residual oil was dissolved in 300 ml 2 *N* hydrobromic acid in acetic acid and allowed to stand 1 hour at room temperature. The solution was concentrated nearly to dryness at 45° and the residue slurried with ethyl acetate to yield 48.9 g (90.5%) tripeptide, m.p. 211–214°. Crystallization from methanol – ethyl

**For a recent review of the problems associated with the synthesis of aspartyl and glutamyl peptides, see reference 9.*

acetate gave (im)benzyl-L-histidyl-L-prolyl-L-phenylalanine methyl ester dihydrobromide as long silky needles, m.p. 217–219°; $[\alpha]_D^{23}$ +26° (*c* 1, methanol), $[\alpha]_D^{26}$ +28° (*c* 1, water) (lit. (6), m.p. 199–201°, $[\alpha]_D^{21}$ −23° (*c* 3, water)).

O,N-Dicarbobenzoxy-L-tyrosyl-L-isoleucyl-(im)benzyl-L-histidyl-L-prolyl-L-phenylalanine Methyl Ester (III)

Compound II (53.2 g, 0.080 mole) was dissolved in 100 ml water, layered with 250 ml ethyl acetate, and 8.9 g (0.16 mole) potassium hydroxide in 15 ml water added, followed by 500 ml cold 50% potassium carbonate. The mixture was shaken vigorously, the ethyl acetate layer separated, the aqueous layer extracted with 100 ml ethyl acetate, and the combined extracts dried over sodium sulphate and concentrated. The total crude ester in 300 ml methylene chloride was added to 20.9 g (0.079 mole) carbobenzoxy-L-isoleucine (3) in 150 ml methylene chloride. The solution was stirred in an ice bath and 17.1 g (0.083 mole) dicyclohexylcarbodiimide in 100 ml methylene chloride added. The mixture was allowed to stand overnight at 5°. The usual work-up yielded 55.0 g (93%) carbobenzoxy-L-isoleucyl-(im)benzyl-L-histidyl-L-prolyl-L-phenylalanine methyl ester, a glass-like material.

The above crude protected tetrapeptide (15.02 g, 0.02 mole) in 80 ml 2 *N* hydrogen bromide in acetic acid was allowed to stand 1½ hours at room temperature and the solution concentrated to dryness at 45°. The residue was dissolved in 15 ml water and the solution extracted with ether to remove benzyl bromide. The aqueous layer was neutralized with 2 equivalents of 40% potassium hydroxide, basified with 200 ml 50% potassium carbonate, and the crude ester extracted into ethyl acetate. The ethyl acetate was dried over sodium sulphate and distilled to yield 12.40 g (100%) L-isoleucyl-(im)benzyl-L-histidyl-L-prolyl-L-phenylalanine methyl ester, a glass-like material.

The above crude ester (0.02 mole) and 11.20 g (0.025 mole) O,N-dicarbobenzoxy-L-tyrosine (18, 19) in 150 ml methylene chloride were stirred in an ice bath and treated with 5.15 g (0.025 mole) dicyclohexylcarbodiimide in 50 ml methylene chloride. The mixture was allowed to stand overnight at 5° and, on working up as usual, gave 30.0 g of an oily residue. The total material was purified by countercurrent distribution in methanol – water – chloroform – carbon tetrachloride 37:10:26:27, 40 ml phases, 136 transfers. The peaks were located by ultraviolet absorption at 278 mμ. The main product had a partition coefficient $K = 0.09$. A by-product with $K = 0.37$ was also present. From tubes 3–25 was isolated 15.2 g (72%) of amorphous O,N-dicarbobenzoxy-L-tyrosyl-L-isoleucyl-(im)benzyl-L-histidyl-L-prolyl-L-phenylalanine methyl ester, sinter from 90°, liquefy 146–151°. Crystallization from methanol gave circular plates, lose shape 89–90°, liquefy above 160°, $[\alpha]_D^{24}$ −43° (*c* 1, methanol).

Anal. Calc. for $C_{59}H_{65}N_7O_{11}$: C, 67.60; H, 6.25; N, 9.36. Calc. for $C_{59}H_{65}N_7O_{11}\cdot H_2O$: C, 66.46; H, 6.33; N, 9.20. Found: C, 66.57; H, 6.53; N, 9.05. After drying at 100°, found: C, 66.91; H, 6.18.

Carbobenzoxy-L-valyl-L-tyrosyl-L-isoleucyl-(im)benzyl-L-histidyl-L-prolyl-L-phenylalanine Methyl Ester (IV)

Compound III (21.0 g, 0.02 mole) in 150 ml 2 *N* hydrogen bromide in acetic acid was allowed to stand 1½ hours at room temperature. The solution was concentrated to dryness at 45°, the residue dissolved in 150 ml 33% methanol, benzyl bromide removed by ether extraction, and the aqueous layer treated with 50 ml each of saturated potassium bicarbonate and saturated potassium carbonate. The basic ester was taken up in ethyl acetate, the ethyl acetate dried over sodium sulphate and distilled to yield 15.6 g (100%) L-tyrosyl-L-isoleucyl-(im)benzyl-L-histidyl-L-prolyl-L-phenylalanine methyl ester, a glass-like material.

Total crude base (0.02 mole) and 5.78 g (0.023 mole) carbobenzoxy-L-valine (14) in 100 ml methylene chloride were stirred in an ice bath and 4.75 g (0.023 g) dicyclohexylcarbodiimide in 50 ml methylene chloride was added. The mixture was allowed to stand overnight at 5°. The usual work-up yielded 18.8 g of a glass which was purified by countercurrent distribution in methanol – water – chloroform – carbon tetrachloride 37:10:26:27, 40 ml phases, 250 transfers. The peaks were located by ultraviolet absorption at 278 mμ. Two materials ($K_1 = 0.16$ and $K_2 = 0.50$) proved to be present. The desired product was the one with the lower partition coefficient, and from tubes 20–55 was obtained 13.4 g (66%) of carbobenzoxy-L-valyl-L-tyrosyl-L-isoleucyl-(im)benzyl-L-histidyl-L-prolyl-L-phenylalanine methyl ester as a white powder, m.p. 188–191°. Crystallization from methanol – ethyl acetate by concentration to the cloud point gave circular plates, m.p. 192–194°, $[\alpha]_D^{23}$ −66° (*c* 1, methanol), λ_{max}^{MeOH} 252, 258, 264, 268, 278.5 mμ, $\epsilon_{278.5}$ 1490. The amino acid composition (except for (im)benzyl-histidine) was determined by Stein–Moore (20) analysis. Found: Val, 1.04; Tyr, 0.98; Ileu, 1.03; Pro, 1.00; Phe, 1.10.

Anal. Calc. for $C_{56}H_{68}N_8O_{10}$: C, 66.38; H, 6.77; N, 11.06. Calc. for $C_{56}H_{68}N_8O_{10}\cdot H_2O$: C, 65.22; H, 6.84; N, 10.87. Found: C, 65.08; H, 6.58; N, 10.61. After drying at 100°, found: C, 66.06; H, 6.80.

Carbobenzoxy-L-valyl-L-tyrosyl-L-isoleucyl-(im)benzyl-L-histidyl-L-prolyl-L-phenylalanine

Compound IV (5.15 g, 0.005 mole) in 45 ml methanol was cooled in an ice bath and 5.0 ml 4 *N* lithium hydroxide added. The solution was allowed to stand ½ hour at room temperature and treated with an amount of ca. 4 *N* hydrochloric acid exactly equivalent to the alkali present. The mixture was diluted with 50 ml water, the product filtered, washed with water, and dried to yield 5.05 g (98%) of the carbobenzoxy-hexapeptide acid, m.p. 171–174°. Crystallization from methanol – ethyl acetate by concentration to the cloud point gave a white powder, m.p. 176–179°, $[\alpha]_D^{26}$ −50° (*c* 1, methanol).

Anal. Calc. for $C_{55}H_{66}N_8O_{10}$: C, 66.11; H, 6.66; N, 11.22. Calc. for $C_{55}H_{66}N_8O_{10}\cdot H_2O$: C, 64.94; H, 6.74; N, 11.02. Found: C, 64.32; H, 6.72; N, 11.19. After drying at 100°, found: C, 64.72; H, 6.54.

L-*Valyl*-L-*tyrosyl*-L-*isoleucyl-(im)benzyl*-L-*histidyl*-L-*prolyl*-L-*phenylalanine Methyl Ester Dihydrobromide (V)*

Compound IV (1.03 g, 0.001 mole) in 10 ml 2 *N* hydrobromic acid in acetic acid was allowed to stand 1 hour at room temperature and concentrated to dryness at 50°. The residue was precipitated from methanol with ethyl acetate and gave the desired hexapeptide ester dihydrobromide as a white powder, 0.79 g (76%), m.p. 220–223°. Crystallization from methanol – ethyl acetate by concentration to the cloud point raised the melting point to 224–225°, $[\alpha]_D^{25}$ −20° (*c* 1, methanol).

Anal. Calc. for $C_{48}H_{64}Br_2N_8O_8$: C, 55.36; H, 6.20; N, 10.77. Calc. for $C_{48}H_{64}Br_2N_8O_8 \cdot H_2O$: C, 54.44; H, 6.28; N, 10.58. Found: C, 53.83; H, 6.24; N, 10.44. After drying at 100°, found: C, 54.02; H, 5.98.

L-*Valyl*-L-*tyrosyl*-L-*isoleucyl-(im)benzyl*-L-*histidyl*-L-*prolyl*-L-*phenylalanine Methyl Ester (VI)*

Crude dihydrobromide, obtained as described above from 6.56 g compound IV, was dissolved in 25 ml water and the solution washed with ethyl acetate. Addition of saturated potassium carbonate solution resulted in a precipitate, which was removed by filtration and washed thoroughly with water and ethyl acetate. The white powder proved to be hexapeptide ester, 3.45 g (61%), m.p. 216–219°, $[\alpha]_D^{26}$ −52° (*c* 1, methanol).

Anal. Calc. for $C_{48}H_{62}N_8O_8$: C, 65.58; H, 7.11; N, 12.75. Calc. for $C_{48}H_{62}N_8O_8 \cdot H_2O$: C, 64.26; H, 7.19; N, 12.49. Found: C, 63.85; H, 7.33; N, 12.50. After drying at 100°, found: C, 65.06; H, 7.29.

Carbobenzoxy-nitro-L-*arginyl*-L-*valyl*-L-*tyrosyl*-L-*isoleucyl-(im)benzyl*-L-*histidyl*-L-*prolyl*-L-*phenylalanine Methyl Ester (VII)*

Compound VI (3.25 g, 0.0037 mole) and 2.12 g (0.006 mole) carbobenzoxynitro-L-arginine (21) were dissolved in 17 ml dimethylformamide, the solution was cooled in an ice bath, and 1.36 g (0.0066 mole) dicyclohexylcarbodiimide was added with stirring. The mixture was allowed to stand overnight at 5°. The dicyclohexylurea was filtered, washed with methanol, and the combined filtrates were diluted with a large volume of water. The resulting white solid was purified by countercurrent distribution in methanol – water – chloroform – carbon tetrachloride 37:10:26:27, 40 ml phases, 200 transfers. The peaks were located by ultraviolet absorption at 270 mμ. The major product had $K = 0.34$ with an impurity at $K = 0.92$. Fractions 24–82 yielded the desired protected heptapeptide, 4.43 g (98%), m.p. 220–221°. Crystallization from methanol gave a granular solid, m.p. 224–225°, $[\alpha]_D^{25}$ −67° (*c* 1, methanol), λ_{max}^{MeOH} 270 mμ, ε 16,700.

Anal. Calc. for $C_{62}H_{79}N_{13}O_{13}$: C, 61.32; H, 6.56; N, 15.00. Found: C, 60.80; H, 6.80; N, 14.96.

Dibenzyl-L-*Aspartate p-Toluenesulphonate*

L-Aspartic acid (13.3 g, 0.1 mole) and 20.9 g (0.11 mole) *p*-toluenesulphonic acid monohydrate were dissolved in 108 g (1.0 mole) benzyl alcohol and the solution diluted with 200 ml carbon tetrachloride. The solution was heated overnight under reflux (continuous water separator). Dilution of the cooled solution with 1 l. ether precipitated the dibenzyl ester toluenesulphonate as white needles, 47.8 g (98%), m.p. 156–158°. Crystallization from 1:1 isopropanol – ethyl acetate raised the melting point to 159–161°, $[\alpha]_D^{26}$ −2° (*c* 1, methanol) (lit. (22), m.p. 158–160°).

Anal. Calc. for $C_{25}H_{27}NO_7S$: C, 61.84; H, 5.61; N, 2.89. Found: C, 61.88; H, 5.52; N, 2.73.

Dibenzyl Carbobenzoxy-L-*aspartate*

Dibenzyl aspartate toluenesulphonate (41.6 g, 0.0858 mole) was suspended in 400 ml chloroform, the mixture stirred in an ice bath and treated successively with 215 ml (50% excess) 1 *M* potassium carbonate and 19.3 ml (0.0945 mole) 4.9 *M* carbobenzoxy chloride in toluene. The mixture was stirred very vigorously for 2 hours at 0°. The chloroform layer was washed with 1 *N* hydrochloric acid and 10% sodium sulphate, dried over sodium sulphate, and the chloroform distilled. The residue was crystallized from cyclohexane to yield, in two crops, 36.7 g (96%) dibenzyl carbobenzoxy-L-aspartate, m.p. 67–68.5° (lit. (23), m.p. 66.5°).

β-Benzyl Carbobenzoxy-L-*aspartate*

The procedure of Bryant *et al.* (24) was followed. From 22.4 g (0.05 mole) diester was obtained 11.8 g (66%) of the desired monoester, thick needles from 1:1 benzene–cyclohexane, m.p. 107–109°; $[\alpha]_D^{26}$ 0° (*c* 1, methanol), +10° (*c* 1, acetic acid) (lit. (24), m.p. 107–109°).

Carbobenzoxy-(β-benzyl ester)-L-*aspartyl-nitro*-L-*arginyl*-L-*valyl*-L-*tyrosyl*-L-*isoleucyl-(im)benzyl*-L-*histidyl*-L-*prolyl*-L-*phenylalanine Methyl Ester (VIII)*

Heptapeptide VII (1.95 g, 0.0016 mole) in 20 ml 2 *N* hydrobromic acid in acetic acid was allowed to stand 1 hour at room temperature. The solution was concentrated at 45° to about 10 ml and diluted with 200 ml dry ether. The resulting precipitate was isolated by filtration, redissolved in 10 ml dry methanol, and precipitated with 200 ml dry ether, yielding 2.24 g (slightly over theory) of a non-hygroscopic white powder, decomp. above 195°, no m.p.

The above product was suspended in 4 ml dimethylformamide, and 0.50 ml triethylamine added and the mixture stirred until the peptide dissolved. The mixture was cooled in an ice bath, the precipitate filtered and washed with 4 ml cold dimethylformamide to yield 0.50 g (100%) triethylamine hydrobromide.

The filtrate was stirred in an ice bath and treated successively with 0.71 g (0.002 mole) β-benzyl-carbobenzoxy-L-aspartate and 0.45 g (0.0022 mole) dicyclohexylcarbodiimide. The mixture was allowed to stand overnight at 5°, dicyclohexylurea removed by filtration, and the filtrate diluted with water and extracted

with chloroform. The product which remained suspended in the aqueous dimethylformamide was filtered, washed with ethyl acetate, and dried to yield 2.06 g of a white powder, m.p. 168–173°. Reprecipitation from methanol – ethyl acetate yielded 0.87 g (39%) of the protected octapeptide VIII, m.p. 193–196°. Slow evaporation of a solution of this material from methanol – ethyl acetate gave circular plates, m.p. 206–208°, $[\alpha]_D^{26}$ −65° (*c* 0.5, methanol), λ_{max}^{MeOH} 270 mμ, ε 17,700.

Anal. Calc. for $C_{73}H_{90}N_{14}O_{16}$: C, 61.76; H, 6.39; N, 13.82. Found: C, 61.27; H, 6.51; N, 13.82.

A sample (5.0 mg) in 6 ml acetic acid and 0.1 ml conc. hydrochloric acid was hydrogenated overnight over 50 mg palladium on barium sulphate (25) in order to remove the protecting groups from aspartic acid and arginine. The residue, after removal of the catalyst, was analyzed for amino acid ratio (except for (im)-benzyl-histidine) by the Stein–Moore method (20).

Found: Asp, 1.15; Arg, 0.96; Val, 1.17; Tyr, 0.95; Ileu, 0.94; Pro, 1.00; Phe, 1.24.

COORDINATION COMPOUNDS OF OLEFINS WITH SOLID COMPLEX SILVER SALTS

I. COORDINATION COMPOUNDS WITH ANHYDROUS SILVER FLUOBORATE[1]

H. W. QUINN AND D. N. GLEW
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received February 15, 1962

ABSTRACT

Interaction of solid silver fluoborate with the gaseous olefins ethylene, propylene, and the four butenes has been observed to provide 12 new stoichiometric solid coordination compounds (silver fluoborate – olefin complexes) of high stability. Experimental investigation of the univariant pressure–temperature stability lines for the complexes has been made and the thermodynamic functions calculated: the heat content change for complex dissociation is between 9 and 13 kcal/mole of olefin liberated. Infrared spectra of the complexed olefins indicate that the strength of the silver–olefin bond is primarily dependent upon the basicity of the olefin and a comparison of the thermodynamics of dissociation shows anomalous behavior on the part of isobutylene and *trans*-2-butene as compared with the regularity displayed by the other four olefins.

INTRODUCTION

Although a number of studies have been reported on the argentation of olefins in solution (1–10), there are relatively few data on the corresponding solid silver salt – olefin complexes, probably since these are not readily formed on exposure of the silver salts to the olefin. Of those silver salts which complex directly with olefins, silver perchlorate forms complexes with cyclohexene and the pinenes which are solids at room temperature containing 2 moles of olefin per mole of silver perchlorate, whilst silver nitrate forms with cyclohexene a complex which is a liquid at room temperature, crystallizing at 0° C (11). Presently, no structural data have been reported for the silver salt – monoolefin complexes, although the structures are available for the related silver salt – cyclic polyolefin complexes $AgClO_4.C_6H_6$ (12) and $AgNO_3.C_8H_8$ (13).

The lower olefin complexes of silver salts are apparently not readily formed and generally exert high dissociation pressures, as observed by Francis (14), who formed the liquid complexes silver nitrate – propylene and silver nitrate – 1-butene, using the olefins under pressure, but was unable to obtain similar complexes with ethylene, isobutylene, and 2-butene. Similar solid complexes of the cuprous halides with the lower olefins $CuCl.C_2H_4$, $CuCl.C_3H_6$, $CuCl.iso\text{-}C_4H_8$, and $CuBr.C_2H_4$ (15), which probably involve copper–olefin interactions analogous to those of the silver–olefin complexes, are relatively unstable, $CuCl.C_3H_6$ decomposing at 20° C and $CuCl.iso\text{-}C_4H_8$ at −18° C. Surprisingly, no reference has yet been made to solid complexes between silver perchlorate and the lower olefins.

In marked contrast to the difficulty of formation and lack of stability of the known silver and copper salt – lower olefin complexes, silver fluoborate readily absorbs ethylene, propylene, and the four butenes at low pressures at room temperature to yield stable solid silver fluoborate – olefin complexes, for which the stoichiometries, pressure–temperature stability lines, and infrared absorption spectra are reported. Also included for comparison is a limited investigation of the solid propylene complexes of silver perchlorate (this salt being isomorphous with silver fluoborate) and of silver hexafluoroantimonate (which has a similar, but larger, perfluorinated anion).

[1]*Contribution No. 41.*

EXPERIMENTAL

Anhydrous silver fluoborate was prepared from silver fluoride and boron trifluoride according to the method of Olah and Quinn (16).

Anhydrous silver hexafluoroantimonate was prepared by reaction of antimony pentafluoride with silver fluoride in anhydrous liquid hydrogen fluoride; the solid silver hexafluoroantimonate was precipitated and the hydrogen fluoride removed by pumping. Both salts were very hygroscopic and were stored under normal pentane until required, when the paraffin was removed by pumping.

Anhydrous silver perchlorate, purchased from A. S. LaPine and Co., was ground in a mortar under pentane to give a smaller particle size.

Ethylene, propylene, *cis*-2-butene, and *trans*-2-butene were Matheson C.P. Grade with a 99.5% minimum purity.

1-Butene and isobutylene were Phillips Pure Grade materials of 99% minimum purity. Before use, all olefins were dried by passage through a column containing phosphorus pentoxide and were freeze-degassed at liquid nitrogen temperatures.

Determination of Complex Stoichiometry

The stoichiometry of the silver salt – olefin complexes was determined by measurement of the weight increase attending complex formation of 250–400 mg of silver salt contained in a quartz bucket suspended from a quartz spiral of sensitivity 5.577 mg/mm, after admission of the gaseous olefin to the thermostated spiral chamber. The spiral extension was measured to ±0.02 mm with a cathetometer by observing the displacement of the tip of the lower hook of the spiral. Temperature control was maintained to ±0.1° C by pumping fluid from a thermostat through an outer jacket of the spiral chamber.

In order to detect all the stoichiometric complexes, the olefin pressures applied to the silver salt were gradually increased and the temperature of the spiral chamber gradually lowered. When olefin ceased to be taken up under a given set of conditions, more pressing conditions were applied until, with the exception of ethylene, the olefin attained its liquid saturation value.

Complex Dissociation Pressure Measurement

Although the approximate locations of the pressure–temperature stability lines for the various silver salt – olefin equilibria were obtained from the stoichiometric studies using the quartz spiral, these olefin pressure data were insufficiently precise for determination of the corresponding thermodynamic functions. A more accurate determination of the complex stability lines (complex dissociation pressures) was therefore conducted as follows. Approximately 2 g of silver salt contained in a 25-ml glass vapor pressure cell was evacuated and then exposed to the olefin at 650 mm Hg pressure at between 20 and 30° C until no further pressure decrease was observed. The temperature of the cell was then decreased to between −5 and 0° C and the system allowed to react until no further pressure drop was detectable; in this manner, the complex with the highest olefin content was obtained. The cell system containing the complex was then allowed to equilibrate with its lower complex or solid silver salt at a series of preselected temperatures, and the equilibrium olefin pressures were measured on a mercury manometer to ±0.01 mm using a cathetometer. After measurement of the pressure–temperature equilibrium line for decomposition of the highest olefin complex, gaseous olefin was removed from the system to furnish the complex of next-lower olefin content, which in turn was investigated in the same manner. Temperatures between −5 and 55° were controlled to ±0.1° C by immersing the vapor pressure cell in a liquid thermostat, while lower temperatures were maintained using freezing monochlorobenzene and chloroform baths.

Infrared Spectra

Samples were prepared by exposing the silver salts to the olefin at pressures such that only the silver salt:2 olefin complex was produced. Nujol and fluorolube mulls of these 1:2 complexes were prepared in a dry box and the infrared spectra recorded with a Perkin–Elmer 221 spectrophotometer equipped with NaCl optics.

RESULTS

Complex Stoichiometry

In Table I are presented the experimental values for the stoichiometry of the silver fluoborate – olefin complexes as determined by the quartz spiral method, together with the integral ratios considered to represent their exact stoichiometry.

Of the olefins studied, ethylene is exceptional in forming complexes with silver fluoborate:ethylene ratios of 1:1, 2:3, 1:2, and 1:3, of which the 1:1 and 2:3 complexes are peculiar to ethylene alone. Furthermore, it is observed (*vide infra Dissociation Pressure Data*) that the 2:3 and 1:2 ethylene complexes undergo phase transitions to yield two

TABLE I

Stoichiometry of solid silver fluoborate olefinates

Olefin	Observed stoichiometry	Exact stoichiometry
Ethylene	$AgBF_4.0.960\pm0.022C_2H_4$	$AgBF_4.C_2H_4$
	$AgBF_4.1.489\pm0.014C_2H_4$	$AgBF_4.1.5C_2H_4$
	$AgBF_4.1.993\pm0.011C_2H_4$	$AgBF_4.2C_2H_4$
	$AgBF_4.2.989\pm0.007C_2H_4$	$AgBF_4.3C_2H_4$
Propylene	$AgBF_4.1.996\pm0.007C_3H_6$	$AgBF_4.2C_3H_6$
	$AgBF_4.2.964\pm0.005C_3H_6$	$AgBF_4.3C_3H_6$
1-Butene	$AgBF_4.1.968\pm0.009C_4H_8$	$AgBF_4.2C_4H_8$

	$AgBF_4.2.927\pm0.006C_4H_8$	$AgBF_4.3C_4H_8$
trans-2-Butene	$AgBF_4.1.859\pm0.009C_4H_8$	$AgBF_4.2C_4H_8$

higher-temperature modifications, giving a total of six distinct silver fluoborate – ethylene complexes. For propylene and the four butenes the lowest complexes, yielding solid silver fluoborate and olefin on decomposition, maintain a 1:2 silver fluoborate:olefin ratio, as reported for the silver perchlorate complexes of cyclohexene and the pinenes (11). The 1:2 complexes of isobutene and *trans*-2-butene were observed not to form 1:3 complexes even at high olefin pressures and low temperatures, which behavior contrasts with that of the other olefins.

The striking one-to-one correspondence of the silver fluoborate:ethylene complex formulae with the 1:1, 2:3, 1:2, and 1:3 series of silver iodide ammoniates observed by Biltz and Stollenwerk (17) suggests isomorphism with similar volume ratios for ethylene molecule:fluoborate lattices and ammonia molecule:iodide lattices. It is, therefore, suggested that the ability of ethylene to form a graded series of silver fluoborate complexes, as opposed to the higher olefins which form, at most, only two complexes, is dependent mainly upon its small size, which permits its incorporation into lattices with only small lattice energy differences. The fewer complexes formed by the other olefins would indicate that in order to incorporate the larger olefins, the necessary lattice expansions are such that only specifically oriented sites can be occupied by olefin molecules to stabilize the complex lattice. The lack of stability of any 1:3 complex between silver fluoborate and isobutylene or *trans*-2-butene probably arises from a blocking of the sites available for such complex formation by the alkyl groups of those olefin molecules already complexed.

Dissociation Pressure Data

In Table II are presented the series of solid silver salt – olefin complexes, values of the constants A and B, with standard errors, for the dissociation pressure equation $\log P$ (mm) $= A - B/(273.16 + t°\ \mathrm{C})$ for complex dissociation to a lower complex or to the silver salt and gaseous olefin, the temperature ranges of experimental investigation, and the complex dissociation pressure (International mm of Hg) computed at 25° C. The constants A and B, together with their standard errors, were derived from the least-squares fit of four to nine experimental pressure–temperature measurements over the indicated temperature ranges. Investigation of the solid $AgBF_4.2$(1-butene) complex was limited to an upper temperature of 37.5° C by fusion of the complex, whilst the $AgBF_4.3$ olefin complexes were necessarily investigated at temperatures below 10° C where the complex dissociation pressures were less than 1 atm.

*Vapor pressures at 25° C from equation.

The relative positions of the linear log P vs. $1/T$ dissociation lines for the six silver fluoborate – ethylene complexes are illustrated in Fig. 1, in which the lines represent the higher complex undergoing dissociation to the next lower complex and gaseous ethylene, the lowest complex yielding silver fluoborate and ethylene. The complexes $AgBF_4.1.5C_2H_4$ and $AgBF_4.2C_2H_4$ are observed to display breaks in their dissociation lines occurring at 25.3 and 27.3° C respectively, indicating phase transitions from a lower-temperature α form to a higher-temperature β modification in each case; the dissociation equation constants, A and B, for both α and β forms of each complex are included in Table II.

A comparison of the propylene dissociation pressures at 25° C for the pairs of complexes $AgClO_4.2C_3H_6$–$AgBF_4.2C_3H_6$ and $AgBF_4.3C_3H_6$–$AgSbF_6.3C_3H_6$ indicates increasing propylene complex stability with these salts in the order $AgClO_4 < AgBF_4 < AgSbF_6$. Since the silver salt – olefin complexes, as represented by Dewar (18), result from direct interaction of olefin with the silver ion and do not involve any large olefin–anion interactions, it is suggested that these observed differences in propylene complex stability arise from differences between the lattice structures of the complexes due to the changing silver ion – anion interactions with changes of anion composition, size, and geometry. The considerably increased stability of the silver fluoborate – propylene complex over that of the perchlorate is unexpected since fluoborate and perchlorate salts are generally isomorphous with similar lattice spacings (19, 20); we are, therefore, forced to conclude that although these complexes may be isomorphous, the energy required for lattice expansion permitting incorporation of propylene is greater for the perchlorates. The even greater stability of the silver hexafluoroantimonate complex most probably arises from the larger radius of the SbF_6^- anion, which increases lattice spacings (21), reduces cation–anion crystal energy terms, and leads to reduction of repulsive energy attending the relatively smaller lattice expansion for incorporation of propylene into the complex.

Thermodynamic Data

In Table III are presented values for the changes of the standard thermodynamic functions with standard errors at 25° C for complex dissociation to the next-lower complex

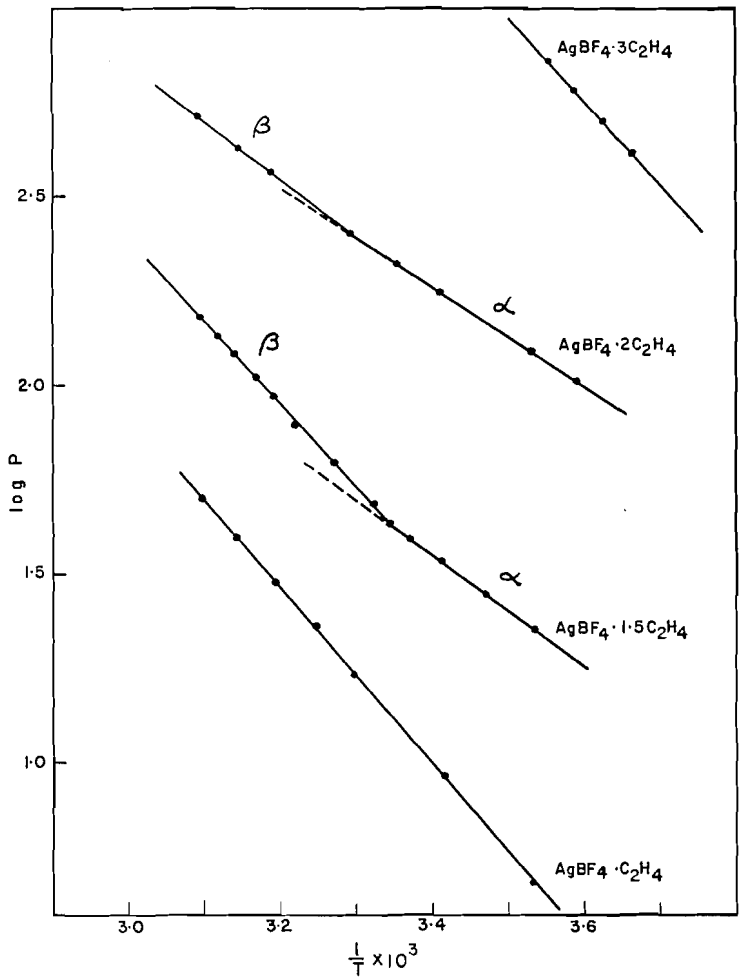

FIG. 1. Stability lines for the solid silver fluoborate – ethylene complexes.

and 1 mole of gaseous olefin at 1 International atm pressure, as represented, for example, by the equation

$$2(AgBF_4.1.5C_2H_4) \rightarrow 2(AgBF_4.C_2H_4) + C_2H_4.$$

These thermodynamic functions, designated by the subscript E, have been derived from the dissociation equation constants in Table II and are expressed in thermochemical calories (1 cal = 4.1840 joules).

In Table IV values are presented for the standard thermodynamic functions at 25° C, designated by subscript D, which represent complex dissociation to solid silver salt and 1 mole of gaseous olefin at 1 International atm pressure, as exemplified by the equation

$$\tfrac{2}{3}(AgBF_4.1.5C_2H_4) \rightarrow \tfrac{2}{3}AgBF_4 + C_2H_4.$$

The occurrence of transitions at so nearly the same temperature in both the $AgBF_4.1.5C_2H_4$ and $AgBF_4.2C_2H_4$ complexes, for which the enthalpy change differences ΔH_D^0 $(1.5\beta) - \Delta H_D^0$ $(1.5\alpha) = +1083$ and ΔH_D^0 $(2\beta) - \Delta H_D^0$ $(2\alpha) = +1023$ cal/mole of ethylene are both positive of the same magnitude, is indicative of similar constitutional

changes occurring in both complexes at the transition points and of probable isomorphism of the ionic lattices of the 1.5α and 2α forms and of the 1.5β and 2β forms. This conclusion is supported by the good correlation with the $\Delta S_D^0/\Delta H_D^0$ regression line for the 1:2 complexes (*vide infra*) shown by the ΔS_D^0 and ΔH_D^0 functions of both the 1.5β and 2β ethylene complexes and the almost equal deviations from that regression line exhibited by the functions for the 1.5α and 2α modifications.

In Fig. 2 are shown the two linear $\Delta S_D^0/\Delta H_D^0$ correlations furnished by the thermodynamic functions for the silver salt.2 olefin and silver salt.3 olefin complexes, from which it is seen that the 1:3 complexes invariably present higher ΔS_D^0 and slightly lower ΔH_D^0 values than the corresponding 1:2 complexes. The $\Delta S_D^0/\Delta H_D^0$ regression line for the 1:2 complexes, if meaningful, extending over the wide stability range from $AgClO_4.2C_3H_6$, $AgBF_4.2C_2H_4$ (β), $AgBF_4.1.5C_2H_4$ (β) to $AgBF_4.2$ *cis*-2-butene suggests a similar ionic lattice type for all these complexes with sufficient spatial extension to accommodate

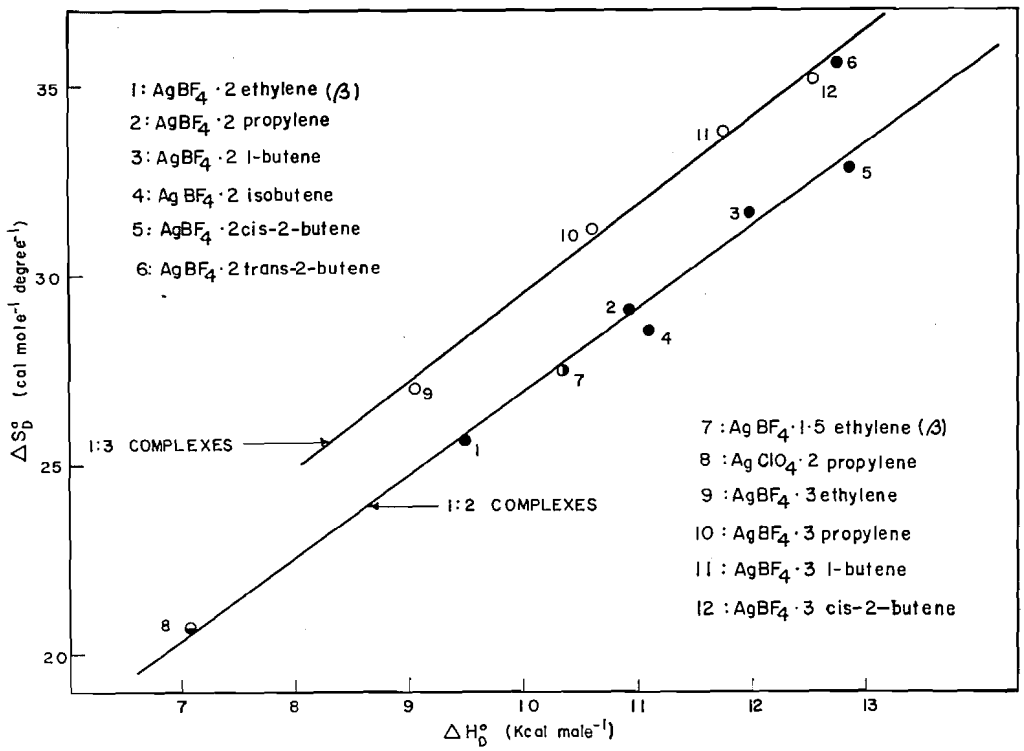

FIG. 2. Entropy–enthalpy plot for the silver salt olefinates.

olefins as large as 1-butene and *cis*-2-butene. The generally increasing ΔS_D^0 and ΔH_D^0 values exhibited by the larger olefins arise from increasing Ag^+–olefin attractive energies, which progressively limit the olefin freedom. *trans*-2-Butene, however, with a normal ΔH_D^0 value equal to that of *cis*-2-butene, presents an anomalously high ΔS_D^0 value, which is most reasonably attributed to its geometrical incompatability with its lattice environment leading to additional severe configurational restrictions. The lower values of ΔS_D^0 and ΔH_D^0 for $AgClO_4.2C_3H_6$, compared with the isomorphous $AgBF_4.2C_3H_6$, arise from increased repulsive perchlorate ion – olefin interactions (as compared with fluoborate ion – olefin interactions) which diminish the attractive orienting constraint of the silver ion – olefin bond. The source of these increased perchlorate lattice repulsions, leading to the enthalpy change reduction of 4000 cal/mole propylene, probably lies in the increased energy of perchlorate lattice expansion and anion displacement required to extend or break the donor–acceptor contacts of the perchlorate oxygen atoms with the electrophilic silver cation. This explanation is similar to that proposed by Sharp and Sharpe (21) for the aromatic complexes of silver fluoborate and perchlorate, except that the donor–acceptor bonding suggested by us is considered to approximate energetically more nearly to hydration and ammination (17) rather than to strong covalent bond formation.

The $\Delta S_D^0/\Delta H_D^0$ regression line for the 1:3 complexes is indicative of a common lattice type in which increases of silver ion – olefin bond strength, reflected in higher ΔH_D^0 values, are associated with increasing olefin restrictions and increased ΔS_D^0 values. The general displacement to higher entropy values of the $\Delta S_D^0/\Delta H_D^0$ line for the 1:3 complexes almost certainly results from the more severe orientation limitations of the olefin imposed

by the higher coordination of the silver cation; the lack of 1:3 complexes with isobutylene and *trans*-2-butene reflects their geometrical inability to pack within the space adjacent to the silver ion.

Infrared investigation of the fluorolube mulls of the $AgBF_4$.2 olefin complexes revealed absorption bands perturbed to lower frequencies for the olefin double-bond stretch vibrations in all complexes from ethylene to *trans*-2-butene. Although the band intensity for the ethylene complex was very low, that for the other olefins, including *trans*-2-butene, was moderate, indicating a small perturbation from central symmetry for complexed ethylene, but considerable non-central distortion of the complexed *trans*-2-butene, with non-symmetric ion fields at the double bond in both cases.

In Fig. 3 is illustrated the linear correlation of $\Delta\nu$ ($\nu_{\text{uncomplexed}} - \nu_{\text{complexed}}$), the olefin double-bond stretch frequency perturbation due to complex formation, with the olefin

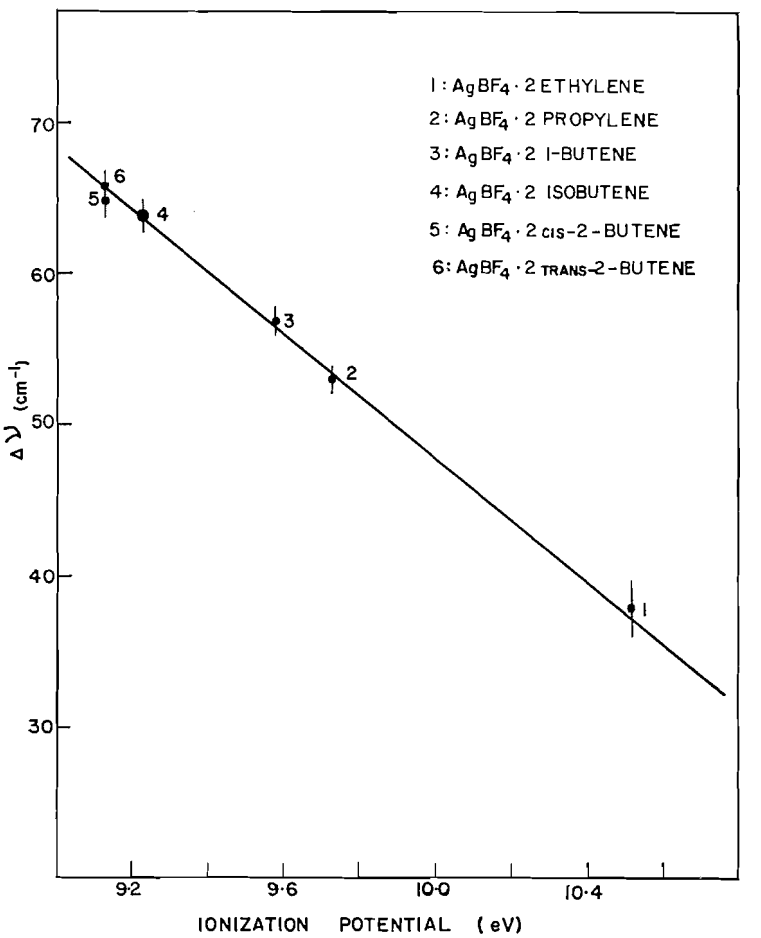

FIG. 3. Complexed olefin double-bond stretch perturbation – olefin ionization potential correlation.

ionization potential for the six solid 1:2 complexes. Values for $\nu_{\text{uncomplexed}}$ were determined from the infrared stretch frequencies of the olefins dissolved in carbon tetrachloride, except for the infrared-inactive ethylene and *trans*-2-butene, for which the Raman values

were used (22). The ionization potentials were taken from the work of Watanabe (23). The correlation shows that, with decreasing ionization potential, i.e. with increasing olefin basicity, the electrophilic silver cation effects increasingly larger perturbations of the olefin double-bond stretch frequency through the formation of stronger Ag^+–olefin bonds. This remarkably smooth linear correlation, involving the stretch frequency perturbation of olefins complexed in a solid ionic lattice and the ionization potentials in the unperturbed gaseous state, indicates that the silver ion – olefin bonds within the complexes must be fully formed or saturated and that other steric and lattice factors dependent upon olefin geometry are smaller and do not sensibly affect the Ag^+–olefin bonds. This point is further supported by the substantial agreement of the infrared shifts 65 and 66 cm^{-1} for *cis*- and *trans*-2-butene in the solid silver fluoborate complexes with the 62 and 65 cm^{-1} Raman shifts (24) for complex formation of these same olefins in aqueous silver nitrate solution, for which the silver cation environment differs considerably.

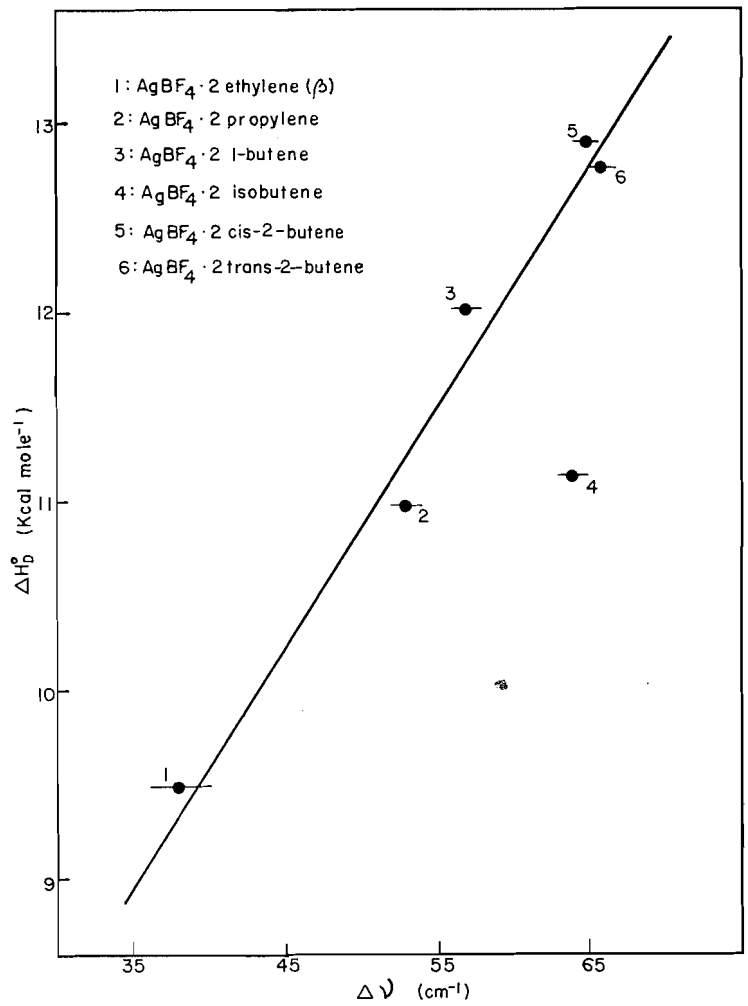

FIG. 4. Enthalpy – double-bond stretch perturbation plot for silver fluoborate.2 olefinates.

Since the Ag^+–olefin interaction energy in the solid silver fluoborate.2 olefin complexes will be some continuous function of $\Delta\nu$, and the correlation of Fig. 3 indicates that geometrical and steric factors little effect $\Delta\nu$, and thus the Ag^+–olefin bond energy, it is to be expected that the value of ΔH_D^0 for complex formation would be predominately determined by the Ag^+–olefin bond energy and should, therefore, correlate with the observed $\Delta\nu$ values. That this is so is illustrated in Fig. 4, where the ΔH_D^0 values for the 1:2 complexes are seen to be linearly related to the corresponding $\Delta\nu$ values. The ΔH_D^0 functions for the ethylene, propylene, 1-butene, and *cis*- and *trans*-2-butenes deviate from the regression line by less than 250 cal/mole of olefin, which is within the 95% confidence limit of error for the ΔH_D^0 values, whilst the ΔH_D^0 for the isobutylene complex deviates significantly by some 1500 cal/mole of olefin below that predicted from its $\Delta\nu$ value. In so far as isobutylene exhibits no deviation in Fig. 3, the low ΔH_D^0 value must be considered a real effect resulting from steric repulsions between the ionic lattice and the isobutylene molecule in its particular geometrical configuration. Since the ΔH_D^0 and ΔS_D^0 for the isobutylene complex correlate in Fig. 2, the reduced ΔH_D^0 value due to lattice repulsion must arise in such a manner that the complexed isobutylene is less severely restricted by the repulsion; this behavior sharply contrasts with that of the *trans*-2-butene complex, which presents a normal ΔH_D^0 but a large ΔS_D^0.

X-Ray diffraction studies now being pursued should aid in the elucidation of the difference between the various solid complexes since a knowledge of the lattice structures could permit a better estimation of the contribution to ΔH_D^0 effected by lattice changes.

ACKNOWLEDGMENTS

The contribution of D. Cook and C. D. Anderson, who have determined the infrared spectra of the complexes, is gratefully acknowledged by the authors.

STEREOCHEMISTRY OF ARSENIC

PART III. *o*-PHENYLENEDIARSINE OXYCHLORIDE[1]

W. R. CULLEN AND J. TROTTER

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received February 1, 1962

ABSTRACT

Crystals of *o*-phenylenediarsine oxychloride, $C_6H_4As_2Cl_2O$, are monoclinic with four molecules in a unit cell of dimensions $a = 14.50$, $b = 8.38$, $c = 7.66$ Å, $\beta = 105.8°$, space group $C2/c$. The structure has been determined from projections along the b and c axes. Each molecule is situated on a 2-fold symmetry axis and is planar except for the chlorine atoms, which lie one on either side of the plane of the other atoms. The values of the bond lengths and valency angles have been obtained. Abnormal valency angles at the arsenic and oxygen atoms are the result of their presence in the five-membered ring, and the unusual stability of the molecule in spite of these angles can be interpreted in terms of aromatic character, involving $d\pi-p\pi$ bonding. The intermolecular separations correspond to normal van der Waals interactions.

EXPERIMENTAL

o-Phenylenediarsine oxychloride (Fig. 1) was prepared by reducing a solution of *o*-phenylenediarsonic acid in concentrated hydrochloric acid with sulphur dioxide (1). The diarsonic acid was prepared by the reaction

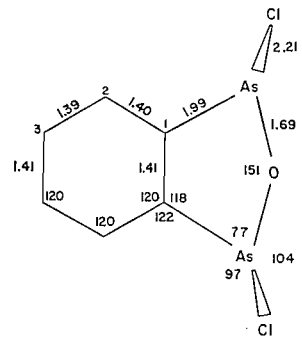

FIG. 1. Measured bond lengths (Å) and valency angles (degrees).

of sodium arsenite solution with diazotized *o*-aminophenylarsonic acid. The crude oxychloride was purified with charcoal and by recrystallization from carbon disulphide. The final product consisted of colorless plates, m.p. 146–149° (lit. value, 148°), with the (100) face developed.

The unit cell dimensions and space group were determined from rotation and oscillation photographs of crystals rotating about the *b*- and *c*-axes, and *h*0*l*, *h*1*l*, and *hk*0 Weissenberg films. The density was determined by displacing carbon tetrachloride from a density bottle.

The crystal data are: $C_6H_4As_2Cl_2O$; M, 312.8; m.p. 146–149°. Monoclinic, $a = 14.50\pm0.05$, $b = 8.38\pm0.02$, $c = 7.66\pm0.02$ Å, $\beta = 105.8\pm0.5°$. Volume of the unit cell = 896 Å^3. d_c (with $Z = 4$) = 2.31, $d_m \sim 2.4$ g cm^{-3}. Absorption coefficient for X rays: $\lambda = 1.542$ Å, $\mu = 143$ cm^{-1}. Total number of electrons per unit cell = $F(000) = 592$. Absent spectra: *hkl* when $(h+k)$ is odd, *h*0*l* when l is odd. Space group is either C_s^4—Cc or C_{2h}^6—$C2/c$.

The intensities of the *h*0*l* and *hk*0 reflections were recorded on Weissenberg films for a crystal rotating in turn about the *b*- and *c*-axes, with Cu K_α radiation, the multiple-film technique being used to correlate strong and weak reflections. The range of intensities measured was about 5000 to 1, the estimates being made visually. The crystal cross sections perpendicular to the rotation axes were 0.5×0.1 mm, but no absorption

[1]*Part I: W. R. Cullen and J. Trotter. Can. J. Chem.* **39**, *2602 (1961). Part II: J. Trotter. J. Chem. Soc. In press.*

corrections were applied; there may, therefore, be some inaccuracies in the measured structure factors as a result of absorption errors. The structure amplitudes were derived by the usual formulae for a mosaic crystal, the absolute scale being established later by correlation with the calculated structure factors. Sixty-three independent $h0l$ reflections and 70 $hk0$ reflections were observed, representing 91% and 83% respectively of the possible numbers observable with Cu K_α radiation.

Structure Analysis

Projection down [010]

Space group $C2/c$ requires that the *o*-phenylenediarsine oxychloride molecule possesses a 2-fold symmetry axis which is coincident with the space group symmetry axis, while Cc imposes no restrictions on the molecular symmetry. The As–As vector was clearly resolved on the *b*-axis Patterson map, coordinates were obtained for the As atoms, and structure factors were calculated with the origin taken midway between two arsenic atoms. A Fourier series was then summed, using as coefficients measured structure amplitudes and calculated signs. Since the phases were based on arsenic contributions only, the resulting electron-density map was necessarily centrosymmetric. Good resolution of the chlorine atoms indicated that space group $C2/c$ was the correct one (absence of a center of symmetry would have resulted in four half-chlorine peaks, the true ones and another two centrosymmetrically related ones). Coordinates were obtained for all the atoms in the molecule, those for the carbon atoms by assuming C—C = 1.40 Å, and structure factors were calculated for all the $h0l$ reflections, using the scattering factors for arsenic, carbon, and oxygen of Berghuis *et al.* (2), that for arsenic being corrected for anomalous dispersion (3), and Tomiie and Stam's (4) scattering curve for chlorine. A second F_o synthesis was computed, and the resulting electron-density map (Fig. 2) indicated small shifts in some of the atomic coordinates. Structure factors were recalculated, and

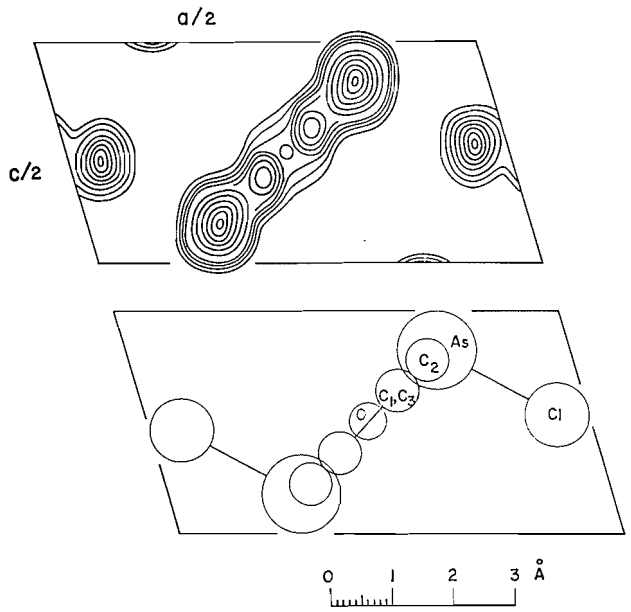

FIG. 2. Electron-density projection along the *b*-axis, with contours at intervals of 2 e Å^{-2}, starting at 4 e Å^{-2}, except at the arsenic atom, where contours above 10 are at intervals of 5 e Å^{-2}.

as no reflections had changed sign refinement was complete. Best agreement between measured and calculated structure factors (discrepancy factor = 0.16 for the observed reflections) was obtained by using a temperature factor of the form

$$\exp -\{3.7 \sin^2\theta/\lambda^2 + 0.0152l^2\}.$$

This corresponds to anisotropic thermal vibrations with the direction of maximum vibration parallel to the *c*-axis. This is probably a real effect, which does not appear to be due to the omission of a correction for absorption, as no thermal anisotropy was indicated for the $hk0$ zone, although the crystal cross sections for both zones were similar. Measured and calculated structure factors are listed in Table I.

Projection down [001]

Coordinates for the As atom were derived from the Patterson projection, and further analysis proceeded by successive F_o syntheses. The final electron-density projection along the *c*-axis is shown in Fig. 3, and

TABLE I

measured and calculated structure factors are included in Table I. No thermal anisotropy was indicated, an isotropic temperature factor with $B = 3.7$ Å^2 giving a discrepancy factor of 0.16 for the observed reflections.

Coordinates and Molecular Dimensions

The final positional parameters are listed in Table II, x, y, and z being fractions of the unit cell edges.

TABLE II

Final positional parameters

Atom	x	y	z
As	0.1004	0.1766	0.4125
Cl	0.2138	0.1742	0.2687
O	0	0.127	0.250
C1	0.043	0.387	0.320
2	0.086	0.531	0.389
3	0.043	0.674	0.320

The bond distances and valency angles in the molecule, calculated from the coordinates of Table II, are shown in Fig. 1. The best plane through the As, O, and C atoms has equation

$$0.5178X' - 0.8555Z' + 1.6383 = 0,$$

where X' and Z' are coordinates in Å units referred to orthogonal axes a', b, and c, and there are no significant deviations of As, O, and C atoms from this plane (maximum $\Delta = 0.01$ Å). The chlorine atoms, however, lie one above and one below the plane at perpendicular distances from it of 2.14 Å.

The standard deviations of the atomic positions (5) are $\sigma(x) = \sigma(y) = \sigma(z) = 0.006$ Å for As, 0.014 Å for Cl, and 0.04 Å for C. For the oxygen atom, the x- and z-parameters are fixed by symmetry, and $\sigma(y) = 0.03$ Å.

Intermolecular Distances

All the intermolecular contacts correspond to normal van der Waals interactions. The perpendicular distance between molecular planes is 3.28 Å, but no atoms overlap directly, the shortest contacts being C—C = 3.87, As—Cl = 4.04, O—O = 4.38 Å. In the b-direction, the shortest separation is O—C = 3.86 Å.

DISCUSSION

The molecule is completely planar within the limits of experimental error, except for the chlorine atoms, which lie one on either side of the plane of the other atoms.

Differences between chemically equivalent bond lengths and valency angles are not significant, the mean values being (with standard deviations):

$$\begin{aligned} \text{As—Cl} &= 2.21 \pm 0.01_5 \text{ Å} \\ \text{As—O} &= 1.69 \pm 0.01 \text{ Å} \\ \text{As—C} &= 1.99 \pm 0.04 \text{ Å} \\ \text{C—C} &= 1.40 \pm 0.03 \text{ Å} \end{aligned}$$

$$\begin{aligned}
\angle \text{Cl—As—O} &= 104\pm\tfrac{1}{2}^\circ \\
\angle \text{Cl—As—C} &= 97\pm1^\circ \\
\angle \text{O—As—C} &= 77\pm1\tfrac{1}{2}^\circ \\
\angle \text{As—O—As} &= 151\pm1^\circ \\
\angle \text{As—C—C} &= 120\pm4^\circ \\
\angle \text{C—C—C} &= 120\pm3^\circ.
\end{aligned}$$

The As—Cl bond distances are only slightly greater than those reported for arsenic trichloride (6) (2.16 Å), and chlorodimethylarsine (7) (2.18 Å) and the As—C distances are very similar to those in trimethylarsine (8) (1.98 Å) and bromodiphenylarsine (9) (1.99 Å). The only As—O distances which are available for comparison are those in arsenic trioxide, As_4O_6 (10, 11) (1.78 Å), and in the arsenate ion (11, 12) (1.75 Å); the corresponding bond lengths in *o*-phenylenediarsine oxychloride are shorter than these.

The general configuration around the arsenic atoms is similar to the arrangement in other trivalent arsenic compounds, with three bonds directed pyramidally, and the lone pair completing a tetrahedron. The angles between the bonds are usually in the range 95–105°, and in *o*-phenylenediarsine oxychloride the angles which are external to the five-membered ring have values in this range, ∠ Cl—As—O = 104° and Cl—As—C = 97°. The formation of the five-membered ring, however, results in a considerable reduction in the ∠ O—As—C valency angle (77°). In addition, the oxygen valency angle (151°) is very much larger than the normal value of 105° (in As_4O_6 the As—O—As angle is 128°). These abnormal valency angles are made more remarkable by the fact that the compound is unusually stable, the As—O—As unit being unattacked by hot concentrated acid, although the bonds can be broken by thionyl chloride to give tetrachloro-*o*-phenylenediarsine (13). The stability, planarity, and unusual valency angles of the five-membered ring suggest that this system might have some degree of aromatic character. The large oxygen valency angle suggests that the oxygen is approaching a state of *sp* hybridization, and that the two lone pairs on the oxygen are in approximately $p\pi$ orbitals. If this is the case, then $d\pi$–$p\pi$ bonding could occur using unoccupied 4*d* orbitals on the arsenic atoms, accounting for the shorter As—O distance in the oxychloride in comparison with the oxide and with the arsenate ion. This $d\pi$–$p\pi$ bonding might also be expected to occur between the arsenic atoms and the phenylene π-electrons, resulting in an extended aromatic system. No shortening of the As—C bonds below normal values has been observed, but these distances have been determined with rather less precision than the As—O length.

We are indebted to the National Research Council of Canada for financial support.

THE CHEMICAL COMPOSITION OF THE WOOD EXTRACTIVES OF SORBUS DECORA (SARG.) SCHNEID.[1]

N. NARASIMHACHARI[2] AND E. VON RUDLOFF
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received February 27, 1962

ABSTRACT

The wood of the showy mountain ash was found to contain about 3% acetone-soluble material. The major constituents of the extract were a polymorphous xyloside of (+)-dimethoxyisolariciresinol, the recently discovered hydroxy diphenyls aucuparin and methoxy-aucuparin, and fatty acid esters of β-sitosterol, another phytosterol, and of untractable phenolic material. Small amounts of free β-sitosterol and a mixture of hydrocarbons as well as traces of an unknown leucoanthocyanidin were also isolated. The xyloside predominated in the sapwood, whereas the aucuparins were found mainly in the heartwood. Gas–liquid chromatography was instrumental in the detection and separation of the aucuparins.

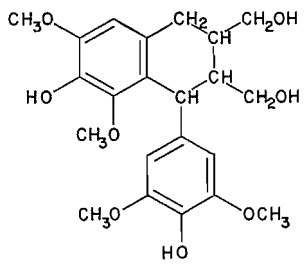
The wood extractives of the showy mountain ash (*Sorbus decora* (Sarg.) Schneid.) have been investigated as part of a continuing study of the chemical composition of the wood and bark of trees and shrubs found in the Prairie provinces. It is a small- to medium-sized tree found from the Atlantic coast westward into Manitoba. The wood is not used commercially and the literature has no references to its chemical composition. Professor H. Erdtman (1) is studying the heartwood constituents of the European mountain ash (*Sorbus aucuparia* L.) and it was at his suggestion that the North American species was investigated. Recently, Erdtman *et al.* (2) have isolated from *S. aucuparia* two new hydroxy diphenyls, aucuparin (4-hydroxy-3,5-dimethoxy diphenyl, m.p. 101° C) and methoxy aucuparin (4-hydroxy-3,5,2′-trimethoxy diphenyl, m.p. 122° C). The two aucuparins, and a xyloside* of melting point 163.5–164° C, $[\alpha]_D$ +41°, obtained from the same wood, were kindly given to us and were instrumental in the identification of the same constituents in *S. decora*.

The freshly milled wood of *S. decora* was found to contain about 3% of acetone-soluble material. The extract was fractionated into petrol-, ether-, ethyl-acetate-, and water-soluble constituents. When further fractionation was carried out, considerable difficulty was encountered because the hydroxy diphenyls could not be extracted quantitatively into aqueous alkali and were present in all but the water-soluble portion. A sparingly soluble sodium salt was obtained from which the two aucuparins were obtained as a mixture. Chromatography gave only partial separations and distillation *in vacuo* also gave only a mixture. The two diphenyls could be separated by fractional crystallization, but since their mixed melting points did not show a true depression it was difficult to determine their degree of purity. Therefore, their separation by means of gas–liquid chromatography (GLC) was investigated, when it was found that the free phenols, their methyl ethers, or their acetates could be separated on a 3-ft SE-30 silicone polymer column at 230° C. This technique was used in all subsequent work to analyze the various fractions for their content of the aucuparins and also to isolate small amounts of the pure compounds. The properties of the pure compounds thus obtained agreed in all respects with those reported by Erdtman *et al.* (2).

[1]*Issued as N.R.C. No. 6826.*
[2]*National Research Council of Canada Postdoctorate Fellow, 1960–1961. Present address: Hindustani Antibiotics Ltd., Pimpri, Poona, India.*
*ADDED IN PROOF: *β-xyloside of (+)-dimethoxyisolariciresinol (H. Erdtman et al. Acta Chem. Scand. In press).*

The neutral components of the petrol- (and ether-) soluble fractions were found to consist mainly of a mixture of fatty acid esters and free β-sitosterol. The ester fraction was saponified and from the non-saponifiable portion β-sitosterol, a small amount of a phytosterol, m.p. 162–163° C, and a hydrocarbon mixture were isolated. The saponifiable portion was acidified, methylated, and analyzed by GLC (3). Peaks corresponding to myristic, palmitic, palmitoleic, stearic, oleic, and linoleic acids in the area ratio of 1:9.2:1.0:1.8:2.8:1.4 were recorded.

The water-soluble portion deposited white crystals on standing. Recrystallization gave a product, m.p. 164–165° C, $[\alpha]_D$+41°. The mixed melting point with the xyloside sent by Erdtman was undepressed and hydrolysis with dilute acid gave an amorphous aglycone and xylose (paper chromatography). The infrared spectrum of the aglycone corresponded to those of lignans. When the wood extract from an immature tree having no heartwood was fractionated, a xyloside of melting point 120–121° C, $[\alpha]_D$+41°, was isolated, but by seeding with the xyloside, m.p. 165° C, it was converted to the higher-melting modification. Recently, Freudenberg and Weinges (4) reported the isolation of the xyloside of (+)-dimethoxyisolariciresinol (I), m.p. 122° C, $[\alpha]_D^{25}$+38°, from the wood of *Alnus glutinosa*, and this compound, kindly made available by Dr. Weinges, did not depress the melting point of the low-melting modification. The aglycones of these xylosides had infrared spectra which agreed in all respects. The polymorphous xyloside from the *Sorbus* species is, therefore, (+)-dimethoxyisolariciresinol xyloside. The xyloside lyoniside, isolated recently by Yasue and Kato (5) from the wood of *Lyonia ovafolia* Sieb. et Zucc. var. *elliptica* Hand.-Mass, is also polymorphous (m.p. 123.5/165.1° C, $[\alpha]_D$+26.7°), which these authors believed to be identical with the above compound. This has been confirmed by Weinges (6), and more recently by Erdtman (1), who has determined the configuration of the xyloside linkage.



I

Besides the two aucuparins, the phenolic or acidic fractions were found to contain traces of leucoanthocyanidin and an amorphous phenolic ester fraction. The spectra and chromatographic behavior of the former showed it to be different from either leucocyanidin or leucopelargonidin. The amount isolated was insufficient for characterization by alkali degradation. The amorphous ester gave, on saponification, a mixture of long-chain fatty acids and a mixture of phenolic alcohols. The phenolic material was not obtained pure. Thin-layer and paper chromatography gave two spots differing from either dimethoxyisolariciresinol or coniferyl alcohol.

The substitution pattern found in ring A of the aucuparins is the same as that in dimethoxyisolariciresinol, and this suggests a close biogenetic relationship. The finding of these three compounds in both the European and the North American mountain ash is of interest in taxonomic correlations. Other *Sorbus* species are being investigated to determine whether these compounds are characteristic constituents of the mountain ash.

EXPERIMENTAL

Known compounds were identified by mixed melting point and comparison of infrared spectra with those of authentic specimens. Melting points were measured on a Leitz hot-stage microscope. Molecular weights were determined by means of a thermometric vapor pressure osmometer (Model 301 Mechrolab Inc.). The GLC experiments were carried out with an instrument of conventional design which was built in this laboratory (7, 8). It has a thermal conductivity cell and helium was used as carrier gas. The 3 ft×¼ in. O.D. (91×0.6 cm) stainless steel column was packed with SE-30 silicone polymer (Dow Corning) on Chromosorb W (40–60 mesh) in the ratio of 1 to 6. The column temperature was 230° C, that of the injector 260–270° C, and the flow rate was 120 ml per minute. The analysis of the methyl esters of the fatty acid mixture was carried out on a 6 ft×¼ in. O.D. poly(ethyleneglycol phthalate) column at 215° C and 60 ml He per minute. The percentage compositions of mixtures were obtained by measuring the area under the peaks by the triangulation method. Retention times (RT) were measured at the initial emergence of the peaks.

The wood of a mature tree of *S. decora* was obtained from the Kenora district, northern Ontario. The wood was cut and separated into sap and heartwood. The milled heartwood (4.0 kg) was extracted with acetone in a Soxhlet extractor for 24 hours. The acetone extract was evaporated to dryness. The residue (120 g) was extracted with petrol (b.p. 40–60° C, 1 liter) under reflux. The clear extract was decanted from the viscous residue. The residue was then similarly extracted with ether. The insoluble residue was taken up in boiling water (1 liter) to give a turbid solution and this was extracted under reflux with three portions (0.5 liter) of ethyl acetate. The aqueous residue was reduced in volume by evaporation on a rotary evaporator and kept at 2–5° C for several weeks. In other experiments the sapwood and wood of a young tree were milled and extracted in the same manner.

Petrol-soluble Fraction (15% of Total Extract)

Evaporation of the petrol solution gave a viscous oil (18 g). An aliquot (10 g) was chromatographed on silicic acid (100 g) using petrol (b.p. 40–60° C), petrol–ether (9:1), chloroform, and chloroform – 2-butanone (9:1) as eluants. The fractions collected (100 ml) were tested for homogeneity by thin-layer chromatography (TLC) on silica gel G with benzene–ether (7:3) as developing solvent.

Fatty Acid Esters and Hydrocarbons (6.0 g)

The fractions eluted by petrol showed on TLC two fast-moving and overlapping yellow spots. The infrared spectra showed a strong carbonyl absorption (1740 cm^{-1}). The combined fractions were saponified with potassium hydroxide (10%) in aqueous ethanol (50%), and the non-saponifiable components (3.0 g) were extracted with petrol ether. The saponifiable portion was worked up in the usual manner to give the free acids (3.0 g). An aliquot was methylated with diazomethane and analyzed by GLC (polyester column), when peaks corresponding in retention time to myristic, palmitic, palmitoleic, stearic, oleic, and linoleic acids were recorded with areas in the ratio of 1:9.2:1.0:1.8:2.8:1.4.

A small aliquot of the non-saponifiable portion was analyzed by TLC, using β-sitosterol (R_f = 0.28) as reference standard. Three distinct spots with R_f values of 0.95, 0.28, and 0.26 respectively were obtained. The mixture was chromatographed on a column of silicic acid. Petrol eluted a yellow band (R_f 0.95) which, on evaporation of the solvent, gave an oily residue (0.6 g). The infrared spectrum corresponded to that of hydrocarbons. The material was distilled *in vacuo* (3 mm Hg), when practically all distilled at about 180° C (air bath). Found: C, 86.50%; H, 12.58%; molecular weight, 309. Analysis by GLC (SE-30 column, 230° C) showed it to be a mixture of at least six components (relative retention time 0.8–2.0, *n*-docosane 1.00) which could not be resolved.

Further elution of the silicic acid column with petrol–ether (9:1) gave impure β-sitosterol (2.1 g). Recrystallization from methanol gave crystalline β-sitosterol, m.p. 138–139° C, R_f 0.28. Elution with chloroform gave a small amount (0.1 g) of an oily residue (R_f 0.26) which crystallized from methanol, m.p. 162–163° C. The infrared spectrum was similar to that of β-sitosterol. The compound could thus be α-sitosterol.

β-Sitosterol (0.5 g)

The fractions eluted with petrol–ether (9:1) from the original column was composed mainly of β-sitosterol (TLC). The pooled fractions were evaporated to dryness and the residue was crystallized from methanol to give β-sitosterol, m.p. 138–139° C.

Aucuparin and Methoxyaucuparin (3.2 g)

The fractions eluted with chloroform gave a viscous oily residue on evaporation, which solidified slowly. The material was triturated with a little methanol and filtered, when crude crystals of m.p. 112–114° C were obtained (3.0 g). Fractional crystallization from methanol gave a small amount (0.1 g) of colorless crystals, m.p. 118–120° C, corresponding in all respects with methoxyaucuparin. The residual material was a mixture of aucuparin and methoxyaucuparin (1:1, GLC, RT = 2.1 and 2.9 minutes) from which the pure components were obtained in mg amounts by preparative GLC (see below). Aliquots of the mixture were methylated and acetylated in the usual manner and GLC analysis gave peaks corresponding to the derivatives of authentic aucuparin and methoxyaucuparin (see below).

Ether-soluble Fraction (21%)

The ether-soluble material (25 g) was taken up in ether (1 liter) and then extracted with aqueous sodium hydroxide (10%, 50 ml). A copious precipitate of an insoluble sodium salt formed, which was filtered off and washed with cold water. The aqueous and ether layers were separated and the alkali extraction of the

ether solution was repeated. Evaporation of the ether layer gave only a trace of residue which, on GLC analysis, gave only peaks corresponding to the two aucuparins. The combined aqueous alkaline solutions (A) were investigated further (see below).

Aucuparin and Methoxyaucuparin (10 g)

The insoluble sodium salt was suspended in cold water, acidified with dilute hydrochloric acid, and extracted with ether. The pale brown residue from the ether extract failed to crystallize from methanol or ethanol. Distillation of an aliquot *in vacuo* (3 mm Hg) gave a distillate, b.p. about 140° C, which crystallized on standing. TLC, using chloroform containing 10% acetic acid, and paper chromatography (*n*-butanol – acetic acid – water, 4:1:1.8) showed only one spot (ultraviolet light, permanganate spray). However, GLC once again showed the two peaks of aucuparin and methoxyaucuparin in a 1:1 ratio (RT = 2.1 and 2.9 minutes respectively). Preparative runs on a mg scale on the same column (glass traps cooled in acetone – dry ice mixture) gave as the first fraction crude crystals, m.p. 95–98° C, which on recrystallization had m.p. 100–101° C. Its properties agreed with those of aucuparin in all respects. The second fraction had m.p. 116–118° C, recrystallized from methanol, m.p. 119–120° C, and was identical with methoxyaucuparin.

Larger amounts of the two diphenyls were obtained by chromatographing the mixture (1.0 g) on a silicic acid column (30 g), eluting with chloroform (25 ml fractions), and checking the contents of each fraction, after evaporation to a low volume, by GLC. The fractions containing mainly aucuparin were pooled, acetylated (acetic anhydride – pyridine method), and the acetate fractionally crystallized. The pure acetate (GLC, RT = 2.3 minutes) formed thick, rhombohedral plates, m.p. 148–149° C. Found: C, 70.34%; H, 5.95%. Calculated for $C_{16}H_{16}O_4$: C, 70.57%; H, 5.92%. Deacetylation with alcoholic hydrochloric acid (1:1) gave pure aucuparin, m.p. 100–101° C. Found: C, 72.72%; H, 6.24%. Calculated for $C_{14}H_{14}O_3$: C, 73.02%; H, 6.13%. Methylation with dimethyl sulphate and potassium carbonate in anhydrous acetone gave the methyl ether as a colorless liquid, b.p. 110° C at 3 mm pressure (RT = 1.5 minutes), which crystallized on standing for a long time, m.p. 68–70° C.

In the same manner, from the pooled fractions containing mainly methoxyaucuparin, the acetate was obtained pure (GLC, RT = 3.4 minutes), m.p. 119° C. Found: C, 67.48%; H, 6.09%; OAc, 15.50%. Calculated for $C_{17}H_{18}O_5$: C, 67.54%; H, 6.00%; OAc, 14.3%. Deacetylation gave pure methoxyaucuparin (GLC, RT = 2.9 minutes), m.p. 120–121° C. Found: C, 69.44%; H, 6.22%; OCH_3, 31.55%. Calculated for $C_{15}H_{16}O_4(3\times OCH_3)$: C, 69.21%; H, 6.20%; OCH_3, 34.20%. The methyl ether crystallized on standing for a long time, m.p. 65–66° C (RT = 2.2 minutes). Found: C, 69.88%; H, 6.37%; OCH_3, 42.30%. Calculated for $C_{16}H_{18}O_4(4\times OCH_3)$: C, 70.05%; H, 6.61%; OCH_3, 45.26%.

Other Phenols from the Ether-soluble Fraction

The ether-extracted aqueous alkaline solution A was acidified with dilute hydrochloric acid and extracted with ether. The ether extract gave a dark brown viscous material (14 g). An aliquot (5 g) was chromatographed on a silicic acid column. Elution with chloroform gave first impure aucuparin, m.p. 100–101° C, and then impure methoxyaucuparin, m.p. 119–120° C. Elution with chloroform – 2-butanone (4:1) gave a dark brown viscous material which solidified into a glass. Extensive drying gave an amorphous powder which could not be crystallized. The material (4.0 g) was dissolved in methanol (25 ml) and placed onto a polyamide powder column (9). Elution with water removed most of the material as a brown, turbid solution, which did not yield any crystalline material. Elution with aqueous methanol (50%) gave a brown, amorphous solid on evaporation to a small volume. It was filtered off and washed with water. The compound gave a positive ferric chloride reaction (green), was soluble in aqueous alkali, and its infrared spectrum had strong adsorption bands in the hydroxyl (3420 cm^{-1}) and carbonyl (1700 cm^{-1}) region. Attempts to obtain it crystalline, or to prepare a crystalline methyl ether or acetate, failed.

Saponification gave a mixture of fatty acids and phenols, but only traces of neutral alcohols. The free fatty acids were separated from the phenols by chromatography on silicic acid and elution with petrol (b.p. 40–60° C). These were methylated with diazomethane (in ether) and then analyzed by GLC. Peaks corresponding to lauric, myristic, two unknown, palmitic, palmitoleic, stearic, linoleic, and linolenic acids were recorded in a ratio of 5:1.4:1:2.8:24:2:1.6:10.7:25.2:1. The phenolic fraction was eluted with chloroform, when a brown solid material was obtained. The phenolic character was confirmed by the infrared spectrum, which also showed a strong CH_2 band in the 2900 cm^{-1} range, and by a positive ferric chloride reaction. TLC analysis gave two partially separated spots R_f 0.66 and 0.72 (coniferyl alcohol 0.37) when chloroform – acetic acid (9:1) was used. Paper chromatography gave two overlapping spots R_f 0.87 and 0.91 (dimethoxyisolariciresinol 0.44) with *n*-butanol – acetic acid – water (4:1:1.8) as solvent. Further attempts at separation failed to yield pure components.

Ethyl acetate soluble Fraction (29%)

Evaporation of the ethyl acetate under reduced pressure gave a viscous material (35 g) which did not crystallize. It gave a positive leucoanthocyanidin color reaction (violet) with *n*-butanol and hydrochloric acid. GLC showed the presence of aucuparin and methoxyaucuparin. When the mixture (0.2 g) was methylated with dimethyl sulphate in the presence of anhydrous potassium carbonate and anhydrous acetone a product was obtained which gave four individual peaks on GLC analysis (RT 0.8, 1.5, 2.0, 2.2 minutes). Three components (RT 0.8, 1.5, 2.2 minutes) could be isolated in mg amounts, two of which corresponded to the methyl ethers of aucuparin and methoxyaucuparin (RT 1.5 and 2.2 minutes respectively). Attempts to isolate the unknowns and the leucoanthocyanidin in larger amounts failed.

Water-soluble Fraction (33%)

The aqueous solution was concentrated *in vacuo* to about 250 ml and was extracted exhaustively with ethyl acetate. On leaving the aqueous solution at 0 to 3° C for several weeks, a crystalline white solid (4.0 g) separated. It was filtered off and recrystallized twice from methanol to give colorless needles, m.p. 164–165° C, $[\alpha]_D$+41.0° (*c*, 0.7%, acetone–water), undepressed melting point in admixture with the xyloside sent by Professor H. Erdtman. Found: C, 57.01%; H, 6.79%; OCH_3, 20.77%; loss on drying, 3.06%. Calculated for $C_{27}H_{36}O_{12}.H_2O$: C, 56.84%; H, 6.60%; OCH_3, 21.77%; H_2O, 3.16%. The xyloside was hydrolyzed enzymatically with hemicellulase (commercial sample) and the hydrolyzate was analyzed by paper chromatography (xylose as reference standard), when a spot corresponding to xylose was obtained. The xyloside was methylated with dimethyl sulphate and anhydrous potassium carbonate in anhydrous acetone to give the dimethyl xyloside, m.p. 58–60° C. Found: OCH_3, 31.47%. Calculated for $C_{29}H_{40}O_{12}$-$(6\times OCH_3)$: OCH_3, 32.08%. This was hydrolyzed with methanolic sulphuric acid (4%) and the methylated aglycone was isolated in the usual manner, m.p. 158–160° C, $[\alpha]_D$+31.9° (*c*, 1.14%, acetone). Yasue and Kato (5) report m.p. 158–160° C, $[\alpha]_D$+30.1°, whereas Weinges (6) reports m.p. 152° C. Found, after drying *in vacuo* at 100° C: C, 60.04%; H, 7.19%; OCH_3, 41.11%; molecular weight, 449. Calculated for $C_{24}H_{32}O_8$: C, 64.27%; H, 7.19%; OCH_3, 41.52%; molecular weight, 448.5. An aliquot of the mother liquors from which the xyloside was obtained was hydrolyzed with sulphuric acid (4%). A deep red solution resulted which, on boiling, deposited a deeply colored polymeric amorphous solid. The material was not investigated further.

In other experiments the sapwood and the wood of the young tree were extracted with acetone and the residual extracts were fractionated by solvent segregation as above. The major portion of the extract was water soluble, and from this fraction the same xyloside crystallized to give a low-melting modification, m.p. 121–122° C, $[\alpha]_D^{25}$+41.0°. The melting point was not depressed with the xyloside of (+)-dimethoxyisolariciresinol, m.p. 122–124° C, sent by Dr. K. Weinges. Found for the vacuum-dried sample: C, 58.60%; H, 6.55%; OCH_3, 21.9%. Calculated for $C_{27}H_{36}O_{12}$: C, 58.74%; H, 6.57%; OCH_3, 22.49%. Methylation and hydrolysis gave the same aglycone, m.p. 158–160° C, as described above. When a solution of this xyloside was seeded with the high-melting form, crystals of m.p. 163–164° C were obtained. An equal mixture of the low- and high-melting modification dissolved in a little water deposited crystals of m.p. 163–165° C. Thus, the high-melting modification appears to be the more stable form.

ACKNOWLEDGMENTS

The authors wish to thank Professor H. Erdtman for his very helpful suggestions and the gift of the aucuparins and xyloside. Thanks are also due to Dr. K. Weinges for the gift of (+)-dimethoxyisolariciresinol xyloside and to Mr. F. E. Sider, district forester, Kenora, Ontario, for having procured the wood of the showy mountain ash. The microanalyses were carried out by Mr. M. Mazurek and the infrared spectra were recorded by Mr. W. C. Haid. We also would like to thank Mr. M. Granat for technical assistance.

GAS–LIQUID CHROMATOGRAPHY OF SOME FLAVONOID COMPOUNDS AND HYDROXY DIPHENYLS[1]

N. NARASIMHACHARI[2] AND E. VON RUDLOFF
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received February 19, 1962

ABSTRACT

Gas–liquid chromatography of the methyl ethers of 36 flavones, flavanones, isoflavones, and chalkones, 2 chromones, and 9 hydroxy diphenyls was carried out, using SE-30 silicone polymer as liquid phase. The results obtained show that this technique can be used for the separation, isolation, and identification of milligram amounts of these compounds. The influence of methylation, acetylation, and hydrogen bonding was demonstrated and is discussed. Dehydration of a 2-hydroxyisoflavanone to the corresponding isoflavone and isomerization between some flavanones and chalkones were encountered. No linear relationship between the number of substituents and retention time was obtained, indicating that substituents at different positions of a flavonoid nucleus influence the retention characteristics in a different manner. This was especially noticeable with some 3- and 5-substituted flavones, but in other instances the difference in retention times was also sufficient to differentiate between position isomers.

INTRODUCTION

The successful separation of simple phenols by means of gas–liquid chromatography (GLC) has been reported by several authors (1–12), but does not appear to have been achieved with more complex phenols. Recently the authors (13) were able to separate and isolate the two hydroxy diphenyls aucuparin and methoxyaucuparin (4-hydroxy-3,5-dimethoxy- and 4-hydroxy-2′,3,5-trimethoxy-diphenyl) and their methyl ethers and acetates by GLC. It was of considerable interest for our studies of wood extractives to determine whether flavonoid compounds could also be chromatographed satisfactorily. Since most flavonoids, or at least their methyl ethers and acetates, can be distilled *in vacuo*, this seemed possible in principle. This paper describes the results obtained with a representative variety of flavones, flavonols, isoflavones, chalkones, flavanones, flavanonols, chromones, and hydroxy diphenyls, or their methylated and acetylated derivatives.

As the flavonoid compounds have high boiling points, only liquid phases suitable for use above 200° C could be considered. Polyesters of the Craig type and bis-(*m*-phenoxyphenoxy)benzene had been used by one of us (12) for the separation of eugenol, isoeugenol, and anisole. These liquid phases proved to be unsuitable for the chromatography of flavonoids. However, as with the hydroxy diphenyls aucuparin and methoxyaucuparin, many flavonoids could be eluted as fairly symmetrical peaks from a 3-ft column containing SE-30 silicone polymer as liquid phase. This substrate was first used in the successful separation of steroids (at 220–265° C) by VandenHeuvel *et al.* (14). Columns containing this liquid phase in 15, 10, and 5% amounts on Chromosorb W, and in 0.5% amount on micro glass beads, were made up and with these columns satisfactory chromatography of the flavonoids and diphenyls listed in Tables I and II was obtained. The first three columns allowed the separation and isolation of milligram amounts, which proved particularly useful for identifying the isomerization products of chalkones and flavanones.

‖Dehydrated to 5,7-dimethoxyisoflavone.

It is common practice to report the retention times (RT) of individual compounds as relative retention time (RRT) with respect to a suitable standard substance. Initially flavone itself was used for this purpose, but this was found to have too low a retention time on the 0.5% column to give accurate RRT values. Therefore, 7-methoxyflavone was chosen, being readily synthesized and more suitable as regards retention characteristics.

EXPERIMENTAL

The gas-chromatographic unit was of conventional design and built in this laboratory (15, 16). The column and thermal conductivity cell were controlled at the same temperature. The injector could be heated separately by means of a variac control. The columns were constructed of 3-ft lengths of $\frac{1}{4}$-in O.D. stainless steel tubing, which was coiled (5- to 8-in diameter) to fit into the heating oven. In preparative runs the exit

TABLE II

gases were led into glass traps which were externally cooled in a dry ice – acetone mixture. Chromatograms were recorded on a 1-mv Honeywell recorder using a chart speed of 6 min/in. The carrier gas was helium, which was introduced at 40 to 60 p.s.i. at the column inlet. The outlet was at atmospheric pressure and the gas flow rate was measured by means of a moving soap bubble. Samples were introduced as solutions (0.5 to 2 μl, 30–50% in acetone or chloroform) with a hypodermic syringe. Retention times were measured at the initial emergence of peaks (12) and these were reproducible within ±0.1 minute for individual compounds. The peaks were of regular shape and no sign of decomposition was detected. Recovery of isolated samples was not quantitative (approx. 50 to 75%).

MATERIALS

The simple hydroxy diphenyls were commercial samples. Aucuparin and methoxy-aucuparin were isolated from the wood of *Sorbus decora* (13); the methyl ethers and acetates were prepared by standard procedures.

Flavones

7-Methoxyflavone, m.p. 110–111° C, was prepared by dehydrogenation with selenium dioxide of 2′-hydroxy-4′-methoxychalkone (17). Flavone, 3-hydroxyflavone, kaempferol, fisetin, and quercetin were commercial samples (chromatographically pure), from which the fully methylated derivatives were obtained by methylation with excess dimethyl sulphate and anhydrous potassium carbonate in anhydrous acetone: 3-methoxyflavone, m.p. 107° C (18); kaempferol tetramethyl ether, m.p. 165–166° C (19); fisetin tetramethyl ether, m.p. 150° C; quercetin pentamethyl ether, m.p. 144–145° C (20). Chrysin dimethyl ether, m.p. 75–76° C, was similarly obtained from chrysin (21). Galangin trimethyl ether, m.p. 195–197° C, was obtained from galangin-3-methyl ether prepared according to the method of Kalff and Robinson (22).

The partial methyl ethers with the 5-hydroxyl group free were prepared by methylation with diazomethane in methanol–ether: galangin-3,7-dimethyl ether, m.p. 145–146° C (22); kaempferol trimethyl ether, m.p. 154–155° C (23); quercetin tetramethyl ether, m.p. 156–157° C (24). Tectochrysin was obtained from natural sources (21).

Isoflavones and Isoflavanones

2-Hydroxy-5,7-dimethoxyisoflavanone, 5,7-dimethoxy- and 5-hydroxy-7-methoxy-isoflavones

2-Hydroxy-4,6-dimethoxy phenyl benzyl ketone (25) (1 g) was dissolved in ethyl formate (10 ml) and the cooled solution was added to ice-cold powdered sodium (1 g). After being left at 0° C for 24 hours the mixture was poured into ice water. The solution

was acidified to pH 2–3 with cold dilute hydrochloric acid and the sticky solid which separated out was filtered, washed with water, and crystallized from methanol to give rectangular prisms, m.p. 145–146° C. It agreed in its properties with those reported for 2-hydroxy-5,7-dimethoxyisoflavanone as reported by Narasimhachari *et al.* (26). Dehydration with acetic anhydride (26) gave 5,7-dimethoxyisoflavone, m.p. 121° C (26). 5-Hydroxy-7-methoxyisoflavone was obtained by controlled demethylation of the dimethoxy compound with hydroiodic acid at 120° C according to Aghoramurti *et al.* (27).

5,7-Dihydroxy-2-methylisoflavone, m.p. 228–229° C, and 5,7-dihydroxy-4′-methoxy-2-methylisoflavone, m.p. 208–209° C, were prepared according to the method of Baker and Robinson (28). Partial methylation of these dihydroxy compounds with 1 mole of dimethyl sulphate and anhydrous potassium carbonate in anhydrous acetone gave 5-hydroxy-7-methoxy-2-methylisoflavone, m.p. 186–187° C (28), and 5-hydroxy-4′,7-dimethoxy-2-methylisoflavone, m.p. 197–199° C (28). Complete methylation with excess dimethyl sulphate gave the corresponding fully methylated derivatives, m.p. 98–100° C and 175–176° C respectively.

5,7-Dimethoxyisoflavanone

5,7-Dimethoxyisoflavone (0.2 g) was hydrogenated in the presence of palladium-on-charcoal catalyst (25 mg) for 24 hours (29). The product was crystallized from ethyl acetate containing petrol, m.p. 151–152° C. Found: C, 71.73%; H, 5.72%. Calculated for $C_{17}H_{16}O_4$: C, 71.82%; H, 5.67%.

Chalkones and Flavanones

The 2′-hydroxychalkones were obtained by the standard procedure. The appropriate *o*-hydroxyacetophenone (1 mole equivalent) and the substituted benzaldehyde (1.5 mole equivalent) were dissolved in alcohol and to the mixture was added potassium hydroxide (2 g/g ketone). The mixture was left in a stoppered flask at room temperature for 48 hours. It was then diluted with water and extracted with ether. The aqueous layer was separated and acidified, when the chalkone was precipitated. It was filtered, washed with dilute aqueous sodium carbonate solution and water, and crystallized from alcohol. 2′-Hydroxy-4′-methoxychalkone, m.p. 104–106° C; 2′-hydroxy-4′,4-dimethoxychalkone, m.p. 110° C; 2′-hydroxy-4′,6′-dimethoxychalkone, m.p. 91–92° C; 2′-hydroxy-4,4′,6′-trimethoxychalkone, m.p. 113–114° C were thus obtained.

The fully methylated flavanones were obtained from these 2′-hydroxychalkones by heating under reflux with alcoholic sulphuric acid (4%). These could also be obtained practically pure from the ether extract of the chalkone condensation (see above) by silicic acid chromatography. 7-Methoxyflavanone, m.p. 89° C; 7,4′-dimethoxyflavanone, m.p. 95° C; 5,7-dimethoxyflavanone, m.p. 144–145° C; 4′,5,7-trimethoxyflavanone, m.p. 128° C were obtained.

Naringenin-7,4′-dimethyl ether, m.p. 114–116° C, and hesperetin-7,3′-dimethyl ether, m.p. 136–137° C, were obtained by partial methylation of naringenin and hesperetin (commercial samples) respectively according to the method of Narasimhachari and Seshadri (30). Similarly, pinocembrinmonomethyl ether, m.p. 110–112° C, was obtained from pinocembrin (21). Sakuranetin was a sample from natural sources (31).

GLC of some of the flavanones and chalkones gave two peaks in varying proportions. Each component was isolated in preparative runs (10 mg) and identified by mixed melting point and comparison of ultraviolet spectra. Re-injection of each component confirmed that thermal isomerization between these flavanones and chalkones took place. The amounts of each formed were determined by measuring the area under the peak (error = ±3% to 10%).

Chromones

Khellin (32) was obtained from commercial sources. Complete methylation of 3-methoxy-5,7-dihydroxy-2-methylchromone (33) gave 3,5,7-trimethoxy-2-methylchromone.

RESULTS AND DISCUSSION

The relative retention times of the hydroxy diphenyls and the simpler flavonoids with reference to 7-methoxyflavone as obtained on the 15% and 0.5% SE-30 columns are shown in Table I. No noteworthy difference in these RRT values was obtained on the 10% and 5% columns, although the actual retention times decreased accordingly. Thus, the RT values for 7-methoxyflavone were 8.1, 5.3, 3.8, and 1.1 minutes on the 15, 10, 5, and 0.5% column respectively. As expected, a fairly regular increase in the RT was observed when the number of substituents in the parent compound was increased. Conversion of a free hydroxyl group to the methyl ether decreased the RT, whereas acetylation increased it to a value above that of the free phenol. These findings hold only for compounds in which no intramolecular hydrogen bonding of free hydroxyl groups can take place. Where hydrogen bonding can occur, the RT of the free phenol is very much lower than expected for a corresponding non-hydrogen bonded compound. Thus the value obtained for 2,2′-dihydroxy diphenyl is practically that of a monohydroxy diphenyl. 4,4′-Dihydroxy diphenyl gave a retention time expected for the dihydroxy analogue. The effect of hydrogen bonding is especially noticeable with 5-hydroxy-flavones, -flavanones, and -isoflavones; e.g., the 5-hydroxy-7-methoxy compound has a much lower RT than the corresponding 5,7-dimethoxy derivative (see Table I). This marked effect was also found with the higher-substituted compounds (see Table II).

Compounds with more than two free hydroxyl groups or three methoxyl groups were not eluted within practical times from the 15, 10, or 5% SE-30 columns at 230–235° C. The use of higher temperatures to shorten the RT values seemed undesirable, not only because of shorter column life, but because the chance of thermal decomposition of injected compounds would be very much enhanced. Decomposition of hydroxy and acetoxy steroids at 220–260° C on the SE-30 substrate was reported by VandenHeuvel *et al.* (13) (see also below). Therefore, 0.5% SE-30 polymer on micro glass beads at 230° C was used for the chromatography of the higher-substituted flavonoids. The relative retention times of tetra- and penta-substituted flavonoids with respect to 7-methoxyflavone are shown in Table II.

Substitution at the various positions of the flavonoid nucleus appears to affect the retention characteristics differently. Thus, 3-methoxyflavone has a much lower retention time than 7-methoxyflavone. The finding that even 3-hydroxyflavone has a lower retention time than the standard indicates that substituents at this position are somehow shielded and do not increase the retention time by an expected increment. Such increases are obtained by substitution at the various positions of the aromatic nuclei (except for the 5-hydroxy and other hydrogen-bonding substituents), but the increments were not regular for each additional group added. This is fortunate, since it leads to different retention times for position isomers and thus facilitates their separation; e.g., 3,5,7,4′- and 3,7,3′,4′-tetramethoxyflavone had RRT 5.90 and 4.72 respectively. Whether the lower value for the latter compound is due to the proximity of the 3′ and 4′ substituent or a markedly different behavior between 3′- and 5-substituted flavones cannot be deduced from the present data. 5-Hydroxy-7,3′,4′-trimethoxyflavanone (Table II) had a considerably higher RRT than 5-hydroxy-7,4′-dimethoxyflavanone (Table I). This suggests again that no general conclusion in this direction can be drawn.

The differences in retention times between the various groups of compounds studied are sufficient to be of value in their separation and isolation. For example, 5,7-dimethoxy-flavone, -isoflavone, -flavanone, and -isoflavanone had RRT 1.95, 1.50, 1.10, and 0.90 (0.60) respectively. The double bond in the heterocyclic ring of the flavones causes a longer retention on the SE-30 columns, and the iso compounds are retained a noticeably shorter time than the corresponding flavones or flavanones. The conjugation of the B-ring with the double bond and carbonyl group in flavones may account for the higher RRT values. The different retention times of different groups of compounds with the same substitution pattern is especially useful in view of the co-occurrence of such groups in plants.

The increase in retention times with increasing number of substituents is much more marked with flavones than with isoflavones (see Table I). A similar conclusion could not be drawn for flavanones and isoflavanones because too few of the latter group were available for study. In general, the RRT values obtained on the 0.5% column were the same or slightly higher than those recorded with the 15% column. However, the value of 5,7-dimethoxyisoflavanone was much lower on the former column (0.6 as against 0.9). Repeated runs at different times, or in consecutive runs, did not change this result. Possibly some minor influence due to the solid support Chromosorb W plays a more significant role in the chromatography of this particular compound.

Two chemical reactions due to the high temperatures necessary for chromatography were encountered. Several of the flavanones and chalkones gave two distinct peaks on the chromatogram (see Table I). The former usually gave a large peak followed by a smaller one whereas some of the chalkones gave two peaks in the reverse order of size. When the RRT values obtained for 7-methoxyflavanone, for example, are compared with those for 2′-hydroxy-4′-methoxychalkone these were found to be the same (within an error ± 0.03) for both peaks. These effects were shown to be due to isomerization between flavanones and the corresponding chalkones by isolating both components and comparing the ultraviolet spectra with the starting materials. The component with lower RRT invariably corresponded to the flavanone and that with higher RRT to the chalkone. On re-injecting 7-methoxyflavanone the two peaks were obtained in the ratio of 7 to 1, whereas with 2′-hydroxy-4′-methoxychalkone it was 1 to 3. This shows that an equilibrium mixture is not obtained during chromatography and different operating conditions may result in different ratios. The finding that 2′-hydroxy-4′,6′-dimethoxy- and 5,7-dimethoxy-flavanone gave only a single peak corresponding to the flavanone structure indicates that certain substituents may stabilize the flavanone structure.

Another type of reaction was encountered with 2-hydroxy-5,7-dimethoxyisoflavanone. This compound gave on chromatography the retention time of 5,7-dimethoxyisoflavone (see Table I). Isolation confirmed that the 2-hydroxyisoflavanone had been dehydrated completely to the isoflavone. This is to be expected, since this dehydration is obtained by chemical means (26, 34, 35). Whalley (35) proposes a trans configuration (2(*a*)-hydroxyl, 3(*a*)-hydrogen) for the eliminated elements. On the other hand, for unimolecular thermal decompositions giving rise to olefins, Barton (36) proposes cis elimination. This aspect requires further study. During the preparation of 5,7-dimethoxyisoflavone it was noted that with sodium and ethyl formate the reaction product was the 2-hydroxyisoflavanone. The formation of this intermediate was reported earlier by Narasimhachari *et al.* (26), methyl formate being used, by Whalley (34, 37) in the synthesis of 2′-substituted isoflavones, and by Baker *et al.* (38) in the condensation of phenyl benzyl ketones with ethyl oxalyl chloride. The infrared spectrum confirms the 2-hydroxyisoflavanone

structure assigned to the intermediate. 2-Hydroxy-4,6-dimethoxy phenyl benzyl ketone was also chromatographed (cf. Table I) to demonstrate that GLC can be readily used to identify unreacted starting material.

Since GLC permits the isolation of practically pure compounds in milligram amounts, and thus allows confirmation of identity by infrared and ultraviolet spectroscopy, this technique appears to be eminently suited for the investigation of mixtures of complex phenols found in plant extractives. This should prove especially useful in surveys of related species for the occurrence of the same, or closely related, flavonoid constituents. The technique is now being applied to current investigations of phenolic fractions in wood and other plant extractives. The results described above also show that GLC can be used with success in the study of chemical changes and reactions of flavonoid compounds.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Professor H. Erdtman for the gift of chrysin, tectochrysin, and pinocembrin. The infrared and ultraviolet spectra were recorded by Mr. W. C. Haid.

REARRANGEMENT STUDIES WITH C^{14}

XII. THE REACTION OF NITROUS ACID WITH 2-α- OR 2-β-NAPHTHYLETHYLAMINE-1-C^{14}

A. G. FORMAN[1] AND C. C. LEE
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

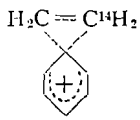
Received February 20, 1962

ABSTRACT

On treatment with sodium nitrite, 2-α-naphthylethylamine-1-C^{14} in aqueous hydrochloric acid or glacial acetic acid gives rise to the corresponding alcohol, which shows rearrangement of C^{14} from the C-1 to the C-2 positions to the extent of 32–35%; the 2-β-naphthyl isomer exhibits 26–28% rearrangement. The significance of these results is discussed.

INTRODUCTION

Isotope position rearrangement in the reaction of 2-phenylethylamine-1-C^{14} with nitrous acid in both aqueous and non-aqueous media has been reported and the results discussed in terms of possible reaction mechanisms (1, 2). The percentage of rearrangement was approximately 20%, considerably more than the 1.5% rearrangement observed for the reaction of nitrous acid with ethylamine-1-C^{14} (3), thus strongly suggesting anchimeric assistance by the phenyl group and the probable involvement of the non-classical ethylenephenonium ion I[2] for at least part of the reaction. This paper reports the degree of rearrangement during the same reaction of the analogous naphthyl derivatives.



I

RESULTS AND DISCUSSION

2-β-Naphthylethylamine-1-C^{14} was prepared from β-naphthoic acid by reduction to the corresponding carbinol, which was converted to the chloride by means of thionyl chloride; the resulting β-chloromethylnaphthalene was treated with potassium cyanide-C^{14} to give the nitrile, which was reduced with lithium aluminum hydride to give the desired amine. Analogously, 2-α-naphthylethylamine-1-C^{14} was prepared starting from α-chloromethylnaphthalene. That no rearrangement had occurred during any step of the syntheses was demonstrated by permanganate oxidation of either of the amines to give the corresponding inactive α- or β-naphthoic acid.

The reaction of the amines with nitrous acid was carried out in dilute hydrochloric acid and in glacial acetic acid, yielding, respectively, 2-α- or 2-β-naphthylethanol and 2-α- or 2-β-naphthylethyl acetate. The acetates were saponified with sodium ethoxide in 95% ethanol. To demonstrate that the saponification of the acetates did not affect the

[1]*Holder of a National Research Council of Canada Studentship, 1961–1962; on leave from the Department of Chemistry, Carleton University, Ottawa, Ontario.*

[2]*Previously we have used "ethylphenonium" as the name of this ion. In analogy with other "onium" ions, such as "ethyleneoxonium" ion, we will use the terms "ethylenephenonium" and "ethylenenaphthonium" in this paper. Instead of "phenonium" ion, the name "benzenocarbonium" ion has also been recorded in the literature.*

degree of rearrangement, 2-α-naphthylethyl acetate was isolated in one experiment and this ester was treated with lithium aluminum hydride to give the alcohol. The purified alcohols were assayed for radioactivity and then oxidized with alkaline permanganate to the corresponding naphthoic acids. A comparison of the molar activities of the alcohol and corresponding acid gave a direct measure of the degree of rearrangement of C^{14} from the C-1 to the C-2 positions. The results are tabulated in Table I.

TABLE I

Rearrangements in the reaction between nitrous acid and 2-α- or 2-β-naphthylethylamine-1-C^{14}

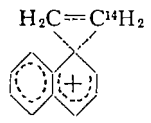
Reaction medium	Compound assayed	Activity* (c.p.m./mmole) Run I	Activity* (c.p.m./mmole) Run II	% rearrangement Run I	% rearrangement Run II
H_2O–HCl	α-$C_{10}H_7CH_2CH_2OH$	54.1	23.8		
	α-$C_{10}H_7COOH$	18.4	7.6	34	32
HOAc	α-$C_{10}H_7CH_2CH_2OH$	223	222 (219)†		
	α-$C_{10}H_7COOH$	78.3	78.2 (76.8)†	35	35 (35)†
H_2O–HCl	β-$C_{10}H_7CH_2CH_2OH$	126	45		
	β-$C_{10}H_7COOH$	34.6	12.7	27	28
HOAc	β-$C_{10}H_7CH_2CH_2OH$	131	125		
	β-$C_{10}H_7COOH$	34.1	32.4	26	26

*Radioactivity was measured in a liquid scintillation counter. Each sample, weighing about 10 mg, was dissolved in 20 ml of toluene containing 4g/l. of DPO and 100 mg/l. of POPOP and then counted for sufficient length of time to give at least 10,000 counts. Under these conditions, use of toluene-C^{14} as an internal standard showed that there was no quenching by the compounds assayed.

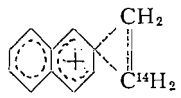
†In this experiment, the acetate was treated with $LiAlH_4$ to give the alcohol.

From Table I, it may be noted that practically the same degrees of rearrangement were observed in both aqueous and acetic acid media. Similar observations were made by investigators of the reaction of nitrous acid with 2-phenylethylamine-1-C^{14} (1, 2). Several attempts were made to carry out the reaction of the naphthylethylamines in anhydrous formic acid in order to determine whether a greater amount of rearrangement would result in this more ionizing medium. However, these attempts were unsuccessful due to the rapid formation of a polymeric tar. Even when the temperature of the reaction mixture was maintained at the freezing point of formic acid, no ester could be isolated.

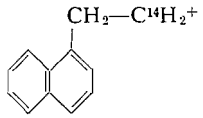
The observed rearrangements may be regarded as the result of some net 1,2-naphthyl shifts in these reactions. Possibly, one may visualize these reactions as proceeding to some extent through the bridged α- and β-ethylenenaphthonium ions II and III, and the remainder through the classical naphthylethyl ions IV and V. On the other hand,



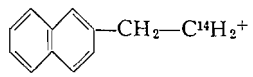
II



III

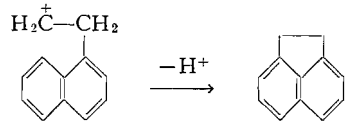


IV



V

it may be more accurate to consider II and IV or III and V as contributing structures of the actual transition states. Should IV be formed during the reaction, one might predict the possible formation of some acenaphthene through internal electrophilic substitution, i.e.



The crude products from reaction of the α-isomer were examined by gas–liquid chromatography and compared with known acenaphthene. No trace of the hydrocarbon was found.

The average degree of rearrangement for the reaction with 2-α-naphthylethylamine-1-C^{14} was 34%. Should the reaction proceed via the ethylenenaphthonium ion II, this higher degree of rearrangement, as compared to about 20% rearrangement for the reaction with the phenylethyl derivative (2), may be due to greater positive-charge delocalization in II as compared to I. The somewhat lower extent of rearrangement of about 27% for the β-naphthyl isomer is to be expected because of less electron localization at the β-position of the naphthalene nucleus, as evidenced by the well-known preference for formation of the α-isomer in electrophilic substitution, and as predicted by valence bond and molecular orbital theory (4).

EXPERIMENTAL

Preparation of 2-α-Naphthyl- and 2-β-Naphthyl-ethylamine-1-C^{14}

β-Naphthoic acid was reduced with lithium aluminum hydride according to the general method of Nystrom and Brown (5). Average yield of β-naphthylcarbinol, m.p. 79.5–80.5° C (lit. (6) m.p. 80–81° C), was 91%. This product was converted to β-chloromethylnaphthalene, m.p. 46–47° C (lit. (7) m.p. 47.5–48.5° C), in 77% yield by the method of Gilman and Kirby (8). The α- and β-chloromethylnaphthalenes were converted to the corresponding nitriles according to Wislicenus and Elvert (9) in 80% yield. 2-α-Naphthylacetonitrile-1-C^{14} was obtained as an oil, b.p. 165–170° C at 2 mm (lit. (9) 183–187° C at 13 mm); 2-β-naphthylacetonitrile-1-C^{14} crystallized from cyclohexane as a pale yellow solid, m.p. 85–86° C (lit. (10) m.p. 85.5–86° C). The nitriles were reduced to 2-α-naphthylethylamine-1-C^{14} and 2-β-naphthylethylamine-1-C^{14}, respectively, by means of lithium aluminum hydride, according to the method of Amundsen and Nelson (11). The yields were about 45%. The acetyl derivatives of the α- and β-isomers melted at 90–91° C and 109–110° C, respectively (lit. (12) m.p. 91° C and 110° C).

Reaction of Amines with Nitrous Acid in Acetic Acid

Sodium nitrite (12 g, 0.17 mole) was added portionwise, with stirring, to a solution of 10 g (0.14 mole) of 2-α- or 2-β-naphthylethylamine-1-C^{14} in 50 ml of glacial acetic acid. After complete addition, stirring was continued for $\frac{1}{2}$ hour and the mixture was then poured into ice water. The resulting material was extracted with ether, and the combined extracts were washed with saturated sodium bicarbonate solution and with water and then dried over magnesium sulphate before the ether was removed. A solution of 8 g of sodium in 250 ml of 95% ethanol was added and the mixture refluxed for 8 hours and then poured into cold hydrochloric acid. The resulting mixture was extracted with ether, and the extracts were washed and dried as described above. The products were collected at 136–142° C at 0.12 mm and 159–166° C at 4 mm for the α- and β-isomers, respectively. Both alcohols solidified on being cooled and were recrystallized twice from petroleum ether. Average yields of twice-recrystallized 2-α- and 2-β-naphthylethyl alcohols for the various runs were 20%. The α-isomer melted at 61–62° C (lit. (6) m.p. 60.5–61.5° C), the β-isomer melted at 67–68° C (lit. (13) m.p. 67.5–68° C).

In another experiment with 2-α-naphthylethylamine-1-C^{14}, 2-α-naphthylethyl acetate was isolated in 57% yield and then reduced to the alcohol with lithium aluminum hydride by the method of Lee and Spinks (2).

Reaction of Amines with Nitrous Acid in Aqueous Medium

2-α-Naphthylethylamine-1-C^{14} (10g, 0.14 mole) was placed in a 1-liter flask and 800 ml of water added. Sufficient concentrated hydrochloric acid was introduced to bring the pH of the solution to 5. The solution

was then frozen to a slush, and stirred while 8.0 g of sodium nitrite in 20 ml of water was added portionwise. With continued stirring during the next hour, small amounts of sodium nitrite were added, together with sufficient hydrochloric acid to maintain a pH of 5. The mixture was stirred for an additional 2 hours, heated to boiling, removed from the heat, and then stirred overnight. It was then extracted with ether and the combined extracts were washed with dilute hydrochloric acid, sodium bicarbonate solution, and distilled water. After drying and removal of the ether, the residue was distilled under reduced pressure.

The reaction with the β-isomer was carried through in the same manner, except that about 1600 ml of water was used for 10 g of amine. Even at this dilution, the amine hydrochloride was almost insoluble and the reaction was carried out with the hydrochloride in suspension.

Although crude yields of the 2-α- and 2-β-naphthylethyl alcohols were comparable to those obtained in acetic acid medium, there was greater contamination by a yellow impurity, necessitating four to five recrystallizations to give the pure products in overall yields of about 5–10%.

Oxidation of 2-α- or 2-β-Naphthylethyl Alcohol or Amine

One gram of the alcohol or amine was placed in 50 ml of distilled water containing 2.5 g of potassium permanganate and 1.0 g of sodium hydroxide. The mixture was heated on the steam bath until complete discoloration of the permanganate occurred (15–20 minutes). The manganese dioxide was removed by filtration and the filtrate washed twice with ether before it was acidified with sulphuric acid. The crude α- or β-naphthoic acid was collected by suction in yields of 30–40%. The use of larger amounts of permanganate and sodium hydroxide and a longer reaction time resulted in decreased yields.

The crude α-naphthoic acid was recrystallized three times from cyclohexane, the β-naphthoic acid recrystallized once from cyclohexane and twice from ligroin, giving pure acids, m.p. 161.5–162° C and 184.5–185° C, respectively (lit. (14) m.p. 162° C and 185° C).

THE REACTION OF ISOPROPANOL VAPOR WITH Hg 6($^3P_1$) ATOMS

PART I. PURE SUBSTRATE

ARTHUR R. KNIGHT AND HARRY E. GUNNING
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received February 8, 1962

ABSTRACT

The reaction of isopropanol vapor with Hg 6($^3P_1$) atoms has been investigated under static conditions at 25° C under continuous and intermittent illumination. The effect of added inert gas and isolation of the 2537 Å Hg resonance line were also studied.

The products of the reaction are H_2 (0.72), CH_3COCH_3 (0.25), CO, CH_4, C_2H_6, CH_3CHO, and H_2O, with the numbers in parentheses representing the quantum yields at zero exposure time. The non-volatile product remaining in the cell was a mixture of C_6-glycols, containing 98.6% pinacol, 1.2% 2-methyl-2,4-pentanediol, and ca. 0.2% or less of 2,5-hexanediol.

Under intermittent illumination, the quantum yield of hydrogen production, measured as a function of light period, t_L, rose linearly with log t_L, and had a constant value of unity for $t_L < 0.45$ msec. A mechanism is proposed involving the primary formation with perfect efficiency of isopropoxy radicals and H atoms.

INTRODUCTION

Recent investigations of the reactions of alcohol vapors with Hg 6($^3P_1$) atoms have shown that for methanol (1, 2, 3) and ethanol (4) the primary process is an almost exclusive split into an alkoxy radical and hydrogen atom. Utilizing intermittent-illumination techniques, values for the primary quantum yield, Φ^0, of hydrogen atom production of at least 0.89 for methanol (3) and 0.96 for ethanol (4) have been found. The corresponding values, as determined by extrapolation to zero extent of reaction, under steady illumination, were 0.45 and 0.53 respectively. The lower values for $\Phi(H_2)$ under continuous illumination were ascribed to a rapid back reaction between hydroxyalkyl radicals and hydrogen atoms competing with H_2 formation by abstraction from the substrate. As the light period was made progressively shorter the mean radical concentration decreased, favoring the abstraction reaction, with a resulting increase in the hydrogen yield. Thus for ethanol, where the α C—H bond energy is presumed to be lower than for methanol, the abstraction step competes more effectively with the back reaction, and higher values of $\Phi(H_2)$ are observed under both steady and intermittent illumination. In isopropanol, which has a tertiary C—H bond, still higher yields of H_2 would be expected under comparable conditions. Furthermore, since the tertiary C—H bond energy in isopropanol would be considerably lower than that of the O—H, demonstration of an exclusive O—H bond scission would give strong evidence in support of the generality of preferential quenching of Hg 6($^3P_1$) atoms at the oxygen site, in the alcohol series.

In the present investigation, the studies carried out in this laboratory on the alcohols (2, 3, 4) have been extended to isopropanol. The reactions of this alcohol with Hg 6($^3P_1$) atoms, under continuous and intermittent illumination, have been examined.

The details of the investigation follow.

EXPERIMENTAL

The apparatus used for the continuous-illumination experiments was essentially identical with that employed for the methanol reaction (2). The techniques and equipment used for the intermittent-illumination studies have also been described previously (4).

The isopropanol was Nichols reagent grade. After degassing and trap-to-trap distillation, rejecting large head and tail fractions, the reagent was stored in a quartz trap connected to the reaction system. Gas chromatographic analysis showed no detectable impurities other than ca. 0.05% water. Mass spectrometric analysis proved the absence of any triisopropylborate in a sample of the alcohol which had been stored in a pyrex vessel for 48 hours. The neon (Airco assayed reagent) was used without further purification.

The analysis of the reaction products was carried out by gas chromatography and mass spectrometry. Products condensable in liquid nitrogen were separated by a 2.5-m 8% didecylphthalate-on-Fluoropak column, operating at 35°, with a hydrogen flow of 80 cc/min. Carbon monoxide and methane were determined on a molecular-sieves column, and by mass spectrometric analysis of the total non-condensable yield. Hydrogen was obtained from the difference between the total non-condensable gas and the yield of CO + CH_4. Mass spectrometry was also employed for hydrogen analyses in the runs with added neon.

For the analysis of the involatile products, which formed as a deposit on the cell walls, two 10-hour runs were performed, and the cell deposit was dissolved in acetone and analyzed for glycols by the same procedure as used in the ethanol investigation (4). The presence of pinacol was confirmed by the sodium metaperiodate titration of Dal Nogare and Oemler (5). Here the cell deposit formed in a 3-hour run was analyzed by carrying out the titration on an aqueous solution of three washings of the reaction vessel.

The condensable products of the reaction were identified by their column retention times and the identification was confirmed by mass spectrometric analysis of each peak trapped from the chromatographic effluent.

In the experiments with filtered light, one reaction was performed with the light beam filtered by a solution of *trans,trans*-1,4-diphenyl-1,3-butadiene in a 1-cm path length cell (6). The solution had a narrow transmission band centered at ca. 2600 Å, with 39% transmission at 2537 Å. In the comparison run, using the same geometry, the light beam was attenuated by several quartz plates arranged to give 40% transmission of the 2537 Å line.

Light intensities were determined with propane as actinometer (7), using the differential method of Back (8) to determine the steady-state value of dH_2/dt. Four light intensities were employed in the experiments and the values, in μeinsteins/min, were (*a*) 1.25 (double sector); (*b*) 1.43 (single sector); (*c*) 1.78 and 1.35 (continuous illumination).

RESULTS

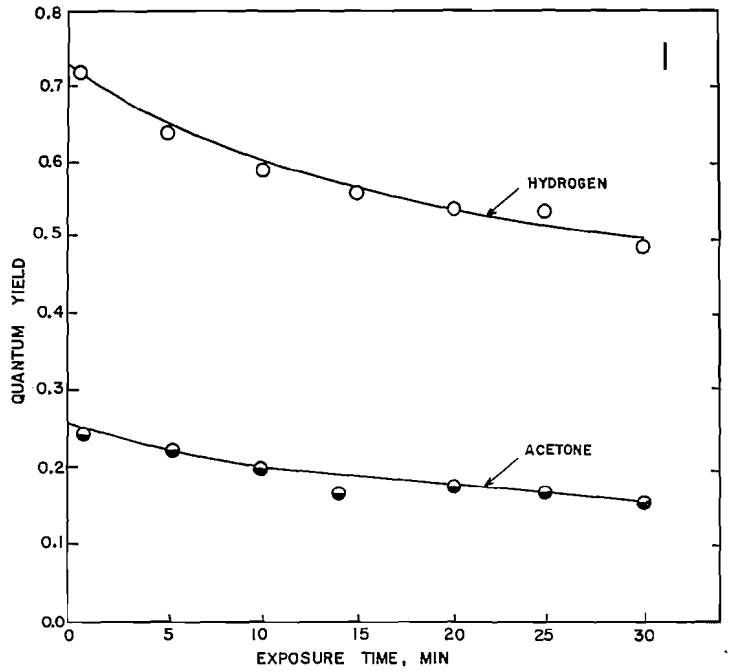
All experiments were carried out at a pressure of 40.0 mm isopropanol at room temperature, 25±1° C. The products of the reaction were found to be H_2, CO, CH_4, C_2H_6, MeCHO, $Me_2(CO)$, H_2O, pinacol, 2,5-hexanediol, and 2-methyl-2,4-pentanediol.

The results of the investigation of the reaction as a function of exposure time are presented in Figs. 1 and 2 as follows: Fig. 1 $\Phi(H_2)$, $\Phi(Me_2CO)$; Fig. 2 $\Phi(CO)$, $\Phi(CH_4)$, $\Phi(C_2H_6)$, and $\Phi(MeCHO)$. In these and subsequent figures for continuous-illumination work, the points given usually represent the mean value for two runs. Water was not determined, but a semiquantitative estimate showed it to be a minor product of the reaction. Glycol formation was not studied as a function of exposure time, but gas chromatographic analysis of the cell deposit gave a distribution among the three glycols of 98.6% pinacol, 1.2% 2-methyl-2,3-pentanediol, and ca. 0.2% or less of 2,5-hexanediol.

The effect of intermittent illumination on the reaction was also investigated, and the yields of hydrogen and acetone, as a function of light period t_L, for dark periods, t_D, of 0.102 and 0.160 sec and a net exposure time of 1 minute, are presented in Fig. 3. No separate study was made on the effect of varying t_D, but as for methanol and ethanol, the quantum yield appeared to be independent of t_D at values greater than 100 msec (cf. Fig. 3). It must be pointed out here that, although the actual value of $\Phi(H_2)$ on the plateau of the curve is 0.98, this should be considered to be unity within experimental error on an absolute scale.

Two runs were carried out at a reaction time of 10 minutes with added neon, with substrate pressure of 40.0 mm. The yields of Me_2CO, H_2, C_2H_6, and MeCHO, uncorrected for competitive quenching by neon, are presented in Table I, along with the same results for a neon-free run at the same exposure time.

To assess the importance of light of wavelength other than 2537 Å on the secondary decomposition of acetone, two reactions at approximately the same absorbed intensity



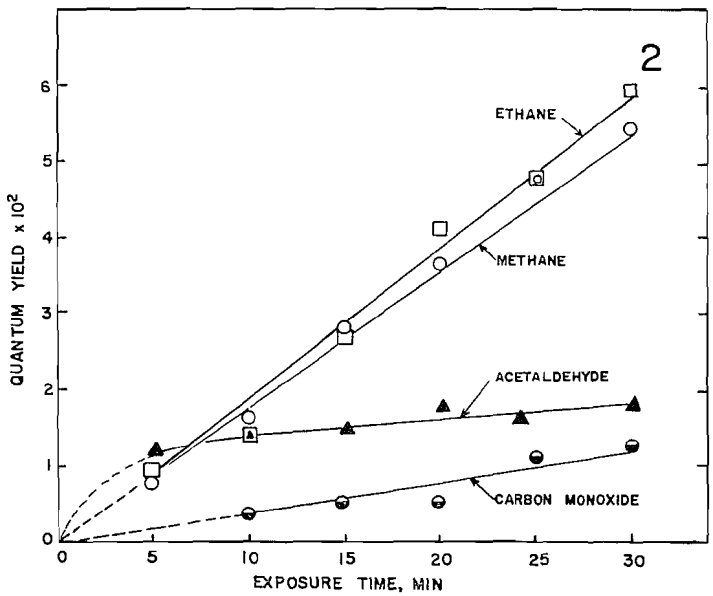


FIG. 1. Quantum yield of hydrogen, ○; and acetone, ◒, as a function of exposure time for pure isopropanol, at a pressure of 40 mm.

FIG. 2. Quantum yield of ethane, □; methane, ○; acetaldehyde, ▲; and carbon monoxide, ◒, as a function of exposure time for pure isopropanol, at a pressure of 40 mm.

at 2537 Å were carried out, with I_a calculated to be 0.6 μeinstein/min. In one of these experiments only the 2537 Å line was admitted using the filter described above. The results of the two experiments at exposure times of 30 minutes are given in terms of ratios of moles of products formed, in Table II.

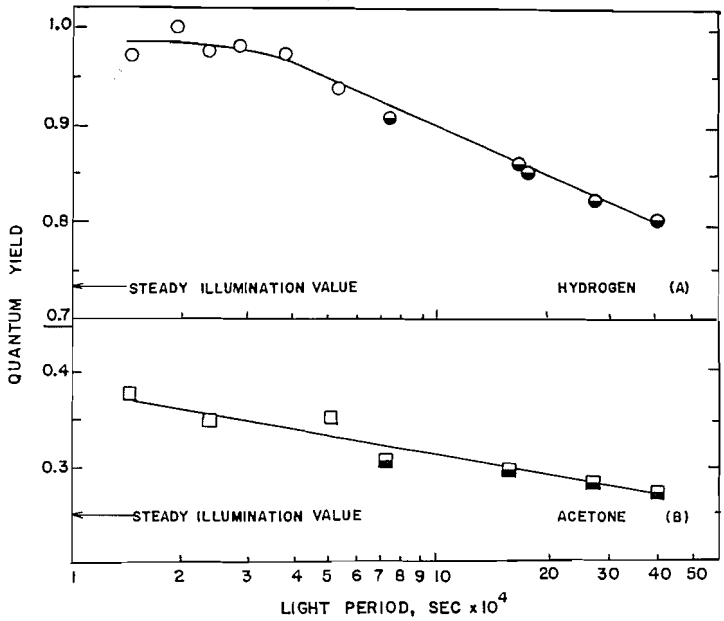

FIG. 3. Quantum yield of hydrogen, curve A, and acetone, curve B, as a function of light period, for dark periods of 160 msec, open symbols, and 103 msec, half-closed symbols, for pure isopropanol at a pressure of 40 mm. The Φ values obtained by extrapolation of the steady illumination data are indicated on the ordinate.

MeCHO	7.8	6.7

DISCUSSION

In Part II of this series it will be demonstrated that the primary process is a scission of the O—H bond, leading to the production of an isopropoxy radical and a hydrogen atom. Including this reaction as the initial step, the following mechanism is proposed to account for the salient features of the isopropanol reaction:

$$Me_2CHOH + Hg\ 6(^3P_1) \rightarrow Me_2C\dot{H}O + H + Hg\ 6(^1S_0) \quad [1]$$

$$Me_2CHOH + H \rightarrow Me_2\dot{C}OH + H_2 \quad [2]$$

$$Me_2CHOH + Me_2C\dot{H}O \rightarrow Me_2\dot{C}OH + Me_2CHOH \quad [3]$$

$$2Me_2\dot{C}OH \rightarrow Me_2CO + Me_2CHOH \quad [4]$$

$$2Me_2\dot{C}OH \rightarrow Me_2C(OH)(HO)CMe_2 \quad [5]$$

$$H + Me_2\dot{C}OH \rightarrow Me_2CHOH. \quad [6]$$

Abstraction from the α-carbon atom in reactions [2] and [3] is indicated by the formation of pinacol as the predominant non-volatile product, and is in agreement with several investigations of radical abstraction reactions from alcohols (9, 10, 11, 12). Trotman-Dickenson and Steacie (13) estimate the activation energy for methyl abstraction from isopropanol to be 7.3 kcal/mole. It appears unlikely that E_{act} for reaction [3] would exceed this value. From the observed yield of the two glycols other than pinacol, reactions [2] and [3] must also result in a small but finite yield of the $\dot{C}H_2CH(OH)Me$ radical.

Reaction [4], as the mode of acetone production, is proposed in preference to the alternative routes:

$$Me_2CHOH + Hg\ 6(^3P_1) \rightarrow Me_2CHOH^* + Hg\ 6(^1S_0) \quad [1']$$

or

$$Me_2COH + H \rightarrow Me_2CHOH^*, \quad [6']$$

both being followed by

$$Me_2CHOH^* \rightarrow Me_2CO + H_2. \quad [4']$$

If an excited molecule were the precursor for acetone, then at high pressures of added inert gas, where collisional deactivation would be the predominant fate of Me_2CHOH^*, a decreased yield of both acetone and hydrogen would be observed. The data in Table I indicate, however, that apart from a slight decrease due to competitive quenching of the resonance radiation by the neon, the yields of these products are independent of pressure of added neon. Furthermore, in Part II of this series it will be shown that at short exposure times in the presence of nitric oxide, there is not the equivalence of $\Phi(H_2)$ and $\Phi(Me_2CO)$ which would be expected if reaction [4'] were an important step in the reaction sequence.

The other possible route to acetone formation would be from the disproportionation of isopropoxy radicals. However, the low stationary-state concentration of this species, as indicated by the absence of hydroxy ethers among the products, would suggest that this reaction is unimportant in the present system.

The increase in $\Phi(Me_2CO)$ at progressively shorter light periods under intermittent illumination, shown in Fig. 3, also favors reaction [4]. Certainly it appears reasonable to assume that the lifetime of H atoms in the system is considerably shorter than that of $Me_2\dot{C}OH$, and hence there should be a major segment of the dark period during which the H-atom concentration is essentially zero, and consequently the sole fate of $Me_2\dot{C}OH$ would be reactions [4] and [5], resulting in the observed increase in acetone production.

Figure 2 indicates that ethane, methane, and carbon monoxide have primary quantum yields of zero, indicating that these products are not of primary origin. It is likely that these products arise from the secondary decomposition of acetone. The experiments with filtered light, given in Table II, in which the secondary decomposition of acetone is shown to be unaffected by isolation of the 2537 Å resonance line, suggest that the acetone is reacting with Hg $6(^3P_1)$ atoms or with the resonance line itself. Steacie and Darwent

(14) have given evidence of the close similarity between the sensitized reaction and the photolysis at 2537 Å. The overall result of the secondary decomposition of acetone can be represented as:

$$Me_2CO + Hg\ 6(^3P_1) \rightarrow 2CH_3 + CO + Hg\ 6(^1S_0) \quad [7]$$

and accounts for the appearance of methane, ethane, and carbon monoxide as reaction products.

Whether the yield of the minor product, acetaldehyde, does in fact extrapolate to zero at zero extent of reaction remains uncertain, but it appears likely that at least some of this minor product may be arising from the decomposition of isopropoxy radicals by the reaction

$$Me_2CHO \rightarrow MeCHO + CH_3, \quad [8]$$

as observed by Wijnen (15) in the photolysis of isopropyl propionate.

Finally, our data for the reaction under intermittent illumination require comment. The observed increase in the yield of hydrogen, as the light period is made progressively shorter, indicates that as the mean radical concentration is reduced, the importance of reaction [6] as a fate of hydrogen atoms produced in the primary process is diminishing, and, in the plateau region of the curve of Fig. 3, the exclusive fate of hydrogen atoms is step [2], resulting in the observed quantum yield of unity.

CONCLUSIONS

The overall features of the reaction are similar to those of the *n*-chain alcohols previously investigated. The presence of a particularly weak C—H bond in isopropanol, however, leads to some important differences. In particular, $\Phi^0(H_2)$ is 0.72 for isopropanol, compared to 0.46 for methanol (2) and 0.53 for ethanol (4). In the intermittent illumination studies, a similar effect is observed. Here at $t_L = 0.15$ msec, the shortest light period studied, values for $\Phi(H_2)$ are 0.89 for methanol (3); 0.96 for ethanol (4), and 1.0 for isopropanol. It may be concluded that for ethanol and isopropanol and likely for methanol, H atoms are produced with perfect efficiency in the primary process.

ACKNOWLEDGMENTS

The authors take pleasure in expressing their thanks to Mr. R. K. Taylor of this laboratory for performing the mass spectrometric analyses.

This research was supported in part by the National Research Council under Block Term Grant No. T 162 (Gunning), which support is gratefully acknowledged.

SYNTHESIS IN THE PYRIDINE SERIES

II. THE SYNTHESIS OF NEW 3,4,5-TRIALKYLATED PYRIDINES

JAMES P. KUTNEY AND T. TABATA
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received February 12, 1962

ABSTRACT

A synthetic sequence leading to new and inaccessible 3,4,5-trialkylated pyridines has been developed. The nature of the synthesis allows the preparation of virtually any type of 3,4,5-trialkylated pyridine by simple, straightforward variations at the appropriate stage.

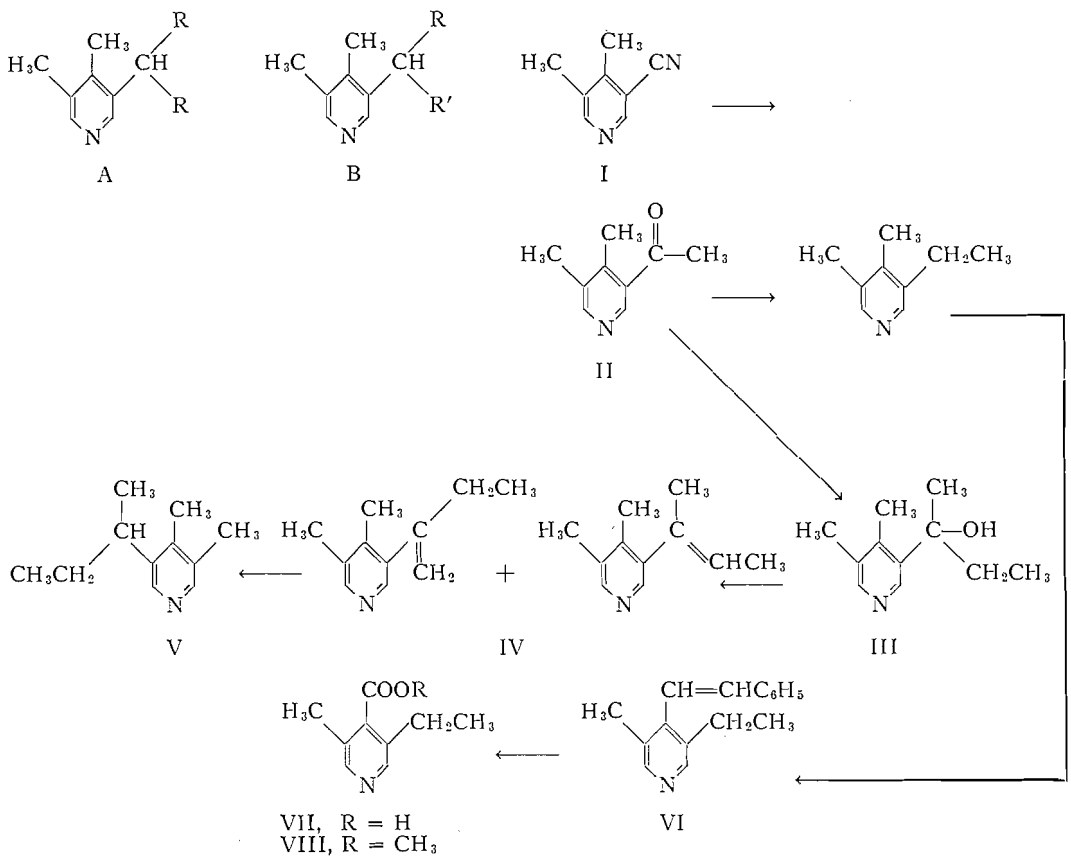
Recently, in connection with the structural elucidation of a new alkaloid, we became involved in the developing of a synthetic sequence to new 3,4,5-trialkylated pyridines. In Part I of this series (1) we described a general approach to this goal and, in particular, indicated that the substance 3,4-dimethyl-5-cyanopyridine (I) was a valuable intermediate for the synthesis of various new trialkylated pyridines of this type. We now wish to describe some of our results which support this view.

There are numerous possible modifications of the cyano group and we have already indicated (1) the conversion of this group to an ester function to provide an intermediate for the preparation of pyridines of the type A. In order to provide entry into another series of branched-chain pyridines (type B) we reacted 3,4-dimethyl-5-cyanopyridine with methylmagnesium iodide to obtain 3,4-dimethyl-5-acetylpyridine (II). The success of this reaction was readily evident from the infrared spectrum of the product, which indicated a virtual disappearance of the absorption due to the cyano function (4.48 μ) and the appearance of the characteristic carbonyl band (5.94 μ). This ketonic substance was subsequently treated with ethylmagnesium iodide, and the expected alcohol, III, was obtained as a light yellow viscous liquid. This substance resisted all attempts to crystallize —a rather surprising behavior since the analogous substance, 3,4-dimethyl-5-(2-hydroxy-2-propyl)-pyridine, reported previously (1), was a crystalline material. Nevertheless, characterization of the substance established, beyond doubt, that it possessed the expected structure. The infrared spectrum possessed a typical hydroxyl absorption and the nuclear magnetic resonance (n.m.r.) spectrum was particularly instructive. The presence of a triplet at high magnetic field (9.22 τ) indicated a methyl group flanked by a methylene carbon which in turn was indicated by a quartet centered at 8.16 τ. Another signal at 8.5 τ was assigned to a methyl group attached to an oxygen-bearing carbon and a weak signal at 4.6 τ was attributed to a proton on oxygen. This evidence established the presence of the 2-hydroxy-2-butyl group attached to the pyridine nucleus. The remaining signals—two sharp spikes at 7.85 and 7.58 τ characteristic of methyl protons attached to the pyridine ring (1), and a doublet at low field (2.08 τ) attributable to α protons on the pyridine ring (1, 2)—served to establish, beyond doubt, the structure III.

The removal of the hydroxyl function had been successfully accomplished in our previous work by means of red phosphorus and hydriodic acid and we attempted to utilize this reaction in this series. In contrast to the successful conversion of 3,4-dimethyl-5-(2-hydroxy-2-propyl)-pyridine to 3,4-dimethyl-5-isopropylpyridine by conducting the reaction at the reflux temperature for 24 hours, the corresponding conversion of III to the desired 3,4-dimethyl-5-*s*-butylpyridine (V) did not proceed to completion. Even

under more drastic conditions (48 hours' reflux), the reaction product always consisted of a mixture, the olefinic substance IV and the desired V. The greater resistance of the olefinic bond to reduction was further indicated by catalytic hydrogenation studies. When the hydrogenation of IV was performed under conditions previously used for 3,4-dimethyl-5-isopropenylpyridine (Adams catalyst, atmospheric pressure, and room temperature), incomplete reduction was observed, as evidenced by an olefinic signal in the n.m.r. spectrum. However, the desired pyridine, V, was obtained when the reduction was allowed to proceed at more stringent conditions (Adams catalyst, 32 p.s.i.). The ultraviolet spectrum of this product was characteristic of an alkylated pyridine and the n.m.r. spectrum provided strong support for this structure.

For the preparation of 3,4-dimethyl-5-ethylpyridine, which was necessary for further studies in this area, we considered the direct reduction of the acetyl function in II to an ethyl group. The most convenient method appeared to be the Wolff–Kishner reduction, a reaction frequently employed in the pyridine series (3). Indeed, reaction of 3,4-dimethyl-5-acetylpyridine under the Huang-Minlon modification of the Wolff–Kishner reduction (4) provided the expected 3,4-dimethyl-5-ethylpyridine. The n.m.r. spectrum was in complete agreement with the assigned structure. It indicated a triplet at high field (8.84 τ) and a quartet at lower field (7.42 τ), to provide strong evidence for the ethyl group. The intense signal at 7.86 τ, characteristic of methyl protons attached to the pyridine ring, and a weak signal at low field, typical of α protons, accounted for the remaining hydrogen atoms.



The successful synthesis of 3,4-dimethyl-5-ethylpyridine allowed us to consider the steric effects of the substituents attached to carbon atoms 3 and 5 on the reactivity of the methyl group at the 4 position. We became interested in this aspect of the problem, since some of our previous work has already indicated that this steric effect could be substantially important in certain reactions. For example, we had indicated previously (1) that 3,5-dimethyl-4-acetylpyridine possesses a very unreactive carbonyl group to organometallic reagents, a factor which must be attributed, at least in part, to the steric influence of the neighboring methyl groups. It appeared to us that some more information regarding this point could be deduced from the aldol-type condensation reactions of 3,4-dimethyl-5-ethylpyridine with such aldehydes as benzaldeyde. This reaction has been utilized in pyridine chemistry on numerous occasions and has proved to be of considerable synthetic value (5, p. 200). When 3,4-dimethyl-5-ethylpyridine was reacted with benzaldehyde under rather drastic conditions, the corresponding 3-methyl-5-ethyl-4-styrylpyridine, VI, was formed in moderate yield. The success of the reaction was easily recognized from consideration of the spectral data. The infrared spectrum, with a weak band at 6.12 μ, was consistent with the presence of a new olefinic bond and the n.m.r. spectrum was particularly informative. The characteristic signals for the ethyl group were still present and, in particular, the intense signal due to the C_3- and C_4-methyl groups in the starting material was considerably reduced and consistent with the presence of only *one* methyl group. The olefinic proton region exhibited a characteristic *AB* splitting pattern with a separation of 17 c.p.s., suggesting a trans orientation of the olefinic bond, and the appearance of the usual aromatic signals served to further confirm the 4-styrylpyridine structure. The ultraviolet spectrum was very interesting in that it was considerably different from the spectra reported previously for compounds of this type (6, 7). The main absorption band at 278 mμ represented a small bathochromic shift from the usual alkyl pyridine absorption (263–268 mμ) but this absorption is nevertheless significantly lower than that of such compounds as 4-styrylpyridine (307 mμ), and the intensity of the absorption of VI is lower. We believe that this rather anomalous spectrum is due to the fact that the neighboring alkyl substituents at the 3- and 5-positions cause the styryl moiety to lie out of the plane of the pyridine ring, thereby reducing the effect of the additional conjugation. From the above results it can be concluded that although the 4-methyl function is somewhat hindered it is still capable of entering into condensation reactions with carbonyl compounds. The yield in this reaction is, however, somewhat lower than reported in other series (8).

The isolation of 3-methyl-5-ethyl-4-styrylpyridine from the condensation reaction was useful in providing a synthetic intermediate for the synthesis of pyridine derivatives possessing different functions at the 4-position. We therefore considered several methods to convert the olefinic linkage to a carboxyl function. This type of reaction has been used in pyridine chemistry for the synthesis of pyridine carboxylic acids or aldehydes (5, p. 207). The reaction of choice involved ozonolysis, and we subjected 3-methyl-5-ethyl-4-styrylpyridine to this reaction. The product of this reaction was the expected carboxylic acid, VII, obtained as a high-melting, crystalline substance. Recently the ozonolysis of vinylpyridines has been shown to yield, under similar conditions, the corresponding pyridinecarboxylic acids (9). This material was readily converted to the methyl ester VIII by treatment with an ethereal solution of diazomethane. The structure of the ester was established, beyond doubt, by the n.m.r. spectrum of this substance. Apart from the characteristic signals for the presence of the ethyl and methyl groups attached directly to the pyridine nucleus, a sharp signal at 6.21 τ confirmed the presence of the ester methyl.

In conclusion, we would like to point out that these studies have provided intermediates which can be used to prepare virtually any type of 3,4,5-trialkylated pyridine. Firstly, it is obvious that any Grignard reaction on 3,4-dimethyl-5-cyanopyridine, followed by the appropriate steps, provides numerous variations to the type of group attached at C_5. Secondly, the appropriate ester analogous to VIII provides entry into various possibilities at C_4 and finally the nature of the alkyl group at C_3 can be likewise varied. It is pertinent to note that in the original Guareschi cyclization, which provides the starting material for the above work, the nature of the alkyl group at C_3 is determined by the nature of the acetoacetic ester molecule used in the cyclization. Consequently appropriate variations in the synthetic sequence will yield numerous new and otherwise difficultly accessible 3,4,5-trialkyl pyridines.

EXPERIMENTAL

All melting points were determined on a Fischer–Johns apparatus and are uncorrected. The ultraviolet spectra were recorded in 95% ethanol on a Cary 14 recording spectrophotometer. Infrared spectra were recorded on a Perkin–Elmer model 21 spectrophotometer. The n.m.r. spectra were taken at 60 Mc on a Varian A60 instrument. In all cases integration of areas under the signals was carried out and the number of protons corresponding to each signal is indicated in parentheses. Values are given in the Tiers τ scale with tetramethylsilane used as the external standard, set at 10.0 τ units. The solvent used was carbon tetrachloride. The analyses were performed by Dr. A. Bernhardt and his associates, Mulheim (Ruhr), Germany, and by Mrs. A. Aldridge, University of British Columbia.

3,4-Dimethyl-5-acetylpyridine (II)

A solution of 3,4-dimethyl-5-cyanopyridine (I, 22.2 g) in anhydrous ether (350 ml) was added slowly to a stirred solution of methylmagnesium iodide, prepared in the usual manner (48.5 g Mg, 385 g methyl iodide) in dry ether (630 ml). After the addition was complete, the reaction mixture was refluxed for 4 hours and then allowed to stand overnight at room temperature. The excess Grignard and the complex were destroyed by the addition of dilute ammonia until there was no further reaction. The resulting mixture was saturated with sodium chloride and extracted exhaustively with ether. The ether extract was dried over anhydrous magnesium sulphate and the solvent evaporated to yield a liquid product. Distillation of this material at a bath temperature of 120–130° at 2.5 mm provided a clear liquid product (10.9 g). This material was suitable for subsequent reactions although it contained traces of the starting cyano compound, which was very difficult to remove by distillation.

Chromatography of a small portion (3.8 g) of this liquid on alumina (250 g) provided a good separation. Elution with petroleum ether – ethyl ether (4:1) yielded a mixture of the acetylpyridine and the cyanopyridine in the initial fractions, and then the pure 3,4-dimethyl-5-acetylpyridine (1.2 g) was obtained in the later fractions. Elution with pure ether removed the remaining material.

An analytical sample of the acetylpyridine distilled at 144° at 22 mm; n_D^{20} 1.4166; infrared: 5.94 μ; ultraviolet: λ_{max} 231 mμ (log ϵ 3.73), λ_{max} 271 mμ (log ϵ 3.40), λ_{min} 254 mμ (log ϵ 3.24). Found: C, 72.43; H, 7.38; O, 10.74; N, 9.39. Calc. for $C_9H_{11}ON$: C, 72.45; H, 7.43; O, 10.72; N, 9.39.

A picrate, m.p. 162–163°, was prepared in ethanol and recrystallized several times from ethanol. Found: C, 47.82; H, 3.81; O, 33.52; N, 14.90. Calc. for $C_{15}H_{14}O_8N_4$: C, 47.62; H, 3.73; O, 33.84; N, 14.81.

3,4-Dimethyl-5-(2-hydroxy-2-butyl)-pyridine (III)

A solution of 3,4-dimethyl-5-acetylpyridine (0.81 g) in anhydrous ether (14 ml) was added slowly to a stirred solution of ethylmagnesium iodide (1.8 ml ethyl iodide, 0.52 g Mg turnings) in ether (20 ml). After the addition was complete, the reaction mixture was refluxed for 12 hours and then allowed to stand overnight at room temperature. The mixture was cautiously treated with dilute ammonia and the resulting basic mixture was saturated with sodium chloride. The reaction mixture was then extracted several times with ether and the ethereal layer dried over anhydrous magnesium sulphate. Removal of the solvent yielded a viscous liquid (1.07 g). This material was taken up in a small amount of chloroform and placed on a column of alumina (100 g). Elution with petroleum ether – ethyl ether (9:1) yielded traces of the starting material. Further elution with ethyl ether and chloroform provided the desired alcohol (III, 0.54 g). A small portion of this material was distilled to yield the analytical sample of the alcohol, as a light yellow viscous liquid (b.p. 144° at .01 mm); infrared: 2.95–3.2 μ, very broad; ultraviolet: λ_{max} 263 mμ (log ϵ 3.36), λ_{max} 271 mμ (log ϵ 3.30), λ_{min} 236 mμ (log ϵ 2.83); n.m.r. signals: triplet centered at 9.22 τ (methyl of ethyl group, area = 3H), 8.5 τ (CH_3—C—OH, area = 3H), quartet centered at 8.16 τ (methylene of CH_3CH_2—C—OH), 7.85, 7.58 τ (methyls attached to ring, area = 6H), 4.6 τ (OH, area = 1H), doublet centered at 2.08 τ (—αH, area = 2H). Found: C, 73.37; H, 9.40; O, 9.11; N, 8.27. Calc. for $C_{11}H_{17}ON$: C, 73.70; H, 9.56; O, 8.93; N, 7.81.

The picrate, prepared in the usual manner, was recrystallized several times from ethanol to yield an analytical sample which melted at 136–137.5°. Found: C, 50.32; H, 4.40; O, 31.22; N, 13.73. Calc. for $C_{17}H_{20}O_8N_4$: C, 50.00; H, 4.84; O, 31.34; N, 13.72.

Subsequent preparations of this alcohol were carried out very conveniently from the acetylpyridine without careful purification of the intermediates. That is, the crude product from the reaction of 3,4-dimethyl-5-acetylpyridine and methylmagnesium iodide was treated directly with ethylmagnesium iodide and this product chromatographed as above. An overall yield of 27% of the pure alcohol was obtained.

3,4-Dimethyl-5-s-butylpyridine (V)

A mixture of 5-(2-hydroxy-2-butyl)-3,4-dimethylpyridine (0.85 g), concentrated hydriodic acid (9.3 ml, 47%), and red phosphorus (1.1 g) was refluxed for 24 hours. After the mixture had been cooled, the phosphorus was removed by filtration and the filtrate concentrated by distillation *in vacuo*. The dark residual oil was taken up in water (6 ml) and decolorized by the addition of sodium bisulphite. The mixture was made alkaline by the addition of potassium hydroxide pellets and the alkaline mixture was then extracted thoroughly with ether. After the ethereal extract had been dried over anhydrous sodium sulphate, the solvent was removed and the residual liquid was distilled using a bath temperature of 60–100° at 0.07 mm. The yield of the colorless liquid product was 478 mg. This product was a mixture of the desired material and some olefin resulting from incomplete reduction (n.m.r. signal at 4.5 τ). This olefinic material was present in small quantities even if the reflux period was increased to 48 hours. Consequently, it was found most convenient to carry out the reduction under catalytic hydrogenation conditions. A portion of the distilled liquid product (102 mg) was dissolved in glacial acetic acid (14 ml) and catalytically hydrogenated over Adam's catalyst (100 mg) at room temperature with a hydrogen pressure of 32 p.s.i. After 5 hours, the catalyst was filtered and the solvent removed on a steam bath *in vacuo*. The residue was treated with water (3 ml), and made alkaline by the addition of sodium bicarbonate and the resulting mixture was extracted exhaustively with ether. After the ethereal extract had been dried over anhydrous magnesium sulphate, the solvent was removed and the residual liquid distilled at 60–70° (bath temp.) at 0.05 mm to provide 73 mg of a pure liquid. A small portion was redistilled for an analytical sample (b.p. 135° at 22 mm); n_D^{20} 1.5078; ultraviolet: λ_{max} 264 mμ (log ϵ 3.41), λ_{max} 272 mμ (log ϵ 3.33), λ_{min} 231 mμ (log ϵ 2.39); n.m.r. signals: triplet centered at 9.18 τ (methyl of ethyl group, area = 3H), doublet centered at 8.80 τ (CH_3—C—H, area = 3H), multiplet centered at 8.38 τ (methylene of ethyl group, area = 2H), 7.83 τ (intense, methyls attached to ring, area = 6H), multiplet centered at 7.2 τ (H—C—CH_3, area = 1H), doublet centered at 1.98 τ (αH, area = 2H). Found: C, 80.95; H, 10.52; N, 8.40. Calc. for $C_{11}H_{17}N$: C, 80.92; H, 10.50; N, 8.58.

A picrate was readily prepared in the usual manner, and this upon several recrystallizations from alcohol provided a pure sample, m.p. 131–132°. Found: C, 52.07; H, 5.03; N, 14.43; Calc. for $C_{17}H_{20}N_4O_7$: C, 52.04; H, 5.14; N, 14.28.

3,4-Dimethyl-5-ethylpyridine

The reaction product (11.1 g) resulting from the reaction of 3,4-dimethyl-5-cyanopyridine (20 g) with a fourfold excess of methylmagnesium iodide was treated with hydrazine (6.5 ml), potassium hydroxide pellets (90 g), and diethylene glycol (13 ml) and heated in an oil bath at 150–170° for 2 hours. The bath temperature was then raised to 200° and the reaction mixture was kept at this temperature for a further 2 hours. The cooled reaction mixture was treated cautiously with a small portion of water and the resulting mixture was distilled. The fraction which came over at 109–116° was treated with more water (250 ml) and this aqueous mixture was thoroughly extracted with ether. After the ether extract had been dried over anhydrous magnesium sulphate, the solvent was removed and the residual liquid was distilled from potassium hydroxide pellets. A fraction (7.6 g) distilling over at 50–70° (bath temp.) at 0.14 mm was completely free from any carbonyl or cyanide impurities and proved to be the desired material. A small portion of this liquid was redistilled (b.p. 115–116° at 22 mm) and provided an analytical sample. n_D^{20} 1.5151; ultraviolet: λ_{max} 263 mμ (log ϵ 3.39), λ_{max} 266 mμ (log ϵ 3.38), λ_{max} 271 mμ (log ϵ 3.31), λ_{min} 238 mμ (log ϵ 2.91); n.m.r. signals: triplet centered at 8.84 τ (methyl of ethyl group, area = 3H), 7.86 τ (intense, area = 6H, methyls attached to ring), quartet centered at 7.42 τ (methylene of ethyl group, area = 2H), 1.98 τ (αH, area = 2H). Literature values (10): n_D^{20} 1.5136; b.p. 217° at 744 mm. Found: C, 79.82; H, 9.69; N, 10.25. Calc. for $C_9H_{13}N$: C, 79.95; H, 9.69; N, 10.36.

A picrate of the substance was prepared in ethyl alcohol and after several recrystallizations from this solvent an analytical sample, m.p. 130–131°, was obtained. Literature (10): m.p. 133°. Found: C, 49.54; H, 4.34; O, 30.88; N, 15.23. Calc. for $C_{15}H_{16}N_4O_7$: C, 49.45; H, 4.43; O, 30.74; N, 15.38.

3-Methyl-4-styryl-5-ethylpyridine (VI)

A mixture of 3,4-dimethyl-5-ethylpyridine (2.82 g), benzaldehyde (6.3 ml), potassium acetate (1.95 g), acetic anhydride (5.9 ml), and a small crystal of iodine was refluxed for 40 hours. The resultant dark brown reaction mixture was cooled and treated with aqueous hydrochloric acid until acidic, and the excess benzaldehyde was removed by steam distillation. The residue from the steam distillation was extracted with ether to remove acidic or neutral materials and the resulting aqueous layer was then made basic by the addition of sodium hydroxide pellets. This basic layer was extracted several times with ether, the ether extract dried over anhydrous magnesium sulphate, and the solvent removed. The residual liquid product was fractionally distilled and a fraction distilling up to 140° (bath temp.) at 0.4 mm, which contained a considerable amount of starting material, was separated. The subsequent fraction (2.59 g) came over as a

yellow slightly viscous liquid at a bath temperature up to 240° at 0.45 mm. A small portion was distilled again to provide an analytical sample (b.p. 153° at 0.02 mm). Infrared: 6.12 μ; n_D^{20} 1.6144; ultraviolet: λ_{max} 276 mμ (broad, log ϵ 4.20), λ_{min} 239 mμ (log ϵ 3.73); n.m.r. signals: triplet centered at 8.84 τ (methyl of ethyl group, area = 3H), 7.78 τ (methyl attached to ring at C_3, area = 3H), quartet centered at 7.37 τ (methylene of ethyl group, area = 2H), four signals centered at 3.2 τ (olefinic H, area = 2H), multiplet centered at 2.72 τ (aromatic H, area = 5H), 1.82 τ (αH, area = 2H). Found: C, 85.42; H, 7.52; N, 6.44. Calc. for $C_{16}H_{17}N$: C, 86.05; H, 7.67; N, 6.27.

A picrate of this substance was prepared in ethyl alcohol and after several recrystallizations from this solvent, an analytical sample, m.p. 182–183°, was obtained. Found: C, 58.23; H, 4.50; O, 24.50; N, 12.52. Calc. for $C_{22}H_{20}N_4O_7$: C, 58.40; H, 4.46; O, 24.76; N, 12.39.

3-Methyl-5-ethyl isonicotinic Acid (VII)

A solution of 3-methyl-4-styryl-5-ethylpyridine (2.32 g, 0.01 mole) in glacial acetic acid (70 ml) was treated with ozone (0.015 mole) at room temperature. The reaction mixture was treated with 3% aqueous hydrogen peroxide (10 ml) and the mixture was refluxed for 10 minutes. The solvent was removed *in vacuo* and the residue washed with ether to remove the benzoic acid. To the ether-insoluble residue water (4 ml) was added, and the mixture was warmed in a steam bath until all the material had dissolved. As the solution gradually cooled, small, needle-like crystals separated (304 mg). Recrystallization of this substance from absolute ethanol provided the pure acid, m.p. 268–269°, infrared: 5.88 μ.

An additional 1.51 g of material was recovered from the mother liquors. Although this latter crop was not as crystalline as the initial crop, it was shown to be the desired acid since on esterification with diazomethane, in a subsequent experiment, it provided the identical methyl ester. Found: C, 65.29; H, 7.00; O, 19.69. Calc. for $C_9H_{11}O_2N$: C, 65.44; H, 6.71; O, 19.37.

Methyl 3-Methyl-5-ethyl-4-pyridinecarboxylate (VIII)

To a stirred solution of 3-methyl-5-ethyl isonicotinic acid (1.5 g) in absolute ethyl alcohol (300 ml) an ethereal solution of diazomethane (containing 2 g CH_2N_2) was added. The reaction mixture was cooled in ice and stirred at ice-bath temperature for 3 hours. The reaction mixture was then treated with 2 *N* hydrochloric acid (35 ml) and extracted with ether to remove any neutral contaminants. The aqueous layer was made basic by the addition of sodium bicarbonate and then extracted continuously with ether for 20 hours. The ether extract was dried over anhydrous magnesium sulphate and the solvent removed to yield a liquid product. Distillation of this material at 70–100° (bath temp.) at 0.2 mm yielded 0.50 g of a clear liquid. A small portion of this substance was distilled again to provide an analytical sample (b.p. 135° at 22 mm); n_D^{20} 1.5025; infrared: 5.78 μ; ultraviolet: λ_{max} 274 mμ (log ϵ 3.48), λ_{min} 238 mμ (log ϵ 2.85); n.m.r. signals: triplet centered at 8.9 τ (methyl of ethyl group, area = 3H), 7.85 τ (methyl attached to ring, area = 3H), quartet centered at 7.5 τ (methylene of ethyl group, area = 2H), 6.21 τ (—$COOCH_3$, area = 3H), 1.83 τ (αH, area = 2H). Found: C, 67.16; H, 7.26; N, 7.90. Calc. for $C_{10}H_{13}O_2N$: C, 67.02; H, 7.31; N, 7.82.

The ester formed a picrate readily and this derivative, after recrystallizing from alcohol, melted at 151–153°. Found: C, 47.21; H, 4.09; O, 35.15; N, 13.43. Calc. for $C_{16}H_{16}O_9N_4$: C, 47.06; H, 3.95; O, 35.27; N, 13.72.

It should be pointed out that we found it very convenient to convert the entire reaction product into the picrate, purify the picrate by several crystallizations from alcohol, and finally regenerate the ester by decomposition of the picrate with lithium hydroxide (11). The recovery in this reaction is good and this provided an excellent method for purifying small quantities.

METHYLATION OF SUGAR DITHIOACETALS

III. D-GALACTOSE DIETHYL DITHIOACETAL[1]

G. G. S. DUTTON AND Y. TANAKA[2]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received March 7, 1962

ABSTRACT

Partial methylation of D-galactose diethyl dithioacetal in tetrahydrofuran with Purdie's reagents yielded 2-, 3-, and 6-*O*-methyl-D-galactoses in approximately equal amounts. Poly-*O*-methyl-D-galactoses were not investigated. These three mono-*O*-methyl ethers were identified as crystalline 2-*O*-methyl-D-galactose, 3-*O*-methyl-D-galactose phenylosazone, and 6-*O*-methyl-D-galactose phenylhydrazone. Paper chromatographic separation of all monomethyl-D-galactopyranoses was achieved by addition of borax to the irrigating solvent.

As a continuation of our study on the relative reactivity of hydroxyl groups in dithioacetals (1, 2) this paper reports the results obtained from the partial methylation of D-galactose diethyl dithioacetal. The dithioacetal was shaken at room temperature with amounts of silver oxide and methyl iodide adjusted to give a reasonable amount of the mono-*O*-methyl ethers. The methylated dithioacetal was hydrolyzed with acid and the deionized hydrolyzate was examined by paper chromatography in butanone–water azeotrope. When the chromatogram was irrigated for a long period the original compact spot of mono-*O*-methyl ethers (R_f 0.08) was found to streak, indicating considerable differences in the mobilities of the mono-*O*-methyl-D-galactoses.

It has been shown that the addition of boric acid to a butanol–water system greatly enhances the resolution obtainable in paper chromatography (3) and the use of borate with charcoal columns has also been recommended (4). The latter method has been used for the separation of 3- and 4-*O*-methyl-D-galactoses (5). In the original paper (3) no ethers of galactose were mentioned and it is now shown that all the mono-*O*-methyl-D-galactopyranoses may be readily separated on paper when the irrigating solvent is butanone–water azeotrope saturated with borax. The $R_{\text{galactose}}$ values of these compounds were 3.60 (2-*O*-methyl-), 2.67 (3-*O*-methyl-), 2.28 (4-*O*-methyl-), and 3.02 (6-*O*-methyl-D-galactose) (60 hours). The methylation product was then shown to contain 2-, 3-, and 6-*O*-methyl-D-galactoses. Neither authentic samples nor the methylation product gave clear separation of these isomers when they were chromatographed for 60 hours in butanone–water azeotrope in the absence of borax. Paper electrophoresis confirmed the presence of 2-, 3-, and 6-*O*-methyl-D-galactoses in the methylation product; M_g values of these isomers were 0.43, 0.76, and 0.90, respectively (cf. ref. 5). Absence of 5-*O*-methyl-D-galactose in the methylation product was shown by electrophoresis of the components in the di-*O*-methyl area of the chromatograms which gave very slowly migrating spots only. In general, monomethylglycofuranose sugars travel on chromatograms about as fast as the corresponding dimethylglycopyranoses (6). The two groups may be readily differentiated by the high electrophoretic mobility of the former (7).

Colorimetric analysis, by the phenol – sulphuric acid method (8), of the mixture of mono-*O*-methyl ethers isolated from the methylation product gave an approximately

[1]*Previous papers in this series have used the term mercaptal. This has been altered to dithioacetal to accord with current carbohydrate nomenclature (rule 32).*

[2]*Present address: Department of Chemistry, Queen's University, Kingston, Ontario.*

equal ratio for these three isomers which was consistent with the weights of these components isolated by paper chromatography.

The 2-*O*-methyl ether isolated from the methylation mixture crystallized as the free sugar. The 3-*O*-methyl ether was identified as 3-*O*-methyl-D-galactose phenylosazone, and the 6-*O*-methyl ether as 6-*O*-methyl-D-galactose phenylhydrazone.

The results reported here thus differ from the case of L-arabinose dithioacetal (2) in that there appears to be no selective reactivity of any one hydroxyl group in D-galactose diethyl dithioacetal.

EXPERIMENTAL

Methylation of D-*Galactose Diethyl Dithioacetal*

D-Galactose diethyl dithioacetal (0.50 g) was dissolved in tetrahydrofuran (150 ml), and silver oxide (2.00 g), drierite (3 g), and methyl iodide (20 ml) were added to the solution. The mixture was shaken for 7 hours at room temperature. The inorganic substances were filtered and then washed with tetrahydrofuran (20 ml). The filtrate and washing were evaporated to a sirup, which was redissolved in chloroform (20 ml) in order to remove a small amount of inorganic impurities by filtration. The chloroform solution gave on evaporation a yellow sirup (470 mg).

The methylation product (470 mg) was dissolved in ethanol (10 ml), and 18% hydrochloric acid (2 ml) was added to the solution, which was refluxed for 5 hours. A yellow sirup (255 mg) was obtained by evaporation of the neutralized hydrolyzate (Duolite A-4 resin) and treatment with charcoal.

Paper chromatography in butanone–water azeotrope showed that the sirup was a mixture of mono-*O*-methyl-D-galactoses (R_f 0.05 (strong)) and unchanged D-galactose (R_f 0.01 (strong)), plus several fast-running components with very weak intensities.

Chromatographic Separation of the Mixture of Methylated D-*Galactoses*

To butanone–water azeotrope (100 ml) sodium borate decahydrate (1 g) was added; the mixture was shaken and left to stand for several hours. The solution was decanted and used as the developing solvent.

The mixture of methylated D-galactoses was chromatographed in this solvent for 40 hours together with standard samples and the mixture was shown to contain 2-, 3-, and 6-*O*-methyl-D-galactoses. The mixture was resolved into its three components by streaking on four 15 cm wide Whatman 3 MM sheets and was developed for 60 hours in the same solvent. Each component was extracted with water (50 ml×3) and was obtained as a sirup on evaporation. These sirups were shown to be electrophoretically homogeneous.

The separation was repeated on a second mixture of methylated galactoses (529 mg) and the results shown in Table I were obtained. The 2-, 3-, and 6-*O*-methyl-D-galactoses were obtained in yields of 13.2, 14.7, and 8.1 mg respectively.

TABLE I

Chromatography* and electrophoresis† of mono-*O*-methyl-D-galactoses

Ether	Movement in mm	$R_{galactose}$	M_g
2-*O*-Methyl	205	3.46	0.45
3-*O*-Methyl	143	2.34	0.81
4-*O*-Methyl	127	2.16	
6-*O*-Methyl	176	2.89	0.90
Mixture	205, 176, 143	3.46, 2.89, 2.34	0.45, 0.81, 0.90
D-Galactose	59	1.00	1.00

*In butanone–water saturated with borax for 40 hours.
†In 0.05 *M* sodium borate, 950–1050 v, 25–30 ma, 45 minutes.

Colorimetric Analysis of the Mono-O-methyl Ethers and Examination of Fast-running Components

A methylation under the same conditions using 2.0 g of the dithioacetal gave a sirup (1.0 g) of methylated D-galactoses, and paper chromatography in butanone–water azeotrope showed the following R_f values: R_f 0.34 (weak), 0.17 (weak), 0.12 (medium), 0.05 (strong), and 0.01 (strong).

The sirup (1.0 g) was chromatographed on a cellulose–hydrocellulose column in butanone–water azeotrope (rate of flow: 10 ml/10 minutes). In tubes No. 80–200 (10-minute intervals) the component of R_f 0.05 was found and this fraction gave on evaporation a sirup (48.2 mg) which showed three spots ($R_{galactose}$ 3.37, 2.88, and 2.38) by paper chromatography in butanone–water azeotrope saturated with borax.

A part of this sirup was chromatographed for 60 hours in the same solvent and the ratio of these three components was estimated by the phenol – sulphuric acid method (8), which gave approximately 1:1:1 for 2-, 3-, and 6-*O*-methyl-D-galactoses.

In tubes No. 40–70 the components of R_f 0.17 and 0.12 were detected without clear separation. Evaporation of these fractions gave a sirup (21.2 mg) which showed two strong spots (M_g 0.23 and 0.28) by electrophoresis (950–1050 v, 25–30 ma, 50 minutes in 0.05 *M* sodium borate solution).

Identification of the Component $R_{galactose}$ 3.46 as 2-O-Methyl-D-galactose

The components which were isolated from the methylation mixtures and corresponded to 2-*O*-methyl-D-galactose were combined. An aqueous solution was deionized with Amberlite IR-120 and traces of borate were removed as follows (9). To the sirup (18.2 mg) was added methanol (5 ml), and the solution was evaporated *in vacuo* without heating. After this procedure was repeated about 20 times, the residue was dissolved in a small amount of warm absolute ethanol, and ether was added to turbidity. After seeding with an authentic sample of 2-*O*-methyl-D-galactose, colorless crystals were precipitated. The solvent was decanted, the crystals were washed with ether and had m.p. 152–154° C. Admixture with authentic 2-*O*-methyl-D-galactose (m.p. 153–156° C (5)) gave no depression of the melting point.

Identification of the Component $R_{galactose}$ 2.34 as 3-O-Methyl-D-galactose

Since the sirup (23.4 mg) corresponding to 3-*O*-methyl-D-galactose failed to crystallize after treatment with methanol, it was dissolved in 20% acetic acid (3 ml) and heated for 5 hours in boiling water with phenylhydrazine (39.1 mg) in absolute ethanol (0.22 ml) and a little sodium metabisulphite. The yellow crystals which precipitated on cooling of the reaction mixture were recrystallized from water and had m.p. 177–179° C, lit. (10) m.p. 176–179° C, and the melting point was not depressed when mixed with 3-*O*-methyl-D-galactose phenylosazone derived from 2,3-di-*O*-methyl-D-galactose.

Identification of the Component $R_{galactose}$ 2.89 as 6-O-Methyl-D-galactose

The sirup (16.5 mg) which corresponded to 6-*O*-methyl-D-galactose did not crystallize after treatment with methanol. It was dissolved in absolute ethanol (1 ml), and phenylhydrazine (9.2 mg) in absolute ethanol (0.06 ml) was added to the solution. The mixture was warmed for about 20 minutes and addition of petroleum ether precipitated white crystals, which were recrystallized from ethanol – petroleum ether and had m.p. 161–162° C. When the product was recrystallized from aqueous methanol the melting point was raised to 171–173° C and the mixed melting point with authentic 6-*O*-methyl-D-galactose phenylhydrazone, m.p. 172–173° C (11), was 171–172° C.

Synthesis of 2,3-Di-O-methyl-D-galactose

The published procedure (10) provided this compound, $[\alpha]_D^{25}$ 51.8° (*c*, 2.15 in water), R_f 0.29 and $R_{galactose}$ 5.00 (20 hours) in ethyl acetate – pyridine – water (2:1:2). This sirupy product gave 3-*O*-methyl-D-galactose phenylosazone, m.p. 178° C, lit. (10) m.p. 176–179° C.

ACKNOWLEDGMENTS

The financial support of the Research Corporation is gratefully acknowledged. We wish to thank Dr. B. Lindberg, Stockholm, Sweden, for a gift of mono-*O*-methyl-D-galactoses. One of us (Y. T.) thanks the National Research Council for the award of a studentship.

5-METHYL-1,2,3-CYCLOHEXANETRIONETRIOXIME: A COMPARATIVE STUDY WITH SOME *vic*-DIOXIMES[1]

R. A. HAINES, D. E. RYAN, AND G. E. CHENEY
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received September 11, 1961

ABSTRACT

A comparative study has been made of 5-methyl-1,2,3-cyclohexanetrionetrioxime with nioxime and dimethylglyoxime; complexes with nickel, copper, and cobalt have been investigated. Dissociation constants of the three reagents, in aqueous solution, have been determined and formation constants of their copper complexes evaluated. Spectrophotometric and potentiometric studies were used to obtain the results.

INTRODUCTION

Numerous investigations of the reactions between *vic*-dioximes and metal ions have been reported (1–5) since the initial report on dimethylglyoxime by Tschugaeff (6). These dioximes can exist in three isomeric forms, as the hydroxy groups can be anti, syn, or amphi to one another; only the anti configuration gives the familiar red precipitate with nickel; the amphi form gives a yellow or green-yellow compound in which one molecule of dioxime is attached to one nickel while the syn form is incapable of reacting with metallic salts (1).

A trioxime, 5-methyl-1,2,3-cyclohexanetrionetrioxime, has been prepared recently (7) and, in preliminary studies, appeared to possess many of the selective properties of similar *vic*-dioximes. However, the presence of the third oxime group makes possible the existence of four isomers: the three hydroxy groups can be oriented so that they are all amphi, two are syn, and the third either anti or amphi to the common central group, and two are anti and the third group amphi. It was thought worthwhile, in view of possible reaction of this third hydroxy group, to evaluate the chelating properties of this trioxime through a comparison with dimethylglyoxime and nioxime employing absorption spectrophotometry and potentiometric titration techniques.

SPECTROPHOTOMETRIC STUDIES

In these studies, absorption spectra of 5-methyl-1,2,3-cyclohexanetrionetrioxime and its complexes with copper and cobalt were determined at various pH values; spectrophotometric studies for dimethylglyoxime and nioxime have been carried out previously by Banks (5). Measurements were made in matched 1-cm silica cells using a Beckman "DU" spectrophotometer equipped with an electronic power supply and photomultiplier attachment; a Beckman Model "G" pH meter, with saturated calomel and glass electrode couple, was used for pH measurements.

Reagent

Aqueous solutions of "White Label" Eastman Kodak 5-methyl-1,2,3-cyclohexanetrionetrioxime were prepared and diluted quantitatively to 0.0001 *M*. The absorption spectra of these solutions were determined at various pH values, adjustments to the

[1]*This work received financial assistance from the National Research Council, and is taken, in part, from the M.Sc. thesis of R. A. Haines.*

desired pH being made with dilute sodium hydroxide and perchloric acid. The difference in the nature of the spectral transmission curves at low and high pH is shown in Fig. 1.

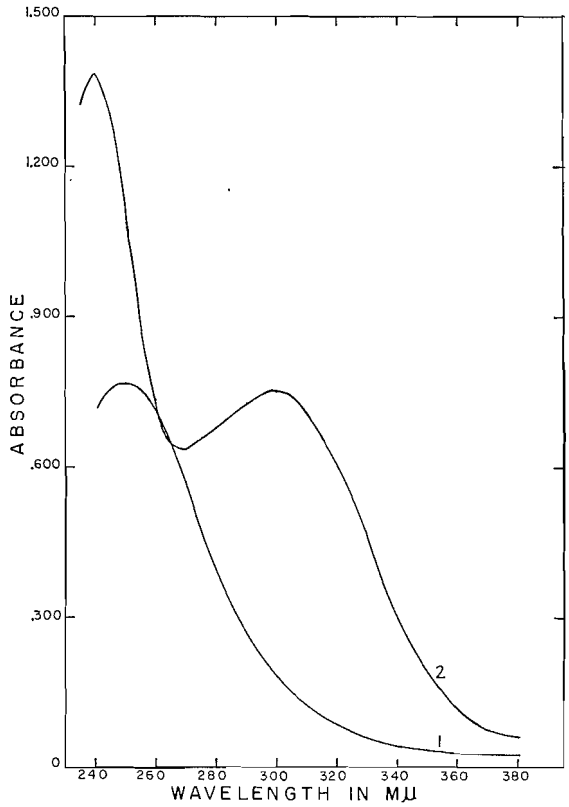

FIG. 1. Absorption spectra of trioxime. 1.16×10^{-4} aqueous solution at pH 2 (1) and pH 11 (2).

The absorption spectra of the reagent shows a maximum at approximately 245 mμ at pH 1, which undergoes a hypsochromic shift and an increase in absorptivity with an increase in pH. In solutions of pH greater than 7, a second maximum is present at approximately 300 mμ and the solution develops a yellow color. Spectrophotometric studies by Banks (5) on nioxime and dimethylglyoxime have shown that maxima occur, for these two oximes, at approximately 230 and 270 mμ. The introduction of the third oxime group into the ring system has resulted in a bathochromic shift of these maxima, which is consistent with an increase in the conjugation of the trioxime system relative to the nioxime system. Molecular extinction coefficients for the trioxime at 240 mμ and 300 mμ are recorded in Table I.

TABLE I

Molecular extinction coefficients of 5-methyl-1,2,3-cyclohexanetrionetrioxime

pH	240 mμ	300 mμ
2	4,770	1,520
4	6,250	1,580
6	6,490	1,620
8	9,010	2,850
10	12,100	5,310
11	12,000	6,500

Metal Chelates

Metal perchlorates, obtained from the G. Frederick Smith Chemical Co., were used to prepare the stock 0.01 *M* standard solutions, volumes of reagent and metal ions were mixed in the desired proportions, pH adjustments made with dilute sodium hydroxide and perchloric acid, and the spectral transmission curves of each mixture determined. Figure 2 shows curves for the complexes of the trioxime with copper and cobalt. Neither the cobalt nor copper complexes shows a resolvable maximum in the visible region; for both chelates a "shoulder" is present at approximately 300 mμ. Cobalt shows a maximum at about 260 mμ but this is unsuitable for most direct analytical measurements due to the strong absorbance of trioxime itself at this wavelength.

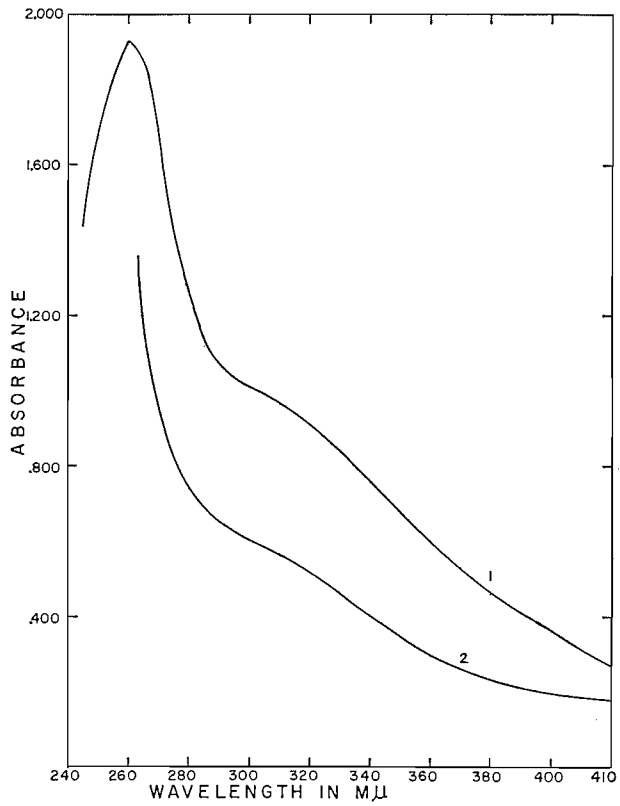

FIG. 2. Absorption spectra of metal complexes: 1, solution 2.33×10^{-4} *M* in cobaltous perchlorate and 6.99×10^{-4} *M* in trioxime at pH 6; 2, solution containing similar concentrations of copper perchlorate and trioxime at pH 4.

Job's method of continuous variations (8) and the molar ratio method of Yoe and Jones (9) were used to determine the stoichiometry of the trioxime copper and cobalt chelates. The continuous variations study yielded results in agreement with those obtained potentiometrically (*vide infra*); as shown in Fig. 3, a 2:1 complex with copper and a 3:1 complex with cobalt are indicated.

The mole ratio method, Fig. 4, showed different results. At 360 mμ the existence of both 1:1 and 2:1 copper complexes are indicated but only a 1:1 copper complex is apparent from measurements made at 410 mμ. With cobalt, at both wavelengths, complexes containing 1, 2, and 2.5 moles of reagent for each mole of cobalt are evident.

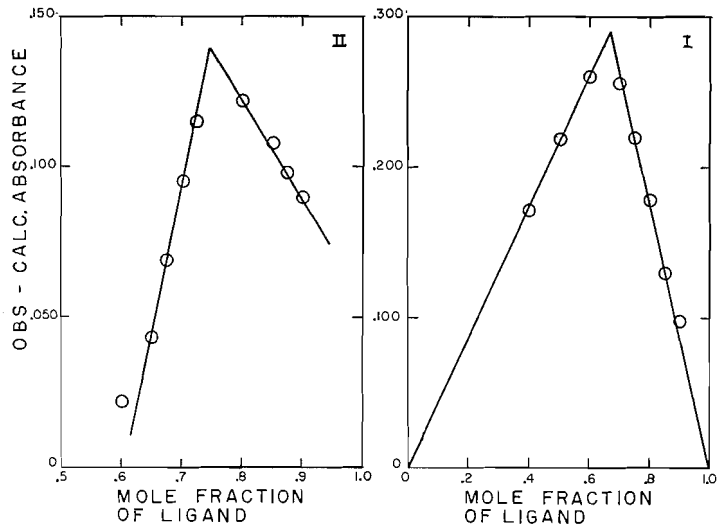

FIG. 3. Continuous variations plot: I, trioxime and copper perchlorate at pH 4 and wavelength 450 mμ (total concentration of copper plus reagent, 3.81×10^{-4} M); II, trioxime and cobaltous perchlorate at pH 6 and wavelength 330 mμ (total concentration of cobalt plus reagent, 3.68×10^{-4} M).

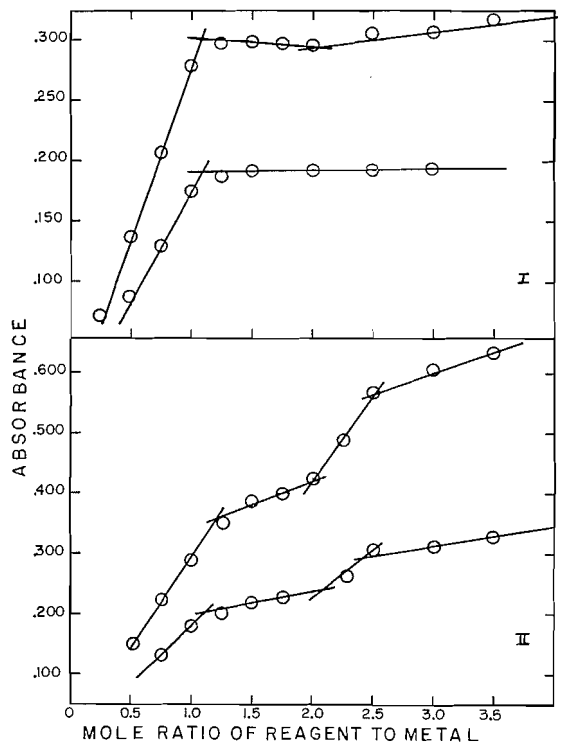

FIG. 4. Mole ratio plot: I, trioxime and copper perchlorate at pH 4; II, trioxime and cobaltous perchlorate at pH 6. Total metal concentration 2.41×10^{-5} M; curves are given for 360 and 410 mμ.

The results obtained by Job's method agree with those previously recorded for other oximes; a 2:1 complex of dimethylglyoxime with copper has been known for some time, and it has recently been shown that 1,2,3-cyclohexanetrionetrioxime forms a 3:1 complex with cobalt II (10).

POTENTIOMETRIC STUDIES

Potentiometric titrations, using carbonate-free 0.1 *N* potassium hydroxide as titrant, were carried out on 5-methyl-1,2,3-cyclohexanetrionetrioxime and its complexes with nickel II, cobalt II, and copper II. Potentiometric methods have been used sparingly for the dioximes and the data reported give formation constants only for dimethylglyoxime in 50% dioxane–water solution (4); it was necessary, therefore, for comparison purposes, to also investigate dimethylglyoxime and nioxime by this technique. These titrations permitted the calculation of the dissociation constants of the three oximes in water and gave information regarding the stoichiometry of the chelates and the relative stability of the copper II complexes based on the magnitude of the respective overall formation constants as evaluated by the Bjerrum technique (11).

Apparatus

The course of the titrations was followed with a Radiometer 4 pH meter equipped with a Beckman saturated calomel and an E-2 glass electrode couple. Titrations were carried out in a pyrex vessel equipped with an outer jacket through which water from a constant-temperature bath was circulated. A temperature of 25±0.1° C was maintained with a Wilkens–Anderson "lo-temp" constant-temperature bath. The vessel was fitted with a loose plastic cover, through which holes were drilled to accommodate a 10-ml microburet, the two electrodes, two nitrogen inlet tubes, a thermometer, and a glass rod for removing drops of liquid from the buret tip. During the titration, nitrogen gas was bubbled both through the solution and passed over it; in order to minimize evaporation losses, the nitrogen was previously saturated with water vapor at 25° C. The buret and reservoir of potassium hydroxide were connected by a continuous system of glass tubing and the atmosphere above each was protected by glass towers containing "caroxite" and indicating "drierite". Magnetic stirring was used throughout the titrations.

Reagents

Nioxime, obtained from the G. Frederick Smith Chemical Co., was recrystallized from water and dried at 50° C in a vacuum oven; the dried material melted at 189° C (reported, 188–190° C (12)).

5-Methyl-1,2,3-cyclohexanetrionetrioxime was a "White Label" grade product of Eastman Kodak. It was recrystallized from water and dried at 50° C in a vacuum oven; this material decomposed at 171–172° C on melting (reported, 170° C (7)) and a titration showed the reagent to be 99.1% pure on the basis of acid assay.

Dimethylglyoxime was "White Label" grade Eastman Kodak reagent. It was recrystallized from an alcohol–water mixture, dried in a vacuum oven at 50° C, and had a melting point of 239° C.

Each of these reagents was dissolved in redistilled water and titrated with 0.1 *N* potassium hydroxide, both in water alone and in solutions containing a known amount of perchloric acid. Titration curves in the presence of perchloric acid are shown in Fig. 5.

The titration curves show that the trioxime is a much stronger acid than the other two oximes; two end points are obtained corresponding to the neutralization of the perchloric acid and of one of the oxime groups. Dimethylglyoxime and nioxime are both extremely

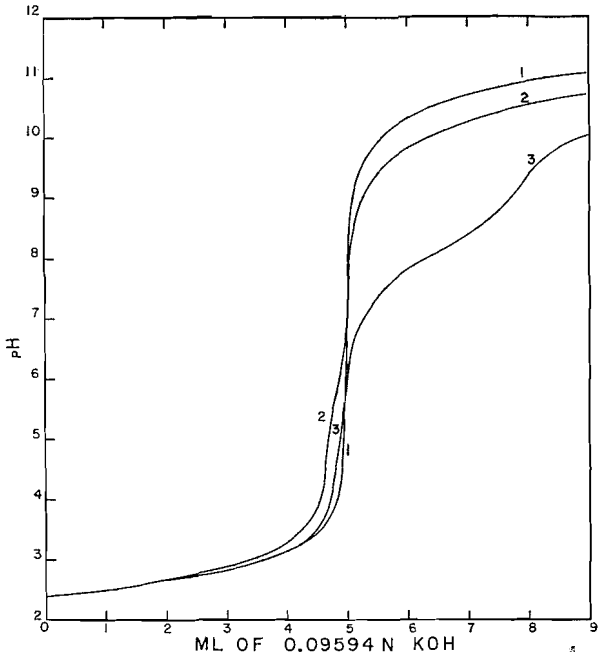

FIG. 5. Titration curves of 2.86×10^{-4} mole of reagent in presence of 50.0 ml of 9.81×10^{-3} N perchloric acid: 1, dimethylglyoxime; 2, nioxime; 3, trioxime.

weak acids and no break occurs in their titration curves after the perchloric acid end point. The titration curve of nioxime (Fig. 5, curve 2) shows one major difference from those of the other oximes—a break occurs before all the perchloric acid has been titrated. The end point cannot be correlated with any common multiple of the quantity of reagent used and it is followed by a second break corresponding to the complete neutralization of perchloric acid. Such an end point must be due to the nature of the reagent itself and not to any basic impurity; repeated recrystallization of reagent had no effect on the end points and the sharp melting point (in agreement with that reported in the literature) also suggests that the reagent is of high purity. The first end point might be due to a protonated species but there is little supporting evidence for this.

Dissociation constants of the three oximes were determined from equations derived for "non-overlapping" and "overlapping" dissociation constants. Data used for the calculations were taken from the half-neutralization portion of the titration curves. For dimethylglyoxime and nioxime, because of the close proximity of their values, graphical determinations of the dissociation constants were necessary. The equilibria involved are:

$$H_2R \rightleftarrows H^+ + HR^-, K_1 = \frac{(H^+)(HR^-)}{(H_2R)}$$

$$HR^- \rightleftarrows H^+ + R^=, K_2 = \frac{(H^+)(R^=)}{(HR^-)},$$

where H_2R represents the oxime under consideration, and parentheses denote molar concentrations. From these equilibria, together with equations for material and charge balance, it can be shown that:

$$\frac{(H^+)+(K^+)-(OH^-)}{T_{H_2R}} = \frac{K_1[(H^+)+2K_2]}{(H^+)^2+(H^+)K_1+K_1K_2},$$

where T_{H_2R} is the total concentration of the oxime.

If

$$\frac{(H^+)+(K^+)-(OH^-)}{T_{H_2R}} = S,$$

then

$$\frac{(H^+)^2S}{(S-2)}+(H^+)K_1\frac{(S-1)}{(S-2)}+K_1K_2 = 0$$

and a plot of $[(H^+)^2S]/(S-2)$ against $(H^+).[(S-1)/(S-2)]$ gives a straight line with a slope equal to K_1 and intercept equal to K_1K_2. Results are shown in Fig. 6.

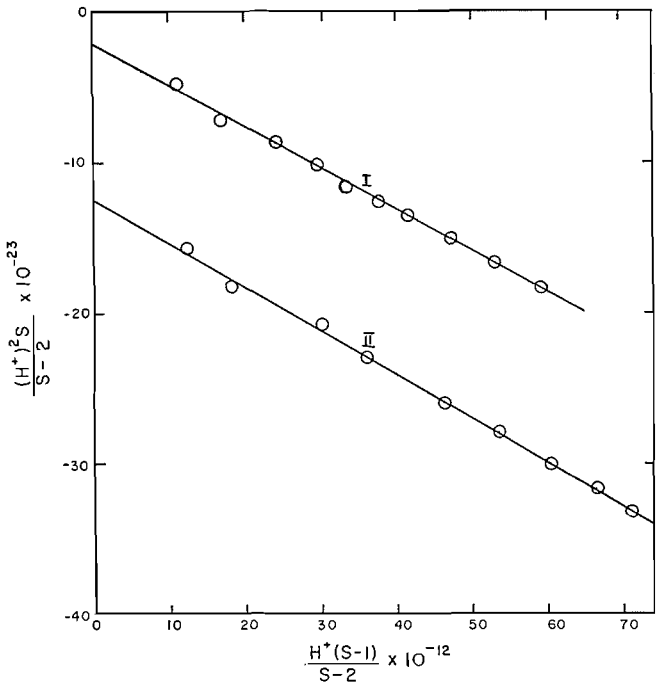

FIG. 6. Graphical determination of dissociation constants: I, dimethylglyoxime; II, nioxime.

The trioxime is a sufficiently strong acid to enable the direct calculation of pK_1 and pK_2, assuming no overlapping of these constants but, in its third ionization, it is too weak an acid in water to permit satisfactory calculations of pK_3 from the potentiometric curves. The results are given in Table II; these are not corrected with respect to activity coefficients of the various species and are from titrations on solutions containing reagent alone.

TABLE II

Acid dissociation constants of oximes, in water, at 25° C

Oxime	pK_1	pK_2
Dimethylglyoxime	10.60	11.85
Nioxime	10.68	11.92
5-Methyl-1,2,3,-cyclohexanetrionetrioxime	8.16	11.30

Metal Complexes

In these titrations different mole ratios of reagent and metal perchlorate solutions were mixed (varying from 4:1 to 1:1) and the liberated hydrogen ion titrated with 0.1 *N* potassium hydroxide; in each instance a known amount of perchloric acid was also present. A plot of the number of moles of hydrogen ion released for each mole of metal ion present should be indicative of the stoichiometry of the chelates; titration curves for each oxime in the presence of metal ions are shown in Figs. 7 and 8.

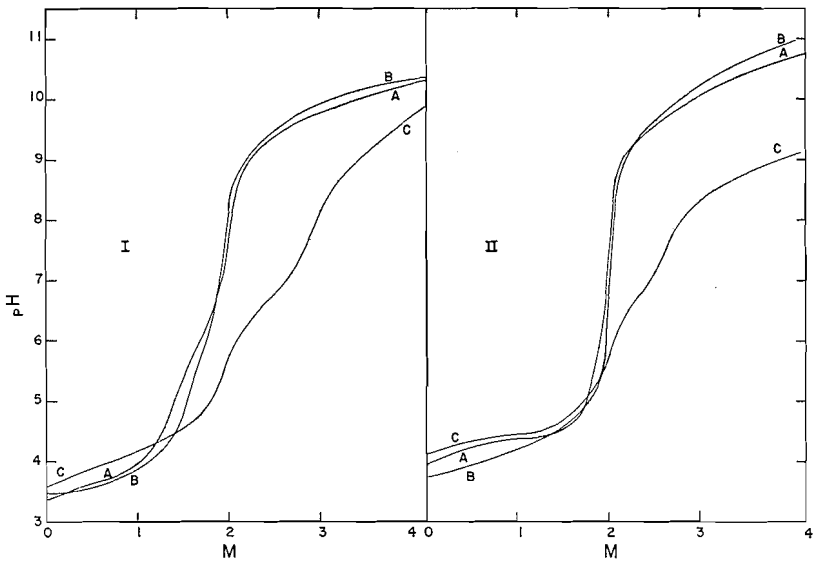

FIG. 7. Plot of moles of base used per mole of metal ion: I, nioxime; II, dimethylglyoxime. Curves A, B, and C are for nickel (3.28×10^{-5} mole), copper (4.06×10^{-5} mole), and cobalt (3.68×10^{-5} mole) respectively at a reagent-to-metal mole ratio of 3:1.

With nickel II, the titration curves for the three oximes were similar, and trioxime formed the familiar red precipitate; the break in the titration curves occurs at a proton-to-metal mole ratio of 2:1. With copper II, all oximes formed yellowish-brown complexes; the titration curves again are similar and show the formation of a 2:1 copper complex. These results suggest that the trioxime is similar, in its behavior with nickel and copper, to the other dioximes.

The reactions with cobalt II, however, appeared to be quite complex and differed with the reagent used. For the trioxime, at a mole ratio of reagent to cobalt of 3:1 or higher, 3 moles of proton were liberated; the solution was colored yellow initially and this color intensified to an orange as the titration progressed. In order to give a more complete

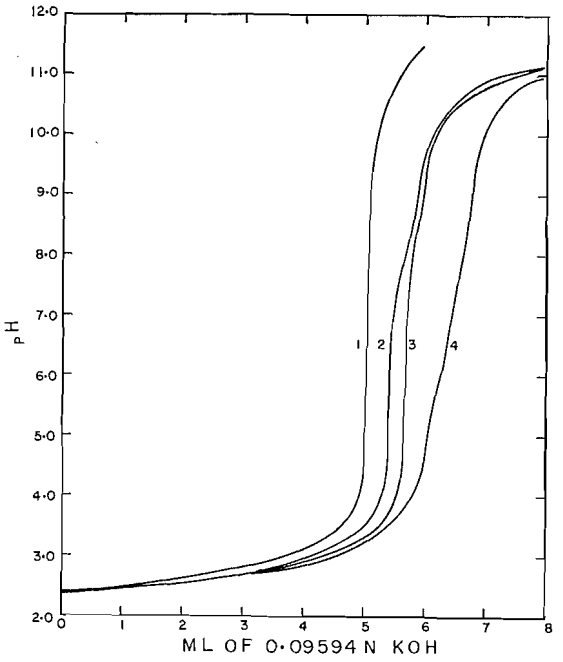

FIG. 8. Titration curves of metal chelates: 1, 50.0 ml of 9.811×10^{-4} *N* perchloric acid; 2, perchloric acid, 2.032×10^{-5} mole copper perchlorate, and 6.096×10^{-5} mole trioxime; 3, perchloric acid, 3.279×10^{-5} mole nickel perchlorate, and 9.837×10^{-5} mole trioxime; 4, perchloric acid, 3.359×10^{-5} mole cobaltous perchlorate, and 10.08×10^{-5} mole trioxime.

representation of the reactions of this reagent, Fig. 8 reproduces the titration curves obtained; two end points are evident corresponding to the liberation of 3 moles of hydrogen ion and a further 2 moles of proton. At a reagent-to-cobalt ratio of 2:1, using the same amount of cobalt, a precipitate occurred at pH 3; it subsequently dissolved between pH 6 and 7, causing a distinct drop in pH, and the number of moles of hydrogen ion ultimately released for each mole of cobalt was 2.70 ± 0.05.

Nioxime also shows the release of 3 moles of proton at ratios of reagent to cobalt of 3:1 or higher (Fig. 7A); no color was present in solution until after the addition of the first few drops of potassium hydroxide, when the solution developed a brownish-yellow color. Nioxime formed no precipitate when it was present in a 2:1 ratio with cobalt II but, as with trioxime, the number of moles in hydrogen ion released was 2.70 ± 0.05.

Dimethylglyoxime differed in its reactions with cobalt (Fig. 7B). A yellow color was formed at all ratios and the titration curve shows two end points corresponding to the liberation of 2 and 2.70 ± 0.05 moles of hydrogen ion.

Formation constants of the copper II complexes of the three oximes were calculated by the Bjerrum method (11). A plot of the formation function $\bar{n}$ (the concentration of bound ligand divided by the total concentration of metal present) against pHR^- (the negative logarithm of the equilibrium concentration of the ligand HR^-) enables the values of the logarithm of the formation constants, $\log K_1$ and $\log K_2$, to be read directly from the curve at $\bar{n}$ values of 0.5 and 1.5 respectively; the $\log K_{av}$ is read at $\bar{n}$ equal to 1.0. These values were read directly from the curves shown in Fig. 9; for nioxime, however, the $\log K_2$ value had to be calculated from the relationship $\log K_1+\log K_2 = 2\log K_{av}$.

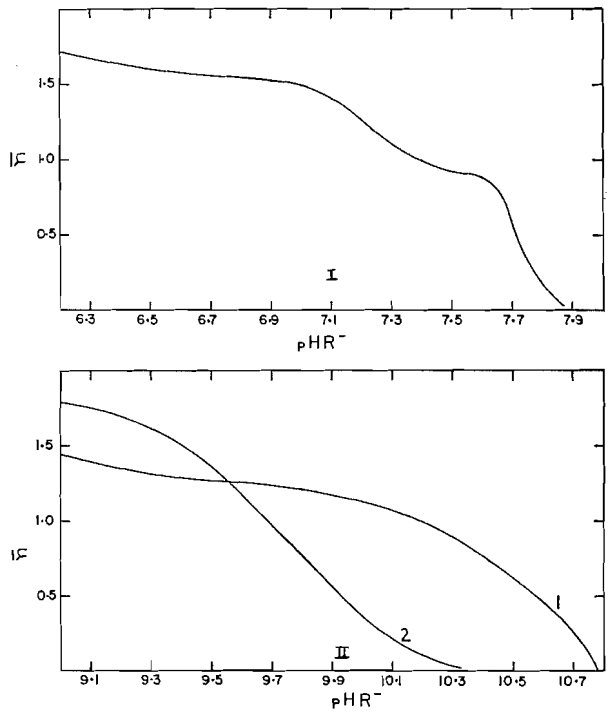

FIG. 9. Formation curves with copper at reagent-to-metal mole ratio of 3:1: I, trioxime; II, nioxime (1) and dimethylglyoxime (2).

Table III shows values calculated from titrations on solutions containing 50 ml or 0.009811 N perchloric acid, 4 ml of 0.01016 M cupric perchlorate, and 1.167×10^{-4} mole

TABLE III

Formation constants of copper II complexes at 25° C

Oxime	2 log K_{av}	log K_1	log K_2
Dimethylglyoxime	19.3_4	9.9_2	9.4_0
Nioxime	20.3_8	10.5_6	9.8_2
5-Methyl-1,2,3-cyclohexanetrionetrioxime	14.7_2	7.7_6	6.9_8

of reagent in a total initial volume of 110 ml (i.e. a reagent-to-copper mole ratio of approximately 3:1). Similar constants for the complexes with nickel were not evaluated because of their low solubility; the value of the solubility product would have been necessary for these calculations. The formation constants of the cobalt complexes were not calculated because of the uncertainty as to the actual species present.

DISCUSSION

The reactions of 5-methyl-1,2,3-cyclohexanetrionetrioxime with copper (II) and nickel (II), as contrasted with similar reactions between nioxime and dimethylglyoxime, indicate that the trioxime reacts in an analogous manner with these two metal ions. It is thus suggested that in the trioxime two oxime functional groups are anti, and thus reactive

toward these metal ions, and the third such group is syn to these two anti-oxime functionalities.

A comparison of the overall formation constants (2 log K_{av}) of the copper II reactions with these three oximes clearly reveals that the copper II – trioxime complex is much weaker than the corresponding complexes formed with nioxime and dimethylglyoxime. This comparatively low value for 2 log K_{av} may be partially attributed to the fact that the trioxime is the strongest acid of the three oximes; however, there is no linear correlation between either the acid dissociation constants of the ligands or the sum of these constants versus 2 log K_{av} for the copper II complexes. This is suggestive that some other factor in addition to ligand basicity is involved in the comparison of the stability of these copper II complexes.

In contrasting the reactions of the three oximes with cobalt II, two significant differences are apparent in the case of the trioxime. First, evidence for a 3:1 trioxime – cobalt II complex has been presented (Fig. 3), and a precipitate is formed on the addition of lead II, nickel II, or more cobalt II to solutions containing molar ratio of trioxime to cobalt II of 3:1 or greater. The corresponding complex with nioxime does not show these reactions; consequently, it is probable that the formation of precipitates by the 3:1 trioxime – cobalt II complex with these dipositive metal ions involves coordination of the additional metal ions with the third oxime group of the reagent.

Second, the presence of a second end point corresponding to the liberation of 5 moles of hydrogen ion per mole of cobalt II added initially (Fig. 8), is characteristic of the trioxime only, and is suggested to be due to an increase in the acidity of the third oxime group.

5-Methyl-1,2,3-cyclohexanetrionetrioxime does not appear, from studies to date, to be a satisfactory reagent for direct gravimetric determinations. Nickel, copper, and cobalt complexes that were precipitated from solution, washed with cold water, dried at 100° C, and then analyzed gave a metal content considerably *higher* than that anticipated from theoretical values and were inconsistent; no decomposition of the complexes was evident and preparation under nitrogen, followed by drying in a vacuum oven, failed to yield more coherent results. These results may be due to the formation of mixtures or to the third oxime group undergoing some reaction in solution that is preventing isolation of pure chelates by this method; this, and a more thorough study of the cobalt complexes of these oximes, are presently under investigation.

INFLUENCE OF STERIC AND POLAR EFFECTS ON BASE STRENGTHS OF BICYCLIC GUANIDINES[1]

A. F. McKay and M.-E. Kreling
L. G. Ryan Research Laboratories of Monsanto Canada Limited, Lasalle, Que.

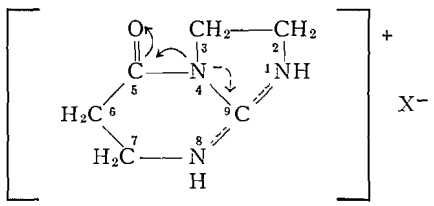
Received March 1, 1962

ABSTRACT

The pK_a and $E_{1/2}$ values of a number of bicyclic guanidines and their keto derivatives were determined. The influence of steric and polar effects on their base strengths is discussed.

INTRODUCTION

Recently it was observed (1) that the guanidine nucleus in 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine could not be converted into a nitroguanidine by the strong nitration medium of absolute nitric acid – acetic anhydride – ammonium chloride, whereas 2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine is readily nitrated to 1-nitro-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*) pyrimidine (2) by this medium. The failure of the guanidine structure in 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*) pyrimidine salt (I) to nitrate was explained (1) by the electron displacements within structure I. There are two opposing electron-attractive forces operating on N_4; one force



I

tends to displace the electrons towards participation in the guanidinium ion while the other force tends to displace electrons in the direction of the curved solid arrows. These opposing forces were considered to give the resonance ion structure more of an amidinium ion character than a guanidinium ion character. This would then explain the failure of 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine to nitrate.

Since the high base strength of guanidine is dependent upon the resonance stabilization of the guanidinium ion (3), it should be possible to measure the quantitative importance of the polar effect indicated by the solid curved arrow in I on the resonance stabilization of the guanidium ion by comparing the pK_a values of bicyclic guanidines with the pK_a values of their keto derivatives. The present study shows that an electronegative substituent adjacent to the guanidine nucleus in bicyclic guanidines has a very pronounced effect on their base strengths.

DISCUSSION

The pK_a values given in Table I show that the base strengths of the 5–6 (II), 6–6 (III), and 5–7 (IV) membered bicyclic guanidines are equivalent. In the 2,3,5,6-tetrahydro-1(H)-imidazo(1,2-*a*)imidazolium ion (V) containing two 5-membered fused rings considerable strain already exists in the bonding of the ring structure. This strain would be

[1]*Contribution No. 35.*

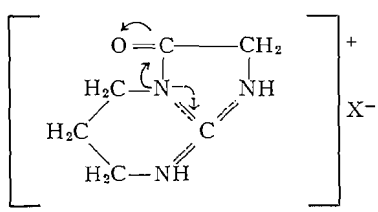
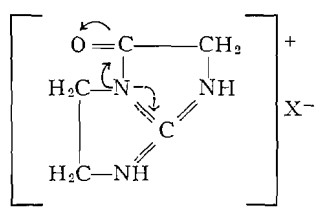
V

increased further by the shortening effect of resonance on the three C- N bonds. Thus the full resonance stabilization of the guanidinium ion cannot be realized in structure V and the base strength is lowered to a pK_a value of 10.60. In the 5–6-fused ring structure II, this strain is relieved by the puckering of the 6-membered ring.

A comparison of the pK_a values of the bicyclic guanidines II, IV, and V with their corresponding keto derivatives I, VI, and VII shows that the effects of the electron displacements indicated by the solid arrows on the resonance stabilization of the guanidinium ion are considerable. The base strengths of the keto derivatives I and VI are 3 pK_a



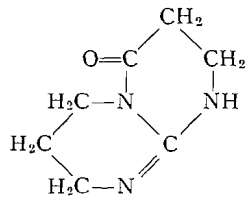
VI



VII

units less than the corresponding parent bicyclic system II. As anticipated, the ΔpK_a value (3.78) is much greater between the 2,3,5,6-tetrahydro-1(H)-imidazo(1,2-*a*)imidazolium ion (V) and its keto derivative (VII). As seen above, the conformation of this almost planar bicyclic system offers some steric inhibition to the resonance stabilization of the guanidinium ion and thus it favors the electron displacement depicted by the solid arrows.

Since it was not possible to determine the pK_a value for 4-keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-*a*)pyrimidine (4) (VIII) in aqueous solutions, all of the compounds,



VIII

with the exception of 1,2,5,6,7,8-hexahydro-3(H)-imidazo(1,2-*a*)-1,3-diazepine,[2] were titrated with standard perchloric acid in glacial acetic acid solutions. The $E_{1/2}$ values for these determinations are given in Table I. No differences were observed in the base strengths of 2,3,5,6-tetrahydro-1(H)-imidazo(1,2-*a*)imidazoline and the other bicyclic guanidines II and III due to the levelling effect of the solvent medium. However, the pronounced effect of the adjacent keto groups in lowering the base strengths of the bicyclic guanidines is still apparent.

The rates of hydrolyses of the keto derivatives of the bicyclic guanidines were investigated in order to estimate the effect of their hydrolyses on the accuracy of the pK_a determinations. These studies are reported in the experimental section. It was found that 4-keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-*a*)pyrimidine would be almost completely hydrolyzed in aqueous solution within the 3 minutes required to run the potentiometric titration. The errors in the pK_a values due to hydrolysis of 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)pyrimidine and 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine are less than 5% while the error due to the hydrolysis of 3-keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole is less than 2%.

EXPERIMENTAL

Bicyclic Guanidines

2,3,5,6-Tetrahydro-1(H)-imidazo(1,2-*a*)imidazole (5), 3-keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole (4), 2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine (2), 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)pyrimidine (4), 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine (1), 2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-*a*)pyrimidine (2), 4-keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-*a*)pyrimidine (4), and 1,2,5,6,7,8-hexahydro-3(H)-imidazo(1,2-*a*)-1,3-diazepine (2) were prepared as previously described. Only highly purified, freshly sublimed samples were used for rate studies and pK_a determinations.

Kinetic Measurements

Weighed samples (0.005 mole) of the keto derivatives of the bicyclic guanidines were placed in volumetric flasks (10 ml) and water at 30.5° was added to the graduation mark to give 10 ml of 0.5 *M* solutions. The flask containing the solution was placed in a constant-temperature (30.5°) bath and samples (1 ml) were withdrawn at timed intervals. Aqueous picric acid solution (11 ml representing approximately 30% excess picric acid) was added to the withdrawn aliquots and after 2 minutes the precipitated picrate was removed by filtration using weighed micro sintered-glass funnels. The picrate was washed twice with 1 ml of water,

[2]*This compound was named incorrectly as* Δ^9*-1,4,9-triazabicyclo(5.3.0)decene in reference 2.*

dried, and weighed. Each lot of picrate was checked for purity by a melting-point determination. The rate of formation of 2-carboxymethylamino-Δ^2-tetrahydropyrimidine from 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)pyrimidine under the above conditions is kinetically first order with mean deviations within 10%. These deviations were due to the variations in efficiency of precipitation of bicyclic picrate and in some cases to coprecipitation of the picrate of the hydrolyses product.

Time, sec $\times 10^{-2}$	11.6	17.6	29.6	44.5	53.7
Reaction %	42.2	53.9	72.4	89.7	99.2
10^4K, sec^{-1}	4.72	4.39	4.31	3.95	4.22

Under the above conditions the half-life for 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)pyrimidine was calculated to be approximately 27.6 minutes while the half-life for 3-keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole was calculated to be approximately 2 hours and 23 minutes.

It was not possible to calculate the rates of hydrolysis of 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo-(1,2-*a*)pyrimidine and 4-keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-*a*)pyrimidine even with this small degree of accuracy because of the coprecipitation of the hydrolysis product with the bicyclic guanidine in the first case and the very rapid hydrolysis of the latter bicyclic guanidine. The hydrolysis of 4-keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimidino(1,2-*a*)pyrimidine was practically complete within 5 minutes. These studies showed that the relative susceptibility of the keto substituted bicyclic guanidines to hydrolysis falls in the following order: 4-keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-*a*)pyrimidine (VIII) $\gg$ 5-keto-2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine (I) > 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo-(1,2-*a*)pyrimidine (VI) $\gg$ 3-keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole (VII).

Potentiometric Titrations

Aqueous solutions (0.01 moles) of the freshly sublimed bicyclic guanidines were prepared with carbon dioxide free water. These magnetically stirred solutions at a constant temperature of 30.5° were titrated with 0.1 *N* hydrochloric acid using a Beckman Model G pH meter equipped with glass electrode (Beckman No. 1190-80) and sealed calomel electrode (Fisher No. 11-505-80).

The pK_a values for 2,3,5,6-tetrahydro-1(H)-imidazo(1,2-*a*)imidazole and 2,3,6,7-tetrahydro-1(H),5(H)-imidazo(1,2-*a*)pyrimidine also were determined by potentiometric titration of their purified hydrochloride salts with 0.1 *N* sodium hydroxide solution. The pK_a values obtained in this manner were identical (within experimental error) with those determined from potentiometric titration of the corresponding free bases.

The potentiometric titrations of the aqueous bicyclic guanidines with 0.1 *N* hydrochloric acid were also conducted with an automatic potentiometer (Potentiograph E 336, Metrohm Ltd., Herisau, Switzerland, with combined glass/calomel electrode). The rate of titration was approximately 1 ml/min. The results with the automatic potentiometer were in agreement with the Beckman Model G pH meter.

The automatic potentiometer was used to titrate solutions of the bicyclic guanidines in glacial acetic acid with 0.1009 *N* perchloric acid in glacial acetic acid. The standard perchloric acid solution was prepared by the method of Fritz (6). The pK_a values determined in aqueous solution and the $E_{1/2}$ mv values determined in glacial acetic acid are given in Table I. The apparent pK_a values were determined from the readings at the half-neutralization points of the aqueous solutions of the bicyclic guanidines.

VIBRATIONALLY INDUCED PERTURBATIONS IN MOLECULAR ELECTRON DISTRIBUTIONS

RICHARD F. W. BADER
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received January 17, 1962

ABSTRACT

It is demonstrated that second-order perturbation theory is useful in determining the manner in which the electron density present in a molecule is changed during a nuclear vibration. Furthermore, it is shown that one nuclear motion will lead to a particularly favorable electronic distortion such that this motion is energetically favored over the other possible motions of the molecule. This allows one to employ the theory to predict the symmetry of the reaction coordinate in both unimolecular and bimolecular reactions. The chemical implications of the electron density changes are discussed.

A reaction has associated with it a reaction coordinate, and any detailed analysis of a reaction mechanism requires a knowledge of how the electron distribution changes for various modes of motion of the system. For example, in a unimolecular decomposition there are a number of conceivable (and actual) ways in which a molecule may dissociate, depending on which vibrational mode corresponds to the most energetically favorable reaction coordinate. In the present approach we consider what effects the possible molecular motions have on the electron distribution. When the nuclei are displaced from their equilibrium positions the electron distribution relaxes in such a fashion as to follow the motion of the nuclei and thus leads to a smaller increase in energy than would be obtained if the electron distribution was static. By determining which nuclear motion allows for the most favorable relaxation of the electron density, we in effect determine the reaction coordinate.

We may treat the nuclear displacements as perturbations and in this way determine what effect these perturbations have on the electronic energy and wave function of the molecule in question. Making use of second-order perturbation theory we find that the energy of the distorted molecular configuration for extension in the i'th normal coordinate, Q_i, is

$$E(Q_i) = E_0 + \frac{1}{2}V_{00}^{ii} \cdot Q_i^2 + \sum_k{}' \frac{V_{0k}^{i} \cdot V_{k0}^{i}}{E_0 - E_k} Q_i^2. \qquad [1]$$

We employed this equation previously and applied it to an interpretation of potential interaction constants (1). We limit our present discussion to an interpretation of the terms appearing in the expression. E_0 is the energy of the undistorted configuration. The perturbations are given by the expressions

$$V_{00}^{ii} = \int \rho_{00} \frac{\partial^2 \phi(\mathbf{r},\mathbf{R})}{\partial Q_i^2} d\mathbf{r}$$

$$V_{0k}^{i} = \int \rho_{0k} \frac{\partial \phi(\mathbf{r})}{\partial Q_i} d\mathbf{r}$$

in which $\phi(\mathbf{r},\mathbf{R})$ is the total potential of the nuclei and $\phi(\mathbf{r})$ is the potential interaction of the nuclei with the i'th electron. We may employ the electron density functions ρ_{00} and ρ_{0k} in the above integrals, as neither $\phi(\mathbf{r},\mathbf{R})$ nor $\phi(\mathbf{r})$ contains terms which involve the

coordinates of more than a single electron. This fact makes it possible to give simple interpretations to $V_{00}{}^{ii}$ and $V_{0k}{}^{i}$. The quantity ρ_{00} is the electron density for the undistorted molecule. Thus the term $\frac{1}{2}V_{00}{}^{ii}\cdot Q_i{}^2$ determines the increase in the energy of the molecule when the nuclei are displaced from their equilibrium positions and the electron distribution is held fixed.

It is the term $V_{0k}{}^{i}$ which allows for a relaxation of the electron distribution and it is this term with which we shall be mainly concerned. The relaxation is brought about by mixing in with the ground state $|0\rangle$ the wave function for an excited state $|k\rangle$. The density expression ρ_{0k} appearing in $V_{0k}{}^{i}$ is thus termed the transition density.[1] *It is a measure of the amount of charge which is transferred within the molecule when the nuclei are displaced from their equilibrium positions.* The expressions ρ_{0k} are the corrections to the electron density of the undistorted molecule. The first-order correction to the wave function due to the mixing effect is

$$|0\rangle' = |0\rangle + Q_i \sum_k{}' [V_{0k}{}^{i}/(E_0 - E_k)]|k\rangle, \qquad [2]$$

and thus the transition density will make a contribution to the electron density found in the distorted molecule,

$$\rho_{0'0'} = \rho_{00} + 2Q_i \sum_k{}' [V_{0k}{}^{i}/(E_0 - E_k)]\rho_{0k} \ldots . \qquad [3]$$

By this mechanism we may explain how distortions of the nuclear framework introduce symmetric or antisymmetric components into the original charge distribution of the molecule.

The transition density does not represent any absolute amount of charge (its integral over all space is equal to zero) but instead gives a three-dimensional representation of the movements of charge density within the molecule. In the molecular orbital terminalogy, ρ_{0k} will be given simply as

$$\rho_{0k} = c\phi_i{}^{*}\phi_j,$$

where $\phi_i{}^{*}$ is the orbital which was occupied in the state $|0\rangle$, ϕ_j is the orbital occupied in its stead in the state $|k\rangle$, and c is a numerical constant. The forms of the ρ_{0k} are thus simple to determine and thus so is the magnitude and direction of the charge shift.

With the above interpretation of ρ_{0k} we may now interpret the integral $V_{0k}{}^{i}$ as the *force* exerted on the nuclei (those which are displaced in the mode Q_i) by the displaced charge density. Differentiation of $\phi(\mathbf{r})$ with respect to Q_i is mathematically equivalent to placing a point dipole, orientated in the direction of the nuclear displacement, on each nucleus which moves in the mode Q_i. Thus, alternatively, $V_{0k}{}^{i}$ may be interpreted as the interaction of the point dipoles centered on the nuclei with the displaced charge distribution.

The manner in which equation [1] may be applied is as follows. It is evident from the denominator in the expression for E that the lowering in energy due to the relaxation effect will be greatest for that mode of vibration which allows for an interaction with the lowest of the excited states. Furthermore, the transition force $V_{0k}{}^{i}$ will be different from zero only if the transition density ρ_{0k} and Q_i have identical symmetries. We then assume that

[1] $\rho_{0k} = \langle 0|-e\{\sum_i \delta(\mathbf{r}-\mathbf{r}_i)\}|k\rangle$ *(see reference 1 or 4).*

the most favored motion, i.e., the one which leads to the smallest increase in potential energy, will be that one whose symmetry allows for an interaction with the lowest of the excited states.[2] The principal change brought about in the electron distribution for any of the nuclear motions is assumed to be determined by the admixture of the lowest excited state of the proper symmetry, an assumption founded on the presence of the term $E_0 - E_k$ in the denominator of the coefficient in equation [3]. Thus we are now in a position to predict the major changes in the electron density accompanying any nuclear displacement, and, in addition, pick out that mode which allows for the greatest relaxation of the electron distribution. Using this method with the same assumptions, we have previously been able to correctly predict the signs of potential interaction constants for a large number of molecules (1). Since the successful prediction of the sign of an interaction constant by this method is determined by the proper selection of the mode which gives the greatest relaxation in the electron distribution, we base our confidence in the present approach on these previous results.

We now show how the information available from an application of equation [1] is of use in the understanding of the chemical properties of molecules, by providing us with information regarding the possible reaction coordinate and the accompanying changes in the electron density during the reaction.

Unimolecular Decompositions

The most obvious application of equation [1] is to the unimolecular decomposition of a molecule. We are interested in determining which relative motion of the nuclei corresponds to the reaction coordinate. We shall consider some triatomic systems first.

We have previously shown (1) that the transition density arising from the admixture of the lowest excited state of the triatomic molecules which possess 16 valence electrons (e.g., CO_2, CS_2, $HgCl_2$) is of Σ_u^+ symmetry,

$$\ldots (\pi_u)^4(\pi_g)^4;\ {}^1\Sigma_g^+ \rightarrow \ldots (\pi_u)^4(\pi_g)^3(\bar{\pi}_u);\ {}^1\Sigma_u^+$$

(the other states resulting from this excited configuration are of irrelevant symmetries ${}^1\Delta_u$ and ${}^1\Sigma_u^-$). The vibration which brings about the mixing in of this lowest excited state is the antisymmetric stretching vibration which is, therefore, predicted to be the energetically favored vibration and the reaction coordinate. The present method then correctly predicts that the unimolecular decomposition of these molecules will proceed so as to produce an atom and a diatomic molecule. The transition density is given as

$$\rho_{gu} = \pi_g^* \bar{\pi}_u.$$

We can employ this information to obtain a qualitative picture of how the electron density is changed during a Σ_u^+ vibration. From the form of the transition density (shown in Fig. 1) we see that charge is displaced from one end atom to the other and removed (in the opposite sense) from one binding region and concentrated in the other. Such a charge migration clearly weakens one bond and strengthens the other. The magnitude of this asymmetric contribution to the charge density increases as the extension in the asymmetric coordinate is increased.

It is possible, of course, that the symmetry of the transition density will change as the molecular dimensions are appreciably altered due to a crossing of orbital energies and

[2]*See the Appendix for further justification of this procedure.*

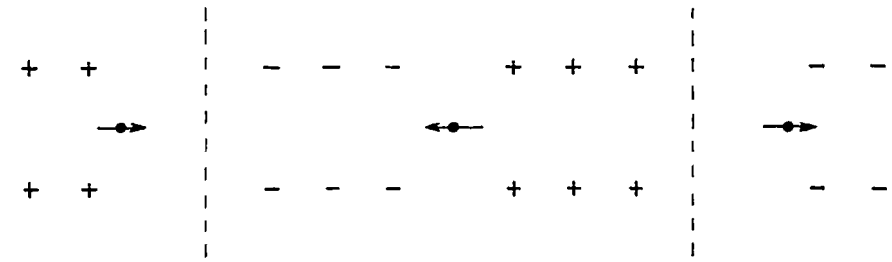

FIG. 1. Schematic representation of ρ_{gu} and its interaction with the antisymmetric stretching vibration. (The negative signs indicate an increase in the electron density, the positive signs a decrease.)

hence to the appearance of a new low-lying excited state. For molecules which contain relatively few atoms, the order of the orbital energies can be predicted with some certainty even for distorted configurations and thus this possibility may be allowed for. For example, in the above-mentioned triatomic molecules, the symmetry of the transition density remains unchanged even for appreciable extensions of the asymmetric coordinate. In more complicated molecules, the order of the orbitals, especially for distorted configurations, is not always predictable with great certainty and the method then loses its usefulness.

As another simple example of the application of the present method to unimolecular reactions we consider the decomposition of the ozone molecule. The method should in this case correctly predict the favored asymmetrical dissociation into an oxygen molecule and an oxygen atom. The ozone molecule contains 18 valence electrons and is therefore bent and of C_{2v} symmetry. Mulliken has given the molecular orbital description of this molecule (3), and we have previously discussed the symmetries of the relevant transition densities (1). The ground state is $^1A_1$ and the lowest excited state which gives a relevant transition density is of B_1 symmetry. Such a transition density favors the unsymmetrical extension of the molecule, which induces an asymmetry in the electronic charge distribution corresponding to a weakening of one of the bonds and a strengthening of the other.

Consider next the unimolecular decomposition of the dialkyl mercury compounds by taking dimethyl mercury as a typical case. The electronic configuration of this molecule, in terms of molecular orbitals is

$$(a_{1g})^2(a_{2u})^2(e_g)^4(e_u)^4(a_{1g})^2(a_{2u})^2;\ ^1A_{1g}.$$

The first four of these orbitals represent the bonding between the hydrogen and carbon atoms, the last two, the bonding between the mercury atom and the carbon atoms. The lowest excited orbital of dimethyl mercury is the antibonding orbital between the carbon and mercury atoms of $\bar{a}_{1g}$ symmetry. The carbon–hydrogen antibonding orbitals are certainly of much greater energy than the $\bar{a}_{1g}$ antibonding orbital, as is the $7s$ orbital of the Hg atom. (Transitions to the $6p_\pi$ orbitals of the mercury atom give an irrelevant transition density of E_g symmetry.) The lowest excited electronic state is, therefore,

$$\ldots (a_{1g})^2(a_{2u})(\bar{a}_{1g});\ ^1A_{2u}.$$

The transition density is of A_{2u} symmetry and the reaction coordinate will be of the same symmetry, i.e., an unsymmetrical vibration of the C—Hg bonds. Since it is the mercury–carbon orbitals which are involved in determining this transition density, it will be the

electron density in the region of the mercury carbon bonds which will be most strongly affected. The transition density is given by

$$\rho_{a\bar{a}} = a_{2u}\bar{a}_{1g}$$

and will be similar in appearance to that for ρ_{gu} in Fig. 1. The theory predicts that the molecule will decompose by the rupture of one of the carbon–mercury bonds to form a methyl radical and $Hg—CH_3$.

Laidler and Steel (2) have pointed out that the high-frequency factors which are found for certain unimolecular reactions may be explained by the simultaneous rupture of more than one bond in the molecule. The azo compounds are examples of molecules which exhibit high-frequency factors in their unimolecular decompositions. Laidler and Steel (2) postulate that their decomposition is via a symmetrical stretching of both $N—CH_3$ bonds. It is of interest, therefore, to apply the present approach to these molecules and determine whether it does indeed predict a symmetrical, as opposed to an unsymmetrical, reaction coordinate.

The order of the molecular orbitals for the C—N—N—C framework is most easily determined by the construction of a correlation diagram which shows the variation in the relative energies of the orbitals as the C—N—N angle is varied. Such diagrams, together with a simple set of rules regarding the degree of hybridization have been shown by Walsh (5) to be of great value in such assignments. The order of the molecular orbitals in the linear case are easily determined. These are listed on the right of Fig. 2. The correlated orbitals for a C—N—N—C framework of C_{2h} symmetry are given on the left of

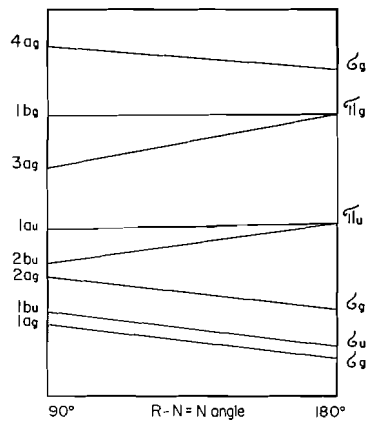

FIG. 2. A schematic representation of the correlation of molecular orbitals in the bent and linear C—N=N—C framework.

Fig. 2. The decrease of the C—N—N angle results in a splitting of the π degeneracies found in the linear case. Notice that if only 10 electrons are involved the molecule will remain linear, as a decrease in the C—N—N angle results in an overall raising of the orbital energies for reasons given by Walsh. In general, however, tetratomic molecules which possess more than 10 electrons (there are 12 in the azo compounds) will be bent due to the occupation of the $3a_{1g}$ orbital, which undergoes a drop in energy as the C—N—N angle is decreased.[3] The reason for this increased stabilization of the $3a_g$ orbital is

[3]*There are similarities and some understandable differences between our Fig. 2 and Walsh's figure for* HAAH *molecules.*

to be found in the fact that in the bent molecule this component of the π orbital takes on an increasing amount of s character. The ground-state electronic configuration of the azo compounds may be represented by

$$(1a_g)^2(1b_u)^2(2a_g)^2(2b_u)^2(1a_u)^2(3a_g)^2;\ ^1A_g.$$

The lowest excited state arises from a transition to the $1b_g$ orbital

$$\ldots (1a_u)^2(3a_g)(1b_g);\ ^1B_g,$$

which gives an irrelevant transition density of symmetry B_g, irrelevant since the C—N —N—C framework possesses no vibrational motions of B_g symmetry. The transition of next lowest energy is due to a transition to the $4\bar{a}_g$ orbital, which is strongly antibonding between the N and C atoms and bonding between the two nitrogen atoms, which gives a transition density of A_g symmetry,

$$\ldots (1a_u)^2(3a_g)(4\bar{a}_g);\ ^1A_g.$$

Therefore, the most favored motions are those of the same symmetry, and the molecule should decompose in a symmetrical fashion, giving two methyl radicals and a nitrogen molecule in one step. This mechanism is thus supported in preference to an unsymmetrical stepwise decomposition corresponding to a B_u motion and a B_u transition density. It is worth noting that as the C—N distance is increased the $3a_g$ orbital will rise in energy (ultimately becoming the same as the $1b_g$ orbital) and the $4a_g$ orbital will decrease in energy. The vibrationally induced A_g component of the electron density thus becomes more prominent as the decomposition proceeds.

Bimolecular Reactions

The transition state of a bimolecular reaction represents the configuration of maximum potential energy along the reaction coordinate, and therefore, as for a stable molecule, the energy is independent of the nuclear displacements to the first order. We may apply second-order perturbation theory to the transition-state molecule to again determine the most favored mode of decomposition. An insight into the electronic changes underlying the reaction may be obtained from a knowledge of the relevant transition density. Or, we may employ the method to test a proposed transition-state configuration. If a transition state is put forward for a reaction which possesses a favored mode of motion which does not lead to the observed products, then it must be discarded.

It is worthwhile noting that the "mixing in" of the excited state in the case of a transition-state molecule must be very pronounced, for the potential energy actually must decrease as the configuration of the transition state is distorted in such a manner as to correspond to a motion along the reaction coordinate. For this to be possible within the framework of the present theory, the following inequality must hold:

$$\frac{(V_{0k}{}^t)^2}{E_0-E_k} > \frac{1}{2}V_{00}{}^{tt}.$$

Thus, in general, we should expect to find that at least one excited state is relatively low lying for transition-state molecules in order that the above requirement may be met. This is in general true, and it is the nature of this first excited state which determines the course of the reaction.

As a simple first example of the application of the present method to a bimolecular reaction consider the complex H—H—H obtained in the hydrogen atom–molecule reaction. The electronic configuration of the complex is $(\sigma_g)^2(\sigma_u)$; $^2\Sigma_u^+$. The first excited state is obtained from the configuration $(\sigma_g)^2(\bar{\sigma}_g)$; $^2\Sigma_g^+$. The transition density is of Σ_u^+ symmetry and it follows that such a complex should decompose in an unsymmetrical fashion to give a hydrogen molecule and atom. Thus, due to the fact that the first excited state is of Σ_g^+ symmetry, an asymmetrical distortion of the charge density is the one most easily accomplished, and thus the asymmetric motion of the nuclei is favored. Such a motion leads to a concentration of charge in one bond and to its depletion in the other and to the observed formation of a hydrogen molecule and a hydrogen atom.

The transition state proposed for an S_N2 displacement on a substituted carbon atom is one in which the attacking nucleophile, the carbon atom, and the leaving group lie on a line. We shall use this case as a simple example of how, in general, a low-lying excited state arises in the formation of a transition-state molecule. In Fig. 3 we show the orbitals

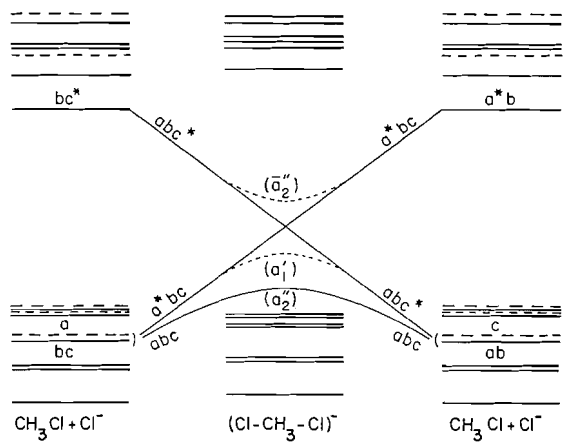

FIG. 3. An orbital correlation diagram between reactants, transition state, and products for $CH_3Cl + Cl^-$. The dashed lines in the right and left columns represent the Cl^- ion orbitals, the solid lines the CH_3Cl orbitals. The $\bar{a}_2''$ orbital and the ones lying above it are unoccupied.

of the reactants, of the transition state, and of the products. The p_z orbital on the entering chloride ion we label *a*, the original C—Cl bonding and antibonding orbitals in the reactant we label *bc* and *bc**, the asterisk denoting antibonding. The approach of the chloride ion to CH_3Cl will result in the formation of three new orbitals, *abc*, *a***bc*, and *abc**; the remaining orbitals in CH_3Cl and on the chloride ion are affected to a much smaller extent. The orbital *abc* will be the most stable of the three. The orbital *a***bc* will start out low in energy (degenerate with *abc* at large separations) and rise in energy as the reaction proceeds. The orbital *abc** will be high in energy at the start of the reaction (corresponding to an excited orbital of C—Cl for large separations) and will fall in energy, as the reaction progresses, to a value below that of *a***bc*. In effect, *a***bc* and *abc** interchange their roles during the reaction. In a first, very crude approximation, we might expect *a***bc* and *abc** to be degenerate in the transition-state molecule. This of course does not occur and the two orbital energies are instead "pushed apart" in the region where the crude approximation would have them intersect. The effect of the formation of the transition state is thus to lower the energy of what was initially an antibonding orbital

between carbon and chlorine and form a new occupied orbital which, as we have seen, will lie relatively close in energy to the vacant, lowered antibonding orbital. The new occupied orbital is high in energy because the bonds it describes are long and weak and the antibonding character of the vacant orbital is lessened for the same reason. The remaining excited orbitals of the complex (e.g., the carbon–hydrogen antibonding orbitals) are, to a first approximation, not affected by these changes in bonding and thus do not undergo any significant lowering in energy. The result is, therefore, the formation of a new low-lying excited state involving the occupation of an antibonding orbital which has been stabilized to a point well below the other excited orbitals of the system.

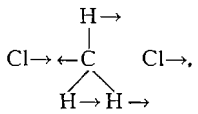
In the transition state (D_{3h} symmetry) the orbitals will be of symmetries a_2'' ($p_{z\mathrm{Cl}} + p_{z\mathrm{C}} + p_{z\mathrm{Cl}}'$, bonding), a_1' ($p_{z\mathrm{Cl}} - p_{z\mathrm{Cl}}'$, bonding), and $\bar{a}_2''$ ($p_{z\mathrm{Cl}} - p_{z\mathrm{C}} + p_{z\mathrm{Cl}}'$), the bar over the last symbol signifying its antibonding character. The electronic configuration of the transition state molecule will be

$$\ldots (a_2'')^2 (a_1')^2; {}^1A_1'.$$

It follows that since the C—Cl bonds are the weakest (and longest) in the molecule, the lowest lying of the antibonding orbitals found in the transition state will be that associated with the antibonding between the carbon atom and the halogens, $\bar{a}_2''$. The lowest excited state is

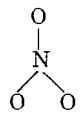
$$\ldots (a_2'')^2 (a_1')(\bar{a}_2''); {}^1A_2''$$

and the transition density is of symmetry A_2''. Therefore, the most easily imposed electronic distortion for the transition state is an unsymmetrical one and the vibration which will induce such a distortion is the asymmetrical motion of A_2'' symmetry,



It is of interest to note that the motion of the hydrogen atoms, which is of A_2'' symmetry, corresponds to an inversion of the molecule as is observed in S_N2 reactions. While one cannot say to what extent the hydrogens participate in this particular coordinate, the motion required to bring about the inversion of the molecule is of the proper symmetry to be both allowed and favored.

As further examples of how the present method may be of use in determining possible reaction coordinates we shall consider the "branched" transition states recently proposed by Thrush and Clyne (6) for the reactions of oxygen atoms with NO_2, O_3, and ClO_2 and of nitrogen atoms with NO_2. The transition states proposed for these reactions are all of the form shown below for $O + NO_2$. Again, applying Walsh's molecular orbital



methods, we find that the transition-state molecules N_2O_2, NO_3, and O_4 (with 22, 23, and 24 valence electrons respectively) should be planar, while ClO_3 (with 25 valence

electrons) should be pyramidal. Thrush has pointed out that the formation of such a transition state is likely in each case, as the highest electron density in the top-filled orbital is found on the central atoms in NO_2, O_3, and ClO_2.

Consider first the complex NO_3 of D_{3h} symmetry. Does this molecule possess a transition density of the symmetry required to favor that nuclear motion which leads to the observed products (NO + O_2)? The structure of the vibrational representation for such a molecule is

$$\Gamma_{vib} = A_1' + A_2'' + 2E'.$$

The electronic configuration of the ground state of NO_3 will be (1, 5) (omitting the 2*s* electrons on the oxygen atoms)

$$(a_1')^2(1e')^4(a_2'')^2(2e')^4(2e'')^4(a_2')^1;\ ^2A_2'.$$

The two lowest unoccupied molecular orbitals are of symmetries $\bar{a}_1'$ and $\bar{a}_2''$ (the bar denoting their antibonding character). Of the excited states arising from occupation of a_2', $\bar{a}_1'$, or $\bar{a}_2''$, only two give states of relevant symmetries, they are

$$\ldots (2e')^3(2e'')^4(a_2')^2;\ ^2E'$$
$$\ldots (2e')^4(2e'')^3(a_2')(\bar{a}_2'');\ ^2E'.$$

The transition density is, therefore, of symmetry E', and the E' vibration is favored as the reaction coordinate over the A_1' or A_2'' motions. Of the possible vibrational motions of this molecule, only those of E' symmetry could give the observed products; both A_1' and A_2'' lead to the formation of N + 3O or perhaps (for A_2'') N + O_3. One component of each of the E' transition densities is illustrated in Fig. 4 together with the

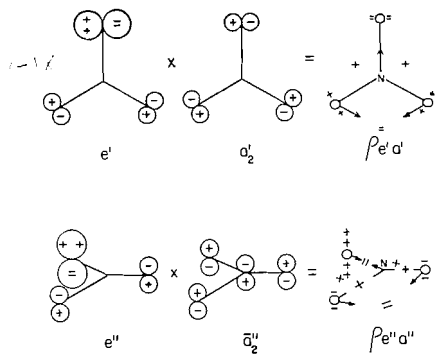


FIG. 4. Schematic representations of $\rho_{a'e'}$ and $\rho_{a''e''}$ for the NO_3 molecule and their interaction with an E' vibration.

contributing molecular orbitals. In each case charge is shifted so as to facilitate an E' vibration. The vibration may, of course, lead to any one of the three oxygen atoms combining with the nitrogen atom, since it is a degenerate motion. This proposed transition state is thus an acceptable one according to the tenets of the present theory, for it possesses a favored mode of motion which leads to the observed products.

The reaction of O with O_3 would, by this mechanism, give a planar D_{3h} transition-state molecule with the electronic configuration

$$\ldots (2e')^4(2e'')^4(a_2')^1(\bar{a}_2'')^1;\ ^3A_1''.$$

The transition state must be a triplet in order to preserve the spin correlation rules. This will force the occupation of the $\bar{a}_2''$ orbital in the case of a planar transition state. The lowest transition of a relevant symmetry is to the state

$$\ldots (2e')^4(2e'')^3(a_2')^1(\bar{a}_2'')^2;\ ^3E'',$$

which again gives a transition density of E' symmetry. Even though NO_3 and O_4 possess different numbers of electrons, both possess the same type of favored motion for their decomposition.

We can most rapidly predict the behavior of the $N + NO_2$ reaction via the proposed branched transition state by considering first the transition complex of greater symmetry obtained from $O + NO_2$ with 22 rather than 23 electrons. The electronic structure for such a complex would be (again it must be in a triplet state to preserve the spin correlation rules)

$$\ldots (2e')^4(2e'')^3(a_2')^1;\ ^3E''.$$

Now consider how the orbitals and states of such a symmetrical complex are perturbed as the nuclear charge of one of the oxygen atoms is decreased by one unit. The symmetry is now lowered to C_{2v} and all the degeneracies are lifted. The $2e''$ orbital now gives orbitals of symmetries $2a_2$ and $2b_2$, a_2' becomes b_1, and the orbital $\bar{a}_2''$ is transformed into one of b_2 symmetry. Before the perturbation, $2a_2$ and $2b_2$ were degenerate and it is reasonable to assume that their splitting is not too great. Therefore, the two states resulting from the splitting of the ground state $^3E''$ may be expected to differ little in energy.

$$\ldots (2a_2)^2(2b_2)^1(b_1)^1;\ ^3A_2$$

$$\ldots (2a_2)^1(2b_2)^2(b_1)^1;\ ^3B_2$$

The relative order of the two states is irrelevant (reversing the order of $2a_2$ and $2b_2$ reverses their order) as the symmetry of the transition density remains unchanged. This symmetry is B_1 and thus a B_1 vibration is favored. There are two possible B_1 motions, one would lead to the formation of 2NO and the other to $N_2O + O$. Thrush has actually postulated that the reactions of $N + NO_2$ to give 2NO and $N_2O + O$ do proceed through the same transition state, from considerations of the relative entropies and energies of activation. The present theory agrees with this postulate, as the removal of the degeneracy of the orbitals should lead to the appearance of two states close together in energy and giving a transition density of B_1 symmetry. Each of the E' vibrations is of course split into an A_1 and a B_1 component by the same perturbation. The transition density will favor the two B_1 components. Thrush also feels that the other products observed for this reaction, $N_2 + O_2$, might arise from the same transition state. This would require a transition density of A_1 symmetry. While an excited state of the proper symmetry to give an A_1 transition density is certainly present, it is, of course, beyond the capabilities of the present method to predict whether or not it is low enough in energy to compete with the B_1 transition density.

The molecule ClO_3 with 25 valence electrons will be pyramidal in shape of C_{3v} symmetry. Its ground state (1) will be (again ignoring the oxygen 2*s* electrons)

$$(1a_1)^2(1e)^4(2a_1)^2(1\bar{a}_1)^2(2e)^4(3e)^4(1\bar{a}_2)^1;\ ^2A_2.$$

The first excited state of proper symmetry is

$$\ldots (3e)^3(1\bar{a}_2)^2;\ ^2E.$$

The molecule ClO_3 should thus decompose to give ClO and O_2, as observed for this reaction, as an E vibration is the favored mode. Neither of the A_1 vibrations, which are the other possible modes of vibration, could lead to such products.

In all of the above applications to transition-state molecules we are describing their instability as due to the presence of a low-lying excited state. The bonds in a transition-state molecule are longer and weaker than usual, and hence the top-most orbitals will be higher in energy and the antibonding combinations will be correspondingly lower in energy, i.e., the separation between the bonding and antibonding combinations in general decreases as the bonding decreases. In such molecules we can thus expect to find a low-lying excited state. In the $O + NO_2$ and $O + O_3$ reactions, both are unstable due to a mixing in of a low-lying E' state arising from the occupation of the $\bar{a}_2''$ orbital. This orbital is antibonding between the outer atoms and the central atom and is formed from the *p* orbitals which are perpendicular to the plane of the molecule. Since all the bonds are long, we expect this to be a low-lying state in these cases, i.e., the $\bar{a}_2''$ orbital is only weakly antibonding. Thus, close to the ground state there is actually an orbitally degenerate state which must be inherently unstable with respect to an E' vibration. In these cases we thus have a situation in which the most easily attained charge distortion is one which is inherently unstable to a motion which does lead to the formation of the observed products.

APPENDIX

This appendix is to provide further discussion of the assumption basic to the present approach that the lowest of the excited states will determine the symmetry of the favored vibration. As a simple numerical example, we may consider the following two nuclear motions of H_2^+ (ground state $^2\Sigma_g^+$):

The lowest excited states of H_2^+ are $^2\Sigma_u^+$ and $^2\Sigma_g'^+$ (which is made orthogonal to $^2\Sigma_g^+$), $^2\Sigma_u^+$ being the lower of the two. We wish to compare

$$(\langle {}^2\Sigma_g^+|\partial\phi(\mathbf{r})/\partial Q_u|{}^2\Sigma_u^+\rangle)^2/(E_0-E_u),\quad T_u$$

with

$$(\langle {}^2\Sigma_g^+|\partial\phi(\mathbf{r})/\partial Q_g|{}^2\Sigma_g'^+\rangle)^2/(E_0-E_g),\ T_g.$$

These quantities are easily evaluated using simple molecular orbitals, and it is found that $T_u = 730$ and $T_g = 70$ (in a.u. $\times 10^4$). Since the terms contribute to a sum it is the difference in their magnitudes which is important. The difference ($T_u - T_g = 660$) is in

fact approximately 10 times greater than the whole contribution from the second lowest of the excited states. This difference is due mainly to the rapid fall in the integral, rather than to the increased energy difference on going from T_u to T_g. We can expect this to be a general result from the following considerations. From Schrödingers equation for the electronic wave function at the equilibrium position,

$$H\psi_k = E_k\psi_k,$$

we may obtain (7)

$$\langle k|\partial H/\partial Q_i|0\rangle = \langle k|\partial\phi(\mathbf{r})/\partial Q_i|0\rangle = (E_0-E_k)\langle k|\partial/\partial Q_i|0\rangle.$$

The term $\langle k|\partial/\partial Q_i|0\rangle$ will in turn reduce to

$$\int \phi_p(\partial\phi_j/\partial Q_i)d\tau,$$

where ϕ_p and ϕ_j are the same molecular orbitals which contribute to ρ_{0k}. The value of this latter integral decreases rapidly as the difference in the orbital energies of ϕ_p and ϕ_j increases (as may be easily demonstrated for simple systems). It represents simply an overlap integral between the derivative of one molecular orbital with another. The more the energies of the two orbitals differ, the smaller is the value of this overlap integral. Furthermore, the value of this overlap decreases much more rapidly than the energy difference (E_0-E_k) increases. Thus the low-lying states will make the major contribution to this particular kind of second-order sum and the lowest of these states will make the largest single contribution.

Terms of the form $\langle k|\partial/\partial Q_i|0\rangle$ occur in the off-diagonal matrix elements of the Born–Oppenheimer approximation (7). It is well known that when an excited state $|k\rangle$ lies very close to the ground state $|0\rangle$ the Born–Oppenheimer approximation breaks down because the terms $\langle k|\partial/\partial Q|0\rangle$ become very large. In fact, when $|k\rangle$ and $|0\rangle$ are degenerate, we have a Jahn–Teller instability. The present approach may be thought of as a second-order Jahn–Teller effect. When $|k\rangle$ and $|0\rangle$ are degenerate, there is no question as to the instability of the system with respect to certain normal modes. When $|k\rangle$ and $|0\rangle$ differ slightly in energy we pass from a first-order effect to the presently described second-order effect where the lowest-lying state $|k\rangle$ will still determine the major effect.

METAL OXIDE ALKOXIDE POLYMERS

PART V. THE HYDROLYSIS OF SOME ALKOXIDES OF TIN (IV), CERIUM (IV), AND URANIUM (V)[1]

D. C. BRADLEY[2] AND H. HOLLOWAY[3]
Department of Chemistry, Birkbeck College, London, W.C.1, England

Received February 23, 1962

ABSTRACT

The polymers formed by the hydrolysis of stannic isopropoxide, ceric isopropoxide, and uranium pentaethoxide have been studied by means of an ebulliometric method. The metal oxide alkoxide polymers formed from the tin (IV), cerium (IV), and uranium (V) alkoxides conform to the requirements of a structural theory. In view of the fundamental nature of the theory a formal mathematical presentation is now given.

INTRODUCTION

Previous work has shown that the remarkable variation of number-average degree of polymerization of the oxide alkoxides of titanium (1), zirconium (2), and tantalum (3) as a function of degree of hydrolysis may be satisfactorily explained on the basis of certain key structures in which the metal atom exhibits a higher coordination number. The success of the theory in explaining the behavior of compounds of both quadrivalent and quinquevalent elements on the same basic structural models suggested that it may be of fundamental importance in relation to metal oxide alkoxides in general and that it should have predictive ability. Accordingly we have set out in a formal manner the mathematical aspects of the theory, including a useful terminology for describing the various structural models. In an attempt to test the predictive possibilities of the theory we have extended the work to the hydrolysis of the isopropoxides of tin (IV), cerium (IV), and the pentaethoxide of uranium (V). The derivatives of tin and cerium both form dimeric solvates of the type $M_2(OPr^i)_8,(Pr^iOH)_2$ and should give polymeric oxide isopropoxides based on mixtures of the model II and model III or of the model II and model IV basic structures. Similarly, the uranium oxide ethoxides would be expected to conform to the same structural models as the tantalum oxide ethoxides, provided that the uranium exhibits a coordination number of six.

EXPERIMENTAL

Preparation of Metal Alkoxides

Stannic isopropoxide was prepared by alcoholysis of the ethoxide, which was obtained by the method of Bradley, Caldwell, and Wardlaw (4). The isopropoxide was purified by crystallization of the solvate $Sn_2(OPr^i)_8,(Pr^iOH)_2$, which lost the coordinated isopropanol when heated *in vacuo*. The resulting $Sn(OPr^i)_4$ was distilled *in vacuo*. Cerium isopropoxide was prepared from dipyridinium cerium hexachloride by the method of Bradley, Chatterjee, and Wardlaw (5). It was purified by recrystallization of the solvate $Ce_2(OPr^i)_8,(Pr^iOH)_2$. Uranium pentaethoxide was prepared by the three-stage synthesis from UCl_4 and sodium ethoxide using bromine as the oxidant, as developed by Jones *et al.* (6). The product was purified by distillation *in vacuo*. All of these compounds are extremely susceptible to hydrolysis and the usual precautions were adopted to control the hydrolysis in these experiments. The uranium compound is also susceptible to oxidation and the experiments were carried out under an atmosphere of oxygen-free nitrogen.

Ebulliometry

The previously described technique (3) was essentially followed throughout. Solutions of $Ce_2(OPr^i)_8,(Pr^iOH)_2$ and $Sn_2(OPr^i)_8,(Pr^iOH)_2$ in boiling isopropanol were prone to decomposition if the amount of

[1] *For Part IV, see reference 3.*
[2] *Present address: The University of Western Ontario, London, Ontario.*
[3] *Present address: Post Office Research Station, Dollis Hill, London, N.W.2, England.*

superheating was high or if the heating was localized. However, by using a silicone oil heating bath and lagging the ebulliometer satisfactory conditions were obtained and the results were reproducible. With the exception of $Ce_2(OPr^i)_8,(Pr^iOH)_2$, which has a low volatility and was recrystallized immediately prior to use, the alkoxides were freshly distilled *in vacuo* immediately before an ebulliometric hydrolysis.

Stannic Isopropoxide

Three separate determinations of the molecular weight were carried out, each involving several additions of solute. Although the concentrations covered almost a 30-fold range there was no evidence of concentration dependence of the molecular weight. The values of n_0 (the number-average degree of polymerization of the metal alkoxide, i.e. n at zero degree of hydrolysis) were: 1.84, 1.88, 1.84. The mean value of $n_0 = 1.85$ was adopted. The results of two ebulliometric hydrolyses are recorded in Table I.

TABLE I

A. Initial concentration of $Sn(OPr^i)_4 = 0.264$ g-mol./kg						
h	0.100	0.190	0.332	0.507	0.724	0.919
n	1.87	2.06	2.43	2.98	3.81	4.95
n_{calc}	1.95	2.09	2.35	2.78	3.59	4.86
B. Initial concentration of $Sn(OPr^i)_4 = 0.310$ g-mol./kg

Uranium Pentaethoxide

The molecular weight of uranium pentaethoxide was determined in boiling ethanol in two separate experiments covering a 15-fold range in concentrations but no evidence of concentration dependence was found. The values of n_0 were 1.47 and 1.49. The average value, $n_0 = 1.48$, was adopted. The results for two ebulliometric hydrolyses of uranium pentaethoxide are given in Table III.

DISCUSSION

A General Structural Theory for Metal Oxide Alkoxide Polymers

A formal presentation of the theoretical aspects of the metal oxide alkoxides will simplify the discussion of the latest experimental results.

First we define a regular polymer series as a set of metal oxide alkoxides having structures which fulfill the following requirements: (*a*) Each polymer in the series may be considered as derived from an integral number of unhydrolyzed metal alkoxide units linked together by metal–oxygen–metal bridges formed in the condensation $M(OR) + H_2O + (RO)M \rightarrow M\cdot O\cdot M + 2ROH$. (*b*) The metal alkoxide repeating units may themselves be polymers but they must have integral values of degree of polymerization which remain constant throughout the polymer series. (*c*) The number of $M\cdot O\cdot M$ links between adjacent units of the metal oxide alkoxide polymer must be constant. Secondly, we define the following variables: (i) the degree of polymerization of the metal oxide alkoxide (i.e. number of metal atoms per molecule) $= n$; (ii) the degree of polymerization of the metal alkoxide repeating unit $= p$; (iii) the degree of hydrolysis (i.e. ratio of water molecules added per metal atom) $= h$; (iv) the number of $M\cdot O\cdot M$ links between adjacent repeating units $= q$.

It follows from the definition of the regular polymer series that $n = p(x+1)$, where x is 0, 1, 2, 3, etc. Since one water molecule produces one $M\cdot O\cdot M$ link between adjacent repeating units, it also follows that $hn = xq$. By eliminating x we obtain the following general description of the members of the regular polymer series:

$$n^{-1} = p^{-1} - q^{-1}h. \qquad [1]$$

The regular polymer series will consist of a distribution of the members of the series so that the number-average degree of polymerization $\bar{n}$ and the average degree of hydrolysis $\bar{h}$ need not necessarily have integral values. Consider a regular polymer series comprising a mole fraction N_1 of the species with $n = n_1$ and $h = h_1$; N_2 of the species with $n = n_2$ and $h = h_2$; and N_i of the species with $n = n_i$ and $h = h_i$. The number-average degree of polymerization

$$\bar{n} = \sum N_i n_i / \sum N_i = \sum N_i n_i \qquad [2]$$

and the average degree of hydrolysis $\bar{h} = \sum h_i n_i N_i / \bar{n}$. Equation [1] will hold (p and q are constant) for each member of the series, i.e. $n_i^{-1} = p^{-1} - q^{-1}h_i$, which may be rearranged to $pq = qn_i - pn_ih_i$. Summation over the whole series gives the following expression:

$$\sum pqN_i = \sum qn_iN_i - \sum pn_ih_iN_i, \qquad [3]$$

i.e.

$$pq = q\bar{n} - p\bar{n}\bar{h}. \qquad [4]$$

Equation [4] may be rearranged to [5].

$$(\bar{n})^{-1} = p^{-1} - q^{-1}\bar{h} \qquad [5]$$

An important feature of equation [5] is the determination of the number-average degree of polymerization $\bar{n}$ by the average degree of hydrolysis $\bar{h}$, since p and q are constant for any given regular polymer series. This is important because it has the consequence

that once $\bar{h}$ is fixed then $\bar{n}$ is fixed irrespective of the distribution of polymer sizes in the system. Thus a redistribution of the polymer sizes for a given value of $\bar{h}$ will not affect $\bar{n}$. Another consequence of equation [5] is a simple classification of regular polymer series. Thus the system can be defined as (p_x,q_y), where x is the numerical value of p, and y the numerical value of q. For example, the regular polymer series based on trimeric titanium ethoxide and termed Model I by Bradley, Gaze, and Wardlaw (1) would simply be the system (p_3,q_4) with $(\bar{n})^{-1} = 0.333_4-0.25\bar{h}$. The regular polymer series called model II and based on either the solvated dimeric metal tetraalkoxide $M_2(OR)_8,(ROH)_2$ (1, 2) or the dimeric tantalum pentaalkoxide $M_2(OR)_{10}$ (3) would be (p_2,q_3) with $(\bar{n})^{-1} = 0.5-0.333_4\bar{h}$. Model III based on the solvated monomeric alkoxides $M(OR)_4,2ROH$ or $M(OR)_5,ROH$ would be (p_1,q_3) with $(\bar{n})^{-1} = 1.0-0.333_4\bar{h}$, whilst the alternative model IV is (p_1,q_2) with $(\bar{n})^{-1} = 1.0-0.5\bar{h}$. The fundamental aspect of the theory of regular polymers is the consequence that the classification (p_x,q_y) fixes the variation of $\bar{n}$ with $\bar{h}$, which will be the same for all systems with the same values of x and y irrespective of the valency of the metal or the geometrical structures involved. It follows that with a knowledge of the structure of the original metal alkoxide and hence the value of x the possible values of y may be deduced from geometrical considerations. Having fixed x and y the variation of number-average degree of polymerization with degree of hydrolysis for the metal oxide alkoxides may be predicted by means of equation [5]. The structures of polymeric metal alkoxides have been discussed by Bradley (7) in terms of the valency of the metal, its higher coordination number, and stereochemistry. The fact that some metal alkoxides have non-integral values of n suggests that more than one value of x may be adopted. However, it is readily shown that the metal oxide alkoxides may still conform to an equation of the same general form as [5]. For example, let us consider a metal alkoxide existing in two polymeric species with $n = a$ and $n = b$ together in a system and let them form metal oxide alkoxides which conform to the regular polymer series (p_a,q_r) and (p_b,q_s). The proportions of the a-mer and b-mer initially present are defined by α_a, where α_a = the ratio of the number of metal atoms present in a-mers divided by the total number of metal atoms in the system. Obviously $\alpha_b = 1-\alpha_a$. Then

$$(\bar{n})^{-1} = \alpha n_a^{-1}+(1-\alpha)n_b^{-1},$$

where

$$n_a^{-1} = p_a^{-1}-q_r^{-1}h,$$

and

$$n_b^{-1} = p_b^{-1}-q_s^{-1}h.$$

Therefore,

$$(\bar{n})^{-1} = \alpha_a p_a^{-1}-\alpha_a q_r^{-1}h+(1-\alpha_a)p_b^{-1}-(1-\alpha_a)q_s^{-1}h.$$

$$= [\alpha_a p_a^{-1}+(1-\alpha_a)p_b^{-1}]-[\alpha_a q_r^{-1}+(1-\alpha_a)q_s^{-1}]h. \quad [6]$$

Substitution of

$$(\bar{p})^{-1} = \alpha_a p_a^{-1}+(1-\alpha_a)p_b^{-1}$$

and

$$(\bar{q})^{-1} = \alpha_a q_r^{-1}+(1-\alpha_a)q_s^{-1}$$

in equation [6] results in [7], which is identical in form with [5]:

$$[7] \qquad (\bar{n})^{-1} = (\bar{p})^{-1} - (\bar{q})^{-1}h.$$

Since α_a may be evaluated from the number-average degree of polymerization of the original metal alkoxide the values of $\bar{p}$ and $\bar{q}$ may be calculated for the metal oxide alkoxides. By similar reasoning it may be shown that for a metal alkoxide existing as three different polymeric species giving rise to the regular polymer series' (p_a,q_r),(p_b,q_s), and (p_c,q_t), equation [8] may be derived:

$$[8] \qquad (\bar{n})^{-1} = [\alpha_a p_a^{-1} + \alpha_b p_b^{-1} + (1-\alpha_a-\alpha_b)p_c^{-1}] - [\alpha_a q_r^{-1} + \alpha_b q_s^{-1} + (1-\alpha_a-\alpha_b)q_t^{-1}]h,$$

where α_a, α_b, and $(1-\alpha_a-\alpha_b)$ are the proportions of metal atoms in species (p_a,q_r), (p_b,q_s), and (p_c,q_t) respectively. By determining the intercept $(\bar{p})^{-1}$ and the slope $(\bar{q})^{-1}$ of equation [7] from the experimental plot of $(\bar{n})^{-1}$ versus h, it is possible to solve equation [8] for α_a and α_b and hence calculate $1-\alpha_a-\alpha_b$. It is clear that we cannot solve a system containing a mixture of more than three regular polymer series.

Stannic Oxide Isopropoxides

Since stannic isopropoxide forms a solvate, $Sn_2(OPr^i)_8,(Pr^iOH)_2$, which is practically dimeric in boiling isopropanol we should expect the variation of $\bar{n}$ with $\bar{h}$ for the oxide isopropoxides to be close to the equation for the (p_2,q_3) regular polymer series. The results plotted in Fig. 1 show that this is indeed the case. A least-squares fit of $(\bar{n})^{-1}$

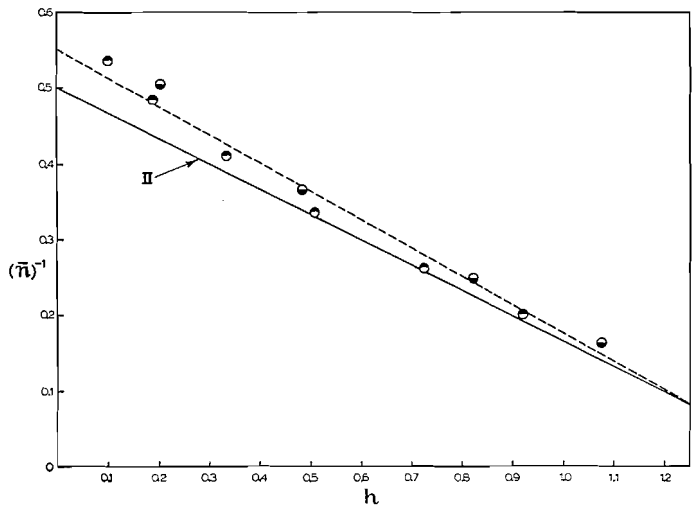

FIG. 1. The variation of $\bar{n}$ with $\bar{h}$ for the hydrolysis of stannic isopropoxide: ◓, data from Table 1A; ◒, data from Table IB. Curve II, $\bar{n} = 6/(3-2\bar{h})$.

versus $\bar{h}$ gave the equation $(\bar{n})^{-1} = 0.5505 - 0.3751\bar{h}$ with a coefficient of variation $\sigma_n = \pm 5.2\%$. There are five changes in sign in the error $\delta\bar{n} = \bar{n}_{calc} - \bar{n}$ ($\bar{n}_{calc}$ given in Table I) when the 11 points are arranged in ascending order of $\bar{h}$. From the intercept $(\bar{n})_0^{-1} = 0.5505$ at $\bar{h} = 0$, a value of $(\bar{n})_0 = 1.82$ was calculated, which compares favorably with the value of 1.85 determined from the molecular weight of stannic isopropoxide.

Assuming that the (p_2,q_3) regular polymer series is accompanied by either the (p_1,q_2) or (p_1,q_3) series we derive the value of $\alpha_{II} = 0.899$ for the proportion of tin atoms in the (p_2,q_3) series. If the (p_1,q_3) series is present then the slope $d(\bar{n})^{-1}/d\bar{h}$ should be -0.333_4. If the (p_1,q_2) series is present then $d(\bar{n})^{-1}/d\bar{h}$ is calculated from equation [6] to be -0.350. The "least-squares" value of -0.375 is obviously closest to that predicted for the mixture of (p_2,q_3) and (p_1,q_2) series.

Ceric Oxide Isopropoxides

Ceric isopropoxide also forms a solvate, $Ce_2(OPr^i)_8,(Pr^iOH)_2$, which is practically dimeric in boiling isopropanol and hence would be expected to produce oxide isopropoxides conforming nearly to series (p_2,q_3). The plot of $\bar{n}$ versus $\bar{h}$ in Fig. 2 shows that such is

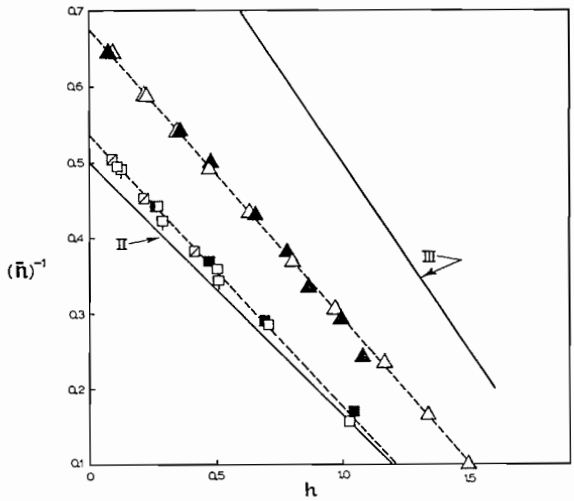

FIG. 2. The variation of $\bar{n}$ with $\bar{h}$ for the hydrolysis of ceric isopropoxide and uranium pentaethoxide: □, data from Table IIA; ■, data from Table IIB; ▨, data from Table IIC; ▫, data from Table IID; △, data from Table IIIA; ▲, data from Table IIIB. Curve II, $\bar{n} = 6/(3-2\bar{h})$; Curve III, $\bar{n} = 2/(2-\bar{h})$.

the case. The least-squares fit of $(\bar{n})^{-1}$ versus $\bar{h}$ gave the equation $(\bar{n})^{-1} = 0.5358-0.3608\,\bar{h}$, with a coefficient of variation $\sigma_n = \pm 2.1\%$. In fact a considerable part of the error resides in the two points of highest and next-highest value of $\bar{h}$, and the coefficient of variation for the first 14 points is only $\pm 1.2\%$, with 8 changes in sign of $\delta\bar{n}$. Values of $(\bar{n})_{calc}$ are listed in Table II. The intercept $(\bar{n})_0 = 0.5358$ at $\bar{h} = 0$ leads to a value of $(\bar{n})_0 = 1.87$, in good agreement with the value 1.86 calculated from the molecular weight of ceric isopropoxide. Accordingly the proportion of cerium in the (p_2,q_3) series is $\alpha_{II} = 0.928$. The slope $d(\bar{n})^{-1}/d\bar{h} = 0.3608$ is much closer to the figure of -0.3456 calculated (eq. [6]) for the (p_1,q_2) series than the -0.3334 calculated for the (p_1,q_3) series. It appears from these calculations that the ceric oxide isopropoxides resemble the stannic oxide isopropoxides in conforming to a mixture of the regular polymer series' (p_2,q_3) and (p_1,q_2).

Uranium (V) Oxide Ethoxides

Although uranium pentaethoxide is practically dimeric in boiling benzene its molecular weight in boiling ethanol ($\bar{n} = 1.48$) suggests that a considerable proportion of monomeric species is present in the alcohol, no doubt due to solvation to $U(OEt)_5,EtOH$. This is extremely interesting because the two previously discussed alkoxides were predominantly

dimeric and a quantitative distinction between the alternative series (p_1,q_2) and (p_1,q_3) was not favored. However, with the larger proportion of monomer species in the uranium pentaethoxide, discrimination between the alternative series should be facilitated. The plot of $\bar{n}$ versus $\bar{h}$ in Fig. 2 for the uranium oxide ethoxides appears to follow a path almost midway between curves II and III. The least-squares fit for the 20 points between $\bar{h} = 0$ to 1.500 was in accordance with the equation $(\bar{n})^{-1} = 0.6755 - 0.3841\bar{h}$, with a coefficient of variation $\sigma_n = \pm 3.2\%$ and 10 changes of sign in $\delta\bar{n}$ ($\bar{n}_{calc}$ values are listed in Table III). A major portion of the errors in $\bar{n}$ occurred for the highest four values of $\bar{h}$. Thus, $\sigma_n = \pm 1.4\%$ for the first 16 points ($h = 0$ to 0.992) and there are 9 changes of sign. From the intercept $(\bar{n})_0^{-1} = 0.6755$ ($\bar{h} = 0$), the value of $(\bar{n})_0 = 1.48$ was calculated in exact agreement with the value determined from the molecular weight of the pentaethoxide. The low value of $\alpha_{II} = 0.649$, calculated from $(\bar{n})_0$, predicts a slope $d(\bar{n})^{-1}/d\bar{h} = 0.3919$ if series (p_1,q_2) is present with (p_2,q_3) and this is close to the least-squares slope of -0.3841. The results thus point unambiguously to the presence of the (p_1,q_2) series and the absence of the alternative (p_1,q_3).

It should be noted that the theory is not confined to metal oxide alkoxide systems but is applicable to any system involving regular polymer series as defined in the text. For example, it is evident that the formation of linear polydialkylsiloxanes by hydrolysis and condensation of dialkyldialkoxysilanes should conform to the requirements of the theory since (p_1,q_1) series will be formed. In this particular system the "central" atom (silicon) of the monomer has a coordination number which is the same as its group valency.

CONCLUSIONS

A general theory to account for the number-average degree of polymerization of metal oxide alkoxides has been formulated mathematically. In addition to explaining the properties of some oxide alkoxides of titanium, zirconium, and tantalum reported earlier, the theory also provides a rational interpretation of some oxide alkoxides of tin, cerium, and uranium. A characteristic feature of the metal oxide alkoxide polymers, namely the formation of relatively low polymers, appears to be a logical consequence of the theory.

ALKOXIDES OF VANADIUM (IV)

D. C. BRADLEY[1] AND M. L. MEHTA[2]
Department of Chemistry, Birkbeck College, London, W.C.1, England

Received February 23, 1962

ABSTRACT

A number of tetraalkoxides of vanadium (IV) have been prepared by alcoholysis of tetrakis(diethylamino)vanadium (IV). Volatilities and molecular weights were determined on the new compounds and compared with the properties of the corresponding titanium compounds. Some of the primary alkoxides of vanadium are polymeric and this polymerization affects not only the volatility but also the color of the compound.

INTRODUCTION

In recent years the alkoxides of a number of quadrivalent metals have been prepared and their physicochemical properties have been studied (1). A notable feature of these metal alkoxides is their polymeric nature, which is believed to be caused by intermolecular bonds between metal and oxygen due to covalency expansion of the metal. An attempt has been made to rationalize the size of these polymers in terms of the stereochemistry of the metal (2). The metal alkoxides thus constitute an important class of coordination polymers. For theoretical purposes it is desirable to study various properties of a series of transition metal tetraalkoxides $M(OR)_4$ (e.g. Ti, V, Cr, etc.) and as part of a wider program we have investigated the preparation and properties of vanadium (IV) tetraalkoxides. The recent discovery of chromium (IV) tetra(tertiary-butoxide) (3) raises the possibility, now being investigated, of synthesizing chromium (IV) tetraalkoxides.

RESULTS AND DISCUSSION

The synthesis of vanadium tetraalkoxides proved to be a major problem due to the ease of hydrolysis and oxidation of these compounds. Thus it was shown by Bradley, Multani, and Wardlaw (4) that vanadium tetrachloride reacted vigorously with alcohols to form vanadium dichloride dialkoxide alcoholates $VCl_2(OR)_2,ROH$; but these authors were unable to prepare the tetraalkoxides by further substitution of chlorine in the presence of ammonia or sodium alkoxide. In attempting to prepare vanadium (III) triisopropoxide by the action of sodium in alcohol on vanadium trichloride we obtained some vanadium (IV) tetraisopropoxide (5) but the method did not seem very promising for synthesizing other vanadium tetraalkoxides. The synthesis of tetrakis(diethylamino)-vanadium (IV) from VCl_4 and lithium diethylamide by Thomas's method (6) offered a convenient route to the vanadium tetraalkoxides by alcoholysis and we have applied this method in the present research.

$$VCl_4 + 4LiNEt_2 \rightarrow V(NEt_2)_4 + 4LiCl$$

$$V(NEt_2)_4 + 4ROH \rightarrow V(OR)_4 + 4R_2NH$$

A large number of vanadium tetraalkoxides have now been prepared and this has established beyond doubt that these compounds do exist although they are rather unstable. Previous work on metal tetraalkoxides (1) has shown how markedly the physical properties of the alkoxide of a given metal depend on whether the alkoxide group contains

[1]*Present address: Department of Chemistry, University of Western Ontario, London, Ontario.*
[2]*Present address: Department of Chemistry, Munshi Singh College, Bihar University, India.*

primary, secondary, or tertiary alkyl groups. Therefore we shall discuss these new vanadium compounds under the three headings primary, secondary, and tertiary, and compare them with the corresponding alkoxides of other quadrivalent metals.

Primary Alkoxides

The primary alkoxides $V(OR)_4$, where R = Me, Et, Pr^n, Bu^n, Bu^i, Am^n, Am^{iso}, $Am,^{act}$ and neopentyl were prepared. Vanadium tetramethoxide and tetraethoxide were brown solids whereas the tetraneopentyloxide was a green solid. The other compounds were dark brown liquids at room temperature. All of the new alkoxides were soluble in benzene, ether, petrol, or the parent alcohol. The tetramethoxide was heated to 200° C at 0.05 mm but would not sublime, and above this temperature it decomposed. This behavior contrasts with that of $Ti(OMe)_4$, which sublimes at ca. 180° C at 0.1 mm, although the latter is practically insoluble in common organic solvents. All of the other vanadium primary alkoxides could be distilled under reduced pressure but some decomposition occurred, as shown by the yield (75–80%) and purity of the distillate. This thermal instability precluded the determination of true boiling points so that the figures quoted in the tables are generally the bath temperatures at which distillation occurred in conventional vacuum distillation apparatus. These temperatures will be 10–20° higher than the boiling points under the specified pressure. The solubility of the vanadium alkoxides enabled us to determine molecular weights ebullioscopically in benzene. In Table I are recorded the volatility and number-average degree of polymerization of the new compounds together with comparable data (7) on the corresponding titanium alkoxides.

TABLE I

	Volatility (°C/mm)		Degree of polymerization	
Alkoxide	Ti	V	Ti	V
$M(OMe)_4$	180/0.1	Non-volatile	Insol.	2.79
$M(OEt)_4$	102/0.1	100–110/0.05*	2.4	2.04
$M(OPr^n)_4$	124/0.1	140–150/0.5*	—	1.39
$M(OBu^n)_4$	142/0.1	150–160/0.5	—	1.31
$M(OBu^i)_4$	—	114/0.05	—	1.30
$M(OAm^n)_4$	158/0.1	160–180/0.5*	1.4	1.27
$M(OAm^{iso})_4$	148/0.1	112/0.01	1.2	1.30
$M(OAm^{act})_4$	140/0.1	142/0.5	1.1	1.10
$M(OCH_2Bu^t)_4$	111/0.1	100/0.1	1.3	1.03

*Bath temperature.

It is clear that with the exception of the methoxides the volatilities of the vanadium and titanium alkoxides are similar. Where comparative data are available it appears that the degree of polymerization is generally smaller for the vanadium alkoxide than for the titanium compound. This is strikingly so in the case of the methoxides, where the titanium compound is insoluble and presumably highly polymeric. The value of 2.79 for the degree of polymerization of $V(OMe)_4$ suggests that it is predominantly in the trimeric form, which is the limiting degree of polymerization for a metal tetraalkoxide in which the metal is octahedrally 6-coordinated (2). It was first shown by Caughlan *et al.* (8) by cryoscopic studies in benzene that in titanium alkoxides $Ti(OR)_4$, where R = Et, Pr^n, Bu^n, the degree of polymerization increased with increase in concentration to a limiting value of 3.0. More recently the very precise measurements of Martin and Winter (9) have not only confirmed that titanium tetrabutoxide attains a limiting trimeric state but also have demonstrated that the concentration dependence of the molecular weight fits a monomer–trimer equilibrium.

$$[Ti(OBu)_4]_3 \rightleftharpoons 3Ti(OBu)_4$$

Although there was no evidence for the variation of molecular weight with concentration in our ebullioscopic measurements with vanadium *n*-alkoxides we nevertheless suggest, on the basis of the non-integral values of the degrees of polymerization, that the vanadium alkoxides resemble the titanium alkoxides in having mixtures of monomers and trimers. It is relevant to observe that ebullioscopic measurements on the titanium alkoxides (7) also showed no evidence of concentration dependence of molecular weight, although non-integral values for the degrees of polymerization were obtained. At present we have no satisfactory explanation of this paradox. A rare example of the detection of concentration dependence of molecular weight for a metal alkoxide by ebulliometric measurements was found by Holloway (15) for niobium pentaethoxide, which exhibits a well-defined monomer–dimer equilibrium. In the straight-chain alkoxides there is a rapid decrease in degree of polymerization with lengthening of the alkyl chain from $V(OMe)_4$ to $V(OPr^n)_4$ but from $V(OPr^n)_4$ to $V(OAm^n)_4$ there is very little change. This is presumably the result of changes in steric effects, which will be most noticeable between the early members of the homologous series. Inspection of a trimer model shows that in the longer-chain derivatives lengthening of the alkyl chains does not cause much additional interference with the polymerization of the trimer.

The lower degree of polymerization exhibited by the vanadium alkoxides compared with the corresponding titanium alkoxides can also be interpreted as due to differences in steric effects. Thus in the case of a given alkoxide group, shielding of the central atom and consequent opposition to polymerization will depend on the size of the central atom, other factors being equal. Hence vanadium, which has a slightly smaller covalent radius (1.22 Å, ref. 11) than titanium (1.32 Å, ref. 11), will be better shielded and accordingly should achieve a smaller degree of polymerization in its tetraalkoxides. Moreover, chromium with a still smaller atomic radius (1.17 Å, ref. 11) would be expected to achieve a smaller degree of polymerization in tetraalkoxides than vanadium. Branching of the alkyl groups will have a pronounced tendency to oppose polymerization and this is shown to a marked degree in the neopentyloxide, which gives practically a monomeric vanadium compound. This is also reflected in the higher volatility of the neopentyloxide compared with *n*-amyloxide.

Secondary Alkoxides

The following secondary alkoxides were prepared: $V(OR)_4$, where R = Me_2CH, MeEtCH, $MePr^nCH$, $MePr^iCH$, and Et_2CH. The tetraisopropoxide was a dark green solid whilst the other compounds were green liquids. Molecular weight determination (ebullioscopically in benzene) showed that all except $V(OPr^i)_4$ were monomeric within experimental error. The degree of polymerization of 1.17 determined for $V(OPr^i)_4$ may be erroneously high due to the high volatility of the solute, and the compound is probably monomeric. The volatilities of these new vanadium compounds are compared in Table II with those of the corresponding titanium and zirconium alkoxides (10). Here it is noteworthy that the monomeric titanium and vanadium compounds are very similar in volatility whereas the polymeric zirconium compounds (degree of polymerization given in parentheses) are considerably less volatile. Another interesting feature is that the monomeric secondary alkoxides of vanadium (IV) are green in contrast to the brown primary alkoxides (except the neopentyloxide which is monomeric and green), which are polymeric. It seems feasible that the brown color of the primary alkoxides is due to the polymeric species. This problem is receiving further investigation. There is little doubt that the monomeric nature of the secondary alkoxides is a consequence of the steric hindrance of the branched alkoxide groups to polymerization.

TABLE II

Alkoxide	Volatility (°C/mm) Ti	V	Zr
$M(OPr^i)_4$	49/0.1	70–80/0.1*	160/0.1 (3.0)
$M(OBu^s)_4$	105/1.2	81/0.05	164/0.1 (2.5)
$M(OCHMePr^n)_4$	115/0.1	110/0.05	175/0.05 (2.0)
$M(OCHMePr^i)_4$	131/0.5	104/0.05	156/0.01 (2.0)
$M(OCHEt_2)_4$	112/0.05	108/0.05	178/0.05 (2.0)

*Bath temperature.

Tertiary Alkoxides

The following tertiary alkoxides were prepared: $V(OR)_4$, where R = Me_3C, Me_2EtC, Me_2Pr^nC, Me_2Pr^iC, Et_3C, and $MeEtPr^nC$. These new compounds are all liquids, the tertiary butoxide being blue and the others dark green. The compounds may be distilled under reduced pressure but some decomposition occurs. They are soluble in common organic solvents and are readily hydrolyzed. Molecular weight determinations in boiling benzene confirmed that the tertiary alkoxides were, without exception, monomeric. The data on the volatilities of the vanadium tertiary alkoxides are presented in Table III with the data on the corresponding titanium and zirconium compounds (12).

TABLE III

Alkoxide	Volatility (°C/mm) Ti	V	Zr
$M(OCMe_3)_4$	64.5/0.4	60–70/0.1*	55/0.2
$M(OCMe_2Et)_4$	109.5/0.3	83/0.05	93/0.1
$M(OCMe_2Pr^n)_4$	141/0.8	111/0.05	133/0.7
$M(OCEt_3)_4$	180/0.5	128/0.05	180/0.4

*Bath temperature.

It is clear that when allowance is made for the different pressures at which the boiling points are recorded, the volatilities of the monomeric tertiary alkoxides of titanium, vanadium, and zirconium are approximately the same. This is to be expected if the central metal atoms contribute little to the intermolecular forces, which are determined primarily by the peripheral atoms in these molecules. Thus the steric effect of the highly branched tertiary alkoxide groups by shielding the central metal atom not only prevents polymerization but also reduces the importance of the metal atom in determining intermolecular forces. Precise vapor pressure measurements on titanium, zirconium, and hafnium tetra(tertiary-alkoxides) revealed that a "heavier" molecular species of this type may produce a more volatile liquid than a lighter species (13). Unfortunately the low thermal stability of vanadium tetraalkoxides makes the determination of accurate vapor pressures a doubtful proposition. However, it is hoped that magnetic and spectral data will be determined on some of these interesting compounds in due course.

EXPERIMENTAL

General Techniques

Since the vanadium tetraalkoxides are very sensitive to moisture and oxygen, special precautions were taken in drying the all-glass apparatus and conducting reactions under an atmosphere of oxygen-free nitrogen. The analytical methods and the methods of drying the methanol, ethanol, isopropanol, and tertiary-butanol were the same as described in the work on vanadium trialkoxides (5). The other alcohols

(prepared as reported previously, refs. 12, 10, 7) were dried azeotropically using ethanol and benzene to remove water as the volatile ternary azeotrope of water–ethanol–benzene. Vanadium tetrachloride was prepared by chlorination of vanadium at 130–150° C and was vacuum distilled immediately prior to use.

Preparation of the Vanadium Alkoxides

The vanadium tetraalkoxides were prepared by alcoholysis of tetrakis(diethylamino)vanadium, which was obtained as a dark green liquid (b.p. 110° at 0.05 mm; found: V, 14.8; Et_2N, 83.8; valency, 4.02; $V(NEt_2)_4$ requires: V, 15.0; Et_2N, 85%) by the reaction of lithium diethylamide with vanadium tetrachloride (6). Since the alcoholysis experiments all involved the same technique, we record here the details of one preparation and summarize the remainder of the results in Table IV.

Vanadium Tetraisopropoxide

A solution of tetrakis(diethylamino)vanadium (5.4 g) in benzene (10.3 g) was frozen at ca. −78° C and to it was added, with vigorous stirring, isopropanol (10.1 g) in benzene (13.1 g). An exothermic reaction occurred and produced a green solution. Removal of the excess of benzene, isopropanol, and the liberated diethylamine, under reduced pressure, left a green solid (4.4 g). Found: V, 17.9; Pr^iO, 80.8; valency, 4.06. $V(OPr^i)_4$ requires: V, 17.8; Pr^iO, 82.2%. Distillation of a sample (3.1 g) under 0.1 mm with the bath temperature at 70° C gave a green solid distillate (2.4 g) which was less pure (found: V, 18.3; Pr^iO, 80.6%; valency, 4.22) than the starting material.

Molecular Weight Determinations

An all-glass ebulliometer incorporating a differential water thermometer was used. The internal calibration technique (14) with fluorene as the standard solute was employed for determining the molecular weights in boiling benzene. The data are recorded in Table V.

About 20–25 ml of benzene were used in each determination and five to six separate additions of each solute were made. We have recorded only the initial and final weights of solute to indicate the range in concentrations covered. The elevation of the boiling point was a linear function of the weight of solute for each compound. The slopes of elevation vs. weight of solute are recorded in terms of mm readings of the differential thermometer per g of solute.

ACKNOWLEDGMENT

REACTIONS OF OZONIDES

II. REDUCTIVE AMINATION OF OZONIZATION PRODUCTS WITH ETHANOLIC AMMONIA[1,2]

D. G. M. DIAPER AND D. L. MITCHELL[3]
Department of Chemistry, Royal Military College of Canada, Kingston, Ontario
Received October 19, 1961

ABSTRACT

Reductive amination of the ozonolysis products of the terminal olefins 10-undecen-1-ol, ethyl 10-undecenoate, 10-undecenoic acid, and 10-undecenamide produces 10-aminodecan-1-ol, ethyl 10-aminodecanoate, 10-aminodecanoic acid, and 10-aminodecanamide respectively. Esters are also formed, in a competitive reaction, by thermal decomposition of the ozonolysis product.

INTRODUCTION

The reaction of ozone with unsaturated compounds has been intensively studied for several decades and has been the subject of two major reviews (1, 2). Early investigations concentrated on the characterization of the fragments obtained by reductive or hydrolytic scission of the ozonization products, while more recent work has examined the structure of these products (3, 4), reaction conditions, choice of solvent (5–7), and selective ozonization (8–11). The study of ozonides as a functional class with particular reference to exploring fully the limits of their reactivity has received considerably less attention than other aspects of this subject. Ozonization as a preparative method has been used by few workers (12–16) and its industrial use is still in its infancy.

It is well known that mild catalytic reduction of ozonization products forms fragments with an introduced aldehyde or ketone function (1, 2). The vigorous reducing agent lithium aluminum hydride, reductively cleaves ozonization products, giving a pair of primary alcohols, but other groups in the molecule are also affected (17–19). Selective reduction of ozonization products, leaving acid, ester, and amide functions intact, may be achieved by sodium borohydride in ethanol or by nickel-catalyzed hydrogenation (15, 17).

The present investigation involves the conversion of the product from 10-undecenoic acid (undecylenic acid) directly to 10-aminodecanoic acid. Similar conversions of the olefin to the primary amine function were performed starting with the amide or the ethyl ester of 10-undecenoic acid or with 10-undecen-1-ol. Reductive amination of aldehydes and ketones is a standard reaction (20–24) but only one example of one-step reductive amination of ozonization products has as yet been reported (25). In the four examples studied, yields of the primary amine product were moderate, but its isolation was complicated by formation of nickel complexes and by the presence of the non-basic by-products, described below. It has been shown, however, that ozonization products may be exploited, on a preparative scale, as aldehyde precursors, and it is possible that, under reducing conditions, they may demonstrate other general aldehyde or ketone reactions.

From ethyl 10-undecenoate (I), the compound most extensively studied, ethyl 10-aminodecanoate (V) was obtained in 35–45% yield, this being identified by comparison

[1]*The financial support for this work was supplied by the Defense Research Board under D.R.B. Grant No. 9530-17.*

[3]*Defense Research Board of Canada Postdoctorate Fellow, 1959–61. Present address: Department of Chemistry, Makerere College, The University College of East Africa, Kampala, Uganda.*

with an authentic sample. This was obtained by reduction of ethyl 10-oximinodecanoate and its identity was checked by analyses, infrared spectrum, and comparison of the derived crystalline hydrochloride and N′-phenylurea.

A non-basic fraction, in 30% yield, was shown to contain at least three major and four minor components. Only one was obtained pure and was conclusively identified as diethyl sebacate (IX). From gas chromatograms the yield was estimated to be about 20%. Ethyl undecanoate and ethyl 10-ethoxydecanoate were tentatively identified by vapor phase chromatography with authentic samples. Ethyl undecanoate doubtless resulted from incomplete ozonization. The ethoxy ester may be formed by nucleophilic ethoxide attack upon an amino group (a known reaction, but unusual) or by reduction of the peroxidic ozonization product.

Basic products (VI, VII, VIII) and the corresponding non-basic fractions (X, XI, XII) were obtained from 10-undecenoic acid (II) its amide (III) and 10-undecen-1-ol (IV). Authentic amino compounds were synthesized as above and the basic products were identified. The major non-basic product from 10-undecenoic acid was ethyl hydrogen sebacate (approx. 8% yield), that from the amide was 9-carbethoxynonanamide (20–30% yield of crude solid) and that from 10-undecen-1-ol was ethyl 10-hydroxydecanoate (approx. 12% yield). Under the conditions employed, reductive amination and ester formation, as indicated in the reaction scheme below, are competitive in a degree largely independent of the nature of the functional group at the far end of the chain:

$$Z(CH_2)_8CH{=}CH_2 \rightarrow \text{ozonization product} \begin{cases} \nearrow Z(CH_2)_9NH_2 \\ \quad \text{V–VIII} \\ \searrow Z(CH_2)_8COOEt \\ \quad \text{IX–XII} \end{cases}$$

I–IV

I, V, IX; Z = COOEt
II, VI, X; Z = COOH
III, VII, XI; Z = $CONH_2$
IV, VIII, XII; Z = CH_2OH

Ethanol is a good solvent for starting materials, ozonization products, and ammonia. It is shown that alcohols react with the zwitterionic ozonization products, giving alkyl hemiperacetals and the peroxidic products of further condensation reactions (1, 5, 26). It is suggested that the ester by-products of the present investigation come from the alkyl hemiperacetals or their derivatives and it may be seen that the esters (IX–XII) may be formed by loss of water from $Z(CH_2)_8CH(OEt)OOH$.

To investigate the above hypothesis of ester formation, ethyl 10-undecenoate was ozonized and heated in *n*-butanol in the absence of hydrogen, nickel, or ammonia. *n*-Butyl 10-undecenoate was treated similarly in ethanol. From both reactions ethyl *n*-butyl sebacate was obtained. Thermal decomposition of alkyl hemiperacetals or other peroxidic products may therefore be exploited as a preparative method for unsymmetrical esters.

These results led us to re-examine the hydroxy esters previously prepared (15) and thought to be impure on the grounds of wide boiling range and difficulty of reaction with phenyl isocyanate. These products were examined by gas chromatography, a technique not available at that time, and it was found that, depending on conditions, hydrogenolysis of the ethanolic ozonization product from ethyl 10-undecenoate may give a ratio of diethyl sebacate to ethyl 10-hydroxydecanoate as high as 2:1. Ester formation is, however, negligible under the conditions of borohydride reduction. Further experiments on the scope and conditions of this hitherto unreported formation of aliphatic esters from ozonization products are in progress.

EXPERIMENTAL

Melting points were uncorrected. Infrared spectra were determined using the potassium bromide pellet technique.

Ethyl 10-Aminodecanoate

A solution of ethyl 10-undecenoate (ethyl undecylenate) (50.0 g) in absolute ethanol (100 ml) was ozonized to completion at a temperature of 10–20° C. Tests for the absence of olefin (bromine in glacial acetic acid) were carried out on aliquot portions and verified by the infrared spectrum of a chloroform solution. The product was not isolated but was transferred to an autoclave hydrogenator* containing Raney nickel W-2 catalyst (6–9 ml settled volume) (27). After assembly of the hydrogenator, the alcoholic solution was saturated with ammonia gas delivered from a storage cylinder at 120–150 p.s.i. The ammonia supply was disconnected, hydrogen was introduced to a pressure of 1200–1400 p.s.i., and the reaction mixture was stirred for 3 hours at 100° C and for a further 3 hours while the hydrogenator was cooling to room temperature. The gases were vented outside the building. After dilution of the reaction product with ethanol (100 ml) and filtration of the solution free from the nickel catalyst, the product was concentrated to a thick syrup under reduced pressure at 40° C. The syrup was repeatedly dissolved in benzene (50–100 ml) and evaporated to dryness under reduced pressure to remove traces of ethanol. The benzene solution (100 ml) of the product was saturated with hydrogen chloride while maintaining external cooling (0–5° C). The solution was warmed to 60° C on the water bath and ethyl acetate or ether was added to incipient turbidity. The solution was stored at room temperature for a day and subsequently at refrigerator temperatures for several days. Additional ether (500 ml) was then added to complete the crystallization. The crude aminoester hydrochloride (18 g) was collected by filtration, washed with ether, and dried under reduced pressure. The mother liquors were concentrated at a small volume, diluted with ether, and extracted with 4 *N* hydrochloric acid (3×100 ml). Basification of these extracts liberated a further small amount of syrupy amino ester (2.5 g), which was collected by ether extraction. Total yield of crude ethyl 10-aminodecanoate hydrochloride was 38%.

In another experiment, under identical experimental conditions except that of increased hydrogenation pressure (2200 p.s.i.), the syrupy reaction product was isolated by ether extraction. The ethereal solution was extracted with cold 4 *N* hydrochloric acid (4×100 ml) and was retained for examination of non-basic products (see below). Basification of the aqueous acidic extracts at 0–5° C with solid sodium hydroxide liberated the amino ester as an oily layer, which was collected in ether or benzene and dried (magnesium sulphate). The product was isolated as the crude solid amino ester hydrochloride (19.0 g, 40%).

A solution of the above hydrochloride (11.2 g) in absolute ethanol was passed down a column of Amberlite IR-400 (OH form) ion exchange resin which had been previously washed with absolute ethanol. Concentration of the eluate gave syrupy ethyl 10-aminodecanoate (8.2 g, 82%), which was distilled to give a major fraction of b.p. 103–104° C at 0.2 mm (6 g) and m.p. 20.5–21.5° C (thermometer immersed). Anal. Calc. for $C_{12}H_{25}O_2N$: saponification equiv., 215; N, 6.5. Found: saponification equiv., 212; N, 6.6%.

The Reinecke salt had m.p. 120–122° C (decomposes on standing). Anal. Calc. for $C_{16}H_{34}CrN_7O_3S_4$: N, 17.7. Found: N, 16.3%. Attempts to distill the amino ester without prior purification via the hydrochloride gave significantly lower yields (9–10% overall) accompanied by large non-volatile pot residues. Attempts to reduce the proportion of non-basic products were unsuccessful. Employment of dilute solutions, low temperatures (−20° C), rapid stirring, "super dry" ethanol, and incomplete ozonization did not significantly alter the yields of the two fractions. Runs using N,N-dimethylformamide as a solvent gave poor yields of amino ester and an increased amount of non-basic product.

Examination of Non-Basic Components

Examination of the concentrated ethereal solution by gas chromatography (200° C, Apiezon M on firebrick, H_2) showed a recording revealing seven components, with 3 major peaks and 4 minor peaks. One of the major components (see fraction *c*) constituted about 70% of the sample. Distillation gave a broad boiling fraction (b.p. 90–130 at 0.1 mm) (14–19 g, 24–30% yield from ethyl undecylenate). Infrared examination revealed that no hydroxyl or amino groups were present but a strong ester carbonyl absorption was present and the spectrum was remarkably similar to that of an ester of a long-chain fatty acid. Fractional distillation through a short jacketted column gave two of the three components, (*a*) and (*c*), as pure fractions:

(*a*) B.p. 76–78° C at 0.1 mm, n_D^{23} 1.4365, chromatographed as a single peak upon admixture with ethyl undecanoate.

(*b*) Not isolated, but the major component chromatographed with ethyl 10-ethoxydecanoate.

(*c*) B.p. 108–112° C at 0.1 mm, n_D^{23} 1.4363, chromatographed with authentic diethyl sebacate. Saponification gave sebacic acid, m.p. 129–130° C, mixed m.p. 130–131° C, acid equiv., 103 (calc., 101.1). The infrared spectrum was identical with that of an authentic specimen of sebacic acid.

A synthetic specimen of fraction (*b*) was prepared by refluxing ethyl 10-hydroxydecanoate (12 g), ethyl iodide (40 ml), and freshly prepared silver oxide (6 g) (28), which was added in portions over a period of 6 hours. After warming for 24 hours, the silver salts were separated and washed with chloroform. The product was concentrated to a syrup under reduced pressure. The above reaction was repeated until a

**Superpressure Division of the American Instrument Company, Inc., Silver Springs, Maryland, U.S.A.*

negligible hydroxyl absorption was observed in the infrared. Fractional distillation through a short column gave a fraction of b.p. 98–100° at 0.4 mm and n_D^{24} 1.4330 which was observed as a single peak when analyzed by gas chromatography. Anal. Calc. for $C_{14}H_{28}O_3$: C, 68.8; H, 11.5. Found: C, 68.3; H, 11.1%.

10-Ethoxydecanoic Acid

The above ethoxy ester was saponified with alcoholic sodium hydroxide for 10 hours at 80° C. A solid formed when the reaction mixture was poured into a slurry of ice and 2 *N* hydrochloric acid and was collected while the solution was cold. After drying over silica gel at 10° C, the solid, after several crystallizations from light petroleum, had m.p. 32–33° C. Anal. Calc. for $C_{12}H_{24}O_3$: acid equiv., 216. Found: acid equiv., 207.

The derived methyl ester, obtained using diazomethene, analyzed as a single component in the gas chromatograph at 225° C.

Ethyl 10-Aminodecanoate Hydrochloride

From ethyl 10-aminodecanoate (1.5 g) in benzene – ethyl acetate the hydrochloride was obtained, m.p. 137–138° C. Anal. Calc. for $C_{12}H_{26}ClNO_2$: C, 57.2; H, 10.4; N, 5.6. Found: C, 56.5; H, 10.2; N, 5.8%.

N-Phenylurea of Ethyl 10-Aminodecanoate

Ethyl 10-aminodecanoate gave the corresponding N-phenylurea on treatment with phenyl isocyanate. It was crystallized from benzene–hexane and from methanol, m.p. 77–79° C. Anal. Calc. for $C_{19}H_{30}O_3N_2$: C, 68.2; H, 9.0; N, 8.4. Found: C, 68.1; H, 8.8; N, 8.5%.

10-Aminodecan-1-ol

The ozonization product prepared from 10-undecen-1-ol (37 g) in absolute ethanol was hydrogenated over nickel in the presence of ammonia as before. The crude product, after solvent removal, was diluted with ether and extracted with cold 4 *N* hydrochloric acid (3×200 ml). The ethereal layer was dried (magnesium sulphate) and concentrated to give a crude non-basic product (11.8 g). The ice-cold acid solution was basified with potassium hydroxide pellets and the separated oily layer was extracted with ether (3×300 ml). After drying and removal of the ether, the crude product solidified in the refrigerator. Wt. 21.3 g (66%). The product was dissolved in benzene, filtered through a pad of charcoal, and allowed to crystallize, first at room temperature and finally in the refrigerator (15° C). After several crystallizations in this manner a melting point of 72° C was obtained. Lit. m.p. 72° (29, 30). Anal. Calc. for $C_{10}H_{23}NO$: C, 68.9; H, 13.3; N, 7.8. Found: C, 68.9; H, 13.3; N, 7.8%. The derived Reinecke salt formed glistening flakes of m.p. 131–132° C (monohydrate). Anal. Calc. for $C_{14}H_{32}CrN_7O_2S_4$: N, 19.2. Found: N, 19.3%.

A portion of the crude non-basic fraction (8.5 g) was distilled to yield two major fractions, (*a*) and (*b*), and a pot residue of which the major portion was lubricating oil expelled from the hydrogenator:

(*a*) 0.95 g, 86–102° at 1 mm. The major component chromatographed with undecan-1-ol.

(*b*) 3.30 g, b.p. 142–145° at 3 mm, n_D^{24} 1.4452. Infrared spectrum identical with that of authentic ethyl 10-hydroxydecanoate. Upon admixture with ethyl 10-hydroxydecanoate, (*b*) chromatographed as a single peak (Apiezon T, on silver-coated glass beads, 290 μ, 170° C) (31, 32). (Lit. n_D^{24} 1.4460 (15).) Saponification gave 10-hydroxydecanoic acid, m.p. 72–73° C (15).

10-Aminodecan-1-ol Hydrochloride

Gaseous hydrogen chloride, passed into a benzene solution of the above aminoalcohol, gave the hydrochloride which, after crystallization from ethyl acetate – ethanol (20:1), was obtained as white flakes, m.p. 126–131° C. Anal. Calc. for $C_{10}H_{24}NOCl$: C, 57.0; H, 11.5; N, 6.7. Found: C, 57.2; H, 11.2; N, 6.5%. The derived Reinecke salt had m.p. 129–132° C.

10-(N-Phenylurea)-1-(N-phenylcarbamate) of 10-Aminodecan-1-ol

10-Aminodecan-1-ol (0.20 g) was warmed on the water bath with phenyl isocyanate (0.3 ml), giving the derivative, which was recrystallized twice from benzene, m.p. 172–175° C. Anal. Calc. for $C_{24}H_{33}N_3O_3$: C, 70.0; H, 8.1; N, 10.2. Found: C, 70.2; H, 8.5; N, 10.2%.

Reductive Amination of 10-Undecenoic Acid with Ammonia

10-Undecenoic acid (57 g) was ozonized as a neat liquid (or alcoholic solution) at room temperature. The product was diluted with ethanol (50 ml) and transferred to a precooled (ca. −60° C) hydrogenator containing Raney nickel catalyst. Liquid ammonia (400 ml) was added and hydrogen (100 p.s.i.) was introduced. After stirring at room temperature for 2 hours, and at 50° C for a further 2 hours, hydrogen was introduced to a pressure of 1500 p.s.i. and stirring was continued for 4 hours. Upon opening the hydrogenator, about 4 g of white product was collected from the walls of the vessel and the shaft of the stirrer. Several crystallizations from hot water gave a product of m.p. 182° C which was identified as 10-aminodecanoic acid, lit. m.p. 183–186° C (33). Anal. Calc. $C_{10}H_{21}NO_2$: N, 7.5. Found: N, 7.1%. The alcoholic solution was filtered and concentrated to a green viscous syrup. The syrup was poured into a slurry of 4 *N* hydrochloric acid and ice, and a yellow doughy solid separated. It was collected and dried over silica gel to give an amorphous resin (40 g, ca. 60%). Increased hydrogenation temperatures gave this solid in yields of ca. 40%. Infrared examination indicated peaks at 3570 (m), 3175 (s), 1710 (s), 1638 (w), and 1570 (w) $cm^{-1} \pm 10$ cm^{-1}.

A portion of the solid (6.7 g) was esterified with absolute ethanol (50 ml) and concentrated sulphuric acid (5 drops). Neutralization was effected by passage down Amberlite IR-400 (OH form) ion exchange resin which had been previously washed with ethanol. Distillation of the ester gave two fractions: (*a*) b.p. 60–105° C at 0.5 mm (1.7 g). This fraction, upon gas chromatographic examination, was found to contain two major components, the higher-boiling component chromatographing with ethyl undecanoate. (*b*) The second fraction, b.p. 120–130° at 0.5 mm (2.15 g), m.p. 23–25° C, had an infrared spectrum identical with that of ethyl 10-aminodecanoate. The derived ester hydrochloride had an infrared spectrum identical with the product described above. The remainder of the product formed a tarry pot residue.

A second portion of the resin was triturated several times with boiling 2,2,4-trimethylpentane. Concentration of the extracts gave a syrup which was esterified with ethereal diazomethane. The extract was examined in the gas chromatograph (225–230°, Apiezon M on firebrick, H_2, 9-ft column) and revealed three main components, (*a'*), (*b'*), (*c'*), and three very minor components which were not identified.

(*a'*) This fraction constituted approximately 80% of the extract. It chromatographed with authentic methyl undecanoate as a single component.

(*b'*) This fraction constituted less than 5% of the extract. It chromatographed with authentic dimethyl sebacate.

(*c'*) This fraction constituted 10–15% of the extract. It chromatographed with authentic methyl ethyl sebacate, which was prepared by treating ethyl hydrogen sebacate (m.p. 35.5–36.5° C) with ethereal diazomethane.

10-Aminodecanamide

A solution of the ozonolysis product prepared from 10-undecenamide (25 g) in absolute ethanol (300 ml) was hydrogenated similarly over nickel in the presence of an excess of dry ammonia. The product was obtained as a green semisolid mass after removal of the catalyst, ethanol, and ammonia. After crystallization from benzene – ethyl acetate, a crude green-colored product (14.65 g), A, giving a positive test for nickel with dimethylglyoxime solution was obtained. Product A was repeatedly triturated with hot 2,2,4-trimethylpentane and the extracts were combined with the mother liquors saved from the above crystallization. The combined extracts on concentration yielded a second product, B, which was crystallized from hot 2,2,4-trimethylpentane. Compound B did not form a Reinecke salt nor did it exhibit color reactions characteristic of amines. Repeated crystallization from 2,2,4-trimethylpentane raised the melting point to 63–65° C and its infrared spectrum was almost identical with that of the amide of ethyl hydrogen sebacate (m.p. 70–71° C). Anal. Calc. for $C_{10}H_{23}NO_3$: C, 62.9; H, 10.1; N, 6.1. Found: C, 63.4; H, 10.6; N, 7.5%.

A portion of the nickel-containing product (3.0 g), A, in ethanol (50 ml) was saturated with hydrogen sulphide and the precipitate was separated by filtration. The filtrate was concentrated to a yellow solid possessing a pungent odor. Several crystallizations from acetone at −20° C gave a pale yellow powder (2.15 g). This product (1.25 g) in absolute ethanol was deionized on a column of Amberlite IR-401 (OH form) resin and the eluate was concentrated to give a white solid (0.67 g). Crystallization from acetone–water gave the aminoamide, m.p. 133–143° C. Anal. Calc. for monohydrate $C_{10}H_{22}N_2O.H_2O$: C, 58.8; H, 11.8; N, 13.7. Found: C, 59.2; H, 11.8; N, 13.4%.

Another run at a higher hydrogenation pressure (1900 p.s.i.) and temperature (100° C) in the presence of liquid ammonia (200 ml) converted the ozonolysis product of 10-undecenamide (25 g) into 17.8 g of A (crude) and 8.4 g of B (found: N, 7.9%).

From the purified 10-aminodecanamide, the derived Reinecke salt (monohydrate) was prepared, m.p. 120–122° C. Anal. Calc. for $C_{14}H_{31}CrN_8O_2S$: N, 21.4. Found: N, 21.2%.

N'-Phenylurea of 10-Aminodecanamide

The phenylurea was prepared in the usual manner and was recrystallized from methanol, m.p. 139–140°. Anal. Calc. for $C_{17}H_{27}N_3O_2$: N, 13.8. Found: N, 14.1%.

10-Oximinodecan-1-ol, Ethyl 10-Oximinodecanoate, 10-Oximinodecanoic Acid, and 10-Oximinodecanamide

Ethanolic solutions of the ozonization products obtained from 10-undecen-1-ol, ethyl 10-undecenoate, 10-undecenoic acid, and 10-undecenamide were hydrogenated at room temperature and at 60–70 p.s.i. over palladium on calcium carbonate catalyst (34). The solution was filtered and warmed with a slight excess of hydroxylamine hydrochloride solution buffered with sodium acetate to yield the following oximes:

(*a*) 10-Oximinodecan-1-ol, from benzene, m.p. 83–84° C. Anal. Calc. for $C_{10}H_{21}NO_2$: C, 64.1; H, 11.3; N, 7.5. Found: C, 63.5; H, 11.2; N, 7.7%.

(*b*) Ethyl 10-oximinodecanoate, from aqueous ethanol, m.p. 56–59° C. Anal. Calc. for $C_{12}H_{23}NO_3$: C, 62.9; H, 10.1; N, 6.1. Found: C, 62.9; H, 9.9; N, 5.9%.

(*c*) 10-Oximinodecanoic acid, from ethanol, m.p. 108–110° C. Anal. Calc. for $C_{10}H_{19}NO_3$: N, 7.0. Found: N, 6.6%. Lit. m.p. 111° (35).

(*d*) 10-Oximinodecanamide, from ethanol, m.p. 138–140° C. Anal. Calc. for $C_{10}H_{20}N_2O_2.H_2O$: C, 55.0; H, 10.2; N, 12.8. Found: C, 54.75; H, 9.84; N, 12.7%.

Lithium aluminum hydride reduction of oximes (*a*), (*b*), and (*c*) in ether gave 10-aminodecan-1-ol (36), m.p. 71–72° C, in yields of 80%, 82%, and 16% respectively with infrared spectrum identical with that of the product prepared by reductive amination of the ozonization product from 10-undecenol (see above).

10-Aminodecanoic Acid

10-Oximinodecanoic acid (0.5 g) in absolute ethanol (60–80 ml) was hydrogenated at 65 p.s.i. and at room temperature over platinum oxide catalyst (37). The product (0.27 g, 57%) was recrystallized from hot water and had m.p. 181–182° C and mixed m.p. 180–182° C with the crystalline product obtained from 10-undecenoic acid. Comparison of their infrared spectra revealed that the two products were identical. Lit. m.p. 183–186° C (33). Anal. Calc. for $C_{10}H_{21}NO_2$: N, 7.5. Found: N, 7.0%.

Ethyl 10-Aminodecanoate

Under hydrogenation conditions identical with those described above, ethyl 10-oximinodecanoate gave syrupy ethyl 10-aminodecanoate. The N′-phenylurea was prepared and had m.p. 78–79° C with the N′-phenylurea described above. The infrared spectra of both specimens were identical in all respects. Anal. Calc. for $C_{19}H_{30}N_2O_3$: N, 8.4. Found: N, 8.6%.

The derived hydrochloride of the amine (m.p. 105–110° C) could not be separated from traces of the secondary amine hydrochloride but had an infrared spectrum identical with that of the ethyl 10-aminodecanoate hydrochloride described above. Anal. Calc. for $C_{12}H_{26}ClNO_2$: N, 5.6. Found: N, 5.5%.

Bis-(9-carbethoxy-n-nonyl)amine

Hydrogenation of a more concentrated solution of ethyl 10-oximinodecanoate (5 g) in ammoniacal ethanol (40 ml) over platinum on charcoal gave a mixture of the primary amine and the secondary amine (2.4 g). The latter amine was recrystallized from light petroleum at −20° C and had m.p. 49–50° C. Anal. Calc. for $C_{24}H_{47}NO_4$: C, 69.7; H, 11.4. Found: C, 69.5; H, 11.6%.

10-Aminodecanamide

A solution of 10-oximinodecanamide (0.5 g) in 85–95% ethanol (75 ml) was hydrogenated over Raney nickel W-2 catalyst for 10 hours at 60 p.s.i. and 22° C. Platinum oxide was then added and hydrogenation was continued a further 8 hours. The solution was filtered and concentrated to a crystalline mass. The product had an infrared spectrum identical with that of the 10-aminodecanamide described above. Anal. Calc. for $C_{10}H_{22}N_2O.H_2O$: N, 13.7. Found: N, 13.4%.

The derived Reinecke salt (monohydrate), m.p. 115–117° C, had an infrared spectrum identical with that of the above Reinecke derivative. Anal. Calc. for $C_{14}H_{31}CrN_8O_2S_4$: N, 21.4. Found: N, 21.9%.

The N-phenylurea derivative had a melting point (from methanol) and had an infrared spectrum identical with that of the N′-phenylurea of 10-aminodecanamide prepared above. Anal. Calc. for $C_{17}H_{27}N_3O_2$: N, 13.8. Found: N, 13.2%.

Thermal Decomposition of Ozonolysis Products in Alcohols

A solution of ethyl 10-undecenoate (20 g) in *n*-butanol (150 ml) was ozonized at 0° C until an aliquot portion gave a negative test for unsaturation (bromine in glacial acetic acid). The solution was autoclaved in a pressure vessel over Raney nickel (5 ml settled volume) at 150° C for 6 hours. The *n*-butanol was removed by evaporation under reduced pressure, at a bath temperature of 90–100° C, and the residual syrup was examined by gas chromatography (Apiezon T on silver-coated glass beads, 270 μ, 9-ft column, oven temperature 175°, H_2 at 40 ml/min). In addition to the volatile fractions, a large single peak and 2 minor less volatile peaks were observed. Fractional distillation at 125° at 0.1 mm gave *n*-butyl ethyl sebacate (9.6 g, 32%), n_D^{22} 1.4402. Saponification equiv.: calc., 143; found, 143.

n-Butyl 10-undecenoate in ethanol was ozonized and autoclaved by the procedure described above. Examination of the products by gas chromatography indicated that the major component had a retention time identical with that of *n*-butyl ethyl sebacate. The presence of other components in the same boiling range was considerably greater when ethanol was used as the solvent, and the above procedure (i.e. *n*-butanolysis) gave a product of higher purity.

THE STRUCTURE OF A SYNTHETIC GLUCAN[1]

I. GENERAL STRUCTURAL FEATURES

G. G. S. DUTTON AND A. M. UNRAU[2]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received December 4, 1961

ABSTRACT

Only D-glucose was obtained on acid hydrolysis of the glucan. Periodate oxidation released formaldehyde, which was believed to arise from C_6 of D-glucofuranose units. From the additional formaldehyde liberated from the borohydride-reduced glucan the degree of polymerization was estimated to be about 165. Complete hydrolysis of the derived polyalcohol gave glycerol, erythritol, D-glucose, and D-xylose. Partial hydrolysis gave glycerol, erythritol, and at least seven non-reducing oligosaccharides. Direct evidence for the existence of relatively large numbers of 1 → 6 and 1 → 4 linkages was found, together with smaller numbers of 1 → 2 linkages. The methylated glucan was freely soluble in chloroform – petroleum ether (5:95), and hydrolysis gave tetra, tri, di, and mono-*O*-methyl-D-glucoses in a 6:6:3:1 molar ratio.

There are many reports in the literature on the polymerization of D-glucose and a few papers on other monosaccharides (e.g. 1–10). Most of these polymerizations have been acid catalyzed at temperatures ranging from room temperature to about 200° C and the yields of polymeric material have varied greatly. There appears to have been no detailed study on the structures of these synthetic glucans, although there is general agreement that 1 → 6 linkages are commonly present and that there is a high proportion of α-glucosidic bonds. In a paper (6) on the glucan obtained by polymerization in the presence of metaboric acid it was inferred, on the grounds of hydrolytic behavior, that there were no glucofuranose units present. It was further stated that the polymer was highly branched, as shown by the large amount of 2,3,4,6-tetra-*O*-methyl-D-glucose obtained. Another recent paper on the glucan obtained by polymerization of 1,6-anhydro-D-glucose again demonstrated the branched nature of the polymer on the basis of periodate oxidation (11).

Since 1958 there has been a group of papers published by Mora and his associates at the National Institutes of Health on the preparation of several synthetic polysaccharides (2–4). Since some derivatives of these synthetic materials have been shown to be biologically active (12, 13) it was of interest to look more closely at the structures of these polymers. The present paper reports the general structural features of the glucan designated as polyglucose II in Table I of reference 3.

Complete hydrolysis of the glucan by boiling it with 1 *N* sulphuric acid followed by chromatography of the product showed only glucose, which was isolated in the crystalline state. Alkaline oxidation or bromine oxidation of the sugar to the corresponding aldonic acid followed by adsorption of the acid on an anion exchange resin left no residue which reacted with Tollens (23) or *p*-anisidine trichloroacetate (24) spray reagents when the effluent was evaporated, thus demonstrating the absence of any sugar alcohols. The low optical rotation of the glucan, $[\alpha]_D^{22}$ 65° (*c*, 1.0 in water), compared with the high positive rotation of alpha-linked glucans, such as amylose (195–210°), suggested that a number of beta-glycosidic linkages were likely present. Exclusively beta-linked glucans, such as laminarin, exhibit a negative rotation between −10 and −25°.

[1]*Presented at the 44th Chemical Institute of Canada Meeting in Montreal, August, 1961.*

[2]*Present address: Department of Plant Sciences, University of Manitoba, Winnipeg, Manitoba.*

Oxidation of the glucan with periodic acid (0.15 *M*) at 5° C resulted in the immediate liberation of formaldehyde (3.92 mg per hexose unit after 20 minutes) with no significant change observed after 3.5 hours, at which time 4.53 mg formaldehyde had been liberated per hexose residue. The glucan had consumed 1.218 moles of periodate per hexose unit when no further formaldehyde production could be detected after 12, 48, and 72 hours. Reduction ($NaBH_4$) of the glucan prior to periodate oxidation resulted in the liberation of more formaldehyde (a total of 4.88 mg per hexose unit), and about 1.235 moles of periodate had been consumed per hexose unit when no further formaldehyde was released. On the assumption that the additional formaldehyde produced in the periodate oxidation of the borohydride-reduced glucan stemmed from the glucitol end-residue (and that the glucitol was not substituted at C_2), the degree of polymerization (D.P.) was estimated (14) to be about 165. These results were in good agreement with those reported by Mora and his associates (2, 3).

Reduction ($NaBH_4$) of the polyaldehyde, $[\alpha]_D^{22}$ 39°, followed by complete hydrolysis of the polyalcohol gave glycerol and erythritol in major proportions and xylose and glucose in lesser quantities. The ratio of glycerol to erythritol was 7:1. The proportionately large quantity of glycerol indicated that numerous branch points and $1 \rightarrow 6$ linkages were present in the glucan. Glycerol and erythritol were converted to the corresponding *p*-nitrobenzoates with m.p. and mixed m.p. 189–193° C and 248–250° C, respectively (25).

D-Xylose, approximately 1% of the original sample, was identified as the crystalline sugar, m.p. and mixed m.p. 142–144° C, $[\alpha]_D^{23}$ 17.5° (*c*, 1.4 in water). This sugar would arise from internal glucofuranose units in which the C_5 and C_6 hydroxyls were not substituted. It was believed that the rapid liberation of formaldehyde upon periodate oxidation of the glucan stemmed from the presence of D-glucofuranose units. Those units occupying terminal positions would be degraded to glycerol whereas some of the internal D-glucofuranose units would appear as D-xylose. D-Glucose, approximately 6% of the original sample, was identified as the crystalline sugar, m.p. and mixed m.p. 142–144° C, $[\alpha]_D^{23}$ 51.8° (*c*, 1.5 in water) and as the phenylosazone, m.p. and mixed m.p. 205–207° C.

Mild acid hydrolysis (0.1 *N* H_2SO_4, room temperature, 8–12 hours) (15) of the polyalcohol resulted in the formation of glycerol, a small quantity of erythritol, and a number of non-reducing oligosaccharides, which will be described more fully in a future communication. The alcohols were transformed, as before, to the crystalline *p*-nitrobenzoates.

In an effort to determine the nature of the aldehydic residues liberated in the mild acid hydrolysis of the polyalcohol, a part of the hydrolyzate was treated with bromine and an excess of barium carbonate, and the mixture left for 24 hours. The bromine was removed by aeration and the barium carbonate by filtration of the solution, which was then passed through cation and anion exchange resins. Acidic material was eluted from the anion resin with alkali and the free acids were regenerated with fresh cation resin. Evaporation of the acidic solution, lactonization, and reduction ($NaBH_4$) of the lactones gave rise to some glycerol (4–5% of original polysaccharide), m.p. and mixed m.p. of tri-*p*-nitrobenzoate 189–192° C, and a number of non-reducing oligosaccharide components, the nature of which was not determined. The isolation of glycerol by this route indicated the presence of some $1 \rightarrow 2$ linkages in the glucan.

The glucan was difficult to methylate. Only after four separate and extended methylations (4–5 days) of the partially methylated product (Kuhn procedure) by Purdie's reagents was a product obtained which showed no OH absorption in the infrared spectrum and which contained 45.4% methyoxyl. This difficulty of methylation of these synthetic glucans has been noted by other workers (3, 6). The product was completely soluble in a

mixture of 5% chloroform in petroleum ether (30–60°). Hydrolysis of the alkylated glucan gave tetra-, tri-, di-, and mono-methyl glucoses in a 6:6:3:1 ratio (approx.). A small quantity (1–2%, approx.) of glucose was also present.

The results of these periodate oxidations indicated that this glucan was highly branched, a fact which was substantiated by the methylation data. The high yield of formaldehyde indicated that at least 15% of the D-glucose units were of the furanose type while the large amount of glycerol obtained shows that the 1 → 6 linkage is of major importance. The ratio of erythritol to glycerol indicated that about 20% of the glucose units were linked at positions 1,4 and/or 1,4,6. The isolation of glycerol from the acidic fraction was definite evidence for the 1 → 2 linkage while the isolation of unoxidized glucose may be due to 1 → 3 linkages. We believe that this is the first time that definite proof has been obtained for the existence of furanose residues in a synthetic glucan, although their presence has been indicated by the work of Mora (13).

EXPERIMENTAL

Paper chromatographic separations were carried out by the descending technique using solvent systems A, ethyl acetate:acetic acid:water (8:2:2); B, ethyl acetate:pyridine:water (9:2:2); and C, butanone:water azeotrope. Whatman No. 1 filter paper was used for qualitative and quantitative studies while Whatman 3 MM paper was generally used to resolve larger quantities of mixtures. The *p*-anisidine trichloroacetate spray reagent was used for detection of reducing compounds while non-reducing polyols were located using ammoniacal silver nitrate.

Unless otherwise stated, evaporations were carried out under reduced pressure with a bath temperature around 40° C. Melting points are uncorrected and specific rotations are equilibrium values at 22±2° C.

Hydrolysis of Glucan

Polyglucose, 1.50 g, $[\alpha]_D^{22}$ 65° (*c*, 1.0 in water) was dissolved in 0.3 *N* sulphuric acid (15 ml) and the solution was boiled for 16 hours. The solution was neutralized ($BaCO_3$) and the filtrate was deionized and evaporated to a sirup which crystallized overnight. A portion (55 mg) of the crystalline material was recrystallized from ethanol to give glucose, m.p. and mixed m.p. 143–144° C, $[\alpha]_D^{23}$ 52.1° (*c*, 0.8 in water).

Bromine Oxidation of Glucan Hydrolyzate

The remainder (approx. 1.10 g) was dissolved in water (15 ml), the flask was wrapped with aluminum foil, and a few drops of bromine were added periodically over the next 72 hours. The solution was kept neutral by addition of excess barium carbonate. The solution was finally filtered to remove excess barium carbonate, deionized, and evaporated. No *p*-anisidine or Tollens-positive residue was noted; hence no polyols were present in the original polysaccharide.

Periodate Oxidation and Determination of Formaldehyde Produced

Glucan (0.383 g) was dissolved in water (20 ml) containing acetic acid (6 *N*, 2 ml) and to this solution was added 0.5 *M* sodium periodate (5 ml). The mixture was left at 5° C and formaldehyde was determined periodically by a method described elsewhere (14). After 20 minutes, 9.27 mg formaldehyde had been liberated, 10.15 mg after 12 hours, and 10.70 mg after 48 and 72 hours. When no further formaldehyde was formed, the periodate uptake was determined by the arsenite method (16) and 1.218 moles of periodate had been consumed per hexose unit.

Reduction ($NaBH_4$) and Complete Hydrolysis of Polyalcohol

To the mixture from the previous experiment was added barium carbonate and barium chloride, the solution filtered, and to the clear filtrate was added sodium borohydride (150 mg). Excess reductant was decomposed with hydrochloric acid after 18 hours and the solution was evaporated to dryness. Methanol containing hydrogen chlorine (3%) was added and evaporated to remove borate (17). The residue, in water (10 ml), was deionized, and upon evaporation of the effluent, the sirup was chromatographed. Non-reducing compounds corresponding to glycerol and erythritol and reducing compounds corresponding to xylose and glucose were observed. The ratio of components was determined by developing a chromatogram in solvent A for 12 hours. The four components were located by spraying guide strips with Tollens reagent, and the components eluted with water from the respective areas. The alcohols were determined by a periodate–chromotropic acid procedure (14) and the sugars by the phenol–sulphuric acid method (18). The molar ratio of glycerol:erythritol:xylose:glucose thus found was approximately 105:15:1:5.

Periodate Oxidation of Reduced ($NaBH_4$) Glucan and Determination of D.P.

To a solution (20 ml) of glucan (0.291 g) was added sodium borohydride (60 mg) and the solution was left at room temperature for 24 hours. The solution was acidified with 10 *N* acetic acid (2 ml), 0.5 *M* sodium periodate (5 ml) was added, and the mixture was left at 5° C. The formaldehyde was determined as before

and 7.415 mg were found after 15 minutes, 8.76 mg after 3.5 hours, with no change after 12, 48, and 72 hours. Comparing the formaldehyde produced after 48 and 72 hours with that found before reduction of the glucan, then 0.383 g of glucan would produce 0.85 mg additional formaldehyde after reduction. Assuming that 2 molar proportions of formaldehyde were produced from the glycitol end-group, the D.P. of the polymer was 165 (approx.). The polyaldehyde was reduced ($NaBH_4$) and hydrolyzed as described in a previous section. The molar ratio of glycerol:erythritol:xylose:glucose was again determined as described above and found to be 110:16:1:5.

Identification of Compounds

The sirups from the above two experiments were combined and the mixture was resolved on Whatman 3 MM paper by development for 12–14 hours in solvent A. *Glycerol:* to the dry sirup was added a 10% molar excess of *p*-nitrobenzoyl chloride and pyridine (2–3 ml) and the mixture was heated at 60–70° C for 30 minutes. Excess aroyl halide was decomposed by the addition of a few drops of water followed by excess saturated sodium bicarbonate. The solid was collected by filtration, washed thoroughly with water, and after recrystallization from acetone, the tri-*p*-nitrobenzoate of glycerol had m.p. and mixed m.p. 188–190° C (25). *Erythritol:* This compound was converted to the tetra-*p*-nitrobenzoate as described for glycerol, m.p. and mixed m.p. 248–250° C. D-*Xylose:* the sirup had $[\alpha]_D^{23}$ 17.5° (*c*, 0.9 in water) and crystallized on seeding. The xylose was dried by washing with ether and had m.p. and mixed m.p. 143–145° C. D-*Glucose:* the sirup, $[\alpha]_D^{22}$ 49° (*c*, 1.2 in water), crystallized spontaneously. The glucose was washed with ethanol and ether and had m.p. and mixed m.p. 144–145° C. The derived D-glucosazone had m.p. and mixed m.p. 206–208° C.

Partial Hydrolysis of Polyalcohol (15)

Glucan (4.50 g) was dissolved in water (120 ml); the solution was cooled (5° C) and 0.5 *M* periodic acid (80 ml) was added. Periodate uptake became constant after 72 hours at which time 1.192 moles of periodate had been consumed per hexose unit. The polyaldehyde, $[\alpha]_D^{22}$ 39° (approx.), was reduced ($NaBH_4$, 2.5 g) after removal of periodate and iodate with barium carbonate. After standing for 24 hours at room temperature, the solution was evaporated to dryness. Borate was removed by repeated evaporations with methanol and finally with methanol containing 1% hydrogen chloride at a bath temperature not exceeding 25° C. The residue was dissolved in 0.2 *N* hydrochloric acid and the solution was left at room temperature for 10 hours. Excess barium carbonate was added, the flask was wrapped with metal foil, and periodically over the next 24 hours, a few drops of bromine were added. The solution was filtered and passed through cation and anion exchange resin columns and the effluent was evaporated to give a sirupy, neutral product. Chromatographic examination in solvents A and B demonstrated the presence of seven non-reducing components with a wide range of R_f values lower than glycerol. Glycerol and a small quantity of erythritol were also identified. The oligosaccharides and the two alcohols were resolved on Whatman 3 MM paper using solvents A and B to effect maximum purification. Glycerol was converted to the tri-*p*-nitrobenzoate, m.p. and mixed m.p. 188–190° C. The tetra-*p*-nitrobenzoate of erythritol had m.p. and mixed m.p. 248–250° C. The composition and characterization of the oligosaccharide fragments will be described in a future communication (19).

Isolation and Reduction of Acidic Fragments

The acidic material, from the bromine oxidation described above, was displaced with 1 *N* sodium hydroxide from the anion exchange resin and regenerated by passage through a cation resin. The solution of free acids together with hydrochloric and hydrobromic acid was neutralized with lead carbonate. After filtration and treatment of the filtrate with hydrogen sulphide gas, the acidic material was finally obtained free from inorganic ions. Chromatography of the acidic residue gave a series of Tollens-positive components and the one with the greatest R_f value was presumed to be glyceric acid. The residue was heated in a cold-finger apparatus at 90° C under vacuum for about 3 hours, after which the residue was dissolved in water (20 ml), and sodium borohydride added (200 mg). The solution was evaporated to dryness after 36 hours at room temperature and borate was removed by careful treatment with methanol containing hydrogen chloride (1%). An aqueous solution (about 15 ml) of the residue was deionized. Evaporation of the effluent left a sirupy product which upon chromatographic examination was found to contain glycerol and a series of non-reducing components with lesser R_f values. After resolution of the mixture using Whatman 3 MM paper and solvent A, glycerol was identified as the tri-*p*-nitrobenzoate in the usual manner, m.p. and mixed m.p. 188–190° C. The nature and composition of the other components have not yet been examined.

Methylation of the Glucan

To polyglucose (3.00 g) suspended in dimethylformamide (DMF) (opalescent solution resulted) was added strontium oxide (10 g), strontium hydrate (1 g), and methyl iodide (20). The consistency of the mixture became thick soon after addition of the methyl iodide and an apparently exothermic reaction took place. Upon stirring (magnetic stirrer) and at the reflux temperature of methyl iodide, the suspension became thin after 1 hour. After 8 hours, additional strontium oxide (8 g) and methyl iodide (25 ml) were added. After 48 hours, methyl iodide was recovered and the slurry was extracted with liberal quantities of chloroform. Evaporation of the chloroform and DMF gave a yellow-brown glass. The product was treated again as described above followed by one treatment with silver oxide, DMF, and methyl iodide (21) and four methylations with Purdie's reagents (26). The final product, a yellow glass, 3.06 g, had a methoxyl

content of 44.4%, a very small OH absorption band in the infrared spectrum, and $[\alpha]_D$ 71° (*c* 2.2 in chloroform). Practically no insoluble residue was noted when the product was dissolved in petroleum ether (30–60° C) containing 5% chloroform.

Hydrolysis of the Methylated Glucan

The methylated glucan (3.00 g) was hydrolyzed with sulphuric acid (22). Neutralization ($BaCO_3$) of the hydrolyzate followed by deionization of the filtrate and evaporation gave a sirup (2.89 g) which upon chromatographic examination using solvent C showed tetra-, tri-, di-, and mono-methyl glucoses as well as a small quantity of glucose. Resolution of these methyl glucoses into the above four classes was effected using sheets of Whatman 3 MM paper and solvent C. The weights of tetra- (985 mg), tri- (880 mg), di- (410 mg), and mono-methyl glucose (135 mg) correspond to an approximate molar ratio of 60:57:28:10. Approximately 1.3% glucose (35–36 mg) was present. The identity of the different methyl ethers of glucose will be the subject of a future paper.

ACKNOWLEDGMENTS

This investigation was supported by a P.H.S. research grant (RG7652) from the Division of General Medical Sciences, Public Health Service (U.S.A.), to whom we express our thanks. We are also indebted to Miss J. Hunter for skillful technical assistance.

STUDIES ON THE CHEMICAL BASIS FOR CHOLINOMIMETIC AND CHOLINOLYTIC ACTIVITY

PART I. THE SYNTHESIS AND CONFIGURATION OF QUATERNARY SALTS IN THE 1,3-DIOXOLANE AND OXAZOLINE SERIES

D. J. TRIGGLE[1] AND B. BELLEAU
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received February 19, 1962

ABSTRACT

Structure activity relationships in the muscarine and the quaternary 1,3-dioxolane (Fourneau series) series are briefly discussed. The most active member of the latter series (2-methyl-4-dimethylaminomethyl-1,3-dioxolane methiodide, (IX), F2268) was shown to consist of a mixture of 60% cis and 40% trans isomers. The same was found to apply to all synthetic intermediates in that series. Unequivocal assignments of configuration were made by relating various intermediates leading to (IX) and its analogs to D-*cis*-1,3-dimethyl-1,3-dioxolane itself, obtained by degradation of 1,6-anhydrogalactose. Attempted separation of cis–trans isomers in the 1,3-dioxolane series was not successful. However, a mixture of *cis*,*trans*-2-trichloromethyl-4-hydroxymethyl-1,3-dioxolane (XVI) could be fractionated by crystallization of the corresponding tosylates. Catalytic hydrogenolysis converted the pure *cis*- and *trans*-trichloromethyl derivatives (XVII) and (XVIII) to pure *cis*- and *trans*-2-methyl-4-hydroxymethyl-1,3-dioxolane tosylates (XIX) and (XX), which eventually afforded for the first time pure *cis*-F2268 and *trans*-F2268 (XXII) and (XXIII).

Optically active members in the 1,3-dioxolane series were prepared. Members of the D(−)-series were conveniently obtained from D-isopropylidene glycerol. Members of the L(+)-series could be obtained in optically impure forms by resolution of *dl*-tertiary bases such as (XXXVI) with D- and L-dibenzoyltartaric acid. The best preparations had an optical purity not exceeding 32%. The resolution of the cis base (X) was unsuccessful.

The synthesis of an oxazoline analog, (XLIV), of F2268 was accomplished. The reaction sequence involves solvolysis of N-acetyl-2,3-dibromo-*n*-propylamine (XLI) to give the 5-bromomethyl-2-methyloxazoline (XLII). This unstable intermediate was reacted with dimethylamine to give the tertiary base (XLIII), which was quaternized with methyl iodide whereupon the quaternary base (XLIV) was formed in good yield. The structure of the latter was established by an independent synthesis of the hydrolysis product (XLV).

Preliminary pharmacological data are reported for the various new quaternary salts. The compounds were assayed for cholinomimetic activity. It is concluded from these studies that quaternary 1,3-dioxolanes display structure-activity relationships analogous to the muscarones. The use of triethylammonium analogs has revealed a large degree of preference of cholinergic receptors for the presence of a cis configuration in 2,4-disubstituted-1,3-dioxolanes. It was also noted that the oxazoline derivative (XLIV) ranks amongst the most active cholinomimetics thus far reported. Relationships between configuration and activity are briefly discussed.

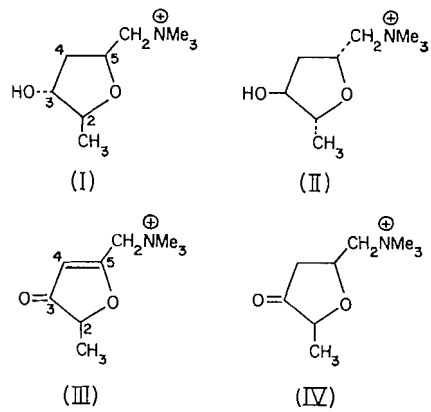
INTRODUCTION

The recent structure elucidation and synthesis of muscarine (1(*a*), 1(*b*)) has created renewed interest in the relationship between the structure and activity of drugs acting on the muscarinic cholinergic receptors. A variety of muscarine analogs have been synthesized and their cholinomimetic activity determined. This subject has been recently reviewed (2), and since then, Waser (3) has examined a number of additional structural analogs. Mention should also be made of the report of Friess, Witkop, and co-workers (4) on the inhibitory properties of a number of muscarine-related compounds towards acetylcholinesterase. It emerges from all these important studies that the optimal structural requirements for muscarinic activity are as follows: (1) The muscarinic receptor displays an almost absolute optical specificity, the non-natural enantiomorph (II)

[1]*Holder of a National Research Council of Canada Postdoctoral fellowship, 1959–1961.*

(Chart 1) being essentially inactive (5, 6). (2) The relative configuration of the substituents on the furan ring of natural muscarine represents also the optimum geometry

CHART 1



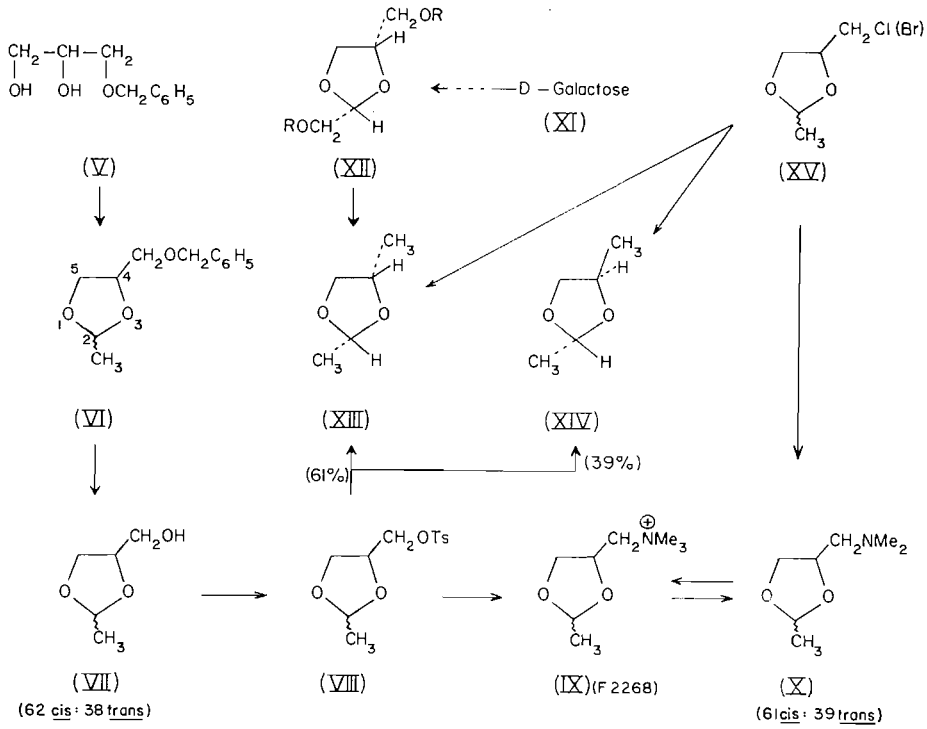
for activity. (3) The asymmetric center at position 5 can be destroyed as in 4,5-dehydromuscarone (III) without drastically changing the activity (7). However, inversion of configuration at the same position but in muscarine is detrimental to activity. The asymmetric center at position 2 is relatively unimportant in the muscarones (IV) (8) but of critical importance in muscarine. (4) The presence of a methyl group at C2 leads to maximum activity; its absence (9, 10), or its substitution for a larger group is detrimental to activity (10). (5) Replacing the furan oxygen by sulphur decreases potency (10). (6) The muscarinic receptor does not display absolute optical specificity towards the muscarones and 4,5-dehydromuscarone, in marked contrast to the specificity towards the muscarine enantiomorph (I) (3, 7, 8).

Some attempts at the interpretation of these unusual and puzzling structure-activity relationships have been made (11) and this problem will be dealt with in a future publication. There is little doubt that much knowledge about the nature of muscarinic receptors will be gained when the stereochemical interrelationships become understood. Some interesting generalizations concerning the optimum structural requirements for cholinomimetic activity have been put forward by Ing (11). The kinetics of drug interaction with cholinergic receptors has been examined in considerable detail, especially by Ariëns and van Rossum (12), who extended the original approach of Clark (13). The principles governing the ability of a drug receptor complex to produce an effect were defined in kinetic terms by Ariëns, Stephenson (14), and more recently by Paton (15). It is now recognized that the properties of drugs can best be quantitated in terms of their intrinsic activity, affinity for receptors, and rate of combination with the latter. In spite of these important contributions to the field of receptor theory, the biochemical nature of cholinergic receptors remains unsolved. We have initiated a program aimed at the elucidation of the stereochemical requirements for muscarinic activity with the hope that these studies might throw light on the nature of the receptors.

It has long been known that certain 1,3-dioxolanes exhibit a high degree of parasympathomimetic activity, a discovery due to Fourneau and his collaborators (16). The most active member of this series is 2-methyl-4-trimethylammoniummethyl-1,3-dioxolane

(IX) (Chart 2), which was reported to match muscarine in potency. All of the structural analogs of (IX) appear to be less active. The structural relationship of (IX) with muscarine

CHART 2



and its analogs is obvious and it was of interest to examine the relation between stereochemistry and activity in the Fourneau series. The effect of structural variations about the 2-position and the cationic head of (IX) has been studied by van Rossum and Ariëns (17), who confirmed the operation of the concept of affinity and intrinsic activity in this series. However, the stereochemistry of (IX) in relation to activity has not been investigated. Because activity in the muscarine series is highly dependent on configuration, relative and absolute, similar dependency would be expected in the Fourneau compound (IX). It is a rather curious phenomenon that the configuration of (IX) has never been established, and of the two possible stereoisomers, only one appears to have ever been obtained or prepared. It is not known as yet whether the high activity of (IX) is associated with a trans or cis configuration about the 2- and 4-positions, a situation which, however, has been clarified in the muscarine series. The optical forms of any quaternary-1,3-dioxolanes have also never been reported or tested. The possible inhibitory effect of these drugs on acetylcholinesterase has also not been investigated.

In this first paper of a series, the synthesis and the configuration of (IX) and a number of analogs will be described. Subsequent publications will deal with their effect on acetylcholinesterase and with generalizations regarding the probable nature of the muscarinic cholinergic receptors.

Relative Configuration of (IX)

The method most generally employed for the synthesis of 2-methyl-4-trimethylammoniummethyl-1,3-dioxolane iodide (IX) (F2268) involves the reaction of epichlorohydrin with acetaldehyde in the presence of stannic chloride whereupon the intermediate 2-methyl-4-chloromethyl-1,3-dioxolane (XV) is produced and thence reacted with dimethylamine to give (X), which is finally quaternized using methyl iodide (16). The quaternary salt (IX) so obtained has been repeatedly reported to melt sharply at 140–141° and we have confirmed this. van Rossum (17) has also showed it to be apparently homogeneous as judged from results of paper chromatography. A total of 38 homologous structures in this series were prepared by this author and all were reported to melt sharply and to give rise to single spots when chromatographed on paper.

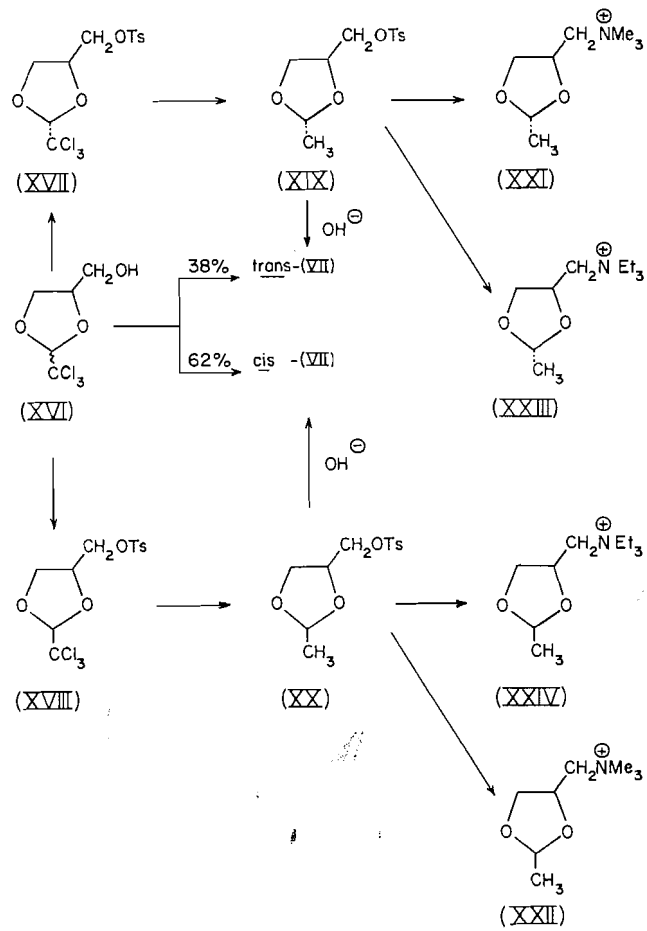
Since the relative configuration of (IX) must be the same as that of the starting dioxolane (XV), we sought to establish the configuration of the latter by relating it to a 2,4-dimethyl-1,3-dioxolane of proven configuration. The reaction of propylene glycol with acetaldehyde has been reported to give a mixture of *cis*- and *trans*-2,4-dimethyl-1,3-dioxolane, (XIII) and (XIV), which has been claimed to be separable by fractional distillation (18). In our hands this separation proved to be far from complete (see Experimental); the fraction of lower boiling point has been assigned the cis configuration. Because of our need for a much more rigorous proof of configuration we sought to synthesize the cis isomer by unambiguous methods. Cleavage of 1,6-anhydrogalactose to D-*cis*-1,3-dioxolane-2,4-dicarboxaldehyde has been reported in the literature (19). Reduction of the latter with sodium borohydride gave the cis diol (XII) (Chart 2), which gave a crystalline di-*p*-nitrobenzoate and a crystalline ditosylate. Attempts to prepare a monotosylate were fruitless, a bicyclic ether being presumably the only product. Hydrogenolysis of the ditosylate with lithium aluminum hydride afforded D-*cis*-2,4-dimethyl-1,3-dioxolane (XIII), which gave rise to a single sharp peak in the vapor phase chromatography (v.p.c.) instrument.

The dioxolane (VI) resulting from the condensation of glycerol 1-monobenzyl ether and acetaldehyde was hydrogenolyzed and the resulting 2-methyl-4-hydroxymethyl-1,3-dioxolane (VII) converted to a crystalline tosylate, (VIII), which eventually afforded F2268 (IX) after reaction with dimethylamine followed by quaternization with methyl iodide. The identity of this material was ascertained by direct comparison (infrared and n.m.r.) with a sample obtained by the general literature method outlined earlier. Hydrogenolysis of the intermediate tosylate (VIII) with lithium aluminum hydride or catalytic hydrogenolysis of the 4-chloromethyl intermediate (XV) afforded 2,4-dimethyl-1,3-dioxolane, which was shown by v.p.c. to consist of a mixture of cis–trans isomers in a ratio of 60:40 (authentic D-*cis*-2,4-dimethyl-1,3-dioxolane (XIII) being used as a standard). In order to establish that crystallization of the quaternary base (IX) did not change the isomer ratio, it was submitted to N-dealkylation by treatment with lithium aluminum hydride (20) and the tertiary base (X) analyzed by v.p.c. The cis–trans isomer ratio proved to be 61:39, thus conclusively establishing that F2268 consists of a mixture of cis and trans isomers in a ratio closely approximating 60:40. This conclusion was confirmed by n.m.r. spectroscopy, which showed clearly the presence of two split methyl groups in a ratio of 60:40 (see Experimental). Moreover, identical v.p.c. patterns were obtained with the product resulting from the reaction of propylene glycol and acetaldehyde. Therefore the synthesis of (IX) proceeds non-stereospecifically and all the intermediates consist of a mixture of 60% of cis and 40% of trans isomers. We have subsequently found this to apply to virtually all solid derivatives in this series. It is clear that *cis*- and *trans*-2,4-disubstituted-1,3-dioxolanes crystallize as molecular compounds and display very

great similarities in their physical properties. Since the time F2268 (IX) was first synthesized *all the pharmacological properties reported for it are, therefore, those of a 60:40 mixture of the cis and trans isomers.* The same would appear to apply to all other homologs, as judged from additional observations recorded below. In view of the structural analogy of (IX) with muscarine, none of the previous pharmacological data can be relied upon for purposes of correlation between stereochemistry and activity.

Numerous attempts to achieve separation of the isomers of (IX) or its precursors on a practical scale by a combination of various techniques were fruitless. However, both the cis and the trans isomers of (IX) could eventually be obtained in pure form by an indirect synthetic route which is described below (Chart 3).

CHART 3



It was found that the reaction product of glycerol and chloral (XVI) (Chart 3) gave a crystalline tosylate melting over a wide range, thus indicating that molecular compound formation was apparently suppressed in this type of 1,3-dioxolane. This proved to be the case, since fractional crystallization of the tosylate led to the isolation of two sharp-melting isomers, isomer A (XVII), m.p. 133–134°, and isomer B (XVIII), m.p. 95–96°. The trichloromethyl group of each isomer was converted to methyl by catalytic hydrogenolysis. The resulting tosylate (XIX) from A had m.p. 66–68° and when submitted to

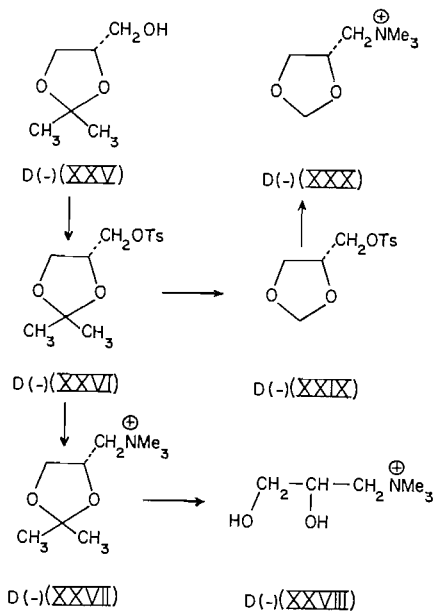
aqueous alkaline hydrolysis gave pure *trans*-2-methyl-4-hydroxymethyl-1,3-dioxolane (VII), as determined by v.p.c. Similarly, the tosylate (XX) from B had m.p. 64–66° and gave, after alkaline hydrolysis, pure *cis*-2-methyl-4-hydroxymethyl-1,3-dioxolane (VII), as established by v.p.c. Reaction of the pure trans tosylate (XIX) with dimethylamine followed by quaternization with methyl iodide afforded *trans*-2-methyl-4-trimethylammoniummethyl-1,3-dioxolane (XXI) (*trans*-F2268), m.p. 131–132°. The homogeneity of the product was confirmed by n.m.r. spectroscopy (single methyl doublet). Similar treatment of the pure cis tosylate (XX) gave *cis*-2-methyl-4-trimethylammoniummethyl-1,3-dioxolane (XXII) (*cis*-F2268), m.p. 143–144°. The n.m.r. spectrum of this compound also proved it to be homogeneous. *This is the first time that the powerful cholinomimetic F2268 becomes available in its pure stereoisomeric forms.*

In view of the fact that the experimental basis for the concept of affinity and intrinsic activity as elaborated by Ariëns and van Rossum lies principally on the inversion of agonistic activity when a trimethylammonium cationic head is changed for a triethylammonium one, it was of interest to prepare the pure *cis*- and *trans*-triethylammonium analogs (XXIV) and (XXIII) of *cis*- and *trans*-F2268. It should be emphasized that Ariëns and van Rossum used what we now recognize to be a 60:40 mixture of cis–trans isomers, thus preventing any definite conclusion regarding the effect of stereochemistry on the cholinolytic activity of triethylammonium analogs.

Synthesis in the Optically Active Series

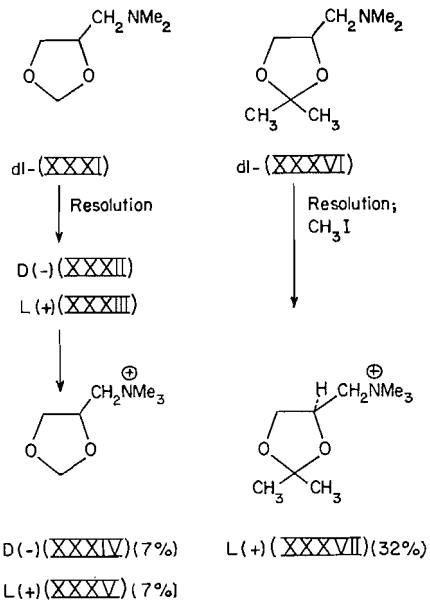
Because of the dramatic difference in cholinomimetic activity between optical isomers in the muscarine series, it was of interest to make available a number of optical isomers in the 1,3-dioxolane series. Quaternary salts of the D-series could be prepared in optically pure forms from optically pure D-isopropylidene glycerol (XXV) (Chart 4). The latter could be converted by way of the D-tosylate (XXVI) to D(−)-2,2-dimethyl-4-trimethylammoniummethyl-1,3-dioxolane iodide (XXVII). The preparation of the 2,2-bisnor

CHART 4



analog (XXX) in optically pure form was best accomplished by mild acid hydrolysis of D-isopropylidene glycerol tosylate (XXVI) followed by condensation with formaldehyde whereupon the tosylate (XXIX) was obtained. Conversion of the latter to D(−)-4-trimethylammoniummethyl-1,3-dioxolane iodide (XXX) was accomplished in the conventional manner described above. In order to gain access to the L-series, the resolution of the corresponding racemic tertiary bases was investigated (Chart 5). Racemic

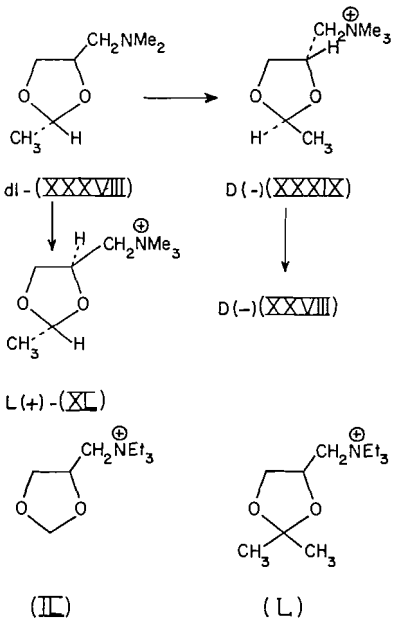
CHART 5



4-dimethylaminomethyl-1,3-dioxolane (XXXI) gave crystalline D- and L-dibenzoyltartrates (XXXII) and (XXXIII), which were recrystallized to constant rotation. The bases were regenerated and converted to the methiodides (XXXIV) and (XXXV). The levorotatory salt is therefore of the D-series. The rotations showed them to be only 7% optically pure. This difficulty in achieving resolution must again reflect the tendency for diastereoisomers of the 2,4-disubstituted-1,3-dioxolane series to crystallize as molecular compounds. Because L-dibenzoyltartaric acid gives rise to (+)-dioxolanes of the L-series, the 2,2-dimethyl tertiary base (XXXVI) (Chart 5) was converted to a crystalline L-dibenzoyltartrate which was recrystallized to constant rotation. Regeneration of the base followed by quaternization with methyl iodide gave L(+)-2,2-dimethyl-4-trimethylammoniummethyl-1,3-dioxolane iodide (XXXVII), which was 33% optically pure.

Application of these procedures to racemic *cis*- and *trans*- (X) was only partially successful. With *cis*-(X) it was not possible to obtain crystalline dibenzoyltartrate salts. However, *trans*-(XXXVIII) (Chart 6) gave a crystalline D-dibenzoyltartrate which was recrystallized to constant rotation. Regeneration of the base and quaternization in the usual way gave D(−)-*trans*-F2268 (XXXIX). The optical purity of the latter was established as follows: It was hydrolyzed with dilute hydrochloric acid and the rotation of the resulting quaternary diol (XXVIII) determined. Comparison of this rotation with that of an optically pure sample (Chart 4) derived from optically pure D(−)-(XXVII) by acid hydrolysis under identical conditions showed the D(−)-*trans*-(XXXIX) to be 32%

CHART 6



optically pure. Using again *trans*-(XXXVIII) but L-dibenzoyl tartaric acid as the resolving agent, L(+)-*trans*-F2268 (XL) was ultimately obtained with an optical purity of 32% (Chart 6).

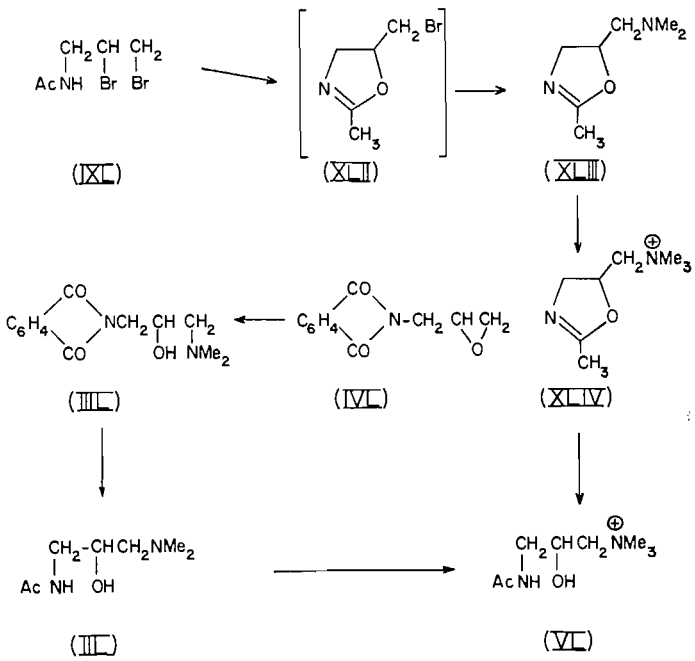
With these isomers of variable optical purity it should be possible to establish whether activity will depend on absolute configuration, as is the case in the muscarine series. If the analogy between muscarine and the 2,4-disubstituted-1,3-dioxolane is real, it would be expected that the isomers of the L(+)-series should similarly be more active cholinomimetics. It will also be of interest to determine the anti-acetylcholinesterase inhibitory property of the various isomeric forms of the above quaternary dioxolanes. This aspect of our work will be reported separately.

Synthesis of 5-Trimethylammoniummethyl-2-methyl-oxazoline Bromide (XLIV)

Perhaps one of the most striking aspects of structure-activity relationships in the muscarine series is the observation that racemic 4,5-dehydromuscarone (III) surpasses L(+)-muscarine in potency (Chart 1). Because D(−)-muscarine displays a very low order of activity, it is surprising that the absence of an asymmetric center at position 5 of 4,5-dehydromuscarone should lead to such a highly active cholinomimetic. Moreover, and in sharp contrast to the muscarine series, the relative configuration of the methyl group in the muscarone series is relatively unimportant, racemic allomuscarone (*trans*-(IV)) being only slightly less active than racemic muscarone (*cis*-(IV)). This result also suggests that destruction of the asymmetric center at position 2 through the introduction of a double bond between carbons 2 and 3 (if this were feasible) might not alter activity in the muscarone series. While this problem is being investigated, it appeared of more immediate interest to transpose this reasoning to the 1,3-dioxolane series and it is obvious that in order to produce a trigonal carbon at position 2 of 1,3-dioxolanes, it is essential that the oxygen atom at position 1 be substituted by a trivalent heteroatom such as

nitrogen. It should be noted that no oxazoline analog in the Fourneau series of cholinomimetics has as yet been reported. Several of the most obvious methods for the synthesis of the desired analog (XLIV) (Chart 7) of (IX) proved unsuccessful. A convenient and

CHART 7



expedient method of synthesis was ultimately discovered which requires the readily available starting material N-allyl acetamide. This was converted to the dibromide (XLI) (Chart 7) as described elsewhere and then solvolyzed in acetonitrile in the presence of silver carbonate. The participation of neighboring amido groups in such solvolyses has previously been demonstrated (21) and allows the prediction that the dibromide (XLI) must be converted largely to 5-bromomethyl-2-methyl-oxazoline (XLII). Attempts to isolate this intermediate were unsuccessful, rapid polymerization of the compound taking place upon removal of the solvent. However, if excess anhydrous dimethylamine was added to the reaction mixture as soon as maximum precipitation of silver bromide had occurred, a good yield of 2-methyl-5-dimethylaminomethyloxazoline (XLIII) was obtained. Quaternization of the latter with methyl iodide finally gave the crystalline salt (XLIV) in high yield. It was desirable to establish the structure of the latter by unambiguous means, since the course of the solvolysis can only be inferred. The quaternary base (XLIV) was hydrolyzed with hot water to give a quantitative yield of 1-acetamido-3-trimethylammonium-2-propanol iodide (XLV). An authentic specimen of the latter was secured by reacting 1-phthalimido-2,3-epoxypropane (XLVI) with dimethylamine, whereupon (XLVII) was produced. Hydrolysis of the latter followed by acetylation and quaternization with methyl iodide afforded (XLV), which proved to be identical with the sample obtained by hydrolysis of the oxazoline (XLIV). It is clear that this method of synthesis of (XLIV) could be extended to the preparation of a variety of trialkylammonium analogs.

PRELIMINARY PHARMACOLOGICAL RESULTS*

The various quaternary dioxolanes and the oxazoline derivative (XLIV) were assayed for muscarinic activity using the guinea pig ileum as the test organ. The minimum concentration of drug necessary to elicit a response is recorded in Table I. Of immediate

TABLE I

Compound number	Concentration, mg/ml, guinea pig ileum ($c \times 10^{-7}$)	Compound number	Concentration, mg/ml, guinea pig ileum ($c \times 10^{-7}$)
Acetyl choline	2.5	L(+)-(XXXIX)†	12.5
(XXI)	12.5	L(+)-(XL)†	0.125
(XXII)	2.5	(XXIII)	500,000.
(XXX)	5,000.	(XXIV)	500.
D(−)-(XXVII)	250,000.	(XLIV)	2.5
L(+)-(XXXV)*	2,500.	(IL)	500,000.
L(+)-(XXXVII)†	2,500.	(L)	5,000,000.

*Optical purity of this isomer is 7%.
†Optical purity is 32%.

interest is the fact that quaternary compounds of the L(+)-series are uniformly much more active than their D(−) counterparts. Hence, the same absolute configurational requirement as in the muscarine series is operative. It is also interesting that *cis*-F2268 (XXII) surpasses *trans*-F2268 (XXI) in potency by a factor of 5. This also parallels the effect of epimerization about the C_2-methyl group of muscarine, racemic allomuscarine being very much less active. However, the magnitude of the differences in potency between *cis*-(XXII) and *trans*-(XXI) on the one hand and (±)-muscarine and (±)-allomuscarine on the other is such as to indicate that the asymmetric center at C_2 of (XXI) and (XXII) is not nearly as important as it is in the muscarine series. In this respect, the ratio of the potencies of *cis*- and *trans*-F2268 suggests that they resemble the muscarones much more than the muscarines. It should be mentioned that Barlow had speculated that *cis*- and *trans*-F2268 would not differ greatly in potency because of a loose structural analogy with the muscarones (IV) (22). It is striking, however, that the L(+)-*trans*-F2268 (XL), which is only 32% optically active, should surpass acetylcholine in potency by a factor of 20. Consideration of the fact that a 32% enrichment in the L(+) isomer increases the potency by a factor of 100 over the pure racemic mixture (XXI) and that the cis racemate (XXII) is five times more active than the latter, suggests that the pure L(+) cis isomer of (XXI) should possess extraordinary potency surpassing all known cholinomimetic drugs. The synthesis of this L(+) cis isomer is under way.

Confirmation that the configuration of the asymmetric center at C_2 of F2268 may not be a critical factor (although it has an influence) for activity is supplied by the high cholinomimetic activity of the quaternary oxazoline (XLIV) in which C_2 is now trigonal. We are fully aware, however, that in this latter case, the presence of a basic nitrogen in the ring introduces an additional factor which may alter the mechanism of interaction with the receptors. We are presently attempting to establish whether the oxazoline (XLIV) interacts with the receptors in the protonated form or as the free base.

Of great interest finally is the marked difference in the relative potencies of the triethylammonium analogs (XXIV) and (XXIII) of *cis*- and *trans*-(F2268). In contradiction with the conclusions regarding the significance of the asymmetric center at C_2 of F2268

Results of our work and that of Dr. M. Pindell and his staff, Bristol Laboratories, Syracuse, N.Y.

(IX), it appears that *in the triethylammonium series (XXIII) and (XXIV) the configuration of the C_2 methyl group is of critical importance.* An interpretation of these results will be given in a forthcoming publication.

EXPERIMENTAL*

cis,trans-2-Methyl-4-hydroxymethyl-1,3-dioxolane (VII)

This was prepared according to the method of Brimacombe, Foster, and Haines (23). The pure alcohol was analyzed by v.p.c. and shown to consist of a mixture of cis–trans isomers in a ratio of 64:36. (see Table II, entry 1). The *tosylate (VIII)* was prepared by treatment with *p*-toluenesulphonyl chloride and

¶Lower-boiling fraction.
**Higher-boiling fraction.

pyridine at 0°, whereupon an oily tosylate was obtained which crystallized from hexane as colorless needles, m.p. 49–53°. Yield: 74%. Calc. for $C_{12}H_{16}SO_5$: C, 52.9; H, 5.9. Found: C, 52.9; H, 5.9%.

cis,trans-2,4-Dimethyl-1,3-dioxolane (XIII) and (XIV)

A solution of the tosylate of *cis,trans*-2-methyl-4-hydroxymethyl-1,3-dioxolane (VIII) (13.5 g, 0.05 mole) in diglyme was added dropwise to a stirred solution of lithium aluminum hydride (1.9 g, 0.05 mole) in diglyme at 100°. The mixture was kept at this temperature for 2 hours, cooled, and treated with 10% sodium hydroxide and distilled (bath temperature 150°). The distillate was dried (Na_2SO_4) and redistilled to give *cis,trans*-2,4-dimethyl-1,3-dioxolane (4.4 g, 86%), b.p. 90–95°. The results of the vapor phase chromatographic analysis are given in Table II (entry 2).

Attempted Separation of cis and trans Isomers of 2,4-Dimethyl-1,3-dioxolane (XIII) and (XIV)

Two hundred grams of the cis–trans mixture was prepared according to the method of Lucas and Guthrie (18). Repeated fractional distillation and vapor phase chromatographic examination of the fractions revealed an increase in the cis content of the lower-boiling fraction and an increase in the trans content of the higher-boiling fraction, but as the results in Table II (entries 10 and 11 respectively) show, the separation was far from complete.

cis,trans-2-Methyl-4-dimethylaminomethyl-1,3-dioxolane Methiodide (IX)

cis,trans-2-Methyl-4-toluenesulphonyloxymethyl-1,3-dioxolane (VIII) (13.5 g, 0.05 mole) was dissolved in 100 ml of a 30% solution of anhydrous dimethylamine in benzene and kept at 100° for 12 hours; the mixture was cooled, filtered, and the excess dimethylamine removed by heating on the steam bath. Addition of an excess of methyl iodide gave a near quantitative yield of the quaternary iodide; crystallization from isopropanol gave colorless needles (82%), m.p. 141° (unchanged on further crystallization). The n.m.r. spectrum (in pyridine) showed two methyl doublets with an intensity ratio of 3:2.

**All melting points were determined microscopically on a Kofler hot stage and are uncorrected. The boiling points are also uncorrected. Infrared spectra were determined using a Perkin–Elmer Infracord instrument. The n.m.r. spectra were recorded with a Varian instrument operating at 60 Mc. Microanalyses by Miss E. Busk, Chemistry Department, University of Ottawa.*

cis,trans-2-Methyl-4-dimethylaminomethyl-1,3-dioxolane (X)

The finely powdered preceding methiodide (IX) (7.2 g, 0.025 mole) was suspended in diglyme (20 ml) with lithium aluminum hydride (0.025 mole) and the reaction mixture heated to 150° for 6 hours and then decomposed with 10% sodium hydroxide (10 ml), filtered, saturated with salt, and extracted several times with ether to give *cis,trans*-2-methyl-4-dimethylaminomethyl-1,3-dioxolane (2.6 g, 71.2%). The results of the vapor phase chromatographic analysis are given in Table II (entry 3).

cis,trans-2-Methyl-4-chloro- (or bromo-) methyl-1,3-dioxolane (XV)

These were prepared from glycerol α-monochlorhydrin or monobromhydrin and acetaldehyde by reaction in boiling benzene, the water being continuously removed with a Dean–Stark trap. The results of the vapor phase chromatography experiments are given in Table II (entries 4 and 5). The configurations were established by hydrogenolysis to the corresponding 2,4-dimethyl-1,3-dioxolanes as follows: *cis,trans*-2-methyl-4-halomethyl-1,3-dioxolane (0.1 mole) in absolute ethanol in which was suspended sodium bicarbonate (0.5 mole) and 10% Pd/C (0.5 g) was reduced at 3 atm pressure of hydrogen for 3 hours. The reaction mixture was filtered and a sample of the filtrate analyzed by vapor phase chromatography to give the results shown in Table II (entries 6 and 7). These results (Table II) confirm the configurations suggested by vapor phase chromatographic analysis of the halomethyl derivatives themselves (see above).

D-*cis-2,4-(Dihydroxymethyl)-1,3-dioxolane (XII)*

Crude 1,3-dioxolane-*cis*-2,4-dicarboxaldehyde (19) (0.1 mole) was dissolved in absolute methanol and cooled in ice. A solution of sodium borohydride (6.0 g, 0.15 mole) in water was added dropwise with stirring at 10–15°. Stirring at room temperature was continued for a further 3 hours, 25 ml of 10% sodium hydroxide was added, and carbon dioxide bubbled in until the solution was saturated. The solution was evaporated to dryness and the residue extracted with ethyl alcohol to give D-*cis*-2,4-bis(hydroxymethyl)-1,3-dioxolane (XII) as a viscous oil (12.1 g, 90.3%). Calc. for $C_5H_{10}O_4$: C, 44.8; H, 7.5. Found: C, 44.3; H, 7.1%. Without further purification, this D-*cis*-2,4-(dihydroxymethyl)-1,3-dioxolane (6.7 g, 0.05 mole) was dissolved in dry pyridine and the solution added dropwise to a stirred and cooled solution of *p*-nitrobenzoyl chloride (20.5 g, 0.11 mole) in dry pyridine; after 12 hours the reaction mixture was poured over ice, filtered, washed with ice-cold water, dried, and recrystallized from benzene to give the *cis*-bis(2,4-dinitrobenzoate) as very pale yellow needles (15.0 g, 71.2%), m.p. 94°. $[\alpha]_D^{22} = -18.5°$ (c = 1.2, acetone). Calc. for $C_{19}H_{16}N_2O_{10}$: C, 52.8; H, 3.7. Found: C, 52.6; H, 3.3%.

The *bis(dinitrobenzoate)* (10.8 g, 0.025 mole) was dissolved in aqueous ethanol (100 ml) containing sodium hydroxide (6 g) and heated under reflux for 5 hours. The solution was cooled, saturated with carbon dioxide, evaporated to dryness, and extracted with absolute ethanol to give D-*cis*-2,4-(dihydroxymethyl)-1,3-dioxolane (XII) (2.5 g, 74.6%) as a viscous oil. Calc. for $C_5H_{10}O_4$: C, 44.8; H, 7.5. Found: C, 44.3; H, 7.2%.

The pure D-*cis-(2,4-dihydroxymethyl)-1,3-dioxolane* (2.0 g, 0.015 mole) so obtained was dissolved in dry pyridine at 0°, and *p*-toluenesulphonyl chloride (6 g, 0.033 mole) was added. After 24 hours at room temperature a large excess of ether was added and the solution was extracted with 10% hydrochloric acid until free from pyridine. The ethereal solution was dried (Na_2SO_4), filtered, and evaporated to give the ditosylate as colorless needles (4.4 g, 66%), m.p. 84–86°. $[\alpha]_D = -25.5$ (c = 2, acetone). Calc. for $C_{19}H_{22}S_2O_8$: C, 51.6; H, 5.0. Found: C, 52.1; H, 5.1%.

D-*cis-2,4-Dimethyl-1,3-dioxolane (XIII)*

This was prepared by lithium aluminum hydride reduction of the preceding ditosylate by the procedure described above in the case of the preparation of *cis,trans*-2,4-dimethyl-1,3-dioxolane (XIII) + (XIV). The yield of crude D-*cis*-2,4-dimethyl-1,3-dioxolane was only 23% and the quantity was not sufficient for purification and empirical analysis. However, vapor phase chromatographic analysis was unambiguous as it showed that the compound could only be pure *cis*-2,4-dimethyl-1,3-dioxolane (XIII) (Table II, entry 8).

cis,trans-2-Trichloromethyl-4-hydroxymethyl-1,3-dioxolane (XVI)

This was prepared according to the method of Hibbert (24). It was found that by increasing the reaction temperature and time to 90° and 24 hours respectively the yield was increased to 65–70%.

The dioxolane so obtained (22.0 g, 0.1 mole) was dissolved in 80% aqueous methanol (100 ml) containing sodium bicarbonate (33.6 g, 0.4 mole) and 10% Pd/C (0.5 g). The mixture was reduced at 5 atm pressure of hydrogen for 5 hours. The solution was filtered and distilled to give *cis,trans*-2-methyl-4-hydroxymethyl-1,3-dioxolane (VII) (7.5 g, 63.5%), b.p. 70–75° at 8 mm. The isomer ratio was 62:38 (Table II, entry 9). Calc. for $C_5H_{10}O_3$: C, 50.9; H, 8.5. Found: C, 51.1; H, 8.6%.

Separation of cis,trans-2-Trichloromethyl-4-hydroxymethyl-1,3-dioxolane (XVI)

The above trichloromethyl dioxolane (892 g, 4.0 moles) was dissolved in dry pyridine (1.5 liters) and the solution cooled to 0° and treated with *p*-toluenesulphonyl chloride (840 g, 4.4 moles) over a period of 12 hours. The reaction mixture was then allowed to stand for 24 hours at room temperature and then poured into 5 liters of ice water. The precipitate was filtered, washed with water, and dried in air to give the *p*-toluenesulphonate (1495 g, 99%), white needles, m.p. 110–120°, which upon repeated recrystallization from methanol yielded the trans tosylate (XVII), m.p. 133–134° (250 g). Calc. for $C_{12}H_{13}SO_5Cl_3$: C, 38.3;

H, 3.5. Found: C, 38.1; H, 3.4%. The mother liquors from the first crystallization yielded, on repeated crystallization from methanol, the cis tosylate (XVIII), m.p. 95–96° (130 g). Found: C, 38.4; H, 3.4%.

cis- and trans-2-Methyl-4-hydroxymethyl-1,3-dioxolanes (cis-VII) and (trans-VII)

The preceding trans tosylate (XVII) (19.0 g, 0.05 mole) was added to 200 ml of aqueous methanol (1:1, v/v) together with sodium bicarbonate (14.8 g, 0.2 mole) and hydrogenated at 3–5 atm pressure with 10% Pd/C catalyst (0.5 g) for 24 hours to give the trans tosylate (XIX), m.p. 66–68°; yield 10.1 g. It was recrystallized from pentane. Calc. for $C_{16}H_{16}SO_5$: C, 52.9; H, 5.9. Found: C, 52.7; H, 5.9%. By the same procedure, the cis tosylate (XVIII) gave the cis tosylate (XX), m.p. 64–66°; yield 9.8 g. It was recrystallized from pentane. Calc. for $C_{12}H_{16}SO_5$: C, 52.9; H, 5.9. Found: C, 52.9; H, 5.6%.

The trans tosylate (XIX) (5.4 g, 0.02 mole) was heated under reflux for 4 hours with a 10% excess of sodium hydroxide in 70% aqueous ethanol. The solution was then saturated with carbon dioxide, evaporated to dryness, and the residue extracted with absolute ethyl alcohol to give chromatographically pure (v.p.c.) *trans*-2-methyl-4-hydroxymethyl-1,3-dioxolane (*trans*-VII), b.p. 76–80° at 9 mm (2.1 g, 70.0%). Similarly, the cis tosylate (XX) yielded chromatographically pure (v.p.c.) *cis*-2-methyl-4-hydroxymethyl-1,3-dioxolane (*cis*-VII), b.p. 78–80° at 10 mm (2.0 g, 67.0%).

Lithium aluminum hydride reduction of the trans tosylate (XIX) and the cis tosylate (XX) by the procedure described above in the case of (VIII) gave the corresponding pure *cis*- and *trans*-2,4-dimethyl-1,3-dioxolanes, as evidenced by v.p.c.

cis- and trans-2-Methyl-4-dimethylaminomethyl-1,3-dioxolane Methiodides (XXII) and (XXI)

cis- and *trans*-2-Methyl-4-*p*-toluenesulphonyloxymethyl-1,3-dioxolanes (XX) and (XIX) (5.4 g, 0.02 mole) were converted into the corresponding 4-dimethylaminomethyl derivatives by the method described above for the mixture of cis–trans isomers. Treatment with methyl iodide and crystallization from ethyl acetate – isopropanol gave pure *cis*-(XXII) and pure *trans*-2-methyl-4-dimethylaminomethyl-1,3-dioxolane methiodides (XXI), m.p. 143–144° and 131–132° respectively. Calc. for: $C_8H_{18}N_1O_2I$: (*trans*): C, 33.5; H, 6.3. Found: (*cis*): C, 33.8; H, 6.1; (*trans*): C, 33.6; H, 6.2%. The n.m.r. spectra (in pyridine) of both isomers showed a single methyl doublet.

cis- and trans-2-Methyl-4-diethylaminomethyl-1,3-dioxolane Ethiodides (XXIV) and (XXIII)

These were prepared in a way similar to that used for the corresponding 4-dimethylaminomethyl compounds. Pure *trans*-2-methyl-4-diethylaminomethyl-1,3-dioxolane ethiodide (XXIII) had m.p. 129–131° (from isopropanol – ethyl acetate) but the cis isomer (XXIV) failed to crystallize. Calc. for $C_{11}H_{24}NO_2I$: C, 40.2; H, 7.3. Found: (*trans*): C, 40.4; H, 7.0; (*cis*): C, 40.5; H, 7.1%.

Other Quaternary Salts of 1,3-Dioxolanes

These were the previously known 4-dimethylaminomethyl- and 2,2-dimethyl-4-dimethylaminomethyl-1,3-dioxolane methiodides (*dl*-XXX) and (*dl*-XXVII), and the 4-diethylaminomethyl- and 2,2-dimethyl-4-diethylaminomethyl-1,3-dioxolane ethiodides (IL) and (L). Their physical constants agreed with the literature values (16).

Resolution of 4-Dimethylaminomethyl-1,3-dioxolane (XXXI)

The amine (XXXI) (0.15 mole) was dissolved in dry ether, and a solution of D-dibenzoyltartaric acid (0.15 mole) in dry ether added and the mixture allowed to stand overnight. The ether was decanted and the viscous precipitate recrystallized to constant rotation from ethanol to give 13.0 g of colorless crystals, m.p. 131–132°, $[\alpha]_D^{20} = -90°$ ($c = 2$, methanol). Calc. for $C_{24}H_{25}NO_{10}$: C, 59.1; H, 5.2. Found: C, 59.0; H, 5.7%.

It was not possible to obtain the (+)-salt from the mother liquors. The above procedure was therefore repeated using L-dibenzoyltartaric acid, whereupon the (+)-salt was obtained in the same state of purity as the (−)-salt.

The free bases were regenerated from the (+)- and (−)-salts by treatment in dry ethanol with an equimolar amount of sodium ethoxide. The precipitated disodium dibenzoyltartrates were removed by filtration after dilution with ether. The filtrate was treated with excess methyl iodide and the pure methiodides collected after 24 hours. Both had m.p. 157–158°. The *D(−)-quaternary salt* (XXXIV) had $[\alpha]_D^{20} = -2.2$ ($c = 2$, H_2O). The optical purity was 7% (see below). Calc. for $C_7H_{16}O_2NI$: C, 30.8; H, 5.9. Found: C, 30.9; H, 5.6%. The *L(+)-quaternary salt* (XXXV) had $[\alpha]_D^{20} = 2.2°$ ($c = 2$, H_2O). The optical purity was 7%. Calc. for $C_7H_{16}O_2NI$: C, 30.8; H, 5.9. Found: C, 30.9; H, 5.8%.

Optically Pure D(−)-4-Dimethylamino-1,3-dioxolane Methiodide (XXX)

D-Isopropylidene glycerol (25) was converted to the *tosylate* (XXVI) by the general procedure outlined above. It crystallized from hexane as colorless needles, m.p. 24–27°. Calc. for $C_{13}H_{18}O_5S$: C, 54.5; H, 6.3. Found: C, 54.7; H, 6.2%.

The *tosylate* was hydrolyzed by heating to 50° in excess 2 *N* hydrochloric acid for 4 hours. The solution was taken to dryness *in vacuo* and the residue reacted in benzene with paraformaldehyde in the presence of some *p*-toluenesulphonic acid. The water was continuously removed with a Dean–Stark trap and the product

isolated in the usual manner. It crystallized from benzene–pentane, m.p. 35.7°. This optically pure D(−)-4-tosyloxymethyl-1,3-dioxolane (XXIX) had $[\alpha]_D^{20} = -10.0°$ (c = 2, isopropanol). Calc. for $C_{11}H_{14}O_5S$: C, 50.5; H, 5.5. Found: C, 50.8; H, 5.4%.

This *tosylate* (*XXIX*) was converted to D(−)-4-dimethylaminomethyl-1,3-dioxolane methiodide (XXX) by the general procedure outlined above. The *methiodide* had m.p. 147–148° (isopropanol); $[\alpha]_D^{20} = -32.5°$ (c = 2, H_2O). Calc. for $C_7H_{16}O_2NI$: C, 30.8; H, 5.9. Found: C, 31.3; H, 5.8%.

D(−)-2,2-Dimethyl-4-dimethylaminomethyl-1,3-dioxolane Methiodide (XXVII)

The preceding tosylate of D-isopropylidene glycerol (XXVI) was reacted with dimethylamine and the resulting base quaternized with methyl iodide by the procedures described above. The quaternary iodide (XXVII) had m.p. 215–216° (ethanol); $[\alpha]_D^{20} = -12.0°$ (c = 2, H_2O). Calc. for $C_9H_{20}O_2NI$: C, 35.9; H, 6.7. Found: C, 36.1; H, 6.4%.

Of this quaternary salt, 200 mg was heated at 90° in excess 2 *N* hydrochloric acid for 5 hours. The solution was taken to dryness *in vacuo* and the residue (XXVIII) made up to 5 ml with water. The solution had $\alpha_D^{20} = -1.38°$. This solution was used as a standard for the determination of the optical purity of other dioxolanes described below.

L(+)-2,2-Dimethyl-4-dimethylaminomethyl-1,3-dioxolane Methiodide (XXXVII)

The corresponding tertiary base *dl*-2,2-dimethyl-4-dimethylaminomethyl-1,3-dioxolane (XXXVI) was resolved with L-dibenzoyltartaric acid in the same manner as described above in the case of (XXXI). The salt was recrystallized to constant rotation. It had m.p. 133–136°; $[\alpha]_D^{20} = 70°$ (c = 2, methanol). Calc. for $C_{26}H_{31}O_{10}N$: C, 60.35; H, 6.05. Found: C, 60.5; H, 6.2%.

This L-dibenzoyltartrate salt was decomposed as described above in the case of (XXXI) and the regenerated base reacted with methyl iodide whereupon the methiodide (XXXVII) was obtained, m.p. 204–208° (isopropanol). It had $[\alpha]_D^{20} = 4.0°$ (c = 2, H_2O). Since the rotation of the optically pure enantiomorph (XXVII) is −12.0°, the optical purity of this L(+)-isomer (XXXVII) is 33%. Calc. for $C_9H_{20}O_2NI$: C, 35.9; H, 6.7. Found: C, 36.1; H, 6.9%.

D(−)-trans-2-Methyl-4-dimethylaminomethyl-1,3-dioxolane Methiodide (XXXIX)

The tertiary base (XXXVIII) was resolved with D-dibenzoyltartaric acid by the same procedure outlined above in the case of (XXXI). The salt, obtained in 25% yield, was recrystallized to constant rotation, m.p. 131–132°, $[\alpha]_D^{20} = -84°$ (c = 2, methanol). Calc. for $C_{25}H_{27}O_{10}N$: C, 60.0; H, 5.4. Found: C, 60.3; H, 5.5%.

Regeneration of the base followed by quaternization with methyl iodide in the usual manner afforded the D(−)-methiodide (XXXIX), m.p. 100–110° (isopropanol), $[\alpha]_D^{20} = -8.25$ (c = 2, H_2O). Calc. for $C_8H_{18}ONI$: C, 33.5; H, 6.3. Found: C, 33.8; H, 6.1%.

A 200-mg portion of the methiodide was hydrolyzed in 2 *N* hydrochloric acid as described above in the case of (XXVII). The resulting quaternary diol (XXVIII) had $[\alpha]_D^{20} = -0.44°$. Since the pure D(−) quaternary diol had $[\alpha]_D^{20} = -1.38°$ under the same conditions, the optical purity of the D(−)-*trans*-methiodide (XXXIX) obtained by resolution is 32%.

L(+)-trans-2-Methyl-4-dimethylaminomethyl-1,3-dioxolane Methiodide (XL)

The same procedure just described above in the case of (XXXIX) was applied throughout except that L-dibenzoyltartaric acid was used. The L-dibenzoyltartrate salt of (XXXVIII) had m.p. 131–132°, $[\alpha]_D^{20} = 85°$ (c = 2, methanol). Calc. for $C_{25}H_{27}O_{10}N$: C, 60.0; H, 5.4. Found: C, 60.1; H, 5.8%.

The L(+)-methiodide (XL) had m.p. 100–110°, $[\alpha]_D^{20} = 8.3°$ (c = 2, H_2O).

The quaternary diol (XXVIII) obtained by hydrolysis had $[\alpha]_D^{20} = 0.44°$. The optical purity of the L(+)-*trans*-methiodide (XL) obtained by resolution is therefore 32%.

With *cis*-2-methyl-4-dimethylaminomethyl-1,3-dioxolane (*cis*-X) no crystalline salts with D- or L-dibenzoyltartaric acid could be obtained.

2-Methyl-5-dimethylaminomethyl-oxazoline (XLIII) and Its Methiodide (XLIV)

After several trial runs, the following procedure proved to be the most convenient: to a solution of 30 g of N-acetyl-2,3-dibromo-1-propylamine (IXL) (prepared by bromination of N-allyl acetamide according to the literature) (26) in 130 ml of dry acetonitrile was added, with stirring, 16 g of dry and freshly precipitated silver carbonate. When all the silver carbonate appeared to have been converted to silver bromide (about 1/2 to 1 hour), it was quickly filtered and 100 ml of a 20% solution of dry dimethylamine in benzene was added. The mixture was stirred and allowed to stand overnight. Another portion of 16 g of dry silver carbonate was added and the precipitated silver bromide filtered off. The filtrate was evaporated *in vacuo* at 40° and the residue distilled *in vacuo*; at 57–58° at 5 mm, 8.5 g of colorless liquid (XLIII) was obtained. It gave a strong band at 1675 cm^{-1} in the infrared. Calc. for $C_7H_{14}ON_2$: C, 59.15; H, 9.85. Found: C, 59.30; H, 10.0%.

The *methiodide* (XLIV) was obtained in high yield by reacting the base with 20% less than the theoretical amount of methyl iodide in acetone (a purer product is obtained in this manner). The yield of colorless crystals, m.p. 134.5–135°, was quantitative (based on methyl iodide). The product can be recrystallized from methanol–acetone. Calc. for $C_8H_{17}ON_2I$: C, 33.8; H, 5.98. Found: C, 33.7; H, 5.88%.

N-Acetyl-N'-dimethyl-1,3-diamino-2-propanol Methiodide (VL) by Hydrolysis of (XLIV)

A solution of 100 mg of the quaternary iodide (XLIV) was heated to 100° in distilled water for 60 hours. The water was evaporated *in vacuo* and the residue crystallized from methanol–acetone, m.p. 119–120°, unchanged by recrystallization. It proved identical with an authentic sample of (VL) synthesized as described below.

1-Phthalimido-3-dimethylamino-2-propanol (IIIL)

A solution of 1-phthalimido-2,3-epoxypropane (40 g) in 250 ml of 20% dimethylamine in benzene was heated to 100° for 4 hours. Evaporation of the solvent gave (IIIL) as a viscous oil. Calc. for $C_{13}H_{16}O_3N_2$: C, 62.8; H, 6.5; N, 11.29. Found: C, 62.3; H, 6.9; N, 11.01%.

N-Acetyl-N'-dimethyl-1,3-diamino-2-propanol Methiodide (VL)

The preceding phthalimido derivative (IIIL) was hydrolyzed by heating under reflux with concentrated hydrochloric acid for 10 hours. The phthalic acid was filtered from the cooled solution and the filtrate concentrated *in vacuo* to give the dihydrochloride salt as an uncrystallizable oil. A crystalline dipicrate, m.p. 207–209° (isopropanol), was prepared. Calc. for $C_{17}H_{20}O_{15}N_8$: C, 35.4; H, 3.5. Found: C, 35.4; H, 3.5%.

The N,N-dimethyl-1,3-diamino-2-propanol dihydrochloride (0.04 mole) was converted to the N'-acetyl derivative by reaction with an equimolar amount of acetic anhydride in some water containing 4 g of sodium acetate. The reaction mixture stood for 2 hours, was neutralized with sodium hydroxide, and evaporated to dryness. The residue was extracted with alcohol–ether and the extract distilled; at 130° at 0.01 mm the acetyl derivative (IIL) was obtained as a vicous oil which could not be induced to crystallize. Calc. for $C_7H_{16}O_2N_2$: C, 52.5; H, 10.1. Found: C, 52.65; H, 10.1%.

The *methiodide* was obtained in the usual manner and crystallized from methanol–acetone, m.p. 119–120°. No depression of the melting point was observed when it was admixed with a sample secured by hydrolysis of (XLIV) as described above. The infrared spectra of the two compounds (Nujol mull) were superimposable. Calc. for $C_8H_{19}O_2N_2I$: C, 31.8; H, 6.3. Found: C, 31.9; H, 6.0%.

NOTES

PHOTOCONDUCTION OF CRYSTALLINE 9,10-DIBROMOANTHRACENE AND 9,10-DICHLOROANTHRACENE

I. C. Smith and E. Bock

It is well known that the absorption and fluorescence emission characteristics in organic crystals can be derived on a molecular basis; i.e. by postulating that crystal interactions exert only a small perturbing influence on the molecules of the crystal, and that the molecules retain their individuality to a large extent in the crystalline lattice. Recently several authors have applied a similar treatment to the process of photoconduction in organic crystals (1–4). According to these theories the major contribution to the photocurrent comes from molecules which have undergone radiationless transitions from the first excited singlet states to the first triplet states (4).

Craig and Hobbins (5) have shown that electronic transitions in the crystalline lattice depend to a large extent on vibrational interactions and multipole electrostatic interactions. This fact would lead one to expect that many strong transitions in the free molecule would be weakened in favor of the low-probability transitions; e.g. singlet–triplet transitions. Consequently, by the triplet-state theory, one would expect a higher order of photoconductivity in halogenated hydrocarbons than in the parent compounds (4). Indeed, as the work of Schneider *et al.* (6) on 9,10-dichloroanthracene has shown, the photocurrent in this compound is several orders of magnitude larger than in the parent hydrocarbon, anthracene. However, in a recent paper Kleinerman and McGlynn (7), on the basis of their results on the photoconductivity of acridine and phenazine—molecules in which the molecular energy levels are more suitably disposed for the population of the triplet state—suggest that the population of the triplet state may be detrimental to the photoconduction process.

In order to facilitate the elucidation of the role played by the triplet state in the photoconduction process we decided to investigate the photoconductivity of 9,10-dibromoanthracene, and also the temperature dependence of the photocurrent in 9,10-dichloroanthracene—a dependence not hitherto determined.

In what follows we give a brief account of our results. Further work is in progress, and we hope in the near future to expand upon this note.

All measurements were made on optically clear crystals grown from solution by cooling or by recirculating supersaturated solvent over seed crystals. The chemicals were purified by primary recrystallization, chromatography on columns of silica and alumina, and final recrystallization. These purifications, and the subsequent growth of crystals, were performed in subdued light under nitrogen. Some of the crystals were stored under nitrogen, but others were stored under air to see if this had any effect upon the surface photocurrent.

Only direct-current conductances were measured. The electrodes were always mounted on the same face of the prismatic crystals—a "surface cell" arrangement. Contact was made by thin platinum wires attached to the crystals by means of an alcoholic suspension of graphite. Except in special cases, all measurements were made *in vacuo* or under dry

nitrogen. The dependence of the surface photocurrents on applied field was found to be linear up to 3000 volt cm^{-1} for all crystals studied of each compound. The variation of the photocurrent in 9,10-dibromoanthracene with light intensity was also linear for the wavelengths 3650 Å, 4050 Å, and 4360 Å. The temperature dependence of the photocurrent fitted an expression of the form $i = i_0 \exp(-\Delta E/KT)$. For crystals stored under nitrogen, $\Delta E = 0.14 \pm .01$ ev. Crystals stored in air showed a discontinuity in a plot of $\log i$ versus $1/T$, yielding two straight lines of different slope. The high-temperature portions of these curves yielded $\Delta E = 0.11 \pm .01$ ev. The low-temperature portions gave $\Delta E = 0.20 \pm .01$ ev. This behavior is similar to that observed by Northrop and Simpson for the dark conductivity of solid solutions of aromatic hydrocarbons (8).

Crystals grown from solutions containing 0.001 mole of anthraquinone per mole of 9,10-dibromoanthracene also showed discontinuous temperature dependences. They yielded values for ΔE of $0.13 \pm .005$ and $0.17 \pm .01$ ev for the high- and low-temperature curves respectively. Crystals of 9,10-dichloroanthracene stored in air showed very little dependence upon temperature in the range 273–373° K. In fact some crystals showed a decrease in photocurrent for $T > 330°$. This is in agreement with work done by Bock, Ferguson, and Schneider (6). Low-temperature studies on these crystals gave exponential temperature dependences with $\Delta E = 0.16 \pm .01$ ev. A discontinuity occurred at approximately 200° K, and the low-temperature straight line gave $\Delta E = 0.23 \pm .01$ ev. Replacement of the nitrogen atmosphere above the crystals by oxygen resulted in an increase in the photocurrent in both 9,10-dichloro- and 9,10-dibromo-anthracene. The dependence of the photocurrent upon the partial pressure of ambient oxygen was found to concur with a Langmuir isotherm for a monomolecular adsorbed layer, as found by Bree and Lyons for anthracene (9). The effect of oxygen was reversible and could be removed by pumping. Ammonia gas was found to decrease the photocurrent in both compounds. Evidence for space charges in both compounds was found, indicating the presence of trapping centers in the crystals. The level of photoconductivity in the chloro compound was several orders of magnitude higher than that in the bromo compound under similar conditions.

These results show that 9,10-dichloroanthracene and 9,10-dibromoanthracene are easily oxidized on exposure to air, and that the oxidation products affect their surface photoconductivities. The reversibility with respect to adsorbed gases shows that the gases also affect the photocurrent through electrical double-layer formation. By analogy with the results of Northrop and Simpson (8) we quote photoconductivity activation energies of $0.14 \pm .01$ and $0.16 \pm .01$ ev for 9,10-dibromoanthracene and 9,10-dichloroanthracene respectively, and impurity activation energies of $0.19 \pm .015$ ev and $0.23 \pm .01$ ev. We quote $0.14 \pm .01$ ev for the activation energy of 9,10-dibromoanthracene, since this value was obtained from measurements on pure crystals which were stored in an atmosphere of dry nitrogen and showed no discontinuity in the temperature dependence over a range of 180 centigrade degrees. The earlier-mentioned value of 0.11 ev for the activation energy, obtained from measurements on crystals which were stored in air and hence were subject to surface oxidation of unknown extent, is significantly different from 0.14 ev, a difference of 0.03 ev, which is three times the estimated experimental precision of 0.01 ev. We are tempted to attribute this discrepancy to the unknown extent of surface oxidation and also to the unknown nature of the impurity resulting from oxidation. We are especially tempted to do so since the activation energies of crystals grown from pure compound, but doped with anthraquinone, the most likely oxidation product of 9,10-dibromoanthracene, yielded values of $0.13 \pm .01$ ev, which are

in agreement, within the experimental error, with the activation energy of pure 9,10-dibromoanthracene. Moreover, since the low-temperature straight-line plot of log i vs. $1/T$ for anthraquinone-doped crystals of 9,10-dibromoanthracene yielded an activation energy of 0.17 ev, and since the corresponding low-temperature lines for air-stored crystals of 9,10-dibromoanthracene and of 9,10-dichloroanthracene gave values of 0.19 ev and 0.23 ev respectively, we suggest that the impurity activation (8) is probably chiefly due to the presence of anthraquinone—the main impurity in these crystals. This suggestion, as to the nature of the main impurity, is in general agreement with the observation of other authors (10, 11). The relative orders of magnitude of the photocurrents are not what one would expect on the basis of the triplet-state theory. Further measurements on the dark conductivities are being made to confirm this statement. The effect of gases on the surface photocurrent shows the majority charge carriers to be positive holes.

CRYSTALLOGRAPHIC DATA FOR DI(PHENYLETHYNYL) MERCURY, POTASSIUM 2,4,6,2′,4′,6′-HEXANITRODIPHENYLAMIDE, AND *dl*-α-ALANINE HYDROCHLORIDE

J. Trotter

Preliminary X-ray examinations of three (unrelated) compounds have been carried out, but, for various reasons, detailed structural analyses are not proposed. The crystallographic data, which might be useful, are outlined in this note.

DI(PHENYLETHYNYL) MERCURY

Crystals of $(Ph.C{\equiv}C)_2Hg$ are small, colorless, diamond-shaped plates, with (100) developed and smaller {011} forms and occasionally (001) faces. The density was measured by flotation in aqueous silver nitrate, but as the crystals appeared to decompose fairly rapidly in this solution the value is only approximate. The unit cell dimensions and space group were determined from various rotation, oscillation, Weissenberg (Cu K_α), and precession (Mo K_α) photographs.

in agreement, within the experimental error, with the activation energy of pure 9,10-dibromoanthracene. Moreover, since the low-temperature straight-line plot of log i vs. $1/T$ for anthraquinone-doped crystals of 9,10-dibromoanthracene yielded an activation energy of 0.17 ev, and since the corresponding low-temperature lines for air-stored crystals of 9,10-dibromoanthracene and of 9,10-dichloroanthracene gave values of 0.19 ev and 0.23 ev respectively, we suggest that the impurity activation (8) is probably chiefly due to the presence of anthraquinone—the main impurity in these crystals. This suggestion, as to the nature of the main impurity, is in general agreement with the observation of other authors (10, 11). CRYSTALLOGRAPHIC DATA FOR DI(PHENYLETHYNYL) MERCURY, POTASSIUM 2,4,6,2′,4′,6′-HEXANITRODIPHENYLAMIDE, AND *dl*-α-ALANINE HYDROCHLORIDE

J. Trotter

Preliminary X-ray examinations of three (unrelated) compounds have been carried out, but, for various reasons, detailed structural analyses are not proposed. The crystallographic data, which might be useful, are outlined in this note.

DI(PHENYLETHYNYL) MERCURY

Crystals of $(Ph.C{\equiv}C)_2Hg$ are small, colorless, diamond-shaped plates, with (100) developed and smaller {011} forms and occasionally (001) faces. The density was measured by flotation in aqueous silver nitrate, but as the crystals appeared to decompose fairly rapidly in this solution the value is only approximate. The unit cell dimensions and space group were determined from various rotation, oscillation, Weissenberg (Cu K_α), and precession (Mo K_α) photographs.

Crystal Data

Di(phenylethynyl) mercury, $C_{16}H_{10}Hg$: molecular weight = 402.9; melting point = 125°.

Monoclinic; $a = 32.3 \pm 0.1$, $b = 17.90 \pm 0.05$, $c = 19.63 \pm 0.05$ Å; $\beta = 110.8 \pm 0.5°$.

Volume of the unit cell = 10612 Å^3.

Density: calculated (with $Z = 32$), 2.0, measured, ~2 g cm^{-3}.

Absorption coefficients for X rays: $\lambda = 1.542$ Å, $\mu = 114$ cm^{-1}; $\lambda = 0.7107$ Å, $\mu = 66$ cm^{-1}.

Total number of electrons per unit cell = $F(000) = 5952$.

Absent spectra: $h0l$ when l is odd, $0k0$ when k is odd; space group is $P2_1/c$.

In addition to the systematically absent reflections, all reflections with $(h+k)$ odd are either absent or very weak, indicating a C-centered arrangement of Hg atoms. However, the long crystal axes and large number of molecules in the cell make the structure too complex for detailed analysis. The presence of 32 molecules in a cell requiring only four asymmetric crystal units suggested that the molecule might be an octamer, but measurement of the molecular weight in camphor by the Rast method gave a value of 373, corresponding to a monomer. The forces holding the eight units together in the crystal are probably then only of the van der Waals type.

POTASSIUM HEXANITRODIPHENYLAMIDE

The structure of the potassium salt of 2,4,6,2′,4′,6′-hexanitrodiphenylamine was investigated because of an interest in the structure of the anion. It was hoped that some useful information about its symmetry might be obtained from the space group and the number of molecules in the cell. The density was measured by displacement of carbon tetrachloride, and the cell dimensions and space group were determined from precession films (Mo K_α).

Crystal Data

Potassium 2,4,6,2′,4′,6′-hexanitrodiphenylamide, $C_{12}H_4N_7O_{12}K$: mol. wt. = 477.3.

Monoclinic; $a = 12.20 \pm 0.03$, $b = 13.01 \pm 0.03$, $c = 10.97 \pm 0.03$ Å; $\beta = 94.4 \pm 0.2°$.

Volume of the unit cell = 1736 Å^3.

D_{calc} ($Z = 4$) = 1.815, D_{meas} = 1.81 g cm^{-3}.

Absorption coefficient for X rays: $\lambda = 0.7107$ Å, $\mu = 4.4$ cm^{-1}.

Total number of electrons per unit cell = $F(000) = 960$.

Absent spectra: $(h0l)$ when $(h+l)$ is odd, $0k0$ when k is odd; space group is $P2_1/n$.

No information regarding the symmetry of the anion can be deduced from the crystal data, three-dimensional methods would be required to determine the structure, and the potassium ion is not heavy enough to apply the heavy-atom method (for the light atoms $\sum f_j^2 = 1562$; for K^+, $f^2 = 324$). Detailed analysis is therefore not being carried out.

dl-α-ALANINE HYDROCHLORIDE

Crystals of *dl*-α-alanine ethyl ester hydrochloride were examined to assist in the interpretation of the e.s.r. spectra of irradiated crystals. Specimens suitable for recording e.s.r. (and X-ray) data were obtained from Eastman Kodak CP grade by slow recrystallization from water. These crystals were thick plates elongated along the c-axis with (100) developed and smaller (001) faces. The density was measured by flotation in a benzene–CCl_4 mixture, and the crystal data determined from precession films (Mo K_α).

It was immediately apparent that an integral number of molecules of *dl*-alanine ethyl ester hydrochloride (molecular weight = 154) could not be accommodated in the unit

cell, so that the crystals under examination must be some other compound. Assumption of four molecules in the cell corresponded to a molecular weight of 125 (*dl*-alanine ethyl ester has molecular weight 117, and *dl*-alanine hydrochloride 126). Analysis of the original specimen indicated that it was the ethyl ester hydrochloride. (Found: C, 39.04; H, 7.84; N, 9.20%. Calc. for $C_5H_{12}O_2NCl$: C, 39.09; H, 7.87; N, 9.12%.) The recrystallized material, however, gave a different result (together with a positive test for chloride), which indicated that it must be *dl*-alanine hydrochloride. (Found: C, 29.78; H, 6.82; N, 11.03%. Calc. for $C_3H_8O_2NCl$: C, 28.70; H, 6.42; N, 11.16%.) Either, then, the ester has been hydrolyzed during crystallization (an unlikely occurrence) or, more probably, the original material contains a small quantity of *dl*-alanine hydrochloride as an impurity, which has crystallized preferentially. The C and H analyses suggest that the crystals contain a small amount of the ethyl ester hydrochloride. (Calc. for $0.93C_3H_8O_2NCl$: $0.07C_5H_{12}O_2NCl$: C, 29.57; H, 6.54; N, 10.98%.)

Crystal Data

dl-α-Alanine hydrochloride, $C_3H_8NO_2Cl$ (slightly impure—probably contains about 7% ethyl ester): mol. wt. = 125.6.

Monoclinic; $a = 9.20 \pm 0.02$, $b = 9.04 \pm 0.02$, $c = 7.31 \pm 0.02$ Å; $\beta = 95° 21' \pm 5'$.

Volume of the unit cell = 605.3 Å^3.

D_{calc} ($Z = 4$) = 1.37, D_{meas} = 1.36 g cm^{-3}.

Absorption coefficient for X rays: $\lambda = 0.7107$ Å, $\mu = 5.4$ cm^{-1}.

$F(000) = 264$.

Absent spectra: $h0l$ when l is odd, $0k0$ when k is odd; space group is $P2_1/c$.

No further work on these crystals is proposed.

to help determine mechanisms (2). In this note the effect of pressure up to about 2.5 kilobars on the rates of hydrolysis of acetyl phosphate mono-anion and di-anion and of acetyl phenyl phosphate is described and the results are discussed in relation to the mechanisms.

EXPERIMENTAL METHODS AND RESULTS

The analytical and high-pressure techniques have been described in previous papers (1, 3). The buffer solutions were as described by Di Sabato and Jencks (1); the effect of pressures up to 2.5 kilobars on the pH of the buffers is not enough to change significantly the relative concentrations of the ions of the substituted phosphates. The first-order rate constants are listed in Table I, and shown graphically in Fig. 1. The accuracy is about 5%.

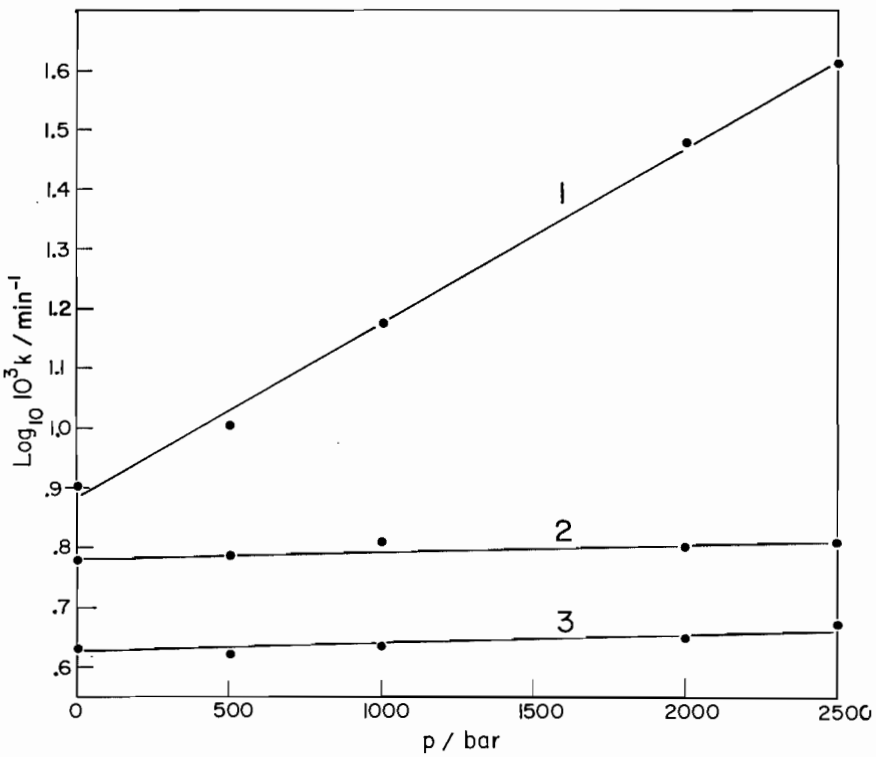

FIG. 1. Effect of pressure on the spontaneous hydrolysis of: curve 1, acetyl phenyl phosphate mono-anion at 60° C, ordinate increased 0.9 units; curve 2, acetyl phosphate mono-anion at 39° C, ordinate decreased 0.4 units; curve 3, acetyl phosphate di-anion at 39° C.

The volumes of activation $\Delta V‡$ at zero pressure calculated from the usual relation $\partial \ln k/\partial p = -\Delta V‡/RT$ are as follows:

acetyl phosphate mono-anion	$-0.6\pm\sim1.0$ cm^3 mole^{-1} at 39° C
acetyl phosphate di-anion	$-1.0\pm\sim1.0$ cm^3 mole^{-1} at 39° C
acetyl phenyl phosphate mono-anion	$-19\pm\sim2$ cm^3 mole^{-1} at 60° C

DISCUSSION

The main mechanisms of hydrolysis to be considered appear to be a unimolecular decomposition of the anion, a bimolecular reaction of water with the anion, and a bimolecular reaction of hydroxide ion with the conjugate acid of the anion.

TABLE I

Spontaneous hydrolysis of acetyl phosphate mono-anion and di-anion and of acetyl phenyl phosphate

*Potassium phosphate buffer, 0.1 M, pH 6.7 at 1 atm.
†Ionic strength brought to 0.6 with KCl.
‡Potassium formate buffer, 0.2 M, pH 2.9 at 1 atm.
§Potassium phenyl phosphate buffer, 0.1 M, pH 4.8 at 1 atm. Control experiments showed no hydrolysis of the buffer under the experimental conditions employed.

The spontaneous hydrolyses of acetyl phosphate mono-anion and di-anion occur with P—O bond cleavage (4, 5). The volumes of activation are $-0.6\pm\sim1.0$ cm^3 mole^{-1} for the mono-anion and $-1.0\pm\sim1.0$ cm^3 mole^{-1} for the di-anion. If the mechanisms involved the attack of water on the phosphorus atom, then the volumes of activation should be considerably more negative because volume would be lost due to the formation of a partial valence bond and to a possible increased polarity. If the mechanism involved a reaction of hydroxide ion with the conjugate acid of the phosphate ion then, from arguments similar to those developed below for acetyl phenyl phosphate mono-anion, a large negative volume of activation would also be expected. For the di-anion, therefore, the mechanism is probably a unimolecular decomposition to give metaphosphate ion (1):

$$CH_3CO_2PO_3^{2-} \xrightarrow{\text{slow}} CH_3CO_2^- + PO_3^- \xrightarrow[\text{fast}]{H_2O} H_2PO_4^-, \qquad [1]$$

as is suggested (6–8) for the hydrolysis of phosphate monoester mono-anions. For the mono-anion, both a similar mechanism,

$$CH_3CO_2PO_3H^- \xrightarrow{\text{slow}} CH_3CO_2^- + HPO_3 \xrightarrow[\text{fast}]{H_2O} H_2PO_4^- + H^+, \qquad [2]$$

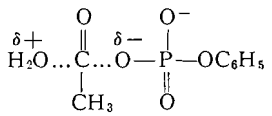
and one in which a proton has been transferred to the leaving acetate group and the transition state is close to acetic acid and metaphosphate ion are consistent with the volume of activation.

The hydrolysis of acetyl phenyl phosphate mono-anion in 90% aqueous methanol occurs with C—O bond cleavage (1) and we shall assume that this also occurs in aqueous solution. The rate is decreased 2.5-fold in deuterium oxide solution (1) and the entropy and volume of activation are, respectively, -28.8 cal deg^{-1} mole^{-1} (1) and -19 cm^3 mole^{-1}. The volume of activation does not allow us to distinguish between the possible

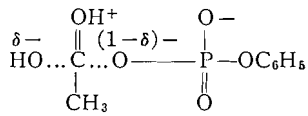
mechanisms, as the following considerations show. A unimolecular decomposition to give acylium ion:

$$CH_3COOPO_3C_6H_5^- \rightarrow CH_3CO^+ + C_6H_5OPO_3^{2-}, \quad [3]$$

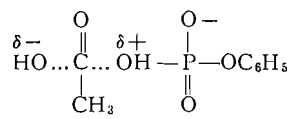
is consistent with the volume and entropy of activation, because the polarity is greatly increased in the transition state. However, the relatively large effect of solvent deuterium oxide, which seems to require that at least one O—H (O—D in deuterium oxide) bond be strongly modified in the transition state, and the great stability of benzoyl phenyl phosphate (9) are difficult to explain by this mechanism. A bimolecular reaction involving solvent could proceed through transition states I, II, III, or IV, which differ in the position



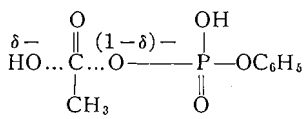
I



II



III



IV

of a proton. Each has, of course, resonating forms. The structures might be further modified if the incoming group adds rather than substitutes, as has been suggested (10) for some carboxyl reactions, and if several water molecules are incorporated into the transition state to aid in proton transfer (1, 11). All of these mechanisms appear to be consistent with the volume of activation and other (1) data. It is interesting to compare the experimental data with calculated values for a special case of mechanism IV, according to reactions [4] and [5]:

$$CH_3COOPO_3C_6H_5^- + H_2O \overset{\text{fast}}{\rightleftharpoons} CH_3COOPO_3HC_6H_5 + OH^- \quad [4]$$

$$CH_3COOPO_3HC_6H_5 + OH^- \xrightarrow{\text{slow}} CH_3COOH + C_6H_5PO_4H^-. \quad [5]$$

It seems likely that the volume and entropy change and the deuterium isotope effect of reaction [4] will be similar to those for the reaction

$$H_2PO_4^- + H_2O \rightleftharpoons H_3PO_4 + OH^-, \quad [6]$$

and those for reaction [5] will be similar to those for the alkaline hydrolysis of esters, in which a hydroxide ion also attacks an acetate group:

$$CH_3COOR + OH^- \rightarrow CH_3COOH + OR^-. \quad [7]$$

The thermodynamic parameters for reaction [6] can be obtained from those for the reactions

$$H_3PO_4 \rightleftharpoons H_2PO_4^- + H^+ \quad [8]$$

and

$$H_2O \rightleftharpoons H^+ + OH^-. \quad [9]$$

The data are given in Table II. They are mostly for temperatures near 25° C but this should not affect the conclusions in any important way. It is clear that the volume and entropy of activation and the deuterium isotope effect are quantitatively consistent with the mechanism given in reactions [4] and [5].

ULTRAVIOLET SPECTRA OF SOME SUBSTITUTED STYRENES[1]

OWEN H. WHEELER AND CELIA B. COVARRUBIAS

Styrene has its main ultraviolet absorption band at 250 mμ (1–4). Methyl groups in the ortho positions have been found (1) to force the ethylenic group out of resonance

[1]*Contribution No. 125 from the Instituto de Quimica de la Universidad Nacional Autonoma de Mexico, Mexico, D.F.*

conjugation with the benzene ring and reduce the intensity of absorption without significantly changing the wavelength. Very few data exist in the literature concerning the absorption of substituted styrenes (2, 6–8) and accordingly a number of ortho and para methoxy- and halogeno-substituted styrenes have been prepared and their ultraviolet spectra recorded.

Apart from the main maximum at 250–275 mμ, other weaker bands were also found in some cases at higher wavelength (styrene 282 (60), 290 (30); *o*-methoxystyrene 320 (1440); *o*-chlorostyrene 295 (840)) and such bands, although often of higher intensity, have been previously reported (2–4, 6–8). It seems unlikely that a simple chromophore like styrene would have other maxima above 280 mμ of high intensity, although weak *B* bands can be expected, and part of this extra absorption may be due to polymerized material in solution.

A *p*-methoxy group produced a large displacement (+26 mμ) in the 250 mμ maximum and the para halogeno atoms caused smaller displacements of about the same order (10 mμ). These shifts are consistent with the electronic effects of these substituents (5). The corresponding ortho isomers all showed smaller displacements than the para compounds and the intensities were considerably reduced. Such effects are typically steric in origin (1, 5). Since the styrenes polymerize in solution, the recorded intensity values cannot be considered reliable. However, the ratios of intensities of the para to ortho isomers were MeO ~ Cl > Br, the order expected on the basis of the steric interference of these groups.

EXPERIMENTAL

Styrenes

The substituted styrenes were prepared from the corresponding substituted benzaldehydes by reaction with methyl magnesium iodide in ether and dehydration of the so-formed phenylcarbinol by distillation with potassium bisulphate (9). The styrenes formed by the decarboxylation of the cinnamic acids (10) were less pure and readily polymerized. The styrenes were all redistilled by short-path distillation at 5 mm with a bath temperature of 100–120°. Their refractive indices are given in Table I.

¶From ethanol.

o-Methoxybenzaldehyde was prepared by methylation of salicylaldehyde (11) and many of the halogenobenzaldehydes by Etard oxidation of the corresponding toluenes (12).

Spectra

The ultraviolet spectra were determined on freshly distilled or recrystallized samples using 95% ethanol. A Beckman D.K.2 spectrophotometer was employed under normal operating conditions.

SPECTROPHOTOMETRIC OBSERVATIONS ON THE CLEAVAGE OF *vic*-DIOLS BY LEAD TETRAACETATE[1]

A. S. PERLIN AND S. SUZUKI[2]

Oxidative cleavage of *vic*-diols and related groups by lead tetraacetate (1) is generally detected and estimated by iodometric titration. An alternative, and in some ways advantageous, means for examining such reactions is offered by the fact that tetravalent lead may be estimated spectrophotometrically (2). Measurements are made at 280–300 mμ, a region in which absorption by Pb (IV) is not maximal (2) (see also Fig. 1, curve A) but in which there is no interference from acetic acid (a reaction product and also the most common solvent) nor from divalent lead.

With the spectrophotometric method lead tetraacetate oxidations can be carried out at higher dilution (ca. 10^{-4} M) than formerly. One advantage gained in this way is that reaction rates for very fast glycols (such as those in which the dihedral angle of the carbon–oxygen bonds approximates 0 degree (3, 4)) are slowed sufficiently[3] for satisfactory measurement, particularly with a recording spectrophotometer. To illustrate, the rate of cleavage of the 2,3-*cis* diol of methyl α- or β-D-erythrofuranoside was found earlier (5) to be virtually instantaneous even at 0° C, so that comparative data were not available. However, the rate for each compound at high dilution has now been estimated readily, and a substantial anomeric difference detected. As with the very much slower methyl D-threofuranosides (5), the 1,2-*cis*-alkoxy-hydroxy anomer (α-D-erythroside) was found to be more reactive than the 1,2-*trans* anomer, the ratio of their second-order rate constants being 3.5 to 1.

SPECTROPHOTOMETRIC OBSERVATIONS ON THE CLEAVAGE OF *vic*-DIOLS BY LEAD TETRAACETATE[1]

A. S. PERLIN AND S. SUZUKI[2]

Oxidative cleavage of *vic*-diols and related groups by lead tetraacetate (1) is generally detected and estimated by iodometric titration. An alternative, and in some ways advantageous, means for examining such reactions is offered by the fact that tetravalent lead may be estimated spectrophotometrically (2). Measurements are made at 280–300 mμ, a region in which absorption by Pb (IV) is not maximal (2) (see also Fig. 1, curve A) but in which there is no interference from acetic acid (a reaction product and also the most common solvent) nor from divalent lead.

With the spectrophotometric method lead tetraacetate oxidations can be carried out at higher dilution (ca. 10^{-4} *M*) than formerly. One advantage gained in this way is that reaction rates for very fast glycols (such as those in which the dihedral angle of the carbon–oxygen bonds approximates 0 degree (3, 4)) are slowed sufficiently[3] for satisfactory measurement, particularly with a recording spectrophotometer. To illustrate, the rate of cleavage of the 2,3-*cis* diol of methyl α- or β-D-erythrofuranoside was found earlier (5) to be virtually instantaneous even at 0° C, so that comparative data were not available. However, the rate for each compound at high dilution has now been estimated readily, and a substantial anomeric difference detected. As with the very much slower methyl D-threofuranosides (5), the 1,2-*cis*-alkoxy-hydroxy anomer (α-D-erythroside) was found to be more reactive than the 1,2-*trans* anomer, the ratio of their second-order rate constants being 3.5 to 1.

[1]*Issued as N.R.C. No. 6821.*
[2]*National Research Council of Canada Postdoctorate Fellow, 1960–61.*
[3]*The retarding effect of high dilution on the oxidation rate of relatively slow glycols (e.g., those of 6-membered ring or acyclic compounds) is very marked. Hence, in using the spectrophotometric method as a microprocedure for examining compounds of this type it may be desirable to accelerate the oxidation with potassium acetate (6, 7; see experimental section).*

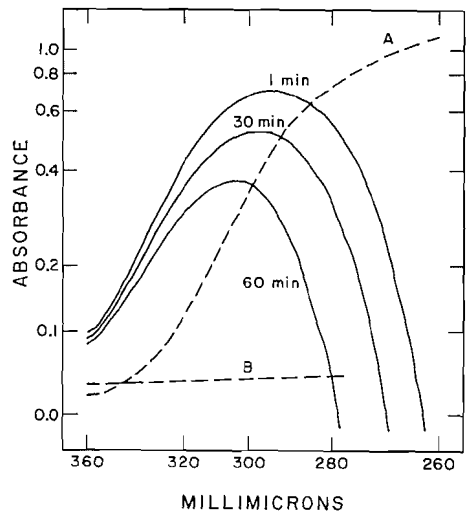

FIG. 1. Absorption spectrum at 1, 30, and 60 minutes' reaction time for a reaction mixture containing lead tetraacetate (84 μg/ml) and D-glucosamine hydrochloride (11 μg/ml) in acetic acid, using a solution of lead tetraacetate (84 μg/ml) in acetic acid as the reference liquid. The broken-line plots represent the absorption curve for (A) lead tetraacetate (84 μg/ml) and (B) D-glucosamine hydrochloride (11 μg/ml) in acetic acid, using acetic acid as the reference liquid.

Another possibility offered by the use of highly dilute solutions is that of examining the oxidation of compounds that are insufficiently soluble under the usual conditions. The behavior of amino sugars, for example, could not be compared directly with that of the 2-hydroxy analogues in earlier studies (8) because of poor solubility (of the crystalline amine hydrochlorides) in acetic acid. Some 2-amino-2-deoxy-D-aldohexoses (the D-gluco, D-galacto, and D-manno isomers), which have now been examined at high dilution, show the unusual property of promoting a marked *increase* in optical density at the outset of the reactions[4] (Fig. 1). This effect was not found with *N*-acetyl D-glucosamine nor with a wide variety of 1,2-dihydroxy compounds, and hence undoubtedly involves complexing between Pb (IV) and the amino group. Although all three aminohexoses show this effect, it appears to be steric dependent since it has not been observed with an acyclic α-amino alcohol (serine), nor with methyl 3-amino-3-deoxy-β-D-xylopyranoside, the 1,2,3-hydroxy-amino-hydroxy grouping of which should be fixed more rigidly than that of the aminohexoses. The present data do not show clearly that the complex is of the 5-membered cyclic type postulated by Criegee (3, 9), but an initial increase in optical density (at 220 mμ) detected during periodate oxidation of some 1,2-diols is consistent with the formation of such an intermediate (10).[5]

The aminohexoses, like the 2-hydroxy analogues (11), are only partially oxidized by lead tetraacetate and show pronounced isomeric differences, but the 1,2-amino hemiacetal group is cleaved much less readily than is the 1,2-hydroxy hemiacetal group.[4]

The spectrophotometric procedure should also facilitate the structural examination of oligosaccharides and partially substituted sugars, particularly when only small quantities

[4]*Thus, at 1, 30, 120, and 360 minutes, respectively, the apparent lead tetraacetate uptake (moles/mole) was:* D-*glucosamine, −0.46, −0.17, 1.02, 2.37;* D-*galactosamine, −0.23, 0.78, 1.10, 1.30;* D-*mannosamine, −0.22, 1.25, 2.19, 2.72. The* actual *uptake of oxidant by* D-*glucosamine in 30 minutes was about 0.3 mole/mole, as estimated by iodometric microtitration of large volumes of the reaction mixture, whereas in half this reaction period* D-*glucose reduced 2.0 moles of lead tetraacetate/mole.*

[5]*B. Coxon and L. Hough (private communication) have recently detected complex-formation between periodate and methyl 3-amino-4,6-O-benzylidene-3-deoxy-α-*D-*altropyranoside.*

of such compounds are available. This possibility has been checked for several oxidations carried out earlier under both potassium-acetate-catalyzed and uncatalyzed conditions (12, 13). The characteristics of the uncatalyzed oxidation, i.e., those dealing primarily with the degradation of reducing end-units (13), remain essentially the same at high dilution. However, the rate of reaction is retarded much more by the concentration change when the linkage is at position 4 than when at 6 or 3, which is of particular value in differentiating between the first two types. (Since 2-substituted aldoses are very unreactive, (1 → 2)- and (1 → 4)-linked oligosaccharides may be differentiated by oxidation at higher concentrations (13).) Also, these differences indicate some possibilities for effecting selective oxidation in mixtures of oligosaccharides, perhaps facilitating chromatographic separations; e.g., with three admixed oligosaccharides, the reducing end-units of which are substituted at positions 4, 3, and 6, respectively, the latter two should be oxidized preferentially at high dilution (yielding a 2-substituted pentose and a 3-substituted tetrose derivative, respectively (13)).

EXPERIMENTAL

Spectrophotometric measurements were made with a Beckman Model DU type instrument or with a Spectracord recording spectrophotometer.

All chemicals used were of reagent grade.

Estimation of Lead Tetraacetate

A stock solution (about 10%) of lead tetraacetate in acetic acid was prepared, the concentration of oxidant measured iodometrically (1), and appropriate dilutions were then made for the spectrophotometric studies.

The absorption curve for lead tetraacetate in acetic acid over the range 250–320 mμ (using acetic acid as the reference liquid) exhibits a shoulder in the region of 280 mμ (Fig. 1, curve A). At this wavelength the relation between optical density and lead tetraacetate concentration was linear and was plotted to serve as a standard curve. There was no indication during the present study that prolonged irradiation exerts an adverse effect on the reaction mixtures, such as is found with periodate oxidation (10, 14). However, in using potassium acetate for catalyzed oxidations, solutions containing more than 5 mg of the salt per milliliter were found to be too unstable for reactions requiring more than 30 minutes.

Lead Tetraacetate Oxidations

The following experiments illustrate the various oxidation conditions used:

(1) A solution of methyl α- or β-D-erythrofuranoside (64 μg) in acetic acid (2 ml) was syringed[6] into a solution of lead tetraacetate (240 μg) in acetic acid (2 ml), and the content of oxidant was measured continuously. Duplicate experiments showed only small variations. The calculated second-order rate constants (min^{-1} $mole^{-1}$ liter) were as follows:

Time (min)	0.35	0.40	0.50	0.60	0.70
k_{27} ($\times 10^{-3}$) α-D-isomer	41.6	38.8	36.3	36.4	37.6
k_{27} ($\times 10^{-3}$) β-D-isomer	10.8	11.9	11.0	11.3	11.3

(2) To a solution of lead tetraacetate (392 μg) in acetic acid (2 ml) was added a solution of 1,2:5,6-di-*O*-isopropylidene-D-mannitol (153 μg) in acetic acid (2 ml). The uptake of oxidant (moles/mole hr) was: 0.49 (1); 0.77 (2); 0.91 (3); 0.97 (4).

When the reaction was repeated in the presence of potassium acetate (5 mg/ml) the uptake of lead tetraacetate (moles/mole min) was: 0.59 (5); 0.79 (10); 0.96 (20); 0.98 (30); 1.03 (90).

(3) A solution of lactose (1.0 mg) in 90% acetic acid (0.2 ml) was added to a solution of lead tetraacetate (20 mg) and potassium acetate (10 mg) in 90% acetic acid (1.0 ml) (12). Portions (0.15 ml) of the reaction mixture were diluted, each to 25 ml, with acetic acid, and the lead tetraacetate content measured. The uptake of oxidant (moles/mole min) was: 4.07 (10); 4.74 (30); 4.91 (60); 5.08 (120).

(4) A solution of a given oligosaccharide (75–100 μg) in water (0.05 ml) was diluted with acetic acid (2 ml) and added to a solution of lead tetraacetate (400 μg) in acetic acid (2 ml). The uptake of oxidant (moles/mole) observed for the representative compounds listed below was:

[6]*An* all-glass *syringe is recommended; spurious absorption, possibly by metal ions, was observed when a stainless steel tip was used repeatedly.*

Time (min)	5	10	30	60
6-*O*-α-D-mannopyranosyl-D-glucose	1.27	1.62	1.91	1.93

EFFECT OF NUCLEAR SPIN ON THE EMISSION OF THE FORBIDDEN LINE Hg 6^3P_0–6^1S_0

G. H. KIMBELL[1] AND D. J. LE ROY

In a previous paper (1) we described a study of the formation and consumption of Hg 6^3P_0 atoms in mixtures of mercury vapor and nitrogen illuminated with 2537 Å. For a mercury pressure of 7.7×10^{-4} mm and nitrogen pressures in the range 0–140 mm we proposed the following mechanism:

$$\mathrm{Hg} + h\nu^* = \mathrm{Hg}^* \quad [1]$$

$$\mathrm{Hg}^* = \mathrm{Hg} + h\nu^* \quad [2]$$

$$\mathrm{Hg}^* + \mathrm{N_2} = \mathrm{Hg} + \mathrm{N_2} \quad [3]$$

$$\mathrm{Hg}^* + \mathrm{N_2} = \mathrm{Hg}^0 + \mathrm{N_2} \quad [4]$$

$$\mathrm{Hg}^0 = \mathrm{Hg}\ (\text{on wall}) \quad [5]$$

$$\mathrm{Hg}^0 = \mathrm{Hg} + h\nu^0 \quad [6]$$

$$\mathrm{Hg}^0 + \mathrm{N_2} = \mathrm{Hg} + \mathrm{N_2} \quad [7]$$

$$\mathrm{Hg}^0 + \mathrm{N_2} = \mathrm{Hg}^* + \mathrm{N_2} \quad [8]$$

$$\mathrm{Hg}^0 + \mathrm{N_2} = \mathrm{Hg} + \mathrm{N_2} + h\nu^0, \quad [9]$$

$$\mathrm{Hg}^* = \mathrm{Hg} + h\nu^* \quad [2]$$

$$\mathrm{Hg}^* + \mathrm{N_2} = \mathrm{Hg} + \mathrm{N_2} \quad [3]$$

$$\mathrm{Hg}^* + \mathrm{N_2} = \mathrm{Hg}^0 + \mathrm{N_2} \quad [4]$$

$$\mathrm{Hg}^0 = \mathrm{Hg\ (on\ wall)} \quad [5]$$

$$\mathrm{Hg}^0 = \mathrm{Hg} + h\nu^0 \quad [6]$$

$$\mathrm{Hg}^0 + \mathrm{N_2} = \mathrm{Hg} + \mathrm{N_2} \quad [7]$$

$$\mathrm{Hg}^0 + \mathrm{N_2} = \mathrm{Hg}^* + \mathrm{N_2} \quad [8]$$

$$\mathrm{Hg}^0 + \mathrm{N_2} = \mathrm{Hg} + \mathrm{N_2} + h\nu^0, \quad [9]$$

[1]*Present address: Department of Chemical Engineering, Imperial College, University of London, London, England.*

in which Hg represents 6^1S_0, Hg* represents 6^3P_1, and Hg^0 represents 6^3P_0 atoms. This mechanism was based on a kinetic analysis of the effect of nitrogen pressure on the absorption of 4047 Å (7^3S_1–6^3P_0) and on the intensity of the emission of the forbidden line 2656 Å (6^3P_0–6^1S_0). The lifetime, τ, of the 6^3P_0 atom with respect to radiation (the reciprocal of k_6) was found to be 4.2×10^{-4} sec.

The question naturally arose as to whether or not the spontaneous emission of the forbidden line was confined to the mercury isotopes having nuclear spin (odd atomic weight), as has been suggested by Mrozowski (2, 3, 4) and Bowen (5). There are a number of experimental methods of verifying this. In the present communication we report the results of one of these methods.

Assuming that $\tau_{even} \gg \tau_{odd}$, the steady-state concentration of Hg^0_{even} should be greater than that calculated from the natural isotope ratio when a mixture of nitrogen and natural mercury is illuminated by 2537 Å originating from a "natural" low-pressure mercury arc. Thus, the apparent value of τ should be greater than we found previously (1) if the analysis beam of 4047 Å contained only the hyperfine component from an isotope of even atomic weight.

The experimental method was similar to that used previously except that the 4047-Å beam was not derived from one of the primary lamps, but from a separate lamp containing only the isotope of atomic weight 198. The lamp consisted of a quartz tube 20 cm long and 7 mm in O.D. containing Hg^{198} and approximately 5 mm pressure of a 95% argon – 5% xenon mixture. It was operated by 2450-Mc microwave radiation from a 125-watt generator.

The temperature of the lamp was maintained within ±0.1° C by a water-cooled quartz jacket. Under fixed conditions in the reaction cell, the absorption of 4047 Å from this lamp was studied as a function of its temperature. The absorption remained constant at approximately 30% over the range 17 to 21° C, but rose to about 40% when the temperature of the lamp was raised to 27° C. For the measurements described below the lamp was operated at 20° C, at which temperature there was apparently insufficient pressure broadening in the lamp to cause any absorption by Hg^0 atoms of odd atomic weight in the reaction cell. The hyperfine structure of the 4047-Å line has been discussed by Schuler and Keyston (6) and by Burns and Adams (7).

To minimize pressure broadening of the absorption line in the reaction cell, nitrogen pressures were confined to the range 0.18 to 8.7 mm. For pressures less than 1 mm the results fitted the equation (1)

$$1/K^0L(Hg^0) = A/(N_2)^2+B/(N_2)+C,$$

with $A = 0.237$, $B = 3.16$, $C = 4.25$. These results are shown in Fig. 1 in the form of a plot of $(N_2)^2/K^0L(Hg^0)$ vs. (N_2).

In our previous work a plot of $(N_2)/K^0L(Hg^0)-A/(N_2)$ was linear up to approximately 6 mm. In the present measurements, shown in Fig. 2, the results are quite similar, an upward curvature setting in at about 5.5 mm. From the linear portion of this curve we derived the values $B = 3.06$, $C = 4.66$, in good agreement with the values obtained in the lower-pressure range. Taking $B/A = 3.06/0.237 = 12.9$ mm^{-1}, and $k_5 = 206$ mm sec^{-1}, it follows (1) that $k_6 = 12.9\times206 = 2.66\times10^3$ sec^{-1}, or $\tau = 3.8\times10^{-4}$ sec. Following the method used previously, the value of $k_7+k_8+k_9$ obtained from C/A was 0.75×10^{11} cm^3 mole^{-1} sec^{-1}, compared to the previous value of 1.09×10^{11}; nuclear spin would not be expected to influence these reactions. Individual values of the three rate constants could not, of course, be obtained from the present data.

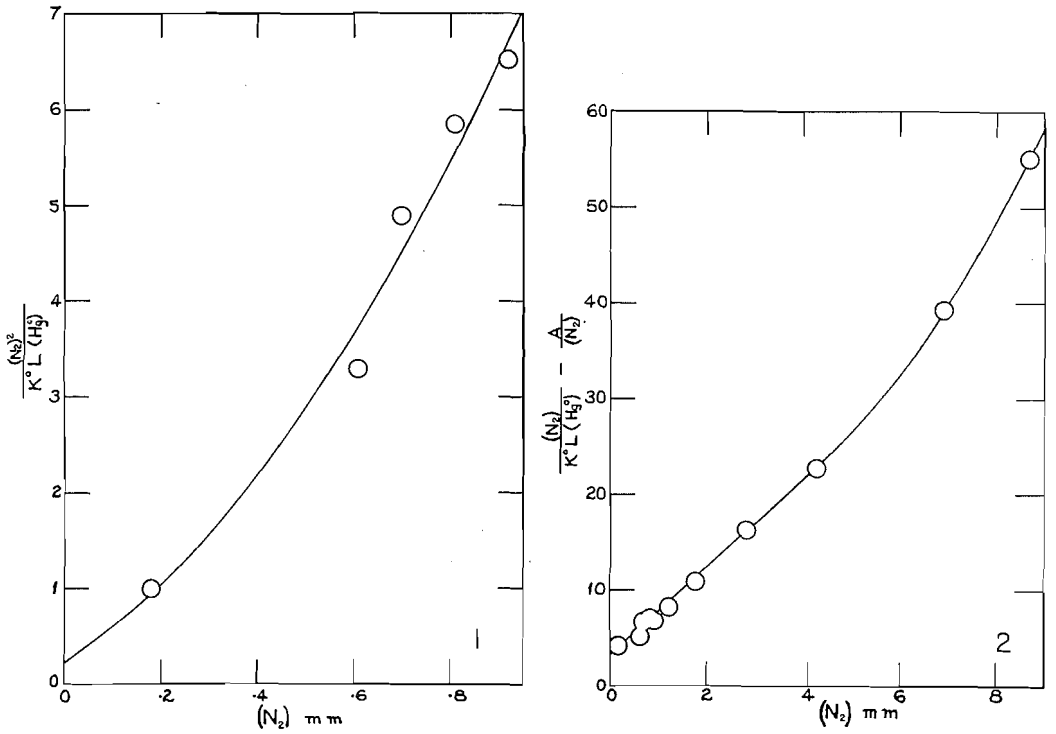

FIG. 1. $(N_2)^2/K^0L(Hg^0)$ vs. (N_2) in the low-pressure range, in which $K^0L(Hg^0)$ is the optical density for the absorption of the Hg^{198} hyperfine component of 4047 Å.

FIG. 2. $(N_2)/K^0L(Hg^0) - A/(N_2)$ vs. (N_2) in the medium-pressure range, in which $K^0L(Hg^0)$ is the optical density for the absorption of the Hg^{198} hyperfine component of 4047 Å and A is the intercept of Fig. 1.

The close agreement of the present value of τ with the value 4.2×10^{-4} sec obtained previously indicates that there is no significant difference between the lifetime of the Hg^0 isotope of mass 198, with no nuclear spin, and the "average" lifetime of all Hg^0 isotopes. It should also be recalled that our earlier work showed good agreement between the results obtained from the absorption of 4047 Å and those obtained from the emission of the forbidden line. One can only conclude that *either* the transition probability for emission of the forbidden line is essentially independent of nuclear spin *or* the exchange reaction $Hg^0_{even} + Hg_{odd} = Hg_{even} + Hg^0_{odd}$ is extremely fast.

TRITIUM RELEASE FROM THE NEUTRON-IRRADIATED LITHIUM-DOPED NICKEL OXIDE

CONSTANȚA MĂNTESCU AND T. COSTEA

Nickel oxide is well known as a catalyst, often used in a series of chemical reactions. Recently one has tried to improve the properties of some semiconductor oxide catalysts by irradiation with high dosages or by doping them with other oxides and irradiating the mixture. To this purpose we have studied the behavior of neutron-irradiated lithium-doped nickel oxide during a post-irradiation thermal treatment. The $Li^6(n,\alpha)H^3$ nuclear reaction takes place by irradiation of the lithium-doped nickel oxide. We thought it would be interesting to pursue the fate of the recoil tritium atoms produced in the crystalline lattice of the doped oxide, as well as the possible chemical reactions of this hydrogen during the thermal spike and/or after reaching thermal equilibrium with the medium.

The lithium-doped nickel oxide was obtained by sintering reagent grade nickel oxide and lithium carbonate at 800° C to obtain $5Li_2O$:100NiO. The powder obtained was then heated under high vacuum for 3 hours at 200° C, after which it was sealed in quartz tubes. The samples were irradiated in these tubes in the IFA reactor, being exposed to an integral thermal neutron flux of 7×10^{15} n/cm^2. Irradiated samples of the same weight underwent isothermal treatment in the temperature range 100–800° C. The activity of the released tritium was measured in a G.M. gas counter using a known technique (1). A trap at liquid nitrogen temperature was placed between the quartz furnace, where the samples were heated, and the counter, so as to trap the condensable tritiated compounds and thus separate them from the free tritium.

It was observed that the bulk of the activity was trapped in the crystalline lattice of the lithium-doped nickel oxide, the released activity during the irradiation being under 1% of the total activity. This activity was divided approximately equally between the condensable fraction at the liquid nitrogen temperature and the uncondensable fraction at the same temperature. This fact shows that the release process requires an activation energy, the tritium or the tritiated compounds being trapped in the crystalline lattice. A second observation indicates that only tritium oxide has been produced—the only volatile compound of tritium at room temperature under vacuo conditions, but condensable at the liquid nitrogen temperature. The results of the isothermal treatment are shown in Fig. 1. It may be observed that for the temperature of 100° C, the samples release free tritium but, at higher temperatures, only tritium oxide is being released. The release process is characterized by a great rate in the first minutes of heating, after which the slope of the curves decreases gradually, reaching at last a pseudo plateau characteristic for a certain temperature. The released activity increases up to a temperature of 400–500° C, after which it decreases substantially at 600° C. For temperatures higher than 600° C, an increase of the activity may be observed.

The investigations are continuing, but some conclusions may already be drawn. There is no doubt that the results obtained may be interpreted if we admit that, in the crystal, the reaction of the formation of the tritium oxide takes place as follows:

$$T + O \rightarrow T_2O. \qquad [I]$$

The oxygen required by the first reaction may arise from the excess of oxygen atoms in the crystal (the nickel oxide corresponds to a formula NiO_{1+x}), or from the oxygen atoms distributed at random as a consequence of the thermal spikes. One puts the question as to whether this reaction takes place in the irradiation period or in the thermal period.

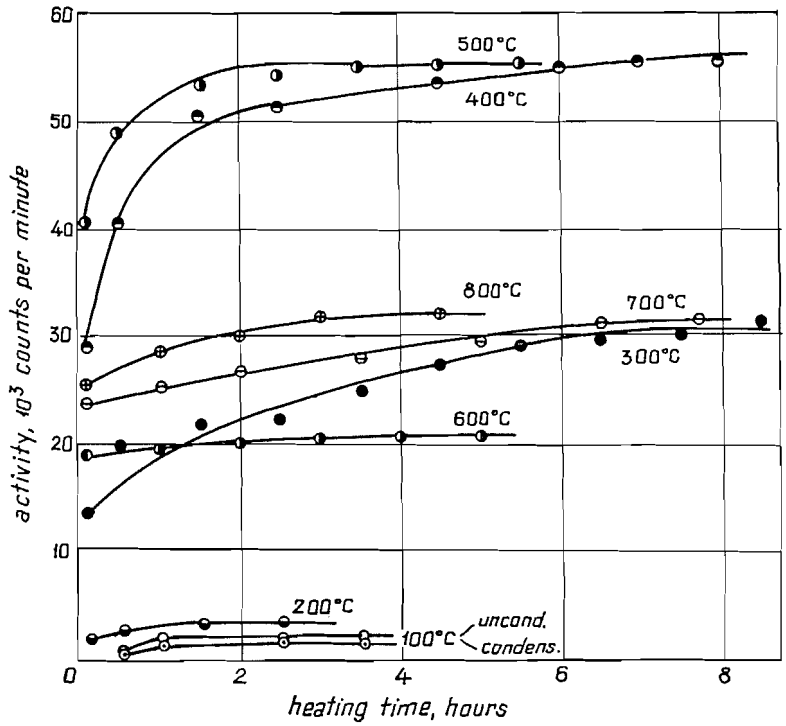

FIG. 1. The release of the tritium activity from the neutron-irradiated lithium-doped nickel oxide at different temperatures.

The fact that the released activity at 600° C is smaller than that released at 400–500° C may be due to any concurrent reaction

$$T + Li \rightarrow LiT \qquad [IIa]$$

or

$$T_2O + Li \rightarrow LiOT + T. \qquad [IIb]$$

The reaction [II*a*], which takes place just at 600–630° C, favors the appearance of the tritium oxide the moment the reactants reach thermal equilibrium with the medium. On the other hand, while reaction [II*b*] supposes that the tritium oxide is formed in the irradiation period, it is not experimentally confirmed because the release of the free tritium concomitant to the decrease of the combined tritium activity is not observed. In favor of reaction [II*a*] is the observation of faint sparks, which shows the presence of oxygen at higher temperature during the thermal treatment.

$$LiT + O \rightarrow Li_2O + T_2O \qquad [III]$$

For the released activity increase at temperatures higher than 600° C, reaction [III] may be used. In this way reaction [I] should be considered as a scavenger of the tritium by the oxygen, especially since, in the respective range of temperature, nickel oxide is a catalyst for the formation of water from oxygen and hydrogen.

It is intended to publish full details of this work elsewhere at a later date.

REACTIONS OF 2,3,5,6-TETRAKIS(β-HYDROXYETHYLMERCAPTO)-1,4-HYDROQUINONE AND RELATED COMPOUNDS

MARSHALL KULKA

Research Laboratories, Dominion Rubber Company Limited, Guelph, Ontario

Received February 19, 1962

ABSTRACT

The treatment of chloranil (I) with alkali and 2-mercaptoethanol resulted not only in replacement of the chlorine atoms but also in reduction to form 2,3,5,6-tetrakis(β-hydroxyethylmercapto)-1,4-hydroquinone (II). The conditions for the preparation of 2,3,5,6-tetrakis(β-chloroethylmercapto)-1,4-hydroquinone (III) from II differed from those required for the preparation of a lower-melting compound (IV) from II by such a narrow margin that exact control of temperature and concentration were necessary in order to avoid erratic behavior in the preparation. The structure of the lower-melting compound has been established as 2,3-dihydro-5,7,8-tris(β-chloroethylmercapto)-6-hydroxy-1,4-benzoxathiin (IV) by analyses and cyclization reactions. The treatment of 2,3-dichloro-1,4-naphthoquinone (VIII) with 2-mercaptoethanol yielded 2,3-bis(β-hydroxyethylmercapto)-1,4-naphthoquinone (IX) and not the quinol as was the case with chloranil. The quinone (IX) could not be converted to 2,3-bis(β-chloroethylmercapto)-1,4-naphthoquinone by treatment with hydrogen chloride because under these conditions only 1,4-oxathio-5,10-anthraquinone (X) was formed. A mechanism for the formation of X which involves intramolecular addition, elimination, and cyclization is described.

A few years ago 2,3,5,6-tetrakis(β-chloroethylmercapto)-1,4-hydroquinone (III) was synthesized in this laboratory in connection with another project. This "four-pronged" sulphur mustard was then submitted to the National Institutes of Health, Bethesda, Maryland, U.S.A., for evaluation in cancer chemotherapy. Preliminary screening results showed it to be active and curative to some extent. This provided a stimulus for further study and a second attempt to prepare III was made. Surprisingly enough the original preparation could not be duplicated and instead of III a lower-melting compound was isolated in high yield. The identification of this lower-melting compound and the explanation for the erratic behavior experienced in the preparation of III constitute the subject of this paper.

The synthesis of 2,3,5,6-tetrakis(β-chloroethylmercapto)-1,4-hydroquinone (III) consisted of two steps—the preparation of 2,3,5,6-tetrakis(β-hydroxyethylmercapto)-1,4-hydroquinone (II) from chloranil (I) followed by the conversion of II to III. It was the second step of the synthesis (II → III) which proved troublesome.

In the first step, the treatment of chloranil (I) with 2-mercaptoethanol in the presence of potassium hydroxide resulted in two simultaneous reactions—the displacement of the chlorine atoms by β-hydroxyethylmercapto groups and the reduction of the quinone to form 2,3,5,6-tetrakis(β-hydroxyethylmercapto)-1,4-hydroquinone (II). 2-Mercaptoethanol proved to be such a powerful nucleophile (as well as a reducing agent) that it attacked

other substituted benzoquinones besides I. Thus when 2,5-dichloro-3,6-bis(dimethylamino)-1,4-benzoquinone or 2,5-dichloro-3,6-di-N-morpholino-1,4-benzoquinone (1) was heated with 2-mercaptoethanol and pyridine, II was formed in high yield. The reduction of chloranil (I) to the quinol by mercaptides with the accompanying nucleophilic attack has been observed before when I was treated with ω-mercapto fatty acids (2, 3).

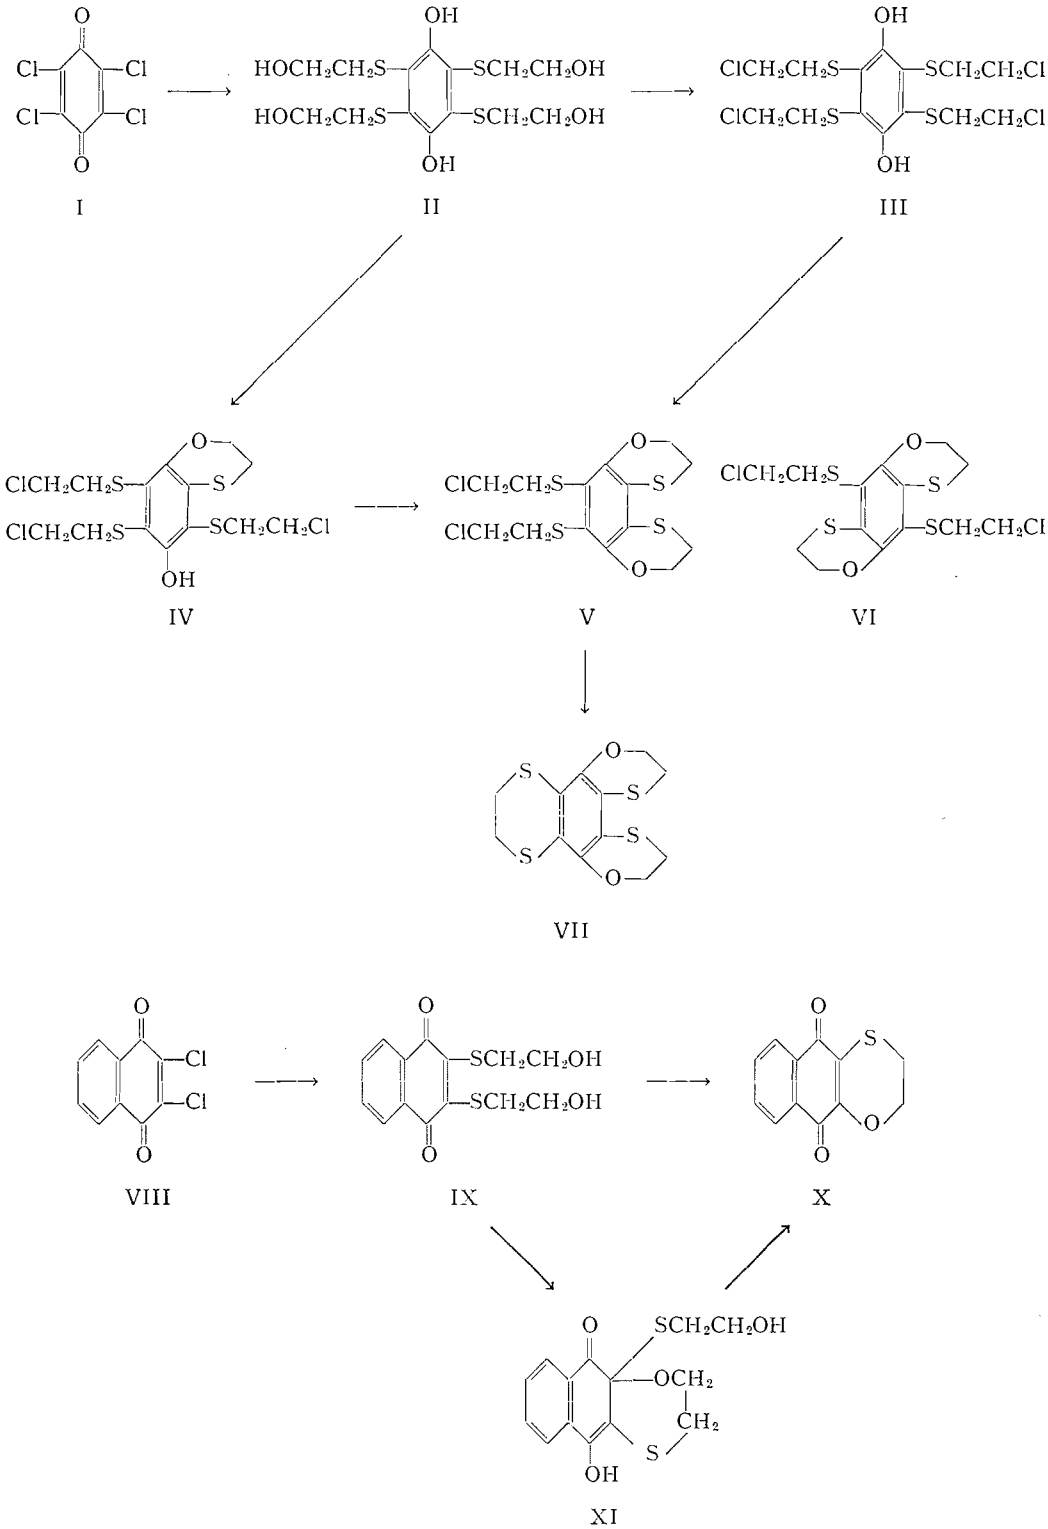
The second step in the synthesis of III, which required the conversion of the hydroxy compound II to 2,3,5,6-tetrakis(β-chloroethylmercapto)-1,4-hydroquinone (III), presented difficulties. Thionyl chloride could not be used for this purpose because II was completely insoluble in cold thionyl chloride and the hot reagent caused decomposition. However, 2,3,5,6-tetrakis(β-hydroxyethylmercapto)-1,4-hydroquinone (II) dissolved readily in cold concentrated hydrochloric acid and when the solution was allowed to stand at room temperature a white precipitate deposited. Analyses and melting point of this product indicated that it was incompletely chlorinated. However, the crude precipitate was now quite soluble in chloroform and the completion of the chlorination could be accomplished with thionyl chloride in chloroform solution. The conversion of II to III was therefore satisfactorily accomplished by the consecutive treatment with concentrated hydrochloric acid and thionyl chloride at room temperature.

Some time after this method of conversion (II $\rightarrow$ III) was developed, an attempt was made to repeat it. It was found that the treatment of II with concentrated hydrochloric acid at room temperature followed by the reaction with thionyl chloride gave a low-melting compound in high yield and no III. After considerable experimentation it became evident that the conditions required for the preparation of III and those for the preparation of the lower-melting compound differed by a small margin only and that "room temperature" had to be defined more precisely. Precise conditions for the preparation of III and those for the preparation of the lower-melting compound are described in the experimental section.

The lower-melting compound, which formed at lower temperatures (20–25°) in strong hydrochloric acid, was shown to be a product of cyclization. Analyses showed the presence of one phenolic group and three β-chloroethylmercapto groups and that its empirical formula was one hydrogen chloride molecule less than that of III. On this basis the structural formula IV was proposed. A study of the properties of this compound gave support to the postulated structure IV.

Pyrolysis of IV yielded ethylene dichloride. The liberation of ethylene dichloride on heating is characteristic of compounds bearing reactive β-chloroethylmercapto substituents (4). Infrared spectra showed the presence of a phenolic hydroxyl and this was confirmed by acetylation. The treatment of IV with 1 mole of alcoholic potassium hydroxide caused dehydrochlorination and cyclization to form 2,3,8,9-tetrahydro-5,6-bis(β-chloroethylmercapto)benzo(1,2-*b*:4,3-*b'*)bis(1,4-oxathiin) (V). The structure V was chosen in preference to the other possible isomer VI because V yielded on pyrolysis a tetracyclic compound VII which sublimed *in vacuo*. The isomer VI would be expected to yield on pyrolysis a polymer which would not sublime. Further support for the assignment of the structure IV lies in the fact that when 2,3,5,6-tetrakis(β-chloroethylmercapto)-1,4-hydroquinone (III) was treated with 2 moles of potassium hydroxide a double ring closure occurred to form the same tricyclic compound V as was obtained from IV by a similar treatment.

The properties of chloroquinones and their derivatives in the naphthalene series differed from those of the benzene series. Unlike chloranil, 2,3-dichloro-1,4-naphthoquinone (VIII) reacted with 2-mercaptoethanol and potassium hydroxide to give mostly tar and



a small yield of an orange-colored compound. When pyridine was substituted for the potassium hydroxide and the temperature strictly controlled a high yield of the orange-colored compound was obtained. This proved to be 2,3-bis(β-hydroxyethylmercapto)-1,4-naphthoquinone (IX) and not the quinol as was the case in the benzoquinone series. All attempts to convert IX to the sulphur mustard 2,3-bis(β-chloroethylmercapto)-1,4-naphthoquinone were unsuccessful. The treatment of IX with thionyl chloride, or with alcoholic hydrogen chloride, or with acetic acid – hydrogen chloride yielded in each case a chlorine-free black compound which sublimed readily *in vacuo* and crystallized as sparkling black crystals. Infrared spectra showed the presence of carbonyl group(s), the absence of hydroxyl groups, and analyses indicated the structure to be 1,4-oxathia-5,10-anthraquinone (X). Apparently this was formed by displacement of one of the β-hydroxyethylmercapto groups and cyclization.

There is one example in the literature (5) of displacement of a β-hydroxyethylmercapto group from 2,3,5,6-tetrachloro-1,4-bis(β-hydroxyethylmercapto)benzene but in this case it occurred in alkaline solution. However, the displacement of methoxy groups in the benzoquinone series by other alkoxy groups (6), by amines (1, 7, 10), and by other groups (1, 7, 8) is not uncommon.

The mechanism of the conversion of IX to X is probably similar to that proposed by Fieser (9) for the methylation of 2-hydroxy-1,4-naphthoquinone by methanolic hydrogen chloride. Intramolecular addition of one hydroxyl group to the conjugated system of the quinone IX occurs to form the intermediate XI. From this, mercaptoethanol is eliminated to form the oxathianthraquinone X.

EXPERIMENTAL

2,3,5,6-Tetrakis(β-hydroxyethylmercapto)1,4-hydroquinone (II)

(a) From Chloranil (I)

To a stirred solution of 2,3,5,6-tetrachloro-1,4-benzoquinone (chloranil) (100 g) in benzene (3.5 l.) warmed up to 45° was added dropwise a solution of 2-mercaptoethanol (200 ml) and potassium hydroxide (96 g) over 2 hours. The temperature of the reaction mixture dropped to 41° during the first few minutes and then rose gradually to 48°. The stirring was continued for another 2 hours. The dark, sticky material which precipitated changed gradually to a light-colored solid which floated in the stirred benzene. The reaction mixture was allowed to stand overnight and then the benzene was decanted from the sticky solid. The solid was stirred with cold water for ½ hour, filtered, washed, and dried, m.p. 141–143°; yield 138 g. Crystallization from aqueous methanol yielded (120 g; 72%) yellowish sparkling crystals melting at 144–145°. Anal. Calc. for $C_{14}H_{22}O_6S_4$: C, 40.58; H, 5.31. Found: C, 40.55; H, 5.18.

Infrared spectra of this compound indicated that it was the quinol and not the quinone. Furthermore, on treatment with zinc and acetic acid, II remained unchanged.

(b) From 2,5-Dichloro-3,6-dimorpholino-1,4-benzoquinone

To a solution of 2,5-dichloro-3,6-dimorpholino-1,4-benzoquinone (3 g) (1) in benzene (250 ml) was added 2-mercaptoethanol (10 ml) and pyridine (10 ml), and the dark reaction mixture heated under reflux for 15 hours. The benzene was removed from the light-colored mixture, the residue was treated with water, and the solid was filtered and crystallized from aqueous methanol. The sparkling crystals (2 g) melted at 144–145° alone or in admixture with those obtained in (*a*).

(c) From 2,5-Dichloro-3,6-di(N,N-dimethylamino)-1,4-benzoquinone

2,5-Dichloro-3,6-di(N,N-dimethylamino)-1,4-benzoquinone (1) was treated with 2-mercaptoethanol as above. The chloro as well as the dimethylamino groups were replaced and reduction occurred to form 2,3,5,6-tetrakis(β-hydroxyethylmercapto)-1,4-hydroquinone (IV) in 70% yield.

2,3,5,6-Tetrakis(β-acetoxyethylmercapto)1,4-hydroquinone

(a) Using Acetic Anhydride

To a solution of 2,3,5,6-tetrakis(β-hydroxyethylmercapto)-1,4-hydroquinone (II) (5 g) in pyridine (15 ml) was added acetic anhydride (10 ml) and the solution was heated under reflux for 2 hours. The pyridine and excess anhydride were removed *in vacuo*. The residue was pulverized, washed with water, and the white solid (6.5 g) was crystallized three times from methanol. This yielded white prisms melting at 90–91°. Anal. Calc. for $C_{22}H_{30}O_{10}S_4$: S, 21.99. Found: S, 22.42, 22.52.

(b) Using Acetic Acid and Hydrogen Chloride

Into a solution of 2,3,5,6-tetrakis(β-hydroxyethylmercapto)-1,4-hydroquinone (II) (35 g) in acetic acid (750 ml) at 60°, hydrogen chloride gas was passed until saturation, and the solution was allowed to stand overnight. The acetic acid was removed *in vacuo* from the amber solution and the residue was crystallized from benzene. The white needles (32 g) melted at 85–87°. Two further crystallizations from methanol yielded a product melting at 90–91° alone or in admixture with that obtained in (*a*).

2,3-Dihydro-5,7,8-tris(β-chloroethylmercapto)-6-hydroxy-1,4-benzoxathiin (IV)

(a) Using Hydrochloric Acid Saturated with Hydrogen Chloride

A solution of 2,3,5,6-tetrakis(β-hydroxyethylmercapto)-1,4-hydroquinone (II) (25 g) in concentrated hydrochloric acid (250 ml) was saturated with hydrogen chloride at room temperature (20°) and the resulting solution was allowed to stand overnight. The hard cake which precipitated was separated from the hydrochloric acid, pulverized, washed with water, and dried. This crude product (27 g), which melted at 98–105°, was dissolved in chloroform (100 ml) and treated with thionyl chloride (15 ml) at 30° in order to complete the chlorination. The solution was allowed to stand overnight and then the solvent was removed *in vacuo* and the residue crystallized from benzene. White needles (20 g) arranged in rosettes and melting at 129–130° were obtained. Repeated recrystallizations did not raise the melting point. Anal. Calc. for $C_{14}H_{17}Cl_3O_2S_4$: C, 37.21; H, 3.76; Cl, 23.6; S, 28.3. Found: C, 37.55, 37.27; H, 3.90, 3.67; Cl, 23.64, 23.19; S, 29.01, 28.84.

(b) Using Concentrated Hydrochloric Acid

In several other experiments the saturation of the concentrated hydrochloric acid solution with hydrogen chloride was omitted. The results obtained were the same as in (*a*). However, in a few runs the 2,3-dihydro-5,7,8-tris(β-chloroethylmercapto)-6-hydroxy-1,4-benzoxathiin (IV) was not obtained but instead the higher-melting 2,3,5,6-tetrakis(β-chloroethylmercapto)-1,4-hydroquinone (III) (see below) was formed. It is believed that the runs which yielded III were performed on hot and humid days.

(c) Using a Higher Temperature

A solution of 2,3,5,6-tetrakis(β-hydroxyethylmercapto)-1,4-hydroquinone (10 g) in concentrated hydrochloric acid (100 ml) was heated at 35–37° for 6 hours. The white, sticky precipitate was extracted with chloroform and the chloroform solution dried and treated with thionyl chloride (5 ml) as in (*a*). The yellow crystals (4.5 g) which precipitated melted at 175–176° and proved to be 2,3,5,6-tetrakis(β-chloroethylmercapto)-1,4-hydroquinone (III) (see below). The mother liquors were taken to dryness *in vacuo* and the residue on crystallization from benzene yielded 3.5 g of 2,3-dihydro-5,7,8-tris(β-chloroethylmercapto)-6-hydroxy-1,4-benzoxathiin (IV) melting at 129–130° alone or in admixture with that obtained in (*a*).

2,3-Dihydro-5,7,8-tris(β-chloroethylmercapto)-6-acetoxy-1,4-benzoxathiin

A mixture of 2,3-dihydro-5,7,8-tris(β-chloroethylmercapto)-6-hydroxy-1,4-benzoxathiin (10 g), acetic anhydride (50 ml), and two drops of concentrated sulphuric acid was heated on the steam bath for 4 hours. The excess anhydride was removed *in vacuo* and the residue washed with ether and with methanol and crystallized from benzene–methanol. The white prisms (5.5 g) melted at 120–122°. Anal. Calc. for $C_{16}H_{19}O_3Cl_3S_4$: C, 38.94; H, 3.85; Cl, 21.58. Found: C, 38.56, 39.32; H, 3.84, 3.99; Cl, 21.37, 21.05.

2,3,5,6-Tetrakis(β-chloroethylmercapto)-1,4-hydroquinone (III)

(a) Using 30% Hydrochloric Acid and Thionyl Chloride

To a solution of concentrated hydrochloric acid (d = 1.19, 200 ml) and water (55 ml) was added 2,3,5,6-tetrakis(β-hydroxyethylmercapto)-1,4-hydroquinone (II) (25 g), and the mixture shaken until dissolved. Then chloroform (250 ml) was added and the mixture was heated under reflux for 3 hours. The chloroform layer was separated, concentrated to 75 ml *in vacuo* at 40°, cooled to 30°, and treated with thionyl chloride (15 ml) at 30–35°. Precipitation began immediately. The reaction mixture was allowed to stand at room temperature for 3 hours and then cooled to 0° and filtered. The lemon-yellow prisms (20.5 g or 70%) melted at 179–181°. Anal. Calc. for $C_{14}H_{18}O_2Cl_4S_4$: C, 34.42; H, 3.69; Cl, 29.10. Found: C, 34.05; H, 3.59; Cl, 28.35, 28.94.

In another experiment, to a solution of II (35 g) in methanol (200 ml) and water (40 ml) was added concentrated hydrochloric acid (500 ml), and the solution was heated under reflux on the steam bath for ½ hour. The precipitate was extracted with chloroform and then treated with thionyl chloride as in the first experiment above. There was obtained 27 g of III melting at 174–176° and at 178–179° after crystallization from benzene.

(b) Using Alcoholic Hydrogen Chloride

Methanol (450 ml) (or ethanol) was saturated with hydrogen chloride at 10°. To this was added 2,3,5,6-tetrakis(β-hydroxyethylmercapto)-1,4-hydroquinone (II) (25 g). After about half an hour of shaking it dissolved. The solution was allowed to stand at room temperature for 2 days and then cooled to 0°. The white precipitate on filtration and drying melted at 159–161°. Repeated recrystallizations raised the melting point by a few degrees only. However, when the crude product was treated with thionyl chloride in chloroform pure III melting at 180° was obtained.

2,3,8,9-Tetrahydro-5,6-bis(β-chloroethylmercapto)benzo(1,2-b:4,3-b')bis(1,4-oxathiin) (V)

(a) From 2,3,5,6-Tetrakis(β-chloroethylmercapto)-1,4-hydroquinone (III)

To a boiling solution of 2,3,5,6-tetrakis(β-chloroethylmercapto)-1,4-hydroquinone (III) (1.0 g) in acetone (150 ml) and methanol (50 ml) was added a solution of potassium hydroxide (0.25 g) in methanol (25 ml). The resulting solution was boiled for a few minutes. The white precipitate which formed quickly was filtered, washed, and dried. It weighed 0.45 g and melted at 226–227° with decomposition. Recrystallization from ethylene dichloride raise the melting point to 228–229° with decomposition. Anal. Calc. for $C_{14}H_{16}O_2Cl_2S_4$: C, 40.48; H, 3.86. Found: C, 40.28, 40.11; H, 3.84, 3.91.

(b) From 2,3-Dihydro-5,7,8-tris(β-chloroethylmercapto)-6-hydroxy-1,4-benzoxathiin (IV)

To a hot solution of IV (35 g) in acetone (700 ml) was added methanol (700 ml) followed by a solution of potassium hydroxide (4.5 g) in methanol (200 ml). After standing for 1 hour the reaction mixture was filtered and the white solid (22 g) melting at 218–220° with decomposition was crystallized from ethylene dichloride. The white prisms melted at 228–229° with decomposition, alone or in admixture with that obtained in (*a*).

2,3,8,9-Tetrahydro-5,6-ethylenedithio-benzo(1,2-b:4,3-b')bis(1,4-oxathiin) (VII) and Ethylene Dichloride from V

2,3,8,9-Tetrahydro-5,6-bis(β-chloroethylmercapto)benzo(1,2-*b*:4,3-*b'*)bis(1,4-oxathiin) (V) (1.0 g) was heated in a Späth bulb at 250° for a few minutes, the distillate being collected in a dry-ice trap. The distillate was treated with a solution of excess potassium *p*-chlorothiophenate in methanol, yielding a white compound (0.32 g) which melted at 92–94° and which did not depress the melting point of 1,2-bis(*p*-chlorophenylmercapto)ethane. This showed that the distillate was mainly ethylene dichloride.

The residue in the Späth bulb was then sublimed at 250° at 0.5 mm pressure. The chlorine-free sublimate was crystallized from benzene, yielding 0.25 g of almost white needles, m.p. 239–240°. Anal. Calc. for $C_{12}H_{12}O_2S_4$: C, 45.57; H, 3.79; S, 40.50. Found: C, 45.61, 45.48; H, 4.04, 3.98; S, 40.68, 41.14.

Pyrolysis of 2,3-Dihydro-5,7,8-tris(β-chloroethylmercapto)-6-hydroxy-1,4-benzoxathiin (IV)

2,3-Dihydro-5,7,8-tris(β-chloroethylmercapto)-6-hydroxy-1,4-benzoxathiin (IV) (25 g) was heated in a distilling flask equipped with a condenser at 200° until no more liquid distilled. The distillate (5 g) had all the physical properties of *ethylene dichloride*. A derivative was prepared by heating the distillate (2 g) with a methanolic solution of excess potassium *p*-chlorothiophenate. The product (4 g) melted at 93–94° and did not depress the melting point of 1,2-bis(*p*-chlorophenylmercapto)ethane.

Pyrolysis of 2,3,5,6-Tetrakis(β-chloroethylmercapto)-1,4-hydroquinone (III)

2,3,5,6-Tetrakis(β-chloroethylmercapto)-1,4-hydroquinone (III) was pyrolyzed in the same manner as was IV above. Ethylene dichloride (0.5 g) was obtained from 2 g of III.

2,3-Bis(β-hydroxyethylmercapto)-1,4-naphthoquinone (IX)

(a) Using Potassium Hydroxide and 2-Mercaptoethanol

To a stirred solution of 2,3-dichloro-1,4-naphthoquinone (VIII) (60 g) in benzene (2 l.) was added dropwise a solution of 2-mercaptoethanol (45 ml) and potassium hydroxide (30 g) over $1\frac{1}{4}$ hours. The temperature was kept at 40° by cooling. The dark reaction mixture was stirred for 2 hours and then let stand overnight. The warmed benzene solution was decanted from the salt and tar, concentrated to about 700 ml, and allowed to cool. The precipitate was filtered and crystallized from methanol, yielding orange needles (12 g) melting at 117–118°. Anal. Calc. for $C_{14}H_{14}O_4S_2$: C, 54.19; H, 4.51. Found: C, 54.53, 54.12; H, 4.51, 4.63.

(b) Using Pyridine and 2-Mercaptoethanol

A solution of 2,3-dichloro-1,4-naphthoquinone (VIII) (100 g) in benzene (1600 ml) and 2-mercaptoethanol (72 ml) was stirred and the temperature adjusted to exactly 54°. Then pyridine (80 ml) was added all at once. When the temperature reached 66° (in a few minutes) the reaction mixture was cooled occasionally on a water bath in order to keep the temperature at 65–67°. In about 15 minutes precipitation was complete and the temperature began to fall. The reaction mixture was cooled, treated with water, the precipitate filtered, washed with water, and crystallized from methanol. The yield of orange needles from two crops melting at 115–116° was 94 g. This compound turned dark and decomposed on standing in air after a few weeks.

2,3-Bis(β-hydroxyethylmercapto)-1,4-naphthoquinol

To a suspension of 2,3-bis(β-hydroxyethylmercapto)-1,4-naphthoquinone (IX) (62 g) in glacial acetic acid (620 ml) was added portionwise, with cooling on a water bath, zinc dust (25 g). The temperature was kept at 25–30°. After being stirred for 1 hour the reaction mixture was filtered and the filtrate taken to dryness *in vacuo*. The residue on crystallization from methanol yielded 39 g of white prisms melting at 124–126°. Anal. Calc. for $C_{14}H_{16}O_4S_2$: S, 20.51. Found: S, 20.52, 20.54. This quinol turned red on exposure to the air.

1,4-Oxathia-5,10-anthraquinone (X)

To a solution of 2,3-bis(β-hydroxyethylmercapto)-1,4-naphthoquinone (IX) (25 g) in methanol (300 ml) at 50° was added a solution of dry hydrogen chloride (120 g) in methanol (200 ml). The temperature rose to

60° and cooling was necessary in order to keep it below 60°. The dark purple solution was allowed to stand overnight and then the precipitated black sparkling crystals (10.5 g) were filtered, washed with methanol and benzene, and dried. This halogen-free compound melted at 230–232° and at 231–233° after sublimation at a temperature of 200° and a pressure of 1 mm. Anal. Calc. for $C_{16}H_8O_3S$: C, 62.07; H, 3.45; S, 13.8. Found: C, 61.52, 62.51; H, 3.49, 3.07; S, 14.16.

The same results were obtained when IX was treated with hydrogen chloride in acetic acid instead of in methanol.

THE ACID-CATALYZED CLEAVAGE OF PHENYLSULPHINYLACETIC ACID

DEREK WALKER[1] AND JOSEPH LEIB
Research Laboratory, Dominion Tar and Chemical Company, Ltd., Ville LaSalle, Que.

Received January 22, 1962

ABSTRACT

A study of the hydrogen peroxide oxidation of phenylmercaptoacetic acid led to a new interpretation of the mechanism of the acid-catalyzed cleavage of phenylsulphinylacetic acid.

Phenylsulphinylacetic acid is known to undergo a facile cleavage to benzenethiol and glyoxylic acid in the presence of mineral acids (1) (equation [1]).

$$C_6H_5\overset{\uparrow}{S}(O)CH_2CO_2H \xrightarrow{H^{\oplus}} C_6H_5SH + OHCCO_2H \qquad [1]$$

This reaction has not been studied in detail although Pummerer (1) and, more recently, Kenney, Walsh, and Davenport (2) have suggested possible mechanisms based on the evidence available to them. The mechanism advanced by Pummerer is summarized in equation [2].

$$C_6H_5\overset{\uparrow}{S}(O)CH_2CO_2H \xrightarrow{H^{\oplus}} \underset{\text{I}}{C_6H_5S(OH)=CHCO_2H} \longrightarrow \underset{\text{II}}{C_6H_5S(OH)CHCO_2H} \downarrow \; C_6H_5SH + OHCCO_2H \qquad [2]$$

Kenney, Walsh, and Davenport put forward the scheme illustrated by equation [3].

$$C_6H_5\overset{\uparrow}{S}(O)CH_2CO_2H \xrightarrow{H^{\oplus}} \left[C_6H_5\overset{\uparrow}{\underset{H}{S}}(O)CH_2CO_2H\right]^{+} \longrightarrow \left[C_6H_5\underset{H}{S}\!-\!O\!-\!\underset{H}{CHCO_2H}\right]^{+} \downarrow \; \underset{\text{II}}{C_6H_5S(OH)CHCO_2H} \rightleftharpoons C_6H_5SH + OHCCO_2H \qquad [3]$$

Thus, according to Kenney, Walsh, and Davenport, phenylmercaptohydroxyacetic acid (II) results from a recombination of benzenethiol and glyoxylic acid. Pummerer, on the other hand, suggested that II was formed prior to benzenethiol and glyoxylic acid.

In this paper evidence is presented to support the view suggested by Pummerer. A new interpretation of the mechanism of the acid-catalyzed cleavage of phenylsulphinylacetic acid is also proposed.

In contrast with previous workers, our study of the cleavage of phenylsulphinylacetic acid was carried out without adding acid to catalyze the reaction. In other words phenylsulphinylacetic acid was the sole source of the protons necessary for catalysis. The

[1]*Present address: Arapahoe Chemicals, Inc., Boulder, Colorado, U.S.A.*

cleavage of phenylsulphinylacetic acid was accomplished in supersaturated aqueous solution, in methyl ethyl ketone, and in benzene. The supersaturated aqueous solution used in the present work was prepared by mixing equimolecular quantities of 30% hydrogen peroxide and phenylmercaptoacetic acid, and controlling the temperature below 40° until the hydrogen peroxide had been consumed. The clear solution thus obtained is supersaturated with respect to phenylsulphinylacetic acid since the solubility of this acid in water at 25° is only about 5%.

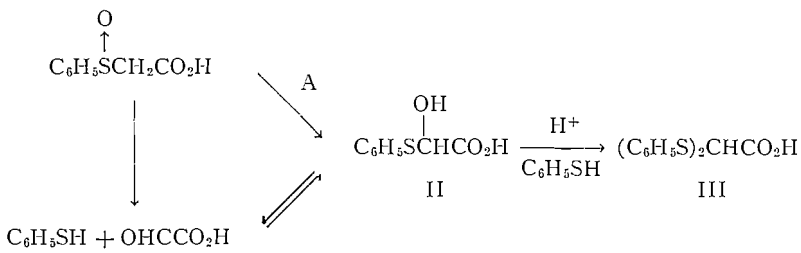
Phenylsulphinylacetic acid, in supersaturated aqueous solution at room temperature, is first converted into a water- and benzene-soluble acidic syrup which, in turn, breaks down into benzenethiol and glyoxylic acid. Further interactions between benzenethiol, glyoxylic acid, and the above-mentioned syrup occur over a period of time. The major products of these interactions are bis(phenylmercapto)acetic acid, diphenyl disulphide, and an unidentified oil. The unidentified oil was isolated from a supersaturated solution of phenylsulphinylacetic acid which had stood for 3 months.

All of these changes are accelerated by heat; higher temperatures favor the formation of bis(phenylmercapto)acetic acid.

The water- and benzene-soluble acidic syrup described above was also obtained by boiling phenylsulphinylacetic acid in dry methyl ethyl ketone or in dry benzene. If a pure sample of phenylsulphinylacetic acid is used no odor of benzenethiol is detectable during the course of this reaction. The properties of the water- and benzene-soluble acidic syrup obtained from the above preparations are compatible with those expected of phenylmercaptohydroxyacetic acid (II). Thus, the water- and benzene-soluble acidic syrup gave benzenethiol in high yield when it was warmed with aqueous mineral acid, and gave a high yield of bis(phenylmercapto)acetic acid when it was allowed to stand with benzenethiol in the presence of an acid catalyst. Further, the water- and benzene-soluble acidic syrup gave tests for an α-hydroxy acid with lead tetraacetate (3) and N-bromosuccinimide (4). Throughout the rest of this paper the water- and benzene-soluble acidic syrup will be referred to as II even though absolute proof of the correctness of this assignment is lacking.

The methods of preparing II suggested that this material was formed by an intramolecular rearrangement of phenylsulphinylacetic acid, and, hence, not by the recombination of benzenethiol and glyoxylic acid, as proposed by Kenney, Walsh, and Davenport (equation [3]).

Further proof for an intramolecular rearrangement of phenylsulphinylacetic acid to II was obtained by studying the reactions illustrated by equation [4].



[4]

According to equation [4], if II is formed intramolecularly (route A), glyoxylic acid will not intervene in the formation of bis(phenylmercapto)acetic acid (III). Thus, formation of III in the presence of a scavenger for glyoxylic acid should provide clear evidence for route A.

When equimolecular amounts of phenylsulphinylacetic acid and benzenethiol were allowed to react in the presence of hydrazine sulphate, III was obtained in 32% yield. This experiment was repeated using equivalent amounts of glyoxylic acid and benzenethiol in place of the phenylsulphinylacetic acid; no III was isolated. These experiments were also carried out without adding hydrazine sulphate. Phenylsulphinylacetic acid and benzenethiol gave a 40% yield of III and glyoxylic acid and benzenethiol gave a 15% yield of III.

The above experiments, while clearly supporting an intramolecular rearrangement of phenylsulphinylacetic acid to II, do not prove that such a rearrangement is the exclusive reaction. It is our impression, however, that the rearrangement of phenylsulphinylacetic acid to II is the predominant reaction.

The above study led us to perfect a novel method for cleaving phenylmercaptoacetic acid to benzenethiol. The cleavage was accomplished by adding 30% hydrogen peroxide to a suspension of phenylmercaptoacetic acid in boiling aqueous mineral acid. Benzenethiol was removed as it was formed, by passing steam into the reaction mixture.

EXPERIMENTAL[2]

Formation and Cleavage of Phenylsulphinylacetic Acid

(1) Uncontrolled Reaction

Phenylmercaptoacetic acid (16.8 g) was treated with 30% hydrogen peroxide (11.4 ml). The resultant mixture soon turned liquid and erupted into vigorous boiling, which continued for about 5 minutes. When the reaction was over the mixture was allowed to cool to room temperature and water was removed under vacuum, in a rotary evaporator heated to about 60° C. A clear syrup was obtained. Digestion of this syrup with hot benzene (2×100 ml) for a few minutes left essentially pure phenylsulphinylacetic acid (9.2 g, 50%), m.p. 108–111° C. The benzene solution was extracted first with aqueous sodium bicarbonate and then with aqueous sodium hydroxide. Repeated extraction of the acidified sodium bicarbonate extract with chloroform removed phenylmercaptohydroxyacetic acid (2.6 g, 14%), which was recovered as a clear syrup by evaporation of the dried chloroform solution. Benzenethiol (0.8 g, 7.3%) was obtained by acidification of the sodium hydroxide extract. Evaporation of the neutral benzene layer gave diphenyl disulphide (1.0 g, 9.2%).

(2) Controlled Reaction

Phenylmercaptoacetic acid (16.8 g) was treated with 30% hydrogen peroxide (11.4 ml). The reaction mixture was stirred and held at about 40° C, by a cold-water bath, until all the hydrogen peroxide had been consumed (starch–iodide paper). At the end of the reaction a clear, colorless supersaturated solution of phenylsulphinylacetic acid was obtained. Evaporation of the water was carried out by the method described for the uncontrolled reaction above. Digestion of the product with hot benzene (2×100 ml) for a few minutes left phenylsulphinylacetic acid (17.5 g, 95%), m.p. 108–111° C. Vacuum evaporation of the benzene gave phenylmercaptohydroxyacetic acid (0.9 g, 5%), which was obtained as a syrup.

Supersaturated solutions of phenylsulphinylacetic acid obtained in the above-described manner were allowed to stand at room temperature in stoppered flasks for longer times:

(a) 6 days.—Faint signs of phase separation appeared in 3–4 days. After 6 days the water was removed by the method described for the uncontrolled reaction above. The following products and yields were obtained: phenylsulphinylacetic acid (11.7 g, 64%, m.p. 107–110° C), phenylmercaptohydroxyacetic acid (3–4 g of a syrup containing some bis(phenylmercapto)acetic acid), benzenethiol (0.8 g, 7.3%), diphenyl disulphide (0.4 g, 3.7%, m.p. 58–60° C).

(b) 3 months.—At the end of this period a heavy yellow oil and voluminous white crystals had separated from the original clear solution. The white crystals were filtered and shown to be diphenyl disulphide (1 g, 9.2%, m.p. 59–60° C). The filtrate when diluted with three times its volume of water still comprised two layers. These were separated and worked up individually. The aqueous layer was repeatedly extracted with benzene, evaporation of which yielded bis(phenylmercapto)acetic acid (0.5 g, 3.6%, m.p. 101–103° C) and benzenethiol (0.5 g, 4.5%). The water layer was evaporated, in a rotary evaporator at about 60°, and yielded phenylmercaptohydroxyacetic acid (1.5 g, 8%). The oil layer (15.5 g) gave an emulsion when treated with benzene (50 ml). The benzene–oil emulsion reacted vigorously with an excess of aqueous sodium bicarbonate; carbon dioxide was evolved and two clear phases resulted. Acidification of the aqueous layer gave bis(phenylmercapto)acetic acid (2.5 g, 18%, m.p. 100–103° C). The aqueous acid solution, after filtration of bis(phenylmercapto)acetic acid, was kept for further work-up. Extraction of the benzene layer with aqueous sodium hydroxide and acidification of the latter gave benzenethiol (2 g, 18%). The aqueous acid solution,

[2]*Melting points and boiling points are uncorrected.*

after removal of benzenethiol, was kept for further work-up. The benzene on evaporation gave diphenyl disulphide (0.5 g, 4.6%). The two aqueous acid solutions obtained above were combined and steam-distilled for several hours. Benzenethiol (2.8 g, 25%) was collected.

(3) Bis(phenylmercapto)acetic Acid Formation

A supersaturated solution of phenylsulphinylacetic acid, prepared from phenylmercaptoacetic acid (33.6 g) in the manner described above, was heated at about 100° C for 4 hours. A heavy oil separated during the reaction and on cooling this solidified. Some water was added, and the solid was broken up, filtered, and washed with water. The aqueous filtrate and water washings were combined and extracted with chloroform. The water on evaporation (rotary evaporator at about 60°) gave phenylmercaptohydroxyacetic acid (9.1 g, 25%).

The chloroform extract was combined with the solid on the filter, and a homogeneous solution was prepared by the addition of benzene. Extraction of this solution with aqueous sodium bicarbonate and acidification of the extract gave bis(phenylmercapto)acetic acid (18.2 g, 66%, m.p. 102–103° C). A trace of benzenethiol was extracted from the benzene–chloroform solution with aqueous sodium hydroxide. Evaporation of the neutral solvent gave diphenyl disulphide (1.8 g, 8.3%).

Cleavage of Phenylsulphinylacetic Acid in Organic Media

(1) Methyl Ethyl Ketone

Phenylsulphinylacetic acid (10 g) was refluxed in methyl ethyl ketone (50 ml) for 4 hours. At the end of this period the methyl ethyl ketone was removed under vacuum (rotary evaporator) and the product was digested with hot benzene. The benzene-insoluble portion was unchanged phenylsulphinylacetic acid (6.5 g, 65%, m.p. 107–110° C). Evaporation of the benzene extract gave phenylmercaptohydroxyacetic acid (3.3 g, 33%).

(2) Benzene

This reaction was conducted in the same manner as was the previous experiment. The benzene suspension was cooled, and unchanged phenylsulphinylacetic acid (8.6 g, 86%, m.p. 108–111° C) was filtered. Evaporation of the benzene gave phenylmercaptohydroxyacetic acid (1.5 g, 15%).

Evidence for the Structure of Phenylmercaptohydroxyacetic Acid (II)

This acid was always obtained as a clear, water- and benzene-soluble acidic syrup. The syrup was miscible with water in all proportions; however, its solubility in benzene was only moderate. The syrup has been described as benzene-soluble throughout this paper because benzene proved a convenient solvent for extracting syrup away from phenylsulphinylacetic acid.

Steam distillation of an acidified aqueous solution of phenylmercaptohydroxyacetic acid led to an almost quantitative recover of benzenethiol.

Phenylmercaptohydroxyacetic acid (3.2 g) and benzenethiol (10 g), when allowed to stand with concentrated sulphuric acid (1 drop) for 4 days, gave bis(phenylmercapto)acetic acid (3.0 g, 62%, m.p. 99–102° C).

Phenylmercaptohydroxyacetic acid gave the tests for an α-hydroxy acid with lead tetraacetate (3) and N-bromosuccinimide (4).

Bis(phenylmercapto)acetic Acid from Phenylsulphinylacetic Acid and Benzenethiol

(1) In the Presence of Hydrazine Sulphate

Benzenethiol (1.1 g) was added to a freshly prepared solution of phenylsulphinylacetic acid (1.84 g) in a mixture of acetic acid (7 ml) and water (3.7 ml). Hydrazine sulphate (1.43 g) was added followed by concentrated sulphuric acid (4 drops). After the mixture had been refluxed for 2 hours it was poured into water (50 ml). The water suspension was extracted with ether, the ether was washed with water, and was then extracted with aqueous sodium bicarbonate. The sodium bicarbonate extract was acidified to give bis-(phenylmercapto)acetic acid (0.88 g, 32%, m.p. 102–104° C).

(2) Without Hydrazine Sulphate

The experiment just described was repeated without the hydrazine sulphate. Bis(phenylmercapto)acetic acid, m.p. 102–104°, was obtained in 40% yield.

Bis(phenylmercapto)acetic Acid from Glyoxylic Acid and Benzenethiol

(1) In the Presence of Hydrazine Sulphate

Benzenethiol (2.2 g) was added to a freshly prepared solution of glyoxylic acid hydrate (0.92 g) in a mixture of acetic acid (7 ml) and water (3.5 ml). Hydrazine sulphate (1.43 g) was added followed by concentrated sulphuric acid (4 drops), and the mixture was refluxed for 2 hours. The resulting yellow suspension was poured into water (50 ml), and the mixture thus obtained was extracted with ether. The ether solution was washed with water and extracted with aqueous sodium bicarbonate. Acidification of the sodium bicarbonate gave no bis(phenylmercapto)acetic acid.

(2) Without Hydrazine Sulphate

The experiment just described was repeated without the hydrazine sulphate. Bis(phenylmercapto)acetic acid, m.p. 102–103° C, was obtained in 14.5% yield.

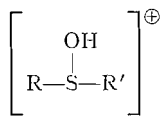
Oxidative Cleavage of Phenylmercaptoacetic Acid to Benzenethiol

Phenylmercaptoacetic acid (8.4 g) and 10% aqueous sulphuric acid (75 ml) were charged to a 250-ml 3-necked flask equipped as for a steam distillation. The third neck was fitted with a dropping funnel. Steam was passed into the mixture in the flask until a steady distillation was in progress. Hydrogen peroxide (10 ml of 30% aqueous solution) was added dropwise over 60 minutes. Benzenethiol started to distill in the steam shortly after addition of the hydrogen peroxide was commenced. Steam distillation was continued until benzenethiol ceased to pass over. Zinc dust (1 g) was then added to the flask and the steam distillation continued until no further benzenethiol distilled. The steam distillate was extracted with ether and the ether dried with anhydrous sodium sulphate. Benzenethiol (4.4 g, b.p. 166–169° C, 80%) was recovered from the ether by distillation.

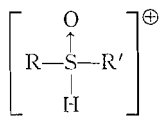
This process was applied to *p*-tolylmercaptoacetic acid; *p*-toluenethiol (m.p. 42–44° C) was obtained in 75% yield.

DISCUSSION

Conjugate acids of sulphoxides with proton have been described by Connor (5) as possessing either structure IV or structure V.



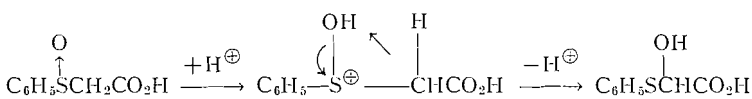
IV



V

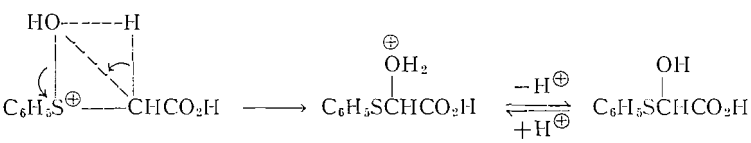
The oxygen atom of sulphoxides is, however, generally regarded as being more basic than the sulphur atom (2, 6, 7). Thus, in the case of the rearrangement of the conjugate acid of phenylsulphinylacetic acid a structure of type IV (R = $C_6H_5\cdot$, R′ = $\cdot CH_2CO_2H$) would appear to be more important than a structure of type V (R = $C_6H_5\cdot$, R′ = $\cdot CH_2CO_2H$).

Our observations provide strong support for an intramolecular rearrangement of IV (R = $C_6H_5\cdot$, R′ = $\cdot CH_2CO_2H$) to II. The following scheme (equation [5]) would seem to fit the experimental facts best:



[5]

The reaction may be concerted in that loss of proton from the methylene carbon atom could coincide with the rearrangement as indicated. On the other hand, such associations as illustrated by the dotted lines in structure VI may lead to a collapse of the molecule in the manner illustrated by equation [6].



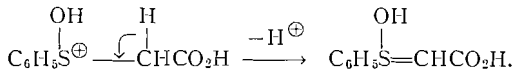
[6]

VI

In regard to equation [5] it is interesting to note that anions in solution do not appear to assist, to a significant extent, in the removal of proton from the methylene carbon atom. Thus, when sodium chloride was added to a standard preparation of II no noticeable increase in the yield of II was observed.

The carboxylic acid group probably plays an important part in the above mechanism by weakening the carbon–hydrogen bonds of the methylene group.

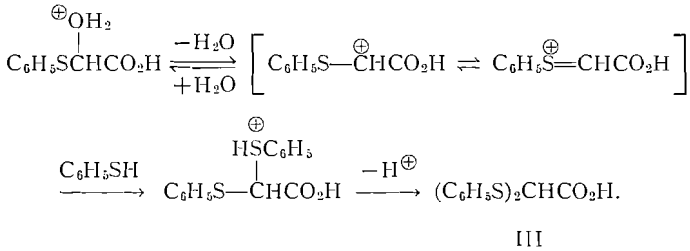
The mechanism proposed in equation [5] shows similarities to that suggested, on intuitive grounds, by Pummerer (equation [1]). The intermediate (I), suggested by Pummerer, might well arise from the conjugate acid of phenylsulphinylacetic acid thus:



I

A close relationship exists between the mechanism proposed in equation [5] and the rearrangement of the chlorosulphonium chloride of thioanisole described by Bordwell and Pitt (8). The work described by Bordwell and Pitt led us to establish a parallel between equation [5] and the intramolecular rearrangement of halosulphonium halides of arylmercaptoacetic acids (9).

The mechanism by which bis(phenylmercapto)acetic acid (III) is formed from benzenethiol and phenylmercaptohydroxyacetic acid (II) undoubtedly follows the general scheme suggested by Campaigne and Leal (10). Resonance stabilization of the carbonium ion intermediate was not suggested by these workers but seems very likely in view of the work of Bordwell, Cooper, and Morita (11). The mechanism may thus be written:



III

The foregoing mechanisms appear to account, in reasonable manner, for the formation of glyoxylic acid, benzenethiol, and bis(phenylmercapto)acetic acid by the acid-catalyzed cleavage of phenylsulphinylacetic acid. Some observations, however, still remain unexplained. Thus, on occasion, supersaturated aqueous solutions of phenylsulphinylacetic acid have given more diphenyl disulphide than can be accounted for by the oxygen of the air in the system. Perhaps the sulphoxide acts as an oxidizing agent (8).

The present paper raises questions concerning the generality of the intramolecular rearrangement of sulphoxides. The influence of ring substituents on the rearrangement of arylsulphinylacetic acids will be mentioned in future papers by us (9). However, since our work was restricted to arylsulphinylacetic acids and related compounds it is pertinent to draw attention to the acid-catalyzed rearrangement of diamyl sulphoxide for which Szmant (12) has tentatively suggested an intermolecular mechanism.

THE PHOTODIMERS OF COUMARIN AND RELATED COMPOUNDS[1]

RAGINI ANET
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received February 28, 1962

ABSTRACT

The photodimer of coumarin is shown to have the head-to-head cis cyclobutane structure I. An isomer, obtained by the lactonization of *o*-hydroxy-*trans*-cinnamic acid, is shown to have the head-to-tail trans structure II. The photodimers of *o*-methoxy- and *o*-hydroxy-*trans*-cinnamic acids have been interrelated.

The photodimer of coumarin has been known for nearly 60 years (1). In the last 20 years, the photodimers of several substituted coumarins have also been prepared (2). These have been of interest, as the substituted coumarins, e.g., the furanocoumarins, are known to react with the skin in presence of light (3). Some of these furanocoumarins, e.g. xanthotoxin, have in fact been used for the treatment of skin depigmentation as occurs in leucoderma, in both the Middle East and in India (2, 4). The photodimers of these compounds are known (5) but the structure of the dimers have not been determined. The present work describes the elucidation of the structure and stereochemistry of the photodimer of coumarin, the parent compound in this series.

A cyclobutane-type structure was assigned to these dimers (2) by analogy with the dimerization of the cinnamic acids to 1α,3β-diphenylcyclobutane-2α,4β-dicarboxylic (α-truxillic)[2] and 1α,2α-diphenylcyclobutane-3β,4β-dicarboxylic (β-truxinic) acid (6). The similarity in ultraviolet absorption spectra of 3,4-dihydro-7-methoxycoumarin and of the photodimer of 7-methoxycoumarin (III) lent support to a cyclobutane structure in which the 3,4-double bonds of the two pyrone rings were involved (8). An incomplete X-ray diffraction study on III published in 1958 (9) confirmed the presence of a cyclobutane ring; no conclusions regarding the disposition of the rest of the molecule were drawn.[3]

On the basis of a cis fusion[4] of the cyclobutane ring to the 6-membered pyrone rings, four structures can be considered for coumarin dimers, and are represented in Fig. 1. There are two sets of structural isomers, head-to-head and head-to-tail, each of which can exist in a cis or trans form. The problems of isomerism are simpler than in the case of dimeric cinnamic acids, where 11 possible isomers can exist.

The elucidation of the structures of the cinnamic acid dimers is largely due to the extensive work of Störmer and his collaborators (for a summary see ref. 6). The German workers distinguished among the various isomers by carrying out optical resolutions on suitable derivatives. With the physical methods now available, these time-consuming procedures are no longer necessary. For example, infrared spectroscopy can be useful in distinguishing between 5- and 6-membered anhydrides, thus allowing a distinction to be

[2]*The relative stereochemistry of substituents on the cyclobutane ring is designated α and β following Fieser's convention for carbohydrate derivatives (7).*

[3]*This work is erroneously reported in the Annual Reports of the Chemical Society (London), 1958, as showing a head-to-head structure for III.*

[4]*Recently, Corse, Finkle, and Lundin (10) have postulated a transfusion of cyclobutane rings to a cyclohexane-1,4-dione ring to explain the n.m.r. spectrum of the photodimer of 1,5-dicarbomethoxy-3-ketopenta-1,4-diene.*

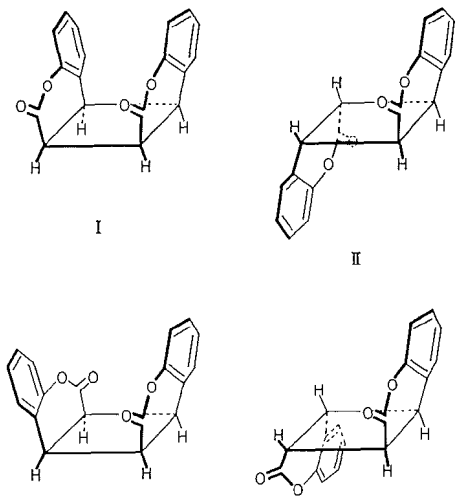

FIG. 1. Four isomeric structures for coumarin dimers. I represents the photodimer of coumarin, and II, the dilactone derived from the photodimer of *o*-hydroxy-*trans*-cinnamic acid.

made between the head-to-head (truxinic) and head-to-tail (truxillic) type dimers. Furthermore, n.m.r. spectroscopy can be a powerful tool in determining the relative stereochemistry of substituents on a cyclobutane ring, by taking advantage of the symmetry properties of these derivatives. Both these methods proved very valuable in the present work.

The photodimer of coumarin was prepared according to the method of Ciamician and Silber (1), viz., irradiation of an ethanolic solution of coumarin with sunlight. The same compound was also obtained by Schönberg's method (11), irradiation of a suspension of coumarin in water.

The only meaningful work reported on the photodimer of coumarin was Schönberg's observation (11) that it dissociated to coumarin on heating. This has been confirmed in the present study. de Jong's experiments (12) on I were of little value, as the products obtained were poorly characterized; no elemental analyses were recorded. For example, alkali fusion of I was reported to give an acid, m.p. 157°, which was claimed to be a cyclobutane dicarboxylic acid. Attempted repetition gives only salicylic acid, m.p. 158°.

In the present work, I was found to give a di-*o*-hydroxyphenylcyclobutane-dicarboxylic acid (IV), $C_{18}H_{16}O_6$, by dissolution of I in hot alkali, followed by careful acidification below 0°. The acid cyclized very readily to I in presence of a trace of acid at room temperature. The cyclization also took place on heating, so that the melting point of IV was not its true melting point, but that of I. The stereochemistry of IV and I was therefore identical.

In order to obtain a dimethyl ether dimethyl ester of the same stereochemistry as I, methylation of IV was tried with diazomethane. However, even after prolonged treatment, the material was largely phenolic. Methylation with dimethyl sulphate and alkali took place slowly, but after 36 hours at room temperature, 65–75% of phenolic compound had reacted, as estimated by the change in ultraviolet absorption spectrum in going from an alkaline to an acid solution (13). As this was expected to be a mixture of epimeric, as well as partially and fully methylated, products, the crude material was treated with diazomethane. A crystalline dimethyl ether dimethyl ester, V, $C_{22}H_{24}O_6$, m.p. 110°, was obtained in 70% overall yield. It was found to be homogenous by chromatography.

The n.m.r. spectrum of V (Fig. 2) was very informative. The spectrum revealed the presence of four different[5] methoxyl groups (τ, 6.26, 6.32, 6.59, and 6.82 (15)). Thus V can

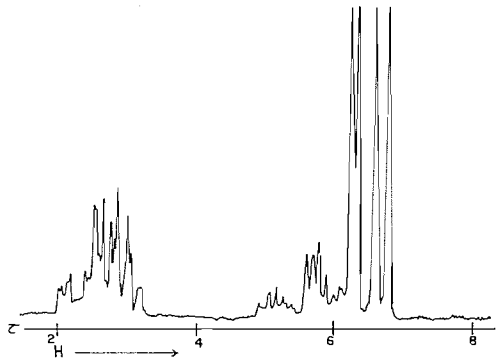

FIG. 2. The n.m.r. spectrum of V in carbon tetrachloride solution. τ values refer to tetramethylsilane as internal standard.

contain no elements of symmetry (axis, plane, or center), based on a time-average structure. This was in agreement with the unsymmetrical nature of the spectrum of the cyclobutane protons (τ, 5.0–6.3). The aromatic protons occurred at lowest field (τ, 1.98–3.6), and intensity measurements showed that the ratio of aromatic protons to methoxyl protons was 8.12.

The absence of symmetry deduced from the n.m.r. spectrum eliminated 9 of the 11 possible structures for a dimethyl ether dimethyl ester derived from the four possible structures for I (Fig. 1), taking into account the possibilities of epimerization. The 11 structures (*dl*-structures being counted as one) are shown in Fig. 3.

The esters can be divided into two groups, five, *a* to *e*, derived from a head-to-tail (truxillic type) and six, *f* to *k*, from a head-to-head (truxinic type) acid. Structures *a* to *e* can be eliminated for V, as all of them have an element of symmetry; *a* has a center, *b* and *e* have a plane, and *c* and *d* have both a plane and an axis of symmetry. None of these compounds can give rise to four methyl bands in the n.m.r. spectrum. Whereas *a*, *c*, and *d* should give rise to only two bands corresponding to six protons each, *b* and *e* would be expected to give rise to three bands in the ratio of 3:3:6. The ester V, and therefore I, can not be derived from a head-to-tail type structure. Of the six truxinic or head-to-head types, four structures, *f*, *g*, *h*, and *i*, can be eliminated. All these will give rise to only two methyl bands, as *f* and *g* have a plane of symmetry and *h* and *i* have an axis of symmetry in the plane of the cyclobutane ring. The two remaining structures, *j* and *k*, are the only possible structures for V, as they contain no element of symmetry. Each of them is formed from a head-to-head type structure for I.

In order to distinguish between the two possible structures *j* and *k* for V, the ester was treated with sodium methoxide in methanol. An epimeric ester, VI, $C_{22}H_{24}O_6$, m.p. 138°, was obtained. The n.m.r. spectrum of VI showed only two methyl bands (τ, 6.32 and 6.46), each corresponding to six protons; an element of symmetry had been restored during this epimerization. The ester VI was shown to be a cis diester as follows. Hydrolysis of VI with alkali gave a dicarboxylic acid, VII, $C_{20}H_{20}O_6$, m.p. 202°. With acetic anhydride, VII gave an anhydride, VIII, $C_{20}H_{18}O_5$, m.p. 121°. No epimerization took

[5]*The bands at τ 6.26 and 6.32 are tentatively assigned to the methoxyl groups on the phenyl rings by comparison with the n.m.r. spectrum of the fully methylated product obtained from the photodimer of 7-methoxycoumarin (14).*

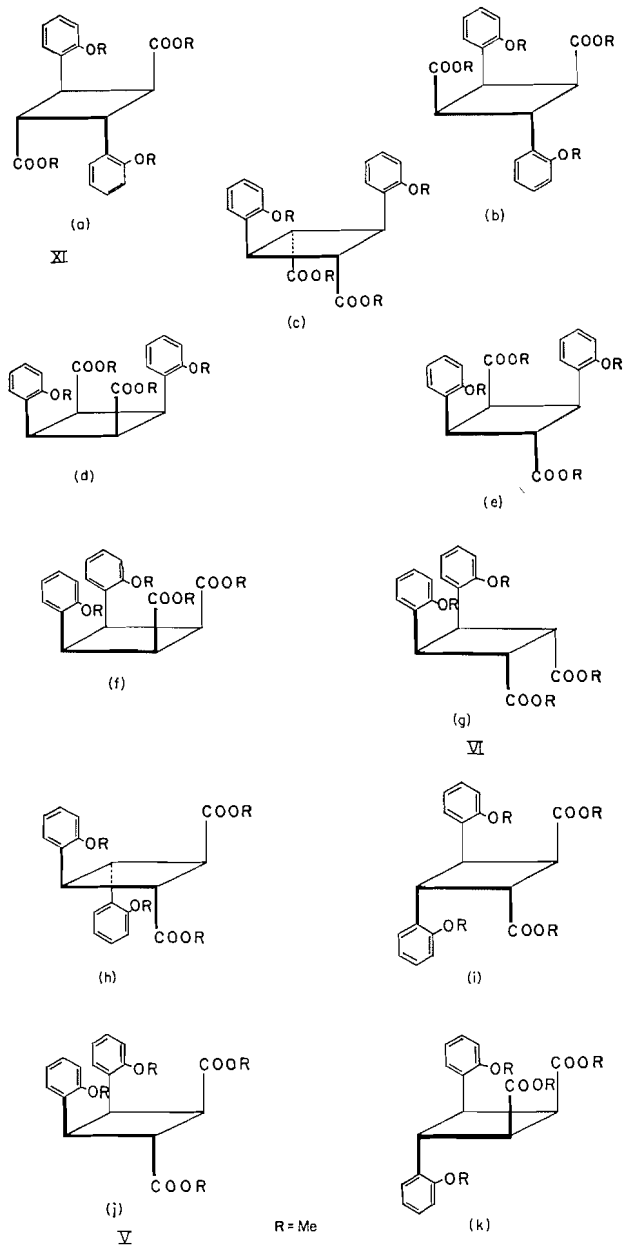

FIG. 3. The 11 isomeric structures for a dimethyl ether dimethyl ester derived from the four structures depicted in Fig. 1. V, VI, and XI are referred to in the text. Only one enantiomer of a *dl*-structure is shown.

place in this sequence of reactions, as VIII could be converted to VII with alkali at room temperature and further to VI with diazomethane. The carbonyl frequencies of the anhydride (1854 and 1768 cm^{-1}) were characteristic of a 5-membered anhydride (16) and were identical with those of the model compound 1α,2α-diphenylcyclobutane-3β,4β-dicarboxylic (β-truxinic) anhydride (6). The formation of a 5-membered anhydride from VI, via the reaction sequence described above, confirmed the head-to-head type

structure for VI, and therefore for V. The application of symmetry principles to the interpretation of the n.m.r. spectrum of V was correct.

Of the two structures for V, viz., *j* and *k*, only the former can give rise to an epimeric cis diester. The latter, *k*, which is itself a cis diester, can not epimerize to a new cis ester, but can only give rise to a trans ester. The structure *k* is therefore excluded for V, which must be 1α,2α-di-*o*-methoxyphenylcyclobutane-3α,4β-dicarboxylate *j*. Epimerization of this ester can lead to two possible cis esters, the all-cis 1α,2α-di-*o*-methoxyphenylcyclobutane-3α,4α-dicarboxylate (*f*) or 1α,2α-di-*o*-methoxyphenylcyclobutane-3β,4β-dicarboxylate (*g*). Of these, the former can be ruled out as it is unlikely that V, with three eclipsed interactions, would epimerize to an ester with four eclipsed interactions, and the ester VI must be 1α,2α-di-*o*-methoxyphenylcyclobutane-3β,4β-dicarboxylate (*g*).

The structure for V establishes the stereochemistry of the two aryl groups. These are 1:2-cis in V and VI, and must also be cis in their precursors, IV and I, as no epimerization of aryl groups is likely under the reaction conditions employed. Since the dicarboxylic acid IV cyclizes so readily to the dilactone I, the two carboxyl groups must be cis to the *o*-hydroxyphenyl groups. The complete structure and stereochemistry of IV and I is therefore 1α,2α-di-*o*-hydroxyphenylcyclobutane-3α,4α-dicarboxylic acid for IV, and the corresponding dilactone for I. These compounds therefore represent the hitherto unknown ω-truxinic acid type.[6]

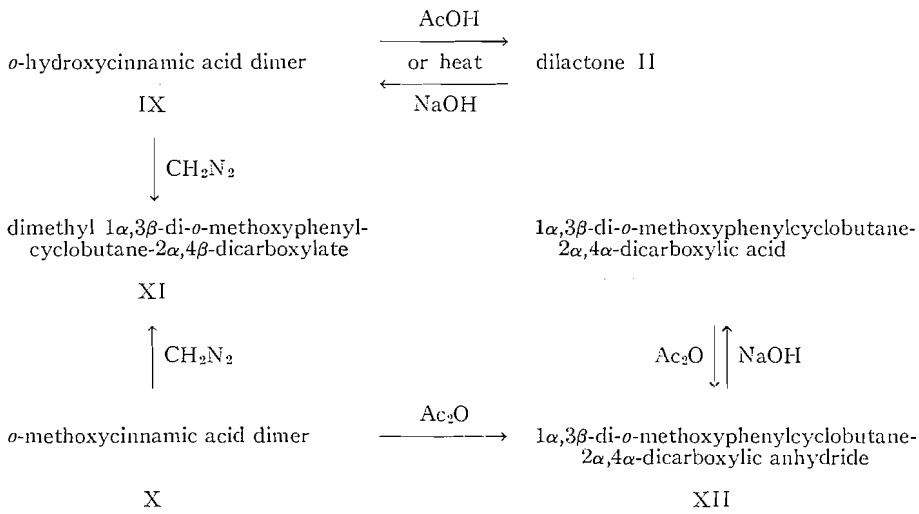
Having established the structure for the photodimer of coumarin, the structures of the photodimers of two related compounds, viz., *o*-hydroxy-*trans*-cinnamic acid and *o*-methoxy-*trans*-cinnamic acid, can be considered. These are of interest, as the photodimer of *o*-hydroxy-*trans*-cinnamic acid has been reported to cyclize to a dilactone, II, m.p. 320° (19, 20), which is isomeric with the photodimer of coumarin.

The photodimers of the substituted cinnamic acids were prepared by irradiation of the crystalline acids with sunlight (19, 21), or with ultraviolet light (20). The photodimer of the *o*-hydroxy acid IX was reported to melt at 320°, which is undoubtedly not its true melting point, but the melting point of the cyclized dilactone II. The photodimer of the *o*-methoxy acid was reported to melt at 264°. These dimers were assigned a head-to-tail trans cyclobutane structure by Stobbe and Bremer (22) by analogy with the dimerization of *trans*-cinnamic acid to 1α,3β-diphenylcyclobutane-2α,4β-dicarboxylic acid (α-truxillic acid). However, this analogy is not strictly valid, as Bernstein and Quimby (23) demonstrated that different crystalline forms of *trans*-cinnamic acid give structurally different acids, i.e. head-to-tail (α-truxillic) or head-to-head (β-truxinic acid). The structures of IX and X could not be considered as established.

In the present work, IX and X were prepared by irradiation of the crystalline acids with ultraviolet light. In the case of the *o*-methoxy acid, the dimer obtained by this method had the same melting point (264°) as that reported in the literature (21). The structures of these compounds were investigated, by essentially the same approach as followed for I. However, as both the *o*-hydroxy and *o*-methoxy compounds were available in this series, the stereochemistry was established by making use of the interrelationships shown in the scheme below.

The dimers IX and X were shown to have the same stereochemistry at all the centers, by preparing the same dimethyl ether dimethyl ester XI, m.p. 132°, from each acid with diazomethane in ether. No epimerization seemed likely under the conditions employed.

[6]*Although all 11 dimeric cinnamic acids have been reported (6), the preparation of 1α,2α-diphenylcyclobutane-3α,4α-dicarboxylic (ω-truxinic) and 1α,2β-diphenylcyclobutane-3β,4α-dicarboxylic (μ-truxinic) acids by Shemyakin (17) is doubtful. Ettlinger (18) has suggested that these are lactonic acids, but the evidence has not been published.*



Treatment of X with boiling acetic anhydride containing a trace of *p*-toluenesulphonic acid gave an anhydride, $C_{20}H_{18}O_5$, m.p. 188° (XII), in good yield. The same anhydride could be obtained if the toluene sulphonic acid was omitted, but the yield of XII was very poor. The anhydride was shown to be intramolecular from its molecular weight (323) and 6-membered from its infrared spectrum (carbonyl bands at 1814 and 1762 cm^{-1}) (16). The model compound 1α,3β-diphenylcyclobutane-2α,4α-dicarboxylic anhydride (γ-truxillic anhydride) (6) showed the same frequencies, and these were slightly higher than those of glutaric anhydride (1802 and 1761 cm^{-1}) (16). This may reflect the strain involved in fusing a 6-membered anhydride 1:3 on a cyclobutane ring. The n.m.r. spectrum of XII, measured in pyridine (24), showed two methoxyl bands (τ, 6.87, 6.93); the two aryl groups were in different stereochemical environment, i.e., one group was cis and the other trans to the anhydride ring. Thus the aryl groups were situated 1:3-trans on the cyclobutane ring.

The stereochemistry of the two carboxyl groups relative to the aryl groups was shown as follows. The dilactone II was easily hydrolyzed to IX and the latter relactonized to give II. The stereochemistry of II and IX was identical. The easy interconversions of II and IX implied a cis relationship of the carboxyl and *o*-hydroxyphenyl substituents. The carboxyl groups were therefore 1:3-trans, and each of them was cis to one of the aryl substituents. That the lactonization of IX to give II involved the formation of 6-membered dihydropyrones was shown by the thermal decomposition of II to give coumarin. The compounds IX and X were indeed derivatives of 1α,3β-diphenylcyclobutane-2α,4β-dicarboxylic (α-truxillic) acid, and the isomer II was the head-to-tail trans compound.

The formation of the anhydride XII had involved the epimerization of one of the carboxyl groups. This was confirmed by treating XII with alkali at room temperature, which gave a new acid, $C_{20}H_{20}O_6$, m.p. 225–226° (XIII), mixed m.p. with X, 199–220°. The acid XIII was readily converted into its anhydride, and was therefore 1α,3β-di-*o*-methoxyphenylcyclobutane-2α,4α-dicarboxylic acid. Treatment of XIII with diazomethane gave a low-melting ester which readily epimerized to XI. The ester was not obtained crystalline, but its n.m.r. spectrum did show three methyl bands in the ratio of 1:1:2. The pattern changed rapidly to that given by dimethyl 1α,3β-di-*o*-methoxyphenyl-2α,4β-dicarboxylate (XI), if traces of acid or alkali were added.

The assignment of the cis structure for the photodimer of coumarin (I) has now received full confirmation by Professor Griffin, Yale University (private communication). Ozonolysis of I gives 1α,2α,3α,4α-tetracarboxycyclobutane identical with the one prepared by Griffin and Veber (25).

It is of interest that Schenck has recently reported (26) that irradiation of coumarin in presence of benzophenone gives a new dimer. A head-to-head trans structure has been suggested for it.

EXPERIMENTAL

All melting points are uncorrected. Infrared spectra were determined on a Perkin–Elmer 'Infracord' instrument except those of anhydrides, which were measured on a Perkin–Elmer single-beam double pass instrument. The n.m.r. spectra were recorded on a Varian V-4302 60 Mc/s instrument.

1α,2α-Di-o-hydroxyphenyl-3α,4α-dicarboxylic Acid Dilactone: the Photodimer of Coumarin (I)

Coumarin (300 g) was dissolved in 3 l. ethanol and exposed to sunlight in eight stoppered pyrex flasks (500 ml) for 4 weeks (May–June). After 1 week, the solution turned pale yellow and started depositing crystals. These were removed periodically, and a total of 4.5 g was collected in 4 weeks. Two crystallizations from glacial acetic acid gave 4 g of I, m.p. 260–262° (decomp.) (lit. m.p. 260° (1)). The ethanolic mother liquors were once again irradiated; after a further 6 weeks, 1 g of I was collected. No crystalline material apart from coumarin was isolated from the deep red solution.

The same compound was also obtained when a suspension of 20 g coumarin in 300 ml water was irradiated with sunlight. The yield of I was 185 mg, which was isolated by extraction of unchanged coumarin with ether.

Alkali Fusion of I: Formation of Salicyclic Acid

One hundred milligrams of I was heated with 0.5 g solid potassium hydroxide at 275° for 10 minutes. The melt was cooled, 5 ml water added, and the mixture acidified with hydrochloric acid. Extraction with ethyl acetate gave a gum from which 22 mg salicylic acid was isolated by extraction with hot petroleum ether (b.p. 80–100°). Recrystallization from the same solvent gave a sample, m.p. 158°, undepressed with an authentic sample. The infrared spectra (nujol mull) of the two samples were superposable.

Hydrolysis of I: 1α,2α-Di-o-hydroxyphenylcyclobutane-3α,4α-dicarboxylic Acid (IV)

Three hundred milligrams of I were dissolved in 5 ml of hot 10% potassium hydroxide. The solution was filtered and cooled to 0°. An ice-cold solution of 2% hydrochloric acid was added gradually with strong cooling, taking care to keep the temperature at 0–5°. The addition of acid was stopped when the solution turned milky. This was then allowed to stand at 0° for 15 minutes. The precipitated acid was filtered off and washed with 10 ml of a citrate–phosphate buffer of pH 7, and then with 5 ml water, followed by 20 ml pentane. The solid was taken up in acetone and filtered. The acetone solution gave 127 mg of the cyclobutane acid IV on evaporation of the solvent below 10°. (Found: C, 66.0; H, 4.7. Calc. for $C_{18}H_{16}O_6$: C, 65.8; H, 4.9%.)

Methylation of I: Dimethyl 1α,2α-Di-o-methoxyphenylcyclobutane-3α,4β-dicarboxylate (V)

A solution of 1 g of I in 10% potassium hydroxide was stirred with dimethyl sulphate (1 ml added at intervals) for 36 hours. The solution was kept strongly alkaline, more potassium hydroxide was added as necessary. After acidification with hydrochloric acid, the product was extracted with ethyl acetate when a gum (0.98 g) was obtained. Attempts to obtain a crystalline material did not succeed. The gum was therefore treated with excess ethereal diazomethane at room temperature. After 2 hours, the excess diazomethane was destroyed by cautious addition of acetic acid and the ether extracted with 1% alkali (twice) and then with water till neutral. The ether extract was dried over anhydrous sodium sulphate and the ether removed under reduced pressure. The residue (0.78 g) crystallized on treatment with a little ethyl acetate followed by petroleum ether (b.p. 30–60°). The crystals, m.p. 104–108°, were chromatographed over alumina, and benzene–ether (9:1) eluted 0.75 g of the dimethyl ether dimethyl ester V, m.p. 110°. (Found: C, 68.7; H, 6.2. Calc. for $C_{22}H_{24}O_6$: C, 68.7; H, 6.3%.)

Epimerization of V: Dimethyl 1α,2α-Di-o-methoxyphenylcyclobutane-3β,4β-dicarboxylate (VI)

The dimethyl ester V (200 mg) was refluxed under nitrogen with a solution of 100 mg of sodium in 25 ml methanol. After 6 hours the methanol was removed, and the residue treated with dilute hydrochloric acid and extracted with ethyl acetate (3×20 ml). The organic layer was washed with dilute alkali and dried (sodium sulphate). Removal of ethyl acetate gave 171 mg of VI, crystallizing from ethyl acetate – petrol ether in colorless plates, m.p. 138°. (Found: C, 68.5; H, 6.2. Calc. for $C_{22}H_{24}O_6$: C, 68.7; H, 6.3%.)

Hydrolysis of VI: 1α,2α-Di-o-methoxyphenylcyclobutane-3β,4β-dicarboxylic Acid (VII)

The ester VI (100 mg) was refluxed with 10% potassium hydroxide (8 ml) containing a few drops of dioxane for 8 hours. The alkaline solution was extracted with ethyl acetate to remove unchanged ester VI,

and the aqueous layer acidified with hydrochloric acid. Extraction with ethyl acetate gave 60 mg of VII, which after crystallization from the same solvent melted at 202° with decomposition. (Found: C, 67.2; H, 5.5. Calc. for $C_{20}H_{20}O_6$: C, 67.4; H, 5.9%.)

Methylation of VII

The acid VII (20 mg) was treated with diazomethane in ether. After 1 hour at room temperature, the ether was evaporated to give 20 mg of VI, m.p. 137–138°, mixed m.p. with VI 138°. The infrared spectra of the two samples (nujol mull) were superposable.

Anhydride from VII: 1α,2α-Di-o-methoxyphenylcyclobutane-3β,4β-dicarboxylic Anhydride (VIII)

The acid VII (40 mg) was refluxed with acetic anhydride (3 ml) for 1 hour. The acetic anhydride was removed under reduced pressure, and the residue dissolved in chloroform. The chloroform solution was washed with aqueous sodium carbonate, and the chloroform layer dried over anhydrous sodium sulphate. Evaporation of the solvent followed by crystallization from acetone – petrol ether gave 28 mg of the anhydride VIII, m.p. 121° after three crystallizations. (Found: C, 70.8; H, 5.5. Calc. for $C_{20}H_{18}O_5$: C, 71.0; H, 5.6%.)

Hydrolysis of VIII

The anhydride VIII (20 mg) was stirred with 5% aqueous sodium hydroxide at room temperature for 10 hours. The aqueous layer was extracted with chloroform to remove unchanged anhydride (2 mg). Acidification of the aqueous layer followed by extraction with ethyl acetate gave 15 mg of an acid, m.p. 202° (decomp.). Mixed melting point with a sample of VII was undepressed, and the infrared spectra (nujol mull) were superposable.

Photodimer of o-Hydroxy-trans-cinnamic Acid: 1α,3β-Di-o-hydroxyphenylcyclobutane-2α,4β-dicarboxylic Acid (IX)

Two grams of *o*-hydroxy-*trans*-cinnamic acid prepared from coumarin (27) was irradiated with ultraviolet light (Hanovia, Type 306). From time to time, the solid was stirred. After 48 hours the solid was extracted with hot chloroform, in which the monomer is insoluble. Evaporation of VIII gave 0.4 g of VIII. The melting point of VIII reported in the literature (320°) was the same as that of the dilactone II, into which it is converted on heating.

Dilactone of IX: 1α,3β-Di-o-hydroxyphenylcyclobutane-2α,4β-dicarboxylic Acid Dilactone (II)

The acid IX (200 mg) was heated with acetic anhydride for 5 minutes. The anhydride was removed under reduced pressure and the residue treated with aqueous sodium carbonate. The insoluble dilactone (163 mg) was collected and crystallized from glacial acetic acid, m.p. 324° (decomp.).

Hydrolysis of II

The dilactone II (100 mg) was dissolved in 5% aqueous potassium hydroxide on heating. The solution was filtered, cooled to 0°, and acidified cautiously with hydrochloric acid till neutral. After standing for 15 minutes, the precipitated acid was collected (40 mg) and found to be identical with IX (infrared spectra).

Decomposition of II: Formation of Coumarin

The dilactone II (50 mg) was heated at 300° for 10 minutes in a test tube. An oily distillate collected at the top of the tube and was treated with a little ether when it crystallized. The crystals, m.p. 68°, were found to be identical with coumarin (mixed m.p.).

Methylation of IX: Dimethyl 1α,3β-Di-o-methoxyphenylcyclobutane-2α,4β-dicarboxylate (XI)

The acid IX (100 mg) was suspended in 30 ml ether containing a few drops of methanol. An excess of diazomethane in ether was added and the mixture allowed to stand at room temperature for 3 hours. It was worked up in the usual manner to give 25 mg of the dimethyl ether dimethyl ester XI, m.p. 132° after crystallization from ether. (Found: C, 68.4; H, 6.4. Calc. for $C_{22}H_{24}O_6$: C, 68.7; H, 6.3%.)

Photodimer of o-Methoxycinnamic Acid: 1α,3β-Di-o-methoxyphenylcyclobutane-2α,4β-dicarboxylic Acid (X)

An acetone solution of *o*-methoxy-*trans*-cinnamic acid prepared by the methylation of coumarin (28) was evaporated on two watchglasses (7-cm diameter) by a fast stream of air. The small crystals thus deposited were irradiated by a Hanovia lamp for 36 hours. From time to time the solid was taken up in cold acetone to remove the sparingly soluble dimer X, and the acetone solution recycled. X (1.8 g) as collected from 4 g of the monomer, and crystallized from chloroform–methanol, m.p. 264° (lit. (21) m.p. 264°).

Methylation of X: Dimethyl 1α,3β-Di-o-methoxyphenylcyclobutane-2α,4β-dicarboxylate (XI)

The acid (120 mg) was esterified with diazomethane as described above to give the same diester (130 mg), XI, m.p. 132°. Mixed melting point with a sample prepared from IX was undepressed and the infrared spectra (nujol mull) were superposable.

Anhydride from X: 1α,3β-Di-o-methoxyphenylcyclobutane-2α,4α-dicarboxylic Acid Anhydride (XII)

The acid X (200 mg) was refluxed with 7 ml acetic anhydride containing 5 mg *p*-toluenesulphonic acid for 6 hours. The acetic anhydride was removed under reduced pressure and the residue taken up in chloroform. The chloroform extract was washed with alkali and dried over anhydrous sodium sulphate. Concentration of the chloroform solution followed by addition of petrol ether (b.p. 30–60°) gave a crystalline anhydride

(154 mg) which, after three crystallizations from chloroform – petrol ether, melted at 188°. (Found: C, 70.9; H, 5.6; mol. wt. (Rast), 323. Calc. for $C_{20}H_{18}O_5$: C, 71.0; H, 5.6; mol. wt., 338.) The infrared spectrum (CCl_4) showed carbonyl bands at 1814 and 1762 cm^{-1}.

Hydrolysis of XII: 1α,3β-Di-o-methoxyphenylcyclobutane-2α,4α-dicarboxylic Acid (XIII)

The anhydride XII (170 mg) was treated with 10% aqueous sodium hydroxide at room temperature for 18 hours. The aqueous layer was extracted once with chloroform to remove unchanged anhydride, and the aqueous layer acidified. Ethyl acetate extraction gave the acid XII (104 mg), which after crystallization from acetone – petrol ether melted at 225–226°. Mixed melting point with X was 199–220°. (Found: C, 67.2; H, 5.9. Calc. for $C_{20}H_{20}O_6$: C, 67.4; H, 5.9%.)

ACKNOWLEDGMENT

I thank Professor A. T. Blomquist, Cornell University, for a gift of β-truxinic acid.

THE BINARY (ANHYDROUS) SYSTEMS $NaNO_3$–$LiNO_3$, $LiClO_3$–$NaClO_3$, $LiClO_3$–$LiNO_3$, $NaNO_3$–$NaClO_3$ AND THE QUATERNARY SYSTEM $NaNO_3$–$LiNO_3$–$LiClO_3$–$NaClO_3$

A. N. Campbell, E. M. Kartzmark, and M. K. Nagarajan

Received January 29, 1962

ABSTRACT

The equilibrium diagrams of the systems $NaNO_3$–$LiNO_3$, $LiClO_3$–$NaClO_3$, $LiClO_3$–$LiNO_3$, $NaNO_3$–$NaClO_3$, and $NaNO_3$–$LiNO_3$–$LiClO_3$–$NaClO_3$ have been investigated by thermal analysis and, to some extent, by X-ray powder photography. All the binary systems are of the simple eutectic type, accompanied, in one instance, by considerable solid solubility. The allotropic transformation of sodium nitrate complicates the equilibria involving sodium nitrate somewhat, especially when there is solid solution.

The quaternary diagram shows that in the (fused) reaction

$$NaNO_3 + LiClO_3 \rightleftarrows LiNO_3 + NaClO_3$$

lithium nitrate and sodium chlorate constitute the stable solid pair. The two invariant points of this system are both congruent.

As a preliminary to an investigation of the thermodynamic and electrical properties of molten salt mixtures, we found it advisable to investigate the equilibrium diagrams of mixtures of the salts named in the title. Because of the low melting point of lithium chlorate we were able to obtain a quaternary eutectic lying at 92.6° C. Such a relatively low temperature greatly facilitates the ease and accuracy of fused salt investigations. In addition, the quaternary system is of interest in itself, since very few investigations of quaternary salt systems have been made in the absence of water. In other words, most of the previous investigations have been isothermal studies of two anions, two cations, and water.

Of the component binary systems, only $NaNO_3$–$LiNO_3$ had been previously investigated, by Benrath and Tesche (1) and by Favorskii (2). Both investigators reported a simple eutectic-type diagram but made no mention of solid solubility.

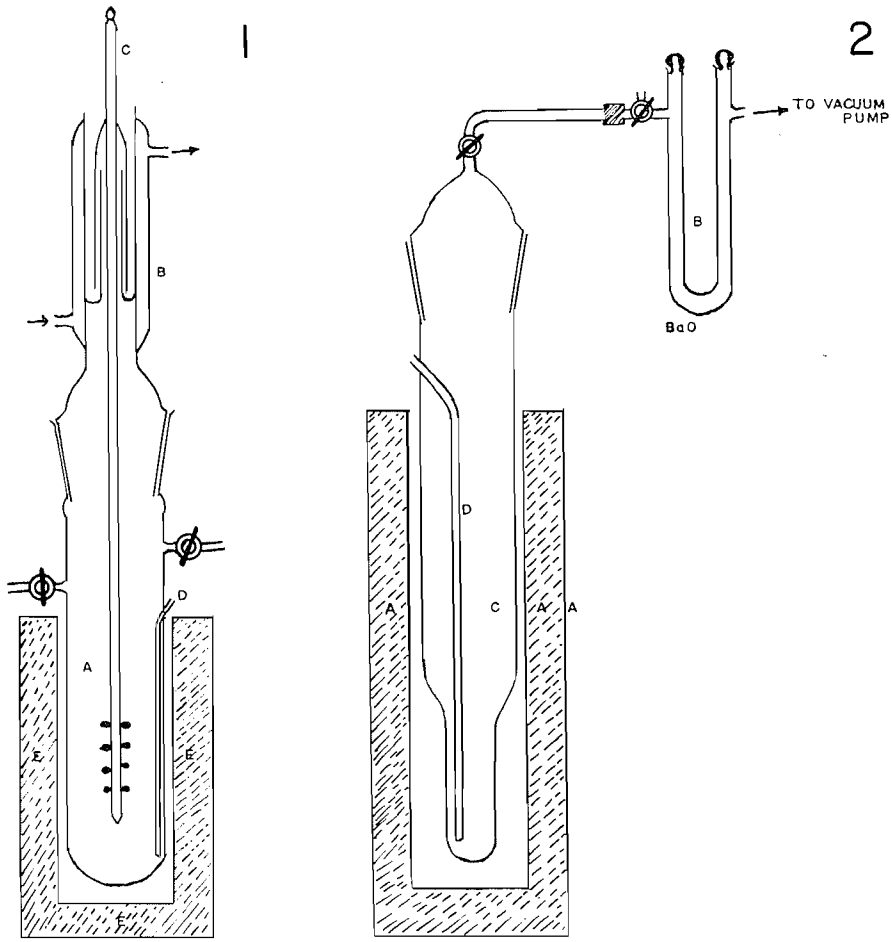
EXPERIMENTAL

All the salts, except lithium chlorate, were purchased and were of the highest purity. The original method for the preparation of lithium chlorate, viz., double decomposition between barium chlorate and lithium sulphate, is due to Potilitzin (3) and to Kraus (4). We used the technique devised by Griffiths (5). Lithium chlorate is extremely hygroscopic and must be handled in a nitrogen-filled dry-box. We used barium oxide to dehydrate the dry-box atmosphere. The final product was heated at 100° C, under high vacuum, for 6–8 weeks. The melting point was 127.8° C.

For the melts which did not contain lithium chlorate, and which were therefore not markedly hygroscopic, it was not necessary to evacuate the space above the melt and the simple apparatus of Fig. 1 was used: it held about 100 g of salt mixture. The figure shows the thermocouple well and inlet and outlet tubes for the introduction of nitrogen. The stirrer passed through a water-jacketted mercury-seal.

Another type of cell (Fig. 2) was used for systems containing lithium chlorate. In this cell the melt was not stirred, but that does not appear to have affected the reproducibility of the results. The cell was loaded with lithium chlorate in the dry-box. After connecting up, it was immediately placed under high vacuum, which was only broken for the introduction of weighed amounts of the second component, an operation requiring only a few seconds.

In order to increase the sensitivity of thermal analysis the furnace in which the salt mixtures were melted was not allowed to cool freely. The current to the furnace was progressively reduced, by using a geared-down motor to operate a "Variac". The motor itself had a low speed. With this apparatus it was possible to continuously reduce the current over about 20 hours. Since only the input voltage was regulated, there was



FIGS. 1 and 2.

a faster lowering of power input at the start than later on and a consequent more rapid decrease of temperature at the beginning of cooling, but this was an advantage since, when a system is partially solid, slower rates of cooling are necessary to establish equilibrium by solid diffusion.

The copper–constantan thermocouple was calibrated using the freezing points of tin (231.9° C) and cadmium (320.9° C) and the steam point corrected for barometric pressure. For thermal analysis the thermocouple was connected through a six-point switch to a Brown Electronik single-point recorder (range 20 mv). The other two points of the switch were connected to a precision potentiometer for the accurate determination of temperature whenever the cooling current indicated a point of interest.

Systems containing large amounts of lithium chlorate supercool considerably, as much as 18°, before solid lithium chlorate separates. Because of the very hygroscopic nature of lithium chlorate direct seeding was impossible, so the following procedure was used. After the approximate location of a point of interest by a preliminary thermal analysis, the experiment was repeated and when a temperature some three or four degrees above the expected temperature was reached, the cell was removed from the furnace, placed on a block of ice, till the liquid became fogged, and then reinserted in the furnace, an operation occupying barely 45 seconds.

It is notorious that the transitions

$$\alpha\text{-}NaNO_3 \rightleftarrows \beta\text{-}NaNO_3 \text{ and } \alpha\text{-}LiClO_3 \rightleftarrows \beta\text{-}LiClO_3$$

are very slow. In order to obtain a satisfactory "break" on the cooling curve the material was kept for 24 hours at a temperature above that of transition. After this treatment, a very sharp "break" was obtained on cooling. In most of these cases, however, heating curves gave equally reliable results and hence were

extensively employed. The equilibrium curves within the solid region, showing the effect of successive addition of sodium chlorate to sodium nitrate on the transition temperature of the latter, were obtained entirely by this procedure.

Use was occasionally made of differential thermal analysis. Copper was found to be a suitable inert body but, when investigating the effect of sodium chlorate on the transition temperature of sodium nitrate and of lithium chlorate, it was found more convenient to use an equal weight of the appropriate pure salt itself. A five-junction copper–constantan thermocouple was used in this work. Since the transition temperature is lowered by the addition of the second salt, due to solid solubility, the transition occurring in the pure material does not prevent its use as the "inert" material.

When investigating the quaternary system, we always commenced from one of the binary eutectics and added a known mixture of the other two salts. After some preliminary attempts, the approximate direction of the eutectic trough became apparent, and it was possible to add salts in the correct proportion to remain in the trough. When a given mixture was off the trough this was of course indicated on the cooling curve by a preliminary point of inflection.

X-Ray powder photographs were taken by the usual technique.

EXPERIMENTAL RESULTS

The experimental results are given in Tables I–VII.

TABLE I

System $LiClO_3$–$NaClO_3$

	Weight% $LiClO_3$	Temperature (°C)		
		Liquidus	Solidus	Transition (in $LiClO_3$)
1	100.00	—	127.9	99.1
2	94.27	126.5	107.1	99.9
3	90.63	125.4	107.1	—

14	5.10	248.5	107.1	—
15	0.00	—	259.9	—

The data of Tables II and III are represented graphically in Fig. 3.

The data of Table VI are plotted by the method of Jänecke in Fig. 4. Table VII contains the eutectic temperatures and compositions of the four binary systems, together with the two eutectics of the quaternary system.

DISCUSSION

The general accuracy of the results is about ±0.5° C, but that of the transition temperatures, freezing points of pure salts, and the eutectic temperatures is higher, about ±0.05° C, since these temperatures were read directly on a precision potentiometer.

$LiClO_3$–$NaClO_3$

When the data of Table I are plotted as the usual T–x diagram, the system appears to be of the simple eutectic type, unaccompanied by appreciable solid solubility. The eutectic temperature is 107.1°±0.05°, and the eutectic composition 34.55 weight% sodium chlorate. The approximate constancy of the figures in the last column of Table I shows that the temperature of the transition α-$LiClO_3 \rightleftarrows \beta$-$LiClO_3$ is unaltered by the addition of sodium chlorate.

$NaClO_3$–$NaNO_3$

The column entitled "others" in Table II gives the temperatures corresponding to solid transformations below the eutectic temperature. Both components exhibit solid solubility and at the eutectic temperature this is considerable. The extents of solid solubility at the eutectic temperature are 21.7% sodium nitrate and 57.2% sodium nitrate respectively. As the temperature falls the solid solubility decreases and the following solid-state reactions occur: (1) α-solid solution of sodium nitrate in sodium chlorate $\rightarrow$ β-solid solution of sodium chlorate in sodium nitrate and (2) β-solid solution

is cooled, was observed in thermal analysis and is given in Table II. The limits of solid solubility at room temperature were determined by X-ray analysis.

Table III shows the effect of additions of sodium chlorate on the transition temperature of sodium nitrate, α-sodium nitrate $\rightleftarrows$ β-sodium nitrate. This transition from a high-temperature cubic form to a low-temperature rhombohedral form was first observed by Kracek (6). He reported the transition temperature as 275° C. This transition proceeds so slowly and is accompanied by so small a heat effect that it is difficult to detect by direct thermal analysis, but it can be detected by differential thermal analysis as 274.6° C.

III	$NaClO_3$	51.46	211.0° C
	$NaNO_3$	48.54	
IV	$LiClO_3$	69.04	107.1 °C
	$NaClO_3$	30.96	
	Quaternary eutectics		
A	Solid phases: $NaNO_3$, $NaClO_3$, $LiNO_3$		147.2° C
	Mole% ClO_3 = 55.51		
	Mole% Na = 66.72		
B	Solid phases: $NaClO_3$, $LiClO_3$, $LiNO_3$		92.6° C
	Mole% ClO_3 = 71.40		
	Mole% Na = 37.32		

The occurrence of two transition temperatures in mixtures containing sodium chlorate shows that sodium chlorate dissolves in both α- and β-sodium nitrate. The equilibrium diagram Fig. 3 is self-explanatory.

The results of the X-ray powder photographs were unequivocal. The line spacings and visual intensities were measured for the pure salts and found to agree with the ASTM index. The lines in the mixtures were all found to be identifiable with those belonging

either to pure sodium chlorate or pure sodium nitrate. It therefore appears that solid solubility at room temperature does not exceed, say, 5%.

$LiNO_3$–$NaNO_3$

The data for the system $LiNO_3$–$NaNO_3$ (Table IV) when plotted give a simple eutectic diagram, unaccompanied by solid solution. In the absence of solid solution, the temperature of the transition α-$NaNO_3 \rightleftarrows \beta$-$NaNO_3$ will not be affected by the presence of lithium nitrate. The α–β change does not appear on an ordinary cooling diagram.

$LiClO_3$–$LiNO_3$

The data for this system (Table V) when plotted also give a simple eutectic diagram, unaccompanied by detectable solid solution.

The data for the quaternary system (Table VI) when plotted by the method of Jänecke yield Fig. 4. Unlike the usual Jänecke diagram, this is not an isothermal diagram but a projection on the base of a composition–temperature model. The diagram shows that in the (fused) reaction

$$NaNO_3 + LiClO_3 \rightleftarrows LiNO_3 + NaClO_3$$

$LiNO_3$ and $NaClO_3$ constitute the stable solid pair. There are two invariant points in this quaternary system, both congruent. The crystallization paths on this diagram are obvious and might well serve as exercise for undergraduate students.

THE STRUCTURE OF LINSEED MUCILAGE

PART II

K. HUNT[1] AND J. K. N. JONES

Department of Chemistry, Queen's University, Kingston, Ontario

Manuscript received January 25, 1962

ABSTRACT

Linseed mucilage has been separated into an acidic and a neutral fraction. The acidic fraction was further separated, by the use of cupric acetate solution, into two fractions, CuI and CuII. *Fraction CuI* contained L-rhamnose, L-galactose, and D-galacturonic acid. The methylated reduced polysaccharide gave on hydrolysis 2,3,4-tri-*O*-methyl-L-rhamnose, 3,4-di-*O*-methyl-L-rhamnose, 4-*O*-methyl-L-rhamnose, 2,3,4,6-tetra-*O*-methyl-D-galactose, 2,3,6-tri-*O*-methyl-D-galactose, and 2,3-di-*O*-methyl-D-galactose (?); L-galactose was lost during the methylation process. Periodate oxidation studies on the material indicated that the polymer was composed of a main chain of L-rhamnose units with most of the L-galactose units attached as non-reducing end groups. *Fraction CuII* contained L-rhamnose, L-fucose, L-galactose, and D-galacturonic acid. The methylated reduced polysaccharide gave on hydrolysis 2,3,4-tri-*O*-methyl-L-fucose, 2,3,4,6-tetra-*O*-methyl-L-galactose, 2,3,6-tri-*O*-methyl-D-galactose, 4-*O*-methyl-L-rhamnose, L-rhamnose, and possibly 2,3-di-*O*-methyl-D-galactose and 3-*O*-methyl-D-galactose. Periodate oxidation studies and a degradation by the Smith procedure indicated the presence of a L-rhamnose backbone with L-fucose and L-galactose units attached as non-reducing end groups.

The neutral fraction yielded a periodate-oxidizable material after one Smith-type degradation. Periodate oxidation studies indicated that the degraded material was branched. Methylation of the degraded polysaccharide followed by hydrolysis yielded 2,3,4-tri-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, 2,4-di-*O*-methyl-D-xylose, 4-*O*-methyl-D-xylose, D-xylose, and traces of 2,3,4-tri-*O*-methyl- or 2,5-di-*O*-methyl-L-arabinose, 2,4-di-*O*-methyl-D-xylose, and 3-*O*-methyl-D-xylose. The main backbone of the degraded polysaccharide appeared to consist of (1 → 4)-linked D-xylose units. Linkages of the (1 → 3) type were also present. The smaller fragments from the Smith-type degradation, L-arabinose, 2-*O*-α-L-arabinosyl glycerol, and glycerol were characterized. A partial acid hydrolysis of the neutral fraction yielded a number of oligosaccharides.

DISCUSSION

The work described here is a continuation of that described in Part I by Erskine and Jones (1). Further work was performed on the neutral fraction which was isolated by these authors and new work on the two acidic fractions is presented.

Recently, mucilages have been separated into acidic and neutral fractions by 'cetavlon' (cetyltrimethylammonium bromide) precipitation (2). Using a combination of borate solution and 'cetavlon' a fractionation of neutral mixtures has been achieved (3–5). This 'cetavlon' method was shown to be very successful in the separation of the components of linseed mucilage. Repeated precipitation of a 'cetavlon' complex yielded an insoluble fraction which contained no pentose sugars, L-rhamnose, L-fucose, L-galactose, and D-galacturonic acid being the only sugars detected. The 'cetavlon' supernatant, after dialysis and subsequent concentration, yielded a neutral fraction which contained only a trace of acidic material. This could usually be removed by a second 'cetavlon' precipitation. Cupric acetate solution (7%) was used to fractionate the acidic mixture into a copper-insoluble fraction (fraction CuI) and a copper-soluble fraction (fraction CuII) (1).

Fraction CuI

Fraction CuI had physical properties which did not differ greatly from samples previously isolated by similar means (6, 7). Whereas other workers reported xylose in this

[1]*Present address: Chemistry Department, The University, West Mains Road, Edinburgh 9, Scotland.*

fraction, only L-rhamnose, L-galactose, and D-galacturonic acid were found, in the approximate molar ratio 2:1:2. Examination of fraction CuI by the Tiselius electrophoresis procedure indicated the presence of two components. The trace component had a mobility identical with that of fraction CuII.

Oxidation of fraction CuI with sodium metaperiodate resulted in the uptake of 1.34 moles of periodate and the liberation of 0.33 mole of formic acid per anhydrohexose unit. The figures indicate that about one third of the residues in the polysaccharide possessed sugar residues with hydroxyl groups on each of three contiguous carbon atoms. Assuming that no significant overoxidation had occurred, the figures above indicate that all the monosaccharide residues had been oxidized. Methylation results indicated that this conclusion was incorrect and hence some overoxidation had probably occurred. The periodate-oxidized polysaccharide was reduced with sodium borohydride and the product after hydrolysis showed, on chromatograms, small amounts of L-rhamnose, L-galactose, and D-galacturonic acid. The high uronic acid content (43%) of fraction I made it labile to alkalies. The uronic acids in the polysaccharide were therefore reduced to hexoses in an effort to keep alkaline degradation to a minimum (8). The reduced polymer was methylated five times using the Haworth procedure, the solution being kept at 0° C and close to pH 7. By using these conditions it was hoped to reduce still further the amount of alkaline degradation. A further reduction with lithium aluminum hydride followed by four Purdie-type and one Kuhn-type methylations produced a fully methylated polysaccharide (OMe, 43.6%) which showed a negligible hydroxyl peak in the infrared. At least half of the material was soluble in light petroleum. This strongly suggests that a large amount of the material was of low molecular weight. No doubt a certain amount of degradation took place during the reduction and methylation and this could account for the low yield. The presence of a large amount of methyl pentose (rhamnose) in the methylated polymer might also have some effect on the solubility of the methylated polymer in light petroleum. The sugars fully characterized were 2,3,4-tri-*O*-methyl-L-rhamnose, 2,3,4,6-tetra-*O*-methyl-D-galactose, 3,4-di-*O*-methyl-L-rhamnose, 2,3,6-tri-*O*-methyl-D-galactose, and 4-*O*-methyl-L-rhamnose. A sugar which might be 2,3-di-*O*-methyl-D-galactose was also obtained but not definitely characterized. Only L-galactose had been detected in the original polysaccharide. It is reasonable to suggest that all the methylated D-galactose derivatives arose from what were originally D-galacturonic acid residues. No L-galactose derivatives were found; it is possible that the majority of L-galactose units were near the periphery of the molecule and were lost during the methylation. From the methylation data the backbone of the polysaccharide appears to consist of L-rhamnose residues linked by a (1 → 2)-type glycosidic bond with some branching at position 3. The D-galacturonic acid was present as (1 → 4)-linked residues either in the main chain or as part of a side chain.

Autohydrolysis of the original polymer supports the above results because L-galactose was the first sugar to appear, followed later by D-galacturonic acid and L-rhamnose residues, the last appearing only after a long time of hydrolysis. This would indicate either that the methyl pentose is attached to the polymer by acid-resistant linkages or that hydrolysis of the L-rhamnose is hindered by the structure of the polymer.

Fraction CuII

Fraction CuII contained L-rhamnose, L-fucose, L-galactose, and D-galacturonic acid in the approximate molar ratio 4:1:2:2 in contrast to the ratio 1:1:3:2 reported by Erskine (6). Examination of this fraction by the Tiselius electrophoresis procedure showed only one peak. This mobility corresponded with that of the trace component in fraction CuI.

Oxidation of fraction CuII with sodium metaperiodate resulted in the uptake of 0.76 mole of periodate and the liberation of 0.13 mole of formic acid per hexose unit. The figures indicate that about one third of the residues was not oxidized. This was confirmed by hydrolysis of the periodate-oxidized reduced material, which gave crystalline L-rhamnose and L-galactose. The high yield of L-rhamnose suggested that the residues were well protected from oxidation. Glycerol, which most probably arose from the oxidation of L-galactose end groups, was also obtained and characterized as the tri-*O*-*p*-nitrobenzoate (9). Fraction CuII was reduced and methylated by the Haworth- and Kuhn-type procedures to yield a methylated material (OMe, 44.9%) containing a negligible hydroxyl peak (infrared). Methylated fraction CuII also contained a large percentage of light petroleum soluble material. After hydrolysis and separation, the methylated fragments definitely characterized were 2,3,4-tri-*O*-methyl-L-fucose, 2,3,4,6-tetra-*O*-methyl-L-galactose, 2,3,6-tri-*O*-methyl-D-galactose, 4-*O*-methyl-L-rhamnose, and L-rhamnose. Easterby (10) had previously methylated a similar fraction and obtained an uncharacterized monomethyl rhamnose which he suggested was the 4-*O*-methyl derivative. In addition, two other sugars which were not characterized were obtained. One was the suspected 2,3-di-*O*-methyl-D-galactose previously obtained from the methylated fraction CuI. The other sugar has the properties of a mono-*O*-methyl-D(?)-galactose, and chromatographic evidence points to its identity as the 3-*O*-methyl derivative. The results indicated that all the L-fucose and most of the L-galactose were present as end groups. From the periodate results one would have expected to find some L-galactose present along the chain length of the polymer. Methylated derivatives corresponding to this were not found, but since only small amounts would be present, they could have escaped detection. The D-galacturonic acid units appear to be combined by $(1 \rightarrow 4)$-type linkages either in the main or side chains.

Neutral Fraction

The neutral fraction was subjected to a Tiselius electrophoresis fractionation and the indications were that it consisted of three components. One component was present in very small amounts and had a high mobility. The other two were present in about equal amounts and possessed low mobilities. A Smith-type degradation (11) performed on the neutral fraction yielded a periodate-resistant polysaccharide as well as a large number of other compounds. The degraded polysaccharide had an optical rotation little changed from the original material. Most of the L-arabinose and all of the D-galactose residue were oxidized by the metaperiodate. The degraded polysaccharide consumed 0.57 mole of periodate and produced 0.10 mole of formic acid per pentose unit. There was still unoxidized D-xylose remaining after this second oxidation. The ratio of xylose to arabinose in the once degraded polysaccharide was 6:1 (estimated).

The degraded material was methylated once with Haworth reagents at pH 6–7 and then once with Purdies reagents. The resulting methylated material (OMe, 37.6%) showed a negligible hydroxyl peak (infrared). The methylated fragments fully characterized were 2,3,4-tri-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, 4-*O*-methyl-D-xylose, and D-xylose. A fragment isolated in small amounts gave L-arabinose on demethylation, and judging by its mobility on paper it was either 2,3,4-tri-*O*-methyl-L-arabinose or 2,5-di-*O*-methyl-L-arabinose. A material with the same rate of movement as 2,4-di-*O*-methyl-D-xylose was also obtained, although no crystalline derivative could be prepared. During the isolation of the 4-*O*-methyl-D-xylose a substance with a rate of movement identical with that of 3-*O*-methyl-D-xylose was obtained. No derivative, however, could

be obtained. The evidence indicates that the main backbone consists of D-xylose units many of which are linked (1 → 4). It is reasonable to assume that considerable branching exists, as indicated by the amount of mono-*O*-methyl and unsubstituted xylose obtained. Erskine (1) did not isolate any 4-*O*-methyl-D-xylose from his methylated pentosan. The original neutral polysaccharide after methylation contained a much higher percentage of unsubstituted D-xylose than did the methylated degraded material. It seems possible that sugar residues originally attached to the 4-position of such D-xylose units in the undegraded polymer were removed during the Smith degradation procedure and left the 4-position available for methylation in the degraded material. These D-xylose units were therefore also linked through C_1, C_2, and C_3 in the undegraded polysaccharide. The isolation by Erskine (1) of 2,4-di-*O*-methyl-D-xylose from the original material suggests the presence of some (1 → 3)-linked D-xylose units. Xylans from the hemicellulose A of wattle wood (12) and the red alga *Rhodymenia palmata* (13) have been postulated to contain some (1 → 3)-linked D-xylose residues.

The alcohol-soluble material from the Smith degradation (11) was separated by acetone into a higher molecular weight insoluble fraction and a lower molecular weight soluble fraction. Very little information was obtained from this higher molecular weight fraction. The acetone-soluble fraction yielded some glycerol after repeated fractionation. The glycerol probably arose as a result of oxidation of hexose end groups or pentofuranose end groups. Free L-arabinose was also identified and could have arisen as a consequence of mild acid hydrolysis of the L-arabofuranoside units left unoxidized by periodate. A third substance obtained pure was probably 2-*O*-α-L-arabopyranosyl-glycerol. The α-configuration was assigned because of the low positive rotation. The (1 → 2)-type linkage seems probable since the glycerol was not oxidized by periodate. Jones (14) has isolated a material of closely similar properties. In neither instance has the material been obtained crystalline.

A controlled partial hydrolysis was performed on the neutral fraction using conditions which differed slightly from those of Erskine (6). At least 12 oligosaccharides were obtained in an approximately 10% total yield. The large number of disaccharides made the task of separating them very difficult and quite often the separated disaccharide was only represented by a very small amount of material. The 4-*O*-β-D-xylopyranosyl-D-xylose previously characterized by Erskine (6) was obtained again and identified. This fact would point to the presence of some (1 → 4)-linked xylose units in the polymer. A second xylobiose, which had $[\alpha]_D$ +94°, and is therefore probably α-linked, was also separated. A crystalline osazone, m.p. 146–148°, was obtained, indicating that the linkage was not of the (1 → 2) type. The R_f value on paper differed from that of both 3-*O*-α-D-xylopyranosyl-D-xylopyranose (15) and the xylobiose already characterized. A D-xylose → L-arabinose disaccharide which Erskine had obtained but not characterized was isolated in good yield. The material had $[\alpha]_D^{22}$ +84°, and arabinose was shown to be the reducing residue by bromine oxidation. The disaccharide had a higher R_f value than galactose in all solvents, and was distinct from 3-*O*-α-D-xylopyranosyl-L-arabinose (16, 17), 5-*O*-β-D-xylopyranosyl-L-arabinose (18, 19), 2-*O*-β-D-xylopyranosyl-L-arabinose (20); it yielded small amounts of a crystalline osazone, m.p. 121–123°. The periodate oxidation results for both the original disaccharide and reduced disaccharide were slightly low for a (1 → 5)-linked pentose disaccharide. This could be the result of the presence of a small amount of contaminant. Until definite proof is available it is suggested that the material could be 5-*O*-α-D-xylopyranosyl-L-arabofuranose (1). Two other disaccharides, which contained (?) D-galactose and L-arabinose, were isolated in small yields. In both materials, L-arabinose was the reducing residue. A second D-xylosyl-L-arabinose disaccharide was isolated

which had an R_f value different from any of the others described earlier. The material yielded an osazone with m.p. 185–187°. Periodate oxidation results were inconclusive. Separation of the higher oligosaccharide by an ion-exchange resin (21) gave various impure fractions. One yielded crystalline material, m.p. 238–240°, which gave only xylose upon hydrolysis. R_f values indicate that the material may consist of three to four D-xylose units. Conclusive identification was hampered by the lack of sufficient material. This work is continuing.

EXPERIMENTAL

Methods

Paper chromatography was carried out on Whatman No. 1 filter paper using the following solvent systems (v/v):

(A) ethyl acetate:acetic acid:formic acid:water (18:3:1:4),
(B) butan-1-ol-ethanol:water (3:1:1),
(C) butan-1-ol:pyridine:water (10:3:3),
(D) butan-1-ol:pyridine:water (5:3:2),
(E) ethyl acetate:pyridine:water (10:4:3).

Whatman 3 MM paper was used in all quantitative separations. Columns for separations of large quantities of sugar mixtures were packed with Whatman 'Cellulose Powder' by the dry method. Borate buffer (pH 9.6) was used in all electrophoretic separations. Optical rotations were observed in water unless otherwise stated. All solutions were concentrated under reduced pressure at 40–45° C. Demethylation of methylated sugars were carried out by the procedure of Allen *et al.* (22). All infrared spectra were made using either chloroform solution (6%) or potassium bromide pellets (0.8%) using a Perkin–Elmer model 21 infrared spectrophotometer. All moving-boundary electrophoresis determinations were performed on a Perkin–Elmer model 38-A apparatus with a standard 2-ml cell. The initial power input was adjusted to 2 watts.

Preparation of Linseed Mucilage

Samples of the crude linseed mucilage were prepared as described in Part I (1). The de-ashed mucilage had $[\alpha]_D^{21}$ −3° (*c*, 0.62 in 0.3 *N* NaOH) and a neutralization equivalent of 683. Hydrolysis of a sample followed by quantitative chromatographic separation of the hydrolyzate on paper using solvents (A), (B), and (C) confirmed the presence of L-fucose, D-xylose, L-galactose, D-galacturonic acid, and L-rhamnose and indicated the presence of arabinose and an aldobiouronic acid.

Fractionation of the Mucilage with 'Cetavlon' (Cetyltrimethylammonium Bromide)

The crude mucilage (10 g) was dissolved in distilled water (1500 ml) and the solution was deionized with Amberlite IR-120(H) resin. An aqueous solution of 'cetavlon', supplied by Eastman Chemicals (10%, 100 ml), was added to the deionized solution, and the precipitate which formed was allowed to settle (2). The precipitate was removed by centrifugation and washed with water. The 'cetavlon' complex was decomposed in sodium chloride solution (10%, 100 ml) and the resulting solution was poured into ethanol. The precipitate was collected by centrifugation, washed with ethanol, acetone, ether, and finally it was dried to a white powder (5.1 g). The 'cetavlon' supernatant was dialyzed against running water for several days. The dialyzate was concentrated and poured into ethanol. The precipitate (2.6 g) was collected by filtration and was then isolated as described above. The acidic and neutral fractions were treated a second time with 'cetavlon'. Each fraction was hydrolyzed and then examined chromatographically in solvents (A) and (B). The 'cetavlon' precipitate contained rhamnose, fucose, galactose, and galacturonic acid and the 'cetavlon' supernatant contained galactose, xylose, and arabinose.

Fractionation of the Acidic Material with Cupric Acetate

The de-ashed acidic material (3.5 g) was dissolved in water (350 ml), and cupric acetate solution (7%, 20 ml) was added. The green gelatinous precipitate which formed was allowed to settle for 5 hours and was then removed by centrifugation. The precipitate was decomposed with ethanol containing hydrochloric acid (1%). The insoluble material was further washed with ethanol until a negative test with silver nitrate was obtained. The precipitate was dried to yield fraction CuI as a brown powder (540 mg). The supernatant was poured into ethanol and the precipitate was removed by centrifugation. This complex was decomposed as before to yield fraction CuII as a white powder (2.47 g). The alcohol supernatant from the last precipitation was concentrated and dialyzed against running water. The dialyzate after concentration yielded only a very small amount of polysaccharide.

Properties of Fraction CuI Polysaccharides

The material was de-ashed by passage through IR-120(H) resin and then isolated as a white powder. Hydrolysis of the material followed by chromatography in solvents (A), (B), and (C) indicated the presence

of rhamnose, galactose, and galacturonic acid in the ratio 2:1:2 as determined by the weights of the fractions. The material had an ash content (23) of 0.7%; it had $[\alpha]_D^{22}$ +121° (*c*, 0.15) and a neutralization equivalent of 400 (pH meter), indicating a 43.4% anhydrouronic acid content.

Tiselius Investigation of the Fraction

Fraction CuI (25 mg) was dissolved in veronal buffer (0.1 *M*, 10 ml). Photographs were taken of the ascending arm in a Tiselius apparatus after 17 minutes (A) and 55 minutes (B). Two peaks were observed, a large one with a mobility (μ) of 14.3×10^{-5} $cm^2v^{-1}sec^{-1}$ and the other small peak with a mobility (μ) of 12.0×10^{-5} $cm^2v^{-1}sec^{-1}$.

Oxidation of Fraction CuI by Periodate

Samples of de-ashed polysaccharide ((1) 0.0549 g and (2) 0.0518 g) were dissolved in distilled water in volumetric flasks (100 ml) and the solutions were adjusted to pH 7 with sodium hydroxide solution (0.01 *N*). Sodium metaperiodate solution (0.3 *M*, 3 ml) was added and the solution was made up to volume (100 ml) and kept in the dark. The periodate uptake was determined by the thiosulphate method (24), and the formic acid by titration with sodium hydroxide solution (screened methyl red as indicator) after addition of ethylene glycol. The following results were obtained as mean values of the two series of analyses and are quoted as moles per mole of hexose unit (calculated as $C_6H_{10}O_5$). Extrapolation of the 'overoxidation' part of the periodate uptake and formic acid yield curve gave a periodate uptake of 1.34 moles and a formic acid yield of 0.33 mole.

Time (hours)	5	19	45.5	69	93
Periodate uptake	0.66	1.22	1.41	1.50	1.54
Formic produced	0.08	0.35	0.44	0.45	0.50

Large-scale Oxidation of Fraction CuI by Periodate

The freeze-dried polysaccharide (203 mg) in water (400 ml) was oxidized with sodium metaperiodate solution (0.3 *M*, 12 ml) for 20 hours. Ethylene glycol was added to destroy excess periodate. After dialysis to remove formaldehyde, ethylene glycol, and salts the polyaldehyde was reduced with sodium borohydride solution (0.6 g in 10 ml) for 9 hours. The excess borohydride was destroyed with dilute acetic acid and the solution was dialyzed against running water for 3 days. The dialyzate was concentrated and poured into alcohol. The precipitate was removed by centrifugation and dried to yield a white powder (192 mg) having $[\alpha]_D^{22}$ +19° (*c*, 0.16). The polyol (170 mg) was hydrolyzed (1 *N* H_2SO_4) for 16 hours on a boiling-water bath. After neutralization ($BaCO_3$) the concentrated solution was fractionated chromatographically using solvent (A). Spraying of the chromatogram with *p*-anisidine indicated the presence of rhamnose and galacturonic acid, with a trace of a material which gave a pink color, R_{rham} 1.53. Chromatograms developed in solvents (B) and (C) and sprayed with silver nitrate showed the presence of several other fast-moving components.

Smith-type Degradation of Fraction CuI

A further portion (500 mg) of this fraction was oxidized with metaperiodate as before and then reduced with sodium borohydride. The polyol was dissolved in sulphuric acid (1 *N*, 36 ml) and left at room temperature overnight (11). The solution was neutralized ($BaCO_3$) and the precipitate was removed by centrifugation. The centrifugate was passed through IR-120(H) resin and the eluate concentrated to a syrup. The syrup was poured into ethanol and the precipitate (5 mg) was removed by filtration. The alcohol supernatant was concentrated to a syrup (350 mg). A portion of each material was hydrolyzed. Chromatography in solvents (A) and (C) indicated the presence of rhamnose, galacturonic acid, and a trace of galactose in the precipitated material. Glycerol, a trace of galactose, and many unidentified materials were indicated in the alcohol supernatant.

Reduction of Fraction CuI

Fraction CuI (5.0 g) was deionized by IR-120(H) resin and then freeze-dried. The freeze-dried material was powdered and suspended in ether (25 ml). Diazomethane (3 g) (25) in ether was added dropwise until a faint yellow color persisted. The ether was removed by filtration and the material was dissolved in water 250 ml). Lithium borohydride solution (1 g in 100 ml) was added dropwise to the solution, which was allowed to stand overnight. The excess borohydride was destroyed with dilute acetic acid and the solution was dialyzed against running water for 3 days. The dialyzate was concentrated and then freeze-dried. The reduction procedure was repeated twice in a boric acid buffer (0.4 *M*) (18). The resulting material (2.1 g) showed a very much reduced carbonyl peak in the infrared spectrum.

Methylation of the Partially Reduced Fraction CuI

The freeze-dried material (2.1 g) was dissolved in water (45 ml). The solution was kept at 0° C (ice) and then adjusted to pH 6 by addition of dimethyl sulphate. Sodium hydroxide solution (30%, 15 ml) was

added dropwise, with vigorous stirring, to the slightly acid solution. After each addition of base the pH was carefully adjusted to pH 6 by further addition of dimethyl sulphate over an 8-hour period until dimethyl sulphate (10 ml) had been added to the solution. This procedure was repeated over 2 days. The alkaline solution was heated for 1 hour at 60° C. After cooling, the solution was brought to pH 6 and extracted several times with chloroform. The aqueous layer was dialyzed for 3 days against running water. The dialyzate was concentrated and the solution remethylated. This procedure was repeated five times. The chloroform extracts were united and then concentrated to a syrup (1.6 g). The syrup was dissolved in water and passed through IR-120(H) resin. The eluate was concentrated and dried to constant weight. This syrup was dissolved in redistilled tetrahydrofuran (20 ml), and diazomethane was added to the solution until nitrogen ceased to be evolved. The solvent was removed and the syrup dried once again. The syrup was redissolved in tetrahydrofuran (35 ml) and the solution added dropwise to a refluxing solution of lithium aluminum hydride (1 g) in tetrahydrofuran (35 ml). After addition of the partially methylated polysaccharide, the mixture was allowed to reflux for a further hour. The excess hydride was destroyed with moist ethyl acetate and the resulting mixture was acidified. The aqueous solution was extracted several times with chloroform. The chloroform extracts were concentrated, and yielded a syrup (1.5 g). The syrup was subjected to four Purdie-type methylations but the syrup (1.14 g) obtained still exhibited a slight hydroxyl peak in the infrared spectrum. The syrup was then methylated by the Kuhn (26) procedure to give a product with a negligible hydroxyl peak in the infrared. The methylated polysaccharide had a methoxyl content of 43.6%. No fractionation of the material could be obtained using chloroform – light petroleum (60–80° C).

Hydrolysis of Methylated Fraction CuI

The polysaccharide was hydrolyzed with formic acid (90%, 50 ml) in the cold for 13 hours. Water (50 ml) was added and the solution was heated on a boiling-water bath for a further 9 hours. The formic acid was removed by vacuum distillation and the formyl esters present were hydrolyzed by several codistillations with water. The resultant syrup was dissolved in a small volume of water and the solution was passed through IR-120(H) resin and A-4(OH) resin. The eluate was concentrated to a syrup (66 mg).

Separation of the Methylated Fragments

The syrup was separated on cellulose with light petroleum (b.p. 100–120°) – butan-1-ol (7:3 changed later to 6:4) and butan-1-ol – methanol (6:4) as eluants to give 11 fractions.

Fraction 1 (21 mg).—This sugar had $[\alpha]_D^{25}$ +26° (*c*, 0.7) and gave rhamnose when demethylated with boron trichloride (22). The syrup yielded a crystalline aniline derivative, which after recrystallization from light petroleum (40–60° C), had m.p. 108–110°, undepressed on admixture with authentic *N*-phenyl-2,3,4-tri-*O*-methyl-L-rhamnosylamine (27).

Fraction 2 (99 mg).—This fraction had $[\alpha]_D^{22}$ +94° (*c*, 1.98) and R_G value identical with that of 2,3,4,6-tetra-*O*-methyl-D-galactose in all solvents. The derived *N*-phenyl-galactosylamine, after recrystallization from ethanol, had m.p. and mixed m.p. 192–193° C (28).

Fraction 3 (76 mg).—This mixture was separated electrophoretically. The faster-moving component was eluted from the paper and yielded a syrup (18 mg) which was added to fraction 4. The slower-moving component was 2,3,4,6-tetra-*O*-methyl-D-galactose.

Fraction 4 (90 mg).—The sugar gave a positive reaction with triphenyltetrazolium chloride (29) and crystallized from ether – light petroleum. The crystals had $[\alpha]_D^{24}$ +22° (*c*, 1.8) and m.p. 97–98° C undepressed on admixture with authentic 3,4-di-*O*-methyl-L-rhamnose.

Fraction 5 (40 mg).—This mixture of sugars was also separated electrophoretically. The slower-moving component was identified as 3,4-*O*-methyl-L-rhamnose.

Fraction 6 (62 mg).—This syrup had an R_G value identical with that of 2,3,6-tri-*O*-methyl-D-galactose in all solvents. It had $[\alpha]_D^{24}$ +70° (*c*, 1.2), which changed to −14° (*c*, 0.2) when dissolved in methanolic hydrogen chloride (1%). A sample of the sugar was oxidized for 3 days with bromine in water. The crude crystalline lactone (30) was isolated and recrystallized from ether to yield 2,3,6-tri-*O*-methyl-D-galactonolactone, m.p. 98° C (31).

Fraction 7 (26 mg).—This fraction was separated electrophoretically into two components. The slower component was added to fraction 8.

Fraction 8 (35 mg).—This syrup, which had $[\alpha]_D^{22}$ +11° (*c*, 0.7), gave rhamnose on demethylation. Paper electrophoresis indicated that the material had the same R_G value as 4-*O*-methyl-L-rhamnose. However, the syrup did not crystallize even when seeded. A portion of the syrup was oxidized with bromine water (3 drops in 1 ml) for 5 days. The crude lactone was isolated in the usual manner. Recrystallization of the material from acetone – light petroleum gave crystalline 4-*O*-methyl-L-rhamnono-δ-lactone, m.p. and mixed m.p. 81–82° C (32).

Fraction 9 (15 mg).—This fraction was not investigated.

Fraction 10 (24 mg).—This syrup had $[\alpha]_D^{27}$ +52° (*c*, 1.2), which became negative in methanolic hydrogen chloride (1%). Demethylation of the syrup afforded galactose. The material failed to give a 'tetrazolium red' test, and it was chromatographically indistinguishable from sugar 5 obtained after methylation of fraction CuII. This was believed to be 2,3-di-*O*-methyl-D-galactose. A crystalline aniline derivative could not be obtained (33).

Acetolysis of Fraction CuI

Fraction CuI (200 mg) was mixed with acetic anhydride (4 ml) and concentrated sulphuric acid (0.1 ml) at 0° C for 28 hours. The solution was then heated at 80–90° C for 15 minutes and poured into ice water (34). The white precipitate was removed by filtration and washed several times with water. The material was dried to a white powder (170 mg).

The acetylated material (59 mg) was deacetylated with sodium hydroxide in acetone. The solution was deionized by passage through IR-120(H) resin and the eluate was concentrated to a syrup. Chromatography in solvent (A) indicated the presence of galacturonic acid and an orange spot, R_{gal} 0.43, and a pink spot, R_{gal} 0.13. A large streak, which probably represented higher oligosaccharides, was noted near the base line. A small portion (50 mg) of the original acetylated product was subjected to acetolysis and the product isolated and deacetylated as before. Chromatography in solvent (A) indicated the presence of three sugars, all of which gave a pink color when detected with the *p*-anisidine spray and had R_{gal} values of 1.00, 0.42, and 0.12.

Autohydrolysis of Fraction CuI

Fraction CuI (100 mg) was dissolved in water (20 ml) and the solution was passed through IR-120(H) resin. The acidic eluate (pH 2) was concentrated to a small volume (10 ml). This solution was refluxed and samples were removed at intervals and examined chromatographically in solvent (A). Galactose was the first to appear after 3 hours. Galacturonic acid appeared only after 5 hours. A disaccharide (R_{gal} 0.7) appeared after 10 hours; the disaccharide had disappeared when the next sample was examined. Rhamnose appeared between 10 and 21 hours and increased until, at 53 hours, the concentration was almost equal to that of the galacturonic acid.

Tiselius Investigation of Fraction CuII

Fraction CuII (25 mg) was treated in the same manner as fraction CuI. Photographs were taken of the 'buffer arm' after 10 minutes (*a*) and 75 minutes (*b*). A single peak was observed which had a mobility (μ) of 12.3×10^{-5} $cm^2v^{-1}sec^{-1}$. Fraction CuII had $[\alpha]_D^{22}$ −5° (*c*, 0.35 in water) and neutralization equivalent of 607.

Oxidation of Fraction CuII by Periodate

The polysaccharide samples (*a*) 0.0488 g and (*b*) 0.0470 g were placed in volumetric flasks (100 ml) and oxidized with sodium metaperiodate as described for fraction CuI. The periodate uptake and formic acid released per mole of hexose unit (calculated as $C_6H_{10}O_5$) were determined as before. The following results were obtained as mean values of the two series of analysis:

Time (hours)	5	11.5	24	35	48	59	72
Periodate uptake	0.54	0.72	0.78	0.80	0.81	0.82	0.84
Formic produced	0.09	0.11	0.15	0.20	0.23	0.24	0.25

Extrapolation of the 'overoxidation' part of the periodate uptake and formic acid yield curve gave, for the periodate uptake, 0.76 mole and for the formic acid yield, 0.13 mole per mole of hexose.

Large-scale Oxidation of Fraction CuII by Periodate

The polysaccharide (1.21 g, $[\alpha]_D^{22}$ −5°) was oxidized with sodium metaperiodate for 30 hours as described before. The resulting polyaldehyde was reduced with sodium borohydride (2 g in 100 ml) overnight. The excess borohydride was destroyed with dilute acetic acid and the solution was dialyzed against running water for 3 days. The dialyzate was concentrated to a syrup and poured into a large excess of ethanol. The resulting white material was collected and dried to yield a powder (1.15 g) which had $[\alpha]_D^{22}$ −95° (*c*, 0.13). The polyol was hydrolyzed with sulphuric acid (1 *N*, 100 ml) for 16 hours on a boiling-water bath. The hydrolyzate was neutralized ($BaCO_3$), filtered, and the filtrate passed through columns of IR-120(H) resin and A-4(OH) resin. The neutral eluate was concentrated to a syrup (381 mg). The A-4 resin was eluted with sodium hydroxide solution (1 *N*, 10 ml) and the eluate passed directly through IR-120(H) resin. The acidic eluate was concentrated to a syrup (139 mg). Separation of the acidic eluate was not attempted.

Separation of the Neutral Fraction

The syrup (381 mg) was separated on a cellulose column with butan-1-ol half saturated with water as eluant, to give 11 fractions.

Fraction A and B.—This material had the same R_f value as glycolic aldehyde in solvents (A) and (C); however, glyoxal phenylosazone could not be prepared from it.

Fraction C.—This syrup was not investigated.

Fraction D (70 mg).—This syrup was identified as glycerol. The derived tri-*O*-*p*-nitrobenzoate of glycerol had m.p. and mixed m.p. 191–193° (9).

Fraction E (138 mg).—This syrup crystallized after a short time. The crystals were recrystallized twice

from moist acetone to yield L-rhamnose hydrate, m.p. and mixed m.p. 91–92° C and $[\alpha]_D^{22}$ +9° (*c*, 0.18).

Fraction F (70 mg).—This material was not investigated.

Fraction J and K (50 mg).—This material crystallized, and after recrystallization from methanol the crystals had m.p. 160–162° C and $[\alpha]_D^{22}$ −87° (*c*, 0.56) (35). Admixture with authentic L-galactose produced no depression in the melting point.

Smith-type Degradation of Fraction CuII

Fraction CuII (500 mg) was oxidized with sodium metaperiodate and this material was worked up as described previously. After cold acid hydrolysis (N H_2SO_4) an alcohol-insoluble material (5 mg) and an alcohol-soluble syrup (310 mg) were obtained. Both materials were hydrolyzed and then chromatographed in solvents (A) and (C). The precipitate contained a large amount of rhamnose, with traces of galactose and galacturonic acid, whereas the syrup contained glycerol, a tetritol, and many unidentified components.

Reduction and Methylation of Fraction CuII

Fraction CuII (10.5 g) was deionized by passage through IR-120(H) resin and the eluate was freeze-dried. The freeze-dried material was powdered and treated with diazomethane in ether (25 ml) until the yellow color persisted. The ethereal solution was removed by decantation and the powder was dissolved in water (500 ml). Sodium borohydride (3.0 g) in water (100 ml) was added dropwise over a 3-hour period. The excess borohydride was destroyed with dilute acetic acid and the solution was dialyzed for 4 days. The reduction procedure was repeated until the infrared spectrum showed that the carbonyl peak had been greatly reduced. The partially reduced polysaccharide was then methylated by the Haworth procedure (four times). The chloroform extracts (of the acidified solution) from each methylation were combined and concentrated to a syrup (4.1 g). This partially methylated polysaccharide was reduced with lithium aluminum hydride in tetrahydrofuran as described before. A Kuhn-type methylation followed by a Purdie methylation yielded a syrup (2.45 g) which had $[\alpha]_D^{22}$ −15° (*c*, 1.42 in $CHCl_3$) and a methoxyl content of 44.9%. The material was not fractionated by light petroleum – chloroform and was soluble in a high percentage of light petroleum. The methylated material was hydrolyzed with formic acid as described before.

Separation of the Methylated Sugars

The syrup was separated on cellulose with light petroleum (100–120°) – butan-1-ol (7:3 later 6:4) and butan-1-ol containing some methanol as eluants, to give seven fractions.

Sugar 1 (39 mg).—The syrup from fractions 1 and 2 had an R_f value identical, in all solvents, with that of 2,3,4-tri-*O*-methyl-L-fucose, $[\alpha]_D^{22}$ −104° (*c*, 0.15). The syrup gave a crystalline aniline derivative which, after recrystallization from ether, yielded *N*-phenyl-2,3,4-tri-*O*-methyl-L-fucosylamine, m.p. and mixed m.p. 133–134° C.

Sugar 2 (280 mg).—This material, from fraction 3, had $[\alpha]_D^{22}$ −94° and was identified as 2,3,4,6-tetra-*O*-methyl-L-galactose. The negative rotation suggested that the L-form had been obtained. The aniline derivative, after recrystallization from ethanol, had $[\alpha]_D^{21}$ −48° (*c*, 0.17 in acetone) and m.p. 194–195°, depressed 15° on admixture with authentic *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-galactosylamine.

Sugar 3 (122 mg).—This material was obtained as the slower zone from fraction 4, using solvent (B). Further amounts were obtained from the slower zone of fraction 5 after paper electrophoresis. The syrup had $[\alpha]_D^{23}$ +84° (*c*, 1.22). The syrup (6 mg) in methanolic hydrogen chloride (1.5%, 5 ml) had $[\alpha]_D^{23}$ −56° (*c*, 0.12) after 24 hours. The material was chromatographically indistinguishable from 2,3,6-tri-*O*-methyl-D-galactose. The sugar solution was oxidized for 3 days with bromine (3 drops) in water (1 ml) and the lactone was isolated in the usual manner. Crystallization from ether yielded 2,3,6-tri-*O*-methyl-D-galactonolactone, m.p. and mixed m.p. 97–98° C, and possessed $[\alpha]_D^{22}$ −37° (*c*, 0.98) (30, 31).

Sugar 4 (181 mg).—This material was obtained from the electrophoretic separation of fractions 5 and 6. A portion of the syrup on demethylation afforded rhamnose. The sugar moved at a different rate to authentic 2-*O*-methyl and 3-*O*-methyl-L-rhamnose. The syrup consumed 1.9 moles of periodate, suggesting it to be 4-*O*-methyl-L-rhamnose. The syrup crystallized after 4 months. Recrystallization from acetone yielded white crystals, m.p. 110–111° C and $[\alpha]_D^{21}$ +26° (*c*, 1.2). A portion of the syrup was oxidized with bromine. The resulting 4-*O*-methyl-L-rhamnonolactone after recrystallization from chloroform – light petroleum had m.p. and mixed m.p. 81–82° C (32). A further portion of the sugar was refluxed with aniline in ethanol to give *N*-phenyl-4-*O*-methyl-L-rhamnosylamine, which after recrystallization from ethanol had m.p. 157–158° C and $[\alpha]_D^{22}$ +142° (*c*, 0.33 in pyridine) (36).

Sugar 5 (58 mg).—This sugar was isolated from fraction 7 by multiple development with solvent (B) on Whatman 3MM paper. The syrup showed galactose on demethylation and had $[\alpha]_D^{23}$ +71° (*c*, 1.11) (37). The material was electrophoretically identical with 2,3-di-*O*-methyl-D-galactose. A portion of the syrup in water (2 ml) was oxidized with bromine (3 drops) for 3 days. The resultant lactone was treated with methanolic ammonia (3%, 2 ml) for 2 days. Removal of the solvent yielded a white material which had $[\alpha]_D^{21}$ +24° (*c*, 0.08). This amide, spotted on paper, was sprayed with sodium periodate followed by a solution of inositol, then with a mixture of ammonia and acetyl acetone (37), when a yellow spot resulted, indicating release of formaldehyde. Oxidation of the amide with sodium periodate resulted in a periodate uptake of 1.85 moles and a formic acid production of 0.90 mole per sugar molecule. The original syrup after treatment for 5 days with methanolic hydrogen chloride (1.5%) had $[\alpha]_D^{22}$ −16° (*c*, 1.0) (38). A crystalline aniline derivative could not be obtained.

Sugar 6 (95 mg).—This material was obtained from fraction 7 after multiple development in solvent (B). The syrup had zero rotation and showed galactose after demethylation. The sugar was chromatographically different from 2-*O*-methyl and 6-*O*-methyl-D-galactose but was identical chromatographically with 3-*O*-methyl-D-galactose. Neither a crystalline aniline derivative nor an osazone could be obtained from the syrup.

Sugar 7 (55 mg).—This sugar was also obtained from fraction 7 by multiple development. The sugar was chromatographically indistinguishable from L-rhamnose in all solvents and had $[\alpha]_D^{22}$ +2° (*c*, 0.7). The material formed a phenylhydrazone which, after recrystallization from water, had m.p. 157–158° C and $[\alpha]_D^{22}$ +42° (*c*, 0.1) (39). Admixture with authentic L-rhamnose phenylhydrazone failed to depress the melting point.

Tiselius Investigation of the Neutral Fraction

The neutral fraction (50 mg) was dissolved in borate buffer (0.05 *M*, 5 ml) and dialyzed against borate buffer for 24 hours. The electrophoresis was performed with the aid of the compensator. Pictures were taken of the 'buffer arm' after 20 minutes (*a*), 80 minutes (*b*), and 390 minutes (*c*). A small fast peak was observed followed by two slow peaks of about the same size.

When the fast-moving peak was no longer visible on the observation screen, the cell was closed and the current switched off. The solutions contained in the 'buffer arm' and 'solution arm' were removed and hydrolyzed separately. Chromatography indicated that there was little difference in the sugar composition of each fraction, although the solution obtained from the 'solution arm' was apparently richer in arabinose.

Large-scale Smith-type Degradation of the Neutral Fraction

The neutral fraction (5.9 g) was dissolved in distilled water (1.2 l.), and sodium metaperiodate solution (0.3 *M*, 162 ml) was added. The reaction mixture was kept in the dark for 96 hours. The excess periodate was destroyed with ethylene glycol (20 ml), and after dialysis to remove formaldehyde, ethylene glycol, and salts, the polyaldehyde was reduced with a solution of potassium borohydride (5 g in 100 ml). The excess borohydride was destroyed with dilute acetic acid. The solution was dialyzed for several days and then concentrated to a thick gel. The volume was adjusted to 150 ml with sulphuric acid (1 *N*) and the solution kept at room temperature for 12 hours. After neutralization ($BaCO_3$), the precipitate was removed by centrifugation. The centrifugate was passed through IR-120(H) resin. The eluate was concentrated and poured into ethanol. The precipitate was collected by centrifugation and dried to a white powder (850 mg). The alcohol supernatant was concentrated to a syrup (2.1 g).

Properties of the Smith-type Degraded Polysaccharide

Hydrolysis of a portion (10 mg) of the polysaccharide followed by chromatography in solvents (A) and (C) showed the presence of xylose and a trace of arabinose. The polysaccharide had $[\alpha]_D^{22}$ −54° (*c*, 0.2).

The degraded material (4 mg) and Enzyme AP19 (supplied by Rohm and Haas Co.) (4 mg) were dissolved in water (5 ml) and incubated at 37° C. Aliquots were removed at intervals and chromatographed in solvent (A). Xylose, xylobiose, xylotetraose, and oligosaccharides were produced.

The degraded material (45.5 mg) was dissolved in water and sodium metaperiodate solution (0.3 *M*, 3 ml) added. The solution was made up to volume (100 ml) and kept in the dark while the oxidation proceeded. Periodate uptake and formic acid production were determined as previously described. Extrapolation of the 'overoxidation' part of the curves to zero time indicated that 0.57 mole of periodate was consumed and 0.10 mole of formic acid was produced per pentose unit (calculated as $C_6H_8O_4$). Hydrolysis of the mixture after oxidation followed by chromatography in solvents (A), (B), and (C) showed the presence of xylose only.

Methylation of the Degraded Polysaccharide

The polysaccharide (800 mg) was dissolved in water (10 ml), and dimethyl sulphate (30 ml) and sodium hydroxide solution (30%, 10 ml) were added, while the solution was vigorously stirred. The solution was kept at 0° C and at pH 6–7. After 24 hours the basic solution was heated at 60° C. The solution was neutralized with acetic acid and concentrated to a small volume (20 ml). This solution was extracted several times with chloroform and the combined chloroform extracts were concentrated to a syrup (770 mg). The syrup was dissolved in methyl iodide and methylated by Purdie's method. The syrupy methylated material (450 mg) was extracted with boiling light petroleum (40–60°). The solution was decanted from the insoluble material and concentrated to a syrup (113 mg). The light petroleum insoluble material (537 mg) was dissolved in chloroform and concentrated to a glass. The glass (found: OMe, 37.6%) displayed a negligible hydroxyl peak in the infrared spectrum.

The methylated material (525 mg) was hydrolyzed with formic acid as previously described to yield a syrup (481 mg) of methylated fragments. The syrup was separated on a cellulose column using light petroleum (100–120°) – butan-1-ol (7:3) and later butan-1-ol – methanol (10:1) as eluants, to give six fractions which were again separated chromatographically to give the following sugars.

Identification of the Methylated Fragments

Sugar 1.—This syrup (46 mg) had an R_f value identical with that of 2,3,4-tri-*O*-methyl-D-xylose and crystallized completely on nucleation. Recrystallization from ether yielded crystals, m.p. and mixed m.p. 88–89° C, which had $[\alpha]_D^{21}$ +19° (*c*, 0.7) (40). The mother liquors were separated on paper using solvent (A) and a further crop of crystals (16 mg) was obtained.

Sugar 2.—This syrup (128 mg) was crystallized from acetone – light petroleum and yielded 2,3-di-*O*-methyl-D-xylose, m.p. and mixed m.p. 80–81° C, and had $[\alpha]_D^{22}$ +25° (*c*, 0.34) (41). The derived *N*-phenyl glycosylamine was recrystallized from ethanol and yielded *N*-phenyl-2,3-di-*O*-methyl-D-xylosylamine, m.p. and mixed m.p. 124–125° C, which had $[\alpha]_D^{22}$ +88° (*c*, 0.14 in ethyl acetate, 5% acetic acid) (40).

Sugars 3 and 4.—The syrup (145 mg) was separated into two components by paper electrophoresis. The faster-moving material (9 mg) corresponded to authentic 3-*O*-methyl-D-xylose and had $[\alpha]_D^{22}$ +6° (*c*, 0.9); demethylation of the derivative afforded xylose. A crystalline aniline derivative could not be obtained. The slower-moving fraction (101 mg) yielded xylose after demethylation; it moved slower than 2- or 3-*O*-methyl-D-xylose on paper chromatograms. The material gave a positive tetrazolium red test and had $[\alpha]_D^{22}$ +6° (*c*, 1.01), in good agreement with the value reported by Hough and Jones (42) for syrupy 4-*O*-methyl-D-xylose. When oxidized with sodium periodate the syrup (4.5 mg) liberated 2 moles of formic acid per mole of mono-*O*-methyl pentose. The syrup failed to yield a crystalline aniline derivative. The derived phenylosazone had m.p. 160–161° C (43). Admixture with the authentic 4-*O*-methyl-D-xylosazone prepared by the method of Hough and Jones (42) failed to depress the melting point.

Sugar 5.—This material (10 mg) was obtained from the same separation as sugars 3 and 4. The syrup was chromatographically indistinguishable from xylose in solvents (A), (B), and (C); it could not be induced to crystallize. The syrup was treated with benzaldehyde and methanolic hydrogen chloride (44) for several days. The derived dibenzylidene dimethyl acetal of D-xylose after recrystallization from chloroform – light petroleum had m.p. and mixed m.p. 207–208° C.
